The total losses in generating room equals (total kv-a. generator capacity) – (total kv-a. generator capacity × generator efficiency).

The total amount of air required for the generator room in cu. ft. per minute equals

$$\frac{10{,}000 \times \text{total loss per hr. in kw-hr.}}{60}$$

The above method will give approximately twice as much air as that required with the forced or positive ventilation schemes shown in Figs. 1, 2 and 3, for the reason that when the ventilating scheme is such that a definite amount of outside air will pass through the machine, a temperature difference of 30 deg. F. to 40 deg. F. (16.7 deg. C. to 22.7 deg. C.) between ingoing and outgoing air is not excessive.

### Existing Stations

Improvement in the ventilation of existing hydro-electric stations can be made economically in many cases. The nature of the improvement depends upon the type of machines and the layout of the station, and each case requires a special study. The following are some of the improvements that have been adopted:

Larger openings in the roof and openings or ducts in the basement or floor.

Fans for supplying outside air and exhausting air from inside where the station does not permit of large openings for natural ventilation.

Humidifiers for cooling incoming air where the amount is limited.

New end housings for generators with external fans for each generator or with suitable duct leading from generator pit to outside, provided the generator has a sufficient fan effect.

Housing the generator in such a manner that the discharged air is carried out of the station through a duct, the generator inlet air being taken from the room.

The object of these improvements is to obtain an increased output from the generating units in cases where the waterwheel capacity is great enough, or to allow the generators to be operated at their rated capacity without overheating and consequent deterioration of the insulation.

In conclusion, good ventilation affords advantages so numerous and important that it is a good policy to give it the most serious consideration in the design of all power stations.

# NOTES ON SELECTION OF SYNCHRONOUS CONDENSERS

By H. L. Unland

Power and Mining Engineering Department, General Electric Company

Synchronous condensers are used ordinarily for regulating power-factor directly, or for regulating the voltage by adjustment of power-factor. The discussion of the selection of synchronous condensers for each of these two purposes are dealt with separately in this article. A number of curves are included which, with their accompanying explanations, render the selection of the size of condenser, to be used in a certain installation, a simple matter. The influence upon regulation by the resistance and the reactance of the generator, the transformers, and the transmission line is discussed; and a concrete example assumed for which a set of characteristic curves is derived to show the synchronous condenser capacity required to maintain constant voltage drop. The article concludes with a statement as to the best location for the condenser.—Editor.

H. L. Unland

A synchronous condenser may be defined as any synchronous apparatus, which, when connected to a circuit excited by an alternating current generator, can be made to deliver to the circuit either leading or lagging current, the magnitude of which can be regulated by varying the excitation at the will of an operator.

This definition includes generators, which can be made to carry the exciting current of the circuit by varying the excitation. Such operation is not taken account of in the following which deals only with the use of machines operating as synchronous motors, either with or without load, which, when the excitation is varied, will require either leading or lagging exciting current.

The following discussion will be limited to circuits of not over 50,000 volts and to short transmission lines where the charging current will be small and where the effects of the charging current will be so slight, compared to the inductive action of the circuits, as to be neglected.

The operation of synchronous condensers can be divided into two classes:

First. The regulation of power-factor.

Second. The regulation of voltage by means of varying power-factors.

In the first class of operation the condenser would probably be installed as a portion of the customer's equipment and would, therefore, probably be removed from the control of the power company. Where a condenser is used, however, for regulating the voltage of a transmission line, the condenser will probably be the property of the owner of the line and will be operated as a part thereof, and moreover will probably be controlled by an automatic voltage regulator.

Some operating companies take account of the power-factor of the customer's load in making their rates, and in such a case it is to the customer's benefit to install condenser capacity and thus obtain the benefit of decreased power rates, if, by so doing, the saving in power cost will pay the fixed charges on the capital required, as well as the increased operating charges, due to the installation of such an equipment. Another instance of the value of the correction of power-factor alone would be in case a customer owns the step-down transformers and, due to the natural growth of his plant, the induction motor load had reached the limit of the transformer capacity. The power-factor of the average commercial induction motor load is in the neighborhood of 70 per cent, so that by installing a synchronous motor, which in addition to delivering mechanical power would also furnish sufficient leading current to raise the power-factor of the whole load, the capacity of the plant could be increased by a considerable amount without increasing the transformer or switching equipment. Under these conditions a synchronous motor of 35 per cent of the total transformer capacity will deliver an energy load of 20 per cent of the total capacity and at the same time raise the power-factor of the system to 90 per cent.

The efficiency of a generator is affected by the power-factor, although this variation is greatly modified by the ratio of the constant to the variable losses in the machine. This is determined by the design of the generator. There will be a difference of 2 to 2½ per cent, however, in the efficiency of a generator operating at normal load and unity power-factor, and the same generator operating at the same kv-a. and 0.8 power-factor. The excitation required by a generator when operating at 0.8 power-factor will be in the neighborhood of 50 per cent greater than that required for the same kv-a. at unity power-factor. This rate of increase in excitation does not continue for power-factors below 80 per cent.

On account of the fact that automatic voltage regulators are so extensively used, the regulation of the generator is of relatively little importance, except insofar as it affects the excitation required. In case a regulator is not used, however, where the generator would have a unity power-factor regulation of 8 per cent the regulation at 0.8 power-factor would be from 25 to 30 per cent. This is due to the fact that modern generators are so designed as to have high inherent reactance in order to limit the instantaneous short circuit current.

The capacity of an a-c. generator is measured in kv-a. and with low power-factors the kw. capacity will be decreased with the power-factor. In many cases the prime mover will have sufficient capacity to drive the generator at full kv-a. output at 1.0 power-factor. Since the power sold is measured in kw. any decrease in power-factor really lowers the capacity of the generator, and this reduction in capacity extends also to the prime movers, so that although the machines might be operating at full kv-a. rating at 0.8 power-factor, in reality 20 per cent of the generator equipment is not available. In a steam generating station this extends also to the auxiliaries, such as boilers, condensers, exciters, pumps, etc., which means a very considerable portion of the investment tied up by operating at a low power-factor.

The effects of varying the power-factor on transformers, although smaller in magnitude than the effects on the generator, must be considered since they occur twice, at the step-up and at the step-down transformers. The losses in a transformer with constant kv-a. output are practically the same for any power-factor. The efficiency of a transformer can be written as

$$\frac{\text{kv-a.}}{\text{kv-a.} + \dfrac{\text{losses}}{\text{power-factor}}}.$$

However, since the losses are usually small in a well designed transformer, the decrease in the efficiency, due to decreased power-factor, will decrease about 0.4 per cent with a decrease in power-factor from 0.8.

Due to the fact that transformers contain a certain amount of inductance it is readily seen that lagging current will cause an increase in the internal voltage drop of the transformer and thus will affect the regulation, particularly in the case of large transformers which usually have a high reactance.

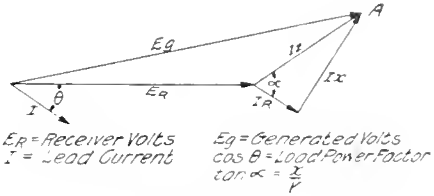

**Fig. 1. Vector Diagram for Circuit having Reactance and Resistance**

The capacity of a transformer decreases with the power-factor in the same manner as in the generating equipment.

In Fig. 1 is shown the general vector diagram for a circuit having reactance $x$ and a resistance $r$ with a current flowing represented by $I$ which lags behind the receiver e.m.f. by the angle $\theta$. It is customary to assume the receiver voltage $E_r$ as constant. The magnitude and location of the vector $E_g$ will then be determined by the vertex $A$ of the small impedance triangle. The reactance drop $(IX)$ is at right angles to the resistance drop $(IR)$ and to the current $I$. For any circuit the angle $\alpha$ has a constant value such that $\tan \alpha$ equals $\frac{x}{r}$. For constant kv-a. and, therefore, constant current the vector $IZ$ will have a constant value, and as the power-factor varies this vector will revolve through a semi-circle, as shown in Fig. 2. The length of this vector will vary directly with the current flowing and, therefore, concentric semicircles can be drawn to show the locus of this point for varying kv-a. loads. The vector $IZ$ at unity power-factor will lead the electromotive force $(E_r)$ by the angle $\alpha$. For lagging current this vector will move in a clockwise direction and for leading current will move in a counter-clockwise direction.

If the kw. output is maintained constant and the power-factor varied, the point $A$ will move along a straight line through the position at unity power-factor, and at right angles to $IZ$ at this power-factor. These lines will then be tangent to the constant kv-a. loci at the unity power-factor point, as shown in Fig. 2.

The only loss in a transmission line, with the exception of the leakage over insulators, which in such circuits as those under consideration can be neglected, is the $I^2R$ loss, which for constant kw. will vary as $\left(\frac{1}{PF}\right)^2$ and for constant kv-a. will remain constant.

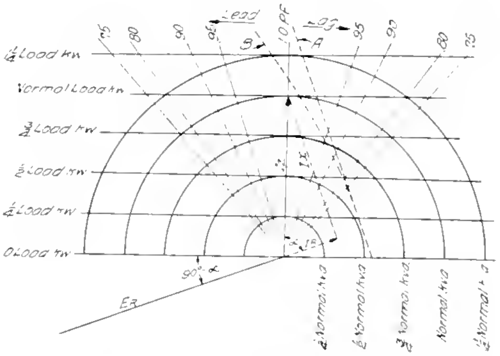

Fig. 2. Loci of Voltage Vectors in Circuit Containing Reactance and Resistance

The efficiency in this latter case, however, will be reduced, due to the fact that the kw. output decreases with the power-factor

The decrease in efficiency, between unity and 0.8 power-factor for constant kv-a. in a circuit, which includes generator, transformers and the transmission line, assuming average values, will be approximately as follows:

| | |
|---|---|
| Generator ............ | 2 per cent |
| Transformers ......... | 0.8 per cent |
| Transmission line...... | 2.2 per cent |

This gives a total of 5.0 per cent decrease in efficiency. The regulation of the system becomes steadily worse with lower power-factors, although the increase varies in different portions of the circuit. This condition results in either greatly increased excitation on the generators or else widely varying voltages at the receiving end of the circuit for varying loads. The capacity of the system for equal heating will be decreased directly with the power-factor. This point is modified, however, in the case of the generator fields, which will suffer an increase in temperature with lagging power-factors, due to the increased excitation required.

The phase characteristics of the synchronous motor are so familiar to all that it will be sufficient to merely call attention to a few points that are of importance in connection with this subject. A representative set of such curves is shown in Fig. 3. For a machine which is to operate as a condenser only, and not to deliver any mechanical output, the no-load curve only need be considered.

It will be noted, by referring to Fig. 3, that the excitation required at full kv-a. output leading with no load on the machine, is approximately twice the excitation required at no-load minimum input or unity power-factor. Such service is usually met with where the machine is to correct power-factor only, since in such service leading current only is usually required. This range of excitation is satisfactory for operation in connection with an automatic voltage regulator, which gives a range of 3 to 1.

In case the machine is required to operate from full kv-a. leading to full kv-a. lagging, the range of excitation is considerably greater, as will be seen from the curves, being for this machine approximately in the ratio of 9 : 1. Such a range is obviously too great for the usual arrangement of the automatic voltage regulator, when applied directly to the exciter field. To meet this special problem a very ingenious and successful arrangement has been developed using auxiliary exciters to automatically control the field of the main exciter on the synchronous machine. Service requiring a range of excitation greater than 3 to 1 is encountered only when a condenser is to regulate the voltage in connection with a high-voltage transmission line having a large charging current.

If a synchronous motor is operated with a varying load and the excitation is held constant, the wattless kv-a. will increase as the load decreases. The variation in the wattless kv-a. under these conditions will be small as indicated in Fig. 4. This curve shows the per cent of wattless kv-a. when a synchronous motor is excited for 0.8 power-factor leading at full load. As the mechanical output is decreased, the field being held

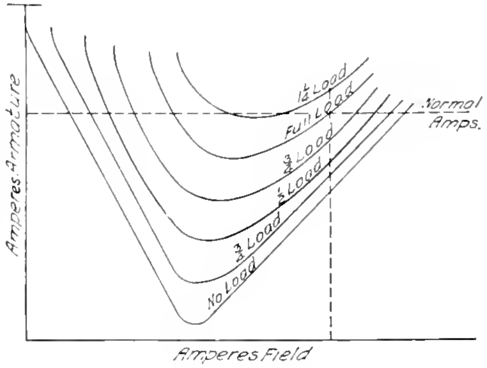

Fig. 3. Phase Characteristic Curves of Synchronous Motor

constant, it will be seen from Fig. 3 that the armature kv-a. decreases, but at the same time the power-factor continually decreases and these two changes tend to neutralize.

The losses in a synchronous condenser will be approximately 4 per cent of the rating for a 1000 kv-a. unit and slightly less for sizes above this. A 200 kv-a. machine will have about 8 per cent losses.

The calculation of synchronous condenser capacity required for correction of power-factor alone is very simple, provided the magnitude and power-factor of the load are known. The well known circle diagram, illustrated in Fig. 5, is very useful for this work and with it sufficient accuracy can be obtained for any practical purpose. As an example, assume a load of 7500 kw. at 80 per cent power-factor lagging. As shown by the curves this corresponds to a total kv-a. of 9375 and a wattless component of 5650 kv-a. Obviously, if it is desired to bring the power-factor to unity it will be necessary to add 5650 kv-a. leading. If it is desired to bring this load to 90 per cent power-factor we find that the wattless component corresponding to this power-factor at 7500 kw. is 3750 kv-a. and this subtracted from 5650 leaves 1900 kv-a. required. If, on the other hand, it is desired to increase the load, keeping the total kv-a. constant, and to obtain a power-factor of 90 per cent, we find that for 9375 kv-a. at 0.9 power-factor, the kw. will be 8400 and the wattless kv-a. 4400. This latter value of wattless kv-a. subtracted from the original 5650 leaves but 1250 kv-a. which must be supplied by a condenser. It will be plainly seen from the above that the condenser calculations depend entirely on what it is desired to accomplish; i.e., whether the power-factor is to be bettered, the actual load increased, or both.

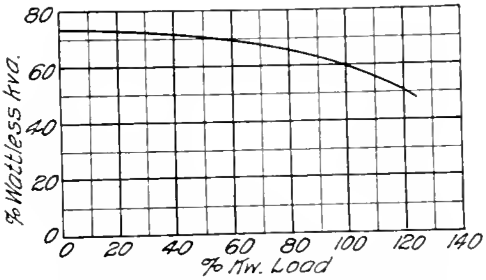

Fig. 4. Relation Between Wattless Kv-a. and Load on Synchronous Motor with Constant Excitation

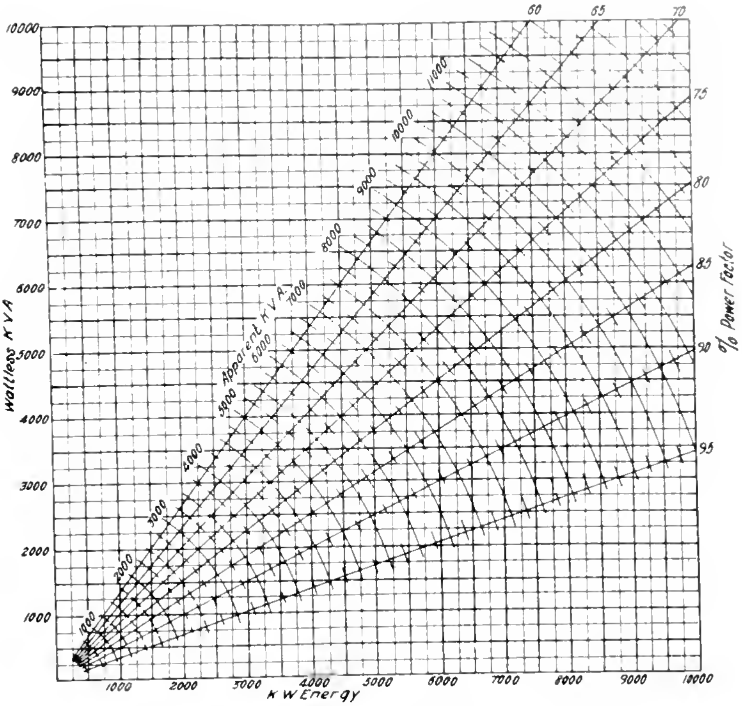

Fig. 5. Relation Between Energy Load, Apparent Load and Wattless Component at Different Power-factors

If accurate figures are not available, in regard to the power-factor and magnitude of the load, the wattless kv-a. of an induction motor load can be estimated for preliminary work. It is well known that the exciting current of an induction motor is practically constant and that the full load power-factor is approximately 80 per cent for 60 cycle motors. Thus the wattless component would be in the neighborhood of 0.6 of the total rated h.p. of the motors which are running. If 25 cycle motors are used the full load power-factors will be approximately 90 per cent and the wattless component will then be approximately 45 per cent of the total rated h.p. of the running motors. These figures vary with the speed, size and type of the motors but can be used for preliminary estimating purposes.

For the above type of service the ideal equipment consists of a synchronous motor which will carry a mechanical load in addition to furnishing power-factor correction. It is not material whether the load on the motor be constant or not, for if the field is excited for the required correction at full load, and the excitation held constant, the corrective kv-a. available will be practically constant as will be seen by referring to Fig. 3.

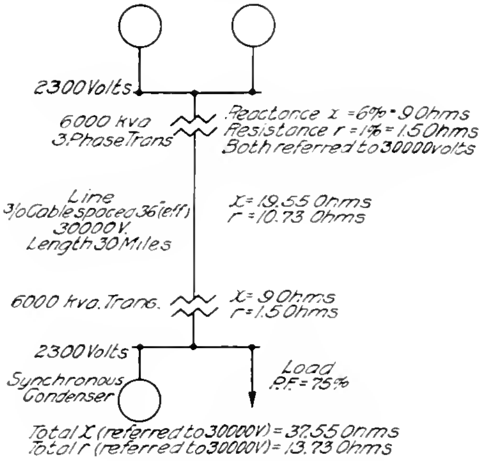

Fig. 6. Simple Transmission Circuit

Where a condenser is required to control or regulate the voltage at the receiving end of a transmission line the capacity of the condenser depends upon the reactance and resistance of the transmission line including transformers, upon the magnitude and power-factor of the load, upon the voltage difference to be held between the generating and the receiving ends of the line, and upon the receiver voltage.

The transformer constants are included in the transmission line for the reason that the voltage at the generator end will be held constant on the low tension buses and, further, the voltage delivered to the load should be maintained constant at the low tension buses at that end of the line. The reactance and resistance of the transformers under ordinary circumstances will in nearly all cases be of about the same magnitude as the resistance and reactance of the line to which they are connected, so that if they are neglected, the voltages actually found on the receiver low tension buses will be considerably different from the expected values. In the following all values of resistance and reactance are the single-phase values or the values from one line to the neutral. These constants for the transformers should be based on the high tension voltage in order to combine properly with the constants of the transmission line. Where a transformer has a certain reactance, for example, *a* per cent, the single-phase reactance in ohms will be given by the expression $\frac{10\,a\,E^2}{K}$. Here $E$ represents the kilovolts between lines and $K$ represents the three-phase kv-a. capacity of the bank of transformers. This formula also gives the resistance in ohms in which case *a* is taken as the per cent resistance.

Referring to Fig. 6, which shows a simple circuit which can be used as a basis for illustrating the calculations, the step-up transformers have been assumed as a 6000 kv-a. three-phase bank. An average value for reactance in power transformers is 6 per cent and for resistance 1 per cent. Using the above formula a value of reactance of $\frac{10 \times 6 \times 30^2}{6000} = 9$ ohms is obtained. These values will apply to both the step-up and step-down transformers. The resistance will then be $\frac{10 \times 1 \times 30^2}{6000} = 1.5$ ohms.

The line as shown is assumed as 30 miles long and consists of 000 cables spaced 36 in. apart. The reactance of the line for these conditions will be 19.55 ohms and the resistance 10.73 ohms.

The approximate formula for obtaining synchronous condenser capacity required to maintain constant voltage drop is given by $I_s = I_w - \frac{V - I_e R}{X}$. In this formula the symbols have the following meanings:

$I_s$ = synchronous condenser current.
$I_{wl}$ = wattless component of the load current.
$I_e$ = power component of the load current.
$V$ = actual voltage difference between generator and receiver.
$R$ and $X$ = resistance and reactance of the line, including transformers.

The above formula can be re-written as follows for a three-phase circuit:

$$K_s = K\left(\sin\theta + \frac{R}{X}\cos\theta\right) - \frac{30\,ae^2}{X}$$

The symbols have the following meanings:

$K_s$ = synchronous condenser kv-a.
$K$ = load kv-a.
$Cos\ \theta$ = power-factor of load.
$Sin\ \theta$ = wattless factor of load = $\sqrt{1-cos^2}$
$e$ = kilovolts between line and neutral.
$a$ = per cent difference in voltage between generator and receiver, expressed in terms of receiver voltage.
$R$ = total resistance of line and transformer in ohms.
$X$ = total reactance of line and transformers in ohms.

The resistance and reactance above are the single-phase or line to neutral values. Using the values as shown in Fig. 6 in the above formula, a set of curves can be drawn showing the relation between kv-a. load and wattless kv-a. required for different values of $a$ or per cent voltage difference. Such a set of curves is shown in Fig. 7, except that instead of kv-a. load this has been multiplied by the power-factor and the kw. values have been plotted instead.

These curves show that without a condenser, at 2500 kw. there will be a line drop of 4000 volts, or 13.3 per cent, and this drop will vary with the load. By adding a synchronous condenser, which will operate between 4300 kv-a. leading and 3200 kv-a. lagging, it will be noted that with 4000 volts drop, the load can be increased to 6000 kw. This drop will be constant for all loads. The dotted curve *B* shows that the power-factor of transmission is very close to unity at 6000 kw. under these conditions.

If a lower value of voltage difference is desired the condenser capacity can be obtained from the curves corresponding to the voltage desired.

The formulæ used above are based on the assumption that there is a straight line relation between the wattless kv-a. and the load. This is not strictly true, as will be understood by referring back to Fig. 2. The dotted curve *B* represents the locus of the generator voltage when held constant. The formulæ used above are based on the assumption that this curve coincides with the straight dotted line *A*.

The distance between these two lines is only a small portion of the generator voltage but is a relatively large fraction of the voltage which must be taken care of by the condenser. The effect of this variation from a straight line relation is shown by the dotted curve *A* in Fig. 7. At 6000 kw. load there will really be required 5000 kv-a leading, whereas the straight line curve would indicate only 4300, making a difference of 16 per cent. The difference in the generator voltage corresponding to this would be only 2 per cent, or if the condenser kv-a. indicated by the straight line were used, instead of obtaining 4000 volts drop at 6000 kw., this would increase to approximately 4600.

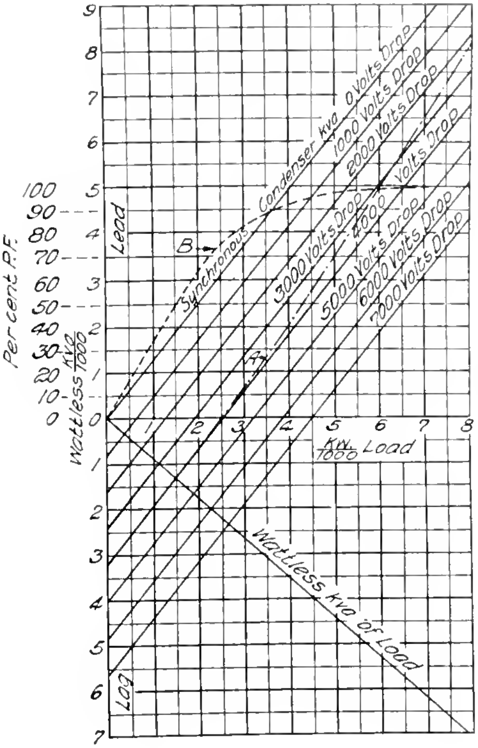

Fig. 7. Synchronous Condenser Capacity Required to Maintain Constant Voltage Drop in the Circuit Illustrated in Fig. 6

If the transmission line only were considered in the above and the transformers not included, the voltage drop for 4500 kw., at 0.75 power-factor would be approximately 15 per cent or 4500 volts—without any condenser being used. The difference between this value and the drop of 7000 volts shown in Fig. 7 represents the drop due to the transformers and in this instance is about 8 per cent which is obviously too great to be neglected.

If the synchronous motor for this service is required to carry an additional mechanical load, care should be taken to see that it does not receive a sudden heavy load while running with a weak field. In such a case it is obvious that there is great danger of the machine falling out of step. Even though the load might not be suddenly applied, the machine might drop out of step if the field is weakened to an undue extent.

For such operation as the above the condenser must be able to deliver both leading and lagging current. If it is satisfactory to have the voltage high at no load and drop with the load, until the desired voltage is reached, then remain constant, the condenser only need deliver leading current. The regulator can have a stop arranged to only allow it to operate when the voltage tends to fall below the desired value.

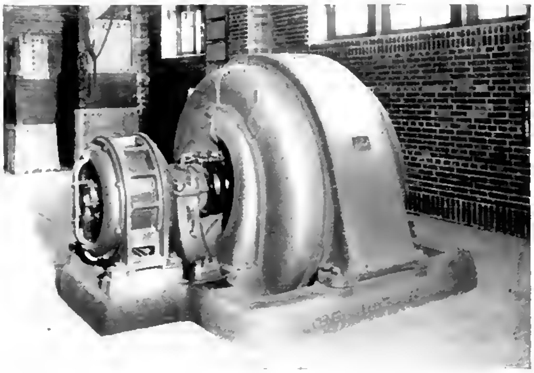

Fig. 8. 1000 Kv-a., 2100 Volt Synchronous Condenser with 35 H.P., 2100 Volt Starting Motor

In addition to improving the voltage regulation of the line the addition of condensers will, in most cases, bring the power-factor very nearly to unity at full load, which will make the losses a minimum and at the same time make available the full capacity of the equipment.

A synchronous condenser which will only be required to deliver leading current will cost approximately 15 per cent less than a synchronous motor having the same continuous rated capacity. If the condenser must deliver both leading and lagging current, the cost will be practically the same as a synchronous motor of the same rated capacity. However, such a condenser will deliver full kv-a. lagging and full kv-a. leading which really amounts to condenser capacity of twice the rating. Thus, if it is satisfactory to have the voltage vary with light load as described above, the first type of condenser can be used at a reduced cost. This also refers to the use of a condenser for power-factor correction only.

In the example just noted relative to voltage control, the addition of 5000 kv-a. in condenser capacity made possible an increase of 3500 kw. in power capacity of the system.

It is thus seen that by the investment of a relatively small amount in the condenser, a much larger amount, represented by the prime movers, generators, transmission line and transformers, is made available. In addition the operating efficiency of the entire system is very largely increased.

This assumed case may apparently be favorable to the use of a synchronous condenser but no attempt has been made to select such values. At any rate it merely emphasizes the possibilities of the use of such apparatus.

For any such installation which may be under consideration the matter should be brought down to a dollar and cents basis, if possible. The cost of the new apparatus should be balanced against increase in capacity. Increased operating costs should be balanced against increase in efficiency, and a comparison should be made of the service with and without the condenser.

In general a synchronous condenser will have the most effect and therefore, will be of the greatest value when it is installed at the same point as the load since in this case it benefits all apparatus between itself and the generator. A further gain is obtained by driving a mechanical load in addition to the corrective action of the condenser.

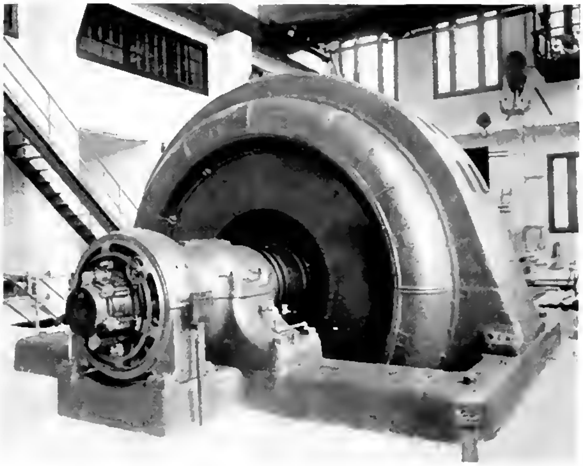

Fig. 9. 15,000 Kv-a., 6600 Volt Synchronous Condenser with Direct-connected Exciter

# PHASE ADVANCERS

By L. F. Adams

Power and Mining Engineering Department, General Electric Company

The following article introduces the subject of phase advancers by a statement of the need of the device and a very brief history of its development. Next is described the construction of the phase advancer, the connections employed in its application and its operation under different conditions. Some numerical examples are then given to show the benefit that is to be derived from the installation of one of these machines, and curves are included which show the effect that these devices have upon the characteristics of the induction motors to which they are connected. The remainder of the article is devoted to a discussion of the commercial views that have been taken of these power-factor improving machines.—Editor.

**L. F. Adams**

As early as 1891 the idea of using paper condensers for providing idle leading current to compensate the idle lagging current due to self-induction in alternating current systems was proposed. However, no real progress was made toward practical applications; conditions then changed and the subject was dropped. For a long time, in many cases, the capacity of the cables in distribution systems provided sufficient compensation.

The great growth in the use of induction motors in recent years has made a marked difference so that now in many cases there is a real need for an improvement of the power-factor in supply systems. The importance of a good power-factor, for various reasons, is very generally recognized, such as keeping down the loss in the lines and increasing the useful output of generators and reducing their cost.

The most commonly used method for improving the power-factor of a system is to install over-excited synchronous motors, converters or synchronous condensers. Paper condensers have had some but not an extensive application. It is the object of this article to give a short explanation of the principles involved and a description, together with the application, of a new type of machine called the phase advancer for improving the power-factor, which is applied to the individual induction motor.

In the synchronous motor the magnetizing field is produced by a rotating magnet excited by continuous current, the frequency being zero. This field is in the secondary winding of the motor. By supplying more continuous current turns than are necessary to produce the magnetic field in any particular machine, it is possible to create in the system a leading current, which will compensate for a lagging current in another part of the system and produce unity or even a leading power-factor.

The phase advancer stands in the same relation to an induction motor as an exciter does to a synchronous motor. However, for the induction motor, continuous current can not be used for the magnetizing current in the secondary because the motor slips under load. The magnetizing current must be a polyphase current of low frequency which corresponds in each instance to the slip of the induction motor.

The phase advancer consists of a continuous current drum armature with a commutator having three brush studs per pair of poles displaced relative to one another by 120 electrical degrees. The stator merely consists of a frame with the laminations assembled but having no slots or windings, see Fig. 1.

The phase advancer is direct connected to a small squirrel cage constant speed induction motor. The power necessary to drive the phase advancer is only that required to supply the friction, windage and hysteresis losses and is therefore comparatively small, i.e., about 1 h.p. for a 600 h.p. 2200 volt induction motor. The copper losses are provided by the main induction motor rotor.

A simple scheme of connections is shown in Fig. 2 where *A* is the induction motor; *B* the phase advancer, direct connected to its driving motor *C*; *D* a standard controller and resistance for starting; *E* a two-pole single-throw short circuiting switch; and *F* a transformer and fuses if the supply source should be of high voltage. The switch *E* is used to short circuit the phase advancer when starting the induction motor *A*, which is accomplished in the usual way by the drum controller. The motor *C* is started, and after the motor *A* is up to speed the switch *E* is opened.

Consider for a moment that the phase advancer is standing still and is receiving current at slip frequency from the slip rings of the induction motor. The phase advancer under this condition acts as a three-phase choke coil, the currents producing a field which revolves in space at a speed corresponding to the frequency of the currents supplied to the brushes. The vector diagram, Fig. 3, shows the phase e.m.f. *E*, at the brushes and the current *I* fed to each brush in which *RI* is the component to overcome resistance and *XI* is the component to overcome the e.m.f. produced by the revolving field (i.e., the e.m.f. of self induction).

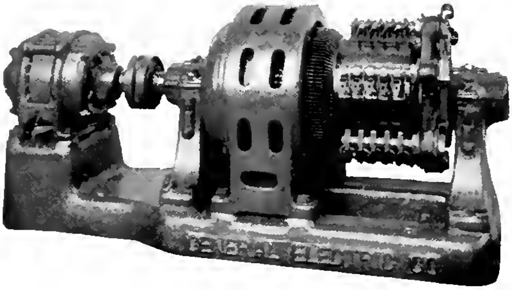

**Fig. 1. Rotary Phase Advancer, 11 kv-a , 520 amp., 12 volts. Driven by 1 h.p. 440 volt induction motor**

Now if the phase advancer is driven in the same direction as that in which the field revolves, the speed of rotation of the field in space will remain unchanged, being independent of the speed of rotation of the armature, because the points at which the currents are led into the winding are fixed in space. Hence when the armature is driven in the direction in which the field revolves and at a speed corresponding to the speed of the field, the relative motion of the field and the armature becomes zero; this is equivalent to the disappearance of the self inductive effect, as is indicated in Fig. 4 which shows the current in phase with the e.m.f.

If the armature be driven at a higher speed than the speed of the field, the *XI* component of Fig. 3 becomes reversed in sign and the vector diagram will be as shown in Fig. 5; that is, the current will lead the e.m.f. This negative reactance e.m.f., in series with the rotor circuit of an induction motor, is able to neutralize the reactances of the induction motor which formerly pushed the primary current into a lagging phase. In this way the condenser effect is produced and the power-factor improved.

It will be recognized that the stationary stator frame in Fig. 1 is not really necessary. The machine then would merely consist of an armature and commutator, but the winding instead of lying on the circumference of the drum would be imbedded in a circle of holes well within the external diameter of the armature so that the iron outside the holes would complete the external path for the flux which passes through the winding. The slow alternating currents supplied from the slip rings of the main motor set up a field which slowly revolves in space while the rapidly revolving armature conductors cut across this field and generate the necessary leading electromotive force. However, the use of the external frame possesses several advantages in that it permits open slots to be used on the armature and enables the commutation to be performed in a thoroughly satisfactory manner.

It will also be noted that the phase advancer can be mounted on or belted to the shaft of the main motor. However, when applied to large motors it is usual and preferable to drive the phase advancer by a small direct connected motor.

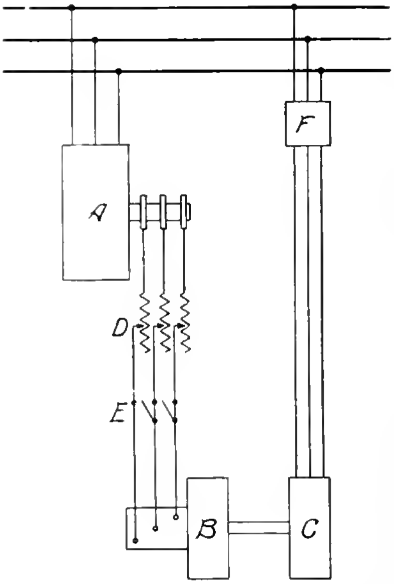

**Fig. 2. Diagram of Connections for applying a rotary phase advancer to an induction motor**

***A*, main induction motor; *D*, starting resistance; *E*, short-circuiting switch; *B*, phase advancer; *C*, phase advancer driving motor; and *S*, transformers and fuses if needed**

The phase advancer can be applied to any induction motor now in service provided it has a wound rotor and slip rings. It can be designed to correct the power-factor to unity or any other desired value from about one-quarter to one and one-half normal load. A new motor designed to work with a phase advancer may be made smaller, that is, an iron machine may be built instead of a copper machine. This results in a cheaper machine but a worse power-factor. This defect is readily corrected by the phase advancer. The saving in cost of the motor itself will go a long way towards paying for the phase advancer. If a very high power-factor is desired it is cheaper to build an iron machine with a phase advancer than a copper machine without a phase advancer. If unity power-factor is wanted the phase advancer is absolutely necessary. A smaller motor has smaller losses so that the power to drive the smaller motor and phase advancer would be in most cases less than that required to drive a large motor without the phase advancer. There is no limit to the size of the motor to which the phase advancer may be applied.

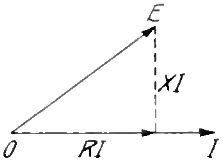

Fig. 3. Vector Diagram showing the current drawn by an induction motor without phase advancer lagging behind the line voltage, i.e., motor operating on a lagging power-factor

Owing to the compensation of the reactance the maximum output of the motor is considerably increased and this is one of the most valuable features of this new design. By the application of a suitable phase advancer the output of an old motor can be increased by 20 to 30 per cent and at the same time improve its power-factor. To secure a high power-factor in machines the clearance between the rotor and stator must be very small, but with the use of a phase advancer to compensate for the power-factor the clearance could be considerably increased.

The phase advancer is intended to be used with induction motors which run continuously in one direction throughout the greater part of the day. If a motor is intended to be started and stopped frequently, reversed, or for variable speed work, the phase advancer can not be used. The most important application of the phase advancer will be to large slow speed motors which have inherently a poor power-factor and to motors which run most of the time at part loads and therefore at a poor power-factor.

An improved power-factor means less copper in the mains, or that the power company can furnish more power from the same size main. Many of the mains in cities are overcrowded and either future customers must be refused or new mains laid. A phase advancer applied to one or two reasonably large induction motors, preferably slow speed, will immediately relieve this condition. As an example, a 30 kv-a. phase advancer is capable of changing the power-factor of a 1300 kv-a. motor from 88 per cent lagging to 95 per cent leading. That is to say, the motor instead of requiring to be fed with lagging wattless current to the amount of 600 kv-a. will relieve the generator supplying the system of a wattless load of 400 kv-a. making a total change in the wattless load of 1000 kv-a. to the good.

Fig 4. Vector Diagram showing the current drawn by an induction motor adjusted by a phase advancer to be in phase with the line voltage, i.e., motor operating on unity power-factor

If the induction motor to which the phase advancer is applied forms a large percentage of the total load on the line then not only is the induction motor improved, but the entire system. To illustrate this we may assume that 50 per cent of the total load consists of small motors with an average power-factor of 75 per cent, the other 50 per cent of a few large motors with an average power-factor of 80 per cent: the total average power-factor would be 78 per cent. If the few large induction motors were equipped with phase advancers and their

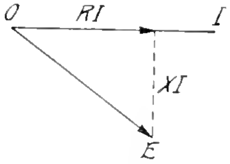

Fig. 5. Vector Diagram showing the current drawn by an induction motor adjusted by a phase advancer to be in advance of the line voltage, i.e., motor operating on leading power-factor

power-factor raised to unity, the total power-factor would be raised to 95 per cent.

Fig. 1 shows a phase advancer as recently built and installed at the Carthage Tissue Paper Company, Carthage, N. Y. The main motor is a 600 h.p. 240 synchronous r.p.m., three-phase, 60 cycle, 2200 volt unit driving a pulp grinder. The phase advancer is rated 11 kv-a., 600 r.p.m., 520 amp. at 12 volts, and is direct connected to a 1 h.p. 600 synchronous r.p.m. three-phase, 60 cycle, 440 volt induction motor. The overall dimensions of the phase advancer set are 60 in. by 22 in. by 27 in. high, and its weight is 1700 lb. The power-factor curves of this 600 h.p. motor operating both with and without the phase advancer are shown in Fig. 8. It will be noted that due to the compensation of the power-factor the line voltage has been increased from about 1980 without the phase advancer to about 2100 with the phase advancer.

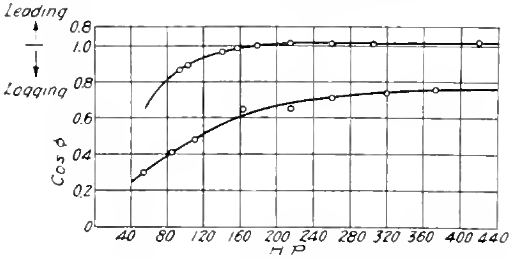

Fig. 6. The lower curve shows the power-factor of a 400 h.p. induction motor when run without a phase advancer. The upper curve shows the power-factor of the same motor with the phase advancer shown in Fig. 7 in circuit

As far as the writer knows this is the only application in this country of phase advancers applied directly to the motor. However, a number of these sets have been installed in Europe and have given very satisfactory results. Fig. 7 shows a phase advancer as built by Brown-Boveri & Company capable of bringing to unity power-factor a 400 h.p. motor. The overall dimensions of the set are 50 in. by 22 in. by 25 in. high and its weight is 750 lb. The power-factor curve of this 400 h.p. motor operating at 160 r.p.m. on 3300 volts, 32 cycles, both with and without the phase advancer, is given in Fig. 6.

Professor Miles Walker in a paper read before the Institute of Electrical Engineers (*Journal of the Institute of Electrical Engineers*, vol. 50, p. 329) gives the following: In a certain mill in the north of England there is a 250 kw. generator which on account of the low power-factor of the motors connected to it is somewhat overloaded. As it would be a rather costly undertaking to install a new generator, the alternative proposition was put forward of connecting a phase advancer in circuit with the rotor of a certain 140 h.p. motor in the mill. It was seen that this at least would help matters, although the capacity of the motor and its phase advancer were not great enough to bring the power-factor up to unity. A 5 kv-a. advancer was installed, with the results shown by the following figures:

TOTAL LOAD ON MILL

| | Amperes per Phase | Volts | Power-Factor |
|---|---|---|---|
| Advancer cut out | 325 | 440 | 0.70 lagging |
| Advancer connected in . . . . . . . | 240 | 440 | 0.92 lagging |

MOTOR LOAD ONLY

| | | | |
|---|---|---|---|
| Advancer out | 105 | 440 | 0.74 lagging |
| Advancer in | 97 | 440 | 0.96 leading |

Whenever the advancer was switched in the voltage of the generator rose from 440 to 470. The figures in the above table were taken after the rheostat had been adjusted to make the voltage normal.

Another case that might be quoted is the case of three 400 h.p. motors installed for pumping water for the Port of London. As the speed of the motors is low the normal power-factor at full load is only 0.55. These machines have been fitted with phase advancers, with the result that they run on a slightly leading power-factor.

The commercial difficulty in applying phase advancers is in deciding who has to pay for them. As practical machines they are completely successful; their commutation gives no trouble and their ability to make an induction motor run at unity power-factor or yield a leading current when desired has been abundantly demonstrated by machines running in commercial service. But, who is to pay the first cost? Motor users can be divided into two classes: First, those who generate their own power, and second those who purchase their power from central stations.

For the first class this commercial problem is readily solved. As this person generates his own power he is evidently deeply interested in his power-factor. This interest not only extends to the power-factor of the system but, as a purchaser of motors, to the individual motors, because every motor with a low power-factor placed on the system means a relatively lower power-factor on the whole system. This class will readily appreciate the value of the phase advancer and in many of these cases in the future we shall see them installed.

For the second class, those who purchase power, the commercial situation on the present basis of tariffs is rather complicated. A large majority of customers purchase power simply on a maximum demand and kilowatt-hour rate. This customer, therefore, is not greatly interested in the power-factor of the motors he purchases and of course is not inclined to spend several hundred dollars in purchasing phase advancers when he can not derive any direct benefit from them. It is true that some slight benefits are derived from the customer's point of view, such as increased output and probable slight gain in efficiency, but these, in themselves, are not sufficient to warrant the initial cost of installing the extra apparatus. In some cases power companies insist that a motor must have a certain power-factor or better and frequently offer their customers a better rate for keeping their load at a high power-factor. As it is to the interest of the power companies to maintain a high power-factor on their system, they must recognize that a customer with a power-factor of unity deserves a much better rate than one with a power-factor of 0.70.

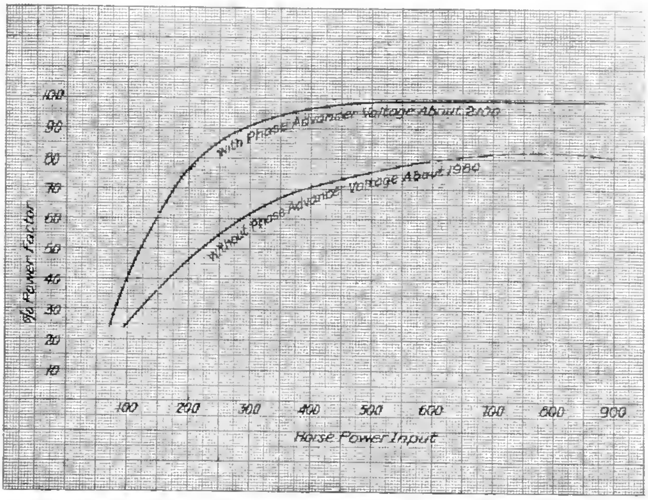

Fig. 8. The lower curve shows the power-factor of a 600 h.p. induction motor when run without a phase advancer. The upper curve shows the power-factor of the same motor with the phase advancer shown in Fig. 1 in circuit

Fig. 7. A Rotary Phase Advancer designed for raising the power-factor of a 400 h.p. induction motor

The commercial success of the phase advancer depends upon the inducement given by the power company to its customer for maintaining a high power-factor. The contract might take the form of a bonus which would be on a sliding scale increasing until 100 per cent power-factor is reached. This bonus might be based on the minimum readings of a graphic power-factor meter. Another way would be to charge for the total kv-a. instead of the kw-hr. An investigation, by Professor Arno of Milan and Mr. Conti, engineer of some Italian power companies, made throughout Italy, with respect to working cost as affected by the power-factor showed that the cost to the power company may be expressed by the formula:

$$\text{Cost} = K\int_0^t (aEI\, cos\, \phi + bEI)dt$$

From a very large number of investigations it was found that $a$ will vary a little but not much and that for an average practical value $A$ can be $^2/_3$ and $b$ $^1/_3$. It can be clearly seen that when a customer is taking no wattless current, i.e., incandescent lighting, $\phi = o$ and cost $= {}^2/_3\, EI + {}^1/_3\, EI = EI$. On the other hand if it were possible to take current at no power-factor at all, $\phi = 90°$, the cost would be $^1/_3\, EI$. That is, the customer pays one third of what he would have to pay if the current he took was energy current and not wattless which seems a fair arrangement. By using a meter of this kind the consumer with a good power-factor would get his power at a cheaper rate than one with a poor power-factor.

The actual saving to the power company and what bonus can be allowed the consumer largely depends on the specific circumstances of each individual case. Some idea of the advantages to be gained by installing phase advancers can be formed from the figures that follow which can be taken as a fairly typical case.

Assume a power company supplying alternating current to a factory, the daily average load of which is 2000 kw., and the power-factor of the system 0.75. Take the load factor at 33 per cent which corresponds to 2890 hours for a year. The annual current consumption is 5,780,000 kw-hr., which at eight-tenths of a cent per kw-hr. means a yearly expenditure of $46,240. The power company has to supply, in addition to the energy current for which the customer pays, all the wattless current for which no payment is made. However, this assumption is not entirely true because power companies would make their rate high enough on the kw-hr. basis so as to include the cost of the wattless power. In this particular case the total output of the station is 2666 kv-a. and the power company is supplying 666 kv-a. of wattless current. Now if phase advancers were applied to say three or four large motors aggregating about 1300 kw. and their power-factor raised to unity, it would be possible to improve the power-factor of the whole system to about 0.95 lagging, assuming the average power-factor of these large motors to be the same as that of the whole system. The power company would, therefore, only have to supply 105 kv-a. of wattless current instead of 666 kv-a. and there would be set free for sale 561 kv-a. or 420 kw. at a power-factor of 0.75. If this is sold to another customer at the same rate and under the same conditions as above it would represent a yearly saving of approximately $9710.

It is evident that the power company could afford to allow the customer 10 per cent on his accounts which would mean an annual saving to the customer of $4624 and to the power company of $5086. The initial cost of the phase advancer to the customer would probably be about $4000 which he would get paid off after the first year and his investment in future years nets him an interest of at least 100 per cent. If the power companies will offer such an inducement then not only will they gain but also the customer.

# SPEED CONTROL OF POLYPHASE MOTORS

By F. B. Crosby

Power and Mining Engineering Department, General Electric Company

The increasingly complex requirements of industrial demands continually result in the exploitation of many ingenious devices, the true worth of which can only be determined by the test of actual service. Until recently only direct-current motors were available for strictly adjustable-speed drives, although the many advantages of the polyphase induction motor often lead to its adoption in spite of its speed characteristics. Several methods of speed control with their inherent limitations are outlined in this article, and two systems recently introduced in this country for dynamic control of polyphase motors are fully described. Relatively simple auxiliary equipment will give to the induction motor the speed characteristics of the direct current shunt motor; at the same time maintaining high power-factor and overall efficiency and retaining the many well known advantages of the induction motor. The new brush-shifting type motor also is described and its exceptional operating characteristics for certain classes of service explained.—Editor.

F. B. Crosby

However great the scientific or popular interest in a new or novel electrical application only the test of actual experience can demonstrate its real economic value. With this truism in mind it is still safe to say that no more certain indication of such possible value can be found than in the widespread and intelligent interest with which the announcement of such application is received. Judged by this standard, the development of an efficient means of obtaining for the polyphase induction motor the speed characteristics of a direct current shunt motor stands first among recent achievements peculiar to the further application of alternating current motors.

Although of far more recent inception the polyphase induction motor in some one of its several forms has to a great extent replaced the direct current motor in the majority of industrial applications requiring constant speed drives. The well known form with a squirrel cage rotor is essentially a "constant" speed machine, that is, the speed varies from synchronism but a few per cent with extreme changes in load, and remains constant so long as the load is unchanged. The squirrel cage motor, however, will develop full load torque at starting only when permitted to draw excessive current from the line and save in exceptional cases with special high resistance rotors, it should not be employed where high starting torque is required. For such service the phase wound rotor with external starting resistance is recommended. This form of motor will develop any required starting torque up to its maximum depending only upon the amount of external resistance in series with its secondary or rotor circuits, the line current being approximately proportional to the required torque. With the external resistance short-circuited, the phase wound rotor gives practically the speed characteristic of a squirrel cage motor, but with resistance in circuit its speed characteristic may properly be designated as "variable," that is, the speed becomes a function of the secondary resistance and the counter torque of the load.

Generally speaking, the ideal machine for industrial applications would be one in which high efficiency and high available starting torque were combined with high running torque and strictly adjustable speed characteristics. The term "adjustable" speed as opposed to "constant" and "variable" is used to cover speeds practically *constant* at *adjustable* values for all loads. This ideal has not yet been fully realized in any single unit.

In the meantime, because of the many advantages of a-c. generation, distribution and application as compared with systems involving either d-c. generation or transformation, the industrial public has largely accepted the occasional compromise in speed or efficiency required by the adoption of the simple and rugged polyphase induction motor. Except for certain applications where a large number of strictly adjustable speeds must be had and consequently where, until recently at least, direct current motors must be used, the induction motor has outdistanced all other types in the contest for reliability and popularity.

With characteristic endeavor to overcome the limitations and improve existing designs electrical manufacturers the world over have gone to great expense in a systematic effort to produce a polyphase motor which would successfully compete with the direct current motor in adjustable speed service. For larger capacities and with limitations discussed below the solution of this important problem has been found in a system of dynamic regulation first exploited abroad by Brown, Boveri & Co., but recently modified and developed by the General Electric Company.

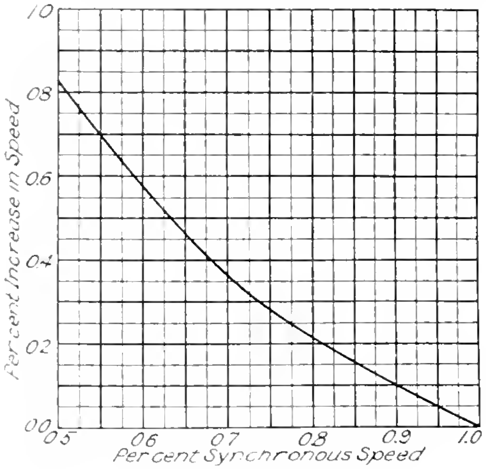

Fig. 1. Curve showing Increase in Speed Due to Diminished Torque

Before discussing this system of speed control it may be well even at the risk of some tiresome repetition to review briefly several methods of speed control for polyphase motors which in the past have proven a more or less satisfactory compromise for the strictly adjustable speed obtainable with dynamic control. Among the more important schemes used are the following:

I. Rheostatic control.
II. Multi-speed windings.
III. Concatenation or cascade.
IV. Internal concatenation.
V. Dynamic control.
VI. Brush shifting motors.

## I. Rheostatic Control

As noted above, the polyphase induction motor when operated with negligible secondary resistance is inherently a constant speed machine. Continuous speed control under constant load can be had by means of an adjustable resistance in the external secondary circuit.

If this external resistance and load each remain constant the speed also remains constant, but any change in either load or resistance produces a corresponding change in speed, the motor tending to accelerate to synchronism as either the load or resistance is reduced. Within a limited range the speed can be maintained approximately constant by increasing either one of these factors as the other is reduced or vice versa, but from a practical standpoint the size and cost of a resistance capable of maintaining any appreciable speed reduction under light loads is prohibitive. This series speed characteristic is of great importance in connection with the effective application of flywheels where a material drop in speed must be obtained in order to render available a portion of the stored energy of the rotating parts as the peak loads come on. On the other hand, it makes rheostatic control wholly impracticable for variable loads at reduced speed such as occur, for example, in the main roll drives in steel mills.

Fig. 1 shows the increase in motor speed corresponding to several initial speeds when the load is suddenly changed from 1¼ to ¼ full load torque without changing the external resistance.

The most serious objection to reduced speed operation for any considerable period of time lies in the fact that with rheostatic control the efficiency is reduced almost in direct proportion to the reduction in speed. For example, if a motor, Fig. 2, is to deliver constant torque from full to half speed the motor input will be constant, but at half speed the efficiency will be something less than 50 per cent, since the h.p. output at the shaft is but half that at full speed with the same electrical input. The relation of rheostatic losses to shaft output for several characteristic types of service is shown in the following table to be constant.

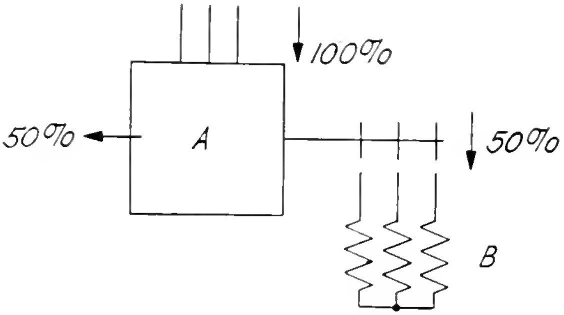

Fig. 2. Diagram of Induction Motor with Rheostatic Control

RELATION OF SHAFT OUTPUT AND RHEOSTAT LOSSES

I. Constant torque.
II. Constant horse power.
III. H.p. inversely as the $n^{th}$ power of speed.

| For any value of $s$ | I | II | III |
|---|---|---|---|
| Torque | $T$ | $\frac{T}{1-s}$ | $(1-s)^{n-1}T$ |
| Shaft h.p. | $(1-s)$H.P. | $HP$ | $(1-s)^{n}HP$ |
| Rheostat h.p. | $s\,HP$ | $\frac{s}{1-s}HP$ | $s(1-s)^{n-1}HP$ |
| or Rheostat h.p. | $\frac{s}{1-s}\times$shaft $HP$ | $\frac{s}{1-s}\times$shaft $HP$ | $\frac{s}{1-s}\times$shaft $HP$ |

Where:

$HP$ = rated horse power at $N$ rev. per min.
$T$ = full load torque at $N$ rev. per min.
$s$ = slip or regulation in per cent synchronous speed $N$.
$1-s$ = speed of motor in per cent synchronous speed $N$.

If the part load efficiencies and respective slips with short circuited secondary are known, the efficiency at reduced speed with rheostatic control and constant torque can be found by plotting per cent efficiency against per cent synchronous speed. A straight line drawn from 0 to the point corresponding to known values of part load efficiency and slip will give the efficiency at any desired speed.

It is evident then that there are two very serious objections to the operations of the standard induction motor with a phase wound rotor and rheostatic control, first due to the effect of the series speed characteristic under varying loads, and second, due to the excessively low efficiency when operated over considerable time intervals at reduced speed and constant load.

### II. Multi Speed Windings

Where two definite constant speeds are sufficient the induction motor can often be supplied with external connections by means of which the polar grouping can readily be changed, Fig. 3, to give the desired synchronous speeds. The cost of such a motor is but slightly more than that of a single speed design provided a 2:1 ratio is used. When a ratio other than 2:1 or where three or four constant speeds are required the conditions can sometimes be met by the use of two independent windings side by side in the same slots, one or both of these windings being arranged for external polar grouping. Three separate windings are not permissible in practical design.

The efficiency of the multi-speed motor is practically constant at full load for each synchronous speed but at the lower speeds the power-factor may become very poor.

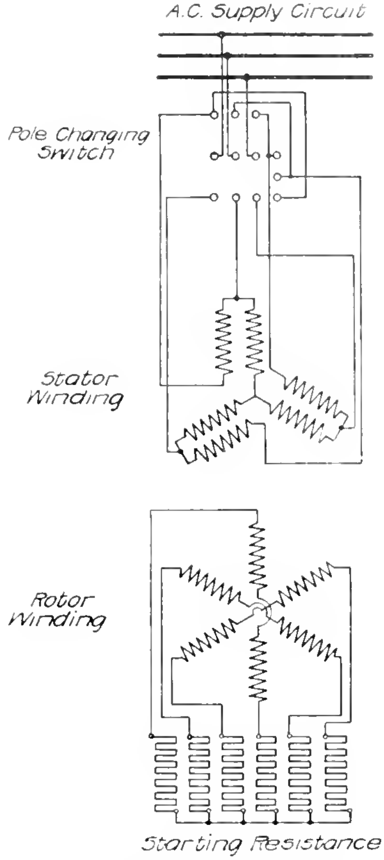

Fig. 3. Diagram of Windings for Multi-Speed Induction Motor

Intermediate speeds can be had with phase wound rotor construction but always subject to the disadvantages noted.

### III. Concatenation or Cascade

Where three or more synchronous speeds are necessary a method involving segregated electrical and magnetic circuits is sometimes employed. This arrangement is commonly known as the concatenated or cascade connection. In general, two single speed motors, one of which at least has a phase wound rotor, are mounted on the same shaft. The primary of motor "A" is connected to the secondary of motor "B." Each of these motors may have either single or multi-speed windings and may be operated independently of the other. The second motor "B" may have either a squirrel cage or phase wound rotor. In the latter case rheostatic control can be employed for intermediate speeds.

Two motors are in direct concatenation if they show a tendency to start in the same direction and in differential concatenation if they tend to start in opposite directions. The several synchronous speeds in concatenation may be determined as follows:

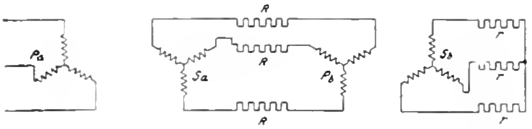

Fig. 4. Diagram of Windings for Concatenated Induction Motor

$$\text{Speed r.p.m.} = \frac{\text{cycles} \times 120}{P_1 \pm P_2}$$

Where $P_1$ and $P_2$ are the number of poles on the first and second motors respectively the plus sign being used for direct and the minus for differential concatenation.

With the multi-speed design mentioned above it is necessary to open the primary circuit when changing from one speed to another: This may be avoided in the concatenated set by introducing resistance, Fig. 4, between the two motors and cutting out step by step when changing speeds. Efficiency and power-factor characteristics do not differ materially from those of the multi-speed motor.

Fig. 5 shows a 600 h.p. six-speed concatenated motor built by the General Electric Company and installed for steel mill service.

### IV. Internal Concatenation

Another method of obtaining two or three definite speeds has been adapted by the General Electric Company to special industrial applications. This consists of a single motor with an internally concatenated winding so arranged that the magnetizing effect of the single winding is practically the same as would be produced by two separate windings. It is, however, a decided improvement over the two windings ordinarily used, since all coils which in such case would neutralize each other are omitted in the concatenated connection. These coils are grouped together and connected to the collector rings for use only at other speeds.

The scheme of connections is shown diagrammatically in Fig. 6. The stator winding is of the full and half speed type which has been in use for a long while. When the primary of the first element is properly connected with two circuits per phase in multiple corresponding to the number of poles, these circuits are in exact opposition for the number of poles in the second element, and form a perfect path for short-circuiting the secondary of the second element. The stator winding, therefore, carries two currents simultaneously; first, a current from the line at full frequency and, second, an induced current at slip frequency.

A serious limitation to the general application of this motor lies in the fact that the three speeds for a given motor must be in the ratio 1-2-3; on account of mechanical vibration the ratio 2-4-6 can not be successfully used.

By inserting an adjustable external resistance between certain points in the stator winding, variable speed control is obtained for the concatenated connection with the slip rings open-circuited. For the other two speeds an adjustable resistance across the slip rings gives the speed characteristics of the ordinary phase wound rotor.

### V. Dynamic Control

As pointed out in the beginning of this article it has been necessary until recently to resort to direct current motors wherever it was essential that close regulation be maintained for a large number of speeds, each constant under varying loads. Two practical methods of obtaining this much desired result have been in use for several years in Europe. Both are subject to modification, yet are fundamentally the same in that each involves certain auxiliary equipment arranged to transfer the secondary or slip energy taken from the collector rings of the main motor

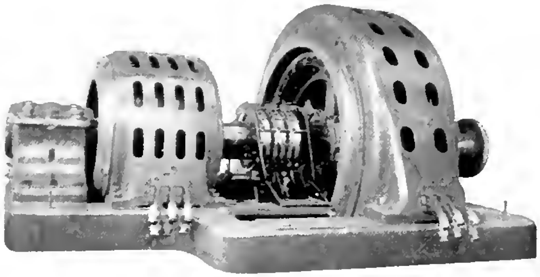

Fig. 5. A 600-h.p , 60-cycle, 514-r.p.m., 2200-volt Concatenated Induction Motor Arranged for Six Synchronous Speeds

at varying frequency and voltage, back to the source of supply at constant line frequency and potential.

These two schemes may be briefly designated as the "rotary converter" and "commutator motor" methods respectively. Both systems were carefully investigated and after very complete factory tests begun at Schenectady nearly three years ago, the General Electric Company adopted the "commutator motor" method, this being by far the more simple of the two systems. The European design has been materially modified and improved to meet the requirements of American practice and will be discussed at greater length below.

The rotary converter method is indicated in Fig. 7. The slip energy of the main motor is transformed in a suitable separately excited rotary converter to direct current which in turn drives a separately excited d-c. motor forming one unit of a two unit motor-generator. The generator is a standard squirrel cage induction motor which is driven above synchronism as an asynchronous induction generator and returns to the system at normal frequency and voltage the transformed slip energy of the main motor. Speed control of the main motor is obtained by varying the field strength of the d-c. motor.

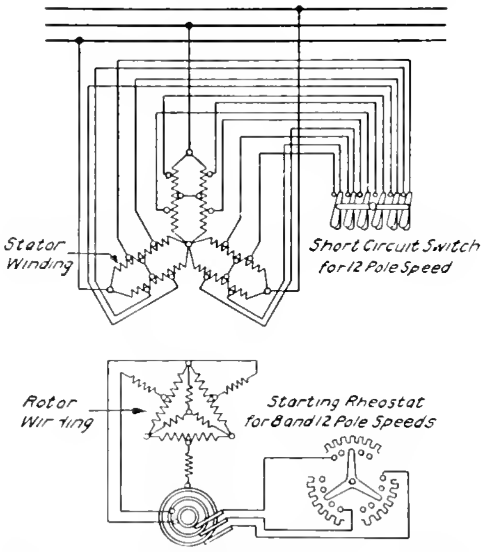

Fig. 6. Diagram of Windings for Internally Concatenated Induction Motor

This method is practically applicable to 60 cycle motors where the range of speed required exceeds 25 or 30 per cent and also for either 25 or 60 cycle motors where the slip energy amounts to 1000 h.p. and upwards. For regulation up to 30 per cent for 60 cycle or 50 per cent for 25 cycle motors the commutator motor method is decidedly preferable.

A point is sometimes made in favor of the rotary converter method, e.g., that standard machines from stock can be used throughout. This is occasionally true for 60 cycle main motors with speed regulation of approximately 30 per cent to 40 per cent, since the maximum slip frequency would be in this case from 18 to 24 cycles, thus permitting the use of a standard 25 cycle rotary. This arrangement compares very favorably with the separate speed regulating set in spite of the fact that a rotary converter and motor-generator are required instead of simply a two unit regulating set.

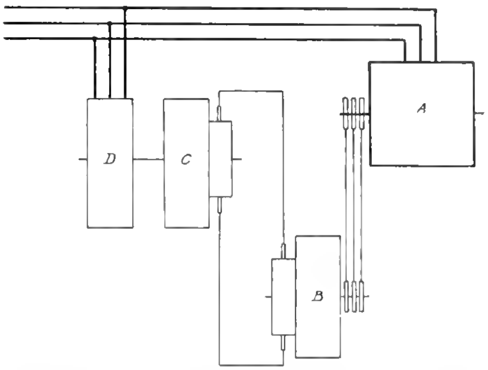

Fig. 7. Diagram of a Rotary Converter and a d-c. a-c. Motor-Generator Arranged for Adjustable Speed Control of Main Induction Motor

For an appreciably greater or less speed range it is probable that the rotary converter would have to be of special design while in case of 25 cycle main motors, which unquestionably include by far the greater number of possible applications, it is certain that to obtain an economical design with high efficiency, a very special rotary converter for operation at slip frequency must be used.

A further limitation of this method lies in the fact that as the main motor approaches synchronism the frequency and voltage impressed on the rotary converter approach zero and operation becomes more unstable at lower slip values than with the regulating set; that is, speeds can not be adjusted as close to synchronism with the rotary as with the regulating set. This point is of special importance in case of low speed motors for 25 cycle circuits.

Theoretically either of these systems will operate equally well for speed control above or below synchronism. By exercising the greatest care the main motor with rotary converter control can sometimes be carried through synchronism by reversing the field of the d-c. motor, provided the rotary converter happens to stop in the proper phase relation when it comes to rest due to reduced frequency and voltage. Its behavior is, however, very uncertain and the only practical method of rising above synchronism involves the use of still another special exciter at this point. Such an arrangement has been tried out abroad and is operative but so far as can be ascertained the results from the standpoint of increased economy of production do not yet warrant the added complexity of equipment.

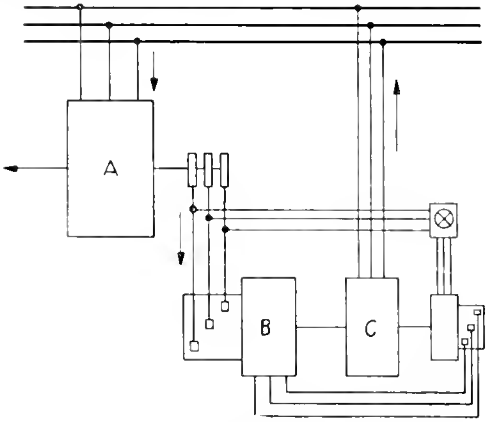

Fig. 8. Diagram of General Electric Speed Regulating Set arranged for adjustable speed control of main induction motor

In passing it is of interest to note that in the fall of 1912 the General Electric Company submitted a formal quotation covering a 2000 kw. rotary and 3000 h.p. d-c. a-c. motor-generator to give approximately 45 per cent speed control of a 6500 h.p.—107 r.p.m., 25 cycle, 6600 volt induction motor already in successful operation. Subsequent developments in the operating conditions rendered speed regulation unnecessary but so far as we can ascertain this was the first and thus far the largest bona fide quotation in this country covering auxiliary equipment for adjustable speed control of induction motors.

Fig. 8 shows diagrammatically the connections of the commutator motor speed regulating set. Referring to Fig. 2, the resistance B, in which the slip energy is dissipated as heat when rheostatic control is employed, is replaced by the three-phase compensated commutator motor B of Fig. 8. This motor forms one unit of a two unit motor-generator the second unit of which is a standard three-phase induction motor with squirrel cage rotor. The series speed characteristic of the commutator motor drives the induction motor C slightly above its normal synchronous speed, causing it to operate as an asynchronous induction generator and return to the system energy proportional to the reduction in speed of the main motor less, of course, the losses in the set itself.

By means of these sets the speed characteristics of the d-c. shunt motor are obtained together with the high power-factor and efficiency at all speeds while the sturdiness, simplicity and general adaptability of the induction motor is retained for the main drive. From what has been said it is evident that the commutator motor receives its energy at relatively low frequencies and in general will have a proportionally small percentage of the main motor capacity. It is also evident that these sets are equally applicable to motors designed for constant torque or constant horse power service. If desired, the characteristics of a compound wound d-c. motor can be obtained and an automatic increase in slip under peak loads when flywheels are used.

A modification of this scheme is shown in Fig. 9 in which case the induction generator is omitted and commutator motor mounted on an extension of the main motor shaft. The general characteristics are unchanged but now the commutator motor must be designed to operate throughout the same range of speeds as the main motor and hence is much more expensive than the former arrangement. This arrangement is particularly desirable where constant h.p. is required at reduced speed since in this case as the speed is reduced the torque of the commutator motor increases in direct proportion. The main motor can therefore be designed for *constant torque* with a very material reduction in cost as compared with the constant h.p. design, and yet, since the slip energy is in this case returned mechanically, the actual total torque increases as the speed decreases and thus maintains constant h.p. at the shaft.

In general, however, the self contained regulating set is quite as satisfactory since both commutator motor and induction generator may be of relatively high speed and inexpensive design compared with the lower speed main motor. Furthermore, the possibility of applying the standard set to practically any normal induction motor with phase wound rotor in the event of a subsequent rearrangement of motor drives is an important advantage.

In Fig. 10 are shown comparative power-factor and efficiency curves for standard induction motors with rheostatic control and with dynamic control. At speeds near synchronism the single motor shows slightly higher efficiency but the margin in favor of dynamic control increases rapidly as the speed is reduced.

In addition to the advantages of adjustable constant speeds under varying loads and high operating efficiency, the possibilities of power-factor correction are often of great importance; if desired unity power-factor can be obtained with all the usual advantages in improved voltage regulation and increased energy capacity in the power system. Unity power-factor correction naturally involves a somewhat more expensive regulating set since the magnetizing current is supplied by the commutator motor instead of directly from the line. The standard set usually has sufficient capacity to raise the power-factor of the main motor about 10 per cent, maintaining at full load an average power-factor of 90 to 95 per cent or in some cases even 100 per cent without increased cost.

In special cases it is entirely feasible to supply sufficient leading current from the commutator motor to give the main motor a leading power-factor and thus obtain a certain corrective effect for power-factor conditions on the external system. The kv-a. capacity, first cost, and copper losses will obviously be increased and the overall efficiency of the system lower in this case.

Contrary to possible impressions the use of these standard regulating sets involves very little additional control equipment. In fact, *so far as the operator is concerned but one single additional act is required in starting or stopping the equipment;* namely, starting the motor-generator set by means of a standard starting compensator.

Automatic magnetic control is used throughout. *To put the equipment in service it is merely necessary to throw first the compensator of the motor-generator and then the master controller to running position. That is all.* The main motor starts; accelerates with current limit, connects the regulating set and automatically drops into a definite speed depending upon the setting of the exciter field rheostat. The desired speeds are obtained by manipulation of this small field rheostat as with a d-c. shunt wound motor.

As the excitation of the commutator motor is increased the tension at the slip rings of the induction motor increases. The current in the secondary of the induction motor is therefore the result first of direct induction between the stator and rotor windings and second of the counter e.m.f. of the commutator motor. The speed-torque and speed-current curves for a given induction motor are fixed by the impressed frequency, voltage and secondary resistance. With these three factors constant there is a definite speed for each value of secondary current and torque. Consequently increasing or diminishing the excitation of the commutator motor produces a corresponding increase or decrease in the speed of the main induction motor. Furthermore, since the excitation is derived from the secondary of the main motor it follows that any tendency to vary in speed, due to varying load, is checked by a corresponding variation in the counter e.m.f. of the commutator motor necessary to supply the required secondary current, or torque, of the main motor.

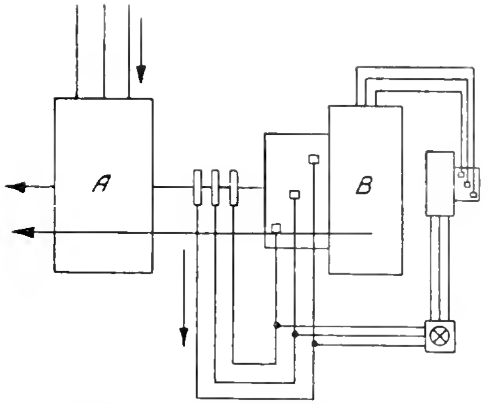

Fig. 9. Diagram of General Electric Speed Regulating Commutator Motor direct connected for adjustable speed control of main induction motor

For the low frequencies involved, the compensating winding of the commutator motor provides practically direct current conditions so far as commutation is concerned. Factory tests have shown absolutely perfect commutation under instantaneous changes from 0 to 100 per cent overloads at 30 per cent regulation with a 600 h.p., 25 cycle equipment.

Eighteen of these speed regulating sets have been sold this past year for use with motors ranging from 250 h.p. to 1300 h.p. for operation on three-phase, 25 cycle and 60 cycle low and high voltage circuits for mine fans and main roll drives in steel plants.

### VI. Brush Shifting Motors

The General Electric Company has also recently placed on the American market a polyphase series brush shifting motor, which for certain classes of service possesses decidedly novel and desirable characteristics. This motor was originally a German invention and for several years has been in successful operation abroad. Its introduction in this country is especially worthy of note in connection with the subject under discussion owing to the simple and efficient means of obtaining speed control. It must not be confused, however, with the commutator speed regulating motor described above as it is entirely different in design.

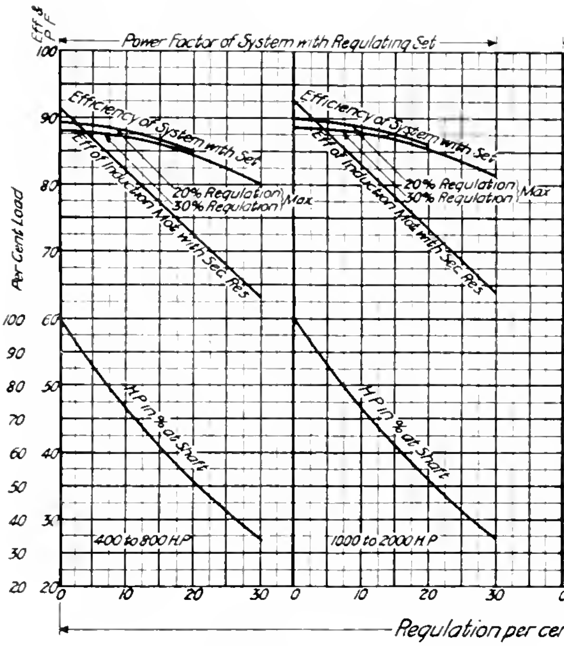

Fig. 10. Over-all Efficiency of Induction Motors operating at different speeds, torque decreasing with speed, (fan service) speed control obtained by speed regulating set and by rotor resistance

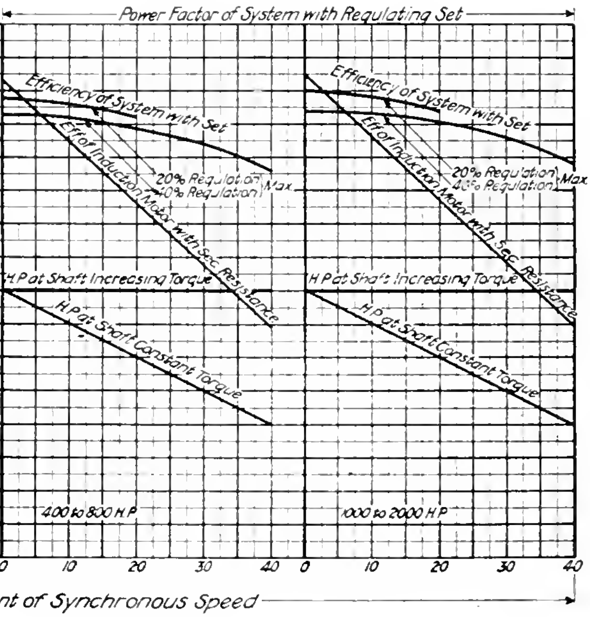

Over-all Efficiencies of Induction Motors operating at constant horse power or constant torque at different speeds, speed control obtained by speed regulating set and by rotor resistance

The brush shifting motor although possessing the characteristics of a series direct current motor, has certain marked advantages in the absence of separate control devices, the high power-factor and efficiency, high starting torque, and chiefly perhaps, in the possibility of obtaining such characteristics in an a-c. motor.

The motor consists essentially of a three-phase distributed winding in the stator identical with that commonly used for the standard polyphase induction motor. The rotor is in appearance and design essentially a standard direct current armature with commutator. The arrangement of windings is shown diagrammatically in Figs. 11 and 12. For ordinary commercial voltages the current passes through a triple-pole single-throw disconnecting lever switch and fuses or suitable oil switch with overload and low voltage features, thence through a series transformer *T* to the stator windings *S*. The current from the secondary of the series transformer passes to the brushes *B* and thence into the rotor *R*.

The chief function of the series transformer is to reduce the voltage impressed on the commutator to a satisfactory working value. This usually is approximately 80 to 90 volts and minimizes the danger of sparking at the commutator. If a transformer is employed to step down the primary or stator voltage to suitable values the series transformer can be eliminated (Fig. 11), but in general it is more desirable to retain the customary standard voltages for the stator and employ the series transformer to obtain the desired rotor voltages.

The most striking feature of this type of machine is the complete absence of external starting or speed controlling devices. The motor is started, accelerated, stopped and reversed by shifting the brushes. This shifting is accomplished by means of worm gear and handwheel mounted on the frame of the machine. If desired, a small pilot motor can be used and perfect control obtained from a remote point.

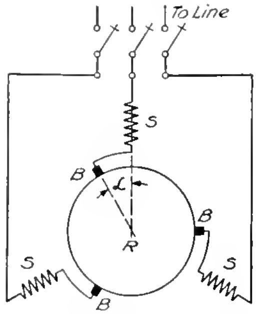

Fig. 11. Diagram of Connections of General Electric Brush-Shifting Motor

Since in effect the total ampere turns in the stator are equal to, and in series with, those of the rotor it is evident that with the brushes set in the same axis as the stator winding, the angle $\alpha=0$ and no field is

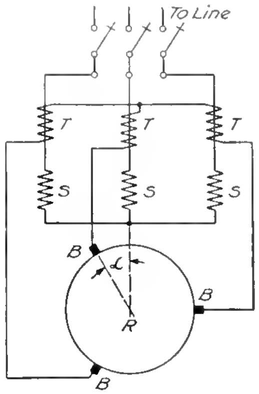

Fig. 12. Same as Fig. 11 Including Series Current Transformer

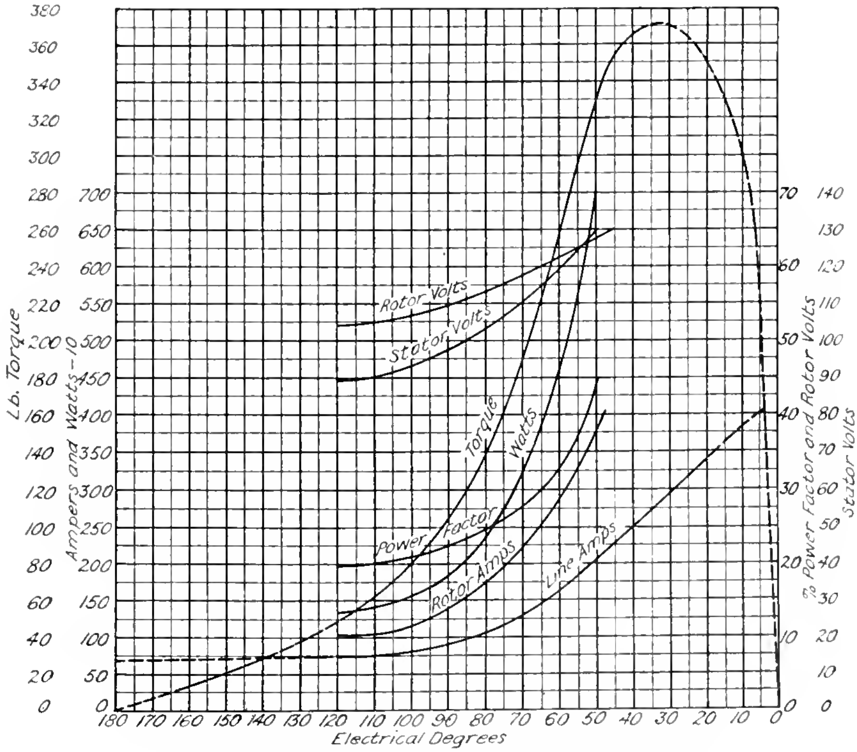

Fig. 13. Characteristic Torque Curves for Standard Brush-Shifting Motor

produced by the line current. If the brushes are now shifted through the angle $\alpha$ the balance between rotor and stator winding no longer exists, and the resultant ampere turns produce an excitation proportional to the current in both windings and to the angle of brush shift. The motor therefore, will develop a torque proportional to the square of the line current and the angle of brush shift. If the angle of brush shift is 180 deg. no torque is developed since the stator field and rotor current are 90 deg. out of time phase. With the brushes in this position, the magnetizing current only, which is about 10 per cent of the normal full load current, is drawn from the line and the main line switch can be closed without starting or in any way injuring the motor. If now the brushes are gradually shifted backward the line current and motor torque increase slowly at first until the motor starts gently. This characteristic is especially desirable in taking up back lash in gear trains or devices where uniform acceleration is important.

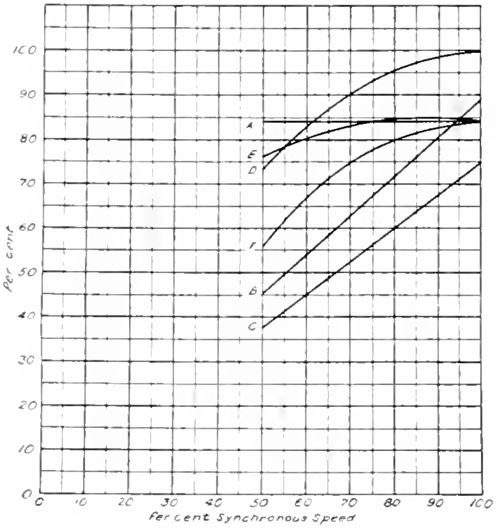

Fig. 14. Comparative Power-factor and Efficiency Curves of brush-shifting motor and induction motor with rheostatic control

| Induction Motor | Brush-Shifting Motor |
|---|---|
| A–Power-factor | D–Power-factor |
| B–Efficiency | E–Efficiency |
| C–Apparent Eff. | F–Apparent Eff. |

As the brush shift is increased the torque curve begins to rise rapidly, as shown in Fig. 13, so that any desired value of starting torque within the limit of the design of the motor in question is available. By actual test some of these motors have started successfully and without appreciable sparking under 400 per cent of normal rated torque. This value, however, is higher than could reasonably be expected in economical design.

By merely shifting the brushes perfect speed control is obtained throughout approximately 75 per cent of the range from rated speed to standstill. In general 40 to 50 per cent speed control is ample and obviously a request for greater range should be avoided unless really necessary as the greater range means a more expensive machine except in certain cases like fan service, where the load falls off rapidly as the speed is reduced.

If the brushes are shifted beyond $\alpha = 180$ deg. the motor will start in the reverse direction. In order to obtain the best commutation, however, it is necessary to interchange two of the primary phases which reverses the rotating field of the stator giving it the same direction of rotation as the armature. Commutation is sparkless from about 10 per cent above to about 70 per cent below synchronism.

The lower speed limit is determined by the torque characteristics rather than by commutation which is very good even to 90 per cent below synchronism. In the higher range of speeds the torque increases rapidly for a given brush shift with any slight reduction in speed, consequently a slight change in the counter torque of the driven device affects the speed but little. The converse is true, however, in the lower speed ranges so that the minimum permissible speed depends largely upon the torque characteristics of the load.

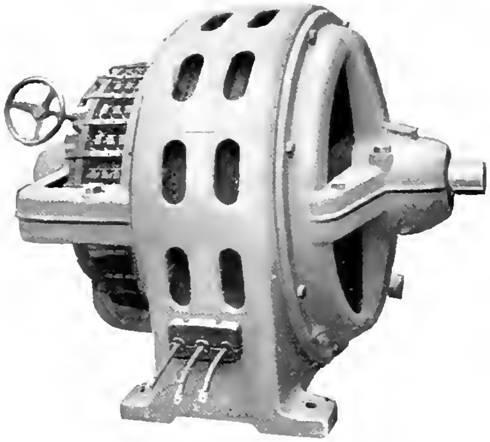

Fig. 15. A 100 H.P., 440-volt Brush-Shifting Motor for Connection to a 100,000 cu. ft. Robinson Mine Fan

For centrifugal fans, pumps, etc., in which the torque falls rapidly, approximately as the square of the speed, stable conditions will obtain even at speeds 70 per cent below synchronism. For load machines offering more or less constant counter torque the lower limit of stable operation is somewhat higher, say about 50 per cent below synchronism.

One of these motors was installed on a cloth printing press and has been in continuous service for more than nine months with most satisfactory results under exceedingly severe starting conditions. Other motors in capacities up to and including 100 h.p. have been in continuous service on mine fans for four to six months night and day with equally satisfactory results.

Fig. 14 shows typical power-factor and efficiency curves for the brush shifting motor as compared with a standard induction motor with rheostatic control.

Fig 15 shows a view of a standard 8 pole, 100 h.p., 375 r.p.m., 440 volt brush shifting motor for direct connection to a 100,000 cu. ft. Robinson mine fan.

Fig. 16 shows typical speed torque curves corresponding to various brush shifts on an 8 pole, 50 h.p., 900 600 r.p.m., brush shifting motor.

# METHOD OF DETECTING FAULTS IN TRANSMISSION INSULATORS

By T. A. Worcester

Power and Mining Engineering Department, General Electric Company

The author brings attention to the seriousness of suspension insulator failures which have occurred during the past few years and to the efforts of operating engineers to locate the causes of these troubles and to relieve their transmission lines from the disastrous effects of frequent failures. Studies were made of various possible methods of detecting weak insulators installed on the line before they actually failed by puncture, but most of these methods were found to be unsuitable because of the bulk, weight and cost of the testing equipment. One company adopted a portable megger for this work, and the results of its investigation are given by the author. Other tests made on punctured insulators with a megger are described and the advantages and disadvantages of this class of instrument are discussed. It is pointed out that such an instrument is not suitable for picking out all damaged, punctured or cracked insulators, but that its usefulness is limited to detecting only those in which the surface of the fracture is conducting.—Editor.

T. A. Worcester

During the last few years an unusual number of suspension and strain insulators have failed while in use on high voltage transmission lines. In the majority of cases these insulators had been given standard factory tests and had been in service for a year or two, so that they seemed to be entirely satisfactory. Their failure has occasioned considerable study, which resulted in the belief that there had been a change in the body of the porcelain due to aging or some sort of mechanical deterioration. The failures were so frequent and on some systems resulted in such serious shut-downs that it became imperative to weed out all bad insulators on the lines before additional failures might occur. Usually after an insulator had failed it could be detected by observation either from the ground or tower. Oftentimes, however, the porcelain skirt was not shattered and the defect was concealed under the cap or was in such a position that it could not be easily noticed. In such instances it became necessary to re-apply voltage to the line so as to damage the defective insulator more severely and make the break noticeable. This method frequently resulted in heavy line surging and the breaking down of other insulators on the system which only prolonged the search for the damaged units. The seriousness of this sort of trouble caused operating engineers to investigate the possibility of locating weak insulators installed on the line, before they had actually failed. Various high voltage testing equipments were considered but these as a rule were heavy, costly and ineffective and in general were not adapted to testing insulators on the line. The engineers of one company after careful consideration of other testing equipments turned their attention to the megger which is a megohm meter or a direct reading instrument for measuring high resistances. This type of instrument attracted attention because it is comparatively light and substantial, can be easily carried along a transmission line, and can be readily adapted to testing insulators installed on the towers.

With a portable megohm meter it is practicable to test every disk of the insulators of an entire transmission line in a comparatively short time. The results of such a set of tests are given in A.I.E.E. Proceedings of Feb., 1914, in the report of the Institute sub-committee on transmission. We quote from this report as follows:

"A megger was secured, giving 500 volts, and reading 1000 megohms. The method of procedure was as follows:

"On a single-circuit tower line a party was organized consisting of engineer in charge of the megger and six linemen, working in pairs. One pair would proceed to ground the line on a certain tower and hold the leads of the megger, which consist of about 100 ft. (30.4 m.) of standard lamp cord, to the individual disks in the strings of insulators, by means of two wooden handles. The readings would be taken, whereupon the megger would be taken to the next tower on which another pair of men were ready to go through the same procedure. With this arrangement about four towers per hour could be tested, each tower being provided with eighteen disks.

"On a double circuit line about 26 towers were covered in ten hours.

"The following results were obtained:

"On a total of 2100 disks under observation, fourteen of this number were found defective.

"Twelve disks had defects invisible from the ground, and in two disks the defects were visible from the ground.

"Of the twelve invisible from the ground, two of these could be noted as defective from the tower, four could be detected by very close inspection, after taking down, and six showed absolutely no defect.

"One of these disks, the defect of which was entirely invisible, measured 300 megohms, two measured 250 megohms, and the balance were less than 5 megohms, which was the lowest point on the scale. Good disks were considerably over 1000 megohms."

Two features of this data are especially interesting, first that with a small portable instrument it is practicable to pick out defective insulators which have no visible defects, and second that there is such a small percentage of defective insulators on the line. These are points of considerable importance. As regards the first, operating engineers are given a means of materially improving the insulation of their lines and of greatly reducing the danger of shut-downs which might be caused by punctured insulators. There is, however, a question which naturally arises, namely: Can all weak or defective insulators be detected with a megohm meter? One is apt to think that when an insulator is fractured or punctured its insulation resistance is negligible. This is not, however, always the case. In some instances the path along the fracture is made conducting by the deposition of metal along the surface or of moisture and dirt, but often electrical punctures or mechanical breaks occur which do not cause conducting surfaces. Insulators of this class are immune against discovery with a megohm meter. This leads to the second point mentioned above which had reference to the small percentage of defective insulators found on the line, and makes one wonder if there were not other units in which there were minute cracks or which had been highly strained mechanically so that they were electrically weakened and would puncture easily with excess electrical strain. It is highly probable that there were such units and that these may cause trouble in the future. This marks the limitation of the megohm meter for testing insulators on the line and indicates that this type instrument can not be unconditionally depended upon. The number of defective insulators which may escape in the megohm meter test is possibly small since exposure to moisture will make a crevice conducting and give a low meter reading. On the other hand many breaks occur beneath the metal cap practically out of reach of moisture. Such crevices may become conducting through ionization or the formation of nitrous oxide in the presence of water, but in case there are several suspension insulators in the strings this action will be slow and may not be noticeable throughout a long period.

It is interesting to examine the results on pin insulators with a megohm meter. The writer recently had occasion to observe some such tests on a number of 18,000 volt two-piece insulators which had been in use for some months on an operating system. Six insulators were under observation. They were first punctured by a high frequency test set and then heated up and the puncture enlarged by several minutes run on a 60-cycle circuit. The insulators were provided with iron thimbles cemented in securely. One insulator which showed quite a sizable puncture at the tie wire groove was wrapped with several windings of fine bare wire so that the wire touched the mouth of the puncture. The megger was then applied and showed infinite resistance between the wire wrapping and the pin thimble. The contact between the wire wrapping and the pin was then moistened with a tiny drop of water and the resistance made negligible. Very likely some of this water went into the hole but the quantity was so small that it could not have wet the surface for any great depth. In another instance the puncture took place through the inner shell just above the exposed surface of the cement which held the inner and outer shells together. The mouth of the puncture was in the cement. Contacts were placed on the pin thimble and on the cement 1/8 in. from the mouth of the puncture. Infinite resistance was recorded. With one contact in the thimble and the other on the cement diametrically opposite the puncture the resistance was 2000 ohms. This indicates that the cement contained a considerable amount of moisture and that this moisture had been driven out for a short distance from the puncture by the heat of the current and arc. When contact was made at the mouth of the puncture the resistance was 500 ohms and when a drop of water was placed on the mouth of the puncture the resistance was negligible. These points are important in that they indicate the uselessness of megohm meter tests where the contacts are at any point except the opening of the puncture and where, as is often the case, the surface of the puncture or mechanical break are not conducting.

It has been suggested that a megohm meter would be a valuable instrument for making tests in the porcelain factories on new insulators. From the above discussion, however, it would appear that but little can be gained by such practice. No defective insulators can be detected in this way which cannot be detected by a high voltage test set and in a factory where the latter can be conveniently and permanently installed it offers the best advantages.

It is not meant by the above to in any way discourage the use of megohm meters as a means of detecting poor insulators installed on a line but it is the purpose to point out their limitations and to allay the impression that this class of instrument is suitable for detecting all defective insulators.

# SWITCHBOARD SIGNAL EQUIPMENT FOR POWER STATIONS

By Emil Bern

Switchboard Engineering Department, General Electric Company

It has been remarked that the switchboard and the switchboard operator constitute the brains of the power plant, for they determine whether the wheels shall run or stand still or what amount of work shall be performed. But human intelligence is required at the machines as well as at the switchboard, and therefore communication between the two places becomes necessary. In this article the author briefly explains the principal systems of switchboard signals for large power plants. Mr. Bern's article on switchboard design in the October, 1913, issue of the General Electric Review also refers to this subject.—Editor.

Emil Bern

In the large modern electrical power plant most of the switching apparatus is usually electrically operated from an instrument and control board located at some convenient point which may be a considerable distance from the machines. This puts the switchboard operator and the machine attendant in relation to each other approximately as the navigating officer on the bridge of a ship is to his engineer. It is of course necessary to have some easy means of communication between the two since it is often of the greatest importance to have orders transmitted instantly and without the risk of the confusion that may be caused by excessive noise or mental strain due to emergency conditions. Many different systems of communication between switchboard and machine attendants are in use to meet the various operating conditions. In all cases it is necessary to have a means of signaling between the control board and each machine, with provision for attracting the attention of the machine attendant wherever he may be. This is necessary because he has usually charge of a number of machines.

## Visual Signals

In many stations it is possible and convenient to locate the control board on a gallery overlooking all the machines, and to design the board so that the switchboard and machine attendants can see, and visually signal, each other between the columns supporting the instrument panels, see Fig. 1. With this arrangement the only signal apparatus required is a gong or a whistle for calling attention, and sometimes a semaphore

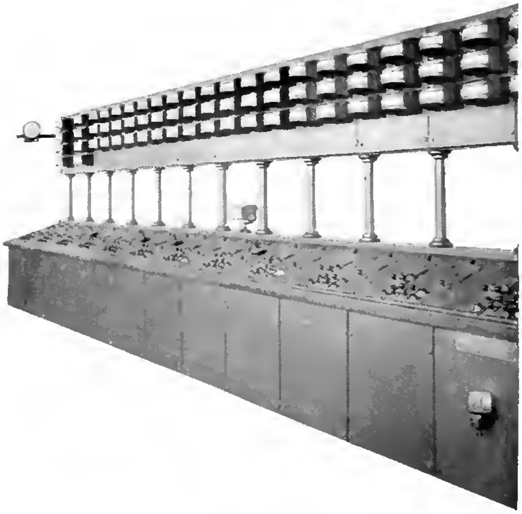

Fig. 1. Gallery Type Control Board which permits the operator viewing the machines through the board

or a few lamps are added to indicate with which machine the switchboard operator desires to communicate.

### Illuminated Sign Signals

In many instances it is not feasible to design and locate the control board so that the operator has a view of the machines. It then becomes necessary to provide a more complete signal equipment. An illuminated sign, installed so as to be in plain sight from every machine, gives often a satisfactory but simple signal device. This illuminated sign carries the designation number of every machine or unit in the station. Each number is energized from the control board by a switch which at the same time sets a gong or whistle in operation. In addition to the unit numbers the sign also contains in illuminated letters the most important signals, such as "START," "STOP," "STAND BY," etc., all controlled by suitable switches on the board. Provision is also made for answering or returning signals to the switchboard. The selection of the signal words should be determined entirely by the method of operation of the particular machines and the division of duties between the switchboard operator and the machine attendant. One prime mover may, for instance, have its governor controlled electrically from the switchboard while another is controlled at the machine by hand only. The signal words should obviously be different for the two conditions.

### Individual Push Button Signals

It is often a great convenience to have individual signal equipments for each unit, both at the switchboard and at the machines; and each equipment complete for transmitting and receiving signals. The push button signal equipment illustrated in Fig. 2 is very compact and reliable. The *stands* at left of the control board are located near the machines. The switchboard signal apparatus is set in the board just above the control bench so as to be in the most convenient position for the operator. The illustration shows six signals for each equipment. These consist of colored glass windows with white letters behind which are small candelabra lamps. Opposite each signal are the two buttons of a flush type three-way switch. Pushing a button at the left of a signal word lights the lamps for that signal word at both ends, and this signal remains until acknowledged by pushing the corresponding button at the receiving end. A gong is installed at

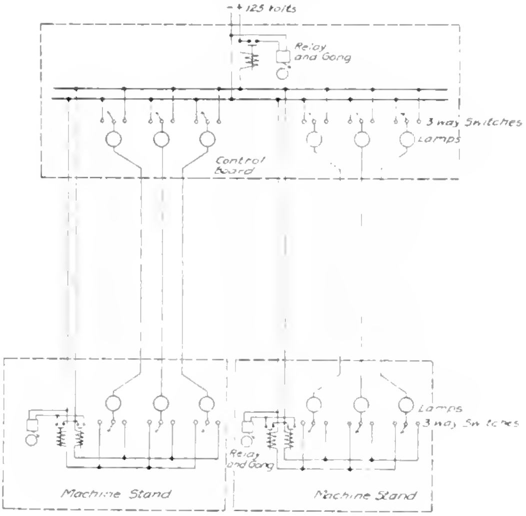

Fig. 3. Connection Diagram of two signal equipments with three signals

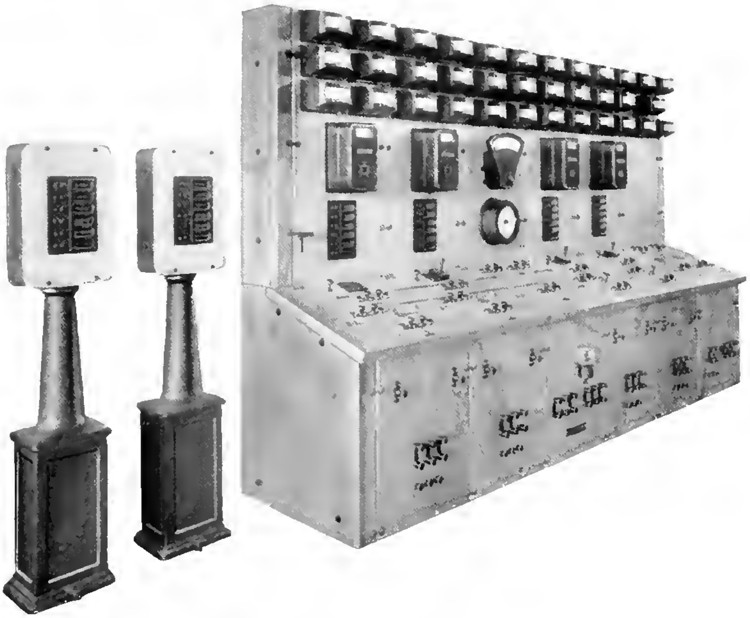

Fig. 2. Individual Push Button Signal Equipment with stands for two machines

the control board, as well as one near each machine and connected so as to ring as long as the signal remains unacknowledged.

Fig. 3 shows the connection diagram for two signal sets of this description. For simplicity, only three signals are indicated for each set. The three-way signal switches are always closed in one or the other positions, from which it follows that reversing either switch closes the circuit; and again reversing either switch opens the circuit. The gongs are energized by relays connected so as to close the gong circuit at each end of the signal set when the current of any signal lamp passes through the relay.

### Dial Signals

Dial signals have long been used on ships. In general they consist of transmitting and receiving dials with the signal words plainly marked on them. A pointer on the receiver dial is mechanically or electrically connected to follow a handle on the transmitting dial. A novel method of gearing the two together employs the now more or less familiar "position indicator" principle, recently designed for the indicating devices on the lock machinery at the Panama Canal.

# SELECTION OF POWER LIMITING REACTANCES

By H. R. Wilson

Power and Mining Engineering Department, General Electric Company

This article calls special attention to the importance of the selection of the correct amount and proper location of power limiting reactances. The large variety of systems of connections in use prohibits a standard arrangement, and therefore the author selects four typical cases and after specifying certain data governing all, proceeds to show the correct amount of reactance and its location in each case.—Editor.

H. R. Wilson

The protection of generators, transformers, and switches, etc., in large generating stations has become of special importance, particularly so in cases where the equipment consists of several large units, the loss of any one of which would be a serious matter. Transmission at high voltages combined with inter-connections with other large systems increases the liability of trouble, and these conditions, added to the necessity of continuous operation, demand that careful attention be given to the location and the amount of protective reactance. The various systems of connections do not allow a selection which will apply to all cases; so it is necessary to treat each case individually. In the following examples, single buses only are considered and it is assumed that all generators and transformers are of the same capacity and that each generator has 15 per cent reactance and each transformer has 6 per cent reactance. As the transmission voltage is too great to allow the use of reactance coils located in either the high tension transformer leads, the high tension bus or the outgoing line, they must be placed in the generator leads, the low tension bus or the low tension transformer leads. In order to obtain a better comparative basis, all calculations are based on a 1:1 transformer ratio.

### Case No. 1

Consider a system consisting of several generators operating in parallel on a single low tension bus, see Fig. 1. If a fault occurs on the bus at $X$ the value of the instantaneous current at the fault is seen by referring to Fig. 2. By introducing protective reactance in the leads of each generator, equivalent to three per cent of the capacity of one generator, the value of the instantaneous current is reduced about seventeen per cent.

If the same percentage of reactance were located in the bus, between adjacent generators, the current at the fault is further reduced and one less coil is required.

### Case No. 2

A fault on the high tension bus is of course more probable than a fault on the low tension bus. Consider a system similar to Case No. 1 with the addition of transformers and a single high tension bus, Fig. 3. If the high tension bus is not sectionalized we find that by connecting a 3 per cent reactance in either the leads of each generator or in the leads of each transformer, the current at the fault is decreased approximately 12 per cent from what would be obtained if the reactance coils had been omitted, see Fig. 4. If the high tension bus can not be sectionalized, as is often the case in systems designed before the matter of protection had been given due consideration, the location of reactance in the low tension bus is useless as far as a fault on the high tension bus is concerned.

Fig. 1

**Case No. 3**

Assume that the system is one where each transformer and each line is a unit, see Fig. 5, and a fault $X$ occurs on the high tension side of the transformers. The relative values of the instantaneous current at the fault without any protective reactance and with 3 per cent reactance connected in the leads of each generator, or in the low tension leads of each transformer, or in the bus between adjacent generators, is shown by Fig. 6.

It will readily be seen that in such a system the introduction of reactance in the transformer leads is very effective as regards limiting the current when the fault occurs on the high tension side of the transformers, but it is of no value if the fault occurs in any transformer or on the low tension bus or in any generator. There is also the disadvantage in that we have the losses in the reactance coils under normal operating conditions and one more coil will also be required than if the reactance is located in the low tension bus.

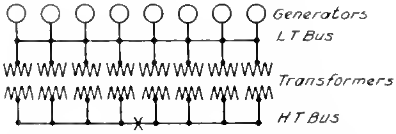

Fig. 3. Representation of a System of Paralleled Generators feeding paralleled transformers in which a fault has developed at $X$ on the high-tension bus

**Case No. 4**

The effect of sectionalizing the high tension bus of a system consisting of twelve generators and transformers, so as to limit the current at a fault on this bus and the further effect of introducing 3 per cent reactance in the leads of each generator or the low tension leads of each transformer or in the low tension bus between the corresponding sections of the high tension bus, will be seen by referring to Fig. 7.

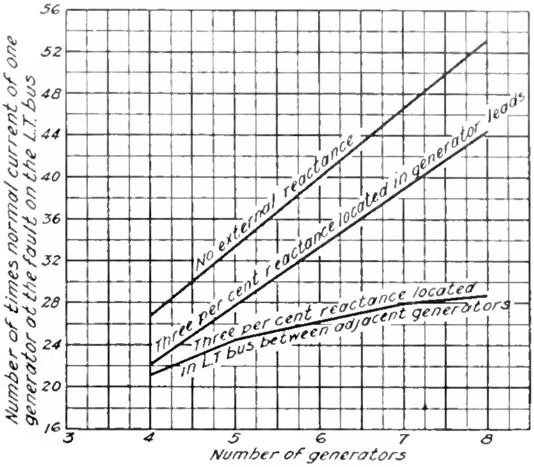

Fig. 2. Curves showing the Amount of Current that will flow at a fault on the low-tension bus of a system such as that shown in Fig. 1. No reactance, and three per cent reactance is employed at various points

Single L. T. bus; Generators, each 15 per cent reactance; Transformers, each 6 per cent reactance; Fault on the L. T. bus.

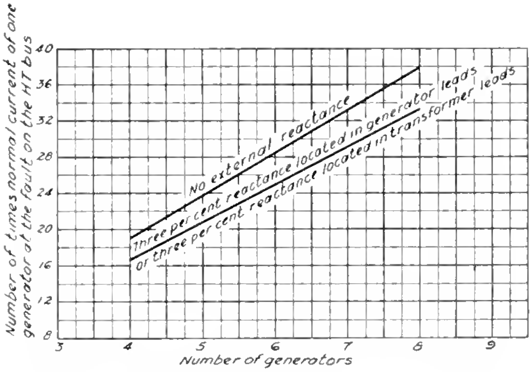

Fig. 4. Curves showing the Amount of Current that will flow in a system such as that of Fig. 3 without reactance, and with three per cent reactance located at various points

Single L. T. bus; Single H. T. bus; Generators, each 15 per cent reactance; Transformers, each 6 per cent reactance; Fault on the L. T. bus.

Taking the case of dividing the high tension bus into three sections, Fig. 8, with no external protective reactance, we find that the instantaneous current at a fault $X$ on the high tension bus is 36 times the normal current of one generator, whereas if the high tension bus is not sectionalized the current is 57 times the normal current of one generator. With the high tension bus sectionalized as shown and 3 per cent reactance introduced into the generator leads the current at the fault X is reduced about 9 per cent from what it is with no reactance; if in the low tension bus at points *A* and *B* it is reduced about 15 per cent and if in the low tension transformer leads it is reduced about 20 per cent.

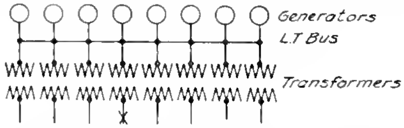

Fig. 5. Representation of a System of Parallel Generators feeding a bank of transformers, which are not paralleled on the high-tension side, in which a fault has developed in the high-tension side of one transformer

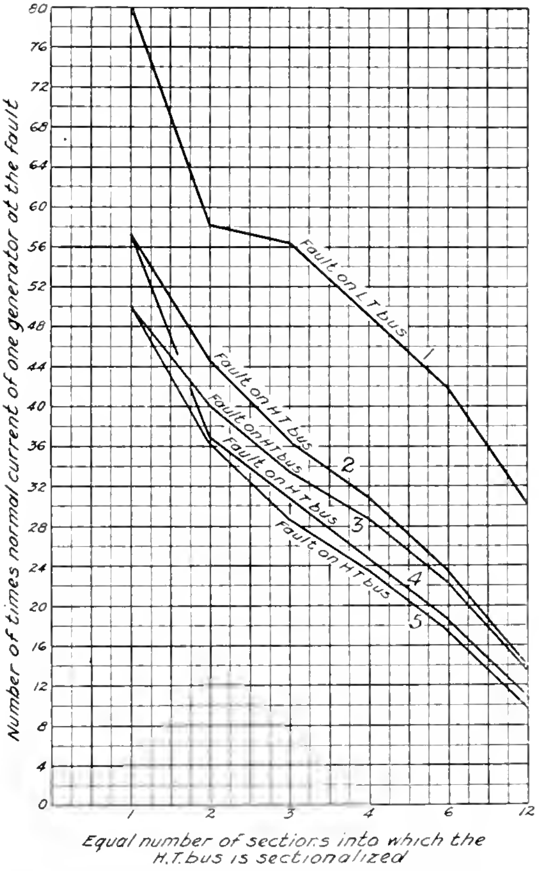

Fig. 7. Curves showing the Amount of Current that will flow at faults in a system in which the high-tension bus is sectionalized into different numbers of groups and which has no reactance or has three per cent reactance located at various points

Twelve Generators, each 14 per cent reactance
Twelve Transformers, each 6 per cent reactance
Single H.T. Bus sectionalized into equal number of sections
(No reactance)
(1)—L.T. Bus sectionalized into equal number of sections with 3 per cent reactance between sections
(2) L.T. Bus—no reactance, not sectionalized
(3)—L.T. Bus—no reactance, not sectionalized
(4)—L.T. Bus sectionalized into equal number of sections with 3 per cent reactance between sections
(5)—L.T. Bus, no reactance, not sectionalized, 3 per cent reactance in transformer leads

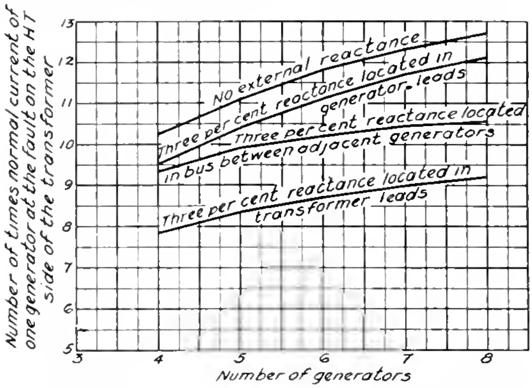

Fig. 6. Curves showing the Amount of Current that will flow at the fault in a system such as that shown in Fig. 5 with no reactance and with three per cent reactance located at various points

Single L.T. Bus; Outgoing Line from each transformer; Generators, each 15 per cent reactance; Transformers, each 6 per cent reactance; Fault on the H. T. side of the transformer

At first sight it appears from the above that the most favorable position for the reactance is in the low tension transformer leads, but there are required ten more reactances of the same size than if they were placed in the bus. In addition there is to be considered the increased losses due, not only to the greater number of reactances, but also, to the fact that reactances in the transformer leads means a constant loss in the reactance coils, whereas reactance in the bus means no loss in the coils, if the total system is operating with equal outputs on each section. Reactance in the bus also gives additional protection to the generators when a fault occurs on the low tension bus or in one of the generators.

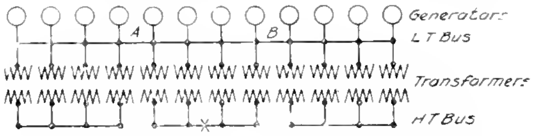

Fig. 8. Representation of a System of Paralleled Generators feeding transformers, the high-tension bus being sectionalized into three groups, fault assumed at *X*

When stating that twelve reactances in the generator leads are required to only two of the same size in the bus, we have assumed that the temperature rise is the same in either case, whereas the temperature rise in bus reactances may be greater, as the current is not normally flowing through them.

Assuming that it is desired in the above example to use bus reactance instead of 3 per cent reactance in the low tension transformer leads and to limit the current at the fault X to the same value as is obtained by the latter, it will be found by referring to Fig. 9 that the amount of reactance required in each of the two coils will be about 4.8 per cent.

If in the preceding system of twelve generators and transformers, it is desired to limit the current at a fault on the high tension bus to thirty times the normal full load current of one generator, the following (Table I) gives the number of protective reactances required and the comparative value of each expressed in terms of one generator, it being assumed that the maximum allowable number of high tension bus sections is four.

The importance of obtaining protection from high tension faults, by the division of the high tension bus into the same number of sections as there are outgoing lines, should be primarily considered, as from the preceding discussion the value of such sectionalizing is readily apparent.

The addition of reactance to systems already installed is often one of the most serious problems, as the existing layout will not always allow radical changes in the same on account of the expense and it is at times necessary to introduce reactance in both bus and generator or transformer leads, whereas if this question had been considered in the original design of the system, far better results could have been obtained at considerably less outlay.

In order to obtain the best results from the use of protective reactance, it is therefore necessary to consider each case on its merits, as the number and capacity of generators, transformers, and outgoing lines, together with the conditions under which the system will operate, have such an essential bearing on the amount and location of the reactance, that it is not possible to select any one location which will apply to all systems.

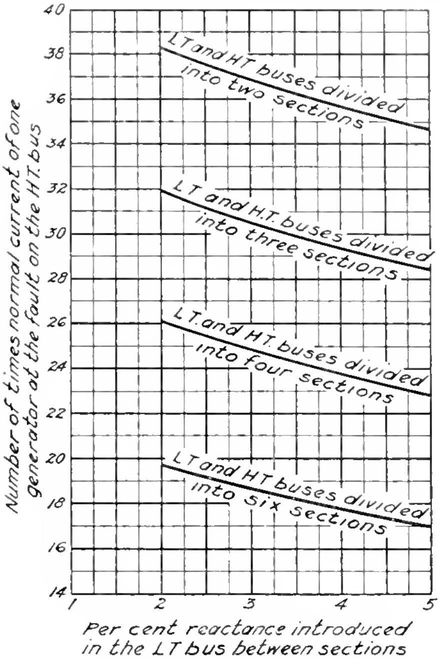

Fig. 9. Curves showing the Amount of Current that will flow at a fault on the high-tension bus of a system in which the low-tension and high-tension busses are sectionalized into equal numbers of groups with the reactance between the low-tension sections

Twelve Generators, each 15 per cent reactance
Twelve Transformers, each 6 per cent reactance
Single L.T. Bus sectionalized into equal number of sections, and reactance coils between sections.
Single H.T. Bus sectionalized into same number of sections as L.T. Bus (no reactance coils)

TABLE I

| Number of High Tension Bus Sections | 1 | 2 | 3 | 4 |
|---|---|---|---|---|
| Reactances in generator leads | (12) 19 per cent | (12) 13 per cent | (12) 7 per cent | (12) 0.96 per cent |
| Low tension bus sectionalized by reactances into same number of sections as high tension bus | * | (1) 32.5 per cent | (2) 3.4 per cent | (3) 0.25 per cent |
| Reactances in transformer leads | (12) 19 per cent | (12) 6.5 per cent | (12) 2.3 per cent | (12) 0.24 per cent |

* As the high tension bus is not sectionalized, the current at the fault on it will be 57 times the current of one generator and the value of low tension bus reactance is useless as far as limiting the current at this fault is concerned.

# THE HYDRO-ELECTRIC DEVELOPMENT OF THE GEORGIA RAILWAY AND POWER COMPANY AT TALLULAH FALLS, GEORGIA

## PART I

By Eric A. Lof

Power and Mining Engineering Department, General Electric Company

This article constitutes a description of the most recently completed hydro-electric development in the South. The power plant will have an ultimate output of 60,000 kv-a., which will be generated by six units, five of which are now in place. This capacity is exclusive of two 3000-kw. units located at the dam to utilize the water released from the reservoir. Three of the main units supply power to the city of Atlanta and smaller municipalities; the remaining two being connected to the system of the Southern Power Company. The hydraulic head of 600 ft. is probably the highest that has been developed east of the Rocky Mountains, and is the highest in this country for which the reaction type of turbine has been employed. The present installment fully describes the hydraulic features and equipment of the development, the design of the power house, and the electrical equipment, including generators, exciters, transformers, oil switches and lightning arresters. The second installment will deal with the transmission lines and the large outdoor substations of the system.

—Editor.

Eric A. Lof

### General Description of System

THE Georgia Railway and Power Company was organized during the latter part of 1911 to take care of the growing demand for electrical energy in the State of Georgia and neighboring territory. It forms a distinct part of the vast network of interconnected hydro-electric power systems which are playing a most important role in the rapid development of the South, and is planned along lines similar to those of the Southern Power Company. Power will be generated in large quantities for the company's extensive light, power and railway service, and for municipalities and private corporations.

The company has taken over the properties formerly controlled by the Georgia Railway and Electric Company, which includes a large gas and steam station in Atlanta. Besides the new 100,000 horse power development at Tallulah Falls, it also owns two smaller hydro-electric plants at Bull Sluice and Dunlap, and several other water power sites which will be developed as the demand arises. Thus when ultimately completed the system will include ten developments with a total capacity of about 350,000 horse power.

The layout and general features of the development at Tallulah Falls is clearly shown by the map, Fig. 1. It comprises a diverting dam and intake a short distance above the Ladore Falls and close to the town of Tallulah Falls; a storage reservoir formed by the construction of this dam; a 6670 ft. tunnel terminating in a surge tank on the bluff above the power plant; five penstocks; and the power house with the tailrace. In addition, a large storage reservoir is under construction further up the river at Mathis, about seven miles from the intake works.

### Hydrography

The annual rainfall varies from 70 to 80 in., the driest months being September, October and November. Hydrographic records have been kept for the past fourteen years, and these show that the lowest average monthly stream flow was 135 sec. ft., while floods of from 5000 to 8000 sec. ft. are quite common in the spring season. A maximum flow of 15,000 sec. ft. has also been recorded during the month of March.

### Storage Reservoirs

The reservoir formed by the diverting dam has a capacity of 106,000,000 cu. ft. and an elevation of 1500 feet, with an available head of 606 feet. Of this capacity, 63,000,000 cu. ft. are available for the waterwheels, the drop in head caused by this release being 30 ft.

The large reservoir at Mathis will have a storage capacity of 1,000,000,000 cu. ft. It is formed by a reinforced concrete dam across the river bed, of the Ambursen type, 90 ft. high and about 700 ft. long, and a like dam of the same type across a depression about 50 ft. below the elevation of the water in the reservoir. The main dam is provided with three motor-operated 48 in. gate valves for draining the reservoir when necessary, and provision has also been made in the construction for housing a future auxiliary power plant. This will contain two 3000 kw. units, which will utilize the water power released from the reservoir, and this energy will then be transmitted to the main power house and there fed into the transmission system.

### Diverting Dam and Tunnel Intake

This dam, Fig. 2, is of the gravity type and is built of rubble concrete and arched to a radius of 900 ft. Its height is 110 ft. and the length along the crest 444 ft. The spillway is 280 ft. long, there being ten 28 ft. openings between the piers which support the highway bridge across the top of the dam. These openings, together with the two 5-ft. diameter sluices which are provided in the dam, give an overflow capacity of 20,000 sec. ft.

Flashboards are installed between the piers for all the spillway openings. Six of these are of the automatic type and are capable of taking care of ordinary spring floods, keeping the pond level within three inches of a constant elevation of 1500 ft. Thus, should the water rise three inches above this mark, the additional pressure on the flashboards will cause them to drop, and with an increased river flow they will continue to drop until they rest in a horizontal position on the dam crest. As the water subsides they will automatically return and maintain the water level in the pond at the same elevation. Each flashboard consists of a steel-reinforced timber panel hinged at the bottom and connected at the top to a 34,000 lb. concrete roller counterweight by two steel cables which are wound in grooves around each end of the roller. These rollers travel on inclined tracks, each end being provided with a geared drum which engages a rack to prevent slipping. The principle of operation is simply a balancing of the moments of force. The pressure on the flashboards is transmitted to the drums through the cables which act to roll the counterweight up the track, while its dead weight tends to roll it down; the two forces balancing each other when the water-

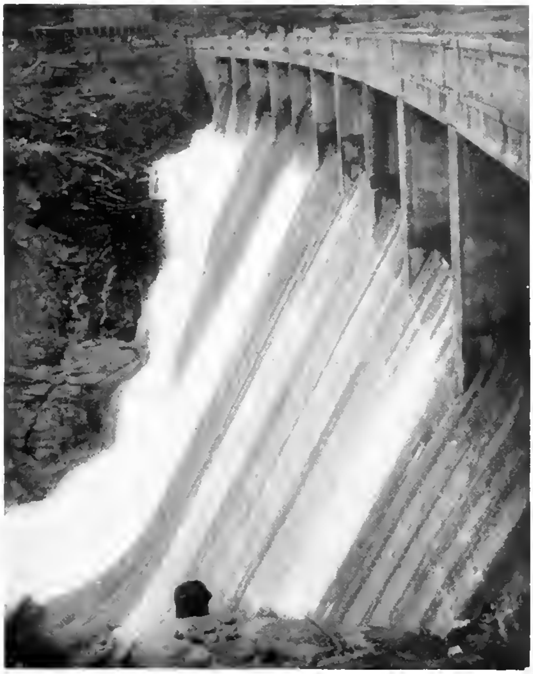

Fig. 2. Down Stream View of Diverting Dam

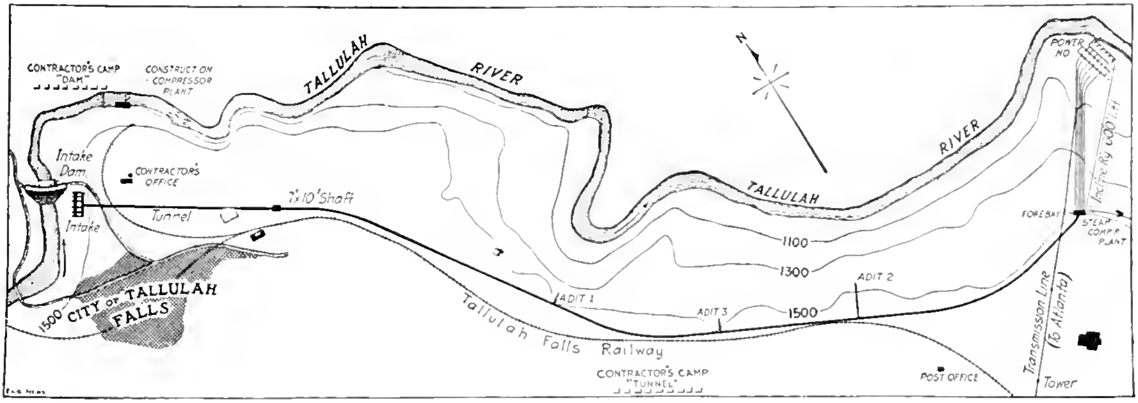

Fig. 1. Map of Tallulah Falls Development of Georgia Railway and Power Company

level is at the fixed elevation. Hand-operated winches are also provided for these flashboards, and their general construction is clearly shown in Fig. 3. The other four flashboards are of the ordinary stationary construction and are so designed that if the water in the pond rises one foot above the normal level the boards will give away.

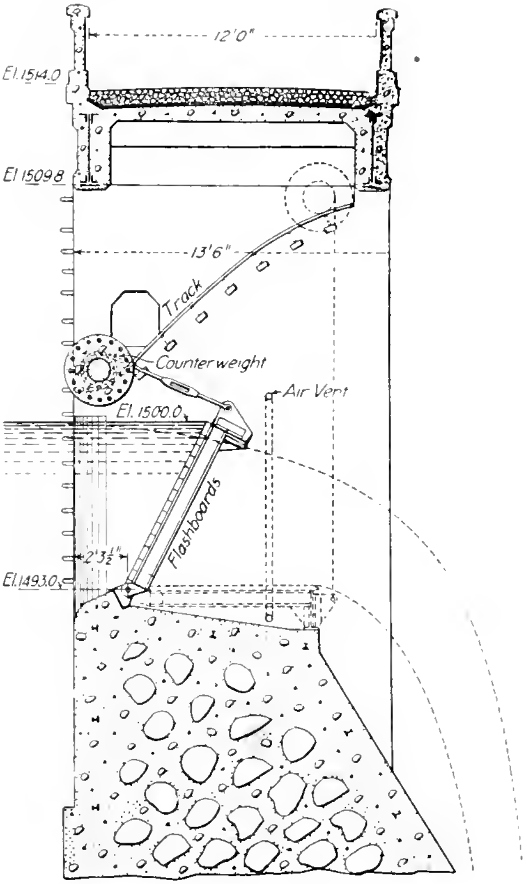

Fig. 3. Automatic Flashboards for Diverting Dam

The intake is a cassion-like self-contained concrete structure, divided by partitions into five sections in order to resist the stresses on the walls due to the hydraulic pressure when the intake is empty and the water in the pond is at its maximum elevation. At the rear of each division wall there is an opening which allows the water to pass to the tunnel entrance located at the center of the rear wall at the bottom. The location of the intake is such that it forms an angle of nearly 90 degrees with the dam. This arrangement has several advantages, among which are the ease with which logs, trees and other floating debris can be cleared away by simply opening one or two of the nearest flashboards. There are two kinds of racks, coarse and fine, the former being placed in front of the head gates outside the intake openings and the latter behind the gates in an inclined position. For three bays the fine racks are provided with rake cleaners which are operated at a speed of 3 feet per minute by a 5 horse power, 220 volt, three-phase induction motor. The five head gates are of structural steel and hand-operated through ordinary gate hoists.

The ground around the intake has been neatly graded and sodded, and electric lighting is provided both at the intake and along the highway bridge across the dam so as to facilitate any night operations that may be necessary.

### Tunnel, Surge Tank and Penstocks

From the intake, the water is led through a concrete lined tunnel which terminates in a surge tank located on the bluff above the power house. This tunnel has been excavated through practically solid rock strata and follows a comparatively straight route. It has a length of 6670 ft. and a cross-section of 151 sq. ft., the bottom being 46½ ft. below the high-water level in the reservoir. The gradient is 0.002, and the tunnel has a maximum capacity of 1555 sec. ft. with a water velocity of 10.3 ft. per sec. The normal flow

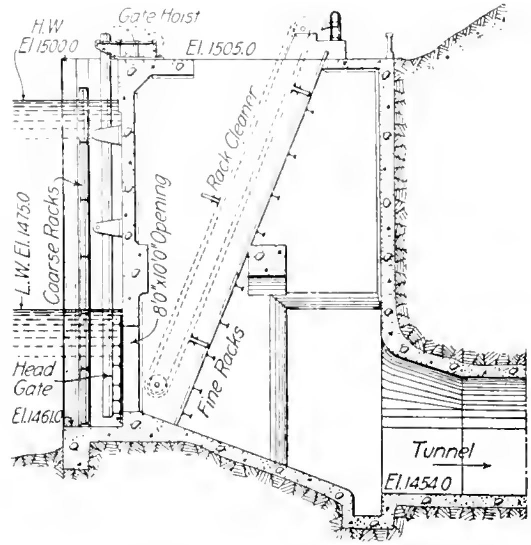

Fig. 4. Tunnel Intake, showing Racks, Rack Cleaners and Gates

with full load on all units in the station is 1160 sec. ft. and a velocity of 7.7 sec. ft.

The surge tank is of a heavy reinforced concrete construction, the bottom being about 63 ft. below the ground level. It is 93 ft. high, with an inside section of 30 ft. by 71 ft, and is designed to take care of the sudden surge that would be caused by closing all of the turbine gates with the machines at 25 per cent overload. At this load the water in the tank will be about 11.5 ft. below the elevation at the intake, due to the friction losses in the tunnel, and the sudden closing of all the gates will set up a surge which will cause the water in the tank to rise to a height of about 29 ft. above the water level at the intake.

From the surge tank five penstocks, ultimately six, run to the power house, 600 ft. below, Fig. 5. These penstocks are of riveted steel pipe for the upper half of the run, the lower part being of welded-steel pipe of German make. Their lengths vary from 1200 to 1258 ft., the diameter being 60 in. and the thickness varying from $\frac{3}{8}$ in. to $\frac{9}{16}$ in. There is one 8-in. air valve at the top of each pipe, and the thickness of the material in the pipes is such that it will resist any tendency to collapse at points below the influence of the vents. Heavy concrete piers are provided for anchoring the penstocks at each change of grade, and at intermediate points they are supported on concrete saddles. The grades exceed 70 per cent, the maximum being 150 per cent. Steel emergency gates are provided at each penstock entrance, hinged at the top side and held open by a chain and hand-operated mechanism at the surge tank. At the upper end of the penstocks 60 in. motor-operated valves are provided. These are equipped with limit switches and are controlled from the power house, the contactor panels being installed in a little house close

Fig. 5. Forebay and Penstocks

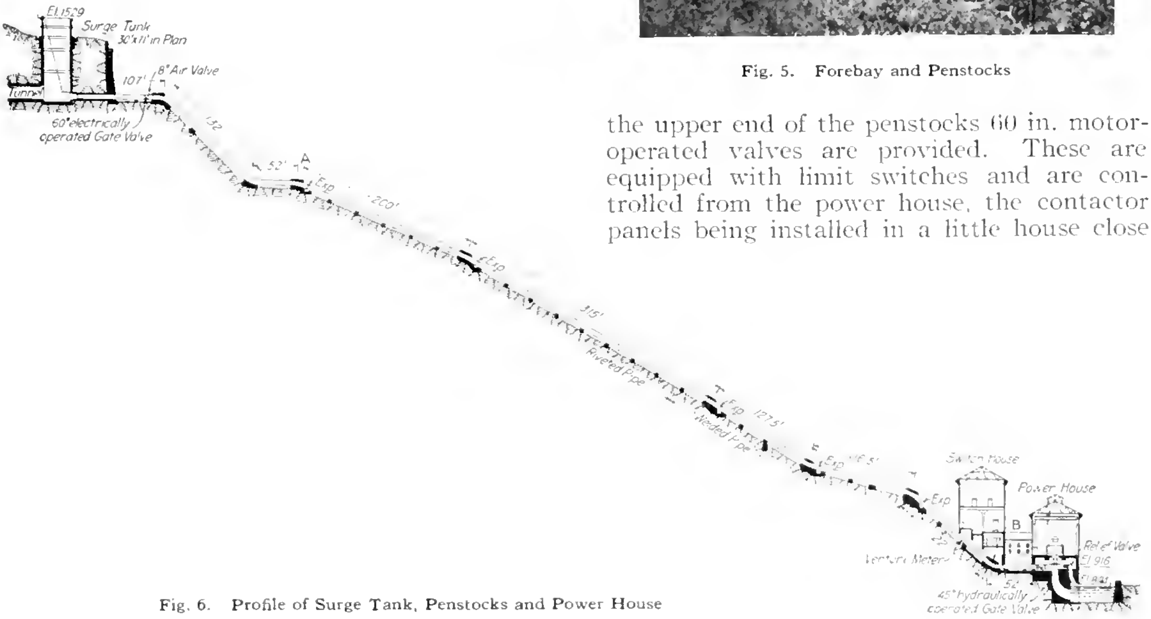

Fig. 6. Profile of Surge Tank, Penstocks and Power House

to the valves. Forty-four inch hydraulically operated gate valves are furthermore placed between each turbine casing and the penstock. They are furnished with pilot valves so that the gate can be held in any desired position during operation, the operating pressure being that due to the head of water in the penstocks. Just outside the switch house a venturi meter is placed in each penstock, the indicating and recording instruments for them being installed on a platform opposite the transformer bays in the switch house. By means of these devices the wheel efficiencies can readily be checked during operation, and for the same purpose a weir is also provided in the tail race channel. The general arrangement of the surge tank and penstocks is clearly shown in Fig. 6.

### Power House and Arrangement of Apparatus

The general design of the power house buildings and the arrangement of the apparatus are shown in Figs. 7, 8 and 9. As seen from these drawings, the power house layout resembles a letter "H" there being in reality two distinctly separate buildings, the power house and the switch house, which are interconnected by a small narrow building containing the control switchboard.

The power house, which faces the tail race, is 186 ft. long, 42 ft. 3 in. wide, and 49 ft. high above the generator room floor. Five generator sets, spaced 28 ft. center to center are installed with room for a sixth unit. The turbines with their pressure pumps, gate controlling mechanism, etc., are located below the generator room floor in the basement. A gallery with a stairway at each end runs along the rear wall of the generator room and leads directly to the control room. Below this gallery are located the exciter switchboard, the field switch panels, and the rheostat compartments. The foundations are of massive concrete, and large steel girders are provided in the generator room floor to distribute the heavy load of the generator frames and that of the revolving field and turbine runner elements, which are supported therefrom.

The building for the control switchboard is, as previously stated, located in the fifteen foot space between the power house and the switch house, forming a connection between the two. It is a two-story structure, the upper floor containing the control benchboard, telephone booths, etc., while the first floor, which is at the same elevation as the generator room floor, contains lavatories and lockers.

The switch and transformer house is a three-story structure, 244 ft. long by 46 ft. wide. The first floor, which is on the same level as the operating room, contains the low-tension switch equipment and busbars. On the second floor are located the transformers and oil filtering tanks, while the third floor contains all the high tension switches, buses and connections.

The buildings consist of a steel framework with the walls constructed of red brick with marble pillaster caps and window sills. The roofing is of reinforced tile construction, colored red to harmonize with the building walls, and a monitor extends nearly the entire length of the ridge of the power house roof. Rolling steel doors are provided at all principal entrances, and steel stairways and railings are installed at several places between the floors. A 60-ton traveling crane is provided in the generator room and an electrically operated trolley hoist has been installed in the switch house for lifting the apparatus to the upper floor.

Before work on the power house could be commenced it became necessary to build an inclined railway from the railway siding on top of the bluff to the power house site below, for lowering material and carrying the working force. The incline averages about 63 per cent grade, the maximum being 100 per cent. The car is at present operated by two steel cables from a steam-driven hoist located on top of the hill, although it is the intention to replace this with motor drive. A safety device is provided to hold the car should the hoisting cables suddenly break or release their pull. It consists of a clutch that will grip a stationary cable laid between the two track rails and securely fastened at the upper end of incline

### Hydraulic Equipment

The five vertical shaft turbines are of the Francis type, built by the S. Morgan Smith Company. They have a normal rating of 16,000 horse power at 580 ft. head when running 514 r.p.m. The runners are installed in cast iron spiral casings discharging into a steel plate draft tube, and the thrust bearing for supporting the generator field, turbine runner and shaft is placed on top of the generator frame. The exciter is mounted directly above the thrust bearing, its armature being direct-connected to the main turbine shaft. Each turbine unit weighs 300,000 lb., and the general design is as shown on page 532.

The spiral casing is made of cast iron in one piece, and the inlet, which has a diameter of 44 in., is connected to the hydraulically operated valve for cutting off the water in the casing from the supply pipe. The weight of the finished casing is 54,000 lb., and it was tested to a hydrostatic pressure of 400 lb. per square inch. Connecting the inner flanges of the spiral casing are twelve cast vanes through which are placed 2¾ in. vanadium steel bolts having a tensile strength of 200,000 lb. to the square inch. These bolts themselves have sufficient strength to carry the entire load of the longitudinal stresses due to the pressure of the water in the spiral casing.

On the inner diameter of the spiral casing is fitted a cast steel guide ring which serves to tie the inner flanges of the casting and to take part of the load of the longitudinal stresses due to the water pressure in the casing. In this cast steel guide ring there are heavy guides or vanes through which are cored large openings so that the water which passes through the upper running joint of the runner can pass from the upper chamber over the runner and through these guide vanes into the lower chamber under the runner and into the draft tube. This relieves the accumulation of water above the runner and so eliminates the thrust due to water pressure on top of the runner. The vanes in the guide ring coincide with those in the spiral casing, so that a smooth surface is obtained in the water passages.

The steel gates of the turbine are of the wicket type with stems forged on and finished all over, while all faces coming in contact with the water are polished. There are twenty-four gates for each runner, the stems being 2¾ in. in diameter with a ½ in. hole drilled the entire length of the stem. Fitted in the top of this hole is a large grease cup which forces grease through the stem and out of the radial openings into the bearings of the gate stems. These bearings are of bronze and are made renewable. On the top of the gate stem is keyed the crank arm which connects the gate to the gate ring. The hub of the gate arm on the gate stem is split, and is held by means of two tension bolts so that when it is necessary to take off the gate arm the tension bolts are relieved and a wedge driven in the split. This opens the hub a small amount, and the gate arm can be easily removed from the stem.

The top and bottom plates of the turbines are made of cast iron and the water faces are fitted with renewable bronze facing plates so that they can be replaced in case of erosion. These plates are also fitted with bronze packing boxes for the gate stems, which pass through the water chambers in the top and bottom plates in such a way that all leakage of water around the gate stems passes through these water chambers and the guide casting into the draft tube, and, as shown by actual operation, there is no leakage water on the outside of the turbines whatever.

The runner is of the central discharge or Francis type, and is made of hard bronze, 88 per cent copper, 10 per cent tin and 2 per cent zinc. It has 18 buckets and is 56 in. in diameter. It was made in one continuous casting by means of cores, and on the crown of the runner is fitted a flange by means of which it is bolted to a forged flange on the shaft. One of the runners and gates complete was sent to Holyoke and tested by the Holyoke Water Power Company. It developed a maximum efficiency of over 88 per cent, and from past experiences in testing high head wheels in place these runners should actually develop over 90 per cent efficiency.

The shaft of the unit is made of nickel steel in two sections. The lower section, which is fitted to the turbine, is 14 in. in diameter and is provided with a forged flange on each end, while the upper section, which is fitted to the rotor end of the generator, has a nominal diameter of 16 in. The complete shaft weighs 20,000 lb.

On the top plate and directly over the runner is mounted a lignum-vitae bearing, which is lubricated by means of a supply pipe from the spiral casing, the water passing through this bearing into the chamber above the runner and out through the guide vane into the draft tube. This bearing is made of lignum-vitae strips 2 in. square placed in a cast iron casing similar to that of the stern bearing of a steamship, and bolted to the top plate.

For supporting the generator rotor, shaft and turbine runner there is placed on top of the generator an oil pressure thrust bearing of the standard type. This bearing was designed for a pressure of 200 lb. to the square inch. There is, however, no pressure-regulating device employed in the oiling system whatever and dependence is placed entirely on the distance or clearance between the disks. The pumps are run at a constant speed and supply a constant quantity of oil to the bearing, the pressure being automatically regulated by the film of oil separating the disks. If the

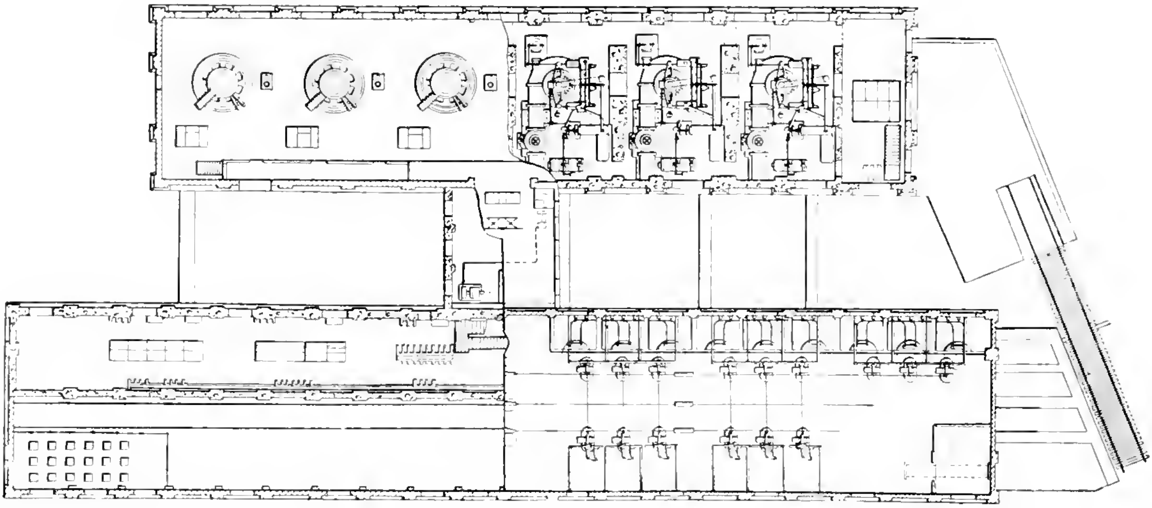

Fig. 7. Plan View of Power House

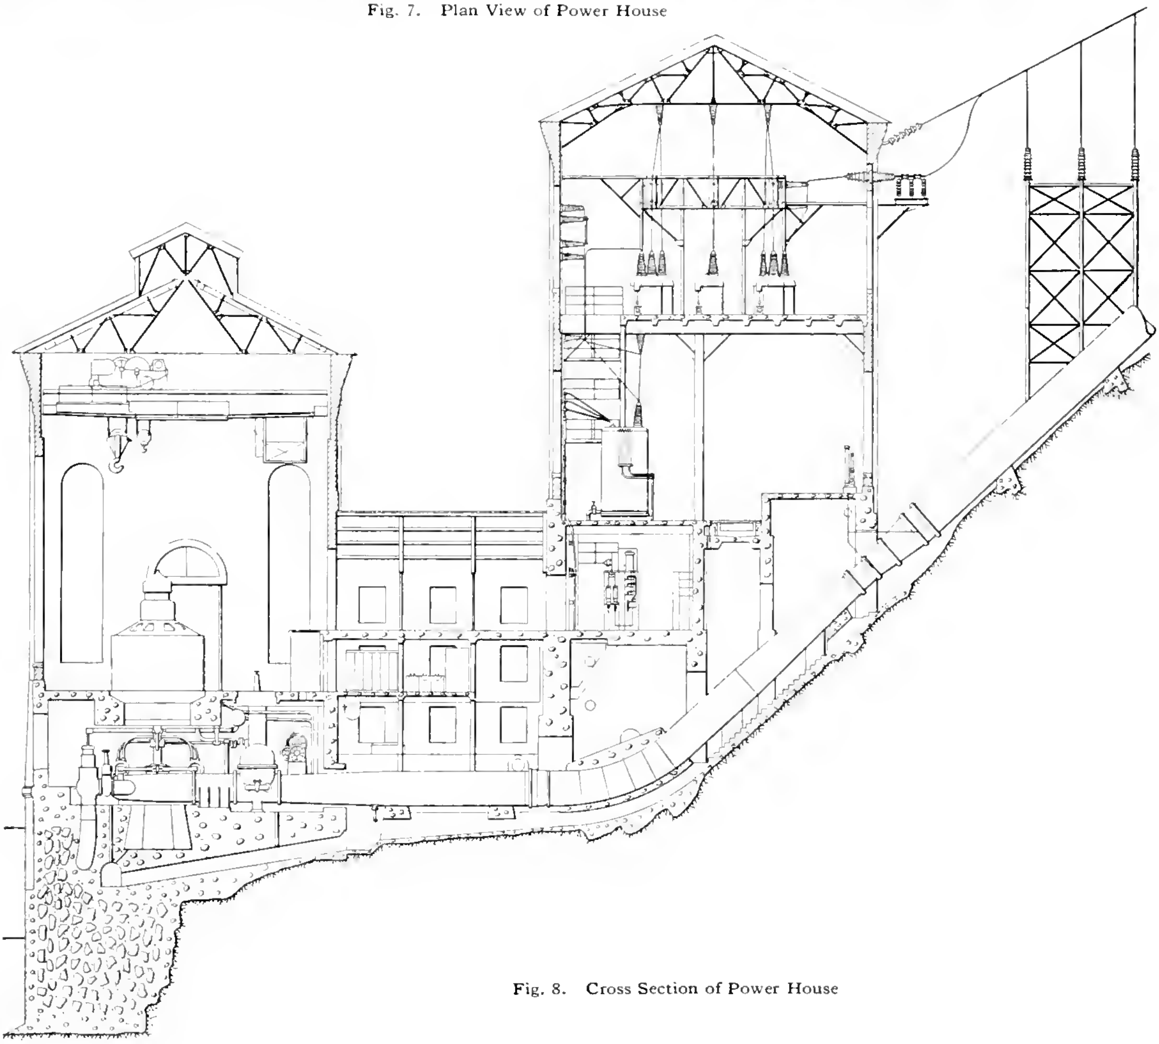

Fig. 8. Cross Section of Power House

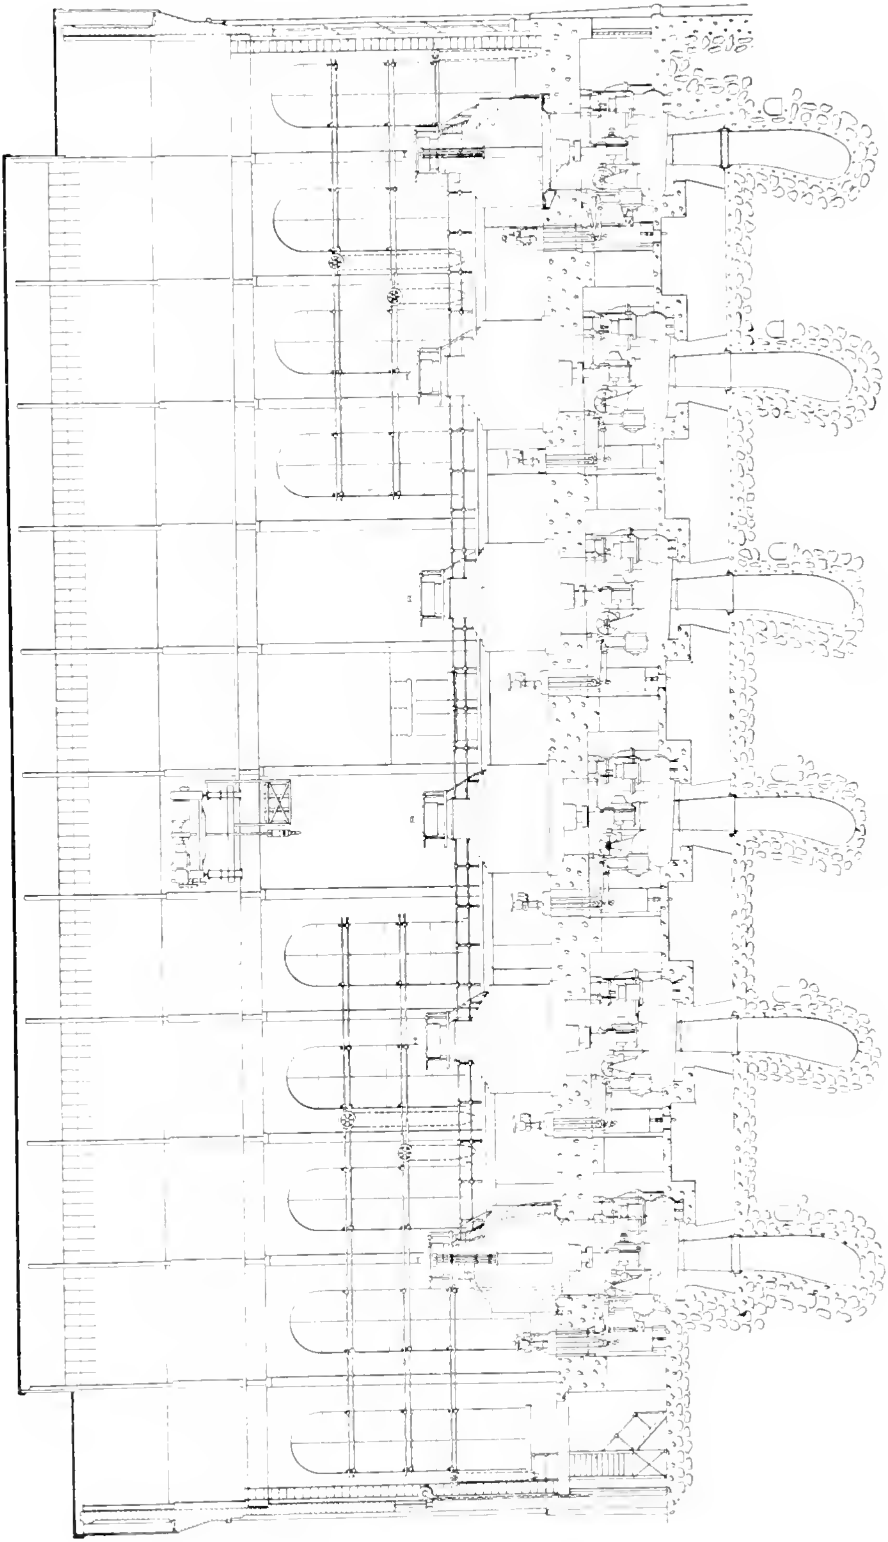

Fig. 9. Longitudinal Section of Power House

load increases the disks are brought closer together, decreasing the area of discharge between the disks and consequently raising the pressure between the disks and equalizing the load. The disks are placed in a suitable housing fitted with a drain pipe which conveys the oil from the bearing back to the receiving tank of the pump.

Fig. 10. Five of the 10,000 Kv-a. Main Generating Units

Each unit is equipped with an independent oil pressure system which consists of two triplex pumps having a normal capacity of 75 gallons per minute each. The pumps discharge the oil into a pressure tank, from which it is piped to the thrust bearing and governor cylinders. It then flows to a common pump tank from which it is again returned to the pressure tank by the pump. One of the triplex pumps is driven direct from the vertical turbine shaft by means of spiral gears and a Morse silent chain drive and the other pump is driven by a 35 h.p. electric motor. In order to insure an absolutely uninterrupted oil supply to the pressure bearings, both pumps are in commission all the time. It is found in actual operation that the oil pressure required in the thrust bearing varies from 140 to 160 lb. per square inch, and as this pressure is also sufficient to operate the gates of the turbines, it is not exceeded in any part of the oiling system. All the piping is equipped with flanges, and all fittings and valves are of the flange type.

The turbines are regulated by oil pressure governors, the actuators of which are placed on the generator floor, and the operating cylinders on the turbine casing. There are two cylinders for each unit, each having a diameter of 24 in. and an 8 in. stroke. Both cylinders are capable of developing a combined effort of 120,000 ft.-lb. at 200 lb. pressure. The piston rods of these cylinders are connected by hardened steel pins to a cast steel walking beam bolted to a cast steel gate ring which revolves on bronze bearings on the top plate. The cast steel gate ring has twenty-four machined slots and into each is fitted a bronze crosshead. These bronze crossheads are connected to cast steel cranks on the gate stem by means of an eccentric pin which allows a small movement of the gates by turning the pin so that they may be finely adjusted independently of one another, thus enabling the gates to be made tight when closed. The oil in the cylinders is controlled by the actuator or governor top, which is placed on the floor of the generator room.

The actuators for controlling the operating cylinders are of the relay valve type, and are equipped with electric speed control. The fly balls are mounted on ball bearings and are driven by means of spiral gears connected to a vertical shaft, which is belted to the main generator shaft. They are connected to a floating lever, one end of which is attached to the compensating arm by means of a dashpot; the other end being connected to the primary valve by a connecting rod and another floating lever, one end of which is connected to the secondary or main dis-

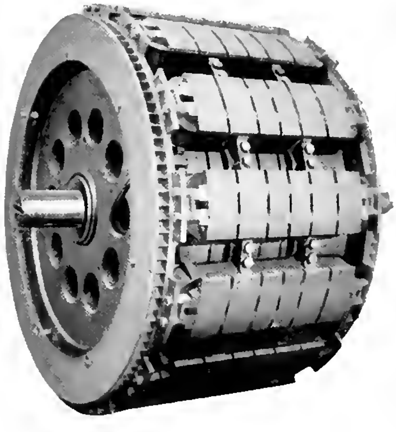

Fig. 11. Revolving Field of Main Generators

tributing valve. The main valve is always under control of the primary valve, which is controlled by the fly ball and the compensating mechanism. The electric speed control is connected to the main floating lever, and is so arranged that the speed can be changed direct by hand or by the electric control.

Each unit is equipped with a 22 in. mechanically operated relief valve, which is connected to the gate-operating mechanism by means of cranks and connecting rods, and so arranged that when the turbine gets below half gate the relief valve is thrown into operation. This valve is equipped with a dashpot and slow closing device. The valve will discharge 115 per cent of the full capacity of the turbine.

The upper portion of the draft tube is of cast iron and the lower part of steel plate imbedded in the concrete sub-structure. The connection between the cast iron draft tube and steel draft tube is made by means of a packing ring and hemp packing. This was done to overcome any discrepancy that might arise during construction. The total length of the draft tube from tail water to the center line of the spiral casing is 22 ft. It is circular in section, being 3 ft. 3 in. in diameter at the top and 8 ft. in diameter at the bottom. A quick closing valve is provided so that if necessary the vacuum in the tube may be broken. This valve is located on the turbine room floor.

**Generators**

The ultimate installation will comprise six main generators, five of which are installed at present (Fig. 10). They are of the three-phase, 60 cycle, vertical revolving field type, having 14 poles and operating at a normal speed of 514 r.p.m. They have a guaranteed normal continuous rating of 10,000 kv-a. at 6600 volts and a 25 per cent overload capacity for 2 hours. When operating at 80 per cent power-factor the temperature rise will not exceed 40 deg. C for normal load or 55 deg. C. for 25 per cent overload for 2 hours. The guaranteed efficiencies were as follows:

| | 1¼ Load | Full Load | ¾ Load | ½ Load | ¼ Load |
|---|---|---|---|---|---|
| 10,000 kv-a. 1.0 p.f. . | 96.0 | 95.5 | 94.5 | 92.0 | 86.0 |
| 10,000 kv-a. 0.8 p.f | 95.0 | 94.5 | 93.0 | 90.0 | 83.0 |

When delivering the normal load of 10,000 kv-a. at unity power-factor and 6600 volts, about 140 amperes will be required for the field excitation, while when delivering 10,000 kv-a. at 80 per cent power-factor and a 10 per cent over voltage (7260 volts) 200 amperes will be required. Under these conditions the excitation pressure will not exceed 250 volts. The field is furthermore so designed that with constant speed and 100 per cent power-factor, the load may be varied from normal rated current to no load and vice versa, and the voltage will not rise or drop more than 10 per cent.

The armature winding consists of form wound interchangeable coils, heavily insulated and tested between conductor and frame at 14,000 volts for one minute. They are Y-connected, the neutral being brought out and grounded through a 3.08 ohms resistance. Only one generator is grounded at one time, but provision is made so that by means of disconnecting switches any one of the generators can be grounded.

The revolving field structure is designed to withstand a runaway speed of 1.7 times normal for one hour. For this reason it became necessary to construct the rotor of rolled steel disks securely bolted together, the laminated pole pieces being dovetailed to them. The field coils are of strap copper wound on edge and substantially insulated so as to withstand a test between coil and core of 2000 volts for one minute. Spacing blocks are provided between the coils to prevent the winding from bulging out as a result of the heavy centrifugal force, and the connections between the coils are also securely fastened to prevent them from working loose.

The generator is furnished with two guide bearings, and the field rotor, as well as the waterwheel runner and exciter armature, is supported from the previously-described oil pressure bearing, this being mounted on the top bracket of the generator below the exciter.

For ventilating the machine, circulation of the air is brought about by small fans furnished at each end of the rotor and also by the natural fanning action of the field structure, ample air ducts being provided to secure a directed and uniform ventilation of the field coils. The air is drawn in at the bottom and discharged at the top after having been forced through the ventilating ducts in the core.

The over-all diameter of the generator is 13 ft. 8 in. and the height from the floor to the top of the exciter 17 ft. 8 in. Its total weight without the shaft is about 76 tons and the flywheel effect ($WR^2$) of the rotor approximately 1,250,000.

### Exciters

A six-pole compound wound commutating pole exciter is direct-connected to each main generator, Fig. 10. These exciters have a normal continuous rating of 100 kw. at 250 volts and a 25 per cent 2-hour overload capacity Each exciter is therefore capable of exciting two generators in case of emergency, and provision is made in the switching equipment so that the machines may be operated in parallel on the field bus, or any unit may be connected to the auxiliary bus as desired. On account of certain changes in load conditions which have taken place since the commencement of operation, it has been found necessary to divide the generating equipment in two sections, each requiring a somewhat different excitation. In order to readily accomplish this and provide a more flexible system, some slight changes are contemplated in the connections so that by simply adding double-throw field switches the exciters can, if desired, also be connected directly to the fields of their respective generators without being operated in parallel.

The machines are designed to withstand a 70 per cent over-speed, as are the generators. They are compounded to give 250 volts from no load to full load and their guaranteed full-load efficiency is 90.0 per cent. Each machine weighs complete about 8000 lb.

### Transformers

For each of the five generator groups there is a bank of three single-phase oil-insulated water-cooled transformers of the shell-type construction. Each transformer has a normal continuous rating of 3333 kv-a. with a temperature rise not exceeding 40 deg. C., this being based on an ingoing cooling water capacity of 12.5 gallons per minute at a temperature of 15 deg. C. They also have a 25 per cent 2-hour overload capacity with a temperature rise not exceeding 55 deg. C., based on a water supply of 15.7 gallons per minute.

The low-tension 6600 volt windings of the three transformers are delta-connected, while the 63,500 volt high-tension windings are Y-connected, this arrangement giving a transmission pressure of 110,000 volts. The neutrals of all the banks are connected through disconnecting switches to a common ground bus, which is grounded through a 127-ohm resistance. The primary windings of all the transformers are furnished with three 5 per cent taps, corresponding to voltages of approximately 60,300, 57,200 and 54,000. They are heavily insulated and the transformers have been submitted to the following high potential tests:

Primary to secondary and core, 220,000 volts for one min.

Secondary to core, 13,200 volts for one minute.

Across the full primary winding, 127,000 volts for five minutes.

The guaranteed efficiencies were:

| | |
|---|---|
| 1¼ load | 98.7 |
| Full load | 98.7 |
| ¾ load | 98.7 |
| ½ load | 98.4 |
| ¼ load | 97.2 |

The regulation:

| | |
|---|---|
| 100 per cent power-factor | 0.9% |
| 80 per cent power-factor | 4.3% |

The transformer tanks are cylindrical and are built of heavy steel plate with cast iron bases and covers. They are all mounted on trucks, which facilitates easy removal from the compartments, of which there is one for each transformer bank.

The cooling coils are of seamless brass tubing and designed to withstand a hydraulic test pressure of 250 pounds per sq. in. A sight flow indicator is installed in the piping for every transformer, and the cooling water supply is obtained from the penstocks through a reducing valve which is installed in a stand pipe on the hillside back of the switch house.

Fig. 12. 10,000 Kv-a. Transformer Bank

Each transformer requires approximately 2800 gallons of insulating oil and a piping system is installed so that the oil can be pumped to a large storage tank and filtered by means of a filter press. This latter is of the portable type and can also be used for filtering the oil of any transformer when in operation. A quick acting valve is provided at the bottom of each transformer tank which allows the oil to be quickly emptied into the tail race in case of fire. The discharge pipes for this run on brackets outside the switch house wall so as to reduce the fire risk to a minimum.

Each transformer is provided with oil gauges and capillary tube thermometers equipped with contact devices for ringing an alarm bell at the annunciator board in case the temperature should reach a dangerous value.

The over-all diameter of each transformer is 8 ft., the height to the top of the cover 13½ ft., and the height to the top of the high tension leads 16½ ft. The total weight, including the oil, is approximately 23 tons.

### Switching Equipment

The system of connections, as illustrated by the diagram, Fig. 13, has been slightly modified owing to the recent addition of a double-circuit transmission line which ties in with the Southern Power Company at Easley, S. C. The voltage required for this line is approximately 90,000, while 110,000 volts is used for the two Atlanta circuits. This fact has necessitated a sectionalizing of the system, and as operated at the present time generators Nos. 1, 2 and 3 are used for supplying energy for the Georgia Railway & Power Company service in Atlanta and other places, while Nos. 4 and 5 are used for the Southern Power Company's load.

As seen from the diagram, the generators are connected directly to their respective transformer banks, a transfer bus being the only connecting link on the low-tension side. The primary windings of the transformers are, however, paralleled by a high-tension bus, while a tie bus is installed on a structure outside the station.

The generators are connected through the low-tension oil switches on the first floor of the switch house to the transformer deltas on the floor above by two 1,000,000 c.m. varnished cambric insulated single conductor cables carried through ducts.

The delta-connection is made of 1¼ in. bare copper tubing mounted on post insulators supported on a pipe framework on the rear wall of the transformer compartments. The low-tension transfer bus consists of two rectangular bare copper bars 3 in. by ¼ in. mounted on insulator supports in brick compartments back of the switches.

There are three low-tension switches for each unit, the generator and transfer switches being of the non-automatic type and of 1200 amperes capacity. The transformer switches, however, are of the automatic type, provided with inverse time limit relays arranged so that they will trip both the low and high-tension transformer switches simultaneously. These switches also have a current carrying capacity of 1200 amperes, and the relays are energized from three 1500 ampere current transformers inserted in the transformer connections.

All the 6600 volt oil switches are of the H-3 motor-operated type with cell construction. Disconnecting switches are provided for isolating each main switch in case of repair. The sectionalizing of the transfer bus is also accomplished by a set of disconnecting switches.

The star connections are made on the high-tension side of the step-up transformers, the neutral points being connected through disconnecting switches to a ground bus which is mounted on the wall of the switch room on post insulators. This bus extends the length of this room and then down to the second floor, where it is connected to the grounding resistance. The other transformer connections are carried through high-tension oil switches located on the switching floor to the high-tension bus, and from there again through high-tension oil switches through wall bushings to the outside tie bus. Disconnecting switches are furnished, as shown by the diagram, for isolating the oil switches and for sectionalizing the high-tension bus, which, besides, is sectionalized in the middle by an oil switch.

The high-tension busbars and connections are of approximately one inch copper tubing spaced 8 ft. apart and mounted on post insulators, the buses being suspended from the roof trusses in the high-tension room directly above the switches. The trusses are of special design in order to give sufficient clearance for the wiring. By this type of truss it is possible to considerably cut down the height of the building and utilize the waste space for wiring.

The high-tension oil switches are of the K-15 solenoid-operated type, one magnet being furnished for each pole. They have a current capacity of 150 amperes. The transformer switches are, as previously mentioned, automatically tripped simultaneously with the low-tension transformer switches, while in closing they operate independently. Inverse time-limit series relays are provided on post insulators for automatically tripping the outgoing line switches, while the bus sectionalizing switch is of the non-automatic type.

An eight-panel direct current switchboard is located on the main floor of the generator room directly under the control board, and contains the switch and instrument equipments for the five exciters and the auxiliary direct current apparatus in the station. Each exciter panel is provided with a 600 ampere, single-pole, hand-operated reverse current circuit breaker with shunt trip attachment, a three-pole double-throw 600 ampere quick break knife switch, an 800 ampere ammeter, a rheostat handwheel, and potential receptacles. Two of the panels contain automatic generator voltage regulators, and two voltmeters are mounted on a swinging bracket at the end of the board. There is also a high and low voltage cutout relay which operates in conjunction with the regulator to lower the excitation by cutting in a resistance in the exciter field circuits should the voltage tend to rise 15 per cent or drop below 50 per cent as in the case of short circuits. The busbars are mounted on the rear of the board and the connections to the exciters as well as those to the generator fields consist of 750,000 c.m. single conductor varnished cambric weather-proof cable installed in conduits.

Generator field panels are installed in front of each generator on the main floor under the gallery. These are equipped with single-pole solenoid-operated field discharge switches and motor-operated rheostat dials, the resistances for which are located in compartments on either side of the exciter board under the gallery. The panels also contain push button switches and lamps for signalling with the operator in the control room.

The main control board is located in the operating room on the top floor of the switch-control house, which, as before stated, joins

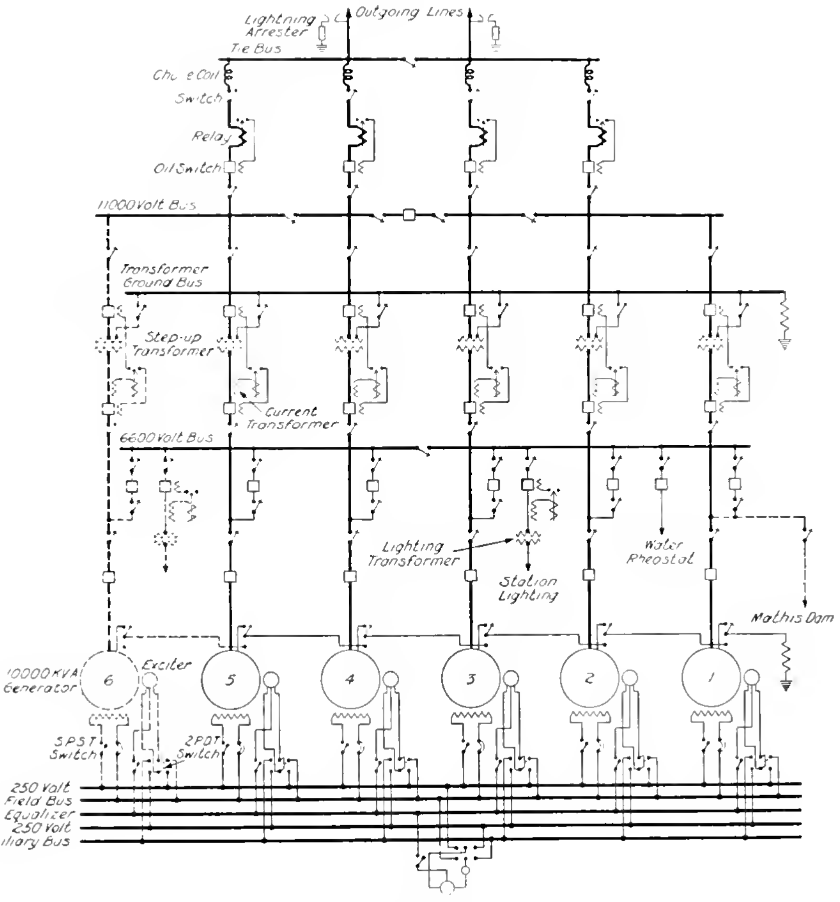

Fig. 13. Wiring Diagram of Power House

the generator building to the switch house. It is of the ordinary benchboard type, made of black slate, the desk containing all the control switches, signal lamps, potential and synchronizing receptacles, mimic buses, etc., while the instruments and meters are mounted on the vertical panels.

The instrument equipment for each generator consists of three a-c. ammeters, one voltmeter, one polyphase indicating wattmeter, one polyphase watthour meter, one power-factor meter and one field ammeter. For each transformer bank there is one ammeter, while a voltmeter and frequency meter are installed for each of the two low-tension bus sections. There are two synchroscopes, one of of them, which has a 36 in. dial being mounted on the wall of the generator room opposite the control board. Each of the outgoing line circuits is furthermore provided with three series ammeters mounted on post insulators. All the current and potential transformers are installed in compartments in the bus structure.

Fig. 14. High Tension Switch Room

### Lightning Arresters

Two sets of electrolytic lightning arresters with choke coils are provided for the two outgoing Atlanta lines, and similar equipments will soon be supplied for the other two lines. They are of the outdoor type mounted on a structure located on the side of the hill adjoining the switch house. Each arrester consists of four tanks, three of which are connected to the line wires through horn gaps, while the fourth tank is connected between the other three and ground.

Fig. 15. Lightning Arrester Equipment

### Station Lighting and Service Equipment

Energy for station lighting and power is supplied from the low-tension bus through a bank of three 20 kw. single-phase transformers stepping down from 6600 to 460 or 230 volts. On the first floor of the switch control house there is also a 125 h.p. Pelton waterwheel, fed from one of the penstocks and governed by a Lombard governor, which drives a 50 kw. 250 volt direct current generator. This can be connected to either the field or auxiliary station bus and is intended for emergency use, such as for providing light and power during shutdown periods of the main units.

A portable high potential transformer is provided and there is a large water rheostat outside the station, means being provided so that either generator can be connected thereto for testing purposes. There is also a small motor-driven air compressor for cleaning and performing other services about the station. The lighting is done by 100 c-p. mazda lamps.

In the following issue there will be a description of the transmission lines and the large outdoor substations of the system.

The construction work for this development has been done by the Northern Contracting Company under the able supervision of Mr. C. O. Lenz, Chief Engineer, 71 Broadway, New York; Mr. C. G. Adsit, Engineer at Tallulah Falls; Mr. C. E. Bennett, Electrical Engineer, and Mr. E. Lauchli, Hydraulic Engineer The entire electrical equipment was furnished by the General Electric Company.

# DRILLING AND PUMPING OIL WELLS BY ELECTRICITY

By W. G. Taylor

Power and Mining Engineering Department, General Electric Company

The methods of drilling and operating oil wells are described and illustrated in sufficient detail to give a clear conception of the requirements of motor drive, and the description and advantages of the electrical equipment are covered in a manner intelligible to oil men. Probably no other induction motor application has been obliged to contend with as complex conditions as the oil well motor; but the saving it effects in time, labor, and expense more than justifies the special features which make the equipments so versatile. The author submits valuable power and cost data obtained from the actual operation of oil well motors in the California oil fields.—Editor.

W. G. Taylor

It is no simple task to drill a hole in the earth half or three-quarters of a mile deep and from four to twenty inches in diameter, and then keep it free from shale and sand month after month while a pump is kept in operation at the bottom of the hole. Yet these are conditions imposed in the production of petroleum, and they have been successfully met at more than 176,000 wells now producing oil in the United States. There are a few wells in the Appalachian and California fields considerably more than a mile in depth, and the improvements being made from time to time in drilling methods indicate that wells of such depth may soon be numerous, as the drilling of new wells is started almost daily.

The steam engine did most of this work. A simple slide-valve type was adapted to this special service long before the electric motor was put into general commercial use, and yet the latter has supplemented steam and gas engines, or has been the initial type of drive installed, on more than 1020 wells during only three years' operation in the California oil fields alone. A number of motors have been in use in the Pennsylvania and West Virginia fields for several years longer, but these were not suitable for the widely different conditions encountered in California, and it was necessary to develop an improved type of motor which was more generally applicable to oil well operating methods of any character.

Several things combined to prevent the earlier adoption of motor drive. The lack of power lines in the fields was due to the fact that the power companies could not anticipate much revenue from them until a motor could be produced which would in every way satisfy the oil operator as well as did his time honored engine. Early trials of various types of motors indicated the special features that were necessary in the electrical equipment and indicated also the most suitable sizes of machines. The results obtained demonstrated clearly that electric drive would effect large savings in operating expenses. However, this saving was not a matter to which the oil producer paid much attention until the falling price of oil awakened his lively interest in the subject. Although oil and natural gas had always been the fuel used for both drilling and pumping, rarely had an oil producer charged to his operating expense the market value of the fuel consumed, and in some cases he had no accurate idea of the quantity used. Under such circumstances it is not surprising that the oil men were at first reluctant to pay cash for power when they could obtain it "free" from their own wells.

.Induction motors were used from the first, not only because the available power supply was alternating current, but because this type of machine was recognized as having the sturdiness and overload capacity necessary to withstand oil field service. Motors were first developed for use on producing wells, and electrical drilling was not attempted until considerable progress had been made on pumping motors. All the operations of drilling are handled by a machine installed at the time the rig is erected, which is replaced by one of smaller capacity when the well is "brought in" as a producer and is "put on the beam." The drilling motor is then transferred to the next new rig.

### Motors for Pumping, Pulling and Cleaning the Well

The principal work of the pumping motor is to pump the oil from the well, this being continuous duty day and night except when it becomes necessary to pull out the rods and tubing to make repairs or clean out the well, and then replace them to resume pumping. It was soon recognized that on the majority of wells all of these operations would have to be performed by the same motor in order to compete at all with the steam engine. On account of the wide range of duty thus imposed, motor equipments of exceptional versatility have been perfected.

To the ordinary observer, the oil well derrick and other parts of the rig make a crude-looking affair, but for convenience of manipulation they can hardly be improved upon. The motor is generally belted to a countershaft, as in Fig. 1, which in turn is belted to the band-wheel. The latter transmits the power through a crank to the walking beam, as is shown in Fig. 2. The well is lined wholly or in part with jointed iron or steel casing, within which a "string" of tubing of small diameter is lowered to the depth at which the pumping is to be done. The lower end carries the pump barrel within which the plunger works with a vertical reciprocating motion imparted to it by the beam, through jointed rods extending down within the tubing and attached to the end of the beam. Suitable check valves in the barrel and plunger govern the flow of oil through the pump.

When it is necessary to pull out the rods and tubing to clean out the well or replace broken rods, worn pump plungers, etc., the bull-wheel, Fig. 2, is operated by rope-drive from the band-wheel and the hoisting line is wound on the bull-wheel shaft, while the walking-beam is disconnected from the crank. The calf-wheel is used only for handling the casing in a similar manner during drilling, and is driven from the band-wheel by a sprocket and chain. The bull-wheel and calf-wheel are each equipped with a powerful hand-operated band brake.

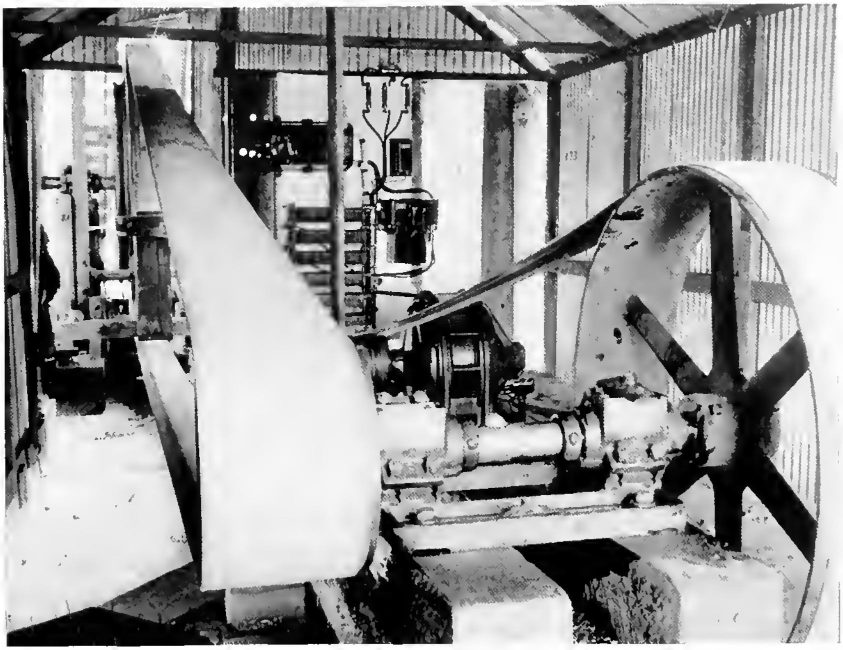

Fig. 1. Two-speed Motor with Countershaft for Pumping, Pulling and Cleaning a California Oil Well

When a well is cleaned, the mixture of sand, mud, and oil at the bottom must be bailed out. The bailer, a long tube with a check valve in the bottom, is handled by a single line on a drum called the sand-reel, which is driven by a friction pulley in contact with the band-wheel. Occasionally light drilling must be resorted to before the sand can be sufficiently loosened to be bailed out.

The oil well pumping motor installations are of two general types, belted and back-geared, by far the larger proportion of them being belted because of their more quiet running qualities. The backgeared motor is generally mounted on the old engine block and the backshaft belted directly to the band-wheel, Fig. 3 showing a typical installation with this arrangement. When a belted motor is used an intermediate countershaft is necessary, the latter being mounted on the engine block and the motor belted to it, as is seen in Fig. 1. Occasionally it is found advantageous to use the old steam engine as a countershaft, disconnecting the connecting-rod and putting suitable pulleys on the engine shaft. A cheap and substantial pulley is sometimes made by lagging the engine flywheel with wooden sections securely bolted to it. In the installation shown in Fig. 4 the engine was utilized as a countershaft, though the photograph was taken before the motor was wired in and while the engine was still pumping the well.

There are now two types of induction motors in use for the pumping, pulling and cleaning duty: the single-speed machine and the two-speed machine. Except in a few cases, both have wound rotors for variable speed, the latter obtainable by means of a controller and secondary rheostat; but the two-speed motor has advantages which cannot be obtained readily by other means, and has therefore gained the higher favor since it was introduced. For both types of motors a synchronous speed of either 900 or 1200 r.p.m. is generally selected as being the best compromise between a motor with too small a pulley and one with a high cost.

In the California fields particularly there is a great necessity for a variable pumping speed, as it is influenced by varying conditions, such as the rate of flow of the oil, the amount of sand accompanying it, the amount of gas or water in the oil, the viscosity of the fluid and the condition of the pump itself. A well is pumped at what the operator considers its maximum economical rate, but this may be limited by the rate at

Fig. 2. Elevation and Plan of Motor-Operated Oil Well Rig

which the oil will flow into the well from the surrounding strata, or by the rapidity with which the rods and plunger will drop in the oil on the return stroke. On the average well the band-wheel speed may vary from 18 to 30 r.p.m. and the motor must consequently be capable of a similar range in speed. However, for the hoisting work necessary when "pulling" the well and cleaning it out, a band-wheel speed of twice this amount is used, and is obtained by changing either the motor pulley or the internal motor connections.

On the single-speed motor the desired hoisting speed can be obtained by putting on a larger motor pulley, which must, however, be replaced by the small one for pumping again. This change of pulleys is so irksome to the oil men that it is seldom made, and in many cases where it is tried the pulleys are soon damaged. The slow hoisting speed obtained with the small pulley materially lengthens the time required to "pull" the well and put it back "on the beam," and this means loss of production to the operator. An expedient for obtaining high hoisting speed is to lag the bull-wheel shaft on which the line is wound. This greatly increases the strain on the rig and for that reason is not considered a safe method by most operators. Furthermore, it does not increase the speed of the sand-reel and thus much time is lost when hoisting the bailer.

Fig. 3. Back Geared Pumping Motor in the Kern River Oil Fields, Bakersfield, Cal. At the right is the weight which counterbalances the rods in the well

Another operation which is impossible unless the motor pulley is changed on the single-speed motor is "shaking up" a well. When sand gets in, it very frequently clogs the pump-valves, but by speeding up the walking-beam sufficiently they may often be cleared without resorting to the expensive process of pulling the well. On the other hand, if the motor is shut down long enough to change the pulley, the well in the meantime may sand up completely, making a pulling job absolutely necessary, the work requiring one or two days time depending on the depth of the well, and thus entailing a considerable loss in production. Occasionally a well requires shaking-up several times a day, and it would be obviously impractical to change pulleys each time.

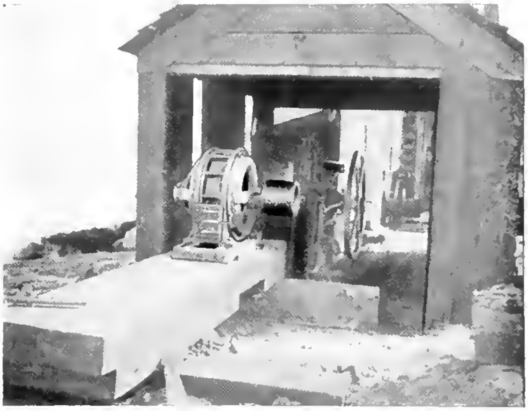

Fig. 4. One Method used by the General Petroleum Co., Taft, Cal. of installing a two-speed pumping motor for belting to the engine shaft

All of these drawbacks have resulted in the extensive adoption of the two-speed variable-speed machine. By a pole-changing switch mounted on the motor frame, the synchronous speed may be instantly changed from 600 r.p.m. to 1200 r.p.m. or back at any time desired, making the high speed at once available for shaking-up, bailing or handling rods and tubing. This method appeals to the oil man on account of its simplicity, and does not have the objections which have been offered to sliding-gear boxes and belt-shifting devices, the operation of which is soon impaired by the wear and tear of heavy duty. On the light redrilling work often necessary when cleaning out a well, the two-speed motor is especially suitable for the wide range of speed and load frequently desired.

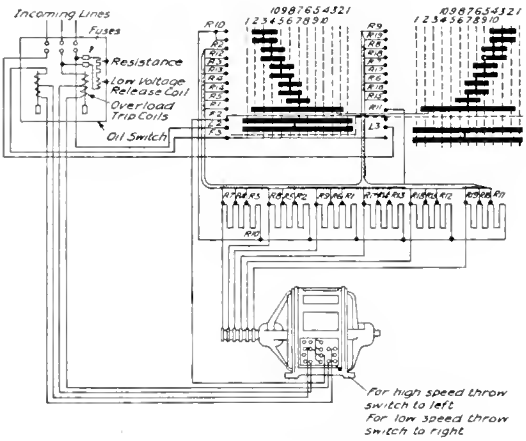

Fig. 5. General Connections for Two-Speed Pumping Motor Equipment

A 25 h.p. motor, rated 8 h.p. on the pumping speed, is the size suitable for the majority of wells. The deeper wells are generally equipped with a 30 15 h.p. machine. As indicated by Table 1, the motor on pumping duty is required to deliver an average of 4 h.p. but this may vary from 1 to 6 or 7 h.p., or higher. A well in the Midway fields in California has been known to require 16 to 17 h.p. for a considerable time for pumping, this heavy demand apparently having been due to a heavy flow of sand with the oil. The power input will vary from day to day and even from hour to hour, and may increase considerably in a short time when the well is sanding up. For this reason the motors are given the liberal ratings stated.

For handling rods and tubing the motor may be required to deliver from 35 to 80 h.p. for short periods on the average well, and even higher in some cases, especially in emergencies and on some of the special operations which are occasionally necessary to maintain the well as a good producer. This is many times greater than the power required for pumping, but it has been successfully obtained by designing the machines with a maximum momentary overload capacity of 300 to 450 per cent of their high speed rating.

As pumping is a continuous day and night load, good efficiency and power-factor on this work are of importance to the consumer and power company. To obtain these on the single-speed motor the windings are arranged to be Y-connected for pumping and delta-connected for pulling, the change being made by a double-throw switch on the motor. The rated capacity is thus increased in the ratio of 1 to 3, and excellent characteristics are obtained on either connection. On the two-speed machines it has already been mentioned that the pole-changing switch accomplishes both a change in speed and capacity, and this change in like manner produces the good characteristics particularly desired when pumping.

### TABLE I

### POWER REQUIRED FOR PUMPING 213 OIL WELLS IN CALIFORNIA

| | Bbl. per Well per Day | Depth of Wells | Kw-Hr. per Well per Day | Kw-Hr. per Bbl. Pumped |
|---|---|---|---|---|
| Max. | 230 | 3110 | 123.4 | 5.843 |
| Min. | 10 | 900 | 27.7 | 0.414 |
| Average | 122 | 1430 | 80.8 | 0.683 |

#### Motor Control for Producing Wells

The controller and rheostat are located near the motor rather than at the derrick, and the former is operated by a rope wheel instead of a handle, with a wire rope running to a similar wheel on the "headache-post" in the derrick within easy reach of the operator, and in all respects similar to the throttle control of the steam engine. But as all speed variation and reversing is done by the controller, the reverse lever used with steam engines and gas engines is not required, so

Fig. 6. Motor-driven Rig showing Counterbalance

that the operator has less effort in controlling the motive power and can give better attention to the work at the well.

In addition to the drum controller and rheostat, the equipment is provided with a wall-mounted oil switch with inverse time limit overload trip coils and low-voltage release. Motor protection is required on either its low or its high rating, and is obtained by the use of double-wound overload trip coils so interlocked with the pole-changing switch on the motor that the proper protection is automatically obtained for either connection of the motor. The method of doing this will be at once seen by reference to the wiring diagram, Fig. 5.

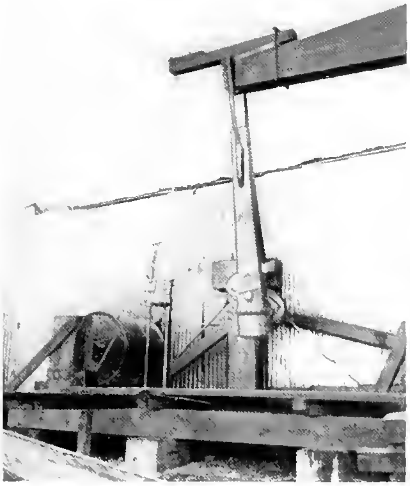

Fig. 7. Tail-Pump Operated by the Walking-Beam

The work of pulling out rods and tubing as well as replacing them requires that they be unjointed and handled generally in 60 foot lengths, and occasionally in 20 foot lengths, and this involves considerable manipulation by the motor with frequent reversals at high speed. The best results are obtained by making use of the high torque capacity of the motor, the full benefit of which is obtained on the intermediate controller points. A number of equipments are now provided with a device which entirely relieves the operator of the necessity of keeping this matter in mind on every reversal, as it automatically stops the controller at the most advantageous point until the input has fallen to a value at which the remainder of the resistance is no longer necessary in circuit. The device also acts as a protection to the motor, as it lowers considerably the average current input while reversing.

### Counterbalances

With the advent of the electric motor in the oil fields and the ease of measuring the power input, attention was directed to some economies which could be effected by minor changes in the rig. The chief improvement was the use of a weight to counterbalance the rods on the beam and thus relieve the motor of the necessity of hoisting the full weight of rods on each stroke. The usual type of counterbalance is shown in Fig. 6. It is installed at a nominal cost, and tests on a large number in use show a saving in power of 8 to 22 per cent, depending upon the depth of the well, weight of rods, etc.

### Tail Pumps

Fig. 7 shows a type of pump operated from the tail-end of the beam, frequently used for transferring oil from the sump to the storage tank or pipe-line. Such a pump increases the power demand from the motor approximately 1.5 h.p. under average conditions.

### Cost of Pumping, Pulling and Cleaning

The greatly diversified conditions encountered in the oil fields cause a wide variation in the costs of operation, though these check closely for similar conditions. The depth of well, the quantity and rate of production, the size of pump, the distance between wells, the number of wells operated and the gravity of the oil all have their influence. In general, pumping a well with

Fig. 8. Power-Head Driven by a 20 h.p. Motor in the Sherman Salt Lake Oil Fields, Los Angeles, Cal.

### TABLE II

### COST OF ELECTRIC POWER FOR PUMPING WELLS ON SEVERAL PROPERTIES IN THE CALIFORNIA OIL FIELDS

| No. of Wells | Average Depth | Rate per Kw-Hr. | Cost per Well per Day |
|---|---|---|---|
| 4 | 800 | $0.015 | $0.80 |
| 2 | 950 | .015 | .65 |
| 15 | 1000 | .015 | .71 |
|  | 1100 | .015 | 1.08 |
| 2 | 1100 | .015 | 1.21 |
|  | 1400 | .015 | 1.05 |
| 1 | 1500 | .015 | 1.13 |
| 62 | 1600 | .01 | .69 |
| 1 | 1700 | .015 | 1.11 |
| 110 | 750–2700 | .01 | .84 |

### TABLE III

### COST OF PUMPING 8 WELLS, DEPTH 1000 TO 2800 FEET, IN THE CALIFORNIA OIL FIELDS

|  | STEAM OPERATION |  | ELECTRIC OPERATION |  |
|---|---|---|---|---|
|  | Sept. 1912 | Oct. 1912 | Jan. 1913 | Feb. 1913 |
| Water | $449.99 | $457.83 | $71.00 | $53.90 |
| Fuel, oil at 50 c., per bbl. | 469.00 | 305.50 |  |  |
| Fuel and electric power at 1½ c. per kw-hr.. |  |  | 340.00 | 329.90 |
| Labor | 448.00 | 448.00 | 450.00 | 383.50 |
| Boiler compound and lubricating oil | 30.00 | 30.00 |  |  |
| Lubricating oil |  |  | 17.50 | 17.50 |
| Totals | $1396.99 | $1241.3 | $863.50 | $784.80 |

Average per well per day—steam . . . . . . $5.41
" " " —electricity . . . 3.49

Saving by electricity over steam $1.92 per well per day.

### TABLE IV

### COST OF PUMPING 12 WELLS, AVERAGE DEPTH 1100 FEET, OIL 15.5° BAUMÉ CALIFORNIA OIL FIELDS

|  | PER WELL PER DAY |  |
|---|---|---|
|  | Steam | Electricity |
| Labor pumping | $1.15 | $1.18 |
| Electric power at 1½ c. per kw-hr. |  | 1.07 |
| Fuel oil | 1.47 | .42 |
| Water | 1.95 | .95 |
| Repairs to boilers and engines | .25 | .06 |
| Repairs to motors, transformers and power lines | None to Date | None to Date |
| Oil, waste and packing | .27 | .17 |
| Totals | $5.09 | $3.85 |

Saving by electricity over steam $1.24 per well per day.

### TABLE V

### COST OF PUMPING 107 WELLS, AVERAGE DEPTH 800 FEET, OIL 13.5° BAUMÉ CALIFORNIA OIL FIELDS

|  | PER WELL PER DAY |  |
|---|---|---|
|  | Steam | Electricity |
| Maintenance pipe-lines, wells, pumps, rigs, boilers, motors, transformers, and transmission lines | $0.95 | $0.70* |
| Labor, including pumpers, boiler men, electricians and well-gang | .65 | .45 |
| Fuel oil at 35 c. per bbl. | 1.17 | .12 |
| Water, waste and lubricating oil | .52 | .13 |
| Electric power at 1 c. per kw-hr. |  | .57 |
| Totals | $3.29 | $1.97 |

Saving by electricity over steam $1.32 per well per day.

* Estimated repairs are added for electrical equipment, as there were none for period covered.

a steam engine requires the following items per well per day.

Fuel oil . . . . . . . . . . . . . . . . . . . . . . 3½ to 10 bbl.
Water . . . . . . . . . . . . . . . . . . . . . . . . 25 to 80 bbl.
Lubricating oil, waste, packing, etc. 15 to 40 cents
(the higher figure is for gas-engines)
Repairs to boilers and engines . . . . 20 to 40 cents

With electric drive the requirements per well per day are about as follows:

Electric power . . . . . . . . . . . . . . . . 45 to 200 kw-hr.
Water . . . . . . . . . . . . . . . . . . . . . . . . . 1 to 20 bbl.
Lubricating oil . . . . . . . . . . . . . . . . . . 1 to 3 cents
Repairs to motors, transformers and transmission lines . . . . . . . . . . . . . . 3 to 6 cents

These figures take no account of the cost of labor, which varies greatly even when other conditions are similar. In general one pumper can look after 8 to 12 gas or steam engines or 15 to 20 motors.

Tables 2, 3, 4 and 5 give actual comparative operating costs for a considerable range of conditions and indicate the excellent results being obtained. The figures are all for wells on the beam and operated by individual motors. In the three latter tables it will be noted that for electric operation a charge is included for fuel and water, this being required for washing and heating the oil, also for domestic purposes, and in some cases for shipping the oil. There are a few leases where steam has been entirely dispensed with, the only water used being for domestic purposes. The oil produced on these properties requires no washing, while motor drive is used for the shipping pumps.

## TABLE VI

### POWER REQUIRED FOR PUMPING OIL WELLS BY PUMPING-JACKS IN CALIFORNIA OIL FIELDS

| No. of Motors | No. of Wells | Average Kw-Hr. per Well per Day | Kw-Hr. per Bbl. Pumped |
|---|---|---|---|

## TABLE VII

### COST OF ELECTRIC POWER FOR DRILLING IN CALIFORNIA OIL FIELDS

POWER RATE 1.5 CTS. PER KW-HR.

| Depth of Well, Ft. | Cost of Power per Foot Drilled |
|---|---|
| 735 | $0.1074 |
| 1495 | 0.1025 |
| 945 | 0.0915 |
| 1356 | 0.1060 |
| 824 | 0.0570 |
| 732 | 0.1040 |
| 1175 | 0.0848 |

### Pumping-Jacks

When the production of several adjacent wells is so low that it is unprofitable to pump them by individual motors, they are operated together by one motor from a central point, providing that they are comparatively free from sand and water troubles. The power-head, as shown in Fig. 8, carries one or more eccentrics, to the yokes of which are attached cables or rods extending to a bell-crank or "pumping-jack" at each well, and by this means imparting the vertical reciprocating motion to the sucker rods. An ordinary constant speed squirrel cage motor is belted to the power-head through a jack-shaft, the latter generally being provided with a friction clutch. A quarter-turn belt connects the latter with the power-head. The outfit is simple and the installation very cheap as no special electrical apparatus is required other than the standard motor and compensator for starting it. When the well is cleaned a portable hoisting equipment is employed, such as is shown in Fig. 9.

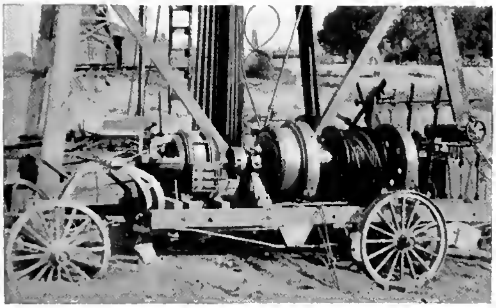

Fig. 9. Portable Electric Hoist used for Pulling and Cleaning Oil Wells Pumped by Pumping-Jack in the Kern Field, Bakersfield, Cal.

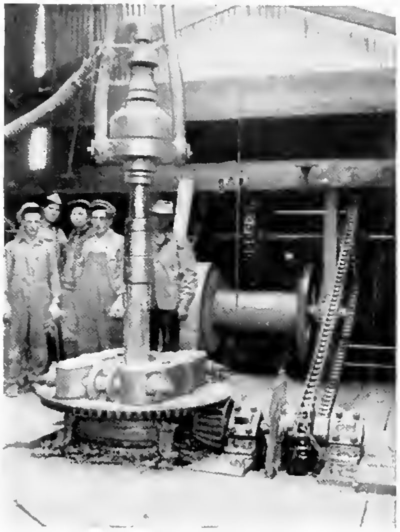

Fig. 10. Rotary Drilling Rig and Crew

The power required for pumping wells by this method depends considerably upon the effectiveness with which the wells are balanced against each other, and is affected also by variations in the depth of the wells, the height to which the fluid rises in the well, the gravity of the oil, the diameter of tubing used and the speed of pumping, as well as the general condition of the wells with respect to sand, gas and water content. A low pumping speed is maintained, generally from 10 to 20 strokes per minute. In Table 6 are given figures taken from the records of several oil companies in California which give a general indication of the motor capacity necessary.

### Motors for Drilling

The two principal modern methods of drilling oil wells are the standard cable-tool method and the rotary process, although in a few instances a combination of these two is used. In cable drilling a heavy stem and bit are suspended from the walking-beam by a steel wire or manila rope, and are raised and dropped on the bottom by the movement of the beam. The drillings are mixed with water in the hole and are removed at intervals by a bailer. In the rotary process a bit is located at the lower end of a rotating column of pipe, which is lowered into the well as drilling progresses. The pipe is held and turned by a turntable as shown in Fig. 10. By means of the so-called "slush-pump" a mixture of thin mud is circulated down through the stem and up outside of it, serving to wash out the drillings and plaster up the sides of the hole to prevent caving.

Fig. 11. Two-Speed Pumping Motor and Control Equipment Installed by the Kern Trading and Oil Co., at Shale, Cal.

As drilling proceeds the well is lined with iron or steel casing unless the strata passed through are so firm that no caving will occur. The casing is inserted in approximately 20 foot lengths, screwed together, and its handling imposes heavy duty on the drilling motor. As has been mentioned, the calf-wheel is used for this casing work. In lowering a string of casing into a well the friction of the sides of the hole caused by the pressure of the surrounding formations may so impede it as to prevent it from sinking farther until relieved by "spudding" the casing. This consists in repeatedly raising and lowering it a few feet until a clear passage is obtained, and requires a very liberal intermittent overload capacity in the motor. Its ability to exert a high torque in an emergency is often the means of freeing a string of casing which may have become "frozen," and which might otherwise have to be "landed" in the hole, and thus necessitate drilling being resumed with a smaller string.

On account of the heavy strains to which the equipment is subjected, the motor for cable drilling is preferred without backgears, and a belted countershaft is therefore used as with pumping equipments. A few installations have been made using a two-speed change-gear countershaft to obtain more economical speed variation, but they have nearly all been discarded because of their rapid depreciation under the severe service. It has also been found that the operators frequently failed to make use of the device because of the time and trouble involved, and furthermore that the tremendous pull obtainable with the low gear was more than the average rig and casing could withstand without injury.

The range in speed required is approximately the same as for producing wells and is obtained by insertion of resistance in the rotor circuit. Other methods requiring more expensive equipment have been tried, but the standard type of variable speed slip-ring motor with the special control described in a subsequent paragraph has met the most general favor. It is natural that this should be the case, as the various operations follow so closely upon each other during the day that the driller is seldom willing to take the trouble to throw switches or shift gears each time, and will not do so if he can get fair results without it.

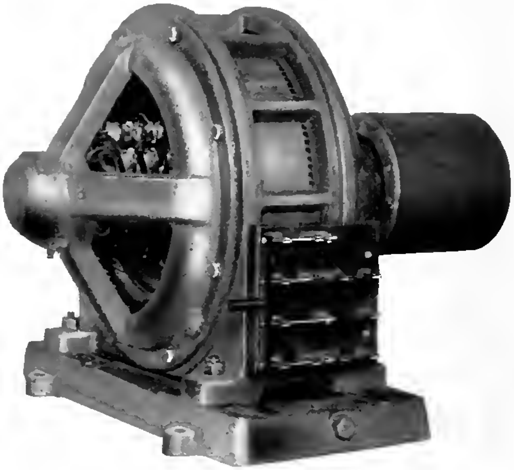

Fig. 12. Two-speed Oil Well Motor for Deep Wells, rated 15 h.p. for pumping and 30 h.p. (continuously) for pulling and cleaning work

The power required for the numerous operations in standard drilling varies considerably. Drilling itself is a fairly steady load on the motor, while the load imposed by the other operations, especially the manipulation of casing, is very intermittent in character, requiring high torque and frequent reversals. A 50 h.p. machine has been found to have sufficient capacity for all drilling work on most wells of moderate depth, but 75 h.p. may be necessary in many cases, particularly for greater depths. The size of motor in any specific case depends, as in pumping, upon the local conditions encountered.

For the rotary process the same type of motor used in cable drilling is well suited for driving the turntable and also the slush-pump. Heavy duty is required of the turntable motor in raising the drill-stem to change bits, and in putting in casing, so that high overload capacity is a necessity.

Fig. 13. 35 H.P. 1200 R.P.M. Constant Speed Motor Driving the Power-head for Pumping 23 Jack-wells in the Kern Field, Bakersfield, Cal.

### Motor Control for Drilling

In cable drilling the bit must fall freely on the down stroke to get the most effective blow, and to accomplish this the motor must slow down when lifting the bit and speed up when dropping it. This "series characteristic" is obtained by so proportioning the pulleys that some secondary resistance will be in circuit when the motor is operating at the correct drilling speed.

Fig. 14. Well No. 3 of the Midway Pacific Oil Co., Fellows, Cal., drilled entirely by electric power. Depth 1900 feet. The transformer installation is typical of the oil fields

The speed of cable drilling requires a very fine adjustment so that the movement of the beam will accord with the natural period of vibration of the drilling line due to its elasticity, as this period changes with the deepening of the well. Deviation from the right speed will not only result in deadening the movement of the bit but may seriously strain the line and the beam. Some of the first motors installed for this work were equipped with a 10 point controller, but it was found that the speed control was not fine enough. This trouble was overcome on later equipments by supplying an auxiliary controller designed to cut in between points on the main controller. A very smooth control with an infinite number of points may be obtained with a liquid rheostat, but this requires good water and close attention for satisfactory operation, neither of which can be given it under average conditions. For this reason it has been discarded by most

California oil men who have tried it, and drum controllers are now given the preference. They are operated by wire ropes extending to the "headache-post" as previously described for producing wells.

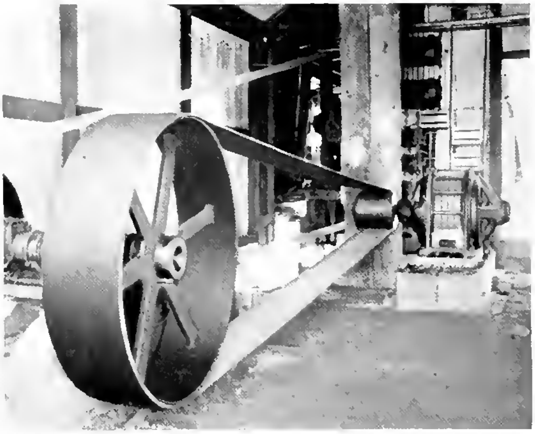

Fig. 15. 50 H.P. Drilling Motor Operating Standard Cable Tools at the Well Shown in Fig. 14

Rotary work also needs a fairly close speed adjustment because of the fact that for each different formation encountered there is a certain speed at which the bit will cut most effectively. The same type of control equipment used in cable drilling is therefore suitable. The slush-pump must also be operated at variable speed, owing to the changing pressure and flow required as the underground formation changes and the depth increases.

Fig. 16. Electric Oil Well Pumping is now used Exclusively Here on the Property of the Indian and Colonial Development Co. in the Desert of the San Joaquin Valley, Cal.

### Cost of Drilling

The cost of power is more variable for drilling than for pumping, as it depends upon the amount of trouble encountered and will be particularly high if there is any casing trouble. The figures given in Table 7, which have been determined from the actual power bills for drilling each of the wells in question, are representative of fairly good operating conditions in which no exceptional difficulties were encountered.

Fig. 17. An Electrically Operated Rig with Crew, for Drilling by the Standard Cable Method. The motor is controlled from the handwheels on the headache-post at the left.

### Summary of Motor Advantages

(1) Considerable saving in time is effected. The work is not necessarily done faster than with engines, but there are fewer delays from engine, steam and boiler troubles, from getting up steam, cleaning boiler tubes, making repairs, etc. The motor pulls the first "stand" of tubing as fast as the last one, while an engine will slow down considerably.

(2) Operating expenses are decreased. No boiler feed water is required, and the losses from leaky engine valves and piping are eliminated. The cost of lubrication and attendance is lower.

(3) Production is increased by the saving in fuel oil and by the steadier pumping motion secured.

(4) There is no power consumption when idle.

(5) Steady speed control is obtained by the steadier power supply. Speed fluctua-

tions due to varying steam pressure are eliminated.

(6) The motor has greater reliability, as it can always be depended upon to respond as expected and give the same speed on the same controller point for similar load conditions.

(7) The motor has a uniformly continuous torque and therefore never has to be "kicked off center."

(8) No time and efficiency are lost due to water choking the steam-pipes after an idle period.

(9) The motor is always ready at a turn of the controller and the speed is not only very easily varied, but is accurately controlled for "spotting" rods and tubing when screwing sections together.

(10) The control is simplified by the omission of the reverse lever required with an engine.

(11) Repairs are fewer and boiler depreciation, which is always high in the oil fields, is reduced or eliminated.

(12) Greater safety of operation is obtained, as the motor cannot run away when the rods part or a hoisting line breaks under heavy load.

(13) Explosions are eliminated and the fire risk reduced, particularly when the boilers are entirely done away with and electric lights are installed.

(14) The power consumption can be accurately measured and thus indicates the condition of the well and the most advantageous operating conditions from the standpoint of cost.

(15) The belts and the motor house in general can be kept cleaner and as a consequence there will be less rapid deterioration of the machinery and rig.

# WHERE FREIGHT IS MOVED BY MUSCLE

By R. H. Rogers

Power and Mining Engineering Dept., General Electric Company

The manner in which freight is handled at transfer and storage points is treated in a particularly interesting way in the following article. The item of cost is the all important factor to be considered when studying this subject, and consequently forms the theme of the article. The methods and figures involved in the movement of freight at railway sheds and at docks are presented. A few years ago muscle was practically the only power used. Today, however, there are installations of electrical equipment which to a certain degree have replaced the former muscle methods, and which have effected a considerable saving. Freight handling by muscle cannot be replaced by handling by machinery under certain conditions and an analysis of these conditions is clearly presented by the author.—Editor.

"Black Han', Black Han', uptown!
Blue Bottle. 'Cross de road! 'cross de road!
Red Boid, Red Boid, down town!"

R. H. Rogers

THIS is the 'sorter directing the toiling coffee bearers to over two hundred consignment piles on the wharf, each pile being distinguished by a flag, showing some well known emblem. As each carrier passes by with a 135 lb. bag of green coffee beans on his head the 'sorter glances at the complicated stenciled "mark" and conjures up in his mind the flag and its location that he has previously assigned to that mark. All day, and day after day, he directs at the rate of fifteen flags per minute with no errors and still has time to skylark, "pat juba" and curse the slow or stupid members of the gang.

The coffee is assembled in rope slings in the ten bag "drafts" in the hold, hoisted on deck by one steam hoist, swung out onto a hand truck on the pier by another steam hoist, dragged back under the shed by two men and there lifted onto the heads of the distributers.

From one hatch twenty-five men and two of the ship's hoists will discharge 750 bags per hour. At another hatch in the same ship the hand trucks were displaced by about 125 feet of portable electric conveyor sections and twenty-five men were discharging 1800 bags per hour. By extending the conveyors into the hold, the work of assembling the drafts would have been avoided and the two steam hoists would have been stilled.

The electricity for discharging the entire 5000 ton cargo as far as the 'sorter would cost the stevedore $14. We venture to predict, however, that the distribution to consignment piles, when they number over ten, will continue by the muscle method until there is some radical change in shipping methods or some new device or process is invented.

Wherever deep sea ships, coasters or river boats are discharging or receiving their cargoes of packages, and in some cases of bulk material also, we find freight being moved by muscle between the remote corners of the dark holds and the far side of the piers, outside bulkheads, "farms" and warehouses. The vertical lifts at the hatches are made by the ship's hoists, for which steam must be kept up, and the long hauls to and from warehouses are usually made by mules. The laborers are paid from thirty to forty cents per hour and mules are rented for sixty cents per hour, driver thrown in.

Tramp Steamer Light at High Tide Showing Difficulties of Mechanical Freight Handling

To take a specific case, we will look at burlap, which we import in enormous quantities for bagging, wrappers, etc. The bales weigh from 1200 to 1800 lb. each and are as hard as a rock. To hand-truck these from the ship's side to the consignment pile in the pier is laborious and no attempt is made to tier them up; to load the mule trucks from the pile is more laborious. The trip to the warehouse is slow and the load small. Then the trucks must be unloaded and the heavy bales tiered up to save the floor space that rents for 35 cents per square foot. What a lot of muscle! The work is now only half done, for when a bale is ordered out the whole process is repeated, in reverse, with a lighter, car or dray as the delivery point.

A standard electric freight handling machine, the battery truck crane, costing all-told $5.00 per day including operator, has eliminated 90 per cent of the muscle represented above and does the same amount of work at a saving of $48 per day.

Wherever freight cars discharge at terminals and receive their quota of outbound freight, there is much labor employed to effect the internal movements—some of it is amply justified, much of it is not.

Take a regular railroad transfer terminal, where less than car load lots are transferred from car to car to make up full cars for long hauls—here hand labor is used exclusively and is justified by the complexity of the work. With a setting of two hundred cars there are 40,000 different possible and probable routes along which to move freight by muscle, because a trucker may go from any car to two hundred different destinations. This complexity excludes any fixed trackage system. The consignments average 490 pounds (a very moderate hand truck load) and as the consignments have to be handled individually nothing can be gained by using a vehicle of greater capacity. The variations in height of car floors, lack of room in cars and passageways, and concentration of work in restricted areas at certain hours exclude any but the elastic, versatile, self-loading simple old hand truck.

The total cost of handling L. C. L. freight in a certain representative transfer terminal is 57 cents per ton, not including overhead, and of this only 17.2 cents per ton is chargeable to labor, so even a considerable reduction in the 30 per cent labor cost would not materially reduce the over-all cost of handling freight for that terminal where over three hundred men pull hand trucks.

Transferring Cargo from Lighter to Freight Car by Hand. One of the many steps in transferring about New York Harbor

Luckily all transfers are not so complicated and the extenuating circumstances are absent. The transfer of package freight from a wagon platform to the spacious main deck of a sound or river steamer is no job for muscle today, for the little electric industrial truck can be easily loaded from a suitable platform with one or two tons of freight (if it is not too bulky) and run through the pier up or down the gangway across the crowned deck to the edge of the carefully tiered freight. An equipment of twenty-one of these trucks in New York is credited with saving $63 per day over the old muscle method.

Where a wide wharf lies between the railroad tracks and the berths of the deep sea ships, one hears from afar the long drawn call of "Oh, dra-a-a-ag 'er! Oh, dra-a-a-ag 'er!" and there is seen a long line of men straining on a rope-fall pulling a log up skids out of a gondola car—gaining two inches on the "dra-a-a-ag" and losing one and three-quarters on the "Oh," until after half an hour the log topples over the edge and falls onto the wharf deck usually between the bumpers placed there to receive it, with consequent superficial or permanent damage to the fabric.

Then follows a mighty struggle with cant hooks, arms and legs and voices, as it is rolled onto a "dollie" a foot high mounted on six wheels. All hands shove the log across the wharf to a pile only two logs high where it is deposited with the aid of much shouting, muscle and perspiration. A few days later the operation is repeated, for the log must be urged and cajoled from the pile to the ship's side where the ship's tackle and hoist can lift it aboard. What an opportunity is here presented for the portable electric crane! Time to be saved, labor to be dispensed with, damage stopped.

In Main Hold of Tramp Steamer showing Part of Her 81,000 Bag Cargo

There seems to be always that intermediate piling of freight in all our terminal operations (with the exception of transfer terminals) consequent to breaking bulk for change of carriers to place in temporary storage.

When a ship discharges flaxseed to be transported inland in canal boats, it seldom goes into the canal boat direct, because of inspection and weighing by the customs officials, and again by the consignee, and because the canal boat is not there at the time. Car loads of manufactured goods or what not for foreign ports must be held in a warehouse, in an outdoor pile or on the pier until the ship is ready to receive it.

Two Men with Hand Truck Handling Coffee in Nine Bag Loads. There were 81,000 bags in this cargo

Even when coffee or sugar is going from a ship to a nearby warehouse piling intervenes, and often expensive hand terraced piling on account of the limited space. The operations of discharging the ship, piling the cargo, tearing it down, and drawing it away are going on simultaneously, the piles acting largely as reservoirs to take up the lost motion between mismated methods of freight handling.

There is an astonishing bulk of material in a ship's cargo and when it is loosely piled on a pier, with aisles between the various consignments, one wonders how it could all have come from the hold of one ship. There are four things that limit the height to which freight can be piled, viz., ability of the material to withstand pressure, head room in the pier shed or warehouse, the load capacity per square foot of floor area, and the cost of high piling by hand as compared with the cost of hand trucking out over a large area. When the pier is small, it is often necessary to pile freight up to the roof if the other conditions permit. This is usually done by relays of men working on terraces, rehandling every item from two to five times. This makes a very expensive process and one that is avoided wherever possible. Where the pier has a liberal area or where there is a large open space inshore, usually called the levee, "farm" or "beach," the freight is trucked, carried, or rolled to great distances and left shoulder high. Space along the water fronts of harbors is very valuable, and when a ship's inward bound cargo is allowed to cover all the neighboring coast there is no room for assembling and handling her outward cargo without excessive amount of trucking unless she is moved to another berth. At the same time other steamers are berthed at the same or in adjacent spaces, each discharging and receiving, adding to the confusion, double and triple handling, and causing delays and congestion.

**Battery Truck Crane Towing Fifty Bags of Coffee from Wharf Building to Warehouse. The rope slings are for hoisting the bags to upper floors**

The cargo of a 10,000 ton ship, allowing 40 cubic feet per ton, equals 400,000 cubic feet. Piled four and one half feet high with aisles occupying one-third the space, we find that the spacious holds have evicted some three acres of freight. Somewhere in the immediate vicinity there must be made ready another three acres of cargo outward bound.

To avoid this obviously inefficient use of valuable area and to reduce the cost of placing a cargo on the pier, there are available several ingenious types of portable stackers that are used independently or in connection with horizontal portable conveyors, industrial trucks, tractors and trailers, hand trucks or "backers," i.e., back loads. On ordinary material these machines will stack a ton per minute up to twelve or fifteen feet high and with a well planned layout on the floor the work can go on practically without interruption hour after hour. The current consumption is small. The power required for a 14 ft. lift at the rate of 136 tons per hour is only 4 h.p. These stackers are among the most valuable tools for supplanting muscle in freight handling, for they are great conservers of space at the same time.

Where large quantities of package freight are placed in storage it is usual to resort to horses and mules for the hauling. The restricted spaces are crowded with animals and their drivers, much damage is done to freight and accidents are not infrequent. On a half mile haul an electric tractor will tow three or four mule trucks twice as fast as a mule will walk, delivering 600,000 lb. of cotton, for instance, in one day, or at the rate of fifteen ton miles per hour, or "a bale-a-mile-a-minute." The cost for a half mile haul per bale, not including loading or unloading the trailers, is less than half a cent.

The question of conveying freight to and from freight houses and piers in cities by other than animal power is a vexing one. The streets in the neighborhood of piers and freight houses become congested during the popular shipping hours and vehicles are subject to long delays that are expensive or disastrous to power trucks. We sometimes see a line of drays waiting for ferry boats, the line frequently being made up of enough drays to load four boats; hence, a team may wait an hour and a half in the line. The load factor, or per-

**Loading a Freight Car by Hand under the Brooklyn Bridge**

centage of full load for full time, is apt to be low in freight hauling service both to and from terminals. A team taking one-quarter load one way and returning light would show a load factor of 12½ per cent and if the team were delayed altogether enough to double its time the load factor would fall to 6¼ per cent. Where industrial concerns have no sidings, but have enough traffic each way to insure a reasonable load factor and care is taken to avoid the rush hours, power trucks possess a great advantage over horses and they have become popular in many cities. However, in West Street, New York, which is a marginal street along piers, the percentage of power trucks is very low—4 per cent according to published observations. The average load one way was 71 per cent, making the load factor 35½ per cent if there were no delays. It is interesting to note in this connection the load factor of freight cars. Droege in his "Freight Terminals and Trains," says that only 55 per cent of the capacity of freight cars is utilized and that they are loaded only 70 per cent of the mileage; hence, the load factor for freight cars is only 38½ per cent.

We learn that the average freight haul is 138 miles and the average cost per ton mile is three mills, making the cost of the average haul 41 cents per ton. How does this compare with the cost of the muscle work required to supplement the locomotive? Twenty-five cents at the receiving station, 25 cents at the delivery station, 17 cents each at two transfers making a total of 85 cents for handling by muscle against 41 cents for hauling by steam. The railroads maintain a standing army of freight handlers three times as large as the standing army of the United States. They have a freight handler for every mile of road in the country. To these must be added the vast unknown army of marine freight handlers or longshoremen, and the still greater number of men and horses that are hauling freight to and from freight houses and piers.

Four Mules Drawing Fourteen Bales of Cotton Three Miles per Hour

Battery Truck Crane Towing Twenty-four Bales Five Miles per Hour

A straight line is the shortest distance between two points, but commerce always prefers to follow the "line of least resistance," which deviates from the straight line by very great amounts on apparently small provocation. The free flow of commerce is opposed by the friction of terminals. The friction of hauling is now very low. Take the case of any of our seaports: Friction begins when the engineer applies the air brakes on entering the city and continues until the ship drops her pilot beyond the bar. To hold and increase its commerce a seaport must make the "line of least resistance" run through that port and no item of lubrication that is needed to overcome the friction of the port is too small to be scrutinized with a view to its reduction or elimination.

The following table shows the charges, exclusive of coaling and provisioning, that must be met by a steamer entering, discharging cargo, receiving cargo and clearing from one of our most prominent sea ports. The ship is rated 3279 tons net, 5154 tons gross, 5780 tons dead weight and 351,760 cubic feet of cargo space. She arrived with 3550 tons of general cargo, on which $12,646.15 was collected for freight, and cleared with 5337 tons of general freight on which $29,493.37 was collected for freight.

| | |
|---|---|
| Custom house entrance $5.70, clearance $2.70 | $8.40 |
| Tonnage due at 6 cents per net ton | 196.74 |
| Officers' night work | 25.00 |
| Noting and extending protest on inward cargo | 15.00 |
| Consular fees | 15.65 |
| Customs' bond on inward cargo | 1.00 |
| Pilotage per ft. on deepest draft bar $4.00, river $1.50 | 268.13 |
| Towage on steamer to 5 berths | 750.00 |
| Harbor fees | 15.00 |
| Wharfage 6 cents per ton for 3 days, 3 cents for 3 additional days and 30 days free | 463.86 |
| Shed charge, 1½ cents per gross ton | 77.31 |
| Watchman on dock for inward and outward cargo | 187.50 |
| Cooperage on inward cargo | 70.65 |
| Cotton inspection, 1½c. per bale | 11.67 |
| Brokerage on outward cargo | 340.12 |
| Grain fittings | 144.10 |
| Damage for packing cargo | 30.00 |
| Stevedore (freight handling) | 3837.80 |
| Total | $6133.78 |

**Portable Conveyor Carrying Coffee from Ship's Deck to Wharf Building at Rate of 1800 Bags per Hour**

Of the above twenty charges, nineteen aggregate 26 cents per ton, while the remaining one, moving freight by muscle, amounts to 43 cents per ton. It is easy to point to the item of friction most worthy of study and attack. Every cent that can be cut off the port charges brings the "line of least resistance" thirty miles nearer. Thirty-three cents reduction will deflect the line 1000 miles in favor of the port. The efficiency of a ship as compared with men and animals is so great that it can carry a ton of freight 1200 miles for what it cost to carry the same amount 200 feet by muscle.

When we learned the rules of spelling and the numerous exceptions to those rules, we were at a loss to know why the exceptions were not the rule and the rule the exception. A similar condition prevails in freight traffic, the exceptions seem to far outweigh any rule of procedure that can be laid down. The manner of handling traffic in a given terminal will be diametrically opposite that in an adjacent terminal.

The obvious disposition of various commodities can be easily imagined, but observation will show that some apparently trivial detail has been overlooked and the actual practice differs materially from your carefully built up theory. It is the unexpected that always happens. Wholesale traffic conditions are not comparable with local peddling traffic, and machinery and methods adapted to the one would be a total failure in the other. Radical changes take place in the whole industry by seasons and by terms of years. An elaborate system and necessary apparatus was designed to handle the terminal work incident to the importation of a certain grain which was arriving every month in the year and in large quantities. Before it was placed in operation it rained, or did not rain, or both, in various countries, and like the turning of the tide the United States became a great exporter of this grain, effectually putting the whole plan out of joint.

Highly specialized machinery is to be avoided, for unless the conditions are very exceptional the load factor measured by the year will be very low. Machinery of general application, versatile like the hand truck, capable of coping with variable conditions and commodities, will be the successful machinery, for it must compete with the most elastic of all tools—"the gang."

There is great reward in store for those ports and terminal authorities who will vigorously attack this tremendous friction item by substituting carefully designed and intelligently selected electric freight handling machinery for the present almost universal aggregation of muscle.

# OUTDOOR SUBSTATIONS AT WARE AND MILLBURY

By A. E. Pope

Electrical Engineer, Connecticut River Transmission Company

The author writes a valuable article on the construction and first year's operation of two outdoor substations, and many interesting construction features are noted. The same standard steel sections used in constructing the transmission lines were used in building the substation, and the type of transformer selected had to provide for efficient cooling in summer and against freezing in winter. Some results of operation are discussed, and the relative cost of constructing substations of similar capacity of the indoor type are touched upon. The operation has been most successful, and the author sees no objection to outdoor substations when up-to-date apparatus specially designed for this purpose is used.—**Editor.**

During the past few years the subject of outdoor substations has been so thoroughly and vigorously discussed by the engineering fraternity that any further comments would at first sight seem futile. So many of these discussions, however, have necessarily been founded only upon hypothetical conditions and preliminary estimates that the following few comments upon an already overtaxed subject may possibly be excused by the fact that they are based upon actual results obtained from the construction and first year's operation of the two stations under consideration.

During the summer of 1913 a tower line designed for 110,000 volts was completed for the Connecticut River Transmission Company, connecting its generating stations at Shelburne Falls with the terminus of its original 66,000 volt line at Millbury, thus completing a double circuit loop. The two outdoor substations were, of course, designed for the higher voltage, but to date both line and substations have been operated at only 66,000 volts.

The substation at Ware is located midway between Shelburne Falls and Millbury, about thirty miles from the former. Due to its location, this station will eventually act as a line switching and transfer station as well as a substation. Arrangements for switching and interconnecting the lines by means of disconnecting switches have already been made, and the entire station is so laid out that oil switches can be installed for this purpose as soon as the load upon the line becomes sufficient to justify the expense. The station is designed for an ultimate capacity of 9000 kw., but only half this capacity, three 1500 kw. units, is installed at present.

Millbury Substation is located about six miles south of Worcester, at the junction of the new line, mentioned above, and the original line from Vernon to Millbury. As the line to Providence will start from this point, and as the difference in voltage will ultimately have to be taken care of here, it will be seen that the function of this station is somewhat diversified. It will act both as a tie-in and equalizing station between the 110,000 volt and 66,000 volt systems, and also as a step-down substation, taking power from either or both systems and delivering it at 13,200 volts. Due to these facts, and also to its geographical location, it has been selected as the operating and dispatching center of the system. The present capacity is 15,000 kw., of which 3000 kw. is converted to 25 cycle current for railway use. The ultimate equipment will be approximately 25,000 kw.

At both Ware and Millbury the selection of the outdoor type of substation was based upon the very obvious fact that for 110,000 volt construction there is no question but that a very appreciable saving in first cost is accomplished, even were the stations to act as substations only. The saving in first cost was also considerably increased by the requirement for switching and interconnecting the high tension lines and also by the necessity for providing space for the future installation of oil switches for accomplishing this switching. This latter advantage of outdoor substations is often overlooked in making a comparison between them and the indoor stations, and is one which should be given due consideration. The desirability of making the investment consistent with the immediate load conditions and increasing this investment only at a rate justified by the increase of load is a feature which must not be ignored in selecting the type of station to be built. The cost of real estate at both locations was practically negligible and the location of the real estate directly on the transmission line lent itself most favorably to the type of station selected. While the idea of placing the low tension apparatus outdoors was taken into consideration, no justification whatever could be found for so doing. Speaking very roughly, a decision such as this may be reached by comparing the increased cost of the outdoor apparatus with the cost of the cubical contents of a building required to house this apparatus. This ratio of building cost to increased cost of apparatus, on switches alone, drops from approximately 250 per cent in the case of 110,000 volt apparatus to 50 per cent in the case of 13,000 volt apparatus. When the further requirement for protecting instrument transformers is considered, the answer is obvious.

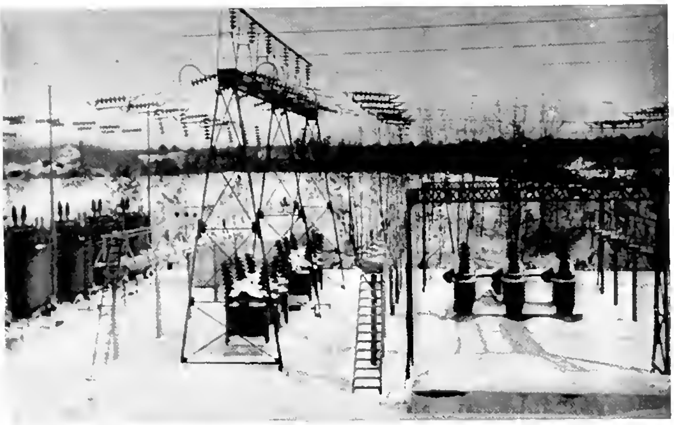

Fig. 1. View of Millbury Outdoor Substation after a blizzard. Note that the snow on the transformers has been melted by their heat, but not that on the oil switches

Considerable study was given to the general type of outdoor layout which would be adopted, particularly the type of supporting steel structure. In working this out, the following ideas were kept in mind: First, that the steel, in weight, factor of safety and method of erection, need be only consistent with the corresponding figures used in the transmission line. Second, that a special design for each substation be avoided and that the steel be so designed in units that different combinations of these units can be used for all outdoor substation work, both in present and future stations. Third, that all high tension overhead work used in substation design, such as insulators, fittings, conductor, etc., should be the same as those used on the transmission lines. As a result of the above, the design adopted consists of square towers, two-legged towers and standard box girders for connecting between these structures. The two bus elevations selected were thirty feet and eighteen feet, and supporting structures were made accordingly. From the above three units practically any required combination could be made up, and each combination was erected independently. In other words, no attempt was made to tie together the entire substation structure. It is believed that the resultant flexibility in the entire substation layout is more reliable than the more or less rigid construction which would have resulted in a special steel structure designed for each substation. The cost is unquestionably less. In many cases where it was necessary to support the suspension type disconnecting switches in the middle of a span, the stress upon the steel structures was greatly decreased by stringing galvanized strands over these switches and supporting the latter from the catenary by a single string of insulators. In most cases, the station layout was so arranged that this messenger wire could be supported from the same steel as the high tension conductors. In one or two instances steel trolley poles were used for such support.

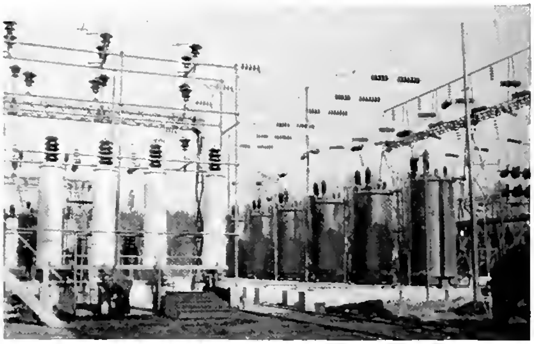

Fig. 2. A View of a Bank of Transformers and Lightning Arresters at the Millbury Outdoor Substation

Fig. 3. A View of a Bank of Transformers, Oil Switches and a Lightning Arrester at the Millbury Outdoor Substation

The question of bringing the low tension conductors into the substation building was carefully looked into, and in the case of Millbury a complete underground system was worked out. The cost of such a system proved to be very much greater than the corresponding overhead system, and a study of its operating advantages as compared with the overhead system resulted very unfavorably to the former. Accordingly, in spite of its somewhat neater appearance, the scheme for coming into the station underground was abandoned and the 13,000 volt lines were brought in overhead in a manner similar to the outgoing distributing lines. The results have been most satisfactory, and the possibility of underground troubles due to water conditions and cable breakdowns has been avoided.

The type of transformers to be used was determined largely by the size of the units involved, this being 1500 kv-a. at Ware and 2000 kv-a. at Millbury. While the possibilities of trouble with the water-cooled type in a northern climate were fully appreciated, yet the difference in cost between these and the self-cooled units, amounting to about 25 per cent net, could not be ignored. The water-cooled units do away with all external oil circulating pipes, and also have the advantage of operating at a much more even temperature throughout the year, with no decrease in capacity during the very hot weather in summer. A study of the possibilities of obtaining cooling water at both station sites showed that the cooling systems could be so arranged and protected that practically all possibility of freezing during the winter months could be eliminated, the result being that the water-cooled type was selected in both instances.

Fig. 4. A View of the Oil Switches at the Millbury Outdoor Substation after a heavy fall of snow

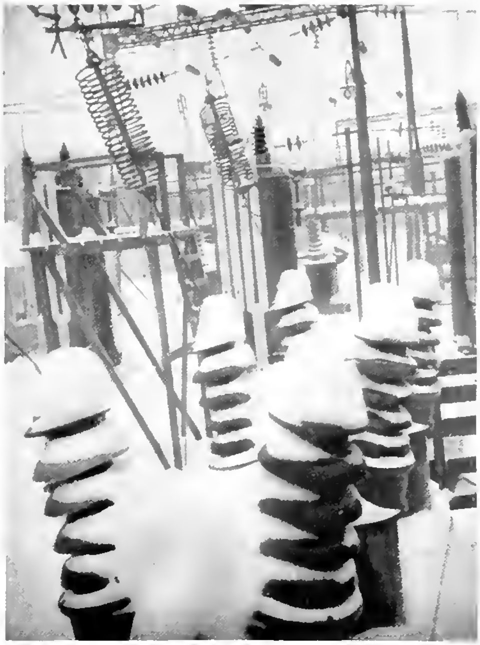

Fig. 5. A Near View of the Snow Covered Oil Switch Insulators. Two Choke Coils are shown in the upper left-hand

At Ware a deep well was driven and a deep well pump installed to supply the make-up water, a cooling basin being constructed in the near vicinity. During the summer the deep well pump is operated almost continuously through the daytime, the surplus water from the cooling basin discharging over a crest. The customary forms of sprays are used during this season for cooling. During the coldest months of the winter the deep well pump is not operated, the sprays are taken off and the discharge pipes turned under the surface of the cooling basin, so that the only cooling effect is from surface evaporation.

The station at Millbury is located practically on an island, with the Blackstone River on one side and the raceway for the Worcester Consolidated steam plant on the other. As the water in this river is entirely too muddy for use in cooling coils, a shallow well was dug near the transformers, about twelve feet in diameter and from ten to twelve feet deep. By this method the surrounding earth, which is a good gravel, was utilized as a natural filter and the water obtained in this manner has proven entirely satisfactory.

Circulation through the transformers is obtained by triplex pumps in a small isolated pump-house located directly above the well. The discharge from the transformers is piped into the river, with a tap discharging back into the well. By means of valves in the two discharge pipes, the water can be returned either to the river or to the well, or divided between the two, with the result that it has been possible to regulate the temperature of the cooling water in the well at all times of the year.

In both stations the water piping is laid below the frost line and the exposed parts running up to the transformers were lagged in a manner similar to steam piping. Special valves were also provided for connection with the compressed air system, in case it became desirable to blow out the cooling coils at any time when it might be impossible to keep the bank of transformers energized. All transformers are so located that they can be run into the station on trucks for any repair work, hoists being provided inside the stations for this purpose. A piping system is also provided for draining the oil from any transformer or switch into a storage tank, and the customary arrangement for treating the oil from this tank or at the transformers is utilized.

The operating results at these two stations during the winter just passed have been very

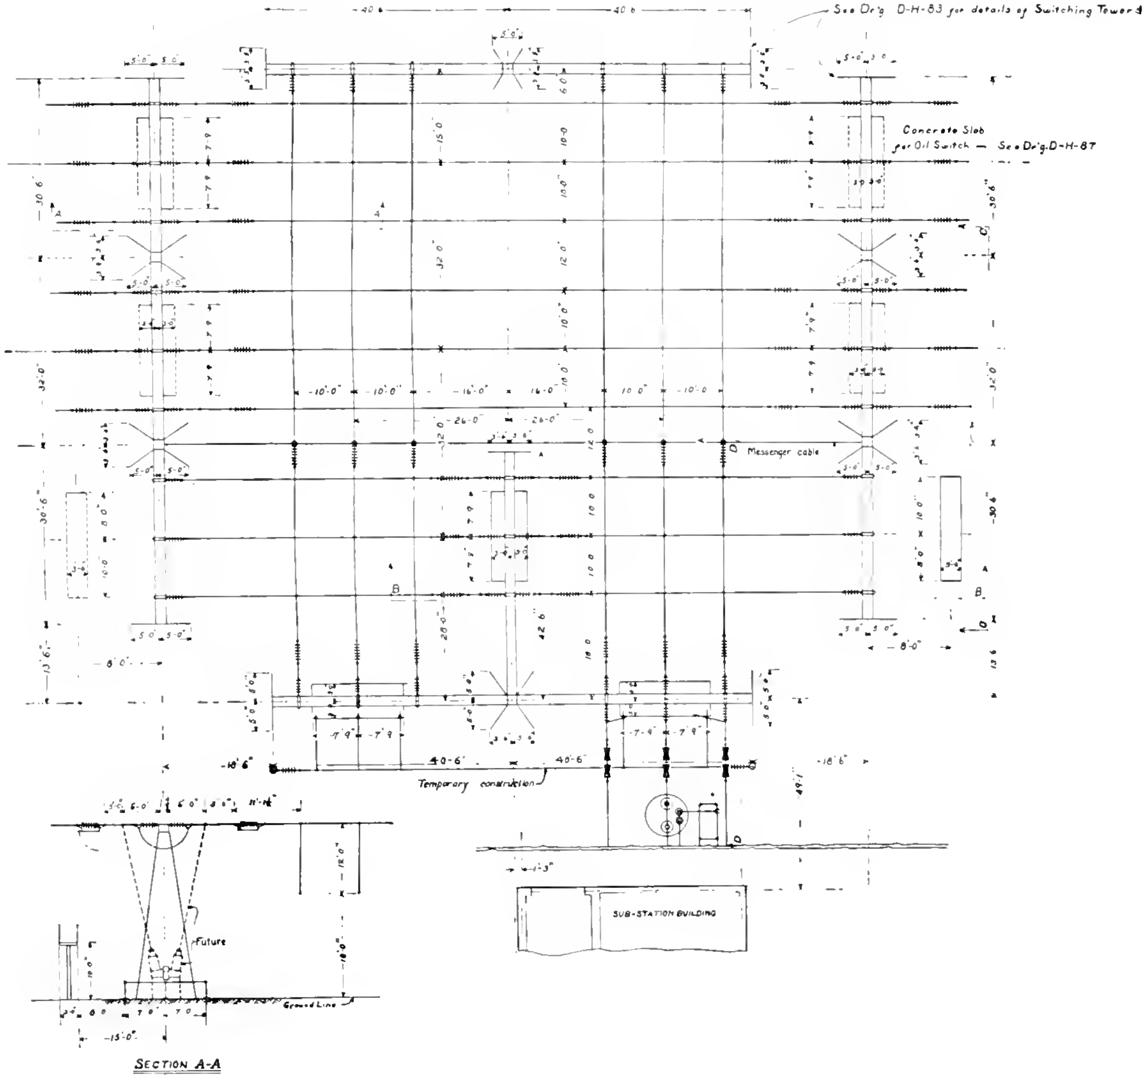

Fig. 6. General Plan of Outdoor Switching Apparatus, Ware Substation

interesting indeed. At Millbury substation the temperature of the ingoing cooling water has been held during the entire year at between fifteen and twenty degrees Centigrade, this regulation being obtained by diverting a part of the discharge back into the well as described above. During the two cold snaps of last January and February, when for periods of three and four days at a time the temperature at night went down to eighteen and twenty degrees below zero, the entire discharge from the transformers at Millbury was diverted into the well, and the cooling water was held at twenty-two degrees Centigrade. During this excessively cold weather the idle bank of transformers was energized in all cases at night, and during the daytime when necessary. The corresponding results at Ware were consistent with the above, although the regulation of cooling water temperature at this station was not as perfect as at Millbury. During the coldest nights at the latter station the minimum temperature of the cooling water was approximately ten degrees above freezing. At both stations, temperature records have been kept on the cooling water during the entire winter and the results carefully noted in conjunction with the transformer temperatures, etc. Both stations have been through a number of sleet storms during the winter, none of which, however, have been very serious, the maximum amount of sleet probably not being over a quarter of an inch. The most serious difficulties encountered during these storms consisted in one case of a solenoid plunger becoming frozen to the concrete switch base, and in another of some trouble in closing a set of disconnecting switches due to the formation of ice around the clips. Both difficulties were minor and did not interfere in any way with the operation of the station.

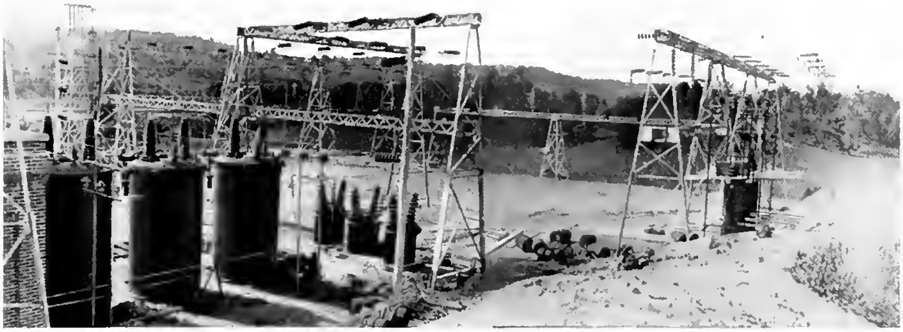

Fig. 7. A Panoramic View of a Portion of an Outdoor Substation showing Overhead Connections, Lightning Arresters, Oil Switches and Transformers

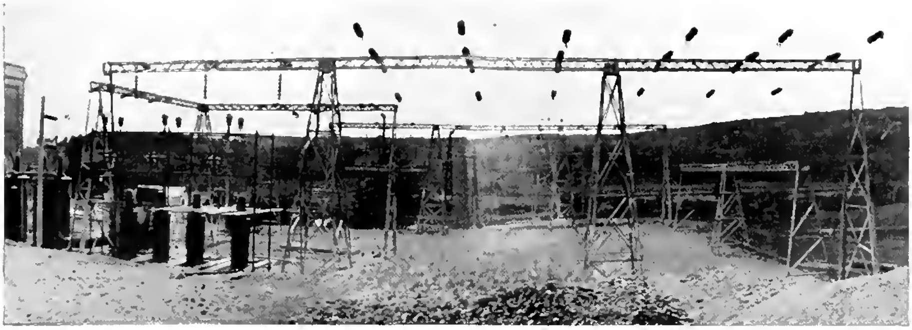

Fig. 8. A Panoramic View of an Outdoor Substation showing Several Transformers and Lightning Arresters at the Left

On February 14th both stations were subjected to a severe blizzard, with high winds and a snowfall of nearly two feet. The temperature of the transformers was such that practically no snow piled up on them, and the accumulation on and about the oil switch bushings caused no trouble whatever.

A comparison of first costs between indoor and outdoor stations is so dependent upon local conditions, upon the function of the station, and the design of either type, that it is very hard indeed to make any general statement which will apply. On the system mentioned above, such a comparison of actual costs between the indoor and outdoor types, corrected for similar local conditions and use and based upon an ultimate station capacity of approximately 10,000 kw. at 66,000 volts, shows a saving in favor of the outdoor type of from 10 to 15 per cent. This difference is not large, and is almost entirely dependent on the type of outdoor construction. Accordingly, the preliminary estimates for stations of this capacity and voltage must be very carefully made, as local conditions may easily result in an almost identical first cost for either type, in which event the choice would rest with the individual. For conditions similar to the above, except for increased capacity and 110,000 volts, the saving would probably run between 20 and 25 per cent. In both of these cases, the estimates have been based upon a simple substation layout without considering any line switching. In the case of Millbury, with its requirements for line switching, the actual saving is estimated at about 25 per cent, but this percentage is reduced by the comparatively high cost of the frequency changer set and building required to contain it. If this feature were eliminated and the station consisted only of the switching and step-down transformer substation, the saving would amount to 30 or 35 per cent.

In practically all discussions of outdoor substations, it has been claimed that all considerations from an operating point of view are unfavorable to this type of construction. While this is to some extent true, yet there are certain advantages of outdoor construction which should at least be given reasonable credit. The simplicity of arrangement and increased spacing throughout invariably tend

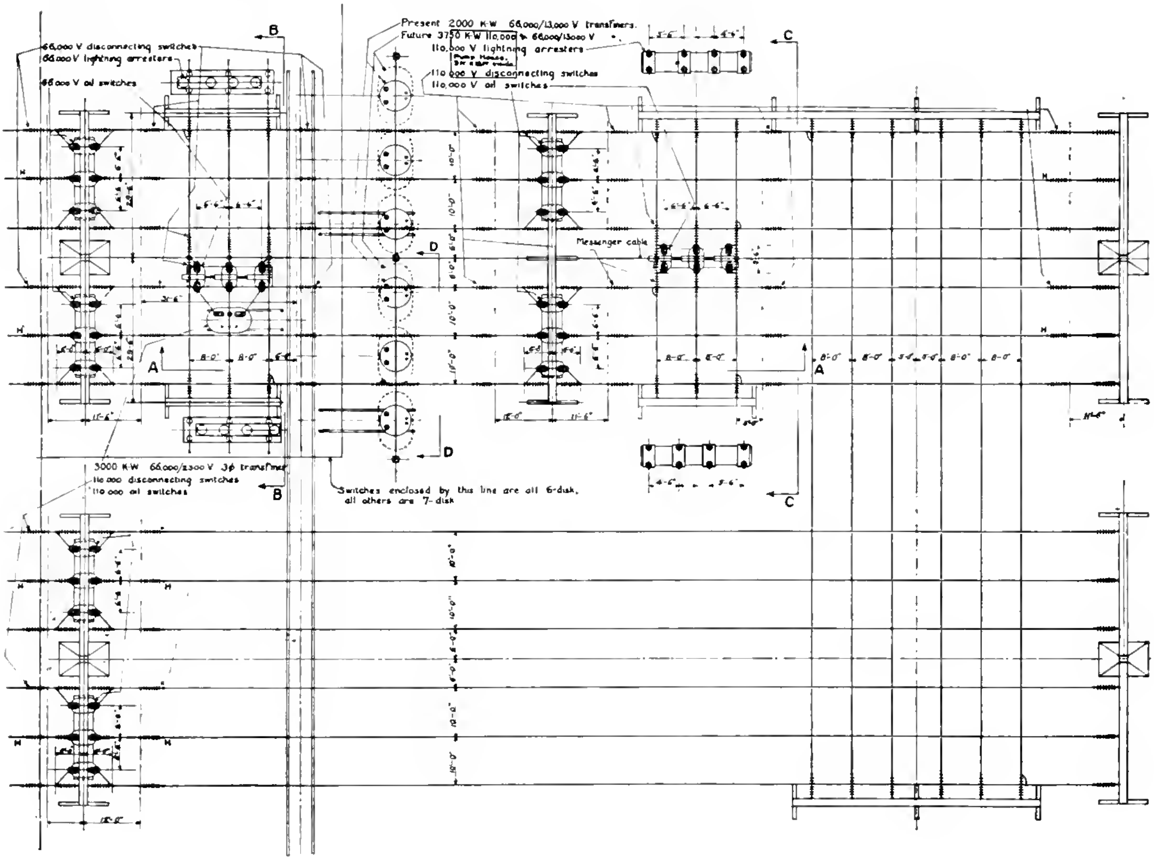

Fig. 9. Millbury Substation Arrangement of Outdoor Equipment

toward freedom from mistakes in handling disconnecting switches and switching by means of them. The outdoor layout also permits the use of standard suspension insulators throughout and eliminates the use of any type of post insulator or entrance bushing on 110,000 volt work. The freedom from fire risk and saving in cost of special fire protection is also a feature which should be taken into consideration. While it is undoubtedly true that the outdoor stations require more constant attention and care on the part of operators, yet it should be borne in mind that this does not necessarily result in increased operating expense, and with the comparatively high-grade class of operators which would be required for any substation of the size and voltage under consideration, it is questionable whether or not this requirement for constant attention to the entire station can be considered a disadvantage. There is quite as much ground for assuming that it will tend toward the more successful and satisfactory operation of the entire system.

From the experience gained in the design and construction of the stations mentioned above, and the results of their operation through a winter as severe as has been experienced for several years, it may be stated that for 110,000 volt work or for 66,000 volt stations where more or less line switching is necessary, the outdoor type of construction is unquestionably justified. For the more simple layouts of 66,000 volt stations, the question is one which must be decided by very careful preliminary estimates based upon the particular conditions involved. In cases where there is some doubt and where the outdoor operation of transformers is unfavorably thought of, a reasonable and very satisfactory compromise could be effected by housing the transformers in compartments adjacent to the operating building, leaving the remainder of the high tension equipment outdoors. With the latter arrangement, the transformers would be practically outdoors for the greater part of the year, but could be enclosed in heated compartments during the more severe weather.

Possibly the most significant feature of the above is the successful operation of water-cooled units in a northern climate. Beyond this, the information will simply add another link in the practical application of the outdoor design. The results which are being obtained from this type, and the constantly increasing number of them which are being installed in all parts of the country for the higher voltages, would seem to prove conclusively that they are practicable and in most cases cheaper. While some of the more conservative engineers still argue against them on the basis of jeopardizing service, it is believed that the operating results of the more modern stations employing the switching and protective apparatus recently developed by the manufacturing companies will in time prove this argument to be groundless.

# ELECTRICITY IN MINES

By K. A. Pauly

Power and Mining Engineering Department, General Electric Company

Each succeeding day it is becoming more fully recognized that the employment of electricity in mining is one of the factors which contributes largely to economical operation. The reasons which have made the application of electricity desirable, the means of procuring this power, and the manner of utilizing it at the mine are the divisions of the subject treated in this article. In the section on the application of electric motors to the equipment of the mine, discussions of the following subjects are included: Suitable voltages to be used; and the drives of pumps, fans, drills, locomotives, hoists and mills. A very interesting and valuable table presents the data on a large number of electrical mine hoisting equipments that have been installed.—Editor.

K. A. Pauly

THE mining industry differs from most others in one essential detail, its location is fixed. Those engaged in many other industries can avail themselves of the advantages to be gained by being located near an abundant supply of comparatively cheap power, and the nucleus of many of our country villages and even cities is the grist mill or saw mill so placed as to take advantage of a small water power. The great electro-chemical plants centered around Niagara Falls are modern examples of the tendency of industries to migrate toward cheap power centers.

Mining operations, because of the location of the mineral deposits, are usually carried on where the conditions are very unfavorable to the development of cheap power, coal mining being an obvious exception, however. Fuel and labor are high, and water suitable for use in boilers is frequently scarce and expensive. The necessity of subdividing mining operations into a large number of small units, necessarily operating at a low load factor, tends to further increase the cost of power. Many mines are operating today with a boiler plant supplying steam for a hoisting engine, a small compressor for supplying air for drills and small underground gathering pumps, with possibly a main steam pump at the foot of the shaft and a ventilating fan on the surface. The coal consumption in pounds per horse power hour of work done will often exceed the steam consumption of a modern efficient plant. Attempts, which no doubt have been successful to a limited extent, have been made to reduce the cost of power by supplying two or more shafts from one central steam plant, but the area supplied from such a steam plant is extremely limited owing to its first cost and inefficiency. The accompanying illustration, Fig. 1, will serve to indicate what distribution of power by steam means, although it fails to reveal the miles and miles of steam pipe hidden underground.

If we can not locate our mines where the conditions are favorable for developing power, we can usually take comparatively cheap power to the mines. Because of the high efficiency with which large quantities of power as electric energy can be transmitted over long distances, power can be placed at the disposal of the mine operator at a price usually considerably below his cost of developing it at the mine. But in addition to this, electricity offers other and important advantages. Extensions in the power equipment, to meet developments in the workings, are possible at a lower cost and with less inconvenience than otherwise. Increased output, which means lower cost of production, always follows the introduction of electric power. Materials are handled with a minimum of delay, especially underground, by the electric locomotive. In those processes of ore extraction in which the speed affects the percentage extraction, the three-phase induction motor with its practically constant speed is an ideal motive power.

Until very recently, at least, the application of electric power to mining operations on a large scale has been less extensive than to most, if not all, other industries: why is this so, if electrification means increased production and lower costs? It has been due to two principal causes. First, the speculative nature and uncertain life of metal-mining operations have not been looked upon with favor by capitalists interested in electric power development. Neither were the mine operators themselves, with few exceptions, in a position to install large central stations at a considerable distance from their mines, owing to the smallness of their power requirements. Second, because the chief advantage of electricity was looked upon as being largely one of improvement in efficiency; coal miners with waste coal at their disposal saw little to be gained by electrification further than the installation of small direct current generators at each mine for lighting and for supplying power to locomotives where lack of gas permitted their use.

But conditions have changed: mining is becoming less speculative, small operators are being united into large companies, and grades of coal once considered worthless now have a considerable value. There are no less than 65 power companies serving mining districts, many of which are largely dependent on the mining industry for a load. As examples of these might be mentioned the Montana Power Company supplying the Butte copper mines, the Virginia Power Company and the Appalachian Power Company in the bituminous coal fields, and the Lehigh Navigation Electric Company serving the anthracite coal fields. In addition to these we have a considerable number of large power systems owned and operated by independent mining companies; for example, the power systems of the Calumet and Hecla Mining Company in Michigan copper fields, the Cleveland Cliffs Iron Mining Company also in Northern Michigan, the D. L. & W. Coal Company and Consolidation Coal Company in the anthracite and bituminous coal fields respectively, and the Calumet & Arizona Copper Company at Bisbee, Arizona.

With power in large quantities available at most of the large mining camps the question often arises, and rightly so, as to whether the large companies should purchase power or make it themselves. This is a very broad question with important advantages pro and con, and each case must be settled on its merits after a thorough analysis of all the elements affecting the problem. The decision for or against purchasing power is usually based on a comparison between an estimated cost of producing power locally and of purchasing it at a definite price. In making power cost estimates great care must be taken not to base them on erroneous assumptions which may result in wrong conclusions. Although the independent plant may appear from the estimate to be more economical, and it may be within the bounds of possibility to operate it within the estimated cost, yet it must be remembered that we have on the one hand a mining company whose efforts are devoted to the production of coal or ore at a minimum cost, in which cost the item of power plays but a minor part. In addition to this, the power cost is handicapped by a low load factor, resulting in high fixed charges and operating costs which combine to give a power cost often higher than estimated. On the other hand, the one object of the public service corporation is that of developing cheap and reliable power. It maintains a competent corps of engineers who devote their entire time to the problems incident to the development of cheap and reliable service. They have at their command the necessary capital to introduce improvements and make extensions which tend toward lower power cost. Assisting them in their efforts, they have the greatest diversity of loads to bring up their load factor. To sum up, so to speak, the one is a coal or ore manufacturer and the other a manufacturer of power.

Fig. 1. An Example of what Distribution of Power by Steam means. Note the long line of exposed pipes

In general the conditions affecting the design of a power system for supplying a mining district do not differ materially from those governing the installation of a similar system for serving an industrial district.

Probably, however, in no other industry is continuity of service so important a consideration; and one of the important factors which is largely responsible for the recent rapid increase in the application of electric power to mining operations is the improvement in the design of electrical machinery and the construction of transmission lines and their successful protection against outside disturbances. Apart from the consideration of production, unless the pumps of wet mines are kept in service a serious and expensive flood may result while the stopping of the ventilating fans of the gaseous coal mine, if but for a short period only, may endanger the lives of many hundreds of men underground. Obviously long interruptions in the power supply might seriously inconvenience the complete underground force, if it occurred at the end of a shift. Wherever possible the transmission system should be laid out on the loop principle, power being supplied at each end of the loop thus reducing to a minimum interruption due to line breakage.

It is coming to be generally recognized that, on account of men working underground where the temperature is rather high and the body frequently wet with perspiration and especially at high altitudes where they are more susceptible to injury by electric shock, 250 to 300 volts is the proper operating potential for underground equipment where the operator is in danger of coming in contact with live parts or wires, although higher potentials have been and can still be safely used when the conditions are favorable. Where there is no danger of the operator coming in contact with live parts, the potential of any apparatus may be made as high as is consistent with reliable service from the machinery involved. Experience seems to indicate that, with present methods of insulating motors, they should not be operated underground at potentials much in excess of 2300 volts; and that unless the operating conditions are favorable motors wound for this potential may prove rather unreliable, especially so if the service is of such an intermittent nature that the windings are alternately heated and cooled at comparatively frequent intervals.

As previously stated, one of the most vital parts of a mine equipment is its pumping plant. Wherever possible, the underground workings are so laid out that the water flows from the face to the main sump usually located near the shaft. Gathering pumps are used where this plan is not possible. These gathering pumps are usually small and are of the direct-acting type, similar to boiler feed pumps, and are driven by compressed air taken directly from the air system supplying the drills. Centrifugal pumps are not suitable, owing to the necessity of priming them each time they loose their vacuum. Where electric power is available, motor-driven pumps will show a very considerable saving over air-driven units which are very extravagant in the consumption of air. They are, however, handicapped by a higher first cost, but except where the conditions are otherwise unfavorable this difference is small in comparison with the improved efficiency.

Motor-driven centrifugal pumps are very generally used for pumping from the main sump, although there is a very pronounced doubt in the minds of many large operators as to whether this is really the best practice, the contention being that the higher efficiency obtainable with plunger pumps warrants their use at a much higher first cost. Where, as is frequently the case, the sump capacity is inadequate to protect the mine against a flood in the event of an interruption in the pumping, except for very short intervals, it is extremely advisable to provide spare pumping units and to use the spare unit alternately with the others, also to provide a drying transformer for supplying just enough current to the windings of the idle motor to keep it dry when at rest. The first cost of such a transformer and the cost of the energy consumed are insignificant in comparison to the insurance that they afford, especially so if 2300-volt motors are used for driving the pumps. Special ventilation may frequently be provided to advantage, for keeping pump chambers cool where there is a tendency for the air to become stagnant.

Because of the nature of the underground workings and the presence of poisonous and explosive gases in many coal mines, it is necessary to provide large quantities of air by forced ventilation. In non-gaseous mines the fans may be run at reduced speed, except when the shift is underground, and an occasional interruption of the air supply during working hours will not cause serious inconvenience. With a gaseous mine it is entirely different. An interruption in the air supply, if only for a comparatively short time, may endanger the lives of all working in the affected area. The miners appreciate the danger so well that they will leave the mine immediately there is a stoppage or material reduction in the air supplied. It is obviously then of the utmost importance that every pre-

Equipments marked with a (*) have been purchased since January, 1912.

caution be taken to prevent the possibility of an interruption in the power supplied to a fan, and until recently many have questioned the advisability of electrifying the fans of gaseous mines. With the development of our larger power systems, many of which are consolidations of smaller independent stations, the feeling of uncertainty is gradually disappearing because of the remote danger of complete interruptions in the service.

Until within the past year fans when electrified have been driven by either variable-speed direct current motors or by induction motors, speed variation over a considerable range being required to provide for increased air pressure as the workings are extended. Provision is usually, if not always, made to provide for a considerably increased air pressure for rapidly clearing the mine of the poisonous gases following an explosion. While, where direct current is available, fans may be driven at variable speed efficiently by varying the fields of these motors the efficiency of the induction motor, except under special conditions, is low. Recently a variable-speed three-phase alternating-current motor has been developed which possesses all the advantages of the direct-current motor, from the standpoint of field control, and thus avoids the necessity of conversion of power to direct current. Speed control is obtainable over a very wide range by simply shifting the brushes on the commutator.

Although the power required by the electric drill is only one fifth that of the air drill, no other piece of machinery used in connection with mining has so completely resisted all efforts of the designing engineers to bring about its electrification, although the ordinary air drill is extremely inefficient from a purely power standpoint. Many electric drills have been produced, some of which have been more or less successful under special conditions, but there has been one recently developed which bids fare to have a very wide application. Rapidly repeated hammer blows are delivered to the drill as in hand drilling. In early tests trouble was experienced with the drills, but improvements in the steel have practically eliminated this.

One can hardly imagine a more inefficient system of underground haulage than are some which are in actual operation in some of the large mines. There are hoisting engines located near a boiler plant on the surface with the haulage rope carried for long distances above ground and then down a bore hole to the head of the slope. In such an installation the friction is often a large part of the work done. Many small air engines, or "puffers" as they are frequently termed, are used where the grades are too steep for mule haulage. These engines take air full stroke and as the air is used cold they have an efficiency not over 15 per cent.

With the development of the gathering locomotive, loaded cars can be taken from the rooms, placed in an underground yard, and the empties returned without the necessity of stringing the trolley wire to the face. From the yard the cars are taken in trains by electric locomotives, where the grades permit their use or by slope hoists where the grades are too steep, to the shafts or out of the mine through tunnels.

Mining conditions impose very severe limits to the design of locomotives. The track gauge varies from 24 inches to standard, the curves are made at a very short radius, the grades are frequently excessive, and with shallow veins the head room is very small. Great ingenuity has been exercised in the design of electric "motors," as the locomotives are called, with the result that there are today rugged, thoroughly reliable, and efficient locomotives suitable for operating under most exacting conditions.

Air locomotives, although very inefficient, have been and will continue to be used, at least for some time in coal mines, although abroad the slope hoist air engine is giving way to the fire-damp-proof motor in gaseous mines. These motors, which are designed on the Davy safety lamp principle to prevent the communication of an explosion within the motor to the surrounding atmosphere, have not been introduced to any considerable extent in this country, although tests at the Pittsburgh Testing Plant of the Bureau of Mines indicate that, with the addition of a simple automatic cut out to disconnect them from the line after the first internal explosion, they should be entirely safe.

Electric shaft hoisting on a large scale was first introduced in Europe, although at an early date scattered installations of quite considerable magnitude were made in America. About two years ago there appeared to be a simultaneous appreciation of the advantages of the electric hoist on the part of American miners and America bids fair to soon rival Europe in the number and size of its electric installations. About five years ago the Eckstein interests in South Africa started to convert their existing steam hoists to electric hoists on a scale which has not been even approached elsewhere, and today there are more and larger shaft hoists in South Africa than in any other equal area. It is worthy of note in this connection that, while America has lagged behind Germany and South Africa in the magnitude and number of its installations, an American company has built the electrical equipment for many of the larger foreign hoists among which are those of the Crown Mines, Ltd., and the New Modderfontein Gold Mining Company, which are the largest electrically-driven hoists in the world, and which require peak loads of approximately 7000 horse power during acceleration.

Many systems of electric hoisting have been proposed, some of which have a very general application and others designed to meet very special conditions, but owing to the many questions involved it will be impossible to attempt to discuss the merits of the several systems in an article of this kind. However, a few remarks with reference to a few important considerations affecting to a more or less degree all types will not be out of place. This subject is discussed more in detail in an article "Some Advantages of the Electric Hoist over the Steam or Air Hoist," by the author, which appeared in the April issue of the GENERAL ELECTRIC REVIEW.

In general, although there are many exceptions, the simplest system is preferable, and in units of 500 horse power and less the variable-speed induction motor geared to the drums by any of the quiet running gears will give entire satisfaction. For equipments involving motors of 1500 horse power and larger, the direct-current motor direct-connected to the hoist drums will usually offer sufficient advantage over the simple induction motor to warrant its adoption, in spite of the additional expense of the motor-generator required with the direct-current equipment. The intermediate range of capacities is the transition field and special local conditions may and will usually be the deciding factor in the choice of either the one or the other type.

The relative capacity of the power system serving the hoist or, if power is purchased, the basis upon which the rate is determined, i.e. the effect of peak demands on the price for power, must always be taken into consideration and, where peaks are heavily penalized or the generating capacity small, a considerable saving in cost of operation can usually be made by relieving the power system of excessive fluctuations by the use of a flywheel.

The great advantage of the electric hoist, and especially of those driven by direct-current motors, over all its competitors is greater safety which, although it usually is difficult to capitalize, may represent a saving during its life quite equal to its first cost.

Greater economy, all factors considered, is a second important advantage of the electric hoist. No better evidence can be offered in support of this fact than the extent to which the electrification of mine hoists has been carried out in coal fields where, if anywhere, efficiency in-so-far as it affects the coal consumption only is of minor importance. Increased production resulting from decreased delays, with its corresponding reduction in the mine overhead charges, is one of the most important factors which is responsible for the adoption of the electric hoist in coal districts, where it has been given a test on a thoroughly commercial scale. Considerable savings result from lower maintenance and repair costs, no inconsiderable item of which are the savings due to increased life of the rope, and to the reduction in cage and shaft guide repairs due to the uniform torque of the electric motor.

As an indication of the rapid strides which are being made in the electrification of mine hoists in this country and the part which we are playing in the development abroad, a partial list of the equipments of 300 horse power and over which have been built by the largest electrical manufacturing company in America is given as Table I, most of which installations it will be noted have been purchased during the past two and a half years.

Electricity is very extensively used wherever power is required in the treatment of minerals from the time they reach the surface until the finished products are placed on the market and, with few exceptions, the standard industrial power motor has very satisfactorily met the requirements in this field of application. Consequently no attempt will be made to discuss each of the several processes in detail, to do which would involve considerable unnecessary repetition. Reference is made, however, to two applications which are of interest because of their bearing on the design of the electrical machinery involved.

Anthracite coal, before it is marketable, must be reduced in rolls to a certain maximum size, and separated by screening into a large number of sizes from the smallest bucket wheat to steamboat coal. Mechanical pickers are used to remove the slate which is present in all coal as it comes from the mine. Probably no motors used in the industrial field, with the exception of those found in steel mills, are subjected to as severe operating conditions. Constant vibration tends to crystallize the shafts, loosen the laminations, break the bars of squirrel-cage rotors and chafe the insulation on the coils. The atmosphere surrounding the motor is filled with a fine sharp coal dust which works its way into the insulation and while this dust is a very good non-conductor so long as it is dry it becomes a very good conductor immediately it is moistened, which may occur as water is used in the process of separating the slate from the coal. By far the greater part of bituminous coal is shipped as run of mine or screened only, but the value of washed coal is being recognized and washeries are installed throughout the soft coal field. Motors applied in these washeries are subjected to conditions quite similar to those of the anthracite breaker.

To meet these severe conditions the coal-mine motor has been developed, the ruggedness of which is apparent from a comparison of it, Fig. 2, with a standard industrial motor of similar capacity, Fig. 3. This is truly a coal mine motor in the design of which some of the ablest and most experienced electrical engineers in the anthracite fields played an important part.

Pebble mills are being used more and more extensively in the process of preparing ores for the Wilfley or similar tables. The Hardinge mill, which is typical, requires motors of approximately 40 horse power geared to the mill which revolves at a very low speed. Because of the dirt and water present, the squirrel-cage motor is rather to be preferred, but when used it must be designed to give a high torque at starting, and its rotor must be capable of storing a large amount of heat without injury because of the severe starting conditions.

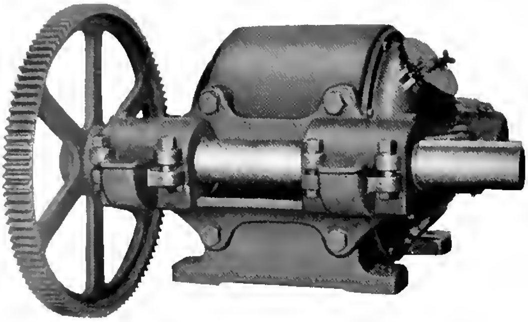

**Fig. 2.** Coal Mine Motor, showing sturdiness of construction

Although low-pressure turbines have not been as extensively applied in the mining field as has been the case in many other industries, in spite of the fact most mine engines are operated non-condensing, this is largely due to the lack of condensing water and the intermittent character of the load of some of the engines. Regenerators have been used in connection with the hoisting engines and a large portion of the energy of the exhaust steam conserved through a mixed-pressure turbine, but the cost of the installation is high under the most favorable conditions. The regenerator capacity required is very large, except where the hoisting is done uniformly and with comparatively short rests between trips. The most interesting installation of the kind in America is the 500 kw.-unit at the "D" shaft of the Newport Mining Company, Ironwood, Michigan.

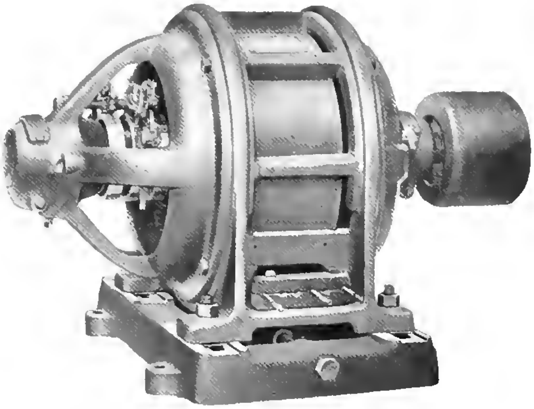

**Fig. 3.** Standard Industrial Motor, of same capacity as motor of Fig. 2

The steam stamps used throughout the Michigan copper country afford a large supply of exhaust steam which, through the low-pressure turbine, will develop sufficient power to perform all the work in connection with the extraction of the copper from the rock. The flow of the steam is uniform so that no regenerator is required and, as the remainder of the mill is always running when the stamps are, there is always a market for the low-pressure power. The largest installation of this kind is that at the stamp mill of the Calumet & Hecla Mining Company, which is operating a 7500 kw., low-pressure turbine-generator from approximately 30 stamps.

Treating a subject so broad as this in so small a space permits of touching only briefly on some of the most important points, although there are many others which must be taken into consideration when dealing with any specific problems. There is one consideration to which attention again is called, and that is the matter of safety. Equipment of the highest grade only should be used; the installation of all wires and cables if carrying currents of dangerous potential should be so installed that the miners can not come in contact with live parts; all apparatus should be thoroughly grounded and the equipment should be placed under the charge of a competent engineer with full responsibility.

# ELECTRIC FURNACES

By John A. Seede

Power and Mining Engineering Department, General Electric Company

The author points out that the power consumed by electric furnaces is constantly increasing and already figures appreciably in the income of power plants. Large electric furnace installations constitute power problems by themselves, and the load factors of such installations are generally higher than other industrial loads, approaching 100 per cent. While this is not true of the small electric furnaces used for heating forging bars, rivets, tools, etc., and for melting various metals, they will have a beneficial effect on the off-peak load. In connection with such furnaces it is interesting to note that the cost of heat utilized is lower with electric power than with fuel oil. The problem of obtaining the reclamation of worn, broken or defective metal parts by arc welding equipments is an application of great importance, and the use of these equipments is rapidly spreading.—Editor.

John A. Seede

In discussing the ability of any apparatus to compete with old and strongly established types, there are a number of things that must be considered that are not obvious at first.

In addition to possessing advantageous features that will enable it to compete successfully, this new apparatus must overcome a strong conservative element before it can come into general use. This is true of the electric furnace, and various reasons are given for its slow development, such as its reputation as a laboratory machine, imagined danger from electric shocks, probable high cost of operation, inability of ordinary workmen to operate it, small capacity limited to one special application, and numerous other equally indefensible objections of similar quality.

The electric furnace is a device in which electric power is transformed into heat with the intention of obtaining certain chemical or physical changes. In view of the high unit cost of heat from electric power the electric furnace appears to be greatly handicapped as compared to the cost of heat obtained from various fuels.

| Source of Energy | Cost | B.T.U. Per One Cent. | Ratio |
|---|---|---|---|
| Coal | $3.00 per ton | 97,000 | 28.4 |
| Fuel oil | 5 c. per gallon | 27,000 | 7.90 |
| Natural gas | 50 c. per m cu. ft. | 22,000 | 6.44 |
| Electric energy | 1 c. per kw-hr. | 3,420 | 1 |

In order to overcome the great differences shown in this table the electric furnace must be much more efficient if it is to compete successfully, and it is interesting to note that in certain operations, other conditions being equal, the electric furnace shows a saving of 15 to 30 per cent in cost of heat alone, as compared to oil furnaces, with oil and electric energy at approximately the figures given above.

With the increasing development of water power and other forms of natural energy, the relative cost of electric power will undoubtedly decrease as the various fuels are exhausted, and we may reasonably expect a rapid increase in the use of electric furnaces.

The power input to the electric furnace may be controlled automatically or by hand, and in either case a better temperature regulation can be obtained than in any other type of furnace. From the upper limit of 3500 to

4000 deg. C. down to the average operating temperatures of 1600 to 500 deg. C. we obtain a range suitable for nearly all metallurgical operations.

Considerable difficulties were first experienced in the early use of the electric furnace by the high temperatures exceeding the limits of commercial refractories, which was an experience entirely outside previous furnace practice. The difficulty was finally overcome by using the outer portions of the charge as a combined refractory lining and heat insulator.

This ability to develop and concentrate heat in the interior of the charge distinguishes the electric furnace from all other furnaces and makes possible the development and commercial manufacture of many products, such as carborundum, graphite, calcium carbide, etc. In addition the absence of large volumes of superheated gases and transference of heat through refractory walls increases simplicity and reliability and gives very much better operating conditions.

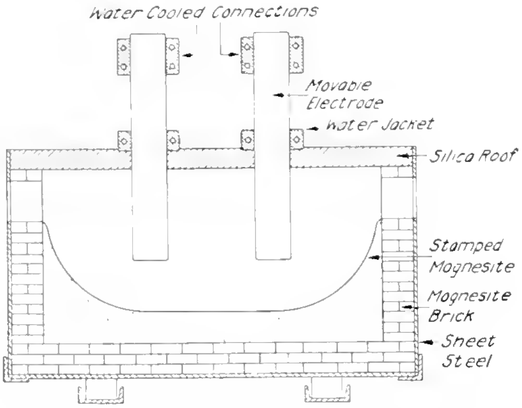

**Fig. 1.** Cross Section Direct Heating Arc Furnace. Current arcs from one electrode to charge and from charge to other electrode

With the early development of the successful calcium carbide furnace many more furnaces were installed than the natural consumption could take care of, with consequent loss to investors. In endeavoring to use these furnace equipments, in order to obtain some return on the investment, the manufacture of ferro alloys, and incidentally the refining of iron and steel, was brought about.

The electric furnace has been very successful in producing high class products from mediocre materials, and it may be said that while in any furnace the best results are obtained with the best raw materials, the electric furnace product is least affected by indifferent quality of raw materials.

The electric furnace of the stationary type consists of a refractory lining of the material being worked on in very high temperature work, or of magnesite, dolomite or silica at more moderate temperatures. This is held in place by a fire brick, silica or magnesia brick lining, which is usually supported by iron framework, except in very large resistance furnaces in which the supporting walls are sometimes of concrete.

In furnaces of the tilting type the steel framework is mounted on trunnions or rollers and is lined with magnesite brick, inside of which is the lining of crushed magnesite or dolomite stamped in place. The roof is usually silica brick through which pass the carbon or graphite electrodes. A water-cooled collar is provided where the electrode passes through the roof, and the electrode contacts are also water-cooled. These devices are necessary in order to insure continuous operation by preventing destruction of the roof, electrodes and electrode contacts.

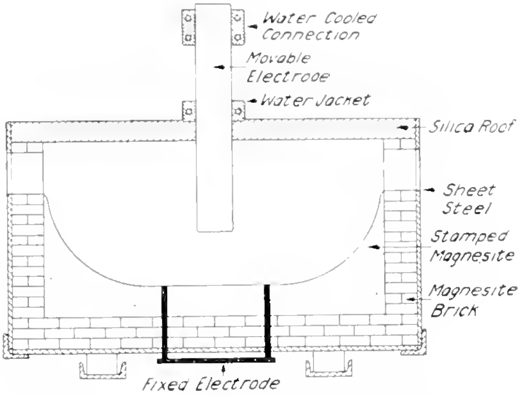

**Fig. 2.** Cross Section Direct Heating Arc Furnace. Current arcs from electrode to charge and then to lower fixed electrode

The carbon electrodes are made of a combination of anthracite coal, petroleum coke and other materials, requiring great care in order to produce a substance that will withstand the high temperatures and severe strains of the electric furnace operation. Nearly all electrodes are now made with screw joints so that very little is wasted, the electrode being fed continuously through the roof.

In electric furnaces the heat is generated by passing electric current through an arc, a resistance or a combination of these two. Accordingly we have two great classes, arc and resistance furnaces, with various combinations of these types. Arc furnaces may be classified as direct, indirect, and smothered.

In the direct type the arc extends from the end of the electrode to the charge, and heating is accomplished by conduction and radiation. In the indirect type the arc extends between the electrodes above the charge, and heating is accomplished by radiation. As examples of the above types we have arc furnaces for melting and refining metals.

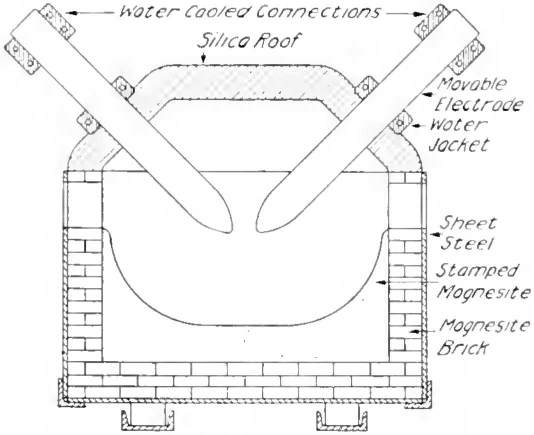

Fig. 3. Cross Section Indirect Heating Arc Furnace. Current arcs from one electrode to the other above charge

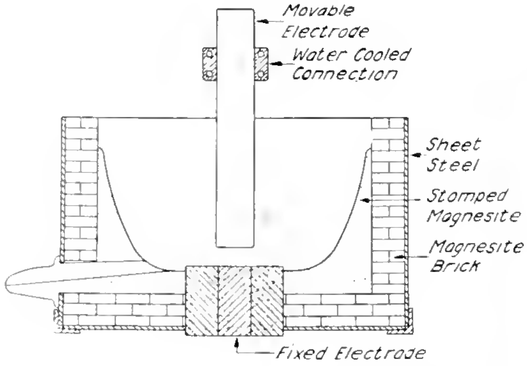

Fig. 4. Cross Section of Smothered Arc Furnace. Current arcs from the electrode to the charge in which the electrode is plunged and the current passes through the charge to the lower fixed electrode

In the smothered type the arc extends from the end of the electrode beneath the surface of the charge, and heating is produced in the charge by arc and resistance heating. Examples of this type of furnace are the ferrosilicon, calcium carbide and other similar furnaces. The resistance furnaces may be classified into direct and indirect types. In the direct type the charge is the resistor and the current is led to the charge by means of carbon or metal electrodes. Under this classification comes the only class of furnace that does not require electrodes, the induction furnace, in which the charge constitutes the secondary of a transformer surrounding an iron core and in inductive relation to a primary high voltage winding. In the indirect type the heat is generated in an internal or external resistor and is transferred to the charge by conduction and radiation.

In certain classes of work the internal graphite or carbon resistor carries the current at the start, but the charge soon becomes conducting and at the end of the run is carrying practically all the current.

In the contact resistor type, instead of developing heat by the ohmic resistance of a conductor, a large number of blocks are used, and the heat is developed by contact resistance. The resistance depends to a large extent on the pressure, and advantage of this principle is sometimes taken to effect a certain amount of regulation. This furnace is used in small moderate temperature work.

Fig. 4-A. Small Smothered Arc Furnace in Operation showing exterior bracing, upper movable electrode and connections to bottom electrode

The regulation of arc furnaces is accomplished by raising and lowering the electrode which lengthens and shortens the arc as required. In automatic regulation the electrode motor is controlled by contactors energized by a current operated relay.

In induction furnaces of moderate capacity and above, in order to keep the power-factor within reasonable limits, it is advisable to use low frequency, and in this case each furnace has its own generator. Under these circumstances we have the most flexible type of control, that is, through the field of the alternating current generator which gives as fine an adjustment as can be desired. Fig. 9 shows a 15 cycle generator driven by 60 cycle synchronous motor with direct connected exciter for use with a 2-ton single-phase induction furnace.

### Electric Smelting

In the practice of smelting, the ore, usually the oxide, is heated with a reducing agent producing carbon monoxide and the metal. The electric furnace has been used successfully to smelt tin, zinc, iron and other metals of which iron and zinc are probably the most important. The smelting of iron is making slow headway, and it is doubtful if the time will ever come when our present efficient methods will be entirely supplanted. The modern blast furnace is a very efficient, highly developed machine, while the electric smelting furnace has been experimented with for a few years only, and with limited capital and without the urgent situation that has forced the development of the blast furnace.

The present electric furnaces have a daily capacity of 25 to 30 tons with a possible immediate increase up to 100 tons as compared to the blast furnace with its daily output of 450 to 600 tons. The ordinary blast furnace consuming one ton of coke per ton of pig iron is to be compared to the electric furnace taking about $\frac{1}{3}$ of a ton of coke and 1700 kw-hr. This means that with coke at $4.50 a ton electric power must be supplied for about $12.00 per horse-power-year, other things being equal. If desired, the electric furnace product can be controlled so as to contain considerably less impurities than pig iron, and in this way be a better raw material for the manufacture of steel.

The electric smelting of zinc has been attacked by a number of investigators, and while conflicting reports are received in regard to the success of the different processes, there seems to be considerable basis for belief that a commercial furnace will soon be available.

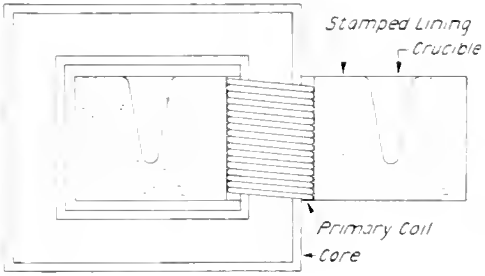

Fig. 6. Cross Section of Single Ring Induction Furnace

## Electric Melting and Refining

This large field covers many applications that are becoming of increasing importance, and we may soon expect to see an electric furnace in every up-to-date plant, not only for melting and refining steel but also brass and other non-ferrous alloys or metals.

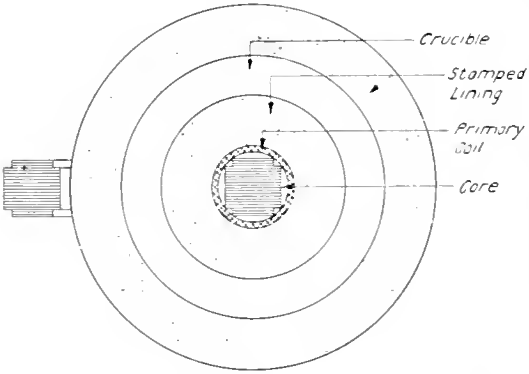

Fig. 7. Cross Section in Horizontal Plane of Single Ring Induction Furnace

Electric furnaces have been used in the manufacture of crucible quality steel for some time, and within the last three years the number has been greatly increased.

Contrary to the opinions of many iron and steel founders the electric furnace for melting and refining steel and iron is a very practical and efficient shop tool. When you consider that an electric furnace equipment requiring comparatively small floor space is available for producing crucible steel quality castings, in intricate shapes, for 5 cents a pound or less from steel scrap costing $10.00 to $12.00 per ton, it is evident that such an equipment should have a widespread use when its value is appreciated.

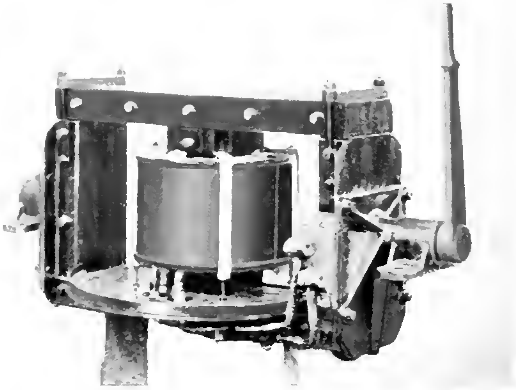

Fig. 6-A. Core and Primary Coil of Simple Induction Furnace ready for putting in refractory lining

Fig. 7-A. Induction Furnace assembled complete with crucible. Cover plates shown beneath furnace

While the induction furnace has been somewhat slower in its introduction than the arc furnace, it will soon hold the record for individual capacity in this country, when the 20-ton unit, now on order for the American Iron & Steel Manufacturing Company, is put in operation.

While these large furnaces are usually operated under the molten metal charging system, the smaller furnaces of 5 tons and below are usually operated with cold metal charging, especially where the demand is intermittent and the metal is used for making steel castings.

Another application requiring less skill and operation is in the making of fine iron castings from cast iron borings and scrap iron. This material, selling from $6.00 to $8.00 per ton, can be made into high grade castings equal to those made from high grade foundry iron and at a somewhat lower cost.

Copper, brass and other non-ferrous metals and alloys require separate treatment and form in themselves an application of great importance. Owing to the formation of poisonous vapors and other difficulties in other types of furnaces, the resistance furnace appears to offer advantages for this class of work. There are several equipments being developed at the present time, one of which not only maintains a constant temperature independent of the amount of material in the furnace but also allows of this temperature being varied according to the requirements of the process.

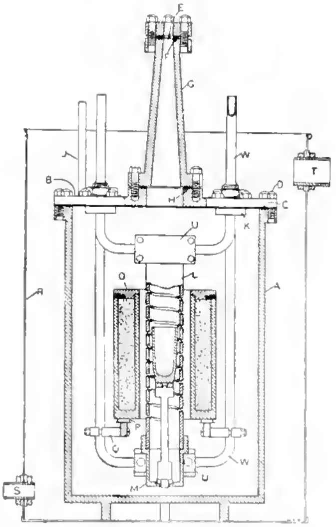

Fig. 8. Cross Section Arsem Vacuum Furnace showing crucible in center surrounded by resistor and radiation shield outside of resistor

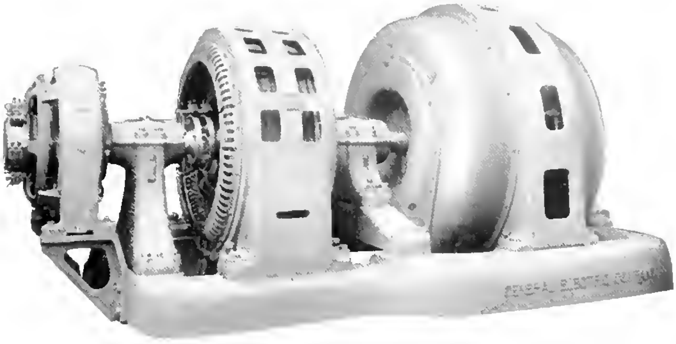

Fig. 9 Motor-Generator Set consisting of two-phase 60-cycle synchronous motor driving single-phase 2200 volt 15-cycle generator and direct connected exciter for use with two-ton single-phase induction furnace

The advantages of such a furnace, particularly where the non-crucible type is used, are many and will undoubtedly lead to a revolution in this kind of work in a short time. These might be listed as consistent even temperature, lack of oxidation products in the metal, small loss of volatile metals due to even temperature and no blast, etc. The absence of superheated gases enables the operator to use more care, increasing the quality of product and decreasing the loss due to metal being spilled from the crucible.

### Forging

The question of a successful electric furnace to heat metal for forging has occupied the attention of investigators for a long time. Such a furnace with slight changes would also be suitable for hardening and general heat treatment of tools, heating drills for sharpening, heating rivets, etc. Several types are now on the market, and in one of them the auxiliary equipment enables the operator to automatically maintain any desired temperature over a wide range, as would be needed with various metals, such as copper, brass, monel metal, nickel steel, wrought iron, etc. This furnace uses a resistor made of foundry coke and practically the only charges against the furnace, outside of overhead charges, are 10 to 20 lb. of coke per day and the electric energy. One of these furnaces was dismantled recently after running continuously six months and investigation showed that the operation could be continued with slight repairs for an indefinite period.

While it is not feasible to refer to all the experiments that have been made on this furnace, one example may be of interest. It is well known that the heating and forging of nickel steel presents many difficulties, and in this connection this type of furnace in competition with an oil-fired furnace, using the same material, operator and forging hammer, gave an increase of 15 to 20 per cent output with a superior product, showing about one-quarter of the scale and no loss of material due to over or uneven heating.

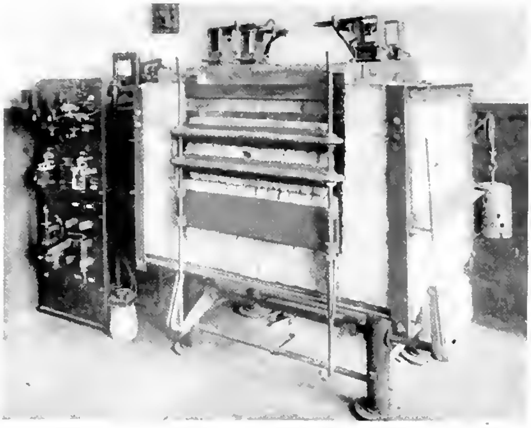

Fig. 10. Resistance Heat Treating Furnace with control panel for automatically maintaining constant temperature

### Drill Heating Furnace

In mining and similar work the expenditure of considerable time and expense is necessitated by bringing drills and other tools from the deep workings to the surface for forging and sharpening. Every time a load of drills is hoisted or lowered the hoisting capacity of the shaft is decreased and great care must be exercised in the prevention of accidents. This same type of furnace could be used in heating these tools in the mine, as there will be very little gas formed and absolute certainty of results which means keeping the producing capacity of the mine at its highest point.

A variation of this type of furnace could be used in melting and smelting the precious metal concentrates on the surface, especially in such situations where fuel is expensive and savings can be made by reducing the weight of the material to be transported.

The heating of rivets in all kinds of construction work offers another wide field that will be of great value.

### Electric Arc Welding

The subject of electric welding may not appear to belong under the subject of electric furnaces, but being an electro-thermic development is included in the list of applications.

Electric arc welding consists in utilizing the intense heat generated in the electric arc to unite various metals by small additions of metal melted in place. The process is chiefly applicable to steel but may be used for wrought iron, cast iron, copper and a few other metals. The electrodes consist of $\frac{1}{4}$ in. or smaller iron or other metal rods for metallic electrode work and of $\frac{3}{8}$ in. to $1\frac{1}{4}$ in. hard carbon for carbon electrode work. When using a carbon electrode the process somewhat resembles soldering, in which case an iron rod is held in one hand taking the place of the soldering stick, while the electrode holder is held in the other hand, taking the place of the soldering iron. When using the metallic electrode the iron rod is held in the electrode holder and serves both as an electrode for making the arc and to furnish metal for the weld. The process is from two to five times as rapid as the gas process and is much safer, as there is absolutely no possibility of injury by electric shock, explosion or asphyxiation. It is difficult for the operator to burn the weld, which can be easily done with the gas process.

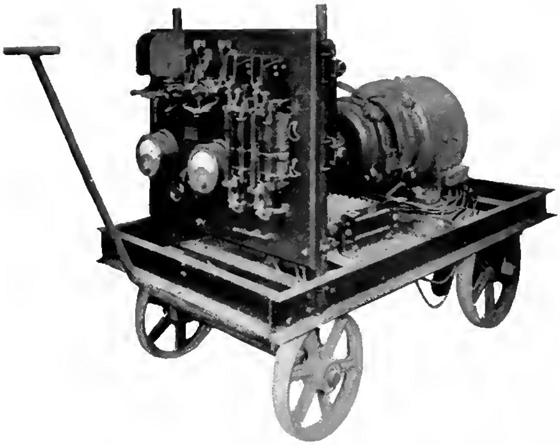

Fig. 11. 200 Ampere Arc Welding Motor-Generator Set with controlling apparatus mounted on truck to form portable equipment

It is generally recognized that metal electrodes give softer and tougher welds approaching the quality of mild steel, and that the limit of current per electrode for such work is 150 amperes. For heavy work the carbon electrode gives successful results and can work much faster, as the limit of current is approximately 600 amperes. In heavy cutting this can run up to 900 amperes or even higher values, depending on the endurance of the operator.

The arc welding equipment usually consists of a 60/75 volt flat compound wound direct current generator, belt-driven or direct connected to a suitable motor with controlling apparatus to vary the current in accordance with the character of the work and automatically protect the generator against overloads without making it necessary for the operator to leave his work. This is done by providing a rheostat in series with the electrode but normally short-circuited by a shunt contactor controlled by a series relay. (Fig. 14.)

On starting work the operator sets the rheostat switch at the proper value for the work and proceeds to weld in a normal manner. If, at any time, the current setting of the series relay is exceeded, the plunger rises slowly, and if the overload continues for one to two seconds the shunt contactor is de-energized throwing the preventive rheostat in series with the electrode and protecting the generator. The operator notices instantly that the current is cut down and lifts the electrode from the work, breaking the arc and restoring the circuits to the normal operating condition. In case of very unusual emergencies the circuit breaker affords additional protection.

Fig. 12. Operator Arc Welding with Carbon Electrode

The value of arc welding equipments in the repair and general upkeep of all kinds of machines has been thoroughly demonstrated and it is to be hoped that all manufacturers will complete their equipments by acquiring one or more in the near future. The removal of broken taps, ordinarily a difficult proposition, is easily taken care of by an arc welding equipment, taps broken off $2\frac{1}{2}$ inches below the surface being removed in 4 to 8 minutes without damage to the thread.

Fig. 13. Control Panel for use with 800 ampere arc welding equipment

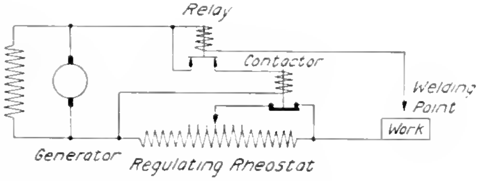

Fig. 14. Line Diagram of Control for automatically protecting generator against overloads

Electric welding equipments are used in: machine shops, to repair worn and broken machine parts and tools; in steam railroad shops, repairing broken engine frames, wheels, cylinders, welding seams and patches in locomotive fire boxes, welding flues; in electric railway shops, welding broken motor frames, gear cases, truck frames, building up worn rails and crossings, flat wheels; in steel mills, repairing broken frames, worn roll passes and wobblers; in steel foundries for cutting off gates and risers, cleaning out and filling slag and sand holes, filling blow holes and cracks; and in general the upkeep of all kinds of metal parts, much of which cannot be done by any other method.

As an example of the results to be expected from one of these equipments it might be said that this standard 500 ampere equipment was installed about three years ago and to date has paid for itself at least fifty times.

There is much that is necessarily left unsaid in an article of this general nature, and it is expected that some of the above applications will form the subject of a detailed discussion in the near future.

# THE CONTROL OF ELECTRIC MINE HOISTS

By M. A. Whiting

Power and Mining Engineering Department, General Electric Company

The author of the following article has divided the subject of the control of mine hoists into its principal and secondary divisions, and under each has presented a very clear description of the equipments employed and their operation. The characteristics of the various commercial systems are discussed and the suitability of each for particular conditions is explained. A good conception of the matter treated may be gained from the main side-headings used in the article, which are: Speed characteristics of direct-current hoists; Speed characteristics of induction motor-driven hoists; Interlocking of electrical equipment with hoist brakes; and overwind protection.—Editor.

M. A. Whiting

THERE is a very limited class of mine hoists in which the motive power runs continuously and the load is accelerated on friction clutches. A hoist of this type can, of course, be motor-driven and the control problems will then be entirely mechanical. In the great majority of hoists, however, successful operation is dependent largely on the control system for the motive power, for if clutches are used they are thrown in or out as a rule only when the hoist is at rest.

This article is confined entirely to a discussion of the characteristics of motors and control equipments as applied to mine hoists, and the mechanical and electrical design of the various parts of the control equipments will not be taken up here.

The method of control whereby a flywheel motor-generator set is used to equalize the power demand of a direct-current hoist motor is of course important as it affects the degree of equalization which can be attained. The control of the hoist itself, however, is not affected in any essential manner by the equalizing control of the flywheel set (although in some cases the characteristics of the hoist may be somewhat dependent upon the size of flywheel selected). The equalizing control for flywheels can therefore most appropriately be discussed under the subject of equalization of power demands, and is not discussed here.

## SPEED CHARACTERISTICS OF DIRECT-CURRENT HOISTS

### (Driven from Individual Motor-Generator Sets by Generator Field Control)

The speed characteristics of this type of hoist can be deduced by bearing in mind the fundamental characteristic of the combined equipment. The shunt-wound direct-current hoist motor has its armature circuit connected directly to the armature of the generator from which it operates, including in this circuit the necessary commutating field winding, etc., also as a rule a circuit breaker and line switch, but without any rheostat in this armature circuit. The hoist motor field is excited always in the same direction and either maintained constant or in some equipments varied within definite limits; for purposes of explanation, however, it may be considered to be constant. The generator field excitation is varied from zero to a maximum in either direction by means of a controller which constitutes the hoist controller. With an equipment arranged in this manner, the generator voltage may be varied at the will of the operator and the hoist motor tends to run at a speed approximately corresponding to the generator voltage. If the hoist motor is pulling the load its speed will be slightly less, and if the load is pulling the hoist motor (as in lowering out of balance or in retarding rapidly) its speed will be slightly greater than this value. The amount of the variation in each case corresponds approximately to the CR drop in the armature circuit. When lowering out of balance or when retarding rapidly, the functions of the entire system are temporarily inverted and the mechanical power returned to the hoist motor by the hoist is converted into electrical power in the hoist motor (which is temporarily a generator). This power is delivered to the generator which therefore temporarily acts as a motor driving the alternating-current motor of the motor-generator set as a generator and as a result a large part of the power returned by the hoist is "pumped back" into the line (the remainder being dissipated as losses in the electrical machines). Over the entire range of controller positions and hoist loads, therefore, any one individual position of the controller gives very nearly the same speed irrespective of the load.

The results obtained in practical operation by the use of this method of control follow logically from the characteristics just described, but as these results may not be entirely obvious to those who consider this subject only occasionally, the results obtained under various typical hoisting conditions will be discussed somewhat in detail. The numerals used identify the conditions which correspond approximately to like conditions for the induction-motor hoist that will be discussed later.

### (1st) Hoisting In Balance or Out of Balance

The speed can be varied by varying the position of the controller. On any one position of the controller, the speed will be practically constant although the load may vary all the way from full load hoisted out of balance to full load lowered out of balance. An apparent exception to this occurs in case of widely varying loads handled at slow speeds. For example, assuming one drum unclutched, a heavy load on the other rope, the controller on the first point in the hoisting direction and the brakes released, the rope pull may be strong enough to revolve the motor in the lowering direction a ainst the motor torque, whereas, in handling a very light load on the same controller point the motor will hoist the load slowly. Even under these circumstances, however, the difference is more apparent than real, as the total difference in speed on this controller point (i.e., the lowering speed with an unbalanced load plus the hoisting speed with a light balanced load) is only a small percentage of the full hoisting speed. It is also to be noted in handling a heavy unbalanced load that although the first controller point in the hoisting direction may not hoist the load only a relatively small further movement of the controller in the hoisting direction is required to start the load.

### (2nd) Retarding and Holding an Ascending Trip

In approaching the dump with a balanced trip, the controller is moved gradually to the off position (or nearly so). This will result in the hoist retarding to a speed corresponding closely to the controller position. If, as is usually the case, the energy stored in the moving system is so large compared with the net rope pull that the hoist does not tend to coast to rest as rapid'y as the controller is turned off, the motor will exert a retarding effort on the hoist to bring it to rest. If the controller is turned back to a partial speed point, instead of all the way to the off position, the hoist will be retarded to a speed corresponding to this controller point, and will continue to run at this speed until the controller is turned farther off or on.

In some of the coal fields it is a common practice, where a high rate of retardation and the utmost economy of time are required, to move the controller gradually back to the off position and then for an instant to about the first or second reverse position. By this time the ascending cage will be entering the dumping horns. The controller is put over to the first or second hoisting point about at the end of the trip; this serves, if necessary, to prevent the trip from stopping too short, and in any event serves to hold the cage into the dump while the coal is spilling without the necessity of using the brake.

### (3rd and 4th) Lowering

With an induction motor-driven hoist, there are two entirely different ways in which an unbalanced load may be lowered by the motor, viz., (3rd) *lowering on counter-torque*, (4th) *lowering above synchronism* (referred to later). With the direct-current system (generator field control), a single method of handling the controller provides a more advantageous control for lowering out of balance than is obtained with an induction motor by the use of either the "counter-torque" or "above-synchronism" methods or a combination of both.

With the direct-current equipment, a heavy load may be lowered out of balance by releasing the brake, and holding the controller on the off position. If the lowering speed thus obtained is slower than desired, the controller may be moved in the lowering direction which will allow the load to overhaul the motor at a rate more rapid than on the off position, but under equally close control. If the unbalanced load is exceptionally heavy and it is desired to lower it at the slowest possible speed, the controller may be moved to about the first or second position in the hoisting direction.

On whatever position the controller is held, when lowering out of balance, if the torque exerted on the motor by the load is greater than the motor torque, the motor will be overhauled a little more rapidly, up to a speed at which its resisting torque has increased to a value equal to the torque exerted by the load.

## SPEED CHARACTERISTICS OF INDUCTION MOTOR-DRIVEN HOISTS

### (1st) Hoisting In Balance or Out of Balance

When hoisting against a certain resisting torque, the speed can be varied by varying the position of the controller; on any one partial speed point of the controller (part of the rheostat cut in) the speed varies with a variation in load; on the last point (all resistance cut out) the speed is nearly constant irrespective of load.

### (2nd) Retarding and Holding an Ascending Trip

When hoisting in balance, the controller may be reversed thereby using the motor to retard the load. (The same thing can of course be done when hoisting out of balance but is practically never necessary as even a small load entirely out of balance will coast to rest very quickly.) In cases where the empty skip or cage rests on bottom at the end of the trip, the motor may be used to hold the loaded cage into the dump without applying the brake.

### (3rd) Lowering on Counter-Torque

An over-balanced or entirely unbalanced load can be lowered against the torque of the motor at practically any speed below full speed. To do this the controller is moved to a point in the hoisting direction on which the torque developed by the motor will be insufficient to lift or even hold the load. The hoist mechanism will therefore revolve the motor backward against its own torque. As the speed at which the motor is pulled in the backward direction increases (the controller being held on a fixed point) the torque exerted by the motor increases until it balances the torque exerted on the motor by the hoist mechanism, and the hoist will then run at this speed. If this speed is too low the controller may be brought nearer the off position, weakening the motor torque so that the load will accelerate the hoist to a higher speed before the motor torque increases to a value sufficient to balance the torque exerted by the hoist mechanism. Similarly the lowering speed may be decreased or the hoist retarded to rest by moving the controller farther toward the full-speed hoisting position.

This method of lowering requires as much power to be taken from the line as if the motor were exerting an equal torque under the ordinary condition in which the motor hoists the load. The full amount of the electrical energy, which the hoist motor takes from the line during this operation, is transformed through the induction motor (less a small fraction dissipated as internal losses in the motor) and is delivered from the collector rings to the rheostat in which it is dissipated. In addition, the mechanical energy developed by lowering the load is converted into electrical energy in the rotor and is likewise delivered from the collector rings to the rheostat. The sum of these two components of energy is manifested as a secondary current proportional to the percentage of full-load torque exerted upon the motor by the hoist and a secondary voltage which is in excess of the standstill secondary voltage by a percentage proportional to the speed in the backward direction.

This method of lowering out of balance is obviously wasteful of power and if used for frequently repeated lowering trips requires a very heavy rheostat. The principal use for this method occurs therefore in vertical shafts for changing levels, also for lowering an occasional heavy load, which it is desired to lower slowly as a matter of safety. The judicious use of a partial application of the hoist brake, in conjunction with the counter-torque of the motor, will provide an additional element of safety and a somewhat greater precision of control; it will ordinarily be unnecessary, however, to apply the brakes except during a portion of the trip, and only at low pressures, so that the resulting wear on the shoes will be very slight.

### (4th) Lowering Above Synchronism

An over-balanced or entirely unbalanced load can be lowered at a speed very slightly above full hoisting speed in the following manner. The brake is released and the controller thrown in the lowering position. The acceleration of the hoist will of course be very rapid, as it is due to the unbalanced rope pull *aided by the motor*. The controller should reach the full-speed position by the time the hoist is up to speed; this is important because, *when lowering out of balance above synchronism the more resistance in the secondary circuit the higher the speed*, which is the opposite effect from that obtained under ordinary conditions. As soon as the load has accelerated the hoist to a speed at which the motor is being driven above synchronism, the motor will begin to generate power which is "pumped back" into the line. This regeneration of power limits the speed, and with the controller in the full running position the speed will not exceed more than about 5 per cent above synchronism. The ideal method of retarding the trip is to apply the brake, and as soon as the brake has taken hold sufficiently, the controller may be brought to the off position and the hoist brought to rest by the brake. Or, if desired, as soon as the brake has sufficiently taken hold, the controller may be thrown to a hoisting position so that the motor and the brake are both used to bring the hoist to rest. Ordinarily it is not entirely safe to retard the trip merely by reversing the controller, as in so doing, there is an appreciable time, while passing from forward to reverse connections, during which the motor has no torque. Unless the unbalance in load is slight it is therefore advisable to have the hoist brake partly applied before reversing the motor.

The foregoing comments apply more particularly to the case of a vertical shaft, or to an incline which approaches the vertical. In case of a typical slope, particularly within about 30 deg. of the horizontal, considerably more latitude is allowable in controlling a descending unbalanced trip. The friction losses, of course, absorb a considerable percentage of the energy developed by the descending empties; furthermore, the acceleration of gravity for a body on a slope is less (in proportion to the per cent grade) than for a body falling vertically. As a result, therefore, the hoist can momentarily be allowed to run free of brake and motor torque, without danger of suddenly reaching so excessive a speed as to incur the risk that the brakes will not take hold properly or that the reversal of the motor will be too severe a shock. Subject to ordinary care in handling the equipment, the method of lowering on the motor above synchronism is therefore particularly suitable for long slopes.

## INTERLOCKING OF ELECTRICAL EQUIPMENT WITH HOIST BRAKES

On any hoist, which is provided with an emergency brake, it is advisable to interlock the electrical equipment with the emergency brake, or brakes. By emergency brakes is meant either a separate emergency brake or simply a mechanism for making an emergency application of the brakes used for ordinary service. This interlocking should be so arranged that whenever the main circuit breaker or oil switch opens, or whenever the voltage fails, an automatic emergency application of the hoist brake (or brakes) will occur. Where the hoist brakes, instead of being applied by a weight and released by air, are applied directly by hand, there is ordinarily no emergency mechanism, and the electrical apparatus, of course, cannot be interlocked so as to make an emergency application of the brakes. However, hand-operated brakes can be designed so as to provide an emergency application by means of a weight that can be tripped out in an emergency in practically the same manner as in an air-operated brake.

## OVERWIND PROTECTION

The subject of overwind protection for mine hoists is one on which there has been a wide variation of opinion and an equally wide variation of practice among mine operators in various regions. The attitude of some has been to put the entire responsibility for overwinds forcibly "up to" the hoist operator and hold him accountable accordingly. This, of course, eliminates any carelessness on the part of the operator which might arise from a sense of dependence on the overwind devices. The opposite attitude has been to use overwind devices that protect as completely as possible. In the latter case it is assumed (not unreasonably) that if the hoist operator becomes less careful on account of the presence of the overwind devices, this is more than compensated for by the protection afforded by the overwind devices. It is, however, not particularly difficult in applying overwind devices, to arrange so that an unmistakable record is made (by breaking a seal or otherwise) for the Superintendent's benefit, that an overwind has occurred. When supplemented by severe discipline for overwinding, this will probably be effective in preventing the hoist engineer from becoming careless about overwinds, on account of the presence of overwind protective devices.

In determining the form of overwind devices to use it is necessary to consider closely the type of electrical apparatus used and the arrangement of the hoist. For induction motor-driven hoists it is necessary to consider also the characteristics of the hoist load in the manner which will appear in the later discussions.

### Head Room

It is obvious that the cost of a head frame increases with the height, and this increase in cost is probably in a greater ratio than the increase in height, which is naturally a very strong consideration in the design of a head frame. But however perfect a system of overwind protection may be, it is of course impossible to arrange so that in case of overwind under all conditions of load and speed the automatic devices will always bring the hoist to rest at exactly the same point in the travel of the ascending cage. It is therefore necessary to have a reasonable amount of head room above the dump, i.e., sufficient to allow for the difference in rate of retardation under emergency conditions according to the characteristic of the load at that time. With a direct-current hoist the head room required is relatively small. With an induction motor hoist the provision for a liberal amount of head room increases greatly the degree of protection which can be obtained by the use of any form of induction motor overwind device.

### Clutched Drum Hoists

For an equipment to operate from several levels, the overwind problem is not appreciably more difficult than for a single level. a certain segregation of the overwind equipment is necessary so that one part can be geared to one drum (or depth indicator), and the other part to the other drum (or depth indicator). Each side of the overwind mechanism therefore maintains a constant relation with its own drum, and therefore with its own rope. The overwind adjustments are therefore not disturbed and do not require any attention due to clutching and unclutching the drums in changing levels.

### Direct-Current Hoists

By virtue of the fact that a direct-current hoist (operated by generator field control) is positively retarded to rest by moving the controller to the off position, as explained at length in discussing the speed characteristics, a very effective overwind protection can easily be provided. This consists of a mechanical device connected to the hoist drum or to the depth indicator, by which as either cage approaches the dump (or the collar, as the case may be) the travel of the hoist drum gradually turns the controller toward the off position, thereby retarding the hoist. Control circuits are also provided whereby, if the cage over-runs the normal maximum height by more than a predetermined amount (which by virtue of the overwind device on the controller can happen only at a low speed), an emergency application of the hoist brakes will be made. (It is taken for granted that on any hoist of sufficient size or importance to be direct-current driven with generator field control, the brakes will be arranged for emergency as well as for service application.) The use of this form of overwind protection provides two things, (1) principally it automatically reduces the speed at a safe rate even if the operator fails to begin retarding in time, (2) incidentally if the hoist operator is standing where he should, with his hands on the levers, the automatic motion of the controller toward the off position reminds him that he is letting the hoist over run.

When particularly required, overwinds for direct-current hoists with clutched drums (generator field control) can be provided so that, in lowering entirely out of balance, the hoist can be retarded automatically, in such a manner that the cage or skip cannot land on bottom except at a greatly reduced speed. This, however, ordinarily requires more mechanism and should not be specified unless it is a distinct advantage.

Good practice recommends that *for direct-current hoists with generator field control the overwind devices be quoted and supplied by the electrical manufacturer.* The reasons for this are principally as follows.

*1st:* If overwind protection is not provided, there is danger that the operator, if the hoist begins to overwind and he becomes excited, will pull the controller instantly to the off position. This, in most instances, will cause the hoist motor to "pump back" into the motor-generator set at an enormous overload which not only may be excessively severe on the descending rope, hoist mechanism, and commutators, but will probably open the circuit breaker, thus losing the services of the hoist motor for completing the retardation and putting this duty entirely on the hoist emergency brake.

*2nd:* The overwind protection afforded by moving the generator field controller automatically to the off position is superior to the protection afforded by any purely mechanical overwind device.

*3rd:* The overwind mechanism for the method referred to (2nd), must practically be built as a mechanical part of the generator field controller itself, and the connection of this overwind mechanism to the drums (or depth indicators) is a simple matter.

### Induction Motor-Driven Hoists

As will be understood by a consideration of the speed characteristics of the direct-current motor with generator field control, in comparison with the speed characteristics of the induction motor, it is impossible to provide so ideal a system of overwind protection for an induction motor-driven hoist as for a direct-current hoist with generator field control. However, by one of the methods which will be described (embodying a centrifugal governor), a high degree of perfection of overwind protection can be attained with an induction motor-driven hoist. It is especially important to bear in mind that any degree of overwind protection, which can be attained with a steam hoist, can be attained to an equal degree (by a similar but usually somewhat simpler means) with an induction motor-driven hoist.

The most obvious method of protecting an induction motor-driven hoist against overwinds is to use a limit switch which cuts off the power entirely and makes an emergency application of the brake. Where the rope speed is low, the head room ample, and where the weight of the descending rope is not excessive, this method may meet all requirements. Suppose, however, the characteristics of the hoist in these respects are particularly unfavorable. In order to be sure the brakes will stop the hoist under the worst conditions (coming up at full speed with a light load, cages balanced) in time to prevent the ascending cage from going into the head sheave, it will be necessary for the overwind to cut off the power and apply the emergency brakes while the cage is still below its normal position in the dump (or at the collar). Coming up at reduced speed, or with a heavy load, or worst of all if out of balance, the operation of the limit switch will then stop the cage short of the dump (or collar).

A refinement of this method, which is often used, is to arrange the limit switch so that resistance is cut into circuit, and the torque of the motor reduced thereby. This tends to cause the hoist to slow down and to continue running at a reduced speed till the position is reached at which the limit switch cuts off all the power and applies the emergency brakes. The introduction of this slow-down feature extends the usefulness of this general method of overwind protection, making it adaptable to a greater variation of operating conditions. However, in hoisting a very light load at full speed, in balance, if the descending cage and rope approximately balance the ascending cage and load, the cutting-in of resistance will have very little effect since the load itself gives very little retarding effort, and the hoist therefore will tend to coast along at nearly full speed until the emergency goes on.

There is an entirely different method of providing overwind protection for an induction motor-driven (or a steam-driven) hoist. A centrifugal governor is used to actuate one portion of the overwind mechanism, and another portion of the overwind mechanism is driven (using a screw, worm, or equivalent means) by the travel of the hoist drum. The results achieved are most easily explained by an example. Suppose that under the worst condition, the hoist can be retarded from full speed to rest in the last 100 feet of travel by a service application of the hoist brakes or by the reverse torque of the induction motor. The overwind will be adjusted so that if the hoist operator has not begun to retard the hoist by the time the 100 foot level is reached, the overwind will trip out, thereby cutting off the power and making an emergency application of the brakes. If the hoist passes this point at a sufficiently reduced speed, say at 80 per cent speed, the emergency will not trip out at this point, and the hoist can continue to run till the next setting of the overwind device is reached (say at the 60 ft. level). If the hoist passes this second point at 80 per cent speed the emergency will trip out, whereas if the operator has reduced the speed to, say 60 per cent, the emergency will not trip out. In like manner other settings may be provided at properly reduced tripping speeds. At the end is provided a setting which will trip at any speed, set to operate just above the dump.

The net result attained by this type of overwind device is that if the operator properly retards the hoist all the way in approaching the dump, the overwind device will have no effect at all. But, if the operator lets the ascending cage run too far up at any speed, the emergency will go on in time to retard and stop the hoist from that speed and position of the ascending cage in the shaft before the cage goes into the head sheave.

This type of overwind mechanism embodying the governor is the best overwind protection for an induction motor-driven shaft hoist where the conditions in regard to overwind are at all exacting. The device is almost entirely mechanical in its nature, and therefore it is outside the field of electrical manufacturing concerns to supply this device. Such overwind devices are in the market, however, and are well known to the mine hoisting trade.

For direct-current motor hoists, operated by generator field control from their own motor-generator sets, this governor type of overwind could, if necessary, be applied and made operative. There is no advantage in this, however, as the action obtained with a generator field control by turning the controller automatically to the off position affords ideal overwind protection, as previously explained.

---

# NOTES ON ELECTRIC SHAFT-HOISTING

By F. L. Stone

Power and Mining Engineering Department, General Electric Company

Coal operators are driven by competition to investigate the merits of the use of electricity in and around the mines. The result of such investigation has been most flattering to this class of machinery. The electrifications of the main hoist has received serious consideration. The following article deals with the methods of handling one set of conditions which frequently face the engineer.—Editor.

F. L. Stone

THE subject of electric shaft-hoisting has been so thoroughly gone over from a technical standpoint that it is not necessary in the present article to touch at any great length upon the actual calculations of the ordinary hoisting problems.

As near as can be learned the first electric shaft hoist of any importance was installed in this country in the mines of the Hecla Mining Company, approximately 14 years ago. The progress made by the manufacturers since that time, up to within the past two or three years was extremely slow and discouraging. Many very attractive propositions came up, but were awarded to the steam engine builder or the compressed air man, because of the operators' lack of confidence in what was comparatively a new and untried method of hoisting in this country. Fortunately this is not the condition today. We have in successful operation in this country a great many electric hoists on both slopes and shafts.

At one time, when a hoisting problem came up for solution, the electric drive was not given serious consideration; fortunately, things have changed and today there is hardly a hoist installed where the electric drive is not given very serious attention.

Without entering into a discussion of the relative merits of steam and electric drive it is sufficient to say the standby losses of the steam hoist mount up most astoundingly, particularly if the hoist is located any appreciable distance from the boiler plant. Fig. 1 is a record showing a continuous indicator card of a typical steam hoist operating in the hard coal region. The conditions of hoisting are approximately as follows:

| | |
|---|---|
| Weight of coal | $3\frac{1}{2}$ tons. |
| Weight of car | $2\frac{1}{2}$ tons. |
| Weight of cage | $4\frac{1}{2}$ tons. |
| Depth of hoist, approximately | 600 ft. |

This was a comparatively new 30 by 60 twin first motion hoist. For the first nine revolutions the hoist takes steam at practically full stroke; and on the remaining ten revolutions there is hardly any work done. The cards were taken simultaneously on the crank end of each cylinder. Cards were also taken on the head ends which show that the valves were properly set. The other indicator card shows the operation of this hoist while men are being raised. It is evident that as the depth of the mine increases the efficiency of the steam hoist improves, and when bodies of ore at such great depths as five to eight thousand feet have to be raised, and Corliss compound condensing engines can be used, the comparison between the electric and steam hoists becomes much more interesting.

When the all-day efficiency is considered, that is to say, when the total pounds of steam evaporated in 24 hours (properly chargeable to the hoist) is divided by the foot-pounds of energy expended in the shaft, the water rate is very high. In all probability in the great majority of cases the steam consumption will be over 100 lb. of steam per shaft h.p.-hr.

Assuming that it has been decided to use electric drive, the question naturally comes up: What is the best arrangement for the operator so that his power bill or his station demand will be the minimum? Will he use induction motor drive, or will he use a direct current motor with generator voltage control, either with or without a flywheel? Shall he use conical or cylindrical drums or a combination of the two?

The question of whether or not the flywheel shall be used depends almost solely upon the rate at which power is to be charged for or the station capacity from which the hoist is to be operated. If instantaneous peaks are to be penalized as is the case in some localities, and the hoisting is to be done with a fair amount of regularity, it would seem as though the flywheel would be the proper arrangement to consider.

By way of illustration assume a set of hoisting conditions which will approximate fairly well the conditions met in many shallow shafts, viz.,

| | |
|---|---|
| Depth of shaft | 220 ft. |
| Weight of cage | 6000 lb. |
| Weight of car | 2000 lb. |
| Weight of coal per car | 2000 lb. |
| Tonnage per hour | 480 ton. |
| Rest period | 5 sec. |
| Size of rope | $1\frac{1}{4}$ in. |

In working up the duty cycle without any reference to the system to be used for the hoist, it will be found that it consists largely of accelerating and retarding in order to get the tonnage. The cycle as calculated is shown in Fig. 2.

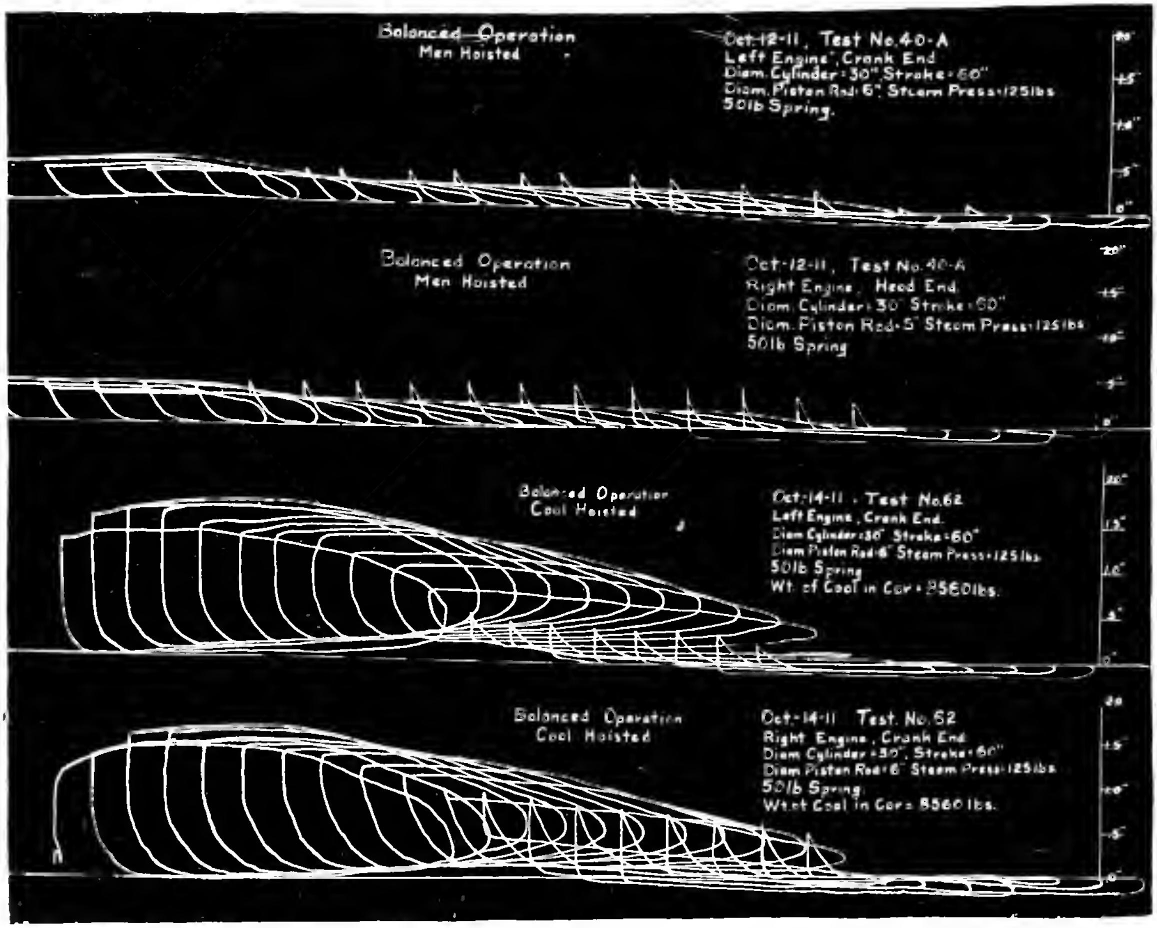

Fig. 1. Continuous Indicator Diagram for Steam Engine-Operated Coal Mine Hoist

This cycle requires approximately 1365 h.p. for 5 seconds, and approximately 330 h.p. for one second, at which point current will be thrown off and the brakes applied to the extent of 800 h.p. torque for four seconds; or the motor could be reversed and the braking done electrically, which of course would be approximately 800 h.p. demand on the line for four seconds. The efficiency of such a duty cycle would be extremely low and everything about it undesirable.

The possibilities of improving such a duty cycle should at once be considered. The obvious way is to reduce the running speed and increase the loads, by double decking the cages or by widening the cages so that two cars per trip may be carried, thus increasing the tonnage per trip to four instead of two. This gives a cycle with a peak of 350 h.p. and an average running of about 210 h.p. as shown in Fig. 3. It will be noted that this permits an increased period of rest. Further improvement might be attained by making the drums conical, to reduce the acceleration peak to 320 h.p. and give the cycle as shown in Fig. 4. The drums in this case were 7 ft. 6 in. to 9 ft. The advantage derived from the use of conical drums in this case is a slightly reduced peak.

All the cycles are plotted to the same scale and form a very good illustration of what can be accomplished by the use of a little foresight in selecting loads, etc. In some instances it might be difficult and even impracticable to carry two cars per trip. Where the breakage of ore is not of great consideration, skips carrying two or three pit-car loads per trip could be considered.

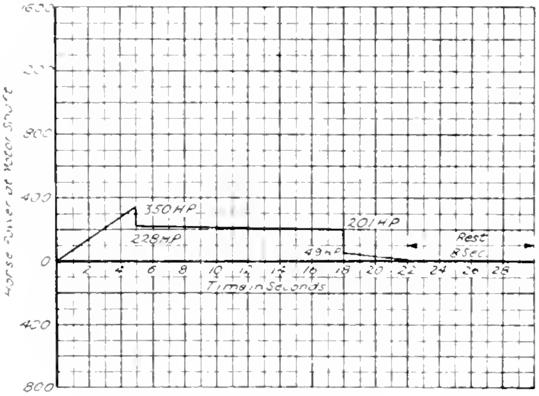

**Fig. 3. Vertical Hoist**

Depth, 220 ft.; tons per hour, 480; tons per trip, 4; max.rope speed, 756 ft. per min., cylindrical drum; trips per min., 2.

The advantages of the conical drum are perhaps not as well exemplified in this cycle as in the case of some other instances where the acceleration is very excessive. Fig. 5 shows an excellent illustration of what can be accomplished in this direction.

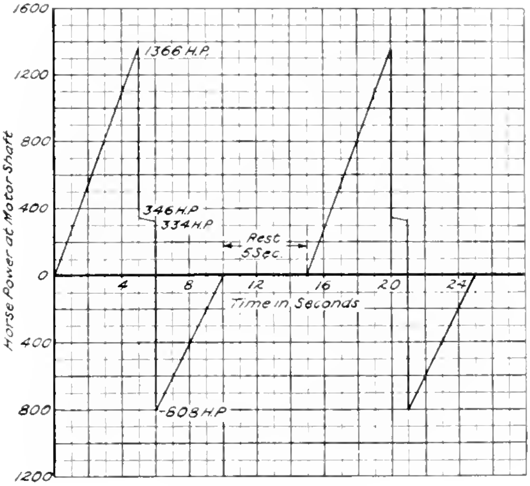

**Fig. 2. Vertical Hoist**

Depth, 220 ft.; tons per hour, 480; tons per trip, 2; max. rope speed, 2400 ft. per min.; trips per min., 4

In general, in regard to conical drums there are instances where they have a slight advantage over the cylindrical drum by virtue of reducing the peak, although this is occasionally off-set by their increased cost and increased weight. Many of the South African installations use a combination of the cylindrical and conical drum, particularly when hoisting from very great depths. This

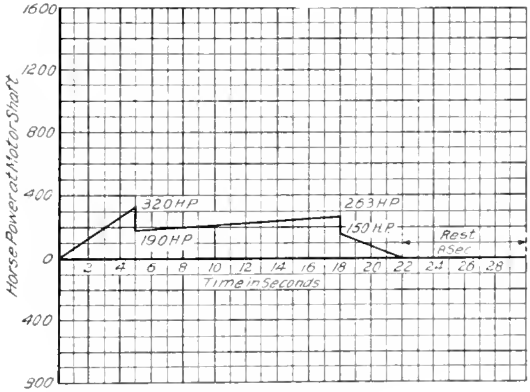

**Fig. 4. Vertical Hoist**

Depth, 220 ft.; tons per hour, 480; tons per trip, 4; max. rope speed, 780 ft. per min.; drums conical, 7 ft. 6 in to 9 ft.; trips per min., 2.

is done to reduce the peak and also to assist in overcoming the enormous weight of rope which becomes a very important factor in deep mine hoisting.

After deciding on the cycle of operation best suited to all conditions we will proceed to examine the three systems used in shaft hoisting; namely, the geared induction motor, the flywheel motor-generator set with direct current motor and generator voltage control, and the synchronous motor-generator set with direct current hoist motor and generator voltage control.

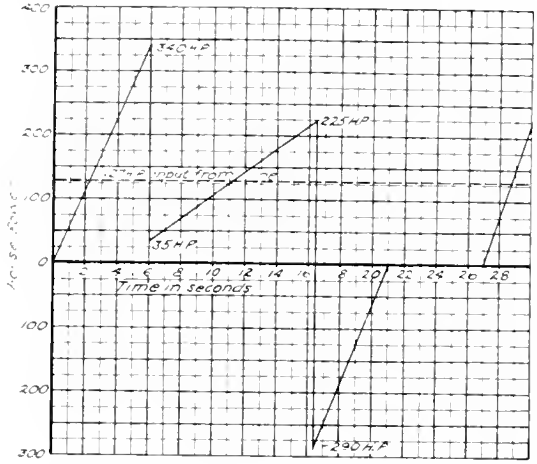

Fig. 5. Balanced Hoist

Depth, 452 ft.; ore per trip, 2400 lb.; drums conical, 5 ft. to 7 ft.; flywheel m-g. set; weight of wheel, 7000 lb.

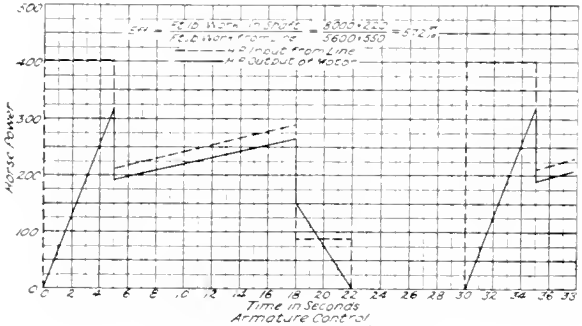

Fig. 6. Induction Motor Hoist

Depth, 220 ft.; tons per hour, 480; horse power seconds per trip, 5600; kw-hr. per trip, 1.162.

The fundamental cycle in all cases is identical and includes no armature acceleration or retardation. With the induction motor, Fig. 6, it will be noticed that the peak will run up to 402 h.p. and hold at this point for 5 seconds. The area above the diagonal line represents the energy wasted in the rheostat. The acceleration and retardation of the hoist motor armature is included. At the end of the accelerating period the consumption drops to 212 h.p. and on account of the conical drums increases from 212 to 287 h.p. at the end of 18 seconds. At this point the retardation has begun, and the input drops to 87 h.p. which is held for 4 seconds, at which point the current is thrown off. The area of this cycle under the dotted line represent the h.p. seconds consumed per trip, which in this instance is 5600, or in terms with which we are more familiar, 1.162 kw-hr., and the overall efficiency from input to motor to ft.-lb. of work done in the shaft is 57 per cent.

The next instance to be considered is the flywheel equipment shown in Fig. 7. As stated before, the only reasons for considering this are: First, a possible penalization of instantaneous peaks or a limited power station capacity, or a very distorted cycle which shows enormous peaks in proportion to the average horse power.

A flywheel equalizing equipment consists of an induction motor driving a flywheel and direct current generator, and finally a direct current hoist motor. The speed of the hoist motor is controlled by controlling the generator voltage; the armatures of the two being tied together electrically with no intervening resistance of any sort. The flywheel is calculated on the basis of operating at 300 ft. per second maximum speed, and the energy given out by the wheel is, to a certain extent, proportional to its drop in speed. In addition to this moving apparatus there is what is known as a slip regulator, which in reality is a current limiting device which prevents the current in the induction motor

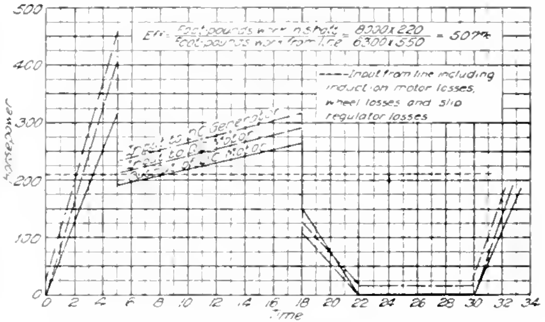

Fig. 7. Flywheel Motor-Generator Driving Hoist

Depth, 220 ft.; tons per hour, 480; horse power seconds per trip, 6300; kw-hr. per trip, 1.307.

from exceeding a predetermined value, and, therefore, the induction motor can deliver only a given torque and everything in excess of this amount must be given up by the wheel. The wheel in the instance shown has approximately 4500 lb. effective weight at 300 ft. per second; and a drop in speed of 7 per cent will take care of all peaks above the average. The actual weight of this wheel will be approximately 9000 lb. The input to the induction motor driving the set is 210 h.p. or 6300 h.p.-seconds consumed per trip, making 1.300 kw-hr. per trip. The overall efficiency in the case of the induction motor will be 50.7 per cent.

The third arrangement is a synchronous motor-generator set with the voltage control for both the generator and motor as shown in Fig. 8. In this instance the input to the hoist motor and the input to the direct current generator are omitted as they will be identical with that shown in the case of the flywheel. The input to the synchronous motor is vastly different, however, from that of the induction motor and flywheel since its peaks and load follow identically the duty of the hoist. The peak demand on the line is approximately 500 h.p. The overall efficiency, including losses when running light during the idle period, shows 56.8 per cent.

The question now comes down to the relative merits of the synchronous motor driven set and the induction motor hoist from an operating standpoint. In order to intelligently select the better of these two equipments it is necessary that we have more information in regard to the actual mining operation than that which has been given. For instance, is there much night work to be done, which of necessity must be an intermittent characteristic. With the synchronous motor-generator set it will be necessary to keep it running all night at no load in order to make a few light trips; while the induction motor stands ready at all times to perform its work with no standby losses. On the other hand, if there is much slow speed running to be done it can only be accomplished by a great sacrifice in efficiency on the part of the induction motor, the efficiency being almost proportional to the present reduction in speed. For instance, half speed must of necessity give less than 50 per cent efficiency.

In regard to hoist operation for individual plants of limited capacity where a flywheel might prove effective, it is questionable if it would not be better engineering to install additional station capacity which would be available for other purposes when the hoist is idle; while the extra money spent for the flywheel set could be used only when the hoisting is actually done.

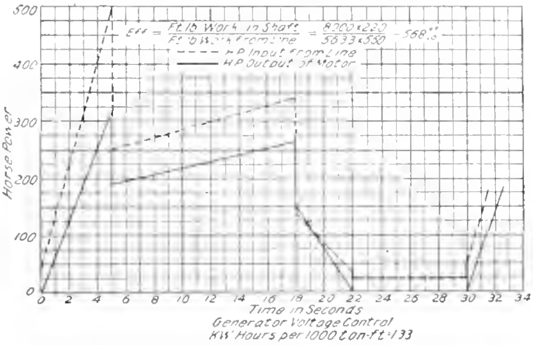

**Fig. 8. Synchronous Motor-Generator Driving Hoist**

Depth, 220 ft ; tons per hour, 480; horse power seconds per trip, 5633; kw-hr. per trip, 1.17.

A hoisting equipment has recently been installed at one of the New River and Pocohontas Mines, in which the hoist motor proper is direct connected to conical drums, and driven by a synchronous motor-generator set using generator voltage control. In addition to driving the generator for operating the hoist, the synchronous motor also drives a third generator, which is used for underground direct current power. There is also a two unit generator set installed in the hoist house which acts as a spare and also operates at night when it is not necessary to run the hoist. All three direct current armatures are interchangeable so that in case of accident to the generator driving the hoist, either one of the other two armatures can be removed from the shaft and put in place of the damaged armature.

The interest displayed in electric mine hoisting from both the theoretical and practical standpoints is decidedly encouraging. It is unfortunate that no hard and fast rules can be laid down for the guidance of operators in the selection of systems and types of apparatus to be used. Practically all cases require the special attention of some one experienced in this line of work. There are usually quite a number of different ways of accomplishing the same result, namely, of getting the material to the surface, and if a mistake is made in the selection of the best method it is liable to prove very expensive for the operator when the life of the apparatus is considered. When power rates are based on the kw-hr. consumption only, the electrical manufacturers are frequently asked to guarantee the kw-hr. per ton of material hoisted, or the kw-hr. per trip. This they are naturally very reticent to do, as the efficiency of the mechanical parts of the hoist intervene between the work done in the shaft and the input to the motor. Guarantees, when so made, must necessarily be safe from the manufacturer's standpoint, and statement should be made of the assumed mechanical efficiency of the hoist proper. In many instances the hoist proposition can be badly handicapped by the selection of incorrect acceleration and retardation values. There are some cases where the size of the motor could be reduced from 10 to 15 per cent by a readjustment of these values. Finally, with regard to the ratings of the hoist motors, it is likely that all hoist motors over 200 kw. should be given their continuous ratings, and temperature rise at which they will operate at these ratings. This rating should be approximately the root mean square of the duty cycle. If this method were in vogue it would make the matter of comparison much simpler than it is at the present time. Occasionally hoist motors will be rated on an intermittent basis, which has little meaning.

# ELECTRICITY AND THE COAL MINING INDUSTRY

By W. W. Miller

Power and Mining Department, General Electric Company

This article points out that, while only a few years ago steam and compressed air were used almost entirely for the power requirements of coal mine operations, electricity has shown such marked advantages over these two systems that it is reasonable to suppose they will be replaced by it within the next few years. In such work the electric motor is now largely used for driving mine pumps, coal cutters, ventilating fans, hoists, gathering locomotives, etc. The author mentions the principal features of each class of service and the type of motor that has been found to give the best results.—Editor.

W. W. Miller

The coal mining industry of the world comprises a yearly production of coal of over a billion tons, and in the United States alone more than five hundred million tons are mined. If this were placed on regulation railroad cars, it would make a train that would reach around the world, without the locomotives necessary to haul it.

In the United States 750,000 coal miners are employed, and the yearly output constitutes approximately 50 per cent of the traffic of the railroads. In the State of Pennsylvania alone there are employed more than 300,000 coal miners, and the output equals that of Great Britain. It is interesting to note that it is estimated that there still remains unmined in the world four million million tons of bituminous coal, and it is approximated that of this amount 271,080 million tons are in America. In the State of West Virginia alone the excavation incident to three years' mining is greater than the excavation in eleven years required to build the Panama Canal.

A careful consideration of the above data makes it evident that electricity must be an important factor in the economic production of coal. In the early days steam and compressed air were used entirely, but the first installation of electricity at once proved its flexibility and value, as well as its superiority.

At the present time every operation incident to the production of coal can be accomplished by the use of electrical apparatus, and while animal haulage and compressed air are still used to a certain extent, it is fair to assume that within the next five years these two systems will be replaced by electricity.

One of the difficulties met with in all mining operations is the disposal of the water found underground. In the anthracite mines of Pennsylvania there is pumped out yearly one billion tons, or approximately three hundred billion gallons of water. The importance of this condition can be appreciated better when it is realized that in many mines ten tons of water are pumped to every ton of coal mined. Where feasible the common practice is to drain the water to a sump, and pump the water from the sump with centrifugal or reciprocating pumps equipped with direct or alternating current motors, varying in capacity from five to one thousand horse power.

Practically all mining installations are made underground, and due to the fact that the mining laws in the several states require substantial housings, this apparatus is placed in concrete compartments; these provisions allow the use of high potential motors.

For parts of the mine which are below the sump level a large number of small portable mine pumps, driven by motors, are used. They are made portable to meet the different requirements incident to the constantly changing conditions. These outfits can be lowered down a shaft, and hauled to any portion of the mine, and immediately put in service. Some companies have as many as three hundred of these pumps in daily operation.

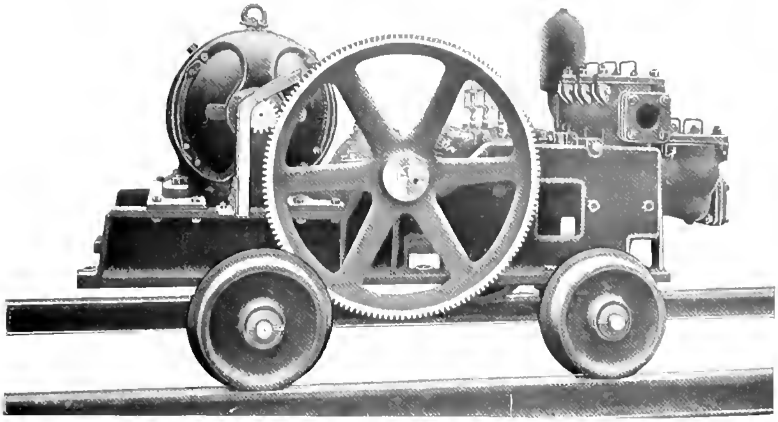

Fig. 1. 7 1/2 h.p. 925 r.p.m. CQ Motor Driving Portable Mine Pump

Formerly coal cutters were all driven by compressed air, but a modern type of coal

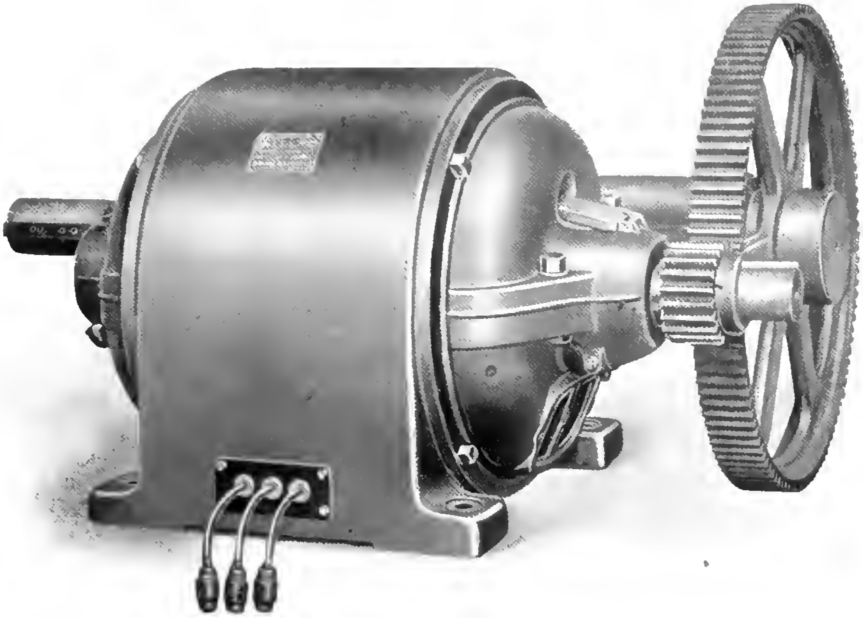

Fig. 2. Back Geared Mining Induction Motor showing Ventilating Inlet on Lower End Shield

cutter, Fig. 4, is mounted on its own truck and is self-propelled and all of its operations are accomplished by its own power, rather than by hand labor. This type of machine was originally equipped with direct current motors, but owing to the general use of alternating current, there has been a large number of alternating current machines built, which are now in successful operation. It was also believed that coal cutters were adapted to mining bituminous coal only. Experiments during the last two years have demonstrated that anthracite coal can be mined by this type of machine, and in the last eighteen months several hundred machines have been placed in successful operation in the State of Pennsylvania.

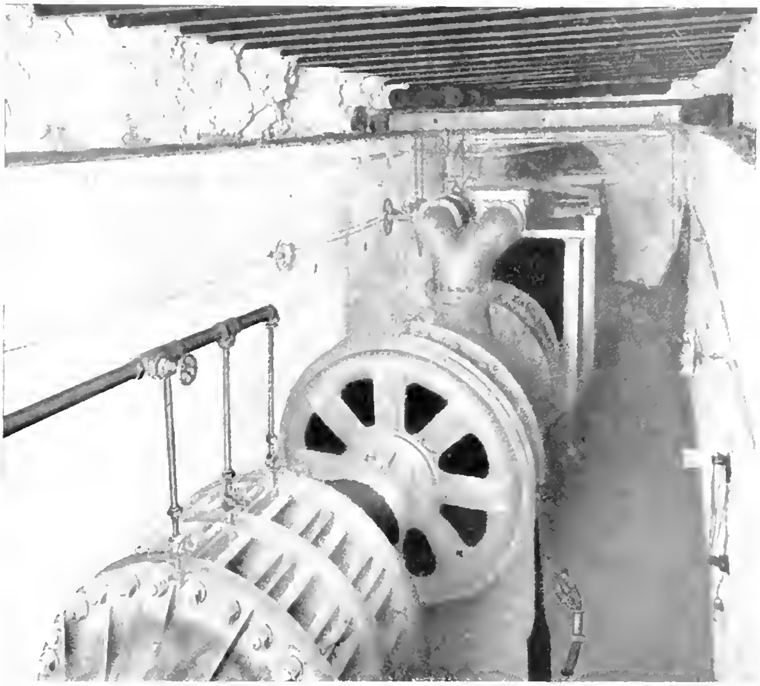

Fig. 3. 1000 h.p. 2300 Volt 720 r.p.m. Induction Motor Direct Connected to 5000 g.p.m. Six-stage Centrifugal Pump Operating Against 500 Ft. Head, Located at Hampton Water Shed Sump. D., L. & W. R. R. Co. Mining Dept.

There are several schemes for mining coal, but the one most generally adopted is the room and entry system, where the coal is mined in the rooms, and then taken from the rooms to the entries or main haulage ways. Formerly this was taken care of by hand power or mules, but the rapid introduction of electricity demonstrated a considerable saving. This hauling is now done by a type of electric locomotive known as a gathering locomotive.

In many mines it is not feasible to install trolley wire and to bond the rails into the room or working faces. To use electric locomotives successfully meant the production of the cable reel locomotive. This was first taken care of by driving the cable reel by a chain and sprocket from the locomotive axle. About 1907 the electric motor driven cable reel was introduced; the use of this reel enables the locomotive to be operated at distances up to 750 feet from the source of supply.

In some mines, owing to physical conditions; severe grades are encountered, in fact so severe that the ordinary locomotive would not operate satisfactorily. This necessitated the development of the wire rope reel or what is known in mining parlance as the "crab." This is simply a motor-driven hoist, placed on the locomotive. In the last eighteen months a storage battery locomotive has been successfully used for gathering, and it is believed by many to be the practical solution of the gathering problem.

After the cars are delivered to the cross or main entry they are made up into large trains, and hauled either to the surface or to the shaft. This service requires, in some cases, the use of locomotives up to twenty tons capacity. Some of the larger mining companies have as many as three hundred gathering and haulage locomotives in daily service.

Ventilation in mines is of vital importance owing to the presence of "coal gas." It is interesting to note that in many mines very little of this deadly gas is found, while in others there is an abundance, varying in quantity from time to time. Most of the ventilating fans are driven by variable speed, direct current motors, two speed alternating current motors, or variable speed alternating current motors of the brush shifting type.

The geological formation of the veins of coal requires different methods of bringing it to the surface, after it is mined. In some cases shafts are sunk to a depth of 1200 ft. In other cases openings are made in the side of the hill, and the coal is either lowered or raised by a type of hoist known as the slope hoist. Most of the shaft hoists have heretofore been driven by steam engines. Installations made during the last two years, especially of the Ilgner System, have demonstrated the flexibility and saving in power secured by the application of electric motors. Most of the slope hoists require motors of such capacity that they can be successfully driven by wound rotor type of motor.

The next stage is the preparation of the coal for market. In the anthracite field this is taken care of in a coal breaker, and in the bituminous field by tipples. Formerly the usual practice was to belt motors to the steel belt conveyors, crushers, shaker screens and car loaders, but the efficiency of the modern motor has resulted in a marked tendency towards direct drive. Most of the operations in these breakers and tipples are of such a nature as will require an extremely substantial motor. A typical type of motor is shown in Fig. 2.

Power at the mines is obtained from turbines or engine-driven units, or from substations with rotary converters, or synchronous motor-generator sets. Many companies operating a number of mines have found it economical to install central stations. Large public service companies are campaigning actively to secure mining loads, and in fact some of them have built central stations, the total load being entirely of a mining nature.

A very considerable tonnage goes to make up the seaboard coal traffic. Coal is hauled to the piers, and loaded in colliers by electrically operated car dumping machines, and at the destination is handled by electrically operated unloading machines.

This article is meant to show that electrically operated machinery is used in every operation in connection with the mining of coal, and that almost every type of electrical apparatus manufactured by large electric companies is used.

Fig. 4. Sullivan Coal Cutting Machine in Operation

# DIRECT CURRENT ELECTRIC DRIVE ON CRANES

By R. H. McLain

Power and Mining Engineering Department, General Electric Company

Overhead travelling cranes are employed for various kinds of work which differ greatly in service requirements, ranging from a heavy lift for a few minutes at long intervals, to continuous operation on all sorts of loads; while others are required to work in highly heated locations and therefore have to be specially insulated. The severity of the service for the kinds of work considered is increasing in the order given, the soaking pit cranes having to operate under the most trying conditions to which such apparatus is subjected. The author discusses the design of motor best suited for each class of service, and goes into considerable detail respecting the best methods of speed control and of braking, whether dynamic, solenoid, mechanical, or a combination of these. The most suitable motors and brakes for the trolley and bridge motions are indicated, and some remarks included on protective devices.—Editor.

R. H. McLain

During recent years many improvements have been made in the electrification of cranes with direct current apparatus, both in regard to the manufacture and the design of the electrical material and in the proper selection of equipment to meet the specific requirements. The service conditions for the various classes of work have been shaped into very definite channels. In some cases a motor is required which will hoist tremendous loads for five or ten minutes at a time and then lie idle for long periods. In other cases, a motor is required to occasionally hoist a very heavy load for a short time and in addition is required to keep busy most of the time hoisting moderate loads. Some industries require a motor to operate in a very hot location, and, therefore, demand special non-combustible insulation.

The controller requirements are classified very much along the same lines; but many new possibilities in controllers have recently been worked out. Dynamic braking for lowering is becoming more popular in order to save the expense, wear and adjustment on mechanical brakes and to gain more refined speed control. In some cases motors, control and solenoid brakes must all be used together to obtain the best conditions for extreme overloads on hoisting, high speed on lowering, and refined speed control. These three pieces of apparatus must be so corelated that the life of none is impaired under extreme operating conditions. The "Safety First" movement has invaded cranes and brought about a demand for absolute protection for the operator; this involves the protection of the motor and equipment as well as of the load on the hook.

### Power House Cranes

About the simplest and cheapest class of crane is the one which is used for setting up machinery in a power house. Once the heavy machinery is set in place the work of the crane is done, except for a few repairs or alterations which must be made at rare intervals. Such a crane may lie idle for weeks. A low hook speed is required and therefore no speed control refinements are necessary. All the control and protective apparatus should be made as simple as possible so that it will be easy for an untrained operator to manipulate and so that it will not get out of adjustment when not in use. The apparatus should be made as inexpensive and small as is consistent with the extremely heavy load which must be handled when the power house is first built or when additions to the power house are made. While the apparatus should be strong no especial expense need be incurred to make it stand wear.

### Machine Shop Cranes

The class of crane which serves machine shops comes next above the power house crane in point of severity of service. They have at rare intervals very heavy loads to hoist but are on duty at all times serving the machines, bringing up raw material and holding parts in place on the assembly floor and so on. High speed in these cranes is not so important merely for the purpose of moving material rapidly, but is frequently important when the crane occupies such a place that its slowness would keep high priced mechanics idle while waiting for the crane. Such a crane requires a series wound motor which can stand extreme overloads, can speed up on light loads, will wear well, and which is light and accessible for repairs. Interpoles come in well on such a motor, because of the overloads and high speeds; split motor frames and large convenient openings to the brushes are well worth while so as to enable repairs being made easily and quickly. Such a motor must be built both for strength and wearing qualities.

A good easily operated controller of the manual type with no live parts exposed to the operator is best adapted to this class of work. Ordinarily there is not enough work done in lowering heavy loads to make it necessary to use dynamic braking; but, if it is used, the controller and especially the motor must give high speeds when lowering so as to speed up the work. To obtain this high speed the controller must have a large number of points and the resistance steps must be just as carefully laid out as is the resistance in the field circuit of an adjustable speed, shunt wound, motor; because the crane motor is connected very much like a shunt wound motor or generator when lowering dynamically.

The motor had best be of the interpole type, although a well designed non-interpole motor can lower at 50 to 75 per cent above its hoisting speed. If correctly proportioned interpoles are used and if the brushes are securely and accurately held at the "neutral" position the motor can easily lower at twice the hoisting speed. An improperly constructed motor either sparks at the commutator or is unstable in speed. In the majority of cases no especial refinements in speed control are needed and ordinary rheostatic control is sufficient; but where very exact work is to be done, such, for example, as requires a uniform speed less than 15 per cent of full load hoisting speed, it is wise to obtain this creeping speed by connecting resistance in shunt with the motor as well as in series with it on the first point of the controller.

Such a connection definitely limits the motor speed to any desired low speed regardless of the load on the motor and makes a most desirable condition for such cranes as are required to do delicate work with heavy loads. Foundry cranes whose hook speed is above twenty feet per minute, frequently use this connection so as to take care of pattern drawing. Hand-operated controllers are good enough for this class of work unless careless operators are employed or the motor capacity is greater than 50 to 75 horse power. Automatic current limit controllers prevent the abuse of the motors and are better able to stand up to service requirements on large motors than hand-operated controllers.

On this class of cranes the solenoid brake is usually series wound instead of shunt wound so as to get quick action, to reduce the number of trolley wires and because a series wound coil uses heavier and, therefore, more substantial wire than a shunt wound coil. If a mechanical load brake is used the solenoid brake need have only sufficient retarding torque to bring the armature smoothly to rest, because the braking action for holding and lowering the load is all supplied by the load brake. About 50 per cent or less of the normal rated motor torque is all the solenoid brake need exert on the shaft of the motor. More torque would produce too violent a stop. If dynamic braking is used, no mechanical load brake is necessary, and, therefore, the solenoid brake must not only retard the armature but must also retard and hold the load. Owing to the fact that the friction losses in the crane machinery help to prevent the load from falling, the brake need only have about 70 per cent of the torque which is required on the motor when it is hoisting its *maximum* load. The exact value required depends on the amount of friction loss in the crane hoist.

Powerful action on the part of the brake does not necessarily produce violent stopping, because ordinarily the dynamic braking really stops the motor and the solenoid brake only has to hold the load, although in case dynamic braking should fail to operate the solenoid brake would have to stop the load as well as hold it. Violent action does take place in the hoisting direction, but this is not objectionable because the weight of the load helps so much with stopping that the violent action is not felt. Still if a very powerful brake is used it will be objectionable in this respect at times, and, for this reason, too much retarding torque should not be demanded of a solenoid brake. It is far better to have a brake just powerful enough, but with ample wearing surfaces so as to be reliable.

### Yard Cranes

The class of crane, as regards greater severity of service, next to the machine shop crane is the shipping yard crane around steel mills. Here speed is everything. Large amounts of raw material must be moved rapidly and on schedule time. The motors and controllers are kept so busy that they should not be worked anywhere near their extreme limits else their life will be impaired. Dynamic braking should be used for lowering and, on motors above 40 to 50 horse power, automatic control should be employed. In fact, for dynamic braking it is far more important to have automatic control than for reversible work because it is easier for a careless operator to damage the motor. In very many places it is profitable to put automatic control on all motors so that the crane can make the greatest speed with the least abuse to the motors, and with the least care and skill on the part of the operators.

Special cranes for handling sand, clay, etc., in buckets or lifting magnet cranes work the motor so hard and so regularly, both when hoisting and when lowering, that the temperature rise is the limiting feature. If these motors are not exposed to the weather it will be economical to use open type motors provided a smaller motor could be used without its being too much overloaded at the commutator. Owing to the fact that the maximum loads are easily determined the motors can be selected with certainty. Dynamic braking for lowering should be used and since the loads do not vary much from a fixed condition the controllers and resistances should be designed for the particular condition so as to get the highest speed possible at all times without abusing the motors. Automatic control should be used on motors above 40 to 50 horse power.

### Soaking Pit Cranes

About the severest crane on electrical apparatus is the crane in steel mills which not only works hard most of the time but works in a high temperature. Soaking pit cranes and some charging cranes come in this class. Here non-combustible insulation should be used in the motor and, wherever possible, on the wiring of the crane. Accessibility of all electrical parts is of vital importance. Automatic control should be used in all cases unless space or temperature forbid. In some cases there is not sufficient room for contactor panels and a small manual controller must be crowded in, although it may have to be repaired every few days. While temperature would have no worse effect on a contactor panel with fire-proof wiring than on a hand-operated controller yet the loss is greater in amount when the contactors are lost and, therefore, it would in extreme cases be better to use hand controllers.

### Trolley and Bridge Motion

Only the hoist motion has been discussed above. The trolley and bridge motion are simpler and usually require smaller motors. The motors should be series wound and similar in general characteristics to the hoist motor which is chosen for the crane. The motor should have as steep a series characteristic as possible so that, after exerting its full torque for starting or pulling over bad places in the track, it will rise to a relatively high speed and gain all the time possible. Simple reversing controllers are used for these motors. In most cases hand controllers are employed but on high speed cranes automatic controllers are used. No dynamic braking is needed but sometimes the motors are stopped by reversing them while they are running. If this is to be done, ample resistance should be used on the first point of the controller to limit the current under this condition and thereby permit of gradual stopping. This method of stopping is not dependable, because it would be ineffective should power fail. Where the trolleys are used for pulling or shoving cars it is advisable to use automatic control to prevent the operator from turning too much power on the motor when it is overloaded. Where automatic control is used for such purposes there should be at least two hand control points on the master controller so that the action of the motors will not be too jerky. Where no such work is required, the trolley motor need have only one point hand control, but the bridge motor should have two points hand control, because the bridge track is usually uneven and consequently if only one point hand control were used it would have to provide sufficient power for starting on an up-grade, and it would cause a jerk where the track is down grade. Ideal conditions are obtained by having two hand points, the first to admit a small current for starting down grade and the second to provide more current for up-grade.

On ladle cranes where the trolley motor is used for pouring hot metal it is often advantageous to have one positive creeping speed point on the controller. This point can be obtained by connecting resistance in shunt with the motor as well as in series with it; but no resistance should be connected in shunt with the armature because there would be a dynamic braking action by the motor if the master controller is thrown to this point after the motor has been running at high speed, and this action would cause the ladle to swing. Solenoid brakes are sometimes used on the trolley motor for stopping, but for satisfactory operation their retarding torque must just fit the needs of the case. Usually 10 to 30 per cent of the rated motor torque is all that is required of the brake. Too much torque would stop the trolley so quickly as to make the hook swing and jerk. Foot operated brakes are almost universally used for bridge motion because of the gradual stopping which can be obtained most advantageously in this way.

### Protective Devices

Crane protective devices have been standardized. On account of the expense and annoyance of replacing fuses they have been practically discarded on cranes; and overload relays in connection with contactor type circuit breakers are used instead. Short circuits and grounds on the crane are relieved by having one single pole breaker and one overload relay in each side of the line. Damaging overloads on the motors are prevented by having one overload relay in the circuit of each motor on the crane. Single-pole knife switches for each motor are frequently used so as to provide a convenient means of tracing out troubles in the wiring. A main line double-pole knife switch is used for disconnecting the crane entirely from the line and, in order to insure that this switch remains open while repairmen, oilers and painters are on the crane, a staple for locking the switch open is used. Any man who goes on the crane can protect himself by locking the switch with his own padlock. Space for several such padlocks is provided so that each individual can insure his own protection with his own padlock and thus prevent accidents due to carelessness or misunderstanding on the part of other people.

Safety for the load is obtained by an emergency switch which is installed within easy reach of the operator. The emergency switch should be convenient to operate and so constructed that an operator can open it quickly without exposing himself to live parts or electric arcs. A back-of-board-switch operated by a front-of-board-knob is best for this purpose and the switch should be double-pole so as to open both lines. The function of this emergency switch is to shut off all power from the crane and allow the solenoid to set. On dynamic brake controllers it gives extra safety to have the motor hold back in an emergency such as occurs when the solenoid brake fails to hold. Hand-operated dynamic braking controllers always have the motor connected to brake dynamically on the lowering side and at the "off" position but not on the hoisting side. If there is a case where a great degree of safety is required a normally closed contactor should be used which would establish dynamic braking connections when power fails even if the controller handle is on the hoisting side. Contactor automatic hoist controllers which give dynamic braking should always be equipped with the normally closed contactor. Hot metal cranes and many others are equipped with more than one solenoid brake so as to get additional protection for emergencies.

Unfortunately there is one problem on the crane hoist which has not been solved to the satisfaction of all users. This is the limit switch for preventing over-travel in a hoisting direction. It is, of course, disastrous to hoist too high as the ropes may be broken and the hook with its load dropped. In many places it is necessary to hoist very near the limit so as to clear obstructions over which the load is to be carried. Therefore the operator must use great care. Two types of limit switches are used but each is objectionable. First is a limit switch which shuts off power and sets the brakes when the hook is raised too high. The switch provides no means of getting power to the motor for lowering the hook and thus penalizes the operator for his carelessness by making it necessary for him to go to considerable trouble to get the hook down. The trouble with this type of limit switch is that much time is wasted every time it is tripped. Incidentally, some one in anger is liable to do something which will prevent the switch from working as designed and thereby defeat the whole usefulness of the switch. The second type of limit switch is one which not only cuts off power when the hook is hoisted too high but also provides a return circuit so that the operator can return the hook simply by reversing his controller. Such a limit switch will function many times without the operator even knowing it and for this reason is liable to wear out quickly or lose its proper adjustment. The result is likely to be an accident because the operator is trained to use the switch and thinks nothing of hoisting too high. It seems that the only way out of the difficulty is to use the second type of switch, see that it is most substantial in construction and, above all, to inspect its condition and its operation at frequent and regular intervals. The very best switch which can be built should not be left unnoticed to do its work. On one point regarding these limit switches there seems to be a consensus of opinion, and that is, that the switch should open the main line power circuit close to the motor and not depend on some control circuit to open a circuit breaker in the operator's cage.

# THE APPLICATION OF ELECTRIC MOTORS TO SHOVELS

By H. W. Rogers

Power and Mining Engineering Department, General Electric Company

Owing to the existing difference of opinion regarding the proper type of motor to be used on electric shovels the author has endeavored to show that the direct-current series motor is not only better adapted to this service but possesses marked advantages over the alternating-current motor both as regards size and power consumption.—Editor.

H. W. Rogers

It often happens that men are slow to adopt new methods and this may be attributed to three causes; first, because they are satisfied with the old methods; second, because they hesitate to abandon a method which they know is good for one which they think is questionable; third, because of the increased investment of capital which is sometimes necessary.

Unlike the hydraulic dredge, which is largely used for contracting work, and which is considerably cheaper when electrically operated than when steam operated, the electric shovel calls for a larger investment of capital than the steam shovel, but the reduced operating expense will warrant the increased investment.

It is hardly necessary to treat with the first reason as those who are familiar with the history and development of the steam shovel during the past fifty years will acknowledge that it is a machine which has not only proven its worth but has probably reached its highest stage of development and efficiency. Any further improvement, therefore, must of necessity be along different lines and with the rapidly increasing power developments throughout the country which make cheap electric power available the electric shovel is logically the next step.

That it is a possibility cannot be denied as there are at present from twelve to eighteen shovels in operation in this country. Some of these are of the type commonly called "friction electric," and although the initial cost and operating expense is low they do not compare favorably with the steam shovel as regards speed. Others are of the "three" or "four-motor type" with automatic control and although they compare very favorably with the steam shovel in all respects they have not all been equipped with a full knowledge of the conditions to be met or the characteristics of the steam engines which the motors replaced. It is very important that the motors be applied with a full knowledge of existing conditions as any misapplication will not only be detrimental to the individual shovel involved but also to future advancement in this field of engineering.

Granting that the electric shovel is a possibility, the fact still remains that its first cost is higher than that of the steam shovel and it must be proven that the saving in operating expenses will warrant the increased investment of capital.

There is probably no class of machinery that presents a duty cycle as severe as that of the shovel, which is very short, varying from 7 to 12 seconds on the hoist, 7 to 12 seconds on the thrust, and from 10 to 18 seconds on the swing, making a complete cycle in from 17 to 30 seconds, and the motor to meet these requirements must have a sufficiently low inertia to permit of rapid acceleration and quick reversals with small power.

It should also be a motor of substantial design, as it must be subjected to severe overloads, shocks and frequent reversals. This is especially true of the hoist motors and, to a lesser degree, of the swing motor; the thrust motor being practically stalled during the digging operation, its duty being to hold the dipper to the bank, although it may revolve or overhaul according to conditions, and is operated at full speed only after the hoisting operation is completed.

A considerable advantage may be gained by using two motors of small capacity instead of one large motor on the hoist as the power required to accelerate is much smaller. This fact will be appreciated by comparing one 150 horse power, 425 r.p.m. motor, which requires 117 horse power torque to bring it to full speed in one second, with two 75 horse power, 500 r.p.m. motors, which require 32.3 horse power torque each or 64.6 horse power torque to bring both motors to full speed in one second. The saving in power represented here is approximately 45 per cent.

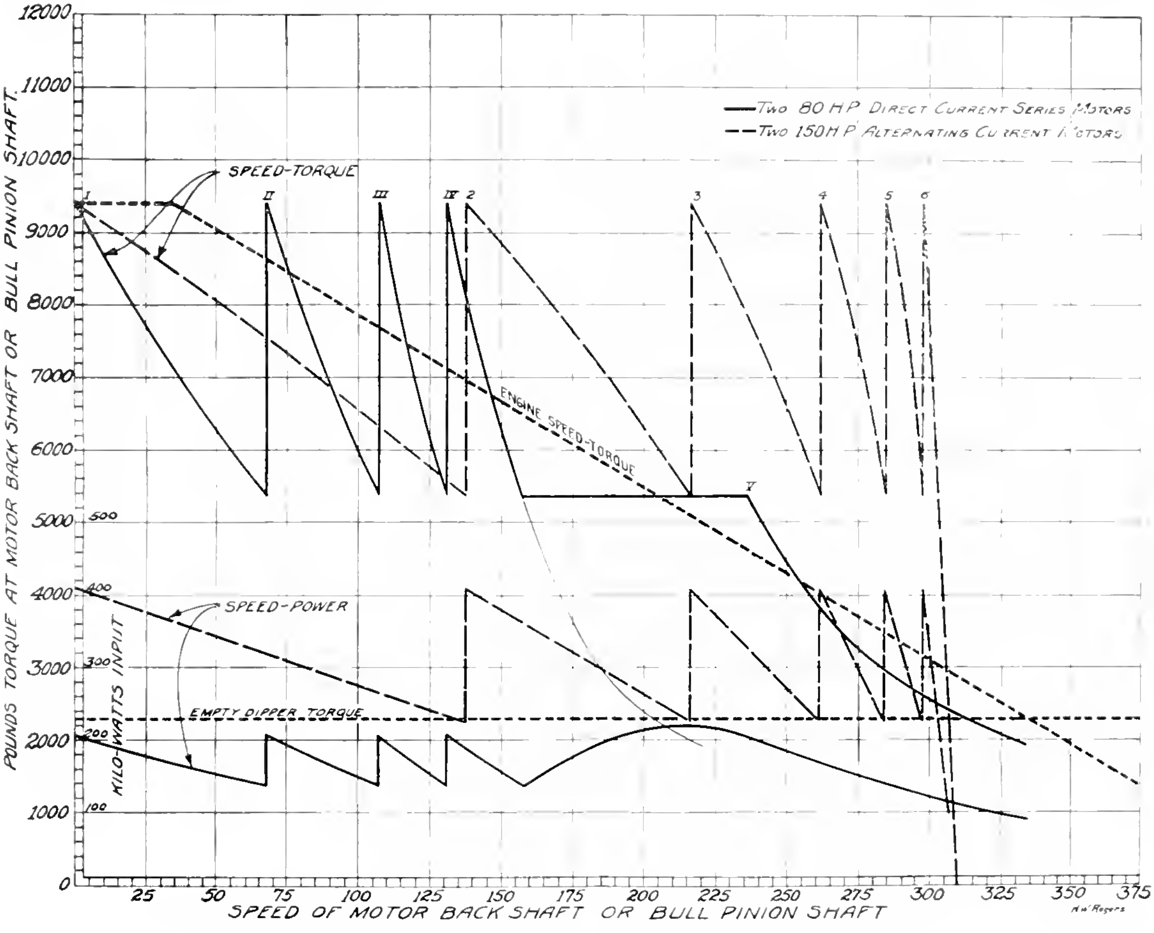

Fig 1. Comparative Size, Characteristics, and Power Consumption of an Instance of Direct and Alternating Current Motors which will accomplish the same results in electric shovel operation

The question naturally arises as to the type of motor that is best adapted to this class of service and without careful consideration of conditions it is natural to assume that either direct or alternating current would be equally satisfactory, but this is not true, as a study of the steam engine and motor characteristics will show.

As the bulk of electric shovels will undoubtedly have to operate from an alternating current source and as there still exists a difference of opinion as to the advisability of using direct current series motors or alternating current slip-ring motors, the curves of Figure 1 have been plotted between speed and torque and between speed and power for two 80 h.p., 500 r.p.m. direct current series motors operating in multiple and two 150 h.p., 450 r.p.m., 60 cycle, slip ring induction motors operating in multiple. The full line represents the speed-torque curve on the series motors with a gear ratio of 3.31 to 1.0 which gives the maximum pull required at 150 per cent normal current, while the broken line represents the speed-torque curve on the induction motors with a gear ratio of 1.45 to 1.0 which gives the maximum pull required at 170 per cent normal current. This corresponds to the torque given on the series motors with 150 per cent normal current and although the gear ratio could be increased to give the required pull at 150 per cent current it is not desirable as it would reduce the maximum speed.

The direct current series motor has the characteristics of the steam engine, in that it gives its heaviest torque on starting, speeds up under light loads, and slows down under heavy loads. It is much easier to control and requires considerably less apparatus, in so far as the control is concerned, than the alternating current equipment.

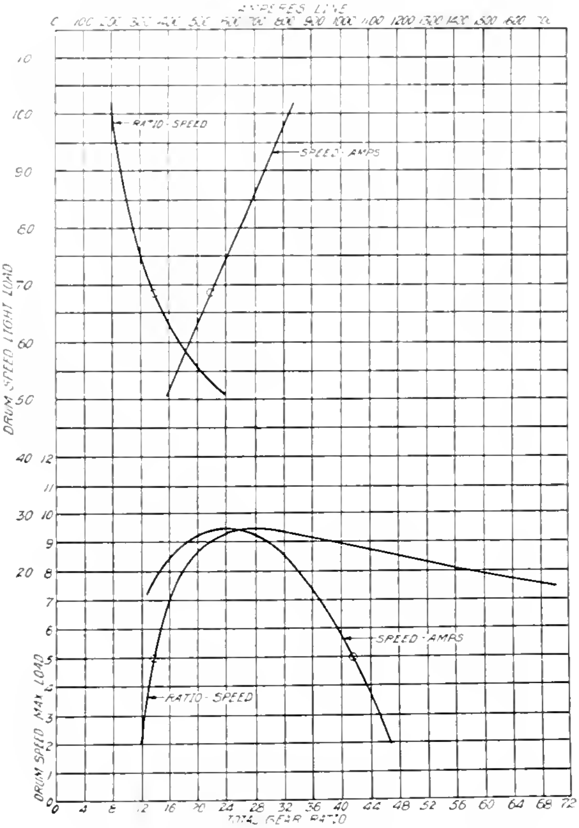

Fig. 2. Curves showing the Effect of Change of Hoisting Machinery Gear Ratio on Speed and on Power

This characteristic is clearly shown on the curve, which represents a five-point control, four of these points being used to cut out the armature resistance and the fifth to weaken the series field, which results in a very high light load speed.

Although sufficient starting torque may be obtained on the alternating current motors, the light load speed, which is very important, is limited by the synchronous speed, and the only means of improving this disadvantage is to reduce the gear ratio or use a higher speed motor. Either of these methods would mean an increase in the motor capacity and an increase in the power required, accompanied by an increase in the armature inertia and a slower acceleration, both of which are very undesirable. This feature will be appreciated from the following data applying to the motors used in plotting the curves.

| | Total $WR^2$ | Diam. Rotor Inches | Per Cent Torque to Bring to Speed in 1 Second |
|---|---|---|---|
| Two 80 h.p., 500 r.p.m. series motors | 444 | 16 | 43 |
| Two 150 h.p., 450 r.p.m. induction motors | 2480 | 30 | 98 |

Under these conditions the natural result is a much larger kv-a. capacity in transformers for the induction motors than kw. capacity of motor-generator set for the direct current motors.

In laying out an electric shovel drive there are four things to be considered; namely, the speed at maximum torque, the speed at light load, the power required by the motors and the gear ratio. Any increase in the gear ratio results in a decrease in the power at both light and heavy loads, an increase in the speed at heavy loads and a decrease in the speed at light loads; and taking all of the variables into consideration the gear ratios used in the foregoing comparison seem to give the most satisfactory results. The effect of the gear ratio on other conditions is clearly shown on the diagram, the light load curves representing a weakened field condition without armature resistance while the maximum load curves represent a strong field with armature resistance.

These curves apply to direct current series motors only.

The saving in operating expense of the electric shovel over the steam shovel will depend somewhat upon the comparative cost of coal and electric power and will vary for different localities, but the greater saving will be effected through the elimination of the fireman, the watchman, the coal passer, teaming for ½ day, the use of water and considerable waste. The natural increased wear and tear of parts having a transverse motion as compared with those having a rotary motion and the elimination of boiler trouble should also be considered.

As an illustration, consider a 120 ton shovel which is ordinarily equipped with a 5 cu. yd. dipper and has an average capacity of approximately 2500 cu. yd. per 10-hr. day. This capacity is based on an average working time of 55 per cent and an average dipper capacity of $3\frac{3}{4}$ cu. yd., or 75 per cent.

With a good grade of coal the steam shovel will require approximately $3\frac{1}{4}$ tons per 8-hr. shift and will make an average of two complete cycles per minute. For the purpose of comparison, however, the maximum capacity of the shovel is taken; i.e., three cycles per minute. Under these conditions either the steam or the electric shovel will have a total working time during one shift of $8 \times 60 \times 0.55 = 264$ min. during which time it will make $264 \times 3 = 792$ complete cycles, and will handle $792 \times 3\frac{3}{4} = 2970$ cu. yd. of material.

The direct current shovel would be equipped with two 80 h.p., 500 r.p.m., 230 volt series motors on the hoist, one 40 h.p., 550 r.p.m., 230 volt series motor on the swing, one 60 h.p., 550 r.p.m., 230 volt, series motor on the thrust, and one 150 kw., 900 r.p.m., 250 volt, direct current generator direct connected to a 225 h.p., 900 r.p.m., 2200 volt induction motor, with four-point reversible automatic control on each motor.

The estimated power consumption during each cycle will be as follows:

| | kw-seconds |
|---|---|
| Hoisting | 1379 |
| Swinging | 522 |
| Crowding | 547 |
| Total | 2448 = 0.68 kw-hr. |

Fig. 4. Interior View of the Shovel of Fig. 3 showing the control panels

The input to the motors equals $792 \times 0.68 = 539$ kw-hr. per 8-hr. shift, or, taking into account the efficiency of the motor-generator set, 657 kw-hr. per 8-hr. shift.

As the shovel is working only 55 per cent of the time, the motor-generator set will be running light 45 per cent of the time, or $8 \times 60 \times 0.45 = 216$ min.

Fig. 3. A Sixty-Five-Ton Electric Shovel equipped with four 550-volt direct current series motors

The power consumption of the set when running light will be approximately 16.77 kw.

$$\frac{216 \times 16.77}{60} = 60.4 \text{ kw-hr. loss per 8-hr. shift.}$$

Therefore the total power consumption equals $657 + 60.4 = 717.4$ kw-hr. per 8-hr. shift when working under the maximum cycle.

The power consumption per cubic yard excavated equals $\frac{717.4}{2970} = 0.241$ kw-hr.

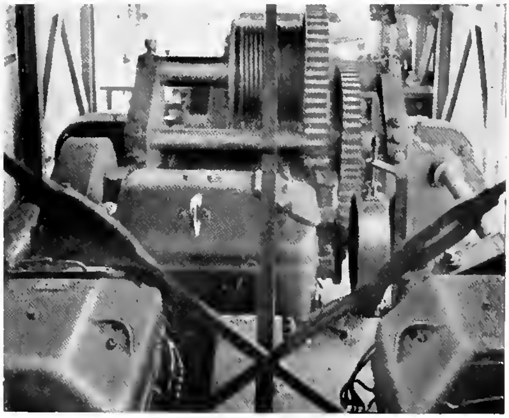

Fig. 5. Interior View of the Shovel of Fig. 3 showing arrangement of the motors

The alternating-current shovel would be equipped with two 150 h.p., 450 r.p.m., 440 volt motors on the hoist, one 50 h.p., 720 r.p.m., 440 volt motor on the swing, one

75 h.p., 600 r.p.m., 440 volt motor on the thrust, and three 125 kilovolt-ampere, 2200-480 volt transformers, with five-point reversible automatic control on each motor.

The estimated power consumption during each cycle will be as follows:

| | kw-seconds |
|---|---|
| Hoisting . . . . . . . . . . . . . . . | 2040 |
| Swinging . . . . . . . . . . . . . | 759 |
| Crowding . . . . . . . . . . . . . . . | 750 |
| Total . . . . . . . . . . . . . . | 3549 = 0.987 kw-hr. |

The input to the motors equals 792 × 0.987 = 782 kw-hr. per 8-hr. shift, or, taking into account the efficiency of the transformers, 796 kw-hr. per 8-hr. shift.

The no-load losses on the transformers will be approximately $\frac{216 \times 3.6}{60} = 13.0$ kw-hr. loss per 8-hr. shift.

Therefore the total power consumption equals 796 + 13 = 809.0 kw-hr. per 8 hr. shift.

The power consumption per cubic yard excavated equals $\frac{809}{2970} = 0.273$ kw-hr.

| Labor per Shift | Steam | Electric |
|---|---|---|
| Shovel runner . . . . . . . . . . | $6.00 | $6.00 |
| Craneman . . . . . . . . . . . . . | 4.00 | 4.00 |
| Fireman . . . . . . . . . . . . . . | 2.50 | |
| Six pitmen at $1.75 . . . . . . . . | 10.50 | 10.50 |
| One watchman . . . . . . . . . . . . . . | 1.75 | |
| One coal passer . . . . . . . . . . . . . | 1.50 | |
| Teaming (½ day) . . . . . . . . . . . . | 2.50 | |
| Oil and waste . . . . . . . . . . . . . . . | 1.50 | .75 |
| Total . . . . . . . . . . . . . . . . . . | $30.25 | $21.25 |
| Saving, electric over steam . . . . | 21.25 | |
| | $9.00 per shift | |

For convenience in comparing the costs of operation on steam and electric shovels, the costs are all reduced to a day basis.

| | Steam | ELECTRIC | |
|---|---|---|---|
| | | Direct Current | Equivalent Alternating Current |
| Interest at 6 per cent | $5.20 | $7.75 | $10.85 |
| Depreciation at 4 2 3 per cent . . . . . . . . . | 4.03 | 6.00 | 8.43 |
| Repairs at 10 per cent | 8.66 | | |
| Repairs at 6 per cent . . | | 7.75 | 10.85 |
| Labor per shift . . . . . . . | 30.25 | 21.25 | 21.25 |
| Total cost per shift . | $48.14 | $42.75 | $51.38 |

It has been assumed that, owing to weather conditions, delays, etc., the shovel working year consists of 150 days and the above figures are based on this assumption; also that the shovel is only working one shift a day.

If the shovel works three shifts a day instead of one shift a day, the interest and depreciation will remain the same, provided the shovel is kept in repair. It is reasonable to assume that the repairs will increase when working three shifts, but not in direct proportion; therefore, this item has been increased 50 per cent.

| | Steam | ELECTRIC | |
|---|---|---|---|
| | | Direct Current | Equivalent Alternating Current |
| Interest at 6 per cent | $5.20 | $7.75 | $10.85 |
| Depreciation at 4 2 3 per cent . . . . . . . | 4.03 | 6.00 | 8.43 |
| Repairs at 15 per cent | 13.00 | | |
| Repairs at 9 per cent . . | | 11.63 | 16.28 |
| Labor (three shifts) . . . | 90.75 | 63.75 | 63.75 |
| Total cost (three shifts) . . . . . . . . . . | $112.98 | $89.13 | $99.31 |

Disregarding the cost of coal and electric power, the saving of the direct-current shovel over the steam shovel would be $810 per year for one-shift operation and $3580 per year for three-shift operation.

The alternating current shovel when working one shift a day would show a loss of $486 per year. On the other hand, if this shovel worked three shifts a day it would show a saving of $2050.50 per year. Any greater saving than that shown would, of necessity, depend upon the comparative cost of coal and electric power, but as this is variable it can only be shown by dealing with each case individually.

Disregarding the cost of fuel, it is evident that the electric shovel is a better proposition than the steam shovel; that the direct-current equipment is far superior to the alternating-current equipment; and that the saving in operating expense will warrant the increased investment.

The control on either the direct or the alternating current equipment is reversible and entirely automatic, all panels being equipped with automatic acceleration, the hoist and crowd panels being also equipped with a "jam" relay which inserts resistance in the circuit in case of very heavy overloads, but does not open the circuit, the resistance being automatically cut out again by the same relay when the overload disappears. The master controllers are located similarly to the operating levers on a steam shovel so that a steam operator will be entirely at home on an electric shovel.

In selecting a shovel equipment it should be remembered that although it is possible to operate with alternating current, it is cheaper to use the direct-current equipment, even with a motor-generator set, and have an outfit which more nearly approaches the characteristics of the steam shovel, and has much simpler control apparatus and requires considerably less power to operate it than the alternating equipment with transformers. In addition to this, any change in the frequency would mean a complete change in the equipment of an alternating-current shovel while it would mean only a change in the induction motor of the motor-generator set, with possibly a change in the generator fields on a direct-current equipment.

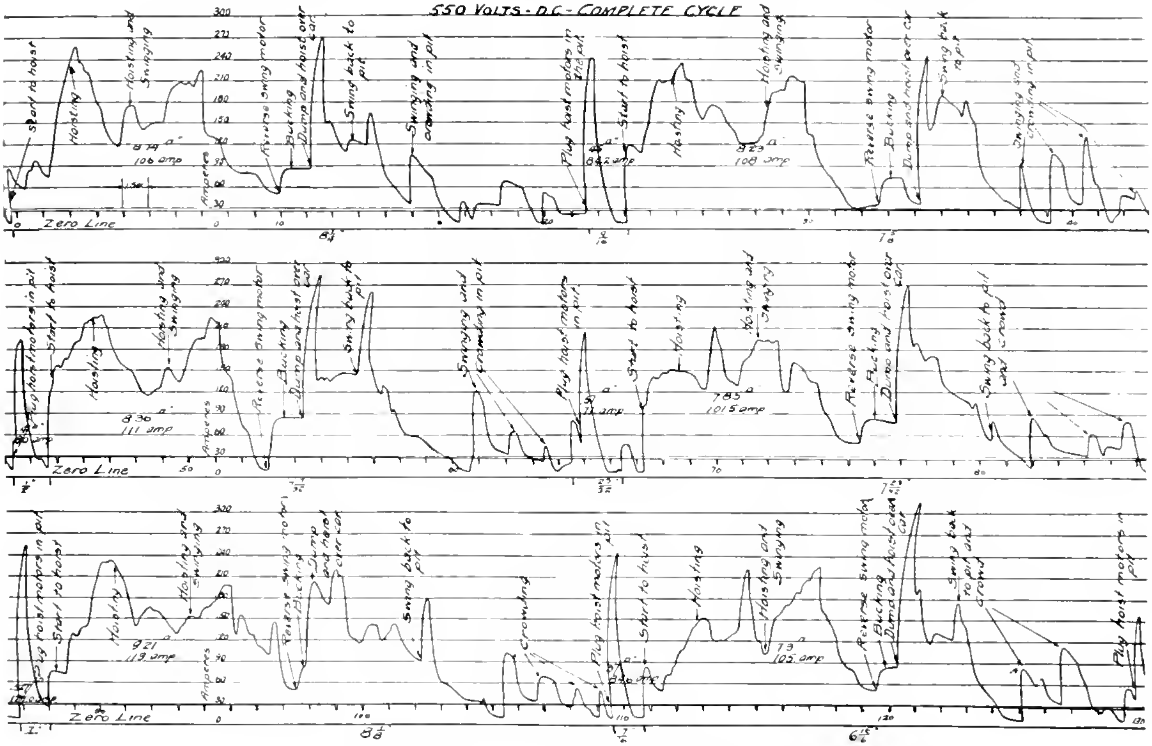

Fig. 6. A Graphic Recording Ammeter Record of the current input to the shovel shown in Fig. 3 taken over a period of six complete cycles

# SOME FACTORS GOVERNING THE SELECTION AND APPLICATION OF INDUSTRIAL MOTORS

By W. L. Merrill

Power and Mining Engineering Department, General Electric Company

The following article calls attention to one of the vital points in the selection of direct current motors for adjustable speed work and shows the fallacy of using the compound wound adjustable speed motor. We hope to have the author treat of other phases of motor application, both from the technical and practical side, in subsequent issues of the Review.—Editor.

W. L. Merrill

In discussing the various questions which arise, concerning the application of electric motors to industrial uses, it should always be borne in mind that there is no one type of motor which is suitable for all requirements. Unless a careful study is made of the specific requirements in each individual case and the correct motor selected to meet the service conditions, very serious mistakes may be made. Both the electric and mechanical features of the motor have to be given due consideration and a correct selection cannot be arrived at until the many various factors have been duly considered.

Before discussing the selection of the correct motor for any given service, it is well to study the different classes and types of motors available.

The tabulation on the opposite page gives the general types of alternating current and direct current motors, classified according to their windings.

From this, it will be seen that a very great variety of motors can be built by combining the electrical and mechanical features, and the list of possible motor designs is extended enormously when we consider the different kinds of bearings available; e.g., oil ring, waste pack, anti-friction, ball, roller, and bearings arranged to take thrust or arranged for vertical drive. In fact, there are so many possible combinations that there is a constant tendency to complicate the individual motor by including too many of the possible features and not limiting the selection to those features which are called for by the service conditions under which the motor is to operate. For instance, if a motor is required to operate under such conditions that acid-proof windings are desirable, after having specified such a winding, it is not necessary to use an enclosed motor for the purpose of protecting the windings from acid fumes, as provision has already been made for this in the type of insulation selected.

### The Fallacy of Compound Wound Adjustable Speed Motors

The tendency to use adjustable speed motors with compound windings is apparently due to a lack of knowledge of the characteristics of such a motor; the benefits gained by this use are in most cases imaginary.

There are two separate and distinct applications of adjustable speed motors: the first, generally used; the second, occasionally. The first case is in connection with machinery in which the load is nearly all dead load and friction, such as ordinary machine tools and the like, requires speeds of 2 to 1, 3 to 1, 4 to 1, and occasionally higher. On this class of machinery not only is no advantage gained by compounding the motor, but it is a positive detriment to its successful operation.

Assume, for example, a motor with a speed range from 300 to 1200. It is inherent in the design of such a motor that at full field or slower speeds, the motor has a heavy flux and the magnetic circuits are well saturated. If a certain amount of shunt winding is removed and replaced by a series winding giving the same ampere turns on the pole pieces with full load current passing through the motor, it will at once be seen that the torque is the same as if it were the original shunt motor. If, however, 100 per cent shunt winding is supplied on the motor and additional turns are supplied as a series winding, very little increased torque will result for the reasons mentioned above, that is, the magnetic circuits of the motor are nearly saturated under such conditions.

The same holds true if the motor is compounded as first mentioned and the control so arranged as to allow more than full load current to pass through at the time of starting.

Assume a shunt motor with a full field speed of 300 and a weak field speed of 1200. The field current at full load is 2 amp., and at weak field 0.45 amp. The regulation of this motor is shown in Fig. 1 as "A." It will be seen that, throughout the speed range of the motor, the speed remains practically constant for any variation or fluctuation of load at any particular setting of the control. This is very essential in the majority of classes of work, and particularly true with machine tool applications. It can readily be seen that, if an irregular casting, for instance, is being turned and the tool cutting at its maximum cutting speed and engaging the work for only a part of the periphery, the tool must not enter the work at a higher speed than it should cut. If it does, the tool will have a very short life. If the speed increases during the interval of light or no cuts, it will be readily seen that, during the remainder of the revolution, the machine speeds up at the interval of light or no cuts and it will be necessary to readjust this speed to the maximum cutting speed desired on the tool, and then when the tool enters the work the machine will slow down of its own accord and the cutting speed will be below normal. This leads to a loss of production. This is exactly what happens when an adjustable speed motor is supplied with compound winding and curves "B" on Fig. 1 show the regulation of such a motor having 80 per cent shunt winding and 20 per cent series winding. It will be seen from the curve that, with this motor running at no load, 1200 revolutions, the speed would slow down to about 600 revolutions under full load, and of course when the load was removed it would again return to 1200, while at the full field speed there would be little effect, due to the series winding.

ALTERNATING CURRENT

- Squirrel Cage

  - Accumulative
  - Differential

The different types of motors, classified according to their mechanical features are listed below. These mechanical features may apply to both a-c. and d-c. motors and any of the windings mentioned above may be used in conjunction with any of these types:

- Open
- Mechanically protected
- Semi-enclosed
- Totally-enclosed
- Enclosed externally ventilated
- Enclosed self ventilated
- Moisture-proof
- Splash or water-proof
- Acid-proof
- Submergible

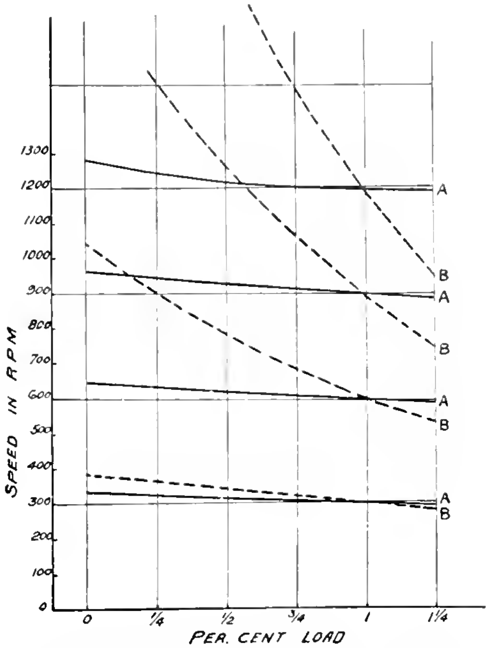

Fig. 1. Curves showing speed regulation of shunt and compound wound variable speed motors. A, shunt motor; B, compound motor.

On the other hand, assume that the motor was adjusted at the full load condition for approximately 1200 revolutions and then the

---

[*] The limitations of this type of motor are discussed in this article.

load was removed. The speed would follow the curve "B," which indicates a run away.

It is even suggested that this would be overcome by using a motor wound with a normal 100 per cent shunt and 20 per cent series winding. Under this condition a motor of this type would follow identically the same curves as shown, for if the motor were adjusted 1200 revolutions at full load, we must have the same flux in the poles, therefore, proportionately less current per turn, since there are the same number of series turns as above. It is therefore evident that the characteristics of a motor of this type is that of the shunt wound motor at full shunt field, gradually approaching the characteristics of the series wound motor at weak field.

To avoid the difficulties mentioned above, it is often suggested by those unfamiliar with the characteristics of such motors that series winding be cut out after the motor is started. First, this materially complicates the control; second, as noted above, little if any added starting torque is given the motor by this type of winding. Therefore, the absurdity is evident of applying such motors with compound winding to increase starting torque with a given current and then cutting this series winding out after the motor is up to speed.

It is often thought necessary to supply such motors with compound windings so that they can be started under weak field conditions; that is, wherever the field control rheostats happen to be left. With ordinary drum controllers as supplied for this service, it is impossible to shut the machine down from high speed to low speed without bringing the field to its full strength. Therefore, for use with such controllers this is unnecessary. With certain types of automatic control it is possible to start motors under weak field conditions where the starting arrangement and the field regulating control are separate.

Ordinarily, motors with speeds of $1\frac{1}{2}$ or 2 to 1 and in many cases higher, can be started equally as well on weak field as on full field and with the higher ratios of speed variation this can be readily taken care of by the use of the so-called "fluttering" relay in the circuit, which gives much better starting conditions than any combination of series winding which is cut in and out during starting.

The second class of applications mentioned above would be where an adjustable speed motor was to drive machinery in connection with a flywheel or heavy inertia load, where it was desired that the motor should speed up and slow down a certain amount with the change in load. Compound winding under such conditions may be advantageous in many cases, but the speed variation of such motors by shunt field control is usually very limited, say $1\frac{1}{4}$ or $1\frac{1}{2}$ to 1 and seldom 2 to 1. Under such conditions they are useful.

Of course, there are exceptions to all rules, and there are very special cases, such as some types of elevator applications, reversing motors for planers, and the like, where it may be necessary to accomplish certain desired results, not conflicting with the above conditions, to use compound wound windings, but these are very limited and for all other classes of work where adjustable speed motors are used, compound windings are not necessary and in the majority of cases are not only an added complication but are a detriment to the equipment as a whole.

## QUESTION AND ANSWER SECTION

### ANNOUNCEMENT

The pages of the Question and Answer Section have been omitted from this issue of the REVIEW on account of space limitations in this our largest number to date.—EDITOR.

# FROM THE CONSULTING ENGINEERING DEPARTMENT OF THE GENERAL ELECTRIC COMPANY

## THIRD HARMONIC

If three auto-transformers, Y-connected with the neutral grounded as the only ground, are used to step up the generator voltage, abnormal potentials to ground may result. These excess voltages are not measured by a voltmeter but may be by indicated static discharges on the leads, or by a spark gap connected between one line and the ground. The reason for this is that the effective value of the voltage read by the voltmeter is not greatly changed, but only the maximum value of the wave is increased which is indicated by a spark gap, or by a stress on the insulation. The cause of the voltage distortion is as follows:

When a sine wave e.m.f. is applied to a transformer, the resulting magnetizing current wave cannot be a sine wave but must follow the changing permeability of the iron; this current wave is a distorted wave containing a third harmonic. The current and voltage waves can never be the same, but if the magnetizing current is a sine wave, the voltage wave must then contain a third harmonic. Hence, if anything prevents or suppresses the third harmonic the voltage must then become distorted.

In a three-phase transformer the currents are 120 deg. apart for the fundamental frequency, or 3×120 or 360 deg. apart for the third harmonic—that is, in phase. Thus for Y-connected auto-transformers the triple frequency magnetizing currents to the neutral must be in phase. The sum of the three currents flowing to a point must be zero. Hence, as the third harmonic magnetizing currents are all in phase, they must be zero to satisfy these conditions—that is, they must be suppressed. This means that the voltage to the neutral cannot be a sine wave but must be distorted, or peaked, or contain the third harmonic, which appears as increased voltage to the neutral and causes extra iron and insulation loss. A distortion does not appear in the voltage between lines because the distortion between one line and the neutral is cancelled by that of the other two lines. The voltage distortion may be eliminated by supplying a path for the triple frequency exciting current; that is, in this case, by connecting the transformer neutral to the generator neutral. This supplies a single-phase circuit for the triple frequency through the line and generator. A current of the proper phase relation flows and the distortion disappears.

If before the connection is made to the generator the transformer is connected to a transmission line a path is supplied for the triple frequency current through the capacity from line to ground. This capacity offers three single-phase circuits. A triple frequency current thus flows, but it has not the proper phase relation for the triple frequency excitation current and instead of eliminating the voltage distortion it greatly increases it. Two or three peaks may occur in the fundamental voltage wave and an increased iron loss result. This distortion, however, also generally disappears when the auto-transformer neutral is connected to the generator neutral. Without this interconnection the distortion is greater in the case where the transformer is connected to a capacity. The peak of the wave may be several times normal. There are other ways of supplying this third harmonic current; for instance, by a closed delta in the transformer.

The transformer third harmonic is a "constant current" effect—that is, the voltage drops when triple frequency current, with the proper phase relation, flows.

There may also be a third harmonic in the generator wave, due to the relations of the windings, which has a "constant voltage" effect and which may produce a very heavy triple frequency current when improper connections are used, or when a path is afforded for these currents. Precautions are thus necessary where several generators are connected in parallel and the neutrals grounded. If all of the generators are of an identical design, very large triple frequency excitation currents may flow unless the field excitation is the same on all the generators. If the generators are not of an identical design dangerously large triple frequency currents may result. When a number of generators are operated in parallel and the voltage is stepped up by auto-transformers, it is often practicable to ground only one generator at a time and to connect this to all of the transformer neutrals.

Whenever auto-transformers are used it is necessary to investigate the possibilities of trouble for the particular case under consideration. Their use is generally not to be recommended. F.W.P.

# IN MEMORIAM

Henry Augustus Pevear, the first and only President of the Thomson-Houston Electric Company, died at his home in Lynn, Mass., on May 14th, of heart failure. His death was not unexpected, as he had been failing for weeks.

Mr. Pevear was in his 86th year, as he was born in Tewksbury, Mass., on September 13, 1828. He is survived by four sons and one daughter, twelve grandchildren and thirteen great grandchildren; Mrs. Pevear and a daughter died a few years ago. He had been a successful morocco manufacturer for forty-five years, and he was one of the group of men who purchased the American Electric Company, re-organized it as the Thomson-Houston Electric Company, and moved it to Lynn in 1883. He was made president of the new company.

Henry Augustus Pevear

During the succeeding ten years, the Company was successful and important progress was made in electrical development. Mr. Pevear retired from the presidency when the Company was consolidated with the Edison General Electric Company. He was president of the Lynn five-cent Savings Bank and a director of the City National Bank for a number of years. He retired from active business about twenty years ago, and devoted himself to charities, to which he has made large donations.

The most notable of his philanthropies was the gift of his large summer estate at Barre, Mass. as the Stetson Home for Orphan Boys, endowing it with $250,000 in memory of his mother. As a memorial to his wife, there is now being erected a children's ward, provided by Mr. Pevear, as a part of the Lynn hospital.

Mr. Pevear combined scrupulous honesty, well balanced conservatism, and straightforward business dealing. He leaves many friends, among whom are men now prominent in the electrical field who worked with him in the Thomson-Houston Company, and who cherish the memory of the association.

# GENERAL ELECTRIC REVIEW

## THE PATHS OF PROGRESS

The thirty-seventh convention of the National Electric Light Association was held in Philadelphia during the first week in June. All who attended many of the sessions must have been profoundly impressed with the progress of the industry, and this impression was much intensified by those papers and reports that compared present activities with those of earlier periods.

The report of the committee on progress, with T. C. Martin as the committee, seems to lend strength to the old adage that when real business is to be accomplished there is nothing like a committee of two with one member sick in bed. Mr. Martin's report is an astonishing document and leaves one somewhat bewildered by the mass of facts and figures that he has so ably marshalled to give a really comprehensive picture of the progress made. The following quotations are from Mr. Martin's report:

"The figures as given for the continental United States show general and remarkable gains for the decade 1902–12. The number of commercial stations or plants increased from 2805 in 1902 to 3659 in 1912, or 30 per cent. The number of municipal plants increased from 815 in 1902 to 1562 in 1912, or 92 per cent, but their relative proportion in the industry has declined. The total income for 1912 amounted to $302,115,599, as compared with $85,700,605 in 1902, or an increase of 252 per cent. The total expenses, including salaries and wages, in 1912, amounted to $234,419,478, as compared with $68,081,375 in 1902, or an increase of 244 per cent. The total number of persons employed in 1912 was 79,335, as compared with 30,326 in 1902, or an increase of 162 per cent. The total horse power of the steam engines and steam turbines was 4,946,532 in 1912, as compared with 1,394,395 in 1902, or an increase of 255 per cent. The horse power of the waterwheels was 2,471,081 in 1912, as compared with 438,472 in 1902, or an increase of 464 per cent. The output of stations amounted to 11,502,963,006 kw-hr. in 1912, as compared with 2,507,051,115 in 1902, or an increase of 359 per cent. The estimated number of arc lamps wired for service in 1912 was 505,395, as compared with 385,698 in 1902, or an increase of 31 per cent. Incandescent and other varieties of lamps wired for service, however, numbered 76,507,142 in 1912, as compared with 18,194,044 in 1902, or an increase of 320 per cent. The horse power rating of the stationary motors served with electricity amounted to 4,130,619 in 1912, as compared with 438,005 in 1902, or an increase of 843 per cent."

It is particularly noted that in the above the term "station" may represent a single station or a number operated under the same ownership and that the electric railway stations are treated under another head by the Census Bureau report and are not included in the total number of 5221 establishments shown above. Such statistics speak more eloquently of progress made than volumes of platitudes and generalities.

It will surely astonish many people to learn that "there were engaged in the manufacture of electrical machinery, apparatus and supplies in the United States in 1909, a total of 1009 establishments."

In dealing with the security of public utilities as investments, the report shows a very promising state of affairs. Mr. Martin in quoting a paper by Mr. Oldham says:

"Mr. Oldham gave instances to show that while municipal and railroad bonds have depreciated somewhat in value in the last ten years, public-utility bonds have generally appreciated in value. A computation was made by the author to show the comparative returns from the three classes of bonds between 1901 and 1912. Representative public-utility, municipal and railroad issues were selected, and every effort was made to make a fair investigation. It was shown that the purchaser of $1,500,000 of public-utility bonds would have received an income on his total investment from date of purchase to July 1, 1912, of $487,500 and a gain in market value of $27,377, or a total of $514,877. From the municipal bonds the income was $326,551, and the loss due to depreciation, $106,989, leaving a net return of $219,562. Income from the railroad bonds was $399,691 and the loss due to depreciation $70,065, leaving a net return of $329,626. Therefore, the net difference in favor of public-utility over municipal bonds was $295,315 and over the railroad bonds was $184,891."

Much of our modern progress can be traced to the scientific study of ways and means effecting economies in every branch of the industry and in finding new fields for the use of energy. The report quoting from an address of Mr. Insull, says:

"Only about 40 per cent of the coal burned per unit generated ten years ago is now required for the same output. He exhibited a diagram showing that from 1896 to 1912 the business of the Commonwealth Edison Co., had grown about $1,000,000 a year to about $16,000,000, the latter figure being divided into $8,000,000 for lighting, a little more than $4,000,000 for industrial motor service and a little less than $4,000,000 for energy for transportation purposes. Improvements in lamp efficiency helped to decrease the cost of electric light. As to the wholesaling of electrical energy, backed by the courage of a body of investors which has stood behind him for more than twenty years, Mr. Insull tried out several experiments, with the result that he has been able to bid for classes of business not until recently supposed to be within the reach of electric-service companies. The problem is to keep the investment working for as many hours of the day and as many days of the week as is possible. About 1902 this effort to fill up the valleys in the load curve as much as possible was begun, and it was so successful that by 1912 the Commonwealth Edison Co. was using its investment 31 per cent more of the time than ten years before."

# RECENT VIEWS ON MATTER AND ENERGY

## Part I

By Dr. Saul Dushman
Research Laboratory, General Electric Company

This is the first installment of a series of articles by Dr. Dushman on our modern views of matter and energy. Modern investigations point to a monistic view of all natural phenomena. The atomic theory, which was originally developed to "explain" the structure of matter, has been extended to electrical phenomena, as the electron theory, and more recently still we have seen the development of an atomic theory of energy or quantum theory. The author discusses here the evidence which has led to the formulation of the electron theory of conduction in metals and gases. The subsequent installments will deal with the atomic view of energy, as well as its application in widely different fields of investigation; and will in conclusion discuss the application of the electron and quantum theories to the development of a theory of the structure of atoms and molecules.—Editor.

## INTRODUCTION

"The close of the old and the beginning of the new century has been marked by a very rapid increase of our knowledge of that most important but comparatively little known subject—*the connection between electricity and matter.* No study has been more fruitful in surprises to the investigator, both from the remarkable nature of the phenomena exhibited and from the laws controlling them. The more the subject is examined, the more complex must we suppose the constitution of matter in order to explain the remarkable effects observed. While the experimental results have led to the view that the constitution of the atom itself is very complex, at the same time they have confirmed the old theory of the discontinuous or atomic structure of matter. The study of the radio-active substances and of the discharge of electricity through gases has supplied very strong experimental evidence in support of the fundamental ideas of the existing atomic theory. It has also indicated that the atom itself is not the smallest unit of matter, but is a complicated structure made up of a number of smaller bodies."[1]

Upon these atomic theories of electricity and matter there has been superposed in the last few years an atomic theory of energy which promises to alter radically all the ideas that have been held hitherto on the nature of energy and its mode of transmission. The experimental observations on the laws of distribution of radiant energy have led to conclusions that are apparently opposed to the electrodynamical equations deduced by Maxwell from the principle of least action. It has been shown that the view that energy is emitted and absorbed continuously is unable to explain the variation in distribution of radiant energy with the frequency of the radiation when this frequency is very high. An atomistic view of energy—or *quantum theory*, as it has been designated, is necessary not only in order to account for the observations of Lummer and Pringsheim and others on the distribution of intensity of radiation in the ultra-violet and visible portions of the spectrum, but this theory also leads to conclusions that are strikingly confirmed by observations in such vastly different fields of investigation as those of specific heats, the photo-electric effect and the production of X-rays.

And piling Pelion upon Ossa, the scientific iconoclast finally concludes that matter in itself has mass only in virtue of the motion of its constituent electrons, thus robbing us at once of what we had hitherto supposed to be a fundamental attribute of matter.

Never in the history of science has there existed such a period as the present: A period in which discoveries have multiplied more rapidly and the scientific imagination has risen to higher flights. It is an epoch.

"When every morning brings a noble
chance,
And every change brings out a noble
knight."

Within the past two decades we have seen the discovery of X-rays and radio-active phenomena on the one hand, and the evolution of the electron and quantum theories on the other. It has been found necessary to discard the old idea that the atoms of the elements are permanently stable and to replace this by the view that the atoms of the radio-active elements are "unstable dynamical systems," while it is quite probable that the atoms of all the elements are more or less unstable.

One of the first conclusions drawn from the application of the theory of energy quanta was that regarding the nature of X-rays. A large amount of experimental evidence has been obtained in the last two years confirming this conclusion and now we have every reason to believe that X-rays as well as gamma rays are electromagnetic waves of extremely short wave length, the frequency of these radiations

---

[1] E. Rutherford, Radio-active Substances and Their Radiations, 1913, p. 1.

being about ten thousand times as great as that of ordinary visible radiation.

Laue, the Braggs and others have shown how X-rays may be utilized to *determine crystal structures.* Mosely and Darwin have still more recently investigated the X-ray and gamma ray spectra of a large number of elements and their observations are most easily interpreted in terms of the atomic model which had been previously suggested by Rutherford and Bohr. Not only are we learning something about the manner in which the atoms and molecules arrange themselves to form crystal structures, but we seem to be on the verge of learning something about the innermost structure of the atom itself.

This is not all. The very concept of matter itself is being questioned. We have been familiar for some time with the notion that the electron possesses mass in virtue of its charge. Now the work of Marsden and Geiger on the scattering of $\alpha$-particles when passing through different substances led Rutherford to the suggestion that the mass of the positive nucleus itself may also be of electrical origin.

The most fundamental magnitude of physics and chemistry is therefore the unit negative charge or electron. Maybe there exists a positive electron corresponding to this unit of negative electricity and it is probable that the positive nucleus of the hydrogen atom is this long-sought-for unit of positive electricity. But the great outstanding fact is that all the investigations of recent years are converging towards a monistic view of natural phenomena. As mentioned above, we have atomic theories not only of matter and electricity but also of energy. Everywhere we are confronted with discontinuities in regions which have hitherto been assumed to be best represented by continuous functions.

The later conclusions must, however, be regarded as not being distinctly at variance with the older views but rather as an extension and evolution of the older theories which has been found necessary, owing to the accumulation of a large amount of new experimental evidence. We must never lose sight of this point, that the observations must always preceed the theory and while the latter may be in a state of continuous flux, the facts remain. To evolve a unitary concept which shall reconcile the known facts of the past with the results of recent investigations is a stupendous undertaking; but the difficulties are by no means insurmountable and judging from the vigor with which the whole problem is being attacked by the foremost scientists of the present time, it is quite certain that the next decade will see developments in physics even more startling than have been accomplished in the past two decades.

As yet the effect of these altered views has been felt mainly by the theoretical physicist. To the practical physicist, the engineer at large, the chemist, and interested layman, these new concepts are either unfamiliar or else disregarded because of a much advocated doctrine which may be labelled empiricism, pragmatism, or agnosticism, according as befits the philosophical views of each individual.

But just as the speculations of Carnot, Meyer and Clausius formed the foundation upon which the engineer of the present has developed methods of energy transformation, just as the almost incomprehensible flights of imagination of Maxwell were realized in the wireless waves as used commercially today, even so no doubt those atomistic theories of energy and electricity which we see under evolution at present will form the starting points for new developments by the engineer, whose happy function it has always been to realize in tangible form what the physicist beholds only as a vision.

It has been thought that an account of the results of the recent investigations might be of interest to that large class of readers whose daily labor is apt to get them out of touch with such developments. If, in the attempt to carry out this object, the writer shall have succeeded in imparting to his readers even a fraction of the information and inspiration that he has derived from the writing of the paper, he will deem his efforts amply rewarded.

## ATOMIC THEORY OF ELECTRICITY

### Charge on a Univalent Ion in Electrolysis

The ionic theory of solution has familiarized us with the idea that atoms or certain groups of atoms in solution carry electric charges which are integral multiples of that carried by a charged atom of hydrogen. These charged atoms or groups of atoms, known as ions, are the carriers of the electric current in the solution and liberate their charges at the electrodes during the process of electrolysis. Thus in the case of a solution of hydrogen chloride (HCl), the ions are $\overset{+}{\mathrm{H}}$ and $\overset{-}{\mathrm{Cl}}$, the positive and negative signs denoting that the hydrogen and chlorine ions are transported during electrolysis in the positive and negative directions of the current respectively.

From Faraday's law and a knowledge of the number of atoms contained in one gram-ionic weight[2] of a substance it is possible to calculate the charge per atom, or the *unit electric charge*. According to Faraday's law, the electric charge carried by 1.008 grams of hydrogen (one gram-ion) is 96,540 coulombs. The number of atoms contained in the above weight of hydrogen is the same as the number of molecules per gram-molecular weight. This is usually denoted by $N$ and according to the most accurate determination it has the value $6.06 \times 10^{23}$.

The unit electric charge as deduced from observations on conduction through electrolytes is therefore

$$\frac{96540}{6.06 \times 10^{23}} = 1.57 \times 10^{-19} \text{ coulombs.}$$

Since 1 coulomb is equal to $10^{-1}$ electromagnetic units (e.m.u.) or $3 \times 10^{9}$ electrostatic units (e.s.u.) the electric charge on a univalent ion in solution may be expressed as $1.57 \times 10^{-20}$ e.m.u. or $4.78 \times 10^{-10}$ e.s.u.

Furthermore, the ratio of the charge to the mass of a hydrogen atom in electrolysis ($e/m$) is $9.654 \times 10^{3}$ e.m.u. per gram.

### Cathode Rays. Ratio of Charge of Mass

In the case of the conduction of electricity through gases and metals, the same question arose as to the nature of the carriers of the electric charges. Obviously the conduction does not take place by means of charged atoms or groups of atoms as in the case of electrolytes. J. J. Thomson, continuing the experiments of Crookes on the nature of the electric discharge in high vacua, showed that the cathode rays observed in these experiments consist of *negatively charged corpuscles* which starting from the cathode move with very high velocities in straight lines and produce a vivid fluorescence wherever they strike the glass walls of the tube. Now it was shown a long time ago by Rowland that a charged particle in motion must produce the same effects as are observed in the case of a wire carrying current. In other words, the direction of motion of a charged particle will be affected by magnetic and electrostatic fields just as a wire carrying current. Furthermore the magnitude of the effects observed depends upon the ratio of the charge ($e$) to the mass ($m$) of the particles and upon their velocity. By observing the amount of deflection suffered by the cathode rays when subjected to magnetic and electrostatic fields, J. J. Thomson concluded that the negatively charged corpuscles constituting these rays have a value of $e/m$ of about the order of magnitude of $1.2 \times 10^{7}$ e.m.u. per gram. Later experiments have led to the more accurate value $1.76 \times 10^{7}$. The velocity of the corpuscles was found to vary from $10^{7}$ to $10^{9}$ cms. p.s.

Comparing the above values of $e/m$ with that obtained for hydrogen ion in electrolytic conduction ($9.654 \times 10^{3}$ e.m.u. per gram), the conclusion follows that either the unit electric charge is much greater in the latter case than in that of the cathode rays or that the mass of the negatively charged corpuscle is

$$\frac{9654}{1.76 \times 10^{7}} = \frac{1}{1835}$$

of that of the hydrogen atom.

Now, apart from the evidence obtained by a large number of experimenters that the corpuscles constituting the cathode ray beams must have masses much smaller than that of the hydrogen atom, there are definite reasons for believing that the unit electric charge in the cathode ray discharge has the same value as that possessed by the hydrogen ion in electrolytic conduction.

### Unit Charge in Gaseous Conduction

When X-rays pass through a gas they cause the latter to become conducting, that is ions are produced throughout the gas. These ions possess the property of acting as condensation nuclei for water-vapor in a supersaturated state and, by varying the conditions of the experiment, the condensation may be made to occur either on the positive or negative ions. By noting the rate of fall of the cloud formed by this condensation, measuring the total charge carried by the condensation produced and knowing the degree of supersaturation of the vapor, it is possible to determine the minimum charge carried by each ion, and consequently the unit negative charge concerned in gaseous conduction. This was the method adopted by C. T. R. Wilsons in 1898.

Within the past two years Prof. Millikan has, however, obtained much more accurate data by the "oil-drop method." In this method the ions produced by the action of X-rays attach themselves to oil-drops suspended between two horizontal plates which are connected to the terminals of a high

---

[2] The gram-molecular weight of any substance is that weight in grams corresponding to its chemical formula. Similarly the gram-ionic weight is the weight in grams corresponding to the formula of the ion.

voltage battery, so that the rate of fall of the charged oil drops can be measured both in the absence of an electric field, and under the combined action of the latter and gravity. From observations on the rate of fall under these different conditions, it is possible to calculate the charge carried by the oil-drop. It was found by Prof. Millikan that in all his observations, the actual magnitude of this charge was always an integral multiple of that calculated for a hydrogen ion in electrolysis, viz.: $4.8 \times 10^{-10}$ e.s.u.; furthermore that while the charge on any oil drop under observation altered from time to time owing to collision with other ions or molecules, the magnitude of the change was never less than $4.80 \times 10^{-10}$ e.s.u. The most accurate value of this unit electric charge according to Prof. Millikan's most recent determinations is $4.77 \pm 0.009 \times 10^{-10}$ e.s.u.

These investigations thus lead to the conclusion that the unit electric charge is the same for both gaseous and electrolytic condition. Consequently the mass of the negatively charged corpuscle constituting the cathode-rays must be $\frac{1}{1835}$ of that of the hydrogen atom.

### Electron Emission from Hot Bodies. Photo-Electric Effect

The cathode-rays of an ordinary discharge tube such as is used for the production of X-rays is not the only case in which these negatively charged corpuscles, or *electrons*, as they have been designated, are obtained in the free state. O. W. Richardson[3] and his associates have shown that heated metals emit negatively charged corpuscles with the same value of $e/m$ as that obtained for cathode rays. The number of these electrons emitted per unit area of surface increases rapidly with the temperature according to the formula

$$i = A\sqrt{T}\epsilon^{-\frac{b}{T}} \qquad (1)$$

where $A$ and $b$ are constants and $i$ denotes the current per unit area.

Dr. W. D. Coolidge[4] has utilized this phenomenon in the construction of an X-ray tube in which the X-rays are produced by the bombardment of a tungsten anode by electrons moving with very high velocity. As source of electrons he used a heated tungsten filament.

In further elaboration of Richardson's work, Dr. I. Langmuir[5] has shown that under certain conditions the electrons emitted from the heated metal can produce a space charge outside the metal which prevents the emission of more electrons and quantitative confirmation has been obtained by the writer[6] of the conclusions deduced by him on the assumption that the thermionic currents obtained are due to the actual emission from heated cathode of charged particles having a ratio of charge to mass of the same value as that obtained for the electrons in cathode ray tubes.

Electrons are also emitted from all metals under the influence of ultra-violet light. This is the well-known photo-electric effect. The more electro-positive the metal, the lower the frequency of the light that is capable of causing photo-electron emission, and in the case of the alkali metals photo-electric currents of considerable magnitude are obtained even when ordinary light is used as a source of illumination.

In the case of both thermionic and photo-electric emission we are dealing with pure electron currents in a vacuum. There is an actual convection of negatively charged corpuscles from the heated metal or illuminated surface (which has to be charged negatively) to the anode. It is true that, within the past two or three years, doubt has arisen among a large number of investigators as to the existence of such pure electron currents in high vacua. The tendency has been to ascribe both thermionic and photo-electric effect to chemical reactions occurring at the surface of the metal. But the results obtained by Dr. Langmuir and his associates on the thermionic currents in very high vacua and by Millikan, Richardson, the writer and others on the photo-electric effect in the best vacua obtainable, only seem to confirm the older views that such pure electron currents actually exist *per ipse* and are not due to any secondary effects due to the presence of gases.

### Electron Theory of Conduction in Metals

The emission of electrons from heated metals and under the influence of ultra-violet light can only be explained on the assumption that at any temperature there are present in the metal a certain number of free electrons and that there exists an equilibrium between the concentration of these free electrons inside

---

[5] Phys. Rev., *2*, 450, (1913).

[6] Phys. Rev., *3*, 65, (1914).

the metal and in the surrounding space. With an increase in temperature the concentration of free electrons in the metal increases and consequently the emission of electrons also increases. The electrons must therefore be regarded as an essential constituent of all atoms.

According to the most recent theory, that suggested by Bohr, the atom is considered as being composed of one or more rings of electrons which are in constant rotation about a positively charged nucleus, the total charge on the latter being equal and opposite to that on all the electrons external to it. Owing to the vibrations among the atoms themselves, some of these electrons acquire sufficient kinetic energy to enable them to travel out beyond the influence of the forces which ordinarily hold them at a fixed distance from the positive nucleus. The latter is consequently able to attract any other free electron that comes within its field of attraction. At any instant there are thus present a certain number of free electrons, and it is by means of these free electrons that both electric charges and heat are conducted through the metal. An electron theory of conduction was suggested even before the investigation of J. J. Thomson by Riecke and Drude. The latter was able in this manner not only to give a theoretical basis to the well-known Wiedemann-Franz relation, according to which the ratio of thermal to electrical conductivity at any temperature is approximately the same for all metals, but he showed that there exists an intimate relation between the electrical conductivity and the thermo-electric properties of any metal.

Regarding the actual number of free electrons present under given conditions, we are as yet unable to draw any definite conclusions. The electron theory of conduction is as yet in a far from completed state. Recent speculations[7] of Keesom and others indicate that a theory in harmony with all known observations will probably be developed in the very near future. But even in its present state the theory proves of considerable advantage correlating a large number of phenomena while simplifying a number of concepts that are prevalent in electrical engineering.

Considering an electric current in a metallic conductor as due to a convection of charged particles, it is seen that electrical resistance may be simply regarded as a frictional resistance tending to oppose the flow of current. It follows also that the energy which we ordinarily conceive as being used to establish a magnetic field is really the energy required to set the electrons in motion, in other words, to overcome the inertia of the charged corpuscles. The same amount of energy must be restored to the conductor when the stream of electrons is suddenly stopped. The physical significance of what is meant by inductance thus becomes apparent.

Again, if the electron is made to oscillate backwards and forwards, as in the case of an alternating electric current, the magnetic field at any point in space must vary correspondingly and since the electron also exerts an electrostatic force, the magnitude of this at any point in space must also vary in a similar manner. In other words, if the motion of the electrons in the wire is harmonic, there will be propagated into the surrounding space two linear harmonic disturbances at right angles to each other and to the direction of motion of the electron. One of these disturbances will cause variations in the magnetic intensity at any point in space, while the other will cause corresponding variations in electrostatic force. It is also evident that such disturbances will affect the electrons in other conductors and these elections will consequently execute harmonic vibrations of the same frequency as that of the original exciting electrons. That is, an electromagnetic wave is produced.

### Zeeman Effect. Explanation in Terms of Electron Theory.

The explanation of the Zeeman effect in terms of the electron theory must be regarded as one of the most important triumphs of this theory.

Assuming in accordance with Bohr's theory of the structure of the atom that light is produced by the vibration of electrons in the atom around a positive nucleus, it easily follows that the frequency of this vibration ought to be affected by a magnetic field, for the latter will exert a force which will either aid or oppose the centripetal force which is exerted by the positive nucleus on the rotating electron, according as the direction of rotation is either right-handed or left-handed with respect to the lines of magnetic force.

If now a source of monochromatic light emitting radiation of frequency $\gamma_0$ is placed in a magnetic field, the frequency of some of the electrons is increased while that of others is decreased. The consequence is that in-

---

[7] Phys. Zeitschrift, *14*, 665, (1913).

stead of one line in the spectrum we perceive three lines, the two outer ones being due to the vibrations set up by the electrons whose orbits are affected in opposite senses, while the center line has the same frequency as the original light and is due to the electrons whose orbits are situated in a plane that is parallel to the direction of the lines of magnetic force.

Denoting the frequencies corresponding to the outer lines by $\gamma^1$ and $\gamma$ respectively, it was shown by Lorentz that

$$(\gamma^1-\gamma)\ \frac{2\pi c^2}{H}=\frac{e}{m} \qquad (2)$$

Here $c$ denotes the velocity of light and $H$ the strength of the magnetic field. The values of $e/m$ deduced by this method have been found to be in good accord with those obtained by measurements on cathode rays and are recognized as of equal weight with these other values.[8]

A similar explanation has been given of the observed rotation of the plane of polarization by a substance in a magnetic field (Faraday effect).

### Electron Theory of Magnetism

The electron theory of magnetism is one of the most important and most interesting applications of the new views. It is evident that the rotation of an electron about its nucleus must produce a molecular magnet having its axis perpendicular to the plane of rotation of the electron. This is the fundamental idea of the electron theory of magnetism. Langevin and Weiss have extended the theory to explain the phenomena of para- and ferro-magnetism. To explain the latter, Weiss has introduced the idea of magnetons or elements of magnetic moment corresponding to electrons.[9]

### Summary

The above are only a few of the many fields of application of the electron theory. It has proven of immense value in correlating a large number of observations, which is after all the prime purpose of any theory, and furthermore its application has led to the discovery of a large number of new phenomena which would not have been otherwise suspected.

Let us review then very briefly what we have learnt regarding the evidence upon which the theory is based and its main assumptions. The fundamental experiments upon which it is based are those of J. J. Thomson and others, showing that electrical conduction in gases takes place largely by means of small negatively charged corpuscles having a ratio of charge to mass which is 1835 times as great as that for hydrogen in electrolysis. Another line of investigation has led to the conclusion that the unit negative charge is the same in all cases. Consequently the mass of the negatively charged corpuscle or electron must be $\frac{1}{1835}$ of that of the hydrogen atom.

In other words, we are led to the conclusion that electricity is transported in multiples of a unit charge which has the magnitude of $4.8\times10^{-10}$ e.s.u. This may therefore be said to be an atomic theory of electricity, similar to the older atomic theory of matter.

The electron theory of the constitution of the atom gives a logical explanation of all the phenomena of conduction. According to this theory the atoms of all elements contain under normal conditions one or more negatively charged corpuscles together with a positive nucleus.

Under the influence of different re-agents, such as ultra-violet light, high temperature, X-rays, $\gamma$-rays, or an intense electric field, the atom may lose one or more of its electrons, and the latter are then emitted with velocities that vary from $10^7$ to $10^9$ cms. per second. These electrons travelling with high velocity are capable of detaching more electrons from gas molecules with which they collide and thus produce the phenomenon of ionization by collision. The positively charged residues or ions produced in this manner are attracted to the cathode of the discharge tube and bombard it with velocities sufficiently great to cause the emission of more electrons. We thus obtain the various phemonena of gaseous conduction which vary from the Geissler discharge to the arc.

Again, the drift of these electrons in metallic conductors under the influence of the electric force constitutes a current, and for the quantitative explanation of this phenomenon, it is only necessary to assume that, owing to the vibrations of the atoms in the solid, there is a continual separation of electrons from these atoms as well as a re-combination of the free electrons with the charged residues so that there is always present a small number of free electrons. On this assumption it is then possible to represent physically not only such electrical concepts as resistance and inductance, but also the mechanism by which electro-magnetic radiations are emitted and absorbed.

[9] E. H. Williams, the Electron Theory of Magnetism. Bull. 63, Univ. Illinois Engineering Experiment Station.

The electron theory of conduction enables us not only to deduce the relation between electrical and thermal conductivity of metals, (Wiedemann-Franz law) but also indicates relations between the electrical conductivity and thermo-electric properties.

Finally, the theory has also received splendid confirmation in the explanation of the Zeeman effect and other magneto-optical phenomena.

# THE DUBLIN, IRELAND, THREE-PHASE FOUR-WIRE DISTRIBUTION SYSTEM

By Gilbert Archer

Assistant to Chief Engineer, Dublin Corporation Electricity Supply

We frequently find, in the various scientific papers, descriptions of the many pieces of apparatus installed in generating stations and the methods employed in regulating and handling these. Such descriptions are always welcomed by electrical engineers the world over, for it keeps them in touch with what is being done in centers other than those with which they are immediately concerned. It is not often, however, that one finds any description of the means used in the distribution of the power generated, from the time it leaves the switchboard at the generating station until the time it is delivered to the consumer in the workshop, business premises or private residence. The author has set out below the means adopted in Dublin, believing that it will be of interest to engineers who have charge of similar networks, or who are employed in designing and laying out systems of distributing cables for future use. The Dublin system is one of the largest three-phase, four-wire secondary distribution systems installed, the connected load being approximately 11616 kw. There is 4500 h.p. connected and the maximum load on feeders is about 5510 kw., the area served by the system being approximately 12 square miles.—Editor.

The city of Dublin receives its supply of electricity as three-phase alternating current, this being generated at 5000 volts. The location of the generating station (marked *A* on Fig. 1) is some $3\frac{1}{2}$ miles from the main distributing station (marked *B* on Fig. 1). From the switchboard at the generating station, trunk feeders—seven in number, at present, each having three cores of 0.15 sq. in. section—bring the supply to the main distributing station switchboard. These feeders are connected to the busbars of the switchboard through three-pole oil-break automatic switches fitted with reverse-current relays. These relays ensure the isolation at the distribution station end of any feeder developing a fault; while other relays in the generating station make equally sure of isolating it at that end. The reverse-current relays are set to operate at 10 per cent of the full load current.

The switchboard in the distributing station, Fig. 2, is divided into five sections, each section being fed by its own trunk feeder or feeders, which are connected by means of sectionalizing oil-break switches of the overload automatic-release type. Normally, the sectionalizing switches are in the "on" position, the five sections being connected together forming one large switchboard. Should the busbars on any section break down to earth or short-circuit, the sectionalizing switches at each end of this section trip out, on account of the rush of current through them, and thus isolate it from the remainder of the board.

From the busbars of the switchboard, subfeeders are led through automatic triple-pole oil-break overload type switches to the different substations erected in various parts of the town. The supply still remains at 5000 volts and the cables used are similar to the trunk feeders, being three-core, paper-insulated, and lead-covered. The cores in this case, however, are only of 0.1 sq. in. section.

Each substation is fed by either one or two high-tension sub-feeders and, in addition to this, certain substations are linked together by interconnecting cables. This makes it possible to feed a substation through another cable, in the event of one of its sub-feeders breaking down, by means of the interconnectors, or to assist one substation, should its own sub-feeder be overloaded, by coupling up the interconnectors and feeding partly from another substation or substations.

Fig. 1 shows the high-tension sub-feeders and interconnectors diagrammatically, *A* being the generating station, *B* the main distributing station and 1, 2, 3, etc., being the substations.

It will be noticed that substations 29, 4, 28, 25 and 23 are connected together with a "ring main," and that Nos. 29, 4 and 28 have two sub-feeders each connecting them with the main distributing station. Into this "ring main" transformer kiosks are connected (represented in the diagram by ■). These are used for supplying the outlying districts where the demand is not large enough to warrant the expense of building and equipping a substation, each kiosk being fitted for supplying 100 kv-a. These kiosks are portable and can be replaced by a substation at any time when the demand increases sufficiently to warrant the change. In this event the kiosk is then removed to some other district.

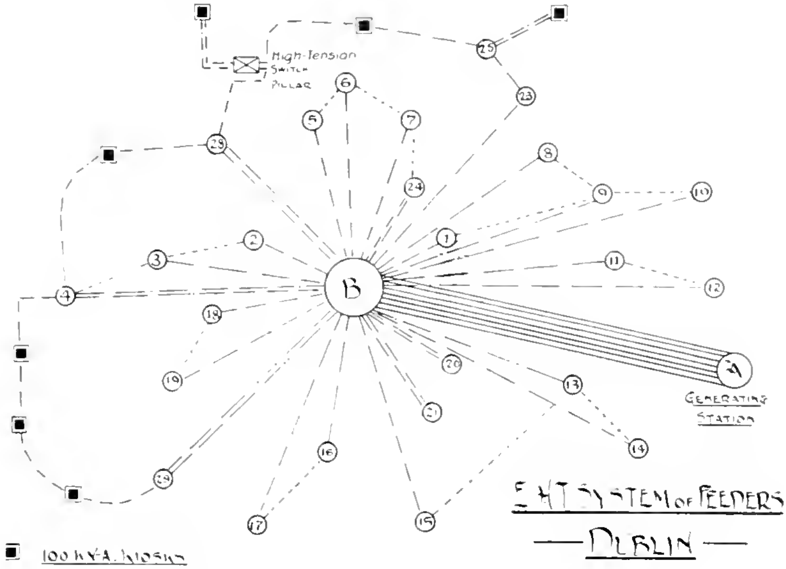

Fig. 1. Diagram Showing the Relative Location of Generating, Distributing and Substations and Connecting Feeders

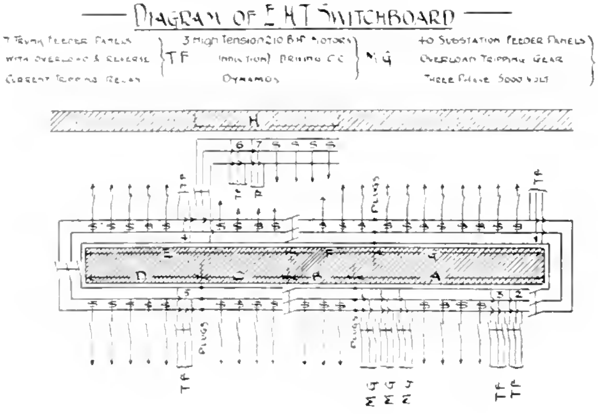

Fig. 2. Diagram showing the Layout of Circuits at the Distributing Switchboard

The high-tension (5000-volt) sub-feeder enter the substation and are connected to the substation high-tension switchboard through a triple-pole automatic oil-break switch of the overload release type.

The primary windings of the step-down transformers are connected to the high-tension busbars in △ through double-pole automatic oil-break switches of the overload release type (Fig. 3), thus ensuring the isolation of any transformer that may break down either in its primary or its secondary winding.

Four transformers are installed in each substation, the size of the transformers varying with the local load conditions. Three are "running" transformers and the fourth a "spare," provision being made so that the spare transformer can be connected up so as to replace any of the three running transformers that may fail (Fig. 4).

Should a transformer break down, it only affects one phase of the supply from that substation, and, when an assistant is sent out it only takes a few minutes to connect up the spare transformer.

The low-tension side of the transformers are connected to the low-tension switchboard in

Y through ammeters and circuit breakers, the spare transformer bus bar being arranged in such a manner that this transformer can be readily "plugged in" in the place of any one of the three running transformers.

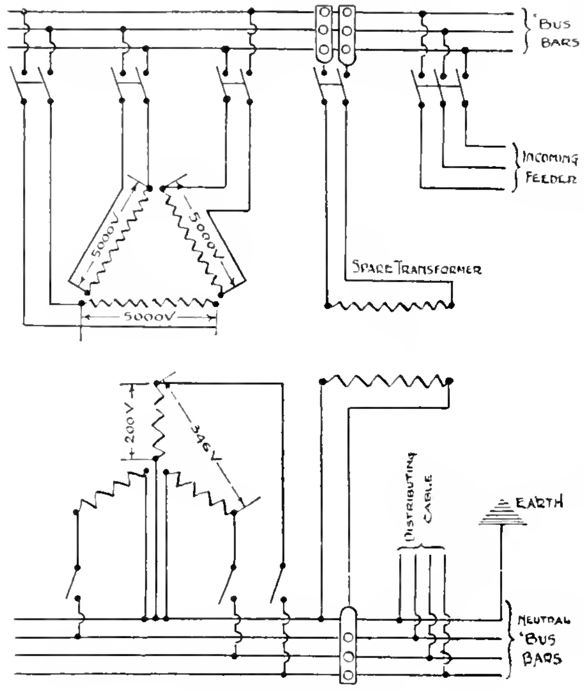

Fig. 3. Transformer Connections in Substation; High-Tension Above, Low-Tension Below

The center point of the "star" or Y connection is connected to an earth bar, which in its turn is connected to an earth plate through a recording ammeter arranged in such a manner that when the earth current exceeds a certain predetermined value this ammeter is automatically short circuited and the earth bar connected direct to earth, for the protection of the ammeters.

From the main transformer busbars of the low-tension switchboard, other bars are fixed horizontally. To these are connected sets of "Downe" fittings for connecting up the low-tension feeder cables which run out from the substation to the different feeding points. Fig. 6 shows diagrammatically the low-tension switchboard with "Downe" fittings and spare transformer bus. A photograph of a substation switchboard panel with "Downe" fittings is shown in Fig. 5.

The feeder cables are *four-core*, paper-insulated, and lead-covered; three of the cores are connected to the busbars of the low-tension switchboard by means of the "Downe" fittings, while the fourth core or "neutral" is connected to the earth bar.

One of the chief advantages of using the "Downe" fitting, Fig. 7, is that it does away completely with the necessity of using rubber insulated cables in the substation; the lead-covered cables are connected by means of a wiped joint to the bottom of the "Downe" fittings, the cores passing through the center of the fitting and each one terminating at a terminal connected with the proper "phase busbar," which is filled in with high-grade compound after all the cores are fixed in position. Each phase is also protected by a fuse and a copper removable link is provided in the neutral that can be removed when it is necessary to carry out any tests on a particular feeder.

The low-tension feeder cables from this switchboard run out to the different feeding points in the area fed by this substation and are connected into feeder pillars, "Downe" fittings being again used (Fig. 8). Three-core pilot cables are run back to the substation from these feeding points and are connected, by means of a three-phase multiple-way switch, to a pilot voltmeter.

In some districts, where the load on the feeders is heavy enough to make it advisable, variable-ratio transformers are installed.

These transformers have a regulating switch connected to taps on the low-tension winding, thus providing a means of boosting the voltage should the pilot voltmeter show that it has fallen below the minimum allowed.

It has been already pointed out that there are three separate transformers, one for each phase, so it is possible to boost the phases separately if required.

As it is only at times of maximum load that the feeders will be likely to be heavily loaded, it is not necessary to have an attendant constantly at the substations where variable-ratio transformers are installed; men are sent there at such times as boosting is required and come away when the necessity has passed.

Distributor cables radiate from the feeder pillars carrying the supply to the consumers' premises. These distributors are *four-core* cables, three of the cores being connected to the "phase" bars and the fourth to the neutral bar in the feeder pillar.

In some cases distributor cables have been run out direct from a substation—for purely local supplies—but it is better practice, and results in a more satisfactory voltage regulation, to arrange matters so that all the distributor cables radiate from definite feeding points.

Each substation has its own natural area assigned to it which under ordinary circumstances it feeds but, in order to meet any eventualities, section pillars are erected at the junction points of the different areas; and by means of these it is possible to connect the area of one substation to that of one, or more, adjacent to it; and in this way feed through the section pillars should any substation be put out of commission through a serious breakdown within it.

By linking up all the section pillars it is possible to make all the low-tension networks of the city into one large interlinked network, with all the substations feeding into it in parallel. It has not been found desirable, however, to adopt this course, and the network is arranged in such a manner that each substation deals with the supply in its own area.

Besides the section pillars, disconnection boxes are used at street corners and points from which a number of cables may radiate. The use of such boxes obviates the necessity of cutting a cable should tests have to be carried out, as any of the cables may be "deadened" by removing the links in the box. A brick pit is built in the pathway or road as the case may be, into which the disconnecting box is placed, and an iron framework round the top of the brick pit carries the pavement cover; thus the box is doubly protected. Fig. 9 illustrates the arrangement employed.

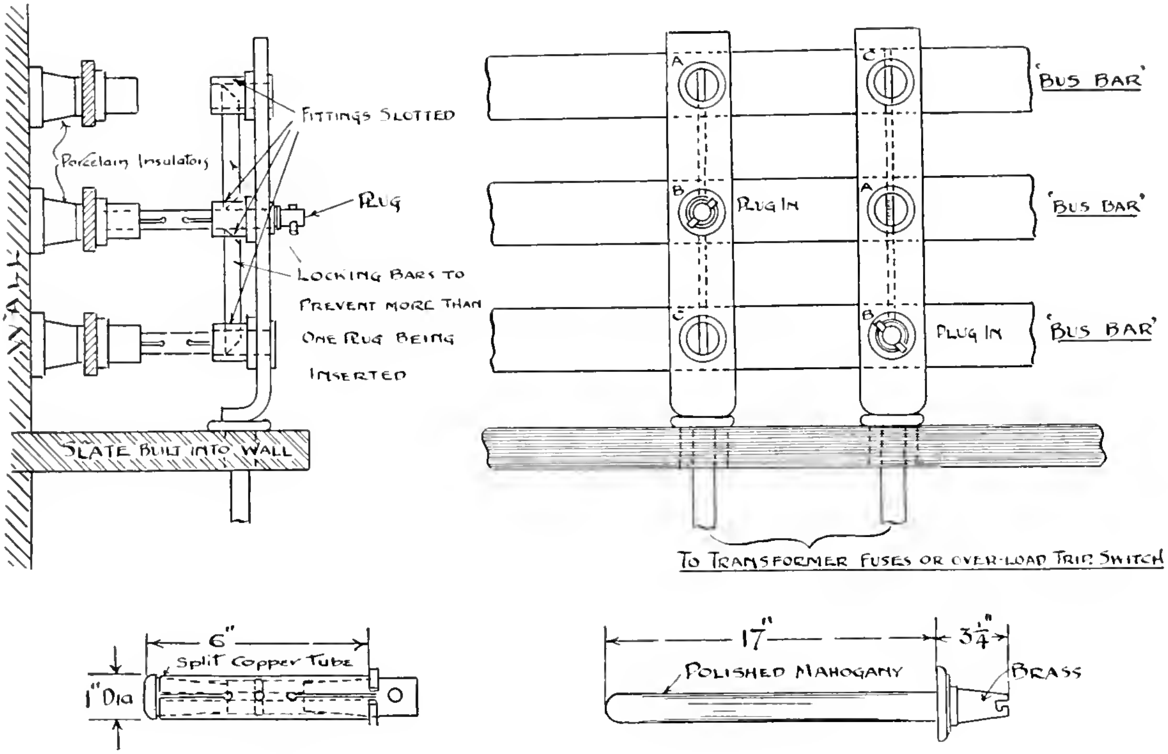

Fig. 4. Plug Connections in Substation for Replacing a Defective Transformer by the "Spare"

From the distributors are taken the house service cables. For these connections cast-iron service boxes are used, the service cables being jointed to the distributors by means of patent clip cable fittings which render it unnecessary to cut the cable, and which make it possible to make joints quickly and efficiently while the distributors are "alive." The construction of one of these service boxes and the location of the clip fittings are shown in Fig. 10; a detail drawing, Fig. 11, and a photograph, Fig. 12, show the method of attaching the clip to the cable.

When the connections are completed the service box is filled in with a special box compound.

All the cables, both high-tension and low-tension, are tested at twice the working pressure after being laid; no periodic high-pressure tests are made. Should a fault develop, it is finally located, after "pinning it down" at the feeding point through a process of elimination, by use of a wire bridge, battery, and galvanometer. The wire bridge employed is of a special construction which gives extremely accurate results, the wire being some 40 to 42 feet long and wound on a drum. This special bridge is made by The British Insulated and Helsby Cable Co., Ltd., Prescot, Lancashire, England.

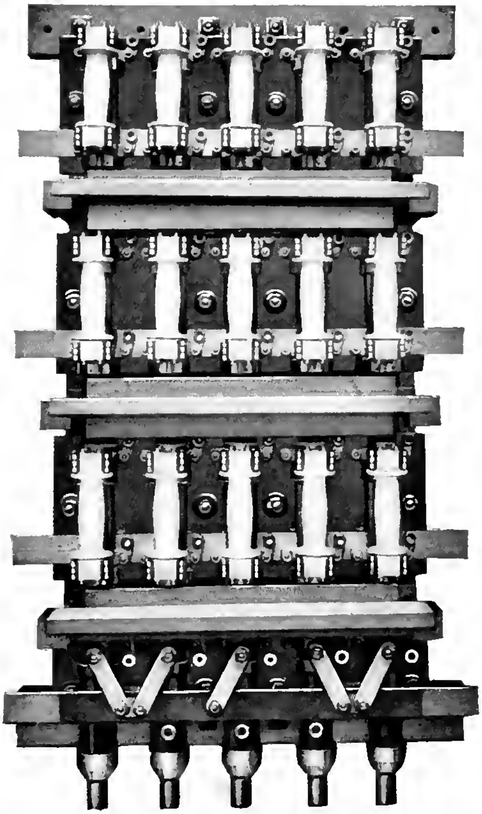

Fig. 5. Low-Tension Board with "Downe" Fittings

The method employed in laying the cables follows:

The cables, as already mentioned, are lead-covered and paper-insulated, the high-tension ones having three cores and the low-tension ones four cores.

They are laid in cast iron troughs with cast iron covers; the cable is supported every foot by creosoted wooden bridge pieces, the trough being filled up with pitch after the cable has been placed in position, and the covers are pressed down while the pitch is still hot. The cast iron troughs are treated with Dr. Angus Smith's solution, before laying.

The trenches in which the troughs are placed are usually about from 1 foot 6 inches to 2 feet deep and in the case of the distributors where more than one line of trough runs in the same trench, room is left between troughs to allow a service box to be put in on either of them.

After the troughs have had their covers placed in position, fine earth—i.e., earth free from any large stones—is filled into the trench to a depth of some 3 inches over the trough, and then a line of hard brick or concrete blocks is placed over the troughs as an indication to future excavators of the presence of electric cables.

The troughing varies in size with the size of the cable used, thus for

A 0.1 in. by 3-core high-tension cable, a 2⅞ in. by 2⅞ in. trough is used.

A 0.2 in. by 4-core low-tension cable, a 2⅞ in. by 2⅞ in. trough is used.

A 0.1 in. by 4-core low-tension cable, a 2½ in. by 2½ in. trough is used.

A 0.05 in. by 4-core low-tension cable, a 2¼ in. by 2¼ in. trough is used.

A 0.035 in. by 4-core low-tension cable, a 2 in. by 2 in. trough is used.

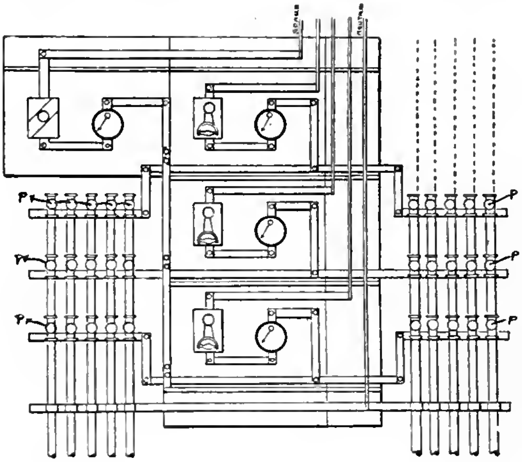

Fig. 6. Representation of Low-Tension Switchboard with "Downe" Fittings and Spare Transformer Bus

The thickness of metal is ¼ in. in all cases.

One important point that must be always borne in mind and receive careful consideration in connection with a three-phase system is the balancing of the loads on the three limbs, for the loads on the three phases must be kept as nearly as possible equal. This is done in Dublin by balancing one installation against another, one being connected between one phase and the neutral line, the next between the second phase and the neutral, etc. In the case of a very large installation a four-core service cable is run into the building and the installation is divided up into three equal sections, each section being connected to a phase and neutral. In order to have the matter of the balancing under easy observation a set of balancing cards is kept—one for each street, and also one for each substation. From these the mains' engineer can see at a glance to which phase a new consumer should be connected in order to preserve the balance.

This has worked out admirably in practice, the balance on the whole system being remarkably close.

Motors, with the exception of those of small power, ¼ h.p. to 4 h.p., are all three-phase and are connected to the phase wires, the neutral in this case not being made use of. The pressure for lighting is 200 volts and for motors 346 volts. There are certain rules in force as to the permissible starting current for motors and their power-factors.

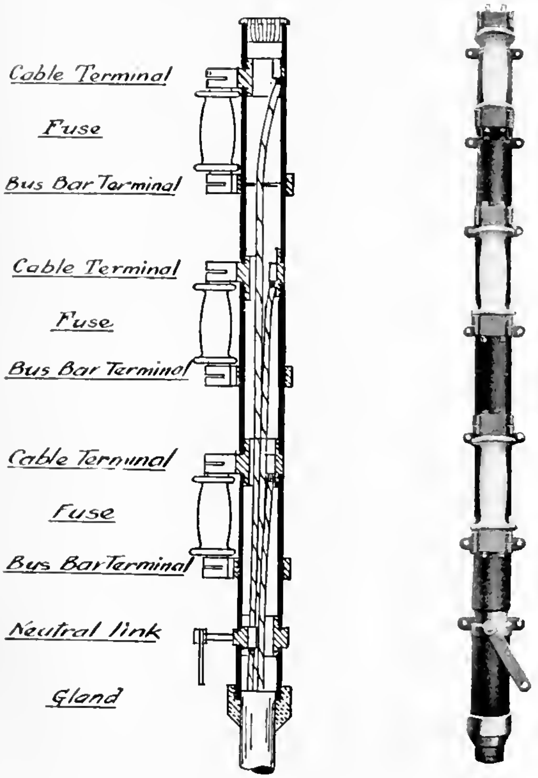

**Fig. 7. A sectional View of a "Downe" Unit and an Exterior View**

The solid system of cable laying which has been described is, perhaps, costly when only the initial expenditure is taken into account; but, when one considers the immunity from the effects of electrolysis which the use of the cast iron troughing gives, and the very exceptional freedom from cable faults that the Dublin system enjoys, the expenditures made on both cable and its laying is fully warranted.

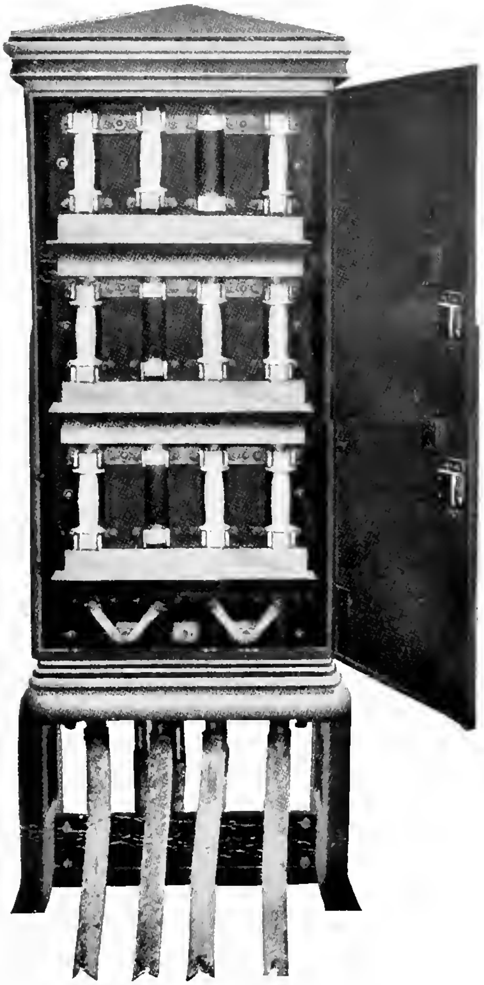

**Fig. 8. A Four-Unit Feeder Pillar**

Practically the whole of the cable laid was manufactured by the British Insulated and Helsby Cables Co., Ltd. Before it was shipped, stringent tests were carried out for insulation and capacity; and after laying the cable was again tested, this time under twice the working pressure, before being put into commission.

In any system of distribution the record of the mains is an important item. It will therefore perhaps be of interest to describe the network filing system adopted in Dublin. This is substantially a method in which the records of all connections in substations, feeder pillars, section pillars, network boxes, etc., can be easily and cheaply brought up to date and kept.

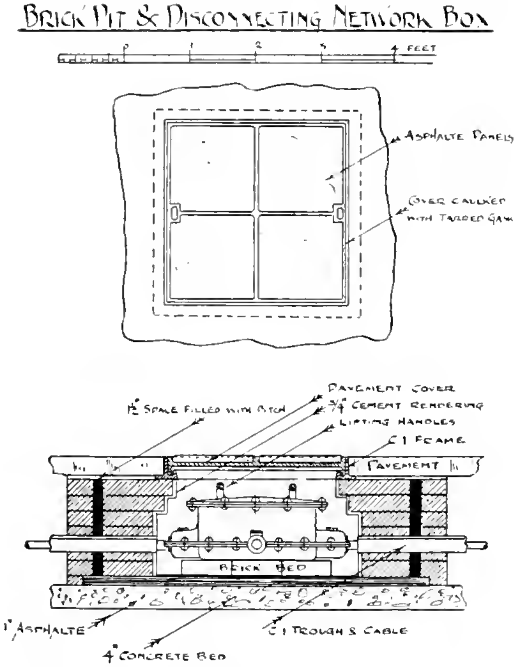

Fig. 9. Drawing Showing Disconnecting-Box and its Pit

Maps, more or less elaborate, are, of course, always made use of but, after all, these are only of use insofar as they are a record of the positions of the mains, it being impossible to mark on them the various possible connections and the changes made in the network connections from time to time.

Now it is obvious to any one, who has even a slight knowledge of the distribution of electrical energy, that alterations and additions have to be made to the mains in order to cope with the increasing demands, and that each alteration or addition may possibly introduce a complete new set of network connections, the old connections being either left as they were or modified to suit the altered conditions. When such alterations are made a record must be kept of them, otherwise the mains' engineer has to depend on his memory or the memories of his assistants. What this might possibly mean may, to a certain extent, be understood by taking a glance at the network supply in Dublin and its added areas. This consists of a network made up of two systems of mains—the older portion originally laid down for a single-phase supply, by the use of concentric cable, and the newer portion for the present three-phase supply—laid out for a certain maximum demand and having additions and alterations carried out from time to time so that the increasing demand could be dealt with. It considers the following points.

1. The system comprises twenty-eight substations with their high-tension switchboards, transformers, and low-tension switchboards; also six-way disconnecting boxes, four-way disconnecting boxes, two-way section pillars, four-way section pillars, six-way section pillars, high-tension three-phase transformer kiosks, radial high-tension feeders, and high-tension ring mains or interconnectors.

2. That it is possible (though perhaps not advisable) to link up the whole of the low-tension network so that it would be fed from all the low-tension substation boards in parallel, or all from one substation.

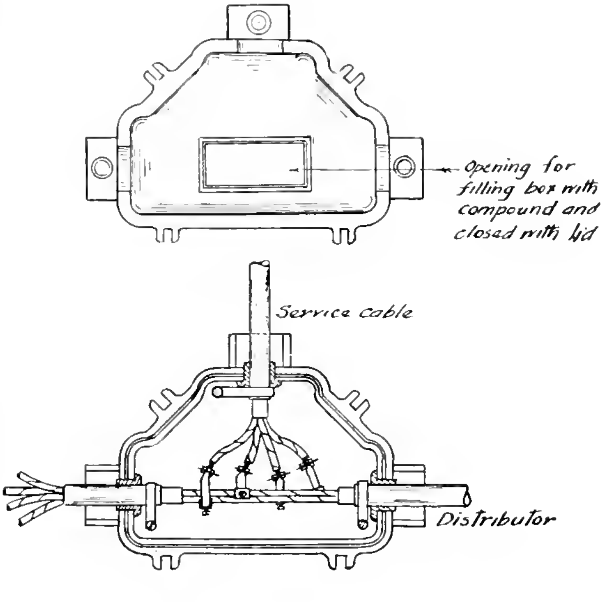

Fig. 10. Service-Box with Connections for Four-Core Service

3. That the substations can be linked together independently of the main station

on the high-tension side by the main distributing station high-tension interconnectors.

4. That alterations for one reason or another are made weekly, one might almost say daily. It then becomes obvious that it is an impossibility for any one to carry in his mind exactly how the connections and linking-up stand.

The system in vogue before the adoption of the present filing system was that of having written reports handed in of every change made in the network, such reports being duly filed for reference. This was all very well in its way; but when any further alteration had to be made or the exact method of linking up at a particular point was in question (perhaps in connection with a substation or cable fault), it became necessary to either trust to the memory of the mains' engineer or to hunt up the files of reports to obtain the necessary information and to make such sketches as were needed for use on the job. Thus a tremendous amount of valuable time was lost.

The originators of the filing system, recognizing the various difficulties attendant upon adequately recording everything attached to a large and complicated system of mains, set out to evolve some means by which records could be so kept that a glance would show exactly how the connections controlling any portion of the network stood.

It was first suggested that a large map should be mounted and that plug-holes should be drilled to indicate positions where it was possible to make connections and disconnections between sections of mains. Very little consideration was necessary to show the impracticability of such a scheme, for the map would have to be enormous to allow the possible alterations to be adequately indicated on, say, a three-phase four-wire system.

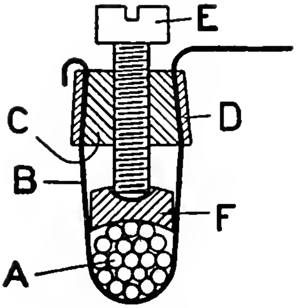

Fig. 11. Cross Section of Special Connecting Clip Used in Service Box

Further consideration of the question led to the decision that it was quite unnecessary to show the *whole* of the cable system when the only parts that allowed of alterations in the way of connections were the switching or the fusing points, and it then became apparent that all conditions would be satisfied if every point on the system, where linking up by links, switches, or fuses were possible, was reproduced diagrammatically and in such a manner that by some simple device it could be shown if a link, switch, or fuse was "in" or "out." Finally, it was decided that a small plug of bone or metal which could be placed in a hole indicating the position of a link, switch, or fuse was the best method to adopt. From this beginning the filing system developed.

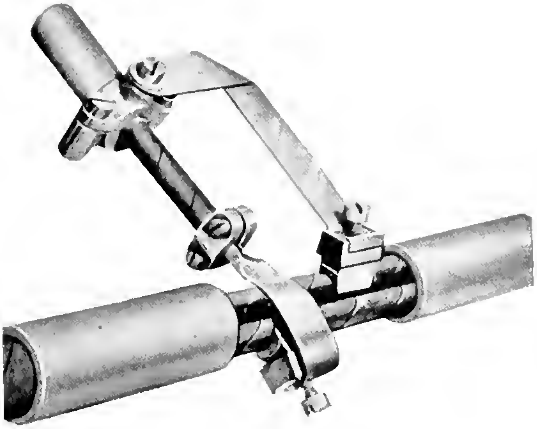

Fig. 12. View Showing Method of Attaching Special Connecting Clips

First of all, the various substations were taken into consideration, and what was the natural or normal network to be fed by each substation was decided upon. This being done, a diagrammatic plan was prepared for each substation network showing all network boxes and section pillars, etc., each carefully numbered, the points where linking up with another substation was possible being indicated. These were called reference plans. Fig. 13 represents such a plan, and it will be seen that it would be possible to link Substation No. 1 with Substation Nos. 2 or 8 in the six-way Box No. 1 at the corner of High Street and Church Road or with Substation No. 15 in the Section Pillar No. 1 at the corner of High Street and Rochester Road.

The next question was to represent the connections in the substation itself, and to do this a diagrammatic sketch was made of the high-tension and low-tension switchboards, plug-holes being provided where links, switches, or fuses were used. Fig. 6 represents one such card and is a diagrammatic representation of a low-tension switchboard (made in the workshops of the Corporation Electricity Department to designs worked out by the staff), the plug-holes being at *p*, *p*, etc.

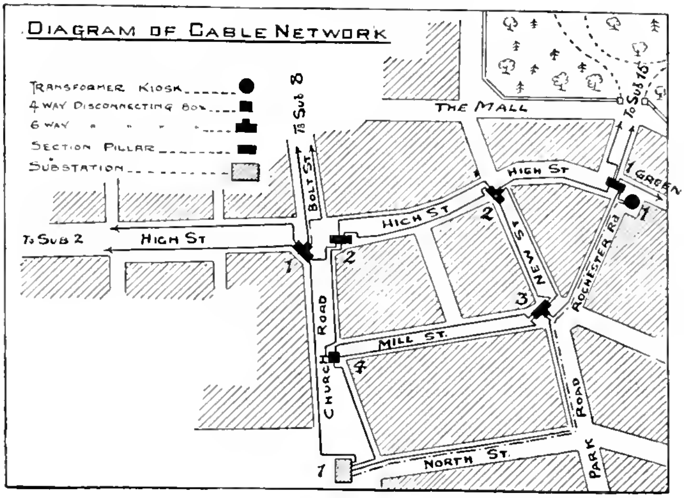

Fig. 13. A Map of a Section of Town Diagrammatically Showing Substation, Feeder, Etc., Layout

The position of the plugs on this diagram will indicate at once which circuits are being fed from the substation. For instance, take the line of cable to the extreme left, which in this case leads to Box No. 1 at the corner of High Street. If the plugs are in the holes marked *p*, *p*, *p*, it would show that this box is being fed from this particular substation; but if these plugs were *not* in, it would show that Box No. 1 was not fed from this substation, and, if the engineer wished to know which substation fed this box, he would have to look up Substations No. 2 and No. 8, as his diagram of cable network, Fig. 13, would show him that it might be fed from either the one or the other.

Provision is made on the substation card for miscellaneous information, such as size of transformers in use, inspections made, etc.

The substation switchboards and the cables radiating therefrom having been dealt with, each section pillar, network box, and transformer kiosk was treated in like manner.

Fig. 14 is a tray in the filing system representing a section pillar (No. 1 six-way), and the position of the plugs will, as in the previous case, indicate which cable is being fed through this section pillar. Thus, if the row of plugs above the line marked "New Street and High Street" are all *in*, it would show that the cable from this section pillar to the corner of New Street and High Street (which enters Box No. 2) is connected on at the section pillar; but if the plugs were *out*, it would show that this cable was disconnected at the section pillar. Likewise, if the plugs above the line "Feeder from Kiosk" were in, it would indicate that this section pillar was being fed from Kiosk No. 1, in which case it would possibly be working in parallel on its low-tension side with the low-tension of Substation No. 1; but this fact would be ascertained by looking at the diagram of those boxes where it was possible to disconnect the low-tension network. Such diagrams will be given later on.

Fig. 15 is a tray in the filing system indicating the low-tension connections in the transformer kiosk, plug-holes and plugs again being used to indicate how the cables leaving the kiosk are connected, the plugs being left out where a disconnection has been made.

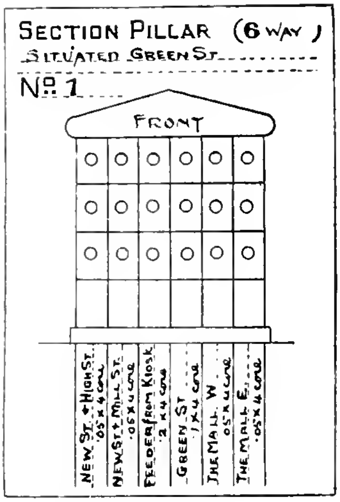

Fig. 14. A Plug-Diagram of a Section Pillar

Figs. 16 and 17 represent a four-way and a six-way network box respectively; let us say Box No. 4 and Box No. 1. It will be again seen that the presence or absence of the plugs in the plug-holes will show how the cables are connected in each box.

Having now made a full set of diagrams for the whole system—and these are very cheaply obtained by using diagrammatic forms, because photographic prints can be got of the various sets of diagrams required—these are firmly glued down onto trays or slides made of hard wood and holes are drilled wherever required for the reception of the bone or metal plugs.

Then a neat cabinet (Fig. 18), was made in which to house the completed trays, a drawer being provided for the plugs not in use and for the reference plans, the whole making a very handy and valuable addition to the records of the station.

The working of the system in actual practice is exceedingly simple. Say a change is made in any network, such as shutting down No. 1 Substation for repairs or alterations. The substation must be made "dead" on the high-tension and low-tension sides in order that the staff can work on the switchboards and transformers, but the low-tension network with its numerous consumers must be kept "alive." First of all, the engineer responsible takes the diagram of cable network and decides at which point to link up with another substation. Assume that by linking with *one* substation the requirements of the case can be met, and that he decides that No. 15 Substation shall take up the load for the time being. He then takes the diagram of No. 1 Section Pillar and sees if the cables to No. 15 Substation, via the Mall, W. and E., are connected at this section pillar. If they are *not*, these links or fuses must be put in, and he gives directions for this to be done, which puts Substations Nos. 1 and 15 in parallel on their low-tension sides. The next step is to take off Substation No. 1, and instructions are given for the high-tension switches to be drawn at the substation and the low-tension fuses to be drawn on all the cables leaving the substation. In the instance under consideration this would also necessitate the shutting down of the Kiosk No. 1, unless special arrangements were provided for feeding this from No. 1 Substation, irrespective of the high-tension switchboard feeding the transformers in the substation. Should the kiosk have to be shut down as well as the substation, its network must be fed from Section Pillar No. 1 also, and the links would have to be put in that would enable this to be done.

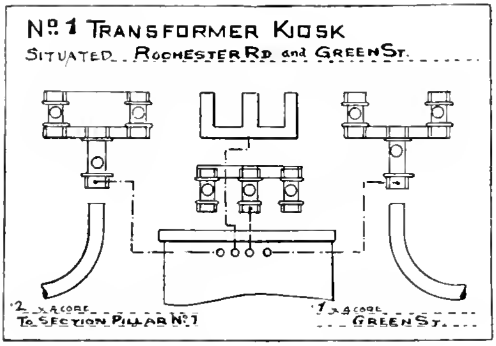

Fig. 15. A Plug-Diagram of a Transformer Kiosk

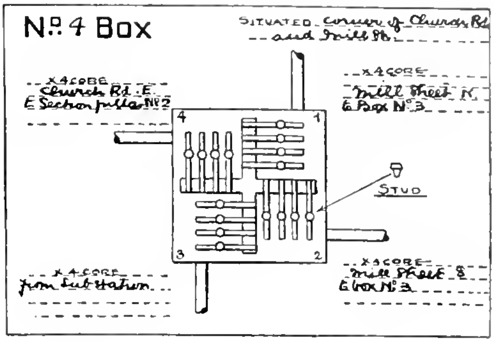

Fig. 16. A Plug-Diagram of a Four-Way Network Box

Having made all the disconnections necessary in the substation, the switch on the switchboard of the central station on the high-tension sub-feeder to Substation No. 1 is drawn, and the substation is "dead" and ready for the men to work on it. Stops are

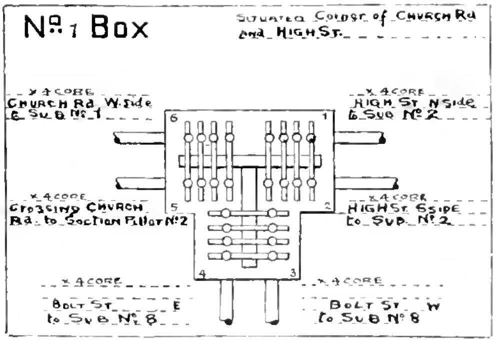

Fig. 17. A Plug-Diagram of a Six-way Network Box

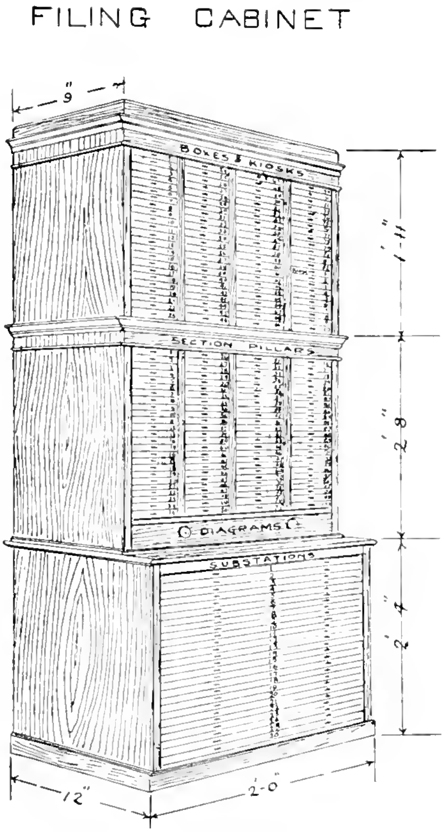

Fig. 18. Drawing of Complete Cabinet for Filing Trays Showing Records of Connections

inserted in the cable units of the low-tension board to denote that these are "alive" up to the fuse contacts on the cable side in order to prevent any one interfering with them. The switchboard, however, is "dead," and can be altered or cleaned as may be required. As each of these operations is carried out the plugs on the different trays affected by the changes are altered to suit the new conditions, and these are left as long as such conditions maintain.

At any time the whole of the conditions of linking and switching at any point of the system, either in the substation or on the network, can be seen at a glance, there being no necessity for hunting over files of papers to unearth remote reports, and trusting to memory is made unnecessary. As far as possible, all chances of mistakes being made are eliminated. As a further precaution against making mistakes, in the actual work of making changes in the substations, the cables are painted different colors; red, blue, and green being the colors used to designate the different phases, while the neutral cable is painted in stripes of all three colors.

Should additions or alterations be made at any time to either network, system, or substation, the cost of making the filing system conform to such alterations is but trifling, as, even if a substation is completely remodelled, it would only require that a new diagram be prepared and fixed to the tray reserved for that particular substation.

There is no doubt that further developments of the filing system are possible, and that the mains' superintendents in charge of networks differing from the one in Dublin would be able to modify it to suit their own purposes.

# HYDRAULIC EQUIPMENT OF THE GATUN HYDRO-ELECTRIC DEVELOPMENT, PANAMA CANAL

By Chas. A. Jackson

Mechanical Engineer, The Pelton Water Wheel Company

In the January, 1914, number of the General Electric Review we published eight articles describing the mechanical and electrical controlling devices of the Panama Canal lock machinery. The present number contains three articles which describe different stages of the production and distribution of electrical energy in the Canal Zone. The following article covers the hydraulic machinery of the installation and the features of its operation. In connection with this description see those by Mr. Eden and Mr. Bern.—Editor.

The permanent electric energy supply for lighting and power purposes on the Panama Canal will be derived from a hydro-electric plant which is being installed at Gatun spillway. The gross head available from Lake Gatun to mean tide level of the Pacific Ocean varies from a maximum of 91 ft. in the extreme flood times to a minimum of 79 ft., to which level the lake may possibly drop after three or four months of absolutely dry season.

The plant is therefore designed to develop the full power output when operating under an effective head of 75 ft. The station has a capacity of 6000 kw. and provision is made for the installation of an additional 6000 kw., the three necessary outlet pipes in the dam having been installed at the same time as the original pipe lines.

The water is taken from Lake Gatun through passages 12 ft. wide, fitted with wrought iron racks 29 ft. 7 in. high to prevent trash from entering the pipelines. Water is admitted into the pipelines through three head gates 10 ft. 6 in. in diameter. These gates are of massive cast iron construction, the seats where water tightness is required being made of bronze.

Each gate is equipped with two steel stems for raising and lowering. These stems are fitted with bronze nuts working in roller thrust bearings; and the nuts are fitted with steel bevel gears arranged to be operated by a 15-h.p., 220-volt, alternating-current motor with a speed of 750 r.p.m. The motor is placed between the stems and has shaft extensions on each side which carry two bevel pinions arranged to engage the bevel gears on the stem nuts. The stands which carry the stem nuts are equipped with hand-operating mechanism, arranged to be disconnected when the gate is operated electrically.

The gates are equipped with automatic control devices, consisting of a limit switch geared to one of the gate stems and a float switch actuated by the water in the pipe. The action of the control is as follows, the gate being closed and the pipeline empty: The gate motor switch is closed at the power house, which starts the motor and the gate begins to open. When the gate has opened a sufficient distance to fill the pipeline in about five minutes, the limit switch opens the circuit and stops the motor. The gate remains in this position until the pipeline is filled and the water rises in the 36-in. diameter air vent just below the gate. At this time it actuates a float switch and again closes the motor circuit, thereby causing the gate to be opened fully, when the limit switch again operates to prevent over-travel. The gate is closed by reversing the main switch at the power house, which causes the motor to operate, the limit switch again stopping the motor when the gate has reached the closed position. In case the electric power should fail, the gates can be hand-operated by two men.

Each of these gates is bolted to a pipeline 10 ft. 6 in. in diameter with an average length of 420 ft. The pipelines are made of $\frac{3}{8}$-in. steel plate in courses 8 ft. long, each course being made of three sheets to form the circumference. The center of each course is fitted with a 3-in. by $\frac{3}{8}$-in. Z-bar ring, which is also made in three sections. After the pipe was riveted together at the plant, the outside was covered with a layer of reinforced concrete to prevent rust.

The pipelines are led down to the rear of the power house on a uniform slope from the spillway, and are connected to the turbines in the power house through 90-degree bends having a radius of 70 ft. Each of the pipelines is arranged for attaching a Pitot tube testing apparatus while its unit is in service; and one pair of portable tubes for taking readings in planes of the pipe at 90 degrees from each other was supplied.

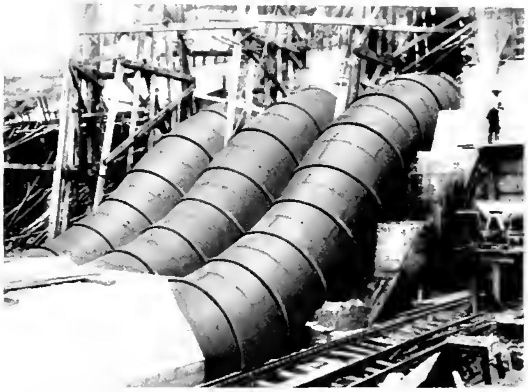

Fig. 1. Gatun Hydro-Electric Station. Close View of "Ogee" Curve Immediately below Headgates. Looking East

This is accomplished by fitting each pipe with two 6-in. saddle nozzle connections located 45 degrees on each side of the vertical center line of pipe. From these connections there are two Pitot tube supports placed across the pipe at right angles to each other with their thin sections pointing in the direction of the flow of water and fitted with guides for the Pitot tubes. These supports are bolted in the pipes and, while they are intended to remain permanently in the pipe, if desired, they can be removed very readily.

Each 6-in. outlet on the pipe is closed by a gate valve with tongued and grooved flanges which match the base on the Pitot tube apparatus. Each Pitot tube is arranged to measure both the static and velocity heads at practically the same point in the pipe, and readings are obtained by means of "U" tubes containing a colored liquid having a specific gravity of about 1.25. Carbon tetrachloride, thinned with gasolene to the proper specific gravity and colored red, is usually used for this purpose.

One end of each "U" tube is connected to the static and the other to the velocity side of the Pitot tube; the difference in height of the colored liquid columns is read, from which the velocity of flow in the pipe is calculated.

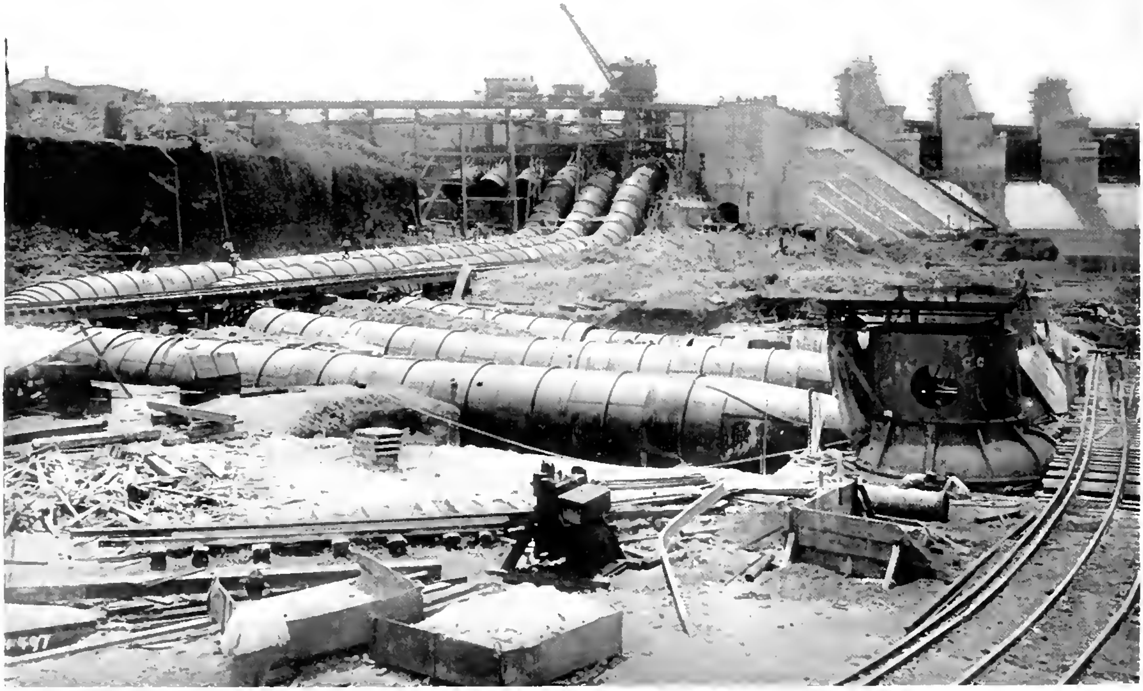

Fig. 2. Left-hand Side of Panoramic View of Gatun Hydro-Electric Installation under Construction, showing Pipelines and Turbines Erected

This form of Pitot tube is very simple and reliable, as it does not require compressed air to keep the head within readable limits and, at the same time, the difference between the static and velocity heads is read off directly.

In order to measure the flow in any pipeline, it is only necessary to bolt the Pitot tube base plates to the valve flanges and open the gates, when the tubes can be pushed into the pipes and readings taken. When the test is completed, the Pitot tubes are withdrawn until they clear the gates; then the valves are closed and the apparatus can be removed.

There are three 2200-kw. main generating units, each of which is driven by a special 50-in. vertical single-runner Pelton-Francis turbine having a maximum capacity of 3600 h.p. when operating under an effective head of 75 ft. and at a normal speed of 250

Fig. 3. Gatun Spillway Dam, looking South from Bridge, showing 14 Crest Gates. Ogee Dam and Baffle Piers. Hydro-Electric Station at Left

Fig. 4. Right-hand side of Panoramic View of Gatun Hydro-Electric Installation under Construction, showing Ogee Spillway Dam

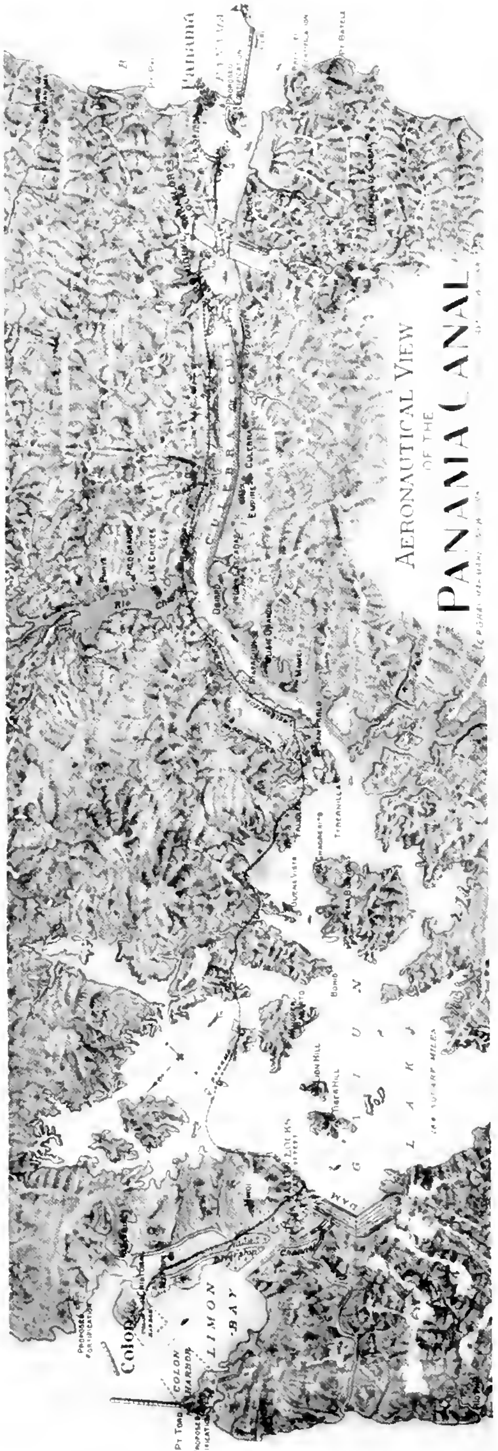

Fig. 5

revolutions per minute. The turbines are located at such a height that the center of the runners is 20 ft. above tail water.

The water is discharged through steel-lined concrete draft tubes, which are 71 in. in diameter at the discharge from the runners and increase to an elliptical section of 9 ft. by 17 ft. at the outlets, which are horizontal, there being a 90-degree bend in the tubes. The linings are made of ¼-in. steel plates, which were fitted together in the shop and shipped knocked down.

The turbines are of the spiral-case type and are fitted with heavy cast iron distance rings which carry the generators. The weight of the revolving parts of each generator and turbine is carried on a roller thrust bearing mounted on top of the generator. The turbine is so designed that the runner exerts an upward thrust of 20,000 lb. when working at full capacity, thereby relieving the thrust bearing of that amount of load.

Oil for the thrust bearing is supplied by a small pump geared to the main turbine shaft, and a tank is provided below the pump to receive the overflow from the bearing. In this way a constant circulation of oil is maintained. As this oil returns to the suction tank, it passes through the lower guide bearing on the main shaft and lubricates it.

The runners of the turbines are made of a special bronze and weigh approximately 7000 lb. each. They are bored taper and held in place on the lower end of the shaft by means of bronze nuts. The surfaces of runner vanes are all hand finished to reduce hydraulic losses.

The speed of the turbines is controlled by Pelton oil-pressure governors, which are mounted on the distance rings and are driven by bevel gearing from the main shaft. Tachometers are mounted above the governors on supports bolted to the distance rings. The tachometers are directly connected to the governor heads.

The governors are fitted with small electric motors for varying the speed of the main units for synchronizing purposes, and a device is provided on each governor for varying the permanent drop in speed from no load to full load. This can be adjusted for any variation from 5 per cent drop to absolutely constant speed from friction load to maximum load. The governors are also fitted with hand-control mechanism for adjusting the gates independently of the oil pressure.

The wicket gates for controlling the supply of water to the runner of the turbine are steel castings with hand-finished surfaces. Each gate has its pivot stem extended upward through a packing gland and is fitted with an operating lever. All the gate levers are connected to the gate ring by means of bronze links, and the gate ring is connected to the governor rockshaft. All of the regulating mechanism is therefore outside the turbine case except the gates themselves. The water passages on each side of the gates are provided with renewable rolled steel wearing plates.

The pressure oil for actuating the governors is supplied by two Pelton rotary pumping units, driven by 10 h.p. alternating-current motors at a speed of 375 r.p.m., each pump being capable of supplying the governors on all three units. The governors work on an open system, there being no vacuum chambers used. The discharge oil from the governors is led into oil sump tanks, from which it passes into the suction of the pumps. Each oil pump is connected to a steel pressure-oil receiver with an air space above the oil. The oil sump tanks and pipe connections are installed in duplicate and valves are provided to enable one set to be cleaned while the other is in service.

The complete hydraulic equipment for this installation, including racks, headgates, pipelines, Pitot tube testing apparatus, turbines, governors and oil pumping units, was designed and built by the Pelton Water Wheel Company; and all electrical apparatus, including headgate motors, limit switches, float switches and motors for driving the oil pumps, was supplied by the General Electric Company.

The shipping weight of the material furnished by the Pelton Water Wheel Company, including the electrical apparatus purchased by them from the General Electric Company, was approximately one thousand tons.

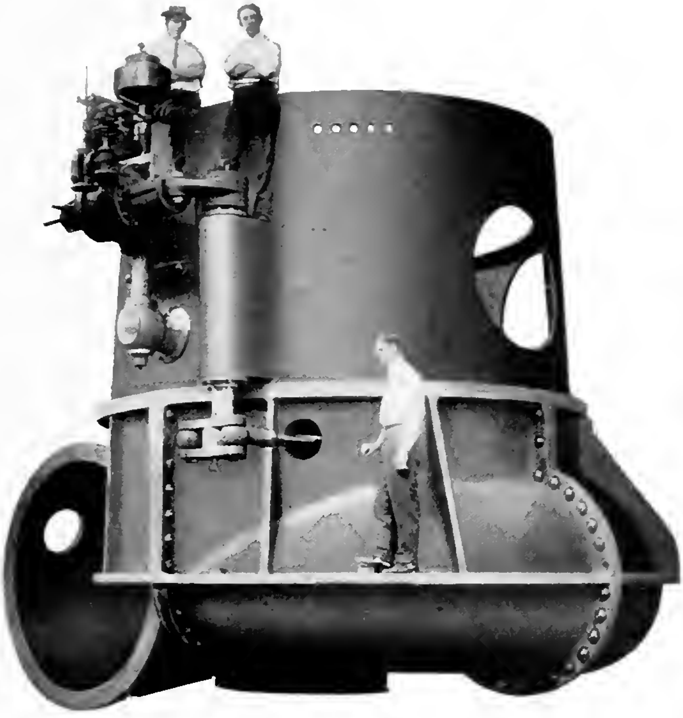

Fig. 6. 3600 H.P. Pelton-Francis Turbine

# ELECTRICAL EQUIPMENT OF THE GATUN HYDRO-ELECTRIC DEVELOPMENT, PANAMA CANAL

By T. S. Eden

Alternating Current Engineering Department, General Electric Company

This article is confined to a description of the electrical generating machinery of the Gatun stations. The number, rating, and location, of the generating units, exciters and motor-generator sets are given; and a brief description of the current-limiting reactance coils that are used in the station is included.—Editor.

The tremendous water storage in Gatun Lake has afforded the U. S. Government a excellent means of providing electric energy for lighting and power purposes on the Panama Canal. This has been accomplished by the development of a hydro-electric station at Gatun dam with a capacity of 6000 kw., provision being made to increase this to an ultimate capacity of 12,000 kw.

For three or four months of every year there is absolutely no rainfall on the Isthmus. During this period it is desirable to conserve the water to as great an extent as possible; consequently, maximum efficiency was demanded for the apparatus from both the waterwheel and generator manufacturers making bids on the installation. The complete electrical equipment was manufactured by the General Electric Company.

### Generators and Direct-Connected Exciters

There are three main generating units of the revolving field type, each being provided with a direct-connected exciter. The generators are three-phase, 25-cycle, with a guaranteed continuous capacity of 2000 kw. at 0.8 power-factor at 2200 volts and 250 revolutions per minute, and with an overload rating of 2500 kw. at 0.8 power-factor for two hours.

The exciters are of 50 kw. capacity at 125 volts, each being capable of furnishing exciting current for two generators under the maximum guaranteed load.

The units are of the vertical type and are similar in arrangement, with the exception of the exciters, to the installation of the Schenectady Power Company at Schaghticoke, N. Y., described in the General Electric Review, April, 1909.

The generators are carried on heavy cast iron distance rings furnished by the Pelton Water Wheel Company, the stationary armatures being bolted to these rings. The thrust and upper guide bearing support consists of a very rigid iron casting, bolted to the top of the stationary armature.

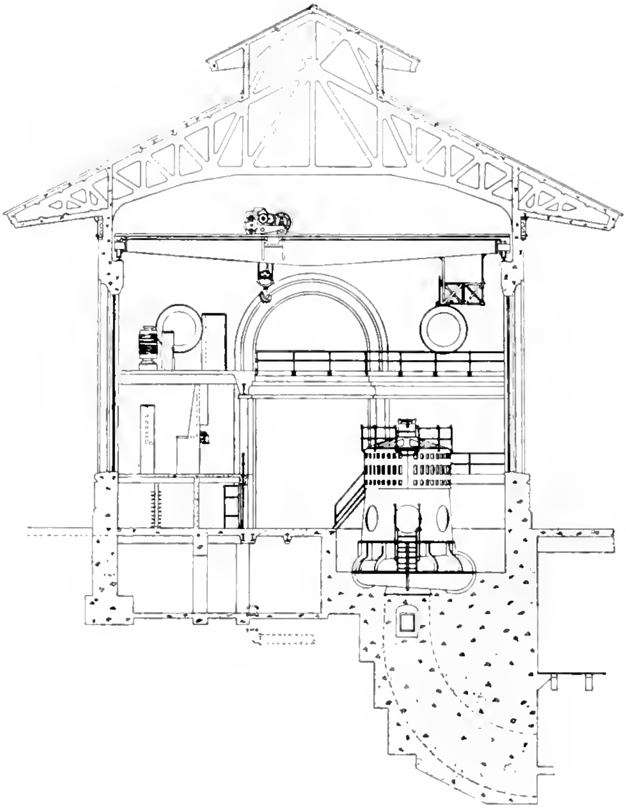

Fig. 1. Cross Section of Gatun Power House

The thrust bearings are of the roller type, manufactured by the Standard Roller Bearing Company, Philadelphia, Pa. These bearings carry the weight of the complete revolving element, consisting of the generator field, No. 1

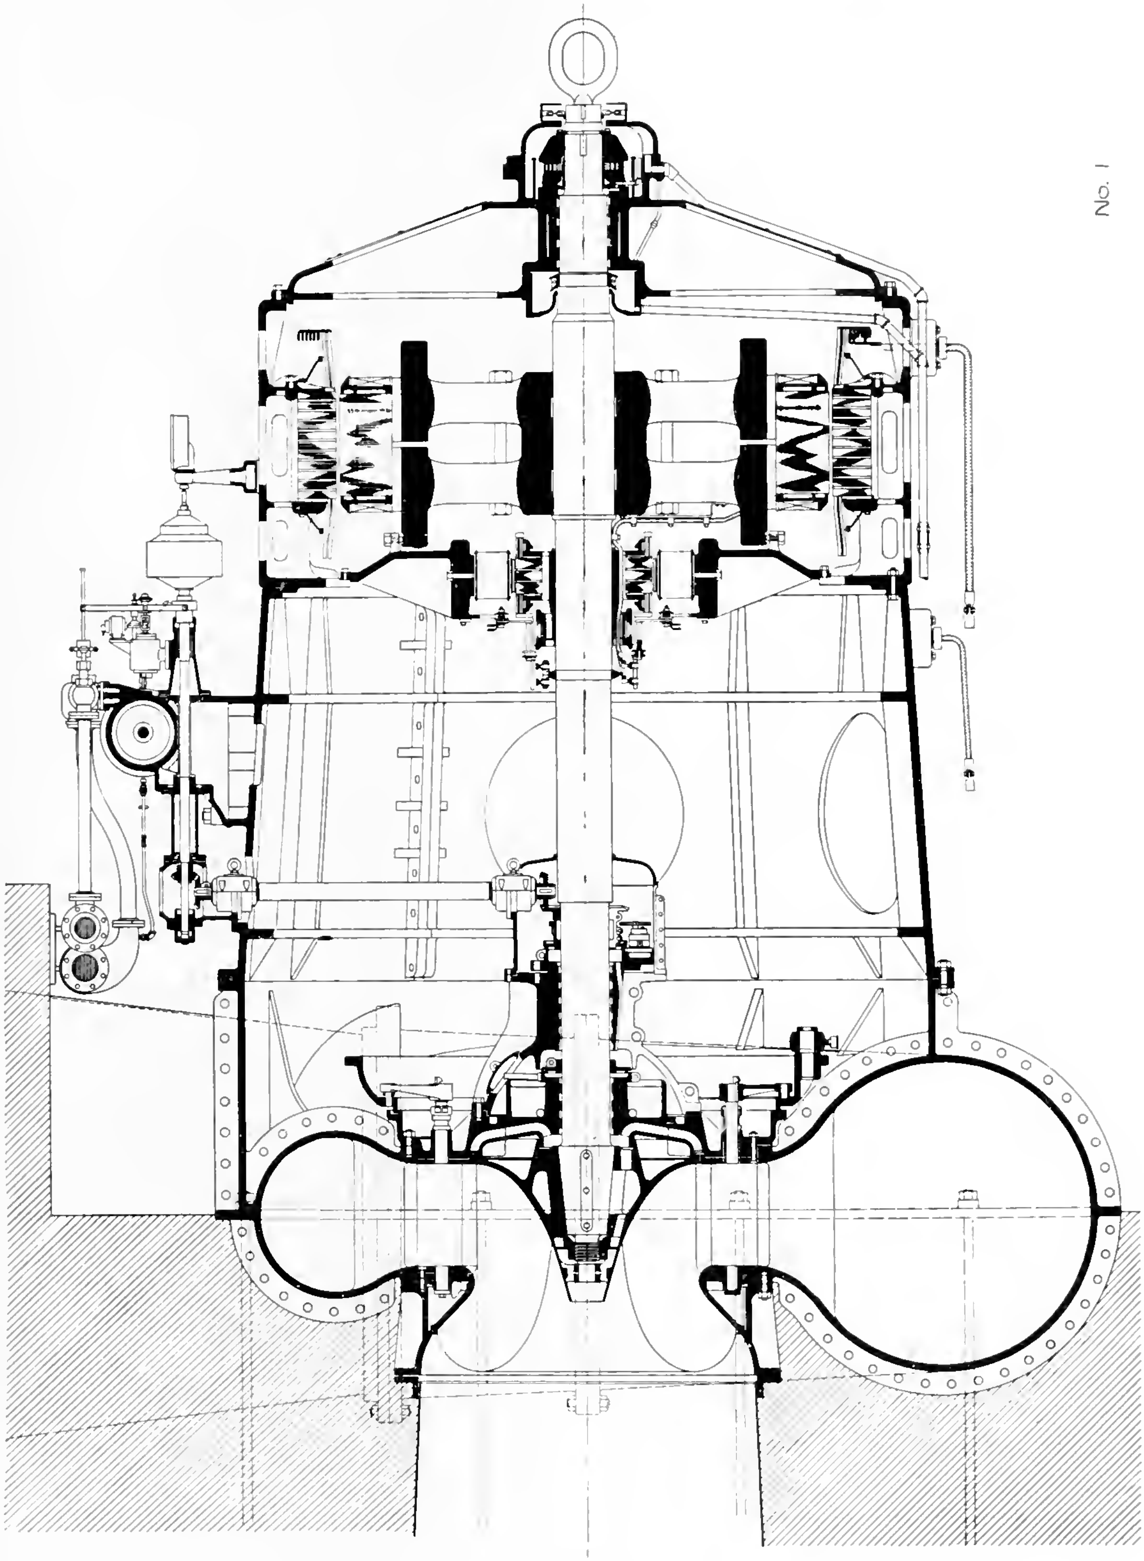

Fig. 2. Cross Section Through Waterwheel, Generator and Exciter

exciter armature and turbine runner, which are mounted in this order on a one-piece shaft. The weight thus suspended is 32 tons. The exciter magnet frame is supported by lugs cast on the stationary armature of the main generator.

Fig. 3. Interior View of Gatun Hydro-Electric Station

The exciter is readily accessible through large holes in the distance ring, a platform being provided inside the ring from which the exciter commutator and generator collector rings may be reached.

Provision is made for securing the magnet frame of the exciter to the revolving element of the generator, so that the complete rotating element, together with the exciter frame, is raised at once in unassembling.

For inspection of the roller bearing, it is necessary simply to remove a speed limiting switch from the top of the shaft and the upper half of the bearing housing. There are two guide bearings, one immediately below the thrust bearing, furnished with the generator, and the other above the waterwheel, furnished by the waterwheel builder. The arrangement of the complete unit is shown clearly in the cross sectional view given in Fig. 2.

The generators, under factory tests, showed an efficiency of 95.1 per cent at 2000 kw., 0.8 power-factor; 94.3 per cent at 1500 kw., 0.8 power-factor; and 92.5 per cent at 1000 kw., 0.8 power-factor. The guaranteed temperature rises of 40 deg. C. above room temperature, of 25 deg. C. under continuous operation at full load, and of 55 deg. C. rise after two hours run at 25 per cent overload, were met with an ample margin. The revolving field was given a running test at twice the normal speed in the testing pit which is provided for this special purpose.

All of the apparatus was subjected to the most rigid and minute inspection during manufacture by representatives of the Isthmian Canal Commission. The insulation of all windings was made moisture-proof on account of the extreme climatic conditions on the Isthmus.

### Reactances

Current limiting reactances were provided to give 5 per cent reactive drop, at 2500 kv-a., 2200 volts, three-phase, 25 cycles. While the generator windings are sufficiently rigid to stand the strain of a short circuit under full load, these reactances will reduce the shock on the windings and will also serve to render the operation of synchronizing the machines easier and safe. Fig. 4 shows the construction of these reactances.

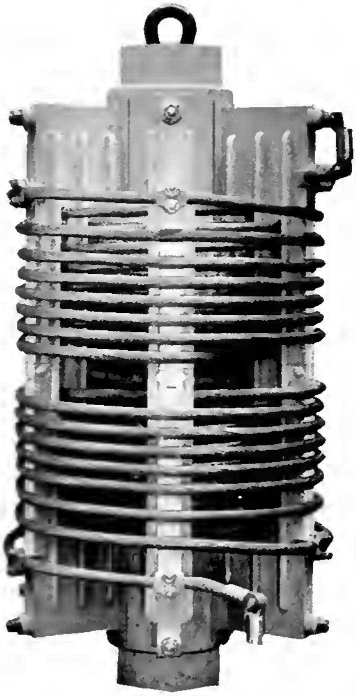

Fig. 4. Current-Limiting Reactance with Concrete Core

**Motor-Generator Sets**

In addition to the direct-connected exciters, two motor-driven exciters are supplied. These consist of a 100-kw., 125-volt, 500-r.p.m. generator, direct connected to a 150-h.p., 2200-volt, 25-cycle squirrel-cage type, induction motor. These are mounted on a common base plate and provided with three bearings.

# SWITCHBOARD EQUIPMENT FOR GATUN HYDRO-ELECTRIC STATION, PANAMA CANAL

By Emil Bern

Switchboard Engineering Department, General Electric Company

The general scheme of controlling and distributing the electrical energy in the Gatun power station forms the subject matter of this article. The fundamental features of the station wiring, instrument and control board, exciter board, and the bus and switch compartments, are described and discussed.—Editor.

The Gatun hydro-electric station is located at the dam of the artificial Gatun Lake.

This body of water, fed by the Chagres River, not only carries the ships the greater part of the way across the Isthmus on a level about 85 feet above the oceans, and supplies the water for passing them through the locks from sea to sea, but it also turns the wheels that generate the electric current for lighting the canal, for operating the gigantic gates and other locking machinery, and for the locomotives which tow the ships through the locks. Electric current will also be used for coal handling plants at both ends of the canal, for machine shops, water works, dry docks, and possibly in the future for hauling trains on the Panama Railroad. To insure continuity of service a steam-electric station at Miraflores, erected a few years ago to supply electric power for construction work, will be held ready to pick up the load when necessary.

On account of the great distance, the current is transmitted at a voltage of 44,000 from the power stations to both ends of the canal. The step-up transformers are, however, not located in the power plants, but in

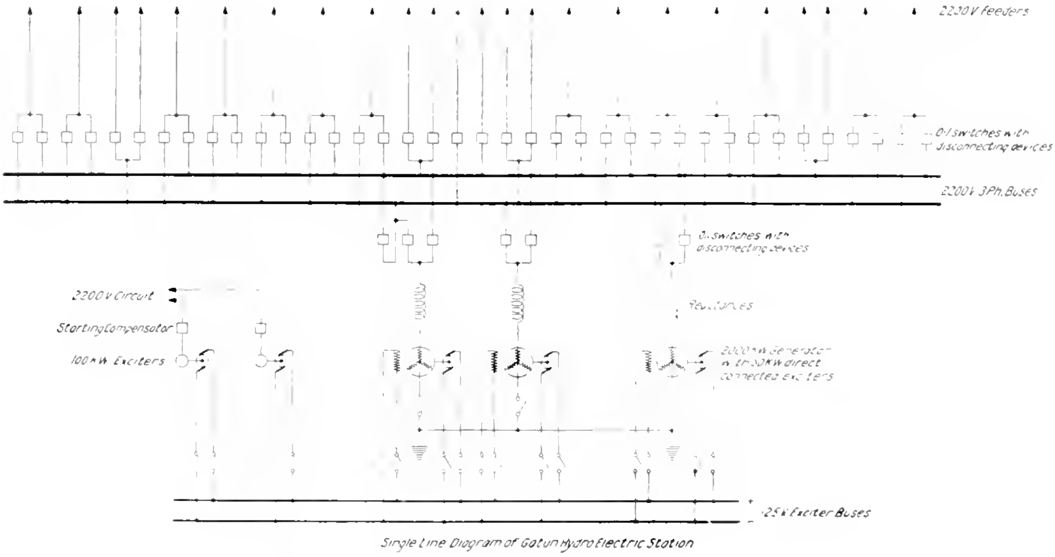

Fig. 1 Single Line Diagram of Gatun Hydro-Electric Station

substations in their vicinities; therefore, the power plants generate and distribute only 2200-volt current.

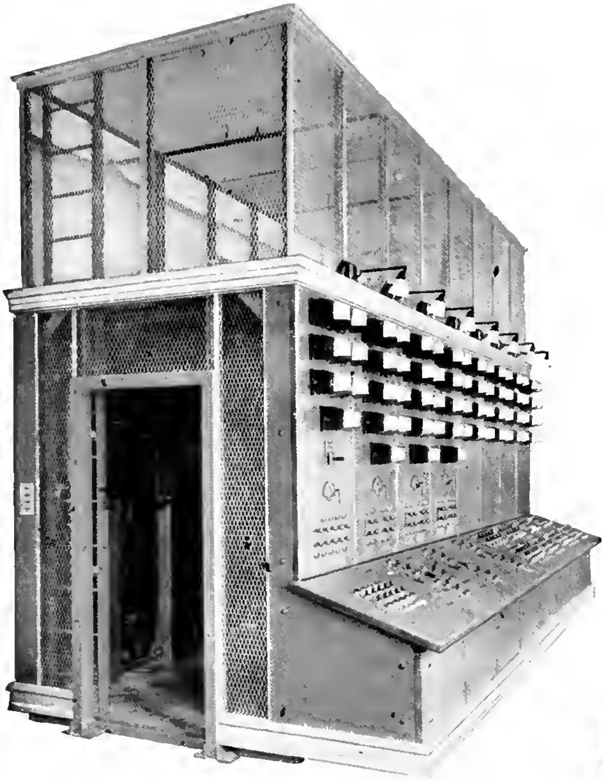

Fig. 2. Instrument and Control Benchboard in Gatun Hydro-Electric Station

### Station Equipment

The Gatun hydro-electric station has at present a capacity of 6000 kw. divided among three generators; and the station plans anticipate the possibility of doubling this equipment, should that amount of power be required for the Panama Railroad. Fig. 1 shows a single line diagram of the principal circuits and apparatus in this station, from which it will be seen that each of the three 2200-volt, 25-cycle, 2000-kw. generators is provided with a 50-kw., 125-volt, direct-connected exciter. In addition to these, there are two 100-kw. exciters driven by 2200-volt induction motors. These exciters can also be used for charging the control battery.

The double bus, double switch system was naturally selected for this station as being the most flexible for the requirement of uninterrupted service, which the engineers of the Isthmian Canal Commission have so carefully considered, though without superfluous complications.

### Instrument and Control Board

The main switchboard is of the benchboard type, as shown in Fig. 2, with vertical rear board for relays, watthour meters, graphic instruments and control battery equipment. The space between the front and the rear boards is enclosed by grille work with doors at both ends, and a metal moulding extending along the floor and the top of the board gives a finished appearance to the whole. On the top of the switchboard is a second story, for the electrically controlled generator and exciter rheostats, accessible by means of a ladder inside the structure. The first panel from the left in the benchboard controls the exciters, the next three the generators, and the remaining four the twenty-four feeder circuits. The system of connections is represented by dummy busses of polished copper on top of the bench. Fig. 3 shows the arrangement of operating busses and fuses, potential busses, instrument resistances, and the channel iron risers with distributing tubes, which carry the instrument and control leads to their points of connection on the board.

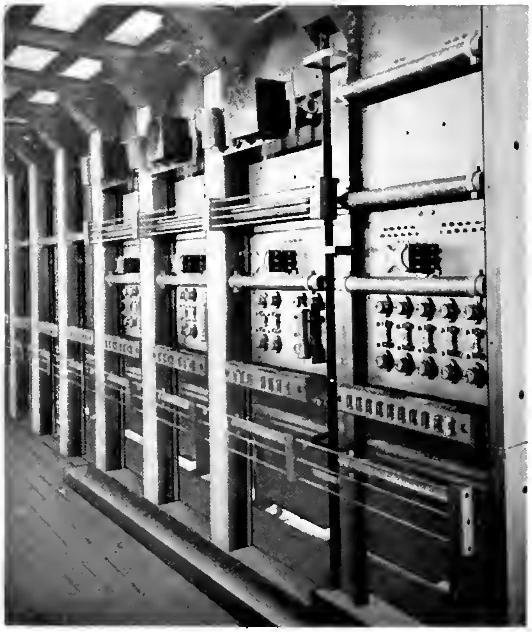

Fig. 3. Interior of Benchboard

A generator voltage regulator, transferable to either of the two sets of busses, is installed on a separate pedestal which also carries the synchronism indicators and clock.

### Exciter Board

As mentioned above, the exciters are controlled from the benchboard, but the electrically-operated exciter switches and field switches are mounted on a separate board located so as to make the exciter connections as short as possible. This arrangement eliminates the exciter busses and the main connections from the control board, but leaves the control of the whole equipment in the hands of the operator.

### Bus and Switch Compartments

The bus and switch compartments are located on two galleries as shown in Fig. 4. On the upper are located the control board near the end of the station (that may be extended) the generator reactances, the compartment for generator current and potential transformers, and the generator oil switches. From the oil switches, connections are made through the floor to the busses on the gallery below, on which gallery are also the feeder oil switches, and the compartment for the instrument transformers and cable bells. On the main floor just below this gallery is the cable vault with racks for the feeder cables.

All compartments are built of concrete with flame-proof doors. The busses and connections are made of solid copper rods of sufficient size to give a rigid construction even where the current is very small. After installation the busses and connections and all joints are heavily insulated with varnished cambric to make them safe.

The oil switches are solenoid-operated and provided with mechanisms for disconnecting them easily for cleaning and adjustment. This feature was described in detail in the January, 1914, issue of the GENERAL ELECTRIC REVIEW.

# PATENTS

## PART II

BY CHAS. L. CLARKE

CONSULTING ENGINEERING DEPARTMENT, GENERAL ELECTRIC COMPANY

Part I of this article, which appeared in the May number of the REVIEW, dealt with the laws relating to patents, the legal meaning of the terms "discovery" and "laws of nature" or "principles," and the things that form proper subjects of patents. The consideration of the rules of law on invention in this issue points to the uncertainties involved in an effort to forecast what the decision of the court may be, when this question arises in patent suits. Guesses as to the result may be made; and the larger the experience, and the better the judgment, the greater is the probability of arriving at a correct guess; but one of the litigants is certainly bound to be disappointed. The question of invention is one of special interest to the engineer engaged in designing new machines or developing new methods of manufacture.

## INVENTION VERSUS MECHANICAL SKILL

### General Characteristics

It will be noted that in the quotations from the Constitution and statutes hereinbefore given, no explanation of the meaning of the word "invented," or of the term "invention," is found; nor has any definition of them ever been incorporated in the statutes relating to patents. The determination of what constitutes invention has, therefore, been left to the courts.

Although the Patent Office may decide that a person has made an invention, and grant a patent therefor, nevertheless, should the owner of the patent bring suit against another for alleged infringement thereof, and the latter attempt to prove that the thing patented was not an invention, and the court agree with him, the patent becomes invalid, as if never granted. Such a result, however, is not derogatory to the efficiency of the Patent Office, or the ability of its staff. The Office in case of application for a patent considers whether the thing sought to be patented required invention; but the prosecution of the application is in secret, as far as the public is concerned, and thus the Office cannot have the benefit of such a full presentation of evidence and argument, on the question of invention, as may be brought to the attention of the court by contestants in a suit after the patent has been granted.

Moreover, it should be borne in mind that the question of invention is, after all, a matter of opinion, as to which even the courts have frequently differed in the same case upon the same presentation of facts. For no definite rule on the subject has been formulated further than the dictum that to entitle improvement to patent protection:

> * * * it must be the product of some exercise of the inventive faculties. (Pearce v. Mulford, 102 U.S. 112, 1880.)

which, as a definition, is merely going around in a circle; we are still in the dark as to the circumstances under which exercise of the inventive faculties is required.

Those faculties employed in making an improvement in a thing that does not amount to invention, are spoken of as *mechanical skill*, scientific skill, and the constructive ability or faculty; such improvement is the work of the *skilled mechanic*, or person skilled in the art or science to which the improvement appertains, or is a matter of engineering, and is not the product of invention.*

We may deduce an indefinite, but somewhat useful, conception of the nature of invention from the decision of Justice Matthews, as to what amounted in a certain case to nothing more than the exercise of mechanical skill:

> It [a patented identifying revenue mark or label] is but the display of the expected skill of the calling, and involves only the exercise of the ordinary faculties of reasoning upon materials supplied by a special knowledge, and the facility of manipulation which results from its habitual and intelligent practice; and is in no sense a creative work of that inventive faculty which it is the purpose of the Constitution and the patent laws to encourage and reward.
>
> It * * * seems to us not to spring from that intuitive faculty of the mind put forth in the search for new results, or new methods, creating what had not before existed, or bringing to light what lay hidden from vision; but, on the other hand, to be the suggestion of that common experience, which arose spontaneously and by a necessity of human reasoning, in the minds of those who had become acquainted with the circumstances with which they had to deal. (Hollister v. Benedict Manufacturing Co., 113 U. S. 72, 73, 1884.)

From the foregoing opinion, mere mechanical skill may be said to reside in the production of a thing, when it proceeds from application of the reasoning faculties naturally to be

---

* For *Mechanical Equivalent*, see Section 9, under "Rules of Law on Invention.

expected of those skilled in the art to which the thing belongs; and is substantially the thing in all essential features, that intelligent mechanics or scientists in that calling may be expected to produce, if made acquainted with the problem to be solved, or result desired. The skilled mechanic is not one whose ability confines him, however, to mere imitation, but a mechanic, who may at least vary from the ordinary in minor particulars without departing from the real substance of the thing.

On the other hand, if the production of the thing does not appear to be suggested by and result merely from skilled knowledge combined with good reasoning, but to require an additional mental something of a so-called creative nature, it may be said to amount to invention. It is the additional mentally created something that the courts search for, and form an opinion as to its presence or absence, in suits where the question of invention is contested.

In line with the foregoing, we quote from an opinion by Justice Bradley:

> It may be laid down as a general rule, though perhaps not an invariable one, that if a new combination and arrangement of known elements produce a new and beneficial result, never attained before, it is evidence of invention. (Loom Co. v. Higgins, 105 U.S. 591, 1881,)

which with its suggestion of exceptions, still leaves us far short of knowing precisely in what invention consists.

Justice Brown, in a case before the Supreme Court, said:

> The truth is the word [invention] cannot be defined in such manner as to afford any substantial aid in determining whether a particular device involves an exercise of the inventive faculty or not. In a given case we may be able to say that there is present invention of a very high order. In another we can see that there is lacking that impalpable something which distinguishes invention from simple mechanical skill. Courts, adopting fixed principles as a guide, have by a process of exclusion determined that certain variations in old devices do or do not involve invention; but whether the variation relied upon in a particular case is anything more than ordinary mechanical skill is a question which cannot be answered by applying the test of any general definition. (McClain v. Ortmayer, 141 U. S. 427, 1891.)

The "fixed principles" referred to above, constitute *rules of law* which have been adopted by the courts as a guide to aid in deciding the question of invention. They are themselves based upon formulated opinions of the courts, and are subject to exceptions, which are also matters of opinion. Thus the whole foundation upon which the determination of the question of invention rests is a veritable honeycomb of opinion, and liable to those uncertainties that are dependable upon the necessarily human disposition and bent of mind of the court. We say this with no intention of belittling in the least the dealing of the courts with the subject, the difficulty of which is well attested by the fact that a decision as to invention is sometimes pronounced wrong, and reversed on appeal to a higher court.

### RULES OF LAW ON INVENTION

We will now consider the rules of law, which mainly by exclusion, that is to say, by designating those *operations that do not constitute invention*, enable the courts, with reasonable uniformity of result, to pass upon the question of invention in the cases brought before them in all their varying aspects. Our dealing with the subject must necessarily be limited, and substantially confined to a general presentation, and illustration in some instances, of such salient features of the rules as may be of peculiar interest to the engineer.

**1.** *It is not invention to produce a process, machine, manufacture, composition of matter or design which any skillful mechanic, electrician, chemist, or other expert would produce whenever required.* (*Walker.*)

No better insight into the reasons for this just rule can be given than by taking space here to quote from the opinion of Justice Bradley in a case in which the Supreme Court declared a patent invalid. It deserves careful reading:

> The process of development in manufactures creates a constant demand for new appliances, which the skill of ordinary head workmen and engineers is generally adequate to devise, and which, indeed, are the natural and proper outgrowth of such development. Each step forward prepares the way for the next, and each is usually taken by spontaneous trials and attempts in a hundred different places. To grant to a single party a monopoly of every slight advance made, except where the exercise of invention somewhat above ordinary mechanical or engineering skill is distinctly shown, is unjust in principle and injurious in its consequences. The design of the patent laws is to reward those who make some substantial discovery or invention which adds to our knowledge and makes a step in advance in the useful arts. Such inventors are worthy of all favor. It is never the object of those laws to grant a monopoly for every trifling device, every shadow of a shade of an idea which would naturally and spontaneously occur to any skilled mechanic or operator in the ordinary progress of manufactures. Such an indiscriminate creation of exclusive privileges tends rather to obstruct than to stimulate

invention. It creates a class of speculative schemers who make it their business to watch the advancing wave of improvement, and gather its foam in the form of patented monopolies, which enable them to lay a heavy tax upon the industry of the country without contributing anything to the real advancement of the arts. It embarasses the honest pursuit of business with fears and apprehensions of concealed liens and unknown liabilities to lawsuits and vexatious accountings for profits made in good faith. (Atlantic Works v. Brady, 107 U. S. 199, 1882.)

**2.** *It is not invention to produce an article which differs from some older thing only in excellence of workmanship.* (*Walker.*)

The incentive for excelling in workmanship proceeds from the better commercial advantage thereby gained in outselling competitors, or in a larger profit. Nickel plate, attractive finish, fine fit and high polish may be of marketable, but not patentable value.

**3.** *It is not invention to substitute superior for inferior materials, in making one or more or all of the parts of a machine or manufacture.* (*Walker.*) *Or merely to change the material.* (*Renwick.*)

It is obvious that substitution of steel or wrought iron for cast iron, or brass for either, where the purpose sought naturally turns attention to choice of the most suitable metal, is within the judgment of the skilled mechanic. And the same may be said respecting many other materials.

*Exceptions:* (*a*) The substitution of rubber-covered rolls for felt in wringing machines was pronounced invention. The rubber rolls were not only elastic, but had the additional quality of impermeability to water, whereby a new property or mode of operation of the machine, and a better result were obtained. (*b*) The advantage of using silver in the commutators and brushes of electrical motor meters in place of other metals is now obvious to the electrician acquainted with that art; along with high conductivity, good electrical contact is maintained in comparison with the use of such materials as brass, copper and platinum under long-continued service. The change to silver would no doubt have resulted in a good patent had not a description of the similar use of silver in electrical whirligigs been published in an almost forgotten little book years before. (*c*) The discovery that safranine-azo-naphthol, long thought to be insoluble and valueless, was soluble by prolonged washing, so as to produce a cheap and valuable substitute for vegetable indigo, was held a patentable invention. (*d*) *It may or may not be invention to substitute one material for another in a process, or in a composition of matter, and other rules than mere substitution must be applied to decide the question.* (*Walker.*) For instance, in a chemical process the reactions must be taken account of, and may be entirely different, and produce radically different results by substituting one element or agent for another.

**4.** *It is not invention to enlarge or strengthen a machine so that it will operate on larger materials than before.* (*Walker.*)

A circular sawmill, adapted to sawing boards from logs, was held not to be invention in view of small circular saws having been used for sawing lath from small wood blocks.

**5.** *It is not invention to change the size or degree of a thing, or of any feature or function of a machine or manufacture.* (*Walker.*) *Or merely to change size or degree.* (*Renwick.*)

(*a*) Invention was found absent in pulverized glue, ground from flake glue. (b) Paving stones made of an old shape, but with sides made rougher than before, to obtain a better bond, were held to be only a change in degree, and not patentable.

*Exceptions:* (*a*) In the early miner's lamp, the flame was protected from draughts by a coarsely perforated metal casing, which permitted passage of light; but the enlarged flame resulting within the casing from an explosive mixture of gas, readily passed through the perforations, and was communicated to the body of gas in the mine. Davy designed a safety lamp in which the casing was also perforated, preferably of wire gauze, with the perforations much smaller than in the old lamp, thereby preventing passage of the flame from the inside to the outside of the casing. Preventing passage of the flame was a new function or result of using the smaller perforations, and the manner of prevention was a new mode of operation. Although not patented by Davy, undoubtedly his lamp was an invention. (*b*) *It may or may not be invention to change the degree of heat, or other agent, used in a process, or to change the amount of ingredient used in a composition of matter, or to change the size of a feature of a design. The question of invention is to be decided by other rules than those of mere size or degree* (*Walker*). For example, old newspapers had been macerated to a pulp, which was treated with alkalies to remove, as far as possible, the oil of the printer's ink; the pulp was then made into paper board. Later on, paper board was made from old newspapers without removing the oil, with an improvement in toughness and elasticity before unknown in the finished product. Although it was demonstrated that a small amount of oil remained in the earlier product, which it was impracticable wholly to remove, nevertheless, the paper board in which all the oil of the ink was allowed to remain, and resulted in a superior product, was held to be invention. It could perform new functions with a new mode of operation by virtue of its toughness and elasticity.

**6.** *It is not invention to devise an aggregation of operations in a process, or of parts in a machine or manufacture* (*Walker*).

Non-patentable aggregation, as distinguished from patentable combination, has been considered hereinbefore in Part I, under the head of *Combination and Aggregation of Parts in a Machine.*

**7.** *It is not invention to duplicate one or more of the parts of a machine or a manufacture; unless the duplication causes a new mode of operation, or produces a new unitary result.* (*Walker.*) *Or merely to duplicate old devices.* (*Renwick.*)

(*a*) To place a pane of glass in the fare-box of a street car, so that the passengers could see into the box, was held not to be invention, when a glass had previously been provided for the benefit of the driver. (*b*) The furnaces of tobacco-curing houses had been provided with a single fire-place on each side of the chimney; it was held no invention to have two or more fire-places of different sizes in place of one.

*Exceptions:* (*a*) Single hydraulic turbines had been so installed on vertical shafts, that in operation the water exerted a considerable downward pressure on the step-bearing, additional to the weight of the shaft and wheel. Placing two turbines, face to face, on the shaft, so that the upward pressure of one counter-balanced the downward pressure of the other, was invention. The duplication of the turbines caused a new mode of operation and produced a new result. (*b*) A patent was sustained for an ice-cutting machine, which consisted of a plough-stock or beam with the usual guiding handles, provided with a number of cutters arranged one behind the other, each projecting downward more than the one in front of it; a deep groove was thereby cut in the ice by a single passage over it, each cutter preparing the way for the following one. The carpenter's plough with a single cutter for cutting grooves in wood by passing the tool back and forth until the groove was of the requisite depth was old; and it was contended that the several cutters in the ice plough were but duplication of the single cutter in the carpenter's plough, and not invention. But the court held that cutting the groove by a successive series of cuts simultaneously produced by a single passage of the ice-cutting machine was a different mode of operation from cutting the groove by successive cuts produced by a number of passages of the carpenter's tool.

**8.** *It is not invention to omit one or more of the parts of a machine or manufacture, unless that omission causes a new mode of operation of the parts retained.* (*Walker.*)

In the Nicholson wood pavement, the blocks were laid on a board foundation, with board strips between the rows of blocks. It was held that omission of the board foundation and strips, so that the pavement wholly consisted of blocks, did not constitute invention, because the parts omitted took their functions away with them, and the retained blocks did no more than they did before the omission, that is to say, they obtained no new mode of operation, and to make the change with this result was merely a matter of choice.

*Exception:* Before the advent of the meat-mincing machine, now in common domestic use, in which a wide, screw-shaped rib on the hand arbor receives the pieces of meat direct from the hopper of the casing, and feeds them forward with pressure against the mincing end-plate and revolving cutters, a similar machine had been made, in which the feed-screw did not extend back to the hopper; instead thereof, a set of radially-placed cutting blades was fixed opposite the hopper on the arbor, and another set engaging therewith on the inside of the casing, to give the meat a slicing, which was thought necessary before it passed to the screw. The cutting blades were not efficient in passing the meat to the screw, and in fact did more harm than good in causing the machine to choke. The discovery that by omitting the cutting blades and extending the screw back opposite the hopper, the screw would receive the meat without preliminary slicing, and feed it forward to the mincing devices without choking, as rapidly as it could be fed through the hopper, thus greatly increasing the efficiency and capacity of the machine, was pronounced invention.

**9.** *It is not invention to change a process, machine, manufacture or composition of matter, by substituting an equivalent for either of its parts; unless the new part, not only performs the function of the part for which it was substituted, but also performs another function, by another mode of operation.* (*Walker.*) *Or merely* *to substitute one old device for another.* (*Renwick*).

This section relates to so-called *equivalents* of parts in a machine or manufacture, of operations in a process, or of substances in a composition of matter—also termed *mechanical equivalents* in machines, and in manufactures and processes of a mechanical nature. Old equivalents are assumed to be ready at the hand of the skilled mechanic, or person skilled in the art to which the thing appertains, to be used by him, one in place of the other, as he may elect, without exercise of invention.

*It is safe to define an equivalent of one thing as a second thing that performs the same function, and performs that function in substantially the same manner (has substantially the same mode of operation) as the first thing.* (*Walker.*)

(*a*) Nitro-glycerine compounded with absorbent matter, as infusorial earth, forms dynamite. A compound formed of nitro-glycerine mixed with mica scales, called mica powder, was held to be the substantial equivalent of dynamite, although in mica powder the nitro-glycerine was not absorbed in the minute capillary tubes of infusorial earth, as in dynamite, but held upon the surfaces of mica scales. The compositions operated in practically the same way with the same result. (*b*) A bulb-syringe in which the inflow tube was connected with the bulb near the connection for the outflow tube was held equivalent to a syringe in which the tubes were oppositely connected with the bulb. No practically different function, operation or result pertained in one syringe over the other. (*c*) It was decided in respect to the operation of lamps in multiple-arc supplied from a compound-wound dynamo-electric machine, whereby the voltage at the lamps was automatically maintained substantially constant as the lamp load varied, that the lamps, as a load upon the machine, were the equivalent of a load of electro-plating cells connected in multiple with a machine of the same character. (*d*) Screws, levers, springs and weights are often equivalents of one another in mechanisms, the skilled mechanic being at liberty to substitute one for the other. But in some instances one of them, say, a spring, may operate successfully in the environments in which it is placed, and perform a desired function, where another, say, a weight, would fail, in which case they would not be equivalents.

**10.** *It is not invention to combine old devices into a new machine or manufacture, without producing any new mode of operation.* (*Walker.*) *Or merely to apply an old thing to perform its usual function with its usual mode of operation, or movement, or merely to change location, arrangement or direction of motion.* (*Renwick.*)

(*a*) There was no invention in substituting a figured hand-operated roller for pebbling leather in place of a smooth roller in a machine previously used for compressing leather. (*b*) Nor in giving paper collars the same surface that had been embossed upon other paper articles. (*c*) Nor in covering hard base-balls with a double cover, after such balls had been made with a single cover, and soft balls with a double cover.

*But while a new combination with an old mode of operation is not invention, an old combination with a new mode of operation may be invention.* (*Walker.*)

(*a*) The relative re-location of old parts of a reaping machine, so as to deliver the grain with the stalks lying cross-wise, instead of parallel, to the line of travel of the machine, with a decided advantage from so doing, was held invention. (*b*) In a seed-sower the centrifugal discharging wheel had been set on a vertical shaft, and spread the seed umbrella-fashion over a limited breadth of ground as the machine traveled along. Turning the shaft in the horizontal position, so that the wheel discharged the seed vertically many feet into the air and distributed them over a very much larger space, was held to constitute invention. (*c*) In a corn-shelling machine consisting of a rotating toothed cylinder and a stationary toothed casing for separating the corn from the cob, a traveling apron for feeding the ears to the sheller, and a winged beater, the latter revolved so as to knock back the ears that might ride upon the others and tend to choke the sheller. The operation was unsuccessful, as the choking was not prevented. It was discovered that by reversing the rotation of the beater so as to drive the riding ears forward, the choking was prevented. This was a new mode of operation, and the patent for the old machine as rearranged was sustained.

*A new combination with a new mode of operation, may be invention; even if all the parts thereof are old, and even if the function of the combination, is also old.* (*Walker.*)

Such is the opinion of the writer from whom this rule is taken, although he adds that several cases contain dicta contrary to the rule, but, nevertheless, believes, as he expresses it, that they must have resulted from incomplete thinking. He cites only one case, that of

Deere & Co. v. Rock Island Plow Co., 84 F. R. 176, 1898, which relates to Waterman patent 480,304, for an improvement in corn planters. The Circuit Court dismissed the bill for want of novelty, thus for non-patentable invention; this decision was reversed by the Circuit Court of Appeals, and the patent sustained by Judges Jenkins and Showalter, Judge Woods dissenting. We have in this case a good practical illustration of the uncertainty attending the determination of the question of invention.

**11.** *It is not invention to use an old process, machine, manufacture, composition of matter, or design, for a new and analogous purpose.* (*Walker.*) *Or merely to apply an old thing to a new purpose, or "double use" of an old thing, as sometimes termed.* (*Renwick.*)

This rule relates to what is called "double use" of an old thing, and applies to its use for a purpose, which, although it may be new, is, nevertheless, so suggestive of the use of the thing for the old purpose, that the new application may not amount to invention.

(*a*) A chamber with two walls having a space between them for a freezing mixture to preserve fish, was decided not to be invention in view of the older ice-cream freezer. The chamber constructed as described was a double use of the freezer. (*b*) A circular saw with removable teeth was not invention because of the earlier use of a circular disk with removable cutters for making tongues and grooves. The saw was put to a use analogous to that for which the disk was employed. (*c*) It was held not invention to use a compound-wound electric generator in a lighting system after the use of such a machine for supplying a system of electro-plating cells had been published, the purpose of the compound-winding in each case being to preserve a practically constant voltage at the lamps or cells (which were connected in multiple) when the number of them was varied. See reference to the same matter under Section 9, relating to equivalents. (*d*) Making changes in the method of communicating power from the armature of an electric motor to a street car axle by means of such well-known devices as friction clutches, cog-gearing and pulleys was held to be only a double use of old things.

*It may be invention to use an old process, machine, manufacture, composition of matter, or design for a new and non-analogous purpose.*

Although torsional springs had been used in clocks, and for closing doors, etc., it was held that the use of a torsional spring in a telegraph signalling key, to serve as the support for the key-lever in place of the old pivoted shaft, thus doing away with bearings, which were subject to wear, besides resulting in omission of the retractile spring for elevating the lever except when depressed by the finger, was for a new and non-analogous purpose, and invention.

*Where a new use of an old thing consists in combining it with other things in a new organization, invention may be present in the combination, though absent from the separate parts.* (*Walker.*)

Although a permanent magnet with a wire coil upon its polar end or ends was old, the combining of such device with other old devices to constitute a telephone, and thereby a new use of the magnet, was pronounced invention.

**12.** *It is not invention to change the form of a machine or manufacture, if in the domain of mere construction.* (*Walker.*) *Or merely to change the form.* (*Renwick.*)

(*a*) A luggage carrier for bicycles was held not invention, as involving merely a change in the form of an ordinary hand bag to fit the available space within the frame of the machine. (*b*) It was held that after a patent had been granted for a storage-battery plate containing rows of holes, there was no invention in making uniform rows of holes, or in merely making the holes round, square or triangular.

*But where change of form involves a change of mode of operation, or of function, or of result, it is invention, unless it is held to be otherwise in pursuance of some rule other than any that relates to form.* (*Walker.*)

(*a*) A coal-car body of conoidal form, instead of the old rectangular form, was held to be invention. The former was subjected only to tensile stresses, in place of the transverse stresses present in a rectangular car body, which introduced a new mode of operation, whereby the new design could be made of thinner and lighter material, and thus have less dead weight to be hauled. (*b*) The pole faces of an alternating current generator are sometimes shaped so that the length of the air gap varies from a minimum under the center of the pole to a maximum at the pole tip, in such way as to obtain approximately a sine curve distribution of magnetic flux over the pole faces, and therefrom the generation of a sine wave of electromotive force in the armature windings. Constructing the pole faces in this form, as contrasted with the older way of making them concentric with the armature face, and thus with an air gap of constant length over the entire pole face, would be invention, if new.

**13.** *It is not invention to change the proportions of a machine or manufacture.* (*Walker.*) *Or merely to change proportions.* (*Renwick.*) *But it may be invention to change the proportions of the ingredients of a chemical combination, or other composition of matter.* (*Walker.*)

Charles Goodyear discovered that by combining crude india rubber with from 6 to 20 per cent of sulphur, and heating the mixture, it became the well-known soft vulcanized rubber, possessing the characteristic of extreme elasticity with additional useful properties over the crude article. A patent was granted in 1844, and was reissued. Subsequently, Nelson Goodyear discovered that if the proportion of sulphur was increased to 25 per cent and more, then upon heating, the mixture assumed the hard properties of horn, was non-extensible, could be moulded, and would take a high polish; it became known as hard rubber or vulcanite. The product was patented in 1851; the patent was later corrected by reissue. The court decided that the product discovered by Nelson Goodyear, resulting from change in the proportions of sulphur and rubber, was invention. The change was accompanied by a change in the properties of the product, and thus a change in mode of operation.

**14.** *It is not invention merely to discover a new property of matter.* (*Renwick.*)

To discover a new property of matter must amount substantially to discovery of a law of nature, which is not invention. Renwick says:

> There does not appear to be any condition of facts in which the *simple* discovery of a new property of matter amounts to an invention; but there are undoubtedly cases in which such a discovery accompanied with a practical application of it, by which the newly discovered property is made available for a useful purpose, amounts to invention.

which is in line with our consideration of laws of nature, in Part I.

*(To be continued)*

# TRANSMISSION LINES AND OUTDOOR SUBSTATIONS OF THE GEORGIA RAILWAY AND POWER COMPANY'S TALLULAH FALLS DEVELOPMENT

By Eric A. Lof

Power and Mining Engineering Department, General Electric Company

The June number of the Review contained a descriptive article of the hydraulic features and generating station of the Georgia Railway and Power Company's new 100,000-h.p. development at Tallulah Falls. The present article deals with the 110,000-volt transmission lines and the outdoor substations. Of the latter, the Boulevard substation at Atlanta will be described in detail. It is the largest station of its kind, and the design involves many very interesting features.—Editor.

## Transmission Lines

The general layout of the transmission system is shown in the map, Fig. 1, and in the diagram, Fig. 2. As seen from these, there is a 110,000-volt double-circuit line from the generating station at Tallulah Falls to the Boulevard substation at Atlanta, a distance of 90 miles. About midway between these two points a tap is taken off for the Gainsville substation. From the Atlanta substation there are two 110,000-volt, double-circuit outgoing lines, one to Lindale, a distance of 80 miles, and the other to Newnan, a distance of 40 miles. The former is tapped at the Cartersville and Marietta substations. In addition to these main transmission lines, there is a 100,000-volt double-circuit line from the Tallulah Falls Station to Easley, S. C., for tying in with the Southern Power Company. The system is furthermore tied in with the Eastern Tennessee Power Company at Lindale, with the Columbus Power Company at Newnan, and with the Central Georgia Power Company at Atlanta.

## Tallulah Falls—Atlanta Line

This consists of six No. 4 0 copper conductors carried on a single steel tower line. Three wires are suspended in a vertical plane on each side of the tower, the vertical spacing being 9 ft. while the horizontal distance between the two circuits is 16 ft., giving a clearance between conductor and the tower members of 5 ft. 6 in.

The towers are of the American Bridge Company's rigid four-legged construction, Fig. 3, spaced between six and seven hundred feet apart on the average. They are provided with four crossarms, the upper for supporting the ground wires and the three lower for the line conductors. Their height is 66 ft., and they measure 5 ft. square at the top, 20 ft. at the base, and have a weight of 5554 lb. The design was based on the following load condition:

(1) A longitudinal pull of 4300 lb. at right angles to the end of any crossarm, which represents the stress due to the dead-ending of one conductor.

(2) A vertical load of 1,500 lb. at the ends of any or all crossarms, this being the weight of the wire and insulators in adjacent spans.

(3) A load of 1500 lb. in any direction at the top of tower, which corresponds to the wind pressure on the projected area of the tower.

(4) A load of 10,000 lb. at right angles to the line or parallel to the crossarms; that is, 2500 lb. at each crossarm. At the same time,

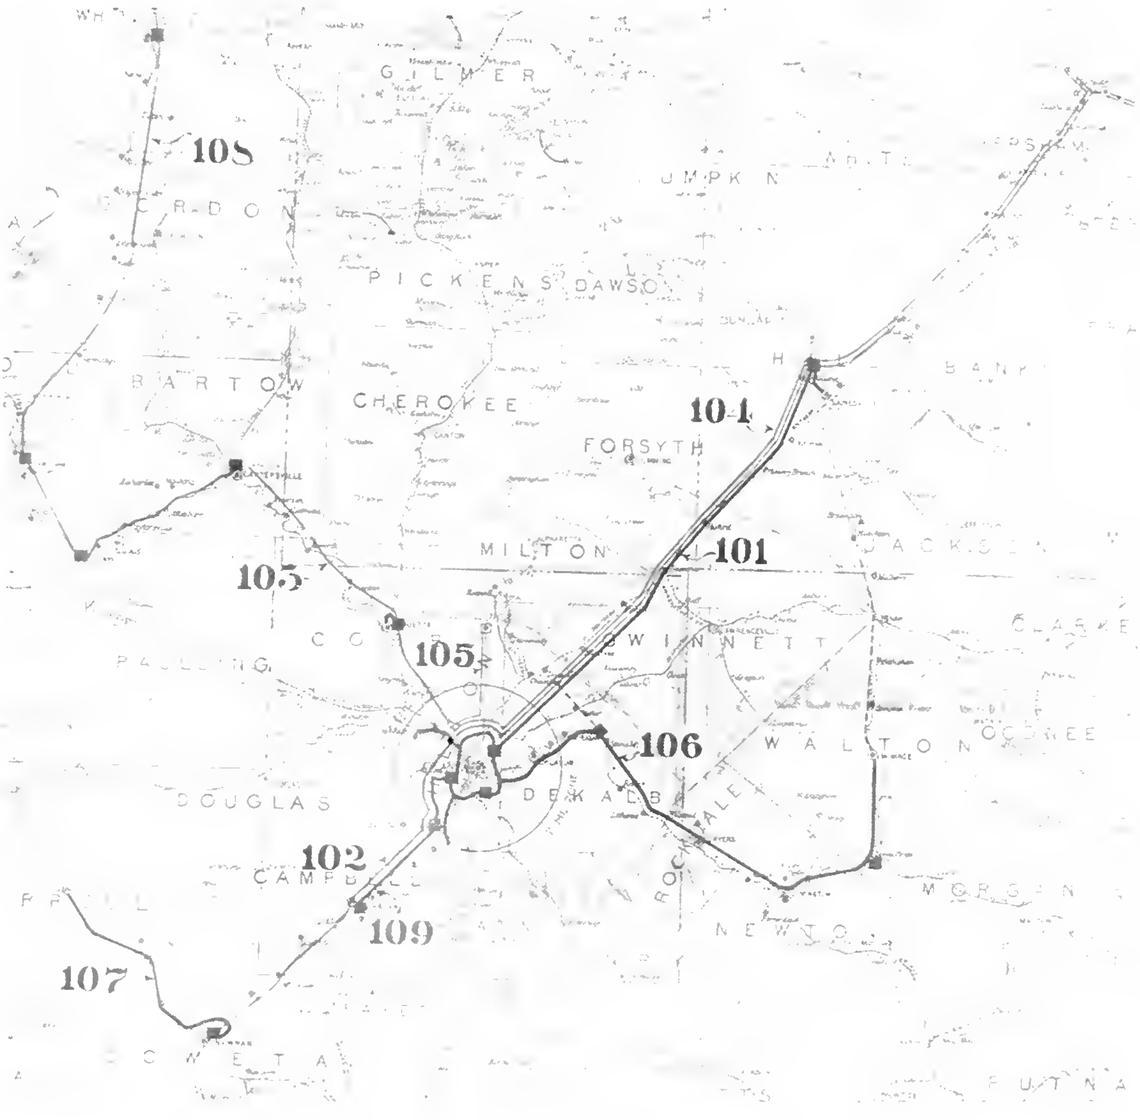

Fig. 1. Map of Section of Country Served by the Georgia Railway and Power Company

a pull parallel to the line or at right angles to the crossarms of 8000 lb.; that is, 4000 lb. in the same or opposite directions at each end of any single crossarm or at any one end of any two crossarms. The first condition represents the wind pressure on the projected area of the arms and wires themselves, and the second condition that two wires may be broken, one on each side of the crossarm at different ends, resulting in a couple which sets up torsional strains in the tower structure.

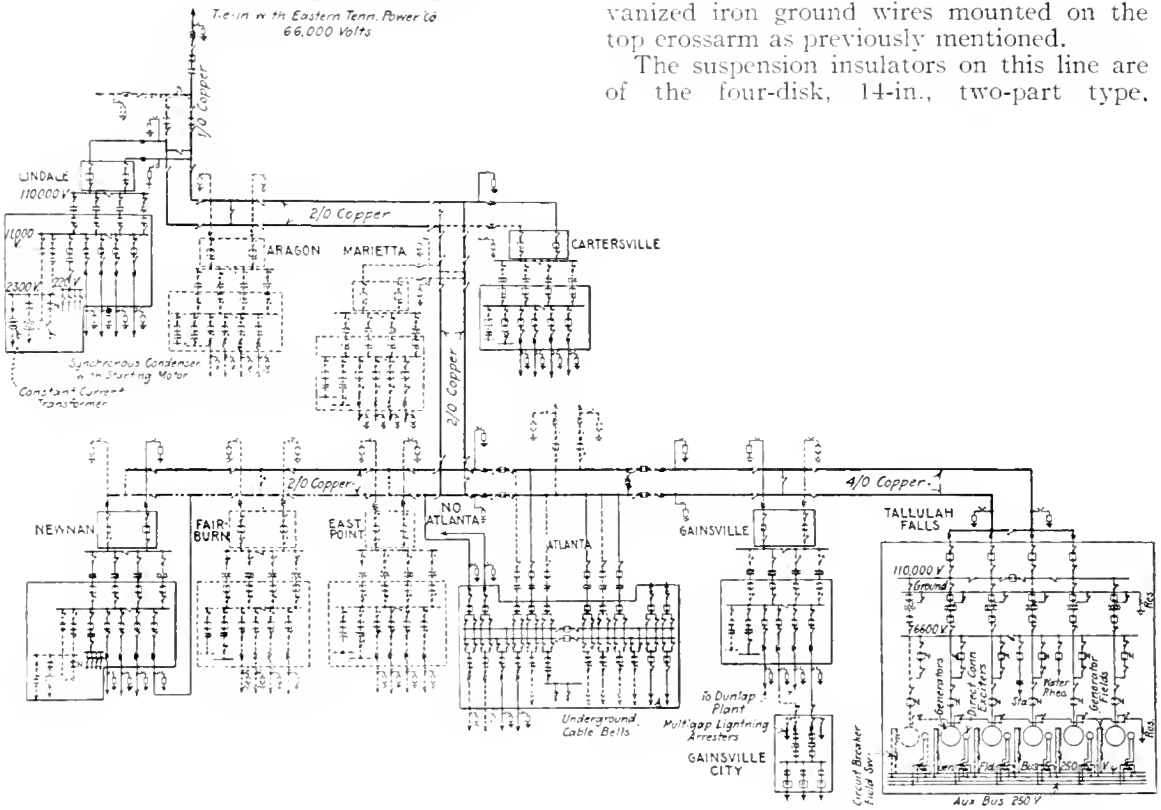

Fig. 2. Wiring Diagram of System

The crossarms are proportioned for a combining of the loads of Case 1 and Case 2, and 1250 pounds horizontal thrust at end of arm. The tower is proportioned for maximum combination of Cases 2 and 3 or 2 and 4. Unit stresses used are 25,000 pounds per square inch net for tension and $\dfrac{25{,}000}{1+\dfrac{l^2}{18{,}000r^2}}$ for compression.

The tower footings are made by extending the corner angles into the ground for a depth of 7 feet, cross angles being bolted to the bottom end.

For the line through the territory around Atlanta special towers are used, which have a height of 80 feet and weigh 8000 pounds. Besides these and the standard towers, angle towers are provided where the direction of the line changes over 10 degrees. These towers, Fig. 4, are of a heavier construction than the standard type and weigh 6880 pounds.

There are two 7/16-in. seven-strand galvanized iron ground wires mounted on the top crossarm as previously mentioned.

The suspension insulators on this line are of the four-disk, 14-in., two-part type, manufactured by the R. Thomas & Sons Company. The strain insulators, on the other hand, consist of five disks.

### Atlanta-Newnan and Lindale Lines

The construction of these two lines is identical, and the design resembles in general that embodied in the Tallulah Falls line. While both lines are of the double-circuit type, only one circuit is erected for each at the present time. The conductors are of No. 2/0 copper, spaced and mounted in a manner similar to the Tallulah Falls line. The towers have a height of 70 ft., measure 4 ft. at the top and 16 ft., at the bottom and have a weight of 4721 lb.

The design of these towers is based on the following load conditions:

(1) A longitudinal pull of 3000 lb. at right angles to the end of any one crossarm.

(2) A vertical load of 1200 lb. at the ends of any or all crossarms.

(3) A load of 1200 lb. pulling in any direction at the top of the tower.

(4) A load of 8000 lb. pulling at right angles to the line or parallel to the crossarms; that is, 2000 lb. at each crossarm. At the same time a pull parallel to the line or at right angles to the crossarms of 5000 lb.; that is, 2500 lb. in the same or opposite directions at each end of any single crossarm or at one end of any two crossarms.

The combination of loading and unit stresses is the same as for the towers with 4/0 wires.

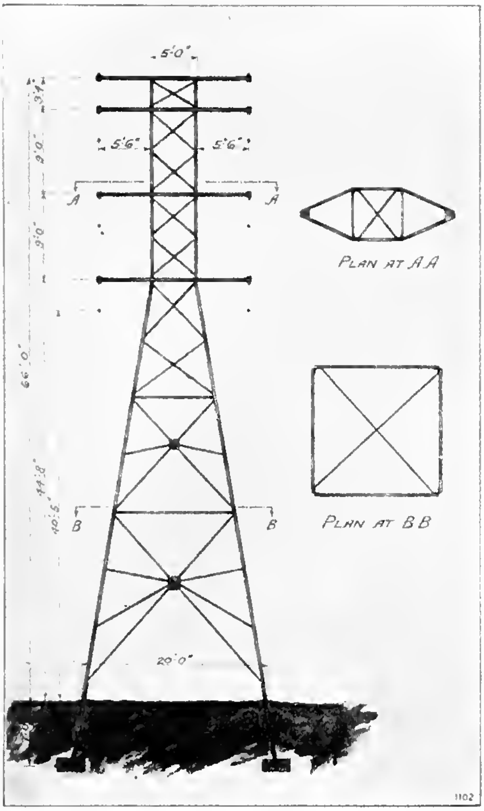

Fig. 3. Standard Suspension Tower, Tallulah Falls-Atlanta Line

The angle towers for these lines are also heavier than the standard type, weighing 6680 pounds each.

There will ultimately be two ground wires for these lines, although at present only one is in place. This consists of a 3/8-in. galvanized stranded steel cable.

The insulators for these two lines are of the Ohio Brass Company's manufacture. They have a diameter of 10 in., the suspension insulators consisting of 5 disks and the strain insulators of 6 disks.

Fig 4. Standard Strain Tower

Provisions are made on all transmission lines for sectionalizing in order to readily locate troubles, and in case of repairs this sectionalizing can be done at all the present substations as well as at the contemplated ones, where switching towers have been erected. In addition to this, means have been provided for sectionalizing every ten to fifteen miles. This being accomplished by connectors inserted in the loops on the strain towers. These connectors are made in the form of ordinary unions, and the lines can readily be opened up, cross-connected, and any sections cut out by the repair crew. After the trouble has been located and the repair made, the connections can be restored just as easily.

### Telephone Circuits

A telephone circuit follows all the transmission lines. It consists of two No. 4 copper-clad wires supported on the towers below the line conductors by 40,000-volt suspension insulators. Transpositions are made at every tower, and the circuit is protected by horn gaps arresters.

Fig. 5. Telephone Booth

Telephone booths, Fig. 5, are erected under the towers at intervals of four miles. These are provided with horn gap disconnecting switches, manipulated from the inside of the booths, for isolating the apparatus from the circuit when not in use. The equipments are furthermore protected with the usual 1:1 insulating transformer, lighting arrester and fuses.

### Substations

All the substations on this system are of the outdoor type, the high-tension apparatus being installed outdoors and the low-tension apparatus indoors. Nine stations are contemplated, as shown by the diagram, Fig. 2. Of these, six have been completed, while only part of the high-tension structure for the others was erected at the same time as the transmission lines. In this manner they serve as switching stations for sectionalizing the lines.

All the substations are of the same general design with the exception of the Boulevard station at Atlanta. This is the largest of them all, being at present time the largest of its kind in existence.

### Atlanta Substation

This station is located on Boulevard Avenue, adjacent to the north side of the city limits of Atlanta. It is laid out for an ultimate capacity of 60,000 kv-a., but at the present time apparatus is installed for only 30,000 kv-a. In order to make a description of this station clearer, it will be divided into two distinct parts; first, that dealing with the high-tension equipment, which is installed outdoors; and, second, that covering the low-tension equipment, which is indoors.

As seen from the diagrams, Figs. 2 and 16, there are at present two 110,000-volt incoming lines from Tallulah Falls and two 110,000-volt outgoing lines, one to Newnan and the other to Lindale. Ultimately, however, there will be two more outgoing 110,000-volt lines, one to each of the last named two places. The incoming lines enter the station through oil switches and connect directly with the two 110,000-volt buses, which can be paralleled by a tie-switch. Similarly, the two outgoing lines are connected to these buses through oil-switches.

There are three 10,000-kv-a. step-down transformer banks installed at the present time, space being provided for three future banks. These are connected to the buses through oil-switches, as shown in the diagram.

The arrangement of the apparatus and the general design of the station is shown by the foundation plan, Fig. 6, and the photographs, Figs. 7, 8 and 9. The transformer banks are located in the center of the station in two rows, and outside of these are the structures supporting the busbars and the high-tension wiring with the connections to the oil switches, which are located on the ground below. These busbar structures are of latticed steel work similar to the steel towers. They rest on concrete foundations, as do all the transformers, oil switches and lightning arresters. The structure and transformer tanks are thoroughly connected to a ground bus.

The busbars consist of copper tubing, which is suspended from catenary copper-clad steel cables. Turnbuckles are provided for taking up any slack or equalizing the stresses, and the messenger cables as well as the buses and other connections are insulated from the structure by 7-disk strain insulators of the Ohio Brass Company's make.

The secondary leads of the transformers are connected to a delta bus, which is mounted on a pipe frame-work back of the transformer banks. From there the connections are lead through bushings down into a tunnel which runs parallel to the transformers and into the basement of the low-tension switch house.

Each of the transformer banks consists of three 3333-kv-a. 110,000/11,000-volt shell-type, water-cooled, single-phase units, connected in delta on both the primary and secondary sides. Both windings are provided with four $2\frac{1}{2}$ per cent taps, so that a constant secondary voltage of 11,000 volts may be obtained with a variation in the primary voltage of 10 per cent above or below 110,000 volts. At the rated continuous full load of 3333-kv-a. the transformers have a guaranteed temperature rise not to exceed 40 deg. C.,

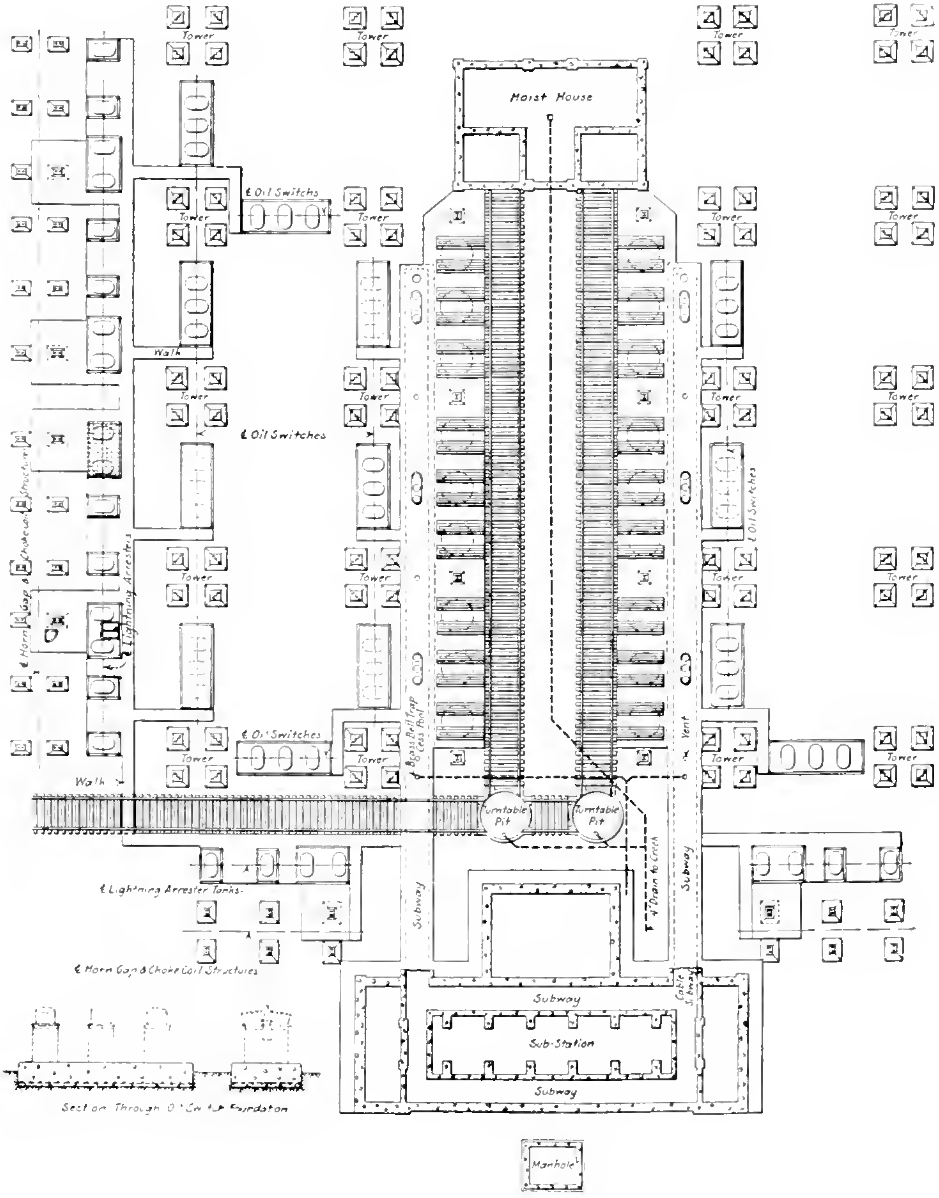

Fig. 6. Plan of Atlanta Substation

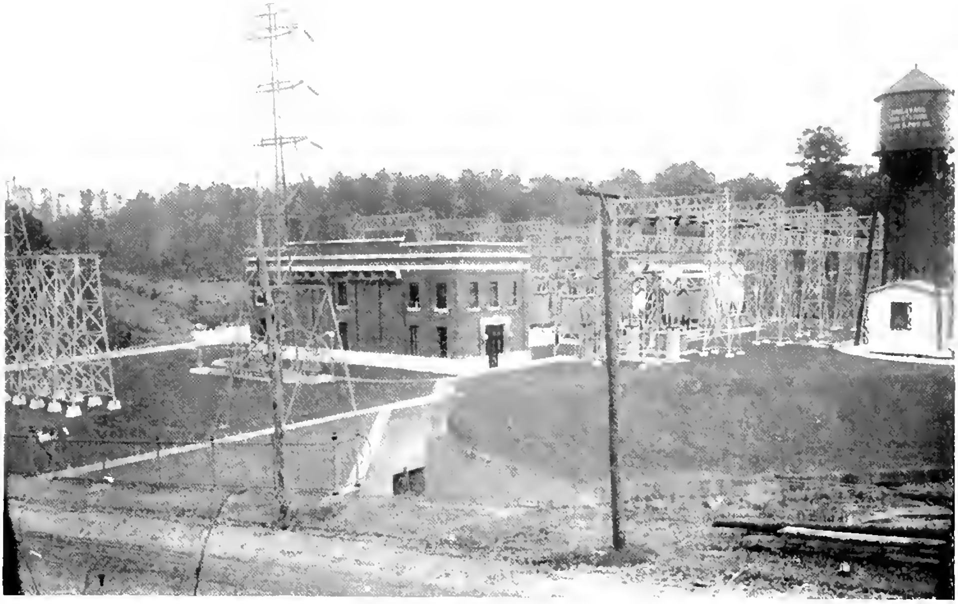

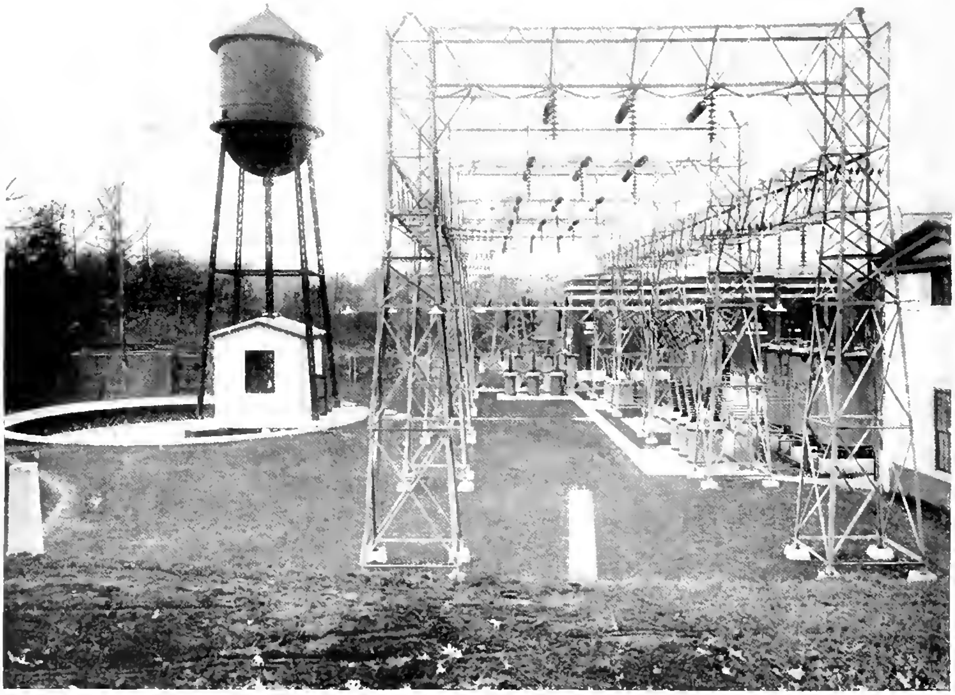

Figs. 7 and 8. Views of Atlanta Substation based on 16 gallons of cooling water per minute at 15 deg. C. For a 25 per cent continuous overload the rise is guaranteed not to exceed 55 deg. C. with 20 gallons of cooling water per minute.

The guaranteed efficiencies are:

| | $1\frac{1}{4}$ Load | Full Load | $\frac{3}{4}$ Load | $\frac{1}{2}$ Load | $\frac{1}{4}$ Load |
|---|---|---|---|---|---|
| 100 per cent power-factor . . | 98.5 | 98.6 | 98.5 | 98.2 | 97.0 |
| 80 per cent power-factor . . | 98.1 | 98.2 | 98.1 | 97.5 | 96.2 |

The regulation:

| | |
|---|---|
| 100 per cent power-factor . | 0.9 per cent |
| 80 per cent power-factor . | 4.4 per cent |

The transformers have been subjected to a one-minute high-potential test of 220,000 volts from primary to secondary and core, and 22,000 volts from secondary to core. Besides this, a potential of 220,000 at suitable frequency was applied across the full primary winding for a period of five minutes.

The transformer tanks are of round construction and are made of heavy boiler iron, with cast iron covers. The height to the top of the high tension leads is 16 ft. and to the top of the cover 13 ft. 6 in., while the diameter is 8 ft. The weight of the complete unit, including oil, is approximately 25 tons.

Pipe lines are installed below the transformers for both the oil and cooling water. By means of these any transformer may be connected with the oil filter presses or storage tanks, which are located in the repair house. For the cooling system it was necessary to drill four wells to a depth of about 450 feet, and the water is forced from these into a reservoir by compressed air. From the reservoir it is pumped by a submerged centrifugal pump into a 50,000-gallon storage tank, which is about 75 feet above the water level in the reservoir, whence it is fed by gravity into the cooling system. Provision is made so that the water in the tank can be emptied into either the waste or the reservoir if desired, for during the summer months the water in the tank may become too warm, when it will have to be let out and cooler water pumped in.

All of the high-tension oil switches are of the remote controlled, solenoid-operated type.

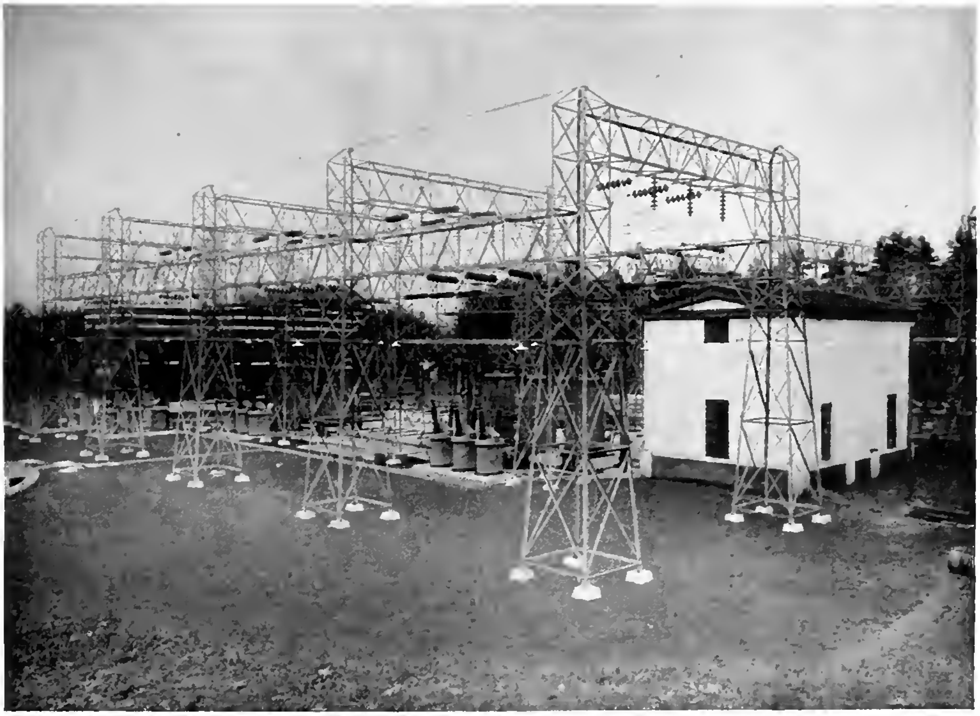

Fig. 9. Another View of Atlanta Substation

With the exception of the bus tie-switch, they are all automatic, being tripped by inverse time-limit relays actuated from current transformers in the switch bushings.

Disconnecting switches are installed, as shown in Fig. 16. They are mounted on post insulators in a slanting position so that they can be readily operated from the ground. To prevent them from accidentally opening, they are provided with safety catches, and the jaws are covered by specially designed hoods to protect them from sleet.

Each of the incoming and outgoing lines is equipped with a three-phase, four-tank, aluminum cell lightning arrester with choke coils and horn gap disconnecting switches. The transmission line ground wires are also continued over the station structure to give additional protection against atmospheric lightning disturbances.

A repair house is located at the further end of the two transfer tracks, which run parallel with and in front of the transformer banks (Fig. 13). Each transformer rests on a wheelbase and can readily be pulled out onto the transfer truck and moved into the repair house, where it is let down into a pit, by a crane so that it can easily be taken apart and repaired. By means of the transfer trucks it is, of course, also possible to interchange transformer units between the different banks, should this become necessary. As seen from the plan of the station, Fig. 6, two turntables are also provided near the low tension switch house and a single track extended clear out to the roadway, so that material can readily be unloaded from trucks or wagons and hauled into the repair shop.

The whole structure, as well as the apparatus, is painted a light gray color and all apparatus is distinctly marked. Besides giving a very pleasing appearance, this gray color causes the apparatus to absorb less heat in the summer, which is of the utmost importance in outdoor installations of this kind. Cement walks are provided where the operators are most likely to pass, and the whole property has been neatly graded and sodded.

Illumination is provided by incandescent lamps spaced around the station. They are provided with large reflectors which prevent any light from being thrown upwards so as to illuminate the bus structure. By keeping this dark, it is possible to detect any defective insulators.

The low-tension equipment is all installed in the switch house, which is a two-story building of red-faced brick with white marble trimmings and parapet. The system of connections is clearly shown in Fig. 16. There are four independent sets of 11,000-volt busbars which, however, are normally tied together so as to form only two sets, resembling a double U. The leads from the transformer secondaries are connected to either of these two sets by means of oil switches and double sets of disconnecting switches. A similar method of connection is used for all the outgoing feeders, of which there will ultimately be nine underground and six overhead.

Figs. 10, 11 and 12 represent plan views of the first and second floors, as well as a cross-section of the switch house, and show the general arrangement of the apparatus. As previously mentioned, the connections from the transformer secondary deltas run through bushings down to a concrete lined 7-ft.-tunnel below the transformers (Fig. 15), and through this tunnel to the basement of the switch house. These leads consist of 1-in. copper tubing supported on insulators, the phases being separated by barriers, as shown in the illustration.

The bus and switch structures are of enclosed construction made of pressed brick and alberene stone; the buses and disconnect-

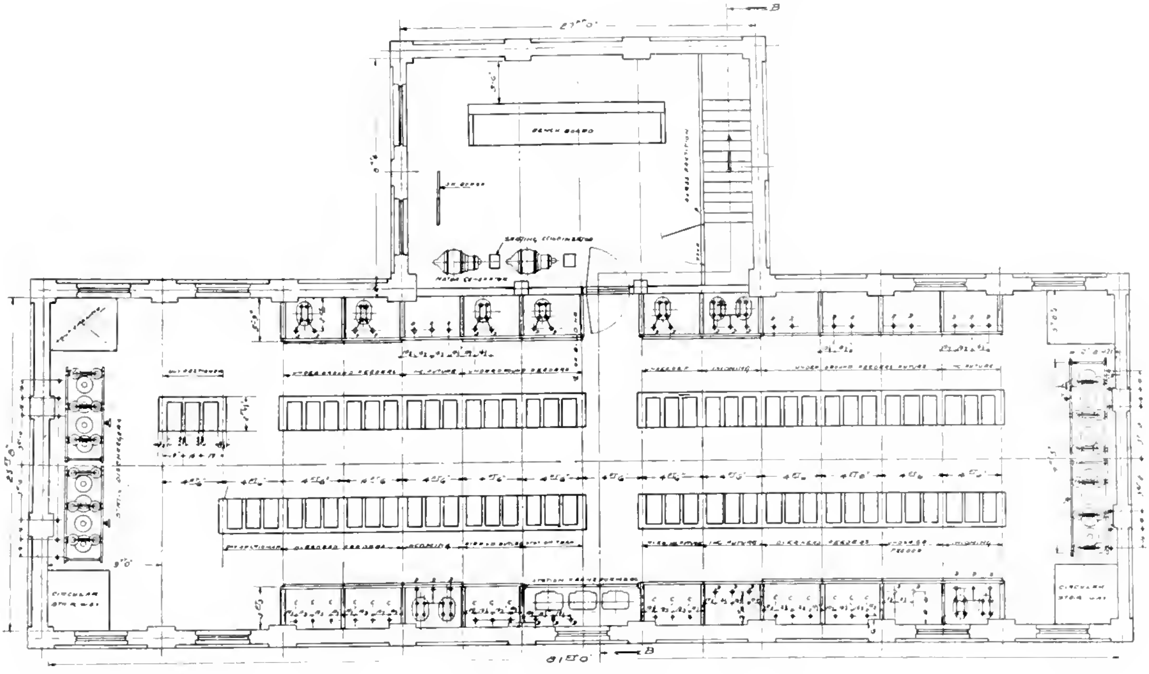

Fig. 11. Plan of Second Floor

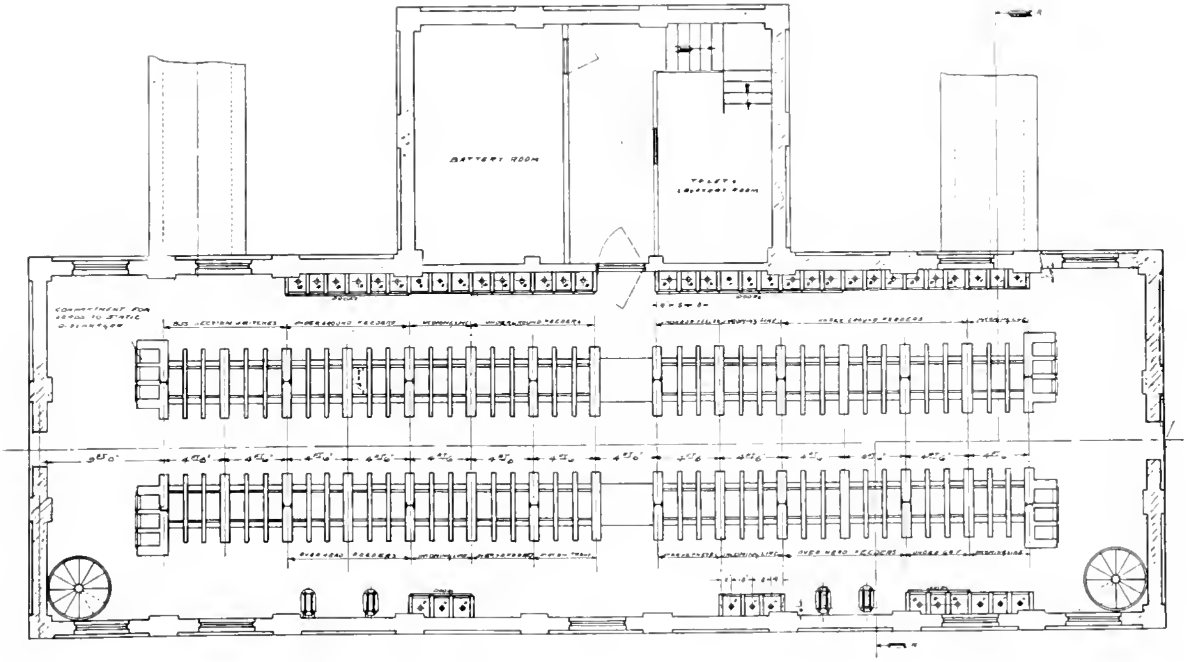

Fig. 12. Plan of First Floor

Fig. 13. Atlanta Substation. Repair House in Middle Distance

ing switches being located on the first floor and the oil switches on the second floor. The first floor in the wing of the building contains a battery room, toilet and lavatory, while the central room occupies the second floor of the wing. This contains the switchboard, telephones and the battery, and as it faces the outdoor portion of the station affords a good view of the apparatus.

The oil switches for the low-tension transformer connections are of the 15,000-volt, 500-ampere, automatic motor-operated type, provided with definite time-limit relays (Fig. 14). The switches for the outgoing feeders are of the same type, and differ only from the low tension switches in that they have a current carrying capacity of 300 amperes and are provided with inverse time-limit relays.

All the apparatus in the station is manipulated from a central board in the operator's room. This is of the usual bench-board construction, made of dull black slate. The vertical panels contain the instruments and relays, while the control switches, indicating, lamp, receptacles, mimic buses, etc., are mounted on the top of the bench.

Electrolytic aluminum cell lightning arresters with choke coils and horn-gap disconnecting switches are provided for each of the outgoing overhead feeders, and each of the four sets of busbars is equipped with a set of static dischargers of the same type. The former are installed outdoors between the station and the dead-end tower structure of the 11,000-volt lines, while the latter are installed on the second floor of the building, two at each end.

For furnishing energy for lighting and miscellaneous power purposes around the station there is provided one transformer bank, consisting of three 10-kv-a., 11,000/220-110-volt transformers, while a 20-ampere-hour, 250-volt storage battery with two 10-kw. charging sets furnish current for the operation

Fig. 14. Low Tension Oil Switch in Atlanta Substation

of all the switches. The switches and instruments for the battery equipment and the station circuits are mounted on a separate vertical switchboard, which is also located in the control room.

### Other Substations

Besides the Atlanta station, there are substations at Gainesville, Newnan, Marietta, Cartersville and Lindale. These are all identical in design and of the outdoor type; the high-tension equipment being installed outdoors and the low-tension equipment indoors in a switch house. Each station is laid out for an ultimate capacity of 12,000 kv-a., and is divided into four transformer banks with four outgoing 11,000-volt feeders. Besides this, provisions are made so that a synchronous condenser can be installed in each station, and space is provided for a bank of local service transformers and an arc lighting circuit.

At the present time the capacity of the installed transformer equipments at the various stations is as given below.

All of these transformers are of the oil-insulated self-cooled single-phase type. Both the primary and secondary windings are connected in delta, and they are provided with the following taps:

110,000 volt windings four 2½ per cent taps.
55,000 volt windings two 5 per cent taps.
22,000 volt windings eight 1¼ per cent taps.
11,000 volt windings four 2½ per cent taps.

When operated at continuous normal load the temperature rise is guaranteed not to exceed 40 deg. C., and when operating continuously at 25 per cent overload 55 deg. C.

The system of connections for the stations is shown by Fig. 15. The transformer bus will be connected to the transmission lines by means of two oil switches, one of which is installed at the present time. These switches are of the hand-operated automatic type, tripped by inverse time element relays, and are protected against rain by a simple corrugated sheet steel house.

Three-pole disconnecting switches are provided for sectionalizing and cross-over purposes, and also for connecting the transformer banks to the high-tension bus. These switches are of the horn gap bolt-type construction, mounted on the top of the steel structure and operated from the ground by a single hand lever for each three-pole unit. While these switches are not intended to be opened under load, they may be relied upon for breaking the capacity currents of the lines and the magnetizing currents of the transformers, although such switching should be avoided, as the arc formed may set up high voltage surges which may be destructive to

Fig. 15. Low Tension Bus Bar Compartments in Tunnel

TRANSFORMER EQUIPMENTS

| Substation | Number of Units | Normal Kv-a. of Each Unit | Total Capacity in Kv-a. | VOLTAGES | |
|---|---|---|---|---|---|
| | | | | Primary | Secondary |

the insulation of the lines and apparatus connected thereto.

Outdoor 110,000-volt electrolytic aluminum cell lightning arresters with choke coils and horn gap disconnecting switches are provided at each substation, and, as at the Atlanta station, the transmission line ground wires pass over the structure and afford additional protection.

The low-tension equipments in all the stations are, as stated, installed indoors. These equipments comprise the 15,000-volt automatic oil switches on the low tension side of

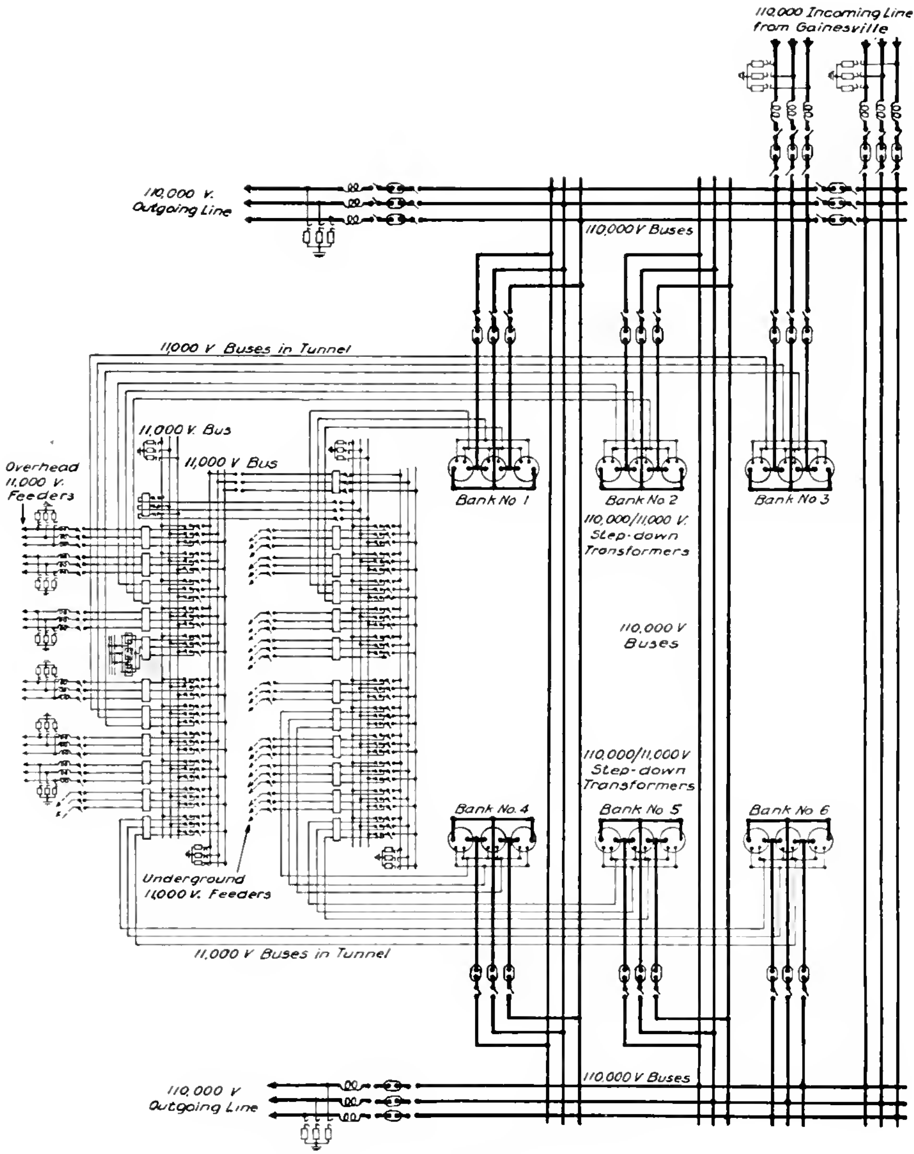

Fig. 16. Wiring Diagram of Atlanta Substation

the transformer banks and those for the outgoing feeder circuits, a 15-kw., 11,000-220/110 volt transformer bank for the station service, and the switchboard containing the instruments, meters, etc. Each of the outgoing 11,000-volt feeders are protected by aluminum cell lightning arresters, which are installed outside the building.

The construction work on the transmission lines and substations as was that on the generating station at Tallulah Falls, was done by the Northern Contracting Company under the supervision of Mr. C. O. Lenz, Chief Consulting Engineer, 71 Broadway, New York City, and Mr. C. E. Bennet, Electrical Engineer.

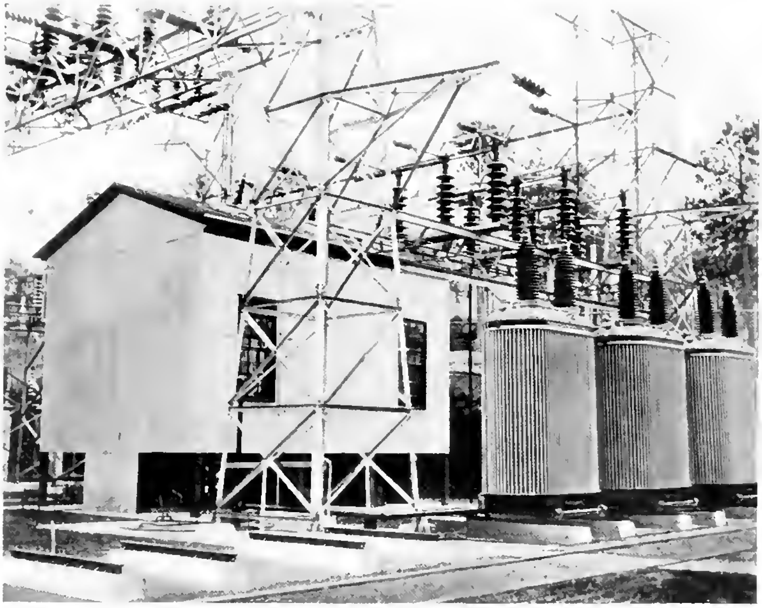

Fig 18. Gainesville Outdoor Substation

# RECTANGULAR WAVES

By G. Faccioli

Electrical Engineer, Pittsfield Works, General Electric Company

The present article explains in an extremely simple and clear manner some of the so-called "mysterious troubles" that are of frequent occurrence and annoyance to the operating and designing engineer, and that must be understood before this class of trouble can be eliminated. That is, the engineer must consider them in the design and protection of apparatus, and the operating engineer must assist him by methods of system operation which minimize the probability and frequency of occurrence of such disturbances; for example, by obviating high tension switching, and the like.—Editor.

A sudden variation of voltage, be it positive or negative, that is to say a sudden rise or a sudden drop of voltage, constitutes one of the most common sources of trouble in the operation of high tension lines.

These sudden variations of voltage, of which a rectangular traveling wave (a traveling wave with a straight front) is a common example, may be due to causes internal or external to the circuit. While the external causes are beyond our control, it is possible to control the internal causes by the proper design and proper operation of the system.

However, the stresses brought upon the apparatus by steep wave fronts are so high that the coefficients of safety, which must be used in building the apparatus so that they will withstand these stresses, are abnormally large; and the problem arises as to whether it is more advisable and cheaper to build apparatus with such coefficients of safety or to build them with lower and more reasonable coefficients of safety, at the same time giving them efficient protection by auxiliary devices. It follows that in recent times considerable work has been devoted to the study of protection of apparatus and lines against steep wave fronts.

Inductance, capacity, and resistance are the three elements at the immediate disposal of the electrical engineer, and we wish to study in this article their influence on waves with steep fronts, and especially on rectangular waves.

The phenomena reviewed hereafter are well known, but an elementary summary of them will perhaps prove useful.

If we consider a rectangular wave arriving at a certain point of a circuit, we see at once that the part of the circuit upon which the rectangular wave impinges is suddenly subjected to the action of the steady potential of the wave. We may conclude, therefore, that the phenomena due to rectangular waves are similar to those obtained in switching circuits onto electromotive forces of constant value.

We will, therefore, approach the problem by reviewing what happens when a continuous e.m.f. is suddenly applied or withdrawn from circuits containing inductance, capacity and resistance; and the results obtained will give a qualitative idea of the phenomena produced by the propagation of rectangular waves.

### I. Effect of Inductance on Rectangular Waves

We will study first what happens when an inductance, $L$, in series with the resistance, $R$, is switched onto an electromotive force, $E$, of constant value. See Fig. 1.

After the switch $S$, is closed, the current has a value of

$$i = I\left(1-e^{-\frac{R}{L}t}\right) \qquad (1)$$

where $I=\frac{E}{R}$, the final value reached by the current, $e$ is the base of natural logarithms, and $t$ is the time.

The voltage, $v$, across the resistance is

$$v = E\left(1-e^{-\frac{R}{L}t}\right) \qquad (2)$$

The electromotive force which is active across the inductance, $L$, and annuls the counter e.m.f., $-p$, generated across $L$ by the growth of the current, $i$, is

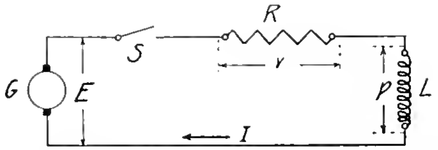

Fig. 1. Circuit Consisting of Inductance, L, in series with resistance, R, connected to source of constant e.m.f., E.

$$p = Ee^{-\frac{R}{L}t} \qquad (3)$$

If the electromotive force, $E$, is suddenly removed from the circuit, by for instance short-circuiting the d-c. generator, then the current assumes the value

$$i = Ie^{-\frac{R}{L}t} \tag{4}$$

The voltage across the resistance is

$$v = Ee^{-\frac{R}{L}t} \tag{5}$$

The voltage generated by the dying of the current across the inductance, $L$, (the impressed e.m.f., $E$, is now zero) is

$$p = -L\frac{di}{dt} = Ee^{-\frac{R}{L}t} \tag{6}$$

and this voltage is consumed by the drop across the resistance.

Fig. 2 shows the gradual increase of $i$ to a maximum, $I$, when the constant potential, $E$, is suddenly applied to the circuit of Fig. 1. In this case, $R = 500$ ohms, $L = 0.01$ henry, $I = 10$ amperes, and $E = 5000$ volts.

Since the drop across the resistance is $Ri$, $v$ is proportional to $i$. Fig. 2, therefore, represents also the growth of $v$ to a maximum, $E$, when the proper scale is taken.

After the current, $i$, has gradually increased in value until it has reached the final value, $I$ (theoretically $i$ will reach the final value, $I$, in an infinitely long time, but practically the final value, $I$, is reached after a short interval of time, as shown in Fig. 2), the electromotive force, $E$, is suddenly removed and the current, $i$, and voltage, $v$, gradually go to zero, as shown in Fig. 3.

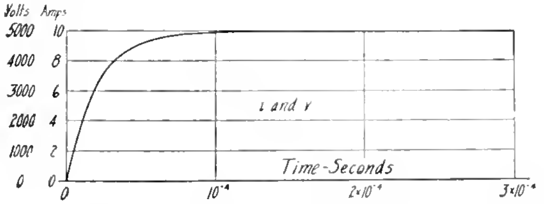

Fig. 2. Growth of Current, i, and voltage, v, when constant potential, E, is suddenly applied to circuit of Fig. 1.

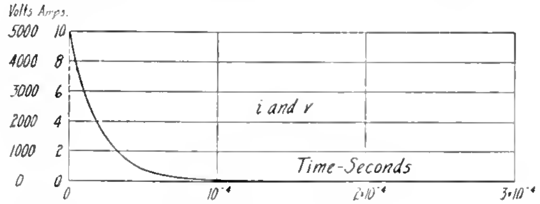

Fig. 3. Decay of Current, i, and voltage, v, when constant potential, E, is suddenly removed from circuit of Fig. 1.

Figs. 4 and 5 give the voltage, $p$, generated across $L$ by the growth and the dying away of the current, $i$, when $R = 500$ ohms, $L = 0.01$ henry, $I = 10$ amperes, and $E = 5000$ volts, as before.

When the circuit is closed and the potential, $E$, is suddenly applied, the counter e.m.f., $-p$, generated across the inductance by the growing current, is $-E$. After this first instant the counter e.m.f., $-p$, gradually goes to zero. This counter e.m.f. is at all times equal and opposite to the impressed e.m.f. The zero value is practically reached after a short time, and then the growth of the current, $i$, is complete to its full value, $I$, and the inductance, $L$, offers no further impedance to the flow of this current, $I$. (See Fig. 4.)

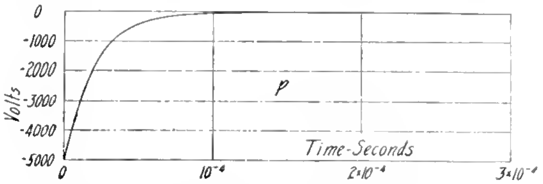

Fig. 4. Voltage, p, generated across inductance, L, by growth of current, i, when constant potential, E, is suddenly applied to circuit of Fig. 1.

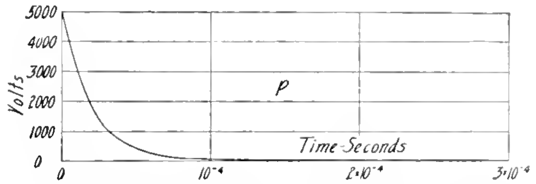

Fig. 5. Voltage, p, generated by inductance, L, when constant potential, E, is suddenly removed from circuit of Fig. 1.

The electromotive force, $p$, generated by the dying out of the current in the reactance, begins with the maximum, $E$, and gradually goes to zero as the current, $i$, dies out. This electromotive force is active and is totally consumed in sending current through the resistance, $R$. (See Fig. 5.)

When the circuit is closed, energy is stored up in the choke coil, as electro-magnetic energy, to a maximum value of $\frac{LI^2}{2}$. When the potential, $E$, is suddenly removed, this energy is given back to the circuit by the inductance and is absorbed by the resistance.

It is to be noted that when the circuit is closed the equivalent impedance of the choke coil is

$$Z = \frac{p}{i} = \frac{Ee^{-\frac{R}{L}t}}{I\left(1 - e^{-\frac{R}{L}t}\right)} = R\frac{1}{e^{\frac{R}{L}t} - 1} \tag{7}$$

This equivalent impedance is plotted in Fig. 6, where $R = 500$ ohms and $L = 0.01$

henry. This curve shows that at the first instant in which the switch is closed the impedance of the choke coil is equal to infinity and that this impedance gradually decreases until, after a theoretically infinite—but practically short—time, this impedance is equal to zero. Thus the choke coil acts at the first instant as an open circuit and gradually becomes a short circuit.

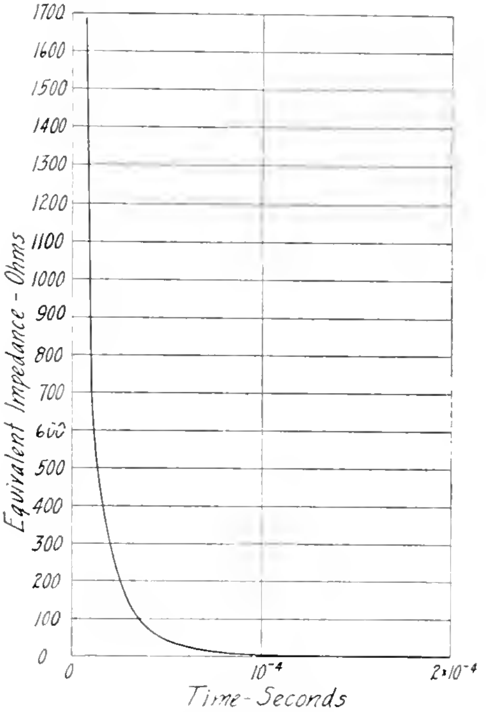

Fig. 6. Equivalent Impedance of Inductance, L, in circuit of Fig. 1, when R = 500 ohms and L = 0.01 henry

When the electromotive force, $E$, is removed, the choke coil acts as a generator of zero resistance, and the circuit has a constant resistance, $R$.

Fig. 7 shows, for comparison, the growth of current, $i$, when $L = 0.01$ henry and when $L = 0.0001$ henry, $R$ being 500 ohms in each case. The inductance in the second case is 1/100 the inductance in the first case and the growth of current requires only 1/100 of the time, that is the change is more abrupt with the smaller inductance. Likewise, if we should have an inductance of 1 henry, the time of growth would be 100 times as long as the time required when $L = 0.01$ henry.

In summarizing the above, we see that the presence of the inductance produces a single energy transient with the following results:

(1) Abrupt changes in potential and current are prevented.

(2) The inductance stores electromagnetic energy and then returns it to the circuit.

(3) The inductance acts at the first instant as an open circuit and gradually becomes a short-circuit.

If the resistance, $R$, is divided in two parts, $R_1$ and $R_2$, in series, all the phenomena above described are naturally the same and the drops across $R_1$ and $R_2$ are obviously proportional to $R_1$ and $R_2$, and, therefore, the energy returned by $L$ and absorbed respectively by $R_1$ and $R_2$ is also proportional to the values of $R_1$ and $R_2$.

### Waves passing from Circuit of Impedance, $Z_1$, to Circuit of Impedance, $Z_2$

Generally, in determining the value of the refracted and reflected waves as a function of the value of the incident wave, the procedure is as follows:

In the case of Fig. 9, for instance, where there is no additional device, Circuits 1 and 2 are directly connected in series and we have $p_1 + p_r = p_2$, that is to say, the voltage of the refracted wave is equal to the voltage of the incident wave plus the voltage of the reflected wave.

We have also $i_1 = i_r + i_2$, that is to say, the current of the incident wave divides into two parts, the reflected part, $i_r$, and the refracted part, $i_2$.

Finally: We know that the ratio between the voltage and current of the incident wave is equal to $Z_1$, the natural impedance of Circuit 1; that the ratio between the voltage and current of the reflected wave is also equal to $Z_1$; and that the ratio between the voltage and current of the refracted wave is equal to $Z_2$, the natural impedance of Circuit 2.

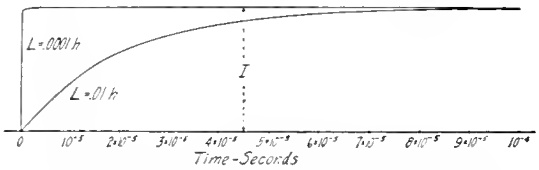

Fig. 7. Showing, for comparison the growth of current, i, in circuit of Fig. 1 when L = 0.01 henry and L = 0.0001 henry, R being 500 ohms in each case

The above fundamental equations are sufficient to determine the values of $p_2$, $i_2$, $p_r$, and $i_r$.

If a resistance, an inductance, or some other device is connected in series between Circuit 1 and Circuit 2, as in Fig. 10 for instance, then the equation of voltage must be modified to show that the voltage of the incident wave, plus the voltage of the reflected wave, is equal to the voltage of the refracted wave, plus the drop across the additional device. The current of the incident wave divides again into two parts—the reflected current and the refracted current.

If, at the junction between Circuits 1 and 2, a device is connected in shunt (as in Fig. 20), the equations must be written to show that the voltage of the incident wave, plus the voltage of the reflected wave, is equal to the voltage of the refracted wave.

The current of the incident wave divides into three parts:

One reflected back into Circuit 1.

The second passing on into Circuit 2.

And the third going through the device connected in shunt at the junction.

It is evident also that the voltage across Circuit 2 must be equal to the voltage across the shunted device.

If the wave is of finite length, we can consider it as the resultant of two infinitely long waves of opposite sign, *A* and *B*, as shown in Fig. 8. The wave *B* lags behind the wave *A* by a time, *T*, which represents the duration of the finite wave.

Then the phenomena occurring at the front of the finite wave are the same as the phenomena occurring at the front of the infinite wave, *A*. The phenomena occurring at the back of the finite wave are obtained by superimposing the condition due to the wave *A*, at the time, *T*, upon the phenomena due to the front of the negative wave, *B*.

Naturally, the phenomena due to the front of the wave, *B*, are equal and opposite in sign to the phenomena occurring at the front of the wave, *A*.

If the wave is of infinite length, then the reflected wave is super-imposed on the infinite wave; whereas if the wave is of finite length, the reflected wave will travel alone back into Circuit 1, as mentioned later in the case of choke coil connected between circuits 1 and 2.

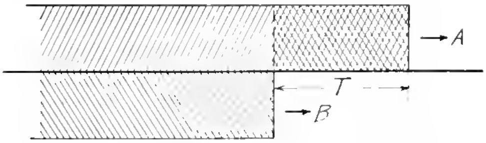

**Fig. 8.** Showing the formation of a wave of finite length by the superposition of infinite waves, A and B, of opposite sign

**Waves of Infinite Length**

Let us apply the results discussed above to a rectangular wave, $p_1$, of infinite length, passing from a circuit of natural impedance, $Z_1$, into a circuit of natural impedance, $Z_2$. (See Fig. 9.) The rectangular wave, $p_1$, is partially reflected at the junction between Circuit 2 and Circuit 1, and it enters the circuit of natural impedance, $Z_2$, with a voltage:

$$p_2 = 2p_1 \frac{Z_2}{Z_1 + Z_2} \qquad (8)$$

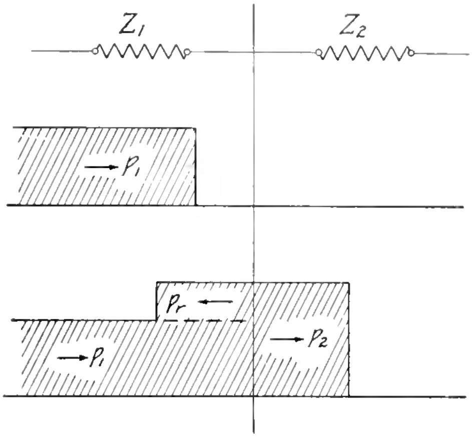

**Fig. 9.** Rectangular wave, $p_1$, of infinite length, passing from circuit of natural impedance, $Z_1$, to circuit of natural impedance, $Z_2$

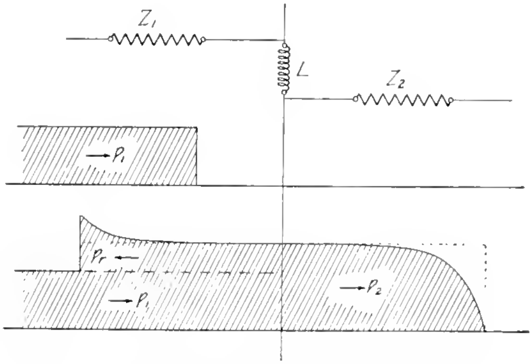

**Fig. 10.** Rectangular wave, $p_1$, of infinite length passing from circuit $Z_1$ to circuit of $Z_2$, an inductance, L, being connected between circuits 1 and 2

The reflected wave which travels back into Circuit 1 has a value of

$$p^r = p_1 \frac{Z_2 - Z_1}{Z_1 + Z_2} \qquad (9)$$

Fig. 9 shows the progress of the refracted and reflected voltage waves, assuming $Z_2 = 3Z_1$. We see that Circuit 2 is subjected to a rectangular wave of voltage $p_2 = \frac{3}{2}\,p_1$, and that a voltage $\frac{3}{2}\,p_1$ is imposed upon Circuit 1, due to the super-imposition of the reflected wave, $p_r = \frac{1}{2}\,p_1$, upon the incoming wave, $p_1$.

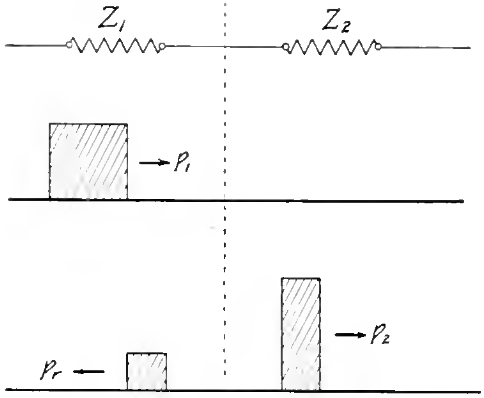

**Fig. 11.** Rectangular wave, $p_1$, of finite length, passing from circuit of natural impedance, $Z_1$, to circuit of natural impedance, $Z_2$

Similar reflections and refractions take place in the current waves, but for brevity, these will be omitted.

Let us now connect an inductance, $L$, between circuits 1 and 2, as shown in Fig. 10.

When the rectangular wave, $p_1$, arrives at $L$, the choke coil acts as an open circuit. Therefore, the voltage of the arriving wave will be totally reflected back into Circuit 1 with positive sign, and the current of the arriving wave will be totally reflected back into Circuit 1 with negative sign.

As the equivalent impedance of the choke coil gradually decreases, the voltage and current of the wave will gradually pass into Circuit 2, until, after a theoretically infinite—but practically short—time, the choke coil acts as a short-circuit. Then the wave passes from Circuit 1 into Circuit 2 in the same manner as if the inductance, $L$, were not present, but the circuits arranged as in Fig. 9.

The energy of the incident wave is divided into three parts:

One part passes from Circuit 1 into Circuit 2.

The second part is reflected back into Circuit 1.

The third part is stored in the choke coil.

Without going into mathematics, and remembering the conditions shown in Figs. 1 to 5, we may say that the voltage, $p_2$, which enters the Circuit 2, grows gradually from zero to a final value:

$$2\,p_1\,\frac{Z_2}{Z_1+Z_2}$$

and we may write

$$p_2 = 2\,p_1\,\frac{Z_2}{Z_1+Z_2}\left(1-\epsilon^{-at}\right)^{*} \qquad (10)$$

The reflected wave has a final value of

$$p_1\,\frac{Z_2-Z_1}{Z_1+Z_2}$$

and its equation may be written

$$p_r = p_1\left(\frac{Z_2-Z_1}{Z_1+Z_2} + \frac{2\,Z_1}{Z_1+Z_2}\,\epsilon^{-at}\right) \qquad (11)$$

Fig. 10 shows the reflected and refracted waves, assuming $Z_1 = 300$ ohms, $Z_2 = 3Z_1$ and $L = 0.01$ henry.

In this case $p_2$ assumes a final value of $\frac{3}{2}\,p_1$.

The reflected voltage, $p_r$, at the first instant equals $p_1$, but assumes a final value $\frac{1}{2}\,p_1$.

Circuit 1, therefore, has imposed on it at the first instant a voltage of $2\,p_1$, which quickly reduces to $3/2\ p_1$. The time required for $p_2$ and $p_r$ to change from the initial to the final value is about 0.5 second.

### Waves of Finite Length

Figs. 9 and 10 refer to the case in which the incident wave has an infinite length.

Let us now consider the case in which the wave has a finite length.

Fig. 11 represents the case in which there is no inductance connected between circuits 1 and 2. The wave has a rectangular front and a rectangular back. It is assumed that $Z_2 = 3Z_1$. Then the ongoing wave has a value

$$p_2 = 2\,p_1\,\frac{Z_2}{Z_1+Z_2} = \frac{3}{2}\,p_1$$

and the reflected wave a value

$$p_r = p_1\,\frac{Z_2-Z_1}{Z_1+Z_2} = \frac{1}{2}\,p_1.$$

In this case the reflected wave travels alone back into Circuit 1, as the short incident wave has passed on.

If a choke coil, $L$, is placed between Circuits 1 and 2, the front of the wave produces obviously the same phenomena as in the

---

*The coefficient $a = \frac{Z_1+Z_2}{L}$

similar case with the wave of infinite length. When the voltage of the wave suddenly drops to zero, the energy stored in the choke coil is returned to $Z_1$ and $Z_2$, at a voltage starting from the value of

$$2\ p_1 \frac{Z_2}{Z_1+Z_2}$$

and gradually decreasing to zero by the formula

$$p_2 = 2\ p_1 \frac{Z_2}{Z_1+Z_2} e^{-at} \qquad (12)$$

This is the equation of the rear of the ongoing wave.

The equation of the rear of the reflected voltage wave is

$$p_r = -2\ p_1 \frac{Z_1}{Z_1+Z_2} e^{-at} \qquad (13)$$

During the discharge of the choke coil into the line the current through $Z_1$, $L$, and $Z_2$ is the same, and, therefore, the portions of energy discharged into $Z_1$ and $Z_2$ are respectively proportional to the values of the impedances, $Z_1$ and $Z_2$; that is to say, if $Z_1 = Z_2$, the energy discharged by the choke coil is equally divided between the Circuits 1 and 2, whereas, if $Z_2 = 9Z_1$, 9/10 of the energy will go into Circuit 2.

Fig. 12 shows the refraction and reflection of a rectangular wave of finite length, assuming an inductance $L = 0.01$ henry connected between Circuits 1 and 2, $Z_1 = 300$ ohms and $Z_2 = 3Z_1$. About 0.4 second is required in this case for the waves to change from their initial to their final values.

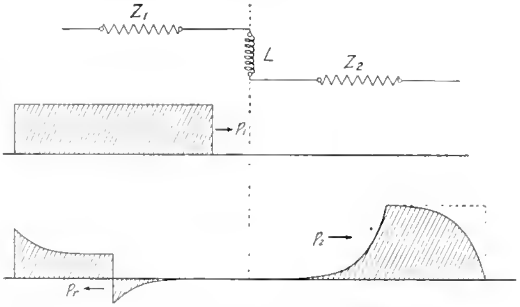

Fig. 12. Rectangular wave, $p_1$, of finite length, passing from circuit $Z_1$ to circuit of $Z_2$, an inductance L being connected between circuits 1 and 2

It will be noted that the reflected portion of the wave consists of positive and negative parts and that there is an abrupt change of voltage where these two portions of the wave join. From this it may be seen that abrupt changes in voltage are not confined to the fronts of waves.

In conclusion: The presence of the choke coil, $L$, connected in series between Circuit 1 and Circuit 2, produces the following effects:

(1) Smooths wave fronts.

(2) Gives the same final value of the wave passing into Circuit 2 as if the inductance were not present.

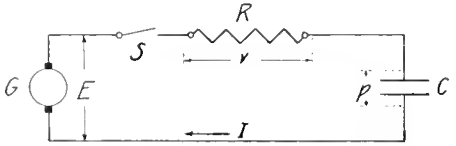

Fig. 13. Circuit consisting of condenser, C, in series with resistance, R, connected to source of constant e.m.f., E.

(3) Increases the value of the front of the reflected wave, because it produces a total reflection at the first instant the abrupt variation of voltage is applied.

It follows that a choke coil connected in series between a line and a transformer will protect the transformer from abrupt variation of voltages originating in the line, but will be an obstacle preventing disturbances originating in the transformer from passing into the line; and, therefore, in this latter respect it will increase the possible dangers to the transformer.

### II. Effect of Condenser on Rectangular Waves

We will now review the phenomena which occur when a condenser, $C$, in series with a resistance, $R$, is suddenly connected to a source of continuous electromotive force, $E$. (See Fig. 13.) In this case, when the switch is closed, the current is

$$i = Ie^{-\frac{t}{RC}} \qquad (14)$$

where $I$ is the maximum value of the current and is equal to $\frac{E}{R}$.

The voltage across the resistance is

$$v = Ee^{-\frac{t}{RC}} \qquad (15)$$

and the voltage spent in overcoming the counter-electromotive force, $-p$, produced by the charging of the condenser—caused by the current—is

$$p = E\left(1 - e^{-\frac{t}{RC}}\right) \qquad (16)$$

If the source of electromotive force is suddenly removed, by for instance short-circuiting the generator, the current, $i$, the voltage, $v$, and the electromotive force, $p$, across the condenser are respectively:

$$i = -Ie^{-\frac{t}{RC}} \qquad (17)$$

$$v = -Ee^{-\frac{t}{RC}} \qquad (18)$$

$$p = Ee^{-\frac{t}{RC}} \qquad (19)$$

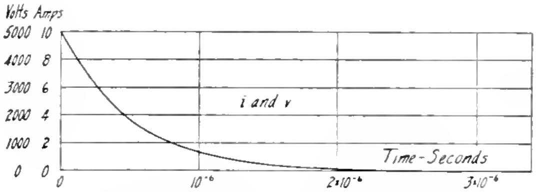

Fig. 14. Current, i, and voltage, v, when constant potential, E, is suddenly applied to circuit of Fig. 12.

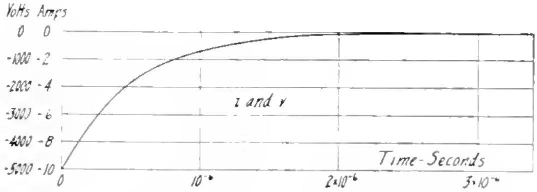

Fig. 15. Current, i, and voltage, v, when constant potential, E, is suddenly removed from circuit of Fig. 12

Fig. 14 shows $i$ and $v$ when the switch is closed, assuming $C = 0.001$ m.f. and $R = 500$ ohms.

Fig. 15 shows $i$ and $v$ when the generator is short-circuited.

Fig. 16 shows the electromotive force, $p$, active across the condenser. This electromotive force is applied by the generator and is opposite in sign to the counter-electromotive force caused by the current charging the condenser.

When the applied electromotive force suddenly stops, the condenser is charged to the full potential, $E$. (Theoretically this would only happen after an infinitely long time.)

Fig. 17 shows how the electromotive force of the condenser gradually dies out, while the condenser is discharging and its energy is being absorbed by the resistance, $R$.

It is evident that at the first instant the circuit is closed the condenser does not modify the conditions, because the maximum current, $I$, flows without producing any drop across the condenser, and this current is only limited in value by the resistance, $R$. This means that at this first instant the condenser acts as a short-circuit.

Then the voltage across the condenser grows gradually, and, therefore, less and less current flows in the circuit, until, after a theoretically infinite time—but practically after a very short time—the full voltage, $E$, is spent across the charged condenser, and both $i$ and $v$ are zero. At this instant the condenser acts as an open circuit.

Fig. 18 shows the equivalent impedance of the condenser, which is also given by following:

$$Z = \frac{p}{i} = R\left(e^{\frac{t}{RC}} - 1\right) \qquad (20)$$

When the electromotive force is removed, the condenser discharges, the current is reversed, and its value is controlled by the resistance, $R$.

While the electromotive force, $E$, is active, energy is stored up in the condenser to a maximum equal to $\frac{CE^2}{2}$ and when the electromotive force, $E$, suddenly stops this stored energy is given back by the condenser and is absorbed by the resistance, $R$.

In Fig. 18, are given for comparison, the equivalent impedance of the condenser when $C = 0.001$ m.f. and when $C = 0.0001$ m.f. It may be seen that with the smaller capacity the equivalent impedance increases 10 times as fast as with the larger capacity; therefore, the current, $i$, and voltage, $v$, die and the voltage, $p$, grows 10 times as fast.

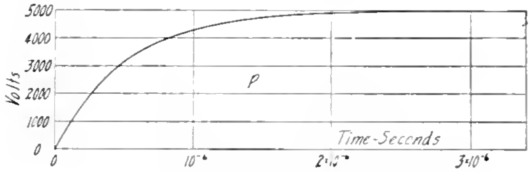

Fig. 16. Voltage, p, when constant potential, E, is suddenly applied to circuit of Fig. 12

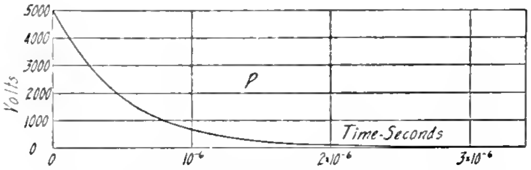

Fig. 17. Voltage, p, when constant potential, E, is suddenly removed from circuit of Fig. 12

The phenomena just discussed are further examples of single energy transients.

We may conclude that the condenser:

(1) Acts at the first instant the circuit is closed as a short-circuit, and gradually increases its equivalent impedance until it becomes an open circuit.

(2) Absorbs energy and returns it when the applied electromotive force stops.

(3) Allows the electromotive force across its plates to grow gradually, so that if the condenser is shunted by a circuit which does not substantially change the nature of the phenomena summarized above, the presence of the condenser prevents an abrupt change of voltage across the shunted circuit.

Fig. 19 shows a resistance, $R_1$, shunted by a condenser, $C$. The voltage across $R_1$ is the same as the voltage across $C$, and, therefore, the voltage across $R_1$ will grow and die gradually, following an exponential law.

*Waves passing from Circuit of Impedance, $Z_1$, to Circuit of Impedance $Z_2$:*

### Waves of Infinite Length

Let us apply the results just obtained to the case of a traveling rectangular wave which passes from a circuit of impedance, $Z_1$, to a circuit of impedance, $Z_2$.

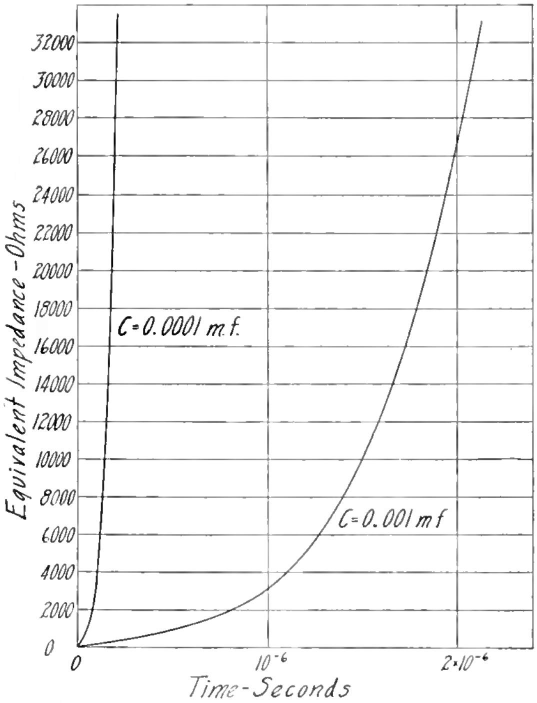

**Fig 18.** Equivalent impedance of condenser, C, in Fig. 12 when C = 0.001 m.f. and C = 0.0001 m.f., R being 500 ohms in each case

At the instant when the wave arrives at the junction between Circuit 1 and Circuit 2, the condenser which is there connected acts as a short-circuit; and, therefore, the voltage of the rectangular arriving wave is totally reflected into Circuit 1 with negative sign, and the current of the arriving wave is totally reflected into Circuit 1 with positive sign. At this instant no voltage and no current enter Circuit 2.

Then the impedance of the condenser gradually rises to infinity, that is to say, the condenser gradually becomes an open circuit. This last condition is reached after a practically short time, and then voltage and current enter Circuit 2, just the same as if no condenser were connected.

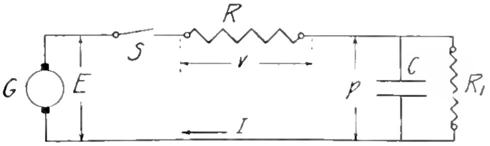

**Fig. 19.** Circuit consisting of resistance, R, in series with resistance, $R_1$, (the latter shunted by condenser, C,) connected to source of constant e.m.f., E

Then the voltage, $p_2$, of the wave passing into Circuit 2 grows from zero to

$$2\,p_1\frac{Z_2}{Z_1+Z_2}$$

where $p_1$ is the voltage of the incoming wave.

Remembering the phenomena connected with the circuit of Fig. 13, we may write the following equations of ongoing and reflected voltage, for a wave of infinite length:

$$p_2=2\,p_1\frac{Z_2}{Z_1+Z_2}\left(1-e^{-at}\right)^* \qquad (21)$$

$$p_r=p_1\left[\frac{Z_2-Z_1}{Z_1+Z_2}-\frac{2Z_2}{Z_1+Z_2}e^{-at}\right] \qquad (22)$$

Fig. 20 represents the refracted and reflected voltage waves. In this case it is assumed that $Z_1=300$ ohms, $Z_2=3Z_1$ and $C=0.001$ m.f.

The final value assumed by $p_2$ is $\frac{3}{2}\,p_1$ and the final value assumed by $p_r$ is $\frac{1}{2}\,p_1$. This, by super-imposition on the incoming wave, gives a total height of $\frac{3}{2}\,p_1$.

The total change from the initial to the final value takes place in about $1\times10^{-6}$ second.

### Waves of Finite Length

For a wave of finite length, the equations of the rear of the ongoing and reflected waves are as follows:

---

* The coefficient $a=\frac{1}{C}\left(\frac{1}{Z_1}+\frac{1}{Z_2}\right)$

$$p_2 = p_r = 2\, p_1 \frac{Z_2}{Z_1+Z_2} \epsilon^{-at} \qquad (23)$$

It will be apparent that $p_2$ and $p_r$ are the same when it is considered that the original wave has disappeared and the discharging condenser impresses its voltage upon Circuits 1 and 2, which are in multiple with the condenser.

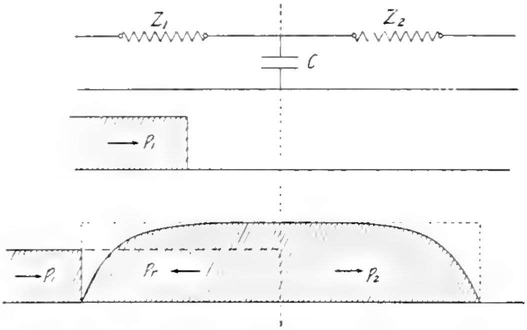

Fig. 20. Rectangular wave, $p_1$, of infinite length passing from circuit of natural impedance, $Z_1$, to circuit of impedance, $Z_2$; condenser, C, shunted across circuit at junction between circuits 1 and 2

Fig. 21 shows the reflected and refracted voltage waves. As in the case of the infinite wave, the total change from the initial to the final value requires about $1 \times 10^{-6}$ second.

The energy of the arriving wave is divided into three parts:

One part passes into Circuit 2.

Another part is reflected back into Circuit 1.

And the third part is stored in the condenser, and then is given back to Circuit 1 and Circuit 2 as soon as the wave $p_1$ stops.

The voltage wave passing into Circuit 2 has a smooth front, but its final value is the same as if the condenser were not connected.

The voltage wave reflected into Circuit 1 has a higher front than if $C$ were not connected, because the condenser totally reflects the voltage wave when an abrupt change of voltage strikes it.

In conclusion: The phenomena are very similar to those obtained by connecting an inductance between Circuit 1 and Circuit 2, and again we see that the condenser connected for instance between a line and transformer protects the transformer from abrupt wave fronts originating in the line and constitutes an obstacle preventing disturbances originating in the transformer from easily passing into the line.

The difference between the inductance and the capacity is that the inductance delays the growth of current because it stores energy under electromagnetic form, and, therefore, it delays the growth of the electromotive force across a resistance connected in series with the inductance; whereas the condenser delays the growth of the e.m.f. across its plates, because it stores energy under electrostatic form, and therefore delays the growth of the electromotive force across a resistance connected in shunt with the condenser.

### III. Effect of Series Resistance

Fig. 22 shows a resistance, $R$, which is supposed to be a pure ohmic resistance and concentrated at one point, connected between Circuit 1 and Circuit 2.

The sudden application of a direct current voltage to a resistance results in a sudden rise of the current to its final value. The resistance does not, as we have seen the inductance and the condenser do, smooth over abrupt wave fronts.

If $p_1$ is the voltage of a rectangular wave, which tries to pass from Circuit 1 into Circuit 2, the voltage, $p_2$, which enters Circuit 2 is

$$p_2 = 2\, p_1 \frac{Z_2}{R+Z_1+Z_2} \qquad (24)$$

and the voltage, $p_r$, which is reflected into line $Z_1$ is

$$p_r = p_1 \frac{R+Z_2-Z_1}{R+Z_1+Z_2} \qquad (25)$$

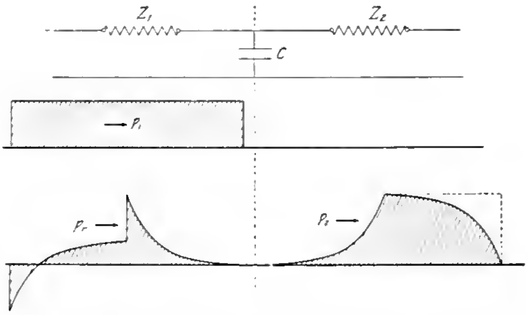

Fig. 21. Rectangular wave, $p_1$, of finite length passing from circuit of natural impedance, $Z_1$, to circuit of natural impedance, $Z_2$; condenser, C, shunted across circuit at junction between circuits 1 and 2

The energy of the wave $p_1$ is divided again in three parts:

One part passes into Circuit 2.

A second part is reflected back into Circuit 1.

A third part is absorbed by $R$.

In the two preceding cases we have discussed, i.e., inductance in series and capacity in shunt, the third part of the energy stored in the inductance or capacity prevented abrupt wave fronts, but was later given back by the inductance or capacity to the circuit. In the case of resistance, the third part of the energy is absorbed and destroyed by the resistance and the wave fronts are not made smoother, but remain rectangular at lower value.

An examination of the formulae giving the values of $p_2$ and $p_r$ shows that the voltage wave passing into Circuit 2 is the same as if the impedance of Circuit 1 were $Z_1+R$; whereas the wave reflected into Circuit 1 is the same as if the impedance of Circuit 2 were $Z_2+R$.

If $Z_2$ is larger than $Z_1$ (for instance if a rectangular wave passes from a line into a transformer), there is always a positive reflected wave. The wave entering Circuit 2 decreases in value with increasing $R$, and is equal to the incident wave when $R=Z_2-Z_1$. Under this condition, however, a reflected wave in Circuit 1 still exists, but the resistance, $R$, absorbs enough voltage to make the voltage wave passing into Circuit 2 equal to the original wave $p_1$.

When R is larger than $Z_2-Z_1$, the wave entering Circuit 2 is smaller than the original wave $p_1$, although a positive reflected voltage wave always exists in Circuit 1 and raises its voltage from $p_1$ to $p_1+p_r$.

If $Z_2$ is smaller than $Z_1$, which is the case when a wave passes from a transformer into a line, there is a negative reflected voltage wave if $R$ is smaller than $Z_1-Z_2$. When $R$ is equal to $Z_1-Z_2$, then there is no reflection.

Fig. 22. Resistance, R, connected between circuits of impedance, $Z_1$, and circuit of impedance, $Z_2$

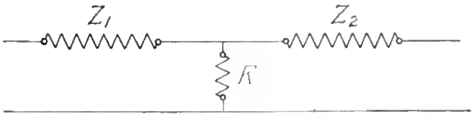

Fig. 23. Circuit of impedance, $Z_1$, connected to circuit of impedance, $Z_2$; resistance, R, shunted across circuit at junction between circuits 1 and 2

When $R$ is larger than $Z_1-Z_2$, then the reflected voltage wave is positive.

The wave entering Circuit 2 has always a lower value than incident wave $p_1$.

It follows that if we connect between a transformer and the line, for instance a resistance $R=Z_2-Z_1$, then voltage waves coming from the line enter the transformer at a voltage equal to the voltage of the line waves, and the voltage waves coming from the transformer enter the line with reflection.

If $R$ is smaller than $Z_2-Z_1$, then the waves coming from the line enter the transformer with increased voltage, and the waves coming from a transformer and entering the line are partially reflected back with negative sign.

Fig. 24. Series resistance shunted by choke coil to afford low impedance to currents of low frequency, and high impedance to currents of high frequency

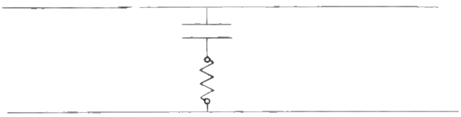

Fig. 25. Shunt resistance in series with condenser to afford high impedance to currents of low frequency, and low impedance to currents of high frequency

If $R$ is larger than $Z_2-Z_1$, then waves coming from the line enter the transformer at lower voltage, and waves coming from the transformer and entering the line are partially reflected back with positive sign.

The value of $R=Z_2-Z_1$ is, therefore, the most favorable.

### IV. Effect of Resistance in Shunt

Referring to Fig. 23, the voltage of the wave entering Circuit 2 is

$$p_2 = 2\, p_1 \frac{Z_2\, R}{Z_2R+Z_1R+Z_1Z_2} \qquad (26)$$

where $p_1$ is the voltage of the incident rectangular wave.

It is evident from Fig. 23 that the voltage entering Circuit 2 must be equal to the voltage existing across the resistance, $R$, because Circuit 2 and $R$ are connected in multiple. Now the voltage existing across $R$ is naturally proportional to the current flowing through $R$ and it will, therefore, be useful in this case to consider currents as well as voltages of the different waves.

The current passing into Circuit 2 is

$$i_2 = 2\, i_1 \frac{Z_1 R}{Z_2R+Z_1R+Z_1Z_2} \qquad (27)$$

where $i_1$ is the current of the incident current wave.

The voltage of the reflected wave is:

$$p_r = p_1 \frac{Z_2R - Z_1R - Z_1Z_2}{Z_2R + Z_1R + Z_1Z_2} \qquad (28)$$

The case of the resistance in shunt is similar to the case of the resistance in series, if in the former case we consider currents and in the latter case we consider voltages. In other words, the reflected waves of currents entering Circuit 2 are the same as if the impedance of Circuit 1 were the combined impedance of Circuit 1 and $R$ in parallel, and the waves of current reflected back into Circuit 1 are the same as if the impedance of Circuit 2 were the combined impedance of Circuit 2 and $R$ in parallel.

If $Z_2$ is larger than $Z_1$, as for instance when $Z_2$ represents a transformer and $Z_1$ a line, then if

$$R = \frac{Z_1Z_2}{Z_2 - Z_1}$$

there is no reflection of the voltage wave and the incident wave, $p_1$, enters the Circuit 2 with unchanged voltage. If $R$ is larger than this limit value, then there will be a partially reflected wave with positive sign, and the voltage wave will enter Circuit 2 with increased voltage. If $R$ is smaller than this limit value, then there will be a partial reflection of the voltage wave with negative sign, and the wave entering Circuit 2 will have less voltage than the original wave. In other words, if the combined impedance of Circuit 2 and $R$ in parallel is equal to the impedance of Circuit 1, there will be no reflection. If the combined impedance is larger than $Z_1$, there will be positive reflection, and if this combined impedance is smaller than $Z_1$, there will be negative reflection of the voltage wave.

However, the current $i_1$, of the incident wave, will divide itself into two currents; one current, $i_2$, entering Circuit 2, and one current, $i_R$, entering the resistance. This current, $i_R$, and the drop across the resistance (which is equal to voltage $p_2$) constitute the amount of energy which is absorbed by the resistance.

The energy is again divided into three parts:

One part is reflected back into Circuit 1.

A second part passes into Circuit 2.

A third part is absorbed by $R$.

We see that if we connect a resistance, $R$, as shown in Fig. 23, between a transformer and a line, the waves coming from the line will enter transformer with higher voltages as long as

$$R > \frac{Z_1Z_2}{Z_2 - Z_1}$$

If

$$R = \frac{Z_1Z_2}{Z_2 - Z_1}$$

then the voltage waves coming from the line will enter the transformer at the same voltage, but with less energy, because part of the current of the original wave is shunted away by $R$.

Finally:

If

$$R < \frac{Z_1Z_2}{Z_2 - Z_1}$$

then waves coming from the line will enter a transformer with less voltage. In any case of course the waves entering the transformer have less energy than the incident waves.

The voltage waves coming from a transformer will enter the line always at less voltage and will be partially reflected back into the transformer with negative sign.

It is obvious that connecting resistances in series or in shunt in lines is impractical, because of the losses which these resistances would produce under normal operating conditions. Therefore, when a series resistance is necessary, it must be by-passed by a choke coil, as shown in Fig. 24. This coil will offer small impedance to currents of normal operating frequency, but very high impedance to currents of high frequency or to abrupt changes of currents.

Likewise, if a shunt resistance is necessary, it must be connected in series with a condenser, as shown in Fig. 25. This condenser will offer a very high impedance to currents of normal frequency, but will offer very low impedance to currents of high frequency or to abrupt changes of currents.

Furthermore, as we have seen, inductance and capacity modify and smooth over the abruptness of rectangular traveling waves, but do not decrease the amount of energy involved; whereas ohmic resistances do not change the abruptness of the waves, but efficiently decrease the amount of energy involved.

It is evident that no one of the devices examined above is sufficient alone to give protection against rectangular waves or similar abrupt phenomena, but it may be foreseen that the combination of these devices may prove very efficient for this purpose.

Considerable study and investigation have been given to the combination of inductance, capacity and resistance to protect against abrupt changes in voltages and current, and this may form the subject of another article in continuation of the present one.

# TELEPHONES FOR POWER TRANSMISSION SYSTEMS

By John B. Taylor

Consulting Engineer, New York

The author first discusses the relative merits of private, leased wire, and exchange service for electric power transmission systems. He then describes the advantages and disadvantages of running the telephone wires on the same towers or poles as the power cables, and also on a separate line paralleling the main transmission line. The conclusion of the article is devoted to brief statements regarding the safety provided by the telephone transformer and the convenience gained by the use of the loud-speaking telephone in this class of service.—Editor.

In the operation of any power transmission system some means of communication between the various divisions, such as generating, receiving, switching and distributing, has come to be an essential part of the undertaking. The telephone rather than the telegraph is, almost without exception, used for this service; and the need for establishing the communication without delay under normal conditions of operation and, as near as may be instantaneous under abnormal and emergency conditions, has resulted generally in the assumption of the construction, equipment and maintenance of the telephone plant by the power companies themselves. In some cases the service is obtained from local or long distance telephone companies, either by the usual exchange connection or by leased circuits. Where the importance of the service warrants it, both private lines and exchange or leased wire service are provided, the independent pole lines and usually different routes giving a certain assurance of continued service through the various hazards that wires must face in the open air.

The route selected for the power transmission lines is generally the logical route for the telephone line and the poles or structures erected for the power wires have naturally been considered for reasons of economy and frequently used for telephone wires also.

There are advantages in having power and telephone wires along the same right of way. Patrol and inspection of the power lines may include the telephone lines at the same time. Portable or more permanent instruments connected at any point along the line reduce delays in reporting and repairing trouble and in the resumption of service after a shut-down to make repairs or for new construction work.

There are disadvantages in placing the telephone wires on the same structures that carry the power wires and also disadvantages in following the same right of way. The fire and life risk from accidental contact between telephone and power wires need only be mentioned. A more frequent and sometimes continual source of trouble is from "induction." Very briefly, conductors which are charged (or alive) and carrying currents exert an "influence" on and through the surrounding space. These influences are usually called "electrostatic field" and "electromagnetic field." Conversely the changing fields "induce" changes and currents on conductors such as telephone wires. The telephone receiver gives sound which may be heard with extremely small currents; and in case of trouble when the conditions such as length of line, operating voltage, short-circuit current, etc., are considerable then induced voltages and currents may become sufficient to ring the bells, give unpleasant shocks, burn out the windings of telephone instruments or even start fires or kill if proper protective devices are omitted or neglected.

While the fields of force extend to an indefinite distance and probably travel to the planets and even to the stars with the velocity of light, practically they become vanishingly small at distances that may be used to separate power and telephone lines. Also of practical importance is the fact that the fields have a "sign" or direction so that the resultant field at any point is only what is left after subtracting all the forces of one sign from those of opposite sign. Thus a telephone wire may be close to two wires transmitting much power at high voltage and yet be free from induced current through being at the same distance from each wire, as the direction of the current in the two power wires is opposite. Similarly a telephone receiver on two wires equally distant from a single power wire may be silent through balanced forces.

For the best telephone service we must make what at first thought may seem almost a fetish of the word "balance." Power generators and transformers should be so designed and connected, as well as the lines themselves, as to insure at all times the same current flow in opposite direction in the two, three or more wires of the transmission lines; the voltage to earth should at all instants of time add up to zero (making allowance for opposite polaritier); current may not be returned by the earth; it may or it may not be permissible to ground the neutral as this may be done in many ways, as the terms "grounded neutral" and "third harmonic" have been made to cover a multitude of sins and their virtues often overlooked.

The telephone circuit must be metallic. Grounded lines inherently call for electrical isolation and even when away from other wires are more susceptible to atmospheric disturbing noises. The final refinement lies in the transpositions. Since the two wires of the telephone circuit must be separated for mechanical and electrical reasons, transposition, ro interchanging the positions of the wires at intervals, makes the neutralization closer. Transpositions are frequently desirable, though not always needed, on the power wires also.

In most cases a transposition of the two telephone wires every 1000 feet is sufficient. Sometimes more are cut in while endeavoring to eliminate undesirable noises, but often such work is worse than time and money wasted if the noise chances to be due to a high resistance ground at some point or to high resistance joints, etc.

Some power lines are transposed every mile or two but in the absence of any specific case to be considered it may be proper to suggest the use of two transposition points—giving, for a three-phase system, three equal sections—between generating and receiving stations or between switching points.

Conditions and requirements of a power company's private telephone differ from exchange service. In exchange service all protective devices aim to save the instruments, cables and switchboards from damage at the expense of the service. The line is opened or grounded on what, for a power line, would be regarded as slight provocation. In many of the early power telephone lines service was bad and frequently interrupted when most needed through following exchange practice in equipping the telephone stations. The gap to ground adjusted to strike at 300 to 500 volts is too sensitive for a power telephone line. Some station operators merely discarded these with attending risks to users and equipment.

In the endeavor to give safe and continuous service in spite of trouble on the power lines, the writer developed the now well known telephone transformer.

This is essentially a "repeating coil" with sufficient insulation between the line and instrument windings to withstand a production test of 25,000 volts for one minute. Some over-zealous advocates of its use have claimed that it will quiet a noisy line. It *may* do this by improving the line insulation, but it is properly regarded as a device to protect instrument and user and enable lines paralleling power lines to be safely connected into exchange systems.

Although, by balancing and transposing, a telephone may give excellent service with the wires on the same towers with high voltage lines, a separate pole line is preferable; and on most of the lines recently built and under construction for use at 60,000 volts and higher a separate line of poles from 50 ft. to 200 ft. removed from the main tower line is set to carry the telephone wires. At these distances the induced voltage with accidental grounds or short circuits is much reduced and the risk of actual contact is practically eliminated.

Unless power transmission conditions alter materially, the telephone will continue an indispensable part of the whole system. Proper provision should be made for lines and equipment in planning new work and tests and inspections to ensure continued high efficiency should be regularly applied. Rapidity and reliability in establishing communication between distant points must exist at all times where there is any pretense of giving first class service. As indicating a possible direction in which there may be some innovations, attention is directed to the increasing use of loud speaking telephones. When an operator is continually in attendance some time may be saved, as there are occasions when seconds are precious, and the operation of ringing and waiting for an answer can be eliminated. A loud speaking telephone has been found to give good service in train dispatching at busy terminals. A loud speaking receiver with amplifying horn is mounted on wall or ceiling close to the tower-man's position and instructions given and questions asked without the customary ringing and answering. With such a loud speaking telephone near the controlling board of a generating station the operator could be spoken to with no delay and without requiring him to lose sight of instruments or use of hands to control switches.

# CENTRAL STATION SERVICE FOR ARTIFICIAL ICE PLANTS

By W. J. Moore

Small Motor Department, General Electric Company, New York Office

Artificial ice is superior to the natural product in every respect; it is purer and more transparent, and the quantity is not dependent upon weather conditions. It is fast supplanting natural ice, even in those localities where the winter weather insures an abundance of the latter. This article describes the principal features involved in the latest method of ice manufacture by the raw-water system, and shows by means of a carefully compiled table and a discussion of its significance that the central station can profitably supply power to ice manufacturing plants at a price that compares favorably, per ton of ice produced, with the costs of steam and gas producer plants.—Editor.

Until recent years the artificial ice plants in this country were driven by steam engines, and the ice was manufactured from the distilled water obtained by condensing the steam exhausted from the engines. In order to entirely remove the cylinder oil from the water supplied in this manner, and thus prevent it from becoming frozen into the ice, a complicated filtration system was necessary.

A marked improvement in the process of ice making was later introduced, namely, the adoption of the multiple-effect evaporator. This machine operates on the principle that less heat is required to evaporate water under vacuum than under atmospheric pressure. By the use of this type of evaporator, it is sometimes possible to obtain an evaporation as high as 50 lb. of water per lb. of coal. With the adoption of the evaporator, distilled water could be secured at low cost and free from oil. It therefore became possible to drive the main compressors by a compound condensing engine, an oil engine, a gas engine, or any other type of prime mover which could be operated economically and which would give continuity of service.

Due to the general realization by central stations that the ice plant was desirable from the standpoint of constant load and high load-factor and in keeping with the practice of making reductions in rates for the class of users taking current at off-peak periods, power companies have been in a position to make attractive inducements to artificial ice plants.

Various methods have been devised for making ice without the use of distilled water, where local conditions are favorable for obtaining satisfactory well, spring, or city water. The original "raw-water system," adopted for the manufacture of ice direct from well, spring, or city water, was known as the plate system; and consisted of freezing water into large cakes sometimes 9 ft. by 16 ft. by 12 in. in size and weighing five tons. In this system cold brine is made to circulate through hollow plates immersed vertically in tanks filled with water. The water is agitated and the ice forming on both sides of the plates rids itself of any air or impurities. The large cake thus formed is removed by a crane to a sawing table and there cut into cakes of the desired size.

Within the last two years considerable progress has been made in perfecting the raw-water can system. This system necessitates a modification of the can, as used in the manufacture of distilled-water ice, because the water must be constantly agitated during the process of freezing. An air pipe is connected at the bottom of the can, through which air is supplied at about 3 lb. pressure. Water in freezing liberates its entrained air and carbon dioxide, which are carried off by agitating the water. If for any reason the agitation ceases, the bubbles of air and carbon dioxide are frozen into the block, which causes the ice to be opaque. The quantity of air required for agitation depends upon the rate of freezing and varies with different waters.

In the process of freezing, small crystals of pure ice are formed. As the crystals form, the soluble mineral salts, being more capable of solution in water than of being frozen into ice, are removed by the water which has not as yet become frozen. If the proper agitation takes place, solids and matter in solution or in suspension are "pushed ahead" of the freezing ice until they arrive at the center of the can.

When about 12 to 40 lb. of water are left still uncongealed in the center of a 300-lb. cake (the amount depending upon the type of freezing system used) this water, which contains practically all of the impurities originally in the 300 lb. of water, is then removed. Various methods have been adopted for removing this core. One method provides for its removal by opening a master valve controlling a drain pipe, which drains out the impure water from 60 or more cans by one operation. Another method is to withdraw the water from the top of each individual can by means of a suction pump. The hole through the center of the cake is then filled with distilled water, or additional raw water, and the cake frozen solid. Ice manufactured by the raw-water system is more sanitary, palatable, and more nearly free from odor than that made by any other system. The cake is transparent and has a slight feathery appearance at the center.

Recent tests have shown that while the impure core-water may contain 200,000 bacteria per cubic centimeter, the entire cake will contain on the average less than 20 bacteria per cubic centimeter after the core-water has been withdrawn, fresh water added, and the cake completely frozen.

Previous to the adoption of the raw-water system, central stations did not consider the artificial ice business as within their field of operations. They regarded the production of the necessary amount of the engine exhaust a serious handicap to economical manufacture by electricity. However, with the advent of this system, central stations could compete in power costs with the gas producer, oil engine, and high-economy compound condensing engine; and their attention was therefore directed to the large possibilities presented by this class of business. Much has been accomplished within a short time in this new field. The city of Chicago has fifteen central-station-driven ice plants (the daily tonnage ranging from 60 to 140 tons each, totaling 1355 tons with an aggregate installation of 5344 h.p.); Buffalo, N. Y., has five, operated by Niagara Falls power; and there has recently been built in Brooklyn, N. Y., two of the largest electrically-driven raw-water ice plants in the world, which are operated entirely by central-station power.

The first cost of a central-station-operated plant is considerably less than that of an engine-operated plant with a consequent reduction in fixed charges, such as interest, depreciation, insurance and taxes. The space required for an electrically-driven plant is less than for a steam plant. The plant operated by electricity may be located in residential sections, where, due to the nuisance of smoke, noise, etc., steam plants would not be allowed. Hence, with this central location with respect to customers, delivery charges and shrinkage are reduced to a minimum and prompt deliveries are assured.

The use of the electric motor meets with favor by the ice manufacturer, since it eliminates engine and boiler troubles: the necessity for making boiler repairs recently shut down a large plant in Brooklyn for five days during the hottest weather.

The artificial ice plant makes the ice man independent of weather and furnishes a grade of ice that is superior to natural ice, for it is purer, cleaner, more transparent, and more uniform in size, purity, and density. The use of natural ice is rapidly decreasing. A number of the Great Lake cities no longer use it, because the streams from which it was taken have become impure due to the increase in population, sewage, and polluting refuse from manufacturing plants, etc. No more natural ice is being shipped up the Potomac River, and a large electrically-driven raw-water plant has been installed at Winnipeg, Canada, where the temperature in the winter is often 40 deg. below zero, and in Minneapolis, Minn., where from zero to 20 deg. below is often prevalent. The city of Buffalo, N. Y., will soon be entirely supplied by artificial ice.

Natural ice can be cut for about 15 cents per ton, but added to this is the cost of shrinkage, storage, loading on cars or boats, transportation, dock rentals, etc. These factors, together with the long hauls from the railroad terminals or docks in the cities, make the final price only slightly less than that of the artificial product. The quality of the artificial product enables the manufacturer to over-balance any difference in price and compete with the natural ice dealer.

In the manufacture of the average article the power cost may be between 2 and 5 per cent, while in ice making it ranges between 30 and 50 per cent of the total cost of production. It is apparent, therefore, that the cost of power largely affects the cost at which ice may be manufactured. The power required to manufacture one ton of ice would of course depend upon the system used, and the type and efficiency of the machinery. Data are available which show that in a raw-water plant of about 100 tons capacity, it may take as low as 45 kw-hr. or as high as 60 kw.-hr. per ton of ice. The average throughout the country is about 52 kw-hr. per ton of ice produced, based on cooling water at 65 to 70 deg. F., the exact figures depending upon the conditions existing at the plant.

An examination of the chart, which has been compiled by the Arctic Ice Machine Company, Canton, Ohio, and which covers the Arctic Pownall system of raw-water ice manufacture, shows the cost from the standpoint of power, labor, and sundries, which include oil, waste, ammonia, and calcium; and also the investment necessary to build a power plant for operating an ice plant employing a simple steam engine using bituminous coal, a compound condensing engine using bituminous coal, a producer-gas engine using bituminous, anthracite, or lignite coal, a gas engine using natural gas, an oil engine using fuel oil, or a plant using motors operated by central station service.

The figures given in this chart are maximum. This is necessarily due to the fact that the figures are compiled for use in all parts of the world. That is, if a chart of this kind was made based on 50 kw.-hr. per ton of ice produced when electrically-driven, and a plant installed where exceedingly warm condensing water was used, or where it might be necessary to go to great expense in pumping condensing water, such figures would come within the data given herewith. The chart in question should also only be used to make *comparison* between the operation and installation cost of different prime movers, data based on local conditions being substituted for those given in the table.

It will be seen that by the use of a simple steam engine about six tons of ice per ton of coal may be manufactured, while with the use of the compound condensing engine this is increased to 11 tons.

It will also be noticed that the lowest operating cost is secured by the use of a producer-gas engine using bituminous coal, while the highest operating cost results with central station service using electric motors at 1 cent per kw.-hr. However, although the cost of operating per day by a producer-gas engine using a $3.00-a-ton bituminous coal is $46.70, and the cost of electrically operating per day with current at $^1{}_2$ cent per kw.-hr. is $47.51, it should be observed that the investment for the power plant using a producer-gas engine is $65.00 per h.p. as compared with $16.00 per h.p. where electric motors are used.

To obtain the total cost per ton of ice, the cost of the water from which the ice is made, and the interest on investment, insurance, taxes, depreciation, maintenance, and management charges on the plant must be added to this cost of operation. It will be noted that the labor in the electrically-driven plant is less than in most other types in that the firemen may be dispensed with.

Although there is a difference in the cost per unit of power, in favor of the gas or oil engine as compared with the electric motor, the final cost of the ice manufactured by the use of such engines may exceed that manufactured by motors operated from central station power, because of repairs, losses due to shut-downs to make such repairs, additional depreciation, etc.

From the central station standpoint the ice plant is a very desirable load. Current is used 24 hours a day, and the peak of the ice plant does not overlap the peak of the central station. The maximum peak of the average central station occurs during the months of November, December, January and February, and between the hours of 4 and 8 p.m. During this time the main compressor motors of the ice plant may, without any inconvenience, be shut down and the small auxiliaries operated without interfering with the production of ice. As a result the central station can consistently offer a low rate for current.

In order to insure continuity of operation and to be in a position to offer a low rate, the central stations may furnish current from their primary system, that is, direct from the main generators, and thus eliminate transformer losses. At Buffalo, high-tension power at 2200 volts is delivered to the compressor motors; in Brooklyn, the primary current direct from the main generating station is delivered at 25 cycles and 6600 volts to the ice plant, where it is transformed to 440 volts for use at the motors.

From an engineering standpoint the ice plant presents a serious problem to the central station as regards reliability of service, for considerable trouble in the ice plant might develop due to momentary shut-downs; more so than ordinarily results from the shutting down of the usual industrial plant. Great care must be taken to prevent momentary interruptions to the service, for when the large compressor motors are shut down it interferes with the ammonia distribution, and, as the ammonia compressors must start under full load, a return of current on the line is very apt to blow the fuses and otherwise interfere with the operation of the plant. It has been found necessary to devise a system of no-voltage relays in order to eliminate possible fuse trouble with its attendant delays.

The question of transformers for use in connection with ice plants is a very important one. Manufacturers of transformers frequently design them bearing in mind that in ordinary use they will have a chance to cool due to variations in load. The ice-plant load is practically constant, and this should be kept in mind in selecting the size of transform-

ers to be used. Where different makes of transformers would operate in parallel in an ordinary industrial installation, such operation in ice plants often results in the burning out of either one or the other make. This is due, of course, to unequal distribution of the load caused by the difference in impedance of the transformers.

It is advisable that the lighting system of the ice plant should have available a source of power other than that furnished by the power circuit from which the motors are operated so that, in case of an interruption to the power supply, the lights can be supplied from this separate source. It is considered good practice, also, to independently connect the motors operating the compressors that furnish the agitating air so that they, too, may have a separate power circuit available. Interruption of the flow of agitating air causes white streaks in the ice.

With reference to the type of motor to be used in driving the main compressors, where alternating current is supplied, it is advisable to use the wound-rotor type. The resistance should be designed for starting duty only, as it is the general practice in ice making to use constant speed.

It is also desirable to use that type which provides for the lifting of the brushes from the collector rings and also for short circuiting them. This device increases the efficiency of the motor, inasmuch as it eliminates from the secondary circuit the resistance of the brushes and the leads to the controller. When it is considered that the ice plant operates 24 hours a day for months at a time, it will be realized that a difference in efficiency of 3 to 5 per cent in the main compressor motors is a matter of importance. Up to 150 h.p. it is well to use induction motors having the internal-resistance type of phase-wound rotor. These motors have met with marked success in this field of application.

# ELECTRICAL EQUIPMENT FOR MOTOR-DRIVEN MACHINE TOOLS

By C. Fair

Power and Mining Engineering Department, General Electric Company

This article presents in a detailed manner the marked improvements that can be made in production by the application of electricity for driving machine tools. The selection of the proper motor and control equipment for such work is carefully considered from various standpoints. Illustrations of a number of typical motor drive installations are included, and also reproductions of oscillograph and recording-ammeter curves, which show the characteristic electrical demands upon the motors used.—Editor.

Originally, lighting was the principal, if not the only, advantage claimed for electricity. Little was known of shop equipments as we now see them. It is doubtful if there were any electrically operated cranes or if there was any electrical transportation in shops. The first few motor drives were scattered and confined practically to line shaft drives and to portable drills with flexible shafts. The individually driven machine tool was about as much of a curiosity then as an individually steam engine driven machine tool is today. When motors were installed to replace the numerous engines scattered about the shops or to break up the long mechanical transmission lines, a great saving in power and improvement in continuity of service were noticed. It was during this period that many of the claims of saving in power were made that now appear rather extravagant. It will be seen how enormous were the power losses when one considers that steam was often transmitted to numerous engines for long distances, from one or more power stations, through small pipes which were often uncovered or else the power was distributed by long shafts transmitting power from one building to another or from one shaft to another, around corners, by quarter turned belts and to various floors, etc. When the long shaft or any part of the long transmission system was broken, it often tied up a large part of the plant until key-ways could be cut and the shafts re-coupled or a section of the shaft replaced, or the belts repaired, as the case might be. Within the past two years an investigation was made of a plant that spread over a considerable area, employing less than four hundred men and the machinery of which was driven by 26 engines, the largest being about 50 h.p.

Today the two important questions continually before the manufacturer are how to increase production and how to decrease cost. In the majority of cases labor is the

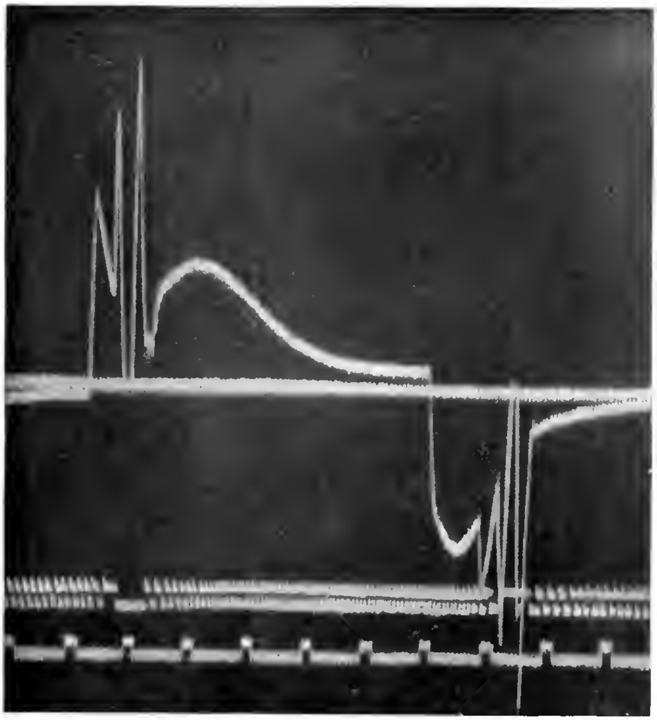

Fig. 1-a

greatest cost of production. Thus, where machine tools are a considerable factor in the production, the importance of obtaining a maximum output from the tool is evident. Tools that are limited in their productiveness because of the lack of power at the tool are a source of expense to the manufacturer, not only on this account but on account of the excessive labor due to the additional time required. The power cost of production is comparatively small, roughly, varying from one to three per cent, while the labor cost is usually a very large item of the production cost, often amounting to fifty per cent and upward. If, therefore, by increasing the power on a given tool its output can be increased, the conclusion is obvious.

The importance of motor drive for the machine shop is every day becoming more evident. Recent tariff legislation is causing American manufacturers to see, as never before, the necessity of using the most modern methods in order to compete with manufacturers of other countries where labor is cheaper; hence the continuous growth in the installation of electrically driven machinery. In practically all new industrial plants where power is required, electrically driven machinery has been installed. Due to the great improvement in motors, accessories, and methods of application, and owing to the large number and variety of motor-driven tools in service today, the relationship of motors and control to machine tools is much better understood by the machine builder and the user than heretofore. Consequently, comparatively little trouble is experienced with either motors or control for the ordinary type of machine tool. Misapplications of both motor and control occur occasionally due largely to insufficient or unreliable information regarding the characteristics of the machine, but the number of these misapplications is relatively small.

The tendency for both over and under-motoring machines is constantly growing less, owing to the

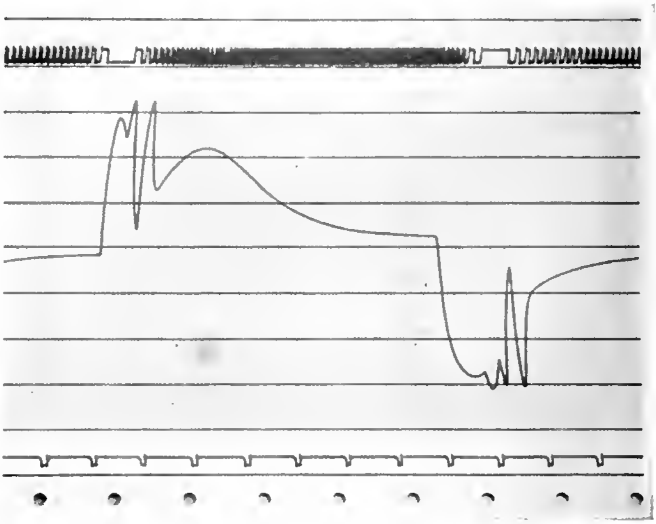

Fig 1-b. Figs. 1-a and 1-b show a comparison of curves made simultaneously on a reversing motor planer drive between the oscillograph with its period of 5000 per second and the graphic recording ammeter with its period of six per second. This comparison made approximately to the same scale of time affords better understanding of the actual value of the curves in the following Figures.

large number of tests which have been made, to the accurate information available, and to the great number of motor driven machines now in service. There is still, however, a slight tendency on the part of some machine builders to over-motor their machines either with the mistaken idea of the strength of the machine or with the idea that possibly prospective customers will be impressed with the enormous power required by their "heavy type" machines. Conversely, other manufacturers want to show how little power it takes to operate their "very efficient" machines and consequently get into overloaded motor troubles. These extremes are gradually disappearing and a more normal condition is taking its place. In a comparatively short time the greatly over-motored and under-motored machine will be a thing of the past, at least insofar as the general type of machine is concerned.

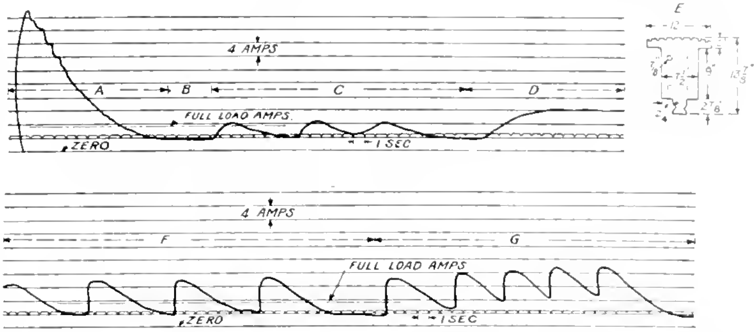

Fig. 2. Curves from a Ferracute Punch Press S. G. 52. A, accelerating the flywheel, clutch not engaged; B, load of flywheel only; C, stroking without punching at the rate of nine strokes per minute, flywheel recovers its energy; D, stroking without punching at the rate of 16 strokes per minute, flywheel recovers very little energy; F, punching piece "E" at the rate of 8 per minute, flywheel nearly recovers its energy; G, punching piece "E" at the rate of nearly 14 per minute, flywheel only partly recovers its energy

A number of manufacturers have already recognized three ratings of motor drive on certain of their machines; namely, heavy, medium, and light. Much of the existing trouble in motor applications to special machines, or to machines rigged for special operations, could easily be avoided if only preliminary tests were made with a temporary motor before making the permanent installation. A not uncommon source of trouble with motor-driven tools, and one that could easily be avoided, is that of attempting to increase the productiveness of the tool considerably by speeding up the machine, increasing the cuts, or attaching automatic feeding devices, etc. Although any one of these changes will increase the productiveness of the tool, the motor must not be overlooked for, if the tool were originally under-motored and the capacity of the motor is not increased when the change is made, trouble is very apt to result. Increasing the productiveness of the tool calls for an increase in power, although there are some cases where this is not true.

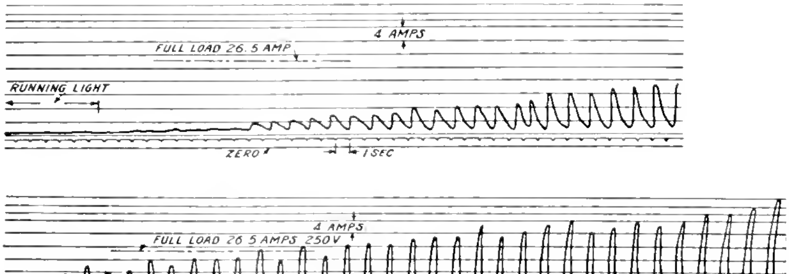

Fig. 3. Shows graphically the effect of automatically rough-shaping gear teeth with a V-shaped tool. Each peak represents a cutting stroke

Although the advantages of the motor drive have been dwelt upon at length numerous times, a brief statement of the advantages derived from electrical installations will perhaps be worth repeating:

1. Maximum output of the direct connected tool due: to greater power and overload capacity, absence of slipping belts, closer speed regulation which allows a maximum cutting speed for metals of varying degrees of hardness, rapid speed changes, quick starts, stops, reversals, independent operation of auxiliaries

and ease of manipulation through convenient control stations. Too much stress cannot be laid on maximum output of tools.

2. Power distribution not only for tools, stationary or portable, but for lights, cranes, elevators, furnaces, welders, transportation, etc. This means that power and light can be had quickly and cheaply in any part of the buildings or yard, permanently or temporarily without regard to structural conditions.

Fig. 4. Group of Nine Drop Hammers consisting of one 2500, two 1600, two 800, two 600 and two 400-lb. hammers, driven from 80 ft. of shafting carrying 18, 30 in. by 8 in. flywheel pulleys and driven by a direct connected 40 h.p. motor. In the middle foreground will be seen a motor-driven air hammer

3. Elasticity in the arrangement of tools. Tools can be arranged to the greatest advantage for sequence of operation in routing work, and also for good lighting as well as for compactness when necessary.

4. Ease of adding new tools and of moving and rearranging tools. Ease of adding new tools means a great deal in growing plants. Rearrangement becomes necessary after reasonable growth or because improvements in methods of manufacture call for a better routing of work.

5. Head room for cranes, hoists, etc. For example, note the expensive manner in which work is often handled because belts or shafting interfere with the installation of cranes or hoists.

6. Facility for running only such tools as are required for overtime work.

7. To a large extent the elimination of belts and belt troubles.

8. Unobstructed light and sanitation. Numerous belts obstruct light, whether natural or artificial. Under the modern structural conditions, avoidance of the well understood difficulties of line shaft installation in concrete buildings.

9. Safety to operators. The individual motor drive offers absolute protection to the operator from accidental starting up of the machine by merely opening a switch. Machines so protected cannot be started unexpectedly by the starting up of line shaft, the creeping of belts from loose to tight pulley, the sticking of clutches, etc., or by the accidental tripping of clutches by the operator. This additional safety is of particular advantage on machines requiring certain setting up operations, as on punch presses, etc., also by the fact that machines can be quickly stopped from any one of a number of motor control stations.

10. Competition today necessarily means the monotonous duplicate system of manufacturing wherein the individual makes only one part of the finished product. It is now recognized as not only desirable but as economical that some form of interest be restored to help break this monotonous routine of duplicate manufacturing. This can and is being accomplished in a manner by making the surroundings attractive. Electric drive not only increases production, but reduces to a minimum many of the unattractive features of the shop, such as overhead revolving pulleys, masses of moving belts, noisy transmission, stirring up of oil and dust, and bad lighting conditions. Electric drive also reduces many heavy manual operations to a minimum by the use of auxiliaries. It pays to capitalize cheerfull surroundings.

The general use of high speed steel has made it not only possible, but necessary for economical production, that the cutting speed be increased in order to meet competition. Increasing the cutting speed naturally means more power; and while much has been said from time to time regarding the increased production and saving in power due to applying the power direct to the tool, yet the writer has very serious doubts if anything like the real importance

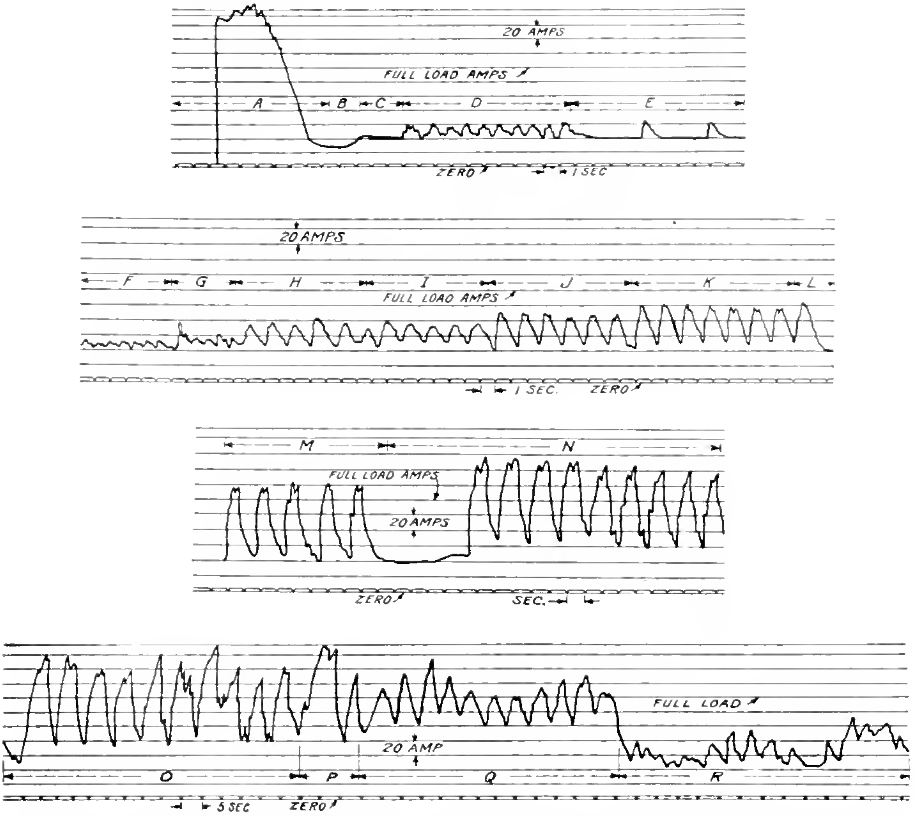

Fig. 5. Results of Tests on Hammers in Fig. 4. A, starting shaft; B, running light; C, hammers up; D, one 400-lb. hammer stroking light; E, forging; F, one 600-lb. hammer stroking (shorter stroke than previous 400-lb.); G, forging; H, one 800-lb. stroking; I, forging; J, one 1600-lb. stroking; K, forging steel commutating poles; L, final lift of hammer; M, one 2500-lb. hammer stroking; N, working steel gear blanks for air compressors; O, P, Q and R, hammers in regular production; O, 2500, 800, 600 and 400-lb. working; P, 2500 and 1600-lb. working; Q, 1600, 800, 600, and 400-lb. working; R, 800, 600 and 400-lb. working

of this direct application of power is realized in many cases, even by those who are advocating it. For instance, the saving of power is looked upon generally as a matter of how much of the transmission friction load can be saved, and, though this saving may amount to 50 per cent, it is in many cases only a part of the real saving, as has been proved by numerous tests made by the writer.

The slipping, due to a belt not being able to pull its cut, means waste power and loss of production. If the cut be heavy enough the maximum slip will be reached when the machine is stalled, the power input remaining approximately the same. The load is now entirely one of friction due to slip in the belt. A familiar illustration of this fact is that of an operator decreasing the depth of his cut on account of the slow down, because the belt will not carry the load. The solution of this would seem to be to increase the size of the belts. This will suffice in some cases, but there are numerous instances where either there is not room to increase the width of the belt or where step cones are used the number of steps will have to be decreased; such means as multiple countershafts or additional gearing must be included to complete the speed range. Furthermore, it is difficult to shift large belts, and this method generally results in much loss of productive time.

As previously mentioned, up to a few years ago in the majority of shops where motors were used they were usually belted to the line shaft or counter-shaft of the tool. Adjustable speed motors were not so commonly used then as now, nor were they made in the great variety of sizes and speeds now obtainable. Today, especially in the case of new tools with their requirements of high power and close speed regulation, it becomes not only more convenient, but in many cases almost a necessity, to apply the motor directly to the tool.

In driving tools with individual motors it will be noted that the motor not only supplies the power and speeds best adapted to the tool, but that in the case of variable speed tools the speed range of the adjustable speed motor alone in many cases will cover the entire speed range of the tool. The motor and its controlling apparatus should whenever possible be connected directly to the tool, thus making a compact unit, which has also the additional advantage of allowing the entire machine to be moved by simply disconnecting the leads and connecting them in the new position. In the case of portable tools this, of course, is an absolute necessity.

Fig. 6. Shows a section of a small shop equipped more than fifteen years ago, nearly all of the machines being driven by individual motors. A number of these machines are the first of their kind to be driven by individual motors, and although fifteen years have elapsed since the original installation, it compares favorably with an up-to-date equipment of today

Many tests have been, and are being made, to determine the kind and the horse power of the motor that should be used for different types and sizes of tools; but up to the present time the motor is generally considered only as a means of driving the tool and not as one of the main elements of the tool construction. Recent motor improvements will produce many new designs in tools with corresponding higher efficiencies.

While there are numerous motor applications to machine tools which are a decided credit to the machine designers and for which due credit should be given, there are still many motor applications where it is only too plainly to be seen that the motor is an after-thought and thus much of the advantage of the application is lost. In order to derive the greatest advantage from motor drive, the motor should as far as possible be direct-connected to the machine. There are today many cases where motors are driving machines through unnecessary auxiliary apparatus. This additional apparatus not only takes up valuable floor space and wastes power, but fails to give the maximum output available when the motor could be connected directly to better advantage and in some cases at actually less cost. From the foregoing it will be seen that the advantages derived from an up-to-date direct method of applying the motor not only increases the productiveness of the tool, but also decreases the actual power required, by the extent of the friction load loss, and also decreases the first cost of the motor on account of the less horse power required. The writer knows of cases where improved drives have cut the power required to half and even less. A cheap first cost is sometimes an expensive investment.

The advantages of individual motor drive for large tools and for certain of the smaller tools have been conceded for years, but there are many tools where either the cost of the motor or the cost of applying the motor to the tool on account of the construction of the machine is prohibitive. This cost could be modified by making the motor a part of the tool rather than a mere addition to it.

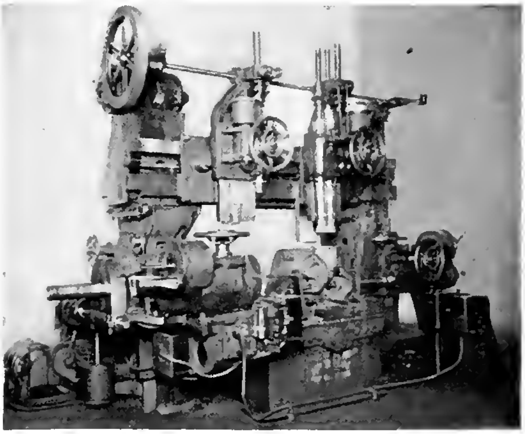

Fig. 7. A Special Five-Spindle Boring Mill. Three-motor drive

Better drives are possible now than they were formerly owing to the greater motor speed range obtainable, to the decrease in size of motor per horse power, to motor characteristics which specially adapt them to the work which they are to do, to more perfect balance of the rotating parts at high speed; and, to a certain degree, to improvements in gears which allow higher speeds without excessive vibration and noise, and to the many recent improvements in control.

Much more exacting requirements of both motor and control are now demanded. Motors driving machines reversing ten times per minute, and operating twenty-four hours per day are now not unusual. Duty cycles that were impossible to meet only a short time ago are now not only practicable but common. With the great variety of motors and controllers now on the market, and the large quantity sold sometimes without the motor manufacturer even knowing for what service they will be used, it would be surprising if trouble did not occasionally occur.

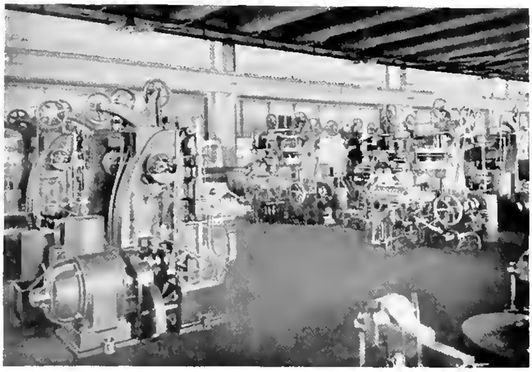

Fig. 9. Group of Individual Motor-Driven Milling Machines each driven by a 10 h.p. motor. Note head-room clearance for cranes

Much of the success of a motor-driven machine depends on its control. Magnetic control, which is coming into more general use somewhat complicates the control situation. While the possibilities of magnetic control are infinitely greater than the older types of control, likewise the chances for misapplication are greater. However, as the characteristics of the different types of control become better known these complications will disappear.

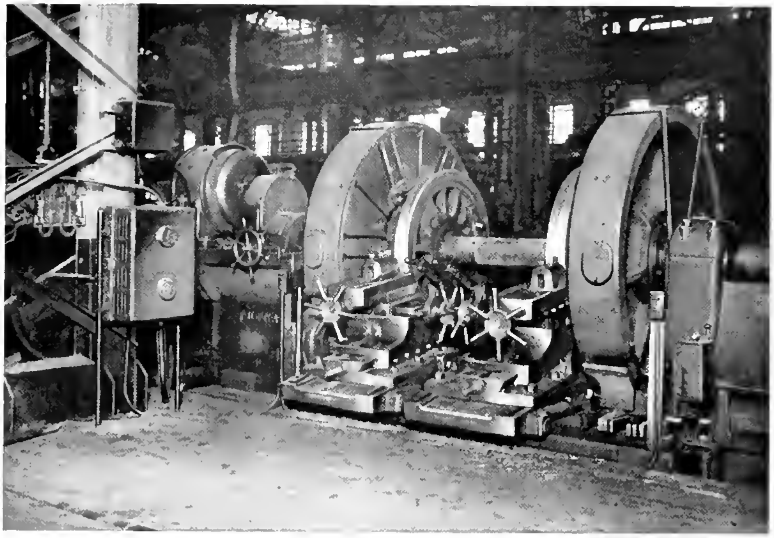

Fig. 8. Motor-Driven Wheel Lathe. Push button control; start, stop and slow down

The increase of the number of individual motor-driven tools is due fundamentally to the facts, as has been shown, that the tool can do more work, do it better, and do it cheaper.

Increasing discrimination is being exercised in applying motor drives. When the work of actually equipping a factory with motor drive is undertaken, it is necessary to study the conditions of operation, which vary greatly with the product manufactured. The arrangement of a factory may be entirely different if many motors are used instead of a few groups. Simply the difference in the position of a number of the tools may greatly facilitate the handling of material.

In general, the most satisfactory electrical equipment for machine shops, using a large number of motors, would be one having available both a-c. and d-c. distribution; a-c. for all constant speed machines and d-c. for adjustable speed machines.

In the smaller shops, with rare exceptions, the choice of motors would depend upon the current available, which in the majority of cases would be alternating current. The very size and product of the small factory makes a proper layout a comparatively simple matter, while in larger factories skill and ingenuity are essential to obtain the most advantageous equipment. The standard motor of today will answer for the majority of the machine tools, although special motors are in some cases necessary.

When equipping tools with individual drives, the controlling apparatus as well as the motor should be attached directly to the tool whenever possible. In the case of portable tools this, of course, is a necessity.

A graphic recording wattmeter in circuit with a tool is of value in efficient management as it not only tells the actual power consumed by the machine, showing whether or not the tool is properly motored, but it also shows whether the tool is operating at its maximum rate, by registering the time of unproductive cycles or the length of time the tool is idle. By analysis, the cause of the lost time may be discovered and a change of operating conditions can be made with a corresponding increase in production.

Table I will, in a general way, aid in the choice of motors. The great variety and the size of tools of the same name make it necessary in a general list, such as this, to double-check a number of tools. It must be kept in mind, however, that various circumstances, such as size and roughness of work, and flywheel capacity, etc., may call for radical departures in the choice of motors, this list being compiled to meet average conditions.

Shunt motors, for instance, are used in the following cases: When work is of a fairly steady nature, when considerable range of adjustment of speed is required as on lathes and boring mills, and on group and lineshaft drives, etc.

Compound-wound motors are used where there are sudden calls for excessive power of short duration, as on planers (not reversing motor drives), punch presses, bending rolls, etc.

Series motors should be used where speed regulation is not essential, and where excessive starting torque is required, as, for instance, in moving carriages of large lathes, in raising and lowering the cross rails of planers and boring mills, and for operating cranes, etc., but not where the motor can be run without load as through a clutch, or belt that might leave its pulley, as the motor would run away if the operator failed to shut off the power.

When in doubt as to the choice of compound or series motors of small horse power, the choice might be determined by the sim-

### TABLE I

### MOTORS FOR MACHINE TOOLS

| Tool | D.C. | | | A.C. | | |
|---|---|---|---|---|---|---|

* Squirrel cage rotor.
† Squirrel cage rotor—high starting torque.
‡ Slip ring induction motor with external rotor resistance.
§ Does not apply to reversing motors.

plicity of control in favor of the series motor.

The alternating-current motor of the squirrel cage rotor type corresponds to the constant-speed, shunt, direct-current motor; but with a high-resistance rotor it approaches more closely the characteristics of a compound, direct-current motor. It is understood that the variable-speed machines checked in Table I under the alternating-current squirrel cage rotor column have the necessary mechanical speed changes.

The slip-ring induction motor with external rotor resistance would be used for variable speed, but this must not be construed to mean that it corresponds to a direct-current, adjustable-speed motor, as it has the characteristics of a direct-current shunt motor with armature control.

The self-contained, rotor resistance type could be used for lineshaft drives, and for groups when of sufficient size.

Multi-speed, alternating-current motors are those giving a number of definite speeds, usually 600 and 1200, or 600, 900, 1200 and 1800 r.p.m., and are made for both constant power and constant torque. These motors would be used where alternating current only was available, and where the speed ranges of the motor, together with one or two change gears, would give the required speeds. These motors should, however, be used with discretion, especially on sizes above six horse power.

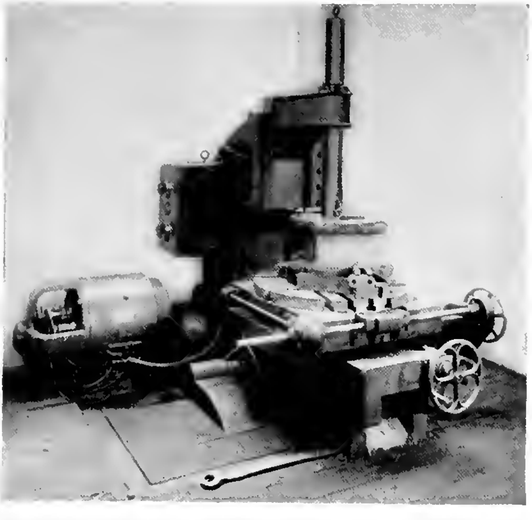

Fig. 11. A Direct-Connected Reversing Motor-Driven Slotter for slotting locomotive driving wheel boxes. Besides the regular control equipment the motor can be started and stopped from a push button station

The adjustable speed, a-c., commutator brush-shifting type of motor with shunt characteristics would, on account of high cost, be used mostly where an adjustable speed motor was highly desirable and where a-c. only was available and where there were not enough machines calling for adjustable speed drive to warrant putting in a motor-generator set.

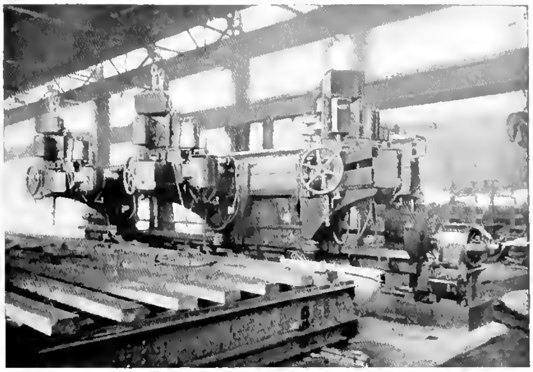

Fig. 10. Is an illustration of a recent direct-geared motor application to radial drills. The 7 1/2 h.p. vertical, adjustable speed motor is mounted on the saddle and geared direct to the drill spindle. Although radial drills have been motor-driven for years, this drive was the means of omitting much of the usual mechanical transmission. The weight heretofore objected to in this type of drive has been overcome by mounting the saddle on large rollers plainly seen in the cut. The drive is in every way satisfactory and part of an original order of forty-two

An important feature in the selection of motors, and one that is often overlooked, is the adherence to the use of standard motors, and by standard motors is meant standard armature shafts as well. The importance of maintaining standard armature shafts will be recognized when it is pointed out that by such an arrangement spare armatures are reduced to a minimum. In emergencies it is often possible, where spares are not carried in stock, to replace the armature or even a whole motor by one from an idle tool, or from a tool of relatively less importance at the time. Also, of course, stock motors can be supplied promptly by the manufacturer and shipments materially improved if special shaft extensions are not called for. That special features in a motor are sometimes desirable, is true; it may so happen that the advantages from some special feature in the motor may more than offset the disadvantages referred to, but in cases where these features are thought necessary they should be carefully considered before final decision.

In the early days of motor drive before the present great variety of sizes and speeds of standard motors were obtainable, many special features were thought necessary in the motor to make it adaptable to the tool; special frames, shafts, and speeds were required, and little thought was given to the interchangeability of parts. In fact, tools which only a few years ago it was thought necessary to drive with special motors are today driven by standard motors, and as a result are easily and quickly repaired. It is therefore easy to recognize in these early equipments the responsibility for part of the existing idea that special features in the motor are still necessary for tool equipments. Many of these special features required for the early drives are now recognized as unnecessary, and today the tool builder in the majority of cases builds his tools ready for attaching standard motors.

The old prejudice existing against the electric motor, which was mostly a mistrust due to a lack of familiarity with its operation, is rapidly dying out, and today motors are found driving machines in shops of every description.

Equally important with the choice of motors is that of control. In selecting the control its adaptability, its accessibility to the operator, the method of attaching it to the tool and in some cases its relative position to other tools should be considered. As an illustration of this last point, an open-type starting rheostat, if used, or unprotected magnetic control, should not be mounted on a machine in such a manner as to be exposed to danger of short-circuit by flying chips. It is now, however, only a matter of time before all live parts of both motor and control will be enclosed. In the majority of cases, a shunt motor of ½ h.p. and less would be started by a switch. Exceptions to this would be motors on tools that must be gotten under way slowly. With adjustable-speed motors, care should be taken to first throw the switch on full field. Series motors up to 8 h.p. or even larger can be started by a switch without resistance. Exceptions to this would be cranes and tools requiring a certain amount of armature speed regulation. Larger motors for tools where starting service is infrequent or not severe, and for lineshafts, and for group drives, would be satisfactorily operated with a dial-type controller, which is cheaper than the drum controller, provided, however, that the controller is placed in a protected position.

When making the installation, accessibility to the controller in case of accident should be kept in mind, even though but of little importance so far as starting up is concerned. The starting apparatus should be placed where the motor or some of the moving parts can be seen by the operator. On individually motor-driven tools, where the motor is started and stopped many times a day, or where the starting conditions are of a severe nature, or where tools are edged along, drum type controllers or magnetic control with extra heavy starting resistance should be used. For adjustable-speed motors using the drum type control, the field control should be connected through fingers making contact on segments of the controller drum and not by sliding contacts on a dial as with the latter trouble will develop sooner or later. With magnetic control, provision should be made in the control either to start the motor on full field or to provide necessary points for starting on weakened field in order to protect the motor. Motors of moderate size and larger, operating under severe duty cycles, are best controlled by magnetic switches. This class of starting apparatus will stand almost any amount of abuse and, by the addition of a simple current limit relay device, becomes practically a fool-proof protection for the motor. There are cases where it might be advantageous to use magnetic control even with smaller motors.

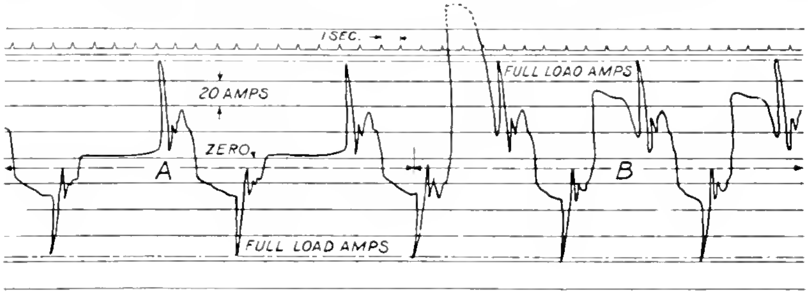

Fig. 12. Curve made from Machine shown in Fig. 11. A, running light; B, cutting

Squirrel cage rotor type motors, two-phase and three-phase, up to 5 or 8 h.p., generally speaking, can be thrown directly on the line, depending largely upon the power conditions. Above 5 or 8 h.p. this type should be operated by a compensator or sliding resistance in the rotor, while for the slip-ring type a controller with external resistance should be used.

Upon the convenient arrangement of the control depends, to a considerable degree, the output of the tool; and the importance of the arrangement from the standpoint of the operator should not be ignored, since the output of a tool will be materially increased when an operator can start and stop the tool and obtain at all times maximum cutting speeds by simply turning a handle. The controller must be placed in a safe position and should be accessible for repairs, which very often mean that some arrangement is necessary to bring the operating handle within easy access of the operator. A familiar illustration of the convenience of control is the arrangement so commonly seen on lathes, whereby the operating handle travels with the tool carriage and allows the operator at all times a complete control of his tool. Strange as it may seem, this most important feature, the convenience of control which bears directly on production, is ignored in many tool equipments.

Exhaustive tests have been and are being made to determine the amount of power required to drive tools. Hasty conclusions should not be drawn from incomplete data since they are apt to be misleading; for instance, where tests are made with motors which are considerably underloaded or over loaded, where efficiencies are not taken into consideration, where the material used and duration of test are not stated, or where there has been failure to state whether the test was a practical one or merely a breakdown test. The conclusions drawn from breakdown tests are often deceptive and should not be used for determining the power required to drive tools, for it does not follow that a tool which stands up longer than another under breakdown conditions will do the same under practical conditions. To develop a general formula that would be of practical value in determining the horse power required to drive tools would be difficult, as the power required varies with the metal worked, the cutting speed, the kind of tools used, the efficiency of the machine, and many other conditions.

The construction of the tool is seldom taken into consideration when estimating horse power, thus some of the worm-driven tools are notoriously inefficient. Other machines are so constucted that the greatest part of the power delivered to the tool is consumed in friction losses and not in useful work; again, the tool may be constructed upon approved lines but may not be stiff enough to stand the strains to which it is subjected thereby causing a considerable loss of power, all of which, as well as the difference in power due simply to the shape of a cutting tool, have been repeatedly proved by tests. Again the duty required of a tool in one shop may be more severe than that in another, from which it will be seen that it cannot be accurately stated that a definite size of motor is required for a given tool. In the majority of cases, however, the horse power for small tools is very well fixed. With the larger tools the variation in horse power required for such tools, of course, is more pronounced, and demand more consideration on account of the size of the motors involved.

Little trouble is experienced in obtaining new tools already arranged for attaching motors, since many of the tool manufacturers are alive to the superiority of the motor drive and have for years built tools especially adapted for motor drives. Unfortunately, others have seen fit to merely arrange a make-shift for attaching the motor, while still others leave the purchaser to attach the motor as best he can, and consequently the best results are not always obtained.

When the driving of old tools by individual motors is under consideration, the speed range, the number of similar tools to be equipped, and the condition of the tool should be considered. It sometimes happens that when a tool in itself would not call for an individual drive, certain circumstances might make such a drive advisable. As an illustration, when the majority of tools in a shop have become individually driven, there might still remain a number of scattered tools, which, unless they were driven by individual motors, would necessitate the running of long lines of shafting; or, in the event of moving into new quarters, a cement building perhaps, it is decided not to use line shafting.

Since production is the ultimate aim of progressive shop management, and since the electric motor is generally conceded to be the greatest factor in increasing production, it is only a matter of time before the motor will be universally used in machine shops.

# FROM THE CONSULTING ENGINEERING DEPARTMENT OF THE GENERAL ELECTRIC COMPANY

## ENERGY DENSITY

One of the most valuable features of electrical energy is the high energy concentration which it permits, allowing the production of higher energy densities than have been reached heretofore.

Usually, when considering high electric energy concentration, we think of the electric arc furnace, where thermal energy densities (temperatures) about twice as high as can be reached by combustion or any other means are obtained. It is interesting to note, however, that still very much higher energy densities can be reached by electrostatic fields in vacuum tubes.

Investigations by the Consulting Engineering Department of the General Electric Company and others have shown that air has a definite dielectric strength, (30 kilovolts per centimeter) at atmospheric pressure, but that much higher voltage gradients are reached close to the terminals of the spark gap, especially if the terminals are brought together to a distance within the dielectric energy distance (the space around the terminals in which the dielectric strength must be exceeded before rupture can occur). The dielectric strength decreases with the air pressure down to a minimum; but with still lower pressure, it increases again, since the energy distance, which increases with decreasing air pressure, becoming larger than the distance between the terminals. At a very high vacua the dielectric strength thus becomes very high, approaching values apparently of the magnitude of a million volts per centimeter. If then we calculate the energy stored in a cubic centimeter of space at a voltage gradient of a million volts per centimeter and the weight of the matter still existing in one cubic centimeter space at the highest vacua which have been reached, we find values per gram of matter of many millions of joules or calories, that is, energy densities thousands of times higher than those of the highest explosive. These energy densities are possibly the highest which can be reached. They are of the magnitude of the internal energy of radio-active atoms, and the phenomena of high electrostatic fields in high vacua thus would be the most promising starting point for an experimental study of the transformation of chemical elements into each other. C. P. STEINMETZ

## PERMITTIVITY OF ORGANIC LEAD SALTS

It has often been claimed that the permittivity of the organic salts of lead, such as the stearate, palmitate, oleate, etc., would be found to be very high—in the range between 10 and 20. Samples of these salts have recently been obtained and subjected to permittivity measurements at 24 deg. C. with these results:

| | PERMITTIVITY |
|---|---|
| Lead stearate | 5.2 |
| Lead palmitate | 5.2 |
| Lead oleate | 5. (Approx.) |

The permittivity of the stearate and palmitate was measured also at 40 deg. C. and found to be much higher; viz., 9½ for each.

The stearate has a similar consistency to that of rosin, the palmitate resembles paraffine, while the oleate is almost as soft as lard. The first two salts are very good dielectrics at atmospheric temperatures. Disks of the stearate and of the palmitate, ⅜ in. in thickness, successfully withstood 60,000 volts applied between 2 in. spheres. S.T.

## ALLOYS OF MAGNESIUM METAL

In the January, 1914 issue, mention was made of aluminum magnesium alloys, and a number of inquiries have since been received as to their conductivity.

A few samples containing about 6 per cent magnesium, 92 per cent aluminum, about 5 per cent iron, 5 per cent silicon, and a small amount of copper have been examined and found to give a conductivity of 52 per cent at 20 deg. C. and a temperature coefficient of 0.0038 from 20 deg. to 52 deg. C., and 0.0033 from 52 deg. to 100 deg. C.

The conductivity of pure aluminum is 57.5 per cent and of pure magnesium 37.7 at 20 deg. C. Therefore a small amount of magnesium does not seriously affect the conductivity.

In some of the recent English magazines we note that English designers are finding considerable use for a new aluminum alloy that goes under the trade name of "Ivanium." This metal is claimed to be 2½ per cent heavier than aluminum, and is non-magnetic. The castings are equal in finish to the finest gun metal, and they may be easily machined and soldered. The melting point is very low, 300 deg. C., whereas both aluminum and magnesium melt at approximately 550 deg. C. This metal is also a good dioxident. J.D.B.

## QUESTION AND ANSWER SECTION

The purpose of this department of the Review is two-fold.

First, it enables all subscribers to avail themselves of the consulting service of a highly specialized corps of engineering experts, or of such other authority as the problem may require. This service provides for answers by mail with as little delay as possible of such questions as come within the scope of the Review.

Second, it publishes for the benefit of all Review readers questions and answers of general interest and of educational value. When the original question deals with only one phase of an interesting subject, the editor may feel warranted in discussing allied questions so as to provide a more complete treatment of the whole subject.

*To avoid the possibility of an incorrect or incomplete answer, the querist should be particularly careful to include sufficient data to permit of an intelligent understanding of the situation. Address letters of inquiry to the Editor, Question and Answer Section, General Electric Review, Schenectady, New York.*

### ALTERNATOR: FULL-LOAD AND NO-LOAD FLUX

**(106) In an alternator delivering constant voltage from its terminals, is the flux entering the armature windings per pole much greater at full load than at no load?**

There has always been a great deal of misconception on this question due to the indefiniteness attached to the term "reactance voltage." If, with the rotor in place, full-load current of the periodicity of the machine is sent from some external source through the stator windings, the voltage across the terminals will have a value which (after correcting for the IR component) is sometimes termed the "reactance voltage." If a similar test is made on the stator when the rotor has been removed, a lower value will be obtained, which has also sometimes been considered as representing the "reactance voltage." Combining vectorially the terminal voltage, the IR drop, and the "reactance voltage" (measured with or without the rotor), a resultant considerably in excess of the terminal voltage will be obtained. This resultant cannot, however, be taken as an index to the amount of flux per pole.

Actually, the flux per pole at full load is only very slightly greater than that corresponding to the terminal voltage plus the IR drop. This has been shown to be the case by fitting an exploring coil in the machine and noting, by readings on a voltmeter connected to its terminals, the fluxes present at no load and at full load. By working backward from such results, proof has been obtained to show that the "reactance voltage" to be employed in a vector diagram, constructed with the true value of the internal voltage as obtained by the exploring coil, is of a very small amount. But since the result, as thus deduced, depends upon the difference between nearly identical quantities, the reactance voltage could not be obtained in this way with any degree of accuracy. We can only arrive at the conclusion that it is very low. The reactance of the end connections is about sufficient to account for it. Consequently, in estimating the internal voltage in an alternator this should be taken as the resultant of the terminal voltage, the IR drop, and the "reactance voltage" of the end connections. No serious error will result from the absence of any exact data for the estimation of the "reactance voltage" of the end connections, since the value employed will, in any case, only slightly affect the estimated internal voltage and the corresponding flux.

From the reasoning given in the preceding, it will be seen that the flux entering the windings at full load is only slightly greater than that at no load.

The subject is inherently complex and, in order to deal with it in as simple a manner as possible, no allusion has been made to the power-factor of the external load. The conclusions stated are more nearly true the higher the power-factor of the load. At low power-factors the end-connection reactance voltage, small as it is, is more nearly in phase with the terminal voltage and consequently occasions a greater difference between the flux at full load and the flux at no load. H.M.H.

### AUTOMATIC VOLTAGE REGULATORS: PARALLEL OPERATION

**(107) It is desired to operate in parallel two alternating current generators which are each equipped with an automatic voltage regulator, the machines being located in separate power houses. Is this possible?**

Yes, this can be accomplished by connecting a current transformer on one regulator 90 degrees out of phase with the potential transformer. With this arrangement, the current winding of the regulator is only energized by the leading or lagging current. Under such an action, the voltage will be automatically changed to correspond to the voltage being maintained by the other regulator. O.C.R.

### INDUCTION MOTORS: LOW SPEED

**(108) What are the objections to the employment of low-speed induction motors?**

Induction motors for operation from a circuit of a given periodicity are of lower power-factor and efficiency the lower the speed. A 300-horse-power, 60-cycle motor for a synchronous speed of 120 r.p.m. would require 60 poles and its power-factor would be less than 0.8 whereas a 300-horse-power, 1200-r.p.m., 60-cycle motor (with 6 poles) would have a power-factor well above 0.9. Low speeds are more practicable the lower the periodicity of the supply. A 24-pole, 25-cycle, 300-horse-power motor for a synchronous speed of 125 r.p.m. would have a power-factor a little above 0.8. In addition to the low power-factors of low-speed, high-periodicity induction motors, the efficiency is low and the cost is excessive as compared for the same output and speed with continuous-electricity motors whereas very-high-speed, squirrel-cage induction motors have higher efficiency and are much cheaper than continuous-electricity motors for the same output and speed.

Recently, phase advancers have been developed and their use in connection with low-speed induction motors removes from them all objections associated with low power-factor, since, when of appropriate design, the phase advancer may bring the power-factor up to unity even at fractional loads, or it can be so designed that the induction motor shall consume a leading current. The phase advancers may be of either the rotating or the vibrating type and will add but slightly to the cost of the combined set. Phase advancers may also greatly increase the stalling load, which is otherwise very low in the case of induction motors for low speeds.

A good description of rotating phase advancers is given at p. 33 of *The Electrical Times* for January 8, 1914, and a description of an installation of a vibrating phase advancer employed with a 330-horse-power, 12-pole, 50-cycle induction motor is given at p. 214 of *Electrical Engineering* for April 15, 1914. The curves published in this latter article show that at half load the power-factor was 0.99 leading and that at full load it was 0.96 leading. The corresponding power-factors without the vibrator were 0.76 lagging at half load and 0.87 lagging at full load. (See article on "Phase Advancers," June, 1914, REVIEW.) H.M.H.

### SYNCHRONOUS CONVERTER: LINE DROP

**(109) What are the reasons for the commonly published statement that synchronous converters will not operate satisfactorily if the alternating-current line drop is 10 or 15 per cent or more, regardless of the use which is made of the direct current taken off? What are some of the other conditions that prevent the successful operation of synchronous converters?**

The feature limiting the satisfactory operation of a synchronous converter under the conditions mentioned is pulsation. This is an alternate acceleration and retardation of the machine with respect to the supply frequency. Pulsations may be set up by changes in frequency, voltage, load, etc., and the amount by which the converter swings out of phase will depend upon the synchronizing current available. As the synchroning current is limited by the resistance of the line, it follows that the higher the line drop the farther will the machine swing out of phase before the required synchronizing current is obtained. The farther the converter swings out of phase, the greater the possibility of its dropping out of step and the greater its tendency to flash over, due to the out-of-phase armature reaction which produces a voltage between the commutator segments under the brushes.

Another effect of increased line drop is that of causing a slower period of pulsation. It so happens that in most machines the natural period, that is, that which takes place when there is no line drop, is usually somewhat higher than the periods of disturbance such as variable impulses per revolution in a steam engine. Owing to the added resistance in the line, the period of swing of the converter is reduced to a value which more nearly corresponds with that of the disturbance, so that the effects are accumulative and the pulsations become more violent. At the same time, the resistance reduces the synchronizing current so that the machine has less current available for bringing it back into phase.

A given machine may operate satisfactorily with line drop in excess of 10 per cent, provided other conditions of operation are favorable. The other principal conditions enabling satisfactory operation are good voltage regulation and uniform frequency, especially with absence of regular periodic variations.

J.L.B.

### TURBINE-GENERATORS: INTEGRAL FAN *vs.* EXTERNAL FAN VENTILATION

**(110) Is it better to circulate the cooling air for a steam-turbine-driven generator by means of an independently-driven fan or by fans incorporated in the design of the rotor?**

Since the conditions involved in machine ventilation vary to a considerable extent in different stations, it would not be practicable to make the assertion that either particular method is the better in all cases. Both arrangements have their advantages and disadvantages, and a statement of these will be given from which conclusions may be drawn to apply to specific instances.

The usual plan is to build the fan as an integral part of the rotor of the turbine generator; and the fan is usually so designed as to *force* the air through the generator, as distinguished from drawing it through by suction. Fans are inherently of low efficiency under the best of conditions and when the design has to be adapted to the space or dimensions available in the rotor, and to the speed of the rotor, the efficiency is lower than would be the case for a design not limited by such considerations. A certain amount of space in the generator is also sacrificed for the purpose of providing for the fan. The cooling air is slightly heated in passing through the fan, owing to the latter's inefficiency. On the other hand, by incorporating the fan in the design of the rotor, the machinery is self-contained and little or no thought or attention need be given to it.

By adopting the alternative plan of employing an independently-driven fan, it becomes entirely feasible to let the fan *draw* the air through the rotor instead of *forcing* it through. Consequently, there is avoided the slight heating of the air, by a fan, prior to passing it through the parts of the generator requiring to be cooled. An independently-driven fan may be of more appropriate proportions and of slightly higher efficiency. Furthermore, in the case of the independently-driven fan, arrangements may be made to operate it at lower speed at times of light load for then less cooling air is required than at heavy load. This will have the effect of increasing the light load efficiency of the plant, which consideration is not by any means of negligible importance. That this is the case will be seen when it is pointed out that the friction of the cooling air is an important component of the total losses in a turbine-driven generator. With the self-contained fan, this loss is a constant at all loads and is consequently a still more considerable proportion of the total losses at fractional loads than at full load. The plan of using independently-driven fans also works in well with the practice, adopted in modern installations, of "conditioning" the air.

Unless air is cleaned, either by passing it through spray washers or suitable dry filters, the passages in the turbine generator may, in the course of time, become clogged by deposits. With self-contained fans, the quantity of air passing through the generator will in time become gradually less, owing to the obstruction in the ventilating passages; and the machine will run warmer. When an independently-driven fan is employed, steps may be taken to increase the pressure impelling the air, and there may be passed through the machine the required quantity, notwithstanding the partial obstruction of the ventilating passages.

DR. WILLIAM D. COOLIDGE

Dr. Coolidge has recently been honored with the Rumford Medal for his invention of Ductile Tungsten and its Applications in the Production of Radiation

GENERAL ELECTRIC REVIEW

### THE PATHS OF PROGRESS

We publish in this issue of the REVIEW, a photograph of Dr. William D. Coolidge, Assistant Director of the Research Laboratory of the General Electric Company, who has recently been honored by the American Academy of Arts and Sciences with the Rumford Medal. This medal was awarded Dr. Coolidge for his invention of ductile tungsten and its application in the production of radiation.

We believe that there have been few inventions that have had such a spontaneous and far-reaching effect upon the electrical industry as has the invention of ductile tungsten. Like most other great accomplishments in the scientific world, ductile tungsten was only finally arrived at after a long and carefully thought-out series of investigations had been made, and many blind alleys were followed before a consistent and persistent research led to the results sought. The results accomplished in this particular case are especially illuminating as showing the excellent work that is being done, and the valuable contributions that are being made to our scientific knowledge, through the medium of our Industrial Research Laboratories. Many great accomplishments have recently been brought about through this medium which it is hard to believe would have been achieved in any other way.

In talking of the particular development under consideration the inventor is emphatic in emphasizing the all important part played by three factors, namely: the corps of scientifically trained men who were constantly co-operating with him, the wonderful facilities at his disposal, and the constant help and encouragement rendered by a large factory organization versed in innumerable processes of manufacture. He further calls attention to the fact that the large organization in presenting to the inventor a definite problem for solution is thereby going a long way towards insuring the attainment of the desired end. Incidentally, the achievement of such results by an industrial research laboratory emphasizes the fact that the world at large very quickly reaps the benefits of the development work carried out by a large modern manufacturing concern.

The outcome of this work has been a revolution in the electrical incandescent lamp. In America alone approximately one hundred million incandescent lamps were made last year and it is surely one of the romances of modern science when we consider that this work has led to so great an increase in the efficiency of the incandescent lamp that it has been estimated to save the public in the neighborhood of $1,000,000 a day. It is on account of the wonderful economy secured by the modern incandescent lamp that the work of producing ductile tungsten will for many years to come, be looked upon as one of the mile-stones of progress in the electrical industry.

The production of ductile tungsten with its valuable physical properties led to a search for new applications. One of the first of these was the substitution of tungsten for platinum as the target or anti-cathode in X-ray tubes. The advantages of tungsten for this purpose have been so marked that it is now practically universally used in all high power tubes. Its superiority is due to its higher melting point, lower vapor pressure, and greater heat conductivity and its use has led to a marked increase in the intensity of the X-rays which can be produced.

The experimental work necessary in producing this new form of target led further to the development of an entirely new X-ray tube with characteristics radically different from those of the older form of tube.

In the older form the operation depended upon the maintenance of a perfectly definite gas pressure within the bulb, while in the Coolidge tube the gas is removed just as thoroughly as possible, so thoroughly in fact that without a special form of cathode no discharge current can be passed through the space between the electrodes. In the new tube current conduction is made possible by heating a portion of the cathode to a temperature at which it emits electrons, the remainder of the cathode serving as a focusing device to so direct the movement of the electrons across the space that they will all bombard the target on a small area called the focal spot, which is the source of the X-rays.

The use of a higher vacuum and of a hot cathode greatly change the characteristics of the tube, doing away entirely with puncturing troubles, with movement of the focal spot, local heating and fluorescence of the active hemisphere, and with the emission of troublesome X-rays from the glass. The discharge current carried by the tube when a definite potential is impressed upon the terminals, and hence the intensity of the X-rays produced, may be either increased or decreased at will, as it depends only on the temperature of the heated portion of the cathode. The penetration of the X-rays produced may be instantly increased or decreased at will by raising or lowering the potential difference impressed upon the tube.

Among the many practical advantages which the new tube offers may be cited the fact that it renders it possible for an operator to do all classes of work ranging from that calling for the lowest to that calling for the highest penetration with a single tube. Further, it becomes possible for him to reproduce exactly what he or some other operator has done before. It also makes it possible for him to produce X-rays of higher penetrating power than have heretofore been available. For the future it holds out the possibility of the production of X-rays of any penetration between that of the present X-rays and of the most penetrating gamma rays of radium.

Another interesting and important application of wrought tungsten is as a metal for the contact points in electric make-and-break devices such as are used in automobile ignition systems and in voltage regulators. Tungsten has already very largely supplanted the platinum metals for this purpose.

It may be of interest to all our readers to note that the founder of the Rumford fund was Benjamin Thompson, one of the many illustrious men who have made the name of Thompson so famous in scientific spheres. Benjamin Thompson, who was created a count by Prince Maximilian, was born in Woburn, Massachusetts, March 26, 1753, and died at Auteuil, France, in 1814. He left America for England at the time of the Revolutionary War and soon afterwards entered the service of Prince Maximilian of Bavaria, whose army be reorganized. He also instituted important social reforms, at the same time that he carried on much valuable research work. The most noteworthy of his investigations conclusively disproved the fluid theory of heat which was then commonly held. In 1799 Count Rumford returned to England and founded the Royal Institution of Great Britain.

Among the illustrious men who have been honored with the Rumford Medal may be noted: Robert Hare, for the invention of the compound blowpipe; John Ericsson, for his caloric engine; Alvan Clark, for his refracting telescopes; George Henry Corliss, for his improvement in steam engines; Joseph Harrison, Jr., for his steam boilers; Lewis M. Rutherford, for his work in astronomical photography; Henry A. Rowland, for his researches in heat and light; S. P. Langley for his researches in radiant energy; Charles F. Brush, for his electric arc-lighting; Elihu Thomson, for his inventions in electric welding, Charles Gordon Curtiss, for his improvements in steam turbines and Frederick Eugene Ives for his color photography.

# THE NATURE OF ELECTRICAL DISTURBANCES IN POWER TRANSMISSION WORK

## Part I

By David B. Rushmore and Eric A. Lof

Power and Mining Engineering Department, General Electric Company

The authors deal at some considerable length with the nature and the means of controlling or eliminating the disturbances which occur in the operation of transmission lines. The disturbances are divided into two classes, i.e., those caused by high currents and those caused by high voltages. In the present article the authors treat of the abnormal conditions resulting from excessive current and in a following number they will deal with the abnormal conditions due to excessive voltage. The disturbances due to high currents may be caused by overloads or short circuits resulting in excessive heating or undue mechanical strains which often damages the apparatus in circuit. The effects of excessive currents can be minimized or prevented by the provision of reactance in the circuit or the introduction of external power-limiting reactance. Careful attention should be given in designing systems to so locate the switches as to sectionalize the network in such a way that the trouble can be confined to a small area. This article is an amplification of a paper recently presented by the same authors before the N.E.L.A. convention.—Editor.

For the sake of analytical study and comparison, all forms of commercial occupation may be considered as manufacturing enterprises. In each case there is a raw material on which is performed certain work or operation, which thereby becomes a finished product to be sold to a consumer. The public service company manufactures and sells electrical energy, although people sometimes think it is selling power. Scientifically speaking, energy cannot be manufactured as the amount in the universe is absolutely unchangeable, but its form can be altered. The raw material of the public service company represents the potential mechanical energy of water-power, or the stored chemical energy of coal or other fuel, the energy of which has previously been received in radiant form from the sun.

All energy, whether it be in the form of mechanical, chemical, electrical, heat or radiant energy, consists of two parts: a quantity factor and an intensity factor.

The transmission of energy, usually erroneously called the transmission of power, may be accomplished in many different forms—electrical energy may be transmitted over wires; water or air under pressure may be conveyed through pipes; gas or oil wherein the energy is in a chemical form may be transported either through pipes or in tank cars, and the most usual form of chemical energy, coal, is usually transported in cars over railroads. Mechanical energy is transmitted through friction drives, gears, belts, ropes, chains, etc., which methods for the purpose of our discussion fall into a different class.

Commercial enterprises having for their object the production of wealth, and therefore necessitating a limitation on the investment, render the attainment of perfection impossible and necessitate the use of a factor of safety, the magnitude of which depends upon the number of failures permissible under the conditions of operation. This is really the reason for the existence of the engineering profession, for there is very little in the way of attainment which cannot be accomplished if the cost be not an element which enters into consideration.

In all instances where energy is being transmitted from one place to another, or changed from one form to another, we have normal operating conditions, and we also unfortunately have what might be termed abnormal conditions. This general statement holds true over practically the entire field of human endeavor. Apparatus is designed generally with due consideration of the conditions of normal operation, but the features involved under emergency conditions must have some consideration, and frequently are the factors necessitating a compromise in designs.

It is always of interest to look at specific cases in the light of broad, general laws. Throughout our civic and social order we have large numbers of individuals who devote themselves to the class of phenomena which comes under emergency or abnormal operating conditions. The medical profession, the police department, and the fire department are all for such business. A large number of machines and appliances are devoted entirely for use when the conditions of operation become abnormal.

In the transmission of intelligence, in the transportation of men, in the transportation of commodities, and in the transmission of energy this statement is generally applicable. This fact is due primarily to the variation in the factors which enter these different situations and the possibility of pre-determining them with accuracy. Also to the fact that materials in general undergo wear and depreciation, that human capacity has its limitations, and that developments are always active on the frontier of knowledge, where facts are first brought to light through experience.

In the specific field of the transmission of energy under pressure, which we may take to include the mediums of electricity, air and water, we have some more or less close analogies between the three divisions with regard to the factors concerned when abnormal conditions obtain and the operation of a system of transmission is disturbed.

The investigation and study of the nature of many electrical disturbances have been accomplished with very great difficulty, due to the character of the disturbances themselves and of the instruments available for their detection and measurement. In the absence of definite experimental knowledge a great deal of theory has been elaborated based upon assumptions, the justification for which in some cases may be open to question. Due to the rapid advance of electrical development there is much that has not as yet become a matter of exact knowledge, but there is also a considerable part of the field that has been explored with some degree of thoroughness, and a better knowledge of the nature of these disturbances is rapidly being attained, as well as a more exact measurement of their magnitude.

The electrical disturbances which generally occur in the operation of power transmission systems can be divided into two broad classes: first, those which are due to excessive currents and, second, those which are due to excessive voltages.

### Excessive Currents

Excessive currents are caused either by overloads or short circuits and may result in overheating and burn-outs of the apparatus, with a subsequent interruption of the service, unless protective measures are provided to prevent the same. It is the maximum temperature at which the insulating material of a machine may be operated for a certain period which determines the load that the machine can carry, and if these safe limits are exceeded, the insulation will rapidly deteriorate. The result of operating at temperatures in excess of the safe limit is to shorten the life of the insulating material, and the damage will increase with the length of time that the excessive temperature is maintained and with the amount of excess temperature, until finally the insulation breaks down entirely.

There is a large variety of insulating material used in the construction of electrical machinery, and it has been found by actual experience that the safe temperature limit does not only depends on the particular material used but also on the method of its application. Based on actual observations of the operations of different classes of machinery for a number of years, the new A.I.E.E. standardizing rules recommend the following safe temperature limits.

Class A1—Cotton, silk, paper and other fibrous materials, not so treated as to increase the thermal limit, 95 degrees C.

Class A2—Same as A1 but treated or impregnated, 105 degrees C.

Class B—Mica, asbestos, or other suitably high heat resisting material, in which any Class A material or binder, if used, is for structural purposes only, and may be destroyed without impairing the insulating or mechanical qualities, 125 degrees C.

Oil in which apparatus is immersed shall in no part be subjected to a temperature in excess of 90 degrees C., and in water-cooled transformers, the maximum temperature shall not exceed 85 degrees C.

The above temperature limits should therefore not be exceeded by any machine when operating at its rated output, and the temperature should refer to the hottest spot where damage to the insulation may occur, which is usually in the interior of the embedded portions of the winding.

As it is usually impossible to determine exactly the maximum temperature attained in insulated windings, it has been found convenient to apply a correction factor to the measured temperature, to allow for the possible difference between the actual maximum temperature and the measured temperature by the method used. This correction or margin of security is provided to cover the errors due to the fallibility in the location of the measuring devices, as well as inherent inaccuracies in the measurement and methods.

In determining the temperature of different parts of a machine, three different methods are recommended in the new standardization rules. These methods are outlined in Table I and give the suggested margin between the observable temperatures and the hottest spot, as well as the temperature rise.

It is also recommended that the standard rating of a machine shall be its capacity when operating with a cooling medium of standard ambient temperature (40 degrees for air and 25 degrees for water), assuming no abnormal barometric conditions. Unless otherwise specified, the rating of any machine shall also be understood as its rating for continuous service.

With large generating units the question of ventilation becomes of great importance and is now given very careful consideration both in connection with the design and the location of the machines. Instead of allowing the paths of the air to be determined by chance, the air is, wherever possible, drawn from the outside and, in some cases, passed through filters. The air is drawn up into the generators, either by forced ventilation or by natural ventilation created by the generator itself. By designing the generator so as to properly direct the paths of flow of the air, a very marked improvement is made in large generators, and by taking this air from the cool space over the tail-race it has, in some cases, been possible to reduce the temperature of the machines very considerably.

### TABLE I

Method of measuring temperatures to determine approximate hottest spot temperatures

| | | METHOD I THERMOMETER ONLY | | | METHOD II RESISTANCE (With Thermometer check when practicable) | | | METHOD III IMBEDDED THERMO-COUPLES OR RESISTANCE COILS | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | | | | | | DOUBLE-LAYER WINDINGS FOR ALL VOLTAGES | | | SINGLE-LAYER WINDINGS 5000 VOLTS OR LESS | | | SINGLE-LAYER WINDINGS ABOVE 5000 VOLTS | | |
| Class | Permissible Hottest Spot Temp. | Hot-test Spot Correction | Limiting Observable Temp. | Limiting Temp. Rise above 40° | Hot-test Spot Correction | Limiting Observable Temp. | Limiting Temp. Rise above 40° | Hot-test Spot Correction | Limiting Observable Temp. | Limiting Temp. Rise above 40° | Hot-test Spot Correction | Limiting Observable Temp. | Limiting Temp. Rise above 40° | Hot-test Spot Correction | Limiting Observable Temp. | Limiting Temp. Rise above 40° |
| $A_1$ | 95° | 15 | 80 | 40 | 10 | 85 | 45 | 5 | 90 | 50 | 10 | 85 | 45 | 10 + (E − 5)* | 85 − (E − 5) | 45 − (E − 5) |
| $A_2$ | 105° | 15 | 90 | 50 | 10 | 95 | 55 | 5 | 100 | 60 | 10 | 95 | 55 | 10 + (E − 5) | 95 − (E − 5) | 55 − (E − 5) |
| B | 125° | 15 | 110 | 70 | 10 | 115 | 75 | 5 | 120 | 80 | 10 | 115 | 75 | 10 + (E − 5) | 115 − (E − 5) | 75 − (E − 5) |

* In this formula *E* represents the rated pressure between terminals in kilovolts. Thus for a three-phase machine of 11 kilovolts between terminals the hottest spot correction to be added to the maximum observable temperature will be 16° C.

In the line of operating generators and transformers within safe limits it has now also become general practice to place temperature coils in the hottest part of the armature from which leads are taken to an indicating device on the switchboard, so that the operator can tell at any moment the maximum temperature to which the armature winding is being subjected.

For cables, the temperature at the surface of the conductor should not be permitted to exceed the following values:

| | |
|---|---|
| For impregnated paper insulation | (85-E) |
| For varnished cambric | (75-E) |
| For rubber insulation | (60-0.25 E) |

where *E* represents the r.m.s. operating electromotive force in kilovolts between conductors.

Thus at a working pressure of 3.3 kilovolts the maximum safe limiting temperature at the surface of the conductor or conductors in a cable would be:

| | |
|---|---|
| For impregnated paper | 81.7 deg. C. |
| For varnished cambric | 71.7 deg. C. |
| For rubber | 59.2 deg. C. |

Excessive currents are, as previously mentioned, also caused by short circuits, and the very high mometary values of these currents may result in severe mechanical strains being imposed on the apparatus of the system. Experience has proved that the magnetic stresses set up under these conditions may be so powerful as to entirely wreck the apparatus, or they may result in a displacement of the windings, which in turn may cause the insulation to break down at different points and put the whole system out of commission.

The short circuit current of an alternator is limited by the resistance and self-inductive reactance, and besides this by the reaction of the armature current on the field.

It is equal to

$$I = \frac{E}{Z}$$

where $E$ is the generated e.m.f. corresponding to the field excitation and $Z$ the synchronous impedance.

The above value of $I$ represents the permanent short circuit current, while the instantaneous value will be very much higher. This is due to the fact that in the first instant, when the generator is short circuited, the current is only limited by the resistance and self-induction of the armature circuit, while a time lag of sometimes a few seconds takes place before the armature reaction becomes effective. The armature resistance and reactance are thus the only two quantities that limit the instantaneous short circuit current. This limiting effect is, however, not constant but decreases slightly with high short circuit currents due to their saturation of the magnetic circuit.

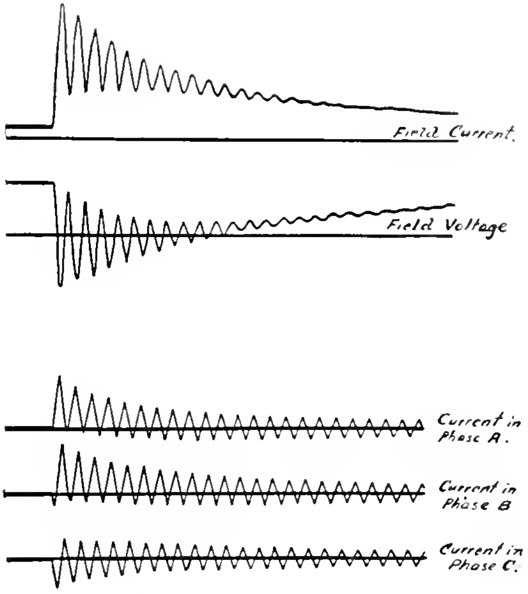

Fig. 1. Oscillogram of Three-Phase Alternator Short Circuit

Considering a waterwheel-driven generator having a resistance of approximately 1 per cent and a reactance of 10 per cent, then the impedance of the circuit will be

$$Z = \sqrt{0.01^2 + 0.1^2} = 0.1 \text{ approximately}$$

If the full load current is 1, the instantaneous short-circuit current would then be equal to

$$\frac{1}{0.1} = 10 \text{ times full load current.}$$

As soon as the armature reaction becomes effective, the short circuit current will be reduced to its permanent value which is only a few times the full load value.

When a short circuit takes place the current becomes lagging, and its effect will be to demagnetize the field poles. In the above example for instance the power-factor is equal to 9 per cent.

$$\tan.\ \theta = \frac{0.1}{0.01} = 10 \text{ and } \theta = 84.5$$

$$\text{thus } \cos.\ \theta = 0.09$$

It, however, requires an appreciable time to reduce the magnetic flux to its low short circuit value, since it is surrounded by the field coils, which act as a short-circuited secondary opposing a rapid change in the field flux, that is, in the moment when the short circuit starts, it begins to demagnetize the field, and the magnetic field flux, therefore, begins to decrease. In decreasing, however, it generates an e.m.f. in the field coils, which opposes the change of field flux, that is, increases the field current so as to momentarily maintain the full field flux against the armature reaction. The field flux, however, gradually decreases, and also the field current which increased considerably the first moment. This is clearly illustrated in the oscillograms shown in Fig. 1.

With the present tendency toward very large generating stations and units, and the concentration of large amounts of power at one place, it is evident that short circuits may give rise to very destructive effects. It therefore becomes imperative that the flow of energy into such faults be limited to a safe value and the damaged part isolated as quickly as possible, so that the trouble does not spread to other parts of the system. The current rush is reduced by providing a sufficient amount of reactance in the circuits. In some cases the inherent reactance of the apparatus may be increased to a value sufficiently high to limit the current to the desired value, while in others it may be necessary to resort to external reactance coils. For high tension transmission systems these may be placed in the generator leads, between the low tension busbar sections or in the low tension transformer leads. In the substations they may, of course, also be placed in the outgoing low tension feeders. Which one of the above locations, or combinations thereof, is preferable depends on a number of conditions, and either has its advantages and disadvantages.

The following example is therefore given in order to show what the value of the short circuit current will be when external reactance coils are provided as shown in Fig. 2. It is assumed that four 12,000-kv-a., three-phase, 11,000-volt generators, having a 12 per cent inherent reactance, are operating in parallel on a low-tension bus. There are two outgoing high-tension lines, each fed through a transformer bank having a capacity of 24,000 kv-a. and an inherent reactance of 4 per cent. It is also assumed that the fault takes place in one line near the station so that the intervening line reactance is negligible. What is then the value of the short circuit current passing through the transformer bank of the damaged line with external reactance coils inserted as shown in the figure? Each coil has a reactance of 6 per cent, based on the full load current of one generator.

The single-phase reactance of a generator, transformer bank or set of reactance coils is obtained from the formula

$$x = \frac{10 \times p \times E^2}{\text{kv-a.}}$$

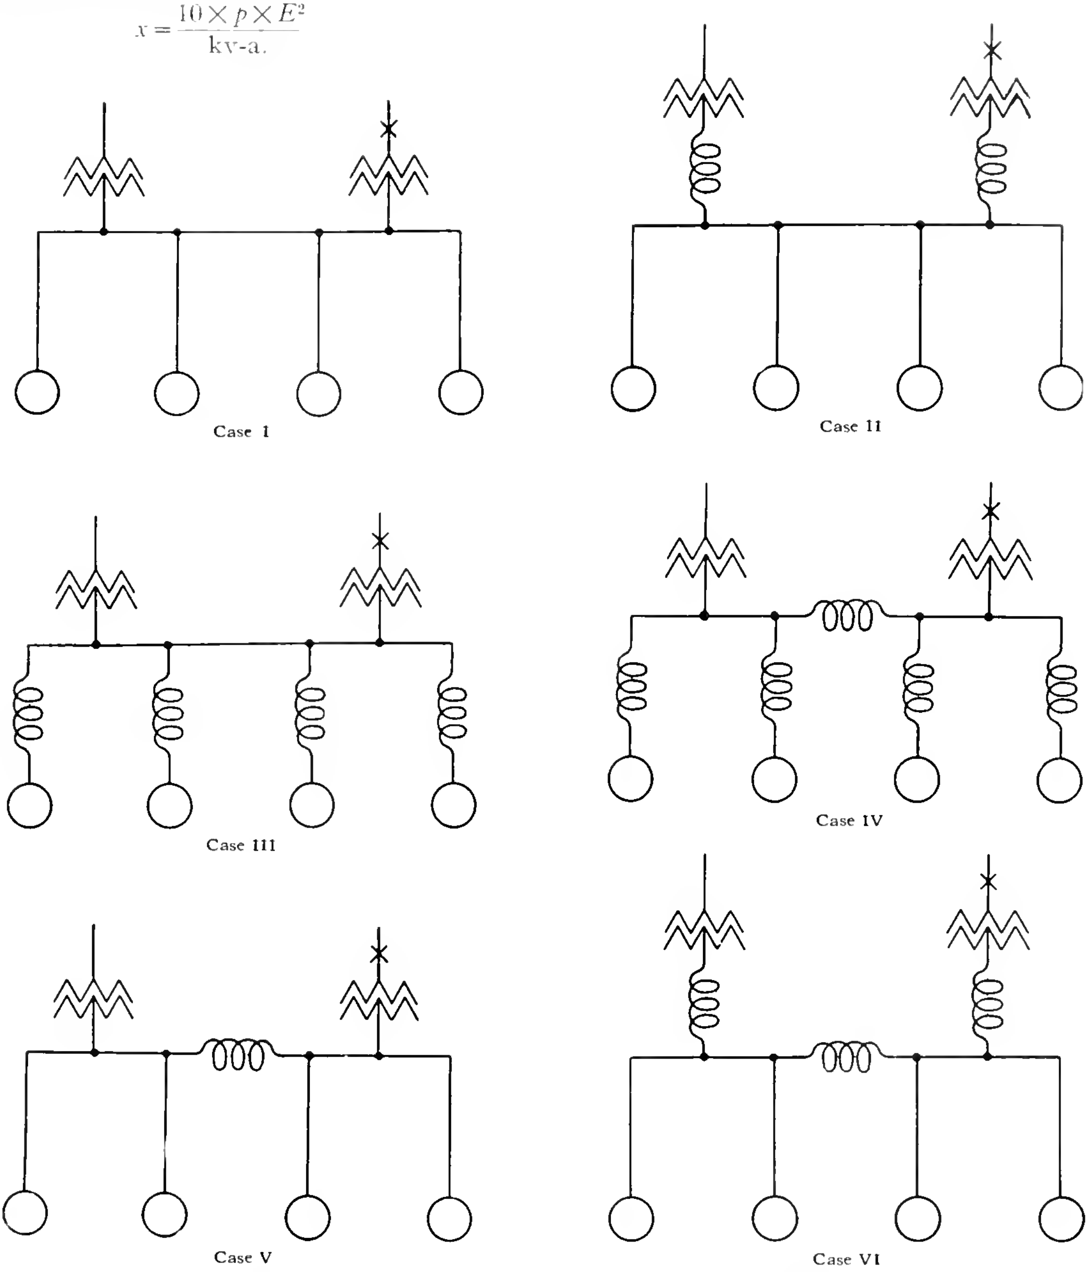
where

$x$ = single-phase reactance in ohms.
$p$ = reactance in per cent.
$E$ = voltage between phases in kilovolts.

Thus:

Reactance of generator

$$= \frac{10 \times 12 \times 11^2}{12{,}000} = 1.2 \text{ ohms.}$$



Case I

Case II

Case III

Case IV

Case V

Case VI

Fig. 2. Various Methods of Installing Power Limiting Reactances

Reactance of transformer bank

$$=\frac{10\times 4\times 11^2}{24{,}000}=0.2 \text{ ohms.}$$

Reactance of set of coils

$$=\frac{10\times 6\times 11^2}{12{,}000}=0.6 \text{ ohms.}$$

*Case 1.* No external reactances.

Reactance of four generators in parallel

$$=\frac{1}{4\div 1.2}=0.3 \text{ ohms.}$$

Total reactance of generators in series with one transformer bank $=0.3+0.2=0.5$ ohms.

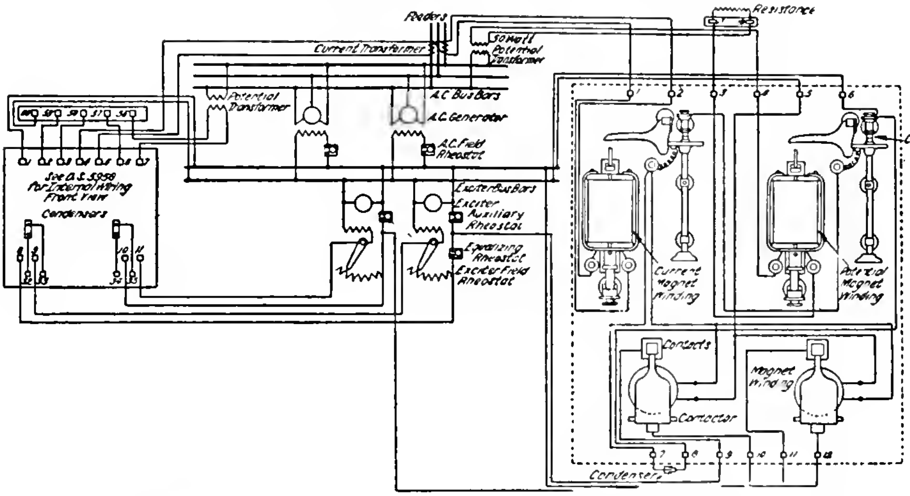


**Fig. 3. Connections of High Voltage, High Current Cutout Relay with Voltage Regulator and Two Exciters in Parallel**

$$\text{S.C.C.}=\frac{11{,}000^2}{0.5\times 1000}=242{,}000 \text{ kv-a.}$$ or approximately 20 times the full load of one generator.

*Case 2.* A 6 per cent reactance is inserted in all the generator leads.

Reactance of the parallel combinations of generators and coils

$=\frac{1}{4\div 1.8}=0.45$ ohms. Total reactance of this in series with one transformer bank $=0.45+0.2=0.65$ ohms.

$$\text{S.C.C.}=\frac{11{,}000^2}{0.65\times 1000}=186{,}000 \text{ kv-a.}$$

or approximately 15½ times one generator.

*Case 3.* The low-tension bus is sectionalized in two groups with a 6 per cent reactance.

Reactance of generators No. 1 and No. 2 in parallel $=\frac{1}{2\div 1.2}=0.6$ ohms.

This in series with the reactance coils

$$=0.6+0.6=1.2 \text{ ohms}$$

and this in multiple with the two parallel generators No. 3 and No. 4

$$=\frac{1}{\frac{1}{1.2}+\frac{2}{1.2}}=0.4 \text{ ohms.}$$

and finally this in series with the transformer bank $=0.4+0.2=0.6$ ohms.

$$\text{S.C.C.}=\frac{11{,}000^2}{0.6\times 1000}=200{,}000 \text{ kv-a.}$$

or approximately 17 times one generator.

*Case 4.* Six per cent reactances inserted in low-tension transformer leads.

Reactance of generators in parallel

$$=\frac{1}{4\div 1.2}=0.3 \text{ ohms.}$$

Total reactance of generators, coils and transformer bank (all in series)

$$=0.3+0.6+0.2=1.1$$

$$\text{S.C.C.}=\frac{11{,}000^2}{1.1\times 1000}=110{,}000 \text{ kv-a.}$$

or approximately 9 times one generator.

*Case 5.* Six per cent reactances in all generator leads and one bus sectionalizing reactance.

Reactance of generators No. 1 and No. 2 with coils $=\frac{1}{2\div 1.8}=0.9$ ohms.

In series with sectionalizing reactance

$$=0.9+0.6=1.5 \text{ ohms.}$$

In multiple with generators No. 3 and No. 4 and their coils

$$=\frac{1}{\frac{1}{1.5}+\frac{2}{1.8}}=0.56$$

and in series with the transformer bank

$$=0.56+0.2=0.76$$

$$\text{S.C.C.}=\frac{11{,}000^2}{0.76\times 1000}=160{,}000\text{ kv-a.}$$

or approximately 13 times one generator.

*Case 6.* Six per cent transformer and bus-section reactances.

Reactance of generators No. 1 and No. 2 in

$$\text{parallel}=\frac{1}{2\div 1.2}=0.6\text{ ohms.}$$

In series with bus-section reactance

$$=0.6+0.6=1.2$$

In parallel with generators No. 3 and No. 4

$$=\frac{1}{\frac{1}{1.2}+\frac{2}{1.2}}=0.4\text{ ohms.}$$

In series with transformer coils and transformer bank $=0.4+0.6+0.2=1.2$

$$\text{S.C.C.}=\frac{11{,}000^2}{1.2\times 1000}=100{,}000\text{ kv-a.}$$

or approximately 8½ times one generator.

## SUMMARY

Case 1—20 times full load of one generator.
Case 2—15½ times full load of one generator.
Case 3—17 times full load of one generator.
Case 4— 9 times full load of one generator.
Case 5—13 times full load of one generator.
Case 6— 8½ times full load of one generator.

The above illustrates clearly that reactance coils inserted in the transformer leads are very effective in reducing the short circuit currents when the fault occurs in the transformers or in the lines. Different values of reactances may be tried and the best combination found. The cost must, of course, be considered and it may be found that a less number of bus reactances may serve the purpose and be more economical. No rule can be laid down and each case must be solved for itself.*

With reactances in the generator leads, the current flowing in the armature winding is limited, and this method, therefore, affords an excellent protection for the generator itself. It necessarily also limits the current that can flow into any short circuit beyond the reactances, inasmuch as the amount of current which can flow is limited to that which the generators can supply. An objection to generator reactances is the fact that a short circuit on or near the busbars will cause a voltage drop on all the feeder circuits connected thereto.

With reactances inserted between the busbar sections, trouble is confined to the particular section on which the short circuit takes place. These reactances will permit a free exchange of current between the sections under normal operation, while under short circuit conditions they will limit the amount of current which would otherwise flow from the adjacent sections. If properly selected, a fault in one section may, therefore, be confined thereto without seriously affecting the nearby sections. Bus-section reactances afford, of course, no protection to the generators connected to the bus to which the faulty line is connected, but they give added protection to the generators on the other sections. As a rule, however, waterwheel-driven generators have a sufficiently high inherent reactance to withstand short circuits for short durations. Under normal operation the losses in bus sectionalizing reactances are negligible.

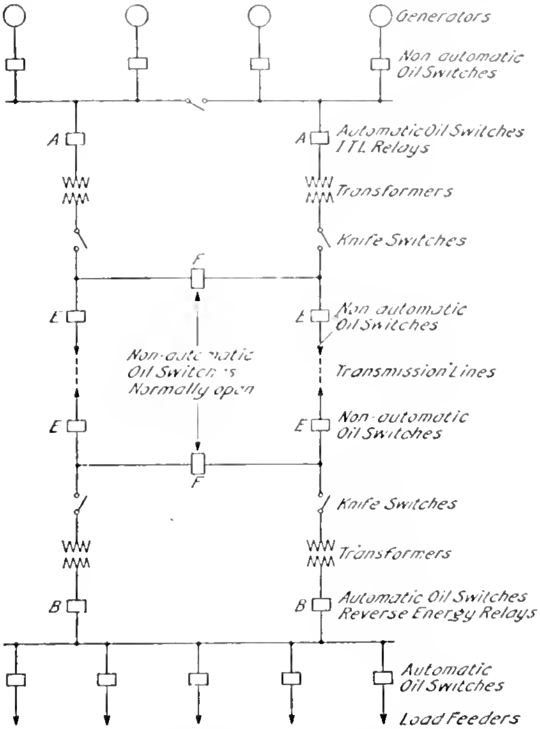

Fig. 4. An Arrangement for Paralleling High Tension Transformers on Low Tension Side. The Banks of Transformers are Equal in Capacity to that of the Line and may be Considered as Part of the Line

Reactance in the low-tension leads of the transformer banks is of considerable value for protecting against short circuits in the lines,

---

where they of course mostly take place. They are, however, not of value if the short-circuits should occur on the low-tension bus, or in the generators or their leads. There is also a constant loss of power in the reactance coils when they are inserted in the transformer leads, as is also the case when they are installed in the generator leads. For large systems, this may reach a considerable value, and must not be ignored when the selection of reactances is made.

Various schemes have been devised for limiting the disastrous effects of short circuits by automatically reducing the generator voltage at such instances and by preventing its rise when the short circuits are cleared. One such method employs a cutout relay in connection with an automatic voltage regulator. If a short circuit should occur somewhere on the system: for example, in the transmission lines, the action of the automatic regulator would naturally be to deliver the maximum excitation to the fields of the exciters and generators, so as to keep up the voltage of the system. This in turn necessitates that the waterwheel governors be wide open, and if the short circuit should be suddenly relieved, the voltage often rises considerably, owing to the time element involved in closing the governors and in demagnetizing the fields. If the voltage rises above a predetermined value, the relay will operate and open one or more contactors, which ordinarily short-circuits auxiliary resistances connected in series with the exciter field circuits. The insertion of these resistances will then result in a lowering of the voltage of the system.

Such cut-out relays may be used to protect a system against either ordinarily high currents or high voltages, and are, therefore, either provided with current or potential coils, Fig. 3. Sometimes two relays are used, one for high and the other for low voltage, the advantage of the low voltage feature being that it reduces the possibility of a sudden rise in voltage after the release of a short circuit. When a short circuit occurs, the voltage, of course, drops to a very low value, and by inserting resistance in the exciter field circuits, as before mentioned, it prevents the voltage from rising when the short circuit is released.

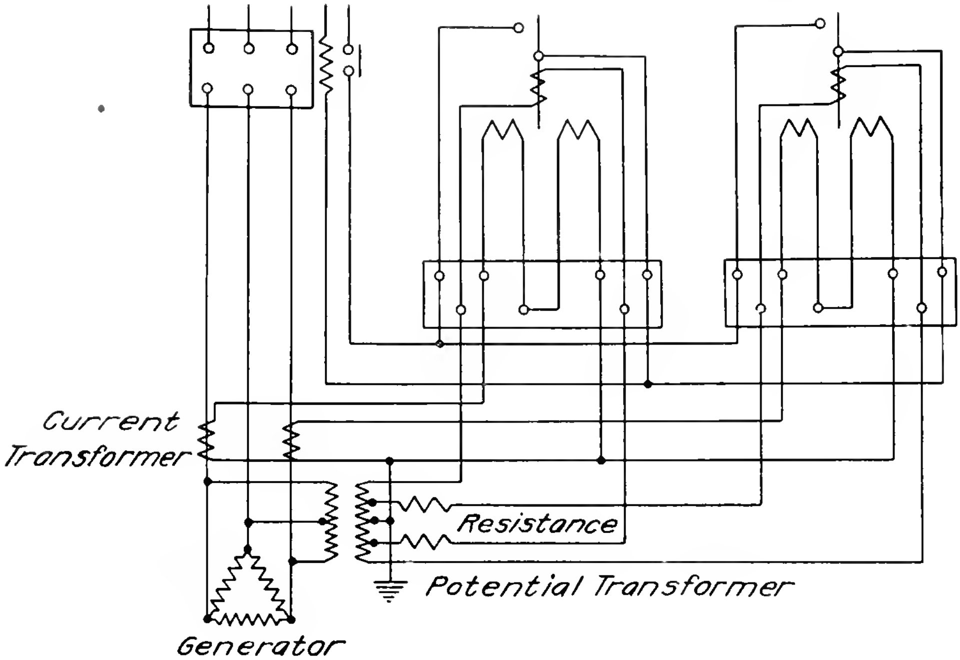

Fig. 5. Reverse Energy Relay

In one of the most recent hydro-electric systems such a relay is adjusted to operate on a 15 per cent rise in voltage and on a 50 per cent drop. Another large system, on the other hand, has an arrangement whereby on short circuits the automatic opening of the bus sectionalizing switches will cause resistance to be inserted in the field circuits of the exciters for the short circuited section, and reduce the voltage of this section to less than half of its normal value. In this manner a certain class of troubles, such as arcing ground, etc., may also be cleared due to lack of potential without even causing the synchronous machinery on the system to fall out of step.

The system of connections and the switching equipment has necessarily a most important bearing on the successful operation of a water-power system, and great care must be exercised in laying out the same. Switches with a safe rupturing capacity should be selected, and the connections and selective switch actions should be such that troubles may be confined to the smallest area possible.

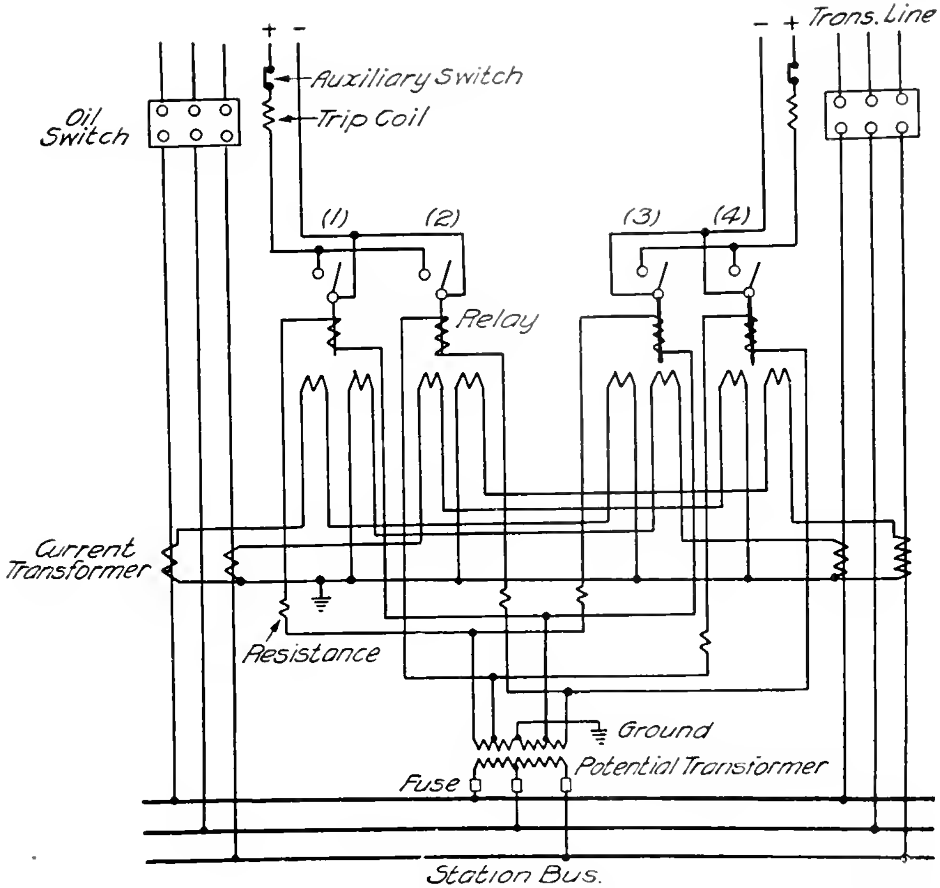

Fig. 6. Reserve Energy Relays, Double Pole, for Parallel Transmission Lines, with Power Flowing in Either Direction under Normal Conditions

Actual experience has demonstrated that high tension switching should be avoided as much as possible, and all disconnecting or sectionalizing under load should be done on the low tension side of the step-up or step-down transformers, so as to prevent any disastrous effects, such as transformer breakdowns, which may be caused by the surges set up by switching in the high tension circuit.

The diagram shown in Fig. 4 represents an up-to-date method of connections for a high tension transmission system.* The generators in each station are paralleled on a low tension bus, and where the total generator capacity is large, the bus should be sectionalized and reactances installed as previously mentioned.

It is preferable to make the generator switches non-automatic as it is of the utmost importance to keep the generators in service, and the possibility of trouble between the generators and the paralleling bus is rather remote. If it is desirable to provide automatic overload protection for the generator switches, they may be equipped with definite time limit relays with a high setting. Reverse energy relays are sometimes provided, Fig. 5, so that a damaged generator may be cut out on a

---

* For Circuit Connections in High-Voltage Systems, see General Electric Review, June, 1913.

reversal of the power in its leads, or the relay may simply be connected to an alarm bell.

It is the general practice to provide double transmission lines and if possible to so arrange the transformer banks that they form a unit with the lines, i.e., one bank or group of banks is provided for each line. These are not connected together on the high tension side, all paralleling and switching being done on the low tension side, both in the generating stations as well as in the substations. The high tension line switches are, therefore, of the non-automatic type and are only intended for sectionalizing purposes, the other sectionalizing switches being kept normally open.

The low tension transformer switches are made automatic, the switches in the generating stations being equipped with inverse or definite time limit relays and the substation switches with reverse energy relays, see Fig. 6, which will only operate on a reversal of power and not on overload. With this arrangement a perfectly selective protection is obtained. Should, for example, a short circuit take place in one of the transmission lines, this would cause a reversal of power in that section of the line nearest the substation, and its low tension transformer switch would immediately open and shortly thereafter the transformer switch in the generating station, thus cutting out the faulty line without affecting the other, which, of course, then would have to carry all the load. By means of the high tension line switches and the sectionalizing switches, the transformer banks can readily be disconnected from the damaged line and paralleled with the other transformer, so as to prevent these from being overloaded.

All the feeder switches should, of course, be provided with automatic switches, equipped with either inverse time limit or instantaneous overload relays with a setting such that any trouble in these circuits will be confined thereto.

# SYNCHRONOUS BOOSTERS IN TRANSMISSION LINES

By Lee Hagood

Lighting Department, General Electric Company

The author wrote a series of articles for the Review on the subject of voltage and power-factor control for moderate voltage systems which were published in our issues of October, November and December, 1912. He later wrote an extensive analysis of this subject for high-voltage systems which was published in the proceedings of the A.I.E.E., 1913. In the present article, he makes an analysis of the application of synchronous boosters to transmission lines. He has pointed out in particular that, when a synchronous booster is driven by a synchronous condenser, an ideal method is secured for deriving flexible voltage for a distribution point on a transmission system. Such voltage is independent of the system's voltage and yet does not involve the local synchronous machines in operating at undesirable power-factors, since the insertion of the booster effects a means of securing only such power-factors in the transmission line itself as is desired to meet the operating conditions.—Editor.

A synchronous booster is simply a synchronous generator in design, and is employed on electric power circuits for controlling voltage. It is intended for series operation in a circuit and hence must be driven synchronously. Synchronous motors offer a convenient method of drive, the booster being arranged on the same shaft so as to secure proper phase relation for the booster voltage. By controlling the field of the booster, any desired degree of bucking or boosting of the circuit voltage may be obtained.

In action, a synchronous booster is quite similar to a feeder voltage regulator. Feeder voltage regulators are designed essentially for feeder circuits; but in some instances are used in small transmission line circuits and in tie-line circuits. In very large sizes, however, feeder voltage regulators become expensive relatively, especially for the higher voltages, such as 11,000 and 13,200.

It is for use in tie-line circuits and in transmission line circuits that the synchronous booster has been developed. It can be built in any size and for any voltage standard for generators. The actual cost per kilovolt-ampere is substantially the same as that of synchronous generators. Quite an advantage accrues from the use of synchronous boosters in that they can be operated in parallel with the same facility as is afforded by two synchronous generators. Another advantage that arises from the use of boosters for large power circuits is that they may be driven by synchronous condensers and thus combine the advantages of the booster for voltage compensation and of the synchronous condenser for power-factor correction.

In view of the fact that a booster must be driven by a synchronous motor, the inherent losses are considerably greater than that of a feeder regulator. For a given amount of power transmitted, the feeder regulator would have losses in the magnitude of two-tenths of one per cent of this power, whereas the synchronous booster with its synchronous motor would have inherent losses between 10 and 15 times this amount. When the booster is driven by a synchronous condenser, however, the improved power-factor will frequently effect a reduction in generator, line and transformer losses more than sufficient to offset the losses of the booster set.

The excitation of a booster may be either automatic or non-automatic. When driven by a large synchronous condenser it is better, in general, to control the excitation of the synchronous booster non-automatically, and that of the synchronous condenser automatically. This arrangement offers a very flexible method of voltage and power-factor control under very adverse line and load conditions.

Fig. 1 illustrates a general case of a synchronous booster driven by a synchronous condenser. It will be assumed that the synchronous condenser is controlled by a voltage regulator, that the booster field is hand-controlled by means of a double-dial rheostat, and that the excitation of the main generator is also controlled by a voltage regulator.

Fig. 2 illustrates the phase relations between the receiver voltage and the current in the line, synchronous condenser and load. For the sake of simplicity, the assumption will be made that the voltage difference between the receiving and generating stations is constant. Let $E_G$ be the generator voltage, $E_R$ the receiver voltage, and $E_B$ the booster voltage. The load current, $I_L$, and its power-factor ($\cos \theta_L$), are fixed by the load conditions. Evidently the line drop for any given load condition will depend upon the power-factor ($\cos \theta$) of the line. Since the voltages $E_G$ and $E_R$ are maintained constant by means of the voltage regulators in each station, the line drop can be varied at will by changing the value of $E_B$. This must involve changes in the line power-factor ($\cos \theta$), since to change the line drop for a given kilowatt load, the line power-factor must be changed. Whatever is done to the line power-factor by means of the synchronous condenser whenever $E_B$ is changed is done automatically due to the voltage regulator. Thus, within the limits of its automatic excitation the kilovolt-ampere load on a synchronous condenser may be changed at will by changing the excitation of the booster.

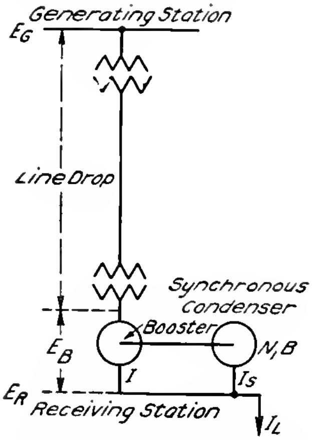

Fig. 1. One-line Diagram illustrating an application of a synchronous booster driven by a synchronous condenser

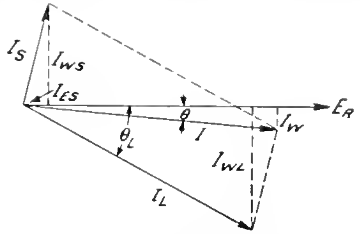

Fig. 2. Vector Relations of the load, synchronous condenser and line currents for the arrangement shown in Fig. 1

The wattless kilovolt-amperes available for power-factor correction from a synchronous condenser driving a booster is slightly reduced below the kilovolt-ampere rating of the synchronous condenser, since a "pump-back" occurs between it and the booster, the booster effecting the equivalent of a mechanical load. The exact value of this load depends upon the booster voltage $E_B$. Since the booster is arranged on the shaft of the synchronous motor so that its generated e.m.f. at full load will be approximately in phase with that of the receiver voltage, the incoming and outgoing currents of the booster may be considered approximately equal and in phase. The leakage reactance of the booster itself is relatively small as compared with the circuit reactance, and for the requirements of this problem may be neglected. In Fig. 2, $I_{ES}$ and $I_{WS}$ are respectively the energy and wattless components of the condenser current, $I_S$; the energy component depending upon the condenser and booster losses and the booster voltage, $E_B$. The line current, $I$, is necessarily the vector sum of $I_S$ and $I_L$. Since the kilovolt-ampere capacity of the booster is usually below one-half that of the synchronous condenser, its effect on the corrective kilovolt-ampere available from the synchronous condenser is quite small.

To illustrate the importance of the advantages which may accrue from the application to a transmission system of a synchronous booster driven by a synchronous condenser, a definite set of operating conditions will be taken. Although the booster set is essentially applicable to systems of moderate sizes, a case will be chosen which involves a large system interconnected with other systems. It will be seen that the principles illustrated are general ones.

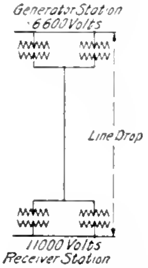

Fig. 3. One-line Diagram of a 110,000-volt, 90-mile transmission line with 4 0 conductors spaced 10 feet vertically

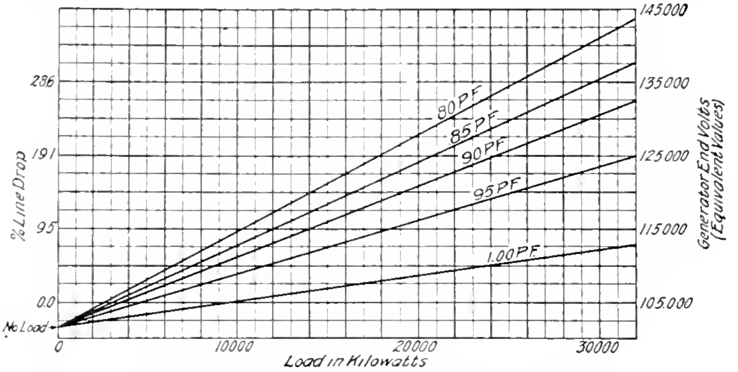

Fig. 4. Relation of Generator Voltage to Receiver Voltage for the line illustrated in Fig. 3. Equivalent values of voltage are used and it is assumed that the receiver voltage is 105,000 and that the power-factors given occur at the receiver end of the line

Fig. 3 illustrates a 110,000-volt, three-phase, 60-cycle transmission line. The generating station is a 60,000 kw. hydro-electric plant, and the receiving station supplies a large city. The transmission line is 90 miles long and consists of two circuits of 4 0 copper spaced 10 ft. in a vertical plane. The transformer banks, in both the receiving and generating stations are 10,000 kilovolt-amperes each. For the sake of simplicity, only one transmission line circuit is shown and the calculations are worked out with the transformer constants included with those of the line. Including the transformer constants with those of the line introduces a slight error, but this, after all, is below the precision required by practical requirements.

Fig. 4 shows a set of curves giving the voltage drops between the receiving and generating stations for different loads and power-factors, under the assumption that the equivalent receiver voltage is maintained constant at 105,000 volts.

When designing a new transmission line or transmission system, or in the operation thereof, the question of suitable line voltage regulation must be carefully considered. This regulation must be within such limits that both proper service and safety to the connected apparatus is secured.

From Fig. 4 the regulation of the transmission line in question may be obtained under various conditions of power-factor and load. For example, if 20,000 kw. were delivered to the receiving station at 0.80 power-factor and at an equivalent voltage of 105,000, the voltage drop would be about 22 per cent; and at no load, to establish the same receiver voltage, the generator voltage must be operated at a value of 4 per cent lower than that of the receiver voltage, thus making a total variation in voltage of the generating station of 26 per cent (in terms of the receiver voltage); in other words, the generating station must operate at a regulation of about 27 per cent. Such a regulation is, of course, out of the question for either satisfactory service or safety to the connected apparatus.

Lightning arresters are designed to relieve a system of transient voltages, such as those set up by lightning, arcing grounds, switching, etc. They offer protection to a system only when the dynamic voltage has a value near that at which the lightning arrester has been charged. If a lightning arrester is called upon to relieve a system of a transient, and the dynamic voltage is much above normal, the arrester is in danger of destruction. Just what margin is allowable is uncertain; however, a safe basis on which to operate would be to figure that the dynamic voltage should never exceed say 15 per cent above that at which it is necessary to charge the arrester. Another important reason for good voltage regulation on a transmission line is the question of the proper exciting voltage for the transformers. If the voltage impressed on the transformer is carried above normal, the core losses and exciting currents begin to increase rapidly and thus excessive heating may be experienced due to the over-voltage, although the kilovolt-ampere load is normal.

Taking all things into consideration, a transmission line should be operated at a voltage regulation less than 15 per cent at the points at which transformers and lightning arresters are located.

Figs. 5, 6, 7 and 8 illustrate the application of synchronous boosters driven by synchronous condensers. The transmission line is the same as that considered in Figs. 3 and 4.

Fig. 5 shows the arrangement of the booster sets. Fig. 6 illustrates the effect of wattless lagging kilovolt-ampere on the line drop, when applied at the receiver end of the line, on the assumption that the receiver voltage is maintained constant and the energy load is zero. Fig. 7 is *derived from Figs. 4 and 6.

The curves of Fig. 7 are based on the following assumptions, viz : the load at the receiving station is supplied at 0.85 power-factor and at an equivalent voltage of 105,000; a voltage regulator is used at both the generating and receiving stations; the relative voltage settings are such as to give a total voltage drop of 6.2 per cent; the excitation of the synchronous booster is hand-controlled by means of a double-dial rheostat; and the transformers are connected approximately for 6600 to 110,000 volts in the generating station, and 103,000 to 11,000 volts in the receiving station. Since the booster can add or subtract voltage and thus change the voltage drop of the transmission line, and since the total drop is assumed constant (being controlled in the two stations by voltage regulators), the booster offers a means of controlling the relative amounts of wattless kilovolt-amperes supplied by them.

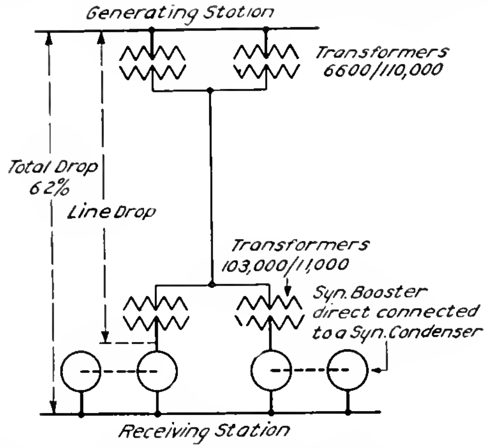

Fig. 5. Illustration of the Application of synchronous booster driven by synchronous condensers for the line given in Fig. 3

The different curves in Fig. 7 show the wattless kilovolt-amperes required from the receiving station for different field settings of the synchronous booster. For convenience, these wattless kilovolt-amperes, which are assumed under automatic control, will be referred to as synchronous condenser kilovolt-amperes. It can, of course, be supplied from any synchronous machine. When an exciter for a synchronous condenser is directly controlled by a voltage regulator, the limits of automatic excitation allow a supply of wattless kilovolt-amperes from about 25 per cent of full kilovolt-ampere lagging to about full kilovolt-ampere leading. By using an auxiliary exciter controlled by a voltage regulator to excite the synchronous condenser exciter, the synchronous condenser excitation may be controlled automatically for a range from full lagging wattless kilovolt-amperes to full leading wattless kilovolt-amperes. If the synchronous booster is set for a buck of 6.2 per cent, then the curve *abc* indicates the synchronous condenser kilovolt-amperes necessary for different amounts of power. Under this condition the line drop is maintained constant at 0 per cent, since it has been assumed that the total drop between the low tension busses of the two stations will be 6.2 per cent. If the booster is set for 1.6 per cent buck, the line drop will be 4.6 per cent, and the synchronous condenser curve

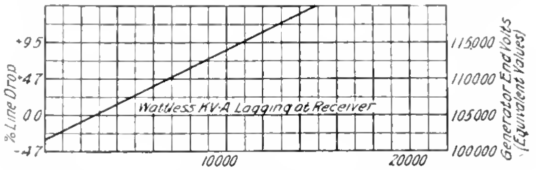

Fig. 6. Relation of Generator to Receiver Voltage for different amounts of wattless lagging kilovolt-amperes at the receiver. It is assumed that the equivalent receiver voltage is 105,000 and the kilowatts zero

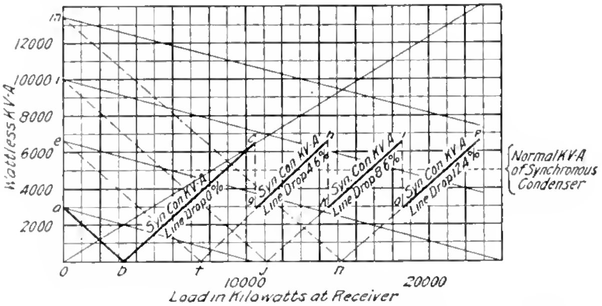

Fig. 7. Wattless Kv-a. Required from the Synchronous Condenser in Fig. 5 for different kilowatt loads at different line drops. It is assumed that the synchronous condenser is controlled by a voltage regulator and that the load is supplied at 0.85 p-f. and at an equivalent voltage of 105,000

---

* The method for determining these curves, etc., is given in the author's article in the Proceedings of the American Institute of Electrical Engineers for 1913, pages 2163 to 2189, entitled "Operation of Transmission Lines."

will be *efgh*; if the booster is set for 2.4 per cent boost, the line drop will be 8.6 per cent, and the synchronous condenser curve will be *ijkl*; and finally, if the booster is set for 6.2 per cent boost, the line drop will be 12.4 per cent, and the synchronous condenser curve will be *mnop*. By using these five settings of the booster, the synchronous condenser kilovolt-ampere can be made to follow the curve *abcghklop* for a load at 0.85 power-factor between 0 and 23,000 kw. In actual practice, the station operator would adjust the boosters in such a manner from time to time as to load the synchronous machines under automatic voltage control in accordance with the most favorable conditions to them, and yet secure the desired power-factor correction for the transmission line itself. The synchronous machines under automatic voltage control may be either the synchronous condensers driving the boosters, or other synchronous machines such as generators or motors, or both. If the synchronous condensers driving the boosters are large enough, it will often work out satisfactorily to have them under automatic control and to excite all the other nearby synchronous machines non-automatically.

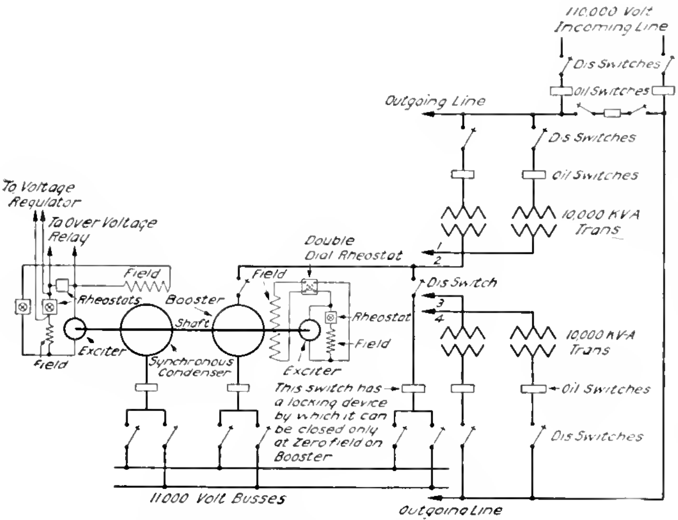

Fig. 8. One line Diagram of an installation where a synchronous booster driven by a synchronous condenser is located in each transformer circuit

In the case illustrated, it has been assumed for simplicity, that the total voltage drop is maintained constant. In actual operation the low tension bus voltages at either generating or receiving station may be maintained at such values as is consistent with the best results. In general, it seems desirable when supplying a lot of feeders from a given bus that means be provided for raising the bus voltage as the load increases, and thus meet the general voltage requirements of the distribution system. This can be done by devices used in connection with the voltage regulator, the simplest being a rheostat located in the circuit of the regulator's potential transformer. The addition of the booster in the circuit allows these voltage changes, since the necessary compensation can be made with it, so as to secure at all times such power-factor conditions as meet the requirements. As has already been stated, the booster makes it possible to control at all times the wattless kilovolt-amperes from the synchronous machines under automatic control. The amount of wattless kilovolt-amperes supplied, however, should always be sufficient to keep the regulation of the transmission line within about 15 per cent.

Fig. 8 illustrates in detail the electrical equipment involved. The two incoming lines are from the 60,000 kw. hydro-electric station, and the two outgoing lines supply a large territory, and at the same time form an interconnection with two or three other large systems. The receiving station itself distributes electric power to a large city. This power is distributed at 11,000 volts to several stations scattered through the city, some of these being generating stations and some substations. The various feeders supplying them may be sectionalized or paralleled, either on the main busses or at the various stations and substations, depending upon the operating requirements.

Only one booster set is shown. A duplicate of this equipment is necessary for each transformer circuit. In the drawing it will be noted that a switch is shown for taking the booster out of circuit. Such an arrangement is considered necessary because of the possibility of accident to the booster set. Although such a thing is very remote, at the same time, continuity of service is of great importance and the extra expense seems warranted. The synchronous condenser field, in addition to being controlled by a voltage regulator, is equipped with a resistance controlled by an over-voltage relay. The voltage regulator will take care of all normal tendencies towards changes in voltage, the over-voltage device being for the purpose of protection from abnormal conditions, such as those which would tend to occur should the load be dropped suddenly. In such an event, the synchronous condenser would automatically be brought to a very weak field and the voltage thereby reduced to a safe value. If a synchronous generator, under say, full load and normal excitation, is supplying a transmission system and the load is suddenly dropped, leaving the machine supplying only the empty transmission line, the voltage can build up excessively. This is owing to the capacity effect of high voltage transmission lines. In a certain case with which the writer is familiar, the measured value of this voltage at the generating station was practically double that of normal. At the receiving end of the transmission line the voltage was, of course, considerable greater. The exact maximum value which might occur for a given transmission line would depend upon the normal voltage of the transmission line, the length, spacing and diameter of the conductors, and the degree of excitation of the synchronous machine at the time of the drop in load. Therefore, to protect a system, from over-voltages, due to a sudden dropping of load, all of the large synchronous machines should be equipped with over-voltage devices. It is a particular protection to have some of these synchronous machines located at the receiving end of the transmission line.

Summarizing, the advantages of the installation of a synchronous booster equipment, as described previously, are as follows:

First: The receiving station is enabled to supply power for distribution at such voltages as the distribution system demands, and yet only supply such wattless current to the transmission line as is consistent with the design of the connected synchronous machines and necessary to keep the transmission line within the limits of safe voltage regulation. An incidental advantage of having a booster in each transformer circuit is that when the transformers are paralleled the division of current can be definitely controlled by relatively exciting the boosters. Some value of this application may apply where the impedance in the circuits are unequal, due to the length of the various feeder circuits before paralleling them.

Second: The generating station is also enabled to operate at such voltages as will afford the best service, independent of the transmission line regulation.

Third: The regulation of the transmission line can be controlled within such limits that safety is secured for the connected apparatus.

Fourth: The power-factor of the transmission line may be regulated within such limits as to secure favorable voltages for other receiving stations on the system.

Fifth: The equipment involved is comparatively cheap and simple to operate, and the energy losses inherent to its operation in most instances will be more than offset by the improved power-factor conditions. The operation of the equipment is exceedingly simple in that the station instruments, etc., give the operator complete information as to the conditions established. As stated the excitation of the synchronous condenser is automatic over a large range, hence the amount of attention required by the complete equipment is comparatively small, and necessary only during periods when considerable changes in load are occurring.

# SOME INTERESTING APPLICATIONS OF THE COOLIDGE X-RAY TUBE

By Dr. Wheeler P. Davey

Research Laboratory, General Electric Company, Schenectady

This article is of particular interest when read in connection with our editorial this month. The physical properties of the Coolidge tube make it useful to the physicist, physician, botanist and biologist alike. The collection of radiographs that accompany this short article show in a striking manner the capabilities of the tube.—Editor.

There have lately been published many very interesting radiographs of flowers, leaves and insects. Typical instances are shown by Pierre Goby, Hall-Edwards and others. These men have found it desirable in such work to use tubes in which the vacuum was widely different from that employed in ordinary radiographic work. For instance, in referring to a splendid radiograph of tulip blossoms, Hall-Edwards (Archives of the Roentgen Ray, June, 1914), who is using tubes of the ordinary type (in this case a "Muller" with a Bauer regulator) notes that "it is rather dangerous to use new tubes for this purpose (although the best results can undoubtedly be obtained by them), for the reason that it is very easy to pass the boundary line and get a vacuum so low that it cannot be raised without re-exhausting the tube." Such difficulties, though they have not prevented securing beautiful radiographs have doubtless kept this method of internal and structural photography from advancing as rapidly as it might otherwise have done.

The Coolidge X-Ray Tube (see Physical Review, December, 1913, or General Electric Review, February, 1914), has proved itself to be an efficient tool in the hand of the medical profession, and it occurred to the writer that it would prove equally valuable to botanists and biologists in connection with the study of plant and animal life.

The main advantages in the use of the Coolidge tube are (1) the independence of the *quantity* and the *penetrating ability* of the rays produced, (2) the ease and rapidity with which the *quantity* and penetration of the rays may be regulated, and (3) the fact that when the tube is once adjusted to the requirements of the operator it needs no further attention. To bring the tube to any desired adjustment, the operator pulls a handle which regulates the current through the tube, thus determining definitely the quantity of X-rays produced. He then adjusts the voltage across the tube until the penetration is of the desired degree. These adjustments are rapid and require the minimum of technical skill.

To illustrate this, the writer took a tube at random (it happened to be No. 280) from the rack and took a number of radiographs of various botanical specimens. It was at once found that, when the proper penetration and exposure had been determined, the radiographs could be duplicated time after time with absolute precision. Then biological specimens were tried, and finally radiographs were taken of dense objects, such as fuse plugs and Ingersoll watches. As in the case of the botanical specimens, all of these radiographs could be accurately reproduced as often as desired.

About this time tube No. 280 was accidentally broken. Another tube (No. 297) was picked at random from the rack and much of the former work was repeated with it. There was no difference noticeable between the two sets of pictures.

It was the original intention to publish only those radiographs taken with tube No. 280, but it was later decided to add such of those taken with No. 297 as seemed to be of peculiar interest. The radiographs reproduced here were not chosen from the total number taken because of any novelty or excellence in the pictures themselves, but rather because they show what a wide range of work can be done with a *single* Coolidge tube, and because they suggest that the Coolidge tube is destined to become a precision-instrument of value to the botanist, biologist and mineralogist as well as to the physicist and the physician.

None of the pictures shown here have been re-touched or altered in any way.

# PATENTS

## PART III

By Chas. L. Clarke

Consulting Engineering Department, General Electric Company

Parts I and II of this article, which appeared respectively in the May and July numbers of the Review, considered the foundation of the patent monopoly in this country, the general laws on patents now in force, the legal meaning of the terms "discovery" and "laws of nature" or "principles," and the things that are proper subjects of patents; also the distinction between patentable invention and mere exercise of mechanical skill including the rules of law, as formulated through the decisions of the courts, in accordance with which a decision is made as to whether the production of a thing required invention. In this issue is presented a bird's-eye view of the salient features of the rules that must be followed in prosecuting an application for a patent, with a statement of certain precautions that must be observed to insure a valid patent, coupled with abundant caution to the inventor not to prosecute his application himself, but to entrust it to a competent attorney. The article concludes with a consideration of the subject of inventing and patenting from the practical standpoint of business common sense.—Editor.

### NOVELTY AND UTILITY

#### Inventions or Discoveries

According to Section 4886 of the Revised Statutes,* as amended March 3, 1897, in order for a thing to be patentable it must, besides requiring invention, be "new and useful." It may be intrinsically new, or a new improvement of an old thing by which the same result is more easily obtained, or a better result secured. But for a thing to be new for patentability, it need not be actually new in the dictionary sense, for it may not have such newness and still be patentable under certain circumstances. The term "novelty" is commonly used by the legal profession to designate patentable newness.

An invention, to have patentability, must also be useful, or have "utility," as termed by the legal profession, substantially in the sense that it accomplishes the purpose intended, and is not obnoxious to law and good morals.

An invention is new for patentable purposes, if not known or used by others in this country and not patented or described in any printed publication in this or any foreign country before the invention was made by the person filing an application for a patent therefor in this country, or more than two years prior to such application, and not in public use or on sale in this country for more than two years prior to the application.

An invention is also new for patentable purposes, although it may previously have been known and used by others in a foreign country, if it was not patented or described in any printed publication in this or any foreign country before the invention was made by the person filing application for a patent therefor in this country.

An invention is also new for patentable purposes, although the inventor may have first patented it in a foreign country, if application for a patent in this country is made *not later than twelve months* after the application for the foreign patent was filed.

#### Designs

According to Section 4929 of the Revised Statutes, as amended May 9, 1902,* in order for a design to be patentable it must, besides requiring invention, be "new, original, and ornamental." It must be new, or possess novelty, in the same sense that things invented or discovered have patentable newness, as previously explained. It must be original, probably in the sense that it must have originated with the only person that can in law be said to have invented it—the term original in the statute seems redundant.

A design, to have patentability, must, besides being new and original, also be "ornamental." But it does not appear from Section 4929 that patentable designs must possess utility, as is specifically required in the case of inventions or discoveries, except so far as it may perhaps be inferred that ornamentation in a design embodies a certain although rather academic utilitarian value.

A design is new for patentable purposes, if not known or used by others in this country and not patented or described in any printed publication in this or any foreign country before it was invented by the person filing application for a patent therefor in this country, or more than two years prior to such application, and not in public use or on sale in this country for more than two years prior to the application.

A design is also new for patentable purposes, although it may previously have been

---

* See Part I, May number of the General Electric Review, page 445.

* See Part I, May number of the General Electric Review, page 446.

known and used by others in a foreign country, if it was not patented or described in any printed publication in this or any foreign country before it was invented by the person making application for a patent therefor in this country.

A design is also new for patentable purposes, although the inventor may have first patented it in a foreign country, if application for a patent in this country is made *not later than four months* after the application for the foreign patent was filed.

### INDEPENDENT AND JOINT INVENTORS

If an invention is made by the exercise of the inventive faculties of one man, he is an "independent inventor," but if a thing is really invented by two or more men, they are "joint inventors." They may have required the help of skilled artizans, mechanics or chemists, to assemble the apparatus, or machinery for working an invented process, or to construct an invented machine for producing a given result, or to turn out an invented article of manufacture in a desirable form, or to handle and bring together the materials forming an invented composition of matter, or perhaps an artist to whip an invented design into shape, but the skilled persons employed to do these things do not thereby participate in making the invention. *If one man does all the inventing and another does all the constructing, the first is the sole inventor.* (*Walker.*)

It sometimes happens, for example, in research work, that a physicist or chemist conceives a certain novel sequence of operations upon a material, or materials, perhaps including applications of electricity, heat, or pressure under delicate and accurately adjusted conditions, and wishes to know the result. He explains his conception to an assistant and instructs him to put the process to test. The investigation may require weeks and months of patient endeavor to bring it to a conclusion, although nothing more than carefully applied skill was called for. Under such circumstances, if the process called for invention, it would reside in the original conception of the sequence of operations by the chief, and not in the laborious work of the assistant. Generous disposition on the part of the chief to promote the welfare of a faithful and able assistant conveys no authority to resign the merit of invention to the latter; the patent must in law go to the real inventor. But should the assistant in his investigation find known apparatus, or machinery, inapplicable for working the process, and invent suitable means therefor, a patent for the apparatus, although not for the process, should be taken out on his application. It is not always easy when several persons have to do with an invention, and the putting of it into practical shape, or its reduction to practice, so-called, to determine whether one of them is the sole inventor, or some of them be joint inventors; all the facts in each case must be taken into consideration to determine the question.

Joint inventors are entitled to a joint patent issued to all of them, but no one of them may alone obtain a patent for a joint invention. And independent inventors of distinct and independent improvements in the same machine may not obtain a joint patent for their several inventions.

The fact that one man furnishes the capital and another makes the invention does not entitle them to a joint patent.

It is not invention on the part of one man to perceive the benefit of a result, if accomplished, and then employ another to devise means to produce that result; if an invention has been made in arriving at the means, it has been made by the person devising the same.

### ABANDONMENT

In general, a person may abandon an unsuccessful effort to make an invention; or, having made an invention, he may abandon it in the sense of not obtaining a patent, thereby in law giving the invention to the public, or he may openly dedicate it to the public; or having made an invention and having applied for a patent, he may under certain circumstances abandon that particular application, by not pursuing it, without abandoning the invention, the obtaining of which may be pursued by a new application. Abandonment may not only result from his own desire, but also from neglect on his part to take proper steps to make and prosecute application for a patent within the times and with the diligence prescribed by law; or by his publicly using, or selling, or permitting others so to use or sell the invention in this country for more than two years prior to his application., and in various other ways.

### LIFE OF PATENTS

Patents for inventions or discoveries in arts, machines, manufactures, or composition of matter, and improvements thereof, are granted for a term of seventeen years.

Patents for designs are granted for three and one-half, or seven, or fourteen years, at the option of the applicant; if granted for one of the shorter terms, the patent cannot afterwards be extended by the Patent Office to a longer term. The life of a patent cannot be extended beyond the term for which it was originally granted except by special act of Congress.*

## APPLICATIONS FOR PATENTS

### Preamble

The prosecuting of applications for patents is signally a business by itself, properly demanding the services of an expert attorney, if the inventor is to feel reasonably assured of obtaining a safe, and as comprehensive or broad a patent as is permissible. An inventor should unless circumstances have given him special training in that line, no more think of prosecuting applications for patents for his own inventions, than of undertaking to conduct a law suit on his own account. We have heard that "the man, who is his own lawyer, has a fool for a client," which experience has shown still holds good, even should the man happen to be a lawyer And we raise the question whether even a patent attorney may not be in the same category, if he undertakes to prosecute the application for a patent for an invention of his own; and whether he had not better eliminate such risk of inefficiency, as may come from doubts and fears over such a personal matter, by letting a brother attorney do the work for him.

The official *Rules of Practice in the United States Patent Office* contain the following pertinent suggestion: "An applicant or an assignee of the entire interest may prosecute his own case, but he is advised, unless familiar with such matters, to employ a competent attorney, as the value of patents depends largely upon the skillful preparation of the specification and claims."

### Application

The application must be made to the Commissioner of Patents.

### Signature

The application must be signed by the inventor, if alive and otherwise lawfully competent so to do.

### Filing

An application will not be placed on the files for examination until all its parts (except the model or specimen, which is seldom required) are received, which must be done within one year after the receipt of the first paper—the petition.

### Abandonment

An application will be regarded as abandoned if all its parts are not received within one year after the receipt of the petition, or upon failure of the applicant to prosecute the same within one year after any action of the Patent Office thereon, unless the delay was unavoidable.

### Petition

The petition requesting the grant of a patent must be addressed to the Commissioner of Patents, state the name, the residence, and the post office address of the petitioner, designate by title the invention sought to be patented, contain a reference to the specification for a full disclosure of such invention, and must be signed by the applicant.

### Specification

The specification is a written description of the invention or discovery, and of the manner or process of making, constructing, compounding, and using the same, and is required to be in such full, clear, concise, and exact terms as to enable any person skilled in the art to which the invention or discovery appertains, or with which it is most nearly connected, to make, construct, compound, and use the same. The principle of the invention, and the best mode of applying it known to the inventor must be given. If the invention is a mere improvement, what is new must be distinguished from what is old.

### Claims

The specification must conclude with a specific claim or claims of the part, improvement, or combination which the applicant regards as his invention or discovery. It is of vital importance that the real invention be expressed in the claims, stripped of all unessential details relating to the particular form in which the inventor may have embodied his invention, as described in the specication. It is in the drafting of proper claims that the service of an experienced attorney is especially advisable. The less a claim says, yet truly expressing the invention, the broader

---

* The last patent extended by Congress was No. 55,469, June 12, 1866, to Henrietta H. Cole for a fluting machine; reissued. April 25, 1871, No. 4,349. It was extended for seven years from June 12, 1883 (the date of expiration of the original patent) by act of Congress, approved Aug. 4, 1886; and the certificate of extension was issued Aug. 9, 1887; *Official Gazette of the United States Patent Office*, Vol. XL, page 814.

is its scope, and the greater is the monopoly sought.

By rule of the Patent Office, *independent inventions* (for example, one invention in steam engines and another in electric generators, the operation of one of which is not necessarily connected with the operation of the other, and thus one of the inventions may be used independently of the other), cannot be claimed in the same application; but where there are several distinct, although *dependent inventions*, (for instance, in an electric generator, one invention for an arrangement of armature coils, and another for a core construction adapted for receiving such coils) which mutually contribute to produce a single result, they may be claimed in one application.

In fact, each claim of an application, or of a patent, must represent a separate invention to be valid.

But should a single patent be granted for two or more unrelated inventions, it might be held, for that reason, to be invalid, though *no patent has ever yet been held void for containing more than one invention.* On the other hand, two or more patents for related inventions that are embodied in one extensive machine may lawfully be granted. (Walker)

### Oath

The inventor must make oath or affirmation that he believes himself to be the original and first inventor or discoverer of the art (process), machine, manufacture, composition or improvement therein, for which he solicits a patent; that he does not know and does not believe the same was ever before known or used; and must state of what country he is a citizen and where he resides, and whether he is the sole or the joint inventor of the invention in his application, as expressed in the claims thereof. He must state under oath that the invention has not been patented to himself, or to others with his knowledge or consent, in this or any foreign country for more than two years prior to his application, or on his application for a patent filed in any foreign country by himself or his legal representatives or assigns, more than twelve months(four months in the case of application for a design patent) prior to his application in this country.

If application for a patent has been filed in any foreign country by the applicant in this country, or by his legal representatives or assigns, prior to his application in this country, he must state the country or countries in which such application has been filed giving the date of such application, and must also state that no application has been filed in any country or countries other than those mentioned, and if no application for a patent has been filed in any foreign country, he must so state; also that to the best of his knowledge and belief the invention has not been in public use or on sale in the United States, or described in any printed publication or patent in this or any foreign country, for more than two years prior to his application in this country. If the inventor is not living or is not otherwise lawfully competent to make oath, say, if insane at the time application is made, corresponding changes are to be made in the oath.

### Drawings

The applicant for a patent is required to furnish a drawing of his invention whenever the nature of the case permits it.

### Models

A model will only be required or admitted as a part of the application when, on examination of the case, the primary examiner in the Patent Office shall find it to be necessary or useful.

### Issue

The final fee for the grant of a patent must be paid not later than six months from the time notice of allowance of the application was sent to the applicant, and the patent must be issued within three months thereafter.

### Re-Issue of Patents

Whenever a patent is inoperative or invalid, by reason of a defective or insufficient specification, or by claiming more than the inventor had a right to claim, provided the error arose through inadvertance, accident, or mistake and without evil intent, the patent may be surrendered, and another patent may be issued for matter within the scope of, or as disclosed by the original patent.

### Design Patents

The proceedings in applications for patents for designs are substantially the same as in the case of patents for arts, machines, manufactures, and compositions of matter. The claim should be in the broadest form for the article, as shown in the drawing.

### Assignment of Patents

An inventor may sell his invention and assign his rights therein to another, and the assignment may be recorded in the Patent Office, whereafter the patent for the invention may be granted and issued to the assignee. In all cases of application for a patent by an assignee, the application must be made and a specification sworn to by the inventor or discoverer, if living and competent.

## INVENTING AND PATENTING

### Why Inventions are Made

Inventions are generally made through trouble experienced in the use of things, which suggests the idea of lessening or overcoming the difficulty by improving the thing, or through striving for a better result, or in perceiving that a new result of a certain kind, would, if accomplished, become a want of more or less value. Thereupon, effort is directed toward making the improvement, or in accomplishing the better, or the new result, and in so doing an invention may be forthcoming. Very few inventions are made in a flash—in the twinkle of an eye—or by accident, or seeming inspiration; in the main they come only with persistent effort, and often after discouraging failures.

### Pursuit of Invention

Conception of methods and means for embodying an idea in usefully operative form arise in the mind of the inventor; artisans, mechanics, physicists and chemists may be called upon to bring their skill to bear upon the problem and assist him. Conferences between them are had; investigation and research are undertaken; the draftsman may be required for making working drawings of models and various apparatus, which have to be built in connection with the work, for experimentation is necessary in the majority of cases; and all this is done, frequently at great expense of time and money, before the end sought is obtained, with the risk meanwhile of final failure and expense incurred without chance for reward.

### Difficulties in the Patent Office

Should success be attained, the next step is to obtain a patent to make the opportunity for reward secure; application for a patent is made and trouble begins. The Patent Office may say that the invention is not new, or that the thing did not require invention, and cite earlier patents, technical journals, and publications of scientific societies to prove it, resulting often in final rejection of the application, or in serious limitation of its scope and the value of the invention allowed. Or the Office may place the application in interference with pending applications of others for the same thing; then come months, perhaps years, of delay and expense in attempt to prove that our applicant was the first one to make the invention, which is often prolonged by interference with still other applications filed after the contest began.

### Infringement and Law Suits Come

Should our applicant prevail and succeed in having the patent awarded to him, then infringement by outside parties begins; suit is commenced against the infringer and the patent comes into court, where the questions arise, whether invention was required to make the thing, whether by reference to prior patents and publications it is old,* and whether it may have been in public use or on sale in this country for more than two years before the patent was applied for, etc.; which must be met at great cost, if the patent is of enough importance to warrant a serious effort to sustain it.

### Note-Books and Records

In a contest in the Patent Office over the granting of a patent to our applicant instead of to others, the history of the conception and development of the invention becomes of vital importance, as it must be related through the testimony of witnesses, which should be as definite and unequivocal as possible, both as to the progressive steps that were made and the times at which they were taken. Often the same sort of history is called for in suits for infringement after the patent is issued.

Dependence upon the unaided memory for good history is a very poor substitute for a written record of events made when they occur; the memory of witnesses should be refreshed and supported by documentary proof. Note-books, well kept by the inventor and by those assisting him, constitute the best of such proof. Therein should be entered daily, on consecutively numbered and dated pages, preferably in ink, a concise but lucid account of experiments made and results obtained, illustrated as far as possible by instructive sketches. The record should be signed or initialed on each page by the inventor or assistant, as the case requires, and is improved, if subscribed to by witnesses

---

* The engineer, because of his technical training and experience, is often called upon to read prior publications to find out whether an invention is old. In examining prior patents he will save time and unnecessary labor by confining attention to the description in the specifications, and to the drawings; time and effort spent in considering the claims, for the purpose of determining whether an invention is old, are thrown away.

who may have seen the work carried on; we remember a worthy example to follow in the person of an eminently prolific and successful inventor in mechanical and electrical fields, who never failed to enter in his journal a full record of the experiments and results of the day, together with carefully made sketches of the apparatus used. These records, covering long years of work, call to our mind the methodical system pursued by Faraday in setting down the original notes of his Experimental Researches in Electricity, which were so well kept that they went to press practically without editing.

While the orderly entering of experiments, illustrative sketches, and suggestive ideas on the pages of note-books is, in general, the proper way to preserve a record of efforts leading to possible invention, nevertheless, circumstances almost inevitably lead to the making of fugitive notes and sketches on loose sheets, besides there may be loose drawings and blueprints; such records should be dated, signed or initialed, preferably witnessed, and pasted in scrapbooks for preservation.

### Value of Inventions

It is not often that an approximation to the just value of an invention can be estimated at the time it is made, for there are numerous uncertainties to interefere with the correctness of even a guess. Application must be made for a patent; this may result after expensive proceedings in denial of a patent for want of invention, or grant of one of limited scope, or to another.

If the patent be obtained, large expense may be necessary to develop the invention in practical form which may prove so burdensome, compared with the benefit derived, as to result in commercial failure; or some other invention may supplant, and drive it from the field.

It is, furthermore, almost certain to be infringed, if of marked utility, which may lead to great expense in effort to susta n the patent, with possible failure and thus loss of the capital put into it.

The value of inventions is, therefore, nearly always a matter which cannot be forecast; the value grows or diminishes as determined by many circumstances, and sometimes by chance.

### Inventor's Reward

A good inventor deserves encouragement at proper times, commensurate with the importance of his accomplishments. But ideas in profusion are not inventions; they must be followed up and embodied in concrete form, if invention is to result; and after that must come commercial development and application before a suggestion of value is arrived at that can be accepted with confidence.

The man ambitious to experiment and invent, spurred on by hope of money reward, should not become over-elated at the prolific appearance of his record for ideas, and for things devised by him, or be misled into imagining these things have considerable immediate value, when in fact, this almost always requires time to demonstrate, and at another's expense, unless he can furnish the requisite capital himself. The inventor is necessary to improve the conditions of civilization, but his labor would be of comparatively little avail except for the capitalist. The inventive faculties and money must go hand in hand to get the best results.

## PATENT DEPARTMENT
## GENERAL ELECTRIC COMPANY

### Relation to Inventors

At the outset we disclaimed special qualification to expound the patent situation in all its aspects from the legal point of view, which naturally must be left for patent lawyers to elucidate in respect to its many sides. We have undertaken only to give engineers a general outline of the nature of patents, and for what, and in what manner, they are granted. To such a general presentation of the subject there are bound to be a great number of exceptions, calling for modification of our broad statements to fit specific cases, which would require the writing of a large volume for their consideration, and the experience of a trained lawyer properly to present.

Therefore, although what we have said about patents may be added to our store of interesting information, and may, we hope, prove of utility, it must not cause the engineer to act for himself where supposed inventions of his own are concerned; he should not judge anything for himself in respect to patent laws in such a case, but should consult a good lawyer in every instance, if a single step taken is to be safe.

In connection with the work of the General Electric Company, any man who believes he has made an invention should, without delay, submit to its Patent Department a clear description of his achievement, and an illustration of it, if possible. This is most important as the first step toward protecting an invention in the interest of the inventor, as well as that of the Company.

He should take special pains to insure that the *real nature* of his invention is understood by the Department; this has sometimes not been done. Reference to this important matter was made, Aug. 1, 1911, by Mr. A. G. Davis, Head of the Patent Department, in a communication forming part of Circular Letter A-549, from which we quote as follows:

> "There have been a number of cases in which patents taken out by the General Electric Company have failed fully to protect the real invention, due to the imperfect communication of the invention to the Patent Department or to the imperfect understanding of the invention by the particular attorney who wrote the case. Inventors are most earnestly requested to take pains to read over drafts of the patent applications sent to them with the utmost care, to be sure that their whole invention in all its aspects is therein fully and clearly described, and in general to make any suggestions which occur to them; in other words, each engineer should try to treat the matter just as he would, if the patent in question, when issued, were to be his own personal property.

It is important that no delay occur in submitting the invention to the Patent Department, because should there be delay, another may independently invent the same thing, and when both parties submit descriptions of the invention, the question as to which invented it first must be determined, since the law permits a patent only to one. This has more than once proved a difficult matter to ascertain, particularly when there has been laxity in keeping dated records, and the memory had practically to be relied upon to supply the information.

# ALTERNATOR SHORT CIRCUITS

By Cassius M. Davis

Railway Engineering Department, General Electric Company

It is of great importance that the operators of electrical machinery should understand the underlying fundamentals of short circuit phenomena. The author has written a most instructive article on the subject. After defining the difference between the armature reaction and armature reactance, he gives an excellent description of the "mechanism" of alternator short circuit, which is accompanied with diagrams. The phenomena attending the building up of the armature current under a short circuit are analyized in detail and the behavior of the armature voltage described. The attendant changes in both the field current and field voltage are cited and Helmholtz's law, as applied to the growth and decay of currents when a short circuit occurs, is stated. Tests of various alternators are given which show that the theoretical calculations correspond closely to the observed facts.—Editor.

## Introductory

The question of short circuit currents on generating and transmission systems has received a great deal of consideration on the part of operating companies during the last few years, owing to the fact that as their systems increased in output accidental short circuits became far more disastrous in their effects than before. When it is recalled that turbo alternators that were built up to a few years ago could *momentarily* give from 10 to 30 or 40 times their rated current when suddenly short circuited, and further, when we remember the mechanical forces exerted on an armature coil, on a busbar, or on a cable increase as the *square* of the current, we easily understand why machines were ruined, buses torn from their supports, and other serious damage was wrought to apparatus and property. Thus, if a generating system of 50,000 kv-a. connected load, which could momentarily yield twenty times normal current, was short circuited, the resulting power would amount to 1,000,000 kv-a., a formidable figure for the central station man to contemplate.

It is for this reason, then, that the subject has been one of particular interest to the operator as well as the manufacturer. In spite of all this activity, comparatively little has been written concerning the general "mechanism" of short circuits. It will, therefore, be the purpose of this article to give a very general discussion of short circuit phenomena, confining the discussion to alternator short circuits.

Questions of design are omitted here as being too important to be introduced in a general survey.

## Armature Reaction and Armature Reactance

In the discussion of alternator short circuits a very careful distinction must be drawn between armature *reaction* and armature *reactance*. Both involve magnetic flux and in this respect they are similar, but in all other respects they differ materially. Armature reactance is a constant of the armature circuit just as the reactance of a transmission line is a constant of the circuit; it is directly dependent upon the inductance and has nothing to do with the amount of current. Armature reaction, on the other hand, is not a constant of the armature circuit in the above sense, but depends on the combined magnetic circuits of the field and armature, and increases or decreases as the armature current increases or decreases. It is a *flux* and exists only when there is current in the armature conductors, while armature reactance exists whether there is current in the conductors or not. The flux of armature reactance interlinks only with the armature turns, thus passing in a large measure along the air gap at right angles to the shaft; while the flux of armature reaction interlinks both with the armature turns and the field turns, crossing the air gap perpendicularly to the pole face and traversing in general the path of the field flux. Fig. 1 is a diagram illustrating the two flux paths, when the armature is supplying a non-inductive load. The drawn lines represent the flux of armature reactance and the dotted lines the flux of armature reaction. The diagram represents the flux from only one phase of a three-phase machine. At the time of a dead short circuit, the load is almost entirely inductive and this condition is shown in Fig. 2. Here it is seen that the flux of armature reaction directly opposes the field flux. It should be noticed that the reluctance of the magnetic circuits for both fluxes depends on the position of the field poles relative to that of the armature coils.

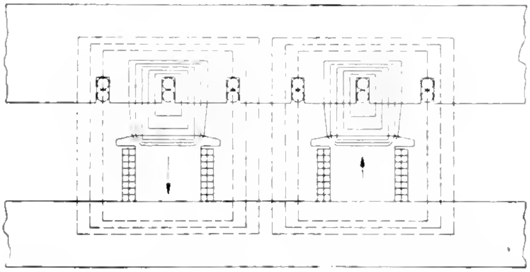

Fig. 1. Diagram Showing Paths of the Fluxes due to armature reactance and reaction where the alternator carries non-inductive load

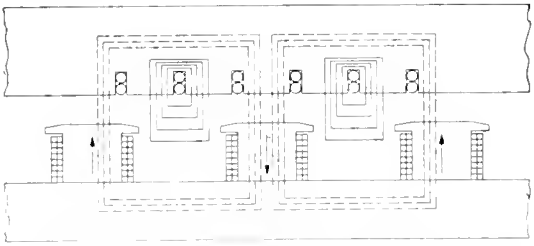

Fig. 2. Diagram Showing Paths of the Armature Reactance and Reaction Fluxes as affected by a short circuit on the alternator

### Description of an Alternator Short Circuit

Consider what takes place at the time of a short circuit:

*First*, the alternator is running (either at no load or full load near unity power-factor) with the field and armature in the relative position shown in Fig. 1.

*Second*, a short circuit takes place and the armature current rises to several times its normal full load value, its instantaneous value being determined by the "nominal generated e.m.f." and the reactance* which is effective in the circuit. At the instant before the circuit is closed the field flux predominates, but as the short circuit current comes on the flux of armature reaction builds up and the relative position of the field and armature becomes as shown in Fig. 2, the flux of armature reaction opposing the field flux.

A current cannot exist in a circuit without simultaneously producing a flux interlinking with that circuit and proportional to the current. The field flux and the flux of armature reaction are of about the same magnitude and opposed to each other. It, therefore, follows that practically all the flux which exists must pass around the armature conductors and crowd in between the armature and the pole face; thus it is the flux of armature self-induction. From this, it can be seen that the initial rush of current is limited only by the self-inductive reactance of the armature circuit.

*Third*, the condition described above cannot exist indefinitely—it is not a condition of stable equilibrium. The field flux, having a certain density before the short circuit when no flux of armature reaction exists or when it has a density corresponding to the load, is now reduced by the opposing flux of armature reaction. Ultimately the resultant flux which issues from the pole pieces, and which is the flux generating voltage in the armature conductors, is very much smaller than that which existed previous to the short circuit.

---

*"Impedance" is of course the proper word to use here, but since the resistance of the circuit is usually quite small in comparison with the reactance it is customary to neglect it.

This change of field flux cannot take place instantaneously, because any flux represents stored energy, and even though the armature current rises to many times its normal in the first half cycle the flux of armature reaction which accompanies it cannot reduce the field flux until after the elapse of a relatively long time.

Fig. 3. Curve Illustrating the Building Up of Single-Phase Alternating Current from zero to a permanent value

Some idea of the amount of energy stored in the field flux may be obtained by considering the flash and its attendant heat when the field switch of an alternator is suddenly opened. If the field circuit were non-inductive, that is, if the field current produced no flux, there would be no flash.

The rapidity with which the field flux is reduced by the armature reaction depends upon how quickly the energy of the field can be changed into some other form of energy and conducted away. It is first changed into electrical energy by virtue of the interlinkage of the field conductors with the varying flux and thence into heat in the resistance of the field circuit.

When the field flux is reduced, and with it the resultant flux, the voltage generated in the armature conductors is decreased and hence the short circuit current diminishes; the decay of current taking place with the same speed as the decay of the field flux.

The final result is that the field flux and the opposing flux of armature reaction reach a condition of equilibrium, and the short circuit current reaches a permanent value which is determined by the "synchronous reactance" of the alternator. This "reactance," it will be recalled, is a combination of armature reaction and armature reactance.

This discussion indicates that the duration of a short circuit current is dependent upon the resistance in the field circuit—the greater the resistance the faster the current dies down to its permanent value. Thus it is advantageous to so design the exciter and field circuits that there is always a fair amount of the field rheostat in circuit.

To recapitulate, the mechanism of an alternator short circuit may now be stated in a few words: The instantaneous current rush is limited only by the inductive reactance of the armature circuit. The armature reaction gradually reduces the field flux and with it the generated voltage and current until a permanent condition is reached—that of the sustained short circuit current.

This general discussion applies to both polyphase and single-phase short circuits. The only difference to be noted is the well known double frequency pulsation of the armature reaction during a single-phase short circuit, which makes itself manifest in the field circuit, as will be seen later. The armature reaction under polyphase short circuit in general is not pulsating except during the first few cycles. The reason for this will be given in another paragraph.

### Armature Current

A short circuit current building up on the armature circuit follows the general laws governing the building up of an alternating current in any circuit. In order to make the discussion complete a brief description of the phenomenon is included.

Fig. 3 represents an alternating current starting from zero and building up to a permanent value. It must be remembered that when a current, either direct or alternating, starts through a circuit, or when it changes from one value to another, magnetic energy must be stored around the conductors, or its amount must be changed. This storage or change does not take place instantly. Hence during the first few moments the change from one current value to another takes place gradually while the magnetic energy approaches its new value. In the figure, the permanent or final value is $i_1^1$, but the actual value, $i_1$, gradually approaches $i_1^1$. The curve $i_1^0$ is called the "transient." This last quantity is the difference between $i_1^1$ and $i_1$, and the rate at which it approaches zero depends on the resistance and reactance of the circuit.

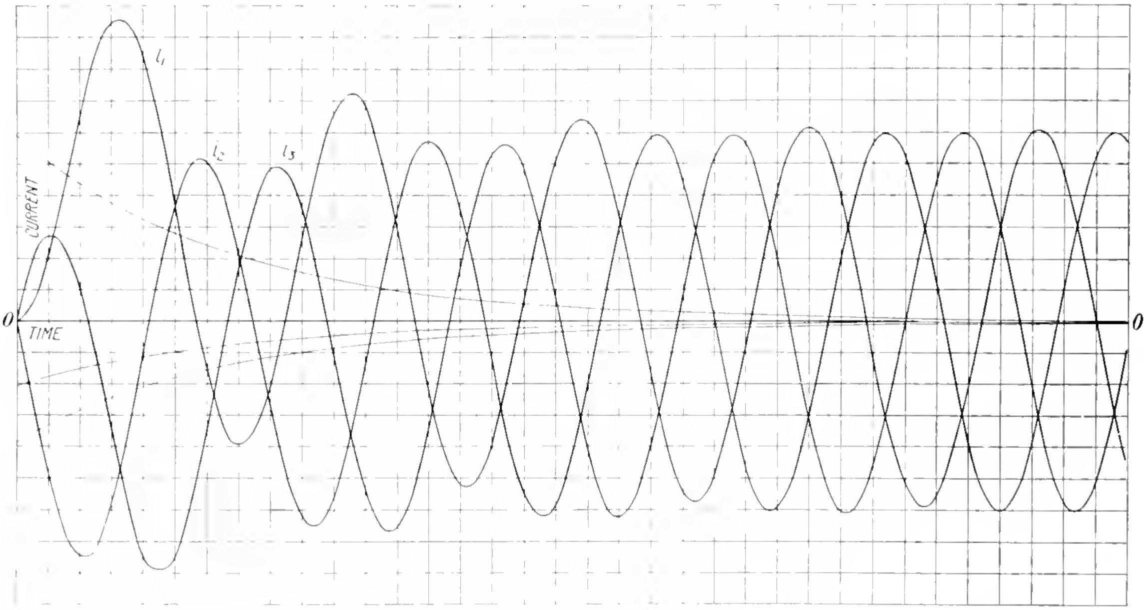

Fig. 4. Curve Illustrating the Building Up of a Three-Phase Alternating Current from zero to a permanent value

If the current starts when $i_1^1$ should be zero, $i_1^0$ disappears and the actual current and the permanent current are coincident. This constitutes the only exception to the statement made in the last paragraph. Really, however, it is no exception at all, since when the actual current and the permanent current are both zero at the same instant there is no change of current and hence no change of stored energy.

The curve $i_1$ is symmetrical with respect to $i_1^0$, so that if an oscillogram is taken of the armature current at the time of a short circuit, the transient $i_1^0$ can be drawn and from its shape (the resistance of the circuit being known) the armature reactance can be calculated.

A three-phase alternating current building up in a circuit is represented in Fig. 4. Here each of the three currents has its own transient, which may be derived in the same manner as was the transient of the single-phase current in Fig. 3.

In an alternator short circuit the armature current does not approach a constant permanent value, but instead approaches a gradually decreasing value, due to the gradual reduction of the field flux by the flux of armature reaction. The armature current during short circuit, theoretically, looks like Fig. 5, which represents the currents in the armature windings of a three-phase alternator.

A glance at Figs. 3 and 4 shows that it is difficult to state just what value a short circuit current has, due to the fact that the

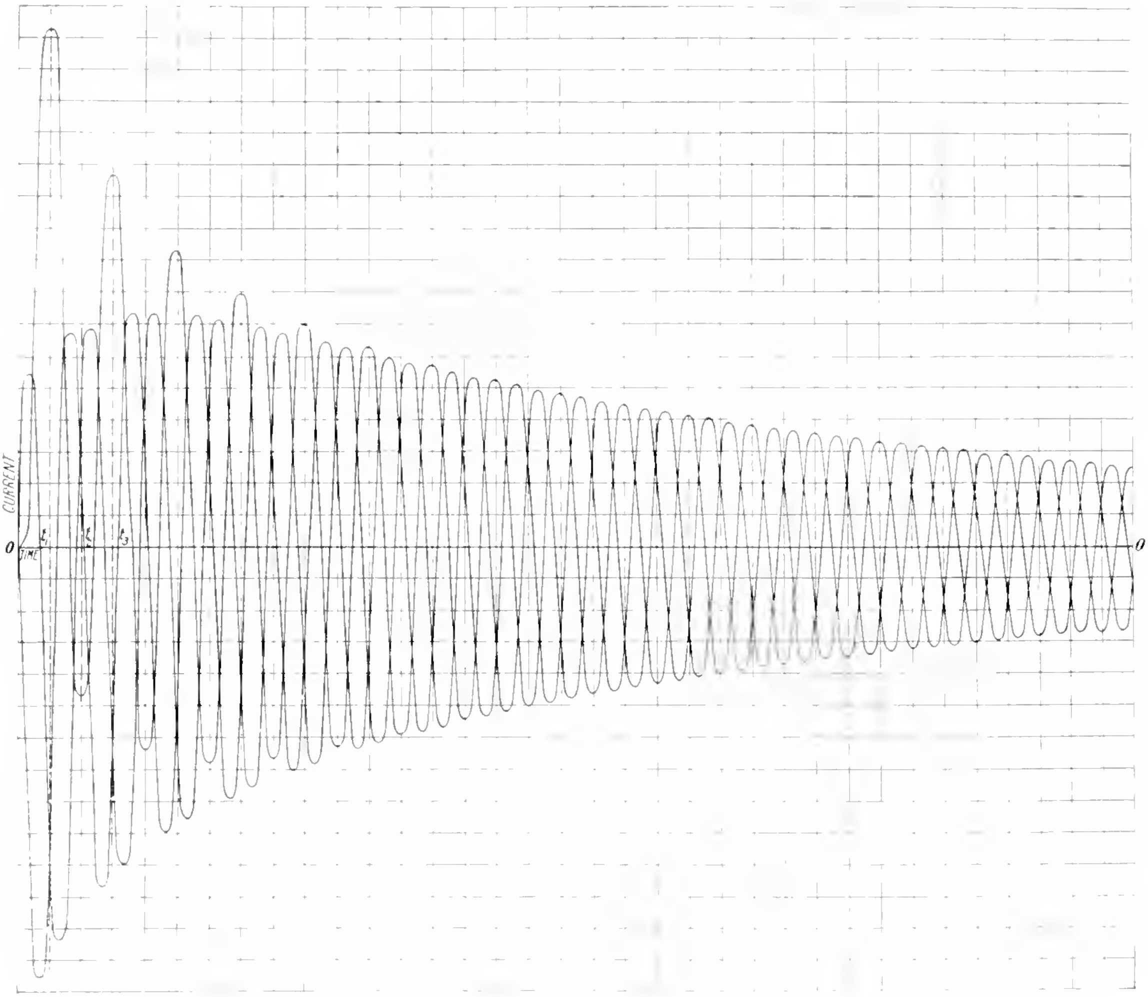

Fig. 5. Curve Illustrating the Growth and Subsequent Decrease of the short circuit current in a three-phase alternator

currents are not symmetrical. One quantity, which is definite whether the current wave is symmetrical or not, is the total amplitude. Suppose Fig. 6 represents an oscillogram of the short circuit current in one phase of an alternator; then the initial current rush may be determined as follows:

Through the positive and negative crests draw the two light lines, and at the first crest measure the total amplitude $a$. This has the value

$$a = 2\,I\sqrt{2}$$

where $I$ is the effective value of the current. Then

$$I = \frac{a}{2\sqrt{2}} \doteq 0.353\,a$$

is the effective value of the current at the first crest and is a true measure of the current. Theoretically, $a$ should be measured at the instant the short circuit begins, but since the actual current is zero at this time, the theoretical amplitude is of no value.

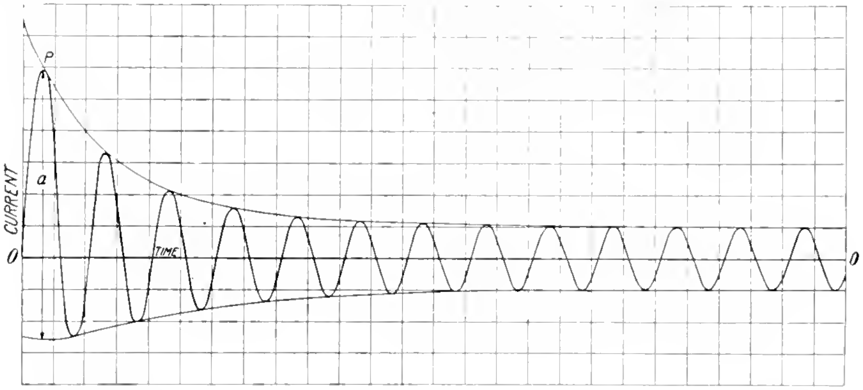

Fig. 6. Curve Representing an Oscillogram of the short circuit current in one phase of a three-phase alternator

This argument assumes a sinusoidal wave shape for the current. This usually is not the case, owing to saturation of the iron at high armature currents. A more accurate method would consist in establishing the medial line (armature transient), and with this as zero determine the root mean square value of the wave.

The actual instantaneous value of the current at the first crest, $P$, may range all the way from $I\sqrt{2}$ to twice this value, depending upon the point of the wave at which the short circuit appears. It is $I\sqrt{2}$ when the short circuit begins at the instant when the final current should be zero; it is $2\,I\sqrt{2}$ when the short circuit begins at the instant when the final current should be maximum. Since the mechanical forces which the armature conductors must withstand are proportional to the square of the *instantaneous* values of the current, the quantity $2\,I\sqrt{2}$ is the one which is the controlling feature in the design of machines to withstand short circuit currents.

The armature current during a single-phase short circuit does not differ from that of a polyphase short circuit, except perhaps as regards magnitude. Experiment shows no definite rule can be given for its magnitude. Some machines have initial single-phase current rushes of about the same magnitude as the polyphase currents, some greater, and some less.

### Armature Voltage

If a polyphase alternator is short circuited on all its phases at the terminals of the machine, the terminal voltage instantly falls to zero. The "nominal generated e.m.f." then assumes a value corresponding to the reactance of the armature circuit and follows the same shape as the armature current. If a polyphase machine is short circuited on one phase only, the voltage of the short circuited phase follows the armature current, while the voltage of the other phases becomes distorted, due to the pulsating armature reaction and to the mutual inductance between the coils of the various phases. Under any condition of short circuit the armature voltage does not rise to more than double its normal value and hence it is seldom a factor which has to be taken into account. Its accurate determination is very difficult and owing to its relatively small importance it has not been very thoroughly investigated.

**Field Current**

There are two effects noticeable upon the field current:

*First.* While the flux of armature reaction builds up it is changing (reducing) the field flux; and wherever a change of flux is impressed upon a circuit it induces an e.m.f. in that circuit which in turn forces a current through the circuit. Consequently, by Lenz's law, when the armature reaction reduces the field flux an e.m.f. is induced in such a direction as to produce a current which tends to maintain the field flux; in other words, the field current rises. The amount it rises depends on how well the armature and field magnetic circuits are interlinked.

As the armature reaction first comes into play it reduces the field flux most rapidly. As it approaches a constant value this reduction becomes less rapid. Hence the field current rises to its maximum value during the first part of the short circuit and then gradually returns again to its normal value.

*Second.* A study of Fig. 5 will show that the armature reaction during the first few cycles cannot be constant in intensity. The instantaneous currents at the time $t_1$ are all high, while at $t_2$ they are all low, and at $t_3$ they are again high. Since the armature reaction is proportional to the armature current, it follows that until the armature currents become symmetrical the armature reaction is alternately large and small. The armature reaction, then, is pulsating with a gradually decreasing amplitude. This induces in the field winding an oscillating current.

The combination of the two effects noted above results in a field current is shown in Fig. 7, the oscillating current being superimposed on the transient field current. The oscillatory part of the current lasts as long as the armature currents remain unsymmetrical; in other words, as long as does the transient due to armature reactance. The transient value of the field current, the shape of which depends on the reactance and resistance of the field circuit, is shown by the line $i^0i$. It immediately jumps up to the value $i^0$ when the short circuit takes place and then gradually dies down to its original value $i_0$ after the armature reaction has reached its full value and the condition of sustained short circuit is established.

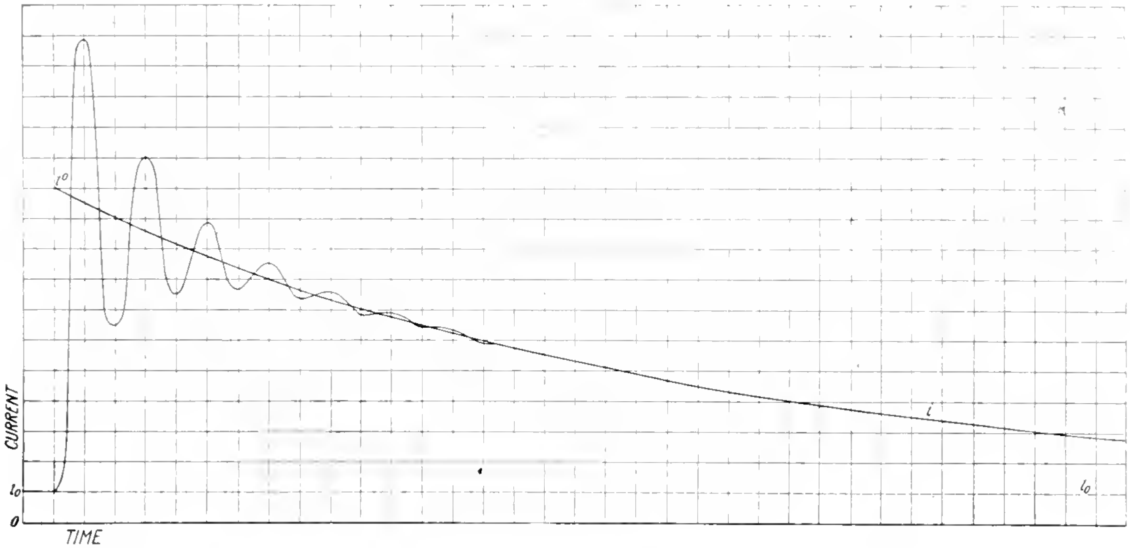

Fig. 7. Curve Illustrating the Growth and Subsequent Decrease to Normal in the value of field current of an alternator when short circuited

It is well understood that a single-phase current in the armature circuit causes a pulsating armature reaction, and furthermore this reaction is of double frequency. The effect upon the field current during a single-phase short circuit is to superimpose a second oscillatory current of double frequency which is alternately in phase with the fundamental oscillation and 180 degrees out of phase. This gives a field current with alternate high and low peaks which gradually approach each other in amplitude until in the sustained condition the field current consists of pulsations of equal amplitude at double the machine frequency.

### Field Voltage

During normal operation the exciter supplies an e.m.f. to the field circuit, but at the time of short circuit the field coils themselves become a source of e.m.f. Although the field current induced by this e.m.f. is in the same direction as that supplied by the exciter, it produces a voltage at the field terminals in the opposite direction. So the net result is a tendency to reverse the voltage at the slip rings. How completely the reversal takes place depends upon the value to which the current rises—thus on the mutual inductance between the field and armature circuits, and on the resistance and reactance in the exciter circuit.

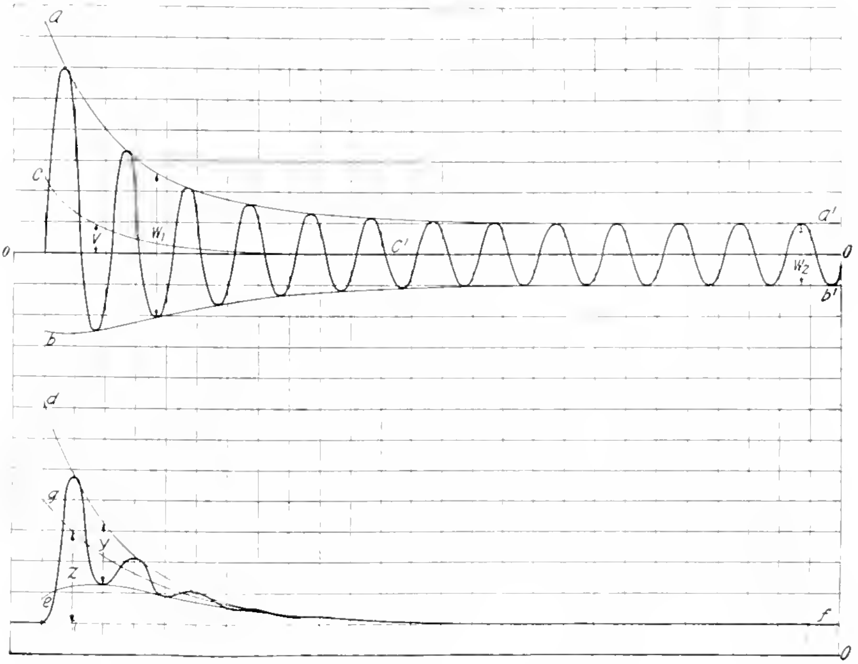

Fig. 8. Curve Illustrating Method for determining the armature and field transients from the armature and the field current

The discussion under *Field Current* relative to single-phase short circuits may be applied here to explain the variations in field voltage. In general, it may be said the voltage at the terminals of the field bears a reciprocal relation to the field current during a short circuit. Thus a single-phase short circuit produces a general depression of the field voltage, from which it slowly recovers in a series of alternate low and high peaks gradually approaching each other in amplitude until a steady double frequency pulsating sustained voltage is reached.

### Law Governing the Growth and Decay of Currents

The building up of the armature current, the decay of the oscillatory part of the field current, the decay of the average field flux (which corresponds to $i^0i$ in Fig. 7), and consequently the decay of the armature current, all follow Helmholtz's law. This law is expressed mathematically by an equation of the form:

$$x = X\epsilon^{-\frac{r}{L}t}$$

or

$$x = X(1-\epsilon^{-\frac{r}{L}t})$$

The first equation applies to an increasing quantity, while the second applies to a decreasing quantity. In these $x$ may be the current or the flux at any instant of time $t$; $X$ is the maximum value to which $x$ ultimately rises, or from which it begins to fall; and $r$ the resistance and $L$ the inductance of the circuit. The equations apply fundamentally to continuous current circuits, but they may be equally well applied to circuits in which oscillatory or transient alternating currents flow. In this latter case they represent the change in amplitude of the waves with time.

From what has already been said it is evident that the transients of both the armature and the field of an alternator may be determined from both armature current and the field current. Reference to Fig. 8 will make this clear.

*From the Armature Current.* Draw lines $aa^1$ and $bb^1$ through the positive and negative peaks respectively. Then draw $cc^1$, bisecting the vertical distance between the two first lines at every point. The ordinates $v$ determine the armature transient, and the ordinates $(w_1 - w_2)$ the field transient. Then $w_2$ is the sustained current and is the zero value for the field transient.

*From the Field Current.* Draw the lines $df$ and $ef$ through the maximum and minimum points. Then draw $gf$ bisecting these two lines. The ordinates $y$ determine the armature transient, and the ordinates $z$ the field.

The values of $v$, $w$, $y$ and $z$, measured at corresponding times $t$ may be now substituted in the formulae given above, and, knowing the resistance of the armature and field circuits, the inductance $L$ can be found, from which the reactance at once follows.

The problem usually appears as outlined above, the reactance being the quantity desired. This arises owing to the difficulty encountered in making satisfactory measurements of the reactance of either the armature or field.

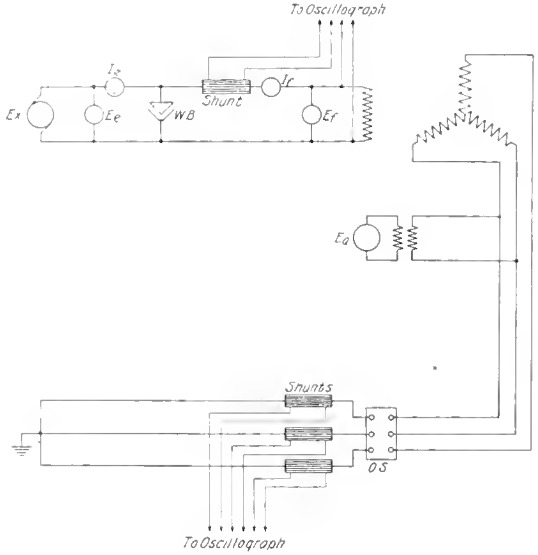

Fig. 9. Diagram of the Connections used in making the short circuit tests used on an alternator

### Tests

Some time ago a comprehensive series of tests was made to determine the characteristics of various alternators and to see how closely they corresponded to theoretical calculations. A short account of the tests may prove of interest in connection with the foregoing.

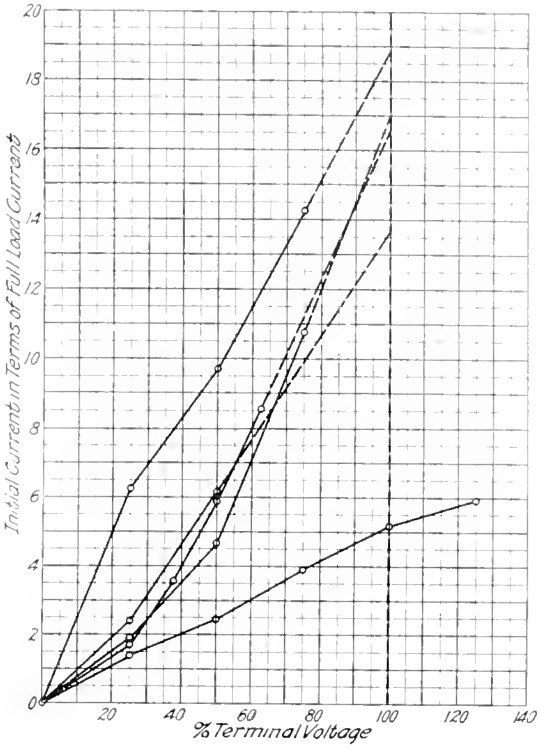

Fig. 10. Curves Showing the Relation between open circuit voltage and initial armature short circuit current of several different alternators

The general scheme of connections is shown in Fig. 9, which is self-explanatory. From previous experience current transformers were found unsuitable for the measurement of transient alternating currents due to the fact that, being inductive apparatus, they had transient characteristics of their own, the effects of which were added to the transient characteristics of the armature circuit. Therefore, direct current ammeter shunts were used as shown in the figure. The water box across the exciter armature was used to eliminate the effect of the unknown reactance of the exciter. The current through it was always several times the alternator field current. Thus, in effect, the alternator was excited by the non-inductive drop across the water box.

Two oscillographs were used, one recording the armature characteristics and the other the field. The two oscillograms taken at each test were easily correlated as to time and speed, since the instant at which the short circuit starts is very sharply defined in both the field current and voltage. In some respects it would have been better if one phase of the armature current had been recorded on the same film with the field characteristics, but for matters of convenience it was thought more desirable to proceed as outlined above.

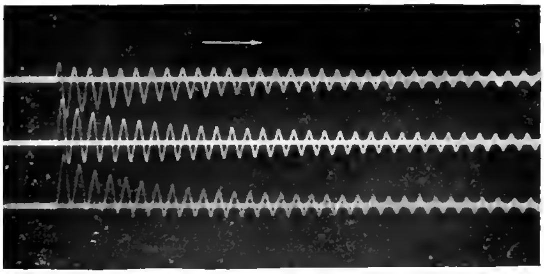

Fig. 11. Polyphase Short Circuit of a 9375-kv-a. turbine-generator at one-half voltage, showing the three armature currents

Previous to each test instrument readings were made of exciter current and voltage, alternator field current and voltage, and alternator armature voltage. Then the oil switch was closed, throwing on the short circuit.

On single-phase short circuits the voltages of the two open phases were recorded in place of the other two armature currents.

With this general arrangement tests were made on several sizes and types of machines at various voltages and under many external conditions of armature and field circuits. In all, some 360 oscillograms were taken which furnish a wealth of data on the subject.

For the purposes of this article it will be possible to give only a brief outline of some of the more interesting features resulting from these tests.

### Agreement Between Theoretical and Actual Characteristics

In general, the tests results agree very closely with their calculated values and perhaps remarkably so in face of the fact that an alternator represents about as complicated a network of interlinked electric and magnetic circuits as can be found.

One of the first assumptions made in connection with alternator short circuits is to the effect that the instantaneous short circuit current is directly proportional to the terminal voltage which exists immediately previous to the short circuit; that, for instance the current at full voltage is four times the current at one quarter voltage, or twice that at one half voltage. Roughly this is true but a glance at Fig. 10 shows the assumption cannot be relied upon. In fact experience shows a tendency toward disproportionately higher currents at full voltage than at lower voltages. A possible explanation of this variation is found when we consider that the armature reactance depends in part on a magnetic circuit which includes the field pole faces, and thus at different field excitations various parts of the pole face assume different degrees of saturation. Therefore, the magnetic constants of the armature circuit change with field excitation and hence with the terminal voltage. It also follows as a consequence that the construction and shape of the pole face, the shape of the armature teeth, the depth of the armature winding in the slots, and various other points have much to do with this particular characteristic.

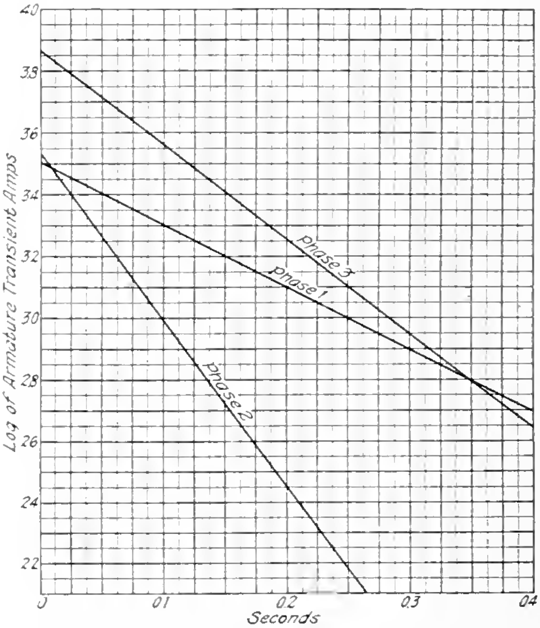

Fig. 12. Curves Showing Unequal Rates of Decay of transients in the three phases at the time of a polyphase short circuit

All the above is apart from the question of wave shape. For instance, suppose the wave at the lower voltages had a peaked crest and at the higher voltages had a flattened crest, then, measuring the total amplitude *a*, as previously described, we would obtain a proportionately lower short circuit value at full voltage.

A second assumption usually made provides an equal rate of decay for the armature transient in all phases on a polyphase short circuit. Experiment, however, shows this is not always true. It would appear from a casual glance at Fig. 11 that all three armature currents become symmetrical at the same time, but on closer inspection we see that the middle current becomes symmetrical after about 7 cycles while the lower current is not symmetrical at 10 cycles, and the upper current is still unsymmetrical at 15 cycles. This is even more strikingly shown in Fig. 12 where the logarithm of the armature transient is plotted against time. Here it is readily seen the three phases have very different transients. As a rule it appears that the wave which is least unsymmetrical has the shortest armature transient. It does not always follow, however, that the most unsymmetrical current has the longest transient.

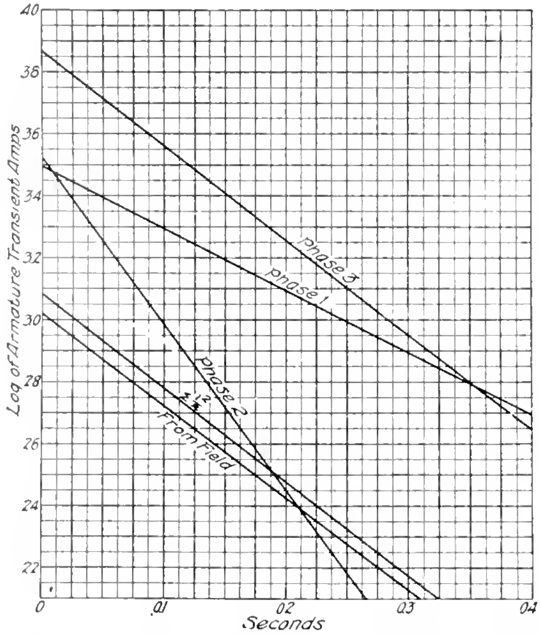

Fig. 13. Curves Showing Armature Transients plotted from each of the phases, from the quantity $\epsilon\frac{i^2}{2}$ and from the field current. Note: The curves $\epsilon\frac{i^2}{2}$ and "From Field" are plotted to scale but their location with respect to the other curves is arbitrary

No satisfactory explanation is yet forthcoming for this peculiarity. It may be due to saturation, or mutual induction between the phase windings, or a combination of these two and other factors. It seems to be taken into proper account by remembering that the magnetic energy stored in the armature circuit is proportional to the square of the current and that the total energy is dissipated in the armature circuit. Thus if $L$ is the inductance of the armature circuit, the stored energy in one phase of a three-phase machine is $w_1 = Li_1^2/2$, in the next $w_2 = Li_2^2/2$ and in the third is $w_3 = Li_3^2/2$ so that the total magnetic energy is $w = \Sigma\, Li^2/2$. It might be supposed the armature transient as determined from the field current would give the true value. But when we consider that the oscillatory portion of the field current lasts as long as the armature reaction is pulsating, which means as long as the armature currents are unsymmetrical, we see the oscillation of the field current would tend to last as long as the longest armature transient, hence is not a true measure of the average armature transient. Fig. 13 shows the five armature transients plotted to the same scale, where it is seen the curves are far from being parallel.

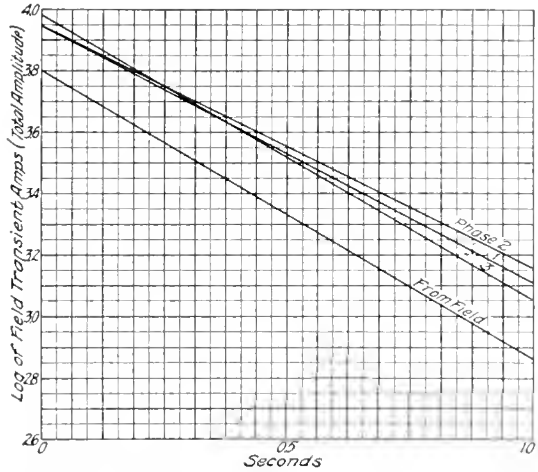

Fig. 14. Curves Showing Field Transients plotted from each of the phases and from the field current. Note: The curve "From Field" is plotted to scale but its location with respect to the other curves is arbitrary

The field transient seems to be more consistent in this respect as is shown in Fig. 14. Here it will be noticed the four curves (three from the armature currents and one from the field current) show fair parallelism.

The following tabulation gives the armature reactance of the 9375 kv-a. turbogenerator from which the oscillograms shown in Fig. 11 were taken.

### ARMATURE REACTANCE AS DERIVED FROM THE VARIOUS ARMATURE TRANSIENTS (See Fig. 11)

Armature reactance from:

| | |
|---|---|
| Upper curve | 1.2 ohms |
| Middle curve | 0.42 ohms |
| Lower curve | 0.79 ohms |
| $\Sigma Li^2/2$ | 0.81 ohms |
| Field oscillation | 0.82 ohms |
| Average current amplitude | 0.78 ohms |

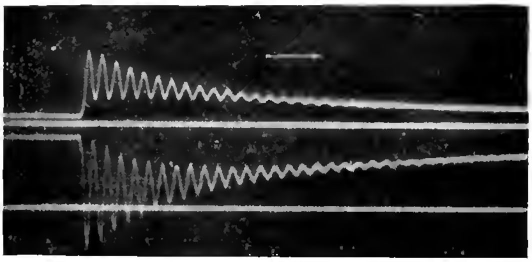

Fig. 15. Polyphase Short Circuit of a 9375-kv-a. turbine-generator at one-fourth voltage, showing the field current (upper curve) and field voltage (lower curve)

It will be noticed the reactance as determined from the measurement of the actual current rush corresponds very closely to the $\Sigma Li^2/2$ value. This fact has been found to generally hold true, which gives added weight to this method of determining the armature reactance.

The results obtained from these tests indicate a very close agreement exists between the actual armature reactance and the reactance as obtained from a measurement of the field oscillation. It is therefore only necessary to take an oscillogram of the field current during a short circuit from which all the characteristics can be calculated. If only approximate values are wanted the field characteristic could be taken at reduced voltage, say 25 per cent and, assuming a lineal armature current relation, the short circuit current at full voltage could very readily be found.

An amortisseur winding on the pole faces seems to have no appreciable effect upon the armature reactance. One small machine was tested both with and without this winding and the currents in both cases were practically identical. Neither does it seem to have any effect on the duration of the field transient as might be expected. There is perhaps a slight tendency to prolong the short circuit when the amortisseur winding is in place but the difference is so small as to be negligible.

## Conclusions

Some of the general conclusions to be derived from the tests may be summarized as follows:

1. The fundamental armature and field characteristics agree closely with those indicated by theory, the greatest deviation being found in the armature transients where the transients of the various phases decay at rates differing from each other, and where they frequently depart from an exponential curve, especially during the first one or two cycles.
2. The real armature reactance corresponds closely to the $\Sigma Li^2/2$ value.
3. The short circuit current is not necessarily proportional to the open circuit voltage just previous to closing the switch.
4. The armature and field transients can be determined from an oscillogram of either the armature or field current.
5. The entire machine characteristics may be calculated and constructed from the field characteristic alone, assuming the synchronous reactance is known. However, the reverse of this is not true. For example, the amplitude of the field oscillation cannot be determined from the armature current without knowing the mutual inductance between the armature and field coils.
6. An amortisseur winding has little or no influence on the reactance of the armature or field.

# DIAGRAMS OF THE POLYPHASE COMMUTATOR MOTOR

By Dr. H. Meyer-Delius

Induction Motor Department, General Electric Company

This is a continuation of the author's previous article on the theory of the polyphase commutator motor. The shunt motor theory is explained, and the geometrical relations are developed clearly showing this motor to be impracticable. The compound motor is then developed along lines similar to the series and shunt motors. The method of obtaining the characteristics graphically is fully demonstrated and the influence of the variable design constants of the motor is explained. The alternating-current constant-speed motor diagram is developed and its similarity to the normal polyphase induction motor diagram is noted. The article concludes with an explanation of the various methods of speed control for this class of motor.—Editor.

In an article by the writer in the General Electric Review for February, 1914, it was shown how a voltage diagram can be developed for the polyphase commutator motor by separating the stator windings into a compensating winding and a field winding. If the compensator winding neutralizes the armature ampere turns entirely, the transformation e.m.f's. induced by the main field in armature and compensating winding must be equal and opposed, so that they don't appear at the main terminals and must not be considered at all in calculations and diagrams. As with d-c. machines, the only remaining e.m.f's. are the rotation e.m.f. $e_r$ induced in the armature by rotation in the main field and the impedance drop $iZ$ in the conductors carrying the main current. The voltage diagram so obtained is shown again in Fig. 1.

In the previous article we dealt with the series motor; we will now study the shunt motor.

### The Shunt Motor

The connections are shown in Fig. 2 for quarter-phase current; $R$ is the d-c. armature and commutator, $C_1$ and $C_2$ the compensating windings, and $F_1$ and $F_2$ the field windings. In a d-c. machine the field $F_1$ would be excited by the terminal voltage between the terminals $T_1$; but with alternating current, the current in the field winding is 90 deg. lagging behind the exciting voltage, and therefore the field $F_1$ is excited by the voltage of the terminals $T_2$. In this way the phase displacement of 90 deg. is made good and the field $F_1$ is again in phase with the terminal voltage $T_1$.

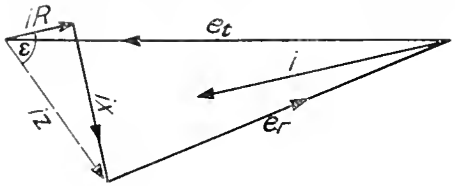

Fig. 1. Voltage Diagram of a Commutator Motor

If the frequency and voltage of the line are constant, the shunt field is also constant in intensity, and just as in a shunt d-c. machine the rotation e.m.f. is proportional only to the speed.

Draw the voltage diagram, Fig. 3.

1. $QE = e_r$ = rotation e.m.f. It is in phase with the terminal e.m.f. $e_t$; its intensity is directly proportional to the speed.

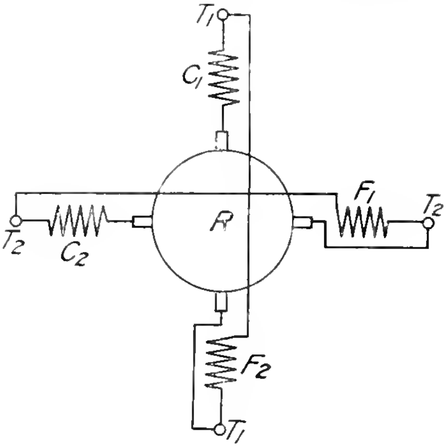

Fig. 2. Connection Diagram of a Shunt Motor

2. $OQ = iZ$ = the impedance drop in the conductors carrying the main current. It is the resultant of the ohmic drop $iR$ and the leakage reactance drop $iX$. As in the series motor, the impedance triangle is of constant shape (corrected commutation assumed); therefore the impedance drop $iZ$ is proportional only to the current and has a constant phase displacement $\epsilon°$ from the current $\left(tan\ \epsilon = \frac{X}{R}\right)$.

At running light the current is zero. Point $Q$ coincides with $O$. For increasing load $Q$ travels from $O$ to $E$. $Q$ coinciding with $E$ indicates standstill, where the rotation e.m.f. $e_r$ is zero.

The diagram is very similar to the voltage diagram of a d-c. motor, Fig. 4. For the plain ohmic drop $iR$ in the d-c. motor we have substituted $iZ$, the impedance drop, since the leakage reactance drop $iX$ must be added. In both motors, if the load increases, the speed will drop; therefore the rotation e.m.f. decreases and the current must grow until its drop is equal to the increased difference between the constant terminal e.m.f. and the decreased rotation e.m.f. But the leakage reactance drop throws the current nearly 90 deg. (really $\epsilon^\circ$) out of phase with the field and the terminal e.m.f. The motor is therefore an extremely poor one, with a constant power-factor of only about 20 per cent for all loads.

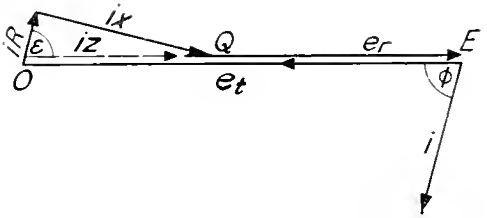

Fig. 3. Voltage Diagram of a Shunt Motor

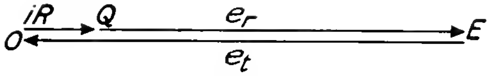

Fig. 4. Voltage Diagram of a D-C. Shunt Motor

These operating conditions may be improved slightly by the connections shown in Fig. 5. The field $F_1$ is excited not only by the terminal e.m.f. $T_2$, but also partly by the other terminal e.m.f. $T_1$. The phase of the resultant field is shifted from the phase of the terminal e.m.f., $T_1$, over an angle which is determined by the ratio of the number of turns of the two exciting windings. This angle, which we will call $\gamma$, is constant for all loads. Since the rotation e.m.f. is in phase with the field, this e.m.f. has a constant phase displacement $\gamma^\circ$ from the terminal e.m.f. Fig. 6 shows the voltage diagram.

For varying load the point, $Q$, of the impedance vector $iZ$ travels on the line $e_r$. It is possible to make the power-factor unity for a certain load; but on departing from that load to either side, the power-factor quickly becomes very low—for lower loads extremely leading, for higher loads extremely lagging. The current is thrown out of phase with the field by the reactance drop $iX$, and the torque diminishes quickly so that the motor breaks down even at slight overloads.

We see that the straight shunt motor is entirely impracticable. In order to make it work it is necessary to compensate the disturbing reactance e.m.f. $iX$ by a series rotation e.m.f. as in the series motor. This leads us to the compound motor.

### The Compound Motor

The compound motor unites the characteristics of the shunt and series motor. The rotation e.m.f. consists of two components:

1. The shunt rotation e.m.f. $= e_{sh}$ with all the properties found in the shunt motor.
2. The series rotation e.m.f. $= e_s$, with all the properties found in the series motor. The series rotation e.m.f. has a constant phase shift, $\beta^\circ$, from the main current, which angle is determined by the phase combination of the exciting winding. As in the series motor, the series rotation e.m.f., $e_s$, has also a constant phase displacement $\delta^\circ = 180 - \epsilon - \beta$ (page 127, General Electric Review, February, 1914) from the impedance drop $iZ$. The intensity is proportional to the main current as well as to the speed of the motor.

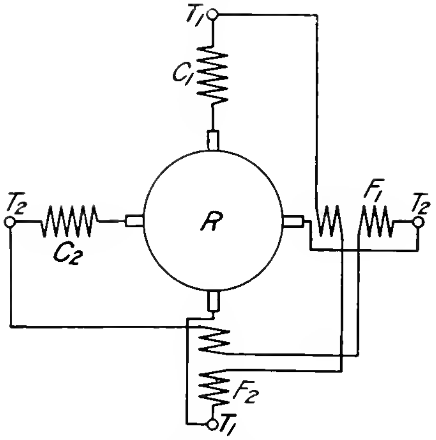

Fig. 5. Connection Diagram of a Shunt Motor with phase combination in exciting winding

We obtain the voltage diagram, Fig. 7:

For a certain load we may have:

$OQ = iZ$ the impedance drop.
$QA = e_s$ the series rotation e.m.f.
$AE = e_{sh}$ the shunt rotation e.m.f.
$EO = e_t$ the terminal e.m.f.
Angle $OQA = \delta =$ constant.
Angle $AEO = \gamma =$ constant.

$OQ^1BEO$ may indicate the voltage diagram for a large load and lower speed. Let us assume, first that the speed for this second load would have remained the same as for the first load.

$EQ = e_{sh}$, and $Q^1A^1 = e_r^1$ are the two rotation e.m.f's., still at the higher speed $n$. The speed for the larger load may be $n^1$. For the actual lower speed $n^1$, the above two rotation e.m.f's must be reduced in the ratio of the speeds $\frac{n^1}{n}$.

Therefore $\frac{Q^1B}{Q^1A^1} = \frac{BE}{AE} = \frac{n^1}{n}$.

1. Thus the lines $AA^1$ and $Q^1E$ are parallel. Further we find $\triangle\, OQA$ similar to $\triangle\, OQ^1A^1$ since (a) angle $\delta$ is the same in both.

(b) $\frac{OQ}{QA} = \frac{OQ^1}{Q^1A^1}$

Therefore angle $AOQ$ = angle $A^1OQ^1 = \alpha$.

If the end of the impedance vector $OQ$ moves on any curve from $Q$ to $Q^1$, the end of the vector $OA$ moves on a similar curve from $A$ to $A^1$. For all points the two corresponding vectors $OQ$ and $OA$ form at $O$ the constant angle $\alpha$. $QQ^1$ and $AA^1$ are also corresponding vectors, since they connect corresponding points.

2. Thus $QQ^1$ and $AA^1$ are shifted from each other over the same angle $\alpha$. Under (1) we found $Q^1E$ must be parallel to $AA^1$.

Therefore the angle $QQ^1E = 180 - \alpha$.

The load point $Q^1$ was an entirely arbitrary point. For any other load point we find the same condition, that angle $QQ^1E = 180 - \alpha$. Thus the locus on which all points $Q^1$ must lie is the circle in which $QE$ as chord subtends angle $\alpha$. This circle is the desired locus for the end point of the impedance vector.

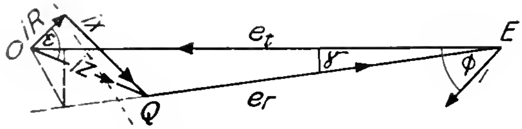

Fig. 6. Voltage Diagram of a Shunt Motor with phase combination in exciting winding

In a similar way as for the series motor, we can draw in this circle diagram lines for the power-factor, input, output, torque, speed and efficiency. These lines are drawn in Fig. 8. $L_1$ is the input line through $O$ forming angle $90 - \epsilon$ with $OE$, the standstill current. At right angles to $L_1$ is the power-factor line $L\phi$, also through $O$. The output line $L_2$ connects the running light point $Q_0$ with the standstill point $E$. The torque line $L_3$ connects the running light piont $Q_0$ with $Q_\infty$, the point for infinite speed. For both points the torque is zero. The latter point, $Q_\infty$, is of special interest.

To study it we draw the line $Q_\infty U_1 U_2$, at right angles to $OU$ (Fig. 9). The machine runs as generator, input and output being interchanged. $Q_\infty U_2$, the mechanical input, is larger than the electrical output, $Q_\infty U_1$, delivered to the line. We know that the torque is zero, and in order that at the same time the mechanical energy may be a finite amount, the speed must be infinitely large. The shunt and series rotation e.m.f's. are therefore infinitely large too. Thus they must be parallel and bucking each other. The angle between the impedance vector, $OQ_\infty$, and the series rotation e.m.f., $e_{r\infty}$, is the constant angle $\delta$. From the fact that $e_{r\infty}$ is parallel to $e_{sh}$, the angle $Q_\infty FE$ must also equal $\delta$. Point F must lie on the circle, because for the impedance vector $OF$ the series rotation e.m.f., which always forms angle $\delta$ with the impedance vector, must again be in phase with the shunt rotation e.m.f. We can find $Q_\infty$ in the following way:

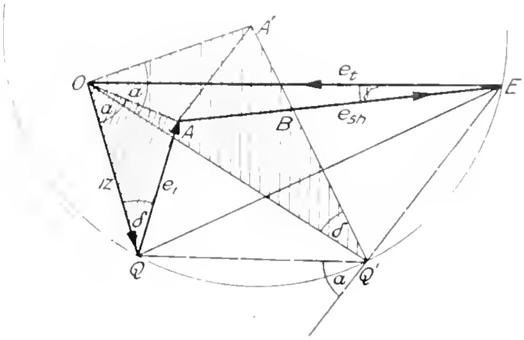

Fig. 7. Circle Diagram of a Compound Motor

Prolong the shunt rotation e.m.f. until it intersects the circle at $F$. Draw the line $FO$ until it intersects the circle at $Q_\infty$. The torque line $L_3$ is found by connecting $Q_\infty$ with $Q_0$.

For point $Q_\infty$, the shunt and series field neutralize each other in their effects. The shunt and series rotation e.m.f's. and the shunt and series fields are opposed and equal. If the fields are generated in the same iron, the total flux is zero. The current is therefore so large as to excite a series field equal to the constant shunt field. Thus we can calculate the current $OQ_\infty$ in the following way:

For normal speed and load let the current be $i$, the shunt rotation e.m.f. $e_{sh}$, and the series rotation e.m.f. $e_s$; then $OQ_\infty = i \times \frac{e_{sh}}{e_s}$.

The speed line $L_s$ is parallel to the torque line through a convenient point $P$ on the output line $L_2$ (see Fig. 8). The line $Q_eQ$ cuts off the length $PN$, which is proportional to the speed. For a load point $Q$, the current is $OQ$ with a phase displacement of angle $QOL\phi$. Draw a line through $Q$ perpendicular to $OC$ ($C$ the center of the circle). $QL_1$ represents the input, $QL_2$ the output, and $QL_3$ the torque. Draw $Q_eQN$. $NP$ indicates the speed. The efficiency may be indicated in the same way as for the series motor.

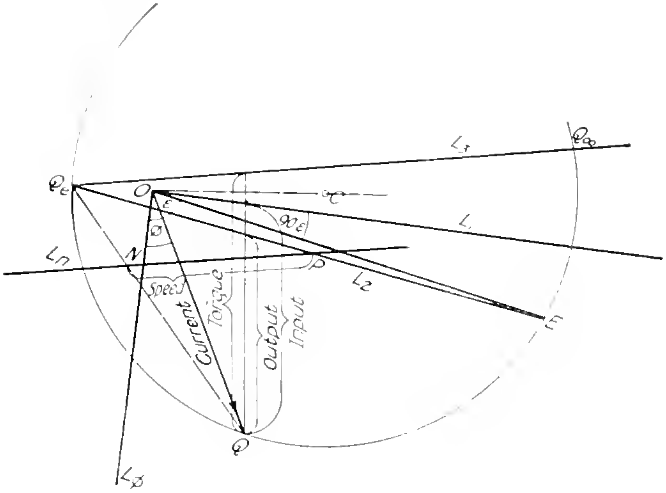

Fig. 8. Complete Diagram for a Compound Motor

To complete the diagram we must add to all currents the constant magnetizing current for the shunt field. This is not a plain wattless current, as it has a small watt component due to the $i^2R$ losses in the exciting winding and the core loss of the field. The magnetizing current may be $im = MO$, with a phase shift of $\phi m$ degrees from the terminal e.m.f. or the power-factor line $L\phi$ (see Fig. 10.) For the load point $Q$ the main current is $OQ$ and the total line current $MQ$. Power-factor line $L\phi$ and input line $L_1$ must be shifted from $O$ to $M$.

### Influence of the Different Constants of the Motor

1. *Shunt excitation.*

If the shunt field is in phase with the terminal e.m.f. ($\gamma = 0$), the running light main current is zero, just as was found for the plain shunt motor of Figs. 2 and 3. The circle therefore goes through $O$, and the strength of the field determines the running light speed exactly as in a d-c. machine. For a stronger field the speed is lower, and for a weaker field the speed is higher.

If the shunt field is given in a phase different from the phase of the terminal e.m.f. ($\gamma_0$), the main current at running light cannot be zero, since the shunt rotation e.m.f. and the terminal e.m.f. can never balance each other, as they are out of phase. A current must flow to close the voltage diagram with its impedance drop and series rotation e.m.f. Since the motor does not do any work at running light (losses neglected), the running light current is a wattless current. Depending upon the sense in which the shunt field is shifted from the terminal e.m.f., the wattless current may be lagging or leading. The latter case is the more interesting one, because it is possible in this way to compensate the magnetizing current of the shunt field, so that even at running light the power-factor can be made unity.

2. *Series excitation.*

It has the same influence on the operating conditions as in the series motor.

Fig. 11 shows the impedance drop $OQ$ and the series rotation e.m.f., $e_1 = QA$. We may again separate two components of the series excitation:

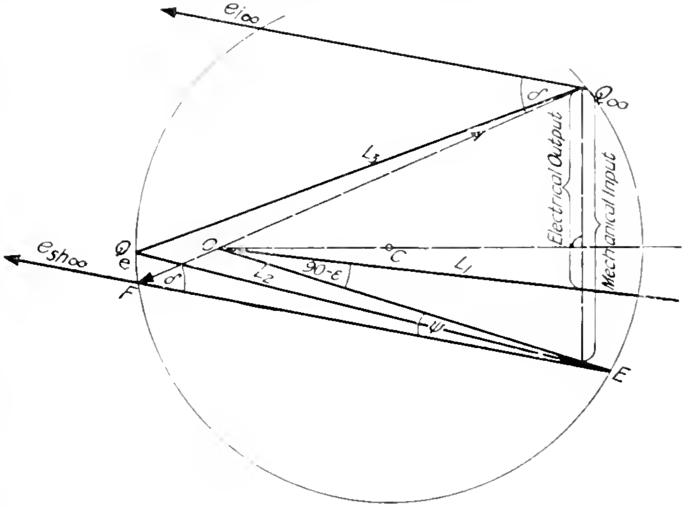

Fig. 9. The Point for the Infinite Speed

(a) $BA$ in phase with main current and its ohmic drop and

(b) $QB$ at right angles or in phase with the reactance drop $iX$.

The first, the watt component $BA$, acts exactly in the same way as the compound excitation in a d-c. motor. It causes a larger speed drop from no load to full load than the ohmic drop alone would do in a plain shunt motor.

The second, the wattless component $QB$, balances more or less the reactance drop $iX$ and checks its bad influence upon the power-factor and speed torque characteristic, found in the plain a-c. shunt motor. If this wattless component $QB$ were exactly equal to the reactance drop $iX$ for all speeds, there would be no difference between the a-c. and d-c. motor. The motor would have unity power-factor for all loads, as do all d-c. motors, and the same speed torque characteristic, efficiency, etc. Since in a shunt motor the speed variation for normal loads is only small, it would seem that these ideal conditions would take place almost exactly. But the reactance drop $iX$ is large compared with the ohmic drop, and only a slight difference between the reactance drop and the balancing series e.m.f. throws the resultant e.m.f. $OA$ rather much out of the phase with the ohmic drop. The power-factor and over-load conditions are therefore no better than those of the series motor, but are about the same.

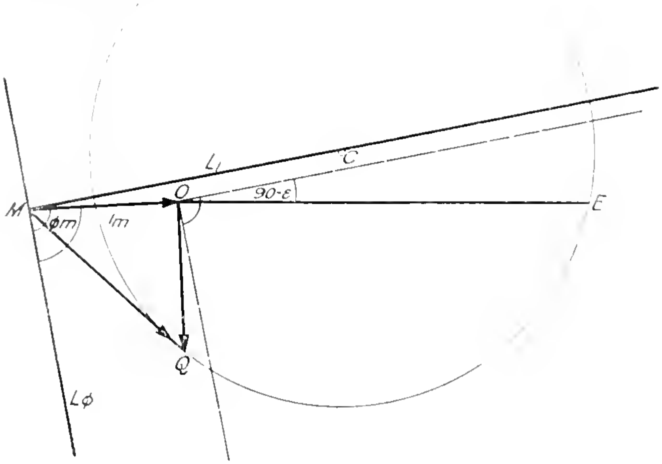

Fig. 10. The Shunt Magnetizing Current in the Diagram

We will now apply the above considerations to the problem of building an a-c. constant speed motor possessing good power-factor and overload characteristics. We have seen that we must build a compound motor in which the reactance drop is balanced by a series rotation e.m.f.

**The A-C. Constant Speed Motor**

For the sake of simplicity we will not compensate at running light the magnetizing current of the shunt excitation by means of a shift (over $\gamma°$) of the shunt field from the phase of the terminal e.m.f. We therefore take angle $\gamma = 0$, or the shunt field, in phase with the terminal e.m.f. For the same reason we will neglect the constant losses of the shunt field excitation and take the magnetizing current of the shunt field as plain wattless current.

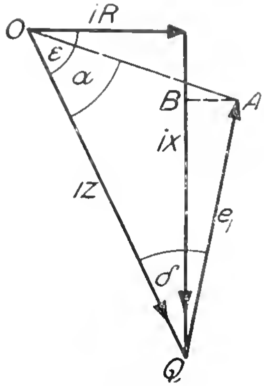

Fig. 11. The Series E.M.F. Diagram of a Compound Motor

In Fig. 12, we have $MO$, the plain wattless magnetizing current, lagging 90 deg. behind the power-factor line $L\phi$, $OE$, the standstill current; angle $EOL_1 = 90 - \epsilon\left(\tan\epsilon = \frac{X}{R}\right)$. For $\gamma = 0$, we have found that the running light main current must be zero, or that the circle must go through $O$. The friction losses neglected, the running light point $Q$ falls in $O$. $OE$ is the output line $L_2$.

In order to draw the circle over $OE$ as chord we must find the bulging angle $\alpha$ for the running light speed, which angle is given by the series e.m.f. diagram for that speed.

The series rotation e.m.f. has here no other purpose than to balance the reactance drop $iX$. It must be therefore chosen in phase with and opposed to the reactance drop. For the sake of simplicity we will assume that the balance is just right at running light.

The series e.m.f. diagram for the running light speed is shown in Fig. 13. Since we must find only angle $\alpha$, the size of the current assumed for this diagram does not matter (the current is actually zero).

$$e_1 = QA = iX$$

$$\text{Angle } \alpha = \text{angle } AOQ = \epsilon.$$

The locus for the current vector $OQ$ in Fig. 12 is therefore the circle in which $OE$ as chord subtends angle $180 - \epsilon$. The center $C$ of this circle falls on the input line $L_1$, and the circle is therefore the semi-circle over the input line.

For the torque line we must locate point $Q_\infty$ on the circle. $OQ_\infty$ forms angle $\delta$ with the shunt rotation e.m.f., which has here the same phase as the terminal e.m.f. Angle $Q_\infty OE$ must be equal to angle $\delta$. From Fig. 13 we find angle $\delta =$ angle $AQO = 90 - \epsilon$. $Q_\infty$ therefore lies on $L_1$, the input line; and $OQ_\infty$, the torque line, falls on the input line $L_1$.

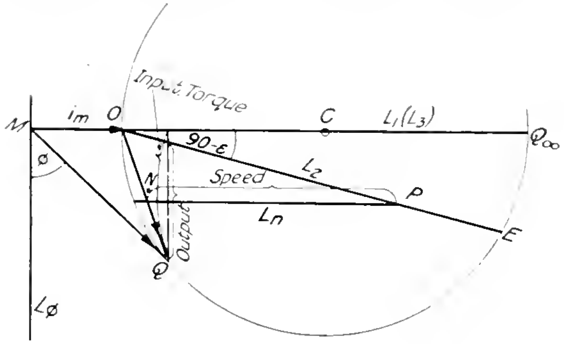

Fig. 12. Diagram of the Commutator Induction Motor (simplified

We can calculate the current $OQ_\infty$ with the formula $\left[OQ_\infty = i \times \frac{e_{sh}}{e_s}\right]$ on page 820. For running light speed the shunt rotation e.m.f. is equal to the terminal e.m.f., $e_{sh} = e$, and the series rotation e.m.f. $e_s = iX$, the reactance drop. It is therefore

$$OQ_\infty = i\frac{e_{sh}}{e_s} = iX\frac{e_s}{iX} = \frac{e_s}{X},$$ the ideal short circuit current.

This diagram is very similar to the circle diagram of the normal polyphase induction motor as first developed by Heyland in 1894. In fact it is the exact induction motor diagram neglecting, for simplicity, those factors that we have previously mentioned. It is interesting to see, in the light of our considerations of the commutator motors, that the normal induction motor appears as a compound motor. Though perhaps at first surprising, it is clear that the compound motor is the most general case of a motor imaginable, and if properly generalized must comprise all motors.

We will study this fact a little closer, since the commutator induction motor is the basis for the practical designs of the polyphase adjustable speed motors.

The connections are shown in Fig. 14. $C_1$, $C_2$, and $C_3$ are the compensating winding distributed in small slots around the whole circumference, as is the stator winding of a normal induction motor. Since the shunt field is in phase with the terminal e.m.f. $(\gamma^2 = 0)$, the field winding, $F_1$, $F_2$, $F_3$, is exactly co-axial with the compensating winding and in an exactly similar way is distributed in the same small slots. It may have the same number of turns as the compensating winding. It is then exactly the same kind of a winding as the compensating winding, and may be just as well united with it to only one stator winding, as shown in Fig. 15.

At running light the main current is zero and the motor takes only the shunt magnetizing current, $i_m = MO$, from the line. For a certain load the main current produces in the stator winding an impedance drop $iZ_1$. The air gap field, therefore, is not alone excited by the constant terminal e.m.f. but by the vectorial difference of the terminal e.m.f. and the impedance drop $iZ_1$, which latter is proportional to the current. To obtain the air gap field we have to add to the constant shunt field a series field, which is in phase with and opposed to the stator impedance drop $iZ_1$. Since at synchronism (the running light speed of the motor) all rotation e.m.f's. are equal to the transformation e.m.f's., we find that at synchronism the strength of the series rotation e.m.f. produced by this series field is equal to the impedance drop $iZ_1$ itself.

We will neglect the small magnetizing current for this series field; the fault is very small and may be easily corrected. To simplify matters we will also neglect the ohmic drop in the stator winding, because we know from the induction motor that this affects the diagram very little. There is, however, no difficulty in drawing the exact diagram. The

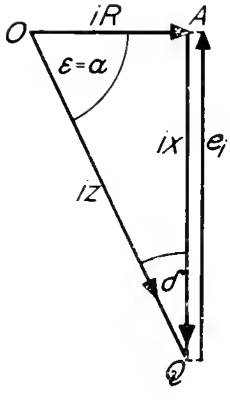

Fig. 13. Series E.M.F. Diagram for the Motor of Fig. 12.

above series rotation e.m.f. at synchronism is then equal and opposed to the primary reactance drop $e_1 = iX_1$ (see the series e.m.f. diagram of Fig. 16).

We see that the placing of the exciting winding in the same slots with the compensating winding or the uniting of it with the latter automatically sets up a series field whose rotation e.m.f. balances the primary reactance drop at synchronous speed.

If the rotor reactance would remain constant, as it does with a commutation artificially corrected by interpoles, the motor would be still rather poor, since the bulging angle $\alpha$ for the circle ($AOQ$ in Fig. 16) is still rather small and consequently the circle is very flat. But fortunately smaller motors of this type commutate without interpoles well enough for practical purposes. It has been shown in a previous article that incorrect commutation causes a decrease in the reactance of the rotor for higher speeds; how much for each type of motor can only be found by test. For the sake of simplicity we will assume that at synchronism the rotor reactance is decreasing just to zero. This is the case for the slip-ring induction motor. It can never be reached by the commutator induction motor, where at synchronism a part of the rotor reactance is always left. The above assumption therefore gives us too good values for power-factor and breakdown point.

The circle diagram is based on a constant rotor reactance. To take in account its variation from the full amount at standstill to zero at synchronism, we assume $\alpha$ series rotation e.m.f. in phase with and opposed to the rotor reactance e.m.f. For synchronous speed the strength of this series rotation e.m.f., $e_2$, is equal to the standstill reactance e.m.f. $iX_2$.

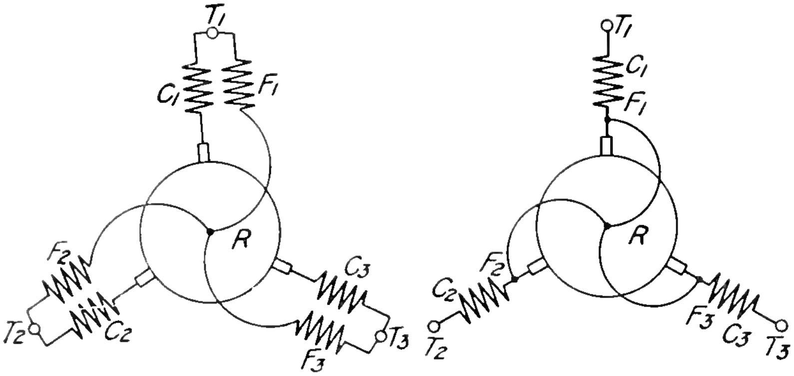

Fig. 14 Fig 15
Connection Diagrams of the Commutator Induction Motor

The total series e.m.f. diagram for synchronous speed is therefore the diagram of Fig. 17. The total reactance e.m.f. $iX = iX_1 + iX_2$ is balanced by the sum of the two series rotation e.m.f.'s $e_{i_1} \times e_{i_2}$. The bulging angle $AOQ$ is equal to $\epsilon$, and we obtain the circle diagram of Fig. 12, which is at the same time the diagram of the normal slip-ring induction motor. We must remember, however, that the circle for the actual commutator motor is somewhat flatter, due to the incorrectly assumed variation of the rotor reactance.

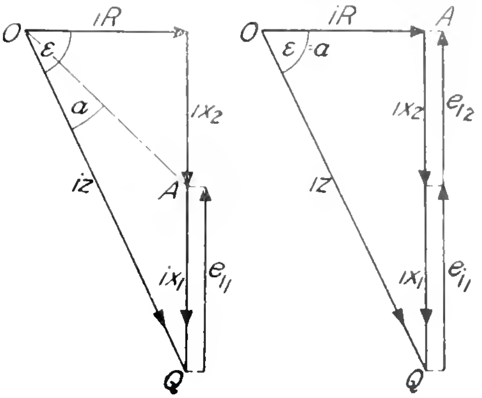

Fig. 16 Fig. 17
Series E.M.F. Diagrams for the Commutator Induction Motor

It is interesting to note by what means the commutator induction motor becomes a practical motor in which the reactance e.m.f., which spoils the plain shunt motor completely, is neutralized. It is due, first, to the fact that the exciting winding is placed in the same slots as the compensating winding or united with the latter one; and second, to the incorrected commutation, possible for small motors with hard carbon brushes.

### Speed Regulation

Just as in a d-c. shunt motor there are two means to obtain speed regulation:

1. Field variation at constant terminal e.m.f.
2. Variation of the terminal e.m.f. at constant field (Ward-Leonard control for d-c. motors).

#### 1. Field Variation

Figs. 18 to 20 show various connections to obtain field variation for three-phase current.

In Fig. 18 the motor has a separate compensating winding $C$ and field winding $F$. The exciting voltage for the field winding $F$ is regulated by a regulating transformer with taps and controller.

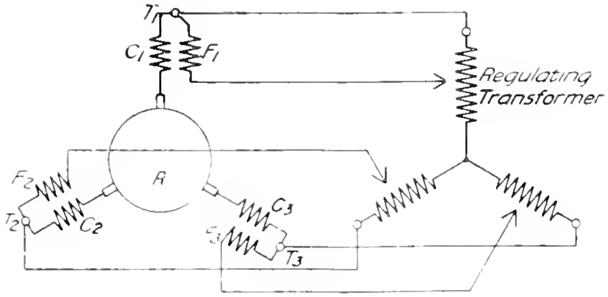

Fig. 18

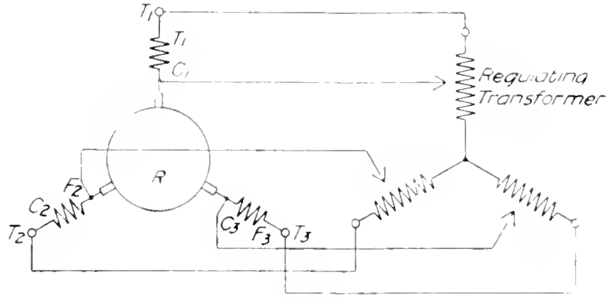

Fig. 19

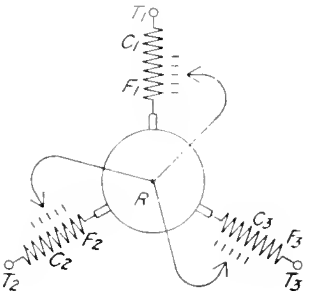

Fig. 20

Figs. 18, 19 and 20. Connection Diagrams for Field Variation

In Fig. 19 the field and compensating winding are united to one stator winding. The regulation of the field is effected in the same way as before.

In Fig. 20 the regulating transformer is united with the stator winding, which has taps connected to a controller.

The effect of all connections is the same; viz., the shunt field is varied in strength. We will develop the diagram for different running light speeds.

For synchronous running light speed we have already obtained the diagram of Fig. 12, which coincides with the diagram of a normal induction motor and is shown again in Fig. 21. Since the phase of the shunt field is kept in phase with the terminal e.m.f. during the regulation, the main current is zero for all running light speeds, and all circles must go through point $O$. Since the terminal e.m.f. is constant, the standstill current $OE$ is constant for all conditions. All circles must therefore go through the two points $O$ and $E$.

The circle for each running light speed is determined by the bulging angle $\alpha$ for that speed. We assumed that for synchronous speed the series rotation e.m.f. just balances the reactance drop $iX$. Then $\alpha$ became equal to $\epsilon$ (see Fig. 22a). Let us assume that the shunt field is increased to double the amount at synchronous speed. The running light speed will be half of the synchronous speed. The series rotation tension $\epsilon$ is therefore also only half of the value at synchronism, when it was equal to the reactance drop $iX$. We obtain the angle $\alpha =$ angle $AOQ$ in Fig. 22b. This angle is much smaller than for synchronous running light speed, the circle is much flatter, and we obtain the circle $B$ in Fig. 21. The power-factor and overload characteristic is rather poor, since only half of the reactance drop is balanced by the series rotation e.m.f.

Let us now weaken the shunt field so that the motor runs at 50 per cent above the synchronous speed. The series rotation e.m.f. increases in the same ratio to $QA$ in Fig. 22c. Angle $AOQ = \alpha$ is large and the circle $C$ in Fig. 21 bulges higher. We obtain high power-factor, even leading, since the reactance drop is considerably over balanced.

It may be noted that the currents for infinite speed $OQ_\infty$ are proportional to each shunt field. We have seen that the torque is zero for this point and that the shunt field and series field are opposed and equal, from which fact it results that the currents $OQ_\infty$ must vary proportionally with the shunt fields or inversely proportionally with the running light speeds. If the synchronous circle is known we can find the corresponding point $Q_\infty$ for another running light speed directly by this fact. The new circle is then determined by the three points, $Q$,, $E$, and $Q_\infty$.

For the complete diagram we must add the shunt field current, which varies with the shunt field. All data for each load may be obtained by the use of the input and torque line $OQ_\infty$, the output line $OE$, and the speed line.

So far we have assumed that the shunt field is in phase with the terminal e.m.f., so that the running light main current is zero. By choosing a proper phase shift for the shunt field from the terminal e.m.f., we have seen that the motor can be forced to take a leading current from the line at running light, which current will balance the magnetizing current for the shunt field. The power-factor and overload capacity may be improved in this way, especially for the flat circle $B$ at the low speeds, as indicated by the dotted circle in Fig. 21.

### 2. Variation of the Terminal E.M.F. at Constant Shunt Field

Figs. 23 to 26 show various connections.

In Fig. 23 the field winding is lying at the constant line e.m.f. The terminal voltage is regulated over a transformer with taps and controller.

Instead of regulating the terminal voltage between the line and the compensating winding, we get the same effect if we introduce the regulating voltage between the compensating winding and the rotor, as shown in Fig. 24.

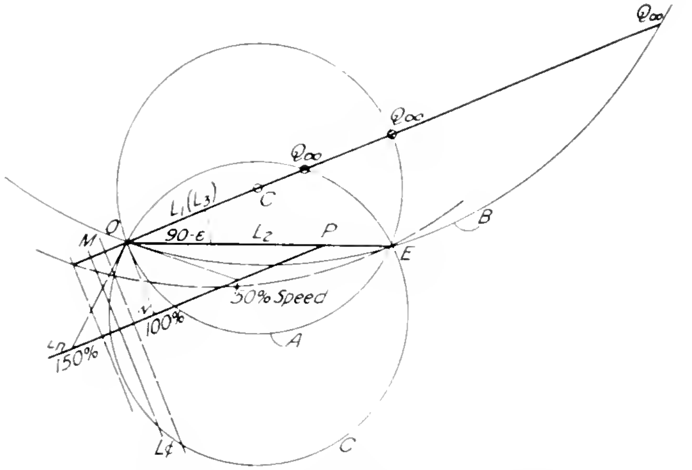

Fig. 21 Diagrams for Synchronism (A), 50 per cent below (B), and 50 per cent above (C) synchronism obtained by field variation

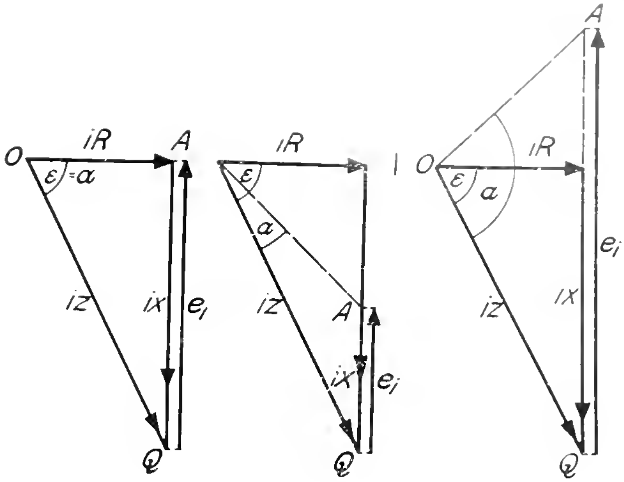
We may then unite the field and compensating winding again to one winding, as indicated in Fig. 25. Finally we can unite the transformer and the stator winding and bring out taps from the stator winding to a controller (Fig. 26).

In all connections the effect is the same: the shunt field is constant and the terminal



Figs. 22A, 22B, 22C. Series E.M.F. Diagrams for the Motor of Fig. 21

voltage is varied, which varies the speed in an exactly similar way as does the Ward-Leonard control for d-c. motors.

We draw the diagram not for the line voltage but for the actually applied terminal voltage. To obtain the line currents from the diagram currents we must only reduce them in the ratio of the terminal to the line voltage.

Assuming again the shunt field in phase with the terminal voltage, the running light main currents are again all zero and all circles go through point $O$. The standstill currents $OE$ vary proportionally to the terminal voltages, or to the running light speeds. The bulging angle $\alpha$ is the same as found before for each speed, obtained by field variation. The circles for synchronism, 50 per cent above and 50 per cent below synchronism are shown in Fig. 27. The overload capacity varies naturally with the applied terminal e.m.f. For the lower speeds it is therefore much reduced as compared with the former motor regulated by the field, and for higher speeds much increased.

The current $OQ_\infty$ for infinite speed is here constant, since the shunt field is constant. If the synchronous circle is known we can

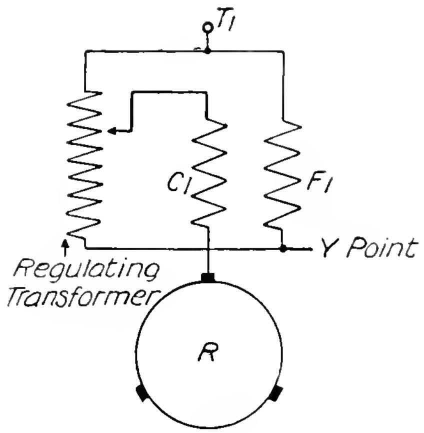


Fig. 23

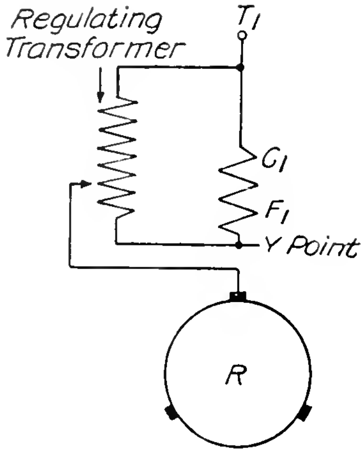

Fig. 25

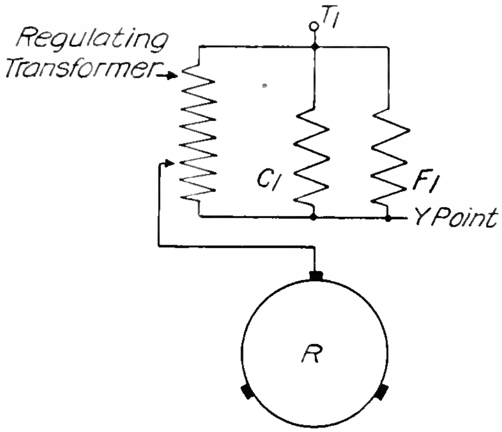

Fig. 24

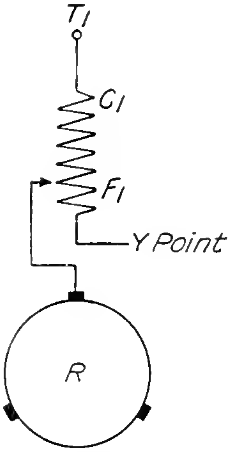

Fig. 26

Figs. 23, 24, 25, 26. Connection Diagrams for variation of the terminal voltage at constant field draw directly the circle for another speed, by reducing the standstill current $OE$ in the ratio of the new speed to the synchronous speed. The circle is then determined by the three points $O$, $E$ and $Q_\infty$.

To complete the diagram we have to add the magnetizing current for the shunt field. Although this current is constant, we must vary it indirectly proportionally with the terminal e.m.f., for the diagram is drawn not for the constant line e.m.f. but for the actual terminal e.m.f.

The diagram is similar to the above diagram for field regulation. It is evident also that here we can improve the power-factor and overload capacity at the lower speeds by shifting the phase of the shunt field from the terminal e.m.f., or what amounts to the same thing, by shifting the terminal e.m.f. from the phase of the shunt field.

The variety of connections suggested by various inventors for speed regulation is large. All, however, are based upon either field or terminal e.m.f. regulation and the diagram may be applied to all of them in a similar way.

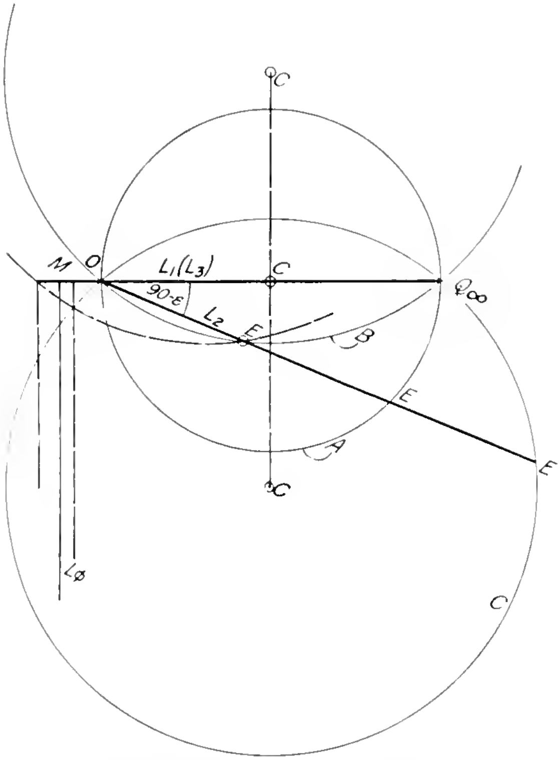

Fig. 27. Diagrams for Synchronism (**A**), 50 per cent below (**B**), and 50 per cent above (**C**) synchronism obtained by variation of the terminal E.M.F. at constant field

# THE BIG CREEK DEVELOPMENT OF THE PACIFIC LIGHT AND POWER COMPANY

By H. C. Hoyt

Power and Mining Department, General Electric Company

The author gives some interesting data concerning the general conditions on the Pacific Coast that have led to so many wonderful hydro-electric developments. In describing the Big Creek Development, he recites some of the unusual difficulties met in the construction work and the vast amount of work necessary before actual construction could begin. His general description of the construction work is full of interesting facts and figures. The electrical and mechanical equipment of the power houses, buildings, transmission line, and the incidental work are described in some detail.—Editor.

In probably no other locality in the world are conditions as ideal for the generation of hydraulic power as in that portion of the United States bordering on the Pacific Ocean. The comparatively low Coast Range mountains offer a barrier to the warm moist winds from the sea, in crossing which a part of their moisture is precipitated on both slopes of the range, while still further east are encountered the high snow-covered peaks of the Sierras, forming a rampart over which the winds can sweep eastward only after giving up practically all the moisture which they carried from the ocean. The resulting rainfall is of such proportions as to give rise to large streams and rivers from a very small drainage area, and at elevations which insure a rapid fall in their course toward the lowlands. But as the flow of these streams is variable between wide ranges, according to the season of the year, their usefulness as a source of power can only be realized by suitable storage of the flood waters. This fact has been so well demonstrated by the operation of all the earlier plants in this territory, where the capacity of the machinery installed is far in excess of the normal stream flow, that hardly a prospective development can now be found which will not include in even its preliminary plans the construction of large storage reservoirs.

A development of this character, recently completed and notable for its size, distance from a market for its power and unusual construction difficulties, is the Big Creek project in Fresno County of the Pacific Light & Power Corporation of Los Angeles.

Prior to the drawing of the plans for the Big Creek development, this company already had in operation six small hydro-electric plants with an aggregate capacity of about 15,000 kw. and three steam plants with a total capacity of nearly 50,000 kw., including 30,000 kw. in modern turbo-generating units. These stations supplied power over a transmission system of more than 400 miles of trunk power lines and nearly 300 miles of distributing lines to seventeen cities and towns of Southern California having a population of over 450,000. To meet its increasing requirements for power it was decided to install another hydro-electric plant, and the site finally selected was on a branch of the San Joaquin River, known as Big Creek, near a point where a natural basin in the hills offered a location for water storage at an elevation of 6800 ft. above sea level.

The site is located in the Sierra Nevada Forest Reserve, and the permit granted by the U. S. Government is the largest ever authorized, covering ultimately 4 power houses, 2 reservoirs, 25 miles of tunnel and the development of 350,000 h.p., the entire development to be completed in 12 years.

Above the reservoir is a drainage area of only about 88 square miles, but mountains on the north and east sides rising to an elevation of 10,000 to 11,000 ft. cause an approximate precipitation over the entire area of 80 in. a year, with a run off equivalent to fully 50 in. For the first six miles below the reservoir site there is a drop of 4000 ft. in the stream which can be utilized for power development. With this high head available a comparatively small volume of water is required and with the aid of a reservoir to equalize the annual flow a development of 140,000 kv-a. is possible within this distance. With the ultimate water storage contemplated it is estimated that this power could be developed for 150 days on the basis of 50 per cent load factor from storage water alone.

The reservoir site had only two depressions in its southern and western banks, besides the channel for Big Creek, which would have to be closed to form a lake 120 ft. deep and 4½ miles long by ½ mile wide, containing 2,310,000,000 cu. ft. of water, and by raising

Fig. 1. Excavating for Dam No. 4. Looking Down Stream

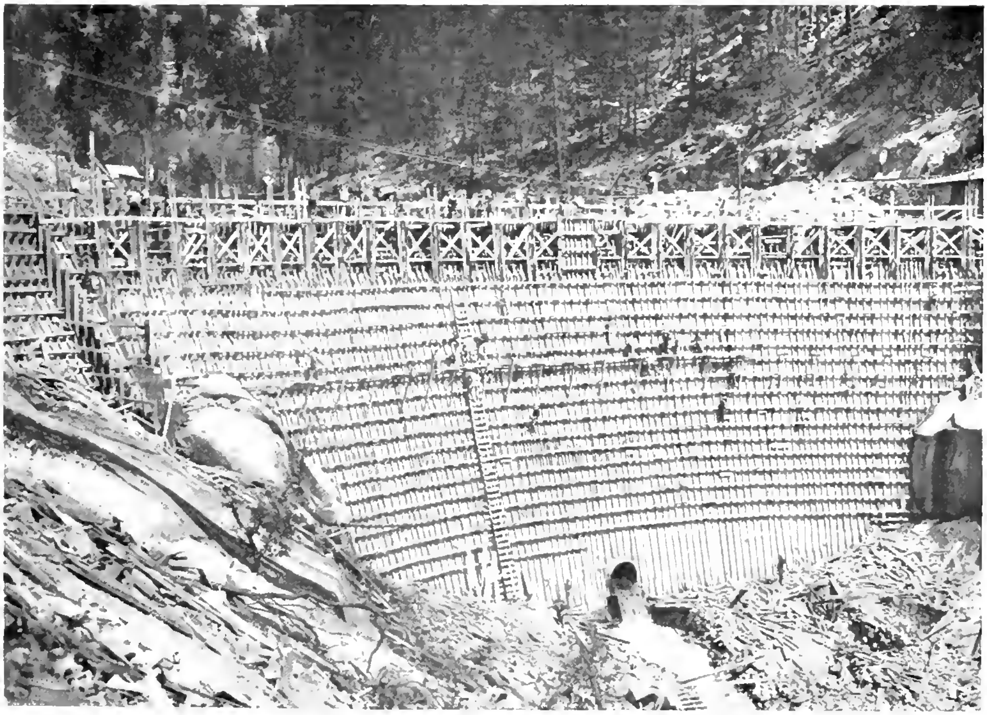

Fig 2. Dam No. 4 in Process of Construction. Down Stream Side

the dams 50 ft., 2,210,000,000 cu. ft. would be added to the storage capacity, which would carry 120,000 kw. at 50 per cent load factor for 240 days.

The final plans for the project were adopted early in 1912, and the schedule called for the completion and operation of the installation in 1913. The latter requirement necessitated the impounding of the flood waters in the spring and early summer of 1913, so that haste in the construction of the storage basin was imperative. It was the first intention to haul the necessary material and supplies from the nearest railroad to the plants in the usual manner by teams, but when estimates were actually made it was discovered that it would require the use of 10-horse teams leaving the railroad siding every five minutes for seven years to complete the entire development. One of the first requirements, therefore, was the construction of a railroad and on January 26th, 1912, orders were issued for such work. In 165 days the line was located, right-of-way purchased, government permit secured, and the last spike driven in a 56-mile standard gauge railroad, the last 30 miles of which was laid through the mountains with grades up to 5 per cent and hardly a tangent worthy of the name. The difference in elevation between the two ends of the road is 4920 ft., and over the mountain division two 60-ton Shay locomotives were required on a six-car train. The road runs along the top of the canyon above No. 2 Power House, and thence to No. 1 Power House below the storage reservoir, with inclines each over a mile in length and having a maximum grade of 85 per cent connecting the railroad sidings with the construction camps at No. 2 Power House and the reservoir basin.

The initial development called for the construction of the reservoir dams to an elevation of 6915 ft.; tunnels and flow pipes with a capacity sufficient to operate six 20,000 h.p. waterwheels under 1900 ft. head; two power houses, each to contain two 20,000 h.p. wheels, with floor space in each for a third unit and provision for extending the power houses for the ultimate development; and 245 miles of double circuit, 150,000 volt transmission line. With only one year in which to complete the storage reservoir and about 18 months to place the entire system in operation, it was necessary that work be rushed on a day and night basis and every provision made to guard against delays. To accomplish this, camps were established at the various dam and tunnel sites, as well as at the two power houses, and as many as 4200 men were employed at one time, while before the completion of the railroad and inclines 1300 horses were in use.

To care for this army of men, bunk houses were constructed having a capacity for 3800 men and dining halls capable of feeding 4250. At one camp alone 865 men could be fed at one time. A main hospital was established, with complete surgical equipment including an X-ray outfit, and "first aid" stations were located at all other camps.

To insure continuation of the work in case railroad communication with the outside world should be interrupted, especially in winter, enough food was kept in stock at times to feed 4000 men for six months; ham and bacon were ordered in carload quantities; flour by the five car loads; while 90,000 gal. of oil fuel, 33,000 bbl. of cement and other materials in proportion were held in reserve. All structural steel work was cut, drilled and fabricated at the site. A complete cement testing plant was installed to examine samples before any of the 186,000 bbl. of cement were used. Thirteen standard locomotives ranging from 25 to 42 tons, and five 60-ton Shay locomotives were used to haul material from the outside, as well as gravel, sand and rock obtained on the site. All lumber for forms, buildings, trestles and construction work was cut from the reservoir site and handled by a saw mill having a capacity of 40,000 ft. per day, in addition to which 8000 cords of wood were used for fuel.

With the exception of the oil-burning locomotives, power for construction work was secured over a 30-mile temporary transmission line from the Crane Valley power house of the San Joaquin Light & Power Company. This line delivered 2400 kw. at 33,000 volts, which was stepped down to 6600 at the main substation for distribution to the various camps, where it was again reduced to 440 volts for motors and 110 volts for lighting. A novel feature was the operation of 15 hoisting engines by compressed air furnished from eight motor-driven compressors during the periods when the air drills were not used extensively; the boilers for these engines being held in reserve for use in case of failure of power, and also to furnish steam for extra heating of the materials when concrete was placed during cold weather.

Both inclines were operated by motor-driven hoists of 300 and 200 h.p. respectively, employing 1 3/8 in. steel cables with special "bridles" for attaching to cars. The hoisting and lowering of cars was regulated from

Fig. 3. Dam No. 1 Completed

Fig. 4. Excavating for Power House No. 2. A Large Portion of this Work was done by Means of a High Pressure Stream of Water, as shown

lookout towers which gave an unobstructed view of both inclines. No passengers were allowed to ride on the inclines, and to further reduce the chance of accidents the inclines terminated at some distance from the camp sites so that the breaking loose of a car would not wreck the work.

The area of the storage reservoir as now constructed is 1544 acres, giving a storage capacity of 53,000 acre feet of water. For the ultimate development, with the dam height raised 50 ft., the storage will be nearly 120,000 acre feet, forming a lake 6½ miles long by ½ mile wide.

There are three dams closing the natural outlets of the reservoir. No. 1, which is placed at the outlet of Big Creek, is the largest and has a top length of 1000 ft. and a maximum height to the spillway of 147 ft. The width of the dam at the top is 10 ft. and at the base 80 ft., and it contains 61,000 cu. yards of cyclopean concrete, all of which was placed in 60 days by nine mixers mounted on a trestle built to the full height of the dam. The mixers fed into concrete chutes leading to the forms; the rock, which constituted about 15 per cent of the total volume, being handled by the same derricks that were used for excavating the dam site. All material was dumped into storage bins from standard gauge cars running on the deck of the trestle and fed from there to the mixers. Three 42-in. hand-operated sluice gates provided with screens are placed in the base of the dam for draining the basin.

The two smaller dams, which close depressions in the side of the basin, are respectively 81 ft. high and 1160 ft. long and 126 ft. high and 600 ft. long, and contain 31,000 and 31,300 cu. yds. All dams are set on solid granite foundation, which is found at from 20 to 90 ft. below the surface of the ground. They have a vertical up-stream face, with the down-stream face stepped to afford a better bond for the concrete when the dams are increased in height.

From the reservoir the water passes through an intake tower of reinforced concrete, 104 ft. high by 20 ft. inside diameter and 2 ft. thick. On its up-stream side the tower is provided with three sets of screens, each 7½ ft. wide and extending to the top of the tower. The screens will be provided with motor-driven rakes covering their entire face. Opposite the screens is a 9-ft. outlet to the discharge tunnel, fitted with a heavy gate valve operated by two stems which can be opened or closed against a head of 140½ ft., this head corresponding to the ultimate height of the dam. Just above the main valve is located a 24-in. by-pass valve to equalize the water pressure in the basin and tunnel. This valve discharges into a 36-in. air shaft open to the top of the tower.

Tunnel No. 1 is 12 ft. in diameter and 3880 feet long, bored through solid granite to a grade of 2 feet per 1000. It will supply sufficient water for the operation of six 20,000 h.p. units working under a head of 1900 ft. A record of 95 feet per day and 282 feet per month was made on this work.

At a point 400 ft. back from the outlet this tunnel connects with a 9-ft. steel flow pipe, one end of which is solidly concreted into the bore of the tunnel, and the other terminating just beyond the tunnel portal in an 84-in. by 60-in. steel plate Y, one branch of which is blanked for use with the future development. The other branch connects with an 84-in. riveted steel flow pipe 6484 ft. long, which varies in thickness from ⅜ in. at the upper end to ½ in. at the lower end. It is laid to a grade of 7½ ft. per 1000 and is supported on concrete saddles about every 35 ft.

An unusual feature of the construction of this flow line was the use of a "go-devil," or self-propelled derrick, which spanned the pipe and rested on a wooden track anchored to the pipe to prevent spreading and supported on blocking from the bottom of the trench. A standard gauge track was constructed in the flow line trench and the pipe delivered on cars within reach of the "go-devil," which would lift a section of pipe and hold it while the car and section of track on which it had stood were removed. The pipe was then lowered into place and aligned, after which one rivet on each side was knocked out and a section of wooden track for the "go-devil" set in place. With this arrangement an average of 240 ft. per day was laid, with a maximum of 300 ft. The trench was later back-filled to give at least eighteen inches of soil over the flow pipe.

At the brow of the hill, 1942 ft. above the power house, the flow pipe terminates in four 44-in. outlets, two of which are blanked for future development, and the other two connected to 42-in. motor-operated gate valves arranged for remote control from the power house. Below the gate valves in each line is a 24-in. stand pipe extending 425 ft. up the hill side and ending in a vertical surge tank 36 in. in diameter and 35 ft. high.

Below the stand pipes, the pressure pipes descend to the power house, one for each generating unit, spaced about 7 ft. apart. Each pipe, which is of German make, is of lap welded steel constuction and built in sections of 20 ft. length. At the upper end the diameter is 42 in. and the thickness $\frac{3}{8}$ in., but as the line descends the mountain the thickness increases in proportion to the pressure under which it will have to operate; and as the maximum thickness for one diameter of pipe is reached the next smaller size is used, up to its limit, until the nozzle casing is reached, where a diameter of 24 in. and a thickness of 1 in. is used. A "go-devil," similar to that used for the flow line except that the two penstocks served as the runaway, was utilized in laying the pipes. About 800 ft. above the power house each pressure line branches through a Y having 26-in. outlets that lead to the nozzles of the two wheels driving each generator. Just outside of the main power house is an annex that houses the hydraulic gate valves.

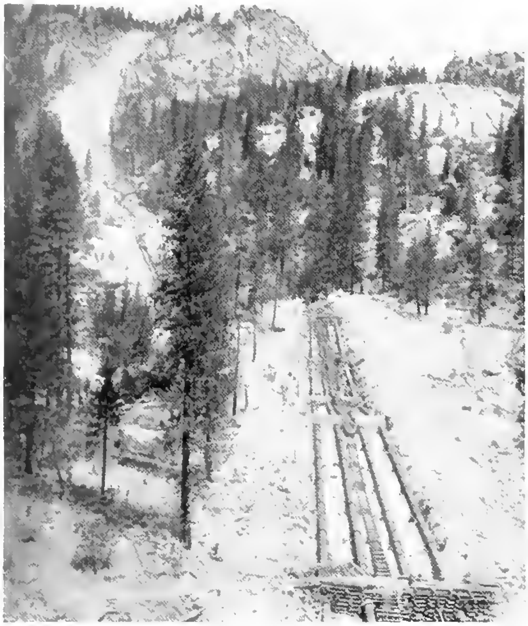

Fig. 5. Penstocks for Power House No. 1

Fig. 6. Penstocks for Power House No. 2

Views from Roof of Power Houses

Each main unit consists of two impulse type waterwheels overhung from either end of the generator shaft outside of the bearings supporting the shaft. Each pair of wheels is designed to deliver 20,000 h.p. when operating under 1900 ft. effective head (2096 ft. static head). The wheels are 94 in. in diameter on the impulse circle and contain 19 cast steel buckets mounted on a nickel steel wheel disk. The shaft for each complete unit is of hollow forged nickel steel, 20 in. in diameter at the bearings, 27 in. in diameter at rotor, by 28 ft. 11 in. long, and is supported by two ring oiled, water-cooled, babbitted bearings 60 in. long. Each pair of wheels with its shaft weighs over 100 tons. Speed control is secured by means of one oil relay or hand-operated governor for each individual wheel so that either wheel may be used alone to drive the generator at partial loads with maximum efficiency and water economy. The speed may also be regulated from the switchboard by remote electric control of the needle valve. The nozzles, which form a jet $5\frac{1}{2}$ in. in diameter having a velocity of about $3\frac{1}{2}$ miles per minute, (over 300 ft. per second), are permanently fixed instead of being deflected for partial loads, and the jet is regulated for varying loads by means of a needle valve. To avoid water hammer or undue pressures in the long pipe lines as a result of sudden changes in the flow, pressure regulators are installed just back of the needle valves and are so constructed as to open a second needle valve in case of excessive rise in pressure, and to close slowly as the pressure is reduced to avoid waste of water. These regulators direct their jet through an energy absorber into the tail race, which is lined with ½ in. steel plates to avoid the destructive action of the water on the concrete under such high heads.

The exciter wheels are also of the impulse type with stationary nozzle and hand-controlled needle valve. Twenty-four buckets are mounted on a 47-in. diameter runner. The 1 5/6-in. jet is supplied from an 8-in. header connecting all four pressure pipes, with a 6-in. connection to the wheel. Speed regulation can be obtained either by hand or automatic governor control, and if the load goes off the jet is deflected by means of a steel hood operated by the speed control device.

The oil for all governors and main bearings is supplied from a central pressure system located in the basement. It consists of two 2½-in. oil pumps, either motor or waterwheel-driven, suction and pressure tanks. Oil flows from the suction tank to the pump, and thence to the pressure tank under a pressure of 200 lb. per sq. in. From the pressure tank it flows to operating valves, cylinders of governors, and lower sides of generator bearings, returning through five stage oil filters and purifiers to the suction tank.

The power house building is 171 ft. long, 84 ft. wide, and 103 ft. high, and is of sufficient size to contain a third generating unit, to be installed at a later date. The operating room is 168 ft. long by 43 ft. wide, and the two units now installed are spaced 44 ft. between centers, while the third unit, when installed, will be placed 62 ft. from No. 2 unit, leaving sufficient space between for work benches, tools, etc. Back of this space is located the exciter bay under the switchboard gallery and in line with the step-up transformer compartments back of their respective generators. At the extreme rear of the building on the main floor are located rooms for storage batteries, rheostats, remote controlled d-c. switchboard and station service transformers. Under these, in the basement, are the rooms for oil storage and treating, while the office and the 6600 volt bus compartments are on the floor above. Directly over the 6600 volt bus compartments are the oil switches for connecting these buses to generators and transformers, and above these the 150,000 volt lightning arresters. On the fourth and fifth floors, directly over the operating room, are located the 150,000 volt buses with their oil and disconnecting switches, while an extension of the roof at the rear of the building forms a canopy under which the lines leave the building without the use of entrance bushings.

The second power house, located about four miles further down stream, is practically a duplicate of the first. From the tail race of power house No. 1 the water flows into a small pool formed by a dam across Big Creek Canyon about 500 ft. below the power house. In addition to impounding the entire flow of Big Creek from the storage reservoir, this dam No. 4 also collects the waters of a small stream known as Pittman Creek, which enters Big Creek Canyon about a quarter of a mile above power house No. 1. The dam is 73 ft. high by 288 ft. long and has one hand-operated 72-inch sluice gate for draining the pool. A syphon intake tower is installed and connects with tunnel No. 2, which is driven through solid granite for a distance of 21,300 ft. to a grade of 3.2 ft. per 1000. This tunnel is also 12 ft. in diameter.

About 250 ft. back from the outlet of tunnel No. 2 a surge chamber 30 ft. in diameter was excavated, the concrete shell extending to a height of 120 ft., or about 30 ft. above the surface of the water in the pool back of dam No. 4. From this surge chamber a 9-ft. gate valve with a by-pass similar to that at No. 1 development controls the flow through the remainder of the tunnel and the penstocks, which begin at the tunnel portal. The arrangement of the penstocks and valves is identical with that at power house No. 1. The effective head at this plant is 120 ft. less than that at the first station, or 1780 ft.; but the increase in water supply at this point, due to the additional flow from Pittman Creek, permits the use of units of the same capacity, although the waterwheels in power house No. 2 have only 17 buckets per wheel. With this exception the equipment of the two stations is identical.

A feature of the construction of the second power house was the removal of about 25,000 cu. yd. of top soil by means of two hydraulic giants delivering a 6-in. stream of water under 250 lb. pressure. (Fig. 4.)

### Electrical Equipment

The general conditions under which the electrical apparatus for this installation was designed are as follows:

"Two power stations, each designed for an ultimate capacity of 105,000 kv-a., generated

Fig. 7. Placing Forms for Anchors for Penstocks, Power House No. 1

Fig. 8 Power House No. 1 showing Line Entrance and Lightning Arrester Horn Gaps on Roof of Building

three-phase, 50 cycles, 6600 volts. This voltage will be raised to 150,000 by step-up transformers and the electrical energy transmitted by a two-circuit line to two substations located respectively, about 135 miles and 275 miles from the generating stations. At the first of these substations approximately 13,500 kv-a. at 72,000 volts will be fed into the system through the 150,000 volt bus by means of suitable step-up transformers. Two transmission lines, each of approximately 60,000 kv-a. capacity, will be connected direct to the station bus without switching or measuring apparatus, and will convey power to the Eagle Rock substation at Los Angeles. From this substation six 18,000-volt and four 72,000-volt outgoing feeders will be supplied through step-down transformers. There will also be installed two 15,000-kv-a. synchronous condensers, with their transformers, to be used for voltage regulation; the condensers to be so arranged that at a future date they may be used as synchronous motors for direct connection to d-c. railway generators. A number of the 18,000 and 72,000-volt feeders will connect this substation with the existing steam and water power stations now in operation on this system. The transmission lines will be about 275 miles long, and will consist of two circuits, each of three steel-core aluminum conductors of 683,000 circular mills. As previously stated, the operating voltage is 150,000, which is about 80 per cent of the critical voltage of the line. The voltage is to be constant at both ends of the line. The transformers, with the exception of the step-up transformers at the power stations, will be connected delta-delta; the power station transformers being delta connected on the low tension side and "Y" on the high tension side, with the neutral grounded. As the system may be operated with ungrounded neutral, all apparatus is to be insulated for the full line voltage and be given a high tension factory test of two and one-half times working voltage for one minute, and twice working voltage test after installation. All apparatus is to be rated on a continuous output basis."

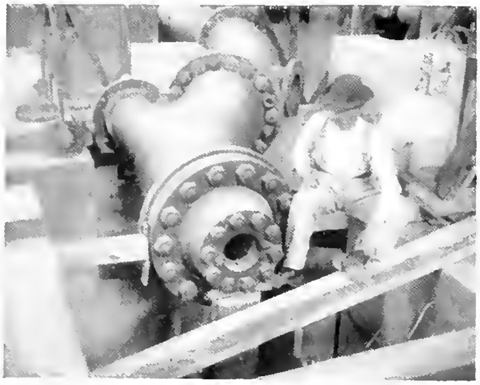

Fig. 9. Lining up a Water-wheel Nozzle. Water issues from the nozzle fitted to this opening with a velocity of 300 ft. per second

To meet these conditions and to care for the initial development, the following equipment was installed: Two main generators for 50-cycle, 6600-volt, three-phase ungrounded "Y" operation, with a continuous rating of 17,500 kv-a. at any power-factor from 80 per cent lagging to 80 per cent leading, and an overload rating of 21,000 kv-a. for one minute, and 25,000 kv-a. momentarily. Each generator is driven by two impulse type waterwheels, mounted on each end of the generator shaft outside of the bearings, and is designed to operate at a normal speed of 375 r.p.m., with a maximum runaway speed of twice normal without excessive strain on the revolving parts. These generators are the largest waterwheel-driven units ever installed. The revolving field of each generator is excited from a separate 250-volt exciter, the exciting current being controlled through a motor-operated rheostat. The guaranteed efficiency of each generator is 97 per cent at full load, exclusive of friction and windage, which were estimated at 180 kw.

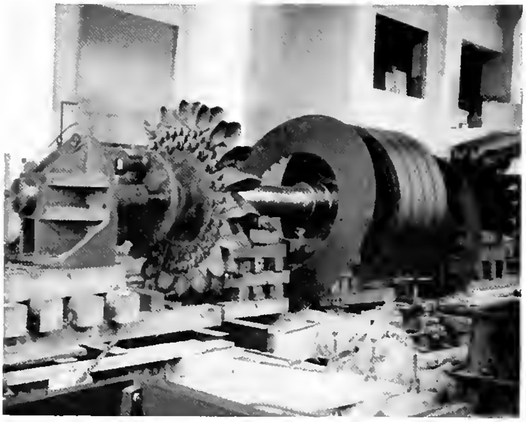

Fig. 10. Assembling Generator and Water-wheel, Power House No. 1

The two exciter units are rated 150 kw. at 250 volts, with a speed of 750 r.p.m. Either unit is capable of exciting both of the main generators. One exciter is waterwheel-driven, with provision for a direct-connected motor at a future date, and the other is both waterwheel and motor-driven. The ultimate installation contemplates the addition of a third motor-driven unit. The exciters are of the interpole compound wound type with shunt winding arranged so that the two halves can be connected in series for self-excitation or in parallel for excitation by means of regulating exciters. In order to secure suitable regulation by means of voltage regulators over the wide range demanded on both the generators and the synchronous condensers, an auxiliary system of excitation for the main exciter units was adopted. The 250-volt main exciters were wound with 125-volt fields, designed for separate excitation from two small auxiliary exciters connected in series, one of which operates at a constant potential of approximately 125 volts, and the other at a varying potential of from 125 to 275 volts. Each of these auxiliary exciters is shunt wound. Therefore, the resulting excitation across the main exciter fields will vary from zero to 150 volts, the voltage regulator operating only on the field of the auxiliary exciter of varying potential. The two auxiliary exciters for the power house consist of three-unit motor-generator sets having a 20 h.p., 220-volt, squirrel cage driving motor direct-connected to a 4-kw., 125-volt generator and an 8-kw., 250-volt d-c. generator. Each of these sets is capable of furnishing excitation for two main exciters.

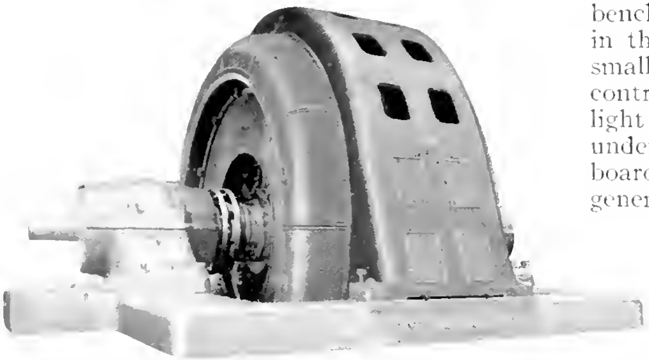

Fig. 11. 15,000 Kv-a. Synchronous Condenser for maintaining equal voltage at both ends of 240 Mile Transmission Line

Two banks of step-up transformers are installed, each consisting of three single-phase water-cooled units having a continuous rating of 5833 kv-a. They are wound for 6600 volts delta on the low tension side, and for 86,700 delta, 150,000-Y on the high tension side, with an additional tap for 135,000 volts. One spare transformer is installed at each power station. The transformers have a guaranteed full load efficiency of 98.3 and a regulation at 100 per cent power-factor of 1.1.

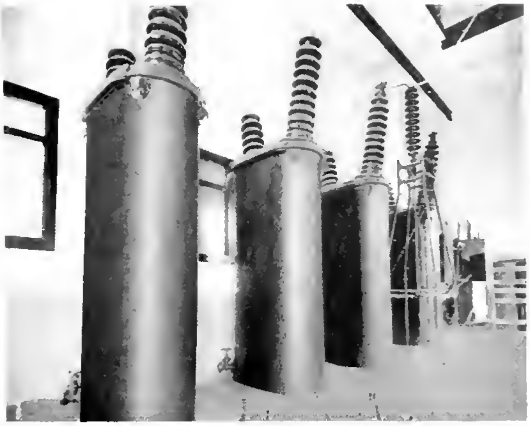

Fig. 12. 150,000 Volt Electrolytic Lightning Arresters, Eagle Rock Substation

The main switchboard, which is of the benchboard type, is located on the gallery in the center of the operating room with a small vertical switchboard near one end to control the storage battery and the station light and power circuits. In the exciter bay under the main switchboard is an auxiliary board for the control of the exciter and generator fields. All of the 6600-volt and 150,000-volt switches are remote controlled, electrically operated, and non-automatic. Duplicate low and high tension buses are installed, with selective disconnecting and oil switches for connecting the generators and transformers to either bus. The 6600-volt buses are installed in separate concrete chambers, while the 150,000-volt bus consists of 2-in. iron pipe mounted on suspension insulators. Each pole of the 150,000-volt oil switches, with its disconnecting switch, is enclosed in a separate compartment. Instrument transformers in the 150,000-volt circuit are of the bushing type, mounted on the oil switches in the outgoing line, the secondaries of these transformers being connected to six ammeters on the line panels, three for each bus selective switch. All control switches are of the twin pull button type and are provided with indicating lamps and a mechanical indicator to show the position of the switch controlled. Mimic buses, showing the complete scheme of connections, are also installed on the benchboard. Disconnecting switches are equipped with a locking device to prevent accidental opening.

Each of the 150,000-volt outgoing lines is equipped with choke coils and an aluminum cell electrolytic lightning arrester, the tanks of which are grounded and are located inside of the building, while the horn gaps are mounted on the roof and operated by mechanical remote control, with an indicator to show the exact position of the horns. A storage battery for operating oil switches and emergency lighting and a battery charging motor-generator set of $3\frac{1}{2}$ kw. capacity are also installed, in addition to four single-phase oil-cooled step-down transformers (one spare) of 125 kv-a. for supplying 220-volt current for station lighting and power circuits.

A complete oil supply system is provided by means of which oil from any transformer, oil switch or lightning arrester may be drawn into tanks in the basement, filtered and returned to any part of the building through a duplicate system of piping operated both by rotary pump and air pressure.

Power house No. 2 is in all respects a duplicate of No. 1 except for the system of excitation. In power house No. 2 each main exciter is of 250 kw. capacity; they are compound wound, with two shunt windings on the same poles, one of which is connected across the armature through a rheostat for self-excitation and the other is separately excited from the storage battery and controlled by a special voltage regulator. Normally the series windings is not in use, but can be switched into circuit from the field control panel in case hand regulation is desired. The 150,000-volt electrolytic arresters have "live" tanks. No choke coils are used, but fuses are installed in series with the horn gaps. The two outgoing lines from power house No. 2 are tapped directly into the lines from power house No. 1.

The duplicate transmission line is 241 miles long, the greater part of which is constructed on private right-of-way cleared to a width of 150 ft. The line crosses two distinct mountain ranges, less than half of the line being in rolling open country. The standard towers are designed to withstand the strains resulting from the breaking of two conductors on the same side, and the anchor towers to withstand breaking of all three conductors and ground wire on the same side. A total of 2214 standard and 187 anchor, angle, or special towers is used. The total weight of a standard tower is 5600 lb. and of an anchor tower 8050 lb. The steel core aluminum cable has an outside diameter of 0.95 in. and weighs 4058 lb. per mile. The total weight of conductor for the two lines is 4,892,000 lb. A seven strand steel ground wire is also installed on both lines, the total weight being 1,306,000 lb. The normal spacing between towers is 660 ft., except where sleet is liable to be encountered, and then the span is reduced to 550 ft. The conductors are located in a horizontal plane about $17\frac{1}{2}$ ft. apart and are strung with a maximum stress in the conductor of 7500 lb., which allows a sag of not less than 25 ft. to the ground, which is increased to 30 ft. at highways. Each line is supported at the tower from nine suspension type insulators on standard towers, and from two sets of eleven insulators each on angle and anchor towers. Each disk has a dry flashover test of 90,000 volts, with a rain test of 56,000 volts, and a net weight, including hardware, of $9\frac{1}{4}$ lb. Where the character of the country requires, the lines are also anchored downward with a similar set of insulators.

Near Bakersfield, and about 135 miles from the generating stations, is located a switching station known as Borel Junction, where tie lines from the Borel station will connect with the Big Creek system. These lines consist of two 72,000-volt circuits from Borel, delivering approximately 13,500 kv-a. through a bank of three single-phase 50-cycle transformers of 4500 kv-a. capacity each. These transformers are wound for 150,000 volts primary and 72,000 volts secondary, with taps for 135,000 and 18,000 volts, and are duplicates of and interchangeable with the main transformers in the Eagle Rock substation. Duplicate sets of hand-operated non-automatic oil switches and disconnecting switches allow for the connection of either Borel line to either of the Big Creek lines. The ultimate arrangement of this switching station allows for the installation of a second bank of step-up transformers and connection to a third 150,000-volt line.

The 150,000 volt transmission line terminates at a step-down substation known as Eagle Rock, about nine miles from Los Angeles, where power from the Big Creek development will be distributed over the various trunk and distributing lines, formerly served by the steam plants. The steam plants will be held in reserve.

The 150,000 volt lines approach the substation from the north, and enter the building one on the east side and one on the west under canopies similar to those for the outgoing lines at the power houses. The lines are connected to the duplicate high tension buses through oil switches located on the fourth and fifth floors of the building. The 150,000 volt lightning arresters are also installed on the fourth floor. The four banks of main step-down transformers, with one spare unit, are placed on the first floor on each side of a central bay, each bank consisting of three single-phase 50-cycle water-cooled units of 4500 kv-a. continuous capacity. They step down the voltage to 72,000 and 18,000 volts, and are provided with taps for 135,000-volt primary operation, it being the intention to use two of these banks for stepping down to 72,000 and 18,000 volts respectively, but to have all transformers interchangeable. All banks are delta connected on both high and low tension sides. Back of the main transformers, on the east and west sides respectively, are located 18,000-volt and 72,000-volt oil switches, duplicate buses, outgoing line switches and lightning arresters. At the south end of the building are located two 15,000-kv-a. synchronous condensers, operating at 6600 volts, 375 r.p.m., for use in regulating the line voltage. With a voltage rise of 9.33 per cent. due to line capacity, and a delivered potential of 150,000 at the substation under conditions of no load, without the use of condensers, would require a charging capacity of 21,000 kv-a. per line. With the use of condensers the potential at both ends of the line can be held at 150,000 volts, the condenser supplying 12,300 kv-a. lagging and the generators 11,750 kv-a. Each condenser is complete with direct-connected exciter, and auxiliary regulating exciters similar to those at the power houses. The condensers are guaranteed to develop their full rated kilovolt-amperes at normal voltage and zero power-factor, leading or lagging. Starting is accomplished by means of half voltage taps in the transformers. Each condenser is connected through oil switches to a bank of three single-phase water-cooled 5000 kv-a. transformers, designed for 18,000 volts primary and 6600 volts secondary, with approximately 33 per cent, 37½ per cent and 45 per cent low voltage starting taps. The following apparatus is also installed: A spare 100-kw. motor-generator set for excitation of both condensers; storage battery with battery charging motor-generator set; station lighting and power transformers (220 volts); a 10,000-kv-a. bank of compensators for paralleling the two Kern River 50,000-volt lines of the same company with the Big Creek system through the 72,000-volt buses at this substation; and a complete duplicate system of oil piping for draining, purifying and storing oil for the various transformers, lightning arresters, and oil switches.

The switchboard, which is of the vertical type, is installed on a gallery overlooking the condenser room and contains the instruments and control switches for the various parts of the system, while integrating wattmeters for the outgoing feeders are mounted on auxiliary panels in the grill work enclosing the rear of the board. The station lighting, power, and storage battery switchboard is installed in the gallery at the right of the main board and the remote control field and exciter panels are mounted on the main floor in the exciter bay. Two sets of buses for the 150,000, 72,000 and 18,000 volt circuits are provided with selective oil and disconnecting switches. All 150,000-volt switches are of the solenoid-operated, non-automatic type; the 72,000-volt switches are of the solenoid-operated type, and are non-automatic for transformer secondaries and automatic for feeders, while the 18,000-volt switches are of the motor-operated type, and are automatic for the outgoing feeders and station lighting and power circuits only. The bus construction is similar to that in the power houses, the 150,000 and 72,000-volt buses being of 2-in. iron pipe, and the 18,000-volt bus installed in concrete chambers. There are six 18,000-volt and three 72,000-volt outgoing feeders of 5000 kv-a. capacity each.

The substation is built of reinforced concrete and structural steel; it is 168 ft. long, 131 ft. wide, and 106 ft. high, and is designed to allow extensions on all four sides to meet the requirements of the ultimate development, which calls for the addition of one 150,000-volt incoming line; two 13,500 kv-a. transformer banks stepping down to 72,000 and 18,000 volts, respectively; four 15,000-kv-a. synchronous condensers, each with its bank of transformers stepping down from 18,000 to 6600 volts; two 72,000 volt; and six 18,000-volt outgoing feeders and possible railway feeder circuits if the condensers are used as synchronous motors direct-connected to railway type generators.

The entire Big Creek development, including power houses, transmission line, switching and substations, was designed and constructed by the Stone & Webster Construction Company and all hydraulic and electrical apparatus was purchased on their specifications.

---

# TRANSPORTATION DIFFICULTIES IN HONDURAS, C. A.

By J. W. Barnett

Superintendent of the Electrical Department of the Rosario Mines,
San Juancito, Honduras, C. A.

The writer tells a most interesting story of the difficulties met with in introducing modern machinery into a country as yet undeveloped. A good idea of the general conditions of the country is given and specific data is presented concerning the work incident to moving heavy machinery into the interior. The collection of photographs materially increases the value of the story narrated in the text.—Editor.

In this day of fast freight and express trains one is surprised at the antiquated methods of transportation still employed in some of the Central American republics. This article deals with conditions as they exist today in Honduras, the most backward of all those states.

Fig. 1. Unloading Freight Boats at the Mainland Port. These Have Just Arrived from the Island Seaport, Amapala, 21 Miles Away

The country is very thinly settled with natives of mixed Spanish, Negro, and Indian blood. Spanish is the only language spoken. Rugged mountains and table-lands occupy two-thirds of the entire area, and are of sufficient altitude to make the climate thereon temperate. The other third of the republic is suited to agriculture, but only a small portion of this is under cultivation. The nights are so cool in the highlands, at any time of the year, that one or two woolen blankets are necessary to enable one to sleep comfortably. Neither the rainy nor the dry season is disagreeable and, so far as climate is concerned, the country is ideal.

But Honduras is bankrupt, stagnant, devastated, and loaded with a national debt of $100,000,000 with accrued interest, the money being borrowed largely to build a fifty-seven-mile railroad, the only one in the whole republic. The people themselves are to blame for this condition.

"Senor," said an old Honduranean, "why should our people accumulate more than one shirt apiece, when a revolution may come at any hour and rob them of everything not on their backs?"

Nearly everyone aspires to be the President. The man with the strongest military support always gets the position. At the last election, six months after a revolution was finished, there was only one candidate for President and one for Vice-President—the successful leaders in the revolt. A notice was posted that a fine of five dollars would be imposed on all the men who neglected to vote. Consequently it went down on record that the candidates were unanimously elected. During ninety-two years of independence, only two Presidents have vacated office without at some time having had to resort to force as a means of holding their places. There has never been enough money in the treasury for a sufficient time to carry out improvements. For this and other reasons foreign capital has not been invested, except in a few instances, as in mining and fruit raising. As a result, the four most important cities of the country are not even connected by a cart road.

The problem of rapid transportation still remains unsolved. Not, however, because engineers are unable to cope with it; but because the movement of agricultural products, minerals, and machinery has been so limited, due to the existing conditions, that the large investment necessary for building good highways and railroads would have been unprofitable. The extremely rough, mountainous character of the country makes it impossible to construct roads cheaply.

There are only a few cities of importance in the whole republic. Porto Cortes, Tegucigalpa (the capital), San Juancito, and Amapala rank among the first. Porto Cortes is the Atlantic seaport, and Amapala is the port on the Pacific coast. Tegucigalpa, the capital, has about 30,000 inhabitants and is only twenty-one miles from San Juancito, where the Rosario mines, the largest in the country, are located.

Fig. 2. Twenty-six Oxen Pulling a Wagon Loaded with a 6-ton Rotor of a 38-pole Low-speed Induction Motor. The number of oxen is increased to 40 on steeper grades. Note the disadvantage at which the oxen pull around the curve

Since this article is to deal mainly with the transportation of heavy electrical and mining machinery into the central part of the country, for the New York and Honduras Rosario Mining Company at San Juancito, a description will be given of the transportation facilities from the Atlantic and Pacific coasts inland to that place.

The mines are two hundred and seventeen miles from the Atlantic port and one hundred and twenty miles from the Pacific port. The only railroad in the country runs from Porto Cortes, on the Atlantic coast, fifty-seven miles inland. This railroad is employed mainly for hauling bananas. Outside of this small stretch of track, there is nothing over which to transport freight and passengers except mule trails and cart roads. The only connection between the Rosario mines and the railroad terminal mentioned is a mule trail one hundred and sixty miles long. About thirty miles of it afford fairly level traveling, while the remaining one hundred and thirty miles are over an almost impassable, rocky, mountainous country. During the rainy season, the absence of bridges across the rivers often compel the pack trains to wait several days for the swollen streams to subside sufficiently to permit fording them. At some fords the cargoes are carried across in canoes, and the mules are obliged to swim the river to resume their journey. The mountain ranges have no general direction, and are broken up in such a way as to make traveling very difficult. It is a startling fact, that if it is desired to take an ordinary unloaded ox-cart from the railroad terminal to the Capitol, or to the Rosario mines, it could only be done by packing it upon the backs of mules.

Fig. 3. Wagon loaded with a generator armature on way to the mines, block and tackle being used to assist in the ascent

Thus the capital, Tegucigalpa, and the mines are cut off from traffic with the Atlantic port, except by pack-train. The letter mail is carried by a native on foot, who makes the trip to the railroad terminal in four days. Pack-trains carry the second-class mail and require from seven to ten days for the trip.

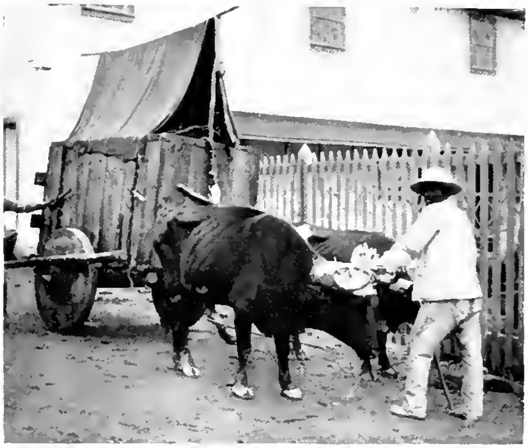

Fig. 4. An Oil Governor for the Pelton Water Wheels at the San Juancito Power Plant. Note the pole resting on the hub of the wheel. This is used as a brake when coming down the mountains

The Rosario Mining Company was confronted with the problem of bringing in machinery for two power-houses, 2200 h.p. capacity, two substations, and a 200-ton stamp mill. The first power-house and substation were installed four years ago. The second power-house, substation, and stamp mill were finished last year. The rotors of the large low-speed compressor motors weighed six tons apiece without their shafts, and the four mortars for the mill weighed four tons each. There were numerous other pieces weighing from 4000 to 10,000 lb., consequently, the idea of bringing in the machinery from the Atlantic coast was out of the question. The machinery, therefore, was shipped from New York to Panama, across the isthmus, and up the Pacific coast to Amapala. Amapala is located on an island, so that all freight must be carried by small boats to the mainland, a distance of twenty miles. These boats are propelled by long sweeps manned by natives. Sails are used when the wind is favorable. The mining company put up its own crane for unloading freight at the mainland. There is a good cart road from the mines to the Pacific port, but even from that side a large mountain range had to be crossed before reaching the mines.

Fig. 5. A piece of good mountain road. A sheer drop of 1000 ft. at the left-hand edge of the road

Fig. 6. A typical Honduranean Cart Road

The transportation facilities of the country offered only two means of bringing the machinery up to the mines, viz., on mule back or on oxcarts. The first method being impossible for the purpose, the mining company had special heavy trucks made to order, in the United States, which would stand the strain of carrying 6-ton pieces over rocky mountain roads.

The quickest and cheapest method of transportation being by pack mules, the companies from whom the equipment was purchased were requested to ship the machinery unassembled, packing as much as possible in boxes weighing 150 lb. or less. A mule will carry 300 lb. but, of course, two 150-lb. boxes balance better on the pack saddle than one 300-lb. box.

Mule freight costs one and a half cents a pound for the trip between the coast and the mines, and the time allowed is fifteen days. Ox carts, which come next to pack mules in cheapness and speed, can handle freight weighing from 300 to 2200 lb. at two cents a pound. Their time limit is twenty-two days and a fine is imposed if they arrive late. Freight generally arrives in half the alloted time but, due to the poor grade of "fuel" used in the mule and ox trains, they are not guaranteed for continuous service. The time limit is made long enough to allow the sore backs and feet of the animals to heal up, and to give them an opportunity to charge their bony "storage batteries" with a little fat. The few horses found in the republic are of a very inferior breed. Mules are used for both pack and saddle animals, in fact they represent both the Pullman and baggage cars for travellers in Honduras.

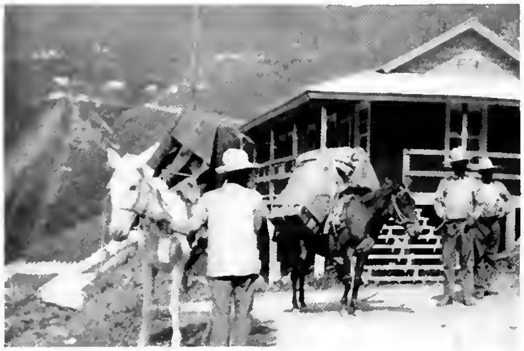

Fig. 7. The only means of transfer of baggage from the mines 160 miles to the railroad terminals on the Atlantic coast. This is the shortest route to the United States

The largest wagons, loaded with the 12,000-lb. pieces, were pulled by thirty or forty oxen. Thirty days were consumed in making the last twenty-one miles of the trip, which was over the highest mountain range. Two revolving fields of the 350 kv-a. generators came assembled on their shafts, and two came entirely dismantled—shafts, spiders, field coils, field poles, wedges, insulation, etc., all being packed in separate boxes. The twelve 125 kv-a. 6600/2200-volt transformers came in a similar unassembled condition, coils, insulation, laminations, etc., being packed in boxes weighing 150 lb. each. The transformer tanks came built up. A wagon loaded with one of the generator fields upset and almost caused the loss of the piece down the mountain side. Profiting by this experience, the remaining generator fields were shipped dismantled, which made them easier to handle and eliminated the danger of springing a shaft.

Fig. 8. One of the three Sections of a tube mill for a 200-ton stamp mill

Forty oxen and twenty-five men were used on each heavy wagon in crossing the mountain range nearest the camp. Blasting out, widening, and repairing the road had been going on for months before the first wagon left the coast on its inland trip. In places the road was blasted out of the faces of cliffs where there was an almost straight drop of a thousand feet. The outside wheels of the wagons ran within a foot of the edge of the precipice at some of the narrowest places. Two oxen were killed at this place, by falling off the road. The cart road twists and winds its way up the rugged mountain side until it reaches an altitude of 7200 feet before it starts to descend the other side by an equally tortuous route to the works of the Rosario mines. Sharp turns occur in the road where the grade is as great as forty per cent, which

Fig. 9. A narrow escape of a 9000-lb. revolving field from a 1000-ft. fall

prevents the oxen from getting a fair chance to pull. Blocks and tackles hitched to anchor posts set at intervals along the road were used at these places, the bulls being hitched to the fall lines of the tackles. Anchor posts were also used in letting the wagons down the mountain sides. In many places a heavy cable had to be fastened from the wagon to trees or rocks farther up the mountain in order to prevent the wagon from going to the bottom of the gulch when the softer sections of the road gave way under the outside wheels. This precaution saved one of the revolving fields, when the wagon carrying it upset on the road near the mines. Each heavy piece of machinery was bolted and lashed with steel cable to the wagon so that it could not fall off regardless of the angle at which the trucks were inclined.

Fig. 10. The Peak of the Hill with the Winding Cart Road on the left-hand side shows the site of the 200-ton stamp mill, shops etc., of the Rosario Mines before construction work began

Twenty-one miles in thirty days is not very fast traveling; but, on account of the condition of the trails, the weight of the machinery, the means at hand, and the fact that not a single piece of apparatus was lost or damaged, speed was not considered a very important item. Not only the roughness and steepness of the road made it tedious work, but other difficulties arose to retard the movement of the wagons. Rains set in and planks had to be dragged along to place under the wheels to prevent them from cutting axle deep into the mud. The oxens' feet were softened by the mud and wore down to the quick, making them unfit for service until leather boots were made for them. At the altitude of the pass, 7200 feet, clouds are present nearly every day, enveloping everything in a dense fog and causing ropes and cables to become muddy and hard to handle. The roads too were slippery.

Parts of machinery which were needed first in the construction work were sometimes unavoidably delayed, which made more work in changing gangs from one job to another before the first was finished.

The works of the New York and Honduras Rosario Mining Company are located on the eastern slope of the San Juancito mountains. The lower Guadalupe power-house is at an altitude of 2900 feet and has a 500-foot head of water. The San Juancito power-house, which runs in parallel with the other, is a mile farther up the mountain at an altitude of 3400 feet and operates under a 1355-foot head. This gives a pressure at the nozzle of 585 lb. The spouting velocity of the water is three miles a minute. A mile and a half above San Juancito are located the stamp mill, offices, quarters, shops, and Rosario substation, at an altitude of 5200 feet. The Pena Blanca substation is half a mile from the mill and its elevation is 6000 feet. Thus, in three miles, the transmission line climbs from an altitude of 2900 feet to an altitude of 6000 feet. Yet, during four years of operation there has not been a single shut down due to lightning, and in fact no serious shut down at all. The power houses are neatly constructed with tile roofs and tile floors, and are equipped with aluminum-cell lightning arresters, traveling cranes, self-contained air compressors for blowing out the machinery, etc. Both patented and "home-made" fool-proof devices have been placed on every piece of apparatus possible to prevent the native operators from damaging it, because from four

Fig. 11. A near view of the mill site when construction work was nearly completed

to six months elapse from the time the repair parts are ordered until they arrive. There are forty-two synchronous and induction motors in operation, ranging from one-half horse power motors to the large thirty-eight-pole, 280 h.p., direct-connected, compressor motors. Two motor-generator sets furnish direct current for the six mining locomotives. Besides these there are six alternators with their exciters and about thirty-five power and light transformers. The wire for the four miles of transmission line was shipped in 125-lb. rolls, so it could be brought in on mule back and handled easier on the steep mountain sides where, in many places, the transmission line runs on an 80 per cent grade.

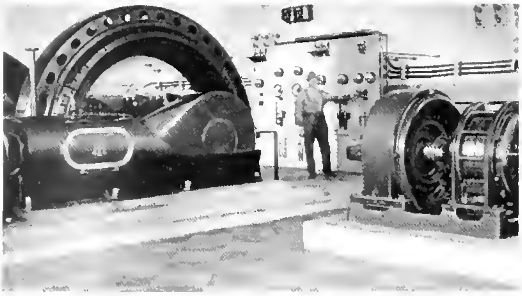

Fig. 12. Two 280 h.p. Induction Motors direct connected to an air compressor, at the Peña Blanca Substation

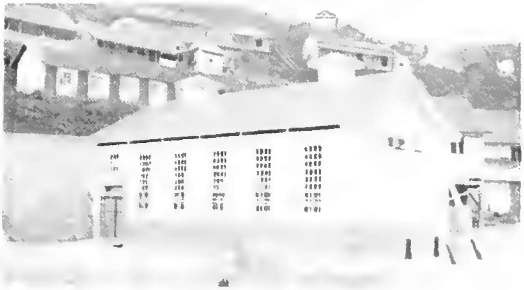

Fig. 13. The San Juancito Power House; one of the two hydro-electric power houses for the mines. This operates under a 1355-foot head water-pressure (585 pounds per square inch). Two 350 kv-a. alternators, 660-volt, 3-phase: two 600-h.p. Pelton Water Wheels

The fruits of all this labor of transportation, construction, and operation often surprises the travelers as they pass the pack-trains from the mines to the coast loaded with bars of gold and silver weighing 125 lb. each, two on the pack saddle of each mule. Every month, from $80,000 to $100,000 worth of bars are sent to the Pacific seaport by the same cart road over which the machinery entered. Only one native with five or six barefooted soldiers are needed to guard the bullion, because the bars are so heavy and the trails are so bad that thieves would find it difficult work to get away with their plunder. Thus the profits of the work are guarded by the largest obstacle to their acquirement, viz., poor methods of transportation.

Honduras has not had a revolution in two years and a railroad will be built into the interior of the country by an English company very soon, so the republic still has hopes for improvement.

Fig. 14. The Arrival of a Pack Train

# A REVIEW OF THE NATIONAL ELECTRIC LIGHT ASSOCIATION'S LAMP COMMITTEE REPORT

By G. F. Morrison

Manager of Works, Edison Lamp Works, General Electric Company

The author shows the growth of the incandescent lamp business in America and the astonishing way in which the tungsten or "Mazda" lamp has superseded the carbon lamp. The average candle-power and watts per lamp are shown in tabular form over a period of years and the steady improvement in efficiency for different sizes of lamps are shown in a striking manner. The improvements which have led to these increases in efficiency are cited. The subject of free lamp renewals is touched upon. This article should be read with much interest by those of our readers who are connected with the electric lighting industry.—**Editor.**

The Lamp Committee's report, which was read at the recent convention of the National Electric Light Association, because of its historical data and comprehensive review of the present situation, was undoubtedly the most interesting report on this subject yet rendered at conventions of this Association.

The manufacture and sale of incandescent lamps have grown to such proportions, and changes have taken place so rapidly that a review of this report will be of vital interest to all persons concerned in electrical development.

The aggregate sales of domestic incandescent lamps, exclusive of miniature lamps, for 1913, was slightly in excess of 100,000,000 lamps. This is an increase of 59 per cent over the total sales for 1907; 20.09 per cent for 1909; 12.40 per cent for 1910; 8.5 per cent for 1911; 5.87 per cent for 1912 and 11 per cent for the year 1913, which latter year shows, therefore, a marked increase in percentage over the two preceding years.

During 1913 the changes in the relative demands for the various classes (carbon, gem, tantalum and mazda) have been most pronounced. The tantalum lamp, for example, has practically gone out of existence. Fig. 1, curves showing yearly sales of domestic incandescent lamps, 1907-1913, is interesting in that it shows that the sale of carbon lamps today is less than 11 per cent of the total lamp business.

The Gem or metallized filament lamp has fallen off slightly in the past year in percentage, probably due to the fact that the Gem lamp was pushed so aggressively by lighting companies in place of the carbon the year before.

The increase in Mazda lamp business during 1913 has been very marked, approximately 60 per cent; the consumption of this lamp exceeding that of all other lamps combined.

In connection with the demand for the different lamps, it is interesting to note the slight change from year to year in the average watts per lamp and the radical increase in the average candle-power per lamp sold. This is brought out clearly in Table I, and is important in emphasizing the increase in the illumination obtained by the use of the Mazda lamp.

Analyzing the sale of Mazda lamps by sizes, it is interesting to note that the 25 watt embraces 29 per cent of the total Mazda lamp business; the 40 watt, 27 per cent and the 60 watt amounts to 15 per cent. In street series lamps we find that the 60 candle-power lamp is the most popular.

The ability of the manufacturer to turn out lamps accurately to a predetermined voltage and efficiency due to the improved methods brought about by drawn wire of exact sizes, makes important the introducing of lamps of the proper size and correct voltage on the lines on which they are to be operated, especially so in view of the rapid increase in the efficiency of Mazda lamps.

There can be no economy and there is an actual loss to the consumer and to the central station company in operating lamps under the voltage for which they are intended and a reasonable amount of attention to securing lamps of proper voltage for the circuits on which they are to be operated will conserve the interests of member companies and improve the service rendered to customers.

It can easily be determined, theoretically, that the total cost of a given amount of light is greater at any efficiency poorer than that of the manufacturer's rating. In fact, the table on this subject given in the report showed that efficiencies even higher than manufacturer's rating are justified from a theoretical cost, but that the manufacturer's selection of efficiency is such as to also give convenient commercial lives. At the same time, it is determined from these tables that when lamps are used whose labeled voltage corresponds to the actual voltage of the socket a higher wattage is consumed than would be the case if the voltage at the socket were lower than that of the lamp label.

Due to the general improvement in quality and the ability to make Mazda lamps for an exact voltage, a change of no little importance has been the abandonment of the three-voltage label and the substitution of a label bearing a single voltage. The efficiency of lamps at the voltage shown on the label corresponds with the high operating efficiency of the three-voltage label. Marked improvements in general lighting should result from this change by having lamps more uniform and operated at a better efficiency.

During the year the quality of Mazda lamps has been greatly improved in several ways. First, by improving the quality of the tungsten wire the filaments have been made stronger, with the result of delaying the condition of brittleness to a much later period in the life of the lamp; second, an improvement has been made in supporting the filament by changing from heavy rigid supports to light semi-flexible or flexible supports, which flexibility protects the filament throughout its life and makes the lamp much stronger; third, the introduction of chemicals into the lamp to prevent or delay the appearance of blackening and to improve the efficiency at which the lamp operates. This practice has been extended to the 25- and 40-watt lamps, and has been greatly improved in the 60 to 500-watt lamps.

The improvements from time to time in the efficiency at which Mazda lamps will operate and yet maintain the same life, the approximate time of the introduction of the various sizes of lamps and the changes in candle-power per watt are shown in Table II

It is to be noted that these improvements in efficiencies have been obtained without any sacrifice of life, which continues to be maintained on the average at not less than a 1000-hour basis.

Through general exhibits at conventions and electrical shows during the Fall of 1913, and description in the GENERAL ELECTRIC REVIEW of October and December, 1913, by Dr. Langmuir, attention was called to developments whereby the efficiency of high amperage Mazda lamps could be greatly increased by the introduction of an inert atmosphere into the lamps. Lamps embodying this improvement differ in appearance from the older lamps, in that they are constructed on what is known as the concentrated filament principle, in which the filament is wound in a small spiral. This spiral filament is supported on anchors so that it is gathered into a very small space, and held away from the stem of the lamp in order to protect the stem from the intense heat.

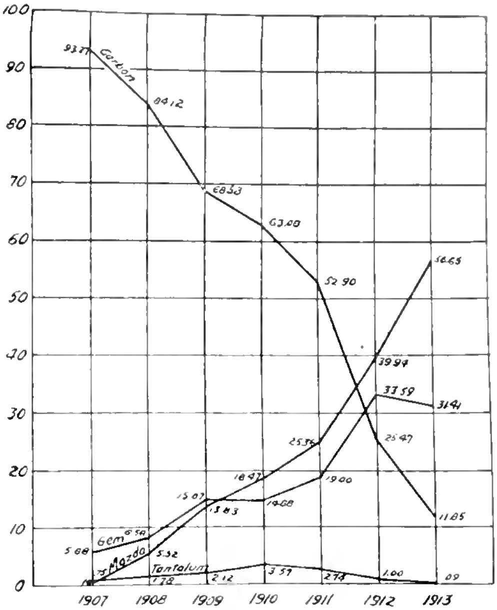

Fig. 1. Curves showing number of lamps of each type, in percentage, in use for years 1907-1913 inclusive

The bulbs used on these lamps are smaller and the shapes may differ somewhat from the bulb shape used on similar wattage vacuum lamps.

The presence of the inert atmosphere in the bulb prevents or delays the volatilization of the filament and any discoloration which takes place is deposited on the upper surface of the bulb, so that it does not interfere with the passage of light through the bulb in the useful zones.

Since May 1, 1913, in addition to the new Mazda lamps referred to, a number of new types and sizes of lamps have been standardized and announced by the manufacturers as additions to their regular schedules and certain types have been removed from the schedule since that time. Tables V and VI indicate these changes.

A number of the larger lighting companies have inaugurated with success during the past year the policy of including within the free renewal list the 100-watt and larger sizes of Mazda lamps. This important step was first

## TABLE I. THE TOTAL CANDLE-POWER AND THE AVERAGE WATTS OF THE TOTAL ANNUAL SALES OF DOMESTIC INCANDESCENT LAMPS, 1907 TO 1913 INCLUSIVE

| | 1907 | 1908 | 1909 | 1910 | 1911 | 1912 | 1913 |

| 35 | 105–130 | Gem | S-19 | 2 3/8 | 5 1/8 |
| 54 | 105–130 | Gem | S-19 | 2 3/8 | 5 1/8 |

taken by some of the companies on August 1, 1913, when Mazda lamps in sizes of 100 watts and larger were included and quite recently, or about May 1st, the free renewal privilege was extended to the 60-watt lamp. It is recommended that lighting companies continue a liberal policy in furnishing lamps of the Mazda type on free renewal basis and extending this privilege to include other sizes as rapidly as reduction in price and the improvement in quality of the lamps may make possible.

The policy of the central-station companies in maintaining a close supervision over the lamp situation is practically unanimous and they are of one opinion as to the advisability of continuing it. This policy aims to maintain a high standard of illumination, and insure satisfactory performance of lamps, both as to amount and color of light and lamp life. This is accomplished by supplying customers with the best lamps on the market, rather than leaving them to obtain them under conditions which would less surely safeguard lamp efficiency and life. This, in turn, protects the legitimate dealer in his lamp transactions with other users of incandescent lamps.

While there is an ever-increasing tendency in the direction of introducing Mazda lamps and the adoption of a broad and liberal policy on the part of the central station, the movement to popularize modern lighting units should be universal throughout the country and this policy should be continued and augmented wherever possible by central station companies to encourage the use and adoption of the Mazda lamp by its customers.

# ICE

By A. R. Smith

Construction Engineering Department, General Electric Company

In several recent issues of the Review there were articles of special interest dealing with mechanical refrigeration and artificial ice. In the present article, the author makes some direct statements concerning the cost of producing artificial ice; both the investment necessary and the actual cost of production are given. The contamination of natural ice is inevitable, while the contamination of artificial ice is either caused by using improper methods or by carelessness. The manufacture of artificial ice, when its advantages are thoroughly recognized, should form a profitable "valley" or off-peak load for central stations.—**Editor.**

A luxury of today becomes a necessity of tomorrow, and conditions which we are content to endure at present are almost unbearable when one becomes accustomed to better conditions. These statements are pertinent to the users of natural ice. It is strange how critical is a community using artificial ice, but the fact is that artificial ice rejected by the customers in the south would be accepted as good quality ice by the patrons of the natural product. Now, why is it that there is so little competition between natural and artificial products in colder climates? Is it the general belief that artificial ice cannot be sold at the same price as natural ice; or, that there is no market for good ice at a slightly increased cost; or, that the initial investment for an ice plant is so great that capital cannot be readily obtained? The writer will attempt to dispel any such views by comparing the quality of ice and the cost of production.

### Selling Price

The fact that artificial ice is being marketed in the south at the same price and in some cases cheaper than natural ice is sold in the north, is very good evidence that competition is feasible in cold climates. As an example, an ice plant manufacturing ice at the rate of 20,000 tons per year and distributing to a trade within a radius of five miles, retails the ice at $8.00 per ton; whereas, in a northern city of 100,000 inhabitants, a company harvesting approximately 30,000 tons per year and distributing within a radius of two miles, retails it at $12.00 per ton.

It is true that the ice season extends over a longer period in the south, but there is not so great a difference as one might imagine. It is also true that in the south the coal and ice business is frequently combined, and the same help and teams are used all the year round, which condition is not so applicable to northern cities, where the majority of people purchase their winter coal supply in the summer. But the superiority of artificial ice should result in a market the entire year when sold in conjunction with natural ice. And, because of the reduced cost of manufacturing ice under high load factor conditions, it should be possible to make a better price to those who purchase ice at all seasons of the year.

### Investment Costs

For the purpose of comparing the investment costs, let us assume a plant of 120 tons capacity, that is, one capable of producing 120 tons of ice per day, and selling 23,340 tons per year (a load factor of 50 per cent) as shown in Fig. 1, and that the plant is built in connection with a steam turbine generating station and obtains steam therefrom.

The approximate cost of such a plant containing two modern and complete 60-ton equipments housed in a first class fireproof structure would be as follows:

| | |
|---|---|
| Ice machinery consisting of: 18 in. by 28 in. compound Corliss condensing ammonia compressors; ammonia condensers; distilled water reboilers; coolers and storage tanks; ammonia receivers and accumulators; freezing tank, cans and covers; ice dumps and lifts; steam, water and ammonia piping. Installation | $51,400 |
| Steam condensers and auxiliaries consisting of: Surface condensers; circulating pumps and air pumps; piping. Installation | 6,000 |
| Building structures consisting of: 70 ft. by 35 ft. by 30 ft. compressor room; 70 ft. by 70 ft. by 12 ft. tank room; sheet cork insulation around tanks; shelter and basin for ammonia condensers | 14,500 |
| Storage rooms consisting of: Two 300-ton storage rooms; two 60-ton handling rooms; all insulated with sheet cork | 17,500 |
| Land | 3,000 |
| Total | $92,400 |

If capital is skeptical, the storage rooms might be dispensed with temporarily and a cheaper building erected for the plant, thereby reducing the cost to some $72,000.00. Or, if the plant is to generate its own steam, the cost would be approximately $82,000.00.

With interest at 6 per cent, depreciation at 4 per cent, and insurance and taxes at 1½ per cent, the fixed charge cost on $92,400.00 would be $10,600.00 per year.

With an output of 23,340 tons per year, the fixed cost per ton would be 45½ cents. But, if the yearly output could be increased to 29,100 tons, as suggested in Fig. 1, the fixed charge cost would then be 36½ cents per ton.

The investment for a storage house for 23,340 tons of natural ice, allowing 10 per cent shrinkage would be $30,000.00, based on a cheap wooden structure costing 3 cents per cubic foot of contents, or a cost of 14.8 cents per ton with the same rate of interest, depreciation, insurance and taxes.

### Production Costs

Naturally, the greater the output the cheaper the manufacturing cost per ton. Curve shown in Fig. 2 will represent a fair cost; it is not exceptional. For instance, a production of nine tons of ice per ton of coal is figured, whereas, a rate of eleven to one has been attained. Steam is figured at 28 cents per 1000 lb.; water at 10 cents per 1000 gal.; engineers at $4.00 per day, and ice pullers at $2.00 per day. Lubricants, supplies and repairs are also included.

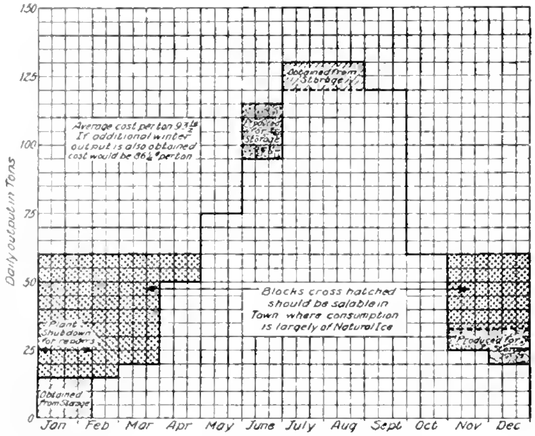

Fig. 1 A Representation of an Average Load Curve for a 120-Ton Ice Plant

Fig. 1 represents what might be termed an average load curve for a city having a six or seven months heating season and which could be handled by a 120-ton plant. It will be observed that the peak during July and August is taken care of by the 600-ton storage capacity and this storage makes possible a complete shut-down during January for repairs, although this is not essential where the apparatus is in duplicate. The average yearly production cost per ton, figured from this and the curve shown in Fig. 2, is 93½ cents.

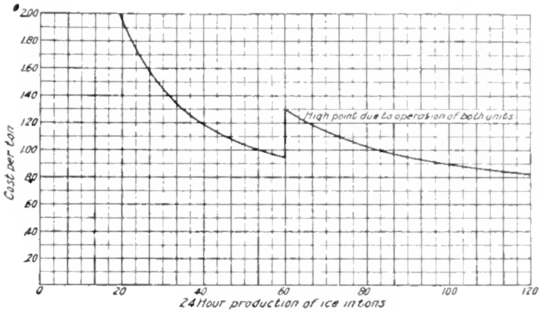

Fig. 2. Curve Showing the Cost per Ton of Ice at Different Rates of Production in a 120-Ton Plant

In a city where the consumption is largely of natural ice, the company could cater to a trade requiring ice in all seasons, and it should not be difficult to improve the load factor as indicated by those sections cross-hatched in Fig. 1. This improved load factor would reduce the cost to 86¼ cents per ton.

There is an expense incident to the harvesting of natural ice and the handling of the ice from the storage to the wagons. Just what this would amount to is rather uncertain, but the writer would hazard a guess of 15 cents per ton. This would not, of course, include the wholesale purchase of part of the quantity, should the winter's crop be insufficient for the trade.

### Total Cost per Ton

| | |
|---|---|
| Artificial ice (23,340 tons output) | |
| Fixed charges | $0.455 |
| Production cost | 0.935 |
| TOTAL | $1.39 |
| Artificial ice (29,100 tons output) | |
| Fixed charges | $0.365 |
| Production cost | 0.8625 |
| TOTAL | $1.2275 |
| Natural ice (any output) | |
| Fixed charges | $0.148 |
| Production cost | 0.15 |
| TOTAL | $0.298 |

From the above it will be noted that if artificial ice is sold at $9.00 per ton and natural ice at $8.00 per ton, the excess cost of the former would be compensated for. Or, if both are sold at \$8.00 per ton, the percentage of the selling price remaining to cover the cost of distribution and profits would be $82\frac{3}{4}$ per cent, $84\frac{1}{2}$ per cent, and 96 per cent respectively. However, the cost of distributing artificial ice should be less than natural ice because the delivery men are not required to cleanse each cake.

Fig. 3. Illustration of a Cake of Artificial Ice Manufactured from Distilled Water.

### Common and Unavoidable Contamination of Natural Ice

Ice is frequently cut from lakes, ponds and streams, the water of which would not be considered suitable for drinking purposes, filtered or unfiltered. This ice may be used in drinking water on the claim that the process of freezing purifies it. Acknowledging that this purification is true under certain conditions, because any visible impurities in artificial ice usually find their way to the core, the last part frozen, there are other considerations which would indicate that impurities can be entrapped. Ice is frequently permeated with particles of coke expelled from passing locomotives; impurities from the air are deposited on top of the ice by falling snow or rain and frozen fast to it; a fracture in the ice often causes the surface to be flooded, carrying with it stream sewage and other impurities, all of which may be entrapped by freezing.

If it is conceded that natural ice should not be used as a direct cooling agent for drinks and edibles, then it loses one of its very important functions. However, it would be quite impractical to legislate against such use and even difficult to evade the use of it personally when eating or drinking in public places. Then there is the straw and dirt which accompanies the ice from the storage and finds its way to the refrigerator of the house, due to the careless washing of the cake by the delivery man.

### Uncommon and Inexcusable Contamination of Artificial Ice

Complaints on artificial ice are not unheard of, and they may be as follows: Salty ice, taste of ammonia, odor in core, presence of oil, presence of iron oxide.

In the can system, the cans are set in a brine consisting usually of common salt water, but sometimes of a solution of calcium chloride. Should a leak develop and the water become salty, it will be detected by its flaky appearance immediately upon the removal of the cake from the can.

Ammonia contamination may occur in the double pipe pre-coolers, or the storage tank. But the former can be entirely dispensed with, with little effect on the cost, and the latter can be absolutely safeguarded by using continuous or welded expansion coils.

The odor in the core which may arise from the presence of oil is entirely eliminated when the water for making ice is obtained from the turbine condensers, as the steam never comes in contact with any lubricating oils. Odor arising from foul boilers is inexcusable if the boilers are properly cleaned and excessive use of boiler compounds avoided.

The presence of rust in the ice can be avoided by using galvanized or tinned piping and utensils for the distilled water, and exercising proper care to prevent oxidation when plant is not in operation, or by using brass piping.

### Treatment of Water for Artificial Ice

Starting with the city drinking water or pure well water, it is first evaporated in the boilers and then, after passing through the turbine, is condensed in a surface condenser. From the condenser it is pumped by means of a centrifugal pump to the reboilers where it is thoroughly boiled to drive off the air and automatically skimmed of any floating material. Thence, it passes through pipe coolers, where contamination from the cooling water can successfully be prevented, to charcoal filters and to the storage tank for filling the cans. In some cases it is again filtered through cheese cloth before entering the cans, but this operation should be unnecessary. The distilling process above mentioned destroys all bacterial life.

### Lasting Qualities of Ice

A quarter to one-third of the natural product is what might be termed "snow ice." This contains usually most of the impurities and melts rapidly because of its spongy nature and consequently more surface exposed to the air. There is no difference in the lasting qualities of the crystal or clear ice, whether produced artificially or by nature.

A good quality of artificial ice contains no air except a slight trace forming the core, thus practically the entire weight represents crystal ice. In fact, cloudy artificial ice which may contain only a thin film of air lines just inside the surface and representing a much better grade than the natural product would be rejected by the trade.

The actual weight of a cake of natural ice is a very uncertain quantity because of the irregular sizes and the loss due to melting in storage and during transportation. A 300-lb. cake of artificial ice ought to weigh from 315 to 320 pounds to provide for shrinkage during delivery; and the weight is determined by setting of the automatic filler. The ice enters the handling room or storage room at approximately the freezing temperature, which should be about 14 deg. F. Both these rooms are refrigerated to a temperature below 32 deg. F. and there is no melting loss or necessity for packing with straw, sawdust or the like. Really, the major portion of the ice is delivered to the wagons at a temperature somewhere between 14 and 30 deg. F., depending on how long it stood in the handling room and how much heat was added to loosen it from the can. Therefore, a certain quantity of heat has to be absorbed by the ice before it reaches melting temperature, a distinct advantage over the natural ice which leaves the storage at just 32 deg. F.

Fig. 4. Another illustration of the cake of ice shown in Fig. 3. The central core which here appears to have considerable width would be only of line width in an edge-on view.

The reader should understand that there are many different and distinct systems of manufacturing ice from raw and distilled water and with and without compressors, and that the foregoing description applies to a comparatively commonplace can system.

# "SAFETY FIRST"

## A FEW INDUSTRIAL EXPERIMENTS ON ACCIDENT PREVENTION SUCCESSFULLY APPLIED AT THE PITTSFIELD WORKS OF THE GENERAL ELECTRIC COMPANY

By Sydney Whitmore Ashe

The following paper is the result of a careful study of the subject of accident prevention extending over a considerable period. It indicates the means taken to analyze this subject, describes the plan followed in reducing certain specific accidents, outlines the method of caring for the injured, gives the educational methods used to carry this work through a large organization and summarizes the results obtained. To give a comprehensive view of this subject various abstracts have been incorporated verbatim in the paper, the author, thinking that they may prove as helpful to others as they have to him in following this work.—Editor.

### Preliminary Study

In systematizing the safety work at the Pittsfield Works of the General Electric Company, a careful study was made of the accidents which occurred over a previous period of several months. To facilitate the study and determine the value of the accident prevention methods instituted, a form was printed and filled out weekly. This form, at a glance, gives the number of accidents which occur and also distinguishes between major and minor accidents. The form also gives data covering welfare trips and medical service which is extended; in fact, it gives at a glance the complete load carried at our emergency hospital each day during the week. In addition to this, a daily record is kept giving the individual detail on the major and minor accidents which occur. A study of this data from week to week revealed the fact that the accidents which occurred seemed to lie in certain groups. These groups consisted mainly of electrical shocks, burned feet in the foundry, eye cases, punch press accidents and strains. Plans were formulated and constructive work begun on each one of these particular groups. After a time, when progress had been made, progress curves, Fig. 1, were plotted for the different departments showing the ratio of accidents to employees. In this way it was possible to detect new fields for endeavor, with the result that in time the rate has been reduced to an extremely low limit.

### Methods Used to Reduce Accidents

There is, at present, a local safety committee, composed of representatives of several departments, the chairman of which is a member of the central safety committee composed of representatives from all of our factories. The purpose of these committees is to meet frequently to talk, standardize guards of various sorts, standardize rules for safety, and issue instructions of all kinds. In addition to the local safety committee, the welfare and educational department publish a works paper. This paper is issued monthly and devotes a large portion of space to safety matters of all kinds. The material is surrounded with interesting notes pertaining to different departments so that the paper will be read regularly by the employees. This paper is given free to every employee. In addition to this, an active educational campaign is carried on continuously, in which the foremen, assistant foremen and employees are drawn together in groups and illustrated talks given them on safety. So soon as any new accident occurs, inspections are made and the cause determined. The manner in which certain classes of accidents have been reduced is described later in detail.

### Electrical Shock

In order to reduce to a minimum cases of electrical shock, a series of meetings were held during which the prone pressure method of resuscitation, as standardized by the National Electric Light Association, was taught. The nurse in charge of the emergency hospital

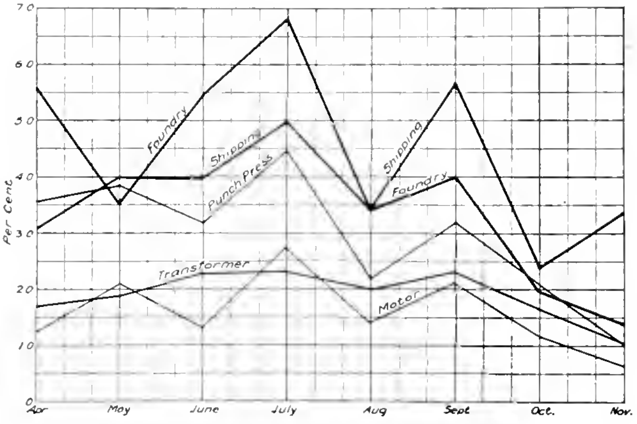

Fig. 1. Progress Curves showing the ratio of accident to employees with regards to time

illustrated the talk with lantern slides, giving the theory of the prone pressure method. This was followed by a demonstration of the method itself. Every three months, a talk is given to the new college men on test, besides giving them a copy of the rules. In this way, every new college man that enters the test is made thoroughly familiar with this method. The foremen and assistant foremen throughout the plant were got together in groups and were likewise instructed in the prone pressure method. From time to time articles describing the method have been printed in the works paper previously referred to.

Five hundred and fifty-volt, two phase current is used for the operation of all machine tools. If we compute the voltages across the outside phases and its maximum value, we find this to be equivalent to about 1093 volts, and in destructive action this is equivalent to about 1500 volts direct current. By calling this fact to the attention of the crane operators, foremen mechanics, carpenters, and electricians, this source of danger has been reduced to a minimum. Calling the danger to the attention of employees and showing them how to resuscitate an individual who has been shocked seems to emphasize the presence of the danger, and keeps the men from getting shocked. In other words, the number of cases of electrical shocks which have occurred during the past year have been reduced considerably, and during this period there have been five cases where the men, receiving voltages up to 15,000 volts, were unconscious and were resuscitated by the prone pressure method by their fellow-employees. One of the most interesting cases was that of a crane man in the foundry, who was resuscitated by a foundry foreman, Mr. Fazakerly, who previous to the shop instructions had been unfamiliar with the method. At the present time there is hardly a shop or an office in which there are not at least three or four men familiar with this method. It is hoped in time, to have every man in the organization trained in the prone pressure method of resuscitation, for it must be remembered that this wonderful, simple and effective method is good not only in cases of electrical shock but also in cases of gas asphyxiation, drowning, and fainting; in fact, in all cases of unconsciousness. In one case it was used by an employee to resuscitate a man who was unconscious from the effects of a fit at a country fair.

Backward Position

Forward Position

Fig. 2. Prone Pressure Method of Resuscitation

An important feature of the prone pressure method is that once an individual has seen a demonstration and has not had occasion to practice it, when the critical situation develops he seems instinctively to know just how to go about doing it. The men are made to feel that the main thing to do with this method is to free the individual, in case of electrical shock, from sources of power and then to begin the method, eliminating as far as possible all lost time. Fig. 2 shows the position of the patient after he has been laid on his stomach, hands stretched over the head and head turned to one side. The second man who appears on the scene removes any articles such as chewing tobacco or false teeth, from the injured's mouth and then places the blanket under him during one of the back strokes of the method. It has been found that the blanket placed under the individual's stomach is quite helpful in increasing the amount of air expelled. Where the prone pressure demonstrations were given to the employees in the foundry, a number of them could not understand the English language. It was necessary, therefore, to demonstrate the method by means of lantern slides and by means of the bell jar experiment showing the action of a cat's lungs. When the demonstration had been completed one of the foundry employees who spoke several languages, addressed the men in several languages. We found as a result of these meetings that the men were intensely interested. In fact, for a time, they carried on meetings of their own during the noon hour. To create additional interest, photographs were taken of the meetings and posted where the men could see them.

Fig. 3. Moulder's Congress Shoe for the Foundry

The use of resuscitation apparatus has been discouraged, owing to its complications of choice of method, time necessary to bring the apparatus to the injured person, and the possibility of having the apparatus used by an inexperienced person. The great factor in resuscitation cases is to "save the seconds" and therefore if every one can be trained in the same system, such as the prone pressure method, and taught to lose no time in using it, it is believed that the greatest efficiency will be reached. The experience at the Pittsfield Works has taught that this is a wise course and by following it, every case, namely five, has been saved since its general introduction. A situation may develop in the future where it will be necessary to modify this practice and supplement it by resuscitation apparatus; but until such a situation develops the present arrangement will be followed. Should occasion arise where it is necessary to use resuscitation methods on a female, instructions have been given the foremen to slit up the waist and corset strings of the injured on the back and apply the method direct to the skin, not standing on any ceremony. In addition to this, individual instruction has been given a number of girls so that they will not lose any time themselves when emergency arises.

### Burned Feet in the Foundry

To reduce foot burns in the foundry, the moulder's shoe, which has been so successfully used by many of our American foundries was introduced. In Fig. 3 it will be seen that this shoe is nothing more than the old fashioned congress shoe. They are arranged so that when metal falls on the toe it will quickly glide off. In case metal should get in the top of the shoe, the shoe can be quickly kicked off. These shoes have some asbestos in the sole, although their principal advantage consists in the point previously mentioned. They are ordinarily sold of a good quality for $2.00, although the cheaper qualities have been sold for as low as $1.50. These shoes were distributed through a local shoe dealer rather than handled by the Company, the dealer giving the employees the benefit of his discount, selling them for $1.80. Quite a number of them have been introduced in this way. Prior to the use of the moulder's shoe, we have had moulders come into the hospital wearing laced shoes with pieces of metal the size of a dollar burned into their feet, the metal having caught in the laces. There has been some thought of using asbestos leggings in addition to the moulder's shoe, and these are now being tried out. A further factor which has contributed towards the reduction of accidents in our work has been the use of a small ladle for carrying metal. Formerly where a ninety-pound ladle was used, there was a tendency to spill the metal, which explodes as soon as it strikes the ground. By using a smaller ladle, less metal has been spilt.

Last November, one of our deputies, who is a practical foundry man, visited one of the largest foundries in the state. The general manager asked him if he could assist him in securing 100 moulders. He said, "I am in great need of moulders. Right now, I have 30 men off with burned feet." The deputy said to him, "Why don't you stop the burns?" And then explained to him how a number of large companies had adopted the plan of purchasing moulders' congress shoes and selling them to the men at cost. This plan enables the foremen of the foundry to enforce the rule regarding the wearing of congress shoes. The manager said he would try the plan and ordered a large quantity of shoes.

The deputy visited the plant a few days ago, and the manager stated to him that the plan of selling shoes had worked out very successfully. All of the foundry men had purchased shoes, also a large percentage of the other shop men. Since the adoption of the plan the manager stated that the burns in the foundry had been reduced 85 per cent.§

### Goggles

There is probably no safety device that pays for itself with a higher rate of interest than that of the safety goggle. These goggles are purchased by the Company and supplied free to any employee who feels that he is in need of them. They are usually used where there is a possibility of flying particles, such as metal chips, molten metal, saw dust, emery, etc., entering an individual's eye. Where possible, the use of these goggles should be compulsory. In the Pittsfield Foundry, there was formerly a very large percentage of eye cases but since the introduction of these goggles, eye accidents have been reduced to a very low minimum. At the present time at least one eye a month is saved from serious injury in this foundry by the use of these goggles. One of the most interesting cases was that of a foundry employee who refused to wear goggles and was discharged. On coming back later he was re-engaged, conditionally, upon his wearing goggles. In about one week's time he came to his foreman with both glasses completely smashed. Both eyes had been saved. He is now one of our most urgent boosters for the use of the safety goggles. Where acetylene torches are used, colored goggles are employed by men so that their eyesight will not be injured by ultra violet light. In a number of cases employees have taken to wearing goggles on their own initiative after reading some of our published literature in our works paper, or after some of our safety talks.

### Emergency Service

The emergency service for the care of the sick and injured at the Pittsfield Works has been very carefully developed over a period of several years and at the present time it seems to be quite efficient. The emergency hospital, Fig. 4, centrally located, is equipped with two rooms, one being used by male patients and the other by female patients. The female nurse and welfare worker has general charge, following up all accidents, re-dressings and sickness in a thoroughly systematic manner. An ambulance is in readiness for service at any hour of the day or night. The hospital handles only emergency work, as the Works have relations with a local surgical hospital where all cases requiring more than temporary treatment are cared for. Instructions are posted at convenient places about the plant covering care of sickness and accidents, and in every large building the emergency service is supplemented by one or two "first aid jars," shown in Fig. 5. These jars are made of glass, are sanitary, and may be used in emergency for carrying water. They are equipped with liquid soap, bi-chloride solution, spirits of ammonia, small scissors, drinking glass, gauze and bandage. When a person is cut and is bleeding, the contents of these jars are to be used to bind up the wound so that the patient can come to the emergency hospital. In all cases where a bandage is

Female Ward

Fig. 4. Interior of Emergency Hospital

---

§ R. W. Price of the Wisconsin Industrial Commission.

placed on the individual they must report to the hospital, where the wound is re-dressed in a thoroughly sanitary way. In this manner it is possible to keep down cases of infection, and out of a thousand cases that may be treated at the hospital it is seldom that one case of infection develops subsequently. There are cases, however, in which an individual will refrain from coming to the hospital for two or three days, sometimes a couple of weeks after the wound has occurred, and in this manner an occasional infected case comes up. It requires constant following up to see that the foremen report all cases as soon as they occur. Some men seem to have a dread of going to a hospital of any kind, but it is found that by giving safety talks among these men, and by having our female nurse participate in the demonstration, greater confidence is developed on the part of the men and there is less reluctance on their part to go to the hospital. If at any time an accident should occur when our emergency service from the hospital could not respond promptly enough, there are all the materials in these first aid jars to make a good sanitary dressing. Thisjar was modeled after the First Aid jar developed by the Norton Emery Wheel Company, except that our jar is a little larger.

Fig. 5. First Aid Jars

### Ruptures

One of the most difficult things to control in a large organization is cases of rupture. Quite recently we have had called to our attention, through a little investigation, the fact that a very large percentage of the employees working in ordinary occupations are ruptured from early birth. It has been suggested therefore, that to detect these cases it would be wise to submit all new employees to a complete medical and physical examination. Some companies are now doing this with very successful results. When it is determined that an individual already has a rupture, it is possible to locate that individual in such a place that he will not have to do heavy lifting.

### Miscellaneous Accidents

There are a large number of miscellaneous accidents which occur from time to time in a large manufacturing organization, and the only way in which such accidents can be avoided is to make a continual study of them and call the possibilities of their recurrence to the attention of the employees by educational means. At Pittsfield, this is done by means of lantern slide lectures and the works paper. Some of these accidents, such as those caused by protruding nails through boards, falls from scaffolding, dropping of tools off cranes, improper packing of boxes or apparatus in freight cars, unguarded manholes, unguarded machinery, emery wheels, saws, and numerous things of a similar nature, can only be avoided by developing in the men the habit of caution. From the manufacturing standpoint this is also a particularly good thing to do, for if men get in the habit of being careful of themselves and their fellow-employees to such a point that it forms a habit with them, they will be careful in the manufacture of the apparatus they are working on. Safety, for instance, in transformer manufacture, which forms 50 per cent of the work carried on at the Pittsfield Works, is paramount, and occasional safety notices in the works paper have done much towards cutting down accidents and

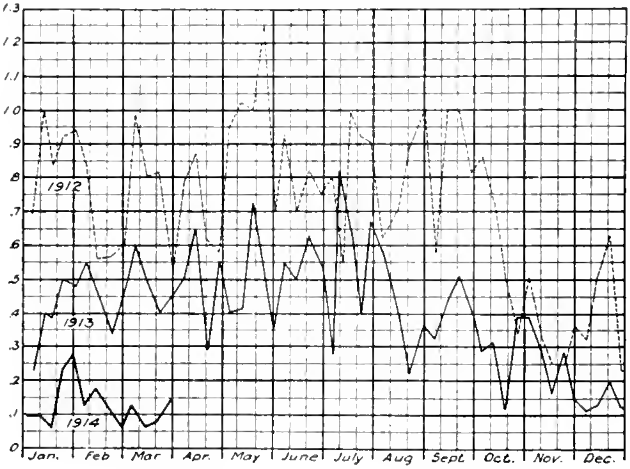

Fig. 6. Curves Showing Progress in Accident Reduction

improving the quality of the goods manufactured.

### Results

The general progress in accident reduction at the Pittsfield Works of the General Electric Company is shown in the ratio curves for 1912, 1913 and 1914, Fig. 6. These curves are plotted in terms of certain accident ratios and the week in the month. The ratio of the number of accidents per week over the average number of employees is used as one ordinate and the week of the month is used as the other ordinate. The progress which is shown in this ratio curve naturally does not make any allowance for variation in production. In times of heavy production where everything is being hurried in the desire to get the product out and make prompt shipment, when the men are tired from working long hours on shifts, the tendency to accidents is naturally greater than when under normal conditions of operation.

Whenever a safety device saves a bad accident, photographs are taken which are useful in many ways. Fig. 7 shows a broken emery wheel, in which the hood no doubt saved a man's life as he was standing directly in front of the wheel when it broke. Fig. 8 shows a pair of pliers used to place materials between the jaws of a punch press. The press repeated and caught the pliers instead of the man's hand, saving several fingers. In addition to safety work, considerable study is made of tuberculosis with a view of detecting all possible incipient cases. The results in this work have been very successful.

Fig. 7. Broken Emery Wheel. The workman was protected by the guard when the wheel exploded

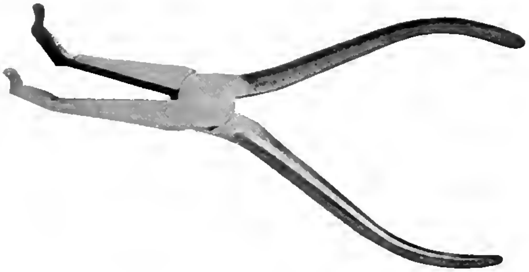

Fig. 8 Pliers Caught in Punch Press. The use of these saves many fingers

### Enthusiasm, Persistency, Co-operative Effort

The quotation, "Remember, gentlemen, what the poet said, that all great movements in the annals of the world are the triumph of enthusiasm, and be enthusiastic safety men," comes near hitting the nail on the head as an effective way of carrying on a successful safety campaign. The American people when stirred seem to have enormous inertia for accomplishment. As a race we are strongly susceptible to appeal, if the appeal is properly made. It is surprising to see how little discipline is really necessary to institute safety measures, and while we occasionally find a man who has to be forced to wear a pair of goggles or to use a pair of pliers under the jaws of a punch press, still as a usual thing the percentage of cases where this is necessary is quite small. It is necessary, however, to be persistent in calling attention to safety measures so as to develop in an individual habits of caution. The method which is used to do this should be occasionally changed. For instance, a series of illustrated lectures and demonstrations can be given the men, followed by occasional articles in a company paper. Inspections can be made and suggestions offered. Co-operative effort, after all, is the key note of success. How to secure the co-operation of the management, the department heads, the foremen, and last but not least the men themselves is the all important problem. In doing this a works paper can be of great assistance as an organ for disseminating information, reaching everywhere, creating good will and in a general way tying the various activities together.

# FROM THE CONSULTING ENGINEERING DEPARTMENT OF THE GENERAL ELECTRIC COMPANY

## A MULTI-RECORDER INSTALLATION

A multi-recorder has been installed and is in operation in the power house of the Schenectady works of the General Electric Company. This recording machine, which has been developed by the Consulting Engineering Department's Laboratory, is designed to automatically print a record of switching operations. Its use has been extended so that by means of auxiliary devices it will record normal, excess, or low potential on a high-tension line; excess currents, short circuits, or grounds; the presence and duration of high-frequency surges; the approach of a storm; the charging and discharging of lightning arresters, etc.

A full description of the multi-recorder is given in the, 1912, A.I.E.E. proceedings (page 825: "Human Accuracy; Multi-Recorder for Lightning Phenomena and Switching" by E. E. F. Creighton, H. E. Nichols and P. E. Hosegood). Dr. C. P. Steinmetz in the March, 1914, proceedings has given some applications of this machine, in an article entitled "Recording Devices." It is the purpose of these notes to describe briefly the recorder as installed in the power station named above and to show how to read its record.

The multi-recorder comprises, essentially, a time stamp and a row of type bars, all electromagnetically controlled. The type bar has two symbols, a dash (—) and a number (from 1 to 50). Each number is arbitrarily assigned to a switch. When the record shows the number, the switch is closed; when the dash is printed in place of the numeral, the switch is open.

The time stamp is operated by a solenoid controlled by a seconds clock. It does not print every second, thus uselessly running out large quantities of paper, but prints only when a switching operation has occurred. The paper moves forward only when a record has been printed. In this respect its action is similar to that of a typewriter.

The multi-recorder prints to the second, but if the operations occur at more than a quarter of a second apart their relative occurrence will be shown by separate successive records printed during the same second. If several operations occur within the same quarter of a second, their record will be printed simultaneously.

Any cross line on a multi-recorder record shows the position of every switch at the second printed at the left-hand side. To see what has just occurred, this line is compared with the line immediately below it, the changes from numeral to dash or vice versa immediately indicate the operation.

The multi-recorder installation in the General Electric power station is a very small one, only thirty-three recording points being used at present. Twenty-two of them are connected to oil switches. Electrical connection is made to the magnets controlling these points by means of cheap auxiliary contacts, mechanically attached to the switch framework. By properly placing these auxiliary contacts, the recorder can be made to print whenever the moving parts of the switch are at any given position. The position generally chosen is that just at the point of entry of the oil switch contact into its finger. The auxiliary contacts are mechanically, but not electrically, attached to the switch.

Three points are connected to high-frequency relays. These relays are connected to the Schaghticoke lines Nos. 1 and 2 on the lightning-arrester side of the horn gaps, and thus give records whenever high-frequency surges greater than a certain magnitude are present. They also record on which line the high frequency is the stronger. During a recent arcing-ground, a high-frequency surge lasting for 31 seconds was recorded.

It is in a case like this, when an arcing-ground or similar line disturbance occurs, that the multi-recorder becomes particularly useful. The high-frequency relays show on which line the arcing-ground occurs, and the electrostatic relay records the lowering of the voltage.

After a little experience an operator can tell the difference between a high-frequency record made during an arcing-ground, and one caused by the gradual breaking down of a coil within a transformer. In the latter case, a series of single surges of high frequency of duration of one second or less will occur, with intervals between successive impulses of several seconds. When an arcing-ground occurs, as has been mentioned, the high frequency maintains for from five to thirty seconds.

In case of a station tied into a transmission system, the electrostatic relays are valuable. When the power has been cut off the tie line because of line trouble, the station operates as well as it can on its own resources. At the instant the line voltage returns, the electrostatic relay contact on the multi-recorder notifies the switchboard operator. No time is lost in telephoning; the multi-recorder can be placed directly under the eyes of the attendant. The device has already been used in this manner since its installation.

The most valuable attribute of the multi-recorder, however, is its obtaining a printed record of the switch conditions of the entire station at any instant. This affords a basis for the analysis of trouble and is a safeguard against useless disputes in the case of an attempt to trace the source of the trouble.

C.F.F.

## VARIABLE-VOLTAGE LABORATORY TRANSFORMER

A variable-voltage transformer recently developed for use in the Consulting Engineering Department Laboratory may prove of interest to others engaged in development work. A standard 20 kw. Type "H" core is used. The primary is wound for 115 volts, two coils being provided to give full excitation when connected in parallel and half excitation when connected in series. The secondary is wound for 1000 volts at full excitation, and a number of taps are brought out. The first 19 coils are arranged to give 50 volts each and the last coil is tapped at every turn, giving 25 two-volt taps. Two switches are provided to make connections to these two sets of taps, so that by proper setting of the dials any voltage from 2 to 1000 can be obtained in 2-volt steps with the primary coils in parallel, and any voltage from 1 to 500 in 1-volt steps with the primary coils in series. Double contacts with resistance between are provided to allow the voltage to be varied without breaking the circuit or damaging the coils which are momentarily short-circuited. Oil immersion is not used as the voltage is low and most of the work done does not call for a long continued full load. The incoming and outgoing connections are made with the standard laboratory jacks and plugs, and the transformer and switches are mounted on an open metal frame carried on heavy castors.

## THE PATHS OF PROGRESS (?)

When we went to press with our last issue the great powers of Europe were at peace one with the other; today Europe is an armed camp and the most powerful military and naval states of the old world are at war. It may well be that before this issue leaves the press the most momentous battle in the world's history, with armies whose very size staggers our imagination, will have been fought—and won—and lost; such is the uncertainty of human events.

This conflict is in very truth *the battle of the nations*, for it is not the armies and the navies alone that are arrayed against one another, but entire nations are fighting directly and indirectly for their political and commercial existence. The results will be of such tremendous importance to the economic and commercial status of all the countries involved, and indeed to all the world in perhaps a somewhat lesser degree, that we need give no excuse or apology for devoting our editorial this month to such an unusual subject. A technical review has no politics, so it is not our purpose to analyze the events that led to this great catastrophe, or trace the blame to any individual nation for substituting for the inestimable blessings of peace, the horrors of war.

It is our prayer and hope that the conflict may be as short as possible and that when it is over it may prove a blessing in disguise by removing the constant dread and probability of war that has overshadowed Europe for more than a decade, and further that it may eventually lead to a curtailment of the enormous expenditure on armaments and thus advance the useful arts.

It may well be that things had reached such a pass that this war was inevitable, the same as some other great events in history, and that the destiny of the empires must still be worked out in this cruel fashion. By those who would have peace at any price it must be remembered that sometimes the price of a prolonged and sound peace is *war*, and we must all be optimists and trust that after this confusion there may be built up a long and honorable peace under which our sciences and industries may flourish even more than in the past.

Science has lent her aid in developing those terrible instruments of destruction which are now to be tested in so tragic a manner, and it is likely that even in this phase of development science has scored a triumph for the benefit of mankind by reducing the time that such a conflict can last and thus avoiding the greatest curse that could fall upon any nation, a prolonged war.

In times of such worldwide disaster courage and faith must play their part in preventing all unnecessary alarms and in sparing any hindrance to peaceful development where such is possible. Especially those countries that are at peace should continue, and where possible stimulate their activities to the utmost limit that prudence will permit. With so many workers called to arms it seems only logical that those who are still able to work and produce should work the harder and be more productive. The fear of the damage that will be sustained by trade is in all probability greater than the actual damage wrought, so it is to be sincerely hoped that the financial heads of industry will temper their fear with courage and stimulate business activities wherever and whenever opportunity may give occasion.

So many great and bloody conflicts have been fought during that gradual process of evolution wherein nations and empires have been made, that it behooves us all, while we are regretting the tragedies of today, to hope and believe that from the present chaos a brighter and more stable future may evolve. The present duty of every individual and every nation alike is to do what little may be in his or its power to minimize the suffering that must inevitably follow and help keep things in general in as normal a condition as possible; and when peace is proclaimed, the duty of us all will be to help repair the damage and see that we still progress along the "Paths of Progress" with as little loss as possible.

# A DESCRIPTION OF SOME AIR BREAK SWITCH TESTS CONDUCTED AT GAINESVILLE, GEORGIA, FOR THE VIRGINIAN POWER COMPANY

By W. P. Hammond

Northern Contracting Company

Air-break switches have been used for a number of years for opening high-voltage circuits. Owing, however, to their characteristic of producing large, long-sustained, flaring arcs when interrupting such circuits, electrical engineers have been reluctant to use them on important lines. Their characteristics require great spacing between adjacent phases for satisfactory isolation and also a comparatively long time for successful circuit interruption. It has therefore been the standard practice to use oil-break switches for practically all important switching operations, since they will successfully confine an electric arc to narrow limits and thus permit a greater concentration of power control apparatus and a more rapid interruption of the circuit. The recent development, however, of the small outdoor substation has opened an extensive field of application for air-break switches. In this case, the low first cost of maintenance and simplicity of operation of the air-break switch make it ideal, since it is only occasionally used for operations equivalent to emergency service.—Editor.

The question as to the feasibility of the use of air break switches for opening heavily loaded circuits has apparently never been definitely settled, much having been said regarding the danger to equipment attending their use as well as the advantages to be derived therefrom. With the idea of obtaining data from which some definite conclusion might be drawn on this question, there was conducted at Gainesville, Ga., during the months of February and March of this year, a series of experiments extending over three or four weeks. The work was carried out under the direction of Mr. C. E. Bennett, Electrical Engineer for Mr. Charles O. Lenz, Chief Engineer of both the Virginian Power Company and Georgia Railway & Power Company, the former concern desiring this information previous to placing an order for a number of switches for use on their transmission system.

The site chosen for the tests is situated about four miles northwest of the City of Gainesville proper, adjacent to the Old Dunlap Power Plant of the Georgia Railway & Power Company and the new high tension lines of this company between Tallulah Falls and Atlanta. The entire output of this station was available for power purposes during the tests, and the high tension lines could be used after twelve o'clock at night to furnish the necessary load. With such ideal location and facilities no expense was spared in making the tests as exhaustive as possible, and the original report contains data on some 275 tests with more than fifty 8 in. by 10 in. photographs and a number of oscillograph records; the instrument for obtaining these records being loaned by the General Electric Company. The several weeks during which the tests were conducted made it possible to note the behavior of the different switches in all kinds of weather. Some of the tests were conducted during a snow storm, some during rain and wind storms, and others in fair weather with practically no wind.

Fig. 1 shows a general view of the switch structure and the manner of connecting up the switches, the incoming leads from the power house being in the extreme right of the picture and the wires connecting with the high tension tower lines immediately above. The switches tested consisted of one LG-9 110,000-volt General Electric switch, and three or four 44,000-volt air break switches of different types. The tests, however, were not regarded as competitive between the different makes of switches, and were conducted mainly for the purpose of determining how different weather conditions affected the operation of air break switches, and the effect on the lines and other equipment resulting from their use.

### 44,000 Volt Switch Tests

Fig. 3 shows a one-line diagram of connections as made for the 44,000-volt switch tests. The power was taken from 550-kw., two-phase, 60-cycle generators in the Dunlap station at 440 volts. This voltage was stepped up to three-phase 50,000 volts through two banks of Scott connected transformers, each bank consisting of two 550-kw. units. There was also available for use in connection with the oscillograph, a spare 50,000 440-volt, 550-kw. transformer which made it possible to take the voltage curve of the oscillograph record from the high tension side of the power transformers. There was placed in the circuit on the power side of the switch, a 50,000-volt 10 to 1 current transformer which was connected to one of the other oscillograph vibrators for recording the current wave. The third vibrator of the instrument was connected to the load side of the switch through suitable potential transformers, but could only be used when that

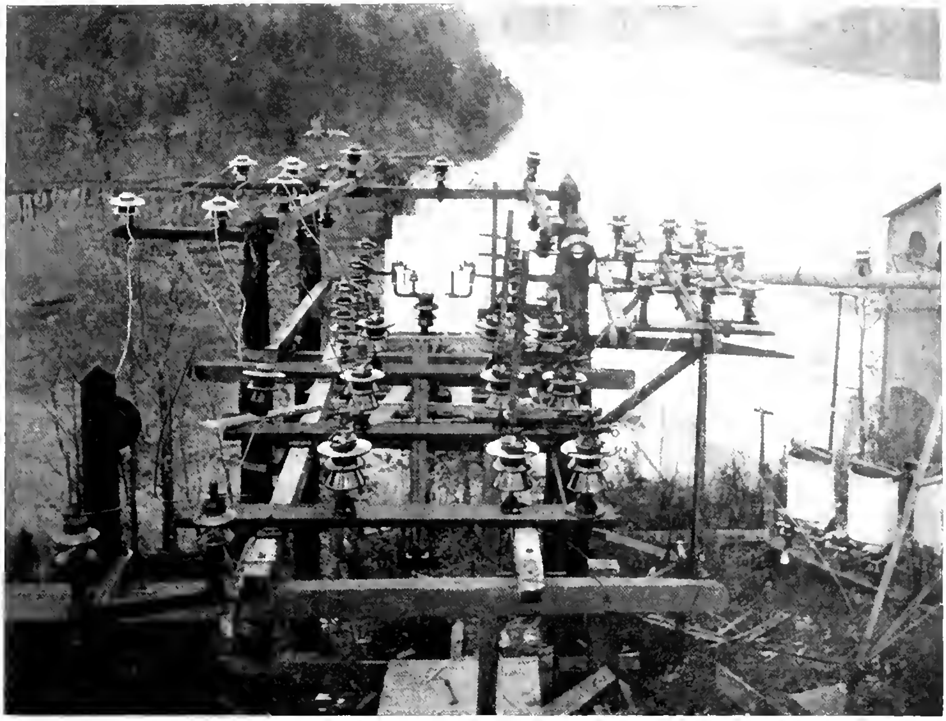

Fig. 1. General View of Switch Structure

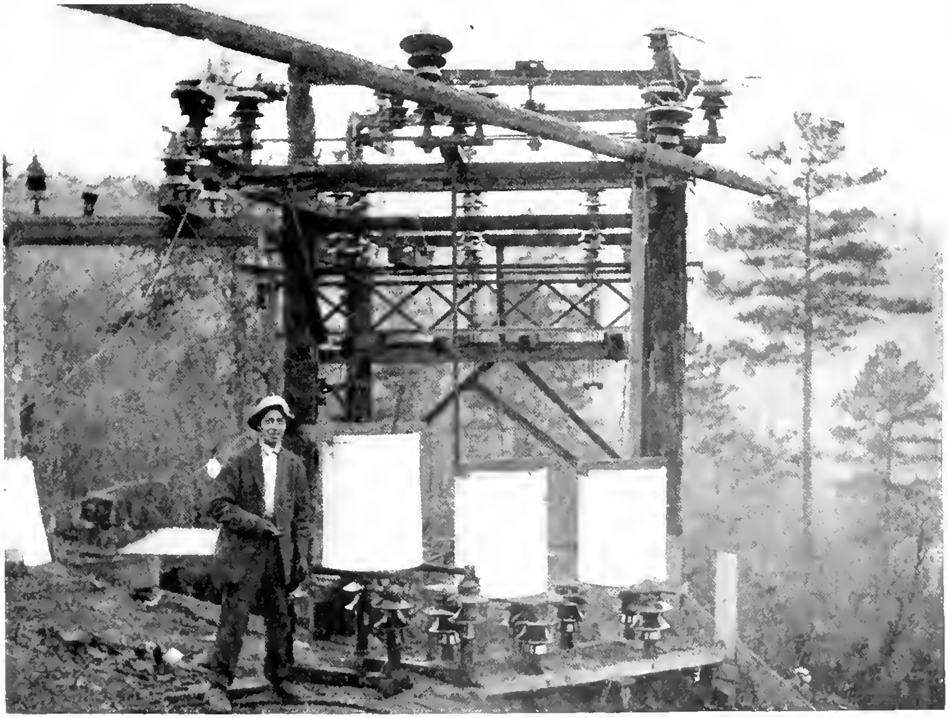

Fig. 2. Water Rheostat

part of the line to which these transformers were connected furnished part of the artificial loading, which was not the case in all of the tests.

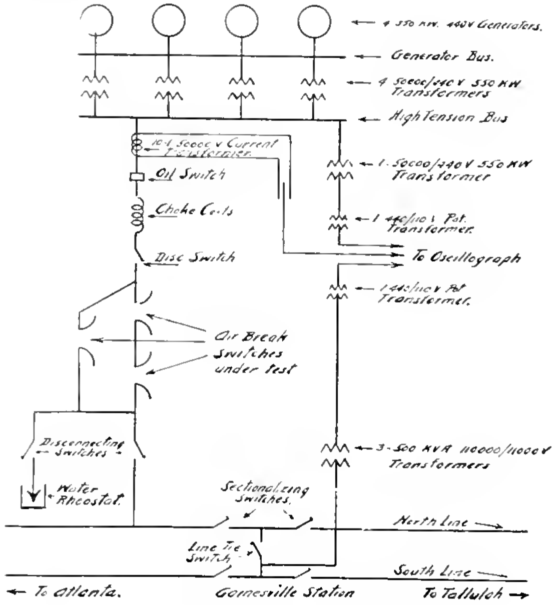

Fig. 3. One-Line Wiring Diagram for 44,000-Volt Switch Tests

As previously stated, the artificial load consisted of the charging current on the high tension lines of the Georgia Railway & Power Company between Tallulah Falls and Atlanta, the tests being conducted after midnight. These lines are constructed of 4/0 stranded copper spaced 9 feet vertically and insulated for 110,000 volts. The distance from Tallulah to Atlanta is approximately 90 miles, the Dunlap station at Gainesville being about midway between. There is a tie switch between the two lines, known as the north and south lines, at this station with sectionalizing switches on both lines on both sides of the station, so that the lines can be easily separated into four different sections right on the grounds where the tests were conducted. Each of these sections of about 45 miles in length furnished approximately 7 amperes charging current at 50,000 volts, making the maximum load with all four sections cut in, 28 amperes, or about 2400-kv-a. of leading power-factor. These four sections, together representing a total of 180 miles, imposed a rather severe load on a 44,000-volt air break switch. It is not often that power is transmitted so great a distance at this voltage, and an air break switch of this rating would probably never be called upon to open a circuit of this length.

A water rheostat was rigged up in the field for furnishing a true energy load, and although rather crude in construction, served the purpose admirably, drawing as high as 50 amperes in some of the tests. See Fig. 2.

In order to get a better check on the voltage surge set up on the load side when opening the circuit with an air break switch, a needle point spark gap was connected between two of the phases, set accurately for different voltages, and the maximum sparking distance noted for each switch under the same load conditions. The same experiment was tried with an oil break switch in the circuit, and the maximum sparking distance recorded when the circuit was opened with this switch was greater than that with the air break switch.

### 110,000-Volt Tests

In Fig. 4 is shown the wiring diagram for connections as made for the 110,000-volt switch tests. The power was taken from one 10,000-kv-a. generator at the Tallulah Falls power house and stepped up through one bank of three 3333-kv-a. transformers delta-Y connected. The switch was connected in the south line at the Gainesville station, as shown in the diagram, and opened under line voltage varying from 65,000 to 120,000, the charging current varying from about 18 to 29 amperes, these readings being taken at the power house. These figures correspond to a kv-a. load of from 2000 to 6000, only half of which was actually interrupted by the switch on account of its location at the mid point of the line.

**Fig. 5. Photographs of Arcs rising from Air Break Switches under Different Conditions**

**Oscillograph Records**

In Fig. 6 is shown one of the oscillograph records obtained while interrupting a load of 3000 kv-a. at 50,000 volts with one of the 44,000-volt switches, the time required to break the arc being three seconds. The upper curve is the voltage curve on the power side of the switch and the lower one the current on the same side. The load was a true energy load obtained by means of the water rheostat.

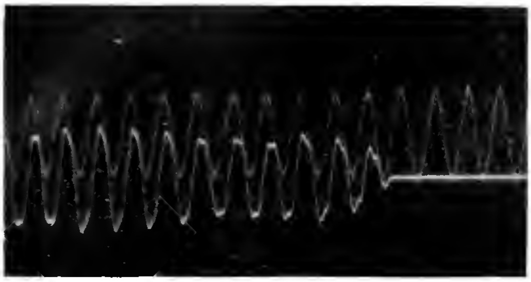

Fig. 6. Oscillogram made at the time of interrupting a 3000-kv-a. Load at 50,000 volts by a 44,000-volt Air-Break Switch

Fig. 7 shows a record obtained while breaking a true energy load of 2500 kv-a. with a different make of air break switch, the time necessary in this case being the same as in the previous one. The upper curve is again the voltage curve on the power side of the switch and the lower one the current.

Fig. 8 shows, for comparison with the foregoing records, a record obtained while interrupting a charging current load of 1720 kv-a. with an oil switch, the voltage and current curves occupying the same relative position as in the records already referred to.

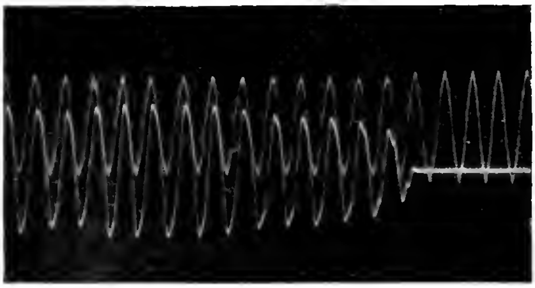

Fig. 7. An Oscillogram made at the time of interrupting an energy load of 2500 kv-a. with an Air-Break Switch

Figs. 9 and 10 are records obtained when opening charging current loads of about 1250 kv-a. with two different makes of air break switches, the upper curve being the voltage, the middle one the current on the power side of the switch, and the bottom one the voltage on the load side.

The remaining cuts shown herewith are actual photographs of the arcs which resulted when opening the circuits under the loads indicated, an explanation of which is hardly necessary.

**General Conclusions**

Complete records were kept of the load and weather conditions of each test, and the actual time in seconds required to break the arc, with a short description of its behavior. The space necessarily forbids the publication of these notes, but several conclusions have been drawn from a careful study of them.

The maximum time necessary in which to interrupt the arc in any of the 50,000-volt tests was 25 seconds and the minimum 2 seconds, the average time for a large number of the tests being 6 seconds. This time period depends more on the weather conditions, especially as regards the velocity of the wind, than the kv-a. load on the lines, this statement being substantiated by the fact that in one series of tests with a certain kv-a. load on the lines, the average time required to break the arcs was much less than the average time in another series under different weather conditions when the kv-a. load was smaller. The average time necessary to interrupt the arcs in the 110,000-volt tests was 7 seconds, the maximum being 16 and the minimum 3.

This means that the air break switch requires anywhere from 120 to 1500 cycles in which to interrupt a circuit, while the oil switch may accomplish this result in half a cycle. This time element in the case of the air break switch produces an effect on the lines similar to a series of light hammer blows, and these blows, although probably not so violent as the one caused by an oil switch,

Fig. 8. An Oscillogram made at the time of interrupting a 1720 kv-a. charging current by an Oil Switch

must nevertheless have a damaging effect on the insulation.

The rating given air break switches by the manufacturers is more or less arbitrary. The spacing adopted, especially as regards the distance between phases, is however, not sufficient, as the lines are easily short circuited by the arcs lapping between the phases. The distance between phases for a 44,000-volt switch should be 6 or 7 feet, and for a 110,000-volt switch certainly not less than 10 feet. The switches tested were spaced 4, 5, 8 and 10 feet, and in many of the tests the arcs lapped between the phases, as shown in some of the photographs. Great care must be exercised in wiring up the switches to prevent the arcs of one phase from lapping the leads to some other phase. In other cases, the arcs are blown directly downwards, and this means that the switch must be properly spaced from the frame or steel structure on which it is mounted to prevent the arcs grounding the lines. The large amount of space necessary for the installation of air break switches because of the foregoing precautions which must be taken is a serious drawback to their use.

It may be safe to advance the opinion that the proper design of an air break switch involves a mechanical movement which will assist in drawing the arcs up the horns, as the heat of the high voltage arcs alone is sufficient to accomplish this only in a very still atmosphere. With the slightest breeze blowing the arcs sometimes hold to one point of the horns for many seconds before exhibiting any tendency to rise. In one of the switches tested, advantage was taken of this point in the mechanical design, and this switch broke the arcs much more readily than the others.

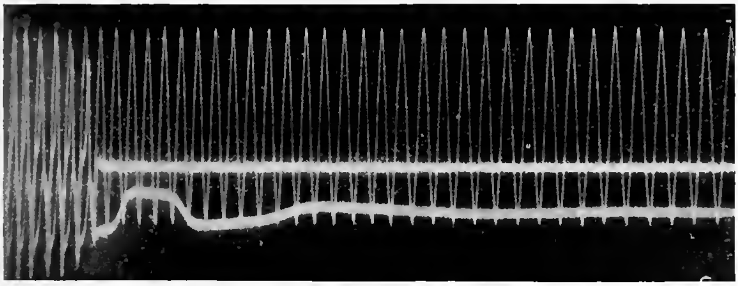

Fig. 9. An Oscillogram made at the time of interrupting a 1250 kv-a. Charging Current by an Air Break Switch

It was found that a true energy current is more easily interrupted than a charging current of the same kv-a. value under the same weather conditions, and that under light loads, high winds materially aid in breaking the arcs, sweeping them from the horns soon after their formation. With heavier loads, or lower winds, however, the arcs lap between phases with the spacing used in these tests before they are blown from the horns.

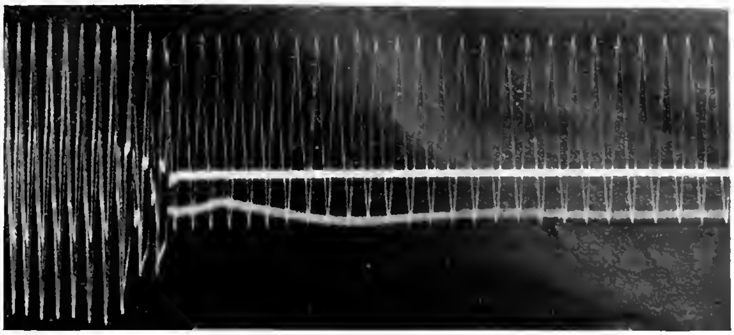

Fig. 10. An Oscillogram made under similar conditions to those prevailing in Fig. 9, except another Air Break Switch was used

The oscillograph records obtained during these tests do not indicate that there is any high frequency set up on the lines by air break switches which is especially dangerous to the equipment. It is possible, however, that the oscillograph does not show such oscillations, and these records cannot be relied upon to establish this fact conclusively. The spark gap test previously referred to in this article would indicate that the surges in the voltage set up by the air break switch are not so violent as those set up by an oil switch, although this statement is not in line with current opinion.

The general conclusion drawn from these tests is that the air break switch will doubtless replace the oil switch for many uses, such as sectionalizing short lines, cutting in and out equipment only occasionally used, for emergency use, etc.; but where frequent switching is necessary and the time element in breaking the circuit of consequence, the air break switch in its present stage of development would hardly prove satisfactory.

# TRAIN HEATING

By Ray Stearns

Railway Equipment Engineering Department, General Electric Company

There are two general types of devices used for train heating: fuel burning heaters and electric heaters. Further subdivision can be made in accordance with the kind of fuel used or with regard to the heat conveying medium employed and its mode of transfer. (In some cases no transfer of heat is made, it being applied directly.) The author of this article discusses these methods of heating with regard to the suitability of each for particular traffic requirements. A large share of the article is then devoted to a detailed description of an actual installation of each of the two most common types of heating devices.—Editor.

Small attention has been paid to the subject of train heating in the discussions of railway electrification; yet, on a basis of energy consumption, the heating problem ranks relatively high in importance when compared with the one of traction. There are many convincing arguments which have led steam road operators to electrify from a traction point of view. The electric locomotive, working at a distance from its source of power, may be shown to out-rank its fuel burning competitor, the steam locomotive. On the other hand, in most cases, the difference in cost between producing the heat electrically and by local combustion of fuels is strongly in favor of the latter.

While there is this relation in cost of producing the heat at a train with electric and fuel heaters, for other reasons of greater importance electric heaters have been adopted in many instances. This article will outline some of the service conditions which must be met in designing train heating apparatus and will point out methods of heating from which certain types of heaters have been selected. Illustrations and diagrams of specific cases will be shown.

Under the heading of train heating we will consider more particularly service conditions where the locomotive must serve both as the tractor and the source of supply for the heating system, the coaches being run on interconnecting steam and electric railways; and conditions where motor cars or coaches are used connected in trains where the heating source may be either local to each car or supplied from a locomotive. The Pennsylvania Railroad heaters on the New York Terminal locomotives are examples of the former case. The Canadian Northern Railway and the Butte, Anaconda & Pacific Railway have heaters illustrating the latter cases.

As pointed out, cost and efficiency are of great importance, yet other features frequently become the deciding factors, as for instance the fire hazard, dust and smoke nuisance with the fuel burning heaters; ease in operating from a point of view of minimum of labor; adaptability to meet conditions of installation and the automatic control of temperature. In the case of electric heaters, voltage affects location and design. General questions of safety to human life are paramount.

The principal problem of design with heating devices is the transmission of the heat through radiation, conduction or convection from the energy transformer to the region to be heated. In meeting railway conditions, the losses in the transformation of the energy, either from fuel or electricity into heat, is very small compared with those of transmission.

Fuel heaters may be gas, oil or coal burning, of which gas should be eliminated in heating trains. Designs vary with the problems of transmission. Electric heaters may be based on generating heat in an electrical conductor with the view of raising the temperature of the entire surroundings and avoiding transmission losses as in the case of the ordinary street car heater with exposed resistance wire. They may be designed with the electrical conductor located at some distance from the region to be heated so that insulating materials are required to confine and direct the heat during transmission. The losses in transmission depend upon the effectiveness of the heat insulating duct. The electric hot-air heater is an example. They may, also, be based on generating heat in a conductor located very remotely from a number of separate regions, the temperature of which is to be raised. An intermediary substance is used in this case to facilitate the transmission of the heat. An example of this is the electric steam unit.

The types of heaters evolved from the above considerations consist chiefly in fuel burners where either hot water, hot air or steam is used in the transmission; electric heaters, using either hot water, hot air or steam; and the direct type where the region to be heated surrounds the heat unit and there is no problem of transmission.

In the case of the fuel burning heaters, the hot air unit and the steam unit have advantages over the hot water unit, since the latter is more troublesome to maintain because of freezing and leakage. The fuel hot-air unit is frequently used on self-contained cars and is one of the most economic ways of heating. The steam unit is adopted where the heating is done from the locomotive and the coaches must be adapted to inter-connecting railway service. A direct unit in the form of a stove is now seldom used.

Where an electric heater is used, the hot water unit is not strongly recommended for reasons of freezing and leakage. The hot water unit may be made up by immersing sheathed wire in a water tank and arranging for a natural circulation of water through pipes. The electric hot-air heater with forced draft is particularly adapted to coaches which operate on an electric zone only. It is safe at all voltages because the unit may be isolated beneath the car floor, or as in the case of a locomotive cab heater, placed in a well grounded iron casing. The transmission of the heat can be done efficiently. The electric steam unit is used when the heater must be installed on the locomotive because of steam-electric operation of trains. Various types of electric steam units have been designed, but the flash boiler takes preference over other types because of the small amount of water heated at one time. This minimizes dangers from escaping steam in case of a damaged boiler. The direct method with resistance units located near the seats is efficient but generally limited to low voltages on account of safety.

Rather than go deeply into the merits of the different schemes, it may be of interest to describe the heaters which have been selected by the Pennsylvania Railroad for their New York Terminal electrification, where the coaches operate in both electric and steam zones, and by the Butte, Anaconda & Pacific Railway and the Canadian Northern Railway, where the coaches operate in an electric zone only.

Fig. 1 shows a type of flash boiler of which twelve have recently been furnished to the Pennsylvania Railroad.

The flash boiler is made up of spiral coils of seamless mild steel tubing, inside diameter 0.494 in., outside diameter 0.675 in. This tubing is connected to the power supply in one continuous circuit to ground and its length is chosen, when thus connected, so as to consume 412 kw. at 650 volts. (See the combined wiring and piping diagram, Fig. 2.) The tubing is divided hydraulically into four sections and so connected that water may be pumped into each of these sections by means of a four cylinder pump. Back pressure at the pump is reduced in this way. When the water, forced by the pump, reaches the tubing, which is heated by the electric circuit, it is evaporated into steam. The amount of water in the tubing is very small at any time. The steam is taken off from each of the four sections and collected in a common pipe for transmission through a thermostat, overflow valve, limiting nozzle, and throttle valve to

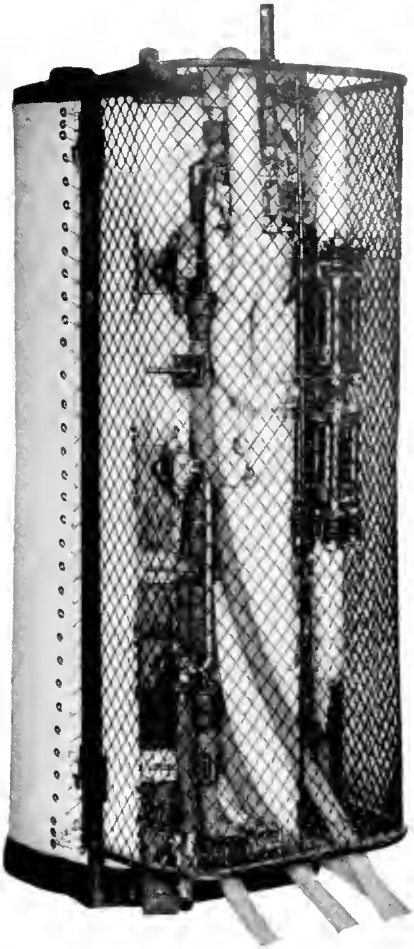

Fig. 1. 412 Kw. Flash Boiler for Train Heating

the steam train line. The boiler absorbing 412 kw. at 650 volts will evaporate water at the rate of 1100 lb. per hour at 100 pounds pressure.

The principal electrical accessory devices consist of the contactors for opening and closing the current supply to the boiler the series motor for driving the pump, which in turn regulates the supply of water to the boiler, and the automatic regulating devices controlling these parts.

The automatic regulation of the boiler must provide for controlling the pressure and temperature of the steam. A governor, similar to those ordinarily used with air compressor systems and protected from overheating by a water column, is used for controlling pressure. By means of this device the electric current and the supply of water to the boiler may be automatically cut off when the pressure rises to a predetermined amount and again supplied when the pressure drops to another predetermined amount. The thermostat which controls the temperature of the steam is designed to displace either of two valves, depending upon its position. These valves control a supply of air from an air reservoir (part of the braking system) to two governors similar to the pressure governor. One of these governors controls the speed of the pump motor and therefore the flow of water, and the other the supply of current to the boiler. By these means the thermostat slows down the pump if the temperature of the steam becomes too low, and cuts off the current with the contactors if the temperature becomes too high.

Relays are provided to protect each section of the heater in case of failure of one of the pump cylinders to properly supply water. These relays function in accordance with the rise in resistance across the different sections of the tubing. The electric circuit is protected with a standard copper ribbon fuse. The steam circuit is provided with a steam gauge for indicating pressure and a safety valve to provide against failures of the automatic equipment. A throttle valve is provided as a cutout when connecting and disconnecting the steam line with the coaches. A limiting nozzle is placed ahead of the throttle valve in the steam line to approximate the generation of steam to the rated capacity of the boiler at 100 lb. pressure. An overflow valve is provided between the limiting nozzle and the boiler for use, as mentioned below, in starting up the boiler.

Referring to Fig. 2, the operation of the boiler is as follows: Water is first pumped

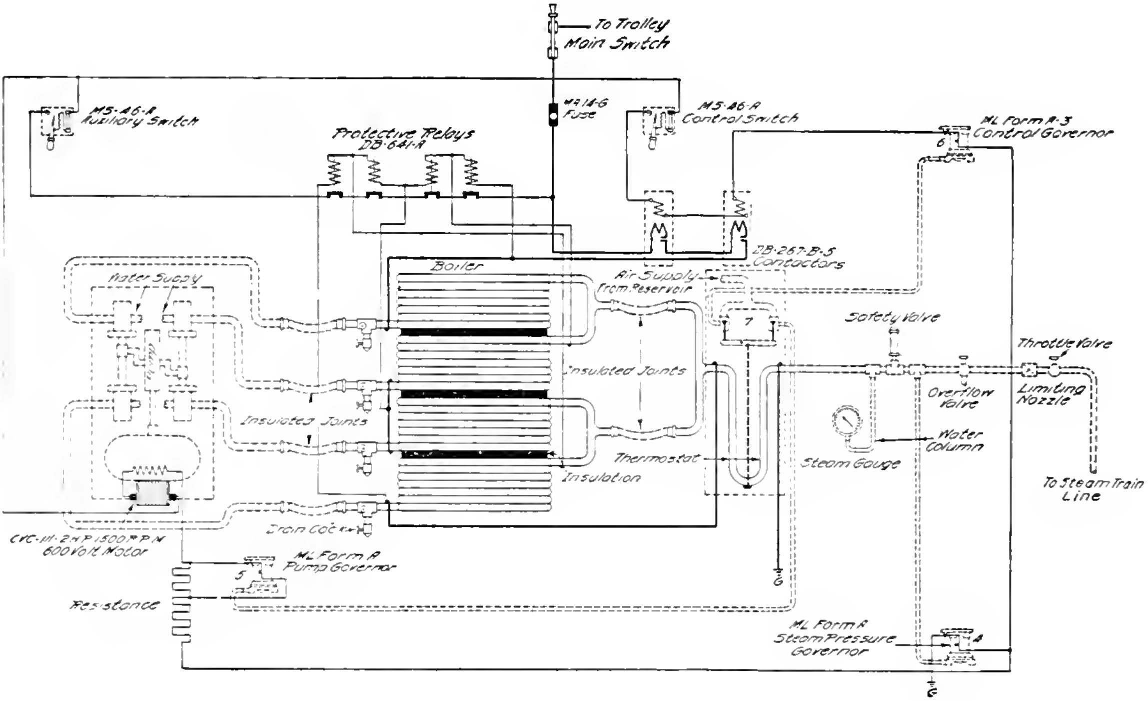

Fig. 2. Connections of Electric Flash Boiler for Train Heating

into the boiler pipes while the latter are disconnected from the electric circuit. This is done by opening the switch in series with the solenoids of the line contactors and closing the main auxiliary switch which controls the power supply to the pump motor. At the same time, the throttle valve in the steam train line is closed and the overflow valve opened. When water appears at the overflow valve, the switch controlling the contactors is closed, causing current to flow in the boiler tubing. When dry steam appears, the throttle valve in the train line is opened and the overflow valve closed.

The steam pressure may then rise to approximately 110 lb., when the steam governor will open, shutting down the pump and opening the circuit feeding current to the boiler. When the pressure drops to 100 lb. this governor will close and the boiler will start generating steam again. If the temperature of the steam rises above a predetermined value as mentioned above, the air valve on the left of the thermostat opens, allowing the air to operate the air governor connected to it. This will in turn open the line contactors, shutting off current to the boiler. When the temperature falls, as a result of this action, this valve will close again and the current will again pass through the boiler. If the temperature continues to drop below a predetermined value, the valve at the right of the thermostat opens, causing air to operate the attached governor, which in turn cuts in resistance in series with the pump motor circuit, slowing down the pump and decreasing the amount of water fed to the boiler. With a rise in temperature, the governor will cut in and the pump will come up to speed again.

It is very essential that clean water be used on account of the pump valves, which are the most sensitive part of the system. Drain cocks connected at the bottom of each section of tubing are provided so that after steam is generated at any time the pipes may be blown out at this point when they require cleaning.

As a result of the experience with a sample boiler on the Pennsylvania Railroad which we have been advised operated equivalent to a year's service, it is not expected that electrolysis will prove a serious factor in the maintenance of the boiler.

The weight of the complete boiler and electrical equipment, not including the water and water tank, is 3500 lb. A supply of 1100 pounds of water per hour, as mentioned above, must be provided for in designing the water tank.

In the case of the Pennsylvania boilers, capacity is not provided for heating the train continuously, since the unit is intended to furnish partial heat either after leaving the New York Terminal, where the train is heated from the station plant, or from the other terminal, where the train is supplied from its steam locomotive. A boiler figured to heat a train to 68 deg. F., during zero weather running 50 miles an hour, must provide for evaporating approximately 200 lb. of water per hour per coach. This provides for heating and losses in transmission, based on the use of steel coaches heat-insulated as much as possible. This figure of course varies considerably with the construction of coaches as practiced on different systems, particularly with regard to the insulation and the ventilation. The figure is given here merely to convey a rough idea of the energy involved in heating a train this way.

Figs. 3 and 4 show the electric hot-air unit furnished the Butte, Anaconda & Pacific Railway for heating their passenger coaches on an all-electric zone. The electrical connections, with a few improvements over those actually furnished, are shown in Fig. 5. The power for the heating unit is taken, in the case of each coach, from a 2400 volt bus line running from the locomotive through the train.

The heater shown in Fig. 5 is divided into three multiple sections, one of which is in series with a series wound fan motor. The two other sections, of different kw. capacity, are used in combination to take care of different weather conditions. The heater, principally because of high voltage, is located beneath the car flooring and air is forced either from the outside atmosphere in mild weather or from the inside of the car in cold weather, through the heater into ducts running the length of the car, with openings at alternate seats. The heater is heavily lagged with heat insulating material, as are also the main ducts, which are located below the floor line. The resistance units are made accessible for removal by dropping the bottom of the heater. A connection box, which may be reached through a hand hole in the bottom cover, is accessible for changes required by radical differences in the weather. The connections for the different weather conditions are indicated on the wiring diagram, Fig. 5.

Generally it may be noted in mild weather that 10 per cent of the total kw. capacity of

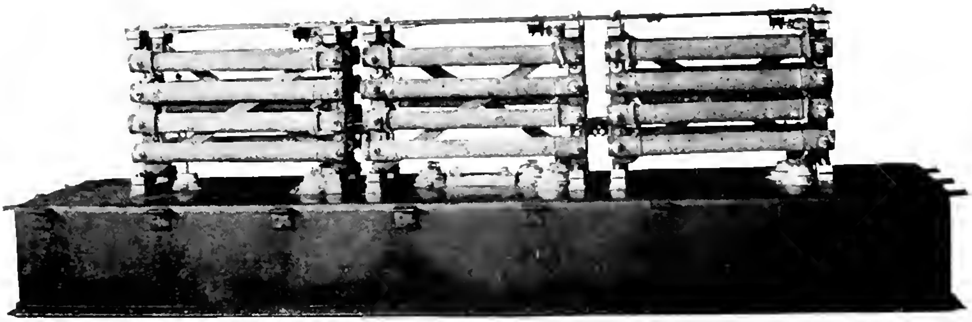

Fig. 3. Electric Hot Air Coach Heater with Cover Removed

the heater is permanently in circuit with the blower. It is thought that under these conditions a certain amount of ventilation will be desired and only a slight amount of heat required. Ordinarily, there is no occasion for running the fan in this service in an electrified zone without some heat in circuit, since the necessity for ventilation results from the car being closed because of a chill in the atmosphere. In summer weather, ventilation without the blower would be provided by opening the windows. With this type of heater it would be very easy, however, to operate the fan independently of the heating unit from the same low voltage circuit which supplies the automatic equipment, and in this way gain ventilation without heat. There does not seem to be many cases where this is necessary, however.

A thermostat, as shown in the wiring diagram, controls, through the means of a contactor, one of the three sections of the heater which represents 50 per cent of the capacity. In case of a sudden change in temperature, which would cause the thermostat to operate, this 50 per cent section is cut in or out of circuit. It is not expected that the thermostat would operate this section, however, in mild weather.

In cold weather, the third section of the heater is connected in multiple with the same circuit which supplies the fan motor section, so that the total permanent heating element, not controlled by the thermostat, is 50 per cent of the total capacity. Then, with 50 per cent permanently connected in circuit for cold weather, the thermostat cuts in and out the remaining 50 per cent.

It is expected that during mild and cold weather the fan motor will operate at the same speed. During zero weather, the third season for which the heater is designed, the

Fig. 5. Connections of 2400 Volt Electric Hot Air Coach Heater

fan speed is reduced by changing the resistance in series with its motor at the connection box. This reduces the ventilating qualities, but increases the heating of the system, to meet this severe service. Furthermore dampers are to be used to take the air from either the inside of the coach or outside atmosphere, depending upon weather conditions.

The wiring is protected close up to the bus line by cartridge fuses which are installed in a grounded iron box. The bus line is located along the roofs of the coaches. The high voltage lead, running from these fuses to the heater, passes through a grounded conduit to the point below the flooring where the heating unit is located. The high tension parts of the wiring are, therefore, isolated in grounded casings, either on the roof or beneath the car. Besides the contactor, which is controlled by the thermostat, there is a second contactor and a disconnecting switch located in the same grounded box. Ordinarily, the heater may be cut out of circuit by means of the switch, giving remote control of the contactors. In case of a heater failure or during inspection the knife blade disconnecting switch is used. As a protection to the heater, in case the fan motor fails, a safety fuse is placed inside of the heater casing, so as to open the circuit leading to the operating coils of the contactors when the temperature in the heater exceeds a predetermined value.

The capacity of this electric hot-air heater is approximately 30 kw. While the information we have available on the subject varies considerably, we estimate that in the case of a wooden car, approximately 70 ft. over buffer plates and 61 ft. over end sills, 30 kw. will give satisfactory heat with this method. This is in zero weather running at as high speeds as 50 miles per hour. At least twice this amount of heat would be required in the case of the average steel coach of the same dimensions to give the same results.

# THE NATURE OF ELECTRICAL DISTURBANCES IN POWER TRANSMISSION WORK

## Part II

By David B. Rushmore and Eric A. Lof

Power and Mining Engineering Department, General Electric Company

The first part of this article appeared in the August issue of the Review, and dealt with the disturbances caused by excessive currents. The present installment, on the other hand, deals with the disturbances caused by high voltages. These are divided into two broad classes: first, that covering those cases of high voltage in which the excess voltage exists between the phase conductors or between the phase conductors and ground; second, that covering those instances of localized high voltage in which the excess potential conditions exist between two points along the same conductor. To the first class belong those disturbances which are caused by poor regulation and resonance. The disturbances caused by switching or lightning may be of such a nature that they may belong to either class. For instance, where the impulses or traveling waves set up are of comparatively low frequency and have a sloping wave front, the disturbance can generally be classed with the former, and where they are of high frequency and have a steep wave front, with the latter.—Editor.

### Excessive Voltages

High voltage disturbances may also be divided in two broad classes. First, that covering actual high voltages in which the excess voltage exists between the phase conductors or between the phase conductors and ground. Second, that covering localized high voltages in which the excessive potential difference exists between two points along the same conductor. In these cases the "conductor" is supposed to include the line wires as well as the generator and transformer windings.

To the first class belong those disturbances which are caused by overspeeds, poor regulation and resonance, while the nature of disturbances caused by switching, arcing grounds, and lightning may be such that they may belong to either class. Where the impulses or traveling waves set up are of comparatively low frequency and consequently of sloping wave front, the disturbance can, however, generally be classed with the former and when of high frequency and steep wave front with the latter.

Excessive over voltages are very apt to occur when waterwheel-driven generators run away, especially if they are provided with direct connected exciters. Actual experience has thus demonstrated that under such conditions the generator and transmission voltages may reach three times their normal value, which of course subjects the apparatus to unreasonable strains. To provide against this, automatic brake equipments are provided or else high voltage cut-out relays which as previously mentioned insert resistances in the exciter fields if the voltage exceeds a certain predetermined value.

In the design of modern long distance transmission lines it is generally the regulation, or the variation in voltage which occurs when the load is thrown on or off, that is the governing factor, rather than the energy loss. Not only may the voltage drop under load be quite large, especially when the load has a low power-factor, but with the high transmission voltages now in use, the capacity effect of the lines becomes very high, which in turn may result in a considerable voltage rise at the substation at light loads. This is now one of the chief arguments against isolated delta connection for long distance high tension lines. It was formerly claimed that such a system could be temporarily operated with one line grounded. Recent experiences on large systems, however, indicate that this is not feasible, as in the event of a ground the charging current, which is a function of the voltage from wire to neutral, will be increased because the neutral is shifted from the center of the delta to one corner. This increase will be about 73 per cent and will of course in turn cause an additional voltage rise at no load, which is not permissible.

The voltage rise caused by the charging current in a long line may cause a breakdown of the air nearest the line conductor and cause corona which may seriously increase the transmission losses. They may also unduly strain other insulations on the system and affect the operation of the lightning arresters, the normal voltage range of which should be kept within reasonable limits for satisfactory operation. On the other hand it is well known how the operation of motors is affected by voltage variations and that the life of lamps is seriously reduced if the voltage is too high, not to speak of the unpleasantness of a variation in the intensity of the illumination, which of course accompanies a fluctuation in the voltage.

From the above it is imperative that the regulation of a modern system be kept within certain permissible limits, and with high voltage systems this is most readily accomplished by installing synchronous condensers with automatic voltage regulators in the substations. As previously stated, the large capacity currents of long distance lines cause a rise of voltage from the generator to receiver at light load, while at full load the lagging current taken by the load will cause a drop of voltage from generator to receiver. It is therefore evident that the voltage may be kept constant or within certain limits at the receiving end, if a synchronous condenser is installed there and its field adjusted so as to make it take a lagging current at no load and a leading current at full load—in the first case to offset the effect of the line capacity and in the second to offset the surplus lagging load current.

The characteristic curves in Figs. 7 and 8 strikingly illustrate the improved regulation which could be obtained on a 130-mile 120,000-volt line by the use of a synchronous condenser.*

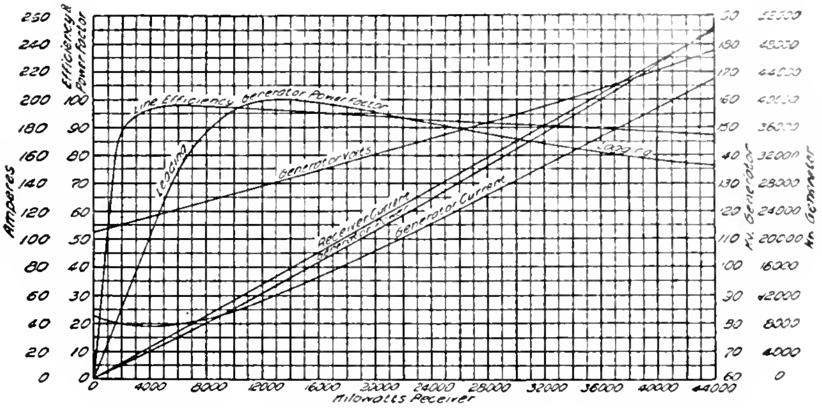

Fig. 7. Transmission Line Characteristic Curves for a receiver voltage of 120 kv. No condenser regulation

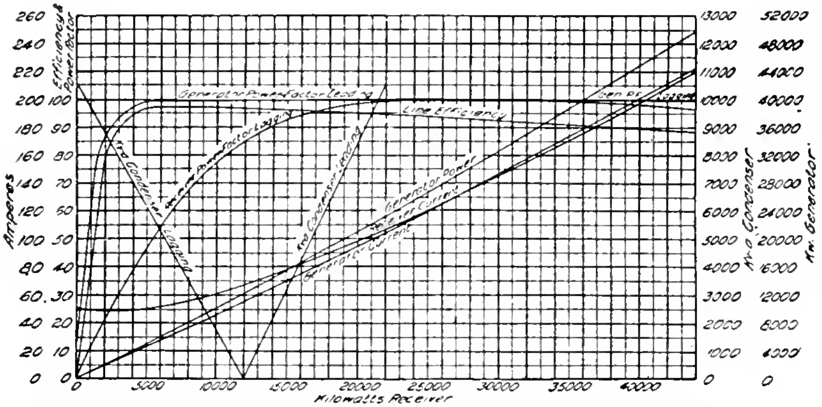

Fig. 8. Transmission Line Curves for a receiver voltage of 120 kv. and a generator voltage of 128.6 kv. Condenser regulation utilized

Resonance must also be guarded against, as it may give rise to large currents which may open the circuit protecting devices and interrupt the service, or the potential may be raised to a value at which the insulation of the system will be broken down. In an electric circuit the inductive reactance and the capacity reactance oppose each other. If of equal value they neutralize each other, in which case the resistance of the circuit limits the value of the current. This may, therefore, reach very high values and when passing through the inductance and capacity the voltage would become very high.

---

* See Practical Calculations of Long Distance Transmission Line Characteristics, GENERAL ELECTRIC REVIEW, June, 1913, and Notes on Selection of Synchronous Condensers, GENERAL ELECTRIC REVIEW, June, 1914.

To illustrate this further; assume a circuit having a resistance of say 50 ohms and a capacity reactance of 1000 ohms; then the total impedance would be equal to $\sqrt{50^2+1000^2} = 1000$ ohms approximately. With 100,000 volts impressed on this circuit the current flow would be $\frac{100,000}{1000} = 100$. If now in addition the circuit contains an inductive reactance of 1000 ohms, it is evident that this entirely neutralizes the capacity reactance and that the current is only limited by the 50-ohm resistance, and in this case would be equal to $\frac{100,000}{50} = 2000$ amperes. With this current flowing the voltage across either the inductance or capacity becomes equal to $2000 \times 1000 = 2,000,000$ volts, which of course, is far beyond destruction.

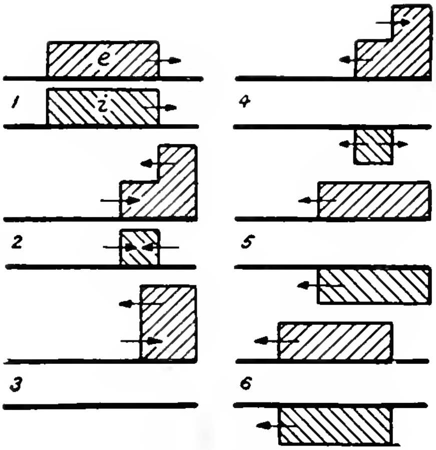

Fig. 9. Reflection of a traveling wave at the open-circuited end of a line

Fortunately the characteristics of transmission systems are such that their inductive reactance is not large enough to neutralize the capacity reactance at the fundamental generator frequency. Since, however, the inductive reactance increases and the capacity reactance decreases proportionally with the frequency, the two reactances come nearer together at high frequencies, such as the high harmonies of the generator wave. These may, therefore, be the cause of resonance rise of voltage between the line capacity and circuit inductance. With modern alternators, however, the higher harmonics are generally so small that there is not much danger from resonance.

Abnormal voltages are also often caused by traveling waves which are set up when the equilibrium of an electric circuit is disturbed. Such disturbances may originate in the circuit itself, as by switching, or they may be due to external causes, such as atmospheric lightning phenomena.

When an electric circuit is connected to a generator or other source of energy, a wave of voltage and current shoots out along the line with a very high velocity and charges the same. If the maximum value of the voltage is $e$ and the maximum value of the current $i$, the wave possesses per unit length an electrostatic energy of $\frac{Ce^2}{2}$ watt seconds and an electro-magnetic energy of $\frac{Li^2}{2}$ watt seconds, $C$ being the capacity in farads and $L$ the inductance in henrys per unit length of the circuit. These two quantities are equal or

$$\frac{Li^2}{2} = \frac{Ce^2}{2}$$

and the relation between the voltage and current at a certain point of the traveling wave is therefore,

$$e = \sqrt{\frac{L}{C}}\, i$$

$\sqrt{\frac{L}{C}}$ is termed the "natural impedance" of the circuit, and is of great value in the study of transient phenomena.

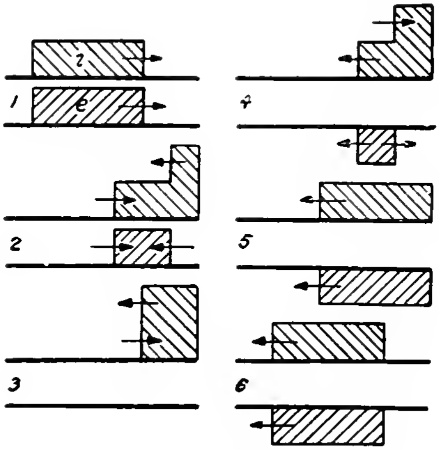

Fig. 10. Reflection of a traveling wave at the short-circuited end of a line

If the line is open-circuited at the farther end, it is obvious that when the wave reaches this point it can not flow any further, but is reflected, the voltage and current of the reflected wave being of the same values as in the original waves, because the energy remains constant. The total current of the incoming and reflected wave must, however, be zero on account of the open-circuited line, and the whole energy is, therefore, stored at this point in the electrostatic field. The reflected current wave must therefore be reserved and its value is —$i$, while the value of the reflected voltage wave at the end of the line where the original and reflected waves overlap is, therefore, equal to $2e$, as shown in Fig. 9.

When the end of the line is short-circuited, however, the conditions are entirely reversed. In that case the voltage at this point must be zero, and all the energy is stored in the electromagnetic field, the value of the total current at the end of the line being equal to $2i$, Fig. 10.

The wave travels twice forth and back over the entire length of the line, after which the conditions return to the same state as at the beginning, Fig. 11. It will, however, continue to oscillate forth and back until damped out by the resistance and leakage of the line, after which it assumes a stationary condition with a charge corresponding to the voltage of the generator.

The wave length is obviously equal to four times the length of the line, and the frequency of the oscillation is,

$$\frac{v}{4l} \text{ or } \frac{1}{4l\sqrt{LC}}$$

where $l$ is the length of the line, and $v$ or $\frac{1}{\sqrt{LC}}$ the velocity at which electric energy travels through a circuit whose inductance and capacity per unit length are $L$ and $C$. This velocity for overhead lines is equal to the velocity of light or 188,000 miles per second.

In the above it was assumed that the end of the line was either open or short-circuited. If a non-inductive resistance, $R$, however, is connected across the end, the voltage of the reflected wave, and thus the total voltage at this point, necessarily depends on the value of this resistance. When $R = \infty$, it naturally resembles an open-circuit, in which case the maximum voltage is equal to double the normal value, while if $R = O$, or negligible, thus resembling a short-circuit, the voltage is zero. With $R = \sqrt{\frac{L}{C}}$ there is no reflected wave at all. If $R > \sqrt{\frac{L}{C}}$ there is a partial reflection with reversal of current, while if $R < \sqrt{\frac{L}{C}}$ there is a partial reflection with reversal of voltage. With an inductive receiving circuit, this acts in the first instant as a resistance of infinite value, and the voltage reaches double value, while a condenser under similar conditions would act as a short-circuit, and the voltage be zero.

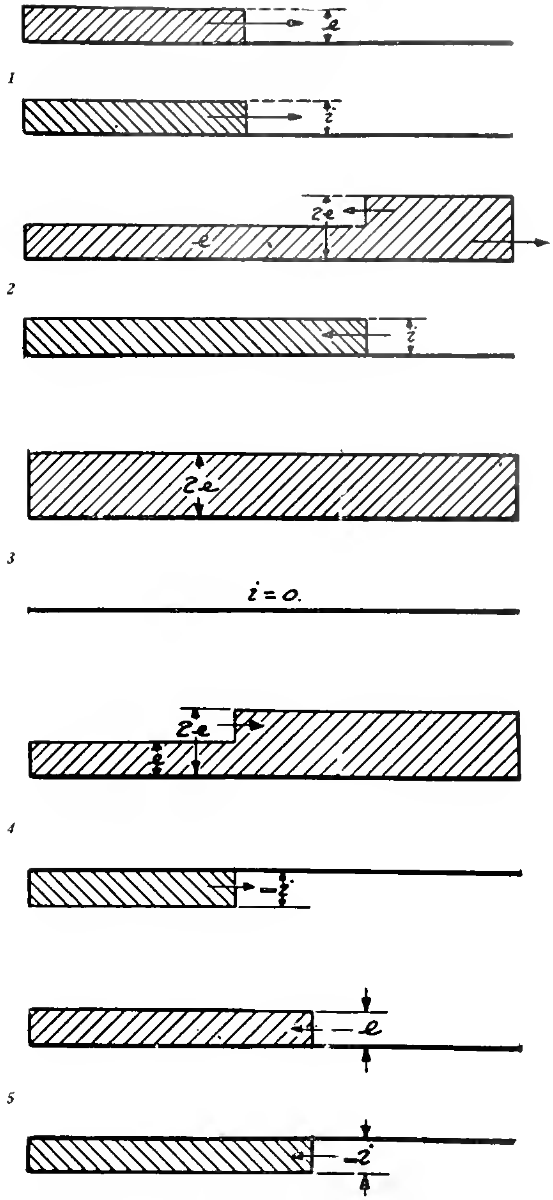

Fig. 11. One complete oscillation of a traveling wave set up when switching in an open circuited line

It is of greatest importance to consider the changes which take place at a transition point between two circuits of different characteristics, when a traveling wave passes from one to the other, such as for example where an underground circuit joins an overhead, or where a transmission line is connected to a transformer.

Assume that a traveling wave with the voltage $e$ and the current $i$ approaches from a circuit having a natural impedance $Z_1 = \sqrt{\frac{L_1}{C_1}}$ and enters a second circuit with a natural impedance of $Z_2 = \sqrt{\frac{L_2}{C_2}}$. Part of the wave will then be reflected and part transmitted. It is also evident that at the transition point the potential will be the sum of the incoming and reflected waves, while the current will be represented by the difference of the two waves since they travel in opposite direction. If we thus denote the voltage and current of the reflected wave by $e_2$ and $i_2$ and of the transmitted wave by $e_1$ and $i_1$, we get the following relations at the transition point:

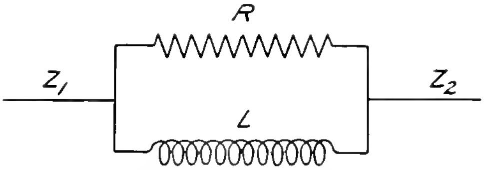

Fig. 12. Protective device, consisting of an inductance shunted by a resistance

$$e + e_2 = e_1$$
$$i - i_2 = i_1$$

but

$$i = \frac{e}{Z_1}$$
$$i_1 = \frac{e_1}{Z_2}$$
$$i_2 = \frac{e_2}{Z_1}$$

The amplitude of the transmitted voltage wave is therefore

$$e_1 = \frac{2Z_2}{Z_1 + Z_2} e$$

and of the reflected voltage wave

$$e_2 = \frac{Z_2 - Z_1}{Z_1 + Z_2} e$$

Similarly we get for the current

$$i_1 = \frac{2Z_2}{Z_1 + Z_2} i$$

and

$$i_2 = \frac{Z_2 - Z_1}{Z_1 + Z_2} i$$

If, therefore, $Z_2$ has a higher value than $Z_1$ it follows that the voltage of the traveling wave is transmitted to the second circuit at an increased amplitude and vice versa. A traveling wave originating in an underground cable will, therefore, enter an overhead circuit with an increase in voltage, while a wave originating in an overhead circuit will pass into a cable system with a lower voltage.

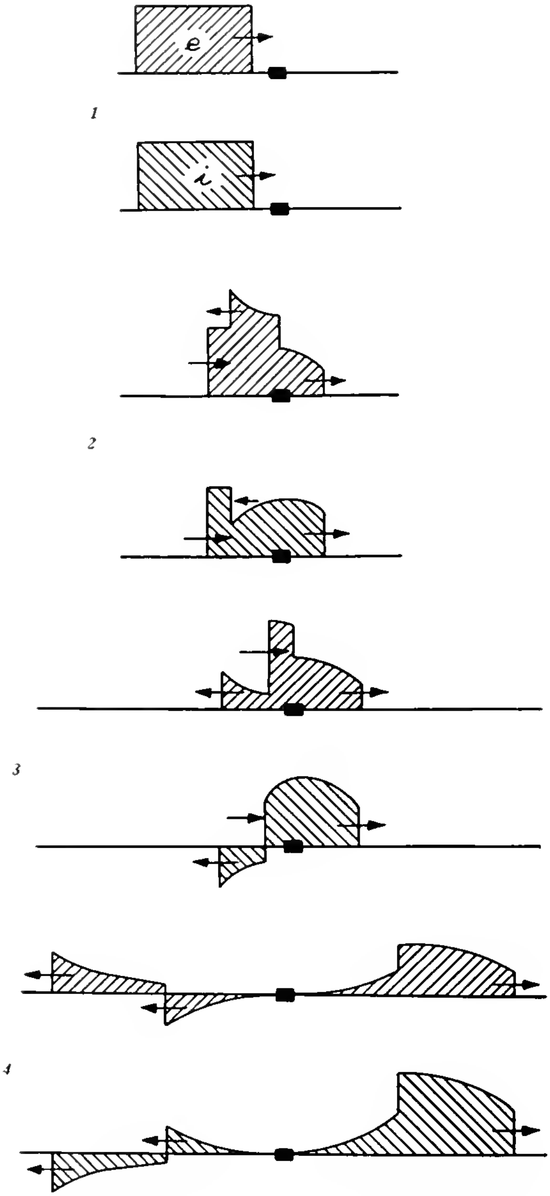

Fig. 13. The reflection and transmission of a traveling wave with concentrated inductance and resistance at the transition point

These relations between the reflected and transmitted waves to the incoming wave are, however, only applicable to cases where the wave in passing the transition point continues its travel in the form of a wave; that is in case we have distributed inductance and capacity on both sides of the transition point. If, on the other hand, resistance, inductance and capacity are concentrated at the transition point, the conditions become entirely different, and it is being suggested that such a scheme should be used for protecting transformers and machinery against the traveling waves entering from the line.

The use of inductance and capacity has been advocated for some time, and both have the properties of changing the wave front of the transmitted wave so that it begins with zero and rises successively. The reflected wave, however, will have a rectangular or steep wave front, similar to the incoming wave.

The energy of the incoming wave is naturally also split up in two parts, corresponding to the transmitted and reflected waves, but there is no reduction in the total energy. This has led to the suggestion by Eino Campo to use a resistance and shunt the same across an inductance, see Fig. 12. In addition to considerably smoothing out the wave front of the transmitted wave, it causes some of the electro-magnetic energy to be dissipated. The inductance forces a wave with steep front to pass through the resistance. This in turn results in a drop in voltage and gives the transmitted wave a lower value than the incoming, while on the other hand part of the energy of the wave is dissipated into heat. The working current, however, passes through the inductance with a negligible drop. Fig. 13 shows how the reflection and transmission of a traveling wave takes place in a particular case with inductance and resistance concentrated at the transition point. The amplitude of the waves as well as their wave fronts are of course dependent on the natural impedances of the circuits on either side of the transition point, as well as on the value of the inductance and resistance concentrated at this point. The calculations are, however, of a rather intricate nature and beyond the scope of this article. It is seen, however, that with a protective device of this kind, both the transmitted and reflected waves have steep fronts although of less height than the original wave. This has led to the suggestion of adding a condenser to Campo's combination, in which case the voltage at the front of both the reflected and transmitted waves would be zero. Both these devices are patented.

The above has dealt with the excess voltages which could occur when a line is connected to a source of energy. Dangerous voltages are, however, also liable to be set up when a loaded or short circuited line is suddenly broken. In this case the voltage rise depends on the value of the interrupted current, and the rapidity with which the circuit is broken, and again on the natural impedance of the circuit.

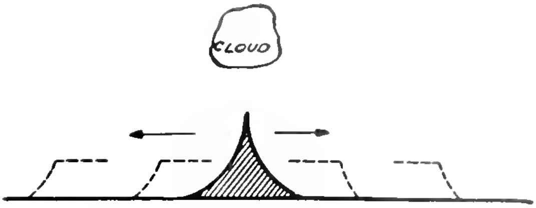

**Fig. 14.** Static charge of a transmission line

It was previously shown that the energy of a circuit was stored in both the magnetic and dielectric fields, corresponding to the current and voltage values. At a certain instant, therefore, the two stored quantities are equal, while if the current is zero all the energy must of course be stored in the dielectric field and vice versa. We thus had:

$$\frac{Li^2}{2} = \frac{Ce^2}{2}$$

and the relation between voltage and current

$$e = \sqrt{\frac{L}{C}}\, i$$

For transmission work the ratio

$$\frac{L}{C} = 138 \log. \frac{D}{r} \text{ ohms}$$

and this value generally falls between 400 and 200 ohms. For transformers, however, it is considerably higher, being around 3000, while an underground cable has a much lower natural impedance than an overhead circuit.

For example if in a circuit having a natural impedance of 400 ohms, a current with a maximum value of 200 amperes is suddenly broken, the surge pressure cannot exceed 200×400=80,000 volts, because this is the maximum value of the voltage wave which is necessary for storing in the dielectric field the whole amount of energy which was previously stored in the electro-magnetic field.

Traveling waves similar to the above are also set up by atmospheric lightning phenomena. The gradual accumulation of static charge on a line from the neighboring atmosphere increases its potential with respect to the earth, which may ultimately become so great as to puncture the insulators. Suppose now that there is a lightning discharge between cloud and cloud or between cloud and ground. This is followed immediately by a redistribution of the electrostatic field, and a general equalization of potential occurs. The static charge so set free moves along the line as an impulse or traveling wave, Fig. 14. Such waves may have a potential many times greater than that caused by switching, and they may have a very steep wave front and thus produce high potential differences between points along the conductor, such as across individual transformer coils or group of coils.

Several forms of protective devices of more or less value have been devised to guard against abnormal voltage conditions. Of these the aluminum cell electrolytic lightning arrester possesses ideal characteristics against such high voltage disturbances, where the excess voltage occurs between the phase conductors or between the phase conductors and ground. The films of the arrester introduce a barrier to the normal potential of the system, but allow the energy of an abnormal disturbance to readily discharge. The arrester is generally used in connection with choke coils, the function of which is to retard and reflect the incoming waves sufficiently to allow the arrester to better perform its duty.

Overhead ground wires are also very generally used to protect transmission lines against excessive static charges, the cost of high voltage lightning arresters making their installation along the line impractical.

The nature of high frequency disturbances is a comparatively recent discovery, and the means and methods for preventing them and protecting against them is still being studied and investigated. The greatest damage caused by such high frequency disturbances has occurred in high voltage transformers, as would naturally be expected. The best protection against them therefore, is, to heavily insulate the individual coil groups, while inductances and energy absorbing devices may, as stated, have to be relied upon for further protection.

---

# NOTES ON THE CORROSION OF CONDENSER TUBES

By E. Bate

Assistant Engineer, New South Wales Government Tramways, Sydney, Australia

While the subject of condenser tube corrosion has received close attention by a few investigators and a moderate degree of attention by many engineers, the complexity of the possible causes of corrosion has prevented the subject from being analyzed so thoroughly that completely satisfactory methods of design and operation may be deduced. A great amount of patience and time is required by the individual investigator. It is the object of the author to present in this article a record of an extensive investigation which he has made and which, in conjunction with quotations from authorities, ought to increase our knowledge of the subject. By a careful reading of this article and a study of the preventive and remedial measures discussed it is hoped that many engineers, who use brackish or salt water in condensers, will find relief from corrosion troubles.—Editor.

The question of condenser-tube corrosion, a problem which has been of very great and anxious interest to power-station engineers for many years, became a matter for special consideration upon the part of the author, as a consequence of troubles experienced at the Ultimo Power House. With a daily load of over 30,000 horse power, and a condenser equipment having a total of 18,000 tubes, it will be realised that occasional outbreaks of corrosion trouble, that threatened at times to develop into a serious epidemic, were the cause of the gravest concern to the management.

In order to avoid confusion with investigations carried out elsewhere, it is proposed to deal with such results as have been obtained by the author, and the theory on which the direction of his work has been based, even though at the present time the case for the author's theories may not be admitted as definitely proved. As much conflicting evidence is forthcoming on this subject, due possibly to unappreciated details, the author proposes to deal simply with his own experience, in the hope that, after due consideration of the same, other engineers may be able to throw further light on the subject by their experience.

Modern condensers of the surface type are very similar in construction. Cooling water is pumped through interior tubes of about ¾ in. diameter, No. 18 gauge in thickness, and from 10 feet upwards in length. Most condensers have the inlet and outlet branches at one end of the condenser, and a water-box at each end, the one at the inlet-outlet end being divided by a horizontal diaphragm.

In the author's experience, condenser tubes have suffered in the following ways, each being a form of corrosion or erosion, as the case may be, and not all necessarily susceptible of the same explanations.

1. The Pit-hole Corrosion.—This is the form of corrosion which has been responsible for nearly all the trouble under the author's notice. It consists of a hole, starting from the water side, and gradually penetrating the metal until a puncture develops and circulating water is admitted to the condensed-steam space. When salt circulating water is used, the condensed steam has to be rejected, forthwith, as unfit for boiler feed; and the tube is of course useless.

2. Some cases have come under my notice of tubes in which the zinc appeared to have completely dissolved away from the interior surface of the tube, leaving a porous and spongy copper residue of no mechanical strength. This form of corrosion is so rare that no opportunity has been given to observe under what conditions it occurs. It seems to be similar to the trouble known as "copper spot," which, however, generally originates from the steam side, and is probably caused by acids in the oily exhaust from reciprocating engines.

Possibly the makers of the tubes could give information that would act as a clue to the explanation why one tube only in a batch of 3,000 should suffer in this way. Conditions inside a condenser must be fairly uniform, so that the peculiarity would seem to exist in the tube as it leaves the maker.

3. There is a considerable tendency for tubes to suffer at the ends where water enters them, and there is a strong tendency for a general loss of metal from the interior surfaces of all tubes at the end remote from inlet-outlet circulating water branches. This seems to be originally an erosion, as distinct from corrosion, aggravated by the high velocities of circulating water demanded by modern designs. The presence of sand or grit in the circulating water would naturally aid this action, and it is significant that erosion is most pronounced at the end remote from inlet-outlet branches, where the stream lines of water flow are likely to be most confused. The remedy would seem to be plain to the engineer, but the question arises as to whether a tube thus eroded tends to corrode at the surface where the skin of metallic oxide has been removed. This can be tested by experiment, and results will be given later.

These three forms of trouble are all of great interest, but the first is of greatest urgency, and will be dealt with almost exclusively in the following notes.

Condenser tubes are commonly made of a brass whose composition is, approximately, 70 per cent copper and 30 per cent zinc. The alloy is cast, drilled, and hard drawn. Almost all the tubes used in the condensers under the author's observation are made to a specification demanding an Admiralty mixture. Four tubes made to this specification were analyzed, and gave the following compositions:

| | PER CENT | | | |
|---|---|---|---|---|
| | No. 1 | No. 2 | No. 3 | No. 4 |
| Cu... | 70.7 | 72.02 | 71.06 | 70.9 |
| Zn...... | 28.65 | 26.65 | 27.05 | 27.24 |
| Sn...... | 0.25 | 0.15 | 0.92 | 1.53 |
| Pb........ | 0.18 | 0.53 | 0.31 | 0.17 |
| Fe..... | 0.07 | 0.35 | 0.37 | 0.06 |

These tubes were all supposed to contain 1 per cent of tin, but, as can be seen, their composition is by no means uniform. Samples Nos. 1 and 4, it may be mentioned, were two out of very few which failed in a certain condenser.

Makers claim that such care and uniformity exists in the practice of tube manufacture, and composition varies so little that the failure of tubes is due to something having no reference to the manufacture. Experience has shown that tubes which last perfectly well in the condensers of one plant may fail rapidly in the condensers of another plant. The converse proposition has also been demonstrated. At the same time, it is undeniable that some tubes will last much longer in a given condenser than others, so that the tube equation is not absolutely negligible.

In the plant under notice, all tubes are of the Admiralty mixture, two condensers having tubes coated inside and out with tin, while the remainder have plain brass tubes, without any tin coating. Since they were first put into service, four years ago, two condensers on the 5000 kw. turbo units have given continuous trouble. These condensers have the tinned tubes of Admiralty mixture. From the first, a considerable amount of work has been carried out in the endeavor to diminish or prevent corrosion. In England, a special research committee, under the direction of G. D. Bengough, has been investigating the subject from a metallurgical point of view for some considerable time, and reports have been published in the technical press, though no very positive results appear to be available as yet.

In a lengthy report, privately prepared by the experts of a leading German company, in 1910, the conclusion is definitely stated that corrosion in condensers is due to two causes only.

(1) Galvanic currents, resulting from a difference of potentials between the different metals in the condenser with sea water as electrolyte.

(2) Stray currents from grounded direct-current systems.

Both are sources of trouble, but are not of the importance in the cases under observation that might be supposed. This report, prepared in the offices of a firm of the very highest repute, seems to emphasize, by its lack of suggestiveness, the necessity for studying the problem at first hand, and neglecting no facts that may be essential to an elucidation of the problem.

The author would suggest that the following possible causes of corrosion be considered:

1. Stray currents from grounded systems.
2. Galvanic currents of general distribution, due to the natural potential difference between the dissimilar metals of which the condenser is constructed.
3. Local galvanic effects, due to some deposit of electrically active material in the tubes.
4. Local galvanic effects, due to the segregation of one metal in an alloy.
5. The use of an alloy which is radically unsuitable to withstand the action of salt water, and which therefore, suffers a general loss of metal.

In addition to these causes, which seem probable, theories have been advanced at various times to account for corrosion, which do not appeal to the engineer as probable, but nevertheless are of interest.

Milton and Larke, in their paper, "The Decay of Metals," Proc. Inst. C.E., Vol. cliv., distinguish carefully between corrosion and decay. Decay is defined as the form of corrosion in which one metal of the alloy is selectively eaten away, as distinguished from the case in which the metal is attacked as a whole. Possibly, these authorities would look upon pit-hole corrosion as a decay, and most certainly "copper-spot" would come within this category. The conclusions of Milton and Larke are as follows:

(1) Decay is more frequent in metals that have a duplex or more complex structure than in those which are comparatively homogeneous.

(2) Decay is due to slower or less energetic action than that causing corrosion. Moreover, it requires an action which removes part only of the constituents of the metal, whereas corrosion removes all the metal attacked.

(3) Both decay and corrosion may result from chemical action alone, or from chemical and electrolytic action combined.

(4) Pitting, or intense local corrosion, is probably often due to local segregation of impurities in the metal, but it may also in some places be due to favorable conditions, furnished by local irregularities, of surface or structure, producing local irregularities in the distribution of galvanic currents.

(5) A percentage of tin in brass, exposed to sea water, is distinctly preservative, while lead and iron are injurious.

(6) To obtain a minimum of corrosion, the internal surfaces of condenser tubes should be as smooth and uniform as possible; and, in order to insure this condition, the cast pipe from which they are drawn should be smoothly bored inside, either before the drawing is commenced or in an early stage of the process.

(7) Experiments with an applied electric current show that electrolytic action alone, even where exceedingly minute currents are employed, may result in severe corrosion or decay.

Most investigators have worked along the lines that, given a suitable alloy, corrosion will be eliminated or greatly reduced. They have experimented in the usual way by suspending pieces of different alloys in salt or fresh water, or in weak acid, and noting the loss of weight in a given time. Such work is undoubtedly very valuable, but the fact always remains that, where one or two condensers in a plant are immune from pit-hole corrosion while others suffer, all using the same kind of tube, purely local conditions must be of much greater importance than the general considerations of alloy suitability.

It is of interest to note the work and theories of Mr. Rhodin (*The Engineer*, July 19th, 26th, and Aug. 2nd, 1907) in connection with the solution of alloys, and they are of special interest to the author since, quite independently, he formulated a theory on an identical basis which gave interesting results. Mr. Rhodin divides alloys into two classes—balanced and unbalanced. From an energy point of view, it would appear reasonable to suppose that an alloy in which both constituents tend to dissolve with the evolution of the same amount of heat would be more stable than one in which the amounts are different for each constituent. Or, looking at the question in the light in which it occurred to the author, assume a copper-zinc alloy, immersed in salt water. The tendency is for oxidation of the metal surface to take place. If the seat of electromotive force of solution is at the surface where oxidation is taking place, particles of the two constituents, infinitesimally close together, will have each a definite solution potential. If these solution potentials balance, then the minimum rate of corrosion is obtained, for if they do not balance, local currents are set up and electrolytic corrosion assists the purely solution or oxidation corrosion. On this theory, and by using the heats of oxidation and molecular weights of copper and zinc, the author arrived at the result that 70 per cent Cu and 30 per cent. Zn is the best alloy of these two metals. Mr. Rhodin assumed that both metals tend to form a chloride initially, and that the weight of metal dissolved will be proportional to the conductivities of the respective metals; and on this basis calculated that a mixture of 61 per cent Cu to 39 per cent Zn was the most stable.

The theory is interesting in that it affords some explanation of the fact, experimentally observed, that corrosion tends to progress at a spot where it has been started by galvanic action, even when the exciting element has been removed. The preceding theory which has been stated quite roughly, appears to the author to be instructive from an electro-chemical point of view, even when pushed to limits. Thus, it is undeniable that perfectly homogeneous metals have very little tendency to lose weight when immersed in an electrolyte, whereas the presence of even slight quantities of impurities is conductive to corrosion. The metals, or pseudo metals, which are least oxidizable are called electro-negative to the more oxidizable metals, such as potassium, sodium, zinc, iron, hydrogen, lead, copper and silver.

The following table of electro-chemical characteristics of the common metals is taken from Prof. S. Thompson's Text Book:

| Substance | Heat of Oxidation of Equivalent | CALCULATED E.M.F. RELATIVE TO | | E.M.F. Observed in Dilute $H_2SO_4$ |
|---|---|---|---|---|
| | | Oxygen | Zinc | |
| Potassium | 69.800 | 3.01 | +1.18 | +1.13 |
| Sodium | 67.800 | 2.91 | +1.09 | |
| Zinc | 42.700 | 1.83 | . . . | |
| Iron | 34.120 | 1.55 | −0.28 | |
| Hydrogen | 34.000 | 1.47 | −0.36 | |
| Lead | 25.100 | 1.12 | −0.71 | −0.54 |
| Copper | 18.760 | 0.80 | −1.08 | −1.047 |
| Silver | 9.000 | 0.39 | −1.44 | . |
| Platinum | 7.500 | 0.33 | −1.50 | −1.53 |
| Carbon | 2.000 | 0.09 | −1.74 | . |
| Oxygen | . . . | . . . | −1.83 | −1.85 |
| Nitric acid | − 6.000 | −0.26 | −2.09 | −1.94 |
| Black oxide of manganese | − 6.500 | −0.29 | −2.12 | −2.23 |
| Peroxide of lead | −12.150 | −0.52 | −2.35 | −2.52 |
| Ozone | −14.800 | −0.63 | −2.46 | −2.64 |
| Permanganic acid | −25.070 | −1.93 | −2.92 | −3.03 |

It is, therefore, quite consistent with the theory of unbalanced alloys that a small segregation of less oxidizable metal in any metallic surface should be the seat of local galvanic action and of corrosion. The segregation is, in such a case, an electronegative segregation and, since the more electro-positive (or more oxidizable) surface immediately surrounding the segregation will continuously dissolve, leaving the electronegative particles undissolved, a corrosion similar to observed pit-hole corrosion could be anticipated. The interesting consideration in connection with the idea of a "balanced" alloy is, however, that by scientifically mixing two metals we may produce an alloy which possesses desirable physical characteristics, and is so proportioned that there is a balance of oxidizability, and therefore a diminished tendency to corrosion.

There is very strong evidence to support the calculation, that the 70 per cent Cu and 30 per cent Zn mixture is stable. Three very prominent station engineers state that a mixture of 70 per cent Cu, 29 per cent Zn, and 1 per cent Sn is the most satisfactory mixture they have used, and this mixture is also favored by the British Admiralty. The function of the 1 per cent Sn is not very well known, but metallurgists insist upon it. It may possibly toughen the alloy by forming the separating film between molecules. Personally, I have observed this alloy to be very satisfactory for condenser tubes, if used as finished from the mill without tinning, but where local conditions are conducive to erosion, an alloy having a tougher surface could be desired, and that question is now receiving considerable attention.

I have observed that there is always a tendency for slow erosion, at the ends of the tubes made from this mixture, in the condensers at Ultimo. Possibly, the comparatively large amount of silt and grit in the circulating water may cause this trouble to be peculiar to that station. It should be understood, however, that while it would be satisfactory to find no traces of erosion, the amount that does take place cannot be considered as of very serious moment.

When confronted with the problem of determining the cause of tube corrosion in two condensers at Ultimo power-house, the possible reasons outlined above were set down and a process of elimination attempted.

A theory was advanced that corrosion might be due to charges of electricity induced in the tubes by the impinging exhaust steam. This theory was investigated by the author, with all the precautions as regards insulation which will suggest themselves to the electrician, but no sign of any change could be detected by the most sensitive instruments available, or by the electroscope.

Dealing with the more probable causes of trouble which have been specified, it has always appeared to the author that it should be possible to determine, by careful observation, to what particular cause any case of trouble can be attributed. For instance, if leakage currents are the source of trouble, this means that currents are finding their way through the circulating water, and are flowing at the places where corrosion occurs, from tube to water. In such a case, we should expect corrosion to occur in patches, and in such a position in the condenser as corresponds to a point where the current is compelled to leave the tube, due to some resistance to its further path through metal. This would naturally be near the tube plate, where, possibly, the contact between tube and tube plate might be poor electrically. If such effects were actually noticed, then careful potential measurements should determine the path of current flow by detecting the differences of potential maintaining the flow.

In a paper before the American Association for the Advancement of Science, June 29th, 1906, at Ithaca, N. Y., Mr. W. W. Churchill discussed the case of condenser trouble due to leakage currents from railroad systems, with special reference to the Bayridge Station of the Brooklyn Edison Co. In this case it was found that rails in the freight yard of the Long Island R.R. were at a potential of 9 volts above the river during peak load. The power-house is situated between the railroad and the river, and conditions were such that the condensers formed part of the path of current flow. Undoubtedly in such a case, there are several elements liable to cause the trouble so frequently experienced in water mains before careful bonding and negative boosting with suitable provision of negative copper was insisted upon. Mr. Churchill installed an arrangement for providing an e.m.f. to counteract this potential with good results. His claim was that, by increasing this counter e.m.f. suitably, the natural potential between the zinc and copper of the alloy composing the tubes was overcome. Corrosion prevented by this means will be dealt with later. The author would suggest that corrosion due to conditions similar to those mentioned would occur in patches, causing widespread weakening of the tube walls and, finally, large irregular holes. Modern condenser tubes are so clean, smooth, and uniform that the claim that slight irregularities of the surface cause the pit-hole phenomena under such conditions seems weak.

The point where current enters the tube should not be a seat of corrosion, and this type of corrosion can therefore, be differentiated in this way from those due to causes (2) or (5). In view of the care taken to provide negative boosters and reduce the potentials of boosting points to within four or five volts of the negative busses in tramway stations, it can confidently be asserted that stray currents are not now a very serious contributing factor to the sum total of condenser-tube corrosion.

General galvanic currents from tubes to water, due to the natural potential difference between the tube metal, the metal of the tube plate, and the metal of the shell, covers and piping (generally cast iron) are possible when the metal of the tube is electro-positive to the other metals. In this fact lies the secret of mistakes often made in considering this question. Generally speaking, the alloy of which tubes are composed is electro-negative to cast iron. Admiralty mixture tubes are most certainly negative to cast iron in sea water, and will, therefore, not be subject to any loss of metal when in contact with cast iron in sea water. On the contrary, it would be expected, and is actually the case, that cast iron covers and water boxes are very strongly attacked and corroded. Here, again, I venture to think that most of the corrosion of cast iron is due, not to the fact that it is in contact with gunmetal in an electrolyte, but to the fact that cast iron is very similar to an "unbalanced" alloy. It contains a percentage of carbon, a strongly electro-negative element (which is a matter of common knowledge because of its use in certain primary cells).

By degrees, during the observation of the phenomena of pit-hole corrosion, the extremely local character of the action was forced under observation, and the conviction grew that some electro-negative material must be responsible for the trouble. The form of failure is just that which could be anticipated from local action due to an electro-negative particle on a surface positive to it. If this is correct, then there seems only two ways in which such a condition can be set up.

1. By segregation in the alloy.
2. By deposit of electro-negative particles on the tube surface.

To determine between these two seemed quite simple, and accordingly great care was taken to have all the faulty tubes removed from the condensers carefully examined.

Before giving particulars of the observations actually made in faulty condenser tubes I wish to point out the extreme importance in the determination of the cause of corrosion of a factor in the action which is not generally thought vital, I mean the question, "How long does it take for a tube, say No. 18 gauge, to become pitted completely through?" The importance of this question can be seen by considering the alternatives named, to which the investigation appears to have been reduced. If segregation in the alloy is the cause of trouble, and if we can definitely say that tubes so affected will corrode, and fail within a certain limit of time, then we should certainly expect all tubes in a condenser to fail within a definite period. It can hardly be that one batch of, say, 30 tubes would fail within three months after being put in service, and that another 30 of the same batch, which, by hypothesis, fail from the same cause, should last three years. It seems impossible that such a discrepancy, or such a wide variation, in corrosion period of tubes whose failure is due to an inherent fault in the metal could exist. But if corrosion is due to some deposit of electro-negative material, and if complete piercing of a tube normally takes place in a short space of time, then it would be reasonable to expect failures to occur just as fast as such deposit takes place and according to the number of tubes so affected. It may be argued that the difference in mass of segregated particles will account for the difference in corrosion period; but, since the segregation must be electro-negative to account for the form of pit-hole, it follows that the mass of the particles will affect only the size of the pit-hole, and not the speed of corrosion, since the electro-negative element is not wasted in such galvanic action, and the wasting of the electro-positive material is governed by the potential between the two elements, which is independent of the size of the element. Engineers whose condensers have suffered from pit-hole corrosion will probably have had a similar experience. Failures start to take place within a month or two after the condenser is put in service, and the average failures per week gradually increase to a steady average rate of failure, with heavy failures now and again. In some cases the trouble may cease after a few months, and the engineer usually concludes that corrosion was due to faulty tubes, which have been eliminated. In several cases I have found that, about the time when failures ceased, some certain treatment of the condensers had been started, which the engineer generally did not connect in any way with the improved conditions. I wish to establish the fact that it is possible to stop failures by methods whose only effect would be to prevent the possible deposit of electro-negative material in the tubes, and, furthermore, to establish the fact that the effect is noticeable very rapidly, which points to the fact that corrosion is a phenomenon whose action is very rapid.

Now turn to another aspect of the discussion of these alternative causes. If corrosion is due to segregation, then it is reasonable to expect that corrosion spots will occur anywhere in a tube. There is no more reason why pit-holes, due to segregation, should be located, say, above the horizontal diametrical plane of the tube surface than below it. But if corrosion is due to a deposit, then, undoubtedly, we can expect with confidence that the majority of holes will be in the lower half of the tube. This anticipation is most strikingly verified as a result of the author's observations. The author's practice has been to have all tubes marked before being withdrawn from the condenser, by making a chisel nick in the tube on the upper end of the vertical diameter at a particular end of the condenser.

Of 468 tubes thus marked and examined, I found that only 21 had a corrosion hole in the upper half of the tube, the remainder were in the lower half. The percentage of failures in the bottom half, being about 96, enormously strengthens the case for the second alternative. In regard to the location of failure holes with reference to the length of the tube, I find that no part can be said to be very much more vulnerable than another. Sometimes a batch will have a decided preference for the center of the tube, sometimes for the ends. The sag of tubes is not sufficient to bring gravity into account in selecting the lowest point of the tube for a location of the action.

This interesting fact, i.e., that corrosion of the tubes under notice took place on the bottom half of the tube, has been corroborated by other engineers whose condensers suffered in the same way, and it became important, since the very strongest grounds were present for suspecting that a dangerous deposit was being left in the tubes, to determine from what source this deposit came.

The author's attention was directed to the corroding cast iron of the circulating system and condensers as a source of troublesome deposit for the following reasons:

1. Although the circulating water brought through the condensers in question is always very dirty, certain condensers taking the same water have been free from trouble.
2. If, therefore, we consider the water at intake in the harbor as free from deleterious material, the troublesome particles must come from the metal in contact with the water on its way to the condenser.
3. Cast iron, unless carefully protected, corrodes severely when exposed to the action of sea water and, as cast iron is a so-called alloy of carbon and iron with traces of other impurities, the products of corrosion will be mainly oxide of iron and carbon. Carbon is, as previously pointed out, strongly electro-negative, and, therefore, of just the nature to cause the trouble experienced.
4. The condensers under particular observation, which gave very serious trouble, were provided with 22 copper stays between tube plate and water box cover at each end, and these copper stays had cast iron sleeves to form distance pieces between tube plates and covers. There were thus 44 cast-iron distance pieces in the water space of the condenser, all of which were found to be badly corroded, especially close to the tube plate, where they were in close contact with the gun-metal surface.

To test this theory, the cast-iron distance pieces were removed, and gun-metal distance pieces substituted, while, at the same time, the cast-iron surfaces in contact with circulating water were all cleaned and painted with a protective coating. It must, however, be understood that the station in question possesses a circulating water system peculiarly liable to produce the trouble which it is required to avoid, for the circulating water is pumped through a distance of, roughly, 300 yards in 36 in. diameter cast iron pipes. To insure that the pipes are not constantly fostering trouble seems impossible. Stations that take circulating water to the condensers, or to the circulating pump intake in concrete or brick ducts, and use either short cast-iron or entirely gun-metal intakes, should therefore not suffer to any appreciable extent from tube corrosion. At the White Bay power-house this policy can be pursued, as the circulating water ducts are entirely of concrete, and the short intake is of gun-metal, the pump body and impeller being of a yellow metal mixture. Inquiries have elicited the information that several plants, which have been free from trouble, have consistently protected their cast iron on general grounds without any idea of thereby preventing the corrosion of condenser tubes.

The measures above outlined were soon productive of marked diminution in the number of tube failures in these condensers, and it can be definitely stated that, up to the present, no tube put in the condensers since the alterations were made has failed. A further trial of the system was rendered possible by the installation, in the same station November last, of an additional condenser, connected to the same pumping plant and containing 3000 tubes, each 15 ft. 3 in. long. This condenser was treated as the above investigation would dictate, and was in no other way specially treated. Up to the present time the condenser has been in continuous service and has not yet suffered a single tube failure. The troublesome condensers, on the contrary, showed tube failures within a few weeks of being put in service.

Another condenser, of somewhat larger surface, and which having been in service for a period of ten months, up to September, 1912, at that date began to show indications that tube trouble might be experienced. This one was taken in hand, forthwith, and treated carefully on the lines suggested by the author's work, with the gratifying result that, to date, the trouble has not reappeared.

It is possible, therefore, to instance four large condensers in one station treated according to this simple process, all of which have given satisfactory results. Additional corroboration should be forthcoming as a result of the operation of the new station at White Bay.

Beside the New South Wales Tramways, I have assurance that in the station of the Adelaide Tramways, which was suffering very severely from tube corrosion, the process was immediately productive of satisfaction.

The report of the Adelaide Tramways Trust Power Station, reads as follows:

"After the power station had been running for nine months without any trouble of this kind, the tubes in all three condensers began to leak, gradually getting worse and worse. The tubes were cleaned periodically, and in November, 1911, all the tubes were thoroughly cleaned and scraped, and all the ferrules were tightened, with the object of improving the contact between ferrule and tube. This, however, had no effect. Zinc plates were hung in the water boxes at both ends of No. 1 condenser in November, 1911. The tubes soon after this began to corrode rapidly, and in February, March, and April, 1912, the electrolytic process was tried on No. 3 condenser. Tubes were hung vertically and horizontally in the intake sump, and also in the Port Adelaide River, adjacent to the Power Station from which the circulating water is taken. All these tubes corroded badly, particularly in the more stagnant water in the sump. In these cases the tubes were suspended by marlin, and no contact whatever with any other metal was possible.

Up to this time none of the attempts which had been made to overcome the corrosion had been successful, and improved results could only be obtained by retubing. In April, 1913 the method of protection employed at Ultimo was tried, and No. 2 condenser was painted inside the water boxes, covers, and pipes with three coats of biturine solution. The result was that corrosion ceased until the paint washed off. No. 3 condenser was treated in a similar manner in the beginning of May, with a similar result. No. 1 condenser, however, was treated in the beginning of May with three coats of Hartmann's Red Hand Anti-corrosive Paint. This lasted three times as long as biturine solution. Whenever an application of paint was made, the trouble immediately ceased, and after a while when the paint washed off, the trouble began again; and it is now only a question of time before the paint is washed off, and corrosion starts again."

The engineer whose plant is suffering from tube corrosion troubles will naturally ask whether, granting the correctness of the theory as to the cause of trouble, it is possible to save tubes which have already started to corrode. It may be that a large number of tubes in a condenser have started to pit, and a saving could be effected by preventing the further corrosion, even if some slight expense were involved. Personally, I am of opinion that local corrosion, once started, can not practically be stopped. It has been proposed and attempted to stop corrosion by the application of electric current to the condenser in such a manner that electrodes in the water space form the anode for the passage of an electric current whose cathode is the tubes. The idea is that, by forcing current into the tubes at all parts of the wetted surface the dissolution of the tube is prevented. For a similar purpose blocks of electro-positive metal are sometimes advised to be suspended in the water space, externally connected to the tube plates, which in turn make metallic contact with the tubes through metallic grummets in the tube packing.

If pit-hole corrosion were a simple matter of electrolytic solution, due to the general potential of the tube, relative to other metallic parts of the condenser in an electrolyte, then these methods of protection would be logical. If, however, as contended above, pit-hole corrosion is due to extremely local galvanic couples, then it seems quite illogical to expect any protection from electro-positive masses, or from the application of electric current, for obviously no general distribution of current can overcome the potential between two parts of the surface almost infinitesimally close together. It has been claimed that the potential of the electrodes, when current is applied, must have a definite value to obtain the best results.

In tests made by the author, it was found that absolutely no diminution of the rate of tube failures was effected by the use of this method although the tubes were undoubtedly receiving current, since a deposit of copper from the copper electrodes was found in the interior surfaces of the tubes. Further, tubes which failed during the time that this test was made, were cut up and were found to be coated with deposited copper right up to the failure hole; in the opinion of the author, most conclusive proof that applied current did not protect the tube from pit-hole corrosion.

An interesting sidelight on the claim that the use of electrode current can prevent pitting is furnished by the following extract from the paper by Mr. W. W. Churchill, mentioned above:

"By this means (i.e., by applying an electro-motive force to balance the potential between railroad rails and river water at all times), we succeeded in properly adapting the sizes of the generating and other apparatus. All corrections were made in a manner to insure a uniform voltage of the various parts of the condenser, to prevent local action, each connection being so made and provided with such measuring instruments as to insure ready adjustment to effect this. The apparatus was designed in accordance with the above statements. Its operation has extended over a period of fourteen months, and with the exception of *about 10 tubes, which have pitted,* the results have been satisfactory."

The paper quoted is the only one which I have been able to find in which an attempt is made to argue the theory that electrode current can overcome pitting, or can overcome the natural potential between zinc and copper at atomic distances apart in an alloy. The words italicized lead very clearly to the assumption that the undertaking succeeded in counter-balancing the railroad leakage potential, but that the method had no effect in preventing the true pitting action.

The author trusts that if the logic of his theory is sound, the result will be a greater confidence in installing large condensing plants, and less anxiety as to the possibility of serious and expensive trouble. It should lead to a modification of those conditions under which large stations draw supplies of sea water through considerable lengths of cast-iron piping, often quite untreated internally, and thus liable to continuous corrosion. The suitability of the Admiralty tube for plants using sea water, when supplied by good makers is, in the opinion of the author, well established, but tinning of the tube seems unnecessary and dangerous.

# THE ELECTRIFICATION OF THE J. G. BRILL CAR MANUFACTURING PLANT

By F. P. Jones, Jr.

Power and Mining Department, General Electric Company

and By F. B. Sullivan

Mechanical Engineer, J. G. Brill Company

This article furnishes a detailed description of the sources of power and the means of energy distribution which have been adopted by the J. G. Brill Company in the electrification of its plant. The electrical installation is a model one, being very flexible to meet the varying conditions of daily load and capable of systematic growth in keeping with the increased demands in production. The following information which is contained in the article will be of particular interest to those who are contemplating the design of a system to supply electric energy throughout a factory: Ratings and other electrical dimensions of the various units comprising the system; diagrams of the relative location of the parts of the equipment; wiring diagrams of the connections between the pieces of apparatus; and photographs of interesting parts of the installation.—Editor.

The J. G. Brill Car Manufacturing Company, located at 62nd Street and Woodlawn Avenue, Philadelphia, Pa., affords a noteworthy example of the modern practice of laying the foundations for future extensions in plant operation as well as in the commercial departments. Due to the many changes in production methods and to the rapid increase of output, this company has at various times found it necessary to remodel and enlarge its power equipment. In view of this past experience, provision for the conditions peculiar to the plant were incorporated in the design of the new scheme of power distribution.

Of paramount importance was the insistance upon safety to employees, which necessitated first, the isolation of all high-tension apparatus beyond access of any other than authorized attendants, and second, the installation of a low-voltage remote control for operating the high-tension switches.

To preclude any possibility of service interruption, arrangements were made for a reserve source of power and for a distribution system wherein any one unit may be cut out without interfering with the whole. To avoid expensive alterations in the future, it was essential that the system be designed with sufficient flexibility to permit of regrouping or of additions without disturbing the other units of the system. Moreover, provision was made whereby such changes may be accomplished without the high expense entailed in laying or taking up long feeder lines. The best solution of this problem was the adoption of a unit basis of design which would readily permit of additions to the generating capacity, or of changes in the location of power consuming elements, without disturbing the present equipment as installed. The system, as finally worked out and installed, is as follows:

Current may be supplied from two sources: The Company's steam plant, capacity 800 kw., 250 volts direct-current; and the synchronous-converter substation, total capacity 1600 kw., 250 volts direct-current (present installed capacity, 600 kw.). Power is supplied to the substation by the Philadelphia Electric Company through two feeder circuits at 13,200 volts, three-phase, 60 cycles. Tracing the distribution in terms of a one-line diagram, the current is taken through a disconnecting switch, through the oil switch, and through a second disconnecting switch to the 13,200-volt station busbar. From there it is taken through a disconnecting switch, through an oil switch to either bank of converter transformers, which lower the voltage from 13,200 to 180, 120, 60 volts, providing one-third and two-thirds starting tap and one hundred per cent running tap for the synchronous converters. The connections as described are shown in Fig. 1. From the synchronous converters, the current is taken at 250 volts through the direct-current converter panels to the direct-current station bus and through the yard bus panels to the main plant distributing system. Paralleled with this source is the Company's steam plant, comprising two 300-kw. and one 200-kw., direct-connected, engine-type, 250-volt, two-wire direct-current generators.

The principal shops are served from this bus through solenoid-operated circuit breaker panels (one panel being located at each important shop distributing point), controlled from the steam plant and from the substation by the multiple control system of connections shown in Fig. 2.

### The Substation

The substation, Fig. 3, located along the Woodlawn Avenue yard-line, is 65 feet 3 inches long by 18 feet 8 inches wide by 37½ feet high. The construction is of concrete and structural steel with brick curtain walls and cement floors and roof. Light is provided by large steel-sash windows of wire glass protected by wire screening. These swing on horizontal pivots to admit air. Proper ventilation is insured by four 24 inch diameter globe ventilators equally spaced along the center line of the roof, in addition to the louvres extending the entire length of the south wall back of the transformer banks.

Large door openings fitted with rolling steel shutters are provided in front of the synchronous converters to facilitate the setting and moving of the machines. Directly over the converters, and extending the entire length of the room, is a trolley crane beam for moving the machines or machine parts.

The wall columns are of 8-inch Bethlehem H-section steel bolted to concrete foundations extending below the frost-line. The 15-inch I-beams supporting the floor of the second story are riveted to the H-section columns and both are encased in concrete.

The foundations for the synchronous converters, both future and installed, are of heavy concrete construction. Between the switchboard and the Woodland Avenue wall is a cable pit 4½ feet wide by 4 feet deep, provided with a removable cover of oak planking which forms the flooring back of the switch-board; all remaining floor space is of concrete. The floor of the pit, the converter foundations, and the floor proper are provided with screened drains leading to the sewer. The spiral stairway leading to the second story is of iron. All cables are enclosed in ducts running along, or imbedded in the walls and floors, and the whole is made as nearly fire-proof as possible.

The lines of the Philadelphia Electric Company are brought underground to a manhole located just outside the yard-line. From this manhole the 13,200-volt circuits are brought underground in lead-sheathed

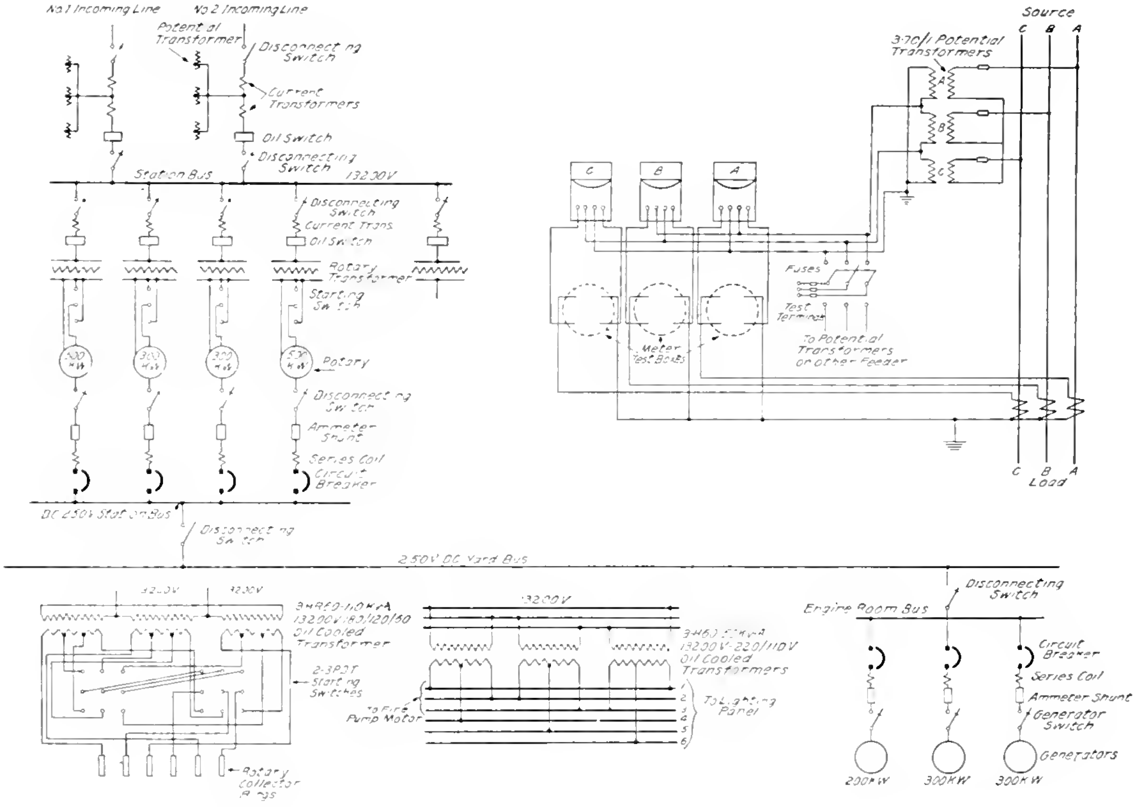

Fig. 1. General Wiring Diagram

cables into the substation, and are carried direct to the high-tension floor through vitrolite conduits moulded to the wall in plaster casing. This casing, flanked by metal conduits containing the control and instrument circuits, can be seen on the back wall of the first floor as shown in Fig. 4.

All high-tension apparatus and connections are located in the second story of the substation. Here are installed the oil switches and the two banks of transformers for the synchronous converters, with spare cells and settings for two additional complete units. In addition there are three single-phase, 60-cycle, 13,200-220/110-volt, 50 kv-a. oil-cooled transformers for the fire pump and yard lighting service. This bank of transformers is shown in Fig. 5.

The oil switches are of the t-p. s-t. type, are of 300 ampere 15,000 volts capacity, and are made up of three single-pole units, solenoid-operated; the solenoid is controlled from the switchboard on the first floor by low-voltage direct current. Each pole is housed in a fire-proof brick chamber with top suspension swinging-type doors made of asbestos lumber. Hand-operated disconnecting switches provide means of isolating any switch for inspection or regular repair work without interfering with the operation of the other circuits.

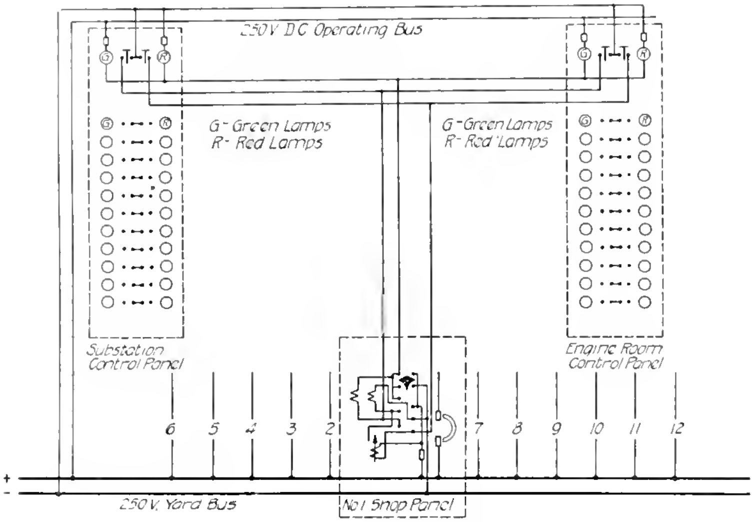

Fig. 2. Shop Control Diagram

Each bank of transformers for the converters is composed of three 110-kv-a., 13,200-volt primary, 180-volt secondary, 60-cycle, oil-cooled transformers of the inherent reactance type, having delta connected primaries, with one-third and two-thirds secondary starting taps and two 5 per cent high-tension taps to permit adjustment of voltage ratio to compensate for variation of the incoming feeder voltage. Like the oil switches, either bank of transformers for the converters can be isolated by disconnecting switches to permit of inspection or repairs.

Fig. 3. Substation Building, Front View from Yard

Fig. 6 shows the setting for these transformers, so graded that, in case of fire, the oil can be emptied direct to the drain pipes. The drain pipes are protected by wire gauze to prevent the flames entering the drains.

Fig. 7 is a diagram of the high-tension floor, showing location of switching equipment, transformers, and space reserved for future installations.

The arrangement of busses and switching apparatus is shown in Fig. 8.

On the first floor are located two synchronous converters and the substation switchboard. The plan of this floor is shown in Fig. 7A. The converters are six-phase, eight-pole, 300-kw., 900-r.p.m., 250-volt machines complete with end-play and speed limiting devices, and provided with break-up switches, equalizing switches, and field rheostats. The panels containing the converter starting switches are mounted near the machines independent of the station switchboard, as shown in Fig. 10. Each of these is equipped with one t-p. d-t., 1000-ampere, 440-volt lever switch and one t-p. d-t., 600-ampere lever switch.

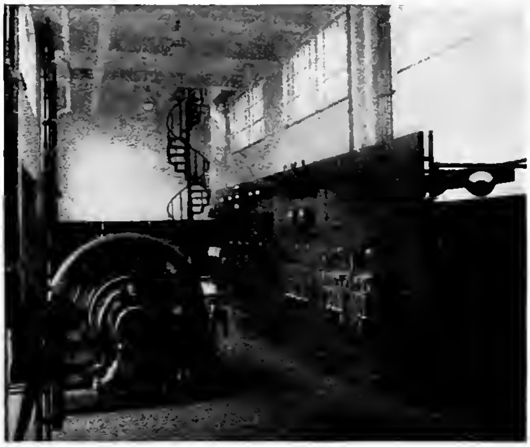

Fig. 4. First Floor of Substation

Fig. 16 shows a photograph of the switchboard as installed; Fig. 11 is back view of direct-current end. Panel 1 is the totalizing instrument panel mounting six single-phase watthour meters arranged in two banks, each bank registering the load of an incoming feeder. Fig. 1 shows the details of meter connections. The instrument transformers for these are located between the disconnecting switches and the oil switches on the incoming lines. Panels 2 and 3 are the incoming line panels of 1000 kw., 13,200 volts capacity, from which are controlled the solenoids operating the oil switches that connect the incoming feeders to the high-tension busbars. Panel 4 is the high-tension control panel for the fire pump and yard lighting circuits, capacity 150 kw., 13,200/220 volts. Panels 5 and 6 are blank alternating-current converter panels, and 6 and 7 are the equipped converter panels of 300 kw., 13,200/180 volts capacity. Panels 9 and 12 are blank direct-current rotary panels, and 10 and 11 are the equipped direct-current rotary panels of 300 kw., 250 volts capacity. Panels 13 and 14 are the direct-current yard bus panels, each mounting four 2000-ampere, 250-volt lever switches for picking up the sections of the yard bus. The alternating-current yard lighting panel No. 15 is provided with two sets of 3-phase busses; one set, 110 volts; the other, 220 volts. This arrangement

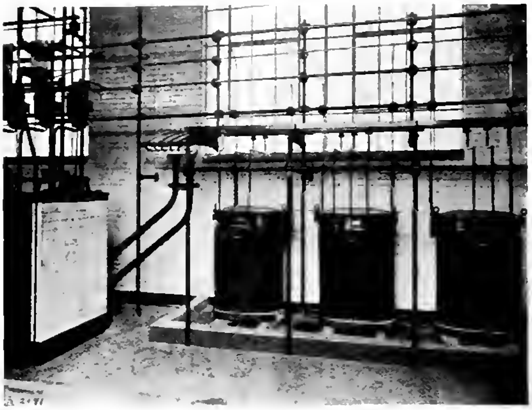

Fig. 5. A Bank of 13200-220/110 Volt, 50-Kv-a. Transformers for Fire Pump and Yard Lighting

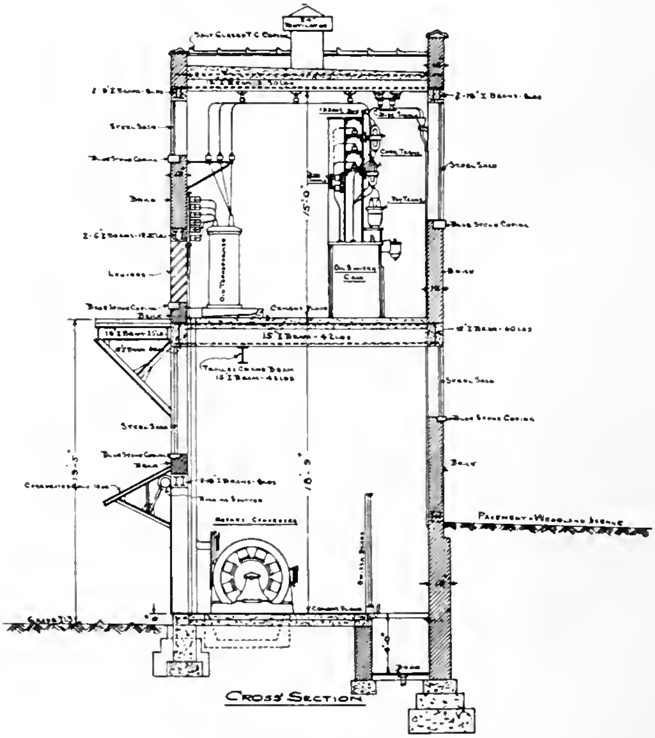

Fig. 6. Cross-Sectional View of the Substation

renders available three-phase 110 volts, three-phase 220 volts, and three-wire 110/220 volts. The transformer connections to this panel are shown in Fig. 1. The shop circuit control panel No. 16 is equipped with 12 s-p. d-t., 250-volt remote-control switches, operating the circuit breakers on the shop panels and tied in parallel with the switches on the duplicate panel, No. 24, in the steam plant. Red and green indicating lamps, showing what shops are thrown on, give the attendant at either place accurate information as to the operation of either board. Panel 17 has a swinging bracket mounting a 300-volt, direct-current voltmeter, which by the use of proper potential plugs will show the voltage of either machine or of the yard bus.

### Yard Bus

In deciding upon a means of serving the various shops of the plant, mature deliberation was given to the advantages of many practical systems compatible with the plant conditions. As stated in an introductory paragraph, provision for future extensions was the objective of the design of the whole system; this is best attained in this particular installation by the use of a yard bus. The location of the substation at the center of the distributed load makes possible the maintenance of a balance on both sides of the bus. As the load diminishes towards either end, the bus can be so tapered that the maximum capacity is utilized at all points. Under any other system, an increase of load upon any section would necessitate running

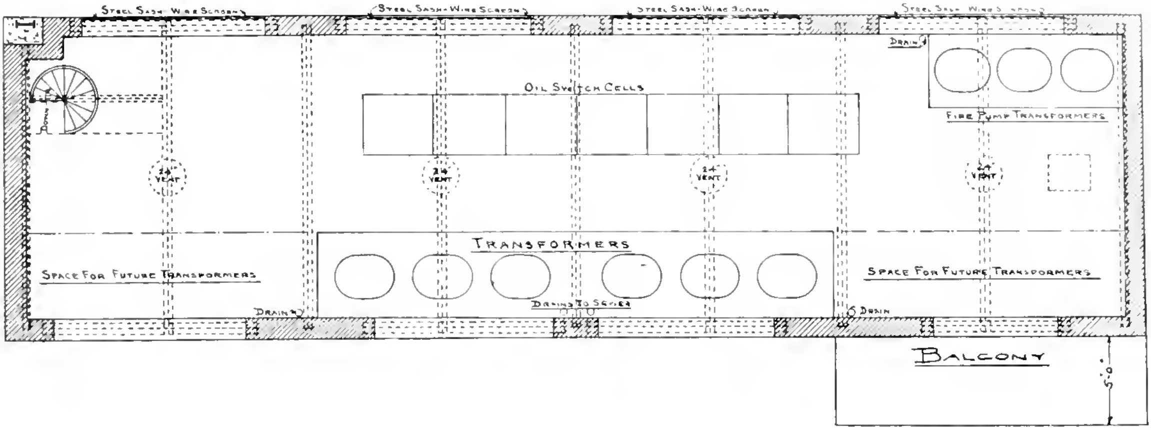

Fig. 7. Plan of the Second Floor of the Substation

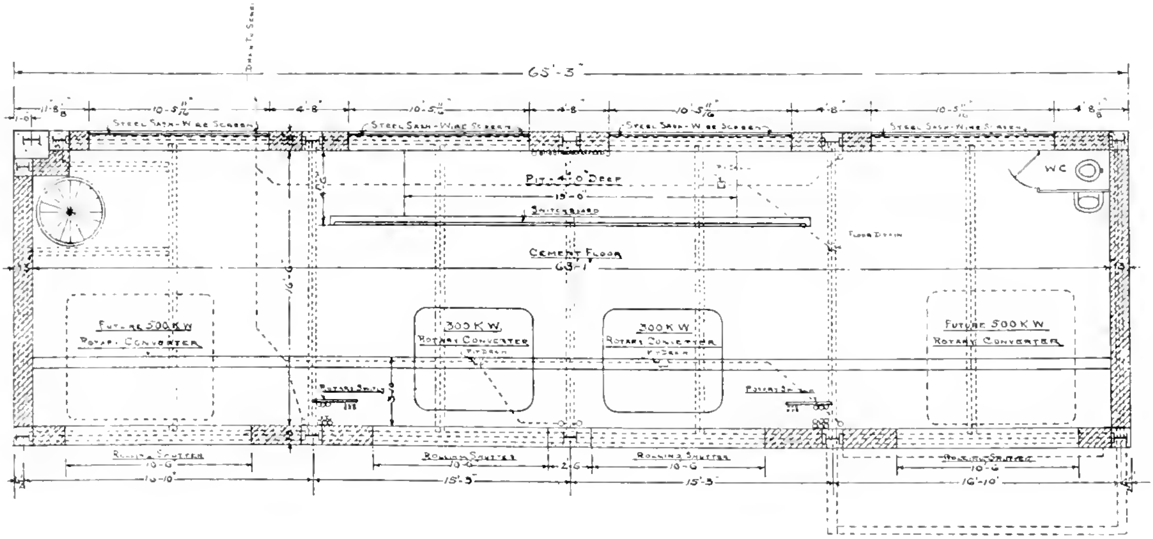

Fig. 7A. Plan of the First Floor of the Substation

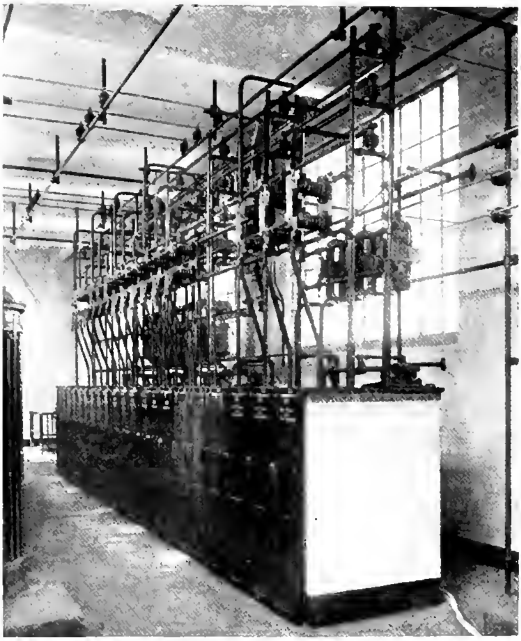

Fig. 8. Front View of Switch Cells

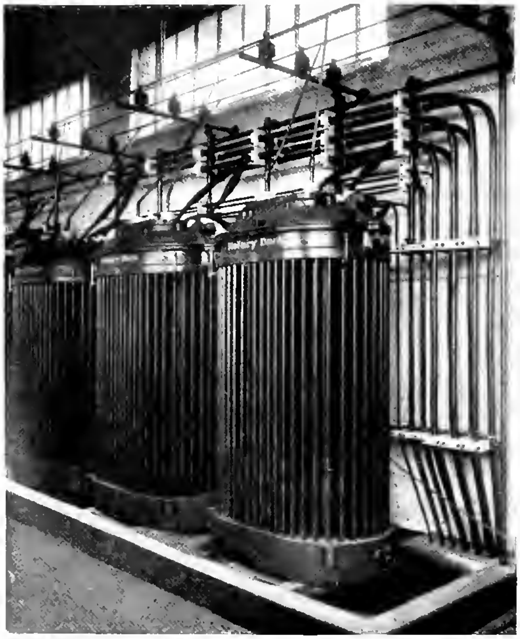

Fig. 9. Main Transformers. Left Front Angle View from West

feeders from the station to the shop, involving a great amount of labor in placing the cables, in addition to the expense of the materials. Under this system, such an increase simply means withdrawing idle cables from one part of the system and pulling them through spare ducts to serve the section upon which the load is thrown; likewise, an increase of the total load calls for no expense other than the cost of the cable and the small installation cost incident to drawing the cable through the ducts provided. Moreover, by the system used, control of all shops is secured from two points and power may be supplied from either or both with no added outlay for copper.

Fig. 12 shows the arrangement of the yard bus and feeder system. The bus, composed of eight 1,000,000 circular mil, varnished cambric, lead-covered cables (four positive

Fig. 10. Synchronous Converters. General View from West

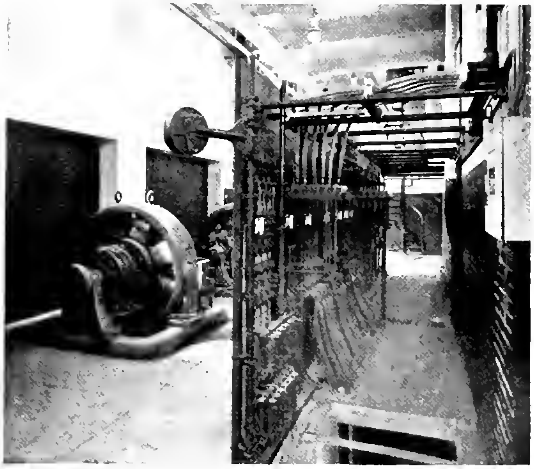

Fig. 11. Back View of the Synchronous Converter Switchboard (Front View, Fig. 16)

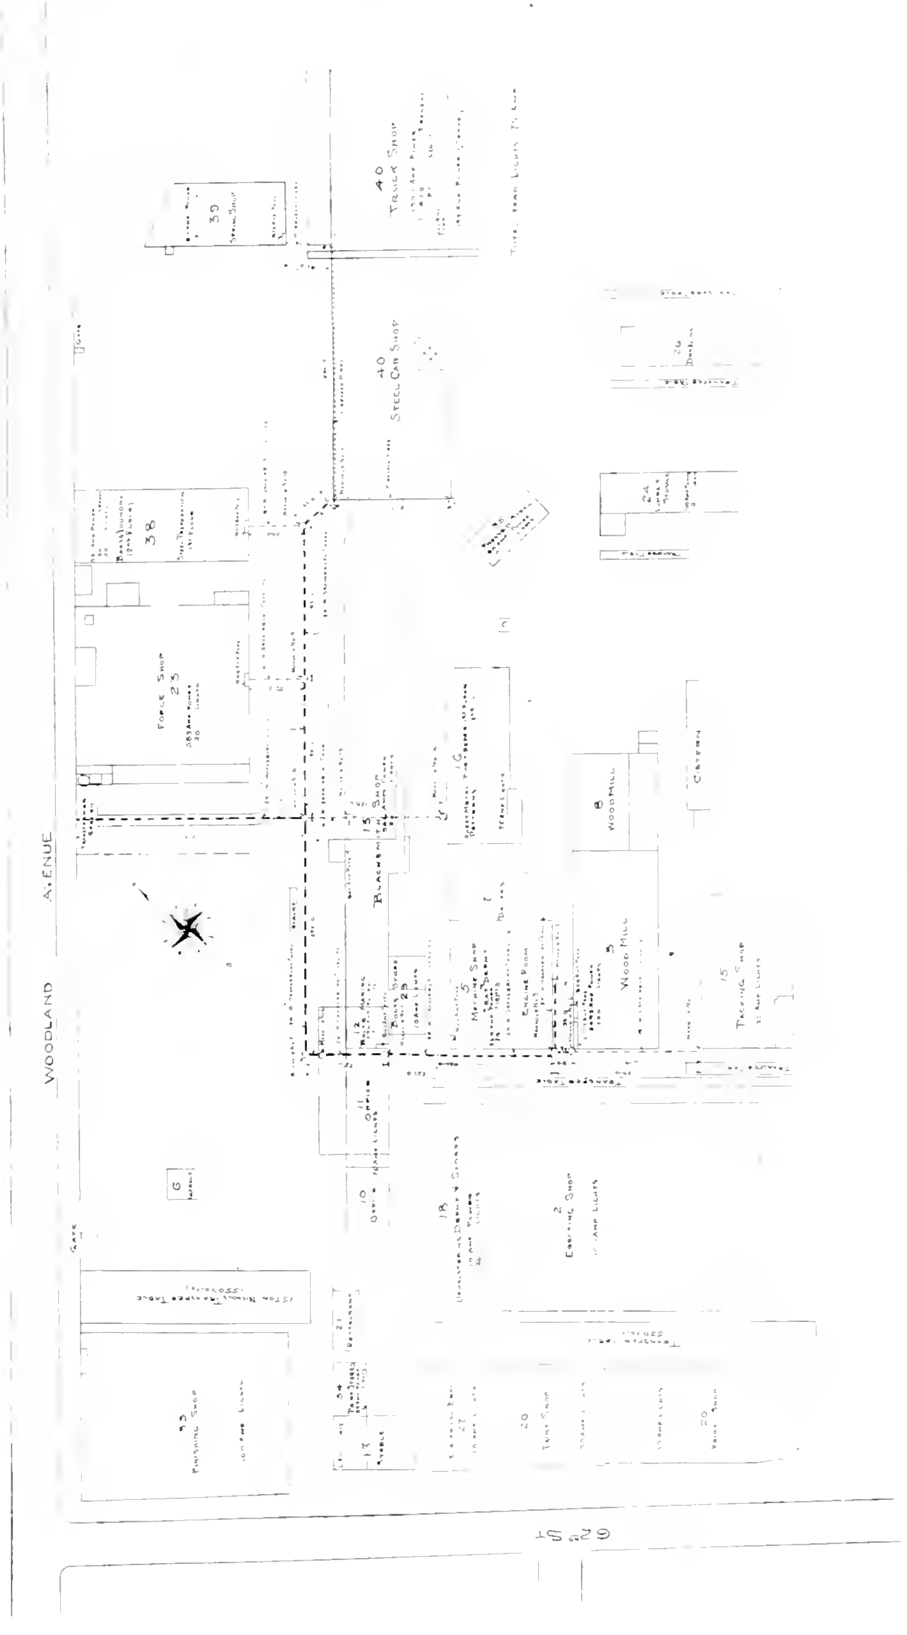

Fig. 12. Layout of the Buildings Showing the Arrangement of the Yard Bus and Feeder System

and four negative), is supplied with direct current at 250 volts from either the substation or the steam plant or from both.

The main bus line ducts consist of twenty-four 4-inch Orangeburg fiber conduits surrounded by concrete, forming a monolith as shown in Fig. 13. This main bus line extends from the substation 212 feet south to manhole No. 8. At a point 300 feet east is manhole No. 11, from which is tapped the overhead lines running under the roof of the truck shops. Manhole No. 12 lies 225 feet west and 235 feet south of manhole No. 8 and from it one branch extends to the wood mill and beyond, the other branch connecting to the steam power-plant switchboard.

As the bus is sectionalized through junction boxes at each manhole, any section may be cut out for faults or for repairs. The standard manhole, shown in Fig. 15, is 7-feet 10-inches long by 4-feet wide by 5-feet 8-inches deep. Fig. 15A shows a standard corner manhole. The floor is of concrete 4-inches thick. Any accumulation of water is drained to the sewer from the manhole at the floor level, which is connected to all manholes by a 4-inch terra-cotta drain. The roof of each manhole consists of a 6-inch slab of reinforced

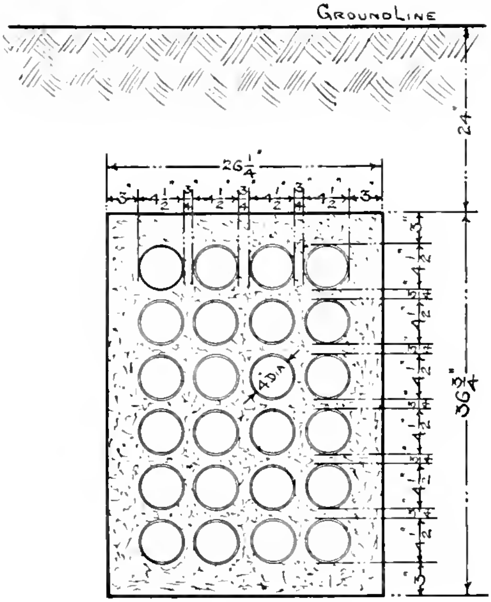

Fig. 13. Vertical Section of the Main Bus Line Ducts

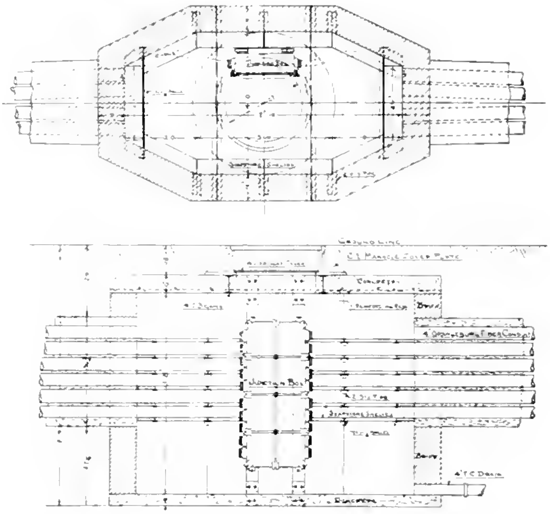

Fig. 15. Sectional Plan and Elevation of the Standard Manhole

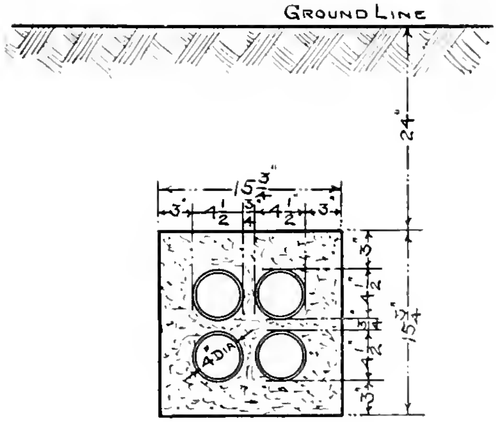

Fig. 14. Vertical Section of the Feeder Ducts

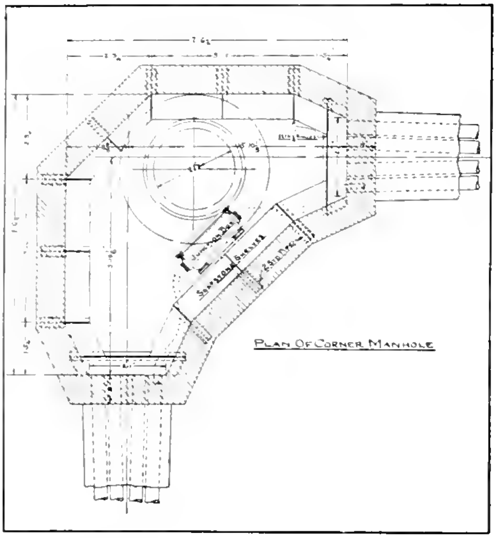

Fig. 15A. Sectional Plan of a Corner Manhole concrete; the cover plate is carried on a 6-inch I-beam imbedded in the roof. The cables are carried on removable soap-stone shelves extending around the sides of the manhole at the level of the lowest part of each row of ducts. These shelves are 1-inch thick, are arranged in sections about 24 inches wide, and are supported by 1-inch angles set in 2-inch pipe thimbles imbedded in the brick walls. The angles may be adjusted in the thimbles for the accommodation of additional shelves. The walls are built of hard-fired iron brick, set in Portland cement mortar. The junction boxes are placed high enough in the manholes to be out of the reach of any accumulation of water that might be expected under conditions incident to any ordinary storm; however, even should the manholes be flooded and the junction boxes be completely submerged during the short time necessary for the drains to relieve these conditions, no damage would be incurred, for the cables are taken into the junctions through stuffing boxes and a gasketed cover is provided, making the junction box water-proof.

Fig. 15 shows the connections for a single junction box. In manholes No. 3 and No. 8 (Fig. 12), it was necessary to use two single-polarity junction boxes, one tying all negative cables and one tying all positive cables. Each of the remaining manholes has one double-polarity junction box containing two busbars, to one of which is connected all the negative cables and to the other is connected all the positive cables.

### Feeders

The feeder ducts consist of four Orangeburg fiber conduits surrounded by concrete. The shop circuits are tapped off the yard bus at the junction boxes as shown in the diagram of the yard bus system, Fig. 14. At present there are installed seven 800-ampere and two 2000-ampere shop distributing panels. Each shop circuit is controlled from both the substation and from the engine room by a 250-volt direct-current circuit.

The control circuits consist of one 5-conductor lead-covered cable between the control panels and each shop panel, one 3-conductor cable and one 2-conductor lead-covered control cable which forms the tie line between the substation and engine room control panels. This tie line places the two panels in multiple and also parallels all signal lights on both panels. Details of two point control of shop panels are shown in Fig. 2.

### Shop Panels

Fig. 17 shows a 2000-ampere and an 800-ampere shop panel located in the lumber mill. These are typical of all shop panels and are equipped with solenoid-operated circuit breakers. Should emergency demand, these can be thrown out by hand, but they can be thrown in only from the substation or from the engine room; however a special lever is kept in the substation by means of which the breakers can be thrown in mechanically should the electrical control break down or fail for any reason. This gives the operator absolute control, precluding the possibility of any load being thrown on without his knowledge. On each shop panel are mounted totalizing meters, registering the load of the circuits which they supply. In order that shop charges may be segregated, the various departments are served through individual watthour meters.

### Steam Power Plant

The present steam power plant consists of two 300-kw. continuous current generators, 130 r.p.m., 225 volts, 1200 amperes capacity, direct-connected to horizontal single-acting non-condensing engine; and one 200-kw. direct-current generator, 175 r.p.m., 225 volts, 800 amperes capacity, direct-connected to a horizontal single-acting, non-condensing engine. Power for operating these generators, as well as the air compressors and hydraulic pumps, is obtained from six 400 h.p. Babcock & Wilcox horizontal water-tube boilers operating at 120 pounds pressure.

The present system is designed to permit the multiple operation of the generators in the steam plant and the converters in the substation.

Fig. 18 shows the switchboard in the steam plant. The diagram of connections is shown in Fig. 1. Panels 19, 20, and 21 are the direct-current generator panels. Panels 22 and 23 are the switch panels mounting the knife switches which pick up the sections of the yard bus. Control panel No. 24 in multiple with its duplicate No. 16 in the substation, controls the solenoid-operated shop panels.

The equalizer switches in this station are mounted on pedestals, each near its respective generator.

### Fire Pump Motor

The fire pump will be connected direct to the city mains and will be operated by a 100-h.p., 220-volt, three-phase, 60-cycle motor, controlled by an automatic starting panel in accordance with standard requirements of the Board of Fire Underwriters. This will be operated from several remote-control, push-button stations located in various parts of the plant.

Fig. 16. Front View of the Synchronous Converter Switchboard. (Back View, Fig. 11)

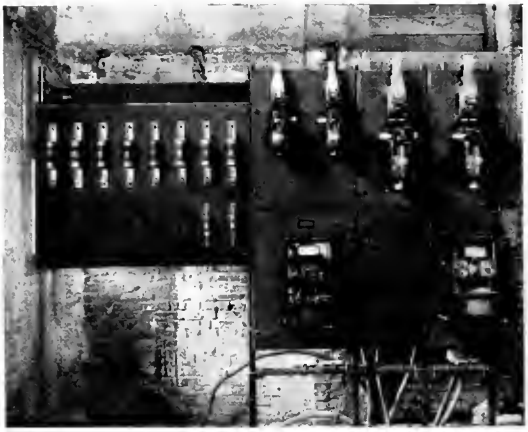

Fig. 17. An 800 and a 2000-ampere Shop Panel Located in the Lumber Mill

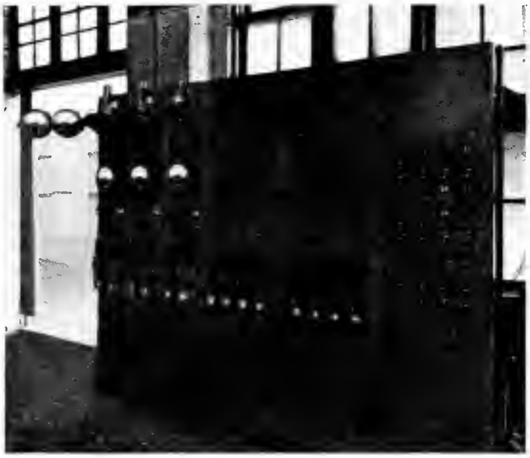

Fig. 18. New Switchboard in Engine Room, Building 5

The transformers and switchboard serving the motor are located in the substation and have been described in preceding paragraphs; the motor, however, will be housed in a separate building of fire-proof construction provided with entrances so located that access may be had in spite of fires in adjoining buildings. Every effort will be made to preclude any possibility of accidents disabling the fire-fighting equipment.

### Standard Equipment

Throughout the plant all electrical equipment is standard, taken directly from stock. This assures prompt duplication of the various devices when required for expansion or spares.

The whole installation has proved to be thoroughly satisfactory and furnishes a striking example of the flexibility that can be obtained from combinations of standard-unit parts.

# RECENT VIEWS ON MATTER AND ENERGY

By Dr. Saul Dushman

Research Laboratory, General Electric Company

## Part II

In this issue the author discusses the experimental evidence which has led to the view that energy is not capable of infinite subdivision. This leads to an atomistic theory of energy which is quite analogous to the older atomic theories of the structure of matter and electricity. The classical dynamics has been found to be inadequate in explaining a large number of recent observations. The necessity has therefore arisen of questioning the validity of some of the so-called fundamental principles, and in propounding the quantum theory, Planck, who is one of the greatest living physicists, has started a movement which promises to radically change all our previous concepts of matter and energy. In subsequent issues, the author will discuss the applications of the quantum theory to a number of problems in physics and chemistry.—Editor.

## ATOMISTIC THEORY OF ENERGY

In the first part we discussed the experimental evidence which has led to an atomistic theory of electricity. We now turn to the discussion of another series of experiments which have apparently led to the necessity of assuming a similar theory of energy; we say *apparently*, because the theory is as yet in a state of transition, and while a certain line of evidence may force physicists to assume an atomistic point of view of energy at the present time, it must not be forgotten that the near future may bring to light another explanation which correlates all the known observations just as well as the quantum theory and yet does not present as radical a departure from previous concepts.

The immediate necessity for a quantum theory arose as a result of investigations that were carried out between 1897 and 1901, by Lummer and Pringsheim, on the laws of distribution of energy in the spectrum of black body radiation. It will therefore be necessary to explain rather briefly what is meant by a "black body" and then discuss at greater length the different attempts that were made to explain theoretically the results of the above mentioned investigations on black body radiation.

### "Black Body" Radiation

A solid or liquid heated to a temperature above that of its environment radiates energy to the surrounding bodies, and as the temperature of the radiating source increases, the energy radiated per unit area increases very rapidly. In general the amount of energy radiated depends not only upon the temperature but also upon the nature of the material of which the radiator is composed. It is always, however, less than that emitted by a "full" radiator or "black body." Such a radiator is defined as one which completely absorbs all radiations incident upon it. No substance is known which is a perfect black body in this sense, although some substances, such as lamp black, approach it quite closely, while platinum and white oxides depart to quite an extent from black body radiation. It was pointed out by Balfour Stewart and Kirchoff independently that the radiation emitted from an enclosed space, the walls of which are maintained at a constant temperature, possesses all the characteristics of black body radiation. For it is evident that inside such an enclosure the energy radiated is equal to that absorbed, and consequently a body situated inside the enclosure attains a temperature which depends only upon the temperature of the walls and on nothing else.

### Stefan-Boltzmann Law

About 1879 Stefan concluded from previous measurements of Tyndall that the total energy radiated per unit area of black body radiator varies as the fourth power of the absolute temperature. Subsequently Boltzmann deduced the same law from thermodynamical considerations on the basis of the electromagnetic theory of light. The most accurate determinations so far made lead to the following expression for the Stefan-Boltzmann law:

$$E = 5.7 \times 10^{-5}\ (T^4 - T_0^4) \text{ ergs per cm}^2 \text{ per sec.} \quad (1)$$

where $E$ denotes the total energy radiated, and $T$ and $T_0$ denote the absolute temperatures of the radiator and the body receiving radiation respectively.

### Distribution of Energy in the Spectrum of a Black Body

At low temperatures the energy emitted by a black body radiator is in the form of heat waves only. When the temperature exceeds 600 deg. C., the radiations having a wave length below 0.76 $\mu$[1] become intense enough to affect the retina of the eye, and as the temperature increases still more the color of the body varies from a dull red heat, through cherry red and orange, up to a bright white heat (about 1500 deg. C.). The energy emitted at any temperature may be resolved into a continuous spectrum and the variation of intensity in different parts of this spectrum can be determined by means of an instrument like the thermopile or bolometer.*

The laws governing the distribution of energy in the spectrum of the radiation from an enclosed space at uniform temperature have been experimentally investigated by Paschen[2], Lummer and Pringsheim[3] and Rubens and Kurlbaum[4], and still more recently by W. W. Colblentz[5]. The results of Lummer and Pringsheim's observations are shown in Fig. 1†, where the ordinates correspond to intensities or emissive powers, which are proportional, and the abscissae denote wave-lengths in microns[6].

The area contained between any curve and the $\mu$-axis is proportional to the total amount of energy radiated by a black body at the corresponding temperature, and the above-mentioned observations were found to be in good accord with the Stefan-Boltzmann law.

It will be noted that by far the largest portion of the spectrum is found in the infra-red region; but as the temperature is increased the position of the wave-length at which the maximum emissivity occurs shifts towards the region of shorter wave-lengths or higher frequencies. This is the explanation of the gradual change in color of a heated body as the temperature changes.

### Wien's Displacement Law

Regarding the manner in which the position of maximum intensity changes with change in temperature, Wien was able to deduce theoretically a relation which is of extreme importance.

He made use of the following well-grounded principles:

1. That according to the electro-magnetic theory there exists a radiation pressure which is equal to the energy per unit volume.
2. That the second law of thermodynamics is applicable to radiation problems.
3. That the Doppler effect, according to which the frequency of monochromatic radiation changes with changing position of the radiating source, is applicable.

Starting with these assumptions, for which there is every experimental evidence, he showed that the wave-length at which maximum intensity occurs, (which can be denoted by $\lambda_m$) varies inversely as the absolute temperature, that is,

$$\lambda_m = \frac{A}{T} \qquad (2)$$

where $A$ is a constant. This is known as Wien's "displacement law." Careful measurements by Lummer and Pringsheim and others have shown that the value of the constant $A$ is 2900 where $\lambda$ is measured in microns. That is, at the temperature of 2900 deg. abs., the maximum intensity occurs at 1 $\mu$, or well in the infra-red region, and the temperature of the radiator has to attain a value of about 5300 deg. abs., before the wave-length of maximum intensity coincides with that wave-length for which the normal eye is most sensitive (about 0.55 $\mu$).

Wien also showed that the maximum intensity varies as the fifth power of the absolute temperature, that is,

$$E_m = B\,T^5 \qquad (3)$$

where $E_m$ denotes the intensity corresponding to maximum wave-length ($\lambda_m$) and $B$ is a constant.

As both these relations have been found to be in splendid agreement with the experimental observations, there is no reason for doubting the validity of the three principles used in deducing them.

### Formulae for the Law of Distribution

While the Stefan-Boltzmann law and Wien's "displacement law" represented great advances in the theoretical treatment of the laws of radiation, there still remained the main problem of obtaining a formula which should express the intensity of any monochromatic radiation as a function of both the frequency, or wave-length, of that radiation and its temperature, in other words, a formula that would adequately fit the curves obtained by Lummer and Pringsheim as in Fig. 1†.

Three formulae have been suggested and each of these is of extreme importance:

The first of these is known as Rayleigh's formula. Written in terms of the wave-length ($\lambda$), the intensity $E_\lambda$, at any wave-length is given by the relation:

---

* The bolometer consists essentially of a series of thin strips of platinum covered with soot. The electrical resistance of these strips changes when they are exposed to the radiation whose intensity is to be measured.

[1] The longest visible wave-length.

[6] 1$\mu$ (micron) = $10^{-4}$ cm. The visible spectrum is comprised between 0.4 $\mu$ and 0.76 $\mu$

† Page 187, GENERAL ELECTRIC REVIEW, March, 1914.

$$E_\lambda = \frac{ckT}{\lambda^4} \tag{4}$$

where $c$ denotes the velocity of light and $k$ is the so-called elementary gas constant.

The second formula was deduced by Wien. According to this formula:

$$E_\lambda = \frac{c^2 h \lambda^{-5}}{\epsilon^{ch/k\lambda T}} \tag{5}$$

where $h$ is a universal constant and $\epsilon$ denotes the base of the natural system of logarithms.

Finally, the third formula was deduced by Planck and states that

$$E_\lambda = \frac{c^2 h \lambda^{-5}}{\epsilon^{\frac{ch}{k\lambda T}} - 1} \tag{6}$$

Written in terms of the frequency $\nu$ instead of $\lambda$ these equations become

$$E_\nu = \frac{\nu^2}{c^2} kT \text{ (Rayleigh)} \tag{4a}$$

$$E_\nu = \frac{h\nu^3}{c^2} \epsilon^{-\frac{h\nu}{kT}} \text{ (Wien)} \tag{5a}$$

$$E_\nu = \frac{h\nu^3}{c^2} \frac{1}{\epsilon^{\frac{h\nu}{kT}} - 1} \text{ (Planck)} \tag{6a}$$

The products $c^2h$ and $ch/k$ are usually denoted by $c_1$ and $c_2$ respectively. The introduction of the constant $h$ is due to Planck and the reason for introducing the same constant in Wien's equation is to indicate the close relationship between the latter and that of Planck.

The measurements of Lummer and Pringsheim and others have shown that of these three formulae, that of Planck is the only one that is valid over the whole range of the spectrum. It is easily seen that Rayleigh's formula cannot be correct, for according to this formula the intensity at any given temperature ought to increase rapidly with increase in frequency, and this increase ought to continue *indefinitely*. The occurrence of a maximum intensity at a frequency which is given by the displacement law shows that the Rayleigh formula cannot be valid over the whole range. Another way of looking at the same facts is to state that the Rayleigh formula is in direct contradiction with the Stefan-Boltzmann law, for according to the Rayleigh formula the total area under any curve would be infinite, instead of being actually a finite quantity that increases regularly with the fourth power of the absolute temperature. As a matter of fact the formula agrees with Lummer and Pringsheim's results, see Fig. 1,* only for large values of $\lambda T$, that is, in the region of long wavelengths and low temperatures, in other words, it describes accurately only the right-hand portions of the curves shown.

Wien's equation on the other hand fits the experimental data only in the visible and ultra-violet regions, that is, in the case of low values of $\lambda T$, but for values of $\lambda T$ greater than 3000, $\lambda$ being reckoned in microns, the emissivities as calculated by this formula are found to be smaller than those observed.

It would therefore appear, at first glance, as if Planck's equation is merely a successful empirical formula for bridging over the gap between the regions in which formulae (4) and (5) respectively are valid. The method of derivation of each of these formulae shows, however, that there is more than pure empiricism in Planck's formula. Now what are the considerations which have led to each of the above formulae?

It is obvious that black body radiation may be regarded from two points of view: Firstly, any body emitting or absorbing radiation must, in the stationary state, be in thermal equilibrium with the radiation in the surrounding space. Secondly, it ought to be possible to apply to these radiations, since they are electro-magnetic waves, the equations derived from the fundamental principles of electrodynamics. The first set of considerations give a *relation between the energy of any source of radiation and its temperature*; the second set of considerations lead to a *relation between the energy of the radiator and the frequency of the radiation emitted or absorbed by it.* Consequently, by combining these two relations it ought to be possible to deduce the desired relation between energy of monochromatic radiation, and its temperature and frequency.

### The Principle of Equipartition of Energy

The simplest relations between the energy of a system and its temperature are found to hold for the case of gases obeying Boyle's and Charles' laws. If $N$ denotes the number of molecules in a gram-molecular[1] weight of gas, $V$ the volume at pressure $P$ and temperature $T$, then the above gas laws can be expressed by the relation

$$PV = NkT = RT \tag{7}$$

---

*Page 187, General Electric Review, March, 1914.

[1] The gram-molecular weight (or mol) of a gas is defined as the weight of 22.24 liters of the gas when measured at 0°C. and 760 mms mercury. Thus the gram-molar weight of $H_2O$ is 2.016+16=18.016, while that of oxygen ($O_2$) is 32. On the other hand, the observed gram-molar weight of mercury vapor is the same as its atomic weight, indicating that the mercury molecule is monatomic. Similar results are found to hold for the rare gases Ne, Ar, He, etc., which are all monatomic.

where $k$ is the so-called elementary gas constant and $R$ is known as the molecular gas constant.

According to Prof. Millikan's most recent determinations[1], the values of the constants involved in equation (7) are as follows:

$N = 6.06 \times 10^{23}$ molecules per gram-mol.
$R = 8.30 \times 10^7$ ergs per mol per degree.
$= 1.99$ calories per mol per degree.
$k = 1.37 \times 10^{-16}$ ergs per degree.

One of the conclusions drawn from the application of dynamical laws to gases is that the kinetic energy ($U$) of a gram-molecular weight of any gas due to the translational velocity of the molecules is given by the relation

$$U = \frac{3}{2} RT \tag{8}$$

or the average kinetic energy of each molecule is

$$U_0 = \frac{3}{2} \frac{R}{N} T = \frac{3}{2} kT \tag{9}$$

Now in all cases we are dealing with large numbers of molecules, and if we resolve their velocities in three directions at right angles to each other, it is evident that the average velocity in each of these directions will be the same, otherwise there would be a drift of molecules in some one direction and consequently a greater pressure in that direction. It also follows from the relation that exists between a given velocity and the three component velocities at right angles to each other, that the average kinetic energy of motion along each of the three directions chosen as axes of reference is the same. In other words, the average kinetic energy per molecule is $\frac{1}{2} kT$ for each of the three directions along which it is capable of motion.

Maxwell and Boltzmann showed that this conclusion could be extended to systems in which the constituent particles are capable of other than translational motion. Starting with the assumption of the validity of the fundamental laws of dynamics, they showed that for any system in equilibrium the kinetic energy will on the average be equally distributed among the different degrees of movability or freedom of the system, and furthermore the *average kinetic energy for each of these different degrees of freedom will be* $\frac{1}{2} kT$. This is the generalization known as the *Principle of Equipartition of Energy.*

The number of degrees of freedom corresponds to the total number of terms required to define exactly the state of the molecule or other component at any instant. As illustrations of the application of this principle may be given the calculation of some specific heats.

### Applications of the Principle of Equipartition

From the dynamical point of view, the heat absorbed by a mass of gas maintained at constant volume is converted into increased kinetic energy of the molecules. Therefore the specific heat at constant volume ought to be equal to the rate of increase of kinetic energy with increase in temperature.

Now let us consider the case of a monatomic gas. According to Boltzmann's principle the average kinetic energy per mol due to translational velocity of the molecules is $\frac{3}{2} RT$. Unless additional energy is absorbed by the molecules as rotational energy, the specific heat per mol at constant volume ought to be $\frac{3}{2} R$, that is, 2.98 calories. This is actually found to be the case for monatomic gases like argon and mercury. The conclusion is therefore drawn that any rotational energy which the molecules may possess adds nothing to the total amount of kinetic energy, which is important in the consideration of the specific heat of monatomic gases.

In the case of diatomic gases, Boltzmann considered the molecule as having a dumb-bell sort of structure. Such a molecule may be assumed to have five degrees of freedom; for not only can the molecule as a whole move in three different directions, but the atoms within the molecule can rotate in two directions which are at right angles to the axis of the dumb-bell. If the average kinetic energy of the molecule is $\frac{1}{2} kT$ for each degree of freedom, the heat capacity per mol of a diatomic gas ought to be $\frac{5}{2} R$. This deduction was again found to be in agreement with experimental data.

But not only was Boltzmann able in this manner to calculate the specific heats of gases, he also applied the same considerations to solids and thus arrived at an explanation of the Dulong and Petit law. According to this law the product of specific heat and atomic weight in the case of elements in the solid state is a constant which has a value of about 6 calories. This law had been derived empirically at the beginning of the nineteenth century; but until Boltzmann enunciated his theory, there appeared to be no reasonable

---

[1] Phys. Rev. 2, 147, (1913).

explanation of such a relation. His argument was to this effect:

Consider an elementary substance in the solid state in equilibrium with its vapor. Assume for the sake of simplicity that the vapor is monatomic. We know that this is actually true in the case of metals like mercury, zinc and cadmium, whose densities in the vapor state have been measured. Now the energy of the atom in the solid state must depend upon the vibration of this atom about a position of equilibrium. It also follows from the fundamental principles of dynamics that in the case of any such source of periodic vibrations, and oscillation, the *average* kinetic energy is equal to the *average* potential energy.

But it is evident that the only conditions under which thermal equilibrium can exist between the atoms in the solid phase and those in the gaseous is that the average kinetic energy of the atom in each state should be the same, and since the average energy of an atom in the gas is $\frac{3}{2}kT$ per atom it follows that the total energy per atom in the solid is $3\,kT$, or $3\,RT$ per gram atom. Consequently the atomic heat must be $3\,R$, that is, 5.96 calories.

Summing up the above discussion it is concluded from the fundamental principle of ordinary dynamics that in any system at equilibrium, the average energy is $\frac{1}{2}kT$ for each degree of freedom. This therefore answers the question as to the relation between energy and temperature.

### Rayleigh's Distribution Formula

Turning to the consideration of radiation as an electromagnetic phenomenon, we may consider as Planck does, that the radiation is produced by means of linear oscillators, similar to those used in the production of Hertzian waves, which emit linear harmonic vibrations.

It is evident from what has been stated in the first section of this paper that the electrons within the atoms can constitute such oscillators, for they vibrate or rotate about a mean position of equilibrium and are held by quasi-elastic forces to the positive nucleus. Such an electron possesses therefore both kinetic and potential energy, the average value of each being the same, and furthermore the average kinetic energy depends only on the frequency.

According to the equations of electrodynamics the relation between the total average energy, $U_\nu$, of an oscillator emitting radiation of frequency $\nu$ as the instensity, $E\nu$, of the radiation emitted is

$$U_\nu = \frac{c^2}{\nu^2} E_\nu \qquad (10)$$

Now consider an enclosure surrounded by absolutely opaque walls and containing black body radiation of the same nature as that emitted by a body at the temperature $T$. The radiation emitted by the oscillators is in thermal equilibrium with the walls of the enclosure and any bodies contained in it. According to the principle of equipartition of energy the average energy of each oscillator must be the same, that is, independent of the frequency, and equal to that of a body with two degrees of freedom. This is evident from the above considerations.

Consequently, the average energy of the oscillator must be

$$U_\nu = kT \qquad (11)$$

Combining (10) and (11) we obtain the Rayleigh equation

$$E_\nu = \frac{\nu^3}{c^3} kT \qquad (4a)$$

In other words, the principle of equipartition combined with the deductions from the electromagnetic theory of light leads to an equation for the distribution of energy in black body radiation which, as stated above, is not in accord with the actual facts.

The question therefore arises: Why should the agreement between Rayleigh's formula and experiment hold only for large values of $\lambda T$? The only assumption made in the above argument is that the principle of equipartition is valid in all cases. Evidently this assumption is justified for a certain upper range of values of $\lambda T$ and not for lower values.

### Wien's Formula

As was mentioned in a previous paragraph, the principles made use of by Wien in deducing his "displacement law" are amongst the most fundamental generalizations of physical science, and the agreement between the results predicted by this law and the experimental observations can be regarded as additional confirmation of the validity of the original assumptions upon which the law is based. It was also shown by Wien from considerations based on the main laws of thermodynamics and electrodynamics that any distribution formula must be of the form

$$E_\nu = \frac{\nu^3}{c^2} \cdot F\left(\frac{T}{\nu}\right) \qquad (12)$$

where $F$ denotes some function of $T/\nu$, whose exact form could only be determined by introducing other assumptions.

In order to determine the form of the function $F$, Wien introduced some "arbitrary assumptions as to the radiations sent out by vibrating molecules," and arrived at an equation of the form

$$E_\nu = \frac{h\nu^3}{c^2} \epsilon^{-\frac{h\nu}{kT}} \tag{5a}$$

or as it is more usually written

$$E_\lambda = c_1\lambda^{-5}\epsilon^{-\frac{c_2}{\lambda T}} \tag{5}$$

This equation thus has no theoretical basis, but it is of interest because it represents the observations quite accurately throughout the range of the visible and ultraviolet portion of the spectrum and has been found to be of great use in photometrical investigations. The discrepancies between the observed and calculated intensities occur only in the region of longer wave-lengths.

### Failure of the Principle of Equipartition of Energy

While the reason for the failure of Wien's formula is thus obvious, there appears to be no such *a priori* reason for the failure of Rayleigh's formula. Although the deduction of this formula as given above brings in the additional concept of the existence of linear oscillators, the same formula may be arrived at independently of this concept, as was actually done by Rayleigh and Jeans[1].

Moreover, *all attempts to deduce a distribution law by applying the principles of classical dynamics and electro-dynamics lead invariably to the Jean-Rayleigh equation.* Hence arises the necessity, as has been pointed out by Planck, of adopting some radical modification of the classical theory. Granted this conclusion, the next question arises as to the particular respects in which the older theories shall be altered, and Planck perceives a way out of the difficulty by discarding the principle of equipartition of energy[2].

Now for a number of years a gradually increasing number of facts had led many physicists to question the general validity of Boltzmann's principle. For one thing, while the law of Dulong and Petit is pretty generally true, the number of exceptions to it had been accumulating during the past century. Thus it was known that carbon, boron, and silicon have atomic heats lower than 6; but it was also observed that the atomic heats of these elements increased with temperature, and at high enough temperatures they behave "normally." Furthermore, the molecular heats of some diatomic gases like chlorine and bromine are nearly a calorie too high, even at ordinary temperatures, and they become even greater at higher temperatures. On the other hand, the molecular heat of hydrogen and other gases decreases to 3 as the temperature is lowered.

To explain these facts it would be necessary to assume that the number of degrees of freedom of a carbon atom or chlorine molecule increases gradually with the temperature. But the Boltzmann concept leaves no room for such a transition stage. An atom or molecule must possess a certain integral number of degrees of freedom; a degree of movability in any definite manner is either absent or present. There can *be no gradual acquisition* by any body of a degree of freedom. The conception of integral degrees of freedom thus presents many difficulties.

These difficulties exist, moreover, not only in the field of specific heats but also in that of radiation, as shown above.

### Planck's Formula

These considerations as well as others, based on the statistical theory of entropy, lead Planck to conclude that the principle of equipartition cannot be as universally applicable as hitherto assumed. Especially does he deny its validity in those cases where we are dealing with oscillators, whether electronic or atomic, which are executing periodic vibrations and in which there is a constant interchange between kinetic and potential energy.

The method of derivation of Planck's formula thus differs from that of Rayleigh in denying that each linear oscillator in the enclosure possesses an average energy $kT$. According to Planck it is only at very high temperatures and for long wave lengths that the average energy of each oscillator approximates to the value $kT$.

Thus the fundamental assumption made by Planck may be stated as follows: *Any oscillator cannot absorb or emit energy continuously, but discontinuously in multiples of a unit quantum* $\delta$, and the total amount of energy possessed by an oscillator at any instant may vary from 0 to any multiple, $n\delta$, of the unit quantum. As the temperature increases, the value of this multiple approximates more and more nearly to $kT$. The problem therefore to be solved is this: What is the average energy of an oscillator when it can take up or

---

[1] Lord Rayleigh, Phil. Mag. *49*, 539 (1900).
J. H. Jeans, Phil. Mag. *49*, 229 (1909).

[2] M. Planck, Abhandlungen d. deutsch, Bunsen Ges. Nr. 7, p. 80 (1911).

give out only a definite fraction, $\delta$, of this energy at any instant? The theory of probability leads to the conclusion that

$$U_\nu = \frac{\delta}{\epsilon^{\frac{\delta}{kT}} - 1} \qquad (13)$$

Combining this with (11), it follows that

$$E_\nu = \frac{\nu^2}{c^2} \cdot \frac{\delta}{\epsilon^{\frac{\delta}{kT}} - 1} \qquad (14)$$

For $\delta = 0$, this equation becomes the same as the Rayleigh equation, as we would expect, since the theory of Planck differs from that of Rayleigh in the fact that the former assumes a discontinuous variation of energy in an oscillator, while Rayleigh assumes the variation to be continuous.

The similarity of equation (17) with Wien's formula leads to the next assumption made by Planck, viz: that the unit quantum which the oscillator can emit or absorb is proportional to its frequency, $\nu$; that is,

$\delta = h\nu$

where $h$ is a universal constant.

Substituting $h_\nu$ for $\delta$ in equation (17) leads to the Planck equation, which is the most satisfactory formula over the complete range of radiations.

### The Quantum Theory

These in brief are the essential arguments used by Planck in deriving his distribution formula. In postulating this so-called *quantum theory* of energy, he discards one of those assumptions of physics whose validity has hitherto never been questioned. The principle of the "Continuity of all Dynamical Effects" has always been tacitly assumed by all physical investigators. As Planck has pointed out in a recent address[1]:

"This principle was formerly taken for granted as the basis of all physical theories, and, in close correspondence with Aristotle, was condensed into the well-known dogma, *Natura non facit saltus* (Nature makes no leaps). But even in this venerable stronghold of Physical Science present-day investigation has made a considerable breach. This time it is the principles of thermo-dynamics with which that theorem has been brought into collision by new facts, and unless all signs are misleading, the days of its validity are numbered. Nature does indeed seem to make jumps—and very extraordinary ones."

The obvious weakness in Planck's arguments is the fact that while he denies validity to the principle of equipartition, he yet assumes the validity of the electrodynamical equations, although both of these are deduced by perfectly similar lines of reasoning from the Principle of Least Action which is the cornerstone, as it were, upon which has been built up the Science of Dynamics. It may be, as Sommerfeld has suggested[2], that this latter principle will have to be restated in another way, so as to satisfy the Maxwell equations on the one hand, and the statistical point of view on the other.

Planck, indeed, has more recently modified his theory in this respect, that he assumes the discontinuity to exist only in the case of the emission of energy, while the absorption is supposed to be continuous. He arrives, in this manner, at the following relation for the average energy, $U_\nu$ of an oscillator.

$$U_\nu = \frac{h\nu}{2} + \frac{h\nu}{\epsilon^{\frac{h\nu}{kT}} - 1} \qquad (15)$$

That is, the average value of the energy approaches $\frac{h\nu}{2}$ as the temperature decreases to absolute zero. The conclusion that such a *residual or latent energy* exists which is independent of temperature is quite in accord with the results of investigations in the fields of specific heats, photo-electric effect and X-ray emission by cathode rays.

From the physical point of view the significance of the constant $h$ is difficult to interpret. Whether the discontinuity exists in the emission of energy only or in both emission and absorption, the conclusion that such a discontinuity exists requires a complete reversal of our previous ideas on the nature and mode of propagation of radiation.

It is therefore no surprise that there exist a number of different interpretations of the quantum theory, and Prof. Millikan enumerates no less than five "different brands" of the theory[3]. Some of these views are evidently at variance with new facts which have been discovered since their orginators first postulated them, and the least radical concept is that the radiant energy is emitted discontinuously in time, in amounts which correspond to multiple of $h\nu$. An oscillator absorbs energy continuously until a total amount $h\nu$ has been absorbed. It then has a chance of emitting the whole of this unit, otherwise the energy absorbed will go on increasing till it reaches $2h\nu$, $3h\nu$, etc., and as

---

[1] New Paths of Physical Knowledge, Phil. Mag., July, 1914.

[2] Abh. d. deutsch. Bunsen Ges. Nr. 7, (1911).

[3] Science, *37*, 119, 1913.

the amount of this energy reaches an exact multiple of $h\nu$ the oscillator has again the chance of emitting the whole of its energy. The quantity $h\nu$ is known as an energy quantum and it may perhaps make matters a little clearer if its value be calculated for some monochromatic radiations.

The dimensions of $h$ are those of *energy* × *time*, and according to the most recent determinations its value is $6.62 \times 10^{-27}$ ergs × second. The yellow line $D_1$ in the spectrum of sodium has a wave length of $0.5896\,\mu$. Hence,

$$\nu = \frac{3 \times 10^{10}}{0.5896 \times 10^{-4}} = 5.088 \times 10^{14},$$

and therefore

$$h\nu = 6.62 \times 10^{-27} \times 5.088 \times 10^{14} = 33.69 \times 10^{-13} \text{ ergs.}$$

Again, the wave-length of X-rays corresponding to 40,000 volts is about $3 \times 10^{-9}$ cms. The frequency of these radiations is therefore $10^{19}$, and

$$h\nu = 10^{19} \times 6.62 \times 10^{-27} = 6.62 \times 10^{-8} \text{ ergs.}$$

When it is remembered that 1 watt $= 10^7$ ergs per sec., it is seen that even in the case of very high frequencies the energy quanta involved are very small, and in the case of all ordinary energy transformations the effect of such minute subdivision would be very insignificant.

In a subsequent section we shall show that this disintegration into energy quanta does become quite pronounced in those cases where we are dealing with the absorption of heat waves at very low temperatures, such as the boiling point of liquid hydrogen and where the total quantities of energy involved are very small. We shall also discuss some applications of the quantum theory which have yielded results that are among the most wonderful achievements of theoretical physics.

## SUMMARY

The quantum theory thus represents an attempt to account for the observed variation of intensity with wave-length and temperature in the radiation from a black body. All attempts to reconcile these observations with deductions based on the older dynamical concepts have so far ended in failure, and it therefore appears necessary to discard the Principle of Continuity of Dynamical Effects in physical science. The recent observations in the fields of radiation, specific heats, photoelectric effect and X-ray emission by cathode particles seem to be best accounted for by the hypothesis that the disintegration of energy is limited in a similar manner to the subdivision of matter. For a long time we have had the atomic theory of matter and the facts in support of this theory have become so numerous that the theory has for most physicists become an article of faith. In a previous section we discussed the evidence which has led to the formulation of an atomic structure for electric charges, and in the above paper we have shown that *there are strong reasons for ascribing an atomic structure to energy*. As yet the physical interpretation of the quantum theory is very indefinite. As Planck states:

"In what way we are to conceive the nature of quanta of a purely dynamical nature, we cannot yet say for certain. Possibly such quanta might be accounted for if each source of radiation can only emit energy when that energy attains at least a certain minimum value; just as a rubber pipe, into which air is gradually compressed, bursts and scatters its contents only when the elastic energy in it attains a certain value."

"In any case, the hypothesis of quanta has led to the idea that there are changes in nature which do not occur continuously but in an explosive manner. I need hardly remind you that this view has become much more conceivable since the discovery and investigation of Radio-active Phenomena. Besides, all difficulties connected with detailed explanation are at present overshadowed by the circumstance that the Quantum Hypothesis has yielded results which are in closer agreement with radiation-measurements than are all previous theories."

# PRACTICAL EXPERIENCE IN THE OPERATION OF ELECTRICAL MACHINERY

By E. C. Parham

Construction Department, General Electric Company

## Part I

In this issue we begin a series of articles based on practical experience in operation, which we believe will be of great interest and use to a number of our readers. The author has made a practice of collecting valuable operating data and notes for some years and has had much experience in "electrical troubles", so many of which can be traced to oversight in operation. The short articles given in this series will be written in plain concise language so that they may be readily understood and appreciated.—Editor.

### TESTING FOR GROUNDS ON A SECONDARY THREE-PHASE LINE

Fig. 1 illustrates the connections of three single-phase transformers as operated on a three-phase supply circuit. Both the primary and the secondary are star connected; the primary neutral is maintained isolated, but the secondary neutral is perfectly connected to ground in order to realize certain advantages incident to that connection. It will be noted that, when a secondary is grounded, an insulation fault to ground on any of the phase wires, as at $g_1$, or at $g_2$, or at $g_3$, will cause a short circuit and will blow the fuse of whichever line is involved.

In a certain instance, an operator called in an inspector to locate a ground on a three-phase distributing line which served a number of mill motors. The inspector did not give the matter of grounded neutral any attention. In applying a test wire, such as $t^1$ in Fig. 2, to flash the three wires of the three-phase line to ground one at a time, all three flashed, indicating a short circuit. Then, suspecting the cause, the inspector applied a voltmeter between each phase wire and ground, and in each case measured about 133 volts. Since 230 volts was the line voltage given by the secondaries of two transformers in series, the voltage of a single coil was equal to $\frac{230}{\sqrt{3}} = 133$ volts. This value, being equal to that measured by the voltmeter, indicated that the voltmeter was figuratively applied across the secondary of one transformer. A grounded neutral, on the secondary side of the transformer, is the only possible condition that would permit of the voltmeter reading a voltage between any line and ground equal to the secondary voltage of only one transformer.

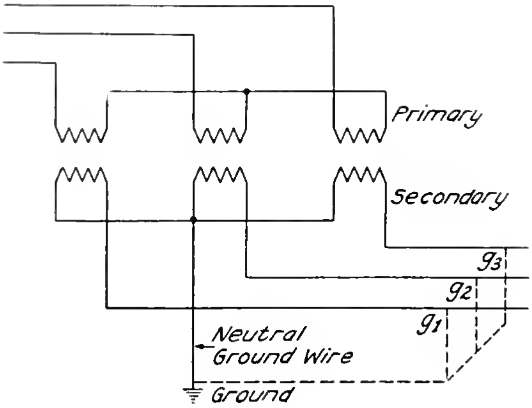

Fig. 1

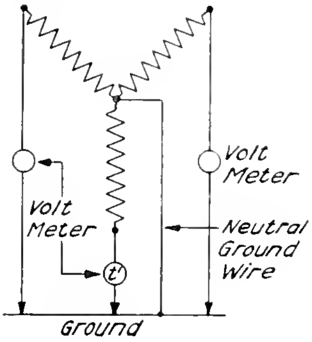

Fig. 2

The possibility of a man getting burned when applying test lines to a transformer service, the neutral of which is grounded without his knowledge, is evident. For this reason, a test for grounded neutral should be the first one to be applied in the absence of any previous information as to whether it is grounded or not.

### INABILITY TO MAINTAIN LOAD BECAUSE OF REVERSED SERIES FIELD

Assuming the shunt field of a compound-wound machine to be correctly connected, the machine will build up its field and promptly generate normal no-load voltage, even if the series winding is connected in reversed. This is true in case the series field opposes the shunt field, even though a *long shunt* connection is used, that is, a shunt field connected outside of the series field, for the small shunt field current in the few series field turns has but little effect. If the shunt field is reverse connected, the machine will not generate at all.

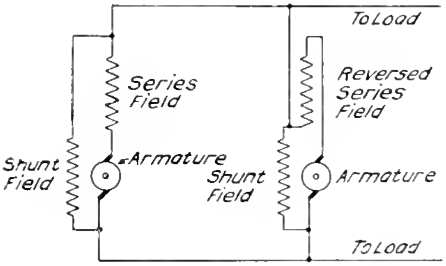

Fig. 3

Many of us fail to make a distinction between a dynamo having the wrong polarity and a dynamo having reversed field connections. With correct connections—and there is only one correct field connection for a given rotation and armature connection—the polarity of the voltage available at the machine depends upon the polarity of the residual magnetism. This polarity is liable to be either positive (+) or negative (−). The polarity of the voltage available at the switchboard may be reversed by reversing the cables between the machine and the board, but in doing this care must be taken to maintain the original shunt field connection at the board, otherwise the result will be no polarity at all.

An inspector went up into a mining camp on an operator's complaint that his machine would not take load. If the operator had taken the trouble to state that he had reversed the direction of rotation of the unit, the inspector need not have made the trip, because he could have instructed the operator by letter. The trouble was merely that the operator had reversed the shunt field but had failed to reverse the series field when he changed the direction of rotation of the dynamo; and the result was that the machine would pick up its no-load voltage but, as soon as an effort was made to put on load, the armature current passing through the series winding in the wrong direction would weaken the field. Had it been necessary to operate the machine in parallel with another dynamo, further complications would have arisen for, as indicated in Fig. 3, the reversed series winding would have caused the equalizing current from the machine No. 1 to pass through the series winding of the machine No. 2 in the reverse direction, thereby tending to decrease the very voltage that the equalizing current should tend to increase. In any instance where a change is made in the direction of rotation of the armature, in the position of brush-holders, or in the connections of the field windings, if, after the change has been made, the machine promptly builds up its field and generates no-load normal voltage with the field rheostat in its usual marked position, but refuses to support the load when the main switch is closed, it probably means that the connections of the series windings must be reversed in order to make them magnetize the field cores in the same direction that the shunt winding is magnetizing them.

### A BURNED OUT SHUNT

The series field shunts of the small and medium sizes of generators are made of german silver ribbon; for the large generators, they may be made up of iron-grid resistance units which afford better radiation. In either case, when making up a shunt due regard must be paid, not only to *resistance*, which determines the amount of current to be by-passed from the machine's series winding, but also to the current-carrying capacity required by the shunted current. In other words, it is possible to build a shunt which will by-pass a current that will result in a favorable degree of compound or over-compound, but which because of running at too high a current density will become so hot as to ultimately burn out, or at least to affect the correct proportional division of the current with another machine in parallel.

In a certain case, an operator complained that he could not keep up voltage on an exciter and sent for an inspector to determine the cause. By the time the inspector arrived, the series field shunt of the affected exciter had burned out and the operator had pressed another exciter of the same rating into service. This exciter was maintaining its voltage. A glance at the burned out shunt showed that it was home-made. When the burned out shunt was replaced with the shunt from the other machine and the discarded machine was placed again in service, the compounding was almost perfect, although a considerable difference might have been expected owing to the differences in two machines which are unavoidable, even though built as nearly as possible alike.

It seems that the operator had scrapped the original shunt as the result of a ground that had burned it beyond repair. In making up a new shunt, with the ribbon he had available, he not only made it of too low resistance, thereby undercompounding the machine, but he used too small a cross-section, and the excessive current by-passed by the shunt finally burned it out.

The inspector took some of the same ribbon and made a satisfactory shunt of correct resistance and of ample current carrying capacity.

### ARMATURE RUBBING POLE PIECES

The readiness with which trouble may be located in a piece of apparatus often depends upon its accessibility. Where careful inspection is made difficult by reason of the location of a device, it is quite certain that no thorough inspection is ever made.

The following will describe a case in which a large direct-current motor was installed near the ceiling in the darkest corner of a forge room. At times it was with difficulty that even the outline of the motor could be seen from the floor. Only one end of the motor was accessible for air-gap inspection, and even then that end was partly obscured by end shield brackets; these conditions made air-gap sighting or gauging difficult, and it would only be a conscientious man with patience, and determination who would complete a thorough examination of the condition of the air-gap. Before serious trouble developed the motor had blown fuses at intervals, the frequency of which increased until production was hampered. The air-gap clearance had been tested, but the man who did the testing was not competent, as is evidenced by the fact that the armature lost a band wire a few days afterwards. Without careful investigation as to whether or not excessive bearing wear was responsible for the trouble, the bearings were believed to be at fault and a new set was installed. The motor then operated for about a week, after which it began to blow fuses again and then lost another band wire, but not in the same place as the first.

The operator then called in an inspector who determined that the second band wire gave way because it had been injured at the time the first one was rubbed off, and further found that the cause of the initial and subsequent trouble was a thin brass jam-nut which had been trapped between one of the pole pieces and its frame seat. This had entered at the time of reassembling the machine after an overhauling sometime previously. It had allowed just enough clearance to permit of installing the armature, but a very little bearing wear had in each case brought the armature band wire and pole-piece hornfiber into rubbing contact. By its braking action this had first caused the fuse blowing and then the weakening of the band wire, until it broke. It speaks well for the motor that the distorted field incident to the displaced pole-piece did not cause sparking at the commutator.

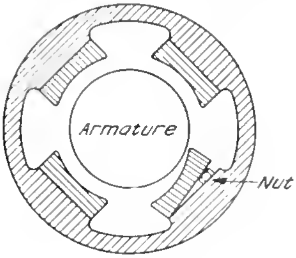

Fig. 4

### A NOISY TRANSFORMER

Since the value of an alternating current passes through zero twice during a cycle, the strength of the magnetic field set up by that current also equals zero twice during the same period. The resulting alternate stressing and releasing of the magnetic bodies that are within the influence of the field, which is periodically reversing in direction and varying in strength, tends to set up vibrations that are audible.

To illustrate: The armature of a solenoid brake, the operating coil of which is energized by single-phase current, may chatter badly unless measures are taken to prevent it. Since the weight of the armature tends to release it when the magnetic flux is passing through the zero value but is prevented from doing so by the quick return of the holding magnetism to a value sufficient to exert a holding pull, the armature, although it cannot actually drop, vibrates enough to hammer the field core. This results in a disagreeable noise.

The core of a single-phase transformer is under similar stresses that vary in strength and direction with the current producing them, and any loose parts within the influence of these periodically varying stresses will become nominally armatures which for the same reason will vibrate just as a poorly adjusted brake armature.

In a certain installation one single-phase transformer in a bank of three, connected to operate on a three-phase circuit, was noisy, but its mates were quiet. On removing the three elements from the tanks of this bank and inspecting them, no difference could be detected except that the core-plate nuts of the noisy transformer were loose. After tightening the nuts and again placing the bank into service, the previously noisy unit operated quietly.

# LOAD DISPATCHING SYSTEM OF THE COLUMBUS RAILWAY, POWER AND LIGHT COMPANY

By Harold W. Clapp

General Superintendent, The Columbus Railway, Power and Light Company

Continuity of service and economical operation are prime requisites for success in the generation and distribution of electric energy. After the equipment for an electrical installation has been selected and installed, there is no surer means of maintaining these desirable qualifications than by the employment of an efficient load dispatching system. This article describes a recently designed system of this type, its various kinds of indicating devices, its means of communication with the parts of the plants and substations that it controls, and the method in which its operations are carried on.—Editor.

The electric energy for the operation of the railway system and for supplying the numerous power and light customers of the Columbus Railway, Power & Light Company, is furnished by a system of six power stations, ranging in size from 250 to 14,350 kw., rated capacity. Current for the railway load is generated at 575 volts, and for power and lighting loads at 4150 volts; while some direct current is furnished at 220 volts on the Edison three-wire system for lighting the central district of the city. The Spring Street station is the largest and contains four a-c. turbo-generators rated at 11,000 kw., and four engine-driven d-c. units rated at 3350 kw. The second largest station has four 220-volt d-c. engine-driven units with a total rating of 2560 kw. The next station in size contains three engine-driven and one turbine-driven alternators, with a total rating of 2100 kw. Located at these stations are seven motor-generator sets varying in size from 300 to 750 kw. capacity; while six other motor-generator sets and four rotary converters are located at points on the system convenient for the proper distribution of energy. The other three stations are very small and are seldom used except in periods of very heavy loads in the winter season, or in case of serious breakdown in the larger stations.

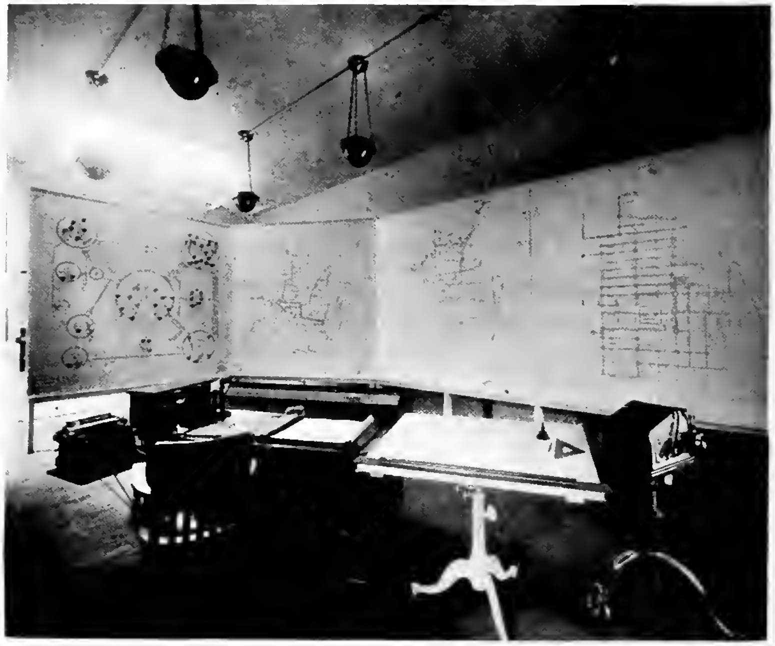

Fig. 1. General View of the Load Dispatcher's Office

All the power stations and substations are tied together by both high and low tension transmission lines, in such a manner as to make a shut-down for more than a few minutes an unknown thing under all ordinary conditions.

The Spring Street station, containing the largest units, is the most economical to operate, and therefore a practice is made of carrying all the load possible on this one station. At times, on Sundays and during the after part of the night, for instance, the load decreases to such a point that it is possible to cut out the prime movers in the second largest or the 220-volt station, and carry its load on its motor-generators from the alternators at the Spring Street station. The load formerly carried by the third largest station, which is also used in winter as a hot water heating plant, is handled during the summer time by Spring Street.

Owing to the fact that the generating equipment was so widely scattered, and that the nature of the service required was so exacting, it was deemed advisable to place the responsibility for its proper handling in the hands of a load dispatcher. Consequently, a load dispatching system was recently placed in operation which it is firmly believed will result in an increased reliability and the production of further economies in general power station load handling over the old methods. An office adjacent to the second largest station was fitted up with maps, telephones, recording barograph, recording electrical instruments and other necessary equipment for the dispatchers to properly supervise the load dispatching and from which to make out detailed daily reports covering their operations. They are kept advised from time to time through the day, by each station, of the amount of load carried and are given a daily report of the generators in service and their current output, from which the load curve for the day is made. Typewritten reports up to 6 o'clock in the morning must be in the hands of the Superintendent of Power by 9:30. The practice is followed of noting on these reports, in red, cases of trouble and fire alarms received over a private line. This office is also supplied with daily and monthly forecasts of the weather conditions. Wireless antennae are now being installed to give advice of approaching thunder storms.

A separate telephone system connects the dispatchers direct with all power stations and all substations except two, the latter being reached through the general office operator. The telephone system is so arranged that the load dispatcher may hold a telephone conference with the switchboard operators at all stations. This has already proved a very valuable adjunct as a time saver in connection with certain phases of daily procedure in the handling of the dispatching system.

The three load dispatchers, who work on eight-hour shifts, are switchboard operators of about ten years' experience and have been given several months of additional preparation for this work by being transferred from station to station in order to become familiar with the load conditions of each.

The photograph of the load dispatcher's office, see Fig. 1, shows at the left a graphic outline of the power station and substation system, giving the manner in which stations are tied together. The next three boards give maps of the city, showing the distributing lines, for railway and power and light. Having this information visibly at hand on the boards, the load dispatcher keeps directly in

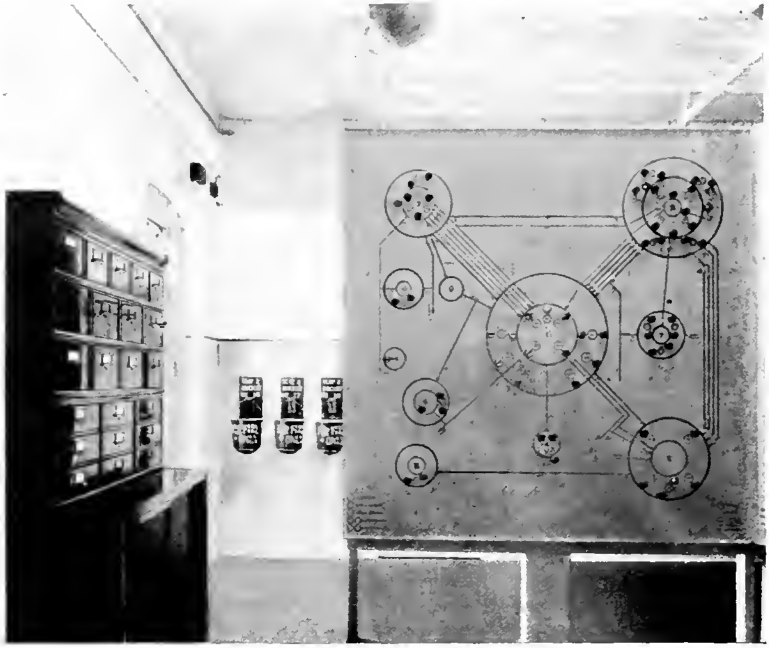

Fig. 2. A Near View of that Section of the Dispatching Board shown at the left of Fig. 1

touch with the changes made at the different stations. In case of trouble on any of the lines, his maps indicate at once how he can get around such difficulties with the use of certain line switches and still make it possible to furnish current with the least possible interruption of service.

The No. 1 board shows the power generating system, each power station and substation being indicated by a large circle. The different tie lines between stations are indicated by lines drawn upon the board in the proper color, and line switches are shown by small spring buttons, which can be turned as occasion demands to indicate whether the line is in or out of service. There are sufficient tie lines between the stations so that, in case of trouble on any line, service may still be furnished by using another line. Within the large circle and indicated by smaller circles, are shown each of the generators, motor-generators, rotaries, boosters, or batteries in that station. Close to these smaller circles are placed lamps under different colored lenses, the colors indicating the class of current delivered; for instance, railway current is shown by a green lens, and alternating current for power and light by a red lens, other colors being used to show rotaries, boosters, etc. At the outer edge of the dispatcher's desk is placed a double row of push button switches, which are connected to the lamps on the board; when he orders a certain generator placed on the line, he simply touches the proper button in the bottom row for that machine and its lamp is lighted. When this machine is cut out of service, he presses the top button and the light is put out; the lighted lamps giving the number of machines in service and the kind of current each is delivering.

The second board shows the alternating current system, giving the station to station tie lines and all primary lines, whether one, two- or three-phase; no secondary lines are shown. The power stations, substations and the largest consumers are also located on this board. This board is used for following up troubles which may arise from time to time and gives the dispatcher a graphic outline of the means which have been provided to supply current at such times.

The Line Department is required to co-operate fully with the dispatchers in handling cases of trouble arising from storms or otherwise, and must also work in conjunction with them in the proper handling of current while any new installations are being made. The load dispatching system has proved its worth several times this summer during lightning and wind storms, because it has brought the dispatchers and Line Department so closely in touch with each other.

No. 3 board outlines the trolley and feeder system, showing in one color the railway feeders, and in another color the double and single trolley lines. This board also locates section insulators, and is intended to be used in case of trouble on the lines, helping the dispatcher at such times to devise a method of supplying current sufficient to operate the cars.

Board No. 4 shows the underground system in the central district of the city. All manholes and junction boxes are located, while the underground and overhead feeders and distributing lines are shown by lines.

Before the load dispatching system was placed in operation, the heavy peaks in the load were handled by the engineers at the different stations as each saw fit, subject at times to approval of the Superintendent of Power, advice of changes made being given from one to another by telephone. In emergencies or in cases of breakdown especially, this system often proved ineffective, resulting sometimes in confusion at a time when machines should have been replaced on the line promptly; this has now been avoided by making one man, the load dispatcher, responsible for getting the machines on or off the line. The load dispatcher knows the steam consumption of each of the steam units, and can so order the plan of operation, in the great majority of cases, so that certain units may be used in preference to others which otherwise might be operated at a greater expense. The great economy resulting from the use of the load dispatching system comes from the fact that the dispatcher can formulate in advance methods of handling the average daily loads, using at all times possible those machines which are most economical in steam consumption. The experience which he accumulates from day to day in handling the system makes his movements in times of trouble, decisive and rapid, the whole tending toward a non-interruption of service plus economical generation of energy, the final goal to be attained being *never-failing service.*

# THE WHITE RIVER DEVELOPMENT OF THE OZARK POWER & WATER COMPANY

By G. W. Saathoff and C. P. Cummings

Ozark Power and Water Company, Joplin, Mo.

As the possibilities for further large water power developments become scarce, the engineer and promoter turn their attention to the smaller streams, where in many cases, by means of storage basins, sufficient water can be obtained for the generation of electricity in profitable quantities near a ready market. The development described in this article is of such a nature. The ultimate capacity of the plant will be 18,000 kw. generated by eight units. The energy is transmitted to distances as great as 150 miles; a ready market being found in the smaller cities thus reached, and in the surrounding lead, zinc and coal mines. The power house, transmission lines and substations are described in detail.—Editor.

The power possibilities of the White River in Southern Missouri have been known in a general way for a great many years, but it was comparatively recently that any definite work was done and a chain of dam possibilities located. About the time of the completion of the general survey, late in 1911, the Ozark Power & Water Company selected a site about two and one half miles up stream from Forsyth, Missouri, and about seventeen miles by water down stream, or seven miles overland from Branson, the nearest railroad station. They soon began active construction work on what is now the largest plant of this character totally within the state.

Fig. 1. General View of the Hydro-Electric Power House and Dam

The construction of the camp was one of the first difficult problems successfully solved by the management. This camp was finally constructed and operated in such a manner as to bring about more healthful conditions than existed in any other community in the immediate district. The successful solution of this problem has proven beyond a doubt that labor trouble may be entirely eliminated and better and steadier labor secured by providing good living quarters for the laborers.

During the early stages of the dam construction practically all of the materials and equipment, with the possible exception of the gravel and sand, were hauled seven miles overland from Branson. Later, however, after the dam had been partially closed, it was possible to handle the heavy machinery and other equipment on gasolene boats and barges over the seventeen-mile water route from Branson.

Fig. 2. An Interior View of Power House. Note the Oil-Drying Apparatus in Operation on the Gallery

On September 1, 1913, the development was first put in commercial operation. The maximum capacity of the plant is computed on a basis of 18,000 kw. in eight units of 2250 kw. each, five of which are running at the present time.

The transmission system extends a total distance of 150 miles from the power site by way of Springfield, Mo., to Joplin, Mo., where connection is made with the 32,000-kw. steam and hydraulic system of the Empire District Electric Company of that city, in a substation jointly owned and operated, and located on West Seventh Street. Other substations are completed in Springfield, Aurora, and Diamond, and plans are prepared for serving all cities and towns along the line.

The principal market for the service is located in the lead and zinc mining fields, of which Joplin, Mo., is the center; the coal mining fields of Cherokee County, Kansas and Barton County, Mo.; the City of Springfield; and the towns and cities between Springfield and Joplin. The population of these communities within reach of the transmission line will aggregate approximately 250,000, and an industrial power load of approximately 50,000 h.p. is now operating by electricity, while the available power business will probably total 200,000 kw. in connected load.

The drainage area of the basin of the White River above the dam approximates 4,350 square miles, extending from the northwestern part of Arkansas to the south central part of Missouri, and having a mean precipitation of forty to forty-five inches per year. The discharge of the river is not always in proportion to the precipitation, but is augmented in a great measure by the infiltration of water from other drainage areas, especially at times of minimum flow.

The White River has been studied, as noted above, very carefully relative to the characteristics of its drainage area and possible power developments, both above and below the present installation. Some preliminary work has already been done on a possible storage reservoir of approximately 10,000 acres in area which will, when completed, provide abundant storage for the present development. The possibilities below are equally as attrac-

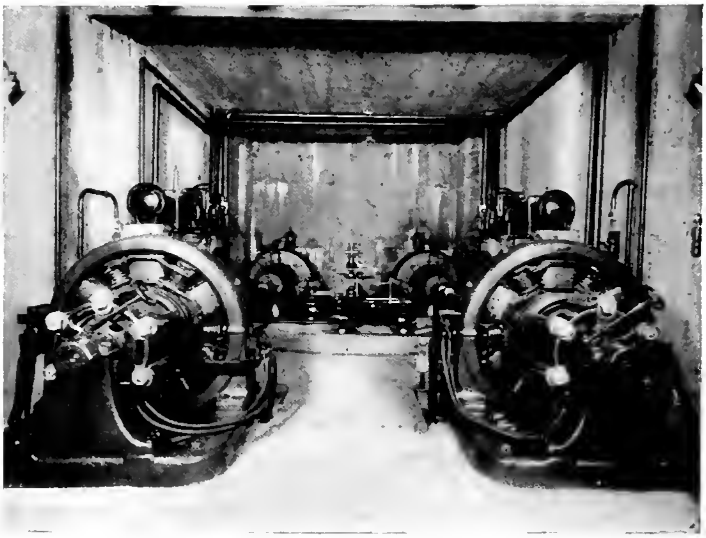

Fig. 3. Exciter Room at Power House

tive and some idea of the available power may be gained from the fact that the crest of the present dam is seven hundred feet above the sea.

The pond formed above the dam is about twenty-two miles long and is by far the largest lake in the state. The lake on one side is lined by high, rocky cliffs, in some places reaching a height of two hundred feet; on the other, by rolling land which, in nearly every case, reaches a height of one hundred feet or more above the bed of the stream. This section of the state now offers to the people one of the finest pieces of natural beauty and a most excellent outing center and is being rapidly settled by summer homeseekers.

The spillway is five hundred and ninety-four feet long, and is of the Ambursen type, with a maximum height of fifty-six feet. The reinforced concrete deck is supported at an angle of about forty-five degrees by vertical, tapering concrete buttresses, spaced with eighteen foot centers and resting on solid close grained limestone with heavy, horizontal strata. A cutoff wall about eight feet deep and four feet wide runs the entire length of the dam at the heel of the deck. The down stream side is open and the water is allowed to fall free after passing the crest. Two openings through the deck, five feet wide by five feet long, are fitted with sliding cast iron gates which are operated electrically and serve as permanent sluiceways. The power house extends from well into the east bank to the middle of the old stream bed. From this point the spillway begins and extends across the river, terminating in a cellular reinforced concrete abutment which projects twenty-five feet above the crest of the spillway. A concrete core wall, resting on rock, extends from the buttress four hundred feet into the west bank, and a heavy earth fill is made both above and below it, preventing any possibility of water overflowing any section of the west bank.

**Fig. 4. Front View of Switchboard Installed at Power House**

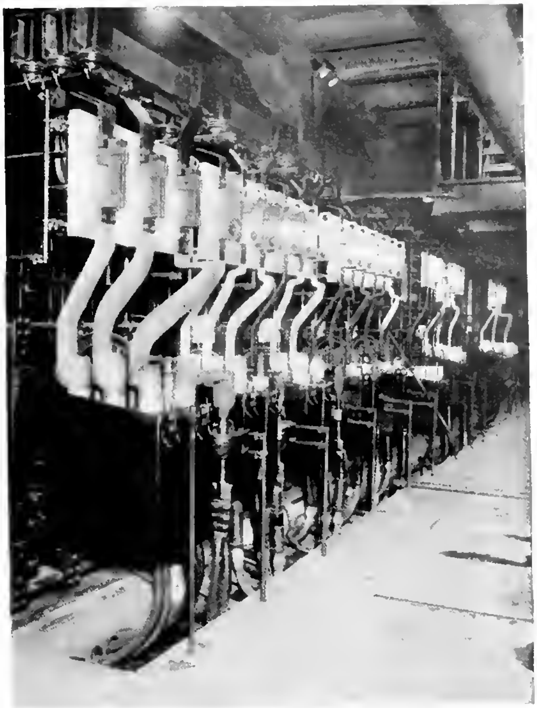

**Fig. 5. Rear View of Switchboard Installed at Power House**

The power house is a reinforced concrete structure, the upper sections of which, on the down stream side, are skeleton frame with brick panels. The roof is supported on steel trusses and covered with book tile and composition roofing. The windows and frames are steel and are operated from the generator floor. The plant equipment is installed on three floors; the lower floor carrying the generators, governors, and exciters, the second floor transformers, switchboard, etc., and the upper floor the high voltage switches and lightning arresters. The main generating station is provided with a thirty-ton traveling crane.

Fig. 6. 66,000-Volt Switches and Lightning Arresters Located at Power House

A four-foot partition wall is placed between the openings for the several wheels. Each opening is twenty-three feet by eighteen feet and has a curtain wall extending several feet below the crest of the dam, which acts as a skimmer to prevent floating debris, ice, etc., from reaching the racks. The openings may conveniently be closed in case it is necessary to work on the head gates, racks, etc.

The trash racks are placed in the intake compartments on a slope of three and one-half horizontal to twelve vertical. The screen is eighteen feet wide and the bars are two and three-quarter inches by one-fourth inch in cross section, and are forty feet long, spaced one and one-half inches on center. The racks are supported on heavy beams and trusses fastened directly to the power house structure.

The head gates are seventeen feet high and nine feet wide; two for each wheel opening, and are made of eight inch steel beams covered with three-eighths inch skin plate. At the bottom of the gate a six- by eight inch timber is attached so that it closes against the back of a ten inch channel, which is placed in the concrete across the opening. The frames and guides are made of rolled channel and beam sections and each gate is provided with a small filler gate to equalize the pressure and prevent excessive friction in opening and closing the main gates. The gate operating mechanism is connected to the gate by a sixty-foot stem, made of ten inch channel, reinforced by six inch beam. This mechanism is arranged for motor or hand power and is mounted on a seven foot platform five feet above extreme high water.

The tailrace has been excavated below the old river channel and the bed and sidewalls have been so built that the water is directed to the center of the stream, thereby minimizing the friction loss in the tailrace.

Each of the five main units now operating consists of twin Francis turbines with fifty-two-inch runners, manufactured by the S. Morgan-Smith Company and designed to operate under working heads from forty to fifty-four feet. The output will vary from 2600 h.p. at forty feet to 4000 h.p. at fifty-four feet, and at the mean effective head of fifty feet the units will develop 3600 h.p. The speed of each of the units is controlled by a Type NS Lombard governor, with an independent belt-driven pump. The wheels are set in a concrete chamber and the discharge is conducted to the tailrace through a single eighteen foot conical steel draft tube flaring from a diameter of nine feet six inches at the wheel to seventeen feet at the outlet, and is inclined on a slope of one horizontal to four vertical. This slope directs the tail water down stream and further eliminates excess friction loss in the tailrace. Two single-runner exciter units with eighteen inch wheels, capable of developing 200 h.p. under fifty-foot head, are used to drive two independent exciter sets. The speed of each of these units is controlled by a suitable Lombard governor.

The generators, which are direct connected to the turbines, were manufactured by the General Electric Company, and are rated at 2250 kv-a. three-phase, 25-cycle, 2300 volts when operating at 214 r. p. m. Each machine is designed for a thirty per cent overload, giving a capacity approximating that of the wheels. The exciters are rated at 175 kw. at 125 volts when operating at 600 r.p.m., and are directly connected to the exciter wheels.

Fig. 7. Double-Circuit Steel Poles

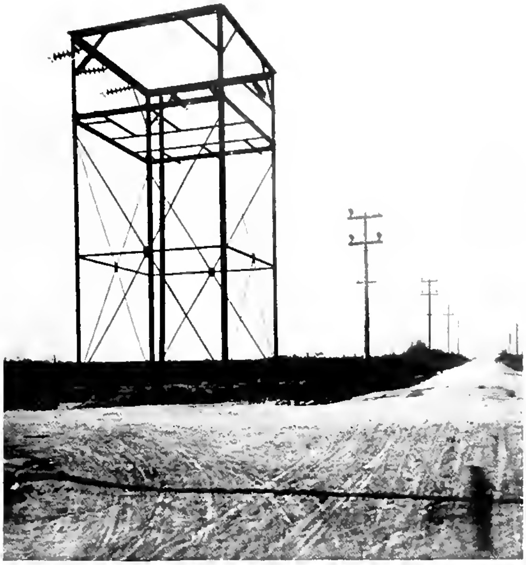

Fig. 9. Steel Four-Pole Tower

Fig. 8. Square Towers

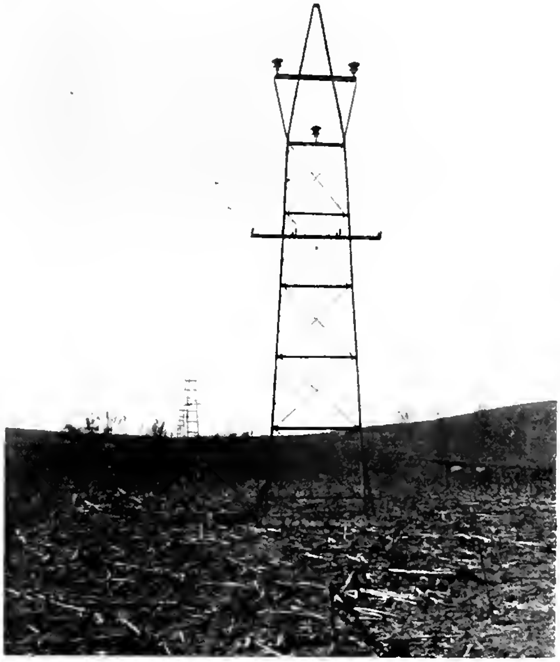

Fig. 10. Standard "A" Frame Tower

Various Types of Towers used on the 66,000-volt Transmission Line

The transformer equipment consists of seven single-phase units rated at 2000 kv-a. each, when operating on 2300 volts to 66,000 volts, and were manufactured by the General Electric Company. The units are arranged in two banks of three transformers each, with one spare. Each bank is provided with individual water circulating pumps, but, under ordinary operating conditions, the water is supplied from the pond above the dam under a sufficient head to guarantee good circulation.

The switchboard is mounted on a transformer gallery overlooking the generator room floor. The main low tension buses and switches are mounted on pipe supports several feet back of the board. The buses and connecting straps to the switches are flat copper while the conductors to the generators and transformers are lead covered cable. The oil switches are electrically operated by energy taken from the exciter buses and are in every case provided with air break isolating switches. All of the switching apparatus, switchboards, etc., was supplied by the General Electric Company. The high tension wiring is on the third floor. Each transformer in the outgoing line is controlled on the high tension side by General Electric solenoid-operated oil circuit breakers, manipulated from the main switchboard. The plant equipment is protected by choke coils and electrolytic lightning arresters on the outgoing line, this apparatus being also located on the third floor. The horn gaps, however, are installed outside, and the conductors from the gaps to the cone stacks are taken into the room through roof bushings.

Fig. 11. The West Seventh St. Substation with Trouble Cars in the Foreground

The plant is connected by a 66,000-volt transmission line with the lines of the Empire District Electric Company at Joplin and the Springfield Gas & Electric Company at Springfield. The line loops through substations at Springfield, Aurora, and Diamond, thus allowing each station to be fed from either direction, although, normally, the line is cut straight through.

The transmission line extends in a northwesterly direction from the hydraulic plant, a distance of approximately forty-six miles, to the Springfield substation. The first twenty-two miles traverses a very rough section of the Ozark Mountains and is carried on steel A frames over a privately owned right of way. From the end of the A frame section the line is carried through a fairly open country and along the county roads on wooden pole construction to the city limits of Springfield. Within the city limits of Springfield the circuits to and from the substation are carried on a single steel pole line.

The line from Springfield to Joplin is built along the public highways under franchises granted by the county courts of the several counties through which the line passes. It is carried on wooden pole construction from the city limits of Springfield to the city limits of Joplin. That part of the line within the city limits of Joplin is similar in construction to that part in the city of Springfield.

The steel A frames used in the mountain district are from forty to sixty feet in height. The legs are built of single seven inch, nine and three-quarter pound channels, and the structures are securely braced by horizontal members with tie rods provided with turnbuckles. The cross arms are made of two angles, three inch by two-and-one-half inch, bolted to the frames, six feet below the apex. Two insulators are carried on this cross arm and a third insulator is carried on the upper horizontal member between the channels. A steel ground wire is clamped to the apex and another below the cross arm. The average span in the steel A frame section of the line is approximately four hundred feet; however, there are some spans that run over one thousand feet. Square strain towers are set about every two miles in a straight run of line and all corners on the entire system are provided with heavy steel "four-poles."

The wooden pole line is constructed mainly of forty-foot Idaho cedar poles, with not less than eight inch tops. That part of the pole below the surface of the ground is treated with Carbolineum and is set in broken stone. The cross arms are of clear Oregon fir, four and one-half inches by six inches by eighty-four inches. The braces are made of one-and-one-half inch galvanized angle iron and are arranged to fasten to the bottom of the cross arm.

The poles used inside the city limits of Springfield and Joplin are of steel latticed construction, fifty feet high, and are made of two nine-pound channels spread two feet six inches on centers. These poles are set on concrete bases and anchored with four one-and-one-quarter inch anchor bolts. The cross arms are seven feet long, made of nine-and-three-quarter pound angle, and are arranged for two circuits. Disconnecting switches are placed on the corner "four-poles" and at intervals in the line, to aid in isolating the several sections for the location of trouble.

Fig. 12. Transformer Room at the Substation

The main power conductors from the hydraulic plant to Springfield consist of three 2/0 stranded hard drawn copper wires. From Springfield to Joplin conductors are 1/0 solid hard drawn copper, except over railway crossings, where 1/0 stranded copper is used. Two complete metallic circuit telephone lines are strung on the transmission structures for the entire length of the line. No. 10 hard drawn copper is used for telephone conductors on the wooden pole construction and is transposed at every other pole, while No. 8 copper clad wire is used on the A frame construction and is transposed at every tower.

The insulators over the entire line are of the pin type, manufactured by the Thomas or Ohio Brass Companies, except the insulators on the dead ends, which are 100,000-volt, suspension type. The pins are the Lee type and the thimbles are cemented directly into the insulators.

The West Seventh Street station forms the connecting link between the 66,000-volt Ozark system and the 33,000-volt Empire system. The building is one hundred and four feet by one hundred and eight feet, forty-two feet high, built of concrete, brick, and structural steel. The roof is of book tile and composition.

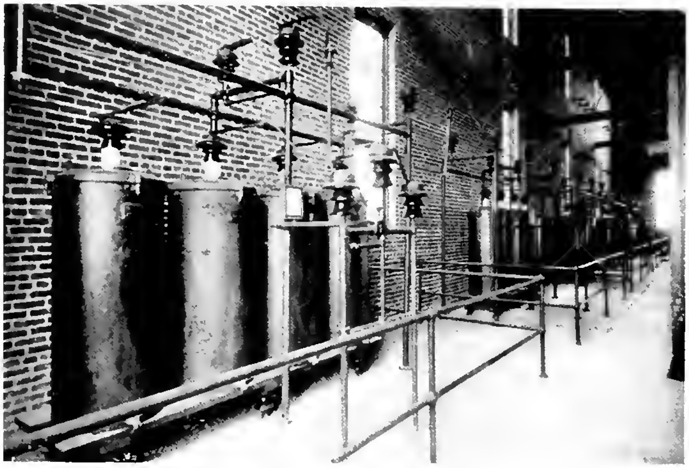

Fig. 13. Lightning Arrester Apparatus at the Substation

The building is divided into three rooms and a basement. The first room contains only the 66,000-volt busbars, oil switches, disconnecting switches, lightning arresters, etc. The layout provides for two outgoing feeders and three transformer switches.

The second and middle room is the transformer room and contains only the transformers, and is laid out for three banks of water-cooled transformers, 66,000 to 33,000 volts, having a total capacity of 30,000 kv-a. and two banks of water-cooled transformers, 33,000 to 2300, having a capacity of 6000 kv-a.

The basement contains a fifty-five-cell battery for the control circuits and emergency lighting, and also rooms for oil storage.

The third room has two stories, the upper floor carrying the 33,000-volt switching apparatus, and choke coils for five 33,000-volt feeders and five transformer banks. The lower floor contains five sets of 33,000-volt electrolytic lightning arresters, two sets of busbars arranged in brick and slate compartments on structural steel columns, one thirteen-panel switchboard carrying the control switches, and four 2300-volt distribution feeders, one motor-generator set for battery charging, and two circulating pumps.

The entire station is operated by remote control.

Fourteen telephone lines from both the Empire and Ozark systems center at this station on a suitable plug board. The attendant at this point also acts as load dispatcher for both systems.

Connection is made with the lines of the Springfield Gas & Electric Company at a station in Springfield, built adjacent to the plant of the above operating company. The building is of brick and steel, with concrete floors, and is eighty by fifty-six feet, with a twenty-four by twenty-five foot wing, and is approximately fifty feet high. The roof is of book tile with composition covering. The station is divided into two rooms, one of which contains the lightning arresters, and the other, which is provided with galleries for switchboard and switches, carries on the main floor a bank of three 1550-kv-a., 66,000-volt to 2300-volt, 25-cycle, single-phase, water-

Fig. 14. Duplicate 33,000-Volt Bus Structure showing Transite Barriers

cooled transformers and one spare unit, two 1250-kv-a. frequency changer sets, rated at 2200 volts, 25-cycle, to 2300 volts, 60-cycle; and one 500-kilowatt rotary converter, necessary transformers, etc. The high tension lines are controlled by General Electric K-15 oil circuit breakers throughout.

The switchboard, which is mounted on a gallery on a level with the operating floor of the Springfield station, consists of twenty-three panels, and controls both the high and low voltage switches of the twenty-five-cycle system, and the twenty-three-hundred volt, sixty-cycle system, as well as the five-hundred volt direct current service. This equipment as well as the transformers, frequency changers, etc., was supplied by the General Electric Company.

The Diamond and Aurora substations are duplicates. The former is located twenty miles southeast of Joplin and the latter about one mile south of the town of Aurora. The Diamond station will supply the cities of Granby, Neosho, and Diamond, Mo., and the mining load in that immediate district. The Aurora station will supply the present operating company at Aurora, which has transmission lines extending to Verona on the west and Marionville on the east. In addition, the extensive mining load which promises to be developed in this section will also be carried.

The substation buildings are of brick and structural steel, forty-eight feet wide, fifty-four feet long and thirty-nine feet high, and are divided into two rooms by a brick partition. In one room are installed the 66,000-volt oil switches and lightning arresters. In the other, space is provided for two banks of 250-kw. transformers and the switchboard.

In connection with the Diamond station a four-room house and frame barn have been built for the use of the patrolman who inspects the adjacent lines and operates the substation.

The operating force at the hydraulic plant consists of a superintendent and seven operators, one operator acting as a relief man. The Springfield station is operated by three men and the Joplin station by the same number. However, the men in the Joplin plant divide their time equally between the apparatus owned by the Empire District Electric Company and the Ozark Power & Water Company. Eight patrolmen, each equipped with a horse and buggy, portable telephone and Prestolite searchlight, make careful inspection of the total line at least twice each week. In addition, two six-cylinder automobiles, fully equipped with all necessary tools and repair equipment, are kept at convenient points, ready to go out at a moment's notice.

Satisfactory arrangements have been made with the Empire District Electric Company by which the latter provides standby service from its large steam plant located at Riverton, Kansas, through the West Seventh Street station in Joplin. However, up to this time, the service has been most excellent, even during the early stages of commercial operation, as well as through some of the severe electrical storms which are quite frequent in the district traversed by the line.

During the first eight months of operation the system has more than met the expectations and estimates of the builders with respect to output, reliability of service, and general operating characteristics.

The company is operated by the Doherty organization.

# THE EVOLUTION OF THE RAILROAD SHOP

By A. I. Totten

Railway and Traction Engineering Department, General Electric Company

The railroad shop of the present day is constructed according to a radically different design than that in vogue only a decade and a half ago. Among the many causes contributing to produce this change, the following have had the greatest influence: heavier rolling stock by reason of more powerful and massive constructions employed, a change in the policy of the management whereby many small shops have been replaced by a few large ones, and the electrification of the shops. In the following article the author explains the changes through which the railroad shop has passed and shows how the old methods of power supply have been supplanted to great advantage by electrification.—Editor.

This country has just passed through an era of steam railroad shop construction unparalleled in the history of railroads. The poorly lighted, antiquated buildings located at division points have been demolished, and in their places there have been erected structures which are representative of the best engineering practice, and which are designed to provide maximum economy in the performance of repairs on cars and locomotives. When we consider these modern shops it is difficult to realize that but a brief fifteen or sixteen years have passed since the first shop to be built along present lines was placed in operation.

In older days it was the custom to locate small shops at objective points on the system, where changes in locomotives on through trains were effected. These shops were designed not only to take care of the general overhauling of locomotives and cars but also to provide storage facilities, for engines when not in service, in the form of a roundhouse and the necessary adjuncts consisting of turntable, coaling station, sand house, oil house, water tank, etc. This is what might be termed the "unit system," inasmuch as each division had the exclusive handling and repairing of all locomotives assigned to it. With the introduction of cranes and other labor saving devices it was ascertained that, in order to reduce the unit cost of repairs, this expensive machinery which was provided must be worked at its full capacity. Therefore, the practice was instituted of placing large main shops at central points for the performance of the heavy general repairs on locomotives assigned to several divisions, and the light running repair work was done at small shops or in roundhouses located at terminals or division points.

The handling of the various parts of the older types of locomotives and cars did not entail the difficulties now encountered in the transference of material in and around the various buildings, which must of necessity be scattered to a considerable degree to allow for trackage space and also to reduce the fire risk which might otherwise prevail. The weights of engines have steadily increased from 135,000 pounds in 1890 to 830,000 pounds, which represents the weight of the triplex locomotive recently constructed for the Erie Railroad. With the increase in size of the rolling stock, the various components comprising the complete units have become heavier and heavier, and parts which were formerly handled readily by manual labor must now be lifted and transferred to the point desired by hoists and cranes.

The introduction of electricity in the shop was made initially for the purpose of producing artificial illumination which would supplant that furnished by oil, candles or gas. The development of the direct-current motor provided a means for driving shafting in the various buildings; and thus made it possible to discard the numerous boiler and engine installations that were distributed throughout the plant and to supplant them by a central power-house from which the current could be transmitted over wires to the motors in the different buildings. This did not materially affect the output of the shop, but it reduced the cost of power by decreasing the amount of fuel and labor required for its generation.

In view of the general satisfaction which resulted from the successful operation of the "group drive" system just described, railroad engineers as well as electrical manufacturers perceived the advantages that would accrue by equipping the larger machines, having variable-speed characteristics, with individual motors. An individual equipment of this sort would provide means by which speed variation could be readily obtained by a controller and resistance, thereby conserving the operator's time through eliminating the necessity for shifting belts on cone pulleys as had been required previously. This was accomplished by what is known as the "multiple-voltage system," so called because several line voltages were provided by balancer sets installed in the power house and connected across the terminals of the generating apparatus. The application of the proper potential for the motor speed desired was obtained by a controller located at a convenient point for manipulation by the machine tool operator. Inasmuch as the motor capacity varied in almost direct proportion to the voltage applied, it will be readily appreciated that this system was not wholly suited for machine tool operation where practically constant horse power should be maintained over the entire speed range. In fact, the difficulties experienced in the operation of the multiple-voltage system demonstrated the inapplicability of this method of speed control for machine tool operation. A further study of the subject resulted in the introduction of the adjustable field control motors, which admirably fulfilled the requirements of the service and are representative of standard up-to-date practice.

With the introduction of electricity for power purposes in railroad shops came the traveling crane, varying from five tons to one hundred and fifty tons in capacity. This replaced the hand jack, pneumatic hoist and manual labor. The work of lifting locomotives from their wheels and replacing them thereon was accomplished in seconds instead of hours, and the handling of heavy parts through the shops and yards was performed rapidly and with a minimum amount of labor and cost. The individual machine hoists were discarded as unnecessary; but, strange to relate they are now being replaced, as it was ascertained that a considerable amount of the tool operator's time was lost while waiting for the traveling crane to handle material around the machine.

We have up to this point mentioned direct current only for shop operation; but with the introduction of alternating-current motors on a cost and operating basis comparable with

Fig. 1. Interior of a Typical Locomotive Shop

direct-current motors, as regards constant speed service, they naturally became quite a factor in railroad shop installations. It is difficult to compare the relative merits of alternating and direct current as applied to railroad shop operation. The alternating-current motors must receive credit for the absence of commutators and consequent freedom from trouble due to this source, but they have not the adjustable speed characteristics of the direct-current motors and hence are not as well adapted to the operation of variable-speed machinery. There are a number of shops entirely operated by alternating current where the speed adjustment of machine tools, having variable-speed characteristics, must be obtained with gear change devices. In the majority of the larger shops both alternating and direct current are used, the former being either purchased or obtained from prime generating units and the latter furnished by motor generator sets or rotary converters driven by alternating current. A number of shops, however, especially the smaller ones, are operated exclusively by direct current. As a general proposition, under average conditions, the alternating-current direct-current combination is preferable for large installations; alternating current exclusively for small shops where current is purchased from central stations, and direct current for small shops where current is generated on the premises. Where the alternating-current direct-current combination is installed, the use of direct current should be confined exclusively to the variable-speed machine tools and alternating current should be used for the operation of transfer tables, cranes, turntables, etc., as well as for the constant-speed drives and illumination of the premises. Under these conditions the proportion of alternating-current to direct-current generator capacity would be about three to one.

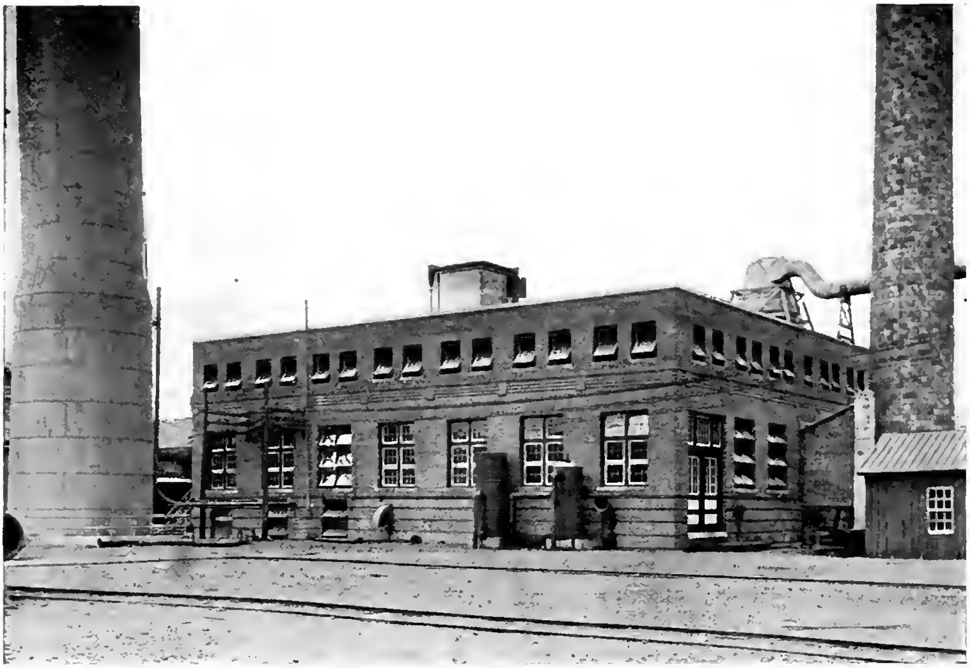

Fig. 2. Power Station for the Chesapeake and Ohio Railroad Shops

In addition to the electrical energy requirements for railroad shops, a large quantity of compressed air is necessary for the operation of pneumatic riveters, drills, chipping hammers, etc., which are used in large numbers throughout the plant. It is also required in lesser quantities for numerous other purposes such as painting, glass frosting, sand hoisting, train testing, cleaning motors and machines, pneumatic hoists, etc. The air compressors, ranging in capacity from 500 to 3000 cu. ft. of free air per minute, are generally placed in the main power house and are connected by pipes to the various outlets located in such a manner as to best fulfill the requirements of the service. These compressors are, for the most part, steam-driven but the growing tendency of railroad companies to purchase current from an outside source has created a demand for motor-driven compressors, the rotating element of the motor being mounted directly upon the crank shaft of the compressor and transmitting power thereto without the interposition of gears or belts. There is a serious objection to large motor-driven compressors, however, due to the wide range of compressed air consumption which prevails in railroad shop plants. In the case of the steam-driven machine, the governing apparatus admirably controls the speed of the compressor to suit the existing demand but, with the motor-driven machine, the speed remains constant and a throttling suction governor or by-pass control relieves the machine when the compressed air consumption falls below the capacity at the fixed speed. This is not an economical arrangement from a current consumption standpoint and the wear on the machine is practically constant regardless of the amount of air supplied. In view of the large size of these compressor units, which require the supply of from 80 to 500 kw. of energy, it would not be feasible to have them start and stop automatically with the rise and fall of air pressure. To overcome the objections cited, and also to reduce the losses caused by long lengths of pipe connecting the various buildings, there now seems to be a tendency to distribute throughout the various departments small air compressor units which have a capacity of from 50 to 200 cu. ft. With units of this size, the motors can be automatically regulated without imposing undue strains on the machinery or the transmission line.

The innovations as heretofore illustrated in shop design and operation were not effected without radical changes in the operating organization. The division master mechanic, who formerly had exclusive supervision of the locomotives assigned to his division, was compelled to release his sovereignty during the time they were undergoing heavy repairs in the main shops, for these shops were governed by shop superintendents who were responsible only for the economical and satisfactory repairs to the equipment.

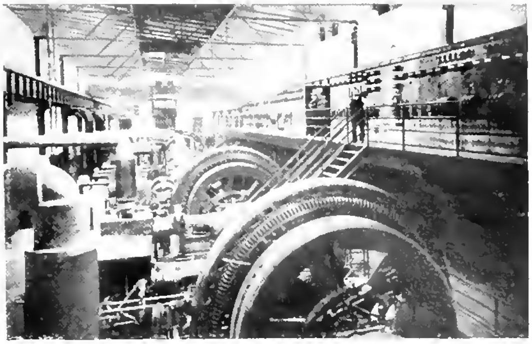

Fig. 3. Interior View of One of the Reciprocating-Engine Driven Power Plants

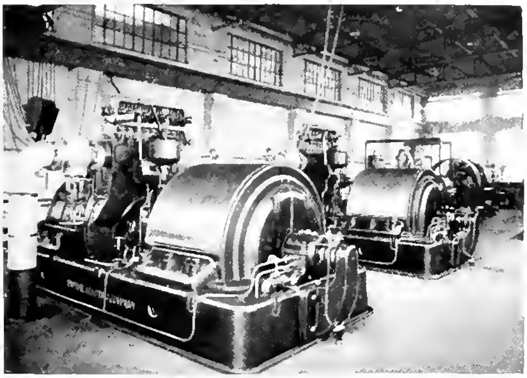

Fig. 4. Interior View of a Recent Steam-Turbine Driven Power Plant for Railroad Shops

The designs of the shops have not been symbolic of unity of sentiment with respect to the various features of construction. The greatest divergence of opinion existed with respect to the arrangement of tracks in the erecting shop which, it might be explained, comprises the keynote of the entire building arrangement and equipment. The longitudinal track design demands two cranes in the erecting shop, each capable of lifting one-half of the weight of a locomotive. The transverse track design requires only one crane of such capacity as to lift the entire weight of the heaviest locomotive in service. With the transverse arrangement, transfer tables were sometimes installed so that the functions of the cranes were limited to the hoisting of engines only after they had been placed on the track upon which the repairs would be conducted. The transfer table is not required if sufficient clearance between the floor and the roof trusses is provided to handle locomotives over each other for the length of the shop. It is not entirely the personal preference of the engineer which decides the arrangement to be followed for, in some cases, the plan of the available land upon which the shops are to be erected proves to be the governing factor.

The locomotive repair shop capacity is generally stated with respect to the number of tracks or pits in a transverse erecting shop and in terms of the number of locomotives that can be accommodated in a longitudinal erecting shop. It is apparent that a certain approximate fixed relation should exist between the floor space required in the different departments and the number of locomotives accommodated in the erecting shop. This relation must be correct and the capacity of the machinery must be properly proportioned in order that maximum efficiency and consequently maximum output for the capital expended may be obtained.

Fig. 5. An example of a Motor-Driven Double-Wheel Lathe in a Locomotive Shop

The output of a railroad repair shop is generally expressed by the relation between the number of locomotives which can be contained in the erecting shop and the number of locomotives repaired in each month, or is defined as the number of locomotives per pit per month. This figure will vary from 0.5 to 3.0, depending upon the average amount of repairs to be performed and the floor space together with the machinery available in the departments contingent to the erecting shop. It is clearly evident that the highest efficiency will be obtained, as well as the maximum output for capital expended, if the installed machinery is such as to enable the erecting shop to turn out the largest number of engines per unit of floor space.

It is not essential to combine the locomotive repair shop and car repair shop in one plant, and the tendency in recent years has been to separate the locomotive and car departments. From a labor standpoint, it is not desirable to operate jointly a car and a locomotive repair shop as dissatisfaction is likely to result between the lesser skilled and lower priced labor employed on the former and the more skilled and higher priced labor employed on the latter.

In contemplating the advisability of purchasing current from central station plants for driving the shops, the question arises as to whether or not the operation of high-pressure boilers can be discontinued when steam for running the generating units is not required. The stumbling block to the discontinuance of high-pressure boiler operation has heretofore consisted of the steam hammers in the blacksmith shop. These could not be economically operated by compressed air under the existing conditions. A recent design, covering a motor and air compressor combination which forms a part of the hammer equipment and furnishes compressed air instead of steam to the hammer cylinder, may overcome this contingency. The use of steam will generally be required for shop heating in winter and also for heating the lye vat solution during the entire year. These conditions can best be fulfilled by the

Fig. 6. A 120-Ton Electric Crane in Use in a Locomotive Shop

installation of low-pressure boiler units of suitable capacity to take care of these requirements.

We are now confronted with questions respecting the future development of the locomotive repair shop. Will further progress be made or is the era of the steam locomotive rapidly passing, to be pointed out to the next generation as an ancient system of propulsion for railroad trains?

Few industries, if any, have been benefited to a greater extent by electricity than have the railroads. It is the agent that operates the signals which guarantee a safe passage for the trains; it operates the shops; it illuminates the shops and yards; it pumps the water to fill the tenders; and it propels the freight and passenger trains in increasing numbers every year. We can now purchase electric locomotives at a cost per pound less than twice as great as the cost per pound for steam locomotives and obtain from them a yearly mileage two times that of the steam locomotives which makes the net first cost of motive power approximately the same for a definite service.

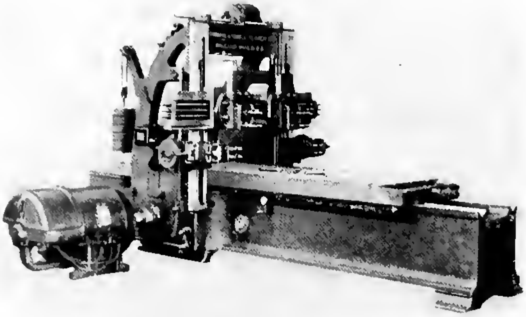

Fig. 7. An Example of a Reversing-Motor Planer Drive in a Railroad Shop

Fig. 8. An Example of the Use of Electricity in Signal Service

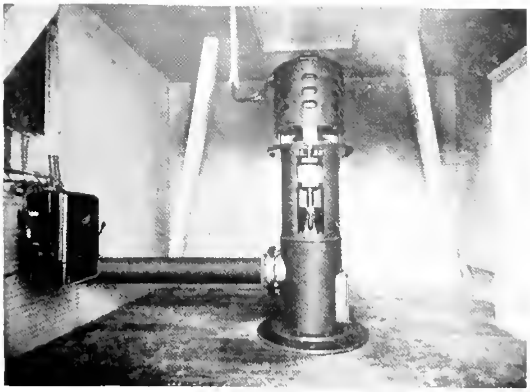

Fig. 9. An Installation of a Direct-Connected Motor-Driven Propeller Water Pump

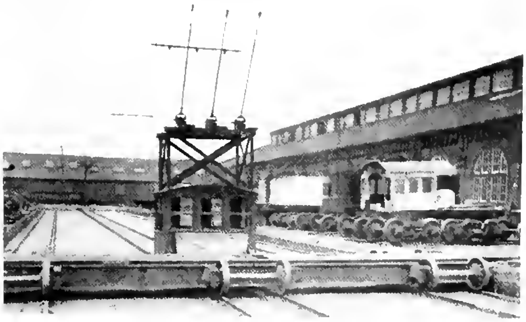

Fig. 10. A Transfer Table Driven by a 10 H. P. Squirrel-Cage Induction Motor

Will the elaborate steam locomotive repair plants be superseded by more simple shops for the electric locomotives costing not more than one-fourth as much as the present steam locomotive shops? Will the average cost of repairs for electric locomotives, namely, 4 cents per mile as compared with the average cost of repairs for steam locomotives of about 9 cents per mile, be a large governing factor in the future of the transportation problem? The next decade should provide the solution.

# FROM THE CONSULTING ENGINEERING DEPARTMENT OF THE GENERAL ELECTRIC COMPANY

## ENERGY OF THE RADIO-ATOM

While in the highest explosives the chemical energy per unit weight, as per gram, amounts to thousands of calories, the energy developed by the spontaneous disintegration of the radio-atoms, as those of radium, thorium, uranium, etc., amounts to many millions of calories, that is, is many thousand times higher than that of the highest explosive. Nevertheless, while in the explosive the energy development when once started becomes cumulative, that is, all the energy is set free suddenly by explosion, all attempts to vary the energy development and therewith the decay of radio-atoms have failed and neither extreme heat nor extreme cold have any appreciable effect on the rate of energy production. The internal energy of the radio-atom is thus of an essentially different character from chemical energy: it follows the probability law; the exponential function. This is the law of energy development of cosmic forces, and, if we consider the solar system of the universe as atoms, the same laws of energy development involved in hurling planetary masses into the universe would occur as when radio-atoms hurl $\alpha$ or $\beta$ particles into space. When a number of masses attract each other by central forces, as the sun and planets and comets in our solar system, or possibly the positive and the negative electrons in the atom, they circle around each other with more or less complex motions. If then in these orbital motions two of the masses approach close to each other, an exchange of energy occurs between them; and it is merely a question of probability when, by such energy exchange, one of the masses receives a velocity sufficient to carry it away from the attraction of the system, into infinite space; that is, a particle is thrown out by the atom, or the solar system.

Our solar system is a stable atom, as it has only one central mass, the sun, and the planets circle around it in nearly circular orbits, thus can never approach sufficiently close to each other to affect each others' velocity materially. It is only the comets, which by their eccentric orbits, may exchange energy with other masses; and comets, once traversing the sun in elliptical orbits as parts of the solar system, have been hurled into infinite space in open orbits. In solar systems having two or more large central bodies—as is not infrequently the case—planets may approach each other so as to exchange considerable energy and disintegration of such systems by particles—planets—being sent out into infinite space, is possible: unstable atoms.

Thus, if we assume the constitution of the atom as similar to that of the cosmic atoms (the solar systems), the internal energy of the atom, which is set free in the electron by atomic disintegration, would be the energy of orbital motions. This would explain the magnitude of the energy, and would also explain the entire independence of atomic disintegration from external influences: it follows the probability law of such coincidence of relative positions and velocities of the particles, which constitute the atom, as would give to one of them a velocity sufficient to escape.

In connection, herewith, it is significant to note that radio activity, that is, instability, is a property of the heaviest atoms.

Incidentally, when we consider the extremely high intra-atomic energy of the radio elements, we must realize that the stable atoms have equally high or even higher internal energies. For instance, uranium, which is considered as the parent of radium, sets energy free in changing to radium, and the internal energy of the uranium atom thus must be higher than that of the radium atom, though the radio activity of the former is millions of times less.

C. P. STEINMETZ

## A SPECIAL TYPE MULTI-RECORDER

The standard multi-recorder is a device that is arranged to print, on a paper ribbon, the exact time an oil switch operates. A single recorder can take care of fifty oil switches, making individual records for each. While this is its particular field, it can be connected to suitable devices for recording lightning, station signals, the stopping and starting of feed-water pumps, etc. However, in some cases it is desirable to have a machine that gives the total number of operations, instead of the exact time that any particular one occurred. For this service a new type of multi-recorder has been developed. It is particularly applicable to screw machines, punch presses, etc., in fact to any machine where it is desired to show the total, instead of the individual happenings. This machine does not make a permanent record, but simply indicates the number of operations completed at the time the record is observed. Each element of the device is nothing more than an electrically-operated Veeder counter. A number of these elements are combined and mounted in a glass case to form a complete machine.

A life run was made on one of the units at a speed of 350 counts per minute. After 2,500,000 operations the Veeder counter failed. If the counter had been run at the normal speed of 40 operations per minute, it is probable that it would have lasted twice if not three times as long. Because the operating mechanism was in good shape, another counter was put on and run at the same speed. This counter also lasted about 2,500,000 operations, checking the first test very closely. The operating mechanism showed almost no signs of wear and could have run four or five times as long.

At the speed that an average punch press operates if the press ran continuously ten hours a day and five and one-half days a week, the counter would last a year. After this twelve months' run, the only replacement that would be needed would be a new counter, which could be easily installed on the old mechanism by removing two screws and one pin. The mechanism should be good for from five to ten years, depending on the speed at which the punch press operates.

A. H. DAVIS

## QUESTION AND ANSWER SECTION

The purpose of this department of the REVIEW is two-fold.

First, it enables all subscribers to avail themselves of the consulting service of a highly specialized corps of engineering experts, or of such other authority as the problem may require. This service provides for answers by mail with as little delay as possible of such questions as come within the scope of the REVIEW.

Second, it publishes for the benefit of all REVIEW readers questions and answers of general interest and of educational value. When the original question deals with only one phase of an interesting subject, the editor may feel warranted in discussing allied questions so as to provide a more complete treatment of the whole subject.

*To avoid the possibility of an incorrect or incomplete answer, the querist should be particularly careful to include sufficient data to permit of an intelligent understanding of the situation. Address letters of inquiry to the Editor, Question and Answer Section, General Electric Review, Schenectady, New York.*

### THREE-PHASE TRANSFORMERS: PHASING-OUT

**(111) Having two three-phase transformers to be connected in parallel, as shown in Fig. 1, please explain in detail what preliminary precautions must be taken, and describe how to phase them out, giving size of potential transformers that should be used, range of instruments or voltage of lamps, etc.**

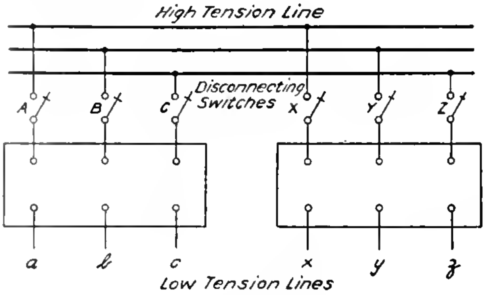

Fig. 1

**In addition, please state what combinations of delta and Y can be used in the parallel operation of the primaries and of the secondaries of the transformers.**

In order to operate satisfactorily two three-phase transformers in parallel, they should have like ratios, impedances, polarities, and phase rotations.

When connecting two transformers of different manufacture, it cannot be assumed that the similar leads of the two transformers will be the ones that should be joined. Before making any electrical tests, it should be made certain, in order to have proper phase relation of the secondary voltages, that the transformers are properly connected. Next, each transformer when connected to the high-voltage line should give equal voltages between the low-voltage terminals, and the values should be equal in both transformers, that is,

$$ab = bc = ca$$

and

$$xy = yz = zx$$

also

$$ab = xy, \; bc = yz, \text{ and } ca = zx.$$

Before the low-voltage leads are connected together, the phase rotation of each set of these leads should be checked so that, when $a$, $b$, and $c$ are connected in that order to the same terminals as $x$, $y$, and $z$, the same direction of rotation will be produced on whatever device is used, whether it be a so-called phase-rotation indicator or a three-phase motor. (Phase rotation can be reversed by interchanging any two of the external leads on one side of a transformer.)

When the voltage and phase rotation are correct, polarity must be determined before all of the low-voltage leads are joined together in the final connection. To make a positive test for polarity, first connect two leads together which are supposed to go together, for instance, $a$ and $x$. Now if zero voltage is indicated across $b$ and $y$ and across $c$ and $z$, $b$ may be connected to $y$ and $c$ to $z$, and the phasing-out is complete.

If, however, the polarity of $x$, $y$, $z$ is opposite to that of $a$, $b$, $c$, even though the phase rotation is the same, twice the line voltage will be read across $b$-$y$ and $c$-$z$. The phase connections on one side of one transformer must then be reversed. That means, if a delta, the delta must be opened at each corner and each coil reversed; if a Y, the neutral must be broken and each coil have its opposite end connected to the neutral point. However, only one side of either transformer should be changed in the case of different polarities. This case also assumes that $a$ and $x$, $b$ and $y$, $c$ and $z$ are the proper terminals to be finally joined.

It may happen that $x$, $y$, and $z$ do not correspond in order with $a$, $b$, and $c$, but should be

$a$, $b$, and $c$ to $y$, $z$, and $x$

or

$a$, $b$, and $c$ to $z$, $x$, and $y$.

In such a case, where the polarity is the same in the two transformers, the voltage readings $b$-$y$ and $c$-$z$ will be 1.73 times line voltage when $a$ and $x$ are joined. The proper relation of $x$, $y$, and $z$ to $a$, $b$, and $c$ may be determined by joining $y$ and $z$ in turn to $a$ and measuring the voltages $b$ to $z$, and $c$ to $x$, or $b$ to $x$, and $c$ to $y$ respectively.

The foregoing, briefly stated, means that if the two leads which are joined together *are the correct ones to be connected*, then the voltage readings taken between the others (corresponding according to phase rotation,) indicate if equal to zero, the proper terminals to be joined; while, if of twice normal voltage, indicate opposite polarity. If any other indication is given, *the leads are not the correct ones to be joined;* and other connections should be tried until either zero or twice normal voltage is read between the leads of the second pair and the leads of the third pair, when the leads of the first pair are connected together. When the reading twice-normal-voltage is obtained, a reversal of the polarity of one transformer should be the only change necessary to prepare the machines for parallel operation.

In measuring the voltages, enough capacity is required to measure twice the normal line voltage. Potential transformers, if used, would most likely be rated at the line voltage and should, therefore, be connected two-in-series when taking the readings during the process of phasing-out. Voltmeters or lamps used on the secondary side of the potential transformer would have to cover the range of voltage of those windings. It should be borne in mind, however, that when only one voltmeter is employed and that one being connected across the secondary of only one of the potential transformers where there are two in series, its readings will have to be multiplied by twice the ratio of the transformer to give the voltage of the high side.

In case the voltage of the low-tension sides of the main transformers is sufficiently low to enable the use of lamps without potential transformers for testing out, enough lamps should be connected in series to properly burn on twice the low-tension voltage.

The following table gives the possible combinations of two three-phase transformers or banks; those marked with an "✓" will operate in parallel, the ones marked with a "×" will not.

Transformer or Bank "A"

| Transformer or Bank "B" | Δ Δ | Δ Y | Y Δ | Y Y |
|---|---|---|---|---|
| Δ Δ | ✓ | × | × | ✓ |
| Δ Y | × | ✓ | ✓ | × |
| Y Δ | × | ✓ | ✓ | × |
| Y Y | ✓ | × | × | ✓ |

R.K.W.

### TRANSFORMERS: PHASING-OUT SMALL POLYPHASE POLE TYPE

**(112) What is the most convenient yet satisfactory method of phasing-out small three-phase, pole type transformers, preparatory to connecting them to the line?**

Since in small three-phase transformers the internal connections are likely to be permanent, mistakes in connection are not as liable to occur as in large transformers, where various methods of internal connection may be used. The simplest way of phasing-out the small transformers referred to is to check their ratio, polarity, and phase rotation before they are taken to the point of installation. When connection is to be made, the primaries should be joined to the line and one secondary terminal joined to its corresponding low-voltage line. If voltages are shown between the other terminals and their corresponding lines, then further combinations of lines and terminals should be tried until the proper ones giving a zero indication are found. For this work, a voltmeter with a range sufficient for indicating approximately twice the secondary or line voltage, or sufficient lamps for the same voltage, are necessary. R.K.W.

### RESISTANCE: TEMPERATURE COEFFICIENT OF COPPER

**(113) When the temperature rise of an electrical machine is to be determined by the increase in the resistance of its windings, what values should be employed for the temperature coefficient of copper?**

At the last meeting of the International Electro-Technical Commission held at Berlin in September, 1913, the following rule, relating to the temperature coefficient to be employed, was adopted.

> For making resistance measurements, there has been adopted as the coefficient of temperature-resistance of copper the value indicated in the table below, which has been deduced from the formula $1/(234.5+t)$. Thus, at an initial temperature of 30 deg. C., the coefficient per degree Centigrade becomes $1/264.5(=0.00378)$.

| Temperature of Windings in Degrees C. at which the Initial Resistance is Measured | Copper—Increase in Resistance per Ohm per Degree C. |
|---|---|
| 0 | 0.00427 |
| 5 | 0.00418 |
| 10 | 0.00409 |
| 15 | 0.00401 |
| 20 | 0.00393 |
| 25 | 0.00385 |
| 30 | 0.00378 |
| 35 | 0.00371 |
| 40 | 0.00364 |

H.M.H.

### AUTOMOBILE LIGHTING GENERATOR: VOLTAGE REGULATION

**(114) Some types of automobile lighting generators have a "third-brush" bearing on the commutator for the purpose of maintaining constant voltage in spite of a variable driving speed. How is this accomplished?**

In the "third-brush" method of regulation two shunt fields are utilized, one being wound so as to oppose the other. Referring to Fig. 1, a main field coil *M* is connected between the load brush *A* and the so-called "third-brush" *C*, while a reversed field coil *R* is connected between brush *C* and the second load brush *B*. Under operating conditions no current flows from the "third-brush," and the two field coils are so balanced that normal voltage is produced. At speeds above normal the armature reaction is sufficient to distort the field flux, thereby giving a higher armature voltage between *B*-*C* than between *A*-*C*. This causes more current to flow in *R* and less in *M*, thereby weakening the field flux and restoring the voltage to approximately the normal value. Since the armature reaction depends primarily on armature current, better voltage regulation is obtained when the generator is under-load. H.S.B.

GENERAL ELECTRIC REVIEW

## THE PATHS OF PROGRESS

The march of events in Europe has already gone far enough for us to gain some idea of how business in general can withstand the shock of the greatest calamity that has befallen the world in the memory of man. It seems safe to infer that, although undoubtedly some industries are seriously affected and others have not yet "found themselves" under the new strained conditions, on the whole the country has met a disaster that might have been expected to cause an economic and industrial upheaval, with better results than might have been anticipated.

In our last issue we expressed the thought that the fear of dire results would in all probability be worse than the damage actually sustained. Now that another month has passed we become more convinced that this is to be the case, and it seems more plain than at the start that if all idle fears are dispelled the country can still keep a great percentage of its working millions engaged in profitable undertakings.

There is no doubt that in America alone there is ample work to be done for providing for our own needs, and that beyond this we must meet the demands of many markets now not being served by some of those countries that are engaged in war.

The manufacturing facilities of America are enormous, and they are fully prepared to keep full speed ahead if capital and credit will brave the situation and not permit undue discretion to bring about unnecessary curtailments of orders and hindrance to useful developments. There was at the first naturally a tendency to delay all orders that were not immediately required and to postpone as long as possible all expenditures that were not actually imperative, but we have reason to hope that now the basic conditions will appear sounder to those that have orders to place and that business will be brought to as normal a condition as possible without delay.

In all cases where there is work that is to be done and the capital is available it would seem both wise and patriotic to avoid delay; wise because it often happens that after the "valley" loads such as many large industrial concerns are carrying now, very large "peak" loads have to be provided for and orders cannot be filled as quickly as desired; and patriotic because it is a real service to the country to keep the wheels of industry running at normal speed and to avoid all unemployment as far as possible.

Such times of stress as we are now passing through will be a real test as to whether the country is the gainer or the loser by big business enterprises. We venture to believe that an order of retrenchment or advance in the production of a large industrial army, like the enterprises of a fighting machine, can be managed better where the forces are carefully organized than where innumerable individual units shift hap-hazard for themselves.

The industrial world as a whole has become so thoroughly organized during the last half century and the inter-communication between the nations has become so complete, that today we can regulate production to meet the varying requirements of the world's markets in a way that was previously quite impossible. The progress that we have made in this direction is so great that we are in a far better position to understand and meet successfully the unusual and unfortunate phase through which we are passing.

It should be specially remembered that large corporations and nations are built up of individual units and that therefore the attitude of each individual is of importance. The employer and the employee each has his duty to perform. In each individual case a little courage will bring better results than much fear.

We sincerely hope that before another month has passed industrial conditions will so far improve that we shall be talking about an increase rather than a decrease in trade, for when we contemplate the markets which must be supplied both here and abroad it seems only reasonable to suppose that a great industrial nation at peace with all the world will find plenty of calls for her manufactured products.

# BEARING CURRENTS

By E. G. Merrick

Alternating Current Engineering Department, General Electric Company

The causes for the presence and the behavior of bearing currents has always been more or less of a mystery to those who have had no time nor opportunity to pursue a thorough investigation of the subject. The author of this article presents his findings, and those of other independent investigators, as being the latest accepted information on the subject. It is believed that a careful reading of them will equip a manufacturer, engineer, or station attendant with such knowledge concerning continuous-current, synchronous, and asynchronous machines as will enable him to eliminate or at least to minimize the annoyance resulting from this undesirable current flow.—Editor.

Trouble is frequently experienced with rotative electrical machinery, due to the destructive effect of current in the bearings. Such current causes a pitting of the bearing linings and even of the journals, which eventually leads to failure of these parts.

As will be explained later, there are certain conditions which give rise to an induced voltage in the shaft. If the circuit, consisting of shaft, bearings and base (or generator frame), is complete, see Fig. 1, it is evident that a current may be produced whose magnitude is limited only by the resistance of the path provided; and, since this resistance is ordinarily of a very low order, frequently currents are induced of sufficient magnitude to produce the destructive effects mentioned.

The theory of the production of these currents is not generally understood and comparatively little data on this subject has been published.

The phenomena have been studied by Punga and Hess,* by Fleishmann† and by Adler;‡ and the writer desires to present briefly the general theory as developed by these authors and to supplement this with comments and the results of his own further investigations.

Consider, first, the case of a four-pole revolving-field alternator as indicated in Fig. 2.

Since the flux $= \dfrac{\text{magnetomotive force}}{\text{magnetic resistance}}$

we have

$$\phi_1 = \frac{\frac{4}{10} NI}{\Sigma \frac{l_1}{\mu_1 q_1}} \quad \text{and} \quad \phi_2 = \frac{\frac{4}{10} NI}{\Sigma \frac{l_2}{\mu_2 q_2}},$$

where $NI$ is the ampere-turns, $l$ is the length, $\mu$ the permeability, and $q$ the cross-section of the various parts of each circuit.

If the reluctances of the two circuits are equal then $\phi_1 = \phi_2$; but these reluctances may be different due to pecularities in the design (which will be explained later), by variations in the permeability of the iron, or even by faulty machining or assembly of the parts. Referring to Fig. 3, if the reluctance of the joints between the two halves of the stator frame is appreciable, the total reluctances of the two circuits will be different and $\phi_1$ will be greater than $\phi_2$ by an amount which we may represent by $X$, i.e., $\phi_2 = \phi_1 - X$. The result of this new condition will be more clearly understood if the flux lines are re-arranged as shown in Fig. 4, the total flux of course remaining unchanged. Each of these fluxes encircle the shaft; at the instant shown, the flux represented by the dotted line $\phi_1$ is turning in a clockwise direction and that represented by the full line $\phi_2$ is turning in a counter-clockwise direction. When the rotor revolves by an amount equal to one pole pitch, it is evident that the direction of both fluxes reverse; each flux has then gone through a half cycle and the resultant field around the shaft, whose intensity equals $X$, has therefore the same frequency as that of the machine;

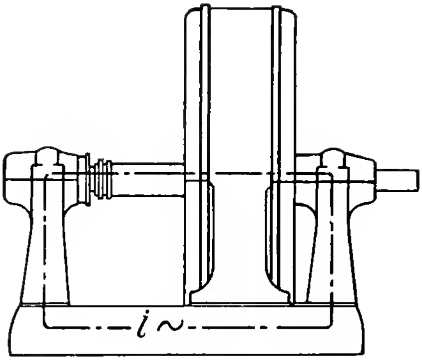

Fig. 1

---

* Elektrotechnik und Maschinenbau, 1907.

† Elektrische Kraftbetriebe und Bahnen. 1909.

‡ Elektrotechnik und Maschinenbau, 1910.

such a condition will of course give rise to an electromotive force along the shaft.

In the case of a six-pole machine, as shown in Fig. 5, the flux $\phi_2$ cuts the joint on one side, while the flux $\phi_2$ cuts the joint diametrically opposite. If the reluctances of the two joints are equal, there will be no difference in the values of the fluxes and no electromotive force will be induced in the shaft.

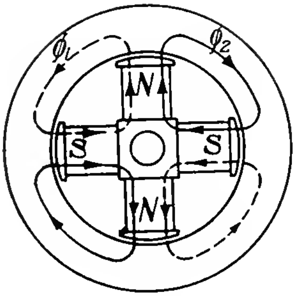

Fig. 2

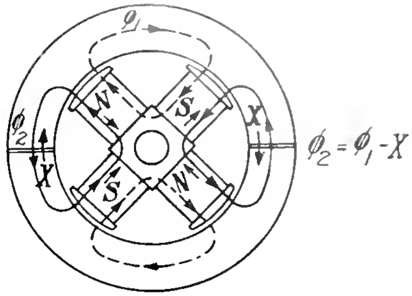

Fig. 3

Fig. 6 shows the case of an eight-pole machine with two joints; and here it is seen that the same condition exists as that indicated in Fig. 4.

An analysis of these conditions shows that:

(a) Where the number of poles is a multiple of twice the number of joints, an electromotive force may be expected to occur in the shaft.

(b) If the number of poles is not a multiple of twice the number of joints, the joints will be evenly distributed between the two flux circuits; therefore, there will be no variation in flux around the shaft and consequently no electromotive force induced in it.

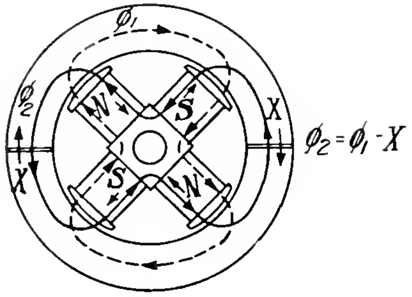

Fig. 4

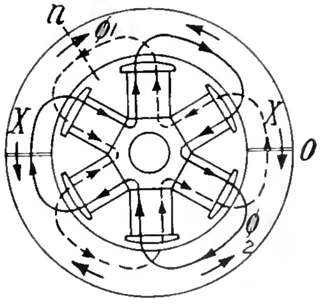

Fig. 5

The conclusions under (a) and (b) are based on a symmetrical distribution of the frame joints; mechanical considerations, however, sometimes require an unsymmetrical arrangement of the joints and this, under certain conditions, may be such as to reverse the rules just stated. Referring to Fig. 5, it will be seen that if the joints had been made at *n* and *o*, instead of diametrically opposite each other, the reluctances of the two circuits would have been different and the conditions therefore would have been such as to give rise to a shaft electromotive force.

This explanation covers the general cases where dissymmetry in the magnetic circuits originates from actual mechanical joints in the stator, which is the principal cause of induced voltage in the shaft; it is evident, however, that a more or less unsymmetrical condition may be produced in other ways; for instance, by a difference in the permeability of the magnetic material constituting the two flux paths, or by a difference in the effective lengths of these paths. The result is the same, however, regardless of what is the cause of the dissymmetry.

It is evident that, in the case of direct-current machines, the conditions are exactly analogous to those given above.

Figs. 7 and 8 show that where the magnetic fields are produced by *alternating currents*, the results are again the same as already described. As indicated in these figures, the arrangement of the stator coils in an asynchronous machine is such that, for each pair of coils, a circuit is formed similar to that of two consecutive poles of the synchronous machine.

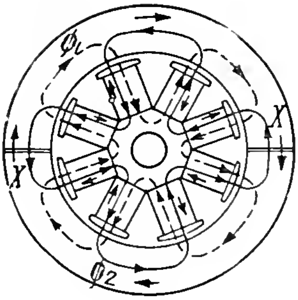

Fig. 6

If the stator shown in Fig. 7 is split at the heavy joint lines, as indicated, $\phi_1$ will be greater than $\phi_2$, which gives, as before, a resultant flux $X$, having the same frequency as that of the incoming line, and which therefore will produce an electromotive force in the shaft. Had the joints been made at the points marked $n$, there would have been no dissymmetry of the circuits and consequently no resulting electromotive force.

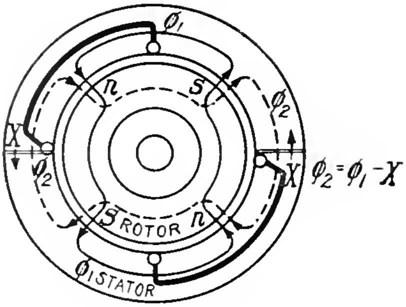

Fig. 7

In the three-phase machine shown in Fig. 8, it will be noticed that phase I is symmetrically placed with respect to the joints and that only phases II and III are effective in producing a shaft electromotive force.

In the case of a two-phase motor, the coils of one phase will be symmetrically placed with respect to the joints and the shaft electromotive force will be due to the other phase only.

As regards the generation of shaft currents, the only difference between machines in which the field is produced by direct current and those in which the field is produced by alternating current lies in the fact that in the former type a shaft electromotive force can be generated only when the machine is running, whereas in the latter type an electromotive force is present whether the machine is running or at rest, its magnitude depending on the relative values of the stator fluxes for the standing and running conditions. Due to the fact that the oil film between the shaft and bearing is maintained only when the machine is running, the standing current of a synchronous machine will be greater than the running current on account of the lower bearing resistance offered when the machine is at rest. Fig. 9 shows the variation of bearing current in a twelve-pole, 700 h.p., 450 r.p.m., 3000 volt induction motor at different voltages for both standing and running conditions.

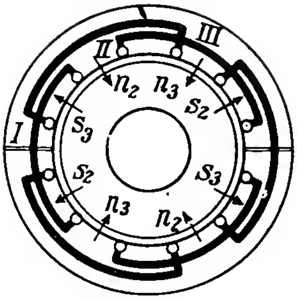

Fig. 8

If $R$ is the reluctance of one of the main flux paths and $r$ that of the joint, or any other cause producing dissymmetry, then

$$\phi_1=\frac{\frac{4}{10}\,\Sigma NI}{R}$$

and

$$\phi_1-\underline{X}=\frac{\frac{4}{10}\,\Sigma NI}{R+r}.$$

Therefore,

$$\underline{X}=\phi_1-\frac{\frac{4}{10}\,\Sigma NI}{R+r}.$$

which shows the importance of the ratio $\frac{r}{R}$ and permits of the following conclusions:

(1) As the diameter at the air gap or the number of poles increases, $R$ becomes greater and $\frac{r}{R}$ smaller and the unbalancing effect due to joints or other causes for dissymmetry therefore diminishes.

(2) The ratio $\frac{r}{R}$ decreases as the ratio of air-gap ampere-turns to total ampere-turns increases.

As the air gap of an induction motor is small in comparison with that usually found in a synchronous machine, it is evident from (2) that induction motors are especially susceptible to the effect of unsymmetrical conditions in their magnetic circuits.

Although, in general, it is possible to predetermine the cases in which shaft currents may be expected to occur, it is absolutely impossible to calculate the magnitude of these currents. This is due to the fact that the bases for calculating either the induced voltage in the shaft or the resistance of the circuit formed by the shaft, bearings, pedestals, base, etc., are indeterminate quantities.

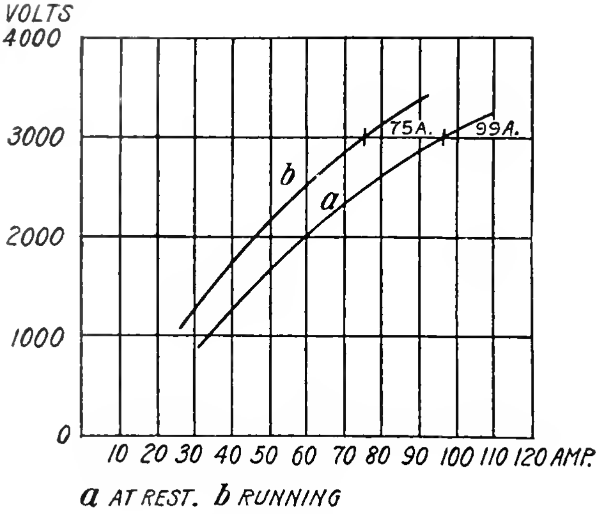

Fig. 9. Variation of bearing current in a 12 pole, 700 h.p. 450 r.p.m., 300 volt induction motor

The voltage factor is influenced by variations in the permeability of the metal comprising the flux paths, and especially by the great variation in the reluctance of the mechanical joints (resulting from imperfect machining or assembling). The predetermination of the value of the resistance is impossible, not only on account of the variations in the oil film between shaft and bearings but also because of the difficulty in determining the true effective lengths and cross-sections of the parts comprising the current path.

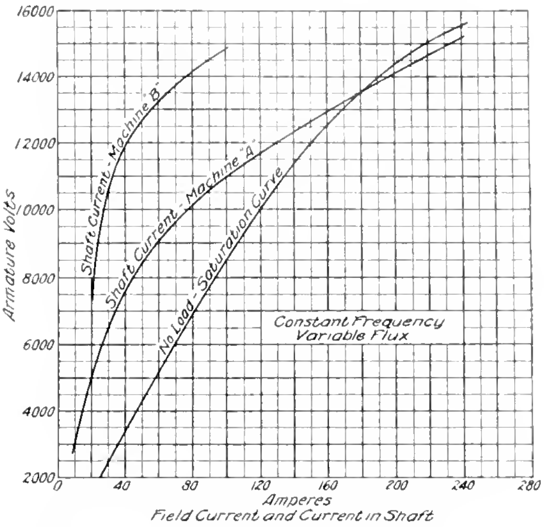

Fig. 10. No-load saturation and bearing curves of 62 pole, 4000 kv-a., 116 r.p.m., 13,200 three-phase alternator

As an illustration of the impossibility of predetermining these factors, the shaft current in an 860 kw. alternator cited by Adler was reduced from 200 amperes to 35 amperes simply by scraping the bearing lining so as to obtain a more perfect oil film over the entire surface of contact. The writer has also found variations of several hundred per cent in the value of these currents as measured on machines of exactly identical design, operating in parallel. This is shown by the curves of Fig. 10 which give the no-load characteristic of two 62-pole, 4000-kv-a., 116-r.p.m., 13,200-volt, 3-phase alternators and the shaft currents in the two machines at normal speed and variable voltage. At normal voltage the shaft currents of machines "A" and "B" are 170 amperes and 60 amperes respectively. Fig. 11 shows the variation of shaft current in machine "A" when running at constant excitation and, therefore, at practically constant flux but at different speeds. The actual observed values are shown by the full-line curve "X." It is interesting here to note again the effect of the oil film between shaft and bearing; the resistance of this film decreases with decreasing speed of the machine, which explains the higher proportionate values of current at low speeds. If this film resistance had remained constant, the shaft current would have decreased in direct proportion to the frequency and would have given a curve approximately as indicated by the dotted line "Y." These machines have an unsymmetrical division of the stator frames, corresponding to joints *n* and *o* of Fig. 5, and prove the exception to the general conclusion (b) regarding the relation of the number of poles to the number of joints.

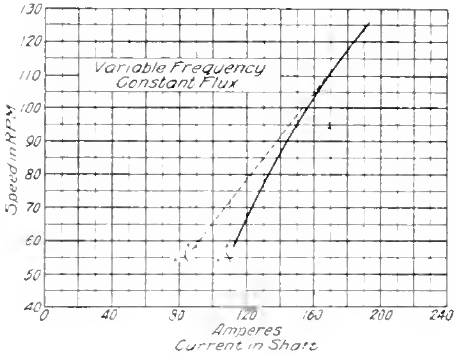

Fig. 11. Variation in shaft current of a 62 pole, 4000 kv-a., 116 r.p.m., 13,200 volt three-phase alternator at constant flux and variable frequency

Extended tests made by the Allgemeine Elecktrizitats Gesellschaft-Union Elecktrizitats Gesellschaft of Stadlau showed that, when the current density in the bearing exceeds about one ampere per square inch of contact, appreciable pitting of the journal takes place; for lower values of current density the pitting is limited to the bearing babbitt.

Of the means adopted by different manufacturers to protect shafts and bearings against the destructive effects of these currents, only two methods are of practical interest, viz.:

Method (A). Brushes are placed on both ends of the shaft and are either grounded on the bearing pedestals or connected together by a heavy copper conductor. The result in either case is to shunt more or less of the shaft current through this path and thus reduce the amount passing between the shaft and bearings. As the resistance of this latter path varies greatly, depending on whether the oil film is more or less perfect, and may be very low as compared with the contact resistance of the brushes, the amount of current shunted by the brushes is indeterminate and the protection afforded is therefore uncertain.

Method (B). In the case of horizontal machines, insulation is inserted between one or more of the bearing pedestals and the machine base, as shown in Fig. 12, the number of points at which the circuit is to be broken depending on the number of bearings and the number and type of machines mounted on the same shaft. This method, applied to vertical machines, necessitates the placing of insulation between the upper bearing bracket

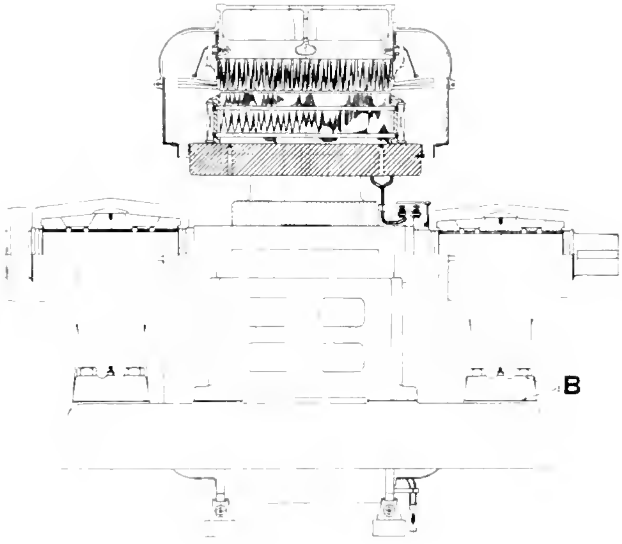

Fig. 12

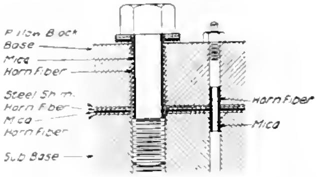

Fig. 12-A. Detail of insulation between pedestal and base shown at B in Fig. 12

and the armature spider and the insulating of holding-down bolts, as shown in Fig. 13. In addition it is of course necessary to insulate all piping, stairs, handrails, etc., which would otherwise complete the electrical circuit. Details of the construction at the points indicated by the arrows in Figs. 12 and 13 are given in Figs. 14 and 15 respectively.

Method (B) does not of course reduce the induced voltage in the shaft, but as this varies from a fraction of a volt to a maximum of possibly ten volts, it is of no consequence, providing the insulation described above remains intact. This method, if properly applied, therefore provides an absolute protection to journals and bearings against the destructive effects of the induced currents which have been discussed.

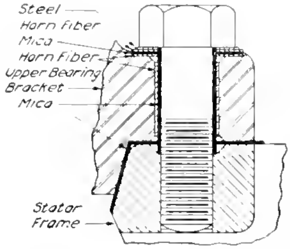

Fig. 13-A. Detail of insulation between bearing bracket and stator frame shown at A in Fig. 13

# SELECTING RAILWAY MOTOR EQUIPMENTS

By J. F. Layng

Railway and Traction Engineering Department, General Electric Company

The following article furnishes outlines of several calculations which have been selected for the purpose of emphasizing the importance of a complete appreciation of all the governing factors (especially the so-called minor ones) which must be considered when figuring on a railway motor equipment that is to fulfill given conditions. Each new railway problem entails the satisfying of a great number of complex factors and if it does not receive the most minute attention, the best results are not likely to be attained. The author of this article, therefore, points out briefly the effects of local conditions and the characteristics of apparatus which must not be overlooked in calculations.—Editor.

When selecting railway motor equipments it is necessary to have a definite picture of the service or of the work to be performed in order to choose a motor of the proper size and correct gearing, for successful performance. Sometimes the failure to appreciate what schedule speeds, maximum free running speeds, stops per mile and car weights mean, causes electrical equipments to be purchased which are either too large or too small. Consequently in some cases an equipment that is more expensive either in first cost or in maintenance than is required is purchased.

To make any schedule speed with a certain number of stops per mile, there is one definite free running speed that will perform the service most economically, not only in regard to power consumption, but also with reference to the size of equipment selected. The variations in the amount of power required for a car operating on free running speed can be illustrated by taking a 40-ton car as an example: When running at constant speed on level tangent track at twenty miles an hour, this car will require 23.1 kw. input. Providing this speed is increased to thirty miles an hour under the same conditions, this car will take 44.1 kw., and at forty miles an hour 76.2 kw., at fifty miles an hour 124 kw., and at sixty miles an hour 188 kw.

It can readily be seen from these figures that an increase in free running speed, which will bear a certain relation to an increase in schedule speeds, shows a very rapid increase in power consumption, and consequently a much larger equipment is required as the faster speeds are approached. Of course the longer the time that can be allowed to perform a certain schedule the smaller will be the equipment, and the cheaper will be the operation.

It is frequently found when investigating service conditions that the stops per mile made by any equipment vary widely from estimates based on superficial observation. The answers that will be given by different train crews as to the number of stops which they make on a particular trip will be surprising, unless they are especially requested to keep an actual record. Frequently answers to this question vary by more than 100 per cent for the same run. The number of stops per mile in interurban work is a much more deciding factor than in city work. In city service, where eight to nine stops per mile are made, variation in the number does not so seriously affect the size of the equipment. The reason for this is obvious from the following: Suppose a car is operating on an eight mile per hour schedule, with ten stops per mile, within an hour it would make a total of eighty stops. With stops of 10 seconds this would mean that the car was standing still for 13.35 minutes, or 22.2 per cent of the total time. Providing the same car is making nine miles per hour, and six stops per mile, the car would be standing still 9 minutes of the time, or 15 per cent. Strange as it may seem, if the stops per mile were sufficiently great, and the schedule speed were reduced, the size of the motor could be greatly decreased.

The information which it is necessary to have in selecting a car equipment is as follows:

1st, Car weight without live load, but including all equipment accessories, except the electrical equipment, which can be added by the engineer.

2nd, Seating capacity.

3rd, Schedule speed.

4th, Stops per mile.

5th, Length of stops.

6th, Grades.

7th, Voltage.

8th, Diameter of wheel.

9th, Layovers either ends of line, or at any point during the run.

Providing cars are to operate in a mixed city, suburban and interurban service, the data insofar as actual running time, number of stops, and length of stops are concerned should be divided into zones. Securing the information in this way makes it possible to have the proper calculations made for the equipment to be selected. The choosing of a proper motor equipment must be based on experience, and is not simply a mathematical calculation which can be determined by a fixed formula. To make a proper selection one must appreciate the large number of operating conditions that exist, and should also investigate the natural growth of the district as well as the future service that the equipment will have to perform. After securing the information to which we have referred, it is customary for the engineer to look over the data he has on equipments of similar size which is doing approximately the same work. Previous experience would also largely guide the engineer in the selection of the gearing, and thus enable him to make a trial calculation to determine whether the equipment he has selected will fulfill the requirements of the service.

Frequently a motor will be selected that can be geared to give the schedule requirements, but the heating may be excessive, or vice versa, the motor being too large for the service, and it will be found that a smaller and consequently lower cost equipment could be chosen for the service.

Manufacturing companies in every case make careful calculations to determine positively that, insofar as the data as presented are concerned, the correct equipment is furnished. Assume that we are to select a motor for city service, on which the general data are as follows:

| | |
|---|---|
| Car weight complete with all equipment | 42,000 lb. |
| Live load | 6000 lb. |
| Schedule speed | 10 m.p.hr. |
| Stops per mile | 7 |
| Length of stop | 10 sec. |
| Average voltage | 500 |
| Diameter of wheels | 33 in. |

By taking the total weight of the car, including the live load, it will be found we have 24 tons. Provided the grades are more than 5 per cent, ordinarily a four-motor equipment would be selected. If this is the case we should have a weight of 6 tons per motor.

In starting an equipment there is a retardation due to the rotary elements, which is commonly figured at 7 per cent additional to the car weight. In this particular case this addition would make a total of 6.42 tons per motor. Previous experience shows that this weight of car in the schedules specified, could be successfully handled by 40 h.p. 600 volt motors having a gearing of 67 to 14.

As a rule city cars accelerate at 1½ miles per hour per second. For the purpose of the trial calculation we will assume that accelerating 1½ miles per hour per second will give the desired schedule speed. In order to accelerate one ton at one mile per hour per second, 91.1 lb. per ton tractive effort are required. It can therefore be seen that if we desire to accelerate at 1½ miles per hour per second 137 pounds tractive effort will be required.

If we refer to the characteristic curve of this motor it will be seen that this will require, for the car weight which we have selected, 1026 lb. tractive effort, or 61 amperes input. This ampere input is approximately the hourly rating of the motor, and should, of course produce satisfactory commutation. Generally speaking it is not good practice, insofar as calculations of schedules are concerned, to have a motor accelerate much in excess of its hourly rating, unless the motor has been specially designed to have a sufficient margin in commutation. With the tractive effort definitely determined from the characteristic curve, it is a simple calculation to find what will be the maximum speed attained with this particular input and the time required to attain this speed. From the average speed and time the distance is readily figured.

After the car has reached the speed corresponding to this first calculation the current gradually decreases, and the increments of speed, time and distance are simply a matter of continued calculation to a point where it is deemed best to throw off power, and coast or brake. The usual rate of braking for a city service is 1½ miles per hour per second. The first figures may show that the calculations with power on have been carried either too far or too short to give the required distance and schedule speed. Usually it is necessary to make several calculations in order to get the values for time and distance, to make the schedule desired. Curves and grades greatly influence the calculations, but to explain the different allowances to be made for them would complicate the discussion, and therefore the explanation has not been included.

Providing the information which we have previously mentioned is given correctly, and the service is actually performed as outlined, it is possible to calculate the actual temperature rise of the different parts of the motor within 2 or 3 degrees. This fact has frequently been proven by actual test in service.

From the figures which have been made to find the speed from the characteristic curve all the different losses in a motor can be definitely determined. These consist of copper losses, iron losses and friction. The sum of these three losses determines the heating for any particular motor.

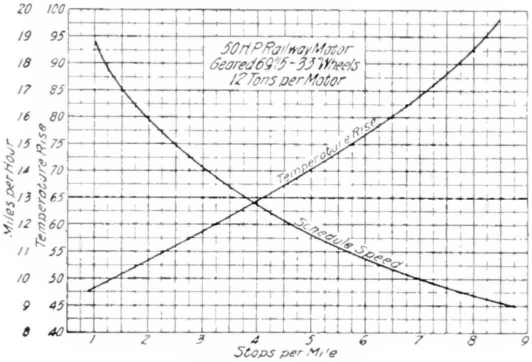

**Fig. 1.** Effect of Stops per mile on schedule speed and temperature for 50 h.p. motor

With closed motors, in making calculations for temperatures, allowance should be made for differences in schedule. A motor when tested on a test stand at the factory will radiate a certain amount of heat. When operating on a car with a schedule speed of 10 m.p.hr. this same motor will run approximately 10 per cent cooler. If the schedule speed is increased to twenty m.p.hr. it will run approximately 18 per cent cooler than if it were tested upon the stand. With ventilated motors the temperature is directly affected by the armature speed, and much greater cooling is obtained. This greater cooling is not only realized in interurban service, but also in slow speed city service. Improvements in methods of ventilation will greatly increase this difference.

Fig. 1 shows the effect of stops per mile on schedule speed and of temperature in the case of a 50 h.p. motor. This particular curve is based on a car weighing 12 tons per motor, 550 volts (average), 33 in. wheels, 69/15 gearing and no coasting. With cotton insulation it is not advisable, as a rule, to run motors much in excess of 65 degrees C. rise. By making slightly more than 4 stops per mile with a 12.6 m.p.hr. schedule it can be seen that the particular motor in question will have a temperature rise of 65 degrees. Providing the stops per mile are increased to 8, the schedule speed will necessarily fall to 9.4 m.p.hr. and the temperature rise will increase to 92½ deg. C. This excess in temperature rise indicates the necessity for correctly stating the service conditions. Providing the car weight had been reduced to a reasonable limit, the equipment would not only be capable of making faster schedule speeds, but would also have a reasonable temperature rise.

Fig. 2 shows the accelerating horse-power in different services for a car having a total weight of 10 tons, and illustrates the effect that stops per mile on this car will have on a required input. With 12 m.p.hr. schedule and 3 stops per mile, 36½ h.p. is required to accelerate this weight at approximately 1½ miles per hour per second. Providing the same schedule speed is maintained and the car makes 5½ stops per mile, 72½ h.p. will be required. With a 9 m.p.hr. schedule and 5 stops per mile, 28 h.p. will be required. If the stops are increased to 8 per mile with the same schedule, 46½ h.p. will be required. With an 8 m.p.hr. schedule and 7 stops per mile, 27½ h.p. will be required. If the stops are increased to 10 per mile, 43 h.p. will be required.

The second curve illustrates the effect of schedule stops per mile on a certain weight of car. The variation of the service requirements shown on this curve illustrates the variation in horsepower required to accelerate cars having a weight of 10 tons per motor, and shows how careful we should be in getting together the facts for the purchase of equipments.

The facts as brought out in this article are intended to illustrate the real necessity for securing accurate service data and the realization that the points which are necessarily covered, while apparently very simple and unimportant, are really the deciding factors in determining the most economical equipment that will give satisfaction in the work it is intended to do.

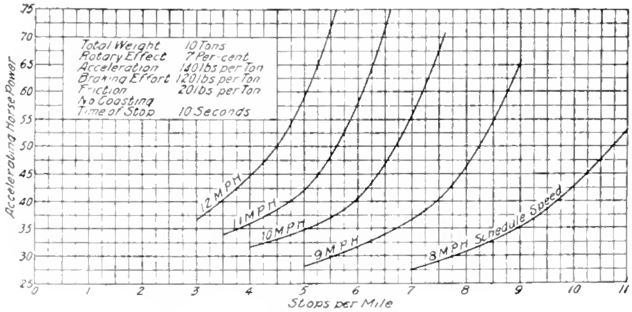

**Fig. 2.** Accelerating Horse power for 10-ton car

# THE KILOWATT RATING OF MOTORS

By H. M. Hobart

Consulting Engineer, General Electric Company

During the past two decades the number of electrical machines placed in use has reached an enormous figure, and, as a consequence, the use of electrical terms and units has become as common as that of mechanical ones—perhaps more so. The *horse power* rating of electrical motors has never been satisfactory and therefore many of the electrical societies of the world, after thorough deliberation, have agreed to specify that all electric motors should be rated in kilowatts. The reasons for making the change and the advantages gained thereby form the text of this article.—**Editor.**

The 1914 Standardization Rules of the American Institute of Electrical Engineers require (see paragraph 139) that motors shall be rated in kilowatts. On account, however, of the hitherto prevailing practice of expressing mechanical output in horse power, the rules recommend that the rating of motors shall, for the present, be expressed both in kilowatts and in horse power until such time as the industry shall become sufficiently accustomed to the new rating. As a convenient and closely correct equivalent, it is useful to remember that the horse power rating of a motor may, for practical purposes, be taken as 4/3 of the kilowatt rating. In order to lay stress upon the preferred future basis, it is considered in the rules that it is desirable that on rating plates, the rating in kilowatts shall be shown in larger and more prominent characters than the rating in horse power.

In taking this step the American Institute of Electrical Engineers is simply falling in line with authoritative precedents. The subject was taken up by the International Electrotechnical Commission (I. E. C.), at the meeting held in Turin in September, 1911. In the fourth edition (Published in 1914 by Julius Springer, Berlin) of Dettmar's little handbook dealing with the interpretation of the rules of the Society of German Electrical Engineers (Verband Deutscher Elektrotechniker) the latest (1913) standardization rules of that society are considered. The subject of the kilowatt rating of motors is there discussed at some little length.

The following is a translation of that part:

> "The horse power, the old unit for the output of motors, was replaced by the kW in the new edition of the standardization rules adopted at the 1913 annual meeting of the V.D.E. In taking this step, the Commission has accepted the following conclusion of the Sub-Committee on Units and Formulae:
>
> "'The technical unit of output is the kilowatt. It is practically equal to 102 kilogrammeters per second and corresponds to $10^{10}$ ergs per second. The abbreviation is kW.'
>
> "Furthermore the Commission is in agreement with the resolution adopted by the I. E. C. in 1911. This resolution reads:
>
> "'1. The output of electric generators is defined as the electrical power available at the terminals.
>
> "'2. The output of electric motors is defined as the mechanical power available at the shaft.
>
> "'3. Both electrical and mechanical powers shall be expressed in International watts.'
>
> "The introduction of the kW rating of motors will undoubtedly be attended with great difficulties. Indeed, it has taken 20 years to reach the decision to replace the horse power by the kW. Already in 1891 W. Kohlrausch made the proposal at the International Electro-Technical Congress at Frankfort.
>
> "During the transition stage until the kW has become established as the unit of mechanical output, difficulties and misunderstandings with the purchasers can easily occur. A good many motor manufacturers have always considered that these difficulties could be best overcome in giving a horse power designation to the motors in addition to the kW designation of their output. The Commission has given this view careful consideration and has concluded that such a plan is not to be recommended, since it would only result in materially lengthening the transition period. As long as the horse power still appears on the rating plate, the purchaser will not accustom himself to the kW. In order to abbreviate the transition period as much as possible, it is therefore advisable to exclusively employ the kW. Consequently the Commission unanimously passed a resolution that the kW rating shall be exclusively employed upon the rating plate.
>
> "The members of the V.D.E. were made acquainted with this resolution in the columns of the E.T.Z. A desirable means of simplifying the calculation of the equivalent rating on the part of the purchaser during the transition stage consists in arranging that for several years a card shall be attached to each machine on which the following conversion figures are given:
>
> "1 kW = 1.36 hp
> "1 hp = 0.735 kW
>
> "For the sake of completeness the equivalents in kilogrammeters per second should be included. The corresponding conversion factors are as follows:
>
> "1 kW = 1.36 hp = 102 kgm per second
> "1 hp = 0.735 kW = 75 kgm per second
> "1 kgm per sec. = 0.0098 kW = 0.0133 hp."

It will be noted that the above conversion factors relate to the *continental* horse power. While the continental horse power is equal to only 735 watts, the horse power employed in America and Great Britain is equal to 746 watts. This difference and the confusion thereby involved constitute an additional reason for preferring the kw. rating of motors. For America and Great Britain the conversion factors become as follows:

1 kw. = 1.34 h.p. = 102 kg-m. per second
1 h.p. = 0.746 kw. = 76.0 kg-m. per second
1 kg-m. per sec. = 0.0098 kw. = 0.0131 h.p.

In a paper entitled "Method of Rating Electrical Apparatus" by Merrill, Powell and Robbins, published at p. 127 of the February, 1913, issue of the Proceedings of the A. I. E. E., the authors, (who constituted the sub-committee appointed by the Standards Committee of the A. I. E. E. to report on the subject of "Rating Electrical Machinery"), put the case as follows:

> "From the pure science standpoint, the kilowatt is a better unit of power than the horse power since it is based directly upon the absolute c.g.s. system, the watt being equal to $10^7$ dyne-centimeters per sec., while if we accept the definition of the horse power as being 550 ft-lb. per sec., it is a gravitational unit and so is not strictly constant, but varies slightly with the latitude.
>
> "Also the kilowatt is the practically universal unit for the measurement of electrical power throughout the civilized world, while the "horse power" besides varying on account of its being a gravitational unit is defined differently in different countries. In several European countries it is defined as 75 kg-m. per sec., while here it is 550 ft-lb. per sec. The difference is about 1½ per cent.
>
> "Then too there seems to be no real reason why both electrical and mechanical power should not be expressed in the same units, and since the kilowatt is much more desirable as a universal unit than the horse power for the reasons enumerated, it is recommended that the output of motors be expressed in kilowatts instead of in horse power."

To assist in facilitating the use of the kilowatt and the watt as universal units of power as well for the physicist as for the engineer and the layman, the following more extended table of equivalents has been prepared:

It is unfortunate that there should be so many alternative units of power in use. To fix ideas as to their relative magnitude they are arranged in the following table with the smallest unit of power at the head of the table and the largest unit of power at the foot of the table. In the second and third columns are given their equivalents in watts and kilowatts.*

1 watt = 1.000 watts = 0.001000 kw.
1 ft-lb. per sec. = 1.36 watts = 0.00136 kw.
1 kg-m. per sec. = 9.81 watts = 0.00981 kw.
1 Continental h.p. = 735. watts = 0.735 kw.
1 English (and American) h.p. = 746. watts = 0.746 kw.
1 kw. = 1000. watts = 1.000 kw.
1 B.t.u. per sec. = 1055. watts = 1.055 kw.
1 kg-cal. per sec. = 4200. watts = 4.20 kw.

---

* Incidentally it should be mentioned that the watt is equal to 1 joule per second and that the joule is equal to $10^7$ ergs, the joule and the erg being units of energy. The erg is the energy expended when a force of one dyne is overcome through a distance of one cm.

## TABLE OF EQUIVALENT VALUES FOR POWER EXPRESSED IN VARIOUS ENGLISH AND METRIC UNITS

| | Watt | Kw. | English H.P. | Continental H.P. | Kg-M. per Sec. | Ft-Lb. per Sec. | Kg-Cal. per Sec. | B.t.u. per Sec. |
|---|---|---|---|---|---|---|---|---|
| 1 watt is equal to | 1.000 | 0.001000 | 0.00134 | 0.00136 | 0.102 | 0.737 | 0.000238 | 0.000947 |
| 1 kw. is equal to | 1000. | 1.000 | 1.34 | 1.36 | 102.0 | 737. | 0.238 | 0.947 |
| 1 English (and American) h.p. | 746. | 0.746 | 1.000 | 1.015 | 76.0 | 550. | 0.178 | 0.707 |
| 1 Continental h.p. | 735. | 0.735 | 0.985 | 1.000 | 75.0 | 541. | 0.175 | 0.696 |
| 1 kg-m. per sec. | 9.81 | 0.00981 | 0.0131 | 0.0133 | 1.000 | 7.23 | 0.00234 | 0.00930 |
| 1 ft-lb. per sec. | 1.36 | 0.00136 | 0.00182 | 0.00185 | 0.138 | 1.000 | 0.000324 | 0.00129 |
| 1 kg-cal. per sec. | 4200. | 4.20 | 5.61 | 5.70 | 427. | 3090. | 1.000 | 3.97 |
| 1 B.t.u. per sec. | 1055. | 1.055 | 0.415 | 0.422 | 107.6 | 778. | 0.252 | 1.000 |

# CALORIZING: A PROTECTIVE TREATMENT FOR METAL

By H. B. C. Allison and L. A. Hawkins

Research Laboratory, General Electric Company

Calorizing will undoubtedly find a wide and varied use in many industries and is a development which will lead to economies in numerous processes of manufacture. Briefly stated, it will prevent metals, especially iron, from burning when subjected to high temperatures for either long or short periods of time, and for one or many heats. The authors give data and illustrations which will interest a large section of the engineering and manufacturing fraternity.—Editor.

Since the close of the bronze age iron has been used for ovens, utensils and tools of every kind for all temperatures up to dull red; but for higher temperatures there has been, even up to the present day, no cheap metal available. Platinum, because of its cost, has been quite limited in application, and the cheaper metals, such as copper, and most of the alloys, such as brasses and bronzes, will not withstand heating in the air to red heat. Nickel and cobalt are the most stable of those metals which may be worked or cast and are fairly cheap and will withstand moderately high temperatures. Some of the alloys containing nickel are also quite permanent in the air at red heat.

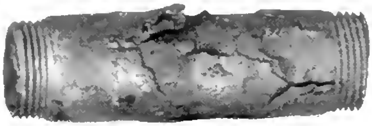
Mr. T. Van Aller has discovered a process of heating metals in revolving drums with mixtures containing, among other things, finely divided aluminum, by which a surface alloy containing aluminum is produced. In the case of copper, this alloy is of the nature of an aluminum bronze, but richer in aluminum than the ordinary alloy of that name and more resistant to heat, so that copper thus treated is protected up to the melting period of the alloy from the scaling which occurs when untreated copper is heated above 300 deg. C. The same general result was obtained in the case of iron and steel. Some use was made of this process, which has been called "calorizing," for treating copper soldering irons and iron resistance wires for heating devices.

Modifications of the process, extending it to further applications, were made by Mr. E. G. Gilson of the Schenectady Research Laboratory. Pieces which, because of their shape or size, are not adapted for tumbling, may be calorized by packing them in, or painting them with, a suitable mixture, and heating them. Thus, the size of the heater is the only limitation on the size of the piece that may be calorized. Wire or ribbon may be treated by a continuous process, by passing it through a heated pipe containing the proper calorizing mixture. There appear to be many places where it is desirable to use iron vessels or apparatus at temperatures above red heat, and at such temperatures, ordinary iron rapidly oxidizes and scales away. After iron is calorized the effect of heating is slight. Instead of burning and the scale falling off, as in the case of untreated iron, practically no effect can be detected after a considerable time—certainly none which injures the surface. This is well illustrated by the two pieces of iron pipe shown in Fig. 1, both from the same kind of pipe, but one of which (B) was calorized. The two were heated side by side, with an ordinary laboratory blast lamp to a temperature of about 900 deg. C. for a period of four hours, then cooled and the heat once more applied for another period of four hours. At the end of that time the untreated pipe (a) was badly burned, the point where the flame was directly applied having been reduced to one-half the original thickness, while the whole surface was blistered. The contrast between this piece and that which was calorized (b) is very marked, for even upon close examination the calorized pipe appears to be unchanged.

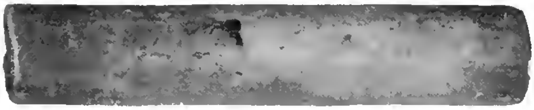
In connection with the piece of calorized pipe used in this experiment, it should be stated that it had previously been used in other work, where it had been alternately heated to 1000 deg. C. and cooled, in an electric resistance furnace open to the air. The total time during which the maximum temperature was maintained was about 50 hours. A rather extreme test has been applied to this same piece lately, by heating it to about 900 deg. C. and plunging it into cold water, after it had cooled to a dull red. This has been repeated three times and the surface shows no signs of cracks or any tendency to scale.

Fig. 2 shows a similar comparison between two pieces of sheet iron tube, one calorized and the other not, which were both subjected to a temperature of 800 deg. C. in a gas furnace for 100 hours. The uncalorized piece is practically destroyed, while the calorized piece is unharmed.

As evidence of the performance of calorized iron under actual working conditions, the tubes shown in Fig. 3 were photographed. These tubes are part of a small nitrogen purification plant which is in use during each working day. They are both heated by gas in a brick furnace, the larger tube to a temperature of about 800 deg. C. and the smaller to about 650 deg. C. The larger tube was calorized and has been in use over 400 hours with no observable deterioration, while the smaller tube, which was not calorized and which has also run 400 hours, is badly burned. The spots on the calorized tube are carbon deposits due to poor combustion in the burners. In Fig. 4 are shown these same tubes after they have run over 650 hours. The calorized tube still shows no evidence of scale while the other tube is almost burned through.



(*a*) Uncalorized Iron Pipe



(*b*) Calorized Iron Pipe

Fig. 1. A Piece of Plain Iron Pipe and a piece cut from the same Tube, but calorized, after being subjected to the same degree of temperature for the same length of time

Another application of this process is to iron wire or ribbon such as is used in electrical heating units. An untreated piece of this ribbon will burn out in four or five hours at the most, whereas tests upon calorized pieces have shown that the life is increased at least fifty fold, and in the best instances over one hundred fold. The results of tests made at Pittsfield indicate that a life of over 500 hours may be expected from calorized heating units run at a temperature of 800 deg. C.

Calorized seamless iron tubing is being used for combustion tubes in the research analytical laboratory where pure oxygen is brought in contact with the metal at temperatures from 900 to 1000 deg. C. These have thus far operated all right and still appear unaltered after nearly 100 hours' use.

The above facts seem to indicate that this is a simple method for extending the use of iron under oxidizing conditions at high temperatures, and for greatly prolonging the life in those instances where it is now used, but must be renewed at frequent intervals. In the case of small muffles on crucibles, where temperatures are below 1000 deg. C., this treatment of cheap cast or wrought iron shapes seems very promising. While the life of the coating depends on the temperature at which it is used, as well as on the duration of time taken in its preparation, i.e., the quantity of aluminum which alloys with the surface of the iron, it does not permit of long use at temperatures much in excess of 1100 deg. C.

Copper parts also, which are exposed to high temperatures, can have their life increased by calorizing. In some cases calorized copper may be used advantageously in place of aluminum bronze. For instance, a large power station had trouble from early corrosion of its condenser tubes. These tubes were aluminum bronze and were supposed to last at least a year. As a matter of fact while occasionally tubes would last as long as six years, other tubes would fail in four to six weeks after they were installed. About two and a half years ago a set of calorized copper tubes was installed and so far not a tube has failed.

Fig. 2. Effect of 800° C. in a Gas Furnace for 100 Hours on a Section of Calorized and of Uncalorized Sheet Iron Tubes

In some cases the life of copper contacts can be increased by calorizing. For instance a set of railway controller contacts which were calorized showed double the life of the ordinary untreated contacts.

As has been said, the effect of calorizing is to produce a surface alloy containing aluminum. The thickness of this alloy varies with the length of time to which the piece is subjected to the calorizing process, and the percentage of aluminum varies through the coating being greatest at the surface. This is shown clearly by a cross-section of a calorized copper rod. The line between the alloy and the unchanged copper is sharp, but the color of the alloy varies from a rich golden-yellow next to the copper to a silvery-white at the surface.

Fig. 5 shows cross-section views of a number of copper rods 1¼ in. in diameter, which were calorized for about two hours. The depth of the alloy is sharply defined.

Fig. 6 shows two cross-sectional photo-micrographs of a calorized copper bar. These photographs are magnified fifty-five diameters. One of them shows the large crystals of the calorized surface, and the other shows the unaltered crystalline structure of the copper a short distance below the surface. In the first of these photographs the blistering of the copper immediately below the calorized surface is shown by the spaces between the crystals of copper. This effect is characteristic of calorizing.

Fig. 7 shows cross-sectional photo-micrographs magnified forty diameters of an iron pipe which was used for some time as a heater for calorizing wire by the continuous process above mentioned. This pipe was packed with calorizing mixture, and its inner surface was therefore subjected to long calorizing treatment. The growth of the long crystals of the aluminum alloy is clearly shown.

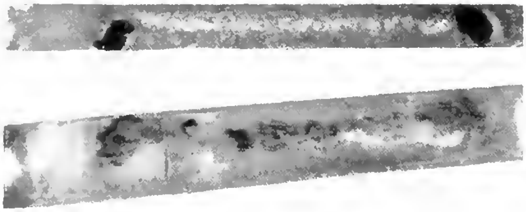


Fig. 3. A Section of calorized Iron Pipe (lower) and a Section of Uncalorized Iron Pipe (upper) after being treated to operating temperature for 400 hours

If the calorizing process is conducted at a high temperature in a mixture rich in aluminum, two layers of different alloys may result. Fig. 8 shows photo-micrographs, enlarged twenty diameters, of a cross-section of an iron combustion tube thus calorized. The first figure shows three layers, or rather five. The outer layers are probably mostly aluminum with a little iron, the next aluminum and iron with the iron predominating, and the middle layer the unchanged iron. The lines bounding the middle layer are especially sharply defined. The second figure shows the same tube after heating in the air at 1100 deg. for 50 hours. The sharp lines bounding the middle layer have disappeared and the crystals now have a radial structure. This is characteristic of all samples fired at this

Fig. 4. Photograph of the same Tubes as shown in Fig. 3 (upper uncalorized), but after 650 hours at operating temperature

Fig 5 Cross-sectional view of several 1¼ inch diameter copper rods after being calorized for two hours

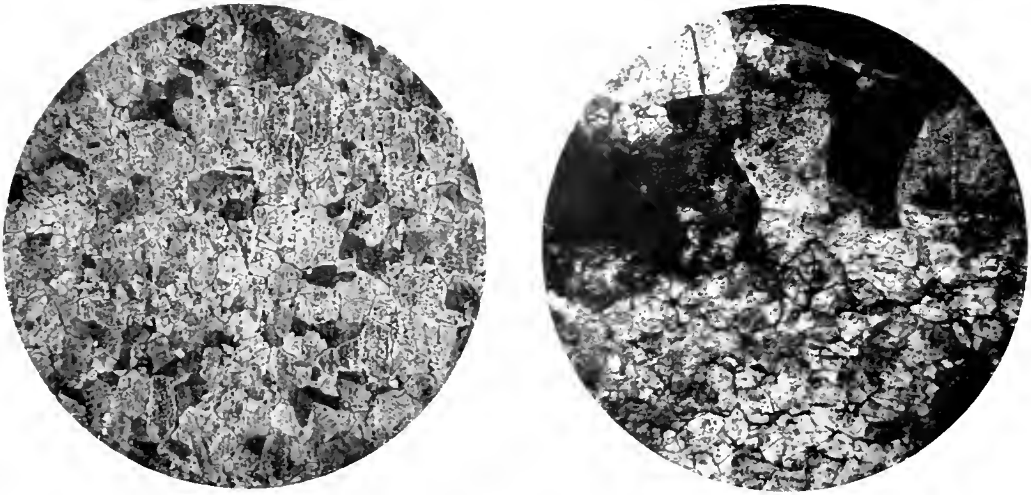

Fig. 6. Photo-micrographs (55 dia. magnification) of sections of a calorized copper bar

high temperature, and is due to a diffusion of the aluminum into the iron, making a more homogeneous structure. The outside layer is still distinct, however, and this is probably due to the oxidation of the aluminum.

When an iron pipe or ribbon is calorized for a heating unit, a portion of the iron becomes alloyed with the aluminum. Naturally this results in changing both the resistance and the temperature co-efficient. The thicker the calorizing coat the greater is the change. This is shown by the following table, in which No. 1 was given a lighter coat than No. 2.

| Sample | Ohms per M (19°) | Temp. Co-ef. Elec. Resis. (0–150°) $+10^{-3}$ |
|---|---|---|
| Iron ribbon | 0.905 | 5.61 |
| Same calorized No. 1 | 2.45 | 1.72 |
| Same calorized No. 2 | 7.6 | 0.151 |

A thin ribbon may easily be calorized all the way through, and then becomes quite brittle.

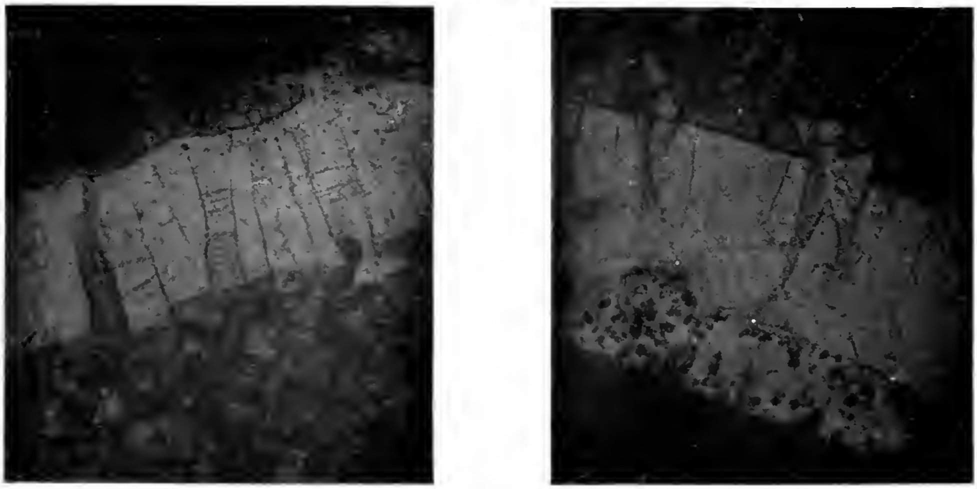

Fig 7. Photo-micrographs (40 dia. magnification) of sections of an iron pipe which has been subjcted to calorizing action for a long period

The dimensions and weight of either a copper or iron piece are slightly increased by calorizing. The increase of dimension is much less than the thickness of the alloy coat, the greater part of which simply takes the place of the original metal. The dimensions may, however, increase several mils and there is a tendency to a greater increase at the edges than on flat surfaces.

For iron, calorizing is intended only for protection at high temperatures. It does not compete with galvanizing, sherardizing, and other similar processes for protection against oxidation or corrosion at low temperatures. Its usefulness lies within a range of temperature much higher than a galvanized or sherardized coat could stand. For copper, calorizing is effective against corrosion at low temperature as well as against oxidation at high temperature. The upper limit is determined by the melting point of the alloy, which is somewhat lower the heavier the calorizing treatment, since that means an alloy with a higher aluminum content.

The probable explanation of the effect of the aluminum in the surface alloy is that a thin coat of alumina forms which prevents further burning of the metal beneath. It is well known that a pure aluminum wire may be heated in the air to a temperature several hundred degrees above its melting-point, without flowing, when the thin alumina shell which surrounds and supports the molten metal is easily seen.

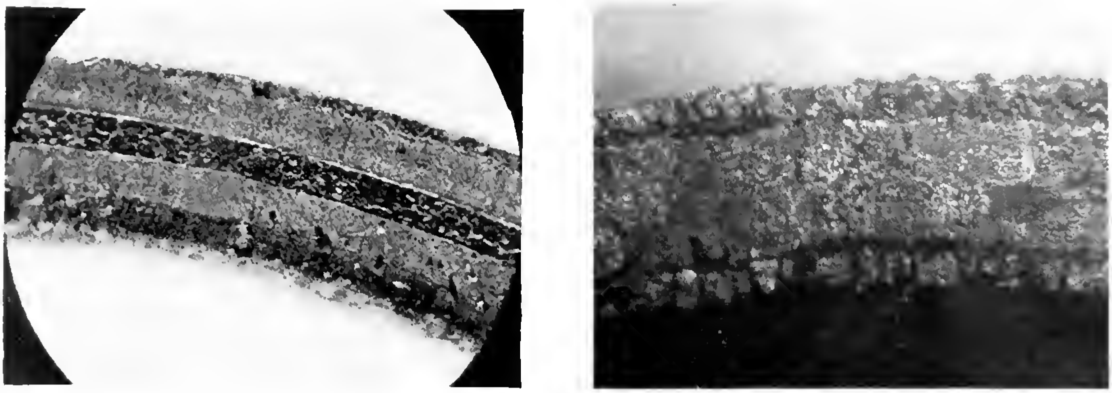

Fig. 8. Photo-micrograph (20 dia. magnification) of cross-sections of an iron tube calorized at high temperature with a mixture rich in aluminum. Left-hand view, before heating; right-hand view, after heating at 1100 deg. for 50 hours

# RECENT VIEWS ON MATTER AND ENERGY

## PART III

By Dr. Saul Dushman

Research Laboratory, General Electric Company

In the previous issue the author discussed the experimental evidence which has led to an atomistic theory of energy, and in the following paragraphs deals with a number of applications of the theory. A glance at the headings of the different sections is sufficient to indicate what an important place has been attained by the new theory in the consideration of physical and chemical phenomena.—EDITOR.

## APPLICATIONS OF THE QUANTUM THEORY

### A Calculation of Specific Heats at Low Temperatures

It has already been mentioned that according to Boltzmann's principle of equipartition, the average energy per molecule or atom of any substance ought to be $\frac{1}{2}\, kT$ for each degree of movability or freedom. Denoting the number of molecules per gram-molecular weight (mol) by $N$, it follows that the total energy per mol ought to be $\frac{1}{2}\, NkT = \frac{1}{2}\, RT$ for each degree of freedom.

Now, the specific heat of a substance is defined as the rate of increase in energy with increase in temperature. It therefore follows that the specific heat at constant volume per mol of any substance ought to be $\frac{1}{2}\, R$ for each degree of freedom.

On this basis, as shown in Part II, Boltzmann was able to deduce values for the specific heats of monatomic and diatomic gases in substantial agreement with those observed, and he was also able to account for the Dulong and Petit law for the specific heats of solids.[1]

### Specific Heats at Low Temperatures

But the gradual accumulation of the results of more accurate investigations showed that not only are there numerous exceptions to the Dulong and Petit law even at ordinary temperatures, but in the case of some diatomic gases the observed molecular heats are much higher than those deduced by Boltzmann. It was known for a long time that the atomic heats (atomic weight × specific heat) of carbon boron and silicon are much lower than the value 5.96 ($=3R$) which they ought to have in accordance with the Dulong and Petit law. But is was observed that the atomic heats of these elements increased with temperature, and at high enough temperatures they behave "normally." More recent investigations by Nernst and his students showed, moreover that at sufficiently low temperatures all the elements begin to exhibit atomic heats lower than 5.96, and that as the temperature decreases the atmoic heats decrease and tend to become equal to zero. Furthermore, the lower the atomic weight, the higher the temperature at which this low atomic heat begins to appear.

As typical of the results actually obtained in these investigations, the atomic heats at constant volume (denoted by $C_V$) of diamond, aluminum and lead are shown in Fig. 1.

It will be observed that while the atomic heat of lead rises very rapidly towards the limiting value as demanded by the Dulong and Petit law, the atomic heat of diamond is 0.00 up to 40 deg. abs., and then rises so gradually that even at 413 deg. abs. it is only 2.53, while it reaches a value of 5.19 at 1169 deg. abs.

### Einstein's Formula for the Atomic Heat of a Solid

According to Einstein these observations are quite in accordance with what one would expect if the atoms of these solids are capable of absorbing or emitting energy only in multiples of a unit quantum, $h\nu$. Now there are good reasons for believing that the longer heat waves emitted by solids are due to vibrations of the atoms themselves. Moreover, consideration of the elastic properties of solids leads also to the conclusion that the atoms in these cases are held together by quasi-elastic forces so that they vibrate about a mean position of equilibrium. Such an atom possesses therefore both kinetic and potential energy and is similar to a Hertzian oscillator. We are therefore justified in applying to the atomic vibrator considerations similar to those used by Planck in deducing his distribution formula. Since the atom of the solid can absorb or emit at

---

[1] See Part II General Electric Review, Sept., 1914, p. 903.

the maximum 3 $kT$ calories, it is evident from the analogy between Planck's linear oscillator and Einstein's vibrating atom that the average energy of an atom will be

$$U_\nu = \frac{3\,h\nu}{\epsilon^{\frac{h\nu}{kT}} - 1} \qquad (1)$$

The only difference between this equation and that derived for the electro-magnetic oscillator, (Part II, equation 13), outside of the substitution of $h\nu$ for $\delta$ in the latter, is due to the fact that the linear oscillator considered in deriving Planck's equation has only two degrees of freedom, while that considered above has six degrees of freedom.

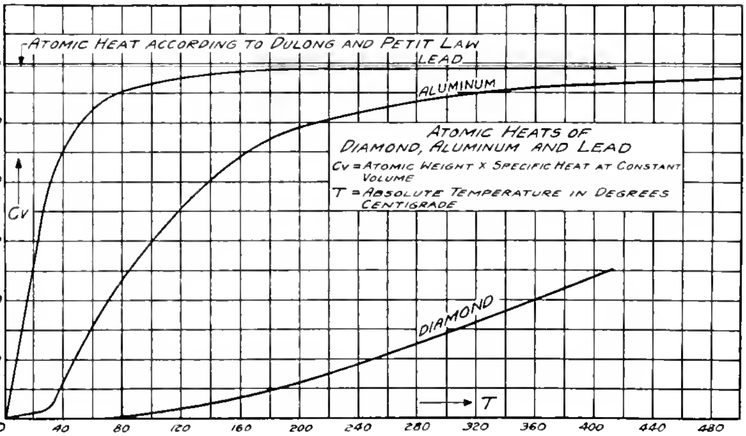

Fig. 1

The total energy per gram atom may be denoted by $W$, where

$$W = \frac{3\,N\,h\nu}{\epsilon^{\frac{h\nu}{kT}} - 1}$$

$$= 3\,R \cdot \frac{\frac{h\nu}{k}}{\epsilon^{\frac{h\nu}{kT}} - 1} \qquad (2)$$

At very high temperatures, where $T$ is large compared to $\frac{h\nu}{k}$, equation (2) becomes,

$$W = 3\,R\,T = 6\,T \text{ calories} \qquad (2a)$$

But this is the Dulong and Petit law, and it is seen that this law has the same validity in the realm of specific heats as the Rayleigh equation in that of black-body radiation.

Differentiating (2) we obtain the equation for the atomic heat at constant volume[2],

$$C_v = \frac{dW}{dT} = 3\,R\, \frac{\epsilon^{\frac{h\nu}{kT}}\left(\frac{h\nu}{kT}\right)^2}{\left(\epsilon^{\frac{h\nu}{kT}} - 1\right)^2} \qquad (3)$$

**Nernst and Lindemann's Formula**

However, the actual observations of Nernst and those working with him were found to be only in qualitative agreement with Einstein's formula. The discrepancies between observed and calculated values were found to increase as the temperature decreased, and consequently Nernst and Lindemann were led to suggest a modification of equation (3) of the following form

$$C_v = \frac{3}{2}\,R \left[ \frac{\epsilon^{\frac{h\nu}{kT}}\left(\frac{h\nu}{kT}\right)^2}{\left(\epsilon^{\frac{h\nu}{kT}} - 1\right)^2} + \frac{\epsilon^{\frac{h\nu}{2kT}}\left(\frac{h\nu}{2kT}\right)^2}{\left(\epsilon^{\frac{h\nu}{2kT}} - 1\right)^2} \right] \qquad (4)$$

This equation agrees splendidly with the data obtained, down to the very lowest temperatures.

The conclusion to be drawn from these results is that in the case of absorption and emission of heat at low temperatures, where the quantities of energy dealt with are very small, it is necessary to assume that this energy is absorbed or emitted only in multiples of a unit quantum $h\nu$, and not continuously as hitherto assumed.

---

[2] Z. f. Elektrochem. *17*, 265 (1911).

### Graphic Illustration of Einstein's Equation

The difference between the old and new theories may be illustrated graphically as follows:

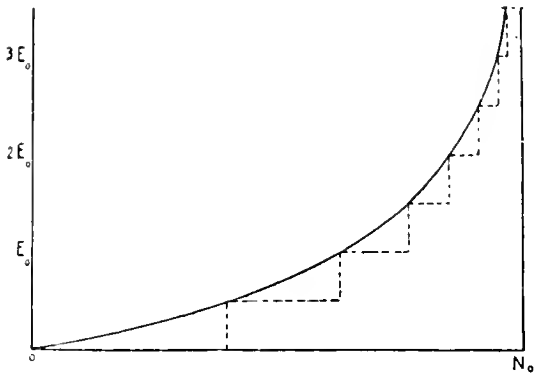

Fig. 2

Consider a gram-atom of an element in the solid state. According to Boltzmann's principle the average energy of each atom is 3 $kT$. Resolving the vibrations of the atoms into three planes at right angles to one another, it follows that the average energy per atom in any plane is equal to

$$E_0 = kT$$

or the total energy for $N_0$ atoms (1 gram-atom) is

$$N_0E_0 = N_0kT = RT$$

This average energy is divided equally into kinetic and potential.

However, the different atoms vibrating in one plane at any instant do not all possess the same kinetic energy. As is well known, the velocities of a large number of molecules moving in any direction vary from zero to infinity, in accordance with Maxwell's distribution law. From considerations based on this law, it can be shown that the distribution of energy among the $N_0$ atoms will follow a curve such as that shown in Fig. 2. The equation to this curve is of the form

$$N = N_0(1 - \epsilon^{\frac{E}{E_0}}) \qquad (5)$$

where $N$ denotes the number of atoms whose kinetic energy lies between the values $O$ and $E$. It is evident that $N_0$ corresponds to the value $E = \infty$, while the total area under the curve is equal to $N_0E_0 = RT$.

But such a law of distribution of energy among the $N_0$ atoms holds only under the assumption that the energy of an atom can vary *continuously*. If, however, we introduce the assumption that the energy of an atom can vary only in integral multiples of a unit quantum $h\nu$, it follows that the distribution law must be represented by a stair-case shaped line such as shown in Fig. 2 under the exponential curve; for those atoms which according to Maxwell's distribution law ought to possess an energy less than $h\nu$ will remain at rest. Similarly as there is no gradation in energy between the values $h\nu$ and 2 $h\nu$, there will be a number of atoms having the same energy $h\nu$, and similar considerations hold for the other groups of atoms. It is easily shown that for such a distribution of energy the average energy is not $kT$ but a smaller quantity, viz:

$$E_0 = \frac{h\nu}{\epsilon^{\frac{h\nu}{kT}} - 1} \qquad (6)$$

### Methods of Determining the Vibration-Frequency

A word or two about the determination of $\nu$, the so-called "Schwingungszahl" or vibration-frequency:[3] Three methods have been used. The first depends upon the determination of the frequencies of the longest heat waves as shown by the dispersion spectrum of the metal. The second one was suggested by Lindemann.[4] Assuming that at the melting point the radius of the orbit of the vibrating atom about its position of equilibrium becomes equal to the distance between neighboring atoms, he deduced a relation between the frequency $\nu$, the melting point $T_m$, the atomic weight $A$, and the atomic volume $V$ of the following form:

$$\nu = 2.8 \times 10^{12} \sqrt{\frac{T_m}{A V^{2/3}}} \qquad (7)$$

The third method which was developed by E. Madelung,[5] W. Sutherland[6] and A. Einstein,[7] assumes a relation between the frequencies of vibration and the elastic properties of the solid. According to the last-named authority the relation is of the form

$$\nu = \frac{2.8 \times 10^7}{A^{\frac{1}{3}} K^{\frac{1}{2}} \rho^{\frac{1}{6}}} \qquad (8)$$

where $A$ denotes the atomic weight, $K$ the compressibility and $\rho$ the density.

On the average the values of $\nu$ obtained by these different methods agree pretty well.

### Debye's Formula for the Atomic Heat of Solids

More recently Debye[8] has shown that instead of one definite value of $\nu$ it is necessary to take into account a whole range of values. According to his argument, the number of frequencies for $N$ atoms per unit volume cannot exceed $3N$. At the highest temperatures, where each frequency has the same average energy $kT$ (corresponding to both kinetic and potential energy), the total energy is therefore $3NkT$ as demanded by the Dulong and Petit law. As the temperature is lowered, the average energy taken up by the higher frequencies is less than that taken up by smaller frequencies, so that finally at the lowest temperatures attainable only those atoms executing vibrations of extremely low frequencies (for which $h\nu$ is very small) can obtain enough energy to vibrate. Now the lowest frequencies are obviously those corresponding to ordinary sound vibrations, and the other frequencies represent overtones. Debye shows that the maximum frequency and the distribution of lines in this "acoustical spectrum" may be calculated from the elastic constants of the material. He thus identifies the *thermal oscillations of the atoms with the elastic properties of the solid.*

Introducing Planck's conclusion that each frequency possesses on the average the quantity of energy given by equation (6) above, and integrating this over the whole range of frequencies corresponding to the acoustical spectrum, Debye obtains an expression for the atomic heat which is much more complicated than that of Nernst and Lindemann. The latter is, however, shown to be a good approximation to Debye's formula at lower values of $T$. Furthermore, the interesting conclusion is obtained by Debye that at very low temperatures the atomic heats vary as the third power of the absolute temperature; in other words, the total energy of a solid at temperatures near the absolute zero is proportional to the fourth power of the absolute temperature. This relation is thus analogous to the Stefan-Boltzmann law for the total energy radiated by a black body.

### (B) Applications of the Quantum Theory to Chemistry

The problem of the determination of specific heats down to the very lowest temperatures is of even greater importance to the chemist than to the physicist. This is due to the fact that a knowledge of specific heat is necessary in connection with the solution of the great problem of chemical affinity. As a matter of fact, Nernst and his pupils had begun their investigations on specific heats even before anyone thought of applying the quantum theory in this field. However, Einstein's suggestion certainly gave added impulse to these investigations, and the result is that not only has the quantum theory been brought to the notice of physical chemists as a possible method of calculating specific heats down to the lowest temperatures, but the new theory has also been applied to the determination of the so-called "chemical constants"—a knowledge of which is also essential towards a complete solution of the problem of chemical affinity.

In the following section we hope to show in what respects the quantum theory has been applied successfully to the solution of this problem.

### Meaning of "Chemical Affinity." Free Energy

The introduction of the term affinity is usually ascribed to Boerhave. He gave this term a meaning that it has retained ever since, viz.: The force that holds together chemically dissimilar substances. The investigations of Wenzell (1777) of Berthollet (1803) and of Guldberg and Waage (1867–1879) led to a clearer understanding of some of the factors influencing chemical affinity. The investigations of Ostwald on the affinity of acids and bases, together with the far-reaching speculations of Arrhenius led to precise methods of measuring chemical affinity in the case of reactions between electrolytes.

It is to Van't Hoff, however, that we owe an exact definition of affinity, based upon the two fundamental laws of thermodynamics. Since it is customary in mechanics to measure forces by determining the magnitude of the forces necessary to just balance them, Van't Hoff suggested that we determine the magnitude of chemical affinity from the amount of work that a reaction can yield when it is carried out in a perfectly reversible manner; that is, under such conditions that the driving forces of the reaction are always balanced by equal and opposite external forces. The affinity of a chemical reaction is therefore to be measured by means of the amount of work that can be obtained when the reaction is carried out at constant temperature in a reversible manner. If a number of substances constituting any isolated system are capable of reacting in more than one way, then in accordance with the principle just enunciated, that reaction will be most

---

[8] Ann. Physik, *39*, 789–839 (1912).

likely to occur from which the greatest amount of work is available when it is carried out reversibly.

Unfortunately, it is not always possible to determine by direct methods the magnitude of this available work, or "free energy" as it has been designated. In the case of gases, the free energy is very easily calculated. In the case of solutions to which the gas laws apply such a calculation is also possible and the dissociation theory of Arrhenius may be regarded as a theory which enables us to determine from the conductivity of an electrolyte its chemical affinity. The measurement of electromotive forces of chemical reactions is a third method of determining chemical affinity, which is of great practical importance. Thus the chemical affinity of the reaction,

$$H_2+Cl_2=2\ HCl$$

may be determined by measuring the electromotive force of a cell whose electrodes are hydrogen and chlorine gas, with hydrochloric acid as electrolyte. These are practically the only cases in which the free energy can be determined directly.

But it is possible to measure directly or calculate in the case of all reactions the total energy evolved or absorbed, for it is only necessary to allow the reaction to occur in a calorimeter and the total heat evolved or absorbed in a measure of the change in total energy.

### Relation Between Total Energy and Free Energy

Is there any relation between the total energy of a chemical reaction and that available as work when the reaction is carried out reversibly? Berthellot (1879) answered this question by stating that the two quantities of energy are equal. This was enunciated by him as the third principle of thermodynamics. Disregarding even the existence of reactions which occur with an absorption of heat and of other reactions which proceed in one direction or the other, depending upon concentration, the "third principle" is shown to be in disagreement with the second law of the thermodynamics.

Let us denote the total energy of a reaction by $Q$, and the free energy (or work available at constant temperature and constant volume) by $A$. Since $A$ is not necessarily equal to $Q$, heat will be either absorbed or given out when the reaction is carried out reversibly (at constant temperature and constant volume), the amount of this "latent heat" corresponding to $A$-$Q$.

Now let us assume that the reaction takes place in one direction at temperature $T_1$ and in the other direction at $T_2$. Let $A_1$ and $Q_1$ denote the free and total energy respectively at $T_1$ and $A_2$, and $Q_2$ denote the corresponding values for the temperature $T_2$. If the transition from $T_1$ to $T_2$ and that in the reverse direction are adiabatic, the whole chain of operations will constitute a Carnot's cycle, and it therefore follows from the second law of thermodynamics that for such a cycle:

$$\frac{\text{Work gained during cycle}}{\text{heat absorbed at higher temperature}}=\frac{\text{difference in temperature}}{\text{higher temperature}}$$

or,

$$\frac{A_1-A_2}{A_1-Q_1}=\frac{T_1-T_2}{T_1}$$

When the difference $T_1-T_2$ becomes very small and equal to $\triangle T$, this equation can be written as

$$\frac{\triangle A}{A-Q}=\frac{\triangle T}{T},$$

or, in the limit,

$$A-Q=T\frac{dA}{dT} \qquad (9)$$

That is, the free energy differs from the total energy by the product of the temperature-coefficient of the free energy $(dA\ dT)$ and the absolute temperature. It is evident that only at the absolute zero are the free and total energy equal, that is,

$$A_0=Q_0 \qquad (10)$$

But at any other temperature this is not generally true, and it is therefore impossible, without the aid of some other assumptions, to calculate $A$ from $Q$.

This is still more evident from the following considerations:

Equation (9) can be written in the form

$$\frac{A}{T}-\frac{dA}{dT}=-\frac{Q}{T} \qquad (9a)$$

Dividing each side of this equation by $T$, the left-hand side becomes the complete differential of $A\ T$, and consequently the equation may be written in the form,

$$\frac{d}{dT}\left(\frac{A}{T}\right)=-\frac{Q}{T^2} \qquad (9b)$$

That is, the second law of thermodynamics leads to a relation between the rate of change of the quantity $A\ T$ on the one hand and the quantity $Q\ T^2$ on the other. In other words, the second law of thermodyanmics gives us the slope at each point of a curve whose ordinates are equal to $A/T$ and abscissae to $Q/T^2$. But it is evident that the slope alone is not sufficient to define the position of a curve absolutely; we require, in addition to this information, the intercept on either of the two axes of co-ordinates. Using the language of the integral calculus, this can be stated as follows:

$$\frac{A}{T} = -\int_0^T \frac{Q}{T^2}\,dT + C \qquad (11)$$

where $C$ is the so-called integration constant and corresponds to the intercept mentioned above.

This equation shows that in order to calculate $A$, it is necessary to know $Q$ for the range of temperatures $0$ to $T$ and also a constant $C$. The variations in $Q$ with temperature depends, however, upon the difference between the specific heats of the substances entering into the chemical reaction and those that are produced,[9] so that

$$\frac{dQ}{dT} = \Sigma C_v \qquad (12)$$

where $C_v$ denotes the specific heat at constant volume per gram-atom of any one of the substances involved.

Hence, the calculation of $A$ depends, in the final analysis, upon three sets of data:

(1) Thermochemical data, giving $Q$.
(2) Specific heats down to absolute zero.
(3) Integration constants, known as chemical constants, $C$.

### Nernst Heat Theorem

There are, however, certain types of reactions for which the constants are equal to zero. A few years ago Nernst put forward the suggestion that in the case of reactions involving solids or liquids, the temperature coefficients of both the free and total energy must tend to decrease indefinitely as the absolute zero is approached. On the basis of this assumption, which is known as the Nernst heat theorem, it can be readily shown that for the above class of reactions, the constant must be equal to zero, and furthermore, that in the case of reactions involving gases the chemical constant is additively composed of the constants for the different substances taking part in the reaction, as determined from their vapor tension curves. Thus, the chemical constant of the reaction,

$$2H_2 + O_2 = 2H_2O,$$

all the substances involved being considered in the gaseous state, can be calculated from the constants of reactions similar to the following:

Solid (or Liquid) Hydrogen $\rightarrow H_2$ (gas).

It is therefore possible to calculate the "chemical" constant of any reaction from tables of constants of the reagents involved.

### Relation of Quantum Theory to Nernst's Heat Theorem

The assumption that the specific heat decreases to zero as the absolute zero is approached is evidently in accord with the experimental data that have been obtained since the Nernst heat theorem was enunciated. Moreover, the quantum theory enables us to calculate the actual values of the specific heats down to the absolute zero, not only for the case of solids, as shown above, but also in the case of gases.[10]

The second part of Nernst's assumption, that $dA/dT$ tends also to decrease to zero as the absolute zero is approached, is justified by Debye's and Keesom's deductions that near the absolute zero the specific heats vary as $T^3$. Otherwise $\frac{Q}{T^2}$ would become infinite as $T$ diminishes.

### Calculation of Chemical Constants

It has been pointed out by Tetrode[11] and more recently by Sackur[12] and Keesom[13] that the chemical constants, as well as the specific heats, may be deduced by considerations similar to those used by Planck in developing his radiation formula. Both Sackur and Keesom conclude that it is possible to express $C$ in terms of the number of atoms in the molecule and the molecular weight (M). Thus

---

[9] This may be readily deduced as follows: Consider a reaction in which $A$ changes into $B$. Allow the reaction to occur at temperature $T_1$ and let $Q_1$ be the heat absorbed. Then heat the product, $B$, to temperature $T_2$. If $C_B$ denotes the specific heat of $B$ the total amount of energy absorbed in changing from $A$ at $T_1$ to $B$ at $T_2$ is equal to $Q_1 + C_B(T_2 - T_1)$. On the other hand, the same final state can be obtained by heating $A$ to $T_2$ and allowing the reaction to occur at this temperature. Denoting the heat of reaction at $T_2$ by $Q_2$ and the specific heat of $A$ by $C_A$, it follows from the law of conservation of energy, that:

$$Q_2 + C_A(T_2 - T_1) = Q_1 + C_B(T_2 - T_1)$$

or

$$\frac{Q_2 - Q_1}{T_2 - T^1} = (C_B - C_A)$$

In the limit

$$\frac{dQ}{dT} = \Sigma C_v$$

where $\Sigma$ indicates that the algebraic sum is to be taken of all the specific heats involved.

[12] Ann. Phys. *40*, 67–106 (1913).

[13] Phys. Zeit. *15*, 695, (1914).

for monatomic gases, the latter obtains the relation (in C.G.S. units),

$$C=3.67+1.5 \log M \qquad (13)$$

For diatomic and triatomic gases, Sackur obtains similar expressions. In these cases, however, the agreement between the observed and calculated values is not quite as good, but the very fact that these speculations lead to results that are in fair accord with experimental data in even a fraction of the cases goes far to justify the application of the method. As Sackur points out, *it is possible by making use of deductions from the quantum theory to calculate the free energy of a chemical reaction at any temperature from thermochemical data obtained at any other temperature.* In enabling us to determine the free energy of any reaction from calorimetric data, the quantum theory becomes, therefore, of extreme utility to the physical chemist.

There is one more point that is worth while emphasizing in this connection, viz.: That while the classical thermodynamics necessarily leaves the question as to the relation between free and total energy only partly answered, the application of the quantum theory taken in conjunction with the laws of thermodynamics leads to a complete solution. Let us consider what this means. The first law of thermodynamics states that in all transformations of energy in an isolated system, the total energy of the system remains constant. The second law states something about the conditions under which heat energy can be transformed into mechanical energy or its equivalent in any other form of energy. The Nernst heat theorem and quantum theory give us additional information as to the inner mechanism of this energy transfer. In this respect the quantum theory holds the same position with regard to ordinary thermodynamics as the kinetic theory holds with regard to the laws of equilibrium, and we believe that for a complete comprehension of natural phenomena both aspects, that is the kinetic as well as static are absolutely essential.

### C) Emission of Electrons by Light and X-Rays. Photo-Chemical Reactions

The atomistic view of the structure of energy has also led to surprisingly simple relations in the consideration of such apparently different fields as the photo-electric effect, emission of electrons by X-rays and photo chemistry.

#### Photo-Electric Effect

The fact that a surface illuminated by ultra-violet light becomes positively charged, and thus facilitates the passage of electricity in such a direction as to charge the surface positively, has been known for a number of years as the Hallwachs or photo-electric effect. The phenomenon has received its simplest explanation in terms of the electron theory, as being due to an emission of electrons under the influence of ultra-violet light. Accurate measurements have shown that the maximum velocity of the emitted electrons is independent of the intensity of illumination and depends only on the frequency of the incident (monochromatic) radiation.

The number of electrons emitted increases, however, with the intensity of the illuminating source. In the case of highly electro-positive metals like sodium and potassium, light of even lower frequency than ultra-violet causes the emission of electrons.

On the basis of the quantum theory it is possible to deduce a relation between the frequency of the incident light and the velocity of the ejected electron.

Denote the initial velocity of the electron leaving the surface by $v$ and let $m$ be its mass. Let $P$ denote the work required to carry an electron through the surface of the metal. The energy for this emission must be obtained from the incident light, and on the basis of the quantum theory this must be equal to $h\nu$. Consequently,

$$\tfrac{1}{2}\, mv^2 = h\nu - P \qquad (14)$$

Denoting by $V$ the potential difference through which the electron must pass to acquire a velocity $v$, and combining (14) with the relation,

$$Ve = \tfrac{1}{2}\, mv^2 \qquad (15)$$

where $e$ denotes the charge on an electron, we obtain the relation,

$$V = \frac{h\nu}{e} - \frac{P}{e} \qquad (16)$$

By measuring $V$ for different values of $\nu$, it is evidently possible to test this conclusion. In the actual experiments it is more convenient to determine the minimum positive potential which it is necessary to apply to the illuminated surface in order to cut down the electron emission to zero. Such measurements are difficult to obtain with any degree of accuracy, and it is only within the past year that excellent experimental confirmation of equation (16) has been obtained. At the meeting of the American Physical Society held in Chicago, November 29, 1913, Prof. Millikan announced that he had obtained such confirmation over a large range of frequencies, the observed value of $h/e$ being within five per cent of that calculated from other data.[14]

### Photo-Chemical Reactions

Einstein has also extended the above arguments to the case of photo-chemical reactions.[15] Assuming that the energy absorbed per gram-molecule in any photo-chemical reaction is $\delta$ then it follows directly from the concept of energy quanta, that

$$\delta = nh\nu$$

where $\nu$ is the frequency of the monochromatic, radiation that supplies the energy of the reaction and $n$ is some integer. This is known as Einstein's law of photo-chemical equivalency.

The proportionality between amount of photo-chemical action and intensity of illumination follows as a direct consequence of this relation.

According to Boll and Victor Henri[16] the actual value of the ratio $h\nu/e$ as determined in most cases is far from unity, varying all the way from $10^6$ to $10^{-3}$. To account for this discrepancy, Baly assumes a disturbing influence of the medium, while Bodenstein[17] assumes the existence of intermediary reactions involving electrons.

The latter theory is extremely interesting and suggestive. Bodenstein makes the assumption along with Stark that in all photo-chemical reactions the first stage is the liberation of an electron as in the ordinary photo-electric effect. Consequently, the energy absorbed must be $h\nu$ per electron emitted. Bodenstein then draws a distinction between what he designates as primary and secondary reactions respectively. In primary reactions, the molecules that have been deprived of electrons react directly; so that for these reactions the ratio between the number of molecules reacting and the amount of energy absorbed $(h\nu/\epsilon)$ ought to be equal to unity.

On the other hand, in the case of secondary reactions, the electron attaches itself to a molecule, renders it active, and becomes free again after the reaction. It is therefore conceivable that the quotient $h\nu/\epsilon$ can become greater than unity.

### Emission of Electrons by X-Rays

A phenomenon closely related to the photo-electric effect is the ejection of electrons from surfaces bombarded by X-rays, and it has been shown that in this case also the velocity of the emitted electrons is proportional to the potential difference between the electrodes of the tube which produces the rays, that is, the "harder" the X-rays, the greater the velocity of the emitted electrons. Assuming, therefore, that the X-ray transfers a quantum of energy from the electron bombarding the anode to the electron emitted from the surface upon which the X-ray impinges, it is possible to calculate the frequency of the latter.

The calculation is similar to that of the emission velocities of photo-electrons. We have

$$Ve = h\nu = \frac{hc}{\lambda} \qquad (16a)$$

as in equation (16). If $V = 40{,}000$ volts,

$$\lambda = \frac{hc}{Ve} = \frac{6.62 \times 10^{-27} \times 3 \times 10^{10}}{4.774 \times 10^{-10} \times \frac{40{,}000}{300}} = 3 \times 10^{-9}\ \text{cm.}$$[18]

This is the order of magnitude of the wave-lengths which have been obtained by measuring the diffraction patterns produced by letting X-rays pass through crystals.

There is a still further similarity between the emission of electrons by X-rays and ultra-violet light. Besides the normal photo-electric effects mentioned above, there exists a selective photo-electric effect which is characterized by the fact that at a certain frequency of the incident illumination there is emitted an abnormal number of electrons. The frequency at which this maximum emission occurs is characteristic of the substance illuminated and decreases with decrease in atomic weight. Similarly there exists a selective X-ray effect, so that at a certain definite voltage in the exciting tube, corresponding to rays of a definite hardness, there occurs an abnormal emission of electrons from the surface upon which the X-rays impinge, and here also the frequency of X-rays required to produce this abnormal emission is nearly proportional to the atomic weight of the excited substance.

---

[14] See also Phys. Rev. *4*, 73, (1914). Prof. Millikan's experimentally determined value of $h$ is $6.561 \times 10^{-27}$.

[15] Journal de Physique, *3*, 277 (1913).

[16] Compt. rend. 158, 32, 1914.

[17] Z. physikal. chem. *85*, 329, 1913.

[18] $e = 4.774 \times 10^{-10}$ electrostatic units; $h = 6.62 \times 10^{-27}$ erg. sec. and $c = 3 \times 10^{10}$ cm. To convert volts to electrostatic units it is necessary to divide by 300.

We find therefore a complete parallelism between the phenomena exhibited by X-rays and ultra-violet light.[19] But while the lowest wave-length so far measured in the ultra-violet is about $10^{-5}$ cm., the above measurements show that hard X-rays are electromagnetic waves with wave-lengths of the order of magnitude of $3\times10^{-9}$ cm. To produce X-rays with a wave-length of $3\times10^{-6}$ cm. would require potentials of about 40 volts, and recent work[20] has shown that even with voltages as low as 17 it is possible to obtain qualitative indication of the production of X-rays. At this voltage the wave lengths of X-rays emitted is 74.55 $\mu\ \mu$. It is interesting to note that the shortest wave-lengths so far detected in the ultra-violet portion of the spectrum is 90 $\mu\ \mu$, so that it would appear as if the gap between X-rays and ordinary visible light has been filled in.[21]

The fact that the emission of electrons by light and X-rays occurs instantaneously has led to the conclusion that the electrons possess a latent store of energy whose average value for each frequency is $\frac{h\nu}{2}$. Consequently the immediate effect of a beam of light or X-rays is to cause the emission of those electrons whose energy content is just below $h\nu$, while the remainder of the incident energy is distributed among the other electrons. It has already been stated in a previous section[22] that Planck has arrived at the same conclusion for the average energy of a linear oscillator, and this conclusion is quite in accord with a large number of recent observations on the behavior of substances at temperatures which are near the absolute zero.

There is still another point to be observed in this connection. While the application of the quantum theory to radiation and specific heats suggests emission and absorption of energy that is discontinuous with respect *to time*, the observations on emission of electrons by X-rays and ultra-violet light lead to the conclusion that the discontinuity exists here with respect to space. In other words, in order to account for the fact that the X-ray carries over undiminished the energy of the electron that produced it to another electron that is emitted by it, it is necessary to assume that the amount of energy represented by it keeps together as an entity or quantum throughout the different transformations. A corpuscular theory of X-rays such as originally suggested by Prof. Bragg accounts for this fact very well; but such a theory is obviously not in accord with the diffraction experiments of Laue and the analogies exhibited by ultra-violet light and X-rays. To reconcile these apparently conflicting facts, it is necessary to assume for X-rays some form of "spotted-wave" theory—but as yet no physicist has dared to propose such a theory.

# PRACTICAL EXPERIENCE IN THE OPERATION OF ELECTRICAL MACHINERY

## PART II (NOS. 6 TO 12 INC.)

By E. C. Parham

Construction Department, General Electric Company

### (6) ALTERNATOR PARALLELING KINK

Most operating station engineers are familiar with the fact that the proportional sharing of load between two alternators operating in parallel is a matter of the proportional supply of energy from their respective prime movers; and that the adjustments of load are effected by adjustments of speed and not by field rheostat adjustments, as in the case of direct current generators.

Two certain alternators, driven by a water-wheel shaft, though not required to operate continuously in parallel, were intended to alternate in 12-hour shifts. On trying to transfer the load from one to the other at the end of a shift, it was found to be impracticable, because the instant they were thrown together their individual breakers would open.

An inspector called in to diagnose the case attributed the trouble to unequal speeds of the generators. The driving pulleys on the water-wheel shaft proved to be of exactly the same size. One generator had an iron pulley and the other a wooden one, the latter one being about $\frac{1}{4}$ in. larger in diameter. The wooden pulley was removed and placed on a lathe and turned down until it was only a trifle larger than the measured difference called for. On again putting the machines into service and throwing them together they would run in parallel for a few seconds, but then the current would begin to climb and finally blow the breakers. The diameter of the wooden pulley was then gradually reduced by applying sandpaper; and the length of time that the machines would parallel without blowing the breakers gradually increased, as the diameters of the two pulleys became more nearly the same. In this manner satisfactory permanent parallel operation was finally obtained, which proved that the breaker blowing had been due to unequal speeds.

### (7) ARMATURE BANDS BREAKING

Armature bands may fail for any of several reasons, for example, (1) foreign object in the air gap, (2) defective banding, (3) armature grounded or otherwise short circuited and bandwire thereby burned, (4) low bearings permitting bands to rub the pole-pieces, and (5) excessive armature speeds. Whatever the cause, the usual result is the grinding of the broken or burned band between the armature and the pole-pieces in such a manner as to destroy all conclusive evidence as to the original cause of trouble. Of the causes named, only No. (5) will be considered here.

Bandwires are designed to stand reasonable over-speeds; but in special cases, as for instance, racing turbines or series motors running comparatively free, the stresses must be reduced otherwise than by increased bandwire strength.

In the instance which is of interest, the bridge of a coal unloading crane was operated by a series motor. The bridge runway was about 600 feet long. The motor armature had burned out several times and in each case a broken band seemed to be involved. An increase in the size of wire and in the number of bands did not seem to help matters appreciably. Finally the services of a competent inspector were engaged. One day he noted that the bridge ran much faster in one direction than in the other, but after measurement found the runway to be level. To check the possibility of a wrongly set or shifted brush-holder, or of there being a field so grounded as to cut out more turns in one direction than in the other, he jacked up the bridge and took motor speeds in both directions; they were approximately the same. He then became convinced that the high winds, which came down the valley directly in line with the runway, were responsible. This proved to be the case. A brake on the bridge stopped all trouble.

### (8) AN EFFECT OF LOW FREQUENCY

A motor designed to operate at a certain frequency will take a certain amount of current when rated voltage is applied to it under a given load condition. With the same voltage and the same load but with higher frequency, the current will be less than at normal frequency; and with lower frequency, the current will be greater. The reason is that in the first case the duration of each period is less and the current has therefore less time in which to reach its maximum value in either direction and, in the second case, each current impulse in either direction has more time in which to increase against the restraint of self induction. In other words, the impedance of a motor is greater for high frequency than for low.

Once an inspector was asked to determine the cause for overheating of a three-phase induction motor which operated a very busy transfer table. The motor received its energy from a hydro-electric station, which also supplied current to an electric railway; the heavy loads of the railway and of the table occurring at about the same time of day. As the water supply was not liberal, the heavier loads would bring down the speed of the alternator, decreasing the supply frequency to the extent of 20 to 25 per cent. To aggravate matters, the voltage was maintained almost constant during the periods of low frequency.

The net result was an increase in the motor current, hence excessive heating. The increase of current in the case described was due to the combination of three reasons: (1) low frequency; (2) voltage higher than should have been applied at the reduced frequency; (3) impaired power-factor, owing to the lowering of the frequency simultaneously with the raising of the voltage. An indirect effect of the low power-factor was to increase the current corresponding to a given effort; this condition prompting the table operator to abuse the motor by advancing its controller more rapidly than would ordinarily have been required.

### (9) ROTOR RESISTOR HEATING

The speed and torque of a slip-ring induction motor are controlled by means of an adjustable external resistance connected to the rotor and to an external controller. These regulating devices have no electrical connection with the stator.

We know that open-circuits or short-circuits in the starting resistance of a direct current motor will prevent smooth acceleration and will cause certain resistance sections to overheat; because the resistance will not then be cut out in smoothly graduated steps and irregularity in one part of a rheostat is likely to overload another part. Similar causes produce similar effects in the case of irregularities in the connections of the resistor of an induction motor.

The resistor of a certain three-phase induction motor, operating a turn-table, was continually causing trouble because of broken resistance grids. The cause of the grids becoming damaged was first attributed to the blow which the table sometimes received when a heavy locomotive passed onto it. The fact, however, that similarly equipped turn-tables in other parts of the system gave no such trouble rendered that assumption very questionable. Closer investigation disclosed the fact that all of the trouble was due to improper contact between the controller fingers of the resistor and their corresponding cylinder segments. Some of the resistor sections that should have been cut out on the more advanced positions of the controller were still remaining in circuit, because their respective fingers failed to make the short-circuit contact. As a result these sections heated, softened, and broke; furthermore, the opening of one section by breakage threw additional load on the other sections which in time also heated and gave way. After cleaning the controller, replacing the fingers and the segments where required, and adjusting the contacts, normal operation was secured and maintained.

### (10) MOTOR STARTING BLEW CIRCUIT-BREAKER

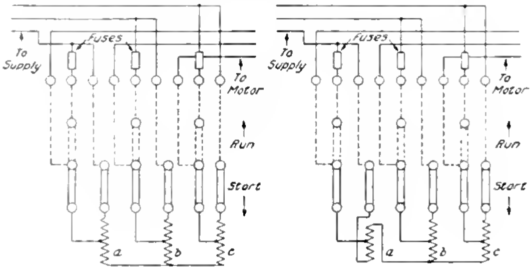
Unless a special resistance is used to reduce the current at the time of moving a controller to the "off" position (this in order to decrease flashing with the attendant blistering of fingers and cylinder tips), the value of the starting resistance sometimes used with direct-current motors is made such as to promptly start the motor on the first controller notch with the maximum load to be started under regular working conditions. This often means that the total starting coil resistance will permit of an initial current flow greatly exceeding the rated full-load current of the motor. This initial current will maintain only for a moment, since at the instant the armature begins to revolve, its counter e.m.f. reduces the current very rapidly.

Considerable annoyance was experienced by the peculiar action of a motor, the circuit-breaker of which would operate as soon as the controller was placed upon the first notch. Tests and inspection proved all internal and external connections to be according to the manufacturer's instructions, and all parts of the circuit to be free from grounds and short-circuits. The motor had normal field strength, the commutating poles were properly connected, and there was no flashing at the brushes when voltage was applied. The current rating of the motor was 13 amperes at 500 volts, and the maximum for which the circuit-breaker could be set was 30 amperes. Upon tying in the circuit-breaker, relying on two 30-ampere fuses for protection, and closing the switch, the motor started and came up to speed in a normal manner. The insertion of an ammeter showed a starting current of about 40 amperes.

The cause of the trouble was that the amount of the current admitted by the starting resistance exceeded that for which the breaker could be set.

### (11) REVERSED COMPENSATOR COIL

Sometimes a standard piece of apparatus will contain a defect even after being most carefully designed, manufactured, tested, and installed; and will then fail under perfectly normal conditions. On the other hand, it is almost unbelievable how such defective apparatus oftentimes will continue to operate with apparent satisfaction.



Figs. 1 and 2

In one instance, a railway motor armature was connected three commutator bars from the correct ones; but it was not discovered until a month later when the car was run into the repair shop because the armature had failed on the opposite end. In another case, one motor of a four-motor car ran for several weeks with a field coil reversed, thereby making three poles of like polarity.

Of interest here, is the case of a starting compensator that was in use two years and then failed. It was repaired and ran for more than a year before failing again. On the occasion of the second repair, some one noticed that the coils were heating more than were the coils of similar compensators doing similar work. Investigation disclosed the fact that one of the coils was reversed, as indicated in Fig. 2 (Fig. 1 indicates normal connections of such a compensator). The original compensator probably had a reversed coil and the error had retained through all repairs. The starting duty of the compensator was comparatively light, otherwise failure would have occurred much sooner, for insertion of ammeters in the starting leads showed greatly unbalanced currents.

### (12) GRADUATING RESISTANCE STEPS

Commutating poles greatly increased the possibilities of motor speed regulation by means of a controller-operated variable resistance in the motor field circuit: the commutating poles oppose the tendency of the armature current to distort the commutating field when the field due to the field magnets is weakened by the introduction of resistance in the field circuit. Variable-speed motor equipments include two rheostats: One, the starting rheostat, is connected in series with the armature and is cut out in graduated steps as the controller is advanced; the other, the field control rheostat, is normally short-circuited but is placed in series with the field step by step. Ordinarily, no part of the field control resistance is connected in series with the field until all of the starting resistance has been removed from the armature circuit, because when a motor is accelerating it requires all of the field available in order to limit the amount of the starting current.

In a particular case of commutator roughening there was no bad cutting, but it was impossible to get the surface to take on a polish. It was soon noted that operation on the starting notches was normal and that on all running positions continuous operation was satisfactory, but that, in passing from one field-control position to the next, the brushes started to spark and spit; this was what was preventing a polished surface. An examination of the field-control rheostat disclosed excessively heated parts, and suggested that perhaps the wrong rheostat was being used. This was confirmed by a checking of the armature speeds, which were found to be too high. On substituting the proper controller with its attached rheostat, the commutator soon took the desired polish.

# SOME RECENT DEVELOPMENTS IN LEVER AND DISCONNECTING SWITCHES

By H. G. French

Switchboard Engineering Department, General Electric Company

Although it is usually to the advantage of all concerned to employ standard or existing types of apparatus in electrical installations, it often happens that some of the conditions of operation are such that this apparatus will not properly fill the requirements. It is then necessary to develop special devices for the purpose, unless those of standard form can be adapted, modified or combined with others to accomplish the desired result. The manner in which this has been done in several cases is illustrated in this article. Special means of interlocking to safeguard service, protect machinery or life, prevent a wrong sequence of operation, or to enable the attendant to operate lever switches of large size with comparative ease, are described in detail.—Editor.

Lever switches are ordinarily the simplest of electrical devices, and of no particular interest from a mechanical point of view; but when it becomes necessary to accomplish more or less intricate circuit connections by such means and provide safeguards against improper operation, some of the developments in this line of apparatus are of more than passing interest. Such contrivances are generally known as mechanical or electrical interlocks, and there are three principal points to be observed in their design; viz., simplicity of construction, so as to avoid undue cost; strength and durability; and convenience of manipulation. In some other cases the unusual features are needed to ensure ease of operation, or semi-automatic action.

The automatic lever switch, Fig. 1, is virtually an interlock between two sources of supply for lights in a station or other location where failure of the normal source must not cause the building to be thrown into darkness. This, of course, is on the assumption that another source of supply is available, such as a storage battery. In main or substations an auxiliary source is generally available, and much inconvenience and sometimes delay may be avoided by this simple device, which ensures a continuous supply for the lights. There is also a field for this switch in the lighting systems of large buildings, such as hospitals, office buildings and apartment houses, in which the installation of a storage battery is not likely to be an unjustified expense.

The operation of this switch is as follows: When failure of normal voltage occurs, the low voltage release drops its armature, which trips the latch from the crossbar above it, and the springs on the hinges of the switch throw it quickly to the upper contacts, which are connected to a storage battery or other emergency source. At the same time an auxiliary switch at the top is thrown into contact, causing a bell or other indicator to operate to attract the station attendant's notice. When the normal source is again in operation, the switch is thrown down by hand and latched: Fig. 1. shows a switch for 100 amperes capacity, 250 volts. Similar switches have been made for 200 and 300 amperes, and they can be made triple-pole as well as double-pole.

Fig. 1. An Interlocking Lever Switch for Automatically Connecting a Reserve Source of Current to the Mains on failure of the Normal Supply

Large direct current motors in industrial service are frequently located at isolated points, and where frequent starting or stopping is not necessary the problem arises of providing a starting switch and circuit breaker arrangement that can be operated with safety by unskilled attendants, and without the possibility of damage to the motor. A large motor panel designed to meet these conditions is shown in Fig. 2. The interlocked starting switch and circuit breaker are so arranged as to make an improper sequence of operations impossible when starting the motor. A mechanical interlock between one pole of the circuit breaker and the lower, or off position of the starting switch, makes it necessary to have the latter in its full "off" position before the left-hand pole of the circuit breaker can be closed. An auxiliary switch, also opened by this movement of the starting switch, allows the coil of the low voltage release to be energized. The starting of the motor can then begin with the step by step operation of the switch, during which the operator must keep depressed a button in the end of the handle, thereby holding open the auxiliary switch until the starting switch has been brought to the full running position. The auxiliary switch is then automatically held open, and the operator may remove his hand. However, should he attempt to leave the starting switch on any intermediate contact, the removal of his hand allows the auxiliary switch to short-circuit the low voltage release coil, tripping the breaker. This in turn cannot be closed again without throwing the starting switch to the full off position again. The motor field switch also controls an auxiliary switch connected in parallel with the low voltage coil, so that the motor field circuit must be closed before the circuit breaker, and if the field switch is opened while the motor is running the circuit breaker is tripped.

The auxiliary switch actuated by the button in the end of the starting switch handle has been specially designed for this service, being entirely enclosed so that dust cannot interfere with the contacts, which also have a rubbing motion when opening or closing. The most reliable auxiliary switch is necessary here, and this design fully meets the requirements.

Another valuable feature of the starting switch used is its definite step by step operation. It is impossible to carry the blade past more than one starting clip (representing a rheostat connection) at one movement of the lever. Moreover, the blade always stops fully in contact with the starting clip. These clips are strongly reinforced so that they are very substantial and reliable and will not become sprung out of good contact. The lever controlling the movement of the blade is in practically an upright position during all of the starting operation, and has a positive stop, allowing exactly the same movement of the blade at each step. In opening the switch a single throw of 180 degrees carries the blade and lever to the full off position.

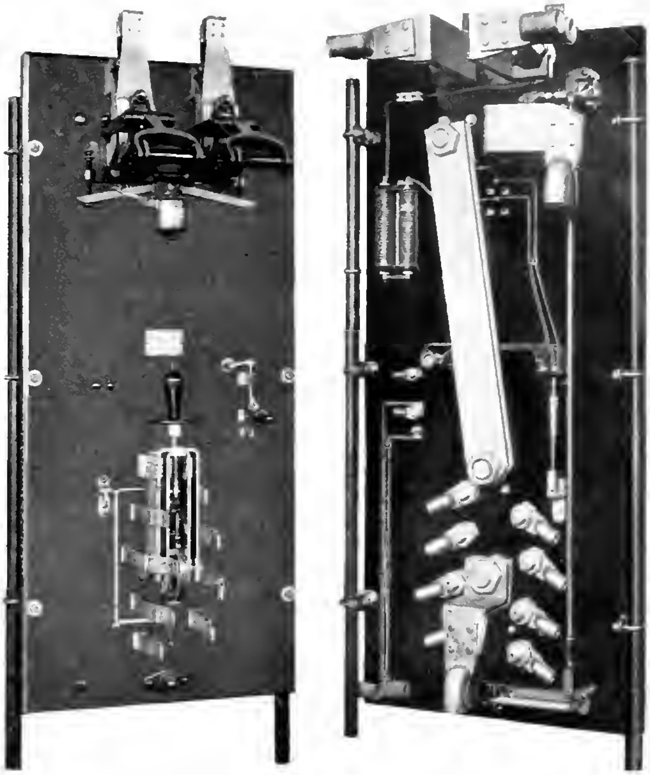


Fig. 2. Motor Panel provided with Interlocks to Prevent Improper Sequence in Operation

From the foregoing it is seen that any mistake in manipulation of this starting panel merely causes the circuit breaker to open, thus protecting the motor. On the other hand, complication is avoided, and it is easy for anyone to operate this apparatus in the proper sequence. Starting panels of this description are in use with large motors for pumps, etc., in isolated locations, and unskilled attendants operate them with entire safety. Panels of 800 to 3000 amperes capacity are available.

A set of six single-pole, single-throw, 15,000-volt disconnecting switches, in two interlocked groups, is shown in Figs. 3 and 4. The poles of each group are located alternately and the hinge blocks connected so as to form three single-pole, double-throw switches, occupying a minimum of vertical space. This set of switches was designed for use in a high tension bus compartment where vertical dimensions were not sufficient for the ordinary triple-pole double-throw set. Were it possible to use such a double-throw set, it would be necessary to join the blades by crossbars, which are undesirable on high tension disconnecting switches. The use of single-throw switches also facilitated their connection to the circuits. There are two three-phases busses, connection to only one of which can be made at a time. The blades are linked near the hinges to insulating rods passing through the central holes of the lower insulators and acting upon a single interlock bar behind the switch panel. A spring with a positive stop for its travel automatically returns the bar to mid-position when the switches are opened, so that the operator does not have to shift the interlock in order to close any set of switches at any time. The interlock mechanism controls a set of auxiliary contacts for the indicating lamp circuits, by which visual indication is provided at the desired place as to the position of the disconnecting switches, thereby showing which bus is connected. The mechanism is also arranged so that it can be fastened with a padlock to prevent the switches of either group being closed, and it may be locked in neutral position so that no unauthorized person can close any switch.

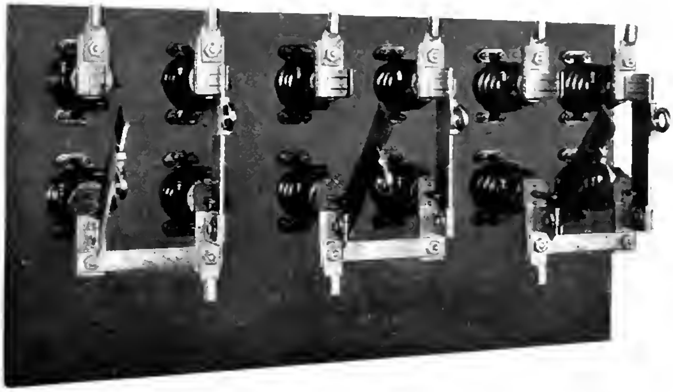

Fig. 3. Six Single-Pole, Single-Throw Disconnecting Switches Connected to Form Three Single-Pole, Double-Throw Switches

The latter feature may be invaluable at times in safeguarding the lives of persons engaged in repair or inspection of other apparatus in series with these switches, and forms a distinct advance in the application of the safety-first idea to high tension station apparatus.

An interlock of extremely rugged construction is shown in Fig. 5. This was designed for the battleship Oklahoma, and its use obviated the employment of various additional switches of large size and a complicated arrangement of connections, thereby avoiding the use of an additional panel where space is at a premium. The switches shown are of 250 volts, 3500 amperes capacity, and are interlocked in two pairs, each pair being entirely independent of the other mechanically. The lower double-throw switch is interlocked, with respect to its right-hand contact, with the single-throw switch in the upper right-hand corner; and the upper double-throw switch is interlocked, with respect to its left-hand contact, with the single-throw switch in the upper left-hand corner. All switches can be closed in the positions shown in the front view, but only one switch of a pair can be closed when in

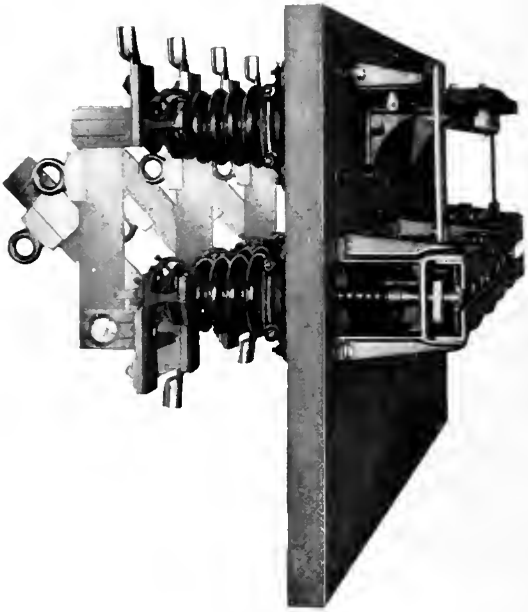

Fig. 4. Side View of Switch Shown in Fig. 3

the positions shown in the side view of the set. The interlocking elements consist of very rigid U-shaped castings, each having two substantial stops extending outward on one side to prevent, when in the proper position, the closing of a switch into a contact beyond. These castings are mounted on heavy bronze rods supported close to the face of the panel and connected to shifting levers, so that when both switches of a pair are open a slight movement of one of the small handles shifts the interlock as desired. Parts of opposite polarity in the mechanism are connected by insulating shafts.

The friction of the contact clips against the blades requires considerable effort on the part of the operator when opening or closing lever switches of high ampere capacity, and these are, therefore, generally limited to single-pole construction. The largest of these are regularly made of the split lever construction, the blades being arranged in two groups, each of which is joined to a handle so that one-half of the switch can be thrown at a time.

Triple-pole lever switches of large capacity would be extremely difficult to operate, if of the usual construction, and especially inconvenient when used for starting large rotary converters from the a-c. side, where it is desirable to throw the larger switch of the pair from two-thirds to full tap without loss of time during the operation. Fig. 6 shows an a-c. six-phase rotary starting lever switch combination, the larger switch being of 4000 amperes capacity. It is of the split lever construction and has two crossbars with separate handles, one-half of the blade of each pole being fastened to one crossbar and the remainder to the other. As the upper contacts are connected to the transformer two-thirds tap for only a short time during starting, they are arranged to make contact only with that half of the switch which must be thrown first to the lower or running side. Half of the blades readily carry the load until the operator can throw over the second section. Large triple-pole switches such as this are easily operated, whereas the alternative would be a considerably more expensive set of large solenoid-operated circuit breakers. Rotary starting switches of this construction of 5000 amperes capacity are in use and are operated without difficulty.

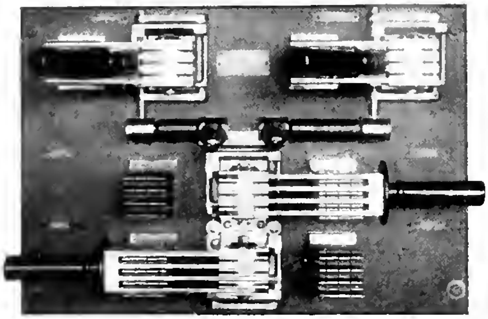

Fig. 5. Interlocked Switch of Special Construction

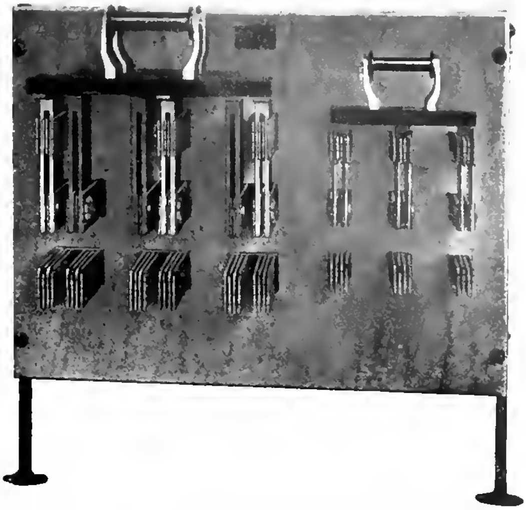

Fig. 6. 4000-Ampere Switch for Starting Synchronous Converter from A-C. Side

In another case, that of a single-pole lever switch for 12,000 amperes, the split lever construction was not considered desirable for the purpose for which the switch was intended, and it was necessary to provide for ease of operation in some other way. This was accomplished by providing a pair of heavy clamps, as shown in Fig. 7, supported from the blade so that the contact clips could be clamped tightly to the blade sections. Spacing pieces between adjoining pairs of clips were provided. The contact clips are not given any "set," or adjustment for pressure, as in the case of the lever switch of standard design, but are left parallel and cause practically no frictional resistance to the movement of the blades when the switch is opened or closed. As this switch is used in a place where it need seldom be operated, the adjustment of the clamps by means of a wrench presents no serious inconvenience.

Pole changing lever switch sets for three-speed induction motors of voltages up to 550 volts consist of two double-throw switches, each usually of four poles mounted side by side, thus resembling a starting switch combination for six-phase rotary converters. They are, however, used only for changing the motor connections, the switching on and off of the current being done by means of the compensator switch. If it were possible for the operator to close the pole changing switches into certain sets of contacts it would allow an induced current to flow in one of the motor windings, and to avoid this the switches must be interlocked in certain positions. In order to avoid a wrong sequence of operations, the adjoining ends of the cross-bars are beveled and overlapped, constituting the simplest conceivable form of interlock, which is at the same time entirely adequate. These pole changing switch sets have been developed in such a way that for motors of different internal connections the order of operation is the same in changing from low speed to medium, and from medium to high speed. The switches are sometimes mounted on a slate base supported on the side of the motor stator, just above the motor connection board, so that the motor and pole changing switch set are a unit. This is of considerable advantage where the available space for switching apparatus is limited.

Fig. 7. 12,000-Ampere Lever Switch of Special Construction

Fig. 8. Single-Pole Pivot Switch with Guiding Clips

A single-pole pivot lever switch is shown in Fig. 8, the feature of interest being the slotted guide for the blade which guards the contact clips against undue lateral strain when the blade is thrown in. The guide brings the

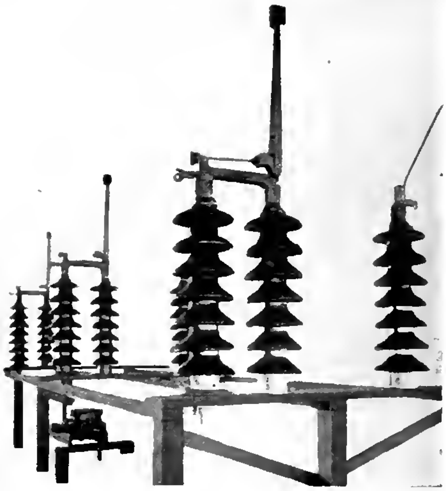

Fig. 9. Motor Operated Mechanism Attached to 110,000-Volt Disconnecting Switch

blade properly into line before it can begin to enter any contact. Such switches are used for changing transformer tap connections to a circuit.

Occasionally, when developing a switching arrangement for unusual conditions, there appears to be a need for some such interlocking device or special construction as has been described; but in a considerable number of such cases it is found to be possible to avoid its use by means of a different arrangement or interrelation of standard apparatus. It may be of interest to mention that sometimes as much thought is required to accomplish this as to develop a complicated interlock to suit the condition.

# THE APPLICATION OF DIRECT-CURRENT MOTORS TO VARIABLE SPEED DRIVE

By R. S. Sage

Power and Mining Engineering Department, General Electric Company

The forepart of this article is devoted to a brief discussion of the elementary principles involved in producing variation of speed in d-c. motors, and shows why the commutating pole is a requisite in the design of motors to be used for wide speed ranges by the field control method. After a short statement as to the general classes of power requirements some space is given to a more detailed description of the three control systems and a discussion of their adaptability to the three general classes of power requirements; the third method (field control) receiving special consideration. The concluding paragraphs deal with the subject of compound windings for motors of this class, and close with the statement that the application of the commutating pole adjustable speed motor should prove of advantage in the majority of drives for variable speed apparatus.—Editor.

With the general appreciation of the advantages of electrical drive in the factory, mill and shop, there has come a continued demand for motor drives to suit the numerous varieties of service conditions that obtain in these fields. Nearly every type of machine has operating characteristics, distinctly its own, and a careful study of these is desirable and often essential before the selection of a drive is made.

Electrical manufacturers have developed standard lines of motors covering a wide range of capacities and speeds, but notwithstanding, on account of the development of new types of machinery and the almost unlimited capacity and speed combinations which are possible, it is often necessary to meet the demand with special designs of motor drives.

The advantages to be gained in the driving of many types of apparatus at variable speeds, without the usual inefficient and more or less unsatisfactory mechanical devices for this purpose, has opened up an extensive field for the electric drive, and at the same time has furnished an incentive for developing the direct current adjustable speed motor to its present degree of perfection.

It is the purpose of this article to outline some of the considerations incident to the application of electric motor drive to variable speed machinery.

As for the induction type of alternating current motor, it does not find extensive application in this field, which often requires continuous service at wide ranges in speed, for up to the present time no method has been devised whereby these operating conditions can be met with a degree of success comparable to that of the best direct current system. Its use, however, on one of the various systems now employed may be advisable under certain circumstances; for instance, if d-c. power is not available and the demand for adjustable speed drive does not warrant the installation of a d-c. generating set.

The subject matter following will therefore apply to the consideration of the direct or continuous current motor only.

The term "adjustable speed" as applied to motors is understood to mean variation of the operating speed, which is under control and capable of adjustment as by some means external to the motor. This is in distinction from variations in speed due to the inherent characteristics of the machine itself, such as the change of speed due to load change in series motors. Under adjustable speed motors are classed shunt motors and compound motors with light series fields.

The advantages reserved to the d-c. motor for many industrial motor applications may be said to be due to the advent of the commutating pole into the design of d-c. apparatus. Indeed, the benefits gained by the use of commutation poles are so many and positive that it is now common practice to supply them with practically all direct current machines, including motors even for constant speed service. Increased overload capacity, better commutating ability under all loads with consequent increased commutator and brush life, reversible operation with one brush setting, decreased bulk per horse-power and speed adjustment possibilities, all declare for real advantages by the use of commutating poles in motors.

### Methods of Motor Speed Control

The fundamental equation of the d-c. motor may be written $V_L - V_R = V_B = K \times \phi \times N$, (1)

where $V_L$ is the line voltage, $V_R$ the voltage drop due to internal and external resistance of the armature circuit, $V_B =$ the back or counter e.m.f., $K$, a constant for a given machine; $\phi$, the armature flux and $N$ the motor speed. Assuming $K$ constant, the only way of changing the speed $N$ is to change the values either of $\phi$, the flux through the armature, or of $V_B$. To change the value $V_B$ requires the variation of the value of $V_R$, if $V_L$ is constant, or of the value of $V_L$, if $V_R$ is constant.

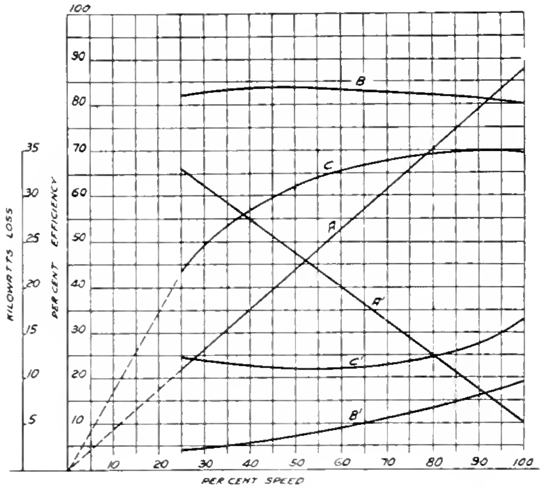

Fig. 1. Comparison of efficiencies and losses of a 50-h.p. motor for 4 to 1 speed range on three systems of control. Curves *A*, *B*, and *C* and $A^1$, $B^1$, and $C^1$, represent efficiencies and losses respectively for armature resistance, field weakening, and variable voltage systems

The manipulation of any one of these three elements therefore constitutes the three general methods of obtaining speed variation in d-c. motors. As a matter of fact, the quantity $K$ may also be variable and produce speed changes, as for example, with a motor having a double armature winding and two commutators. However, this method, as well as a few others, are eliminated from discussion as being comparatively uncommon and limited in their application.

These three general methods as put into practice consist of the following:

(a) *Variation of* $V_R$, by means of a variable external resistance in the armature circuit, the field being excited by a constant line voltage producing constant value of flux through the armature. The internal voltage drop at full load current being only about 5 per cent of the line voltage, the speed is, for a given armature current, practically inversely proportional to the external resistance. Since the entire armature current passes through the external resistance, the energy absorbed by the system is proportioned between the motor and the resistance in the ratio of the voltage across them so that the efficiency for a given current varies nearly directly as the speed, as shown in Fig. 1 (A).

(b) *Variation of* $V_L$, or supply voltage. In this method $V_R$ becomes simply the internal voltage drop and is constant for a given current; also as the field is excited at a constant value from an outside source, the speed varies directly as the line voltage. The usual method is to vary the voltage of a motor-driven generator by means of an adjustable rheostat in its separately excited field, one such generating set being required for each motor controlled. The only losses incurred (external to the motor itself) in thus reducing the speed of the motor are those of the generating set and generator field rheostat. The efficiency of this method is in general considerably higher than for the previous system, especially at reduced speeds. An adaptation of this system, known as the multiple voltage system, is also used, in which two or more supply circuits are provided at different constant potentials, with switching arrangements for throwing the motor from one to the other. Intermediate speeds may be obtained either by means of resistance in the armature circuit or by field weakening, which method will next be described. In the multiple voltage system there is necessary either several individual generators for each circuit, a single generator with balancer set, or a three-wire generator or rotary converter with auto-transformer.

(c) *Variation of $\phi$*, the flux passing through the armature, gives the third general method of speed adjustment. This may be accomplished in a somewhat indirect way by changing the reluctance of the magnetic path, as by varying the air gap, removing iron from the magnetic circuit, or by decreasing its effective area. The simplest and most practical method is, however, to change the value of the field current by inserting an adjustable resistance into its circuit, a single constant voltage circuit being applied to the armature. From equation (1) it follows that the speed is inversely proportional to the flux, $V_R$ being the internal voltage drop only. The currents handled and losses involved in this system are comparatively small, resulting in high efficiency and ease of manipulation.

The difficulty which until recent years rendered this system impractical for any considerable speed range was that due to the decreased commutating ability at weak field strengths. A brief review of the chief causes of this condition may be of advantage at this point.

Consider the ordinary non-commutating pole motor: The distribution of the magnetic flux around the periphery of the armature may be represented by plotting a curve showing volts as ordinates and commutator bars as abscissæ. Such a curve is shown in Fig. 2. Curve $F$ represents the shape at no load, which is due to the field alone, and $A$ the flux due to the magnetization of the armature under load, this being displaced 90 degrees from the field flux. The resultant flux distribution at full load would then be as shown by curve $r$, in which it is seen that the neutral position is shifted back to the point "$n$," at which point the brushes must be placed for good commutation; i.e., at this point the voltage is zero. Now, if the main field strength is weakened, it will readily be seen that the distortional effect of the armature strength shown in the curve $r$ will become very much aggravated and the neutral position still further shifted from the geometrical neutral. Furthermore, the field strength necessary for the reversal of the short circuit current during commutation is greatly weakened. The result is that commutation is accomplished with a great deal of sparking and operation rendered impractical. This shifting of the neutral, even in motors with slight field weakening, makes the ordinary motor unfit for reversing duty.

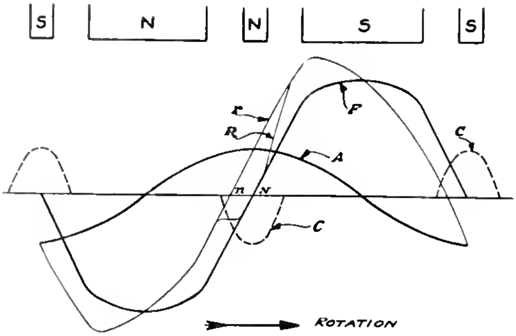

Fig. 2. Flux Distribution

$F$—Field form of shunt field alone—no load.
$A$—Field form produced by armature magnetization—full load.
$r$—Resultant of $F$ and $A$—full load.
$C$—Commutating field—at full load.
$R$—Resultant of $F$, $A$ and $C$—full load.
$N$—Geometrical neutral point.
$n$—Neutral point displaced by field of $A$.

In practice, where commutating poles are not used, it is necessary that the field strength have about double the armature strength for good commutation. For this reason it is found that the limit of speed increase by field weakening for such motors is ordinarily 15 to 30 per cent.

The use of the commutating pole, however, has overcome these difficulties to a large extent and the large number of this type of motor now in successful operation, through speed range ratios of three to one and four to one, and even higher, demonstrate its practicability for this system of speed control.

From the foregoing it is seen that the function of the commutating pole, or interpole, is to provide a flux which will neutralize the neutral shifting effect of the armature cross magnetization, and also to furnish sufficient commutating flux for the reversal of the current in the short circuited coils under the brushes.

The poles are placed midway between the main pole pieces and are magnetized by a winding which is in series with the armature, thereby producing a flux which is proportional to the distorting flux of the armature.

The curve $C$ represents the field produced by the interpole and $R$ the resultant field. Its effect is seen in keeping the neutral point stationary, under which condition a motor of otherwise good design is capable of having its speed increased by field weakening to a point where the armature strength exceeds the field strength by a large percentage.

### Power Requirements

The power requirements of variable speed apparatus can be divided into three general classes as follows:

1st: Loads requiring constant power; i.e., torque inversely proportional to the speed.

2nd: Loads requiring constant torque; i.e., power directly proportional to the speed.

3rd: Loads with power increasing faster than the speed; i.e., torque increasing directly in some proportion to the speed.

These statements follow from the fact that rotative power is the product of the torque and speed.

The service may be continuous or may be intermittent for any of these load conditions.

The torque developed by a motor is directly proportional to the armature current and the field flux, and for a given machine the torque in foot pounds is given by

$$T = 0.00196 \times Ca \times q \qquad (2)$$

where $Ca$ is the armature current in amperes, and $q$ is the volts per r.p.m. in terms of terminal voltage. (The torque available at the motor shaft is this value multiplied by the efficiency.) By referring to equation (1) it is seen that the quantity $q$ is proportional to the flux $\phi$, being the product of the design constant $K$ and flux $\phi$. From the equation (2) the current and speed relations are readily observed for any of the power conditions mentioned above and with any of the different systems of control.

### Most Suitable Method of Control

While the determination of the system which can be most advantageously employed in obtaining speed adjustment in d-c. motors is dependent upon a number of factors, and a study of each individual application is advisable before a selection is made, the nature of the operating conditions is the first great consideration and in many cases eliminates at least one system from further consideration. For example, the speed range may be so large that the field control method alone is impractical; or the adjustment required may be so fine and at the same time the range so great as to eleminate all but the generator field control method. Again the speed regulation at any particular setting may be of great import, thus prohibiting the use of armature resistance control.

Among other factors which have an important bearing on the system used are operating efficiency, cost of energy, first cost of apparatus, ease of control, reliability, etc.

### Speed Control by Armature Resistance

Speed control by the armature resistance method may be said to be permissible under quite a number of conditions, but as a means of obtaining even a moderate range in speed with either constant power or constant torque for continuous service, it is entirely inapplicable from a standpoint of economical operation. Aside from its low efficiency, bulky and expensive rheostats are required, which obviously constitute disadvantages.

Another serious objection to its use is the series characteristics which obtain at varying torques. At low speeds, changes in torque (i.e., armature current) are accompanied by nearly proportional inverse changes in speed. Hence it is not adaptable to those drives which are subject to load fluctuations and which require nearly constant speed irrespective of load.

Applications which may admit of its use are those which require greatly reduced power at the low speeds; viz.: Service of the third class mentioned above, or constant torque intermittent service. Thus it is used for driving fans in which the power required varies nearly as the cube of the speed. Or again, its use is often satisfactory in combination with field control to obtain extreme low speeds, especially if the output is low at this speed or if for short running periods. For example, it is used with printing press motors (usually in combination with field control) to secure low speed running for short periods.

Were it not for the indirect advantages secured by commutating poles, their use in motors on the simple armature resistance system, to obtain perfect commutation, would perhaps not be necessary, since those conditions which render good commutation difficult are particularly lacking in this system.

The chief concern from a design standpoint is for the radiation of the losses at the low speed without undue temperature rise. The ventilation, being appreciably restricted at low speeds, the heat radiating ability is considerably poorer, so that for a given loss the temperature rise of the motor, both armature and field, is greater the lower the speed. Since in equation (2) the quantity $q$ is constant for this system of control, it follows that the torque is directly proportional to the armature current; therefore for constant torque service the current taken by the motor is constant at all speeds and the $I^2R$ losses constant. (Actually the current must increase at low speeds on account of the lower efficiency.) The capacity of the motor is therefore determined by the power output at the maximum speed with margin sufficient to enable the motor to run cool under the low speed conditions.

### Adjustable Supply Voltage

As previously stated, this system provides a very flexible and rather efficient method of speed control, and. moreover it is not subject to the objection in the foregoing system regarding instability of speed on fluctuating torques, since the motor is directly across the supply circuit and the speed change under various loads is that due to the inherent regulation only. Curve *C*, Fig. 1, shows the efficiency of a 50-h.p. constant torque motor on this system. Its use, however, is limited on account of the cost of auxiliary generating apparatus. The generating set usually consists of a motor-driven generator which operates the working motor directly off its terminals; or the generator may be connected in series with the motor and the line circuit and deliver variable voltage to the motor by a "boost and buck" action. The multiple voltage system also requires a considerable outlay in generating machinery and also in a suitable distributing system requiring the use of three or more wires. The chief disadvantage is therefore that of high cost.

This system is applicable particularly to constant torque service or that of the third class above, and provides a very efficient means of starting heavy loads. It is used for motors driving the rolls of paper calenders, cold rolls in steel mills, and also for mine hoists, etc.

The remarks made above regarding the capacity and commutation conditions for motors with armature resistance control apply also to this system of control.

### Variation of Field Current

This system affords a simple and efficient means of speed adjustment in motors on a single constant voltage circuit without the use of auxiliary apparatus other than a field rheostat. By reason of its simplicity of operation, comparatively low first cost and high efficiency, it finds more extensive application than either of the foregoing systems, for industrial service.

The efficiency of this type of adjustable speed motor falls off comparatively little at high speeds, the tendency being for the decreased field losses to offset the increased friction and windage loss. Fig. 1 (*B*) shows this characteristic for a 50-h.p., 4 to 1 speed motor for constant torque. For constant rated power output the curve would be little changed, being slightly higher at the 50 per cent speed point. At low speeds the efficiency is apt to be high at light loads and at high speeds high at overloads.

The change in speed from no load to full load of shunt wound adjustable speed motors is but a small percentage of the full load speed, usually not exceeding 5 or 6 per cent, and the regulation tends to be lower at weakened field, due to the weakening effect of the commutating field on the main field. Thus the undesirable series characteristics encountered with armature resistance control do not obtain.

### Limitations (Field Control)

A reference to equation (2) will show that in this system the torque is inversely proportional to the speed and that the output is constant throughout the speed range. It is therefore primarily a constant output system. However, at the high speeds, on account of the increased radiating ability, it is possible to increase the armature current and thereby the torque and output. The amount the current can be increased depends upon the speed range, and for speed ranges approximating 3 to 1, it is ordinarily limited by commutation rather than heating.

Motors obtaining increased speed by field weakening are being built to successfully operate through ranges of 4 to 1, and in small capacities even 5 or 6 to 1, and the limitation is, in a great many cases, a mechanical consideration. Thus it is impractical to run commutators at much above 5500 feet per minute peripheral speed because of the difficulty experienced in obtaining perfect brush contact at these speeds. Again, in the larger sizes the commutator construction necessary to withstand the high strains is costly, involving as it does the use of shrink rings, possibly more expensive brush rigging, and in some cases forcing the design out of the bearing bracket type into the pedestal bearing class, which again means increased cost.

These difficulties especially attend motors designed for voltages of 230 volts and less. Adjustable speed motors for field control to operate on voltages above 230 volts, e.g., 500 to 600 volts, are subject to closer limitations in capacity and speed range than on the lower voltages, so that a finer electrical design is often necessary with a resulting higher cost. It is therefore advisable, if possible, to operate on the lower voltages, particularly on wide speed ranges.

If the field weakening system is applied where constant torque only is required, then generally speaking, there will be available at low speeds a capacity in excess of that required. This, of course, means higher first cost of motor, since the size of the motor is determined by the maximum output required and the minimum speed at which it is necessary to run.

Fig. 3. Standard Type of Planer Motor. Rated 35 h.p., 250/1000 r.p.m., 230 volts. The planer is one of the more recent to which the adjustable speed motor has found application

This fact is sometimes overlooked, and when a motor is wanted, for example to deliver 25 h.p. at 400 r.p.m. and 50 h.p. at 800 r.p.m., it is often not appreciated that this machine will be very close to the size of a 50 h.p. at 400 r.p.m.

If it is known, however, that the output necessary at the low speed is less than at high, i.e., constant torque or class 3 service, it is often possible, especially in the case of wide speed ranges, to apply a motor in a smaller frame than would be required for constant horse-power throughout the range. This is also often the case even in constant horsepower service when it may be necessary to operate at full output at low speeds for short periods only.

It is seen, therefore, that although theoretically an adjustable speed motor for constant torque service by the field weakening method would be larger than one for the same service by the armature rheostatic method by the ratio of the speed ranges, practically it may be made smaller than this.

### Applications (Field Control)

In the field of application requiring constant output to which this system is adapted, is included all machine tool drives, comprising lathes, boring mills, shapers, drill presses, cold saws, milling machines, etc. The driving of rubber calenders and cold rolls in steel mills are also notable examples of this application.

Examples of those applications which require constant torque and for which the field control method is very often used are centrifugal pumps, plunger pumps, positive blowers, air compressors, conveyers of various sorts, hoists, rotary printing presses, etc.

The recent application of the d-c. motor to reversing planer drive affords a good example of the capability of the commutating pole motor to successfully operate under rapidly varying power and speed conditions. These motors ordinarily have a speed range of 250 to 1000 r.p.m., with their rated output based on a two-hour run at 500 r.p.m. On the cutting stroke the speed is from 250 to 500 and at the end of the cut the speed is brought to zero, the motor reversed and the speed increased to 1000 r.p.m. in the opposite direction in the course of a few seconds. The return stroke is made at 1000 r.p.m. and the motor is again brought to a standstill and reversed for another cut at low speed. The control equipment is such as to allow the return and cut to be made at any desired speed within the speed range.

The question as to whether armature control should be combined with field control, thus giving a lower first cost motor, is dependent upon the total range, the output desired at low speeds and its duration, cost of energy, etc., and consideration of these factors should determine the advisability of its adoption.

Thus in service of the nature of class 3, in which the range is wide and the power drops off greatly with the speed, as in centrifugal fans and some types of blowers, there is a possibility of greater efficiency at low speed, besides a lower cost motor, by adopting armature control in part.

The General Electric Company has standardized sizes as large as 50 h.p. for 4 to 1 speed range at 230 volts for constant output, continuous duty, and 3 to 1 at 550 volts; and have built for continuous service 4 to 1 motors in 75-h.p. to 125-h.p. capacities, with reduced torque at the extreme low speeds. There are also in successful operation numerous adjustable speed motors of larger horse-power capacities, among which are duplicate 300-h.p. 230-volt motors with a speed range of 400 to 800 r.p.m. by field control, for constant output continuous service, for driving cold rolls, in a steel mill. These are also capable of carrying two-hour overloads of 25 per cent at either speed and maximum momentary loads of 200 per cent and 175 per cent respectively at 400 r.p.m. and 800 r.p.m. For similar service the same company has furnished a 225-h.p. 500-volt motor for operation through a speed range of 225 to 675 r.p.m.

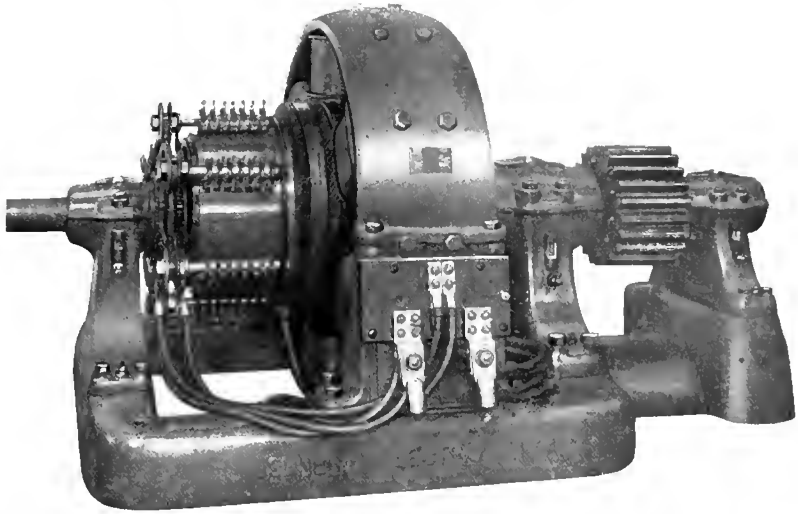

Fig. 4. One of a Pair of 300 H.P., 400 800-R.P.M., 230-Volt Motors for Gearing to Cold Rolls of Sheet Steel Mill

### Compound Wound Motors

For most adjustable speed applications using field control shunt wound motors are satisfactory, having good regulation and in reversing service allowing of simpler connections. However, compound wound motors are sometimes desirable usually on account of the higher starting torque afforded with the same armature current, as for example with reciprocating air compressor drive or apparatus having a high static friction to overcome.

Often a machine requires a strong torque at starting, but when up to speed requires better regulation than afforded by a compound motor. For this service the motor is supplied with its usual strength of shunt field winding and in addition is wound with a series winding which is in service only at starting and is automatically cut out by the starting rheostat when the machine has reached its running speed. The use of motors for printing press drive affords an example of the application of this type of winding.

When for any reason an adjustable speed motor with any considerable speed range is made compound wound and the series winding left in service at the maximum speed, it is important to make sure that the motor will at all times be positively connected to a load sufficient to hold its speed below the maximum for which the armature has been mechanically designed to run. For at extreme weakened shunt field, the field produced by the current in the series winding may be a large proportion of the total field strength and the loss of this series field by losing the load would leave the machine with such a low field flux that the speed might attain a sufficiently high value to cause an arc-over or mechanical rupture of the armature.

Since motors for wide speed ranges are generally designed with high flux densities at the low speed it is questionable if the addition of a series winding for starting purposes would produce an additional torque of any practical magnitude.

In concluding it may be said of the electric drive for variable speed machinery that its problems admit of simpler solution and its application finds greater scope, through the adoption of the commutating pole type of motor with field control on a single voltage circuit, and there are comparatively few instances in which it is not of advantage to either wholly or partially apply this system.

# THE ECONOMIC SIGNIFICANCE OF THE RELATION BETWEEN LINE VOLTAGE AND LAMP VOLTAGE

By M. D. Cooper

Engineering Department, National Lamp Works of General Electric Company, Cleveland, Ohio

Long continued study and investigation, in which the author has taken a large part, has shown that the rated voltage of incandescent lamps is on many occasions not the most economical value of electric pressure to apply. After a detailed discussion of the many factors influencing the quality and cost of electric power and light, the author describes several cases in which all persons concerned were benefited by lamp operation at slightly over-voltage, or at least not below rated voltage. To substantiate the arguments presented in favor of an over-voltage operation the author concludes with facts taken from electric census reports, which show that the tendency of practice has been in this direction for a number of years.—Editor.

In earlier days electric light was considered a luxury, to be afforded only by the family whose income was above the average. Electrical development has been so fast that now-a-days electric light is considered by a majority of its users to be a necessity and it could be classed as a luxury only in the humblest of homes. Except in those places where cheap gas is available, electric light is fully as cheap, if not cheaper, than any other form of artificial illuminant. This cheapness may be due to the fact that small customers are served at a loss, yet if *full* exploitation of the possible field were made, such relative economies could be made that the service would become profitable. The future promises early developments which will materially aid in the realization of the full possibilities in the lighting field. When this condition comes about, electric light will be no longer classed as a luxury by anyone, but will become an economic necessity for any and all who use artificial light.

The marvelous commercial development that has taken place in the electric lighting industry is in no small degree attributable to the fact, which is the boast of the industry, that while other elements of the cost of living have continually increased, the cost of light has continually decreased. This decrease in the cost of light is due mainly to the continual increase in the efficiency of the apparatus for generating and distributing electric energy and for translating this energy into light. As the cost of operation has decreased, corresponding decreases in the rates of charge for electricity have been made.

That decreasing the price of a commodity will increase its consumption is an economic axiom which no one will deny. The relation between the decrease in price and the increase in consumption will depend largely upon the nature of the commodity. The Massachusetts Board of Gas and Electric Light Commissioners has furnished some interesting figures on this relation as applied to electrical energy. Data compiled from their report show the sales of current in various cities and towns as depending upon the average selling price per kilowatt-hour. During the period of time covered by the data, it is reasonable to assume that no marked changes transpired in selling methods, amount of sales effort, etc., and that therefore the figures show the true economic significance of the effect of selling price on sales. The figures given show that the consumption varies inversely as the square of the price approximately, indicating, for example, that a 10 per cent reduction in price would result, not in a loss in gross income, but actually in a gain of 10 per cent. The latest census of the electric light industry also gives interesting figures on this subject:

| Year | Million Kw-Hr. Sold | Population (1900 and 1910) | Sales—Kw-Hr. per Capita | Income from Sale of Current | Average Price per Kw-Hr. |
|---|---|---|---|---|---|
| 1902 | 1880 | 76,303,387 | 24.6 (=100%) | $ 84,000,000 | 4.48c. (=100%) |
| 1912 | 8628 | 89,912,353 | 96.0 (=390%) | 287,000,000 | 3.33c. (= 74%) |

Thus for a decrease in price of 26 per cent, there followed an increase in sales per capita of 290 per cent. These figures would indicate that the sale of current varies inversely as the 4.6 power of the average selling price. The change in price is in this case not the only cause of increased sales, since during the ten year period there was a vast increase in the amount of sales effort expended.

If it were possible to obtain figures on electric *light*, instead of electric *energy*, it would probably be found that a similar conclusion would result—namely, that a decrease in cost of light of any given percentage would result, not in a proportionate reduction in the amount spent per capita for light, but in an increase in this expenditure of at least as great a percentage.

At the time of the introduction of the tungsten filament lamp it was greatly feared that its use would make heavy inroads upon the income of the central stations. Sufficient time has now elapsed to fully dispel this fallacy, for it has been found that the resultant decrease in the cost of light has so extended the use of light and the possibilities of electric service, that the balance is entirely on the other side of the ledger. To quote a statement of a prominent central station manager, "The mazda lamp and the flatiron are the sheet anchors of the electric lighting industry."

To illustrate the general economic or commercial aspect of the relative cost of light and the relative satisfaction derived from its use, may be cited the case of two small middle-western cities. One is a town of 2500 inhabitants and the other of 300 inhabitants. They are located near together and are both supplied from the same station, under the same management and under like policies.

The larger town has 150 electric customers or 30 per cent of the total possibilities and the smaller town has 50 customers or 80 per cent of the total possibilities. In casting about for a reason for this difference it was found that the lamps in the larger town were operating under such voltage conditions that they failed by about 30 per cent to give their full rated candle-power, while the lamps in the smaller town were burned up to voltage and thus were giving their full rated candle-power. It was stated that in the larger town complaints of dim light were numerous. As nearly as could be ascertained, the difference in quantity of light obtained was the sole reason for the great difference in the realization of the possibilities of electric service in these two towns.

The term "electric service" has in recent years come to mean much more than the mere supply of electric energy. Many stations are supplying free renewals of incandescent lamps and free renewals of arc electrodes, many offer inducements of financial assistance in the installation of wiring, many maintain periodical inspection of current consuming devices to see that they are operating properly, many render assistance in the design of lighting or power installations, and many supply current consuming devices free or at reduced rates. These and many other items are included under the general term "electric service."

That these items of service are profitably given shows it is a good commercial policy to increase the use and satisfaction that the customer derives from his electricity supply.

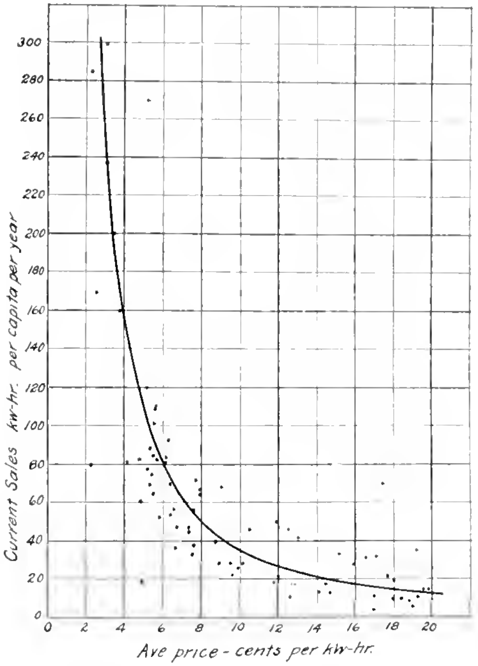

Fig. 1

Except in the case of power consumers, it is *light* that constitutes the main item of electric service, and by the degree of satisfaction and the economy in its use is the customer's opinion of the service gauged. Any increase in the economy of light production that it is possible to make will therefore result in distinct gain to the station.

The production of light by means of incandescent lamps involves the consumption of two things—current and lamps. For any given type and size of lamp, the amount of light it will give or the amount of energy it will consume is merely a question of the length of life it is desired to obtain, and conversely, the length of life obtained is merely a question of the light production or current consumption desired. Light and life are mutually exclusive—either is obtained at the sacrifice of the other, hence the satisfactory operation of incandescent lamps depends upon getting a proper balance between these two items.

The cost of light is made up of the same two items, the cost of energy and the cost of renewals. As the electric pressure supplied to a lamp is increased, the cost of energy per candle-power decreases and the cost of renewals per candle-power increases. Since the increase in one and the decrease in the other are ordinarily not of the same magnitude, it therefore follows that a change in the impressed voltage will affect the economy of light production. As the voltage is increased up to a certain point, the decrease in energy cost per candle-power is greater than the increase in renewal cost per candle-power; therefore, with this point as a limit, an increase in the voltage supplied to a lamp will result in an increase in the economy of light production.

The controlling factor in determining at what voltage or at what efficiency a lamp should be operated has in the past been the length of the lamp life which the public deemed to be satisfactory. In the early days of the carbon lamp, a life of about 500 hours was considered satisfactory, and as the quality of the lamps improved the life became longer and longer, till the public became accustomed to the use of lamps which were very long lived. When the tungsten filament lamp first appeared on the market, it was relatively expensive, and in order to keep the proper balance between energy cost and renewal cost, it was rated at such an efficiency that it gave a very long life. This still further increased the public idea as to the life which a lamp should give. As the quality of the lamps has been improved and as the price has been reduced, the life has been held at the same figure, when economically and logically it should have been reduced. The net result today therefore is that in the opinion of the public the quality of a lamp is a matter largely of the length of its life, and not, as it might better be, a matter of its economy in the production of light.

In actual point of fact, the energy element in the cost of light is of far greater importance than the lamp renewal element. Take for example a 40-watt lamp; during its rated life of 1000 hours it will consume 40 kilowatt-hours, which at ordinary lighting rates would cost from \$3.00 to \$4.00. The lamp cost is only \$0.30, or less than one-tenth of the total cost of operating the lamp. The renewal cost being relatively so small, it is apparent that it is not economical to conserve the \$0.30 item at the expense of efficiency of utilization of the \$3.00 or \$4.00 item.

An increase of one per cent in the voltage supplied at the terminals of a mazda lamp will result in the following characteristic changes: An increase in candle-power of 3½ per cent; an increase in energy consumption of 1½ per cent; and an increase in renewal expense of 15 per cent. Since the renewal expense is generally less than one-tenth of the total expense, a 15 per cent increase in this item is equivalent to not more than 1½ per cent on the total; therefore, an increase of one per cent in voltage will cause an increase of about 1½ per cent in the total cost of operation, and since the corresponding increase in candle-power is 3½ per cent, it follows that each per cent of increase in the voltage supplied will result in a net gain to the customer of ½ per cent in the economy of light production. Since the renewal expense increases relatively faster than the energy expense, there is a limit to the voltage increase which will result in a gain in the economy of light production. For ordinary cost of current, this limit is from 4 to 8 volts above the rated voltage of the lamps. Within this limit, and particularly if lamps are being burned at a pressure less than their rated voltage, an increase in line voltage will be a distinct benefit to the central station's customers in amount of light and in economy of its production, and to the central station in amount of revenue.

Increasing the voltage on the circuits of a central station results in a paradoxical condition whereby everybody gains—the customer gets more light, better light, and cheaper light, the central station sells more current, and the lamp manufacturer sells more lamps. It is true that the expenditure the customer makes is not decreased, but he gets an amount of light proportionately greater than the increased expenditure, therefore the change is a net gain for him.

The fallacy of the fear that increasing the efficiency and candle-power of lamps will cause a proportionate reduction in the income of the central station has now become fully demonstrated. On the introduction of the tungsten filament lamp such fears were expressed. The introduction of the lamps has been very gradual, and although the average income per socket may have, in general, been slightly decreased, yet the extension of the electric lighting field and the lengthening of the hours' use of light, due to the lesser cost, have maintained the income not only above the point which would be representative of a decrease proportional to the increase in efficiency of the lamps but actually have lead to an increase in income. Such increases in candle-power as are brought about by slight increases in voltage would not be of as great a magnitude as the change from carbon to mazda lamps, hence should not occasion any fear of decreased income due to customers using smaller lamps.

It is interesting to note in this connection the marked increase in the general standard of illumination that has come about during the last few years. Records show that the average candle-power of all incandescent lamps sold in this country has increased from 26.0 in 1911 to 28.3 in 1912, and to 32.5 in 1913. These figures, in connection with those previously given as to the decrease in rates and increase in central station income, conclusively show that the best way to develop the lighting industry is to give the customer full advantage of every increase in efficiency and economy and every decrease in cost of light that can possibly be made.

By reason of its control over the voltage delivered to incandescent lamps on its circuits, and in comparison with the significance of the rated candle-power, wattage and life of the lamps, the central station has entire command over the quantity and quality of the light received by its customers, over the economy of the production of this light, and over the revenue obtained therefrom. The following table shows the effect of various impressed voltages on the candle-power of a 110-volt mazda lamp:

| Voltage Supplied to a 110-Volt Mazda Lamp | 106 | 108 | 110 | 112 | 114 | 116 | 118 |
|---|---|---|---|---|---|---|---|
| Effect on candle-power | Loss 12.1% | Loss 6.2% | Normal | Gain 6.5% | Gain 13.3% | Gain 20.3% | Gain 27.7% |

**Similarly, the following table shows the effect of voltage on wattage:**

| Voltage Supplied to a 110-Volt Mazda Lamp | 106 | 108 | 110 | 112 | 114 | 116 | 118 |
|---|---|---|---|---|---|---|---|
| Effect on wattage | Loss 5.69% | Loss 2.85% | Normal | Gain 2.89% | Gain 5.81% | Gain 8.75% | Gain 11.73% |

Under a straight meter rate, the effect on income will be proportional to the effect on wattage.

These figures point out the fact that it is advisable for a central station to maintain on its lines a voltage which is no lower than the rated voltage of the lamps used. It is of course impossible to maintain exactly the same voltage at all parts of the distributing system—the many possible causes of voltage variation preclude the possibility of such an ideal state of affairs. The figure which should be thought of as the "voltage of the lines" is the average voltage at *customers' lamp sockets* during the *time when the lamps are in use.* As far as a lighting customer is concerned, it makes no difference to him what the voltage may be at noon, provided, of course, that he is not using his lamps at that time—but it is an extremely important consideration with him that the voltage should not be too low in the evening or at any other time when he wants to use his lamps.

The maintenance of a uniform voltage on its lines by the central station does not always lead to a solution of the "proper voltage" question, since it has often been found that quite a number of different voltages of lamps are found upon the circuits. Unless enough variation in voltage is experienced to warrant the central station in supplying more than one voltage of lamp, it is generally found that the lamps of voltages other than the standard supplied by the central station have been secured from some local dealer. If these lamps are of a higher rated voltage, their use entails a loss of revenue to the central station, a loss of light to the users, and a loss of renewal business to the dealer who sells them. In the great majority of cases where dealers follow such a practice, the reason generally is that the central station is selling lamps at a price the small dealer cannot meet and therefore, in order to make any lamp sales at all, the small dealer feels compelled to use as a selling argument the greater length of life which the lamps will give when they are of a rating a few volts higher than the voltage of the circuit. Where such conditions exist, a positive injury is being done—not only to the parties directly concerned, the customer, the central station and the dealer, but also to the entire electrical development of the city, since the attention of the light-using public is being directed to an element in the cost of light which is of relatively small importance, and opinions are being formed in their minds which will be detrimental to the highest development of lighting service.

In those places where electrical dealers are not supplying the correct voltage of lamps for use on the central station circuits, the station has an admirable opportunity for increasing its revenue and improving its lighting service by taking steps to secure the use of lamps of the proper voltage. In many cases a dealer is supplying an improper voltage of lamp merely because he does not know what the right voltage is or perhaps because the voltage of the circuits has been changed and he has not been informed of the change. In such cases a letter or a phone call will suffice to improve conditions. With respect to the voltage of lamps sold there lies one of the most easily arranged and executed, the most far-reaching, and mutually most profitable lines of cooperation between central station and dealer.

The expectation of the public in regard to the life of incandescent lamps is largely a matter of habit. In places where the lamps have been burned under voltage, with consequent loss of light to the customer, loss of revenue to the station and loss of lamp renewal business to the lamp distributers, the public has come to expect a long life from its lamps; but on the other hand, where the voltage has been kept up to or above the lamp voltage, the customers have become used to a shorter lived lamp and are willing to thus sacrifice a little on life for the sake of the greater and better illumination.

Even where a considerable increase in line voltage is made, the customers are not slow to appreciate the greater illumination secured even though they soon find out that it is obtained at the expense of an increased outlay for lamps. A case in point was encountered recently in the investigation of the voltage conditions upon the circuits of a middle-western city. In this city were two central stations—a private plant and a municipal plant. There was very close competition between the two stations and each one was doing everything possible to improve and extend its service. In a number of places, particularly commercial lighting installations, it was found that both companies had a service entrance and that the customer was provided with a throw-over switch so that he could burn his lamps upon either circuit. Measurement of voltage in such places showed that the pressure on the municipal lines was about 5 volts higher than on the lines of the private company. A number of these customers drew comparison between the amount of light delivered when the lamps were on the private lines and when they were connected to the municipal lines. In all such cases, sufficient experience had been had with operation on both of the lines so that the resulting costs were fully known and appreciated, yet the sentiment of the customers was that they very much preferred burning the lamps on the circuit having the higher voltage.

The comment of a central station manager along similar lines is pertinent to the subject under discussion. He stated, "I do and always have belonged to the 'plenty-of-voltage' class and find that after giving a customer plenty of voltage at his lamps he will not go back to a high voltage lamp for a low voltage circuit. You cannot get light without juice and plenty of it and the average consumer falls in line with this practice very easily unless somebody comes along and says, 'The voltage is too high; the station is all wrong; you ought to go down and see those fellows and find out what they are giving you.' Down he comes and says, 'What kind of voltage are you giving me? My lamps won't stand it. There has got to be something done.' 'Well,' I say, 'you can increase your particular voltage to suit yourself, then kick for lack of illumination, but please keep your nose out of the plant's voltage if you want illumination!'"

The fact that improving the voltage conditions upon the circuits of the central station is a profitable business procedure is fully borne out by the results of many tests which have been made by the organization with which the writer is connected. Two years ago, a series of voltage tests on the circuits of central stations in various parts of the country showed that as a general average the lamps were burning four volts below their rated voltage. Similar tests of a year ago showed an average of two volts under voltage, while a much more extended series of tests very recently conducted shows that upon all circuits investigated the average voltage corresponded almost exactly with the voltage of the lamps.

The advantages to the customer from the standpoint of increased illumination, illumination of a better quantity at increased economy, the advantages to the central station from the standpoint of increased revenue and improved service, and the advantages to the electrical dealers who supply lamps, all point to the fact that lamps should be operated at a voltage certainly not less than their rated voltage.

# NOTES ON THE USE OF THERMO-ELECTRIC APPARATUS IN HIGH FREQUENCY SYSTEMS

By August Hund

Research Laboratory, General Electric Company

This paper deals with thermo-electric phenomena and shows their application to technical apparatus. The scope of the paper is to show the use of certain apparatus which may be built very readily for laboratory purposes and which are very convenient for measuring currents up to the highest frequencies independently of the shape and length of wave.—Editor.

Most of the instruments used for the lower commercial frequencies cannot be employed for similar measurements in high frequency systems unless special precautions are taken in their design. This is due to the effects of capacity, resistance, and self and mutual inductance. The magnitudes of these quantities are dependent on the frequency and wave-shape. It is therefore readily understood that high frequency apparatus based on the dynamometric principle cannot be considered, and that electrostatic instruments are only applicable where the voltage is rather high. Since many wireless stations are operating with spark systems which produce more or less damped waves it is desirable to be able to design an instrument whose indications are independent of the wave shape or frequency.

All the above requirements are satisfied by a meter which operates on the principle of heat production due to resistance, since the indication is a result of integrated effect and is therefore independent of wave form or frequency. It is due to this fact that the hot wire type of meter has been largely adopted for this class of service. However, this type of meter inherently requires a rather large consumption of energy and is not available for small currents. In the latest type of high frequency meter the resistance is used to heat up one or more thermo-couples and the indications of the instrument are proportional to the e.m.f. of the thermo-couple.

## Heat Evolution Due to Currents of Various Wave-Shapes

In the following section a mathematical treatment is given, in order that the reader may gain a thorough insight into just what happens when the $I^2R$ loss is dissipated. Consider the simplest case, a continuous current $i$ flowing through a conductor of ohmic resistance $r$. We obtain for the quantity of Joule's heat $q$, produced in one second:

$$q = \frac{1}{4189} \cdot r \cdot i^2 \; Cal\ sec \qquad (1)$$

In case of an undamped oscillatory current which obeys the sine law, the heat produced per second is

$$q = \frac{1}{4189} \cdot \frac{1}{T} \int_0^T i^2 \cdot r \cdot dt \; Cal\ sec \qquad (2)$$

where $T$ is the period of a complete cycle. The instantaneous value $i$ is given by the equation

$$i = I\ max. \sin 2\pi f t$$

in which $f$ denotes the frequency. By substituting the effective value of the current,

$$I\ eff = \sqrt{\frac{1}{T} \int_0^T i^2\, dt}$$

in equation (2) we obtain the relation

$$q = \frac{1}{4189} \cdot r \cdot I^2 eff \; Cal\ sec$$

$$= \frac{1}{4189} \cdot r \cdot \frac{I^2 max.}{2} Cal\ sec \qquad (3)$$

Now let us consider the case of damped oscillations. In this case the amplitude of each oscillation gradually diminishes and finally reaches zero; then the oscillations start again with the same original amplitude and continue to diminish as before. That is, wave trains of oscillations are produced, and at any instant the value of the current may be represented by

$$i = I_0 . \epsilon^{-\delta t} \sin (2\pi f) t$$

where $I_0$ denotes the maximum amplitude of the current, that is, the initial value of the discharge, and $\delta$ the damping factor of the oscillation, which is equal to $\frac{r}{2L}$, where $r$ is the ohmic resistance and $L$ the effective self-inductance of the circuit in question. Hence the expression for the energy converted into heat per second may be written

$$q=\frac{1}{4189}N.r\int_0^\infty I_0^2\epsilon^{-2\delta t}\,sin^2\,(2\,\pi\,f)t.dt$$
$$=\frac{N.r.I_0^2}{4189.4\,\delta\left(1+\frac{\delta^2}{(2\,\pi\,f)^2}\right)} \qquad (4)$$
$$\cong\frac{N.r.I_0^2}{4189.4\,\delta}Cal\ sec$$

where $N$ is the number of damped wave trains per second. The logarithmic decrement, $\Delta$, is very often used by present day writers. If it were introduced, equation 4 would become

$$q\cong\frac{N.r.I_0^2}{4189.4.\Delta.f}Cal\ sec \qquad (4a)$$

Hence the effective value of the current of a damped oscillation is expressed by

$$I\ eff\cong I_0\sqrt{\frac{N}{4.\Delta.f}} \qquad (5)$$

since by definition the effective value of any current is that value which a continuous current must have, in order to produce the same Joule's heat with a given resistance.

### Thermo-Electricity—Peltier Effect—Thomson Effect

In 1822, Seebeck found that by heating two dissimilar metals at the contact where they touch one another, a thermo-electric force is produced. For instance if a thermo-couple consisting of two different metals, such as bismuth and antimony, has its junction point heated, a thermo-electromotive force is produced and if the terminals are connected, a thermo-electric current will flow from *Bi* to *Sb*.

In 1834, Peltier discovered that a direct current flowing through a junction of two different metals will heat or cool the point of contact of the two metals according to the direction of flow. Thus if the positive terminal of the applied electromotive force is connected to the bismuth terminal and the negative terminal to the antimony, the junction of the thermo-couple will be cooled, since the latter is absorbing heat; and if the current be caused to flow in the opposite direction there will be an evolution of heat, or in other words the junction point will heat up. Hence we learn that the Peltier effect is reversible and not like the Joule's heat effect, where there is always an evolution of heat regardless of the direction of current flow. It can therefore be seen that the thermo-electric current $i_g$, which is made to flow through a galvanometer, will obey the following equation

$$i_g=k_1\,i_0^2\pm k_2\,i_0 \qquad (6)$$

where $i_0$ is the direct current which is exciting the thermo-couple, and $k_1$ and $k_2$ are constants. The law of heat generation in such a circuit is expressed by

$$q=\frac{1}{4189}\,(i_0^2r\pm V.i_0)\,t \qquad (7)$$

where $V$ stands for the thermo-electric potential difference due to the heating of the junction.

Lord Kelvin discovered a phenomenon similar to the Peltier effect. It is observed in metal conductors where there exists a difference of temperature at different points. For instance, if the direction of the current through a copper wire is the same as that of the heat flow, we obtain an evolution of heat, while if the current flows from a place of low to one of higher temperature an absorption of heat will occur. This effect (Thomson effect) is zero for lead, and therefore it is customary to tabulate the thermo-electric power of different metals with respect to lead. It was later discovered that iron when used with another metal has an inversion of its thermo-electric force at high temperatures. Cummings has experimentally demonstrated that a thermo-couple consisting of iron and copper reaches a neutral point at 275 deg. Centigrade; above this temperature iron is positive and below it negative with respect to the copper. This inversion of the thermo-electric effect was also observed by the writer to be present in crystal detectors, such as are used in wireless telegraphy. For instance when a Marconi wave meter carries too large a current in virtue to its being too closely coupled to the circuit whose wave length is to be measured, the polarity of the crystal changes and the deflection of the galvanometer will be reversed. This is due to the fine contact point becoming overheated on account of the excessive incoming high frequency current. This phenomenon indicated that the rectification by means of such a crystal detector (usually some metal against lead sulphide) is very probably due to a thermo-electric effect, since we observe what is evidently a case of thermo-electric inversion.

### The Thermo-Electric Diagram

In order to better illustrate the thermo-electric relations, the thermo-electric diagram is given, see Fig. 1. This diagram was first suggested by Lord Kelvin, and is very convenient, since from it we are able to read the thermo-electric power of any metal at any temperature. The thermo-electric powers in micro-volts per degree Centigrade are plotted as ordinates, while the abscissae give the absolute temperature of the junctions in degrees Centigrade. Thus for instance at 250 deg. the iron corresponds to −5 micro-volts, for if the iron is heated up to 249½ deg. and the lead to 250½ deg., so that the difference of temperature between the metals is one degree, the voltage of such a thermo-couple will be 5 micro-volts and the current will flow from lead to iron. On the other hand, if a platinum-lead couple be at the same temperature there will only be a voltage of 2 micro-volts and the current will flow from platinum to lead. It therefore follows that the thermo-electric force of a couple consisting of platinum and iron is 7 micro-volts at 250 deg., the platinum being positive.

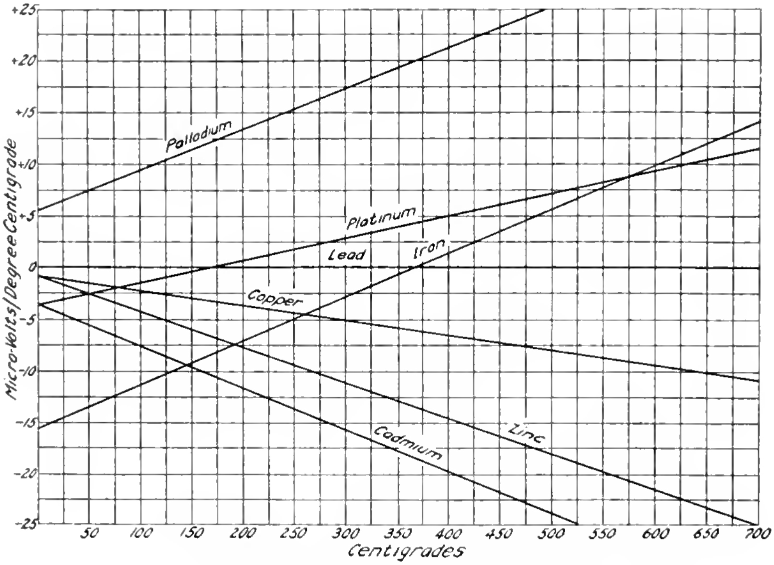

Fig. 1. The Thermo-Electric Diagram for various Metals based on Micro-Volts per Absolute Degree Centigrade

Furthermore, we can study the "electric heat convection" which is known as the Thomson effect. In the case of metals whose characteristics in Fig. 1 slant downward, such as, for instance, cadmium, the heat convection is in the direction of the flow of the current, while in the case of metals whose thermo-electric force increases with temperature, such as iron, the heat travels in the opposite direction to the current. According to the numerous investigations of Le Roux and others, lead does not show any Thomson effect, accordingly there will be no heat convection owing to current flow in this metal, and therefore its characteristic is taken as the axis of abscissae.

### Explanation of the Thermo-Electric Phenomena

According to the electron theory of conduction an electric current in a metal is due to a connection of negatively charged corpuscles or electrons, under the influence of the potential gradient acting at every point in the metal. These electrons are present in all substances as essential constituents of the atoms. Owing, however, to vibrations of the atoms some of the electrons are being continually set free while others are re-entering into combination with the charged residues of the atoms. There are therefore always present a certain number of free electrons, and it has been shown by Richardson that the emission of electrons by heated bodies leads to the assumption that the number of these free electrons increases with the temperature according to a law which is similar to that of the rate of evaporation of a substance. These free electrons are in most cases held back by forces on the surface of the conductor. But when such a material is heated up, the kinetic energy of the electrons becomes sufficiently great to allow some of them to overcome this surface retardation and escape.

On the basis of this theory it is possible to obtain at least a qualitative explanation of the thermo-electric force and the Peltier and Thomson effects. The derivation of the relations involved are all given in Richardson's original paper,* but it has been thought that an illustration of the manner in which the theory may be applied might be of interest in this connection.

Assume a constantan and manganin wire to be soldered together and the junction to be heated to a definite temperature. As soon as this temperature is applied to the junction of the two metals, electrons will be emitted and

---

*A paper on Electric Conduction presented at the twenty-first general meeting of the American Electro-Chemical Society, Boston, Mass., April 19, 1912.

therefore a current will flow from the metal which has emitted the greatest number of electrons to the metal which has lost the fewer electrons since it will be the least positively charged of the two. A field will be built up due to this current flow, which will tend to stop further emission of electrons. The current flow will increase until a stable condition occurs in which the constantan and manganin will each be receiving as many electrons as they are giving off. Under this steady condition the manganin wire will have the potential $V_{Mn}$ and the constantan wire the potential $V_{Co}$, we therefore can write the expression for the difference of potential between the manganin and the constantan wires which is the electromotive force at the terminals of this couple

$$V_{Co}-V_{Mn}=\frac{1}{e}\left(w'_{Co}-w'_{Mn}\right)+{}_{Co}P_{Mn} \quad (8)$$

where $e$ is the electric charge of an electron and $w'_{Co}$ and $w'_{Mn}$ the internal latent heat of evaporation of the constantan and manganin wire respectively. The second term of this equation gives the part due to the Peltier effect; it is very small in comparison with the contact potential, that is, the term, $\frac{1}{e}(w'_{Co}-w'_{Mn})$. Considering the Thomson effect we remember that the two elements of the couple are of the same material but their temperatures are different. The intrinsic potentials of the two elements are not equal, due to this temperature difference and therefore the electric potentials of the electrons are different. Richardson has also introduced a formula for the specific heat of electricity, based on this assumption. The formula shows that the Thomson coefficient (specific heat of electricity) is dependent on the temperature coefficient of the latent heat of evaporation of the electrons from the metal.

### The Application of Thermo-Electricity to Measuring Instruments

As was previously pointed out, hot wire meters are not appropriate for the measurement of very small currents, and have a relatively high consumption of energy. For instance the most sensitive hot wire instrument of Hartmann & Braun has a resistance of 9.37 ohms and an energy dissipation of 333 × $10^{-4}$ watts for a 100-mm. deflection, while an ordinary thermo-couple has a consumption of about 50 × $10^{-4}$ watts for a 100-mm. deflection. If such a thermo-couple be placed in a vacuum, the dissipation of energy will be reduced about tenfold. For this reason Flemming, Hausrath, and others have used such thermo-electric instruments with galvanometers of low resistance. †

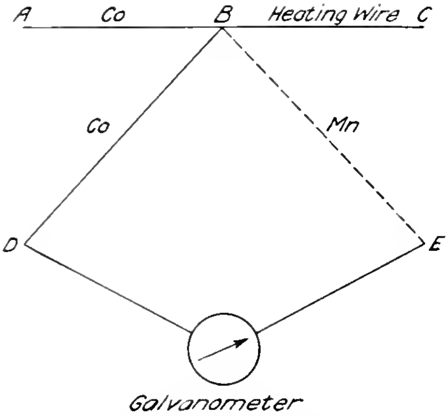

Fig. 2. A Thermo-Electric Current-Measuring Apparatus Employing One Thermo-Couple

Since this apparatus also renders invaluable aid in the measurement of minute direct currents or of small currents of lower frequencies, it seems worth while to give a brief description of those types which can be made up for laboratory purposes.

We shall first consider a thermo-couple, as shown in Fig. 2. $ABC$ is a very short heating wire of constantan, $BD$ and $BE$ are short pieces of constantan and manganin wire respectively. These wires have a diameter of about 2 mils. $BD$ and $BE$ are welded together with the heating wire by means of a very small joint as shown. As soon as a current passes through $ABC$ the junction point $B$ will become heated up and a thermo-electric current will flow through the galvanometer. The condition for maximum sensibility is attained when the resistance of the galvanometer is equal to the internal resistance of the thermo-couple. When using a Deprez-D'Arsonval galvanometer one is able to measure currents as low as 50 × $10^{-6}$ amperes with an ordinary thermo-couple in air. If the effective value of the current to be measured is $I_{eff}$ and the resistance of the short heating wire $ABC$ is $r$, the direct current

passing through the galvanometer may be expressed by the equation

$$i_g = k \, . \, r \, . \, I^2 \, eff \qquad (9)$$

and the deflection $\alpha$ of the galvanometer is given by the expression

$$\alpha = k^1 \, . \, I^2 \, eff \qquad (10)$$

where $k$ and $k^1$ are constants. If $n$ such thermo-couples are connected in series, the deflection $\alpha_n$ of the galvanometer will be

$$\alpha_n = k^1 \, . \, n \, . \, I^2 \, eff \qquad (11)$$

The arrangement of such a system of thermo-elements is shown in Fig. 3. The incoming oscillatory current must pass through the block condenser $C$, which should be of sufficient capacity (about 2 micro-farads) to be approximately a short circuit for the high frequency current being measured, and be of infinite resistance to the thermo-electric current produced in the couples. The galvanometer current is made to pass through a choke coil with an inductance of approximately 0.1 henry, in order to prevent the high frequency current flowing through the galvanometer. In most cases the inductance of the galvanometer itself is sufficient. The design must be so arranged that the points $B_1B_2B_3$, etc., are very fine spots, while the joints at $A_1A_2A_3$, etc., are thoroughly soldered to copper rods which support the thermo-couple and are set perpendicular to its plane. These relatively massive copper rods which support the thermo-net also serve the purpose of conducting the heat away from the joints. Hence, if a current be made to pass through the thermo-elements the $B$ junctions will be heated up, while the $A$ junctions will remain at practically the temperature of the surrounding air. In this way we can obtain a relatively high thermo-electric force at the expense of a somewhat increased dissipation of energy; nevertheless the energy consumption is always far less than that of an equivalent hot wire instrument. The disturbances due to air circulation may be effectively overcome by putting the whole thermo-electric system under a cover. Table I is given in order that the reader may gain some conception of the magnitude of the quantities involved. The couples as used by the writer are shown in Fig. 3 and were made up of about four mm. lengths of constantan and manganin wires. The constantan wire had a diameter of 3 mils, and the manganin wire a diameter of 2 mils.

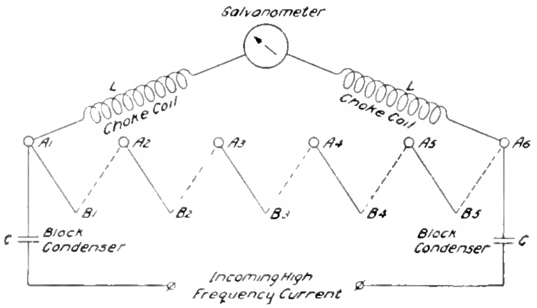

**Fig. 3.** A System of Thermo-Couples and Galvanometer which will give a large Deflection in measuring a small Current and which requires but a small Expenditure of Energy. Its use is limited to Alternating-Currrent Measurements

The indicating instrument was a Hartmann & Braun milli-voltmeter having an internal resistance of 160 ohms, with an 18 milli-volt scale. This combination will of course not give the condition for maximum sensitiveness since the internal resistance of the thermo-couples was only about one-ninth that of the resistance of the milli-voltmeter which replaced the galvanometer of Fig. 3. For this reason Table II is also given. Here a Paul instrument with an internal resistance of only 53.5 ohms was used. All readings are for high frequency currents taken from an Alexanderson machine at 40,000 and 65,000 cycles per second. The indications for these two frequencies did not show any appreciable discrepancy.

For very accurate measurements the arrangement as shown in Fig. 4 is suggested, since here a separate heating wire *AB* is provided, which is located very near to the joints $C_1$, $C_2$, $C_3$, etc. This system can be calibrated by means of continuous current. In order to insure the proper relative location of the joints with respect to the heating wire it is well to fasten it to the thermo-net at different places by means of an insulating material. This arrangement is not quite as sensitive as that shown in Fig. 3, but has the great added advantage that it can be used for direct or alternating currents up to the highest frequencies. This system cannot be used under a vacuum since there would be practically no thermo-electromotive force because the heat conductivity in a vacuum is almost zero. When only two couples are to be connected in series the writer has always used the scheme shown in Fig. 5. In this case the current in any couple cannot flow from the constantan to the manganin and therefore the Peltier effect will not be present, but the thermo-electric forces will nevertheless be added. If large currents are to be measured a shunt must be used, since a thick heating wire of low resistance would change its resistance with changes in frequency, due to skin effect. Even at the lower frequencies errors are liable to be introduced by such parallel paths; we will therefore analyze the conditions and study the means for overcoming these errors. Assume that the heating wire whose resistance is $r_h$ and self-inductance $L_h$ has a current of $I_h$ flowing through it and that $r_s$, $L_s$ and $I_s$ are the corresponding quantities of the circuit in parallel with it. The vector addition of these two currents gives the current in the external circuit. Fig. 6 shows the wiring diagram for this scheme. For the case of sine wave currents the ratio of the magnitudes of the currents in the parallel branches is given by the equation

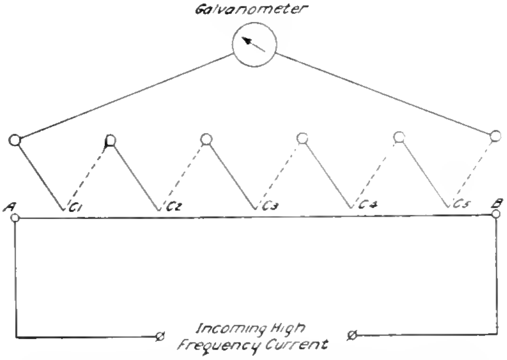

Fig. 4. A System that is more accurate than that of Fig. 3 but not quite as sensitive. It is equally Applicable to both Alternating-Current and Continuous-Current Measurements

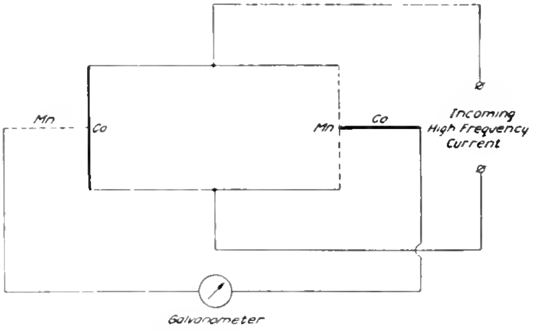

Fig. 5. A Good Scheme of Connections when but two Thermo-Couples are to be used

$$\frac{I_h}{I_s} = \sqrt{\frac{r_s^2+(2\,\pi f\,L_s)^2}{r_h^2+(2\,\pi f\,L_h)^2}} \qquad (12)$$

It is evident from this expression that even if the ohmic resistance and self-inductance did not alter with changes of frequency, the current ratio would not remain constant, since it is dependent on the wave length of the high frequency current in question. This means that such an instrument is not suitable for measurements in high frequency systems except at only the one definite frequency at which it has been calibrated. On closer consideration of equation (12) it becomes apparent that it is possible to keep the ratio, $\frac{I_h}{I_s}$, con-

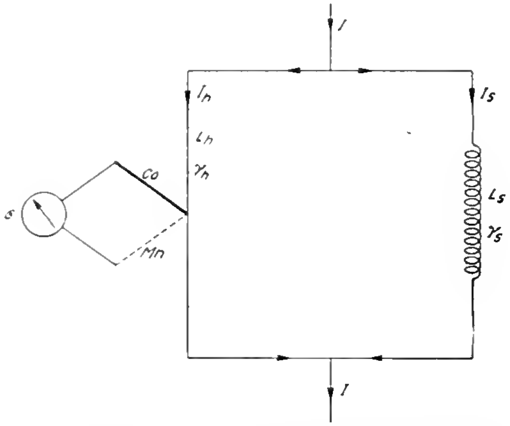

Fig. 6. The Thermo-Couple System shown in Fig 2 shunted to measure heavy Currents. As shown, can be used only at the frequency at which it is calibrated

stant, if the self-inductances are sufficiently large so that the effect of the ohmic resistance becomes practically negligible in comparison with the influence of the inductive reactance.

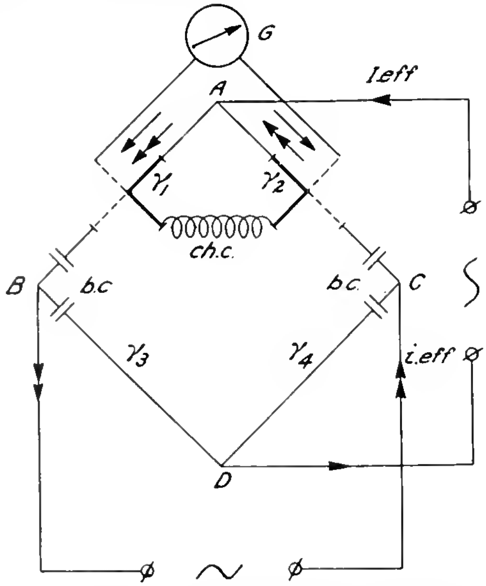

Fig. 7. Scheme of Connections for a Thermo-Cross Bridge, an Arrangement giving Deflections directly proportional to the amount of Current

Then equation (12) becomes

$$\frac{I_h}{I_s} \cong \frac{L_s}{L_h} \tag{13}$$

Therefore if additional self-inductances are inserted in the two branches, providing of course that there is no mutual inductance between the two branches, we obtain an apparatus which can be applied to any frequency. If for instance, the instrument is to be used with frequencies of from 5000 to 100,000 cycles per second, the value of the self-inductance should be so chosen that the resistance will be negligible as compared to $2\pi.5000L$. In general if the error of the combination is not to exceed $\mu$ per cent the self-inductance of the branch is given by the equation

$$\frac{1}{L_h} \leqq \frac{2\,\pi f}{r_h}\sqrt{\frac{1}{(1-\mu)^2}-1} \tag{14}$$

Since it is practically impossible to avoid entirely the effects of mutual inductance, when working with such high frequencies, it has accordingly been found advantageous to use capacities instead of inductances for reactances. Then the general expression of the current ratio is

$$\frac{I_h}{I_s} = \frac{\sqrt{r_s^2+\left(2\,\pi f\,L_s-\frac{1}{2\,\pi f\,C_s}\right)^2}}{\sqrt{r_h^2+\left(2\,\pi f\,L_h-\frac{1}{2\,\pi f\,C_h}\right)^2}} \tag{15}$$

If the values of the capacities are so chosen that the effects of the resistance and self-inductance are negligible, the equation becomes

$$\frac{I_h}{I_s} \cong \frac{C_h}{C_s} \tag{16}$$

which is likewise constant at all frequencies. The value of the capacity then is of course to be so chosen that the effect of ohmic resistance and inductive reactance becomes negligible in comparison with the capacity reactance at the highest frequency at which measurements have to be made, that means, for the above example, $r_h$ has to become negligible in comparison with $\frac{1}{2\pi\,.\,100{,}000\,.\,C_h}$.

If the error of the combination shall not exceed $\mu$ per cent the capacity is given by the expression

$$C_h \leqq \frac{1}{2\,\pi f\,.\,r_h}\sqrt{\frac{1}{(1-\mu^2)}-1} \tag{17}$$

All the thermo-electric apparatus above described have a sensibility proportional to the square of the current being measured. We naturally desire an apparatus which will have indications directly proportional to the current, so that the divisions of the scale may be uniform. This requirement has been satisfied by using the thermo-cross bridge, as shown in Fig. 7. This arrangement is based on the superposition of two currents one of which is constant and known. Suppose two equal thermo-crosses are inserted in the branches *AB* and *AC* of the bridge. There are then in each branch two thermo-elements soldered together at one point. The heavy lines represent constantan wire and the dotted lines, manganin wires. The bridge is so balanced that the resistances of all the branches have neither inductive nor capacity effects. Let the current which flows through *AD* be *Ieff*, and that through *BC* be *ieff*, and assume them to be in synchronism. For any instant we have in *AB* the current

$$\frac{I+i}{2}$$

and in *AC*

$$\frac{I-i}{2}$$

where $I$ and $i$ represent the instantaneous values. The heat produced in the branch $AB$ is

$$q_{AB} = \frac{1}{4189}\left(\frac{I+i}{2}\right)^2 . r\ Cal\ sec \qquad (18)$$

and in $AC$

$$q_{AC} = \frac{1}{4189}\left(\frac{I-i}{2}\right)^2 . r\ Cal/sec \qquad (19)$$

$q_{AB}$ and $q_{AC}$ produce electromotive forces in the thermo-elements, being at right angles to the branches of the bridge. The elements are in series, with polarity opposed to one another. A choke coil (*ch. c.* Fig. 7) keeps back the high frequency current from flowing through the galvanometer. The block condensers (*b.c.* Fig. 7) limit the thermo-electric current to the bridge. The direct current $i_g$ which flows through the galvanometer may be expressed by the equation

$$i_g = i_{g_{AB}} - i_{g_{AC}} \qquad (20)$$

The relations for the currents $i_{g_{AB}}$ and $i_{g_{AC}}$ are

$$\begin{aligned} i_{g_{AB}} &= k\,.\,r\,.\left(\frac{I+i}{2}\right)^2 \\ i_{g_{AC}} &= k\,.\,r\left(\frac{I-i}{2}\right)^2 \end{aligned} \qquad (21)$$

where $k$ is a constant. At any instant the current flowing through the galvanometer under the above conditions is

$$\begin{aligned} i_g &= 2\,.\,k\,.\,r\,.\,I\,.\,i \\ &= k^1\,.\,I\,.\,i \end{aligned} \qquad (22)$$

Assuming the current $I$ to be the constant, the equation 22 then becomes

$$i_g = \text{Const}\ i \qquad (23)$$

This term shows that the direct current $i_g$ is directly proportional to the current $i$ for a constant value of $I$. As the deflection of the ordinary galvanometer is also proportional to the current flowing through it, it follows that the indicator of the thermo-cross bridge will deflect directly proportional to the current. By utilizing the above method we are able to measure very small currents.

Assuming that the current $I$ and the current to be measured $i$, are not in phase with one another, we can then write for pure sine waves

$$\begin{aligned} I &= I\ max.\ sin\ (2\,\pi f)t \\ i &= i\ max.\ sin\ (2\,\pi f\,t + \Psi) \end{aligned} \qquad (24)$$

At any instant we get for the current flowing through the galvanometer

$$i_g = k^1 . I_{max}\, sin\ 2\,\pi f\,t\,.\,i_{max}\, sin\ (2\,\pi\, ft + \Psi)$$

where $\Psi$ is the displacement of phase between $I$ and $i$. For the average value we obtain

$$i_{g_{AB}-g_{AC}} = k^1 . \frac{1}{T}\int_0^T I\ max\,.\,i\ max\,.\,sin\left(\frac{2\,\pi}{T}t\right) \times sin\left(\frac{2\,\pi}{T}t + \Psi\right)dt \qquad (25)$$

Solving, equation 25 gives the expression

$$i_{g_{AB}-g_{AC}} = k^1 I\ eff\,.\,i\ eff\ cos\ \Psi \qquad (26)$$

which shows that for a constant current *Ieff* the deflection of the galvanometer is proportional to the effective value of the current. The displacement $\Psi$ only diminishes the sensibility, but can be kept constant, and thus does not affect the proportionality of the thermo-cross bridge. Furthermore, we learn that the above arrangement can be used as phaseometer.

In order to prove the proportionality of the thermo-cross bridge Tables III and IV are given here. Both tables show that the deflections $\alpha$ of the galvanometer increase linearly with the currents to be measured. The results in Table III satisfy the equation

$$\alpha = 300\,.\,I\ eff$$

and those of Table IV are represented by

$$\alpha = 265\,.\,I\ eff$$

TABLE III

| 0.14 | 38.0 | 271 | $r_3 = 36.4\Omega$ |
| 0.16 | 42.5 | 265 | |
| 0.18 | 47.5 | 264 | $r_4 = 36.7\Omega$ |
| 0.20 | 52.0 | 260 | $f = 50$ cycles/sec |
| 0.22 | 58.5 | 266 | *I eff* not in phase with *i eff* |
| 0.25 | 66.0 | 264 | |

As the data in both tables were obtained under the same conditions, we have $cos\ \Psi = \frac{265}{300} = 0.8825$ as an expression for the displacement between *I eff* and *i eff*. This corresponds to an angle $\Psi = 28°3'20''$.

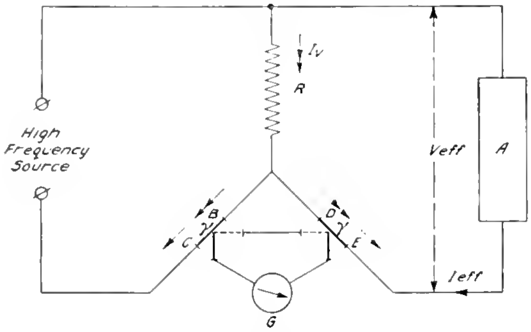

Fig. 8. A Variation of the Thermo-Cross Bridge shown in Fig. 7. Both Current and Energy can be measured on this Bridge

A modification of this thermo-cross bridge is shown in Fig. 8. This arrangement not only enables us to measure the current but also the energy of a high frequency system and therefore we have a high frequency wattmeter operating by the action of thermocouples. In Fig. 8, *A* represents the device which consumes the energy, *BC* and *DE* are small heating wires for the two thermocouples, which are indirectly heated. *V eff* denotes the drop in potential across the energy consuming apparatus and *I eff* the corresponding current. *R* is a resistance which is so large that the current flowing through it is proportional to the voltage drop over the energy consuming apparatus. Then at any instant the current $\left(\frac{I_v}{2}+I\right)$ will flow through the heating wire *BC*, and the current $\left(\frac{I_v}{2}-I\right)$ will flow through the wire *DE*, where

$$I_v = k . V \tag{27}$$

That is, the current $I_v$ is proportional to the voltage $V$. Hence if the instantaneous values of the voltage and the current carried by the load at *A* are expressed by the relations

$$V = V\ max. sin\ (2\pi\ ft + \phi)$$
$$I\ = I\ max\ \ sin\ (2\pi\ ft)$$

the galvanometer deflection $\alpha$ is given by

$$\alpha = K . \frac{1}{T} \int_0^T V max. I max. sin\left(\left(\frac{2\ \pi}{T}\right)t + \phi\right) \times sin\left(\frac{2\ \pi}{T}\right)t\ dt = K . V\ eff . I\ eff\ cos\ \phi \tag{28}$$

where $K$ is a constant and $\phi$ the phase displacement between the voltage and the current. Equation 28 indicates that we are thus able to measure the energy of a high frequency system. It is yet to be noted that in equation 27 it was assumed that $I$ is proportional to the voltage across the apparatus which is consuming energy. This assumption is not quite true since there is also a drop in the heating wire, *DE*, which has the resistance *r*, therefore the actual expression for the value of $I_v$ becomes

$$I_v = k(V + V_1) \tag{28a}$$

where $V_1$ is the drop across the heating wire. This correction factor is derived in the following section, and a diagram of connections given in Fig. 9, which shows an arrangement that eliminates this error. The derivation is given for the case of a direct current, since the correction factor will be the same for both alternating and direct current, as *R* and *r* are assumed to be non-inductive. According to Kirchhoff's law the algebraic sum of the incoming and outgoing currents at a point is zero. Hence for the junction point, *O*, we obtain

$$I_1 = I_2 + I_v \tag{29}$$

and by solving for $I_1$ and $I_2$, we get

$$\left.\begin{aligned} I_1 &= I + \frac{I_v}{2} \\ I_2 &= I - \frac{I_v}{2} \end{aligned}\right\} \tag{30}$$

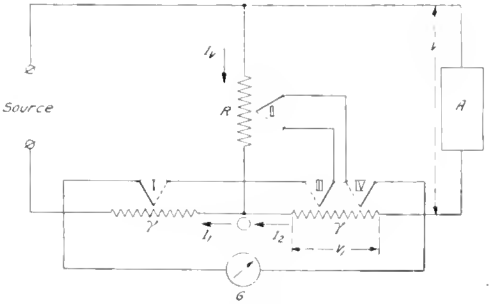

Fig. 9. A Scheme of Connections which is an Improvement over that shown in Fig. 8

The actual dissipation of energy in *A* is

$$W = V . I_2 \tag{31}$$

If only the thermo-couples *I* and *III* are used, the deflection of the galvanometer will be

# APPLICATION OF POWER APPARATUS TO RAILWAY SIGNALING

By H. M. Jacobs

Signal Accessories Department, General Electric Company

This article is the second of a series of three on the subject of railway signals that the author has contributed to the Review. It deals with automatic block and interlocking signals; the former being located along the right-of-way, while the latter are placed at terminals, cross-overs, etc., and are controlled from towers. The automatic block signals are built for operation on a-c. and d-c. circuits; the d-c. signals receiving their current in most cases from storage batteries located at convenient points along the route, while the a-c. signals are supplied with energy from transmission lines. The interlocking signals are either manually operated or are controlled through electric-pneumatic or all-electric devices. The final article of the series will consist of descriptions of some of the larger installations, and will appear in the December issue.—Editor.

In an article in the December, 1913, issue of the General Electric Review, there was given, in a most elementary way, a short historical sketch of the general development of railway signaling and an interpretation of the various day and night indications of the semaphore signal in most common use. It will be remembered that railway signals are divided roughly into two general classes; viz, automatic block signals and interlocking signals, the difference being that the latter are located where there are switches, junctions or cross-overs, and are controlled by an operator located in a tower, while the former are located along the stretches of track outside the interlocking zones and are automatic. This article will give a short description of the various systems of each class of signals, showing in each case the application of the various kinds of power apparatus.

## Automatic Block Signals

Automatic block signals may be divided into two general classes, d-c. operated and a-c. operated. As all d-c. signals are operated by batteries, this class may be further subdivided according to the various battery systems used; viz., primary batteries, portable storage batteries, and stationary storage batteries.

It is well for us to consider the d-c. systems first, for actual automatic block signals did not come into existence until after the invention of the d-c. track circuit; and it was quite natural that, inasmuch as the track circuit was fed from a battery, the signal mechanism should be operated from a like source of power.

Primary batteries were first used, the renewals being made on the ground. Following this came the portable storage battery, the discharged batteries being exchanged for batteries newly charged and taken to convenient charging stations. Some roads now employing this system have battery trains which periodically exchange charged sets for those discharged, the charging being done at one or more large plants conveniently located along the system. Some of these plants have generating apparatus as large as 50 to 300 or 400 kw. capacity. Other charging stations are located at the railroad shops, the power for charging being taken from the main d-c. busbars, as in this way the necessity of special generating apparatus is avoided. Still other roads establish charging stations at several convenient pumping plants to take care of the batteries on each particular division. In this case the charging equipment may consist of a small generator capable of charging from three to five groups of batteries, and driven by either a steam turbine, marine engine, or gasolene engine, and controlled by a simple switchboard. By designing the apparatus so that its operation is exceedingly simple, the pump man always on duty may look after the charging and in this way effect a great saving in labor.

The third class, or stationary battery scheme, employs at each signal location duplicate sets of batteries so connected to a battery charging switch that they may be interchanged without interrupting the discharge line or opening the series charging line. The switch is also arranged so that when a battery is sufficiently charged it may be cut off from the series line and allowed to stand idle until required. Fig. 1 illustrates such a switch in the position of transferring batteries. It has two interlocked motions; namely, a transverse motion, to interchange the batteries on the discharge circuit, and a vertical motion to cut off the one battery from the charging circuit and cut the series line through the switch without interruption by first inserting a resistance at the moment of cutting off the battery and then inserting a short-circuiting strip. The motions are so interlocked that the battery cannot be cut off from charge until it has first been cut free from the charging line. At no time is it possible to interrupt the discharge circuit. On account of the varying rates of discharge of the track batteries and signal batteries, these are grouped on separate switches. The line side of these switches is connected in series with the line side of the switches at the adjacent locations, until several consecutive locations (the number of which depends on the total number of cells of batteries possible to have on charge at any one time and the voltage drop in line wire) are connected in series to one feeder from a small power station. These charging stations usually feed out at a maximum of 600 volts on each of two lines running in opposite directions along the right-of-way. If the track has a branch line at this point, or a junction, more feeders are added to accommodate it.

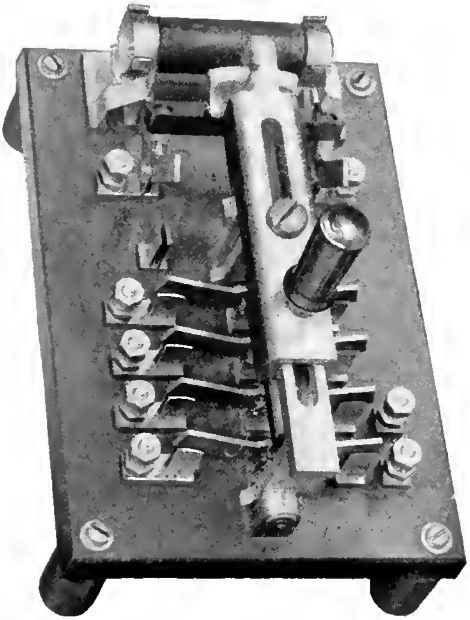

Fig. 1. **Battery Charging Switch and Diagram of Connections**

The power apparatus usually consists of a two unit motor-generator set, the generator delivering power at 350 to 600 volts to the switchboard. In each feeder there is located a line rheostat to independently maintain the proper charging current. Fig. 2 illustrates a two-way switchboard built for the New York Central & Hudson River R. R., and Fig. 3 a motor-generator set similar to the one controlled from this board. The line rheostats are mounted on the wall of the station.

One other system more or less special should be mentioned; that employing both d-c. and a-c. Batteries are used for the operation of the signals and a-c. for the track circuits in order to overcome the effect of heavy foreign current. Instances of this kind are very rare and usually are a reconstructed d-c. system arranged to overcome increased foreign current. When it is necessary to install a-c. track circuits, the whole system is usually changed to a-c. operation.

The reader may have wondered where the batteries at the various signal locations are housed. Figs. 4 and 5 illustrate respectively a typical battery well and chute, and it will be noted that every precaution is taken to protect the batteries from frost.

For the systems described above, the power apparatus required is as follows:

(*A*) *Primary battery systems.*
- Track circuit resistances (except where used with gravity cells or high internal resistance batteries).
- Low voltage lightning arresters.

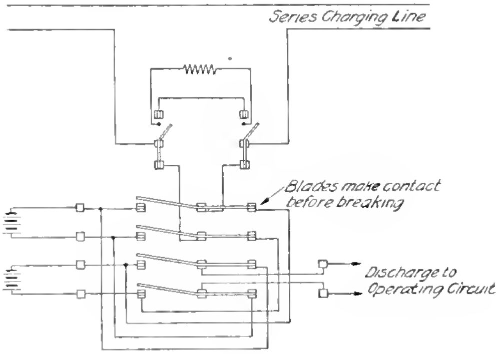

**Fig. 1-A**

(*B*) *Portable storage battery systems.*
- Complete charging equipment: Prime movers, generators, switchboards and rheostats.
- Track circuit resistances.
- Low voltage lightning arresters.

(*C*) *Stationary storage battery systems.*
- Complete charging equipment: Prime movers, generators, switchboards and rheostats.
- Choke coils, 600 volt lightning arresters.
- Battery charging switches.
- Track circuit resistances.
- Low voltage lightning arresters.

On account of the impossibility of static conversion and the impracticability of rotary conversion of direct current, and the excessive losses at low voltage transmission, no extensive d-c. system without the use of batteries has been devised. Alternating current, of course, will permit of transmission at high voltages and transformations to the proper working voltages by means of static transformers at various locations, thus effecting a very great saving in transmission line losses.

Fig. 2. Switchboard for Series Line Charging, New York Central & Hudson River Railroad

As noted in the previous article, a-c. systems came into use as a remedy for the disturbing effects of propulsion current on electrically operated roads. Its adoption on steam railroads is largely a question of reduced maintenance, elimination of foreign current troubles due to proximity of interurban trolley lines, power economy over battery systems, ability to run longer track sections, or anticipation of future electrification. It is not our purpose to discuss the relative merits of the two systems, a-c. and d-c., or of the various subdivisions.

The continuity of service of an a-c. system depends almost entirely on the reliability of the generation and transmission system. Only in the third mentioned class of d-c. signals is there a transmission line, and should this fail for a few minutes or even a few hours the system would continue to operate because the batteries connected thereto are not the ones in operation at the time being. But the continuity of operation of a-c. signals is a direct function of the transmission line service; and for this reason the generating apparatus, controlling and switching devices, and the transmission, transformation and protection systems must be of the very best. The majority of roads using a-c. signals have the customary aerial line paralleling the tracks.

Some roads generate and transmit single-phase; others generate three-phase and transmit single-phase, using the other two phases locally for lighting and power; while still other roads generate and transmit three-phase. A single-phase secondary distribution system may be supplied from a single-phase line, or from one phase of a three-phase transmission line; but a two-phase secondary distribution system must be supplied from a polyphase transmission line—three-phase with T-connected transformers or two-phase with two transformers per location. But the writer knows of no instance where an extensive two-phase transmission system is in operation, probably because of the greater economy of the three-phase transmission.

The usual transmission voltages are 4400, 3300 and 2200, and at each location this is stepped down to 110 or 220 volts for operating the signal mechanism, and further to 6, 8, 10, 12 or 15 volts for the track circuits and lights. The lowest voltages are obtained sometimes by taps or extra coils on the main transformers and sometimes by separate trans-

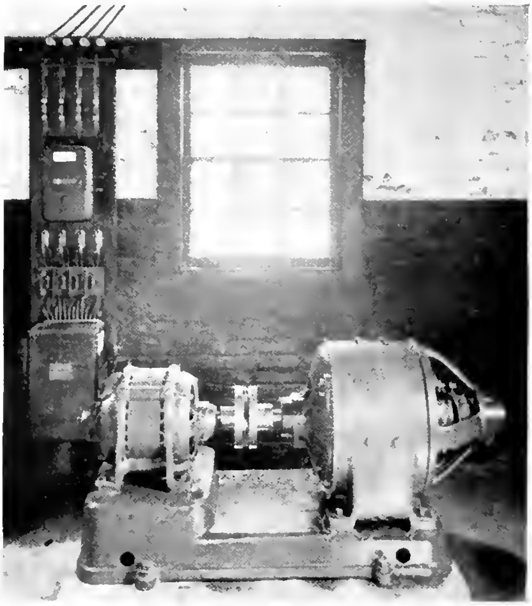

Fig. 3. Motor-Generator Set Controlled from Switchboard shown in Fig. 2

formers connected to the 110-volt circuits. Frequencies are either 25 or 60 cycles, and when a choice may be made for steam or d-c. roads, 25 cycles is the more preferable, as power at this frequency is more efficiently transmitted through the rails, thus making possible longer track sections. But if there is a possibility of a-c. electrification of part or all of the road, 60 cycle will be chosen, since the propulsion current will undoubtedly be 25 cycles and the frequency of the signal circuit must not be a low harmonic of the propulsion current on account of interference and false indications resulting therefrom.

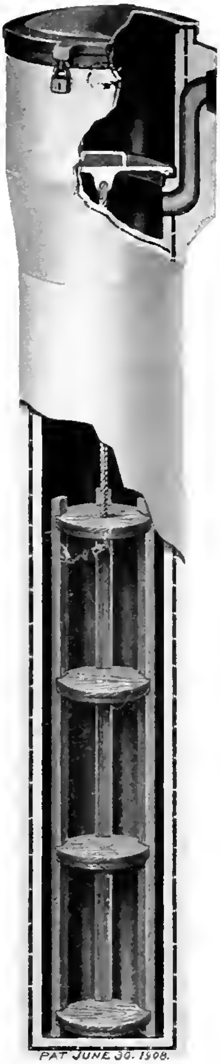

Fig. 5. Concrete Battery Chute

The Chicago, Milwaukee and St. Paul Railroad will soon place in service the last 40 miles of a 458-mile installation of automatic signals on which work was started the latter part of 1912. The complete installation is operated from a single-phase, 4400-volt, 60-cycle transmission line supplied at intervals exclusively from 2200-volt, 60-cycle commercial sources. In only one instance is the supply considered unreliable and to provide against interruption a synchronous motor-generator set with storage battery reserve has been installed.

Fig. 4. Concrete Battery Wall

In three-phase transmission various means are resorted to, to balance the load. In some instances, the signal load is carried entirely on one-phase, and the station and building lighting, which is connected at night only, on the other two. Inasmuch as the power factor of the signal system is usually from 50 to 65 per cent, it has been found advisable to carry the signal load and the lighting load balanced on all three phases as nearly as possible. In one instance on the Southern Railway this has been nicely accomplished

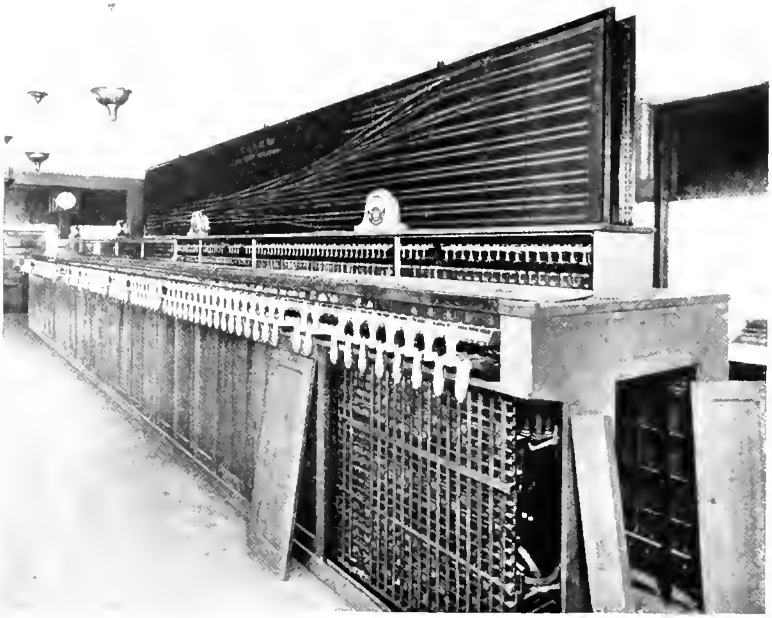

Fig. 6. Electrodynamic Interlocking Machine, Chicago & Northwestern Railway, Chicago, Ill.

by transposing the line wires at such intervals as to divide the particular installation into approximately three equal parts, the two lower wires being used throughout for signal purposes and the top wire and alternately one of the lower wires for the station lighting. The signal load is thus equally distributed and the lighting load so distributed as to obtain practically an equally balanced load at all times. Because of the inherent characteristics of T-connected transformers, a practically balanced two-phase load will give a similarly balanced three-phase load; but to guard against the unbalancing effect of heavy traffic on one track and light traffic on the other, the two phases supplying the two tracks are interchanged at intervals. This system has been adopted as standard by the Atchison, Topeka & Santa Fe R. R.

All of the above mentioned systems have been of the aerial transmission line construction. The Pennsylvania R. R. has done, and is doing, much in underground transmission with single-phase, 3300 volt, 60 cycle power. The wires are laid in asphaltum pitch in wooden trunking about two feet under the surface. This system is extremely expensive, but it eliminates the troubles due to wind and sleet storms, lightning, and kindred aerial line troubles. It also introduces by its capacity quite a correcting influence for low power-factor.

The power apparatus required for the various a-c. systems comprises in whole or in part the following power apparatus:

Generators: Steam, gasolene or motor driven.
Switchboards.
Transformers and fuses.
Lightning arresters, choke coils and line material.
Line sectionalizing equipment: Oil switches, line (power) relays.
Resistance units and reactance coils.

### Interlocking Signals

The second general class of railway signals, interlocking signals, are those located at switches, junctions or crossovers, and are controlled by one or more operators located in a tower. They are so termed because their movements are controlled by a mechanism the parts of which are so interlocked as to

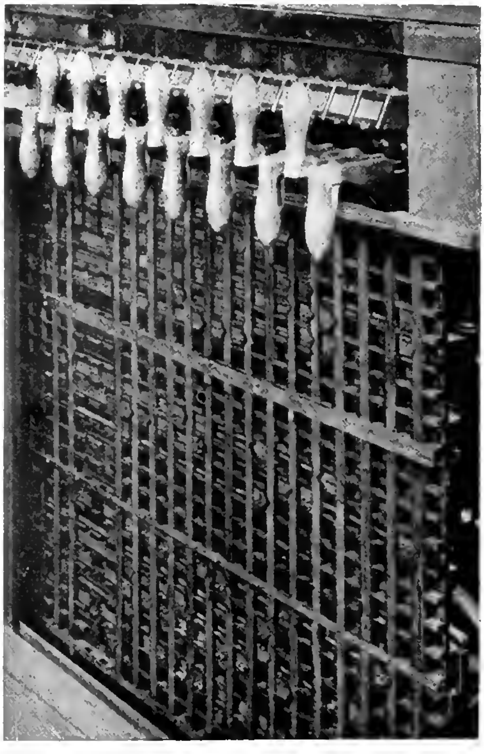

Fig. 7. Detail of Locking Bed of Machine shown in Fig. 6

prevent the movement of the switches and signals that would give conflicting information for the movement of trains. Each separate switch, signal or derail is operated by a separate lever, except in certain cases where they are operated always in conjunction. The levers are all concentrated in a single frame. The interlocking is accomplished in a so called "locking bed" placed in either a horizontal plane back of the levers or in a vertical position in front of the machine. Fig. 6 illustrates a machine of the latter type. By a combination of horizontal or locking bars, and vertical or tappet bars, with locking dogs, certain levers are locked against movement by the movement of others. Such a combination of levers and interlocking rods with their accessories forms what is called an interlocking machine. A section of a machine of this kind showing the interlocking rods, is illustrated in Fig. 7. The locking bars carry V shaped dogs which fit into similarly shaped notches in the tappet bars in such a manner that when one tappet bar is moved vertically by its lever one or more locking bars are moved by the dogs which engage them, and the dogs on them slip into the notches on various tappet bars, thus locking and preventing the movement of their corresponding levers by the operator. In this principle of locking all types of machines are the same.

Fig. 8. Mechanical Interlocking Machine with A-C. Electric Locks. A-C. Indicator on Wall

There are today in common use three general types of interlocking; viz.: The mechanical, the electro-pneumatic, and the all-electric.

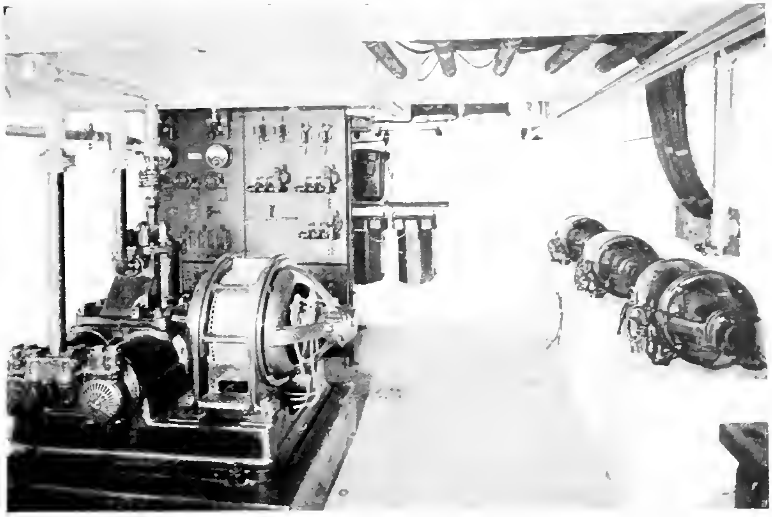

Fig. 9. Power Equipment in Basement of Tower at Montclair, N J., Delaware, Lackawanna & Western Railroad

While passing through some railroad yards the reader has doubtless noticed rows of one-inch iron pipe parallel to the tracks on pipe carriers extending from a signal tower to the various switches and signals. These pipes are the medium by which the signal devices are mechanically controlled by the operator in the tower, and the plant is of the "mechanical" type. Such a plant is illustrated in Fig. 8, and shows clearly the locking bed where the levers are interlocked against movements as described above. Mechanical plants are restricted to small territory owing to the limited physical strength of the operator; power-operated interlocking plants, electro-pneumatic and "all-electric," therefore afford more extensive control.

In electro-pneumatic plants the signal devices are operated by compressed air under low voltage electro-magnet control from the machine in the tower. Fig. 9 shows the power equipment in the basement of the Montclair, N. J., Delaware, Lackawanna & Western Railroad tower. Relay racks occupy the entire ground floor and the interlocking machine is on the second floor. Compressed air at 90 to 100 lb. per sq. in. is supplied from either one of the two duplicate motor-driven

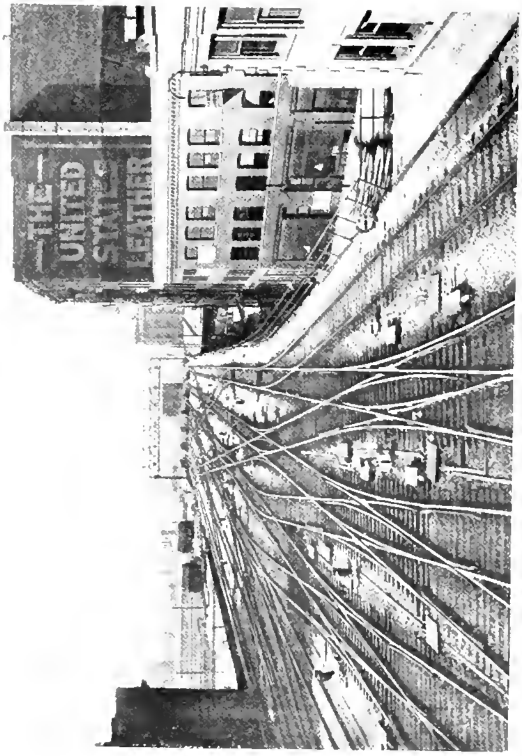

Fig. 10. Track Layout of Switches and Signals Controlled from Machine shown in Fig. 6

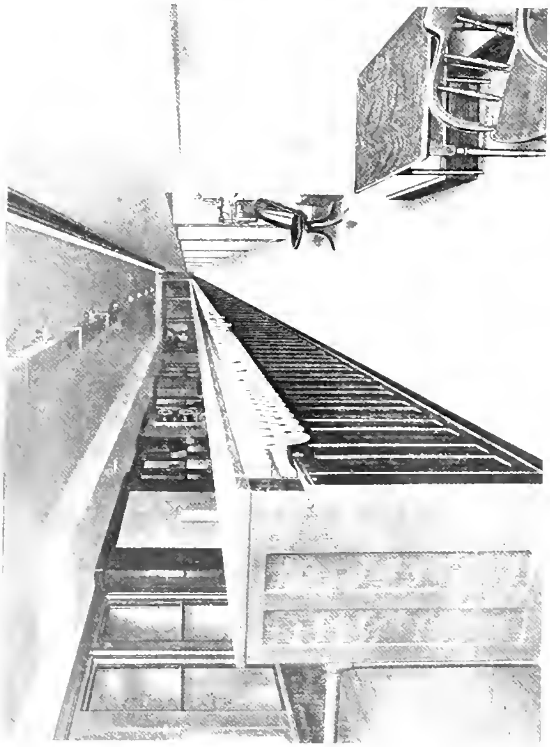

Fig. 11. Electrodynamic Interlocking Machine, Grand Central Terminal, New York City

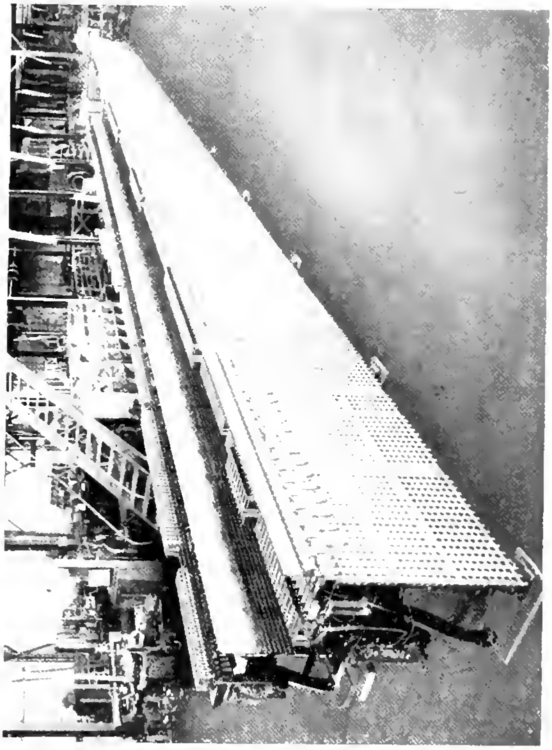

Fig. 12. Two Electrodynamic Machines for Grand Central Terminal, Partly Assembled in Factory

Fig. 13. All-Electric Interlocking Machine, New York, Westchester & Boston Railroad, Columbus Avenue Tower

compressors. Power for operating the magnet valves on the signals and switches is supplied through the machine controlling mechanism from a 20-volt storage battery, and the track circuits are fed from two 5-volt groups of storage batteries in multiple. All batteries are in duplicate and the switchboard is so arranged that the idle batteries may be charged from the motor-generator sets in various combinations. This installation will be described more fully in a succeeding article.

"All-electric" machines require quite an extensive power plant equipment, as independent circuits of three different voltages are necessary, each supplied from a single or duplicate set of batteries. The signal and switch motors operate from a 110-volt main battery, the machine locks, lights, and indicators from a 15- to 20-volt battery and the track circuits from an 8- to 10-volt battery. For this a charging equipment is required, the choice of which is governed by commercial power conditions; for instance, steam or gasolene engine-driven generators in isolated plants or where the commercial power is unsatisfactory, and motor generator sets or mercury arc rectifiers where dependable commercial power is available.

The application of alternating current for machine locks, lights, indicators and track circuits has simplified the battery charging problem, making necessary only the 110-volt battery for operating the signal and switch motors. The charging apparatus then consists either of a mercury arc rectifier equipment or switchboard with motor-generator set. The battery is usually of sufficient capacity to operate the interlocking several days on a charge. To guard against interruption in service, auxiliary alternating current generating apparatus consisting of gasolene- or steam-driven units are frequently used, but at many interlockings the traffic conditions are such that the time required to put such auxiliary units into service would cause very serious delays. In some cases to overcome this the storage battery has been made extra large, and the motor-generator set normally used for charging it arranged for reverse operation; that is, the d-c. generator may operate as a motor driving the a-c. motor (which in such a case must be of the synchronous type) as an a-c. generator. This arrangement is used at Jamaica, N. Y., on the Long Island Railroad. In case the a-c. source of power is not of the same frequency as the signal circuit, the motor is made of the induction type, of sufficient capacity to drive both the a-c. generator and a d-c. generator for charging the battery. Should the a-c. source fail, the d-c. machine will act as a motor driving the a-c. machine loaded as before. In some instances more than one supply is available and automatic switching equipments are oftentimes provided to shift the operation from one to the other.

The accompanying illustrations show several interesting views of interlocking machines and installations. Fig. 6 previously referred to shows the General Railway Signal Company's electro-dynamic machine at the Lake Street tower, Chicago & Northwestern terminal, Chicago, and Fig. 10 the track layout of switches and signals controlled therefrom. The iron boxes located between the tracks enclose the switch motor machanisms. The dwarf signals to govern slow speed and back-up movements, located between the tracks and the semaphore signals on the structural steel towers across the tracks, are clearly shown. Fig. 11 illustrates a similar type of machine built by the same company and installed in the Grand Central terminal of the New York Central & Hudson River Railroad, New York City. To handle the immense amount of traffic, a second similar machine is required, one having 360 and the

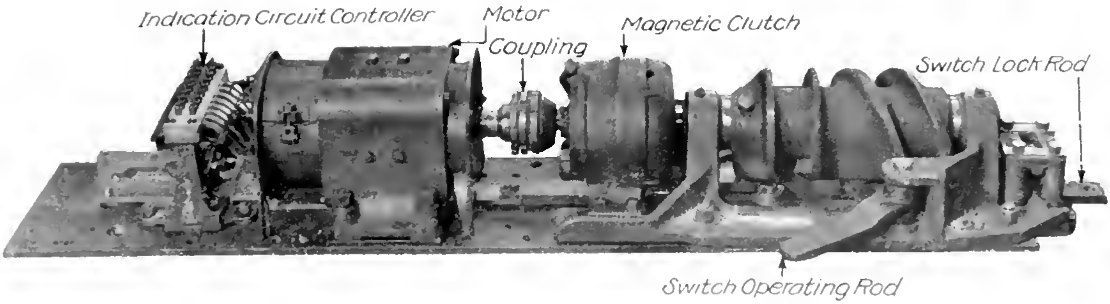

Fig. 14. Electrically Operated Track Switch

other 400 operating levers, both of which are shown in Fig. 7, as assembled in the factory. A small machine installed in the Columbus Avenue tower of the New York, Westchester & Boston Railway Company, built by the Union Switch and Signal Company, is illustrated in Fig. 8. Directly above the machine is a track diagram which shows at a glance just which tracks are occupied and which are clear.

In a succeeding article several installations of power apparatus for signal use will be described in detail and the application of various kinds of equipment shown.

---

# THE HEATING AND TEMPERATURE SECTION OF THE A.I.E.E. STANDARDIZATION RULES

By H. M. Hobart

Chairman of Subcommittee on Rating, 1914, A.I.E.E. Standardization Rules

Consulting Engineer, General Electric Company

The basis of this article is a table (supplemented by references and explanatory notes) which has been prepared by the author to furnish, in a clear and compact form, a record of the limits of "observable" temperature rise as prescribed by the 1914 A. I. E. E. Standardization Rules. The simplicity of presentation and convenience of application to which the rules have been reduced in this table should be appreciated by all interested in the heating of electrical machinery.—Editor.

In sections numbered from 149 to 200 inclusive of the 1914 Standardization Rules of the A.I.E.E. are set forth the new requirements as regards heating and temperature. On most occasions the data which is really needed relates to the permissible temperature rise. In the Table presented in this article, the endeavor has been made to give in definite form the permissible values of the observable temperature rise for various occasions. Three methods numbered I, II and III have been given, to which resort may be made in determining the temperature of electrical machinery. A hasty study of the rules might lead to the conclusion that these are *alternative* methods, and that any one of the three may be used in any case. A closer study of the rules will show that this is not the intention. Irrespective of the order in which these methods are numbered, the most general method is that numbered II. In the Table in section 192 of the rules, this is designated as the "resistance method;" but there is a parenthetic statement reading: "With Thermometer Check when Practicable." Method I is designated: "Thermometer Only." Close study of the rules shows that the purpose is, that of these two methods, number II is the fundamental method and number I is a special case to which resort is permitted under certain circumstances. With the exception of machines for which the limits are definitely stated and for which Method III is exclusively employed, the general case will require Method II. The spirit of Method II (which is that adopted by the I.E.C.) is that both resistance and thermometer measurements shall be made, and the highest temperature obtained by either method shall be regarded as the observable temperature.

With the present attitude entertained in many quarters toward resistance measurements, however, it was felt that it would be premature to make the use of resistance measurements mandatory for all cases. Furthermore, the expense of the resistance as compared with the thermometer method would make it unreasonable to employ it in the case of small machinery made in large quantities. Consequently, Method I was provided, and under certain circumstances (set forth in the text of the Standardization Rules), the supplier of the machine can elect to employ exclusively thermometer methods. But when this prerogative is exercised, the permissible limit of observable temperature is lower than when he employs Method II and makes both thermometer and resistance measurements. If the supplier of the machine elects to employ exclusively thermometric measurements, he has no option but to accept the penalty of keeping within the lower observable temperature rise. There is another group of cases where resistance measurements would not be desirable, as in the case of series windings, where the contacts and connections constitute a considerable percentage of the total resistance. In such instances, the rules state (see section 179) that the resistance measurements need not be made. This does not throw the case amongst those to which Method I applies, since it is not a case of

## TABLE SHOWING, FOR VARIOUS KINDS OF MACHINES, THE LIMITS FOR THE "OBSERVABLE" TEMPERATURE RISE, PRESCRIBED IN THE A.I.E.E., 1914, STANDARDIZATION RULES

| | Description of the Winding or Parts | Prescribed Methods for Determining the "Observable" Temperature Rise | | LIMITING RISE OF "OBSERVABLE" TEMPERATURE A1 | A2 | B | Corresponding Ambient Temperature of Reference* | Remarks |
|---|---|---|---|---|---|---|---|---|
| I | All windings in which the conductors have bare surfaces, (such as edgewise-wound strip conductor, or copper castings), against which thermometers may be directly applied. | Use Method I, qualified by Section 176. [See also the first footnote on Page 26.] | | 50 | 60 | 80 | 40 | † |
| II | Stator field windings (with conductors covered by insulation) whose proportions and design do not preclude reasonably accurate commercial determinations of the temperature by the resistance method. Also rotor field windings of these proportions and design when the speed is not too high to permit of making satisfactory estimates from thermometer readings taken at intervals after shutdown. | Method II is prescribed. But the party supplying the machine has the option to employ exclusively Method I, if he accepts the penalty of keeping within the lower limits. | When Method II is Employed (See Section 177) | 45 | 55 | 75 | 40 | |
| | | | When Method I is Employed (See Section 175) | 40 | 50 | 70 | 40 | ‡ |
| III | Field windings on rotors of turbo-generators and other extra-high-speed machines. (See last footnote on Page 26.) | Method II, with exemption from requirement to make check reading by thermometer. | | 45 | 55 | 75 | 40 | |
| IV | Stator and rotor field windings (with conductors covered by insulation) where the joints and connections form a considerable part of the total resistance. (See Section 179.) | Method II, but employing only thermometers. (This is *not* Method I, since that relates to the *arbitrary* exclusion of resistance measurements when they could approximately be made.) | | 45 | 55 | 75 | 40 | § |
| V | Armature windings on all rotors. Also armature windings on all stators of machines with cores of less than 50 centimeters length (if of not over 500 kv-a.), irrespective of voltage. Also armature windings of all stators of machines of less than 50 centimeters width (if for less than 5000 volts), irrespective of rating. (See Section 185.) | Method II is prescribed. But the party supplying the machine has the option of employing exclusively Method I, if he accepts the penalty of keeping within the lower limits. | When Method II is Employed (See Section 177) | 45 | 55 | 75 | 40 | |
| | | | When Method I is Employed (See Section 175) | 40 | 50 | 70 | 40 | |
| VI | Armature winding on all stators of machines with cores of 50 centimeters length and greater. Also armature windings of all stators for 5000 volts and over, if of over 500 kv-a. rating, regardless of core length. (See Section 185.) | Method III is prescribed | For double-layer windings. (See Section 186.) | 50 | 60 | 80 | 40 | |
| | | | For single-layer windings for a pressure of 5000 volts or less. (See Section 186.) | 45 | 55 | 75 | 40 | |
| | | | For single-layer windings above 5000 volts. [E represents rated pressure between terminals in kilovolts.] (See Section 186.) | 45-(E-5) | 55-(E-5) | 75-(E-5) | 40 | |
| VII | Transformers in which the windings are surrounded by air. (See Section 180.) | Method II is prescribed for all cases. (See also Section 180.) | | 45 | 55 | 75 | 40 | |
| VIII | Transformers in which the windings are immersed in oil and in which the oil is cooled by the circulation of water through a coil of pipes immersed in the oil. (See Section 194.) | Method II is prescribed for all cases. (See also Section 194.) | | 50 | 50 | 50 | Temperature of Inlet Water 25° | |
| IX | Transformers immersed in oil but without water cooling. (See Section 193.) | Method II is prescribed for all cases. (The stated rises are permitted only in so far as they do not occasion a temperature in excess of 90 degrees in any part of the oil, as required by Section 193 of the rules.) | | 45 | 55 | 75 | 40 | ¶ |

---

* When the machinery is to be employed in locations with an ambient temperature exceeding that of reference, the approved rise must be reduced by the amount of the excess. But in the absence of special information the standard ambient temperatures of reference set forth in Sections 153 and 157 are to be assumed.

† When conductors of copper castings are supported by Class C insulation, no temperature limits are specified.

‡ When the temperatures are obtained after a shut-down, the methods of bringing the rotor to rest should be such as to influence these temperatures as little as possible.

§ In this case, the results from resistance measurements would be too low and it would be futile to make them.

¶ The 90-degree limit for the oil will usually control the rating.

(Continued on following page)

* When the machinery is to be employed in locations with an ambient temperature exceeding that of reference, the approved rise must be reduced by the amount of the excess. But in the absence of special information the standard ambient temperatures of reference set forth in Sections 153 and 157 are to be assumed.

† For temperature rise in service, see Section 440.

electing to employ only thermometer measurements, when resistance measurements could reasonably be employed. In such a case as this, the supplier of the machine is not compelled to keep within the observable temperature corresponding to Method I, since he does not arbitrarily select the alternative of making thermometer measurements only, and hence there is no reason why he should pay the penalty of keeping within the lower limits of temperature rise.

Other instances which come within Method II and in which only one kind of measurement need be made are those where it would be impracticable, or unreasonable, to require the thermometer check. Amongst such cases is that of rotors of turbo-generators. It takes a long time to bring such rotors to rest, and by the time it is practicable to take thermometer measurements of the temperature of the rotor, so long an interval has elapsed that such measurements would be of no value. The endeavor has been made to bring together in the accompanying table, in the briefest practicable form, the most important data relating to the observable temperature rise permitted by the rules. It would be desirable however, that in addition to consulting the values set forth in the table, the accompanying sections of the rules to which reference is made should be consulted with a view to understanding their real intent.

The designations $A_1$, $A_2$, B and C, in the table, relate to the classes of insulation and may be interpreted by referring to Sections 188 and 190 of the rules.

# FROM THE CONSULTING ENGINEERING DEPARTMENT OF THE GENERAL ELECTRIC COMPANY

## OSCILLATING CURRENT TRANSFORMER

The Consulting Engineering Laboratory has recently developed a portable oscillating current transformer, designed for the purpose of testing insulators and bushings with high frequency high potential.

The advantages of testing with high frequency high potential are, that the corona spreads more evenly and clings more closely to the surface of the porcelain, and thus searches out more thoroughly for flaws in the porcelain than the 60-cycle high potential. The high frequency test approximates more nearly to the conditions under which insulators fail in service, namely, surges due to lightning and arcing grounds. The testing outfit is more compact and easier to handle than the corresponding 60-cycle outfit. The high frequency testing outfit for testing insulators up to 150,000 volts is shown in the illustration.

The oscillating current transformer consists of two concentric windings arranged vertically in a stoneware jar and immersed in transil oil. The two windings are connected together at one end and grounded, the outer coil consisting of a few turns of copper strip wound on a form of treated wood. The ends of the coil are brought out through the stoneware jar under the oil and are connected to a condenser and spark gap. The condenser is charged by a 13,200-volt 2½-kw. transformer. When the voltage across the condenser reaches a sufficient value to break down the spark gap, an oscillatory discharge takes place through the oscillation transformer, the frequency being equal to $\frac{1}{L\pi\sqrt{LC}}$ This oscillation is communicated to the high tension coil wound in a single layer on a hard rubber form. The voltage induced in the high tension winding depends on how nearly the natural frequency of the two circuits coincide. By making the frequency of the high tension winding considerably higher than the low tension winding, it is possible to obtain good regulation, as the addition of more insulators decreases the frequency of the high tension circuit, and this brings it more nearly into resonance with the low tension circuit. With the outfit shown in the illustration the addition of 16 suspension type insulators tested in multiple in strings of two, gives a voltage drop of 20 per cent.

A reactance divided into two coils is connected in series with the secondary of the 60-cycle transformer, so as to limit the current through the transformer when the spark gap breaks down and to prevent a power arc forming across the spark-gap.

Oscillating Current Transformer

The high frequency high potential is controlled by varying the length of the spark gap in series with the condensers. Voltages ranging from practically zero to 170,000 volts can be readily obtained.

The apparatus is supported on an angle iron frame mounted on casters and enclosed on all sides with perforated iron. A wooden cover encloses the top and supports a sphere gap, which is used for measuring the high frequency high potential; a graduated scale enables the gap to read off directly in volts.

The supply voltage is 110 volts 60-cycle; fuses and disconnecting switches are mounted inside the frame, the main switch being connected with a rod to a handle shown in the near corner of the illustration. The handle immediately below this is connected through a rod to the spark gap. These handles represent the entire control of the apparatus.

The frequency of the low tension circuit of the oscillating current transformer is 220,000 cycles.

P. E. Hosegood.

## QUESTION AND ANSWER SECTION

The purpose of this department of the REVIEW is two-fold.

First, it enables all subscribers to avail themselves of the consulting service of a highly specialized corps of engineering experts, or of such other authority as the problem may require. This service provides for answers by mail with as little delay as possible of such questions as come within the scope of the REVIEW.

Second, it publishes for the benefit of all REVIEW readers questions and answers of general interest and of educational value. When the original question deals with only one phase of an interesting suject, the editor may feel warranted in discussing allied questions so as to provide a more complete treatment of the whole subject.

*To avoid the possibility of an incorrect or incomplete answer, the querist should be particularly careful to include sufficient data to permit of an intelligent understanding of the situation. Address letters of inquiry to the Editor, Question and Answer Section, General Electric Review, Schenectady, New York.*

### CROSS-ARM BRACES: CHOICE OF POSITION

**(115) Why are the cross-arm braces used in pole-line construction sometimes attached to the pole side of the cross-arm while at other times they are fastened to the other, or outer side, of the cross-arm?**

**What are the merits of each method of fastening?**

There is only one real argument, and that dictates that the braces shall be placed on the outer side of the cross arm. By bolting them to this face, they assist the arm in resisting the twisting action to which it is subjected when an abnormal line strain developes due to a wire or cable breaking. When this unbalanced pull is in the direction away from the side of the pole to which the arm is attached, the braces are placed under compression; and, correspondingly, when the pull is in the other direction, the braces are placed in tension.

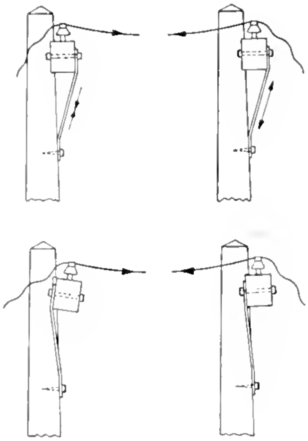

Fig. 1

If the braces are attached to the inner face of the arm, they can only provide support for an unbalanced vertical load on the arm. By accomplishing this only, they do not fulfill their complete function.

Fig. 1 will assist in making this explanation clear.

T.A.W.

### AUTOMATIC VOLTAGE REGULATORS: PARALLEL OPERATION

**(116) Will you please publish a detailed diagram of the connections which were briefly described in the answer to Question No. 107 (GENERAL ELECTRIC REVIEW, July, p. 771). It is desired that the diagram be applicable to the operation of two alternators controlled individually by separate automatic voltage regulators. The system which the units feed in parallel is three-phase delta connected.**

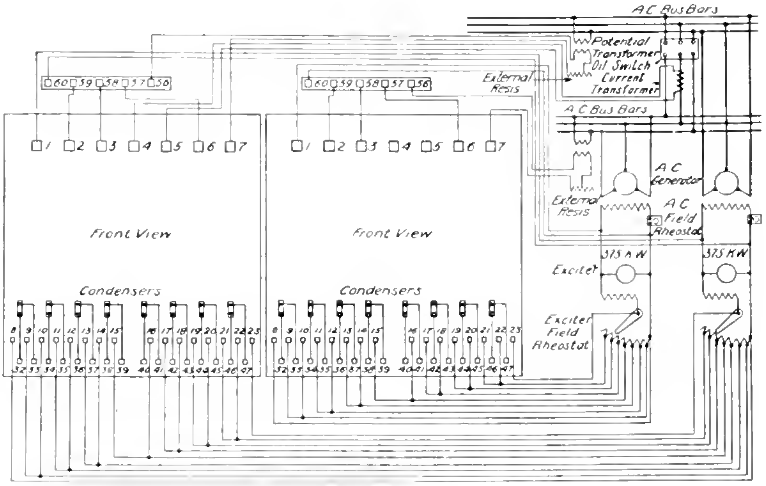

Fig. 1

Fig. 1, illustrates the automatic voltage regulator connections to be made for the control of the equipment specified.

O. C. R.

### AUTOMATIC VOLTAGE REGULATOR: CHANGE FROM A-C. TO D-C.

**(117) Can a standard alternating-current automatic voltage regulator be altered so as to operate on a direct-current circuit?**

No, certain inherent features in the design of an automatic voltage regulator for use on alternating current preclude any changes being made in it which will enable it to operate satisfactorily on direct current.

H. A. L.

### POLYPHASE SYNCHRONOUS CONVERTER: OPERATION ON SINGLE-PHASE

**(118) What would be the result if a synchronous converter was started up from the d-c. end and synchronized on the a-c. end, only one phase however being closed, the other two remaining open? The system is 25 cycle, three-phase, with generator neutral grounded. The transformer at the converter is delta double-star connected. The converter supplies an Edison three-wire system with grounded neutral. Also, what would be the result if an attempt were made to pick up load on the converter under these conditions?**

A synchronous converter connected as specified in the question, and supplying the neutral of the Edison three-wire system, would have a greater tendency to pulsate due to increased line drop, which is the result of operating single-phase instead of three-phase. The severity of the pulsation would be fixed by the characteristics of the particular machine and its supply line. It is altogether likely, however, that the converter would run satisfactorily at no-load on single-phase.

The amount of load that the converter would be capable of carrying is determined by this tendency to pulsate. If its operating characteristics were such that the machine would run stably at no-load and under load, the amount of d-c. power which could be drawn from it would be in the neighborhood of one-third normal capacity at unity power-factor with normal heating. This is based upon a value of heating between the maximum and average temperatures of the windings.

The d-c. voltage, of course, would be lower on account of the increased line drop and the change in the ratio of conversion within the machine. At no-load the decrease would be slight and under load probably somewhat more than 3 or 4 per cent. With normal field excitation of the converter, the d-c. voltage would also be decreased due to the reaction of the magnetizing current of the idle transformers which would be supplied by the converter. This 3 or 4 per cent is approximate and is accounted for by the change in ratio and drop in the secondary connections of the transformer, the surplus being due to the high-tension line drop, the amount of which cannot be predicted, of course, without knowing the dimensions of the line and the amount of energy being converted.

J. L. B.

### FEEDERS: TROLLEY CIRCUITS

**(119) What are the general considerations involved in the layout of trolley-wire feeders, particularly those for a line fed from one end?**

Feeders on railway systems have two functions; first, to increase the conductivity or carrying capacity of the trolley circuit, second, to permit sectionalizing the trolley wire.

Those sections of the trolley wire, which of themselves would be of insufficient capacity to carry the load, have taps spaced at frequent intervals (say 1000 ft. or oftener) at which additional current is brought in from feeders. For those other sections, which have a greater proportional current-carrying capacity, one or two taps are sufficient.

In the case of a stub-end feed with a number of cars operating over the entire section, it is frequently desirable to taper the feeders in order to get sufficient carrying capacity near the substation. That is, two or more feeders will go out from the substation and end in the trolley wire, one at a short distance, another at a farther point, and so on.

For the most economical use of the copper, the trolley should be fed at frequent intervals from every feeder where there are multiple feeders, but in practice the feeders are sometimes kept isolated from each other for special reasons. As an example of this, one feeder may be "boosted" to a higher voltage than normal and fed into the extreme end of the trolley wire so as to raise the potential at that point.

As regards uniform or tapered feeders it can be said that, for *approximately* the same maximum voltage drops, the weight of copper will be the same in either case.

It is customary to install switches across the section insulators in the trolley wire, in order to tie the whole system together and to get the greatest benefit from the copper installed by permitting one section to help those adjacent. In this case the section switches must be opened in order to isolate a section.

G.H.H.

### MINING LOCOMOTIVES: DETERIORATION

**(120) Will low voltage, due to very poor rail bonding, cause overheating and a rapid rate of deterioration of the mining locomotive motors to which it is applied?**

Overheating and a greater than normal deterioration of mining locomotive equipment (and in fact of any direct-current series-motor tractive apparatus) may well be expected when the condition of the rail bonding is bad.

Practically all mining locomotives use direct-current series motors. The speed of this type of motor is directly proportional to the counter e.m.f. at the motor terminals; and, therefore, when the applied voltage is low (for instance, due to poor rail bonding) the motor speed and consequently that of the locomotive is low. This lowered speed will not appreciably change the value of the current drawn from the line by the motor if the load on the locomotive (equivalent of torque) is to be maintained the same at the decreased voltage; because it is a fundamental law of the series motor that the value of the current required is dependent only upon (and directly proportional to) its torque output. Since the armature or field current of the motor will not be less at the lower voltage and constant load, the number of heat units liberated in the motor will remain the same as at full voltage, neglecting core losses (these will decrease slightly but are a small percentage of the total heat loss); and consequently the *rate* of increase of temperature with continuous operation will remain nearly the same for either condition of voltage. If, as under ordinary conditions, the locomotive would be required to perform the same amount of work per day, it would become hotter at low voltage than at normal, because it would take a longer time to accomplish the work at the lower speed. Although not a commercial probability, if the motor is to be run only for the same length of time at low voltage as at normal, and in doing so perform a less amount of work (proportional to the reduction of the voltage) it will operate at normal temperature.

G. H. S.

### PHASING-OUT: PECULIAR VOLTAGE MEASUREMENTS

(121) Fig. 1 is a diagram illustrating the transformer connections at both the power-station and the substation end of a certain distributing system at the time of phasing-out a new transformer *D*.

Transformer *C* was in service, feeding the overhead and the underground lines that supply small motor and lighting customers. The customer's transformers on these lines transform the voltage to 230 volts. The middle points of the low-tension side of these transformers are grounded and the customers receive power at 115 volts (obtained between these grounded middle points and either of the outside lines). The 2300-volt lines are non-grounded.

Peculiar conditions were found when the phasing tests were made between the new transformer *D* and the 2300-volt bus. In operation a regulator similar to the one connected to transformer *C* was used with this transformer, *D*. However, at the time of this particular test, it had been taken out of the circuit altogether because of trouble which had developed within it.

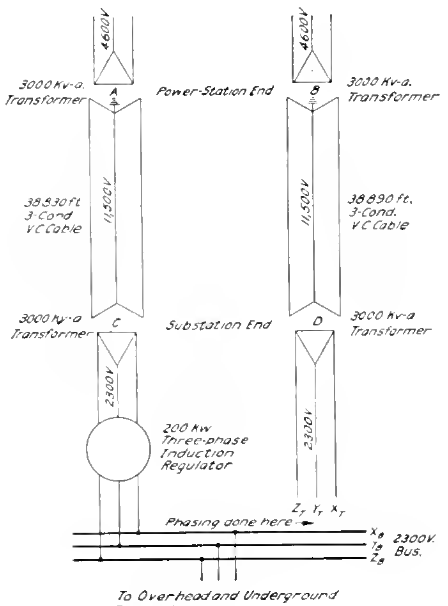

Fig. 1

| Voltmeter and potential transformers connected between | Volts | Voltmeter and potential transformers connected between | Volts |
|---|---|---|---|
| $X_T$ and $X_B$ | 0 | $Y_B$ and $Z_B$ | 2280 |
| $Y_T$ and $Y_B$ | 0 | $X_B$ and $Z_B$ | 2280 |
| $Z_T$ and $Z_B$ | 0 | $X_T$ and gr. | 1100 |
| $X_T$ and $Y_B$ | 3880 | $Y_T$ and gr. | 1060 |
| $Y_T$ and $Z_B$ | 3840 | $Z_T$ and gr. | 1100 |
| $Y_T$ and $X_B$ | 2800 | $X_B$ and gr. | 1180 |
| $Z_T$ and $Y_B$ | 3520 | $Y_B$ and gr. | 1310 |
| $X_B$ and $Y_B$ | 2200 | $Z_B$ and gr. | 1416 |

Denoting the lines coming from the new transformer *D* as $X_T$, $Y_T$, and $Z_T$, and the bus as $X_B$, $Y_B$, and $Z_B$, the tabulated data were obtained.

It can be seen that apparently $X_T$, $Y_T$, $Z_T$ and $X_B$, $Y_B$, $Z_B$ can be thrown in parallel, that is, the deltas representing the voltages of the two circuits seem to coincide.

How is it possible to get such high values of voltage when taking the cross voltage readings, $X_T - Y_B$, $Y_T - Z_B$, and $Z_T - Y_B$? Why are the voltages to ground considerably different for the transformer and the bus? The voltages for the transformer are too small to locate a neutral in the center of the delta, while for the bus they are too large. What is the cause of this? There is no electrical connection between the transformer and the bus.

Considering the bus voltages first, it will be found that by plotting a triangle the sides of which respectively represent the values of the voltages between the buses and then laying off the corresponding voltages to ground these three latter meet in a common point. This shows the neutral to be a definitely fixed point which may be explained by the fact that the capacity of the network, to which the bus is connected, is appreciable and that the neutral is held so by the capacity current to ground.

Turning to the readings obtained on the new transformer, it naturally would be supposed that each voltage to ground would be the same, and be of a value approximately 57.7 per cent of the line voltage. The actual readings obtained are near enough alike to assume that, since each was taken separately, the neutral point shifted in each case with respect to the line. Because the new transformer is not connected to the buses or to any system of appreciable electrostatic capacity, there is only a very small capacity current and the neutral, therefore, is unstable. When a potential transformer is connected from one line to ground, it appears only natural that the voltage across it should drop to some value below the actual value existing before the potential transformer was connected. If three potential transformers and three voltmeters had been connected in Y, the voltage reading from each line to neutral would have been equal and of a value approximately 57.7 per cent of the line voltage.

The fact that zero voltage was read between $X_T$ and $X_B$ and between the corresponding *Y* and *Z* lines would seem to indicate that the proper lines were about to be connected together, but this is not positive proof as the bus and the new transformer secondary are stated as being entirely insulated from each other. The higher voltages obtained on the cross readings, however, make it appear that in this instance, at least, two points, (for instance $X_B$ and $Z_T$) were connected together when the other readings were taken.

The most pertinent comment drawn forth by such a test (and the one whose importance should be emphasized) is that, *if no connections other than those of the potential transformer were made between the two three-phase lines, none of the readings taken between the bus and the new transformer terminals can be assumed as positively indicating anything in particular.*

GENERAL ELECTRIC REVIEW

## THE PATHS OF PROGRESS

Our last November issue was devoted to "Electric Railways" and at that time we stated that we hoped some day to issue a special number on "Electric Traction" covering some of those problems involved in the electrification of steam railroads. So the present issue is devoted to "Electric Traction," and we hope that the contributions will be read with interest and profit by those concerned with our heavy traction problems. The articles cover a wide field, and we believe much valuable operating data are contained in the articles written specially for this issue by those responsible for the operation of the various steam roads that have been electrified. We wish to express our appreciation of the generous help given us by these contributors.

It is gratifying to find that in all cases where a direct comparison of the operating expenses before and after electrification can be made, that marked economies can be traced to the change in motive power. A most striking example of the results that may be expected from the electrification of many of our steam railroads can be found by studying the figures found elsewhere in this issue relative to the first year's operation of the Butte, Anaconda & Pacific Railway. The service on this road is of an unusually severe nature and the unparalleled results obtained as set forth in the detailed statements of the economies effected, speak most eloquently for the 2400-volt equipment. In fact there is little doubt but what the success of this particular installation will have a far-reaching effect on determining the choice of equipment for many other installations.

The Canadian Northern electrification at Montreal has adopted apparatus and equipment similar to that of the Butte, Anaconda & Pacific Railway, and we have every reason to believe that their judgment in this matter was influenced by the success achieved by the higher voltage direct-current system under the severest kind of operating conditions. As is well known, the Chicago, Milwaukee & St. Paul Railroad is contemplating the electrification of a whole steam road division, and here again we expect to see the direct-current system used, with a trolley potential as high as 3000 volts. When this last named electrification is completed we confidently expect to see operating economies effected of a nature which will determine the trend of much future work.

We believe that is it becoming very thoroughly recognized that the adoption of electric traction, even for the severest kind of railroad service, involves today nothing in the nature of an experiment. Electric motors and locomotives and all the incident apparatus and equipment have been designed and tested beyond the point where there is any room left for discussion as to their capabilities. Electric equipment is available today for all classes of service, ranging from the ordinary city street car service, both light and heavy interurban service (the latter often closely approximating steam road conditions), right up to the severest steam road requirements, whether these are to be considered for slow or moderate speed freight service or high speed passenger service of the most exacting nature.

There are articles in this issue dealing with both the design of motors and the design of locomotives for heavy traction service which we believe will be read with considerable interest. The article describing the Illinois Traction System is of special value as showing how some interurban roads are approximating steam road conditions and how thoroughly all the equipments and appurtenances of some of these roads have been developed to meet the severe conditions and give the highest class of service with safety, economy and satisfaction to the public in general.

Many of the most notable examples of steam road electrification up to the present time have been the electrification of large city terminals. In these instances the change from steam to electric operation has been primarily made to eliminate the smoke nuisance and the change had been rather a matter of compulsion than choice. The same law of necessity has dictated the electrification of the various tunnels now operated electrically. In the case of most terminal electrifications the change in the mode of operation has been accompanied by the building of most elaborate terminal buildings, and the entire rearrangement of tracks. Some of our modern steam road terminal buildings are the most elaborate and pretentious buildings erected in modern times, and the cost has run into many millions of dollars. The benefits derived from electrification have been varied and most pronounced; but as such tremendous sums of money have been expended at the same time, which, while providing improvements, were not necessitated by the change in the form of motive power, it is hard in most instances to arrive at anything like a correct figure for the economies secured by electrification. For instance, the property holders in the immediate neighborhood and the city itself must make enormous gains by the improvement in real estate values. If the railroad is one of the property holders, and in many instances this is the case, they also make large financial gains in this direction. Is this profit taken into consideration in computing the benefit conferred by electrification? Most new electrified terminals operate on two levels, thus saving enormously in the ground area covered, and this in a locality where real estate is enormously valuable. Is this gain considered? It has been proved many times that any improvement in service will stimulate traffic and therefore electrification will increase traffic returns. This in common with many other points should be taken into consideration.

In all cases that we know electrification has shown operating economies sufficient to justify the expenditure; but when millions upon millions have been spent on other improvements at the same time, it is difficult to differentiate what proportion of the outlay can correctly be charged against electrification as distinguished from all the other improvements that have been effected at the same time.

It is most unfortunate that the calamity of the great European war should have broken out at a time when the finance of the country was going through such a trying period. The period immediately preceding the war practically amounted to a second reconstruction period, but there is little doubt that the potential and basic wealth of the country can overcome the effects of these trying times and meet successfully the strained financial conditions imposed by so large a section of the world being thrown into confusion by war.

It is during a reconstruction period of any kind that we look for ways and means of effecting economies, so it is natural that if economies can be obtained by electrification, and we maintain that they can, a study of the operating conditions of many steam roads would be profitable at the present time.

We fully recognize that the technical considerations are not the paramount issues, but that the problem has resolved itself into one of finance. The engineers and manufacturing concerns have eliminated any technical difficulties that existed. The main hindrance to many schemes of electrification at the present time is to be found in the difficulties encountered in raising money and especially in raising money for railroad purposes, but we believe that when those who can dictate the "doing" or "not doing" of things, realize that a tendency to construct rather than destroy has started they will stimulate in every available way, to the utmost limits of their power, any efforts put forward by the railroads to secure economies. Should pessimism give way to confidence, a great impulse will be given to the electrification of steam railroads, and we shall then proceed along the paths of progress, in spite of all obstacles, with greater energy in the future than in the past.

# DEVELOPMENTS IN ELECTRIC TRACTION

By W. B. Potter

Chief Engineer, Railway and Traction Department, General Electric Company

After mentioning briefly some of the more important features of development in electric railways, the author passes on to a consideration of some of the problems of steam road electrification. The requirements of design in both electric motors and locomotives are reviewed and some of the factors governing the choice of higher direct current voltage for heavy traction work are set forth.—Editor.

W. B. Potter

THE electrification of railways has naturally been extended in the classes of traffic where the substitution of electric power has afforded advantages not obtainable with power of some other character. Electric motor cars, as compared with the horse or cable car, were immediately recognized as a more efficient method of transportation, and the extraordinary development of the trolley car service was a natural result.

During the early development of electric equipment for transportation purposes the individual motor car and the electric locomotive received about equal attention. Because of the greater opportunities in urban service the motor car soon became more prominent, and for a number of years the motor car equipment received almost exclusive attention.

Results obtained in trolley car service demonstrated beyond question the success of electric power and did much to establish confidence in the reliability of electrical equipment. For the heavier service of handling trains the use of a motor car as an electric locomotive was but a natural development. The entrance of electric power into the domain of the steam locomotive really began in the early nineties with small trains in passenger service. The Intra Mural Railway at Chicago in 1893, where motor cars were used as electric locomotives, initiated in this country the permanent invasion of the extensive steam service on elevated lines.

The further development of multiple unit control, permitting any number of motor cars in a train to operate in unison, made possible a schedule performance which even the largest of steam locomotives would be incapable of handling, quite apart from the objectionable features incident to the use of steam.

The earlier applications of electric power to regular steam railway service were in most cases for service in tunnels and railway terminals, with the object of eliminating the smoke and gases common to the use of steam locomotives. The Baltimore & Ohio Tunnel which commenced operation in 1895 was the first instance of electrification as applied to heavy traffic, and the first electric locomotives to successfully initiate the struggle for supremacy with steam locomotives under main line requirements.

The electrification of main line service is no longer an experiment. The heaviest traffic can be successfully handled, and therefore there remains only the question of whether it will pay. As a rule, excepting the expense incident to the initial investment, the cost of operation with electric power will be less than with steam, and often this saving will show a handsome return on the investment. There are many instances, such as tunnels and terminals, where other considerations than the financial showing are of paramount importance. Even in such instances there are often local conditions where the value of property will be enhanced, or where territory necessary to steam service can be made available for other purposes and therefore remunerative.

The possibility of handling heavier, or even equal trains at higher speeds is becoming better recognized as a means of increasing the tonnage over a given route, and so provide for an increasing traffic more economically than by the construction of additional lines under steam operation.

Electric locomotives for heavy traffic must be so constructed as to withstand the severe shocks and strains which occur in the handling of trains, and to facilitate inspection and maintenance the electrical and other equipment should be conveniently located. Much attention has been given to the development of different general types, and many varieties of electric locomotives differing both in mechanical design and electrical equipment have been built and tested.

Variations in the mechanical construction are influenced largely by different methods of transmitting the power from the electric motor to the driving wheels. The motor car and steam locomotive have both served as models, with innumerable variations in which their characteristics have been differently combined and in many cases with indifferent success. Geared or gearless motors mounted on the driving axle, or in special cases a combination of gearing and parallel rods, each with reference to its fitness for the particular purpose, are the most promising methods of drive. Guiding trucks will undoubtedly be used in high speed service and doubtless at slower speeds with very heavy locomotives where the weight distribution on the track may be of importance.

The character of electrical equipment, considering the larger power required in main line service, is influenced by the problem of electric transmission to the locomotive and the collection of current from the conduction circuit. As the amount of current varies inversly as the voltage, the transmission and collection are therefore made easier at higher potentials. The development of equipment suitable for higher voltages has received much attention, and there are at present a number of important railway electrifications of this character on which alternating or direct current is used. The respective merits of alternating or direct current involve many details of which only a few are of general interest as influencing the trend of commercial development.

The equipment for alternating current, whether three-phase, single-phase or split phase, does not at present appear susceptible of many improvements by which the cost may be reduced, and there is further an uncertain investment for counteracting the influence of the alternating current on telegraph and telephone lines.

Direct current operation at potentials higher than 600 volts is no longer in the experimental class; the most important electrification being the Butte, Anaconda & Pacific, where successful operation at 2400 volts has been fully demonstrated

A vital question affecting the use of direct current in heavy service is the amount of current which can be successfully collected from the conducting circuit, particularly from an overhead construction, as with the third rail there is ample margin even at 600 volts.

As a device for collecting current the ordinary trolley wheel has proven successful in handling far heavier equipment than originally contemplated. The roller pantograph, which is in effect an elongated trolley wheel, has proven very successful in service for which the ordinary trolley wheel would not be suitable. The sliding pantographs, of which there are many in service, when fitted with copper faces have a collecting capacity even exceeding that of the roller, and there is no doubt a pantograph equipped with a suitable sliding collector will successfully collect current to the full capacity of the overhead conductor.

An improvement in the overhead catenary construction, accomplishing the double purpose of securing greater flexibility and an increased conductivity, is obtained by the use of two conductors lying close together in the same plane, with the supporting hangers located alternately so that the mid-span of each conductor is opposite the supporting hanger of the other. Within practical limits 1000 amperes may easily be collected from a single 0000 conductor and 2000 amperes from two 0000 conductors. With a copper conductor and copper faced sliding collector having grease lubrication, the tests and obtainable records indicate a life of the conducting wire fully comparable with that commonly obtained with a trolley wheel or roller pantograph.

It is a reasonable statement that with a potential not exceeding 3000 volts, no difficulty will be experienced in collecting from an overhead construction the current required by locomotives in the heaviest passenger or freight service. The choice of a higher direct current voltage is, therefore, a question of economics—whether the saving in copper or further spacing of substations will justify the greater cost of rolling stock equipment at a higher voltage. Careful estimates, comparing 3000 volts with higher voltages up to 6000 as applied to main line operation, show practically no advantage in favor of the higher voltage. In the majority of cases in this class of service the investment for locomotives is by far the larger item as affecting the selection of the voltage.

As between the different systems the indications point strongly toward the more general adoption of direct current for main line electrification and heavy railway service generally.

# THE POSSIBILITIES OF AN ELECTRICAL COMMISSION

By Frank J. Sprague

Consulting Engineer, New York

The author makes a strong plea for all manufacturing and engineering interests to subordinate all discussions of non-essentials, in order to view the general problem of steam road electrification in its broadest aspects and to co-operate for the common good. He points out the financial and economic aspects of the problems and reviews some of the most important technical considerations.—Editor.

Frank J. Sprague

"STAGNATION of export freight traffic, dwindling domestic and passenger revenues, piling up of unpaid obligations, passing of interest payments of railroad securities aggregating nearly $600,000,000, and early maturity of as much more in fixed charges and short term notes,"—such are the conditions, tersely described, confronting trunk line railways at a time of unparalleled harvests, because of unwise or dishonest financing, overmuch regulation by Public Service Commissions and a war convulsing half the civilized world.

To those hoping for, and believing in the ultimate operation of railways by electricity, the situation seems fraught with tremendous consequences, for the results of the financial paralysis brought about will be felt throughout the life of the present generation.

Must we, therefore, give up the hope of advance in electrification, or is there some means of mitigating its enormous cost to such an extent as will in some measure remove the incubus now resting upon railway financing? If so, then it behooves all manufacturing and engineering interests to lay aside or subordinate the discussion of non-essentials, view the general problem in its broadest aspects and co-operate for the common good.

What I have often pointed out, that electrification is primarily a financial problem, and will ordinarily only be adopted when the results to be attained will accomplish something that steam cannot, or will return a larger net dividend on capital than when the latter is expended in some other way, must be accepted as true. Therefore the first requisite for any hope of success is to reduce the capital charges of electrification, this in spite of the repeated claims that differences of opinion as to systems, or the necessity of the acceptability of some single standard, has been the greatest barrier to advance.

That the latter has an influence is undeniable, but as I stated at the recent meeting of the National Electric Light Association in Philadelphia, the matter of power supply is more important than the question of system, for everyone who looks forward to the future of our country sees a specter arise, the failure of our coal and timber supply. With an ever increasing demand for power we must then fall back upon hydraulic supply, but meanwhile we should conserve our natural resources by making use of the diversity factor possible to large commercial stations properly located and interconnected, for such can not only relieve the railways of the cost of large stations with ample reserve, operated at a low load factor, but supply the power at a reasonable cost.

Referring, however, to the matter of systems, it is undoubtedly wise to see if it is not possible to remove the discordant note which has been so dominant, or at least soften its character; and the question arises, to what extent and by what means can railway electrification be now standardized and its probable development be determined?

It is a subject to which I have given much thought, and to its solution no small amount of energy. For many years after the advent of the a-c.—d-c. substation, higher potentials for the direct current secondary distribution was generally discouraged and deferred, at first because of difficulties in motor construction, some real and others assumed, and later because of the advent of a new system which promised to remove the limitations of potential on the working conductor and the objection of moving apparatus in substations, and sometimes even of the substations themselves.

The so-called "Battle of the Systems," limited for trunk line consideration in the

United States, was at first defined by those who committed themselves to advocacy of a single system, as a choice between single-phase trolley operation to 11,000 volts or over, at either 15 or 25 cycles, and 600 volts d-c., third-rail operation from substations supplied from a high tension prime station, as typified in the New York, New Haven and the New York Central installations. In Europe, on the other hand, the disputants divided themselves into three camps, the English in practice principally advocating direct current, the Swiss, German and Swedish engineers single-phase, and the Italians polyphase operation.

It was unfortunate that the comparison between systems, and especially between direct current and single-phase, was based on an over enthusiastic belief in, and acceptance of the merits and accomplishments of the new system, and an unwarranted disregard of the possibilities of the development of the older one along the lines which I had for many years advocated.

It had long seemed to me that in each of the systems there were certain normal maxima of operating potentials, at which there would be established a balance of advantages for that system; that there was nothing in the art which prevented successful operation at the working conductor at 6,000 volts for polyphase operation, 11,000 to 15,000 volts for single-phase, 1200 to 1500 volts for direct current with a protected third rail and from 2500 to 3000 volts with direct current trolley; that there were inherent differences in the weights and costs of single-phase and direct current motor equipments, when built and operated under like conditions of reliability, which were irremedial, and which were likely in a large measure to offset whatever advantages might be achieved in efficiency of the secondary transmission; that in view of the coming necessary interconnection of power supplies, in which railroad use would be but one of many, an arbitrary adoption of a specific cycle for trunk line operation was of questionable advisability; and, finally, that only after the inevitable development of each of the systems to its natural limits could any final determination be made whether, on the one hand, conditions were so varied and the application of electricity so catholic that no one system could be accepted for general application to the exclusion of all others, or, on the other hand, that there was a definite trend in the favor of some one system towards which the activities of engineers, manufacturers and railway officials should be bent.

This general position and contention was not an advocacy of any one system, but a prophecy of development, and a plea for conservative action and judgment. Time, I think, has vindicated the correctness of this attitude, and while perhaps it has not lessened individual solidarity of belief and zeal, there has been some mitigation of asperity in the advocacy of systems, and a tendency to unite, to some extent at least, on a more general advocacy of electric operation as a substitute for steam, wherever proper, on broader grounds and for more cogent reasons than sentiment and minor differences in transmission efficiencies.

The art has steadily advanced. Polyphase equipment seems best at about 6000 volts and 15 cycles; single-phase remains generally at about 11,000 volts at both 15 and 25 cycles; and direct current has already arrived at 2400 volts, and even a much higher voltage is proposed for the overhead trolley, with any required initial voltage for transmission.

Polyphase operation is still limited to concatenated speed variations; single-phase, when carried out with commutated motors, permits variation with a variable tap transformer; and with direct current speed variation to any essential degree is attained by grouping of motors, and, thanks to the interpole construction, by variations of field strength.

We have, therefore, practically arrived at, or certainly are in sight of the limiting potentials and practices which I have indicated, and for which, so far as applicable to direct current practice I have, oftentimes to some discomfort as a prophet, been the advocate. But with these various goals reached, it is but fair to say that there is still no general agreement as to many fundamentals, and professional and manufacturing rivalries the world over are unduly manifest.

Urban and interurban transportation, surface, elevated and subway, and terminal and subway problems have all been successfully solved, the aggregation of any required amount of power has been made possible by the multiple unit system, the reliability of electric operation has been established, and of late the attention of the transportation world is being directed anew and with keener interest to the possible inauguration of electricity in place of steam on trunk line divisions. With the possibilities and dangers of far-reaching and costly mistakes, shall the settlement of the problems involved be left to the necessarily slow and independent solution of individual trials?

I may be pardoned if I express the belief that no railway official however broad his experience, no manufacturing company whatever its resources, no electrical engineer however experienced, confident or self-assertive, can alone settle this question. The problem is too big, it involves too many financial, techincal and operating problems, it comprises too great an assemblage of advantages and disadvantages viewed at different angles, for any single mind. Even if such a one should be entirely correct in final analysis and prophecy, his dicta cannot carry the necessary measure of authority for general acceptance, nor should it do so. Of course, I do not mean that this or that railway problem cannot be met and successfully solved, operatively, by one or more methods, and by many able men, but varied as such solutions are and will continue to be under existing conditions, manifestly they cannot have broad national acceptance.

In the various electrical fields in which I have been more or less active I have always been a firm believer in meeting a condition of stagnation by some commensurate risk, and then to secure standardization by effective co-operation. Risks in an unknown field, with problematical results, are naturally undertaken by the enthusiast whose prophetic vision ignores ordinary financial restrictions, in the hope of laying a foundation of development which in the end promises commensurate reward; but once the way has been blazed in a new field of endeavor, then the attrition of mind against mind in co-operative effort is needed to formulate the grounds for the most stable and satisfactory advance.

It was with this idea in mind that, some two years ago, I addressed myself to the problem of trying to find some means of breaking through the wall of inertia which, buttressed by ignorance, disbelief and sometimes even by misrepresentation with regard to the possibilities of electrification, was interposed between accomplished facts and the hoped-for wider application. I sought to find some way of meeting existing conditions, financial and other, in the trunk line situation, and while demonstrating the financial advantages of electric operation to suggest some plan to relieve the railways in a large measure of the financial burden of electric equipment.

It seemed that the time had come when steps could be taken to remove the unnecessary asperities and soften the differences which had characterized the advocacy of systems, and to determine in some authoritative way the lines along which the future development should or should not take place. If engineers and manufacturers were sincere in their belief as to the economic advantages of electric operation in the place of steam, something surely could be done to manifest that belief in a substantial financial way, either singly or in co-operation; and the best interests of the art would be subserved if the great manufacturing companies could come to a common basis of understanding, and unitedly bend their energies toward common lines of development. It also seemed that, in connection with the future and inevitable concentration of small into great power stations, and their interconnection of supply of electric energy for a thousand and one purposes, there was an opportunity for the development of a financial organization outside of the manufacturing and railway companies which could play an important part in railway electrification,—in short, in general power stations would be found a great leveller of industrial class demands.

Various phases of the question were discussed with many manufacturing officials and a number of consulting engineers. Progress was slow, and still is, although some encouraging advance has been made towards a better understanding. At first it was thought by some that the American Railway Association, or possibly the American Institute of Electrical Engineers, through suitable committees, could be instrumental in arriving at the necessary conclusions. But it is almost unnecessary to point out that every committee of such an organization is made up of men absorbed in their individual businesses, that these committees can meet but infrequently, are more or less unwieldly, and are generally dominated by one or two members. As a rule, their conclusions cannot well indicate more than a general review of what has been accomplished, and voice with some measure of authority facts already self-evident. Nor could any uncompensated group of men of the necessary ability and experience afford to give the time for adequate study, or assume the great responsibility of decisions of far-reaching importance.

Then, too, the American Railway Association represents what I may term the defensive organization, that is, a conservative group of railway men whose methods of operation the believers in electricity hope to change. If, of course, this association held anywhere near equal beliefs in the new motive power, it could be most effective. but I believe through agencies which, although under its direction, would be external to itself.

The fact must be accepted that electricity is playing an increasingly important part in the evolution of steam railroading, and with the already successful handling of terminal problems the public is demanding with growing force that the smoke nuisance shall be abated in large centers of population.

Congestion at terminals is requiring a solution that can seldom be met with lateral enlargement, but must rather be solved through changed methods of operation which will reduce switching and "dead" movements, and permit utilization of space on more than one level.

Greater earnings must be looked for in a larger use of the capital already tied up in investment, as by the increase of frequency of service and capacity permissible by the use of electricity.

Increase in efficiency and economy also, as well as in capacity, may be expected under suitable conditions of freight traffic.

At terminals, important returns may be anticipated from the results of electrification, such as the reclamation of air rights for commercial development, and the use of cheap power for heat, light and improved methods for mechanically handling freight.

I believe that the application of electricity to problems of transportation by various systems has now sufficiently advanced to give entire confidence in the hope that correct solutions may be arrived at, no matter whether there is indicated a definite trend towards a particular development, or on the other hand a catholicity of application.

Yet we must recognize the fact that one of the great barriers to the consideration of the electrification of trunk lines is the radical differences in opinion between engineers and manufacturers as to what shall be the preferred future system or systems, as well as ignorance of the facts as to equipment and operative cost. In short, because the doctors do not agree, or are not entirely frank in their diagnoses.

Consider for a moment what the bewildered railway official and financier must view, and is asked to digest: Steam and water power central stations operated at 15, 25, 40 and 60 cycles, either limited to special use or seeking the advantages of co-operation and diversified supply; polyphase systems operated at constant or concatenated speeds, but with high weight factor of motive power, with double overhead lines at 6000 volts at 15 and 25 cycles, and with regenerative braking on descending grades; single-phase operation at 11,000 to 15,000 volts, at 15 and 25 cycles, with or without step-up and step-down transformers, with comparatively high efficiency of local transmission, but with the disadvantages of low weight factor and high equipment cost for rolling stock; direct current operation with third-rail at 600, 1200 actual, and 1800, 2400 volts proposed, and with overhead trolley at 600, 1200, 1500, 1800, 2400 actual and 3500 volts proposed, from rotary or mercury rectifiers, or motor-generator substations; top contact third rails with or without protection of various kinds, and under contact rails protected by sheathing; trolley lines, flexible and rigid, with simple or catenary suspension, and cross span and bridge supports; geared and gearless locomotives, solid and quilled armature suspensions, symmetrical and unsymmetrical arrangement of trucks and motors, solid and articulated cab constructions, direct and side rod drives; high and low centers of gravity; variable bridge and tunnel clearances; and so on to the end of the chapter.

If a representative technical society could arrive at some common conclusions, not only as to the present state of the art but the probable trend of development, such would probably be accepted by the manufacturing companies and engineers in general, and would go a long way toward relieving steam railway officials of at least one serious problem.

But the members of a technical society can not give, uncompensated, the time necessary for the comprehensive study necessary; and if similar conclusions could be arrived at by the manufacturing companies' engineers, in consultation with the officials of representative railroad companies, probably the same result would be achieved. But the engineers of these companies, however able, are concerned in the designing, manufacturing and sale of apparatus, and hence possibly and naturally biased to some extent in favor of their own creations. If, therefore, this general problem could be referred to representative engineers selected by, and occupying a confidential relation to the manufacturers, their engineers and the railroad companies, and who could be made the repository of the technical advances and facts individual to the companies, as well as the construction and operative facts on the railway installations already made, similar effective conclusions might be hoped for.

If we assume this latter procedure, the practical question is, can there in any manner be organized a group of consulting engineers of sufficient judgment and experience, technical training, independence of judgment and knowledge of railway and electrical conditions, men big enough to subordinate their preconceived opinions in the face of facts, to whom such momentous questions could be submitted for at least advisory conclusions.

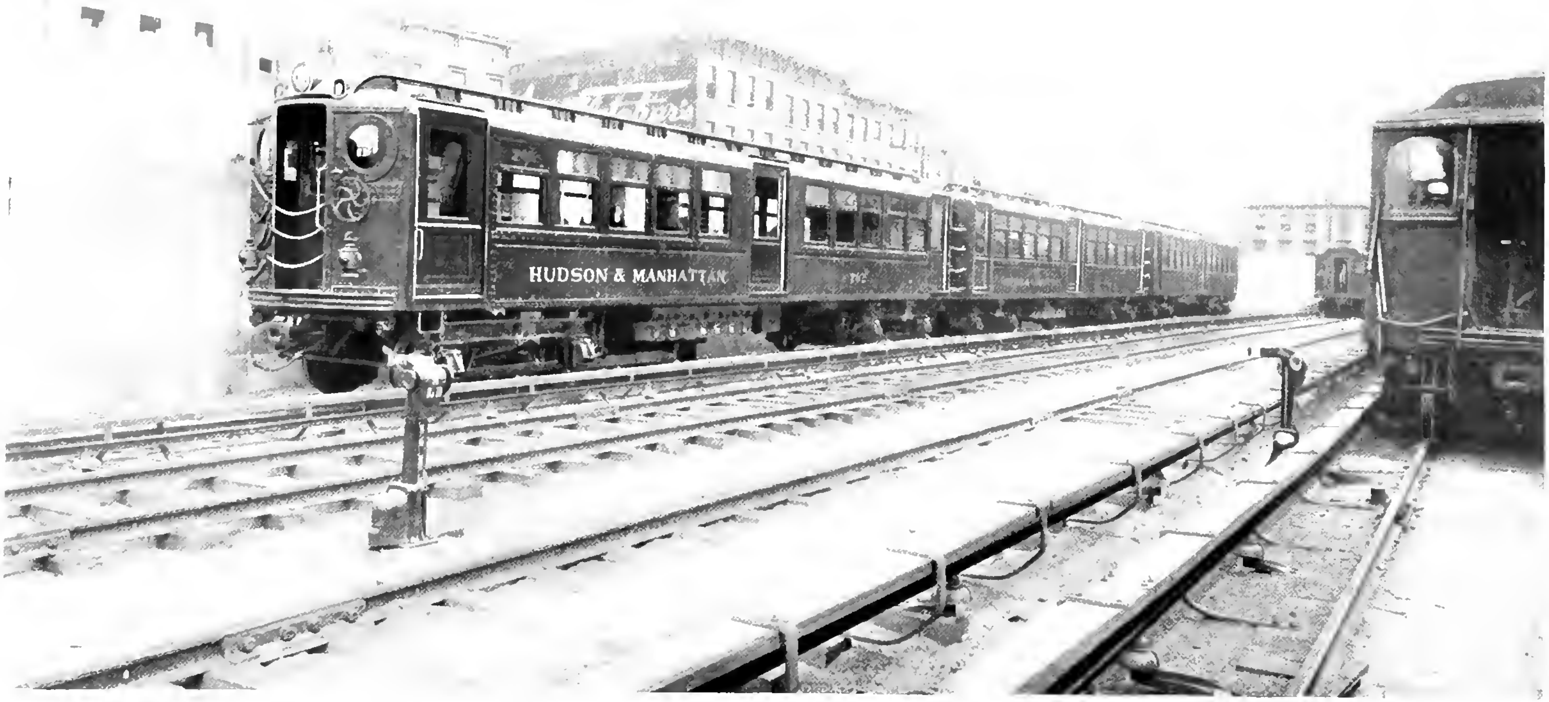
It seems to me that one of the troubles which has confronted electrical engineers, when dealing with the trunk line problem, has been a lack of a common ground of understanding, that they should be in more intimate touch with the actual facts with regard to steam operation, its possibilities and economies, as well as the limitations of increase of capacity to provide for future needs. If so, then much greater headway could be made by such a body of engineers, fitly representing various phases of opinion and experience, persona grata not only to each other and manufacturing companies, but to the railway companies as well, if instead of attempting to arrive at conclusions from theoretical discussions, or application of known facts to assumed conditions, they should apply their studies to some concrete case or cases which should embrace in extent and variety all the principal problems of trunk line electrification.

Most of the electrification projects in connection with trunk lines which have been carried out in this country have been dictated by local terminal necessities which could not be met by steam operation, but for the more extensive projects other reasons must prevail. Even with a settlement of system and demonstrated ultimate economy of operation and increase of capacity denied to steam operation, the financial problem facing the railroad man is a most serious one, for it is certainly true that the assumption of the actual cost of power supply, as well as that of rolling stock, the provision of reserve, and the individuality of installation and development constitute a serious burden which, if it could be in a large measure eliminated, would tend to accelerate electrification.

Assuming, therefore, some general agreement as to standards and the best methods of electrification, would not such be materially advanced if, as I have already indicated, the burden of reliable power supply at a reasonable rate and with ample reserve, and the possible provision of rolling stock on a basis of usage, could be undertaken through the agency of outside capital, leaving the railroads only the minor burden of supplying fixtures along the right of way, and co-operating with the power companies in the erection of general power supply lines upon their own property?

To effectively carry out the ideas above crudely set forth, I may state that at least one of the principal manufacturing companies has expressed itself as being favorably inclined to co-operate in the creation of a technical commission, to be composed of disinterested engineers of wide and varied experience, who shall make a thorough study of the various systems of electrification as applied to such situation or situations as may be taken up; that it is prepared to bear any required part of the expenses of such a commission incident to the making of a comprehensive study of trunk line problems; that it is in favor of some scheme of financial development which shall relieve the railroads of a part of the burden of raising capital; and, finally, that it only awaits the necessary co-operation of railroad officials to make effective this joint effort to avoid the heavy costs of mistakes due to individual judgment, on the threshold of a possible great electrical development in transportation whenever the financial skies make such practicable.

Despite this promising advance, the proposal has met with sufficient obstruction to thus far prevent its adoption in the form which promises the greatest effectiveness, but need that be the final result?



Three-Car Train on the Hudson and Manhattan Railroad. Mr. L. B. Stillwell deals with the operation and maintenance of these cars and their equipments in his article entitled, "Co-ordination in Railway Equipment"

# CO-ORDINATION IN RAILWAY EQUIPMENT

By L. B. Stillwell

The author dwells on the fact that it is not only the goodness of the individual elements of equipment that determines the success of a railroad, but that the ultimate results must depend upon the proper co-ordination of all the constituent practice. The equipment of the Hudson and Manhattan Railroad is analyzed to support the authors contentions, and many valuable tables of statistics are given showing the operating costs, detentions, etc.—Editor.

The gross earnings of a transportation system will largely depend on its traffic winning characteristics. Primarily traffic is influenced by the frequency and reliability of service and by the comfort and security afforded to passengers by the rolling stock and equipment.

Reliability of service depends not only upon the proper design and construction of car bodies, trucks, motors, control, air brakes and brake rigging, but also, and especially, upon the proper assembling of these constituent factors and their effective co-ordination.

Transportation service may be broadly considered as a commodity, with the rolling stock and power equipment as the production plant and the right-of-way as the distributing plant. Obviously, the commercial success of a transportation system, as with any other enterprise, will depend on its ability to meet the specific requirements of the territory involved, and upon the efficient co-ordination of the many integral parts of the complete transportation production machine, consisting of the power generating plant, the transmission system, the rolling stock, the car maintenance shops, and all the auxiliary equipment of signals, telephone system, etc.

The large sums involved in the construction, equipment and subsequent operation of electric railway properties warrant the most thorough investigation of such a project to determine its true economic character "before the fact." The subsequent analysis of the actual operating expenses of a property is often in the form of an inquest.

In the selection of equipment or right-of-way, for a transportation system, the first cost and fixed charges should always be considered in reference to the cost of operation, upkeep and amortization. Investigation will frequently show that a relatively higher first cost of equipment will be fully warranted by attendant reduction in operating expenses.

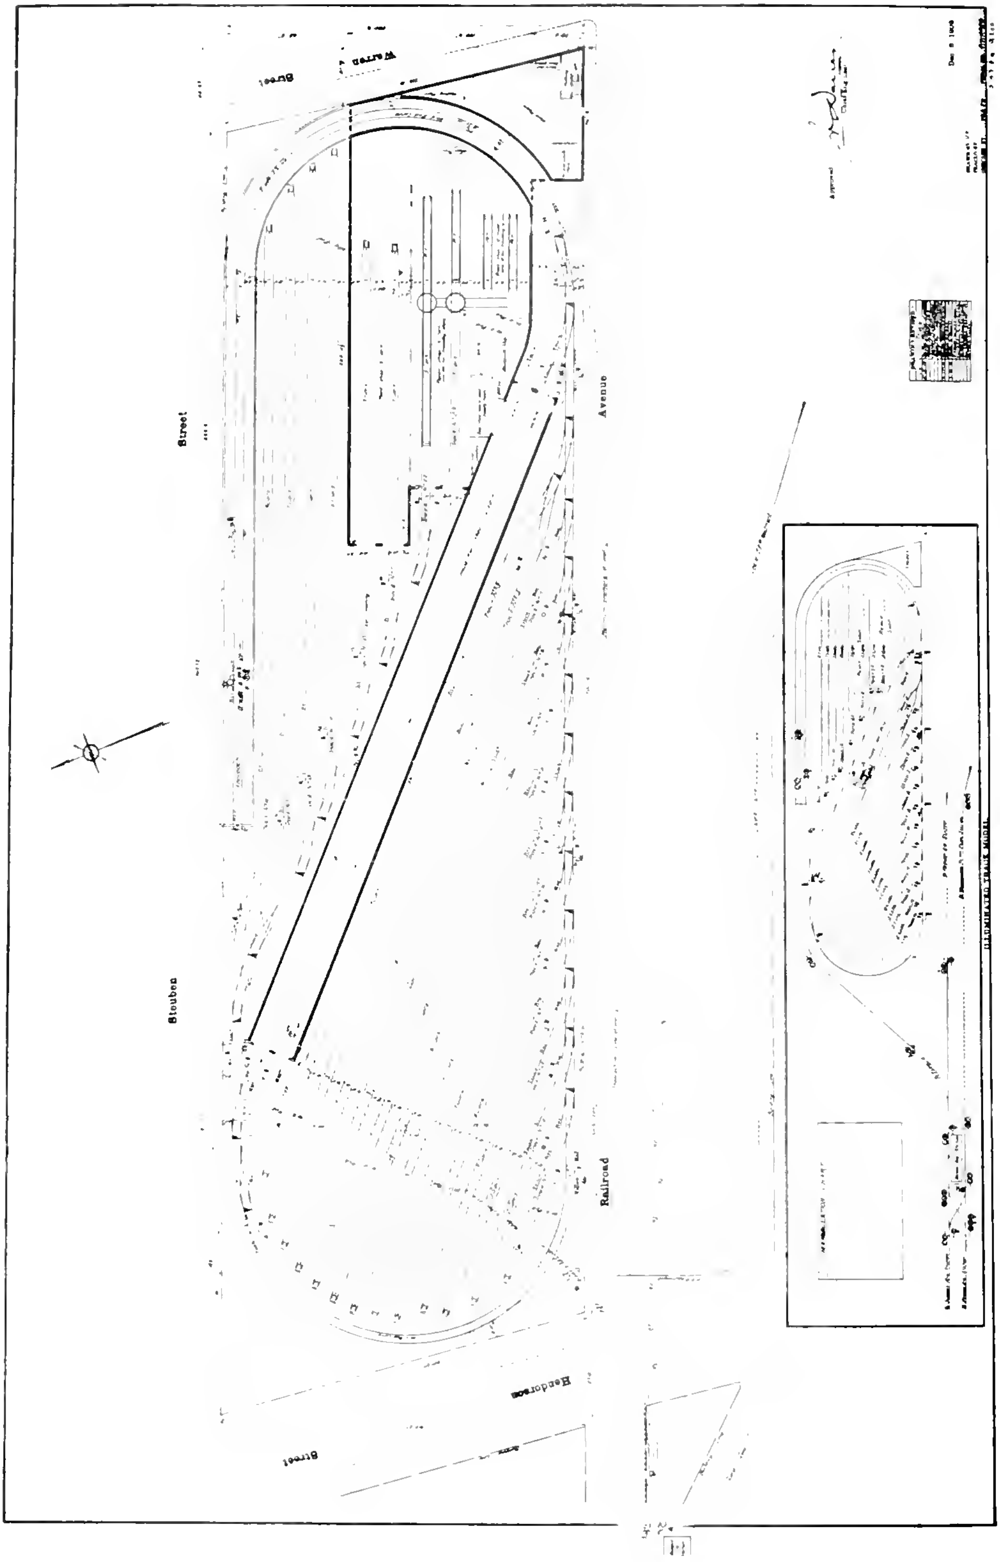
The competent consulting engineer, experienced in railway equipment and operation, is best fitted to make a comprehensive study of the operating conditions of a proposed system, and to thoroughly co-ordinate all the many necessary details so as to insure the greatest traffic winning service, with the minimum expense for operation and maintenance.

The proof of the pudding is in the eating thereof. Likewise, the test of a railroad is the analysis of its operating expenses. Though the pudding be of the best of materials, but only half-cooked, indigestion may be confidently expected; likewise, the railroad material may be the finest of its kind, but if the amalgamation of the whole be not skillfully accomplished, disappointment will be experienced with the financial returns.

In equipping the Hudson & Manhattan Railroad, the executive officers of the company placed upon the consulting engineers direct and full responsibility, not only for the selection and installation of motors, control equipment, air brake work, and wiring, but also for the actual design of car bodies, trucks and brake rigging, as well as for the plans and equipment of the inspection and repair shops. As a result of this policy, provision was made in the design of the cars for the convenient and effective support of motive power and brake equipment, and the completely equipped motor car is characterized by unity of design in a very exceptional degree.

The accompanying costs of maintenance of the rolling stock of the Hudson & Manhattan Railroad have been carefully compiled from the records of the railroad company in order to analyze as thoroughly as possible the detail expense of operation involved in the specific service in which the cars are used. A short description of the equipment is given to illustrate to what extent careful car design and selection of equipment can be made to contribute to reliability of service and to low cost of operation.

In selecting the motive power equipment for the Hudson & Manhattan Railroad cars, due consideration was given to the peculiar conditions of service imposed by the fact that the cars were to operate entirely in



Railroad Avenue Car Yard, General Plan of Interlocking Plant tunnel service under the Hudson River, and that the bulk of the traffic would consist of carrying passengers to and from suburban and through line steam railroad trains operating on definite schedule. It is obvious that a satisfactory service under these conditions would require absolute reliability and regularity of train operation, in order that close connections may be assured, and the further realization that delay of trains in the tunnel service would soon cause the traveling public to lose confidence in the system, effecting a consequent loss of traffic. As the profile of the tunnel system includes several grades of approximately 5 per cent, it was necessary to provide ample motive power per car to meet the possible contingency of the presence of a "dead" motor car in a two-car train, on the maximum grade. That this liberal motive power equipment per ton of car weight is a good investment, aside from its necessary purpose of accelerating the dead car in case of stopping at a signal on a grade, is evidenced by the remarkably low maintenance cost of the motors, and the almost entire freedom from commutator and kindred troubles.

As reliability of service depends primarily on the adequate upkeep of motive power apparatus by thorough inspection and repair, particular attention was given to the facilities afforded for this work.

Thus, in the car design, careful provision was made for the application of control apparatus, so that every contact surface and working part of the apparatus can be thoroughly and readily inspected and maintained by the repair men. This was done with full regard to the human element and with a realization that what is easy to do will be done and what is hard to do will be neglected.

In the design of the inspection shop, particular attention was given to the arrangement of inspection pits, so that abundance of daylight is admitted to the underside of the car by the use of an elevated track for the car and low windows in the side walls of the building. Further a permanent hanging gallery is provided to give access to the car body at its floor level, and thus make it possible for window cleaners and car body inspectors to proceed steadily with their work and in no way interrupt the equipment inspectors at work on the trucks and control apparatus beneath the car body. The work thus proceeds in an orderly and expeditious manner and the capacity of the inspection pit is greatly increased thereby. Many expedients have been devised by the operating force to assist in the dispatch of their work and every operation has been studied with a view to its efficient and economical accomplishment.

The arrangement for switching cars to and from the inspection pit is such that no interference occurs with other yard movements. No back-up movements on the inspection pit are necessary and there is no "dead" mileage for bringing in cars for inspection.

In the design of the repair shop, provision was made for adequate natural lighting, and the machine tool equipment was carefully selected to meet not only the routine repairs of car equipment, but to furnish facilities for repairs of power house and elevator machinery and incidental light repairs required by other departments of the road. Power operated hoisting apparatus was installed so that the physical energies of the shop men are reserved for productive effort. This in itself greatly assists in the securing of the best class of workmen, as well as greatly advancing the rapidity of repair work. The arrangement of the shop is such that all the members of the working force are under the constant and unobstructed observation of the foreman, as no intervening walls are permitted. Any delay to the progress of the work of an individual or gang can be instantly noticed in this way and remedied, without the constant patrolling of the shop by foremen.

As the item of labor is the largest in the cost of maintenance of equipment, it is obvious that the facilities for accomplishing necessary work should be carefully considered in the original design and equipment of the shop, as in many cases no additional cost will be involved.

The development of railroad motive power equipment has been greatly promoted by the interchange of information between various operating men, engineers and manufacturers, through the medium of conventions, committee work and trade journal enterprise, as well as by direct contact between the various interested parties. It is reasonable to expect that the hearty co-operation of all concerned, in patient, constructive analysis and criticism of existing systems, designs, shop methods and methods of manufacture will lead to still further reduction in operating costs and improvement in reliability of service.

The desirability of publishing operating costs and records of reliability of service should be apparent to all, as it unquestionably has a stimulating effect in encouraging operating men to sustained efforts in these directions.

The railroad repair and maintenance shop is a fruitful field for the designing engineer. A careful analysis of the design of parts of apparatus finding their way to the scrap heap will often enable a designing engineer to accomplish radical reductions in the cost of maintenance, with a possible trifling expenditure of effort, by arranging for a change of design or of material in faulty apparatus.

Much has been written about the education of employees in the special work on which they are engaged, and no question can be raised as to the desirability of careful selection and training of those connected with the operation and maintenance of equipment. It cannot be too strongly impressed upon the operating force that *constant proper maintenance is far better than occasional heavy repairs*. It is obviously cheaper to keep out of trouble than to get out of trouble.

Table 1

### DELAY RECORD HUDSON & MANHATTAN RAILROAD

| | 1910 | | | | | 1911 | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | No. of Detentions | Minutes Detention | Per Cent Trains on Time | Miles per Detention | Miles per Minute Detention | No. of Detentions | Minutes Detention | Per Cent Trains on Time | Miles per Detention | Miles per Minute Detention |
| January | | 30½ | | | 17,150 | 15 | 49½ | | 37,200 | 11,300 |
| February | | 21 | | | 22,300 | 2 | 3½ | | 282,000 | 161,500 |
| March | | 35½ | 99.18 | | 15,050 | 2 | 7 | 99.87 | 312,000 | 89,300 |
| April | | 7 | 99.47 | | 72,100 | 2 | 3½ | 99.79 | 297,000 | 169,500 |

* Average for ten months.

The arousing and sustaining of the interest of every employee connected with the service is always a potent factor in any industry. This is particularly true in transportation systems, where reliability of service largely depends upon the intelligent and faithful efforts of many individual workers.

The Hudson & Manhattan cars are all motor cars, each equipped with G-E Type M control and two G-E 76 motors. The line voltage is 650. The commutation was a matter of special consideration in the selection and design of these motors, and their low cost of maintenance and freedom from commutator troubles is noteworthy. Flash-overs are practically unknown on the road.

Tables 2 and 3 and Fig. 1 are arranged to illustrate the distribution of expense of maintaining the rolling stock of the Hudson & Manhattan Railroad:

Fig. 1 shows the cost of maintenance of rolling stock from January 1st, 1910, to December 31st, 1913. It will be noted that the average for the four years is 1.48 cents

### Table 2

## MAINTENANCE COSTS OF CAR EQUIPMENT ON HUDSON & MANHATTAN RAILROAD

### Subdivided in Accordance With I.C.C. Standard Classification of Accounts

| Number | Name of Account | 1910 | 1911 | 1912 | 1913 |
|---|---|---|---|---|---|
| 29 | Superintendence | 0.1112 | 0.1128 | 0.1386 | 0.1166 |

| April | 0.0044 | 0.0026 | 0.0541 | 0.0762 | 0.0320 | 0.0617 | 0.0125 | 0.0129 | 0.1870 | 0.0891 | 0.5325 | 1.9475 |
| May. | 0.0047 | 0.0010 | 0.0605 | 0.0767 | 0.0335 | 0.0541 | 0.0106 | 0.0148 | 0.1781 | 0.0985 | 0.5325 | 1.9375 |
| June. | 0.0060 | 0.0057 | 0.0740 | 0.0745 | 0.0387 | 0.0679 | 0.0116 | 0.0190 | 0.1971 | 0.1090 | 0.6035 | 2.1415 |

per car mile. The high peaks in the early part of 1911 and in 1913 are due to extensive painting and car body repairs. This low cost of maintenance is not due to neglect of apparatus, as is evidenced by Table 1, which illustrates the reliability of service by recording the percentage of trains on time during the same four years, and the average miles per minute of delay over the same period. It is worthy of note that the average reliability of service for the four years has been 99.599 per cent of trains on time, while the average miles per delay was 59,654, and the average length of delay was three minutes.

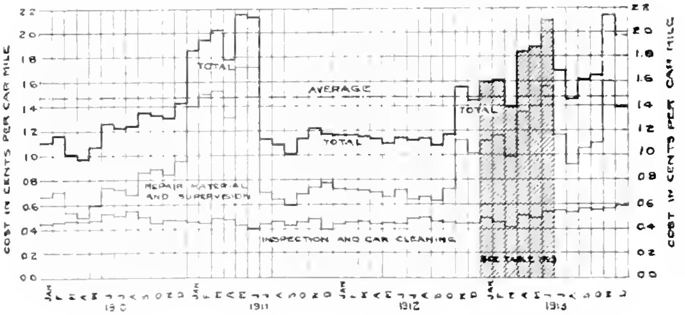

Fig. 1. Curves Showing Costs of Maintenance of Car Equipment During a Four Year Period

Table 2 shows the costs of maintenance of car equipment arranged in accordance with the Interstate Commerce Commission's standard classification of accounts, from which it will be seen that the average cost of maintenance of electrical equipment for the four years was about 0.1354 cents per car mile, being less than 10 per cent of the total cost of car maintenance.

Table 3 is compiled to illustrate the relative costs of maintenance of various portions of the equipment during the period of six months in 1913, indicated by the cross-sectioning on Fig. 1. It is noteworthy that the average total cost of labor for repairs and inspection for motors during these months was about 0.005 cents per car mile and for control about 0.04 cents per car mile.

The low maintenance costs of the motor and control equipment illustrate the result of close co-operation between the manufacturers and the operating and engineering representatives of the railroad, special attention being given to the accessibility of the apparatus for inspection and repair, the low cost of the parts to be replaced on account of wear and tear of service, and the liberality of design of working and current carrying parts.

Car cleaning on the Hudson & Manhattan road forms a considerable item of the total cost of the maintenance. Specific conditions of tunnel service require that the interior of the cars be kept free from dust or loose material of any nature, as the strong drafts occasioned by the movement of the car would, if dust laden, be a considerable annoyance to passengers. Traffic winning service, therefore requires frequent sweeping out of the cars at terminals, and as particular provision was made for this work in the design of the car, it will be of interest to record that cars are regularly swept at terminals while on service tracks, the time allowed for this work being 45 seconds. The interior of the cars was specially

Fig. 2. View of Underbody of Car, Showing Ease with which Resistance Grids and Contactor Box can be Inspected

designed to avoid ledges or crevices capable of retaining dust or dirt. Such features materially aid in the accomplishing of the necessary work. The average cost of car cleaning for four years is $5.01 per car per month.

The Hudson & Manhattan maintenance costs are used as an illustration of the saving to be secured by careful selection and design of equipment for a system operating under special conditions. The same engineering methods were employed in the case of the New York, Westchester & Boston Railway, where a high speed suburban service is furnished; the rolling stock being maintained at a cost of about 2.36 cents per car mile.

---

# THE FINANCIAL ASPECT OF STEAM RAILROAD ELECTRIFICATION

By William J. Clark

Manager Traction Department, General Electric Company

American railroads are not able at the present time to take advantage of the recognized economies to be secured by electrification, owing to the political and economic conditions which prevail in railway finance. But the present conditions will not be permanent, and the author makes a strong appeal to America to take every available advantage of the general situation to create a new set of conditions which will benefit the trade of the country as a whole. This would stimulate railroad finance and put the railroads of America in a position where they could take advantage of the recognized economies to be secured by electric operation.—Editor.

William J. Clark

At the present, when the very foundations of world finance are shaken by the most terrific of all wars, it is difficult to write comprehensively upon any of its specific phases, and obviously the financial aspect of steam railroad electrification is one of these.

The advancement of the electric traction art and its great economic advantages over steam in the operation of railroads have been generally conceded for several years. Yet, the great majority of American railroads have not been able to consistently favor its introduction, in view of their difficulties in raising the necessary capital to make this possible, or even to care for their more pressing immediate requirements. This is because of America's own political and economic conditions which have most seriously handicapped railroad finance.

The great objective and desire of American railroad management is to furnish the best transportation facilities which political, governmental and financial conditions will permit, the last of which are virtually determined by the other two; as is exemplified in the European situation of today, the far reaching effects of which unfavorably affect the financial aspect of steam railroad electrification here for the time being.

All economic truths are recognized however, and taken practical advantage of so soon as incidental factors permit; consequently full realization of the fact that electric operation increases the net earnings of railroads will eventually, in itself, so shape the financial aspect of their electrification that electric traction will then "come into its own."

When the adjustment of the pressing and most important questions of universal finance which have ever arisen will be accomplished cannot now be determined, but in connection therewith almost inconceivable opportunities are presented to America, which if taken full advantage of cannot fail to bring to it unprecedented permanent progress and prosperity of every character; and the extensive electrification of American railroads should be an important element in the creation and maintenance of such conditions.

Most essential to this country, in its attempt to secure the greatest possible advantages from the present general situation, is immediate realization by its entire people that great financial, industrial and commercial policies and enterprises, which yesterday were considered by some as of individual interest only to others more favored than they, now stand out as that which alone can and will, if unobstructed in their legitimate spheres and logical development, bring the maximum of personal benefits to all.

Illustrative of this, as very recently intimated by the President of the United States, a reversal of our present public policy toward the railroads has become an absolute necessity; for we cannot have immediate and unbroken progress and prosperity without increased and improved railroad facilities that are already needed to meet the present transportation requirements of the country. It is impossible to promptly secure these unless the investment of private capital in our railroads is at once made more attractive than it now is, and delay in their acquirement would well nigh prevent the complete realization of present hopes and opportunities.

Even though America should eventually secure adequate railroad facilities through the adoption of the most costly and continuing uneconomic course possible, viz., government ownership and operation, it would be at far too late a date to meet the demands of the present situation; for, as is well known, the estimate of the Interstate Commerce Commission as to the time required to make a physical valuation of the railroads is five years.

The possible future return upon, and the reliability of investments in American railroads has also an important and immediate bearing upon the reshaping and adjustment of the world's financial conditions to the advantage of this country for the most serious problem which confronts it, in such regard, is presented by European holdings of American securities, which principally consist of its railway issues. Unquestionably, many of these will soon be marketed here, which means gold exportation or its practical equivalent, the establishment of temporary European credits on this side of the ocean.

The extent of these transactions will depend upon the actual necessity for sale, plus the possibility of Europeans being able to make what they may consider to be more reliable and attractive investments elsewhere; in which connection it should be remembered that rates of interest throughout the world will doubtless be higher in the future than during the recent past.

Obviously, the smaller the total of these sales, the greater will be the amount of American capital available for internal requirements and the expansion of its commercial and similar interests abroad, which will in time create fundamental lasting betterments at home.

Therefore, if the earning power of American securities is increased and European faith in their solidity is upheld by a favorable attitude on the part of our public and government, their amount, which must be absorbed here, will be kept down to the lowest possible minimum,—probably to a much smaller total than is now expected,—for these securities held abroad are almost entirely in the possession of actual investors, who, unless forced to dispose thereof, would be content with a fair return upon these investments, providing their future is well assured.

A growing mistrust of our securities exists in Europe, so there is immediate necessity for its removal. Otherwise, a wholesale unloading in this country may occur, with the serious results already indicated; viz., that when we most need capital to meet our internal requirements and to take full advantage of our unequalled opportunities abroad, it will be extensively absorbed by purchases of what Europe will sell in our stock exchanges, at whatever prices can be realized. If these are slaughtered, then possibilities of financial panic and disaster, with resultant depression and stagnation in everything, would confront the United States instead of its gigantic advancement toward all that any nation could possibly wish.

It is not reasonable to suppose, however, that the American people, who have successfully met every great crisis and emergency of the past, will now be so lacking in patriotism and intelligence as not to meet all the requirements of the present extraordinary situation, and thus secure every possible advantage for the United States and its citizens, both collectively and individually.

Therefore, we can at last reasonably look for long deferred justice being done to our railroads, and the resultant improvement in the financial aspect of American railroad electrification.

# MULTIPLE UNIT TRAIN SERVICE ON THE NEW YORK CENTRAL AND HUDSON RIVER RAILROAD

By Edwin B. Katte

Chief Engineer, Electric Traction, New York Central and Hudson River Railroad Company

The electrification of the New York Central Terminal led to many changes in the operation of suburban service. The author discusses some of these and compares the old steam with the new electric schedules. The multiple unit cars and their equipment are described at length and the tests made on the multiple unit trains are given.—Editor.

The suburban service of the New York Central and Hudson River Railroad Company was electrified primarily to eliminate the smoke nuisance in the Park Avenue tunnel and was mandatory by State Law. Early in the electrification studies of the Grand Central Terminal and the lines leading thereto, it was apparent that the suburban service could be best handled by multiple unit cars, and the through service, that is trains operating beyond the suburban zone, by electric locomotives.

The advent of electricity materially changed the methods of operating the Grand Central Terminal as well as the two divisions of the railroad adjacent thereto, and it is for this reason that a direct comparison between steam and electric operation cannot readily be made. The principal operating changes which were effected are as follows:

The jurisdiction of the Grand Central Terminal Manager formerly extended to 57th Street, New York City. From this point, the operation of suburban trains on the main line was under the Superintendent of the Hudson Division, and Harlem Division trains were under the Superintendent of that division. At the present time, the Grand Central Terminal Manager is also the General Superintendent of the Electric Division and his jurisdiction extends over the suburban zone from Grand Central Terminal to North White Plains on the Harlem Division, a distance of 24 miles, and from Grand Central Terminal to Croton, on the main line, a distance of 34 miles. This includes the entire suburban service, with the exception of trains on the Putnam Division, which do not enter the Grand Central Terminal, and Peekskill trains, which latter service is handled by multiple unit cars drawn by steam locomotives between Croton and Peekskill, a distance of 6 miles. For these reasons it is difficult to compare the former steam service with the existing electric operation. It is accepted that the service is better because of the quicker acceleration and affords a greater cleanliness in operation, but the relative cost has not been determined.

A direct comparison of train schedules in steam and electric operation is given in the table below:

### COMPARISON OF SUBURBAN TRAIN SERVICE

| Items | Hudson Division | | Harlem Division | |
|---|---|---|---|---|
| | Steam | Electric | Steam | Electric |
| Date of time table | Dec. 1906 | Dec. 1913 | Dec. 1906 | Dec. 1913 |
| Number of trains per 24 hours | 54 | 44 | 59 | 64 |
| Number of trains per max. hour | 5 | 7 | 8 | 10 |
| Fastest schedule time between terminals, min. | 65 | 68 | 51 | 46 |
| Average schedule time for local express min. | 72.4 | 72.0 | 56.6 | 51.2 |
| Average schedule time for locals min. | 79.2 | 76.6 | 64.5 | 59.1 |

Electric operation in the case of the New York Central and Hudson River Railroad Company was not a choice, it was a necessity and was not installed with the hope of effecting any economy in operation, but to permit trains to enter New York City under Park Avenue without smoke and to make possible the new Grand Central Terminal. The property owners along Park Avenue have benefited financially more by the change in motive power than has the railroad company, and if the railroad company were permitted to enjoy a portion of the revenue derived by the city in taxes on the increased

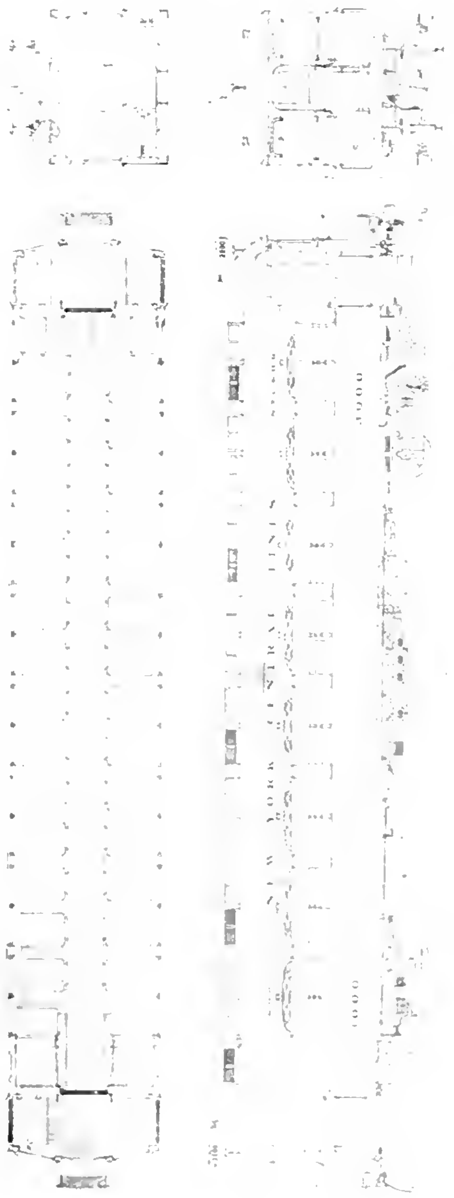

Fig. 1. Drawing of one of the Earliest All-Steel Passenger Motor Cars

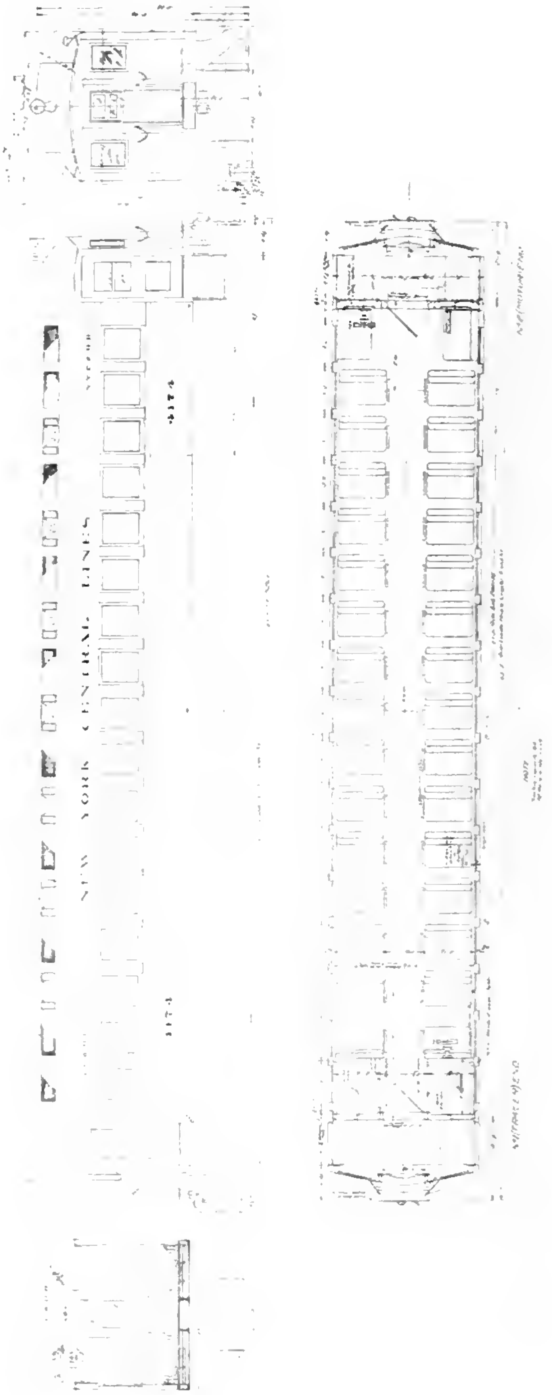

Fig. 2. Drawing of the Latest Type of All-Steel Passenger Motor Car

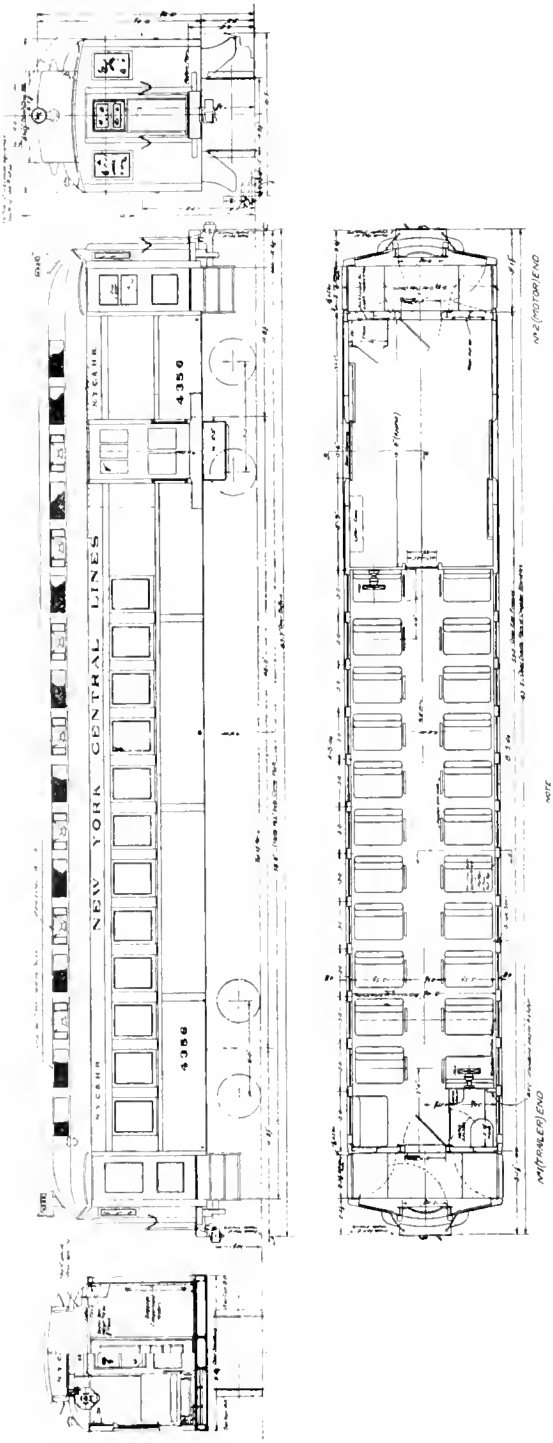

Fig. 3. Drawing of the Latest Type of All-Steel Combination Smoker and Baggage Motor Car

valuations of Park Avenue property, the heavy fixed charges on the cost of electrification could more easily be carried and electric operation would assume a more favorable commercial aspect.

### Multiple Unit Motor Cars

The multiple unit cars of the New York Central and Hudson River Railroad Company are of all-steel construction and consist of an original lot of 125 motor cars built by the American Car & Foundry Company, 55 trailer cars built by the St. Louis Car Company and 6 combination baggage, mail and express motor cars built by the latter company. A subsequent order of 19 motor cars and 6 combination baggage and smoking motor cars has been filled by the Pressed Steel Car Company. The original cars were the first all-steel passenger cars used on a trunk line railroad and the design was necessarily crude in the light of the present steel cars, since they were made up almost wholly of structural steel shapes and plates commonly rolled by the steel mills and of other stock parts.

The original motor car general drawings are reproduced in Fig. 1. This car weighs 105,800 pounds, of which 26,900 is in the trucks, 12,200 in the motors, 48,300 in the body, and 18,400 in the body equipment which includes the electric, gas, steam and brake apparatus, also seats, basket racks, cooler, tool box, etc. The body is 50 ft. long and 9 ft. $8\frac{5}{8}$ in. wide over sheathing, and the height from track over roof is 13 ft. $9\frac{1}{2}$ in. The length between coupler knuckles is 62 feet. The seating capacity is 64 passengers. The framing is of the side girder type with a 6-in. angle side sill, a bulb angle below the windows and the side sheathing $\frac{3}{16}$ in. thick forming a plate girder on each side of the car, carried by the cast steel bolsters and supporting the floor system by means of built-up cross members at the ends of the body and at three points between the trucks. The center sills are shallow "I" beams, transmitting the buffing and draft forces, and acting as cantilevers beyond the end sills to carry the platforms. The floor is of fireproof composition laid on galvanized steel sheets with keystone shaped corrugations and wooden floor strips.

The outside of the car above the window sills is covered with steel sheets $\frac{1}{8}$ in thick, and the inside with sheets and moldings $\frac{1}{16}$ in. thick. The ceiling and roof are of composite board. The doors except the vestibule end doors are of the sliding type, a feature which however, has been abandoned on the later cars. The vestibule is completely enclosed and is used as a motorman's cab. The master controller and brake valve are so located that when the vestibule end door is open, as it normally is except at the front of trains, it conceals and protects them. Two saloons at the same end of each car are provided. The seats are reversible, of the "Walkover" type, and are rattan covered.

Both steam and electric heat are provided; also gas and electric light, thus permitting the cars to be operated outside of the electric zone. Electric fans are placed at each end. The switches and fuses for light, heat, fans and air compressor are placed on a slate switchboard in one of the body end bulkheads. Control, circuit breaker and headlight switches are placed overhead in each vestibule. The main motor fuse and the main auxiliary fuse are under the car. The cars are connected by a bus line on each car for supplying current to a car while crossing gaps in the third rail. Resistance is inserted in the bus line on each car, to keep down the rush of current. All wiring is in iron pipe conduit, excepting wiring for heat, light and fans, which is in Sprague flexible conduit.

The draft gear is of a type developed especially for these cars. The coupler is 8 ft. 9 in. long, pivoted at a point three feet ahead of the bolster, and designed for curves of 135 feet radius. Connections are made from the coupler shank to the forward corners of the truck, to guide the coupler to the center of the truck when rounding curves. The buffer is mounted to swing with the coupler. The brake and signal pipes are carried on the sides of the coupler shank and connected at the pivot, by lengths of hose, to the pipes on the body.

The cars built by the St. Louis Car Company are of essentially the same design as those built by the American Car & Foundry Company. They were originally used as trailer cars but were designed to be later equipped with motors and this has now been accomplished on 36 of the 55 trailer cars.

The cars furnished by the Pressed Steel Car Company during the year 1913 represent the latest practice in steel car construction. They are almost an exact reproduction of the New York Central main line all steel coaches, though shorter in length. The appearance is illustrated in the reproduced general drawings given in Figs. 2 and 3.

They follow the earlier cars in arrangement and equipment, the principal differences being as follows:

Body length increased 3 ft. 2 in. to accommodate larger seats.

Seat spacing increased from 34½ in. to 36 in. to accord with main line practice.

Doors hinged instead of sliding, to accord with main line practice.

Doors steel instead of wood.

Roofing steel instead of composite board.

Wooden floor strips omitted.

Gas omitted, as cars do not operate beyond the electric zone.

Steam heat omitted for the same reason as the gas.

Electric heaters along side of car instead of under seats, this being possible since the steam pipes are omitted.

Window arrangement changed to accord with main line practice.

Wood furring eliminated.

Greater use of heat insulation and sound deadening material.

Use of cast steel combined body bolster and platform.

Space between cars reduced by forward extension from vestibule end door posts.

Two switchboards instead of one to facilitate handling.

The side girder type construction of the original motor cars is retained and this is the principal difference between these and the main line coach. The Commonwealth Company's cast steel combined bolster and platform is used in the underframe from the end of the car to a point back of the bolster, where the sills are attached to it. The center sills are of the same size as in the earlier cars but reinforced by a ¼ in. top cover plate. The floor arrangement follows closely that of the main line coach, viz., galvanized "Chanarch" sheets covered with composition flooring and a sub-flooring of light flat flanged sheets carrying insulating material. The two switchboards are on opposite sides of the car in the end bulkhead. One carries the switches and fuses for lights, heaters and fans, handled by the trainmen; the other back of the motorman contains the compressor switch and main switch, and the control apparatus. The weight of this car is slightly greater than that of the earlier design. The wheel spacing and loading are shown in the diagrams and tables.

**Trucks**

The original motor and trailer trucks are of special design and were built by the American Locomotive Company. They are illustrated in the group of drawings in Figs. 4 and 5. The principal dimensions of the trucks are as follows:

| | Motor Truck | Trailer Truck |
|---|---|---|
| Wheel base . . | 7 ft. 0 in. | 6 ft. 0 in. |
| Frame centers . | 6 ft. 8 in. | 6 ft. 4 in. |
| Wheel diameter . | 36 in. | 33 in. |
| Journals . . . . | 5½ in. by 10 in. | 5 in. by 9 in. |
| Weight equipped without motors . . | 15,300 lb. | 11,600 lb. |

The motor truck has cast steel side frames of the locomotive type, suspended directly without equalization from the ends of elliptic springs above the journal boxes. The trailer truck has 8-in. "I" beam side frames, which later have been reinforced by ½-in. plates. The pedestals are of cast iron with single equalizers. Both trucks have cast steel transoms of channel section, spread at the ends for a broad connection to the side frames and formed to receive the spring plank hangers, the brake hangers, and on the motor trucks the brake levers. The bolsters are of cast steel with center bearings cast integral. The journal boxes are of the Symington type, with pivot lids, and have stirrups cast on the bottom to carry the third rail shoe beam. The wheels are of the cast center, steel tired type. On the motor truck one wheel on each axle has its hub extended to a length of 14 ⅜ in. and has a seat of 15½ in. in diameter on which the motor gear is shrunk. The ends of the motor axle bearings are directly against the finished surfaces of the wheel hubs.

The motor trucks under the last lot of motor cars and under the converted trailer cars were of a special design built by the Standard Motor Truck Company.

Note 1—.Weights shown for No. 2 end and total are with A. L. Co. motor truck. For S. M. T. Co. motor truck deduct 450 lb.
Note 2—.Weights shown for No. 2 end and total are with S. M. T. Co. motor truck. For A. L. Co. motor truck add 450 lb.

The dimensions, etc., given for the earlier motor trucks apply approximately to these also, except that the weight is 14,700 lb., being 600 lb. less. The center and side bearings, brake connection and drawbar connections are so arranged that the truck as a whole will interchange with the earlier truck. Most of the features standard on the trucks of the manufacturer are included in these trucks. All the principal frame members are pressed steel, of channel section. There is the usual pedestal jaw on the outer side of each journal box, but the inner pedestal jaw is omitted and the boxes tied together rigidly by the equalizers. The elliptic springs are of unusual design, the leaves in each band being divided into two groups, each group tapering separately. The bolster is of cast steel. Its side swing is dampened by a friction device consisting of two sets of steel leaves, one attached to the bolster and the other to the transom, which are interlaced and pressed together by adjustable springs. The brakes are supported from the non-spring-borne parts of the truck. The third rail shoe beam is shorter than on the earlier trucks and is carried by the equalizers instead of by the journal boxes. On these trucks the wheels are solid forged steel and the gears are mounted directly on the axles.

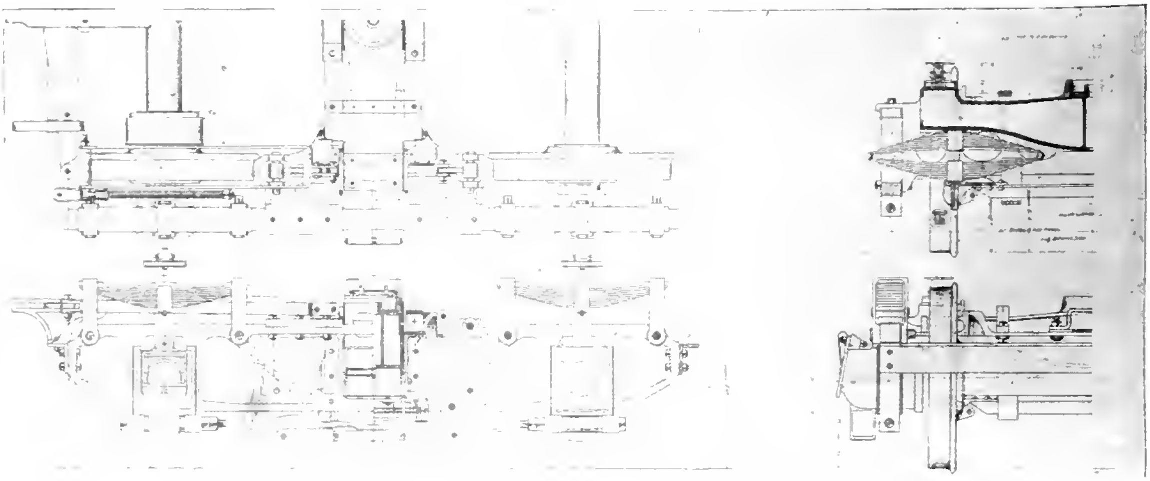

Fig. 4. Drawing of one of the Original Motor Trucks. The Motor is not shown here

### Motor Equipment

The motors for all of the motor cars have been furnished by the General Electric Company and are known as GE-69-C which may be briefly described as follows:

Their one-hour rating at 600 volts is 200 h.p. at the axle. They are of the box frame type and are run closed without ventilation. The frame and gearcase occupy all the space between the wheel rims, with only sufficient clearance to permit the use of flanged brake shoes. To economize space the armature bearings are set entirely within the general outline of the frame and extend inside the armature core head and the commutator shell. The motor is journaled directly on the axle, and supported at the opposite side by a nose resting on the truck transom without springs. The motor not being of a recent type, further description seems unnecessary.

### Multiple Unit Control Equipment

The control equipment on all of the motor cars is of the Sprague-General Electric type, consisting essentially of solenoid-operated contactors which make the different electric connections of motors and regulate the resistance in series with them, a solenoid-operated reverser, and master controllers for controlling the current supply to the solenoids of the contactors and reversers. The contactors (15 on the earlier cars and 11 on the latest), the reverser and a circuit breaker are mounted in boxes under the cars, with convenient removable covers for inspection. There are four forward positions of the controller handle: 1st, motors in series, all resistance in circuit; 2nd, same, resistance cut out; 3rd, motors in parallel and resistance in circuit; 4th, same, resistance cut out. The second and fourth are running positions; the first is used for low speed switching. In the reverse direction, only the first two positions are available. The motorman places the controller handle in any one of the above positions, and the connections are automatically advanced, resistance being cut out step by step, and the motor connections changed from series to parallel, under control of a current relay which permits each successive step to be taken only after the increase of speed and counter e.m.f. has reduced the current to a given value. A system of interlocks prevents any further advance of the control steps in case the reverser fails to throw or any contactor fails to open or close when it should. The master controller has a "dead man's handle," a device consisting of a button on the handle, connected with a small valve inside the controller, whereby, if the motorman relaxes his hold on the handle, an emergency valve is caused to open and allow air to escape from the brake pipe, causing an emergency application of the brakes.

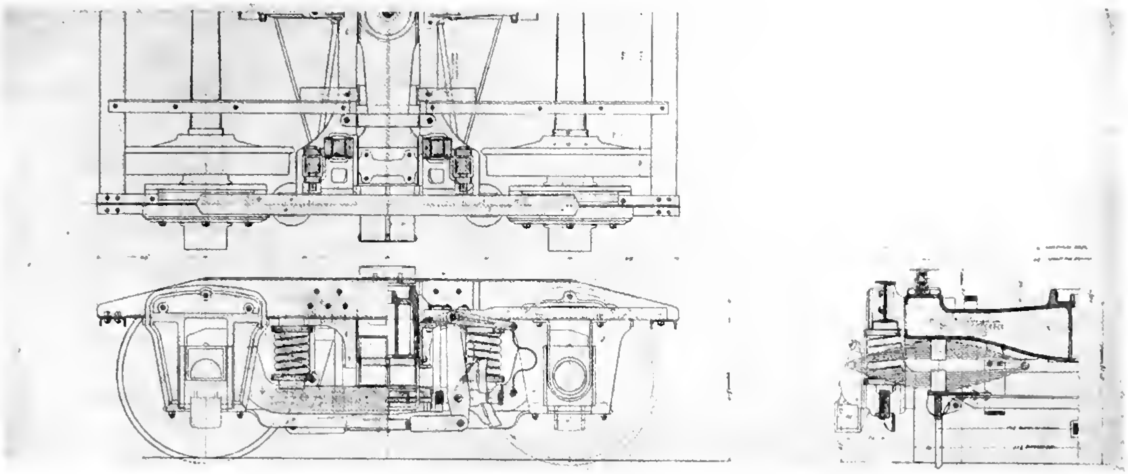

Fig. 5. Drawing of one of the Original Trailer Trucks

### Air Brake Equipment

The air brake and train signal equipments were furnished by the Westinghouse Traction Brake Company. Both are arranged for operation in connection with standard coaches and with steam locomotives. The brakes are known as Schedule AML, and have the modern features of graduated release, quick recharge, high emergency pressure, etc., which greatly facilitate suburban operation by increasing the flexibility of the brakes and the accuracy of stops. The compressor, known as D-2-EGX, has a capacity of 25 cubic feet of free air per minute and supplies air to two 16-in. by 60-in. main reservoirs. Air is supplied through a feed valve set at 90 lb. to a line running through the train known as the "control pipe" from which air passes to the engineer's valve and the triple valves. This is in addition to the usual brake pipe through which the action of the triple valves is controlled. The brake cylinder is 14-in. by 12-in. The levers are arranged to give shoe pressures equal to 90 per cent of the weight at the trailer end of the car and 100 per cent at the motor end, the excess at the motor end being an allowance to compensate for the rotative inertia of the armatures. The air signal equipment on each car is a combination of the usual car equipment and locomotive equipment with signal valve and whistle at each end of the car.

### Multiple Unit Train Service

Express multiple unit trains consist of from two to ten motor cars, a photograph of a six-car train is given in Fig. 6; local trains are usually from three to twelve cars in length and are made up in the proportion of two motor cars to one trailer.

From typical service tests made in January, 1908, with multiple unit trains, the following statistics have been selected:

### MULTIPLE UNIT TRAIN TESTS

| Items | Test No. 1 | Test No. 2 | Test No. 3 | Test No. 4 |
|---|---|---|---|---|
| Location of tests | Harlem Div. | Harlem Div. | Hudson Div. | Hudson Div. |
| Total wt. of train | 365T | 330T | 200T | 165T |
| No. of motor cars | 6 | 6 | 3 | 3 |
| No. of trailer cars | 1 | 0 | 1 | 0 |
| Total miles run | 12.5 | 12.5 | 6.3 | 6.3 |
| Av'ge speed m.p.h. | 31.4 | 29 | 23.6 | 21.3 |
| Number of steps | 3 | 3 | 2 | 1 |
| Watthours per ton mile | 35 | 37 | 35 | 31 |

A direct comparison, on the New York Central Railroad, of the cost of steam and electric operation for suburban service is not possible because of the changed operating conditions previously described; nor can any accurate statement be made of the complete cost per car mile for the reason that the multiple unit cars are not equipped with wattmeters, and the current generated at the power stations is used for so great a variety of service that the amount of current delivered to the cars cannot be segregated with any degree of accuracy. It is, however, generally conceded that the cost of operating and maintaining multiple unit trains is less than the cost for a similar service with steam trains. Nevertheless, the saving is not sufficient to cover the first cost of the electric installation.

The benefits which have accrued from electric operation are enjoyed more by the public than by the railroad. It is obvious that adjacent property owners and municipalities through which electric trains pass are more benefited than the railroad, and it has not been demonstrated that the railroad has yet received adequate return on the investment.

Fig 6. A Six-Car, Multiple Unit Express Train

# ECONOMIES OF STEAM ROAD ELECTRIFICATION

By A. H. Armstrong

Assistant Engineer Railway and Traction Engineering Department,
General Electric Company

The author calls attention to the fact that the electric locomotive has demonstrated conclusively that it can obtain operating results in any class of service that will compare favorably with steam operation. Many of the operating features in steam road service in which economies could be secured by substituting electric for steam locomotives are cited, and the sources of the probable economies to be secured with the extensive introduction of electric locomotives on main line steam roads are summarized.—Editor.

A. H. Armstrong

THE success attending the operation of electric locomotives has furnished ample proof of the fitness of this type of motive power to replace the steam engine in any class of service. It is natural that in the early days of electric locomotive construction there should be a wide diversity in types and systems of operation. Uniformity of design will be obtained only after the weaker forms of construction have succumbed to the test of continued commercial operation. It is fair to state that in no class of railroading is there so much attention paid to detailed operating figures as obtains in the several electrical installations. While such figures reflect in a great measure the special conditions surrounding each particular installation, there are nevertheless general records of reliability, economy in operation and cost of maintenance that are doing a great deal to settle the much discussed questions of forms of locomotive construction and systems of distribution.

In every installation, with perhaps no exception, electrical operating results have disclosed a favorable comparison with previous steam operation. Indeed it becomes more apparent that main line railroading today is *steam* railroading governed, in a large measure, by the limitations of the steam engine itself. The length of engine division facilities provided at terminal points, coal and water facilities, the length of a crew run, the tonnage and speed of trains and even the profile of the road itself are all governed by the possible performance of the steam engine and are all subject to radical change with the substitution of the electric locomotive.

In this connection, it must be remembered that the attractive results so far obtained with electric locomotives of considerable capacity have been largely secured in city terminal and tunnel installations with but the two exceptions of the New York, New Haven & Hartford and the Butte, Anaconda & Pacific. Through service to New Haven has been of such recent date that operating figures are not yet obtainable, but the details of operation published in this issue, as given by Mr. Cox in his A. I. E. E. paper at Spokane, covering the first six months of operation of the Butte, Anaconda & Pacific are of special interest as indicating the savings effected over previous steam operation. The Butte, Anaconda & Pacific Railway handles trains of the heaviest freight class and its success in regard to both reliability of service and economies effected contributed in no small measure to the decision to electrify a considerable part of the main line of the Chicago, Milwaukee & St. Paul Railway lying in the same territory.

Many of our electric interurban railways, in magnitude of tonnage hauled and mileage of track, approach some of the smaller steam railway lines, but the mind of the steam railroad operator has been rather slow to accept interurban operating figures as applying in equal degree to his larger problem of transportation. To the electrical engineer, however, the electrification of the main steam line differs from the interurban problem only in the size of the electric locomotives involved, as turbo-generator units and step down substations are already in operation of a capacity considerably in excess of the needs of the average main line steam service. Interest therefore centers particularly in the electric locomotive, not only as regards its design and cost, but because this new type of motive power which can be built of unlimited capacity and speed bids fair to break through many traditions surrounding the operation of steam railways, with resultant benefits of a far-reaching nature. The usual length of a steam engine division may vary from 110 miles in the mountains to 150 miles on the plains, but with the electric locomotive requiring inspection only after 2500 miles run (the present practice in the New York Central and Pennsylvania electrical zones) there is no reason why engine divisions should not be much longer than this. The longer electric locomotive run is entirely possible, as this type of motive power is not dependent upon coal and water facilities, has no need to reach a round house to have its fires cleaned, boiler washed, etc.; in fact, has no operating base, and furthermore can be kept in operation twenty-four hours a day up to the limit of what good practice determines as a reasonable mileage to run between inspections. The flexibility of such a type of motive power can hardly be overestimated and the fact that it is ready for instant service at any time it is reported for duty should effect certain economies in operation and eliminate much lost time in present steam railroading, which is directly chargeable to the limitations of the steam engine itself.

Carefully compiled statistics indicate that certain western railroads purchase in the neighborhood of 12 lb. of coal for each horsepower-hour of actual work expended at the driver rims in hauling trains of all classes. Whether the electrified steam railroad depends for its source of power upon coal or water power, there will be considerable fuel economy effected. If coal is the best source of power then the modern turbo-generator power house is so economical as to use considerably less than half the coal now demanded by the steam engine when effecting the same tonnage movement, even after including all losses of transmission and conversion of power necessary to reach the electric locomotive.

The recent contract closed with the Montana Power Company by the Chicago, Milwaukee & St. Paul Railway is an example of the advantage of purchased power in localities favored with abundant and reliable water power. If the results obtained in the electrification of the Butte, Anaconda & Pacific Railway, operating under a similar contract, should be duplicated in the coming Chicago, Milwaukee & St. Paul installation, the saving of possibly half the previous coal expense should in itself constitute largely to the economic success of the undertaking. The coal required for the present movement of its trains constitutes roughly four percent of the entire gross ton mileage, the saving of which is not to be overlooked when considering the change to electric locomotives.

During the past decade of increasing costs, electricity is one of the few commodities that has steadily decreased in price, and this lower cost of power has been attended with improvements in electrical apparatus tending to even greater reliability and efficiency in operation. Looking forward to the further developments which the future should promise, the fuel advantages of the electric locomotive appear to be on a permanent basis.

Steam locomotives of great weight on drivers and capable of giving a tremendous drawbar pull are in general use, but such steam units deliver their maximum pull at very moderate speeds and in consequence their ton mileage capacity per hour is limited. It was left to the coming of the electric locomotive to provide a hauling unit capable of giving the greatest drawbar pull which the draft gear will permit and at a speed that may be as high as desired. In other words, one electric locomotive can be built to haul just as heavy a train as the steam engine, and at a much higher speed. Furthermore, this very powerful unit can be operated by a single crew. This means that the congestion of single track mountain divisions will be greatly relieved as full tonnage trains can be hauled at speeds as high as permitted by the alignment of the road with no restriction due to the profile. Or to put the matter differently, the introduction of the electric locomotive bids fair to greatly diminish if not eliminate the handicap of "the ruling grade."

From the operating records of the several electric railways employing very heavy locomotives, the fact becomes apparent that such locomotives can be maintained in good original condition at an expense considerably below that for an equivalent capacity in steam engines. Coupled with the much lower cost of maintenance is the greater reliability of the electric locomotive in service, an advantage that will leave its economic effect all along the line of operating costs. Undoubtedly one of the reasons contributing to the low cost of electric locomotive maintenance is that its wearable parts are easily replaced by spare parts in a few hours, thus permitting repairs to be made at leisure under the best shop conditions and with a force continuously employed.

The completion of the extensive electrification work now under way upon the Chicago, Milwaukee & St. Paul Railway will afford the first service data of the operation of a complete main line engine division. The conditions call for the movement of very heavy freight and passenger trains over both level track and two per cent mountain grades and great economies as well as operating advantages are anticipated. The success of this installation will demonstrate on the broadest scale whether the economics of electrification can offer an attractive return upon the initial investment required, and will prove the desirability of replacing the steam engine by the electric locomotive, at least on mountain grade divisions where the steam limitations are most keenly felt.

To summarize the sources of probable economies with the extensive introduction of the electric locomotives on main steam roads, marked savings should be effected in the following items of expense:

Fuel expense both as regards reduced cost of electric power, elimination of coal tonnage and coal facilities required with steam engines.

Reduced cost of engine maintenance, both direct shop expense and round house expense, which latter is practically eliminated. The fewer breakdowns of electric locomotives should also be reflected in lesser crew expense for overtime and other items.

The greater capacity of the electric locomotive as regards speed on heavy grades not only introduces considerable ecomomies, but may defer for a long time the heavy expense of double tracking a mountain grade division suffering from the limitations of steam engine performance.

Besides the direct advantages of electrification applying generally to all roads, the greater flexibility of electric power and its greater safety due to removing the fire risk and substituting electric for air braking, together with the many secondary advantages of the electric locomotive, will all have greater or less weight, depending upon the local conditions governing any particular instance. With such possibilities of radical changes in operation, it can be confidently expected that direct savings may be materially added to by great advantages in operation that may be somewhat difficult to express in terms of operating expense.

On the Butte, Anaconda & Pacific Railway

# RAIL SECTIONS AS ONE ELEMENT IN STEAM AND ELECTRIC TRACTION

By P. H. Dudley, C. E., Ph. D.

Consulting Engineer, New York Central Lines, New York

This article, coming from the pen of such an eminent authority on rails, should be of special interest and value to all railroad engineers. After some interesting general data and historical facts, the author gives such a wealth of valuable information on many different phases of rail and track construction, as well as operating data and tests of intrinsic value, that a short summary is impossible. The article is concluded by a few short and valuable paragraphs on the electrical resistance of steel rails, a subject on which we hope to publish later on, a more extended article from the same author.—Editor.

P. H. Dudley

The 6-inch 100-lb. steel rail section, laid first in 1892 on the New York Central & Hudson River Railroad, was designed with a broad thin head for an ample bearing surface of the wheel treads on a stiff rail, which could distribute a large portion of their loads to the wheel spacing for a smooth riding track. The fact is not generally appreciated that the wheel load spacing of the equipment controls the spans of the bending rails on the flexible crossties in the ballast, rather than their spacing under the rail. It was, as a rail section of that date, the most efficient engineering structure in use in the world and has fulfilled its complex functions with safety, precision and economy as an essential element of the means of railway transport. (See Fig. 8.)

The modern steel trains, the Empire State Express, the Twentieth Century Limited and others, each have a kinetic energy greater than the heaviest projectile of any high power guns yet fabricated. The stored energy for the speed of the train can be absorbed and rendered inert through several wheel contacts on the rails, when the engineer touches the handle of the air brakes to stop his train. The artillerist concentrates the stored energy of a projectile upon a single contact for destructive effect, while the railway engineer carries and distributes the total load of a train on many wheels, and therefore absorbs the stored energy for the speed of the train through several contacts on the rails for safety and utility. The weight of the rails on their flexible crosstie supports in the ballast and subgrade, occupied by the length of the steam railway or multiple unit train on its several wheels, may be but one-hundredth of the load which the rails can carry when subdivided, distributed and constrained through several wheel contacts. A rail of suitable stiffness on the flexible crossties in the ballast, due to the principle of efficiently subdivided, distributed and constrained loads, is better for good track, smooth riding of the equipment, and economical operation, than that of the major part of the wheel loads concentrated on each crosstie, through a weak rail section.

The 6-inch 100-lb. section is a model of efficiency through its metal to limit and distribute the reduced strains of its wheel loads to the crosstie supports, for it can withstand thousands of repetitions with marvellous exactness for similar conditions of service without failure.

### Some Interesting Historic Developments in Transportation

Schenectady being in the valley of least resistance to travel from east to west and vice versa, inherited the Indian trail and canoe, then developed transportation, by (1) the Conestoga wagon, (2) the stage coach, (3) the canal, (4) steam railroads, (5) electric traction.

The Mohawk & Hudson Railroad from Schenectady to Albany was chartered in 1826, although active work upon its construction did not commence until 1830 and 1831 for the Saratoga and Schenectady Railroad. Mr. John B. Jervis was Chief Engineer of both roads for construction. Locomotives were then in their primitive stage of evolution, of small tractive effort, and able to ascend only moderate gradients of a few feet per mile. Mr. Jervis was therefore obliged to construct for the Mohawk & Hudson Railroad an inclined plane operated by a stationary engine, for the ascent and descent of the cars at Schenectady, from the Mohawk River to the plateau on its banks. A similarly inclined plane was constructed from the Hudson River for the Albany terminal. The alignment of the track of the Mohawk & Hudson Railroad for 14 miles on the plateau was composed of three tangents connected by two curves. The one about midway of the line was 396 ft. long, and of 23,000 ft. radius; the second near Albany was 594 ft. long, and of 4200 ft. radius. The head of each inclined plane connected with the tangent at either end by a curve 528 ft. long and of 1100 ft. radius. To make the gradients and curves easy for the locomotives, the cuts and fills were heavy, and the cost of the railroad averaged $40,228 per mile, a large sum for 1831, but a small cost for the principles elucidated.

The New York Central & Hudson River Railroad now occupies the original line from Carmen to Karner, and includes the curve of 23,000 ft. radius. The total length of the railroad at first was 15.86 miles, and it did not run into the business portion of the Capital; but later a branch line for passengers was permitted in State Street. New York State had just completed its Erie Canal, and the Mohawk & Hudson Railroad Company at first was not allowed to transport freight.

We can study with profit the historic but frail structures of the track, the primitive locomotives and the strap iron rails for the principles of construction which eventually directed their evolution into types in 83 years for the present developments. This has required the application of the facts of experience and the principles of science of the preceding ages, on a more extensive scale than ever before in the history of mankind.

The superstructure of the track for the Mohawk & Hudson Railroad on the plateau between the inclined planes at Schenectady and Albany was constructed of a strap iron rail, $2\frac{1}{2}$ inches wide, and $\frac{9}{16}$ of an inch thick, with the upper corners rounded to $1\frac{7}{8}$ inches and spiked in the center of longitudinal stringers 6 by 6 inches, for their strength as a girder, Fig. 1. The author has one of the original rails and a piece of a stringer. To make an expected enduring track of rigid supports in the roadbed, pits 2 ft. square and with 3-ft. centers were prepared for each line of stringers, and in each pit were placed about nine cubic feet of broken stone which cost $2.00 per cubic yard. Near Schenectady, to support the stone blocks, the broken stone was placed in two parallel trenches. Stone blocks were placed on these foundations, each of $2\frac{1}{4}$ cubic feet, 16 inches in height, with a top surface of 15 by 16 inches, and upon these stringers were laid and attached by knees and spikes to support the strap iron rails. The iron formed the bearing surface for the wheel contacts and the guide for the flanges of the wheels of the passing locomotives and cars, and the stringer as a separate piece supplied the strength as a girder.

Mr. Jervis opened the Mohawk & Hudson Railroad Aug. 9, 1831, with the locomotive "DeWitt Clinton," which was carried upon two pairs of drivers and weighed $6758\frac{1}{2}$ pounds, and was intended to be under three gross tons, exclusive of the light four-wheel tender. The three cars were stage coach bodies with flanged wheels for the track. The length of the entire train was less than that of one of the present Pacific types of locomotives.

A locomotive named the "John Bull" was built by Robert Stephenson & Son, Newcastle-upon-Tyne, and weighed 12,742 pounds and had under the front end a pair of rigid carrying wheels, while the single pair of driving wheels carried 8745 pounds. The wheels of both locomotives were 4 feet 8 inches in diameter, and the wheel base of each, 4 feet 6 inches. The weight of the "John Bull" was too great for the superstructure, and was not subdivided and distributed by a wheel base sufficient in length to ride steadily over the track, and was seldom used as originally made.

Mr. John B. Jervis was constructing the Saratoga & Schenectady Railroad when he opened the Mohawk & Hudson. Three miles of track were finished with stone blocks set upon broken stone, which carried the stringers, the same as used for the Mohawk & Hudson Railroad. The strap rail was an angle iron spiked on the upper inner corners for the track, to provide for inch flanges on the engine drivers and wheels. Mr. Jervis built the balance of the line with crossties upon which the stringers were placed to support the small angle strap iron rails, and ballasted the track for the flexible superstructure and an elastic roadbed, the principle in use today on all steam railroad tracks. The design of the superstructure of the track of the Mohawk & Hudson Railroad on the rigid supports is shown in Fig. 1, and the Saratoga & Schenectady Railroad on elastic supports in Fig. 2, from the best information to date. Fig. 3

shows the original English locomotive "John Bull," by Robert Stephenson & Co., 1831.

Mr. Jervis found the engines were more severe upon the strap iron rails of the Mohawk & Hudson Railroad than was expected, and in 1832 he designed his leading four-wheel truck, arranged for both lateral and vertical flexibility to guide the front of the locomotive in place of the ordinary carrying pair of wheels of the English construction, see Fig. 4. This was also to extend the running gear of the engine, to subdivide and distribute the front truck load on the rail for the following driving wheels. The wheel base of the engine constructed on this important principle was found much easier upon the track and was extensively copied, and in a few years another pair of driving wheels was added for new engines, constituting the American eight-wheel or 4-4-0 type of engine.

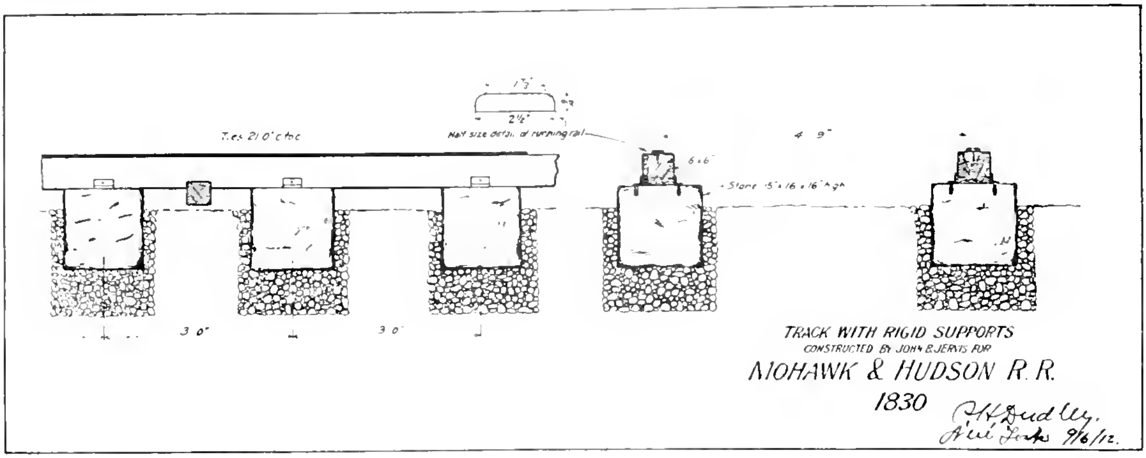

Fig. 1

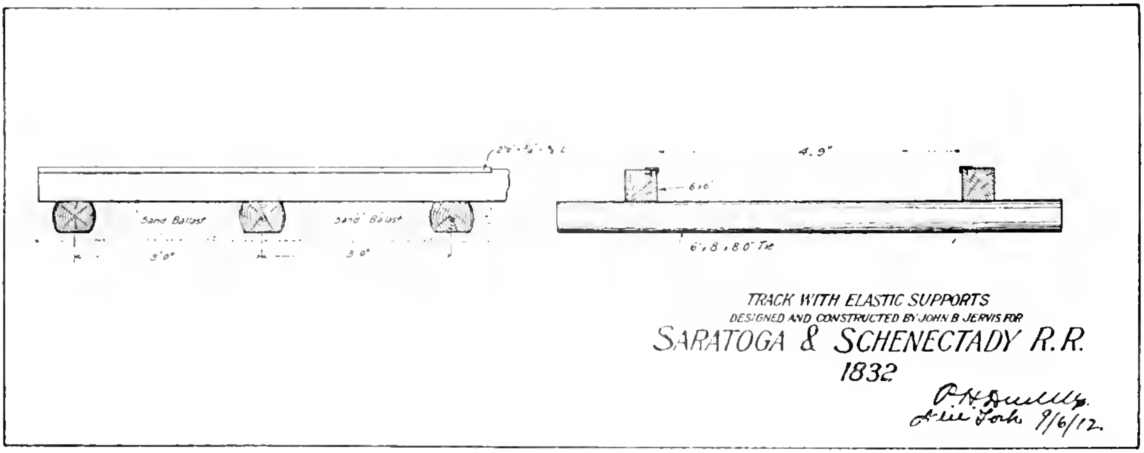

Fig. 2

The locomotive in evolution had now reached a type capable of enlargement, so flexible in the wheel base as to carry sufficient weight on the driving wheels for adhesion to pass around sharp curves and ascend gradients of 40 feet per mile, and superseded the inclined planes worked by stationary engines, used in the earlier railways.

My tribute to the enduring work of Mr. Jervis on the Mohawk & Hudson Railroad, for all coming time, is for his adoption and practice of the principle involved in the leading four-wheel truck for flexibility, and extension of the wheel base of the locomotive for subdivided, distributed and constrained wheel loads on the rails, crossties, ballast and subgrade. The practice of the principle of a flexible superstructure on an elastic roadbed, used on the Saratoga & Schenectady Railroad, is now followed by all steam railways of the world.

### Iron Tee Rail Sections

Robert Livingston Stevens in 1830 designed for the Camden & Amboy Railroad a section of rail, the principle of which combined in one piece the bearing surface for the wheel treads, the guide for the wheel flanges, and the strength for the girder, with a base to rest upon and be spiked to the crossties. This was the prototype of our present rail sections, and was rolled in 1831 by Guest & Co. of Wales. It did not come into general use on account of the expense for many years, and then the head was made more pear-shaped. The construction of the early railways with iron rails was slow, for at first all the iron used was imported from England or Wales.

There were only 23 miles of railway track in this country in 1830 composed of strap iron rails laid upon wooden or stone stringers, and only increased to 2818 miles in 1840, as the frail superstructure of the track had not taken suitable form for its development; and strap iron rails were prohibited by law in New York State in 1844. The physical properties of wrought iron were sufficient for the installation of the early railways but inadequate for their development.

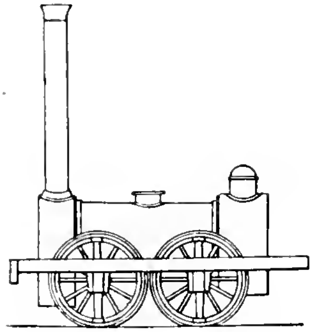

Fig. 3. "John Bull," Hudson and Mohawk Railway, 1831

### Bessemer's Invention for Making Steel

Bessemer steel replacing iron rails marks a distinct epoch in the construction of mileage, maintenance and operation of railways. Bessemer's grand conception was the application of the fact that one-half of one per cent of carbon combined with iron made a ductile steel of greater physical properties than wrought iron, and as cast iron contained from $3\frac{1}{2}$ to 4 per cent of carbon, 1.25 to 2.5 per cent of silicon, 0.50 to 1 per cent of manganese, 0.03 to 0.06 of phosphorus, a non-ductile and brittle product, he made a suitable converter and blew air through the bath of molten cast iron to burn out, first, the silicon and manganese, then the excess carbon above that desired for his grade of steel. This direct method proved only possible with the nearly pure Swedish irons. It was required in all other countries to select pig iron in which the impurities of phosphorus and sulphur would be 0.1 or under, as required for the grade of steel, and then decarburize the molten bath by blowing air through it and subsequently recarburize the blown metal with the desired carbon, manganese and silicon contents. This was a success, and, by the large product which could be made, rendered possible the present railway development by the use of steel rails of greater physical properties and more homogeneous product, to replace those of iron of inadequate physical properties.

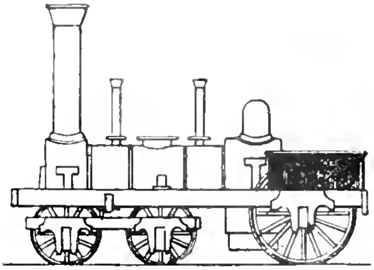

Fig 4. First Bogie Engine, Saratoga and Schenectady Railway. Jervis' Four-Wheel Front Truck Engine, Built by Robert Stephenson & Co., 1833

The use of Bessemer steel rails commenced in this country in 1863, with imported English brands of 500 to 1000 tons for trial. The early rails cost \$100 to \$120 gold per ton, which, with the premium, made the cost from \$240 to \$260 in currency during the Civil War. The early Bessemer steel rail sections were from three and one-half to four and one-quarter inches high, and the weights ranged from 56 to 60 pounds per yard.

The engineers of the New York Central & Hudson River Railroad made deflection tests and in 1870 increased the height of the rails to four and one-half inches, and the weight of the section from 60 to 65 pounds per yard. Large tonnages of the 65-lb. section were rolled in England and France, and the third and fourth tracks were laid with it about 1870 and 1871, and cost from $100 to $110 per ton. These early steel rails were so expensive that the weights of the sections were rolled as light as was considered safe for service. They were not stiff, and had small mechanical properties, and deflected to a marked extent under the wheels, and transmitted concentrated instead of distributed loads to each crosstie. A committee of the American Society of Civil Engineers, in 1873, studying the small wear of the rail under the light wheel loads, came to the conclusion that it would be desirable to design for economical reasons what was termed a residual section, and then add sufficient metal to the top of the head for several years' wear, see Fig. 5. They modified entirely the type of the section, reduced the percentage of the metal in the base and used more in the deep head, providing, as they supposed, for many more years' duration. The question of a section as an engineering structure for stiffness to reduce the train resistance and maintenance was not considered, as it was in advance of the ideas of the evolution of rail sections at that date.

The deep, heavy head, and the change from the thick to the thin base, did not make as safe a girder for heavy traffic, nor result in an equal quality of metal in the rail, as had been secured in the shallow head and thick base of the early sections, to which type we are now reverting from experience, for superior girders. The light steel rails, however, enabled the railway companies to save the cost of renewing the iron rails so often, and lessened the operating expenses, though it did not permit much increase in the wheel loads of the locomotives and cars over those

used upon the iron rails. The railway officials were anxious to improve their tracks and increase the wheel loads of the motive power and equipment to run faster and heavier express trains, and also haul larger freight train loads. I made a track indicator, with a special 6-wheel truck, to measure and record autographically the undulations of the rails in the tracks, to determine what was necessary to improve them in an economical manner.

### Inspection of Tracks with Track Indicator

I commenced the investigation of the undulation of the rails by my track indicator in 1879. The New York Central at that time had 4½-in. 65-lb. steel rails, see Fig. 5, in general use upon the main lines, and upon some of the subsidiary lines, 56 and 60-lb., and the height was from 4 to 4½ inches. The Boston & Albany had a 4½-in. 72-lb., and the Pennsylvania, two sections of 4½-in. 67-lb.

The diagrams taken from over 10,000 miles of the Eastern lines demonstrated the fact that the rails did not have sufficient mechanical properties to distribute the loads in the wheel spacing to any marked extent, as each crosstie received nearly the major percentage of the wheel effects. The crossties cut under the rail seats with rapidity, which permitted the light equipment to cause destructive, expensive and useless injury, while the train resistance was high, as well as the cost of maintenance and operation. I added a mechanism in 1881 to sum up the undulations into feet and inches, shown on the large diagrams, of one inch in length of paper to 50 feet of track, from which the amount per mile and section was secured for tabulation, and afforded definite measures of what labor could do and what could be expected from stiff rails in the track.

The investigations by my track indicator showed on all of the lines that the rails had taken definite forms in the track, which I classified under three distinct types: First, second and third forms of permanent set.

First form: Rails which were low at the joints and high in the center.

Second form: Rails low in the joints and center, but high in the quarters.

Third form: Rails more or less wavy on the surface due to conditions of manufacture.

There were combinations of the first and second, and the second and third upon a few rails.

The forms of permanent set also indicated that the rails were not sufficiently stiff so the track could be maintained in good condition for any length of time without constant attention to surfacing by the trackmen, and the results of their labor did not become cumulative from year to year. The rails began to take a set after one or two years cutting out at the joints under the passing wheel loads, the unit fiber strains being higher than in the present stiffer sections. It was evident that the section should have sufficient metal for its elasticity to carry the wheel loads before the permanent set occurred.

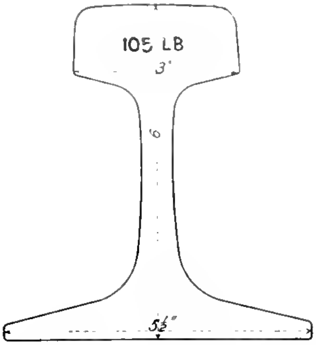

Fig. 9. New York Central & Hudson River R. R., 1912

I designed the pioneer 5-in., 80-lb. steel rail for the New York Central in 1883, Fig. 6, to furnish the superintendents of motive power and the engineers of maintenance of way a better steel rail section as an engineering structure than ever before used. It was, as a girder, 66 per cent stiffer than the 4½-in., 65-lb. section of the New York Central & Hudson River Railroad, secured by the addition of only 15 lb. or 23 per cent more metal per yard, and an increase of ½ in. in height for the section. The rail was rolled in April, 1884, and laid in July of the same year, on the four tracks from Grand Central Station to Harlem Junction, 5½ miles. The demonstration of its value in stiffness was a satisfaction to railway officials, and soon was followed by a 5-in., 80-lb. section for the Michigan Central Railway, and a 5-in., 85-lb. section for the Pennsylvania Railroad. The value of stiffness in rails as girders was so obvious that in 1883, after I had designed the 5-in., 80-lb. section already mentioned, and before it was rolled, I stated, upon the Boston & Albany diagrams for the year 1883, that it would be possible for them with new stiff rails on a well ballasted roadbed to reduce the undulations of the track to between the fifteenth and sixteenth line upon my condensed diagrams.

I distributed the area of metal for the head, web and base of the Boston & Albany 95-lb. section, which was limited to $5\frac{1}{32}$ inches in height by the railway company, owing to the curvature and heavy gradients of the line. I commenced to roll the rail in 1891, and the entire line of 200 miles of double track from Boston to Albany was completed in the summer of 1897. My inspection of the track in the autumn showed the average undulation for the entire track was 15 42/100 lines per mile upon my condensed diagrams, and confirmed the estimate of 1883, fourteen years in advance of its consummation.

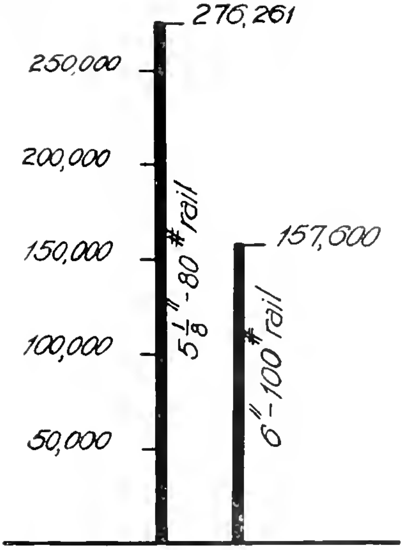

Fig. 10. Comparison of Total Stresses on Worn $5\frac{1}{8}$-in., 80 lb. and Worn 6-in., 100-lb. Rails under the same Locomotive. N.Y.C. & H.R.R.R., July, 1913

### Stiff and Heavy Rail Sections

I designed a series of stiffer and heavier rail sections, after the demonstration and experience with the first 5-in., 80-lb. by the New York Central & Hudson River Railroad, of which the 6-in., 100-lb. section, rolled March 12th, 1892, has been described. The $5\frac{1}{8}$-in., 80-lb., (Fig. 7) of which several hundred thousand tons have since been rolled, was over 10 per cent stiffer than the original 5-in., 80-lb., and some of the first made in 1892 have just been replaced by the 100-lb.

I made all my sections with broad and thin heads joined to the web with $\frac{1}{2}$-in. fillets and 12-in. radii for all sections under 70 pounds, and 14 inches for those which were heavier. The thinnest portion of the web was above the neutral axis, to form a larger junction with the base.

### Quality of Metal in the Rails

When I increased the height of the sections to augment their stiffness for smoother tracks which would check the deflections and reduce the area of contact between the wheels and rails slightly, I knew it would be necessary to increase the physical properties of the metal in the stiffer rails to avoid rapid wear and deformation. I introduced, for that reason, the low phosphorus 0.06 and 0.56 to 0.65 carbon Bessemer steel for the heavier sections. The Boston & Albany rails were rolled in 1891 out of the tougher steel, and I obtained 12 to 16 per cent ductility in the metal under the drop test, which had become obsolete for testing rails until this reinstatement. The specifications were that if 90 per cent of the butts, one from each heat, should withstand a weight of 2000 pounds falling 20 feet without fracture, and any of the remaining 10 per cent gave 4 per cent elongation per inch before breaking, the heat would be accepted. Less than 5 per cent of the heats failed under the 20-foot drop test. This high grade of steel was made for the New York Central and Boston & Albany Railroads from 1891, and continued until the low phosphorus ores were exhausted in 1898.

The metal was tough and tenacious and had so large a duration strain factor that but few breakages occurred in the zero or lower temperatures of winter, and practically none in the summer. I rolled over 500,000 tons of such metal in three-rail ingots for 30-ft. rails in the 80, 95 and 100-lb. sections. I commenced in 1893 to mark the top rail "A," the second "B," and the third or last rail of the ingot "C." The subsequent service in the track furnished the first opportunity to study the wear of the rails from the different positions of the ingots. The practice of the use of a letter to designate the position in the ingot is general for the railroad companies of the United States for rails and some wheels and tires.

The "A" rails of Bessemer steel with a trace of entrained slag and oxides wore the most rapidly under heavy traffic, but the breakages were not much in excess of either

"B" or "C" rails. It was this fact of the service tests of fourteen years that enabled me in 1907 to check the general adoption of a 20 to 25 per cent discard from the ingot. Improvements in making the steel and sound ingots to secure the full ductility of the metal due to its composition, is now the general practice and the wasteful discard is avoided.

### Reductions of Undulations in the New York Central & Hudson River Railroad Tracks, From 1881 to 1914

The undulations as summed up by the track indicator in 1881 on the New York Central and Boston & Albany Railroads averaged 8 ft. per mile, though there were some miles of 12½ ft., and others as low as 5 ft. on new rails. The New York Central & Hudson River Railroad has a chart showing the reductions of undulations in the track from 1881 to 1907, as measured by my track indicator. A curve also shows the increase in driving wheel axle loads on the engines. It is instructive and shows that, as the stiffness of the rails increased, the average undulations of the track decreased from 8 ft. per mile to 2¼ ft. in 1900, while the driving wheel axle loads increased from 30,000 to 60,000 lb. before 1907. The undulations of the track for 1914 are estimated to average about 2 feet or less per mile. The reductions in undulations of the track, by the stiffer sections as better engineering structures, have lessened the generated wheel effects and enabled heavier wheel loads and trains to be run as steam railway traction progressed.

The Empire State Express was installed Oct. 26th, 1891, with Mr. James Buchannan's 100-ton locomotive, and drew four cars of more than double its weight—the educator of the world for heavy high speed trains. The train today is three times its former weight and is composed of 8 to 10 Pullmans. Freight trains of 90 to 100 cars of about 4000 tons are now ordinary, as the train resistance is less per ton for long and heavy trains than for a single unit run by itself.

It is obvious that such progress in steam railway traction has been secured only by the utilization of important principles of construction of the equipment and the permanent way, which is apparent from observation and experience. There is, of course, difference of opinion for the reasons of the results, and the facts can be learned only by measuring the strains in the rails under the passing wheel loads.

The original 100-lb. section, to meet the progress in transportation, has been increased to a 105-lb. section, by the addition of fillets of one-inch radius to join the web and base, and the web thickened to ⅝ of an inch without other changes in dimensions. This was for additional stiffness and strength, and the rolling of basic open hearth steel from 0.63 to 0.75 carbon; see Fig. 9. The new splice bars also fit the original 100-lb. and thus join in the track the 100 and 105-lb. rail sections.

### The Equilibrium Depression Between the Track and Wheel Loads of the Passing Locomotives and Cars

The moving wheel loads of the locomotives and cars depress the rails, crossties, ballast and subgrade from the trackman's surface to the momentary equilibrium depression, and the specific deflections under the wheel contacts of the rails on the flexible crossties are limited by the strains produced in the metal of the section.

The depression is merely momentary for the rails, crossties, ballast and subgrade for they return practically to the trackman's surface after the train has passed.

## THE STREMMATOGRAPH

The stremmatograph is an instrument of precision which I designed, and completed its construction in 1897, to determine the unit fiber strains in the rails when attached to the base between the crossties under moving trains. It is the function of the stremmatograph to make autographic records of the longitudinal unit fiber strains of the elasticity in the metal of the rail section exercised in the base, due to the action of each individual moving wheel load, and its reactions on the flexible supports in the ballast and subgrade. The strains in the base are balanced in the head by those of an opposite character. The strains for a given unit length in the spans of the bending rail controlled by the wheel spacing of the equipment reverse above and below the neutral axis of the section for each passing wheel as a rule, consequently there is a series of alternating unit fiber strains to balance the stresses set up in the metal of the section to carry the wheel load effects. The unit fiber strains or balanced stresses developed in two different rail sections as simple beams of like sections on rigid supports and load are inversely proportional to their respective moments of inertia, according to the laws of mechanics.

The tests on 80 and 100-lb. rails with the stremmatograph show for the entire wheel base of the same locomotive with smooth wheels, that the above law of mechanics is equally true for the sum of all the unit fiber or balanced stresses per individual wheel, in two rail sections of different moments of inertia, on the flexible crosstie supports in the equilibrium depression of the track, until a speed is reached where the weaker section develops wheel effects in a faster ratio than the stiffer rails. The track construction and roadbed must be similar for both sections of rails; see Fig. 10.

The comparative tests were made on the New York Central & Hudson River Railroad at Coldwater, N. Y., July, 1913, upon a worn $5\frac{1}{8}$-in., 80-lb. rail rolled in 1892 and laid in track No. 3, and a worn 6-in., 100-lb. rail rolled in 1905, and laid in track No. 4, by the side of track No. 3. The worn 80-lb. rails had carried over three hundred million tons of traffic, and the worn 100-lb., one hundred and thirty-five million tons. The moment of inertia of the 80-lb. rail had been reduced from $28.5^4$ inches to $26.3^4$, according to the profile of the head, and were 30-ft. lengths spliced with 36-in. angle bars for a 3-tie supported joint. The moment of inertia of the 100-lb. had been reduced from $48.5^4$ inches to $46.77^4$, while the rails were 33 ft. long and spliced with 36-in. bars for a similar joint to the 80-lb. rail.

The ballast was gravel under each track, and the tests were made against the direction of the traffic on the 80-lb. rail owing to conditions beyond control, but with it on the 100-lb. rail.

The engine was a Mikado; the wheel base was 2-8-2; the total weight of the locomotive was 491,300 lb.; and the total length of wheel base was 68 ft., 11 in. Its tender had the usual two pairs of four-wheel trucks, a total of 10 wheel contacts upon one rail. The locomotive was nearly new; the drivers and wheels were of normal rotundity, which rendered possible speeds from $6\frac{1}{2}$ to 60 m.p.h., without the generation of large wheel effects.

The total stresses of each of eight tests upon the worn $5\frac{1}{8}$-in., 80-lb. for one rail, and six tests upon the worn 100-lb. rails for a range of speeds from $6\frac{1}{2}$ to 45 m.p.h.—140 different wheel effects for the two sections—compare within 1.52 per cent of being inversely proportional to the moments of inertia of the worn rails. Single experiments upon each section of rail for the same speed are within less than 1 per cent of the theoretical comparison. This is proof that the metal in the 80-lb. section after its 21 years of service, owing to its quality, has not deteriorated in elastic properties in the slightest degree.

These tests involve also another law of the moving locomotive, ascertained by the stremmatograph, namely, the moving locomotive as a machine on good track, distributes its total load through its center of gravity to the several but individual wheel contacts on the rail. Fig. 10 shows the comparative diagrams of the average total stresses for the eight tests on the 80-lb., and six tests on the 100-lb. rail. The mean of the total stresses per test on the 100-lb. rail was 157,600 pounds, and on the 80-lb., 276,261 pounds, and would be double in each case for both rails of the track.

The diagrams show the comparative value of the two sections as engineering structures, for the crossties, ballast and subgrade receive greater intensity of pressures, and must furnish more support for the 80-lb. than is required for the 100-lb. rails. The capacity and stability of the track of 80-lb. rails is less than that of the 100-lb., and therefore exacts more labor in maintenance, for in the practice of engineering the roadbed is strengthened by the 6-in., 100-lb. rail. The rail section on its flexible crosstie supports with its several distributed wheel loads, by the experimental proof in the track of the stremmatograph, follows the laws of mechanics for a single deflection, with the advantage of the acquired constraint per wheel, and it is one reason why, mechanically, that it has been possible to secure the present progress in steam railway traction.

Jervis's principle of subdivided and distributed loads has empowered, without injury to the rails and roadbed, the use of a heavier total load for adhesion and expended tractive effort to be distributed through several wheel contacts for locomotives and electric motors, than was formerly possible through a single pair of drivers, or the 4-4-0 class of locomotives. The wheels of the engine and tender must be included for the total stresses of the steam locomotive, therefore the tender running gear must be included for the wheel effects for each class of locomotives. The 4-4-0 would have the following designation: 4-4-0+4-4, or eight wheel contacts on one rail. This class has been superseded by the 4-4-2+4-4 for heavy passenger service, and this in turn by the 4-6-2+4-4 class. There are a number of railways with mountain gradients and rails of 90-lb. or less per yard, where the class of locomotives of 4-8-2+4-4 is used to advantage. For freight service of slower speeds and larger train loads, the Mikados of 2-8-2+4-4, are in general use, and a class of 2-10-2+4-4 are employed when a larger tractive effort is required. The loading and constraint of the rails in the equilibrium depression would be still better with a class of 4-10-2+4-4 wheel base and drivers about 57 inches in diameter.

### Basic Open Hearth Rails

The progress in transportation during the past few years has required the replacement of Bessemer rails of 0.10 phosphorus and 0.50 carbon, by basic open hearth steel of 0.04 phosphorus and 0.63 to 0.75 carbon, for 100-lb. rails or over, to secure a duration strain factor of the metal which would carry the high speed trains in temperatures of 30 deg. below zero without fracture of the rail, as so frequently occurred in Bessemer steel.

The unit fiber stresses of 18,000 to 20,000 pounds under a driver at 30 m.p.h., would be applied from zero to the full amount in about 0.04 of a second, and at 60 m.p.h. it would be 0.02 of a second from measurements by the stremmatograph. This is quick time for the application and distribution of so large unit fiber strains which are balanced by the limited stresses set up in the metal. The basic open hearth rails, from the experience with them in the track, prove to have a greater duration strain factor in the metal than it was possible to secure in all of the 0.10 Bessemer steel rails at the low temperatures. The rails are made under the specifications for the New York Central Lines elongation and ductility tests for basic open hearth steel rails which were introduced in 1910, to secure those of the maximum ductility, purity and homogeneity of the steel, due to its chemical composition for service in temperatures 40 degrees below zero F.

The drop tests are made from each melt, one from the crop of the top bar of the second, middle and last full ingot. The crop, 4 to 6 feet long, is stamped with a spacing bar of six 1-in. spaces in the center of its length on the base, head or side, as desired.

Each butt for basic open hearth rails for acceptance of the melt, must show under the drop of 18 feet for the 80 and 90-lb. sections, and 20 feet for the 100-lb. section, at least 6 per cent elongation for one inch, or 5 per cent for two consecutive inches before fracture. The elongation of each of the six spaced inches is measured by a flexible rule, divided into hundredths of an inch, therefore the increased one-hundredths after the drop give the percentage of elongation per inch of the metal. The ductility is completely exhausted in one test for each melt, and is made in rotation from the different ingots in succeeding melts. The melter has the ductility of the last melt, before he taps another from the same furnace, which has enabled a greater uniformity of the steel to be obtained than was possible before the tests. The specifications for the ductility tests have been adopted by the American Railway Engineering Association for use by the railroads in the United States.

### The Wheel Problem

The wheel consists of a tread constructed of uniform radius revolving upon its axis of lesser rolling and with less axle friction than would be produced by sliding on its support, and is the mechanical embodiment of a principle for transportation so ancient that its origin is unknown. The wheels and drivers are the only contacts on the rails to support and carry the equipment, and it is requisite that the material of their treads should be homogeneous and able to maintain their rotundity for a considerable length of service.

A 36-in. wheel makes 560.2 revolutions per mile, and for a static load of five tons the repetitions upon the metal of the tread are equivalent to 2801 tons per mile. To run from New York to Chicago, the applied static tons per mile equal 2,718,164 mile-tons per wheel for the trip, exclusive of generated wheel effects.

The New York Central Lines are giving special attention to the wheel problem by measuring the wear and deformation on thousands of sections of marked wheels to secure a metal in the wheel treads which will maintain their rotundity under the large mile tons of service and the action of the brakeshoes to control the trains.

### Electric Traction

The principles and practice elucidated by the stiff rail sections for steam railway practice apply equally to electric traction. The latter has the advantage for city traffic, for imbedded girder rails on rigid supports with welded joints can be used to carry millions of tons of traffic, before the track requires adjustment or renewal of the rails.

Electric traction has rendered possible the large underground terminals like the New York Central & Hudson River, the Pennsylvania and the Hudson & Manhattan Railroads, and the subways in New York City. The 10 and 12-car multiple unit trains with 2 to 5 minutes headway, and all the appliances for safety of control in their movements, are models of electric traction.

The trolleys in the cities and country roads are usually constructed with light T rails which could be replaced with advantage by stiffer sections.

The electrical engineers have the unique problem of developing motors on similar principles to those that determined the evolution of the steam locomotive.

### Resistance of Steel Rails as Electric Conductors

The 70-lb. contact rails for the Grand Central Terminal were made of Bessemer steel in 1905, and continue to the present time, of the following desired composition:

| | |
|---|---|
| Carbon | 0.10 |
| Manganese | 0.40 |
| Silicon | 0.05 or less |
| Phosphorus not to exceed | 0.10 and as much less as possible |
| Sulphur not to exceed | 0.08 and as much less as possible. |

The manganese was just sufficient to roll the steel which gave a resistance of 8 to 8½ times that of copper. The resistance in some of the recent Bessemer 70-lb. contact rails is from 9 to 10 times that of copper, though the higher figure is from the upper part of the ingot, and doubtless was rolled cold. The resistance of a 70-lb. New York Central & Hudson River Railroad standard section of the ordinary composition for the rail was 12.5 times that of copper; of the 100-lb. Bessemer, 11 to 12 times; while the 105-lb. section in basic open hearth steel is only about 10.6 times.

Basic open hearth 70-lb. contact rails can now be obtained of about 0.10 carbon, but with phosphorus and sulphur each under 0.04, in which the resistance is guaranteed to be not over 7 times that of copper. This needs confirmation for the steel of the entire ingot.

The strap iron rail with its 6 by 6 inch wooden stringer for the girder of the Mohawk & Hudson Railroad of 1831, and the 6-inch steel section of 1892, are historic illustrations of the progress of railway transportation as governed by the rail section.

Twentieth Century Limited

# THE ELECTRICAL OPERATION OF THE BUTTE, ANACONDA & PACIFIC RAILWAY

By J. B. Cox

Railway and Traction Engineering Department, General Electric Company

The author wishes, at the outset, to gratefully acknowledge the assistance of Mr. H. A. Gallway, General Manager of the Butte, Anaconda & Pacific Railroad Company. It is through his co-operation and effort that the operating data given herein are made available. Information of this character has seldom been published and that it is here given to the public is a tribute to the broad sighted policy of Mr. Gallway's company. This article gives a description of the work done and nature of the operating conditions. The direct comparison of the operating costs before and after electrification are of the utmost value as showing what may be expected from electrification even in such a severe character of service. This paper was read before the Pacific Coast Convention of the A.I.E.E., at Spokane, Wash., on September 10, 1914.—Editor.

J. B. Cox

The Butte, Anaconda & Pacific Railway was built in 1892 principally for the purpose of conveying the ore from the mines at Butte to the Washoe smelter, which had been located at Anaconda, twenty-six miles west of Butte, where an abundant supply of water, so necessary in the reduction of the ore, was obtainable. The tracks connecting Butte and Anaconda constitute the main line which is approximately 25.7 miles in length. As the mines are mostly around the top of Butte Hill, and the shafts through which the ore is hoisted to the surface are scattered over a considerable area, yards were built at a convenient point on Butte Hill for the concentration of the cars containing the ore from these shafts, as well as to serve as a distribution point for the supplies to the mines. A branch locally known as the Missoula Gulch line, see Fig. 2, was built from these yards to connect with the main line at Rocker where yards were also established.

Since the concentrator at the smelter is also on a hill, at an elevation of approximately 340 ft. above the main line, it was advisable to establish another yard at East Anaconda from which to distribute the ore and other supplies to the different centers on Smelter Hill. The lines from these yards at East

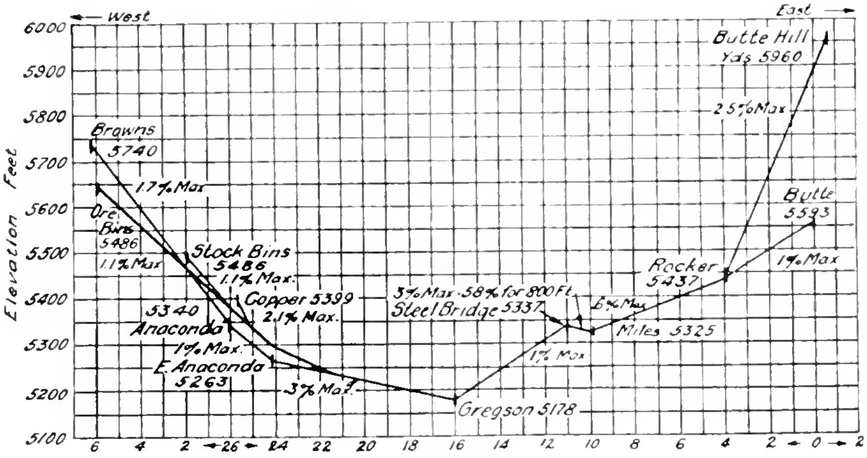

Fig 1

Anaconda to the smelter are known as the Smelter Hill lines, the longest branch of which is that leading to the concentrator which is about $7\frac{1}{4}$ miles in length. Two spurs lead off from this main track, one to the stock bin yards and the other to the copper tracks; see Fig. 4.

Fig. 2. Outline Map of Railway Lines on Butte Hill for Collection of Ore and Delivery of Supplies

From the Butte Hill yards spur tracks radiate about Butte Hill to the shafts of the various mines and to other points where supplies are to be delivered; see Fig. 1. Bins for receiving ore, as it is hoisted from the mines, are located near each shaft and from these bins the ore is loaded into hopper bottom steel ore cars of 50 tons capacity each. These loaded cars are delivered to the Butte Hill yards where they are made up into trains and taken down to the Rocker yards where they are made up into still larger trains and taken over the main line to the East Anaconda yards. Here the trains are broken up to be transported in smaller units up Smelter Hill to the concentrator yards. Thus practically all of the ore cars are handled by five different engine crews between the ore bins at the mines and the receiving bins at the concentrator.

A total of 27 steam locomotives were owned by the railway company, classified as follows:

| | |
|---|---|
| Switching | 7 |
| Consolidation | 8 |
| Mastodon | 10 |
| Passenger | 2 |

The coal used on the steam locomotives was obtained from the mines at Diamondville, Wyoming, and had to be transported approximately 395 miles for delivery to the bins of the railway company at which point its average cost was approximately $4.25 per ton.

The machinery at the mines and the smelter had mostly been electrified, and the results had been so satisfactory that the railway company had a study of their conditions made for the purpose of investigating the advantages that might be expected from the electrification of their lines. The result of this was the placing of a contract in December, 1911, with the General Electric Company for the electrical equipment of the main portion of their line consisting of the main line, spurs and yards between Butte and Anaconda, the Missoula Gulch line between Rocker and the Butte Hill yards, and the Smelter Hill lines. Owing to local conditions on the spur tracks leading to the various mines from the Butte Hill yards it was thought advisable not to electrify these until a later date.

Three of the steam switching locomotives listed above were used daily on Butte Hill for collecting ore from, and delivering supplies to the various mines from the Butte Hill yards. The Georgetown extension to Southern Cross, 22.9 miles west of Anaconda, was under way at the time; but as it was expected that only a few trains per week would take care of the traffic over this branch for some time, its electrification was not seriously considered in the original study.

It is fair to assume that a vital consideration leading to the electrification of this railroad was the rapid development and physical consolidation of a network of hydro-

**Fig. 3.** Map of Missoula Gulch Lines, Rocker to Butte Hill Yards

electric power plants in the territory tributary to the railroad.

A contract for the power for the operation of the road was made with the Great Falls Power Company, which, operating under the same management and in physical connection with the system of the Montana Power Company, was enabled to guarantee an ample supply of power at all times with exceptional freedom from interruptions to service and at a reasonably low price.

The tracks recommended to be electrified totaled approximately 90.5 miles, all of which are supplied with power from two substations, one being located in the Missouri River Power Company substation on Butte Hill and the other in the substation building on Smelter Hill, from which electrical power for operating the machinery there is distributed. At each of these substations there was vacant space for the location of the extra apparatus required for the operation of the railway, and the transformer capacity already installed at each place was sufficient to meet the extra demand required for the operation of the railway.

### Power

The Anaconda substation is connected with the Butte substation by three high tension trunk lines. The Butte substation receives power over five separate transmission lines from six hydro-electric stations of the following rated capacities:

| | | |
|---|---|---|
| Big Hole development | 3,000 kw. | 60-ft. head |
| Madison River development | 9,000 kw. | 110-ft. head |
| Canyon Ferry development | 7,500 kw. | 35-ft. head |
| Hauser Lake development | 14,000 kw. | 60-ft. head |
| Black Eagle development | 3,000 kw. | 44-ft. head |
| Rainbow development | 21,000 kw. | 110-ft. head |
| Total | 57,500 kw. | |

There is also now under construction the Great Falls development, with a capacity of 60,000 kw. and with a 155-foot head; see Fig. 7.

All of these plants are on the Missouri River water shed, and operate with a free interchange of power, and all, except the first, are located in a series below the new Hebgen reservoir, now being completed on the head waters of the Madison River, with an available capacity of 300,000 acre-feet of storage.

The individual plants are also provided with storage reservoirs aggregating 125,000 acre-feet of total available storage capacity. All of these reservoirs operating under one control are capable of developing from stored water alone, in addition to the power otherwise available from the natural flow of the river, the equivalent of about 100,000 electrical horse power for a period of 100 days.

In view of this development, the generally recognized advantages of purchasing electric power from a large operating system, instead of developing the required power independently, were readily apparent in the case of the Butte, Anaconda & Pacific Railway. The railroad was relieved of all the first cost of development and transmission of power, and of all operating expense up to the point of delivery of power to the two substations. The cost of the delivered power is less than it would have been from an independent development, because the power company is enabled to operate large generating stations at a relatively high load factor (about 75 per cent), whereas an independent plant purely for the operation of the railway would have to operate in this case at about 30 per cent load factor, with correspondingly high fixed and operating charges per kilowatt-hour actually used. The large number of generating stations and the complete network of transmission lines already developed by the power company afford ample insurance against the interruption of the railroad service due to possible failure of any part of the generating or transmitting system of the power company. The enormous inertia or flywheel effect of the motor loads connected to the power system maintain extremely steady speed and voltage under the most extreme variations of load on the railroad.

### Substation

The original equipment of each substation was practically the same, consisting of two 1000-kw., three-unit motor-generator sets with the necessary starting and operating devices. Each motor-generator set consists of a 1450-kv-a., three-phase, 60-cycle, 720-r.p.m. synchronous motor coupled direct to two 500-kw., 1200-volt direct current generators, one at either end, the two generators operating in series and supplying 2400-volt direct current to the trolley lines. The generators are compound wound and have compensating pole face windings as well as commutating poles. The series fields are connected on the grounded side of the armatures while the main fields are separately excited from a 125-volt circuit. The motor-generator sets are capable of carrying overloads up to three times normal load momentarily and 50 per cent overload for two hours. The value of this characteristic will be

Fig. 4. Map of Smelter Hill Lines

appreciated when it is noted that each electric locomotive unit has a continuous rating of approximately 900 kw., or almost equal to that of a single motor-generator set, and frequently 16 of the 17 units purchased are in service simultaneously, 11 of which are concentrated at the Anaconda end at intervals.

### Locomotives

Seventeen 80-ton electric locomotive units were purchased originally, fifteen of which are being operated in freight service and two in passenger service. These units are practically interchangeable with the exception of the gearing, the passenger locomotive being geared to operate normally at 40 to 50 m.p.h., while the freight locomotives are geared to operate at from 15 to 25 m.p.h., the maximum free running speed being approximately 35 m.p.h.

The continuous tractive effort of the freight units is 25,000 lb., at 15 m.p.h., but they are capable of exerting a maximum tractive effort of 48,000 lb., for 5-minute intervals, based on a co-efficient of adhesion of 30 per cent.

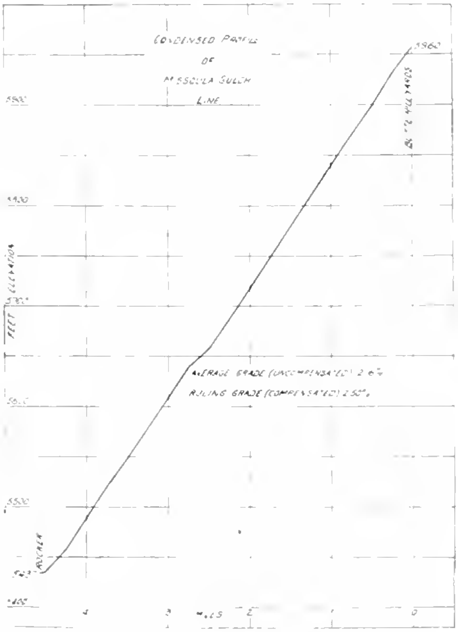

Fig. 5. Condensed Profile of Missoula Gulch Line

All the locomotive units are of the articulated double-truck type, with twin gears mounted on projections provided on the wheel centers for the purpose, and in general mechanical design are similar to the electric locomotives in operation on the Great Northern Railway, the Detroit River Tunnel Railway and the Baltimore & Ohio Railroad. Each unit is equipped with four GE-229-A commutating pole motors, wound to operate at 1200 volts each, but insulated for 2400 volts, so that two are connected permanently in series and the four are arranged in pairs, thus securing the usual two running points, with the difference that on the series position all four motors are in series and in multiple position the two pairs are connected in series-parallel.

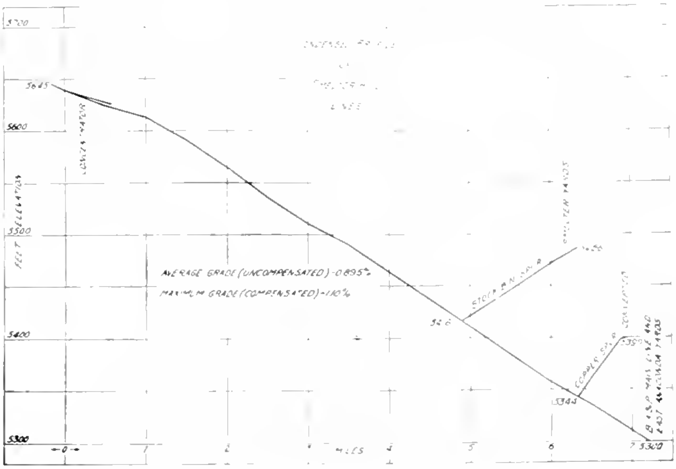

Fig. 6. Condensed Profile of Smelter Hill Lines

The horse power of each motor on the standard rating is approximately 300 h.p., making the hourly rating of each locomotive unit about 1200 h.p. The control equipment is of the multiple unit type and provides a total of 19 steps, ten of which are in series and nine in series-parallel. The 2400-volt contactors, switches, fuses, etc., are located in enclosed compartments where they can be reached only by deliberate effort. The current for the operation of the control equipment, the air compressor and the lights on the locomotive, as well as the lights on the passenger coaches, is supplied by a 2400/600-volt dynamotor located in the main compartment of each locomotive unit.

A blower which provides artificial ventilation for the main motors and the rheostats is direct connected to the armature shaft of this dynamotor. The principal data and dimensions pertaining to the electric locomotives are as follows:

| | |
|---|---|
| Length inside of knuckles | 37 ft. 4 in. |
| Length over cab | 31 ft. |
| Height over cab | 12 ft. 10 in. |
| Height with trolley down | 15 ft. 6 in. |
| Width overall | 10 ft. |
| Total wheel base | 26 ft. |
| Rigid wheel base | 8 ft. 8 in. |
| Track gauge | 4 ft. $8\frac{1}{2}$ in. |
| Total weight | 160,000 lb. |
| Weight per axle | 40,000 lb. |
| Wheels, steel tired | 46 in. |
| Journals | 6 in. by 13 in. |
| Gears, forged rims, freight locomotives | 87 teeth |
| Gears, forged rims, passenger locomotives | 80 teeth |
| Pinions, forged, passenger locomotives | 18 teeth |
| Pinions, forged, freight locomotives | 25 teeth |
| Tractive effort at 30 per cent coefficient | 48,000 lb. |
| Tractive effort at one hour rating | 30,000 lb. |
| Tractive effort at continuous rating | 25,000 lb. |

### Operation

Work on the electrification began in the spring of 1912 and the first electric locomotive was run in Anaconda on May 14th, 1913, about a year later.

On the 27th of May two ore trains were hauled up Smelter Hill with electric locomotives and on the following day, May 28th, a double-unit electric locomotive took over the regular day service of hauling the ore from the East Anaconda yards to the concentrator yards; the distance between being approximately seven miles. The ruling gradient is 1.1 per cent and is compensated. The grade is fairly uniform through the entire distance; see Fig. 6. The steam locomotives used in this service were of the Mastodon type, weighing 108 tons, 83 tons of which was on the drivers. The weight of the tender loaded was approximately 55 tons, making the total weight of locomotive and tender about 163 tons, which would average closely to the weight of the double-unit electric locomotive superseding it. The steam locomotive ordinarily made six round trips per shift, hauling 16 loaded ore cars per trip, equaling 96 cars per shift.

The average time for the trip from East Anaconda to the concentrator yards with 16 loaded cars for the steam locomotive was about 45 minutes. The double-unit electric locomotive began only 16 cars per trip but made 8 trips per shift, delivering 128 cars per shift. The average time for the uphill trip with the electric locomotives was about 22 minutes or approximately half the time required by the steam locomotive for the same number of cars. Empty cars were taken to East Anaconda on the return trip which being all down grade, gave the electric locomotive no decided advantage, as the speed in either case was limited to about 25 m.p.h. for safety on account of the curves in the line. The number of cars hauled per trip with the electric locomotives in the beginning was kept the same as it had been with the steam, for it had been decided to make the change-over by gradually replacing one steam locomotive at a time with an electric locomotive, taking the engine crew off the one and placing it on the other; thus breaking them in on the electric locomotives in regular service.

One of the regular steam engineers had been given special instructions on the electric locomotives during the trial running in order that he might become competent to act as instructor to the other engineers until they were sufficiently familiar with the electric locomotives to be left alone.

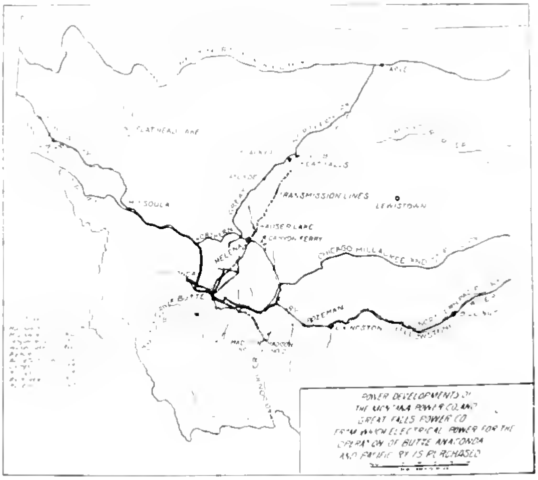

Fig. 7. Power Developments of the Montana Power Company and Great Falls Power Company from which Electrical Power for the Operation of Butte, Anaconda and Pacific Railway is purchased

The load per trip in this service was gradually increased from 16 cars to 25 cars, which is to be the standard for the present. The average time for the uphill trip with 25 cars is about 26 minutes, so that eight trips per shift is easily made, making a delivery of 200 cars possible, or an increase of slightly more than 108 per cent over what had been possible for the same crew with steam locomotives. These loaded ore cars average from 70 to 72 tons each, making the trailing load for a 25-car train from 1750 to 1800 tons.

On arrival at the concentrator yards, the ore trains are taken by a switching engine called the "spotter," which places it, one car at a time, over the weighing scales; after which they are re-arranged for placement over the concentrator bins from which the ore is fed by gravity to the crushers.

On June 20th this spotting service was taken over by a single-unit electric locomotive and on July 2nd the night service up Smelter Hill was taken over by the double-unit electric locomotive. The steam locomotive used for the spotting service was of the consolidation type and weighed 93 tons, 83 of which was on the drivers; the tender weighing loaded 62 tons, making the total weight of engine and tender, 155 tons. The steam locomotive used in the night service on Smelter Hill was similar to that used in the day service. When the electric engines were put on the night service all the handling of ore between East Anaconda and the concentrators was done electrically and the hauling capacity per crew was so much greater that it was no longer necessary to have a "spotter" crew on the night shift, so that this crew was eliminated and the night crew hauling the ore up Smelter Hill did their own spotting on arrival at the concentrator yards, it being no longer necessary to make the regular number of trips. Thus where formerly during steam operation four engine and train crews had been required, with electric locomotives three similar crews were able to do the same work and in less time, thereby reducing the number of crews required in this particular service by 25 per cent.

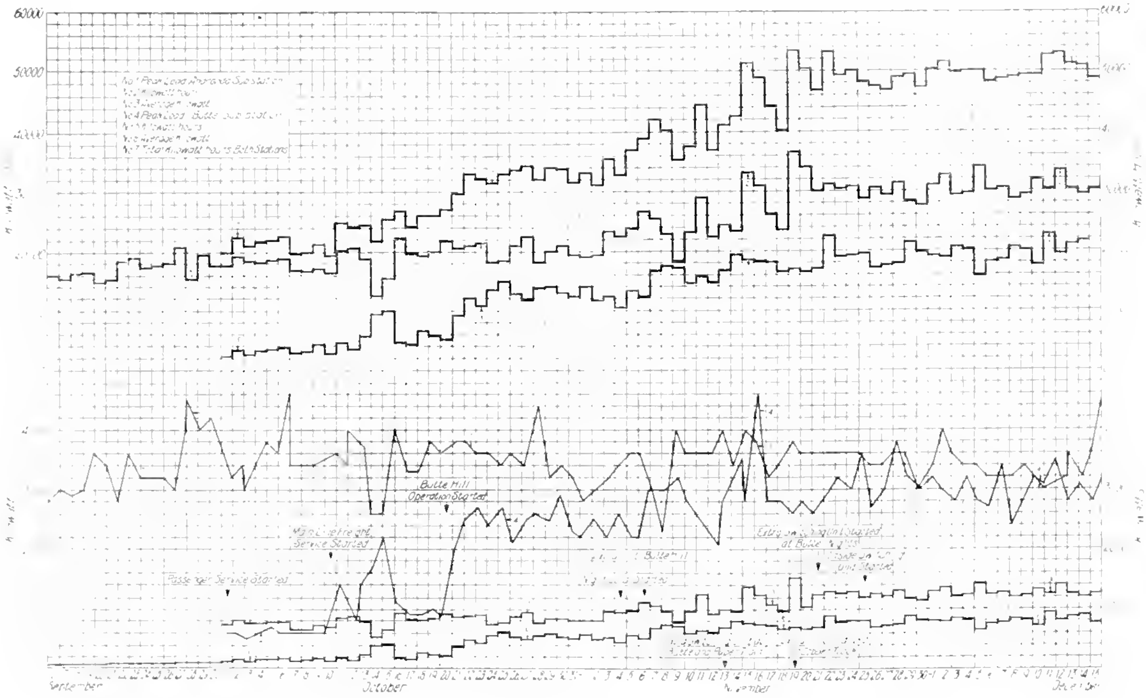

Fig. 8. Diagram of Substation Loads

On July 9th the stock bin engine was replaced by an electric unit. This engine is engaged mostly in a switching service, placing cars of coke, coal and other supplies at the smelter. The type of steam engine used here was the same as that used for the "spotter" service described above.

Another engine, locally known as the "tramp," because of the irregularity of the time or place of its service, was partially replaced on July 24th. As some of the tracks over which this engine had to operate at times had not been equipped with overhead wires, the infrequency of their use not warranting the expense, and as other conditions made it necessary to keep one or more steam locomotives in operation, the service of this electric unit was intermittent. This practically completed the electrification of the Smelter Hill service and no further extension of electrical operation was made until October, as the trolley construction on the main line was not completed until that date.

On the forenoon of September 30th an inspection trip was made over the main line from Anaconda to Butte and in the afternoon a special train carrying officials and visitors from a neighboring road was taken from Butte to Anaconda and return by one of the electric locomotives intended for the passenger service. On October 1st the regular passenger service between Butte and Anaconda was taken over for electrical operation. The steam locomotives used in the passenger service weigh approximately 80 tons, 60 tons of which is on drivers; the tender loaded weighing 52 tons, making the total weight of engine and tender 132 tons. The distance between the Anaconda and Butte stations is 25.7 miles, and the schedule time for the trip is one hour. No change has been made in this time though a reduction of 20 per cent would be possible with the electric locomotives were such desired. The standard passenger train consists of one mail and baggage coach and two to four passenger coaches, but as many as 12 passenger coaches are handled by a single electric unit on special occasions, such as excursions and on holidays.

The baggage coaches average approximately 40 tons in weight and the passenger coaches 45 tons each, making the gross weight of the three-car electric train approximately 210 tons, whereas that of a similar steam train was 262 tons—a reduction of 19 per cent in favor of the electric locomotives with approximately the same weight on drivers in each case. As had been done in the freight service the steam engineers in the passenger service, were transferred from the steam to the electric locomotives with but little previous instructions, and after the first day or so were left mostly to themselves. It may be of interest to note here that on the day shift, averaging four trips per day, during the first five months the passenger train did not come in late a single time on account of engine trouble. A comparison of the delays to the passenger trains for the month of June, 1913, with steam operation with the same month with electrical operation in 1914, is shown in Table 5. The results from Table 5 are given below.

| | | DELAYS ON ACCOUNT OF | | | | | | | | TOTAL DELAYS ALL CASES | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | No. of Trains | Meeting Points | | Power | | Engine Failure | | Lost Run Time | | | |
| | | Hr. | Min. | Hr. | Min. | Hr. | Min. | Hr. | Min. | Hr. | Min. |
| Steam, 1913 | 272 | 15 | 49 | | | | 44 | 4 | 13 | 20 | 46 |

| Decrease | 8* | 11 | 55 | | 27 * | | 20 | 3 | 48 | 15 | 36 |
| Percentage of saving due to electrical operation | 2.94* | 75.66 | | | | 45.45 | | 90.10 | | 75.12 | |

* Increase.

June was taken at random for a comparison, as that month's records were still in the office file, but the results are considered representative of general performances.

On October 10th a double-unit electric locomotive was put in the day freight service on the main line between East Anaconda and Rocker, a distance of 20.1 miles. The steam locomotive replaced in this instance was of the Mastodon type weighing 103 tons, 77 tons of which was on drivers, the tender loaded weighing 55 tons, making the total weight of locomotive with tender 158 tons. The standard train hauled on the trip west was 50 to 55 loaded ore cars weighing approximately 3500 to 4000 tons gross, and the average running time of such trains, where no stops were made, was about 1½ hours, corresponding to an average speed of approximately 13.4 miles per hour. In the beginning the electric locomotive took only the standard train but made the trip without any stop in about one hour, corresponding to an average speed of 20 m.p.h. The ruling gradient on the westward trip is 0.3 per cent and about half the distance is down grade. On the 0.3

per cent grade with a 55-car train, the steam locomotive made about 7 m.p.h. The electric locomotives with a similar train now make about 16 m.p.h. on the same grade.

The weight of the trains hauled by the electric locomotives on this run have been gradually increased up to 65 loaded ore cars averaging about 71 tons each, making the gross weight trailing about 4620 tons. Adding 160 tons for the weight of the double-unit electric locomotives and 20 tons for the caboose makes a gross train weight of approximately 4800 tons.

The remainder of this main line freight service was gradually taken on during the months of October and November, thus completing the electrification of the main line service. As many as 76 ordinary freight cars loaded with coal, coke and general merchandise have been taken in a single train on the west bound trip, and 85 empties are frequently taken from East Anaconda to Rocker east bound, the ruling grade being 1 per cent.

Table 4 gives comparative results for the month of June, 1913, with steam operation and the same month in 1914 with electrical operation of this main line service, showing that with a slight increase in the total tons of ore hauled the average tons per train was increased from 1761 to 2378 or 35 per cent, thus decreasing the average number of trains per day from 12.5 to 9.3 or 25.6 per cent.

Table 3, giving a comparison of the time per trip for these trains, is representative of the gain in this direction to be added to the decrease in the number of trains. The average time per trip during steam operation was approximately two hours, twenty-five minutes, while with the electric locomotive it was approximately one hour, forty-five minutes, showing a decrease of forty minutes or 27.5 per cent. These figures represent the time put in by the crews between Rocker and Anaconda, the distance being 21.8 miles.

The result of these improvements is indicated in Tables 1 and 2 which show that the overtime in this particular service has been decreased 73.5 per cent and the total time 42 per cent, resulting not only in greater economy to the railway company, but in shorter and easier hours for the crews.

The service on the Missoula Gulch line, running between Rocker and Butte Hill yards, was taken over for electrical operation on October 20th. This line is 4.5 miles in length and the ruling gradient is 2.5 per cent; see Fig. 5. The steam locomotives used on this line were of the Mastodon type, weighing 106 tons, 87 tons of which were on the drivers, the tender loaded weighing 56 tons, thus making the total weight of engine and tender 162 tons. Two complete crews had been required to handle this service during steam operation averaging six trips per day each. A single crew with a double-unit electric locomotive has been doing this work successfully. Thirty-five to forty-five loaded ore cars are taken down from Butte Hill yard to Rocker and about an equal number of empties taken up. In addition to the empties large quantities of timber and supplies for the mines are delivered over this line.

On November 25th the last of the electric locomotive units went into service, thus completing the electrification originally intended. The full electrical service has, therefore, now been in operation more than nine months and that on Smelter Hill more than 15 months, so that the total locomotive miles operated would be approximately close to an average year's performance.

This was the first installation of 2400-volt direct current apparatus for the operation of a railway in this country, 1500 volts being the highest heretofore installed for such purpose. The results have been more satisfactory than had been anticipated, and the development charges due to such imperfections as usually show up during the first year of operation have been perhaps smaller than is customary with an undertaking of like magnitude, even where standard apparatus is used.

Difficulties especially attributable to the higher potential have been negligible, and, while there have been occasional instances of arcing and flashing or short circuits due to ordinary causes the resulting damages have been really smaller than might be expected from a like occurence of a 600-volt installation of equal capacity.

The original brushes supplied in the motors chipped badly and before all these had been replaced it was often found, when the units were brought in for regular inspection, that some of the brushes were broken all to pieces, and while there was evidence that a flash-over might have occurred sometime no harm had resulted other than the blowing of the motor fuse. On the replacement of the fuse, the engine was continued in service until its regular time for inspection, when the cause of the fuse blowing would first be discovered.

The fact that the locomotives continued in service thus is sufficient evidence of the harmlessness of the arc-over and in no instance of the kind has any real damage been done. The locomotives have made from 25,000 to 50,000 miles each, and without exception the motors are in excellent condition. The wear on the commutators is imperceptible and the general performance of the entire equipment is quite as satisfactory and promising as that of any railway equipment with which we have had experience in similar service.

The overhead construction has been quite satisfactory and a recent examination of the trolley wire shows no indication of unusual wear. The roller pantographs are operating quite successfully, the average life being from 10,000 to 12,000 miles per roller. Where a double-unit locomotive is operated the two pantographs are connected electrically by a main bus line, and the average current collected by each when ascending the grades with a standard load is from 350 to 400 amperes. Two pantographs operating in multiple thus will collect more than double the current that can be successfully collected by a single pantograph for the reason that sparking is usually due to the momentary breaking of contact between the trolley wire and the roller, caused by hard spots on the line. When two pantographs are operated in multiple both do not encounter these hard spots at the same instant, hence one or the other always makes good contact so that the flow of current is not so frequently interrupted and consequently the sparking is greatly reduced. The double units operating on Smelter Hill were run experimentally for several days with only a single roller making contact with the wire, the operation being quite successful with the single roller collecting an average of 650 to 750 amperes while running at16 to 17 m.p.h., and 800 to 1000 amperes during the accelerating period in multiple. The sparking was not

Tons ore hauled during month—311,450.

serious except at hard points in the line and with two rollers in multiple there should be no difficulty in collecting 500 to 600 amperes per roller, which at 2400 volts should be equal to the requirements of any ordinary locomotive unit.

The bearings first used in the rollers were provided with ordinary bushings lubricated with oil, but when the bushings became slightly worn the oil was thrown out along the spindle and had to be replenished at comparatively frequent intervals. This was not serious in the operation of the freight locomotives but became more so when the passenger service was started, as the higher speed caused the oil to be thrown out more quickly, resulting in very short life of the bushings. Slight changes were made in the bearings and grease was substituted for the oil as a lubricant, which proved quite satis-

factory. However, the vibration which results from too much play in the bearings of the roller when operating at high speeds made it desirable to increase the life of these bearings as much as possible, so that later roller bearings with grease lubrication were installed with excellent results. As yet these have not been in operation a sufficient length of time to definitely indicate how long they may be expected to last, but it would appear that the bearing will last much longer than the roller and that the attention required for the adjustment and lurbication of the bearing and the roller will be negligible.

On account of a decision of the mining company to divert to the Washoe smelter at Anaconda the shipment of approximately 3000 tons of ore per day that had previously been sent to the smelter at Great Falls, which will increase the ore traffic over the Butte, Anaconda & Pacific approximately 25 per cent, an extra motor-generator set, a duplicate of the original sets, has been installed in the Anaconda substation as a spare. Also four additional electric locomotive units were ordered and will be delivered within the next three months. These units will be duplicates of the original ones except that they are to be arranged for operating with an extra tractor truck attached when desired. This tractor truck will be a duplicate of the standard truck used under the regular units, with two standard motors mounted on it, and with the necessary arrangements for coupling both mechanically and electrically, so that the standard unit and the tractor truck may be

GRAND AVERAGE—1768 tons per train, time per trip, 2 hr. 25 min.—2122 tons per train, time per trip, 1 hr. 45 min.

RESULT—20 per cent increase in tonnage per train; 27.58 per cent increase in time per trip.

On June 5, 1914, one main line crew was taken off and the tonnage of the remaining trains increased so as to handle the regular business.

operated as a single unit. The motors of the tractor truck are connected with those on the standard unit in such a manner as to place all six motors in series on the series points of the controller, and with a series multiple connection with three motors in each series in the multiple position of the controller. This arrangement will make the tractive effort of the new unit 50 per cent greater than that of a standard unit for the same input with a reduction in the free running speed of about 33⅓ per cent.

This arrangement was advisable because of the increase in the weight of the trains taken up Smelter Hill, which amounted to approximately 56 per cent. A single unit when used in the "spotting "service is taxed close to the slipping point of its wheels when accelerating these heavier trains on the 0.5 per cent grades under ordinary conditions of weather, and have to be handled very carefully with the continuous use of sand when the condition of the rail is unfavorable. Connecting the additional motors in series will also result in considerable power economy, since with a single unit the controller is seldom off the series resistance points on account of the heavy trains handled and the short movements required.

Small change in the personnel of the maintenance or operating departments of the railway has been made on account of the

GRAND AVERAGE—12.5 trains per day, 1761 tons per train.—9.3 trains per day, 2378 tons per train.

RESULTS—25.6 per cent less trains. 35.0 per cent greater tonnage per train.

electrification and there has been no reduction in salaries or wages. An extra man with electrical experience was placed in the shops to supervise the electrical repairs to the locomotives and three linemen were retained for the maintenance of the trolley system.

The three steam switching locomotives used for concentrating the ore at and distributing supplies from Butte Hill yards are continued in this work for reasons heretofore stated. Another steam locomotive is used on the Georgetown branch and a fifth one operates at intervals over unelectrified tracks at the Anaconda end. Approximately 20 per cent of the total locomotive miles now being operated is by these five steam locomotives, the cost of which as shown in Table 6 is upwards of 40 per cent of the total cost of all locomotive performance.

The electrification of the remaining tracks on Butte Hill has been recommended and no doubt will be commenced at an early date. Table 6 referred to was made up from the regular monthly locomotive performance sheets of the railway company from which the principal saving resulting from the electrification may be noted. The saving from the partial substitution of electric power for coal is the chief item, being at the rate of $150,727.04 per year, which is remarkable when it is considered that more than 39 per cent of the total combined costs for fuel and power for the period considered was for coal and charged against electrical operation. In this instance, the saving in this item alone would undoubtedly justify the expenditure covering the entire cost of electrification. It is to be noted that with a single exception, that for depreciation of equipment, every item of expenditure in the locomotive performance sheet shows a substantial percentage of decrease in favor of electrical operation.

It is the practice of the railway company to adjust depreciation charges on all locomotives at the beginning of each half year. The amount to be charged to the depreciation of a new locomotive for the first half year it is in service is determined by taking a fixed percentage of its cost to the company, one-sixth of this amount being charged against the locomotive each month for the half year, at the end of which the amount of the depreciation for the period is deducted from the original cost of the locomotive to give a new value of which the original fixed rate of percentage is taken, in determining the amount of the depreciation for the following half year and so on.

The Interstate Commerce Commission ruling does not permit a depreciation charge until the locomotive actually becomes the property of the railway company, and as the electric locomotives were not formally taken over by the company until March, 1914, the proper monthly charge begins only with that month in the regular monthly performance sheet from which Table 6 was compiled. In fairness to the performance sheet, only the proper monthly depreciation charges were made, but as some of the locomotives had been in service eight months before these changes began an adjustment was necessary to make a proper distribution of the back depreciation, so that while Table 6 shows only the proper monthly charge for the six months compared amounting to $8471.84, in Table 7 under "Maintenance of Equipment" the total back charges were included amounting to $20,047.48. It is evident that the depreciation record on this basis for the first months of service would be comparatively high.

The total saving from locomotive performance alone, as indicated by Table 6, is at the rate of $237,581.82 per year to which should be added the credit of handling an increase of traffic at the rate of 13,938,136 ton miles per year, or 8.77 per cent more than was handled by the steam locomotives during the period compared. To this saving from locomotive performance should be added the saving from trainmen's wages which is at the rate of $31,146.30 per year, or a desrease of approximately 21 per cent, due largely to the elimination of overtime (see Tables 1 and 2) making the total saving from these two items $268,728.12 per year. From this should be deducted $10,839.12 for maintenance of the distribution system leaving $257,889 as the net operating saving per year due to electrical operation.

The roadmaster states that it is quite evident that the electric locomotives are much easier on the track at curves, but that there is no noticeable difference on tangent track; and that while sufficient time has not yet elapsed to form definite conclusions, present indications lead him to expect that any difference relative to his work will be favorable to the electric locomotives.

Arranging the items of expense appearing in Table 6 in the order of their usual appearance in the summary of a standard locomotive performance sheet and placing them on a yearly basis we have the following results:

# Table 5. BUTTE, ANACONDA & PACIFIC RAILWAY

† Decrease. * Increase.

The total cost of the electrification including a change of signal system on Smelter Hill, the extra motor-generator set recently installed at Anaconda, interest during construction and all incidentals due in any way to the electrification, was in round numbers $1,201,000.00. This does not include the step-down transformers, which are the property of the power company; but on the other hand no deduction has been made for the salvage due to the elimination of 20 steam locomotives.

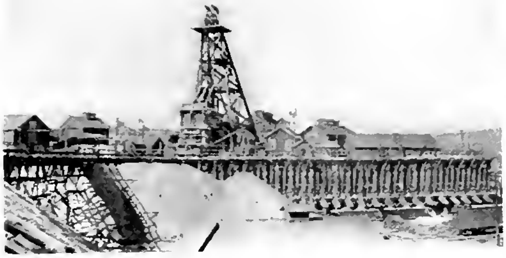
| Item of Operating Expense | Steam 1913 | Electric 1914 | Decrease 1914 | Per Cent Decrease |
|---|---|---|---|---|
| Fuel and power | $315,235.74 | $164,508.70 | $150,727.04 | 47.81 |
| Repairs | 124,787.90 | 92,278.08 | 32,509.82 | 26.05 |
| Enginemen's wages | 104,461.18 | 71,225.28 | 33,235.30 | 31.81 |
| Engine-house expenses | 29,907.80 | 18,638.38 | 11,269.42 | 37.68 |
| Water | 4,953.66 | 1,193.70 | 3,759.96 | 75.90 |
| Lubricants | 9,751.44 | 4,942.32 | 4,809.12 | 49.30 |
| Other supplies | 5,823.52 | 4,552.36 | 1,271.16 | 21.83 |
| Total locomotive performance | $594,921.24 | $357,339.42 | $237,581.82 | 39.93 |
| Trainmen's wages | $147,632.30 | $116,486.00 | $31,146.30 | 21.10 |
| Grand total | $742,553.54 | $473,825.42 | $268,728.12 | 36.19 |
| Ton-miles hauled | 158,917,720 | 172,855,856 | 13,938,136 | 8.77* |

*Increase.

If a correction be made for the item of depreciation in Table 6, charging the regular monthly amount of $2711.13 begun in March for each of the six months making the total of this item for the period $16,266.78, instead of $8,471.84 as it stands on the performance sheets, the total saving per year from locomotive performance would be reduced to $221,991.94, making the total net saving $242,299.12, which is equivalent to 20.02 per cent on the entire cost of the electrification, to say nothing of the increased capacity of the lines, the improvement in the service and more regular working hours for the crews as is indicated in Table 5 comparing the delays to traffic, and Tables 1 and 2 showing the decrease in overtime.

From Table 7 it will be seen that if taken on the basis of the increase shown in net operating revenue or operating income, this percentage is slightly greater, the rate of increase per year for these items being $288,150.80 and $282,016.96 respectively.

The estimate on which the decision to proceed with the electrification of the road was made placed the annual net saving expected at 17.5 per cent of the cost, so that the results financially have been quite as satisfactory as the general performance of the equipment.



Hoist and Storage Bins on Butte Hill

# THE CANADIAN NORTHERN TUNNEL AND TERMINAL ELECTRIFICATION

By W. C. Lancaster

Electrical and Mechanical Engineer, Montreal

A brief description is first given of the nature of the work being undertaken on this important electrification. The author then discusses why 2400-volt direct current was selected in preference to other available modes of operation. It will be noted that the successful operation of the Butte, Anaconda & Pacific Railroad had an important influence on the decision. Both the 2400-volt locomotive and multiple-unit power equipments are described in some detail. The power supply and substation equipment are also discussed.—Editor.

W. C. Lancaster

The Canadian Northern will become a transcontinental railway in June, 1915, when it is expected that the last link, the line between Edmonton and Vancouver, will be ready for operation. This newest transcontinental line will connect the Pacific Coast with Montreal and Quebec, and will operate, when completed, over 10,000 miles of track.

Its principal eastern terminus will be Montreal. To gain access to the heart of the city it was necessary to tunnel Mount Royal which forms a natural barrier between the commercial and financial sections and the country to the west. Any other route would have entailed the enormous expense of a right-of-way through thickly populated and valuable property, with numerous street crossings and other disadvantages. To the west of the mountain all the way to the Riviere des Prairies there are only farms and a few scattered villages, quite inaccessible to the city on account of the detour necessary around Mount Royal. A large section of this farm land was purchased, subdivided and incorporated as the Town of Mount Royal; more commonly known as "The Model City." Between this suburban district and Montreal a quick and frequent service will be maintained by means of multiple-unit trains.

The railroad crosses to the Island of Montreal near its western end, and follows the south bank of the Riviere des Prairies to the Cartierville yard. This yard will be used for the storage and sorting of freight; and for changing the steam and electric engines. Here also will be located the repair shops for the electric locomotives and multiple-unit cars.

From the Cartierville yard the railway runs easterly through the new town of Mount Royal, where the tracks are depressed sufficiently to allow the streets to be carried over them. The multiple-unit trains will stop about once every mile throughout this suburban district. The locomotive trains, however, will stop only at Mount Royal.

The west portal of the tunnel is located at the foot of the westerly slope of the mountain. The tunnel is 3¼ miles long and descends on a six-tenths of one per cent grade from the west portal to the terminal station. It is all tangent, except one 2-deg. curve, and is of double track construction. Each track is in a separate tube, the advantages of this being economy of construction, provision for ventilation, and safety of operation.

The east portal is at the terminal station in the city, the tracks at this point being about 45 ft. below the street surface. From this station the railway will run over a viaduct down to the St. Lawrence River to connect with the belt line operated by the Harbor Commission, thus gaining connection with the docks. As a part of the proposed viaduct across the lower level of the city there will be an elevated freight station in the center of the commercial district for the receipt and delivery of local freight.

Electrification of the tunnel was necessary both for comfort to the passengers and for reasons of safety. But, aside from these reasons, the large number of light suburban trains that are to be run at frequent intervals make electric operation more economical than steam; especially when the cheap electric power obtainable at Montreal is considered in favor of electric traction, and the expense of operating steam locomotives during the Canadian winters is fully taken into account.

The initial electrification will be carried from the terminal in the city as far as the Cartierville yard, a total of about ten route miles and thirty track miles. Later, it is expected that this will be extended a considerable distance as the country to the west of Mount Royal becomes more thickly settled.

The details of the Mount Royal tunnel and terminal are as follows:

**Tunnel**

| | |
|---|---|
| Length, feet | 17,000 |
| Rock excavation, cubic yards | 405,000 |
| Earth excavation, cubic yards | 20,000 |
| Concrete, cubic yards | 50,000 |
| Steel and iron, pounds | 4,400,000 |
| Splicing chambers, spacing in feet | 400 |
| Grade, per cent | 0.6 |

**Terminal Station**

| | |
|---|---|
| Length, feet | 1,200 |
| Width, feet | 350 |
| Maximum depth, feet | 50 |
| Rock excavation, cubic yards | 95,000 |
| Earth excavation, cubic yards | 540,000 |
| Concrete, cubic yards | 100,000 |
| Structural steel, pounds | 8,000,000 |
| Reinforcing steel, pounds | 3,500,000 |

The 2400-volt direct current system was selected after an exhaustive study had been made of all the available systems of electrification. The choice quickly narrowed down to three, namely; single-phase, 11,000-volt trolley; low voltage direct current, 600-volt trolley; and high voltage direct current, 1200 to 2400-volt trolley. A careful comparision was made between these systems as applied to the electrification under consideration both as regards first cost and operating cost.

For single-phase it would have been necessary to install frequency changers in the substation, all the available power around Montreal being at 60 cycles. Thus the chief point in favor of single-phase, the economy of transformation by means of stationary transformers instead of rotating machinery, would not have applied in this case. Another thing against this system was the necessity for a large number of multiple-unit cars. It was found that the cost of these would be extremely high compared with d-c. equipments, owing chiefly to the motors being heavier and more complicated for the same output.

As regards the use of low voltage direct current, 600-volt trolley, the main considerations were future long distance extensions and the necessity for a third-rail. If the electrification is extended for any considerable distance, as seems likely, the 600-volt system would be obviously far more expensive than one in which a higher trolley voltage is used. A third-rail was considered out of the question on account of the snow conditions prevalent in Montreal a large part of the year.

For these reasons it was thought best to use a voltage of 1200, 1500, or 2400 direct current. When future extensions were considered, 2400 volts seemed best on account of the economy in copper and substations and it therefore came down to the question of whether this high voltage which had recently been put on a commercial basis in this country would result in engineering or operating difficulties that would more than offset the economy to be gained by its use.

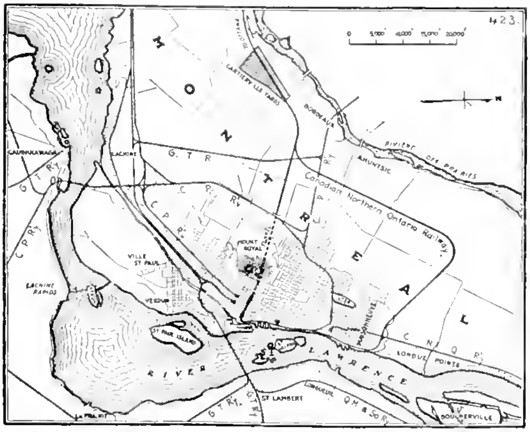


Fig. 1. Map of the Terminal Lines at Montreal showing Line through the Mt. Royal Tunnel

A little consideration shows, however, that 2400-volt direct current cannot be called experimental. When 1200-volts first came into general use, two 600-volt generators insulated for 1200 volts were operated in series to obtain the desired potential. Similarly the motors were insulated for 1200 volts but each wound for 600, and two connected permanently in series. There was little difference in the design of these machines from the old standard 600-volt generators and motors except for the extra insulation and the use of commutating poles. The matter of insulation was easily accomplished, much higher voltages having been used for a long time on alternating current machinery. Commutating poles, which are of comparatively recent developement, have done more than anything else to make high voltage direct current successful, as they overcome commutating difficulties which would be serious without them at the higher voltages.

For the first 1200-volt system, then, the generators and motors were wound for 600 volts and insulated for 1200 volts. The next step was to wind these machines for 1200 volts so that one could be used in place of two in series. This has been done successfully.

When this matter was being studied a year ago seven railroads in the United States were using motors and generators wound as well as insulated for 1200 and 1500 volts. Abroad there were at least six railroads using machines wound for 1000 volts or higher. On all these railroads this high-voltage direct current machinery had been throughly tried out and was entirely successful.

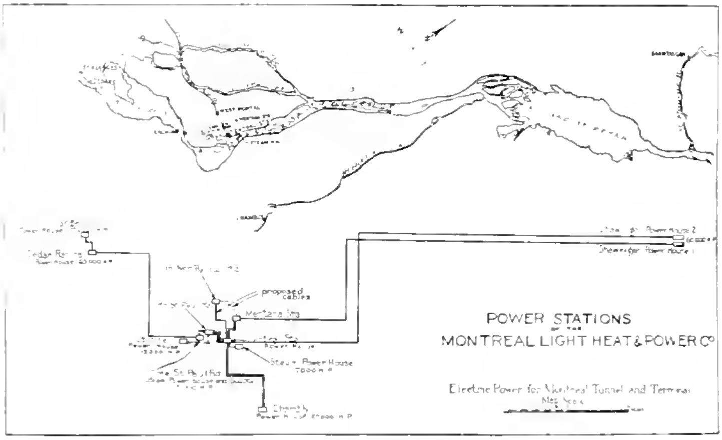

Fig. 2. Map showing the Source of Electric Power for the Montreal Tunnel and Terminal

Thus it was a comparatively simple matter to go one step further and connect two of these motors or generators wound for 1200 volts in series and insulate them for 2400 volts; this being comparable with the first simple step of connecting two 600-volt machines in series for 1200 volts.

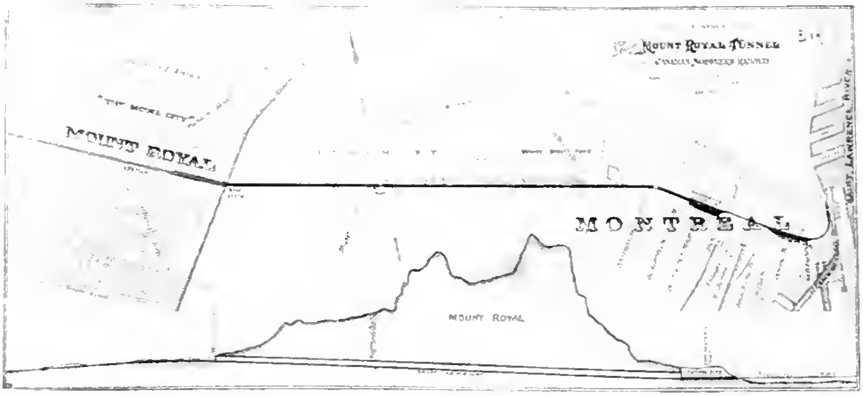

Fig. 3. Map and Profile of the Canadian Northern Montreal Tunnel and Terminal

That this can be done satisfactorily has been proven by the successful operation of the Butte, Anaconda & Pacific Railway electrification in Montana for more than a year.

The first order for equipment which will serve to start the operation of the tunnel and terminal included six locomotives, eight multiple-unit car equipments and two 1500-kw. motor-generator sets with switchboard, exciters, and other auxiliary apparatus.

The locomotives weigh 83 tons each and are geared for a free running speed of 45 miles per hour. It was not thought necessary to resort to any of the special methods of connecting the motors to the driving axles, such as are used on the rod and gearless type, as the schedule for the locomotive trains does not call for high speed. The motors will therefore be nose-supported in the usual way and geared to the axle by means of twin gears.

The locomotive has four axles with all the weight upon the eight driving wheels. The running gear consists of two four-wheel trucks articulated together by a heavy hinge. The equalization of the trucks is accomplished by a semi-elliptic leaf spring over each journal box, connected through spring hangers to the frame and to the equalizer bars. The equivalent of a three-point suspension is thus obtained. The friction draft gear is mounted in the end frame casting of the truck.

The cab, of the box type, is divided into three compartments; the center compartment for the control apparatus, and the two end compartments for the operator. Each operator's compartment is supplied with controller, control switches, ammeter, speedometer, air brake and pantograph control, air gauges, 2400-volt cab heater, bell rope, and control for the whistle and sanders; thus providing the locomotive with complete double end control.

The motor equipment consists of four commutating pole motors wound for 1200 volts and insulated for 2400 volts, two of these motors being permanently connected in series for operating on the 2400-volt trolley circuit.

The one-hour rating of each motor is 315 h.p. at 1200 volts. The motors are designed for forced ventilation which is obtained by means of a blower in the locomotive cab. Either pair of motors may be cut out in case of emergency by a special handle on the change-over switch. The locomotives are operated as two-speed machines with 10 points in series and 7 points in series-parallel. The controller is of the non-automatic type and has two handles, one to regulate the applied voltage at the motors and the other to control the direction of rotation of the motors.

The rheostats forming the external motor resistance are placed near the roof of the cab where they have ample natural ventilation.

**Fig. 4. Tunnel under Construction showing "Bottom Heading" Method**

Current at 125 volts is used for operating the contactors and for lighting the cab and headlights. This is supplied by a motor-generator set, the motor of which has two 1200-volt windings and two 1200-volt commutators in series for operation on 2400 volts. This set is mounted in the center cab and also drives the blower for providing forced ventilation to the main motors.

Two trolleys are placed on each locomotive. These are of the roller pantograph type pneumatically operated and mounted on insulated bases.

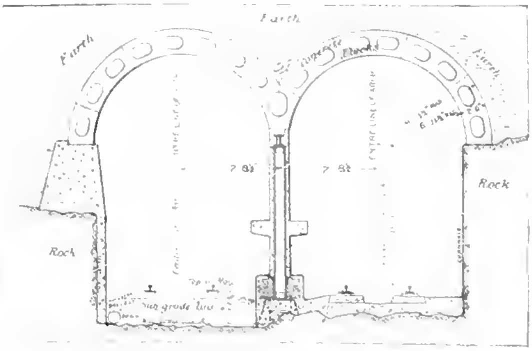

**Fig. 5. Typical Tunnel Section in Earth**

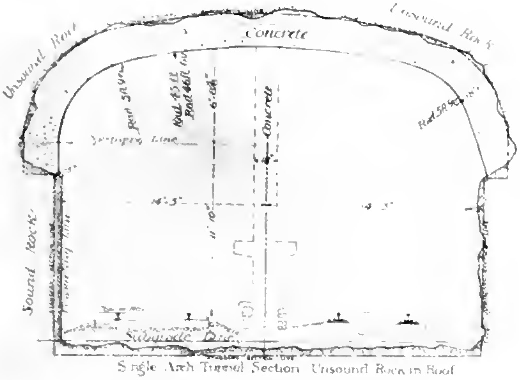

**Fig. 6. Typical Tunnel Section in Rock**

Combined straight and automatic air brake equipment is used, including a 2400-volt motor-driven air compressor, the motor having two 1200-volt windings and commutators operating in series on 2400 volts and direct

**Data on Locomotive**

| | |
|---|---|
| Length inside knuckles | 37 ft. 4 in. |
| Length over cab | 31 ft. 0 in. |
| Over-all height with pantograph down | 15 ft. 6 in. |
| Height over cab | 12 ft. 10 in. |
| Over-all width | 10 ft. 0 in. |
| Rigid wheel base | 8 ft. 8 in. |
| Total wheel base | 26 ft. 0 in. |
| Total weight on drivers | 83 tons |
| Wheel diameter | 46 in. |
| Tractive effort at 30 per cent tractive co-efficient | 49,800 lb. |
| Tractive effort at one-hour rating | 20,300 lb. |
| Tractive effort at continuous rating | 14,500 lb. |

connected to an air compressor having a piston displacement of 100 cubic feet of free air per minute. Some of the principal dimensions and characteristics of these locomotives are as given in preceding tabulation.

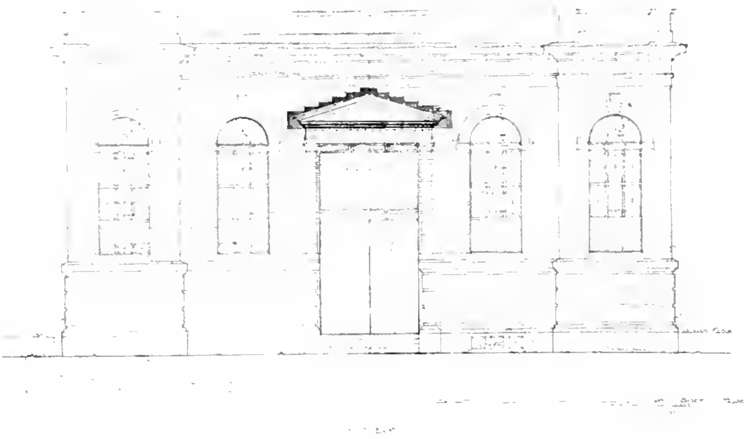

Fig. 7. Elevation of the Exterior of the Terminal Substation

**Multiple-Unit Cars**

The multiple-unit cars will be run under five-minute headway through the tunnel during the rush hours and will serve the suburban territory west of the mountain. It is expected that at first only one-car trains will be operated, but that very shortly after the terminal is put into operation longer trains will be necessary. The equipments for these cars are designed for a maximum of five cars per train. The running time between the town of Mount Royal and the main passenger station in Montreal will be 7½ minutes for a five-car train. Beyond the town of Mount Royal there will be a stop about once every mile to the end of the electrification. These cars are designed for a schedule speed of 20.6 miles per hour with a layover at each end of five minutes. They will make the round trip in one hour.

The motor equipment consists of four fully ventilated 140-h.p. 1200-volt commutating pole motors, insulated for 2400 volts. Two of these motors are permanently connected in series for 2400-volt operation. Ventilation of the motor is accomplished by drawing air into the armature at the pinion end by means of a fan on the armature shaft. The air passes longitudinally through the whole interior of the motor and is expelled through an opening in the motor frame at the commutator end.

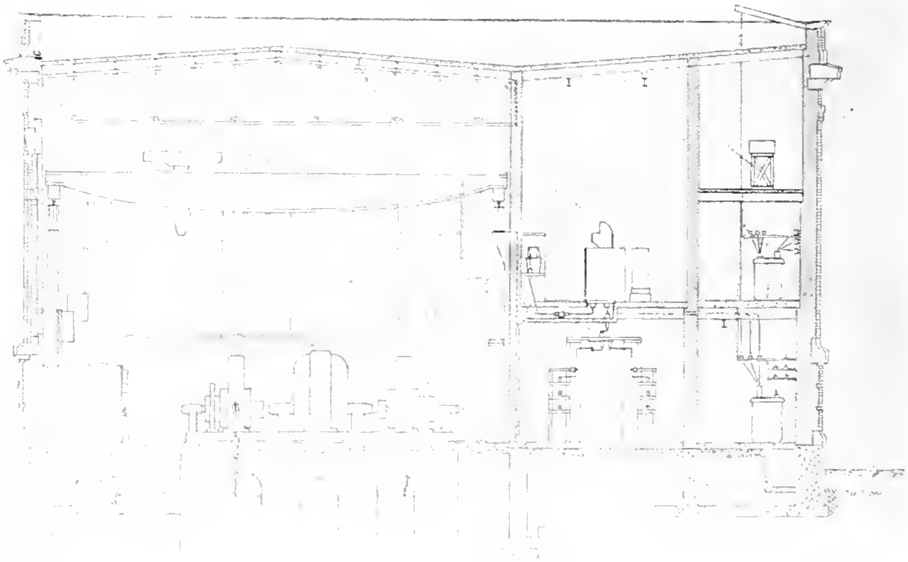

Fig. 8. Sectional Elevation through *A-A* of Fig. 9

The control is of the non-automatic type for multiple-unit operation. The equipment includes a motor-generator set for furnishing 600-volt current for the contactor circuits, air compressor and lighting circuits. This set consists of two 1200-volt motors operating in series on 2400-volts direct connected to the 600-volt generator. The master controller, contactors, switches, reverser and pantograph are all of essentially the same construction as those already described for the locomotives. The controller will have five steps in series and four steps in parallel. It differs from the locomotive controller in having the ordinary motorman's operating handle instead of a lever. This handle is provided with means for cutting off the power and applying the brakes in case the motorman removes his hand.

The electric hot-air system of car heating is used. One complete heater is placed underneath each car and receives its energy direct from the 2400-volt supply. This heater has a capacity of approximately 42 kw. and is constructed for two heat combinations so as to conveniently and economically provide for the changes in temperature. The heating equipment consists of the heating unit, the blower and the regulating mechanism; the controlling switch and thermostat of the regulating mechanism being arranged for operation from the 600-volt supply. Air is

Fig. 9. Plan of the Terminal Substation

forced through the heating unit by means of the blower and distributed to the car through air ducts along the sides. The blower is operated by a motor connected in series with the heating unit on the ground side. The capacity of the blower is 1100 cubic feet of free air per minute.

The cars are of steel construction and weigh loaded and equipped approximately 120,000 lb. Cross-seats are used near the center of the car and longitudinal seats near the ends, thus giving plenty of room near the doors where most crowding occurs when passengers are leaving or entering. The underframing of the car is entirely of steel and the car body of steel except for window frames, wainscoting and headlining, which are of wood. The heat insulation for the sides, roof and ends of the car consists of three-ply "Salamander" and is secured to the steel by means of glue and "Clinchite" nails spot welded to the sheet steel.

The outside and inside finish and all the fittings and other details conform as nearly as possible with the Canadian Northern standard practice. The principal car dimensions are as follows:

| | | |
|---|---|---|
| Length over buffers | 67 ft. | 5¾ in. |
| Length over body corner posts | 57 ft. | 6¼ in. |
| Truck centers | 42 ft. | 9 in. |
| Width over side sill angles | 9 ft. | 10½ in. |
| Width over eaves | 10 ft. | 2¾ in. |
| Height top of rail over roof | 13 ft. | 0 in. |
| Height top of rail to underside of side sill | 3 ft. | 7½ in. |
| Center to center of body side bearings | 4 ft. | 10 in. |
| Center to center of deck sills | 5 ft. | 6 in. |

### Substation

There will be only one substation required until electric traction is extended for a considerable distance. This substation is located at the west portal of the tunnel near the top of the 0.6 per cent grade. Three-phase 60-cycle

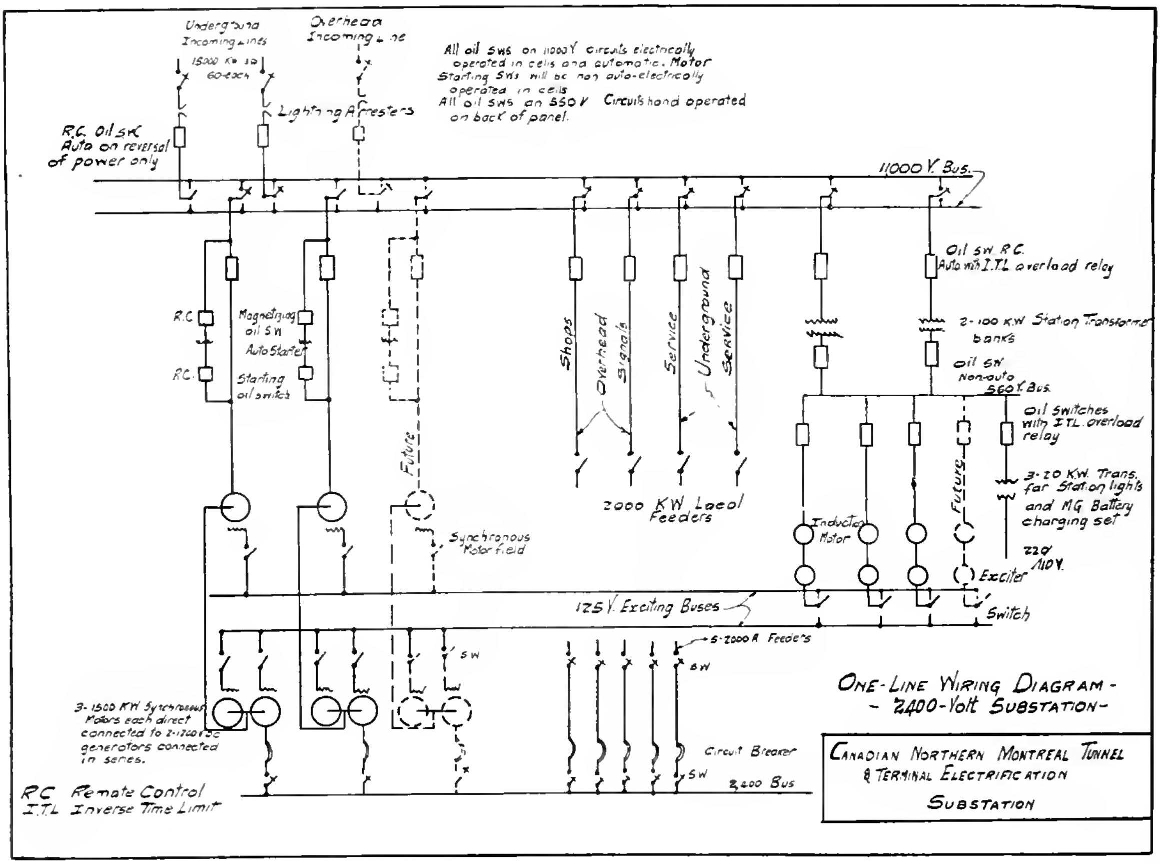

Fig. 10. One-Line Wiring Diagram of the 2400-Volt Substation

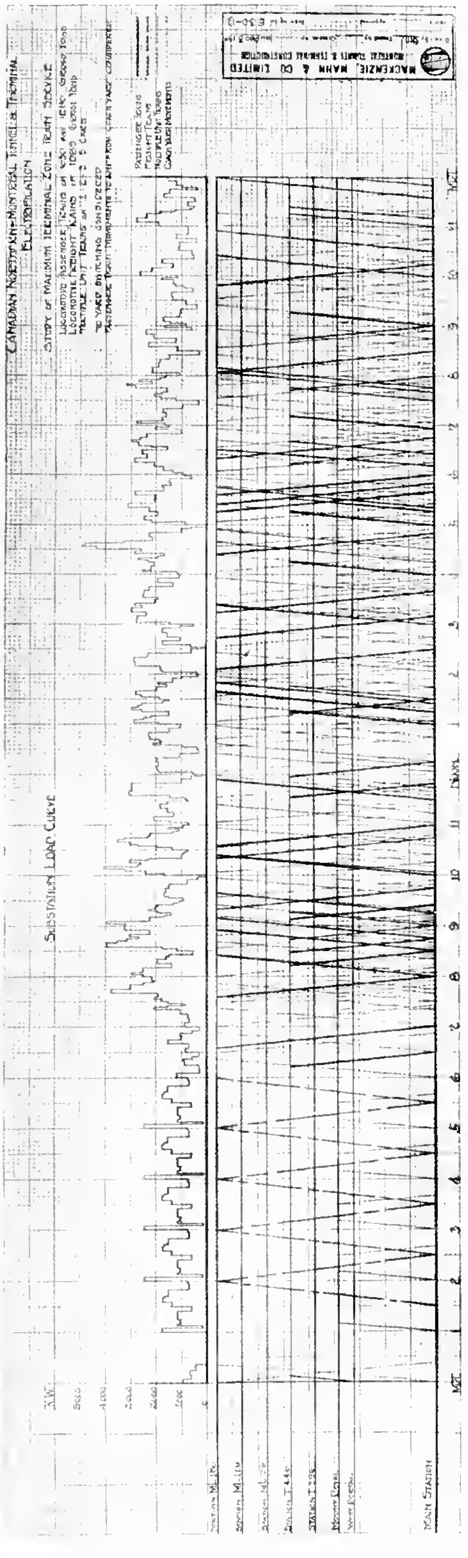

Fig. 11. Combination Curve of Substation Load and Train Service for the Terminal Zone

11,000-volt power will be purchased and delivered at this point from the Montreal Light, Heat & Power Company. This company distributes electric power from six water power stations aggregating 170,000 h.p. All of these are connected to a central distributing station, which is only a short distance from the east end of the tunnel in Montreal. Two sets of cables, one set a spare, will be installed from this central station through the tunnel in ducts and underground all the way to the substation. In addition to these underground lines, an overhead transmission line will connect the power company's Montana Street transformer station just north of Mount Royal with the substation. The switches on these incoming lines will be so arranged that the 11,000-volt busbars can be quickly changed from one to the other.

Besides the water power generating stations the power company has two steam generating stations with a total output of 32,000 h.p. These act as a reserve only and are connected to the central distributing station by underground feeders. Continuity of power supply is thus amply provided for.

The alternating current power will be converted into 2400-volt direct current power for the trolley circuits by means of 1500-kw. motor-generator sets. Two of these sets are being installed at present, one of them being a spare. There will be space provided in the station for a third motor-generator set which will be installed when the load increases beyond the capacity of one set.

Each of these sets consist of two 750-kw., compound wound, commutating pole generators wound for 1200 volts, insulated for 2400 volts, and direct connected to an 11,000-volt synchronous motor operating at a speed of 600 r.p.m. These generators are permanently connected in series. The shunt fields are separately excited. The pole face winding, series and commutating field windings are all connected on the ground side of these generators so that the armatures are the only parts subjected to the full potential of 2400 volts. Separately exciting the shunt fields would ordinarily be objectionable for the reason that if the commutator should arc over due to a short circuit on the line the generator voltage would tend to hold up and maintain the arc. To overcome this objectionable feature a limiting resistance is placed in series with each of the shunt fields. This resistance is cut into the circuit by means of a contactor operated by current coils excited from the 125-volt bus and connected in series with the auxiliary switch attached to the main direct-current circuit breaker. When this circuit breaker opens the auxiliary switch is also opened, thereby allowing the contactor to open and cut in the additional resistance, thus reducing the voltage of the generators. A speed limit device is also used. The contacts of this device are connected in series with the trip coil of the circuit breaker. In case of about 15 per cent over speed, or more, a revolving weight due to centrifugal force opens the switch, thus killing the low-voltage release coil of the circuit breaker and causing it to open.

These sets have a continuous capacity of 1500 kw. each and an overload capacity of 200 per cent for five minutes.

The switchboard is composed of thirty-two panels of natural black slate. These control various outgoing circuits for signals, tunnel lighting, and miscellaneous power as well as the substation machinery. Nine of these panels comprise the 2400-volt direct current board. The 2400-volt circuit breakers and lever switches are mounted on panels back of and above the main switchboard. They are operated by means of insulated handles on the front of the main board so as to eliminate any possibility of the operator coming in contact with the 2400-volt circuit. The breakers are enclosed between fireproof barriers. They are equipped with powerful magnetic blowouts to extinguish the arc, and are provided with a re-setting device operated from the front of the board. The field switches are mounted back of the panels with their operating handles on the front of the main board.

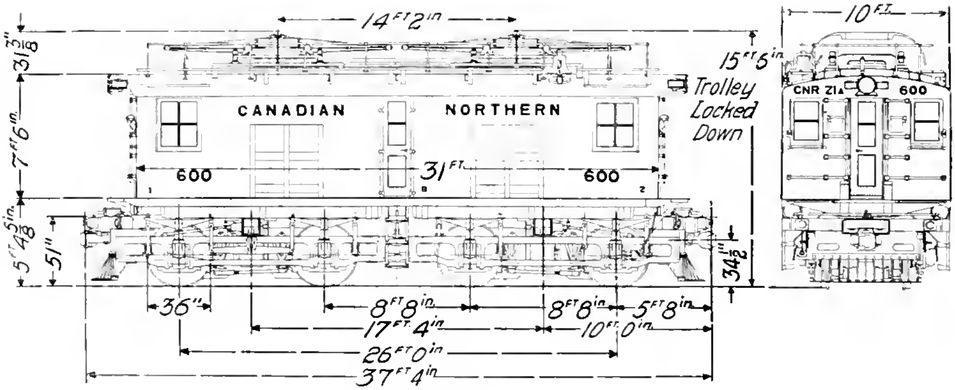

Fig. 12. Dimensioned Outline Diagram of a Canadian Northern Locomotive

There will be three motor-generator exciter sets, each consisting of a 50-kw. 125-volt generator of the commutating pole type direct connected to a 550-volt 1200-r.p.m. induction motor. Normally one exciter will furnish exciting current to the fields of the synchronous motors, and another the current to excite four generators, the third exciter being a spare.

Two banks of transformers, one a spare, each consisting of three 100-kw. 60-cycle 11,000/550-volt single-phase transformers will be installed to furnish low voltage alternating current for operating the exciters and various motors. Other small transformers will step down from 550 volts to 110 volts for lighting the station. Emergency lighting will be taken care of by means of a storage battery, which will also furnish current for operating the oil switches in case of a complete shut-down, when current from the exciter will not be available.

The substation building is 88 ft. long by 70 ft. wide by 34 ft. high and consists of a machinery section and a switching and auxiliary section. The machinery room contains the two 1500-kw. synchronous motor-generator sets with the foundation for a third set, and three exciter sets with space for a fourth. It also contains the switchboard. A 25-ton traveling crane is provided in this room. This crane will handle the heaviest piece of machinery. Under this room there is a basement where rheostats are located beneath the switchboard and where there are also storage and locker rooms.

The switching and auxiliary section is divided from the machinery section by a heavy fire wall. Underneath half of this is a basement containing rooms for oil storage and for the furnace which provides heat for the building. This section is divided into a busbar room, oil switch room, lightning arrester room, power transformer room, battery room and feeder entry room. Fire walls and doors fully guard against the possibility of any fire spreading.

The machinery room has a glazed brick dado extending 10 ft. above the floor. Above this, the room is lined with a light cream-colored brick. Ample windows are provided for light and ventilation. Revolving ventilators are located in the roof over the machinery.

The exterior of the building is finished with a dark red tapestry brick with parapet, cornice and other trimming of moulded concrete imitating dressed sandstone.

Outside the tunnel the overhead construction will be of the catenary cross-span construction supported by means of cedar poles spaced 150 ft. on tangents. The messenger cable will be of 5/8-in. steel. The height of the trolley will be 23 ft. above the rail. The hanger spacing will be 15 in. and the deflection 28 in. One 500,000-c.m. feeder will be installed from the substation to the Cartierville yard.

In the tunnel the messenger cable will be an aluminum cable one inch in diameter having a steel core as reinforcement. This cable will have a conductivity equivalent to a 400,000-c.m. copper cable. There will be no other feeder in the tunnel. The messenger supports will be spaced 80 ft. apart and the height of the trolley in the tunnel above the rail will be 16 ft.

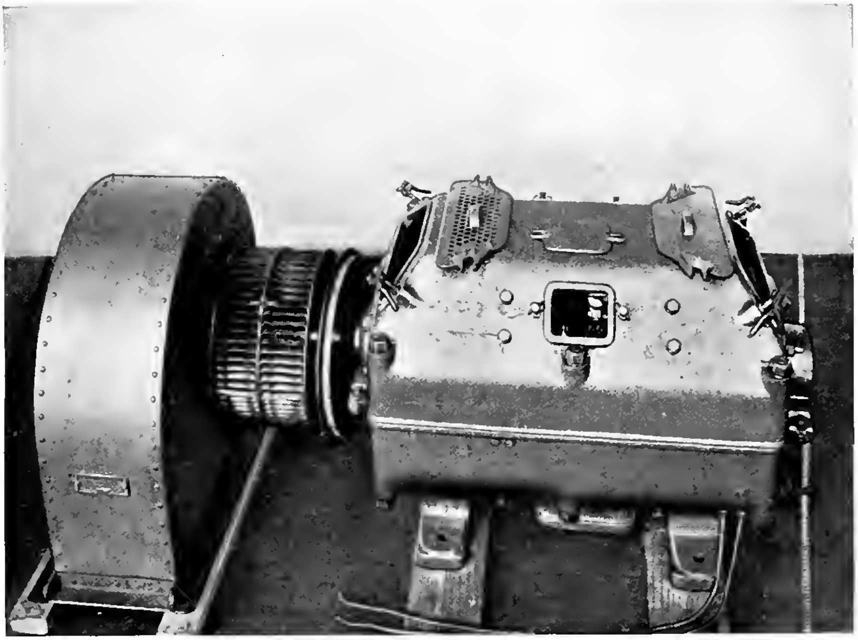

Fig. 13. Motor-Generator Set for Operating the Locomotive Control and Blowing the Main Motors

# HIGH VOLTAGE DIRECT CURRENT RAILWAYS

By G. H. Hill

Assistant Engineer, Railway and Traction Engineering Department,
General Electric Company

The writer points out that, important as is the physical success of higher voltage direct current apparatus, the economic success under industrial conditions is of still greater moment. After several references to the successful operation of the Butte, Anaconda & Pacific Railroad, the problems of transmission and distribution are discussed and illustrated with a hypothetical example. Other important problems are dealt with, and the article is concluded with a summary of the voltages for which direct current apparatus has already been designed for different fields of service.—Editor.

G. H. Hill

THE successful operation of the first extensive heavy freight electrification in this country is undoubtedly gratifying to all those who are interested in electric railway progress. The first year's operation electrically of the Butte, Anaconda & Pacific Railroad, just now ended, has demonstrated a success from every point of view. Even the most conservative must agree that electric apparatus in general and the specific apparatus employed in this instance in particular, is well adapted for the heavy, rough service involved.

The condition of the equipment throughout indicates an ample margin in capacity and freedom from any source of undue depreciation. The fact that the operation and maintenance has been in the hands of substantially the same force as under steam operation is in itself significant.

Important as is the physical success of the apparatus, of still more importance to the industry is the economic success. The very complete data of costs of operation of the Butte, Anaconda & Pacific Railroad, when a steam railroad and since being converted, which are now available, indicate a remarkable saving by electrification. This is clearly set forth in the statistics given elsewhere in this issue.

There is no special feature that makes this railroad peculiarly fitted for electric operation. The cost of coal is high and electric power reasonably low, but this is the condition throughout most of the trunk line mountain districts. Moreover, the savings shown include a material amount of traffic and switching service still being done by steam locomotives. While it may not have appeared economical at the start to electrify all of these branches and yards, it appears that a further source of saving would be opened by so doing.

Whether or not this splendid demonstration of the possibilities of electric traction could have been possible with any other system of electrification is, in a broad sense immaterial. To railroad men the fact is demonstrated that heavy grade steam railroads, freight as well as passenger, can be equipped electrically; that the apparatus can be operated by the same organization throughout; that the equipment is sturdy, capable of the hardest usage, free from weaknesses and defects and that from the very start most substantial economies can be realized.

At the same time the fact that the Butte, Anaconda & Pacific Railroad is equipped with the direct current system at 2400 volts establishes beyond question the fitness of this system for use in electrifying the mountain divisions of the great trunk railways, and is one solution of this important problem.

One of the natural questions that arise in this connection is what ultimate voltage will be found desirable to use for heavy railroad work. It is frequently assumed that the highest possible voltage is most economical and that the line potential is limited only by the possibilities of producing operative apparatus. While such limitations may have existed some time ago, the experience gained in the development and use of 1200 and 2400-volt systems, combined with the diligent study and vigorous experimenting which have been carried on, has demonstrated conclusively that both generating and motor equipments can be successfully built for at least double the voltage of the Butte, Anaconda & Pacific. This can be accepted as a reasonable and conservative statement. The application of still higher voltages is, therefore, not a matter of physical possibilities in producing apparatus but of the comparative economical results. The highest line potential is not necessarily the most economical or the best suited for all conditions of profile and traffic and it is necessary to consider all these conditions in order to determine the most suitable voltage for electrification.

It is obvious that a given amount of power can be transmitted at high voltage over longer distances with a given amount of copper, or over the same distance with less copper, than at low voltage. The problem of transformation and distribution from the high tension alternating current transmission to the rolling stock is somewhat more complex. This can best be illustrated perhaps by a crude example:

Suppose a railway were equipped with light cars consuming an average of 100 kw. each and operating on a close headway one mile apart. The load would be uniformly distributed over the system. If the line were of 500 volts, the substations of 500 kw. could be spaced about five miles apart with no feeder copper to reinforce the 4/0 trolley. A 1000-volt line would have substations of 1000 kw. spaced ten miles and a 3000-volt line potential would have substations of 3000 kw. spaced thirty miles. In each case the total substation capacity and the amount of copper would be the same.

The sole advantage of spacing substations farther apart would arise from the lower cost of apparatus and buildings per kw. At about 1000-kw. capacity per substation this cost approaches a minimum, while for a given voltage the cost of feeder copper increases rapidly with the greater spacing. At the same time the cost per kw. of generators and the weight and cost of the rolling stock increases at an accelerating ratio with the voltage. The balance in costs will be reached for the assumed railway at about a twelve mile spacing of substations and with 1200 volts line potential. On the other extreme, if the railway load consists of, say, two train units each consuming 5000 kw. spaced 50 miles apart it is obvious that substations spaced less than fifty miles will have to have substantially the same capacity each as if spaced fifty miles, so that there is a marked saving in total substation capacity by the wider spacing and the balance will arrive at about 5000 volts and 50 miles spacing. The illustration is quite crude since many other conditions enter into the problem such as varying train weights, grades and necessity for moving train fleets with a deranged schedule.

It is clear, however, that the size of train units and the density and distribution of the traffic have the determining influence upon the most economical voltage to be used as well as the substation spacing. Many local conditions will enter to modify any general conclusions. There are usually certain natural locations for substations, on account of grades, branch lines or existing stations so that each problem must be studied individually both with reference to present conditions and future growth.

The limit in weight of train units on grade sections, due to the strength of car structure and drawbars, air-brake operation and other similar considerations, makes an input of about 5000 kw. per train, not including acceleration, the maximum that will have to be dealt with.

Where traffic is dense enough to warrant electrification at all and the future growth is properly considered, it is generally found that the minimum first cost and operating cost is reached at about 3000 volts for the heaviest train service.

Many situations and many conditions indicate a lower voltage than this, for instance where multiple unit train passenger service is a considerable factor the advantages of a line voltage of about 1500 volts are quite apparent.

Motors of less than 175 or 200 h.p. increase rapidly in weight per h.p. at voltages over 700 or 800 so that four-motor equipments with series parallel control become disproportionately heavy and costly above 1500 volts. The control apparatus as well becomes rather complex and bulky for installing beneath the car floor. The lower power demand per train unit and the frequent spacing of trains which this class of service involves naturally influence the conclusion toward a lower voltage, while the size, weight and cost of the cars emphasize the economy of moderate voltage. The use of 1200 volts for suburban lines is not only most economical for the character of the traffic, but presents especial flexibility in combination with 600-volt lines, with which they usually connect. The large number and wide distribution of 1200-volt railways now in successful operation firmly establishes this voltage as standard for suburban service.

The just demands for some degree of standardization require the elimination of too great a variety of line voltages. The needs of all classes of service seem to be well met by apparatus already well developed and to a large extent in practical use. This may be summarized as follows:

600 volts for city service,
1200 volts for suburban lines connecting with 600-volt city lines,
1500 volts for moderate mixed freight and passenger traffic,
3000 volts for heavy trunk line service.

Future development will probably follow these lines, since this classification is already fairly clearly drawn in railway practice, as a result of much study and experience.

Steam railway organizations are confronted with many perplexing problems in the consideration of the inevitable electrification. It is of inestimable value to their progress, as well as to that of the electrical industry, to be able to present one satisfactory solution with respect to the electrical system and apparatus to be employed that is already developed, tested and proven. Several railways have, as a result, already adopted the 2400 and 3000-volt direct current system for important electrifications now under way.

---

# THE OPERATION OF THE OREGON ELECTRIC RAILWAY

By L. B. Wickersham

Assistant General Manager, Spokane, Portland and Seattle Railway System

In last November's issue we published quite an extensive account of this 1200-volt system, and in the present article the author deals with the operation of the road since that date. The operation and maintenance of the passenger cars, an analysis of the power costs and of the substation data as regards "input," "output" and "efficiency," and a resume of the cost of maintenance for the whole electrical system, make a complete and interesting story. The tables accompanying the article are of great value.—**Editor.**

As the physical features of the 1200-volt system of the Oregon Electric were fully described in the General Electric Review, November, 1913, shortly after the 1200-volt system was put into operation, the present article is largely supplemental and is based upon operating data since that time.

It will be recalled that this line was formerly a 600-volt system operating 50 miles south to Salem, with a branch line of 19 miles to Forest Grove. An additional 72 miles south from Salem was completed in the late fall of 1912, at which time was also completed the changing over of the entire system from 600-volt to 1200-volt operation. The results contained in the table given are, therefore, the statistics on the first fiscal year of operation under the 1200-volt system.

### Cost of Operation and Maintenance

In Table I is given the operating cost for passenger service per car mile, also the monthly train mileage and car mileage over this period.

In column 1 the cost of maintenance of electrical equipment is shown in cents per car mile, while column 2 gives the maintenance cost of passenger cars themselves, exclusive of electrical equipment. Wages of motormen and trainmen are shown in column 3, and column 4 represents the power cost in cents per car mile. Common charges between freight and passenger operation are divided, as is usual, upon a car mileage basis.

It is interesting to note that the maintenance of equipment of cars, including electrical equipment averages for the year approximately 1.75 cents per car mile.

At the time the change was made from 600- to 1200-volts, two of the 600-volt GE-73 motors were retained on each car and new GE-205 600/1200 motors used on the high side. That the use of the old 600-volt motors in connection with the 1200-volt operation has not served to increase the maintenance cost of the equipment is very evident from the tabulated figures given, and justifies the investigations and conclusions of the engineers of the General Electric Company and the railway company.

The total cost of all maintenance of passenger equipment is approximately 2 cents per car mile, which is considered to be an excellent record in the maintenance of equipment at this time. The cost herein given includes the depreciation charged against the equipment.

It will be noted that the total operating expenses per passenger car mile is 22.9 cents, and that the average car mileage is 197,465, and that there is an average of 2.5 cars per train.

### Power

Power for the operation of these lines is purchased from the Portland Railway, Light & Power Company. The contract calls for $1.25 per month per kw. of maximum demand; the maximum demand being the average power during the hour giving the largest number of kilowatts delivered during any one-hour period, and is determined from the load sheets for each month separately.

The companies purchase both direct current and alternating current from the power company, the direct current being supplied in the city of Portland, while the alternating current is delivered at 60,000 volts at the railway company's substations. Printometer attachments are used for the measurement of both the direct current and the alternating current. The summation of the printometer readings at the company's two direct current substations and at their two power plants represent the daily load curve of the railway company on which the maximum demand is based.

A consumption charge of 4.75 mils per kw-hr. is charged for all power delivered to the railway company's substation and is measured on the low side of the transformer at the railway company's various substations. On the direct current readings the company pays an additional two mils for conversion. The direct current furnished amounts to approximately ten per cent of the kilowatt-hours furnished.

In Table II is shown the segregation of power costs for the fiscal year 1913–1914. The company has installed meters upon its freight equipment and in this way is able to effect an accurate segregation between passenger and freight. This enables an accurate determination to be made of passenger power costs, so that the operation of the passenger equipment can be studied and by supplementing this data with that obtained from coasting meters placed on certain equipments, motormen are instructed in the proper handling of their cars with the view of securing low power consumption. In addition to this, watthour meters have been placed on several of the passenger equipments and the actual consumption required to make certain runs determined. Motormen have learned the amount of power consumption required to make certain runs under economical handling of equipment and are encouraged to reduce this as much as possible.

Car heating tests have been made so as to properly segregate the heating and lighting from propulsion. An effort has been made to operate the freight trains as much as possible during the night hours, and careful attention is given to eliminate unusual peak load conditions.

It will be noted that the load factor has been maintained at between 40 and 50 per cent. The reason for the low load factor in July, 1914, being the heavy travel on the Fourth, which caused unusual peak conditions and necessarily lowered the load factor. The average for 14 months from June, 1913 to July, 1914, inclusive, was 46.3. The average cost per kw-hr. delivered at the

company's substations over this same period, including the direct current delivered, was 0.9 cents per kw-hr.

In Table II the amount of power billed includes the power supplied the United Railways, which is operated in conjunction with the Oregon Electric Railway, as they both operate under the same power contract, thereby deriving the advantages of the combined load factor. The balance of the

## TABLE II

### SEGREGATIONS OF POWER COSTS FOR FISCAL YEAR 1913-1914

| | June 1913 | July 1913 | August 1913 | September 1913 | October 1913 | November 1913 | December 1913 | Average |
|---|---|---|---|---|---|---|---|---|
| Power bill (Oregon Electric & United) | $9696.35 | $9764.02 | $10464.23 | $10687.28 | $11559.89 | $11493.20 | $10986.20 | |
| Kilowatt-hours per month | 1,115,055 | 1,148,840 | 1,221,780 | 1,255,550 | 1,392,345 | 1,375,960 | 1,299,945 | |

## TABLE IV

### COST OF MAINTENANCE

| | Substation | Transmission System | Distribution System | Poles and Fixtures |
|---|---|---|---|---|
| 1913 | | | | |
| July | $760.52 | $275.83 | $837.87 | $399.58 |
| August | 243.04 | 320.50 | 979.42 | 452.21 |
| September | 161.57 | 161.81 | 770.70 | 576.92 |
| October | 147.42 | 218.98 | 807.12 | 878.02 |
| November | 797.21 | 273.04 | 1034.97 | 1549.02 |
| December | 636.33 | 284.13 | 1031.02 | 1515.17 |
| 1914 | | | | |
| January | 253.25 | 298.66 | 686.31 | 1489.23 |
| February | 523.69 | 291.71 | 562.43 | 1487.63 |
| March | 437.78 | 276.17 | 589.89 | 599.68 |
| April | 587.68 | 39.85 | 219.34 | 58.37 |
| May | 479.98 | 71.23 | 344.19 | 144.08 |
| June | 549.29 | 25.44 | 45.23 | 168.35 |
| Total per year | $5577.76 | $2537.35 | $7818.03 | $9318.26 |

Miles of line, 150.
Maintenance substations per mile road per year, $37.18.
Maintenance overhead lines per mile road per year, $131.10.
NOTE:—Seventy-two miles of line and four substations were new in 1912.

table is segregated and is statistical for the Oregon Electric alone.

It should be noted that the propulsion cost per car mile and the kw-hr. per car mile for propulsion alone are given separately from the car lighting and heating cost per car mile and car lighting and heating kw-hr. per car mile.

It will be noted that the approximate average propulsion kw-hr. per car mile is 3.1. This is at the meters and represents approximately 2 kw-hr. per passenger car mile at the cars, which is considered to be an economical performance, considering the weight of the equipment and the grades over which these lines operate. The average cost of propulsion measured at the meters is approximately 2.72 cents per car mile.

It will also be noted from the table that the average power cost per car mile on revenue freight is 1.66 cents per car mile, or 61 per cent of the cost per passenger car mile.

An approximate conclusion which may be drawn from this comparison between the cost per car mile in passenger and freight is the difference in tractive power per ton mile exerted to handle freight and passengers under actual running schedule.

It should be understood that these figures are averages of monthly computations, therefore approximate, but representing fairly well the average conditions of operation over the period given.

### Substation Operation

In Table III is given the output and input of each of the substations and their monthly efficiency. The average of the monthly efficiencies is also shown.

All of these substations operate rotary converters, with the exception of Harborton, on the United Railways, which operates motor-generator sets. Multnomah, Moffat and Tonquin have 600-volt rotaries in series, while the other substations have 1200-volt rotaries. Harborton has two 600-volt motor-generators in series.

The direct current output at Station E and Jefferson Street station are also shown in this table.

It will be noted that the average efficiency as averaged from the monthly efficiencies of the various substations on the Oregon Electric is 84 per cent while the efficiency of the Harborton substation averages about 62 per cent. While this difference in efficiency between the Oregon Electric and United Railways substations is partially due to the class of service which they supply, there is clearly a difference of 15 per cent in the operation of rotaries, as compared with the motor-generators.

Substations on these lines are shut down at certain intervals during the day whenever a shut-down of 30 minutes can be obtained with no trains in the zone supplied by the substations. These shutdowns are handled according to regular schedule, subject to such variations as may be given by the dispatcher in case of extra movements.

It will be noted that substations such as Orville and Pirtle, which are located on the south end of the line, show remarkably high efficiencies. These are obtained by keeping the capacity of the substations as low as is consistent with the maximum demand conditions upon them, supplementing them with a portable substation during days of unusually heavy movement, such as the Fourth of July, Rose Festival, etc.

Table IV gives the maintenance figures for substations and overhead lines for the fiscal year 1913–1914. It should be noted that 72 miles of the line, from Salem to Eugene, were constructed in 1912 and are, therefore, practically new. This is also the case with four of the substations on the south end.

On the other hand, the balance of the line has been in operation over seven years, and the pole reinforcements and renewals were begun a year ago. It is expected that the work of this kind during the fiscal year 1914–1915 and the following year will complete the reinforcement or renewal of practically all of the poles on the old part of the line.

It should be noted that the substation maintenance per mile of road per year over this period averages $37.18, and that the maintenance of overhead lines per mile of road per year averages $131.10.

# THE BALTIMORE AND OHIO ELECTRIFICATION

By J. H. Davis

Electrical Engineer, Baltimore and Ohio Railroad

The author has written an interesting account of this the first heavy electric traction undertaking in America. The physical characteristics and history of the road, the power supply, distributing system, locomotives (old and new), the operating features, and the cost of operation and maintenance are all discussed; the latter features being amplified by some valuable tables. The high maintenance charges on the Class OE-1 and OE-2 locomotives are explained by the fact that these units were much overloaded, and that for the period for which the figures are given there were no adapt facilities for re-winding armatures of this size. The high cost of third rail maintenance that has been experienced on this road is accounted for by the large amount of renewal work and the unusual local conditions.—Editor.

J. H. Davis

When it was suggested that an article on the Baltimore & Ohio electrification would be of interest in this number of the General Electric Review it was felt that, in view of the previous descriptions, very little could be said at this time with which students of heavy traction were not already familiar. However, the fact that the Baltimore & Ohio electrification was the first undertaking of this nature in the United States, and as changes have recently been made to provide for much heavier traffic conditions than originally existed, and also, as data on the cost of operation and maintenance is fairly complete over a long period of years, it was felt that a review of this subject including a statement of physical characteristics, a brief history of the reasons for electrification, together with a description of the equipment now in use, tonnage handled, sources of supply of electricity, as well as data on the cost of operation and maintenance, would prove interesting. The need of actual operating data has been felt by engineers and railroad managers who are considering the subject of trunk line electrification, and notwithstanding the fact that considerable information of this character is now available, the same has not been made public except in a few instances. Where the exact conditions of operation are stated and the data is properly used there should be no objection to its publication.

## Physical Characteristics

That portion of the Baltimore & Ohio Railroad which is electrified lies within the city limits of Baltimore, and is a part of the so-called belt line, extending from Camden Station on the west to Waverly interlocking tower on the east, a distance of 3.75 miles. There are eight tunnels in this zone, together amounting to 48 per cent of the total distance, the longest tunnel, which is between Camden Station and Mount Royal Station, being 7300 feet in length. This tunnel contains two tracks while there are four tracks between Mount Royal and Huntingdon Avenue, from which point to Waverly there are two tracks. That part of the zone through which trains are handled by electric locomotives is entirely upgrade, the difference in elevation amounting to 150 feet, which gives an average through grade of 0.9 per cent, the ruling grade being 1.52 per cent and maximum curvature, 10 deg. 16 min. Special attention is called to this fact as trains are handled electrically only in the upgrade direction, the electric locomotives returning light, which results in a unit power consumption that is in all probability larger than that for most other existing steam railroad electrifications. Fig. 1 shows map, profile and curvature diagram of the electrified zone.

## History

During the early 1890's the Baltimore & Ohio constructed the Belt Line Railroad which furnished a direct rail connection between the main line west of Baltimore and that east. Previous to this it was necessary to ferry the trains across an arm of the Patapsco River. One of the requirements of the ordinance governing the construction of the line through the city was that the trains be operated electrically. In addition the number and lengths of the tunnels necessitated special means for reducing the amount of locomotive smoke and gases, for which electrification undoubtedly offered the most satisfactory solution. The first trial trip with electric locomotive No. 1 was made on June 27, 1894, but the belt line was not opened for traffic until May 1, 1895. Regular service with a total of three electric locomotives was begun on August 1, 1895. An overhead distribution system was installed, but as it never proved satisfactory it was replaced in 1902 by the third rail system. Four electric freight locomotives were purchased in 1903 and another of the same type in 1906. With the increasing traffic and weight of trains the capacity of the power plant and feeder system became inadequate, with the result that in 1909 a contract was entered into for purchasing current from the Consolidated Gas, Electric Light & Power Company of Baltimore, and a synchronous converter substation was built near the center of the electrified zone. In 1910 and 1912 a total of four locomotives of a more powerful type were placed in service and the original three were retired.

### Power Supply

The direct current system is used, 675 volts being maintained at the d-c. bus. Originally all power was supplied directly from the power plant, built for that purpose, located at the western end of the zone. The generating station is supplied with five 500-kw., 700-volt, direct current generators direct connected to tandem compound non-condensing Corliss engines. A large proportion of the plant output, however, is used for the railroad's shops and other purposes. As but one train at a time was handled through the zone the load was of an intermittent and high peak character. To obtain more economical operating conditions as well as to improve the voltage on the line a storage battery substation was subsequently installed near the Mount Royal passenger station, a mile and three-quarters from the power house. A booster system of control was used which included a booster located in power house, thus permitting a reduction of the generating voltage to 550 in order that current could be used for industrial motor purposes. This booster limited the power house output to 900 kw. for traction purposes which, with the battery, was sufficient to handle one freight train of 1600 tons weight including electric locomotive and one light passenger train simultaneously.

With the increase in train weights and in the amount of traffic handled there finally resulted a condition where the system of generation and distribution of power was totally inadequate to meet the demands. A study of the situation developed that power obtained from a large central station plant under a suitable rate schedule would prove the most satisfactory from an operating as well as economic point of view. In 1909, therefore, a contract was entered into with the Consolidated Gas, Electric Light & Power Company for furnishing power in the form of 13,000-volt three-phase, 25-cycle current. A synchronous converter substation was built by the railroad adjoining the Mount Royal battery station. Three 1000-kw., 650-volt synchronous converters with the necessary auxiliaries were installed, sufficient space being provided for an additional machine. The battery, which is of 3200-ampere hours capacity, at an eight-hour rate, or 3200 amperes for a period of 20 minutes, at the maximum discharge rate, has been retained for peak work and is controlled by the Electric Storage Battery Company's carbon pile regulator system. The present capacity of the station is sufficient to permit handling simultaneously two freight trains of the present tonnage rating, e.g., 2400 tons including electric locomotives, and one passenger train, which will take care of the probable traffic requirements for some time. The power plant is operated in parallel with the substation, it having been found economical to do so as long as it is continued in service. Plans are now under way, however, for closing it down in favor of purchasing current for the entire requirements of the railroad in Baltimore. Experience thus far has fully demonstrated the operating advantages and economics of purchased current, under suitable form of contract, for this character of service. The ability of a large central station system to absorb without disturbance the abnormally high peaks occuring with the simultaneous starting of trains on the grades, as well as the fluctuations of longer duration, caused by the intermittent character of the load, the ability of the railroad to increase indefinitely the demands for power without an additional outlay of capital for power plant equipment, and the elimination of the necessity of having to carry the fixed charges on reserve plant equipment are all decided advantages in favor of the use of central power station.

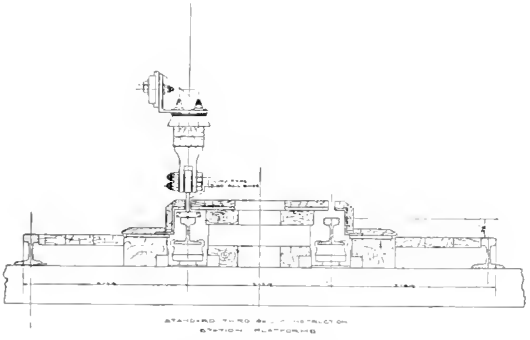

Fig. 2. Method of Mounting and Protecting the Third-Rail at Station Platforms

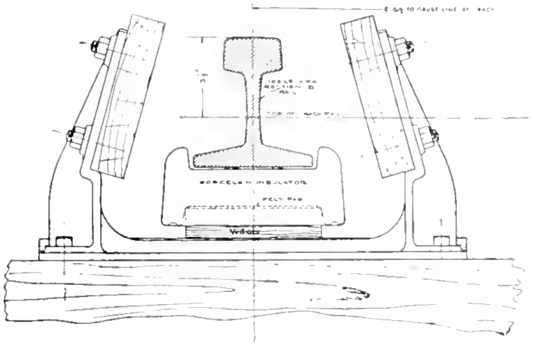

Fig. 3. Latest Type of Third-Rail Construction Adopted. This is now Standard.

### Distribution System

The original installation comprised an overhead system of power distribution. The contact conductor consisted of two Z bars so arranged as to form a box-like structure with a slot in the bottom. Outside of the tunnels this was supported from towers by catenary construction and in the tunnels by direct hangers. In this overhead slot the collector shoe, attached to the locomotive by a pantograph, was allowed to slide. As would be expected, from our present knowledge of methods of collecting current, the system was unsatisfactory, while the presence of gases from steam locomotives resulted in high maintenance cost. In 1902, the overhead conductors were replaced by a third-rail system, the larger part of which is still in service. On account of the flush platform construction at the passenger stations a special form of protection was provided, which is shown in Fig. 2. As a further safety precaution, automatic sectionalizing switches were installed but, proving unsatisfactory, were discontinued.

To provide a continuous supply of current to the locomotives at double slip switches, where the gaps were too great to be spanned by the third-rail shoes, a special arrangement of movable third rail is used to avoid the necessity for overhead conductors. These consist of a structural T iron located inside the crossing tracks and at such other points where the standard third rail would be fouled by trains using the crossing tracks. In the operating position these are level with the top of the third rail, but normally are lowered to the track rail level, in which position current is automatically cut off as a safety precaution. The rails are controlled from the signal towers and are properly interlocked with the switch levers.

After ten year's of service the third rail in the Howard Street Tunnel became so badly corroded, due to action of the locomotive gases and electrolysis, as to require its complete renewal, at which time the type of insulator and guard board support were modified to overcome certain faults in the original design. The design as modified has been adopted as standard for future replacement, and is shown in Fig. 3.

### Locomotives

Three types of locomotives have been used; the original locomotives designated as class LE-1, the second lot of locomotives designated as class LE-2, which were designed exclusively for freight service, and the last lots purchased designated as classes OE-1 and OE-2, which are of the Detroit Tunnel type and are used for both passenger and freight service. After 15 year's service the original locomotives were retired on account of obsolescence; one of them however, has been preserved intact for exhibition purposes as being the first electric locomotive used in this country under steam railroad conditions. Accompanying photographs show the different types of

locomotives, while the principal data pertaining to the electrical, mechanical and operating features are given in Table I.

### Operating Features

The service in the electrified zone is very similar to helper locomotive service except the road locomotives furnish no assistance. The ruling grade in the zone is 1.52 per cent while that of the remainder of the steam locomotive division is but 0.8 per cent. This necessitates that the electric locomotives be able to develop twice the tractive effort required of the steam locomotives. On account of the shortness of the run, steam locomotives are hauled through the zone with their trains. The electric locomotives return light as, on account of the grade, westbound traffic operates through the zone without requiring power from the steam locomotive except for starting.

The present maximum rating for freight trains handled over the belt line is 2200 actual tons, including the steam locomotive weighing 230 tons. Two class OE-1 or OE-2 locomotives haul these trains on the maximum grade at a speed of 15 miles per hour, which is nearly twice the speed obtained with the railroad's Mallet steam locomotives on corresponding grades and with full loading.

Fig. 4 shows the results of a dynamometer car test with two class OE-2 electric locomotives hauling a 2450-ton train over the belt line, the total weight of train including the electric locomotives being 2709.7 tons. These curves are typical of freight train performance excepting that the weight is above normal.

### Cost of Operation and Maintenance

Data showing the traffic handled and the total cost for operation and maintenance in dollars per thousand ton miles, including the weight of the electric locomotive, and in dollars per electric locomotive mile, including mileage running light, for a period of several years, are given in Table II. As would be

| Grand totals | $1229.00 | | $1972.00 | |

* Includes complete renewal of third rail, jumpers, etc., in tunnel and extensive rebonding throughout electric zone.

expected from the grade conditions the power cost is by far the largest item. The cost of current per kilowatt-hour at the d-c. bus comprises the cost of purchased current, generated current and substation operation and maintenance. As the cost of purchased current includes fixed charges while that of current generated by the railroad and substation operation does not, the figures given do not represent the total actual cost per kilowatt-hour.

Table III shows the mileage made by electric locomotives and cost of maintenance over a period of nine years. The maintenance of the class OE-1 and OE-2 locomotives has been abnormal on account of considerable number of armature burnouts, caused by overloading due to handling trains beyond their capacity. In addition as the railroad has no facilities for repairing armatures of this size the expense has been large. This trouble has now, however, been overcome and it is expected that the maintenance will again fall to the normal of between 3 and 4 cents per locomotive mile.

Table IV shows the cost of third-rail and feeder maintenance in dollars per mile of third rail for the past two fiscal years. Cost of third-rail maintenance is rather high due to considerable amount of renewal work that has been necessary. The heavy traffic conditions and the somewhat unusual amount of curvature requires rather frequent track renewals and consequent rebonding.

# DESIGN OF MOTORS FOR HEAVY TRACTION WORK

By Edward D. Priest

Engineer, Railway Motor Department, General Electric Company

This article includes a discussion of the design of electric motors for heavy traction from many different view points, considerations governing the choice of the geared or gearless type, the mounting of motors, the type of drive, the center of gravity, the number and size of motors, ventilation, mechanical losses, electrical losses and other important factors are ably discussed. Some of the earlier types of electric locomotives are considered and their motors and driving gear briefly reviewed.—Editor.

**Edward D. Priest**

It is not the purpose of this paper to discuss or compare d-c. vs. a-c. railway motors for heavy traction work, but to briefly consider general lines of design which have been followed in the past or which may be followed in the future whether motors are a-c. or d-c.

Motors for heavy traction work can be conveniently divided in mechanical construction into two general types,—geared and gearless. Either type may be applied with or without side rods.

For slow speed heavy traction work the gearless motor with a low armature speed is abnormally expensive to build and low in electrical efficiency. A gearless motor is not suited for this class of work. For intermediate speeds the gearless motor is less handicapped in this respect, and for high speeds not too seriously handicapped, since the peripheral speed of the armature approaches the speed at which it is desirable to operate any armature, geared or gearless. The question then of whether a motor for this work should be geared or gearless is largely influenced by the locomotive speed desired.

It can be assumed that within the limits of practical design the single reduction geared motor will generally have a higher total efficiency than a gearless motor for speeds under approximately 30 miles per hour, and for speeds higher than 30 miles per hour the bi-polar gearless motor will have a higher efficiency. The reason for the reduced efficiency of a gearless motor in low speed work is because of high $I^2R$ losses made necessary by the low armature speed. The increase in $I^2R$ loss is greater than the gear loss incident to the use of geared motors.

At light loads a gearless motor is especially efficient because of the absence of gear loss, and possibly bearing loss. The percentage of gear loss and bearing loss is high in a geared motor at light loads and low torque, while the percentage loss is comparatively low at low speeds and heavy torque. For short runs in which acceleration is a large factor the problem of power efficiency is somewhat complicated.

At the continuous tractive effort rating, in work for which geared and gearless motors are normally suited, the electrical efficiency of d-c. motors will vary from about 91 to 93 per cent, the geared motor generally having the higher efficiency and the gearless motor the lower efficiency.

The method of mounting motors and transmitting power from the armature to the driving wheels has a large influence on efficiency, whether the motor be geared or gearless.

A gearless bi-polar motor, with an armature mounted directly on the axle without bearings, has a mechanical efficiency of 100 per cent, practically all mechanical losses being eliminated.

If the armature of a gearless motor is mounted on a quill surrounding the axle, the quill being carried in bearings supported on the motor frame and power transmitted through a flexible drive to the driving wheels, the mechanical efficiency at the continuous rating of the motor is possibly 97 per cent.

If a gearless motor is mounted on a locomotive frame and power transmitted through connecting rods, the mechanical efficiency is possibly from 85 to 90 per cent, depending on the number and arrangement of driving parts.

A single reduction geared motor, mounted directly on the axle, at its continuous rating has a mechanical efficiency of approximately 96 per cent, and possibly 94 per cent when mounted on a quill for flexible drive through a coupling.

If a geared motor is mounted on the locomotive frame and power transmitted through connecting rods, the mechanical efficiency is possibly 85 to 90 per cent, or about the same as for a gearless motor. The mounting of a geared motor on a locomotive frame can generally be made in such a way as to reduce the number of connecting rods as compared with a gearless motor.

It will be noted, therefore, that for mechanical efficiency in transmitting power from the armature to the driving wheels, the bi-polar gearless motor mounted directly on the axle has the highest efficiency; that there is but little difference in mechanical efficiency between a geared motor mounted on the axle and a gearless motor with flexible drive mounted on a quill surrounding the axle, and that the mechanical efficiency of geared and gearless motors with side rod drive is approximately the same for each type.

The importance of high efficiency is of course largely influenced by the cost of power, which varies widely in different localities and with different conditions, so that the question of efficiency becomes more or less important depending upon the location of a given installation and other determinable factors.

From the standpoint of operation there is a great diversity of opinion concerning the correct mounting of motors on locomotives for heavy traction work. Both in this country and abroad a large number of different mountings have been tried. The side rod construction has been used in many varying and ingenious types, but in the writer's opinion it is doubtful if electric side rod locomotives can be built at a "right price" or operated with complete success. As has been pointed out, the mechanical efficiency of transmission is low and the design is to a considerable extent complicated. To transmit power from a rotary motion through a reciprocating rotary motion always seemed to the writer forced and illogical as compared with more direct methods.

While not unmindful of the advantages, at high speeds, of a high center of gravity, which can be readily secured by the use of connecting rods, it is the writer's opinion that equal and possibly superior results can be secured in a more direct and simpler construction.

It is clear that the simplest form of mechanical drive is obtained by mounting a motor, either geared or gearless, directly on the axle. If then, this type of motor permits a design of locomotive which has a higher power efficiency, satisfactory riding qualities, as regards the effect on track and road bed, no higher first cost, probably lower, and no increase in maintenance, probably lower maintenance, it would obviously seem the right type.

A low center of gravity can be compensated for by distributing the load over a greater length of track with a larger number of driving wheels and axles and by a proper design in respect to the arrangement of parts and distribution of loads. An increase in the number of driving wheels has the advantage of reducing the concentrated load per axle and also flange and rail head wear, the pressure between these parts being sufficiently reduced to prevent undue abrasion of the metal, so that, while the number of contact points would be increased, the actual wear would be reduced. The arrangement of motor axles, trucks and superstructure in a locomotive largely affects the riding qualities of the locomotive. There may be an advantage in equipping a locomotive with motors of different size or even different types, using for instance light motors on leading axles and heavier motors on intermediate axles. While at first thought this may seem complicated, in the writer's opinion it is not a serious complication.

It is not the purpose to enter into a lengthy discussion of the riding qualities of locomotives but to point out that whatever defects exist at high speeds in a low center of gravity can be successfully overcome by proper design.

The writer's conception of a motor for heavy traction work would be a motor of suitable capacity for mounting on a locomotive having a weight per axle of from twelve to twenty tons. If a geared motor, it would be of the single reduction, single geared type, mounted directly on the axle, and if a gearless motor it would be of the bi-polar type with the armature mounted directly on the axle. The driving wheels would be comparatively small in diameter, approximately 34 in. to 42 in.

For either high speed or low speed heavy traction work the natural development is toward an increase in the number of motors rather than an abnormal increase in the size of motors. It is thought that the development of motors along this line will materially cheapen the cost of locomotives, it being possible to construct frames and trucks of cheaper material and with less finish. There is a wide application for motors of moderate size, and consequently costs can be reduced by manufacturing in large quantities. The capacity of locomotives can be regulated by the number of motors and axles used.

It is quite possible to design motors so that they can be utilized partly to perform the functions of a truck, thus doing away largely with the truck frame and completely with truck journal bearings. This type of geared motor seems especially applicable to low speed work. The initial cost of electric locomotives is a handicap to the electrification of steam railroads. Anything which can be done to reduce the cost will materially promote electrification.

In the design of motors for heavy electric traction it is necessary to provide suitable means for ventilating the motors in order to secure motors of reasonable size and cost. Although motors can be designed for quite effective self ventilation with suitably designed fans constructed as a part of the armature; to obtain the most effective results external blowers are required. The capacity of a motor to perform work depends not only on its efficiency but on its ability to dissipate heat. Assuming for instance that a closed motor can dissipate 2000 watts, a self-ventilated motor can dissipate 4000 watts, and an externally blown motor 6000 watts, thus the externally blown motor has a capacity to perform much more work than a completely enclosed non-ventilated motor. It will be understood that these values are quite approximate and are used to convey a general idea of the value of ventilation.

The amount of heat which can be dissipated is influenced not only by the volume of air blown through the motor, but by the distribution of the air, i.e., the flow of air to be most effective must be properly distributed and the air should come into intimate contact with the heated parts. In passing between intake and exhaust the air should be made to take up as much heat as possible.

Another way of increasing the capacity of a motor of given weight is to increase the permissible temperature at which the motor can be run. This can be accomplished with satisfactory results by using insulating materials which will successfully withstand higher temperatures. It is the writer's opinion that electric motors will in the future be operated at materially higher temperatures than now ordinarily prevail; indeed, satisfactory insulating materials are at present available to accomplish this. Under certain conditions the ultimate permissible temperature may be fixed by power efficiency rather than by the effect of heat on the materials used. It is desirable that the temperature at which the motor is designed to run should not be controlled by limitations of insulating materials.

In designing motors it is important to secure the right relation between copper loss and core loss. In certain classes of service the core loss may be of less relative importance than the copper loss, and vice versa. A motor may have a high core loss at nominal rating, i.e., one hour run at 75 deg. C. rise, and yet have a low core loss for continuous service at light loads. If the work is largely acceleration, nominal load core losses are relatively of less importance than copper losses.

In heavy traction work motors are occasionally subjected to excessive overloads for short periods of time. This is especially true with motors designed for high speed heavy passenger service where the continuous rating of the motor is considerably under the slipping point of the wheels. Such motors should be designed to withstand high momentary copper temperatures, possibly as high as 200 deg. C. or even higher. The momentary copper losses may be abnormally large, while the amount of heat which can be radiated in the short interval of overload is small. Practically all the heat has to be stored in the copper until it can be slowly dissipated. In the design of such a motor provision should therefore be made for high temperatures and all electrical connections made so that they will not be damaged by heating.

In heavy traction work the continuous load on the motor is usually high and therefore commutating characteristics must be especially good in order that the commutator and brushes will not be damaged. Railway motors of ordinary design may be heavily overloaded with considerable sparking for a brief period, if there follows a comparatively long period of light load during which the commutator recovers, as it were, from the effects of the heavy load. Free running at a light load allows the commutator to take on a polish which removes the injurious effect of the overload.

Heavy slow speed traction motors are sometimes abused by running them down grade at high speed. With an efficient design for low speed locomotive work a high gear reduction must be used. This at a high locomotive speed, as on down grades, gives a high armature speed; too high for safe operation. In addition to this a slow speed heavy traction locomotive, if designed to the best advantage, does not have riding qualities suited for high speed running. It should be understood that there must be restrictions on the maximum speed of an electric locomotive which is designed for low speed, as there are restrictions on the maximum speed of a steam locomotive which is designed for low speed. It is fundamental that electric locomotives can not be economically designed for low speed heavy traction work and without change be suitable for high speed traction work. The two kinds of service are fundamentally different and should be differently treated.

In the past few years marked advances have been made in the design and manufacture of gears and pinions for railway motors. The use of high grade heat treated steel has very largely increased the strength and life of gears, and indirectly the average efficiency of motors, since the correct shape of the gear teeth is maintained for a longer period. Motors mounted on the axle with single reduction gearing in heavy slow speed traction work have a gear life of approximately 300,000 to 400,000 miles, and a pinion a life of approximately 150,000 to 200,000 miles. This makes the cost per mile for gears extremely low, almost insignificant. It may be stated, therefore, that there is no practical objection to the use of gears in heavy traction work because of their maintenance cost. For sentimental reasons there may be an objection to gear noise, but with well cut, well lubricated gears this can be reduced to a minimum. Practically the only objection to gears is the loss in power, but even this is low with well cut single reduction gearing.

For high speed work the gear problem is somewhat more difficult than for low speed work. The strength of gear teeth is ordinarily ample to transmit the torque of the motor up to the slipping point of the wheels. At a high speed on a rough track, due to uneven rail joints, cross-overs, etc., blows may be delivered to the teeth which theoretically are beyond their elastic limit. It is the writer's opinion that such blows are almost entirely the cause of broken pinion or gear teeth when such occur. Incorrect spacing of gear teeth or variations in the thickness of teeth, due to errors of manufacture, may at high speed cause abnormal tooth stresses. This of course can be largely overcome by accurate methods of machining. Excessive tooth strains can also be largely eliminated by the use of spring gears, i.e., gear rims held by springs so that the rim can have a slight movement in rotation independent of the axle.

Probably the first electric motors ever designed, certainly the first to be manufactured, for heavy steam railway electric traction work, were the motors used on the 96-ton locomotives manufactured by the General Electric Company for the Baltimore & Ohio Railroad. These locomotives were designed to haul trains through the B. & O. tunnel at Baltimore, and have a capacity to handle 1200-ton freight and 500-ton passenger trains, including a dead steam locomotive, through the tunnel up an 0.8 per cent grade. The design of the motors was started in the spring of 1892, but owing to delays in building the tunnel, the locomotives were not completed and put into service until July 1, 1895. They have operated successfully for many years, at times hauling 1800- and 2000-ton trains.

Although the speed at full load was low, approximately 15 miles per hour, the motors were designed without gears owing largely to the desire of the Railroad Company to avoid the use of gears and the lack of experience on the part of the manufacturer with geared motors of such large capacity. At that time heat treated, high grade steel gears, such as are now in use, were not available. The motors were designed with six poles, two motors in series on 700 volts. The armature was mounted on a quill shaft which was supported in bearings on the motor magnet frame. Power was transmitted to the driving wheels through a spider mounted on each end of the quill. Arms radiating from the spider projected between the spokes of the driving wheel. Between the arms and the spokes, blocks of rubber were interposed, the rubber being of such size and shape as to permit a considerable movement between the motor and the wheels and axle. On the whole this arrangement worked very well. It was found, however, that the cost of the rubber made it rather expensive to maintain.

With modern knowledge of motor design, especially in respect to the availability of gear drive for heavy work, motors for this class of service would unquestionably be designed for operation with gears. In fact, all locomotives of later design for use in the B. & O. tunnel service have been equipped with geared motors.

Although not for heavy haulage work an interesting example of motor design for a mining locomotive was a motor made by the Thomson-Houston Company in 1889 for the

Erie Colliery, near Scranton. This motor was mounted on the main frame of a two-axle four-wheel locomotive. Power was transmitted through double reduction gearing to a jack shaft and from the jack shaft through crank pins to sliding blocks in slotted or Scotch yoke connecting rods to the driving wheels. This was one of the first electric locomotives to be used in mine haulage in America. It was successfully operated for twenty-three years, being taken out of service about two years ago. A better construction would have been to mount the motors directly on the axle and to transmit the power through gears. The use of side rods at that time was more or less a concession to sentiment which assumed that electric locomotives should have side rods because steam locomotives had side rods.

A light locomotive of better design was built by the Thomson-Houston Company at an earlier date than this side rod locomotive. The locomotive had a two-axle four-wheel truck with a small double reduction geared motor mounted on one axle. The motor was designed in December, 1887, for the Tremont & Suffolk Mills, Lowell, Mass. It remained in service until the year 1900. This was possibly the first practical use of an electric locomotive in a manufacturing plant. The motor was known as F-6 and had about 3-h.p. capacity.

An interesting type of motor designed for a 30-ton two-axle locomotive was made by the Thomson-Houston Company in 1892. The motor was known as the L.R.R. It was a four-pole gearless motor with the armature mounted on a quill shaft surrounding the axle. Power was transmitted from the quill through a somewhat novel coupling to the driving wheels. The coupling, without the use of springs, allowed complete flexibility of movement between the quill and the axle for the full amount of clearance between the quill and axle. Mounted on one end of the quill was a spider with an inclosing outer rim. Projecting from the spider toward the driving wheel, at diametrically opposite points, on the spider, were pins of rectangular cross section. Ninety degrees from these pins were two similar pins projecting from spokes of the driving wheel. Power was transmitted from the two opposite pins on the spider to the two pins on the driving wheel through an intermediate floating member surrounding the axle and slotted to receive the pins. The floating member was carried entirely on the pins and to prevent undue movement, parallel to the axle, comparatively light springs were interposed between it and the spider, and between it and the driving wheel. The driving pins were free to slide in the slots of the floating member so that except for a movement in the direction of rotation there was freedom of movement between the motor and axle.

Probably the simplest gearless motors which have ever been designed for heavy traction work are the motors known as bipolar motors used on the locomotives which have been in operation for a number of years in the New York Central and Hudson River Railroad Grand Central Terminal service, New York. In mechanical construction it would be difficult to conceive of a simpler design. The armature is mounted directly on the axle and is free to move in a vertical direction between pole pieces attached to the magnet frame which forms part of the locomotive truck frame. These motors were designed for high speed and are remarkably efficient at free running.

# THE INTERURBAN RAILWAY OF THE ILLINOIS TRACTION SYSTEM

By H. E. Chubbuck

Vice-President Executive, Illinois Traction System

This article includes a general description of the physical characteristics, nature of service, energy supply, and equipment of one of the largest interurban systems in the world. It will be noted that in many respects the service rendered closely approximates that given by many steam railroads. The sleeping- and parlor-car equipment and freight traffic are reviewed and some interesting notes are given concerning the operation of the system.—Editor.

Like the entire electric railway industry, the Illinois Traction System has grown rapidly. The present property, with nearly a thousand miles of street and interurban track, and with light, heat and gas service in six states, had a modest beginning with six miles of track built in 1901 from Danville to Westville, Illinois. The growth of this property has followed the controlling ideas of its president, William B. McKinley, who in the early days of the interurban railroad, undertook the construction of a group of roads that would unite the substantial cities of Central Illinois in which public utilities could also be operated.

The general construction plan included tracks and roadways, comparable with those of the steam roads, and so designed that the heaviest freight and passenger equipments might be handled economically. Energy for the propulsion of the trains was to be furnished from large generating stations so located as to secure economy in fuel delivery and in the distribution of the output. The results show how well the far-sighted plans of the builders have been realized.

Numerous public utilities have been built or purchased and rehabilitated during the period of interurban development, until now electric lighting and power service is furnished in 92 cities, street railways are operated in 24 cities, gas is furnished in 13 cities, steam heat in 11 cities, and water in two cities.

Modern plants have been installed and distribution systems designed to afford good service with high operating economy.

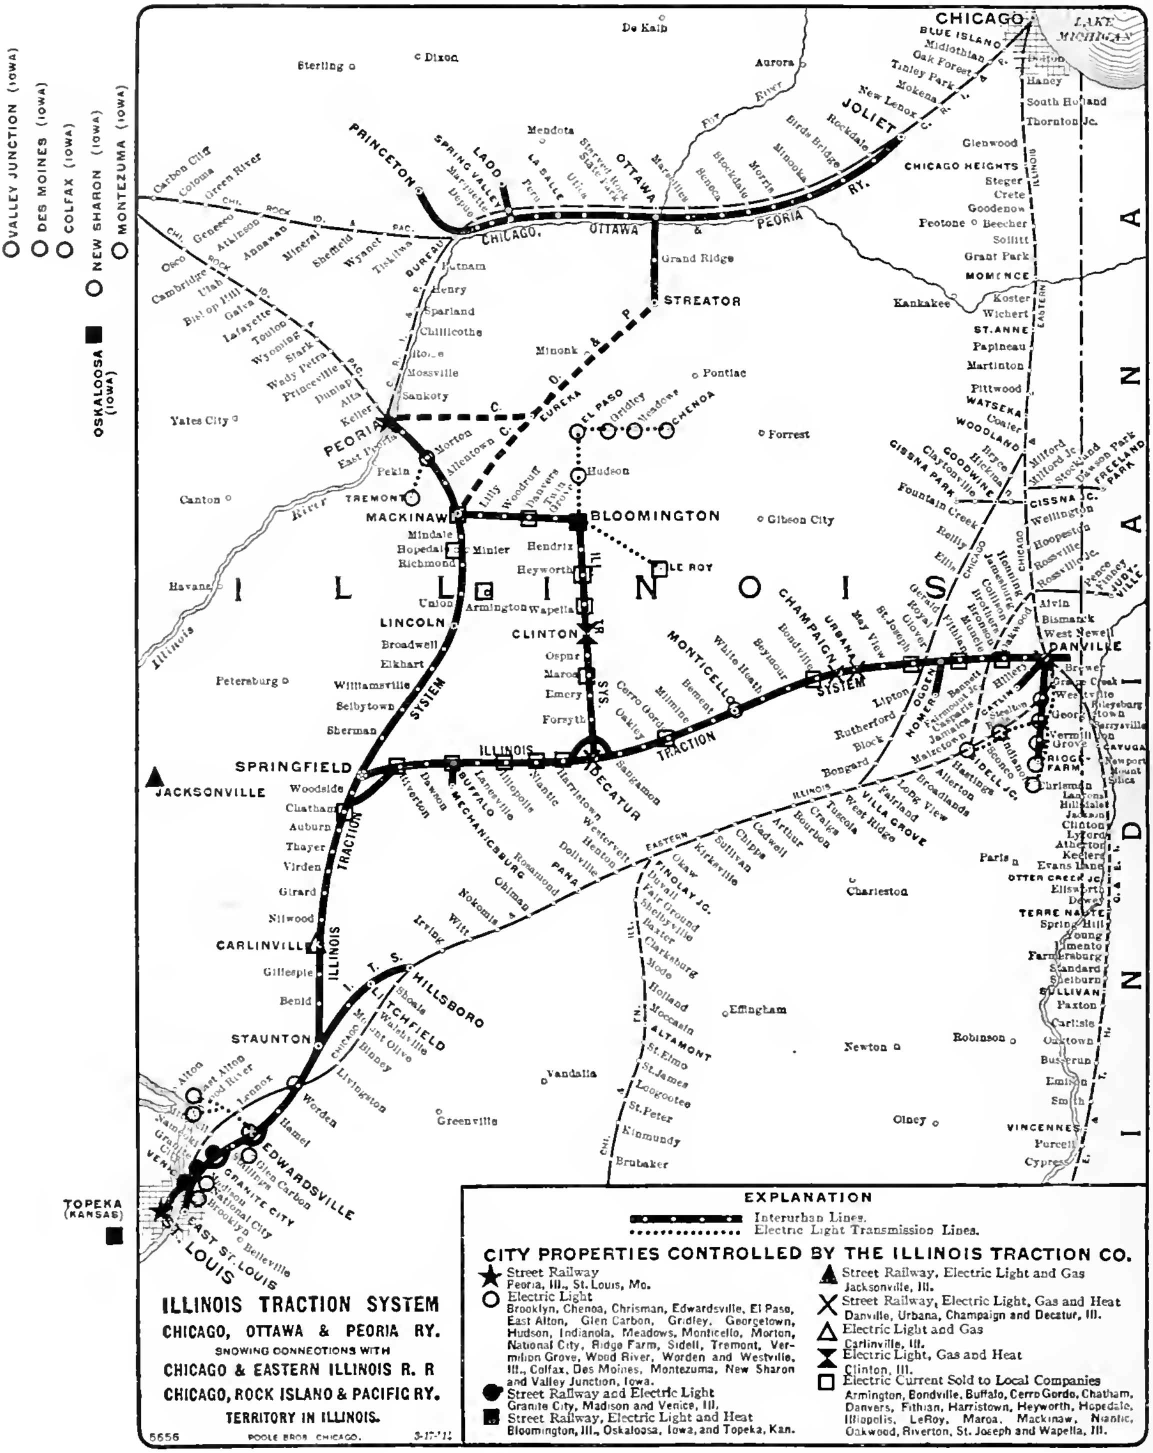
No doubt our electrically-operated railway system in Central Illinois is the most interesting part of our system, and, therefore, that will be described and some of its most notable features will be set forth in this article. A map shows the location of our Illinois interurban lines and the following table gives the mileage, equipment, etc., of the interurban system.

| | |
|---|---|
| Miles of main line track operated | 431.90 |
| Miles of passing track, sidings, etc. | 32.54 |
| Miles of shop and yard track | 13.15 |
| Miles of industrial track | 13.52 |
| Population served by road | 2,500,000 |
| Passenger motors | 89 |
| Passenger trailers | 21 |
| Parlor cars | 7 |
| Sleeping cars | 5 |
| Combination passenger and baggage | 4 |
| Express motors | 17 |
| Express trailers | 98 |
| Line motors | 6 |
| Steel locomotives | 21 |
| Box cars | 116 |
| Gondolas | 319 |
| Flat cars | 37 |
| Refrigerator cars | 9 |
| Scenery cars | 2 |
| Hopper bottom cars | 228 |
| Cabooses | 13 |
| Miscellaneous and work cars | 54 |
| Substations | 40 |
| Central power stations | 4 |
| Belt lines | 4 |
| Miles protected by block signals | 150 |

Referring again to the map of the interurban system it will be noted that the main division of the Illinois Traction System extends from Peoria on the north, to St. Louis, Mo., on the south, a distance of 174 miles. At Mackinaw Junction, about 20 miles south of Peoria, the Bloomington & Decatur division branches off the main division. From Springfield the lines extend eastward as far as Danville, a distance of about 125 miles, serving Decatur, Champaign and Urbana and intermediate points. From Danville a branch extends southward to Ridge Farm, and another to Catlin. On the eastward from Stanton, a branch extends to Hillsboro.

The company also operates a 17-mile interurban road between Galesburg and Abingdon and between Galesburg and Knoxville.

The northern branch of the McKinley interurban system is known as the Chicago, Ottawa & Peoria Railway. It extends from Joliet on the east to Princeton on the west,



Map of Illinois Traction System. Chicago, Ottawa & Peoria Railway, showing connections with Chicago & Eastern Illinois Railroad serving Ottawa, LaSalle, Peru, Spring Valley, Bureau and intermediate points. This division has 106 miles of track and at Joliet connection is made with the Chicago & Joliet Railway, which offers a through electric service into Chicago. A branch extends northward from Spring Valley to Ladd and another division extends southward from Ottawa to Streator.

**Service**

Over the entire system trains are moved in either direction practically every hour in the day and schedules are arranged to fit local conditions in accordance with traffic demands. The passenger trains operated consist of limited and local passenger service, parlor and sleeping-car service, fast merchants' dispatch freight service, general freight trains and the transportation of heavy freight, such as trains of grain and coal in carload lots. The limited passenger trains stop only at the larger towns and cities and are supplemented by local trains stopping on signal at country highway crossings. The Illinois Traction System now has in operation "belts" around the cities of Edwardsville, Granite City, Springfield and Decatur. By the use of these belt lines, long, heavy trains of standard freight cars may be drawn around the cities by electric locomotives at a good speed. This arrangement also prevents the disturbance of passenger schedules and makes possible traffic connections with steam railroads and industrial tracks to manufacturing plants that otherwise would not be easily accessible. Similar belt lines are contemplated around other cities on the line.

With the growth of the interurban system there has also followed the development of public utilities in many cities in Illinois, Iowa, Kansas and Missouri. Practically the entire mileage of the Illinois Traction System is on private right-of-way, the greater part of which is sixty-six feet or more in width. The design of the roadway and track is similar to that of steam railroads, the rails weighing seventy pounds per yard. They are spiked to standard ties and ballasted throughout with gravel, crushed stone and chatts, which are the tailings from Missouri zinc mines. All the ties installed in the past four years have been treated with a creosote preservative compound to reduce the cost of future maintenance work. A separate tie replacement fund has been established for tie renewals.

**Supply of Electrical Energy**

The generation and distribution plants, for furnishing the electrical energy used in propelling the trains, have been designed with due regard to an immediate low operating cost and future enlargement. The central stations located at Peoria, Danville, Riverton near Springfield, and Venice near St. Louis, have a total normal capacity of 27,500 kw. These plants are connected through the medium of a 33,000-volt three-phase transmission system, a large part of which is carried on an independent pole line to insure continuity of service. The generating stations have been located with due regard to the low cost of fuel and economy in distribution. At two locations large under-water coal storage tanks have been built.

Parlor-Car Train

The plant at Venice which is of the most recent design has a peak load capacity of 13,000 kw., which can be quadrupled by completing extensions contemplated in the original design. No power-driven conveying plant is required for handling the coal and ashes at this station because it is so located at the east approach of the McKinley Bridge that the coal is carried over the 800-ton bunkers in standard railway hopper cars, and the ashes fall into the cars on the ground level beneath the boilers.

The generating stations at Peoria, Riverton, and Danville include the latest types of steam-turbine-driven generating machinery. The high tension transmission lines uniting the capacity of the four large generating stations also serve for distributing energy to the forty rotary converter substations in which it is transformed and converted into 650-volt current, suitable for distribution over the trolley wires and feeders to the cars.

The accompanying illustrations show the character of the overhead distribution system. It consists of flexibly supported trolley wires, supplemented by bare copper feeders of 000 and 000,000 capacity respectively, so placed as to enable heavy locomotive-drawn freight trains to be operated along with the local and limited passenger trains, without unduly low voltage conditions.

Standard Substation and Waiting Station

Rotary converter substations are located at intervals of approximately 10 miles. These are attractive structures and most of them also serve for passenger stations. They are built of pressed buff brick, trimmed with limestone, and have French tile roofs with overhanging eaves.

### Rolling Stock

A statement of the various classes of rolling stock has been given. Standardization of equipment has been followed so that, should occasion demand, any traction car or locomotive could be hauled over any steam railroad in the United States and meet all requirements throughout in the matter of coupling arrangements, air brakes, wheels, etc.

As this system conducts a general railway business in all its branches its supply of passenger and freight equipment must necessarily be large and varied. Special types of cars must be at demand for the hauling of special classes of business and the company has made it a principle to keep its equipment right up with business demands. An example is to be found in the construction of special scenery cars for the handling of theatrical properties, automobile cars, refrigerator cars, etc. All of these special types of equipment have been designed by the company and contain many modern and special appliances not found on the equipment of other lines. Strength, serviceability, safety and comfort has been the motto of the Illinois Traction System in the designing of its passenger equipment.

The regulation passenger coaches have developed from a coach weighing 60,000 lb., and measuring 38 feet in length to a coach weighing 100,000 lb., measuring 68 ft., 4 in. in length. Motors have progressed from 35-h.p. to 200-h.p.

The Illinois Traction System has operated sleeping cars for more than six years and observation parlor cars for nearly three years. The sleeping cars are 57 ft. long, over bumpers, and 9 ft., 7 in. wide, and weigh 84,000 lb. The bodies are of a heavy substantial Pullman-type construction with segmental arch roofs. They are mounted on steam-coach type, four-wheel, steel-frame trucks with quadruple elliptic bolster springs, and are provided with the M.C.B. contour, high-knuckle couplers. There are twenty berths in each car, the design of the upper and lower berth being uniform. The cars are illuminated by seventy mazda lamps, fed from a special panel governing a Gould storage battery of sixteen cells.

### Sleeping-Car Service

A sleeping-car service is given between Peoria, Springfield and St. Louis. Two four-car trains make this 174-mile run each night. The combination motor-express cars which haul the sleeping-car trains were described in the *Electric Railway Journal* for Febuary 2, 1911, page 275. These cars are 52 ft., 6 in. long, 9 ft., 5⅜ in. wide, have an underframing and body of heavy design and are equipped with four 140-h.p. motors. These motor cars haul a trailer coach and two or three sleeping cars satisfactorily at the average schedule speed of about 23 m.p.h. which includes time

Standard Shelter

for cutting in and out extra cars at Springfield and making all station stops between 6 and 7 a.m. as the terminals are approached. The motor cars weigh about 100,000 lb. each. All sleeping-car trains are equipped with air brakes with universal valves in place of triple valves.

The sleeping-car trains have brought to this railway system traffic which it otherwise would not have had. Practically all of the passengers who now take the sleeping-car trains, both in the coaches and in the sleepers, would otherwise have taken steam trains had the Illinois Traction System not introduced the sleeping-car service. The business has gradually increased until now five sleeping cars are required, four of which are in operation daily and a fifth in reserve for over-hauling and for special parties, to which latter use it is frequently put.

### Parlor-Car Service

In 1911 the Illinois Traction System inaugurated an extensive parlor observation car service which has since been expanded, until now, seven fine, large heavy 80,000 lb. parlor cars are in use. Parlor cars are attached to limited trains. The running time of a limited passenger motor car with trailer attached from St. Louis to Danville, 227 miles, is nine hours and fifteen minutes, and the running time between St. Louis and Peoria is six hours and forty-five minutes. Thus the schedule speeds of these trains are about 25 m.p.h., including all stops and dead time at junctions.

These parlor observation cars are 57 ft. long, 9 ft., 7⅛ in. wide, are mounted on standard steam-coach, steel-frame, four-wheel trucks with quadruple elliptic bolster springs, and are equipped with the Sharon type M.C.B. coupler. There are eight double seats, twenty-two mahogany chairs and six Pullman-type camp stools in the parlor cars.

The rates for seats in the parlor cars are approximately ½ cent per mile in addition to the regular first-class fare. A minimum rate of 15 cents is observed. All terminal station agents sell seat tickets and make reservations in advance for parlor-car seats and sleeping-car berths.

The energy consumption of these limited trains with heavy observation parlor-car trailers, as compared with the same limited motor cars, shows that while the motor car alone consumes about 64 watthours per ton mile, the same motor car, when hauling the parlor car as a trailer in the same run, consumes about 46 watthours per train ton mile.

Freight and express traffic is handled by motor express cars drawing trailers and by large electric locomotives. Twelve all-steel locomotives have been built in the company's shops from designs made by its mechanical department, each weighing sixty-three tons and having a drawbar pull of 35,000 lb. A locomotive, with its four 200-h.p. motors, can handle long freight trains with the ease of a large steam railroad locomotive.

Distance Signal in "Proceed" Position. Also showing High Tension Overhead Construction, Trolley, Feeder, Telephone and Signal Wires

### Shops

Inspection and repair shops are located at each of the larger cities on the road, the work being done supplementing that of the main repair shops which are located on a fifteen-acre tract just east of Decatur. The Decatur shop machinery is housed in three large fireproof buildings, designed and built particularly for the maintenance of electric railway rolling stock. The tools in these shops are such as not only to make all repairs to cars, but to also build new equipment. A new group of shops has been started at Granite City, where a fireproof repair shop building has been constructed, designed to handle the maintenance and inspection work on the interurban cars of the division south of Springfield and on the street cars operated in the St. Louis bridge service.

**Operation**

All trains are operated under orders transmitted to the train crews by telephone from centrally located dispatchers. A complete system of remote control signal semaphores to assist the dispatchers in controlling the movements of trains has been installed over the entire road. Every possible safeguard, such as double checking of orders, spelling out the names of meeting points and the use of high grade duplicate telephone apparatus, is employed to increase the safety of operation.

McKinley Bridge, St. Louis

The rules under which the trains are dispatched and operated have been based on the best experience in steam and electric railway service.

**Automatic Block Signals**

In addition to the foregoing system of safeguards, most comprehensive plans for the protection of trains by automatic block signals have been executed. An extensive investigation resulted in the purchase of sufficient automatic block signal apparatus to protect fully 150 miles of track.

The signal equipment was made by the Union Switch & Signal Company, and attention is called to the fact that the automatic block signals adopted as a standard by this road are of the type which have given satisfaction on many thousand miles of steam railroad tracks of the larger trunk lines.

These signals are fully automatic and protect a train by displaying semaphores in the "stop" position at a sufficient distance in front, and behind it, to provide for ample braking distance in case there should be misinterpretation of the dispatcher's orders. They protect the meeting point of trains at sidings as well as curves and subways. They are also designed so that any derangement of the running rails, track bonds, signal wires or open switches would cause them to assume the "stop" position.

The workmanship of this signal installation, costing about $500,000, has been executed with a view to obtaining the maximum safety as a first consideration combined with low maintenance cost. During four years in which these signals have been in operation their performance has been more than 99.97 per cent perfect.

**McKinley Bridge**

In 1907 construction work was started on the McKinley Bridge at St. Louis and the bridge was opened to traffic in October, 1910. The length of the bridge and approaches is over 8000 feet and its carrying capacity is 12,000 pounds per lineal foot as against 10,000 pounds per lineal foot for any other structure across the river. The main bridge carries two railroad tracks through a center space of 26½ feet; two roadways 14 feet wide each are carried on cantilever brackets. The total width of the bridge over all is 65 feet and the clearance above low water is 85 feet. Under the east approach stands the Venice power plant previously mentioned. The approach on the Missouri side passes over 24 acres of freight yards owned by the company and from this approach the double tracks of the system reach into the business district of St. Louis, where there is a modern passenger station and a commodious express-freight terminal with large receiving platforms and sheds for the freight and express business.

Type of Elevator, Illinois Traction System

**Freight Traffic**

The Illinois Traction System is now handling over its lines, trains of standard railway equipment and has built up its freight and express department along standard lines established by the steam roads. The tariffs are based on those established by the steam roads and methods of operation follow closely those laid down by the well established railway systems.

Interchange arrangements exist between this electric system and many steam roads. A typical illustration of this is found at Glover, where there is a physical connection between the Illinois Traction System and the Chicago & Eastern Illinois Railway. By means of this connection a through service for package freight to and from Chicago is maintained.

At Glover there is located a transfer elevator, by means of which grain may be shipped from Illinois Traction points to Chicago, Nashville and St. Louis.

The grain shipping facilities offered by the company have developed rapidly during recent years and are becoming an important factor in the movement of crops from the big grain belt of central and southern Illinois. At present there are twenty-two elevators, ranging in capacity from 10,000 to 50,000 bushels, on the lines. The elevators are substantially built and equipped with modern grain handling machinery, which afford quick shipping facilities for the farmers in the territory.

There are six coal mines whose output is handled exclusively or partly by the Traction System.

Track connections have been established with seven roads, including the St. Louis Terminal Railway Association. Joint rates for through business have been established with eleven roads, and through rates covering grain have been arranged to Chicago, Detroit, Toledo, eastern seaboard, Mississippi River and Gulf points. In general we render to our communities every service offered by steam railroads and our frequency of trains and the convenience of our stations and terminals has won for the Illinois Traction System a steady increase in revenue.

---

# MAINTENANCE AND OPERATION OF THE DETROIT RIVER TUNNEL

By J. C. Mock

Electrical Engineer, Michigan Central Railway Company

The author reviews the physical and electrical characteristics of this most interesting installation and then gives quite an extensive analysis of the traffic conditions. The locomotive mileage, the delays to traffic, and the power consumption are fully dealt with. The maintenance of both the third rail and the electric locomotives is given and the article is concluded with a brief account of the signal and interlocking system. —Editor.

J. C. Mock

On September 18, 1910, three days after the third rail was first made "alive" in the Detroit yards, the Michigan Central began operating freight trains through the tunnel. The 16th and 17th were allowed for test runs. These were made with a two-thousand-ton train of loaded coal cars and were intended to verify, under actual service conditions, the quite exhaustive tests made on locomotive No. 7500 (which was the first of these locomotives built,) during the fall and winter of 1909 on the New York Central test track near Schenectady. They also served to teach the motormen how best to handle a heavy train with a locomotive at both ends. To prevent objectionable surging, it is important to know first where and how much the brakes should be applied, where to release and where the power application should begin.

Previous to these runs the motormen's training was restricted to running the locomotives light or attached to construction trains composed of a few flat cars. The crews were selected from the switch engine crews employed in "working" the ferry boats; that is, splitting and making-up trains and placing cars on and taking them off the ferry boats. They were taken in turn and taught to operate the electric locomotives.

As the yard tracks could not be connected in a permanent way to the tunnel tracks until September 15th, the same day that third rail was first made "alive," the only training track available from July 25th to August 5th was the east-bound tunnel track as far as each summit. The third rail on the west-bound track was connected through a short time afterward.

The first official trip made through the tunnel by an electric locomotive under its own power was on July 26th, with Mr. H. B. Ledyard, Mr. W. K. Vanderbilt, Jr., and party. For about three weeks after freight traffic was started, the tunnel was operated only eight hours a day, from 8:00 a.m. to 4:00 p.m. On October 9th a twenty-four-hour freight service was established and on October 16th all passenger and freight trains were put through the tunnel.

It took all the month of October to trim up the construction work and trim down the forces and to get adjusted to the new conditions. The operating officials felt immediate relief, the delays were insignificant as compared with ferrying, and the schedules were changed. A daily record showing a summary of the details of tunnel operation for the month of November, 1910, follows. This, as will be noted, is the first full month of 24-hour tunnel service.

| | |
|---|---|
| Total tons hauled | 1,223,012 |
| Total tons hauled, east-bound | 588,042 |
| Total tons hauled, west-bound | 644,970 |
| Total cars loaded | 30,672 |
| Total cars empty | 6,469 |
| Average daily cars hauled | 1,238 |
| Average time of trip | 16.4 min. |
| Average time of trip, freight trains | 20.9 min. |
| Average time of trip, freight trains, east-bound | 18.3 min. |
| Average time of trip, freight trains, west-bound | 23.5 min. |
| Average time of trip, passenger trains | 9.2 min. |
| Average time of trip, passenger trains, east-bound | 9.8 min. |
| Average time of trip, passenger trains, west-bound | 8.6 min. |

A brief statement of the physical, electrical and traffic characteristics and conditions of the tunnel route is necessary to an understanding of the above summary and of the data which follow:

**Physical Characteristics**

| | |
|---|---|
| Length of passenger train haul | 2.8 miles |
| Length of freight train haul | 3.6 miles |
| Length, summit to summit | 13,000 ft. |
| Length of tunnel | 8,400 ft. |
| Length of open cut | 4,600 ft. |
| Length of nearly level portion of tunnel | 800 ft. |
| Length of eastern slope | 7,300 ft. of 1½% grade |
| Length of western slope | 4,900 ft. of 2 % grade |

**From U. S. Government Data**

| | |
|---|---|
| Elevation of Detroit River (mean) | 575 ft. |
| Elevation of rails at Windsor summit | 606.5 ft. |
| Elevation of rails at Detroit summit | 601.5 ft. |
| Elevation of rails at middle of tunnel | 508 ft. |

The total curvature is 2900 feet. Of this about 1300 feet is 2 deg. which is the maximum. This curvature is divided into two nearly equal parts, the inner ends being approximately 2000 feet apart, so that all but 600 feet of the subaqueous tunnel tracks are straight. It will be seen from the above data that traffic west-bound must be lifted 98.5 feet and traffic east-bound 93.5 feet.

**Electrical Characteristics**

Current is purchased at 4600 volts, three-phase, 60 cycles. A substation to convert this current to 650 volts d-c. is located on the Detroit side of the river, 3600 feet from the Detroit summit and 9400 feet from the Windsor summit. The third rail feeders running from the substation to the tunnel by way of the Detroit shaft, which has the same location, relatively, as the substation to the two summits, are as follows:

Three 2,000,000 c.m. feeders joined to the third rail at the bottom of the Detroit shaft, one to the east-bound and two to the west-bound third rail.

Two 1,000,000 c.m. feeders run to the Windsor summit to circuit breakers in the interlocking tower and then to the third rails.

Two 1,000,000 c.m. feeders run to the circuit breakers in the 15th St. interlocking tower and then to third rails.

One 1,000,000 c.m. feeder runs eastward from the substation and is connected directly to the third rail of the east-bound track at the Windsor shaft.

A 1000-kw. motor-generator set in parallel with a 650-volt, 2520-ampere (for one hour) battery supplies current to the third rails through these feeders. A detailed description of the electrical apparatus and the distributing system will be found in the General Electric Company's Bulletin No. 4834 of May, 1911.

**Traffic Conditions**

From the beginning the Detroit River Tunnel proposition was to provide facilities for the expeditious handling of the traffic, not only of the Michigan Central, but the Grand Trunk, Canadian Pacific, Wabash and Pere Marquette, the business that is required to be taken across the river at Detroit for the last four roads being about equal to the Michigan Central in both passenger and freight. When the plans were forumlated in 1904, this total was about 2000 cars daily and it was found by an analysis of the Michigan Central Railroad records of the ten year's previous that the increase in business was about 5 per cent per year. At the start of the tunnel operations, therefore, it was to be expected that the Michigan Central would have to handle about 1270 cars daily and from the record of the first month's operation, as will be seen, it was 1238 cars. The other roads have not exercised their privilege of using the tunnel and the writer does not know if their business has been as close to the estimate as the Michigan Central business. But the following data, condensed from the record of trains through the tunnel, taking the months of June and December for each of the three years 1911, 1912 and 1913, furnish a good basis for obtaining the daily average for the three-year period.

| Year | TRAINS |  | CARS |  | TONS |  |
|---|---|---|---|---|---|---|
|  | June | December | June | December | June | December |
| 1911 | 43 | 50 | 1287 | 1361 | 40,530 | 44,872 |
| 1912 | 45 | 51 | 1215 | 1368 | 38,960 | 47,960 |
| 1913 | 50 | 55 | 1422 | 1412 | 45,567 | 45,837 |

From the above we find the daily averages for the three-year period to be as follows:

|  |  |
|---|---|
| Trains | 49 |
| Cars | 1,328 |
| Tons | 44,000 |
| Train miles | 160.4 |
| Car miles | 4,652 |
| Ton miles | 151,600 |

**Passenger**

|  |  |
|---|---|
| Trains | 20 |
| Cars per train | 8.5 |
| Train miles | 56 |
| Car miles | 476 |
| Tons per train | 425 |
| Tonnage | 8,500 |
| Ton miles | 23,800 |

**Freight**

|  |  |
|---|---|
| Trains | 29 |
| Cars per train | 40 |
| Train miles | 104.4 |
| Car miles | 4,176 |
| Tons per train | 1,225 |
| Tonnage | 35,500 |
| Ton miles | 127,800 |

The character of the traffic is best shown by an example of one day's operation. Below is the record of trains run through the tunnel on August 1, 1914. All freight trains are run as extras and they have been assigned numbers, beginning with 100 as the first of the eastward and 101 as first of the westward trips. The passenger trains are given their time table numbers.

## FREIGHT TRAINS

| EASTWARD |  |  |  | WESTWARD |  |  |  |
|---|---|---|---|---|---|---|---|
| Train No. | No. of Cars |  | Tons per Train | Train No. | No. of Cars |  | Tons per Train |
|  | Loaded | Empty |  |  | Loaded | Empty |  |
| 100 | 53 |  | 2253 | 101 | 35 | 5 | 1044 |
| 102 | 18 | 6 | 808 | 103 | 25 | 28 | 1697 |

| 48 | 6 |  | 395 | 36 | 13 |  | 590 |
| 14 | 8 |  | 470 |  |  |  |  |
| 22 | 6 |  | 365 |  |  |  |  |

|  |  |
|---|---|
| Total number of trains | 51 |
| Total passenger and express | 22 |
| Total freight | 29 |
| Total tons, freight | 35,564 |
| Total tons, passenger and express | 9,945 |
| Total cars | 1,299 |

The foregoing details of one day's train movements are of trains varying in class and weight from local passenger trains of 200 tons to freight trains of over 2000 tons. The freight of these trains is not always of the same class. If there is not enough fast freight to make up a train of proper tonnage, other freight is added. The fast freight trains are ordinarily not over 1600 tons and other freight trains are frequently over 2000 tons. It is quite important from the standpoint of economy in operation, as well as in the saving of time, to avoid splitting any trains delivered to the electric yard that are made up and ready to be forwarded over the adjacent divisions. It is also important from the same standpoint to haul them with the least number of locomotives; since every locomotive crew consists of three men; a motorman, a second man who is called "motorman's helper," and a conductor. The conductor couples the engines and sees that the trains are in order to move. All trains above 1000 tons are ope ated by two locomotives, one being used at each end, except on an occasional express or passenger train exceeding 1000 tons. For these both locomotives are put on the head end. The head motorman controls the air. The rear locomotive is coupled into the train line the same as a car. As the locomotives are equipped with both straight and independent air brake equipment, the rear motorman can set the brakes on his locomotive but not on any part of the train.

The details of operation of a freight train with two locomotives passing through the tunnel westbound are:

(a) Coupling of locomotives by conductors (one on each end).
(b) Both motorman charge train line and head motorman applies brakes.
(c) Rear motorman cuts out train line control.
(d) Conductors inspect trains (each one-half train).
(e) Conductors signal brakes off.
(f) Head motorman releases brakes.
(g) Rear motorman whistles O.K.

NOTE.—Three whistles in Windsor and two in Detroit. By rule, all westward moves by electric locomotives are "back up" and all eastward moves by electric locomotives are "go ahead." This rule is made because the electric locomotives are the same at both ends.

(h) Head motorman repeats whistles.
(i) Leverman phones yardmaster at "receiving" yard.
(j) Yardmaster if ready to receive it says: "Let it come."
(k) Leverman clears signal.
(l) Head motorman moves train without help of rear locomotive, until rear locomotive is within about 1000 feet of bottom of grade.

Table I—LOCOMOTIVE TESTS

| | TRIP NO. | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|

| Bottom of grade to portal (kw-hr.). | | 47 | 45 | 45 | 36 | 37 | 20 | 26 | 48 | 5 |
| Portal to stop (kw-hr.).. | | 34 | 44 | 32 | 47 | 33 | 40 | 30 | 34 | 2 |
| Total (kw-hr.)... | 11 | 102 | 92 | 89 | 84 | 86 | 64 | 65 | 82 | 9 |
| Watts per ton mile.. | 35 | 41 | 37 | 36 | 34 | 35 | 26 | 26 | .... | 30 |

NOTE.—For these tests, electric locomotive No. 7505 was equipped with two 600-ampere recording wattmeters, Stewart speedometer indicating speed and recording distance. Weather—clear. Rail—dry. Temperature—about 40 degrees.

(m) Rear motorman here applies power to full multiple position of controller and as the summit is approached gradually reduces power so that when his locomotive has reached the summit the power is off.

During the movement, the rear motorman must observe the ammeter for any sudden variations and shut off power immediately when it occurs.

The maximum speed permitted is 30 miles for freight and 35 miles for passenger trains. Table I shows the results of test runs made for the purpose of determining the best speed for trains and the watts per ton-mile at different speeds. The trains are handled without surging at the higher speeds, less brake shoe wear and, of course, with less power.

### Locomotive Mileage

Until January 1, 1914, the old Third Street passenger station was used, and all passenger trains were run between the station and tunnel by steam locomotives and switched by them, so that no account was taken of the electric locomotive switching mileage. It was a rather small item, because freight trains to be taken through the tunnel are delivered by steam locomotives to the designated yard track ready to be forwarded, so that practically no switching service was performed by the electric locomotives other than an occasional damaged car being switched out of a train.

Since the new passenger yard was put into service, the switching required, because of the changes in the make up of through passenger and express trains, is now done with electric locomotives and the switching mileage is an important factor, especially as the total mileage is low; the whole tunnel operation being really a switching service. Cyclometers were, therefore, put on in order to determine the allowance which should be made for switching mileage. The following table shows the mileage record for the month of August, 1914.

| | | |
|---|---|---|
| **Freight** | | |
| Principal | 3,808 | |
| Helper | 3,808 | |
| Light | 1,821 | 9,437 miles |
| **Passenger** | | |
| Principal | 2,004 | |
| Helper | 186 | |
| Light | 486 | 2,676 miles |
| **Yard Switch** | | |
| Freight | 1,088 | |
| Passenger | 1,087 | 2,175 miles |
| Total | | 14,288 miles |

The total locomotive mileage for the three-year period, from 1911 to 1913, was 415,247; a yearly average of 138,816; and a monthly average of 11,568. If the switching mileage of 2175 for August is deducted, it will be very nearly the same as the average locomotive mileage for the previous three-year period. We find the total daily average mileage for the locomotives for all service is 377.5, but that the total train mileage for the same period is only 160.4. This apparent discrepancy is reconciled if the subdivision of service is analyzed. Referring to the August mileage: The train miles designated as "principal" are 5812, or nearly 41 per cent of the total of 14,288 and the ratio of train miles to the total for the three-year period, from 1911 to 1913, is 40 per cent.

The freight helper mileage, as will be noted, is the same as the principal mileage, indicating that every freight train is taken through the tunnel with two locomotives and in the passenger service is included express and passenger trains which occasionally exceed the tonnage hauling capacity of one locomotive.

While fewer enginemen would be required if all trains requiring two locomotives could be run as double headers, it is not possible to do so because the high draw bar pull required results in the parting of trains. While the new coupling apparatus has a drawbar pull equal to that needed to haul 2000 tons up a 2 per cent grade, all the couplers are not new and it is found much better to keep the drawbar pull below 50,000 lb. The rear locomotive provides a place for a conductor (flagman) to ride.

Detroit and Windsor are the ends of divisions and the river the frontier line between Canada and United States, so the steam locomotives and cabooses of trains arriving at these terminal points would not be taken across in any case.

The freight is classified in yards that lie just beyond the electric zone and in these yards the "made up" trains for the tunnel are inspected. Much of the fast freight, however, is through business—Chicago to Buffalo—and does not need classification in the Detroit territory. Such trains are inspected in the electric yards. These frequently contain

Table II RECORD OF NUMBER OF TRAIN DELAYS AND TRAIN MINUTE DELAYS

| | FREIGHT | | | | PASSENGER | | | | THIRD RAIL |

| 12. Contactors | | | | | | | | | |
| 13. Third-rail circuit breaker open on overload | 1 | | | | 1 | | | | 22 |
| Total | 23 | 1285 | 6 | 300 | 5 | 62 | | | 22 |

bad order cars which must be set out. Rigid inspection is maintained so that very few delays result from defective equipment when the heavy grades are taken into consideration. A statement of these delays for the three-year period is given in Table II, and shows clearly the nature of the defects in cars, as well as all other causes of delay.

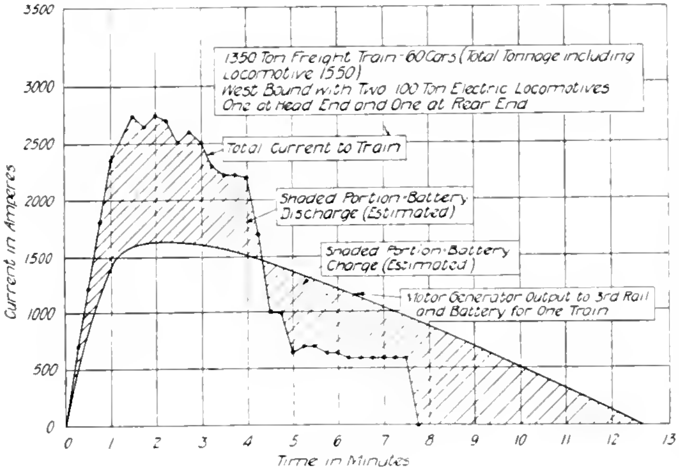

**Fig. 1. Power Curve of 1350-Ton Train**

It is quite evident that the load factor cannot be good and also that the peaks, under unrestricted operation, will be very high. While it is possible to operate with only forty-nine trains a day so that two freight trains will not be ascending the grades at the same time, it would not have been proper to require such an operating condition by limiting the power supply. Equipment was, therefore, installed of a capacity sufficient to furnish power for two trains to ascend the grades simultaneously and also to do switching. In the statement of power opposite the first item is the amount of purchased power. The records upon which bills are made are from meters located on the switchboard in the substation.

The cost per kilowatt-hour for traction, when to the cost of primary current is added only the conversion and transmission losses, and the cost of operating and maintaining the substation and distribution system, including third rail, is $0.018.

Although much of the fast freight is run in what is known as "symbol trains," which have a schedule, their time of arrival at intermediate points is by no means certain. These, as well as all other freight trains are run as "extras." It is, therefore not possible to anticipate with any exactness the hourly load, nor even the daily load, as the freight trains vary from day to day, not only in weight but in number. But if the weekly or monthly average for the period of a year is taken, it will be found quite near to that for any particular week or month, the tonnage averaging a little higher for the six winter months than for the six summer months. There is the morning and evening peak here as in every other place where there is any considerable volume of transportation, although not so marked, when considering the tonnage, as in most cases. The freight trains under normal conditions can be and are quite evenly distributed over the twenty-four hours, the passenger load super-imposed on this comparative even load causing the peaks. In one sense the load is all peaks. The light and auxiliary power averages about 150 kw. with a maximum demand of 300 kw., whereas a two-thousand-ton freight train requires nearly 3000 kw. for a few minutes. The power curve for a 1350-ton train is given in Fig. 1.

## TOTAL KILOWATT-HOURS USED

| | 1911 | 1912 | 1913 |
|---|---|---|---|
| Substation input | 4,749,145 | 4,653,290 | 5,145,745 |
| Substation output | 2,977,650 | 3,144,945 | 3,461,650 |
| Total output for traction....... | 1,758,400 | 1,844,770 | 2,223,940 |
| Total output for light and auxiliary power... | 1,219,250 | 1,300,175 | 1,237,710 |

## AVERAGES

| | |
|---|---|
| Substation input for one year.................... | 4,849,393 kw-hr. |
| Substation output for one year.................... | 3,179,748 kw-hr. |
| Traction output for one year....... .......... | 1,942,370 kw-hr. |
| Light and auxiliary power output for one year...... | 1,252,378 kw-hr. |
| Output per day for three-year period............. | 5,320 kw-hr. |
| Cost per day for traction current........... | $95.50 |
| Watts per ton mile.. | 35.1 |
| Cost per ton mile... | $0.00063 |

### Third-Rail Maintenance

The maintenance of twenty miles of third rail, including supervision, for the year 1913, was \$2,690.00; or \$134.50 per mile and \$7.40 per day. One of the principal items which goes to make up this total is the cost of replacement of burned and broken insulators. During the year 1913, there were 1200 replacements due to burning and 360 replacements due to breaking, costing \$936.00. Of the total burned insulators, 375 were on the tunnel tracks, 370 in the east-bound tunnel and only 5 in the west-bound. The great difference is due to the fact that practically all refrigerated freight is east-bound and brine drippings from these cars drops on the third rail. The application of grease and roofing paper over these insulators has greatly reduced the trouble from burned insulators, but has by no means eliminated it, and I am of the opinion that it will not be entirely eliminated until tanks to retain the brine are provided on all refrigerator cars.

| | No. Active Levers | Signals | Switches | Track Circuits | No. of Levermen |
|---|---|---|---|---|---|
| Bay City Junction (24th St., Detroit) | 48 | 21 | 25 | 6 | 3 |
| 20th St., Detroit | 155 | 82 | 73 | 76 | 4 |
| 15th St., Detroit | 172 | 75 | 72 | 60 | 4 |
| Windsor Summit | 37 | 21 | 14 | 5 | 2 |
| Windsor Tower No. 2 | 39 | 21 | 18 | 4 | 2 |
| Windsor Tower No. 3 | 29 | 17 | 12 | 0 | 2 |
| Through Tunnel | | | | 11 | |
| Total | 480 | 237 | 214 | 162 | 17 |

### Locomotive Maintenance

The maintenance force consists of:

- $\frac{1}{3}$ road foreman of engines time
- 1 mechanical man (foreman of the shop)
- 1 electrical man
- 1 air brake man
- 1 helper

All inspecting, cleaning and repairing, including the changing of tires (but not the turning of them) is done by this force at a small inspection and repair house located near the middle of the Detroit electric yard.

Taking the total cost of labor, material and supplies for the six locomotives for the period of eighteen months, from July, 1912, to December, 1913, and reducing to an average monthly basis, we have:

| | |
|---|---|
| Labor | \$406.03 |
| Material, including shop machinery | 168.77 |
| Total per month | \$574.80 |
| Average cost per locomotive mile | \$0.0498 |

The life of tires under the operating conditions up to the present is approximately three years. After two turnings they are scrapped. Tire maintenance is much the largest single item in the maintenance cost.

### Signals and Interlocking

All train movements in the electric zone are governed by interlocking and block signals. Except for the Windsor freight yard, all signals are controlled by a-c. track circuit, as well as from the interlocking machines. The table above shows the location and size of plants and number of levermen used for operating twenty-four hours each day.

Tunnel tracks between summits are signaled for running in either direction on both tracks and here only are the double-rail track circuits installed, as all four rails are wanted for the return of the propulsion current. In the yards one rail is used for the signal track control and the other one for the propulsion return current. Visual indication is given the leverman, showing what section of track is occupied by trains in the Detroit yards or the tunnel.

All the modern auxiliaries, such as, conductors platform signals, telephones and telautograph apparatus are furnished to assist in the expeditious and safe handling of trains.

# THE OPERATION OF THE THIRD-RAIL SYSTEM OF THE NEW YORK STATE RAILWAYS

By George N. Brown

Electrical Engineer, New York State Railways, Utica-Syracuse Lines

This article deals in a comprehensive way with the operation of the Oneida Line of the New York State Railways since it was electrified. The power consumption for a full year is analyzed in detail, and the efficiency of each section of the transmission and distributing system, as well as a detailed statement of the costs of substation operation for a period of six and one-half years, are given. The power consumption of both the limited and local cars is recorded and a comparison is made between the cost of maintenance of the overhead and third-rail conductors. The interruption of the power and third-rail circuits are tabulated for a period of seven years. The data should be of great value to operating men.—Editor.

George N. Brown

On June 15, 1907, the electrified division of the West Shore Railroad, known as the Oneida line, a part of the New York State Railways, was formally put in service and it might be of interest at this time to look back over the seven years of the road's operation to see just what changes have been made in the equipment and to investigate not only the continuity of power service but also what this power has actually cost.

The third-rail division of the New York State Railways, which is the electrified portion of the West Shore, extends between the westerly limits of the city of Utica and the easterly boundry of the city of Syracuse. This road was formerly double-tracked throughout, but to accommodate the different classes of service a third track was provided between Clark Mills and Vernon to allow faster units to pass the local trains. Between Oneida and Canastota a fourth track was laid to permit the electrically operated units to pass steam trains that may be held up in this section, owing to the presence of water stations and freight yards. The length of the electrified portion of the West Shore is slightly greater than forty-four miles. Of this 30.515 miles are laid with double tracks, 8.843 miles with three tracks and 4.582 miles with four tracks, making a total mileage of 105.887. The tracks throughout are laid with 80 lb. rails.

The Oneida line cars operate between the business centers of Utica and Syracuse, a distance of 48.52 miles. The limited trains cover this distance in one hour and twenty-eight minutes, making the run of forty-four miles over the West Shore in sixty minutes, with two station stops, Oneida and Canastota, and two railroad crossing stops. The local trains have a running time of two hours and two minutes, but make a detour through the city of Oneida, which adds about three miles to the total distance. Express and baggage service is also maintained, two trains operating in each direction daily, except Sunday.

### Source of Power

Power is supplied by the Adirondack Electric Power Corporation from a steam plant located in the city of Utica. Energy for the operation of the Utica lines of the New York State Railways is also obtained from this same source.

The equipment of this plant consists of four General Electric vertical turbines, having a total rated capacity of 6000 kw., the machines generating three-phase 40-cycle current at 2300 volts.

### Transmission Line

Power is transmitted to Clark Mills substation, a distance of eight miles, at a pressure of 60,000 volts on a steel tower line. These towers, with bases seventeen feet square and having a normal spacing of 550 feet, are made for a double transmission line, but at present carry only the three power wires and one ground wire. These are all of the same size, consisting of six copper wires stranded, forming a cable with a capacity equivalent to that of No. 000 solid wire and having a diameter of half an inch. The minimum clearance between conductors at any point in the span is six feet. The insulators have four petticoats and are of the pin type and were tested on 140,000 volts.

All energy is metered at Clark Mills substation on the high tension side and is paid for on the kw-hr. basis.

The transmission line, which parallels the West Shore tracks and extends from the Clark Mills substation to the Manlius Center substation, a distance of thirty-three miles, is made up of three conductors, each having a capacity of a No. 0 wire. The cables are built up of seven strands of hard drawn copper. These towers are built for a single transmission line and have a normal spacing of 480 feet. Thomas insulators of the pin type are used and spaced seven feet apart at the corners of a seven-foot equilateral triangle. No ground wire is used.

### Substations

As shown on the map, Fig. 1, there are five substations on the Oneida line, four of which are used for railway purposes, namely, Clark Mills, Vernon, Canastota and Manlius Center, and one located at Oneida City, which is used to transform energy from 60,000 volts to 2300 volts, at which the lighting and industrial loads of Oneida and Canastota are supplied. The average distance between the railway substations is approximately ten miles. The buildings are all of neat appearance, as will be seen by referring to Fig. 2, which shows also the architectural characteristics. They are constructed of brick with litholite trimmings and both the roof and the floors are of concrete. Each substation is provided with a heating apparatus and is equipped with a lavatory. An excavation beneath the floor level provides facilities for running cables and also for housing a battery of accumulators for the operation of the 60,000-volt oil switches. The electrical apparatus installed and the design of each station is identical in all respects, with the exception that no outgoing oil switch is required at Manlius Center substation, as the transmission line terminates at that point. The transmission line enters the building from the rear and in each case is connected to the high tension buses through disconnecting switches. An oil switch and disconnecting switches are installed in the outgoing line in three of the substations.

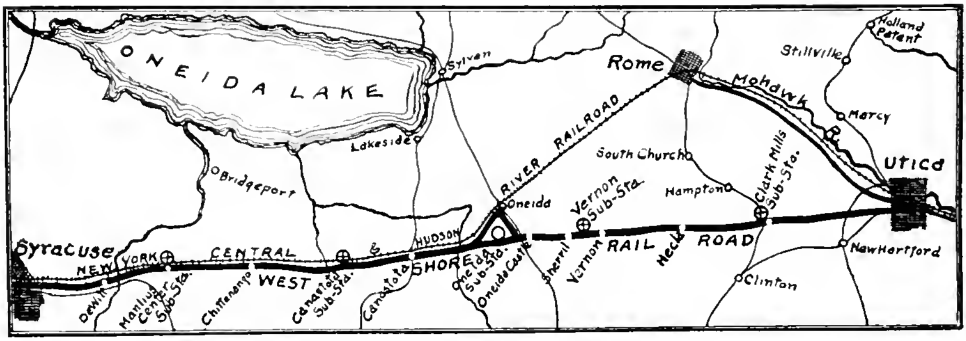

Fig. 1. Map of Third-Rail System, New York State Railways, Oneida Line

The building is divided into two sections, the operating room and the high tension compartment. The former contains the transformers, reactance coils, rotary converters and switchboard, as is shown in Fig. 3, while the latter houses all the high tension apparatus, such as oil switches, low equivalent lightning arresters, choke coils and busbars.

The equipment of each of the substations consists of two three-phase 40-cycle 300-kw. rotary converters made by the General Electric Company, together with two three-phase 330-kw. 40-cycle transformers, having a primary voltage of 34,600, and when "Y" connected 60,000 volts. The secondary when delta connected gives 370 volts. These transformers are operated "Y" connected on the primary side with delta connections on the secondary. Full load on the direct current side of the rotary converter is 500 amperes at 600 volts. These machines are started from the alternating current side on half-voltage taps from the transformers.

At the Oneida substation the electrical equipment consists of an oil switch, disconnecting switches, and three 275-kw. transformers, 40 cycles, 60,000 to 2300 volts, made by the General Electric Company. An electrolytic lightning arrester is connected to the transmission line at this point. This station, as previously explained, supplies energy for a lighting and industrial load, and is operated by the Adirondack Electric Power Corporation, power being purchased from the Oneida line.

### Operating Force

The operating force in the power department consists of one chief operator, eight substation operators, a meter inspector (who spends about one-third of his time on this line) and a change operator, who takes care of the shifting of men not only in the four Oneida substations, but also in the two substations in the city of Syracuse. To maintain the high tension line and third rail, together with some three miles of trolley wire in the city of Oneida, there are required one line foreman, two high tension patrolmen, and four linemen.

### Cost of Power

Table I shows not only the cost of operating the substations year by year since the road started operation, but also what has been paid out for power during that time. The alternating current is metered at 60,000 volts at the Clark Mills substation, and the power which is metered at the Oneida substation, plus a 1 per cent line loss, is deducted from the Clark Mills reading, leaving the net a-c. kw-hr. used for railway purposes. During 1913 a test was made to determine the various losses of transformation, transmission and conversion, following the energy from the 2300-volt busbars at the turbine plant in Utica back to the negative side of the rotaries through the return circuit. On the basis of these tests Table II was prepared, showing power data for the year 1912.

Fig. 2. Exterior View of Clark Mills Substation, Oneida Line

### Substation Load

Practically no trouble has been experienced with any of the substation apparatus during the seven years that it has been in service. At Sherrill, on this line, is located a large and growing manufacturing concern, known as the Oneida Community, which requires a considerable extra service for the transportation of its employees to and from this plant. At the present time there are a number of three-car trains and some six or eight two-car trains which are shown on the regular schedule, and most of these operate with the extra cars only as far as Oneida. This means that Vernon substation is subjected to a heavier load than any of the other substations. Fig. 4 shows the d-c. ampere load of this station on September 9, 1913, and from this chart an idea may be gained of the swings taken care of by this apparatus.

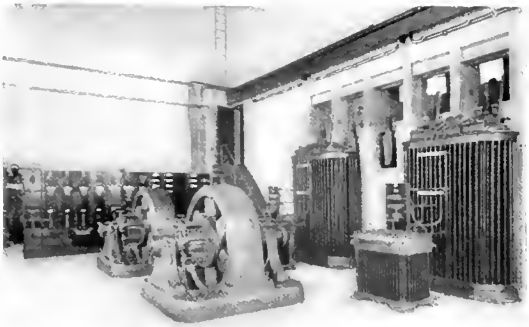

Fig. 3. Interior View of Clark Mills Substation, Oneida Line

### Changes in Substation Equipment

During the seven year's of operation a number of small additions or changes have been made to the substation equipment, either for greater safety or the betterment of the service. Chiefly among these are:

*First.* The installation of a concrete wall, one foot in height, forming an enclosure around the transformers, which in turn has a drain to the outside of the building. Drain pipes are carried from the base of each transformer to a valve housing on the outside of the substation. This box has a wire glass front and furnishes easy access to the transformer valves, and by their operation the oil can be drained from the transformer tanks. This is in line with suggestions made by the Fire Underwriters, and although it is decidedly uncommon that a transformer casing should puncture and then the oil should become ignited, yet the cost of piping up the transformers was so small that it was considered a good investment.

*Second.* It was found that a number of the mechanical oscillators on the rotary converters were damaged when the machine arced over, as at such times excessive current would flow from the armature shaft to the frame of the machine through the oscillator. This trouble has all been eliminated by placing on the opposite end of the armature shaft two small copper brushes and connecting them up permanently to the frame of the machine, which in all cases is ungrounded. This furnishes a more direct path for this current and no damage is done to the balls or raceways of the oscillator.

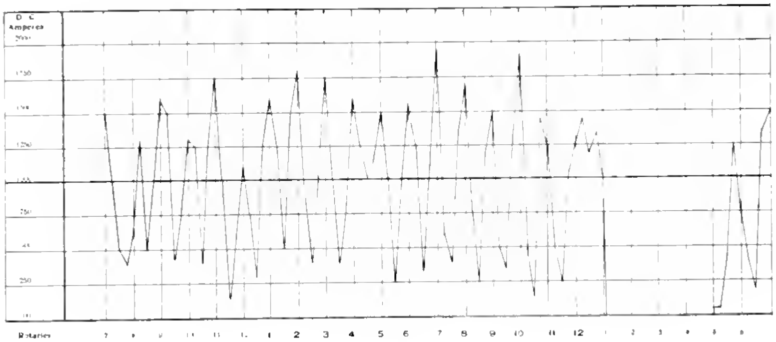

Fig. 4.

*Third.* Disconnecting switches have been placed at the back of two of the substations, Clark Mills and Vernon, so that power may be taken off from the high tension bus structure

| December | 468,300 | 450,200 | 18,100 | 3.90 | 354,560 | 95,640 | 20.4 | 75.70 | 345,451 |
| AVERAGE | 456,000 | 432,242 | 23,638 | 5.18 | 343,000 | 89,200 | 19.6 | 75.20 | 334,000 |

Deductions made as follows:
Column 1 − Column 2 = Column 3.
Column 3 ÷ Column 1 = Column 4.
Column 5 = Metered on d-c. bus.
Column 1 − Column 5 = Column 6.
Column 6 ÷ Column 1 = Column 7.

Column 9 − Column 10 = Column 11.
Column 12 = Column 11 changed to a-c. equivalent.
Column 11 − Column 13 = Column 14.
Column 14 ÷ Column 12 = Column 15.
Column 14 − Column 16 = Column 17.
Column 17 ÷ Column 12 = Column 18.

in the substation, and by closing these disconnecting switches, power can be supplied to the transmission line beyond either of these substations. These disconnecting switches simply shunt the station busbars, so that in case of any trouble in the high tension room of the substation, service would only be temporarily interrupted to the substations beyond. It is planned to install these disconnecting switches back of the Canastota substation; none being required at Manlius Center substation, due to the fact that there is no outgoing line.

*Fourth.* It has been found that when the transmission line has been struck by lightning, not only one, but sometimes a number of insulators adjacent to each other and all on the same leg, have been shattered. This has lead to an investigation and it has been determined that there are too many grounds on the transmission system, which is "Y" connected with the neutral grounded at each bank of transformers, making in all ten such grounds on the system. It is planned now to operate with only one permanent ground on the system and that one to be located at the turbine plant in Utica, and having in circuit 500 to 1000 ohms resistance. When trouble has developed on this line, after testing out and finding the affected leg, it has proven helpful to be able to operate three-phase with two wires and using the earth as a third conductor. However, this feature can be retained by having disconnecting switches in the grounded neutral at each substation.

Average for the seven year's of operation:—
High tension, 7 hours and 50 minutes.
Third rail, 45 hours and 54 minutes.

**Car Equipment**

The original equipment consisted of 15 passenger cars weighing 78,144 lb. each, fully equipped, and having four GE 73, 75-h.p. motors, together with Type M control. This type of car is shown in Fig. 5; also two express cars weighing 90,000 lb. each, having the same electrical equipment. On September 1, 1912, two new steel passenger cars with parabolic fronts were added, weighing 76,100 lb. each and equipped with four GE 201, 50-60-h.p., motors, and having Type M control. This car is shown in Fig. 6. Tests were made to determine the power consumption on both these types of cars, not only for interurban service, but also for city operation. Table III shows this data both for limited and local service.

Fig. 6. Steel Car, Weight 76,100, lb. Equipped with 4 GE-201 (50-60 h.p.) Motors, Oneida Line

Fig. 7. View of Third Rail Showing Form of Jumpers Used, Oneida Line

**Third Rail**

As previously stated, there are over 105 miles of third rail. The form of rail employed is the bullhead under-running type and is of the same cross section as that employed in the electrification of the New York Central terminal; it has a further resemblance in that it is arranged for an under-running contact.

The weight of the rail is 70 lb. per yard and is supplied in lengths of 33 ft. No special composition was used to secure higher conductivity as the traffic conditions did not warrant it. The rail has, however, the equivalent conductivity of a copper cable of 1,023,000 c.m. cross section. Soldered bonds were used throughout. In Fig. 7 is shown the arrangement of the third rail on tangent track. The covering seen in the illustration is made of long leaf yellow pine in three parts and held together by No. 10 screws. The wooden covering is not subjected to any special treatment, but is painted before being applied to the rail. Another form of covering used to some extent is made of fiber and is molded in the form of the rail. From the illustration of the third rail it will be seen how the jumpers are carried under highway crossings and the method of fastening the rams' horns to the third rail. When replacements are made to such jumpers a fiber conduit is used instead of an iron pipe, as was the original installation, it having been found out that an action, either chemical or electrolytic, soon pits the pipe and allows moisture to get into the cable.

Fig. 8. View of Third Rail under Snow Conditions, Oneida Line

In regard to the cost of maintenance of the third rail, Table IV shows the comparison of overhead and third rail maintenance per mile of single track for the cities of Utica and Syracuse and the Oneida line.

With its third-rail construction, the Oneida line has never been seriously handicapped by snow. This may be due to the fact that the line extends east and west and has no deep cuts. Fig. 8 shows the third rail under snow conditions. It might be added that no effort is made to clean the snow out from under the third rail, the contact slippers on the car being sufficient for this purpose. Very little data are at hand in regard to the losses due to leakage through snow, but as far as can be determined dry snow piled around and over the third rail does not increase this leakage. When the snow starts to melt, that is, with wet snow against the third rail, the leakage is ten times greater than normal. This is also the case when there is a considerable quantity of rain falling.

On the system there are two types of third-rail insulators, one wooden and the other porcelain. Of the wooden type there are 4500 in service and of the porcelain type, 44,097. From a test section of the third rail containing both kinds of insulators, data were obtained in regard to the yearly leakage, and applying these figures to the 105 miles of third rail, it is found that the yearly loss, due to leakage, is 14,430 kw-hr. This, at the average rate of $0.0125, will amount to $180.38.

### Interruptions

Table V shows the total number of hours per year that the service has been interrupted during the past seven years on both high tension line and the third rail. This table shows an average yearly interruption on the high tension line of 7 hours and 50 minutes and on the d-c. side or third rail of 45 hours and 54 minutes. It should be borne in mind that there are two d-c. feeders out of each of the four substations and that this represents the total length of time the d-c. was interrupted on all feeders.

# TYPES AND SYSTEM OF DRIVES OF ELECTRIC LOCOMOTIVES

By A. F. Batchelder

Engineer, Railway Locomotive Department, General Electric Company

The author gives an interesting review of drive systems used on electric locomotives, from the earliest types built for heavy traction in this country up to the latest examples employed in our modern installations. The article should be of considerable value to those interested in the design of electric locomotives.—Editor.

A. F. Batchelder

The installation of electric locomotives by the Baltimore and Ohio Railway Company, for their tunnel at Baltimore, Md., in 1895, demonstrated beyond a doubt the practicability of heavy electric traction.

This first installation consisted of three 96-ton locomotives, each being designed with a running gear made up of two trucks, each of which had two axles and a short wheel-base. Each axle was equipped with a gearless motor mounted on a quill surrounding the axle, the wheels being driven through pieces of rubber, acting as springs.

These locomotives have proven to be very successful in the slow speed service required at the tunnel, but experience from their operation has given much useful data as to where improvements should be made in the design, especially where high speed is required. Later in 1903 the Baltimore and Ohio installed four additional locomotives weighing 80 tons each for slow speed freight service.

These new locomotives were made at a much smaller manufacturing cost than those of the first installation, and are different in design, having a single four-axle truck with a long rigid wheel-base with a motor geared to each axle. These locomotives were also very successful and were operated at a smaller cost of maintenance than the first type. Again in 1900 additional locomotives weighing 90 tons each were installed for higher speed service.

These 90-ton locomotives have a running gear consisting of two-axle trucks each having a short wheel-base, joined together with a hinge connection. These units are similar in design to the locomotives that had been installed at the Detroit River Tunnel on the Michigan Central Railroad in 1909. They were so satisfactory in service that the next installation made in 1912, of 100-ton locomotives, were of the same type.

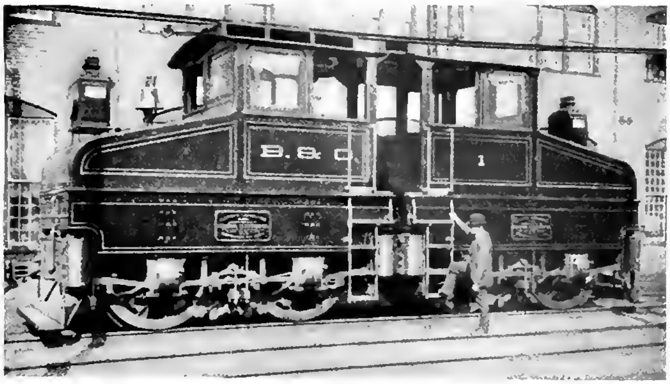
Since the date of the first installation in 1895 many other installations have been made in different parts of the world, and many different designs have been made and are in operation, or have been experimented with, in an attempt to produce the most perfect machine to meet the requirements as governed by the kind of power or by the special conditions of the railroad on which they were to operate.

A large percentage of the most important installations in America, operated both with high or low voltage direct current and with three-phase current systems, have installed the last type adopted by the Baltimore and Ohio Railroad Company for freight and low speed passenger service. Of these, the following may be cited: The two installations of the Baltimore and Ohio Railroad Company: at the Baltimore Tunnel; the two installations of the Detroit River Tunnel Company, on the Michigan Central Railroad, at Detroit, Michigan; one installation at the Great Northern Railway Company, for the Cascade Tunnel, Washington; two installations on the Butte, Anaconda and Pacific Railroad, Montana, one installation on the Canadian Northern Railroad at Montreal; one installation at the Bethlehem-Chili Iron Mines Company, Chili; one installation for the Commonwealth Edison Company, Chicago, and one installation for the Wilkes Barre & Hazleton Railway Company, Pennsylvania.

This type has the advantage of being economical to manufacture, easy and cheap to maintain, easy on flange, rails and road bed, and satisfactory for speeds up to 50 m.p.h.; all of these advantages have now been proved in service by several years of operation.

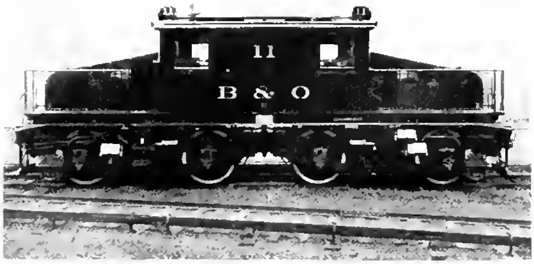
Second Installation on Baltimore and Ohio Railroad

Important installations which have adopted other types are the New York, New Haven and Hartford Railroad Company, the New York Central and Hudson River Railroad Company, the Pennsylvania Railway Company, the Norfolk and Western Railroad Company. The first and second installations of the New York, New Haven and Hartford Railroad Company for high speed passenger service were of a similar type to the first installation of the Baltimore and Ohio Railroad Company with the difference that steel springs were used in the driving wheels instead of rubber, and these locomotives were afterwards changed by adding a guiding axle to each truck. Later, other installations were made using locomotives with geared motors, but retaining the quill and spring drive feature. All the data the writer is able to get on this system of drive indicate an excessively high cost of maintenance.



First Installation on Baltimore and Ohio Railroad

The first and second installations of the New York Central Railroad Company were with running gears having a four-axle truck with a two-wheel pony guiding truck at each end. This was changed later by substituting four-wheel trucks in place of the



Third and Fourth Installations on Baltimore and Ohio Railroad

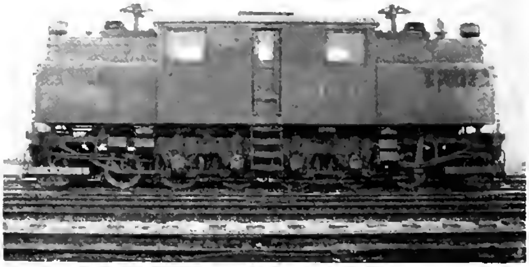
two-wheel trucks. Each of the four driving axles is equipped with a motor armature mounted direct on the axle, the field being so arranged as to allow the necessary vertical movement of the armature. This type has proven satisfactory and has the advantage over other types because of its simplicity and low cost of maintenance.

First Installation on New York, New Haven and Hartford Railroad

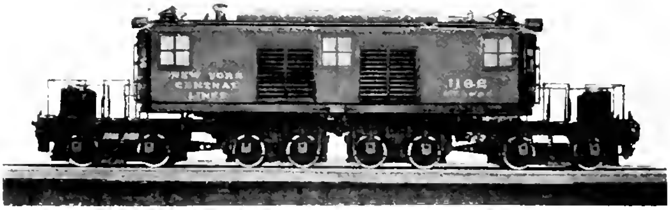
The third and fourth installation by the New York Central has the same motor construction as the first, but in order to obtain the benefit of greater starting effort, the guiding trucks are provided with motors, and in order to operate on sharp curves, the middle truck is articulated at the center. This type has all the advantage of the first, with the addition of the greater tractive effort, relative to its weight, for starting purposes. This type is satisfactory for operation at speeds up to 75 miles per hour.

The first and second installations by the Pennsylvania Railroad Company have two four-wheel trucks coupled together and a four-wheel guiding truck at each end, being the same wheel arrangement as the third and fourth installations of the New York Central, excepting that the joint between trucks, which on the Pennsylvania is a link connection, on the New York Central is a hinge connection. The motor equipment consists of two motors mounted on the main truck frames and the drive is arranged through diagonal side rods to jack shafts and then in turn through parallel side rods to the driving wheels.

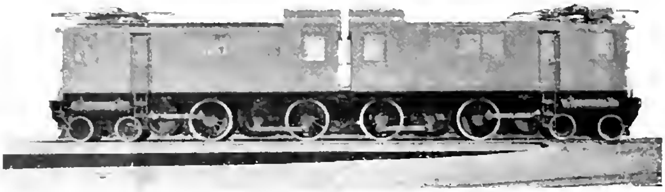
This drive was invented by the writer and was patented* by him in 1911. A sample machine was built and tested in the meantime, and the results indicated considerable losses in the transmission of the power from the motors to the wheels, and from such data as the writer is able to obtain from actual operation, the cost of maintenance is



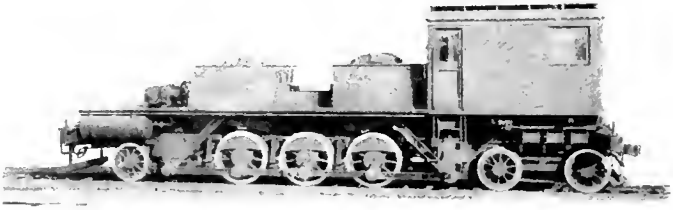
First and Second Installations on New York Central and Hudson River Railroad



Fourth Installation on New York Central



Sample Locomotive Geared and Side Rod Drive



Sample Side Rod Drive Locomotive

---

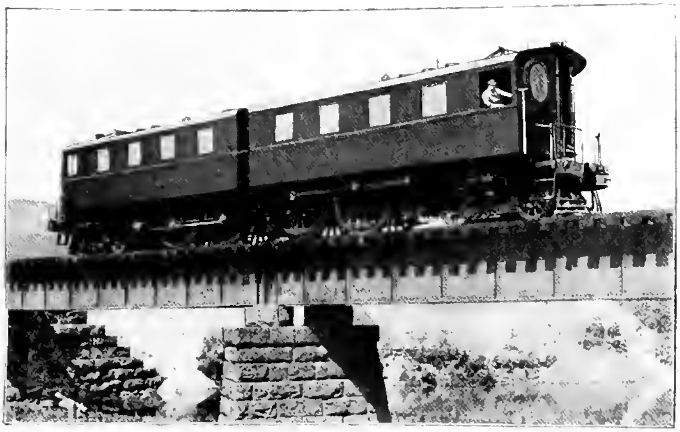
*Patent No. 988,067.

excessively high as compared with other types. The manufacturing cost is also higher than those of the New York Central type for the same capacity.

The first installation by the Norfolk & Western Railroad Company is of a similar wheel arrangement to that of the Pennsylvania Railroad, but with two-wheel guiding trucks in place of the four-wheel trucks and a hinge joint instead of the links between the trucks, and the motors are geared direct to the jack shafts which in turn are connected to the drivers through parallel rods. A design similar to the Norfolk and Western was presented at the Meeting of the American Institute of Electric Engineers, at Jefferson, N. H., in July, 1910, by the writer.

A sample locomotive with geared and side rod drive differing from the Norfolk & Western by having a jack shaft for each axle was built and tested in 1912 and the results of the test indicated this arrangement to be successful and that it could be used to advantage where it is necessary to spring support the motors to absorb the vibration due to the pulsating torque as with single-phase series motors.

It appears to the writer, judging from the results obtained in operation and from the general satisfaction given by the type of running gear and system of drive used in the last installation of locomotives adopted by the Baltimore & Ohio Railway Company, that this design may be considered generally settled and standard for freight and slow speed passenger service. For the high speed passenger service, however, it is not so apparent that the design is settled, owing to the limited number of installations for this class of service, but from such data as the writer is able to obtain on costs of manufacture, cost of maintenance, and general satisfaction in operation, it would seem that the design adopted by the New York Central and Hudson River Railroad Company has the advantage.



First and Second Installations on the Pennsylvania Railroad

# A DESCRIPTION OF THE PHYSICAL CHARACTERISTICS OF THE DALLAS, WACO AND CORSICANA INTERURBAN 1200-VOLT RAILWAY

By Luther Dean

Chief Engineer, Southern Traction Company

The author gives a brief description of a new 1200-volt interurban road. The article is mainly confined to a description of the physical characteristics of the railway and its equipment; some interesting notes are given concerning the construction of some of the bridges.—Editor.

The lines of the Dallas, Waco and Corsicana Interurban Railway are made up of approximately 171 miles of main-line track, with about 2 miles of second track, and about 5 miles of sidings. About 80 miles of this track were laid with 80-lb. A.S.C.E. tee-rails; and the balance, except for about 5 miles in city streets, were built with 70-lb. A.S.C.E. tee-rails.

The standard roadway section is 16 feet in width at the sub-grade on embankments and 24 feet in cuts; an allowance for shrinkage was made so as to have the embankments full width after seasoning. The embankment slopes were made so as to be one and one-half horizontal to one vertical after settlement. The highest "fill" is just south of Dallas, where a 15-ft. concrete arch culvert was built. The top of the embankment is 65 feet above the bottom of the culvert.

First quality 6 in. by 8 in. by 8 ft. seasoned white oak ties were used and they were spaced 17 ties to a rail length of 33 feet. These ties were placed on 6 inches of gravel ballast, except in paved city streets, where 6 inches of concrete was placed under the ties. This concrete was brought up to 1 inch above the top of the ties to make a foundation for the paving.

The maximum grade outside of the city streets is 2 per cent and the maximum curvature, except where governed by streets, is 6 degrees. Of the 127 miles of interurban track recently laid out and built, 91.43 per cent is of tangent track.

Eighteen steel bridges or steel viaducts, having a total length of 3513 feet, have been constructed. The longest viaduct is 1455 feet long and carries the interurban track over the main-line and side tracks of two railroads at Waxahachie, and over the Waxahachie Creek. The longest single span is 150 feet, this being one of three such spans which were used in crossing the Brazos River at Waco. The steel bridges and steel viaducts are all designed according to Cooper's specifications for E-30 loading. In constructing the piers for the Brazos River bridge, reinforced concrete cribbing was used to protect the excavation. This cribbing was made 12 inches in thickness and was beveled at the bottom so as to allow it to settle easily as the excavating progressed. It is about 16 feet in height and extends from bed rock to the bed of the river. It was built up in sections so as to carry on the excavation to better advantage and, after bed rock was reached, the bottom was sealed up and the cribbing was used as a form for the piers.

Two reinforced concrete ballast deck trestles were built, one of these trestles being 660 feet long and the second being 340 feet long. One 50-ft. reinforced concrete arch and one 40-ft. reinforced concrete culvert were also built. The reinforced concrete structures were all designed for Cooper's E-40 loading.

Pile deck trestling to the extent of 11,147 feet (equal to 2.1 miles) was built. The longest single trestle is across the Chambers Creek bottom, where the total length of opening is 1660 feet. The trestles were severely tested during the record floods in December, 1913, but they withstood the strain without damage. These floods demonstrated the necessity for large openings.

There are three terminal and three intermediate substations. The terminal substations are each equipped with two 400-kw. three-piece motor-generator sets, designed so as to deliver both 600-volt and 1200-volt direct current. The three intermediate substations and the portable substation are each equipped with one 400-kw. two-piece motor-generator set, designed to deliver 1200-volt direct current only. There are also two 300-kw. 600-volt sets in the Waco substation, these sets being used for city service.

Alternating current at 2300-volts and 60 cycles is delivered to the Traction Company at the different switchboards by the Texas Power & Light Company. The terminal substation at Waco is in the power house of the Texas Power & Light Company, and the other terminal stations and the intermediate stations are located in brick buildings measuring 40 feet by 50 feet overall with a clear inside height of 15 feet. These different substations are approximately 30 miles apart, and are located as follows:

The terminal substation in the Texas Power & Light Company's power house on the Brazos River, Waco.

Terminal substation at the city limits of Corsicana.

Terminal substation at the intersection of the Waco and Corsicana Lines, about 1 mile south of the Dallas city limits.

Intermediate substation, at Ennis, midway between the Dallas and Corsicana substations.

Intermediate substation just south of the City of Waxahachie.

Intermediate substation at Hillsboro.

The substations are all connected with 350,000 cir. mil. copper cable, and this cable is provided with cutout switches about midway between substations.

No. 0000 trolley wire is used and catenary construction is adopted outside the city streets, where a greater span construction is necessary.

The standard poles are of Idaho cedar, 35 feet in length, having 9-inch tops, and spaced 150 feet apart on tangents, but at a shorter spacing on curves. Eleven-point suspension was used with long bracket steady-braces.

The interurban cars consist of twenty-two passenger motor cars, each having an overall length of 53 feet 6 inches, an overall width of 9 feet, and a seating capacity of 56 persons; ten trail cars 54 feet 2 inches long, 9 feet wide, seating 54 persons; six motor express cars measuring 50 feet by 9 feet overall; two express trail cars with same size bodies, and two motor work cars.

Each interurban motor car is provided with four 100-h.p. motors and has a switch so that it can be operated at full speed on either 600-volt or 1200-volt direct current. The passenger motor cars have single-end control and the express motor cars are provided with double-end control. All the cars have electric heaters and both air and hand brakes.

Current at 600 volts is used within the city limits of Dallas, Corsicana and Waco, and 1200-volt current on the remainder of the system. The city cars on the four miles of city track in Waxahachie are also operated on 1200 volts.

The selector telephone system was adopted and two complete circuits (four wires) are carried the full length of the lines. No. 10 B.&S. copper wire with porcelain insulators was used throughout, and each telephone is protected by a transformer.

There are three railroad crossings where the grades could not be separated and these crossings are protected with derails and with an interlocking device designed to be operated by the conductor. The device is arranged so that the derail cannot be closed until after "danger" signals have been set on the steam line, and these "danger" signals cannot be set if there is a train within 2000 feet of the crossing unless released by a time lock which is set so as to release in thirty seconds.

# CRITICAL SPEEDS OF RAILWAY TRUCKS

By E. F. W. Alexanderson

Consulting Engineer, General Electric Company

The author deals with the theoretical considerations governing the critical speed of railway trucks, and it should be borne in mind in reading this article that the conclusions arrived at refer to trucks only and not to a car or locomotive as a whole. Critical speeds of railway equipment are of the utmost importance to the designing engineer, and the author therefore gives considerable attention to the phenomenon of "nosing," making an extended mathematical analysis of the critical speeds of railway trucks with different arrangement of motors.—Editor.

E. F. W. Alexanderson

THE theoretical possibilities for the application of electric power are wonderfully broad, and the fundamental theory for the phenomena which are dealt with in the design of electric power machinery is so simple and so well known that calculations and conclusions do usually not need to be confirmed by tests. In the construction of almost any electrical machinery, the designer therefore finds that his limitations are not in what can be accomplished by electric current, but in what it is permissible to do from the mechanical point of view with the material with which he must deal. The mechanical phenomena which constitutes these limitations are usually so involved that it is scarcely ever attempted to base a design on theoretical considerations; results are arrived at by the method of "cut and try," with the application of large factors of safety. On the other hand, it is being more and more fully realized that the different mechanical problems that are encountered in the design of high speed machinery cannot be approached at all without a reasonable understanding of the fundamental physical principles which control the operation of such machines. One of these considerations is the so-called "critical speed," or mechanical resonance. The phenomenon of critical speed can usually be determined with a considerable degree of accuracy if exact data of the physical properties and dimensions of the material that is used are available. The critical speeds that must be considered in the design of high speed rotating machines like turbo-alternators are of the same nature as the pendulum movement, and the pre-determination of this phenomenon is the subject of the same mathematical principles as the pendulum.

The subject of this article is the analysis of another form of critical speed, which, in its nature is quite different from the pendulum movement. Although it has been known for a long time that it is dangerous to run a railway truck beyond certain speeds, it is not generally realized that the movement of a railway truck is subject to a critical speed and that this critical speed can be predetermined mathematically from the dimensions and inertia of the truck and from the clearance between the flange and the rails.

The danger in operating any railway truck at high speeds is primarily due to the approach of the critical speed. Here it must be realized that if the term "critical speed" is used for the danger point for the railway truck, the nature of the action differs from the critical speeds which have the character of pendulum movement inasmuch as the pendulum effect appears only at a certain speed, beyond which it disappears again, while the critical speed of a railway truck is the speed at which mechanical oscillations become accumulative, and operation beyond this speed becomes more and more dangerous because the oscillations are limited only by the physical strength of the material in the track. The oscillations which appear at the critical speed of a truck are usually known as "nosing," and this phenomenon was first brought to general attention by experiments on the high speed car of the Berlin-Zossen Railroad. As a matter of record, it is probably remembered by most railway engineers interested in electric traction, that the experiments of the first year had to be discontinued on account of the severeness of the nosing at speeds which were considerably lower than those at which it was intended to run. During the next year the truck was rebuilt on extremely strong foundations, and with the use of a truck that fitted the track with great exactness it was possible to carry out the experiments. However, it was undoubtedly these mechanical difficulties that were responsible for the fact that the Berlin-Zossen experiments never become the starting point of any practical developments.

The nature of the phenomenon which is known as "nosing" is substantially as follows:

If the truck at some particular moment is in position on the track so that it runs towards one rail at a slight angle, the front wheel, when it strikes the rail, will be reflected by an elastic blow and the truck turned around on the track so that it will be headed towards the opposite rail at a greater angle. When the truck hits the other rail it will be reflected again in a still greater angle, and this action will become accumulative until the maximum angle is reached at which the truck can stand on the track within the limitations of the clearance between the flange and the rail. The reasons why the truck is reflected at a greater angle than the angle of impact are given in the theoretical analysis following: It is found in this analysis that contrary to the ordinary conceptions of the mechanical reflection of a single object, like a ball, the angle of reflection may be greater or smaller than the angle of impact. In order to understand in a general way, the phenomenon of "nosing," it may be sufficient to know that a certain truck when striking the track will be reflected at a greater or smaller angle than the angle of impact, depending upon the speed at which it strikes and the angle of impact. For instance, if a certain truck running at 60 m.p.h. strikes the rail at an angle of 1 deg., it may be reflected at an angle of 1 deg. At speeds greater than 60 m.p.h. it would be reflected by more than 1 deg., and at speeds less than 60 m.p.h. it would be reflected by less than 1 deg. If on the other hand the truck strikes the track at an angle of ½ deg., a speed of 85 m.p.h. would be required to reflect the truck by ½ deg. From these considerations it is apparent that if the clearance between the flange and the rail is such that the maximum angle at which the truck can stand on the track is 1 deg., the critical speed of nosing is 60 m.p.h. This means that at all speeds below 60 m.p.h. the angle of reflection must be smaller than the angle of impact, because the maximum angle at which the truck can strike the track is 1 deg. If the truck runs at a speed above 60 m.p.h., the truck may strike the track at an angle of nearly 1 deg. and there may be a tendency for it to be reflected at an angle of 1 deg. or more. Inasmuch as it is not possible for the truck to be placed at more of an angle than 1 deg., it follows that a part of the energy of the first impact is left over to increase the force of the second impact; thus the truck will be kept in a continous state of oscillation, reaching in each swing the maximum angle which is permitted by the track clearance.

The factors that determine the critical speed for any particular truck are the inertia of the truck, the distribution of masses in the truck, the frictional resistance between the wheels and the rail, length of the wheelbase, and the flange clearance.

When the front wheel of the truck strikes the rail it rebounds by an elastic blow and the truck receives a rotating movement around a certain point on the other side of the king pin, which in the following discussion will be called the center of rotation. The first step in the calculation is to determine the distance from the front wheel to the center of rotation. This is done by a consideration of the distribution of the masses in the truck and also the mass of the car which is attached to the king pin. For the sake of calculating the movement of the truck it is sufficient to consider the car as a single weight attached to the king pin. The mass of this weight is calculated separately from the distribution of masses in the car and will be called the equivalent mass of the car referred to the king pin. After the center of rotation has been determined, the inertia of the truck and the mass attached thereto can be calculated with reference to the center of rotation. Thus it will be seen that the glancing blow of the truck against the rail will give the truck a rotating movement around its center of rotation, and the kinetic energy of this rotating movement depends upon the angular velocity and the inertia of the truck with reference to the center of rotation. The rotating movement of the truck is possible only by the sliding of the wheels on the track and therefore the kinetic energy of rotation can be given to the truck immediately after the blow is used up by the friction of the truck and rails. The kinetic energy is proportional to the square of the initial angular velocity, whereas the energy absorbed by friction is proportional to the frictional torque and the angular movement. Thus it is apparent that the sliding movement, which continues until all the energy is used up, will cover an angle which is proportional to the square of the initial angular velocity. On the other hand the angular velocity is proportional to the speed of impact and the angle of impact. Thus it is apparent that if the angle of impact is twice as great in one case as in another, the speed being the same, a sliding movement will result which will cover an angle four times as great. Similarly, if the angle of impact is the same, but the speed is twice as great, the resulting angular movement will also be four times as great. If the above reasoning is expressed mathematically, an equation can be derived giving the relations between the angle of impact, the angle of reflection, the inertia of the truck and the frictional resistance.

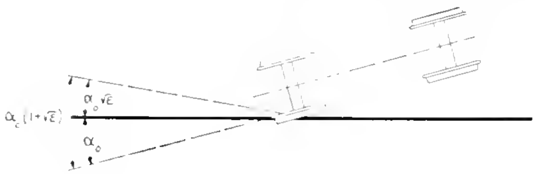


Fig. 1

### Mathematical Analysis of Critical Speed

$I$ = inertia of truck around center of rotation.

$T$ = frictional torque around center of rotation.

$W$ = weight on the wheels.

$B$ = wheel-base.

$R$ = center of from wheel to center of rotation.

$\delta$ = flange clearance.

$V$ = velocity of truck in meters per second.

$\alpha$ = angle of impact.

$\omega_0$ = initial angular velocity.

If the wheel strikes a perfectly elastic blow, it is apparent from diagram, Fig. 1, that the initial angular velocity after rebound is

$$\omega_0 = \frac{2V\alpha_0}{R};$$

or if the blow has an elastic co-efficient $\epsilon$

$$\omega_0 = \frac{(1+\sqrt{\epsilon})V\alpha_0}{R}$$

Substituting,

$$\alpha_0 = \frac{\delta}{B}; \quad \omega_0 = \frac{(1+\sqrt{\epsilon})\,V\,\frac{\delta}{B}}{R}$$

Furthermore, we know

$$T = -\frac{d\omega}{dt}I$$

Integrating this equation we get

$$t = -\frac{I}{T}\omega + C_1 = \frac{I}{T}\frac{d\alpha}{dt} + C_1$$

and integrating again

$$\frac{1}{2}t^2 = -\frac{I}{T}\alpha + C_1 t C_2$$

Substitute for determination of integration constants,

$$\omega_0 = \frac{(1+\sqrt{\epsilon})\,V\,\frac{\delta}{B}}{R}$$

we get the time for the complete movement

$$t = \frac{I}{T}\,\frac{(1+\sqrt{\epsilon})\,V\,\frac{\delta}{B}}{R}$$

Substituting this value for "$t$" in the second equation,

$$\frac{1}{2}\left(\frac{I}{T}\,\frac{(1+\sqrt{\epsilon})\,V\,\frac{\varrho}{B}}{R}\right)^2 = \frac{I}{T}\alpha$$

the condition for critical speed is:

$$\alpha = 2\alpha_0 = 2\frac{\delta}{B}$$

Hence the equation determining the critical speed is:

$$\frac{1}{2}\left(\frac{I}{T}\,\frac{(1+\sqrt{\epsilon})\,V\,\frac{\delta}{B}}{R}\right)^2 = \frac{I}{T}\,2\,\frac{\delta}{B}$$

This equation solved for "$v$" gives the general expression:

$$v = \sqrt{\frac{T}{I}\,\frac{B\,R^2}{\delta\,(1+\sqrt{\epsilon})}}$$

The formula becomes more convenient to use if the equivalent mass at the front wheel is substituted for inertia in accordance with the relation:

$$I = m\,R^2 = \frac{P}{9.8}\,R^2$$

where "$P$" is the mass in kilograms, the expression for critical speed thus becomes:

$$v = \sqrt{\frac{T}{P}\,\frac{B}{\delta\,(1+\sqrt{\epsilon})}}$$

"$T$" is the frictional torque of the wheels opposing the sliding movement. If the weight on the two axles is equal, $T$ is the same regardless of the center of rotation and can be expressed:

$$T = \frac{Wf}{B}$$

where "$W$" is the weight on the wheels and

"$f$" the co-efficient of friction. Thus we get

$$\text{Critical speed } V = B\sqrt{\frac{W}{P} \cdot \frac{9.8\, f}{\delta\,(1+\sqrt{\epsilon})}}$$

In this expression the quantities "$W$" and "$P$" are definitely known and can be calculated from the design, whereas the quantities "$F$," "$S$," and "$E$" depend upon local conditions of track. Inasmuch as the object of this treatise is to analyze and compare designs irrespectively of conditions of track, it is permissible to substitute numerical values that are representative of average conditions of track. Thus, it will be assumed:

Co-efficient of friction $f = 0.2$
Elastic co-efficient $\epsilon = 0.75$
Flange clearance $\delta = \frac{7}{16} = 0.011$ meter.

Hence, we get:

$$\frac{9.8\, f}{\delta\,(1+\sqrt{\epsilon})} = 94$$

or in round figures, 100.

Hence, we get the simple expression for critical speed

$$V = 10\, B\sqrt{\frac{W}{P}}$$

where "$B$" is the wheel base in meters,
"$W$" weight on the wheels in kilograms,
"$P$" equivalent mass at front wheel in kilograms.

Reduced to the English system this formula becomes:

Critical speed $V_c = 72\, B\sqrt{\frac{W}{P}}$ miles per hour, the units being feet and pounds.

**Shock on Track**

The shocks on the track can be expressed by the product of mass and velocity, $MV$

The mass $M$ is the equivalent mass at the front wheel designated $P$

The velocity of the shock at the critical speed is·

$$v_s = V_c \frac{\delta}{B}$$

Hence the shock

$$= P\, V_c \frac{\delta}{B}$$

At any definite speed between the critical speed the shock is proportional to the square of the ratio of the running speed to the critical speed. This assumption is based on the approximation that the angle of oscillation is proportional to the speed, and hence the velocity of impact proportional to the square of the speed.

The ratio of running speed to critical speed will be expressed by $\frac{V_r}{V_c}$

Hence, we get the shock on track at running speed $V_r$

$$\text{Shock} = \left(\frac{V_r}{V_c}\right)^2 P\, V_c \frac{\delta}{B}$$

which, reduced to numerical values for an average track, becomes

$$\text{Shock} = 1.1\, V_r^2 \frac{P}{B^2}\sqrt{\frac{P}{W}}\, 10^{-3}$$

and in English units

$$\text{Shock} = V_r^2 \frac{P}{B^2}\sqrt{\frac{P}{W}}\, 10^{-3}$$

where "$V_r$" is running speed in miles per hour.
"$P$" = equivalent mass at front wheel in pounds.
"$B$" = wheel-base in feet.
"$W$" = weight on wheels in pounds.

The following is a numerical calculation of the characteristics of a truck in a specific case. The specifications of the trucks are as shown in Fig. 2. The inertia mass of the car body referred to the king pin is calculated on the assumption that the car is designed on the principle that the other king pin should be the center of rotation for any oscillations of the car body resulting from shocks on the king pin. The equivalent mass of the car body is assumed to be rigidly attached to the king pin. For the critical speed and shocks on the track, one calculation is made assuming that the truck is spring-connected to the car body so that is is free to move and another calculation is made under the assumption that the truck is rigidly attached to the car body. The facts will lie somewhere between these two extreme assumptions.

**Specifications of Truck with One Motor**

| | |
|---|---|
| Wheel-base | 69 in. |
| Weight of truck | 9,000 lb. |
| Weight of motor | 4,100 lb. |
| Weight on wheels | 40,000 lb. |
| Inertia weight of car at king pin | 27,400 lb. |

Distribution of masses is shown in Fig. 2.

**Radius of Gyration**

$$13100\, r^2 = (42^2 \times 3600) + (10^2 \times 4100) + (27^2 \times 5400)$$

$$13100\, r^2 = 10{,}720{,}000$$

$$r = 28.6.$$

**Center of Rotation**

$$f_1 = F/2 \times \frac{27}{28.6} = 0.477\ F$$

$$f_1 + F/2 = 0.977$$

$$F/2 - f_1 = \frac{0.023}{0.954}$$

$$\frac{R + 1.6}{0.977} = \frac{2 \times 28.6}{0.954}$$

$$R = 2 \times 28.6\ \frac{0.977}{0.954} - 1.6 = 57 \text{ in.}$$

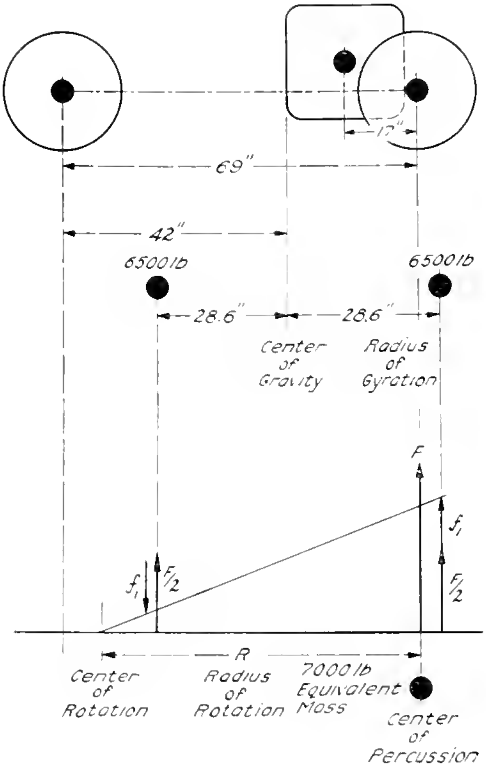

Fig. 2

**Equivalent Mass of Truck at the Wheel**

$P \times 57^2 = 6550 \times 58.6^2 + 6550 \times 1.4^2$

$P = 7000$

Similarly it can be figured that the combined mass of the truck and the car is 8700 lb.

Substituting the figures thus found in the formula for critical speed:

$P = 7000 = 3200$ kilograms

$W = 40{,}000 = 18200$ kilograms

wheel-base $= 69$ in. $= 1.75$ meters

$$v_c = 10 \times 1.75\ \frac{18{,}200}{3200}$$

$v_c = 43$ meters per second

$= 97$ miles per hour.

**Shock on Track**

Shock on track at 45 m.p.h. = 20 meters per second

$$= \frac{3200}{1000}\ \frac{20^2}{1.75^2}\ \frac{3200}{18{,}200}$$

= 170 kg. meters per second

= 1220 lb. foot-seconds.

Similarly we find for truck rigidly connected to the car.

Critical speed = 85 m.p.h.

Shock on track at 45 m.p.h. = 1730 lb. foot-seconds.

In order to illustrate the results that are obtained by using the above described method for analyzing the running qualities of a truck, a table is given showing the principal characteristics of a typical railway truck with motors suspended in different ways. Three characteristic methods are shown for the suspension of the motors, viz.: The ordinary arrangement of two inside-hung motors, one inside-hung motor, and one motor outside hung. (Table on opposite page.)

The two characteristic figures that must be examined in order to judge the running qualities of a truck are the mass of the truck referred to the front wheel and the critical speed. The mass referred to the front wheel is calculated without any arbitrary assumption and is determined from the well known principles for inertia and unsymmetrical shock. The critical speed is calculated in accordance with the principles outlined above.

The conclusion that can be drawn from the figures for the mass and critical speed are, in general, that the higher the mass and the lower the critical speed, the harder will be the shocks on the track at any speed. In order to combine the conclusion from the figures for mass and critical speed, a figure is given for the shock on a track at 45 m.p.h. This has an intermediate speed which is of interest for high speed as well as low speed equipments. In order to arrive at this figure for shock, an assumption has been made which cannot be mechanically proven to be exact, but ought to be a fairly close approximation to facts. This assumption, as stated above, is that the oscillations of the truck are directly proportional to the speed, and reaches the maximum value at the critical speed. Thus, if the critical speed is 50 m.p.h. the angle of oscillation at 45 m.p.h. would be 90 per cent of the maximum, whereas if the critical speed were 100 m.p.h., the angle of oscillation would be only 45 per cent of the maximum at 45 m.p.h. On the basis of this assumption, the shock on the track at any speed can be expressed in mechanical units. The units for the shock is the product of mass and velocity, and therefore the shocks are expressed in units of one pound at one foot per second.

In arriving at these figures, the weight of the car, as well as the weight of the truck, has been taken into account. However, the car is attached to the truck with a semi-flexible connection, and therefore the shock resulting from the weight of the car cannot be as great as the shock resulting from the truck itself. In order to determine the limits of error introduced by this unknown factor, all the figures are given in two ways; viz.: With a perfectly rigid connection between the car and truck and with a perfectly flexible connection. It will be seen that these two extreme limits give results which are not very far apart, and the true value which must lie between these limits can be determined with fair accuracy.

Inasmuch as the phenomena referred to are not subject to measurement with any degree of accuracy, or at any rate only under great difficulties, it is hoped that the method for analyzing the running qualities of trucks, as presented in this paper, will be of some value to the designers in comparing the merits of the different constructions. The object of this analysis will have been accomplished if a practical method is provided for arriving at relative values for the sake of comparison.

| Type of truck | | Two motors—inside-hung | | One motor—inside-hung | | One motor—outside-hung | |
|---|---|---|---|---|---|---|---|
| Connection between truck and car | | Flexible | Rigid | Flexible | Rigid | Flexible | Rigid |
| Wheel-base | B | 6 ft. 6 in. | 6 ft. 6 in. | 5 ft. 9 in. | 5 ft. 9 in. | 5 ft. | 5 ft. |
| Weight on wheels in lb. | W | 40,000 | 40,000 | 40,000 | 40,000 | 40,000 | 40,000 |
| Equivalent mass at front wheel in lb. | P | 8,000 | 9,700 | 7,000 | 8,700 | 14,000 | 15,000 |
| Critical speed in m.p.h. | $7.2\, B\sqrt{\frac{W}{P}}$ | 99 | 91 | 94 | 84 | 58 | 56 |
| Shock on track at 45 m.p.h. lb. × ft. per second | $0.0078 \times 45^2 \times \frac{P}{B^2}\sqrt{\frac{P}{W}}$ | 1,330 | 1,800 | 1,400 | 1,940 | 5,200 | 5,800 |

# CURRENT COLLECTION

By F. E. Case

Engineer, Railway Equipment Department, General Electric Company

Both the European and American current collecting devices are reviewed in this article and considerable attention is paid to the collection of large currents and the development of pantograph trolleys for higher direct current voltage installations. A great deal of study has recently been given to the details of construction of both overhead structures and current collecting devices, and has led to the development of pantograph trolleys that can successfully collect the large currents necessary in heavy traction work.—Editor.

F. E. Case

The long familiar overhead trolley wire is almost universally used for the conduction of current to the collectors of cars used in city street service.

On account of local requirements in the cities of Washington, D. C., New York, London, Paris and a few other places, cars operating in the streets collect their current from two iron rails partly enclosed in a conduit located in the road bed between the running rails. The cost of such an installation is prohibitive except where the density of traffic is very great and local restrictions prevent the use of the trolley.

Many interurban roads use the trolley, some from preference, but more of them on account of the major portion of their lines being along highways, where a contact rail could not be installed.

Practically all 600-volt roads in this country which are operating heavy cars in trains over private rights of way exclusively, use the contact rail and shoe on account of their great simplicity and reliability.

## European Development

For many years some European manufacturers have furnished sliding bow collectors for the same operating conditions under which the trolley wheel is used in this country. The collector contact is usually an aluminum bar several feet long with a groove in its upper face in which a mixture of graphite and grease is placed for lubricating purposes.

There is nothing very special in the trolley line construction under which these bows are used, although it is necessary to provide a smooth under-run for the bow by avoiding suspension and pull-off points lower than the trolley wire. The wire is also staggered to prevent notches being worn in the bow.

The adoption of high voltage alternating current for electrified steam road and other heavy service made it necessary to provide a current collector which would better fulfill the conditions of operation. A contact rail, lying near the ground, could not be considered on account of the apparent impossibility of properly insulating it and maintaining a sufficient protection of life.

It was desirable, first, to continuously maintain a proper contact with the wire at all speeds in order to avoid sparking; second, to permit operating the cars or locomotives in either direction without lowering the trolleys or turning them around on a pivot; and third, to obtain a reasonable life of contact and trolley wire. The final result was the pantograph trolley.

Many of these trolleys are supplied with a single bow contact. This bow is from five to seven feet long and pivoted at its ends to the pantograph frame. Owing to the movement of the bow about its pivoted points, which are about twelve inches below the top, the contour of the wearing surface assumes an arc of a circle. The contact bar is of aluminum with a small percentage of copper for slightly hardening it. It is made as light as possible in order to reduce its inertia to a minimum and thereby permit operating with a light pressure against the wire. The auxiliary springs give an upward pressure of about eight pounds. If a much higher pressure was used the life of the aluminum contact bar would be greatly reduced, owing to the small area in contact with the wire.

This low contact pressure necessitates a very flexible suspension of the trolley wire, and the elimination of sags between points of support. To accomplish this the trolley wire is suspended from a secondary, or messenger wire at intervals of from ten to fifteen feet. This general method of hanging is used to some extent in this country and it practically eliminates the sag in the trolley wire as the points of support are so close together. The trolley wire is hung by loose links from the messenger wire, which permits a certain amount of vertical flexibility absent in older forms of suspension.

Continental experience demonstrated that to secure the maximum life of the trolley wire with a collector bow of the type adopted, it was necessary to use a relatively soft metal for the bow contact and provide for lubricating it. Also, that to prevent grooves being worn in the contact surface, and to distribute the wear to the best advantage, the trolley wire should be staggered from one side of the track center line to the other. In several recent installations the amount of this staggering has been at the rate of one meter per 100, necessitating the use of a very long bow contact.

Many of these catenary trolley installations use automatic tension adjusters, which maintain a substantially constant strain on the trolley wire at all temperatures. As the difference in length of the copper wire between summer and winter is about six feet per mile it is evident that the automatic device has at least a theoretical advantage in preventing excessive strains in winter and too much slack in summer.

The current collecting capacity of a single bow is about 150 amperes maximum for ordinary railway locomotive service, and a life of about 5000 miles is obtained where the trolley wire has a total stagger of three feet.

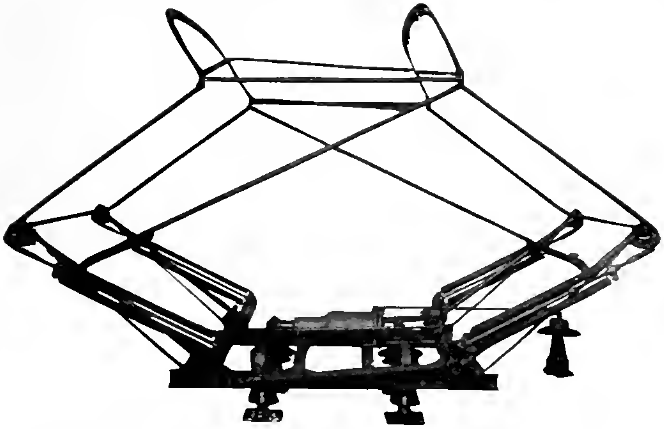

Fig. 2. A European Double-Contact Pantograph

Many high speed locomotives have been equipped with two pantograph trolleys for simultaneous operation in order to insure a continuous contact with the trolley wire. Recently, however, pantograph trolleys have been provided with two independent bow contacts for accomplishing the same purpose.

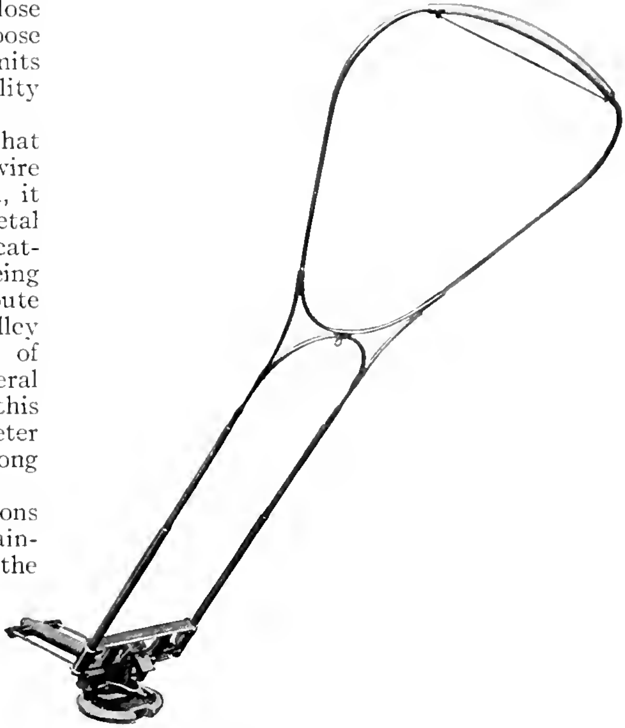

Fig. 1. A Foreign Bow Trolley for Light Service

### American Development

The trolley wheel has been extensively used in this country in a class of service where it has been taxed to its uttermost capacity. Several roads are operating cars equipped with four 125-h.p. 600-volt motors, the current being collected with a trolley wheel. The life of the wheel under these conditions is naturally much less than when operating on smaller cars and collecting less current.

No material changes have been made in the trolley wheel during the past decade. Improvements have been made in the method of lubrication, the collecting springs at the ends of the hubs and other minor features. The shape of the groove and the general dimensions of the wheel are practically fixed by the size of the trolley wire and the form of overhead frogs and crossings. It, therefore, appeared impossible to develop a trolley wheel having a materially larger collecting capacity and for this and other reasons, which will be discussed later, a different form of collector was found necessary.

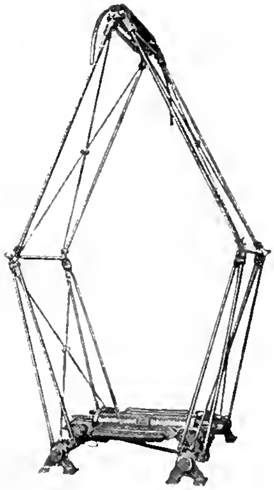

Fig. 3. A Roller Contact Pantograph

With some of the first high voltage a-c. car equipments put into service in this country, the ordinary trolley wheel was used. A form of bow collector was afterward tried but eventually it was abandoned in favor of a pantograph trolley having a thin steel collecting pan. It was found in several instances that this pan caused an excessive wear of the copper trolley wire, especially where grease was not used for lubricating it. This sheet steel pan has less collecting capacity than a trolley wheel and would not be at all suitable for heavy d-c. locomotives operating at even the highest voltage yet used.

Recent railway installations of 1200, 1500 and 2400 volts have in several cases used some form of the pantograph trolley.

The roller type of pantograph trolley has been successfully used for a number of years in the vicinity of San Francisco on heavy cars operating both singly and in trains on 600 and 1200-volt circuits.

Brass rollers five inches in diameter and twenty-four inches long were first used, but practice demonstrated that steel rollers gave a much greater mileage without apparently increasing the wear on the trolley wire. Steel roller contacts in operation upon cars and locomotives have given a life of over 15,000 miles in a service requiring the collection of 500 amperes during acceleration.

The roller contact pantograph, however, has less collecting capacity than a shoe sliding upon a rail, owing to its smaller area of contact, which is virtually no more than a point.

While the contact rail and shoe have such a decided advantage in regard to the quantity of current which can be collected, there are, in many cases, physical limitations which prevent their use, at least exclusively on 600-volt circuits. For elevated and underground railroads this method of conduction and collection has been used very successfully. For the electrification of existing steam roads, however, such questions as clearances in tunnels, over bridges and at congested terminals where there are numerous switches and cross-overs, frequently necessitate the use of a supplemental overhead conducting rail.

With the adoption of high operating voltages the general use of the contact rail, close to the ground, is questionable, as there would naturally be a certain amount of decreased reliability. A 1200-volt interurban road in California is, however, successfully operating over a portion of its line with an under-running protected contact rail. Prob-

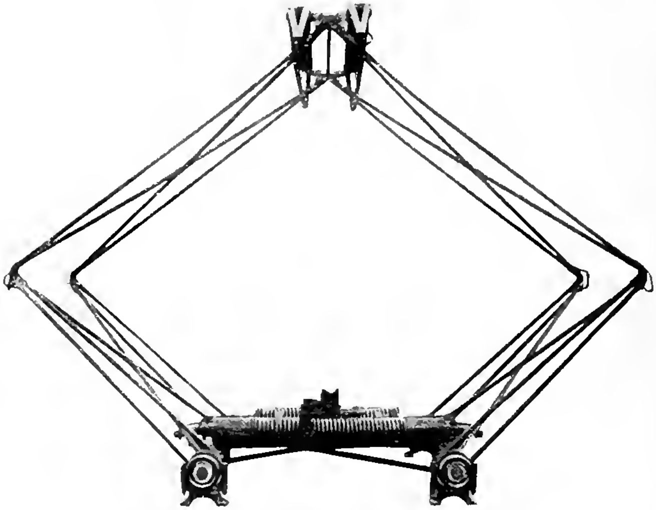

Fig. 4. A Double-Sliding-Contact Pantograph

ably this voltage is close to the reliable operating limit, but the other considerations previously mentioned may have a greater influence on the selection of the method for conducting current to the car or locomotive collectors.

Bearing in mind the limitations of the contact rail, and of the trolley wire collecting devices described, it was evident that a greatly improved form of current collection was necessary for use at increased voltages, currents and speeds.

Since the pantograph trolley possessed the advantages of not accidently leaving the trolley wire and requiring no attention when reversing the direction of train movement, it was logically chosen as the medium for supporting the collectors. The pantograph had the further advantage of being readily raised or lowered by the motorman.

The current collecting capacity of the contacts upon the existing pantographs had proved inadequate for this more severe service. Investigations and extensive life tests showed that a very material increase in the area of contact between the wire and collector was absolutely essential. It was further determined that copper contacts operating on a copper trolley wire were superior to other metals. Pantographs embodying these features have been operated in regular service and given excellent results. The copper bars are attached to pans of thin sheet steel about 42 inches long and 5 inches wide and cover approximately three-quarters of the upper surface. Pivoted arms between the pan and the pantograph frame permit the copper bars to maintain contact with the trolley wire for their full width. At the same time the arms provide for a quick movement of the contacts which enables them to rapidly follow small inequalities in the trolley line. Supplemental springs bring the pan into contact with the wire, giving a pressure of about ten pounds.

Two pans are used on each pantograph in order to insure a continuous contact with the wire and provide abundant capacity. Having two pans, permits increasing the upward pressure of the main springs of the pantograph to substantially double the amount which could be satisfactorily used with but one pan. This higher pressure makes the trolley as a whole more quickly responsive to sudden variations in height of trolley wire and ensures a more constant pressure of the contacts against the wire.

A pantograph trolley of this type has successfully collected 2000 amperes at speeds up to 40 m.p.hr. This current is more than a 0000 trolley wire can conduct for any considerable period without injurious heating.

To meet heavy service conditions, where one 0000 trolley wire would have insufficient conducting capacity, two parallel wires may be used. Such an installation has been tried with very satisfactory results. Not only is the conductivity of the overhead system doubled but the collecting capacity of the pantograph is greatly increased.

Several thousand car movements under a trolley wire with the pantograph collecting heavy currents produced a wear of the wire so slight as to compare most favorably with that obtained with the roller type of pantograph or trolley wheel when operating under their average conditions. It is essential for the successful collection of heavy currents, with this latest form of pantograph, to provide an overhead line possessing uniform flexibility.

The wear of the contacts and trolley wire is materially decreased by the use of a lubricant. Staggering the wire distributes the wear more evenly over the surface of the contacts and gives them a longer life. The side sway of the car or locomotive, together with the lateral variations in the position of the trolley wire on tangent track and curves also distribute the wear. Local conditions determine how much staggering, if any, is necessary to give the most economical life of contact. With a proper installation the contacts should wear at least three or four times as long as a good trolley wheel and at the same time collect a considerably greater amount of current.

# A REVIEW OF SOME EUROPEAN ELECTRIC LOCOMOTIVE DESIGNS

By S. T. Dodd

Railway and Traction Engineering Department, General Electric Company

The author makes a valuable analysis of European electric locomotive design and discusses not only the details of construction but also the general tendencies prevailing abroad that have led to the acceptance or rejection of particular types. The design of the electric locomotives for the Prussian State Railways, the Silesian State Railways, Baden State Railways, the Midi Railway of France, the Loetschberg Tunnel, the Simplon Tunnel and the Italian State Railways are all reviewed and discussed. The author comes to the conclusion that the development of electric locomotives in America has been more conservative and productive of more economical results than that in Europe.—Editor.

S. T. Dodd

In a number of discussions on electric locomotive design the writer has encountered arguments, based on European practice, pointing to the advantage of the side rod drive. This type of design has been repeated so frequently in European locomotives that it is quoted as showing the satisfaction with which it is regarded by Continental engineers.

In the following article the writer has attemped to analyze the conditions and tendencies of electric locomotive design in Europe. The object of this analysis is to attempt to show the extent to which various European locomotive designs have been satisfactory or otherwise, as indicated by the reports which have been published of tests on experimental types and as shown by the latest types ordered and built by European manufacturers. The study is not based on personal observations of the locomotives under discussion, but on a general review of the articles which have been appearing in the technical press during the last few years, and it gives the personal impressions obtained by the writer from such a review.

In making such a study it must be noted that the development of electric locomotives in Europe has been influenced by certain considerations differing from those that obtain in this country, and that must be kept in mind if one is to appreciate facts in their proper relations. The most important of these might be classed as follows:

(a) The influence of preconceived engineering opinions.

A good illustration of this is given by an extract from the *A. E. G. Journal* of April, 1912.

> "The two requirements already known from steam locomotive practice, namely, a high center of gravity, and the use of a parallel crank drive were already adopted for electric locomotives in the year 1902."

The fact is that on the Prussian State Railways at least the satisfactory performance of high speed steam locomotives largely determined the mechanical design of the first electric locomotives. It was planned merely to replace the boiler and fire box of the steam locomotive with an electric motor and to retain as far as possible the mechanical arrangement and method of drive of the steam locomotive. The least that can be said of such a decision is that the arrangement referred to is still open for discussion in the year 1914, and an arbitrary decision on this point 12 years ago must have tended to retard rather than to advance engineering practice.

(b) The large number of experimental locomotives built for the purpose of determining the preferred type.

Illustrations of this are to be seen in nearly every experimental electrification referred to. The European railways are largely state owned and very possibly political considerations often demand that orders for sample locomotives of practically the same type should be placed with a large number of different manufacturers. No other than political reasons would seem to justify increasing the cost of electrification with experimental locomotives to the extent that seems customary in Europe.

(c) The premature publication of locomotive designs.

The large number of manufacturers building electric locomotives and the keen competition between them seem to cause them to advertise, as contracts, orders for locomotives which are in many cases only tentative, and to describe in technical articles designs which are more or less experimental and which are changed before the locomotives are fully completed. This tendency is rather misleading to one studying European locomotives if he starts out under the impression that all designs of locomotives described in the technical press are actually built, and in successful operation.

Keeping these considerations in view we will review briefly the results of some of the most important electrifications.

### Prussian State Railways

In accordance with a law passed in 1909 it was decided to begin the electrification of the Prussian State Railways upon a stretch connecting Magdeburg, Leipsic and Halle, the total length of line being about 100 miles. As an experimental equipment to determine the types of locomotives to be selected for various classes of service, a length of 16 miles from Dessau to Bitterfeld was first electrified and equipped with locomotives. On this experimental piece of track some 12 or 15 different locomotives have been tried out.

Fig. 1 shows the experimental type of locomotive ordered for high speed passenger service. This is a 2-B-1 locomotive. A classification which indicates that it has two leading axles, two driving axles and one trailing axle. It is equipped with one large motor driving, through vertical connecting rods, a jack shaft which in turn is connected to the driving wheels through horizontal side rods. Of this type three locomotives were purchased from three different manufacturers. Each of these locomotives had a weight of approximately 75 tons with 35 tons on drivers and were to be designed for maximum speeds of about 80 miles per hour. The reports which have reached us regarding the operation of this type is that it was very successful as far as its ability to make high speeds without serious vibration was concerned. There does not appear to have been any development of the "critical speeds" which limit the operation of many other types of side rod locomotives, but some difficulties have occurred in the breakage of cranks and jack shafts. It will be noted that the connecting rod is vertical and at right angles to the side rods on the same side of the locomotive. As a consequence all the forces transmitted through the connecting rods on one side must be transmitted through the jack shaft to the side rods on the other side. The jack shaft is, therefore, subjected to a series of suddenly applied reciprocating torsion strains and these strains were regarded as the explanation of the breakages which occurred. A very liberal design of jack shafts and cranks, and great care in alignment of bearings, have not been sufficient to entirely eliminate this trouble, and in spite of the ease on the track and the successful high speed operation of the locomotive, it seems to be questionable whether this type will ever be duplicated.

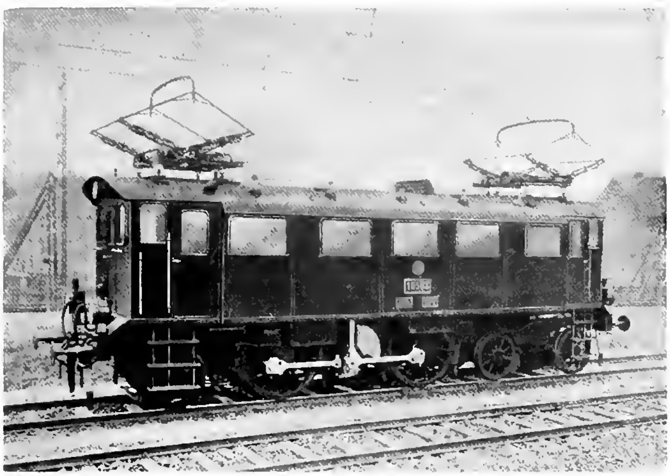

Fig. 1. Dessau-Bitterfeld Experimental Line. High speed passenger locomotive. Side rod drive with vertical connecting rods

In place of this for express service it has been decided to try a 1-C-1 type with three driving axles and two idle axles. Orders have been placed for four sample units of this type, although according to the latest information received by the writer only two had been delivered. No photographs have been published and no very definite information as to the results of the tests of this type have been obtained. Each of these locomotives is equipped with one motor of 1000-1800 h.p. The motor is placed high in the cab and drives, by a connecting rod slanting approximately 45 degrees, to a jack shaft, from which the power is transmitted through side rods to the driving wheels. The experiments upon the passenger locomotive, Fig. 1, seem to have eliminated the consideration of vertical connecting rods and to have determined that the connecting rod should have as much slant as possible in order to reduce as far as possible the reciprocating torsion strains in the jack shaft.

Fig. 2. Dessau-Bittersfeld Experimental Line. Freight locomotive with side rod drive

The experimental freight locomotive is shown in Fig. 2. This is an O-D-O type; i.e., it has no leading axles, four driving axles and no trailing axles. It is a slow speed locomotive weighing 70 tons with a rated speed of 15.5 m.p.h. and a maximum speed of 37.5m.p.h. Of this type seven units have been ordered of five different manufacturers of which five have been delivered. Looking at the subject from an American standpoint, it is a little surprising that it should have been thought necessary to do as much experimental work on this type as is indicated by the number of units ordered. There is every reason to expect that at such speeds almost any type of electric locomotive would be perfectly satisfactory. In fact, it is difficult to see the reason why a high placed motor and side rod drive should have been considered necessary for freight service. The reasons usually adduced as demanding a high center of gravity do not apply at such speeds as are attained in freight service, and the uniform success of the slow speed geared locomotive for freight work would have led to the supposition that a straight geared motor would have been selected without question for this work.

As a result of the experimental work extending over about four years, the Prussian State Railways have decided to proceed with the electrification of the whole Magdeburg-Leipsic-Halle line and have placed their order for 36 locomotives for this electrification. Of this order 26 are for medium or low speed service, and the type of locomotive selected is shown in Fig. 3. This is a geared side rod locomotive classified as a B-B type; i.e., one having two independent trucks each of which has two driving axles. It is equipped with two motors each geared to a jack shaft, which in turn is connected to two driving axles through a Scotch yoke or slotted side rod. The locomotive can develop 600 h.p. at a speed of 13 m.p.h. and is capable of maximum safe speeds of a little over 30 m.p.h.

In addition to the locomotives described above, various other types have been tested on the Dessau-Bitterfeld for the State Railways of Silesia, Baden and Bavaria. It appears that practically all the high speed, direct drive, side rod locomotives tested have given more or less trouble from developing "critical speeds" and by breaking rods, cranks and crankshafts under some conditions.

It is difficult for one not in personal touch with the developments to speak authoritatively, but apparently the result of four years of experimentation and study on the Prussian State Railways has been to discredit the direct driven, side rod locomotive and to point toward some type of gearing and side rod or simple gearing as the most satisfactory drive for medium or low speed service, while

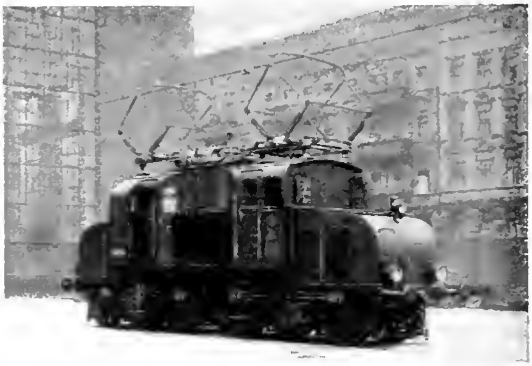

Fig. 3. Magdeburg-Leipsic-Halle Line. Medium speed passenger and freight locomotive. Motors geared to jack shafts with side rod drive

the type of locomotive for high speed or passenger service is not yet clearly indicated.

### Silesian State Railways

Another electrification of considerable extent is being undertaken at the present time by the State Railways of Silesia, the mountainous district of southeastern Germany near the Austrian border. The first section to be electrified is from Lauban to Konigzelt. This stretch is 81 miles in length and will later be extended to Breslau, a total distance of 125 miles. Trials of multiple-unit cars on this line were made on July 14, 1914, and it was then expected that regular multiple-unit service would be in operation before the end of the present year.

The Silesian roads traverse a mountainous territory with severe grades which demand heavy locomotives. The preliminary locomotive contracts and designs have evidently been largely influenced by the same considerations which affected the Prussian State Railways, and the first experimental locomotives for the line have been built and tested out on the Dessau-Bitterfeld experimental tracks. One of these locomotives is shown in Fig. 4. It is a 1-D-1 type with four driving axles, weighing over 100 tons, and driven by two large motors. The two motors are connected by sloping connecting rods to a common jack shaft which in turn is connected to the driving wheels through horizontal side rods. Two locomotives of this type by different manufacturers have been tested and according to all accounts have not given a very good account of themselves. Both these locomotives developed trouble from severe vibration at certain speeds, resulting in broken rods and cranks. Referring to this question of vibration the *Railway Gazette* (London) of October 24, 1913, says:

> "From these reasons it is probable that the heavy express locomotives for the mountainous district of the Prussian State Railways will not be of the type with an elevated motor and parallel crank action as was the first intention, but with two motors each of half the efficiency of the elevated one and with intermediate toothed gearing and sliding crank."

In addition to the two locomotives which have been built and tested for this line, a number of other interesting types have been proposed and described.

One of these is a C+C locomotive with two three-axle trucks, each of which is equipped with two motors geared to a common jack shaft which drives the three axles through horizontal side rods.

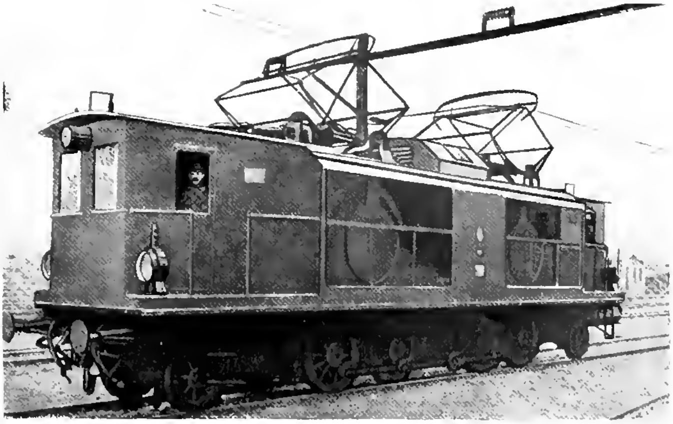

Fig. 4. Silesian State Railways. Heavy express locomotive with side rod drive

Another is a B+B+B locomotive with three two-axle trucks having one motor on each truck. The motor is geared to a jack shaft which drives the two axles through horizontal side rods.

Another is a AA+AA+AA locomotive also with three two-axle trucks, but having two motors on each truck. Each motor is geared directly to one driving axle.

A most interesting type is a 2-D-1 locomotive, the design of which is shown in the line drawing in the upper part of Fig. 5. This is equipped with one large motor of 1800 h.p., driving two jack shafts through a solid triangular rod.

The upper point of the triangle engages with the crank of the motor and the base of the triangle connects together the cranks of two jack shafts which are in turn connected to the driving wheels by horizontal rods. This is very similar to the triangular rod drive used on one of the experimental locomotives for the Midi Railway of France referred to later in this article. The Midi locomotive had two motors connected to the driving wheels through a solid triangular rod of which the apex engaged with the crank of the driving wheel, and the base connected together the cranks of the two motors. The proposed Silesian locomotive has one motor connected to the driving wheels through a triangular rod of which the apex engages with the crank of the motor and the base connects together the cranks of the two jack shafts. The Midi construction was later altered to a more flexible type and one would not anticipate any different results from one of these arrangements than from the other.

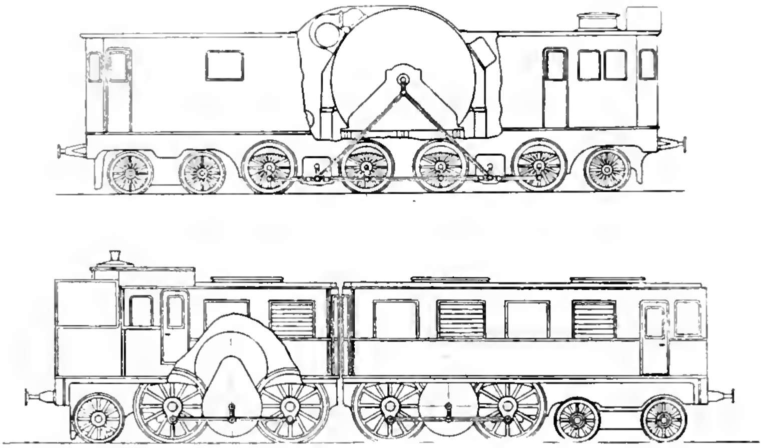

Fig. 5. Silesian State Railways. Proposed express locomotives. Upper, triangular side rod drive; Lower, geared side rod drive

It is reported that the same manufacturers are building a 2-B-B-1 locomotive for the Lauban-Konigzelt electrification, the design of which is shown in the line drawing in the lower part of Fig. 5. The fact that this has the same weight and aggregate horse power as their single unit locomotive at least gives rise to the suspicion that there is some question as to the success of the single motor triangular side rod drive.

### Baden State Railways

Another electrification worthy of mention embraces a road known as the Wiesenthalbahn in the southern part of the state of Baden. In 1909 the Baden State Railways ordered ten locomotives for the operation of their experimental section from Basel to Sackingen, a distance of 30 miles. If this installation is successful it will later be extended as far as Mannheim, a distance of 130 miles in a straight line covering probably from 200 to 300 miles of track. Of the ten locomotives described in the earlier announcements, only one has been completed, which is shown in Fig. 6. This locomotive was tested on the Dessau-Bitterfeld line. A study of the construction of the locomotive impresses anyone familiar with locomotive design with the idea that it would not be suitable for high speed service. The location of the motors at the outer ends of the locomotive made it evident that serious oscillations might be anticipated around a vertical axis which would make it hard on the track at high speeds, and the pony trucks do not look as though they had sufficient weight or friction to dampen those oscillations. Running gear troubles and instability in running might be expected to develop.

Apparently the remainder of the order of ten locomotives has been completed according to another design, of which a line drawing is shown in Fig. 7. In this design the two motors are set close together at the center of the cab and drive a jack shaft through independent rods sloping at an angle of about 45 degrees. The wheels are driven by horizontal side rods, the center one of which carries the driving box on the jack shaft crank, and the motor connecting rods are separately knuckled to this box. Unfortunately, this design does not seem to have been completely successful. The line was scheduled to be running in the latter part of 1912, but was not running a year from that date. Several articles could be referred to on the troubles developed by these locomotives, but perhaps the best summary of observations is given by Lydall (*Journal of the Institution of Electrical Engineers*, 1913, part 230, page 383), from which the following is a condensed abstract:

> "After a great deal of observation it was found that at a certain speed the connecting rods and coupling rods on both sides of any of these locomotives started to vibrate and that this vibration gradually increased as the speed rose until at a speed of about 36 km. per hr., it reached a maximum of considerable amplitude. At this speed there seemed to be the equivalent of resonance as the vibration practically disappeared as soon as the speed had risen to 40 km. per hr.
>
> "It is of interest to remark that this performance of coupling rod systems is observable on practically all locomotives in which the effort of the motors is transmitted to the driving axles by means of connecting rods. It is especially noticeable where two motors are connected to a single jack shaft and is also observable with Scotch yokes as on the locomotives for the Loetschberg Tunnel on which breakages of the yokes have taken place. The same experience, to a less extent, is found where one motor drives a single jack shaft as on the 1-C-1 for the Prussian State Railways. The same effect has also been observed on the 2-B-B-2 locomotives of the Pennsylvania Railroad although in this case the vibration is very slight."

Reports indicate that on account of the difficulties with the driving rods on the Wiesenthal locomotives it is proposed to rebuild the driving mechanism by introducing a slotted arrangement at the jack shaft, the nature of which has not been very clearly explained in publications.

In addition to the ten locomotives, two locomotives of a different type have been ordered for the Wiesenthal, only one of which had been delivered up to the end of 1913. The design of this locomotive is shown in Fig. 8. It differs from the preceding in that there is no jack shaft and the motors drive the middle one of the three driving axles, thus decreasing the total length of the rigid wheel base and the overall length of the locomotives. The driving box on the crank pin is carried on one of the motor connecting rods, instead of being carried on the horizontal rod as was done in the previous design, the other motor connecting rod and the horizontal rods being knuckled to this driving box. No adverse reports have been recorded on the operation of this so-called "double rod drive" but it has not been used in a large number of cases and until it has had considerable practical application it is too early to conclude that it is the solution of the driving rod troubles.

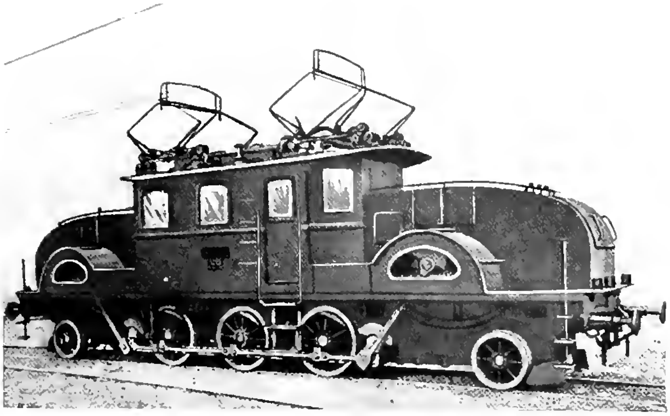

Fig. 6. Baden State Railways. Experimental locomotive with two jack shafts and side rods

**Midi Railway of France**

The Midi or Southern Railway of France has been making a study of the electrification of a line 175 miles in length in the neighborhood of Toulouse. As an experimental section there has been electrified and equipped a 15 mile line in the Eastern Pyrenees from Ille to Ville-Franche. The principal grades of this line are 2 per cent.

The road is not state owned, but the water power development is at the expense of the state so that state control is probably to a large extent effective, and the same characteristics mentioned on the Prussian State Rail-

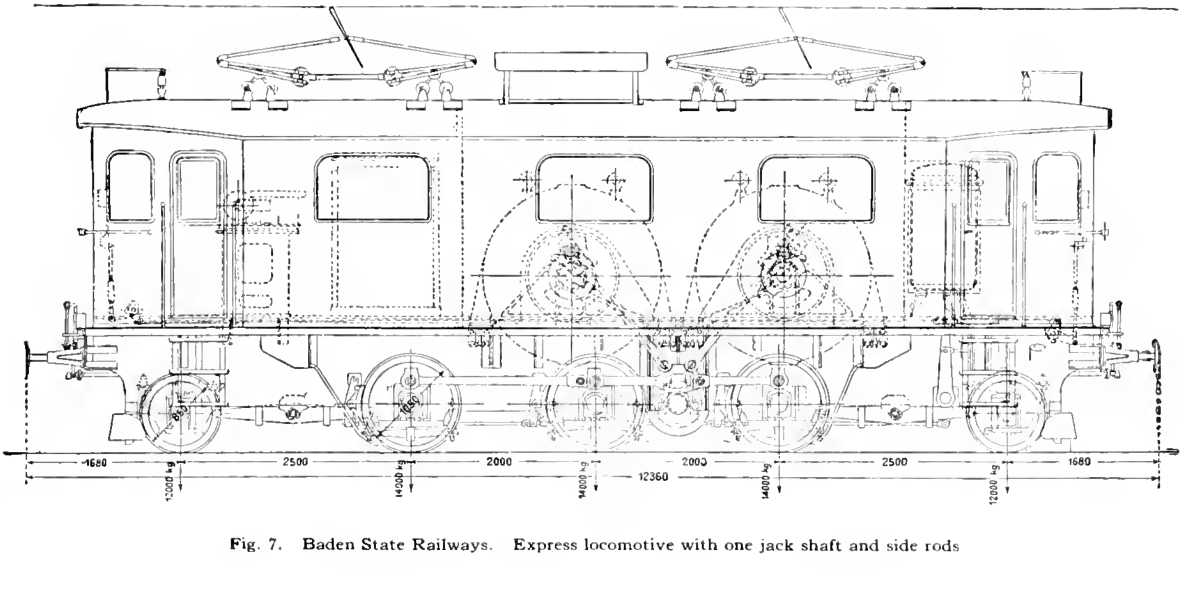

Fig. 7. Baden State Railways. Express locomotive with one jack shaft and side rods

ways are to be noted on this electrification. For the experimental installation six locomotives were ordered from as many different manufacturers. To what extent the designs of the locomotives were determined by the experimental types specified for the Prussian State Railways it is hard to say, but it is a fact that all but one of the locomotives made use of side rods in one form or another. All the locomotives were of a 1-C-1 type, having three driving axles and two leading axles. The weight of each was approximately 90 tons with 60 tons on drivers, and all were to be suitable for maximum speeds of about 68 m.p.h.

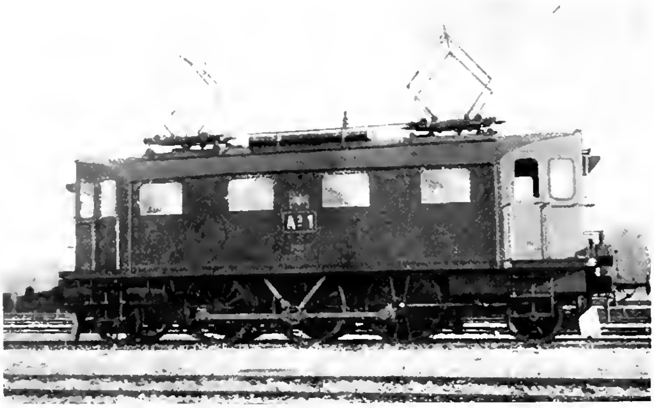

**Fig. 8. Baden State Railways. Later type of express locomotive with "double rod" drive without jack shafts**

Fig. 9 shows one of these experimental locomotives. This locomotive was equipped with two motors, each driving a jack shaft through sloping connecting rods. These jack shafts were located at each end of the locomotive, between the outer driving wheel and the leading wheel, and were connected together and to the driving wheels by horizontal side rods.

A second locomotive had a very similar arrangement of motors and driving mechanism to that shown in Fig. 9, the principal differences being in the design of the electrical apparatus.

A third type of locomotive is shown in Fig. 10. This also had two motors but instead of being connected to a jack shaft the motors were connected together through a triangular rod approximately the shape of an equilateral triangle. The lower point of the triangle engaged with the crank of the middle driving wheel and the other points engaged with the cranks of the two motors. It is apparent on inspection that the horizontal pressure of the driving rods against the lower point of such a deep triangle gives rise to vertical stresses against the cranks of the two motors, and sets up skew stresses in the motors and locomotive frame. An elaborate mathematical paper by Kleinow (*Elektrische Kraftbetriebe und Bahnen*, 1913, page 337) discusses the pressures produced by various shapes of triangular rods and shows that they may rise to excessive amounts with such a deep triangular rod. How much trouble developed from this source in the Midi experiment the writer is unable to say. After the first publication and description of the drive it was changed to the "double rod drive" which we have discussed in detail in our description of the locomotives on the Wiesenthal railroad. It will be noted that the rod shown in Fig. 10 is this "double rod" type rather than the solid triangular type first designed for this locomotive.

Another Midi experimental locomotive is shown in Fig. 11. This is a geared side rod type of locomotive equipped with two motors, each geared to a jack shaft set well down between the driving wheels. The center of the jack shaft is nearly in line with the center of the driving wheels and power is transmitted from the cranks of the jack shafts to the center wheel by a flat triangle or Scotch yoke, and from there by horizontal side rods to the other two axles.

**Fig. 9. Midi Railway, France. Experimental locomotive with two jack shafts and side rod drive**

The last of this set of experimental locomotives is shown in Fig. 12. This is a geared locomotive with three motors one over each

Fig. 10. Midi Railway, France. Experimental locomotive. Motors coupled with triangular rod

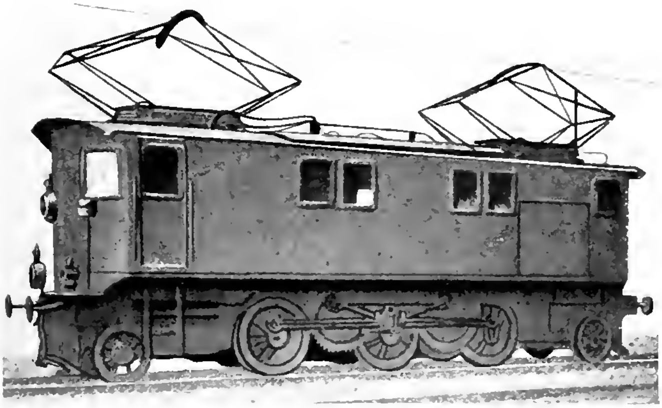

Fig. 11. Midi Railway, France. Experimental locomotive. Motors geared to jack shafts coupled with Scotch yoke

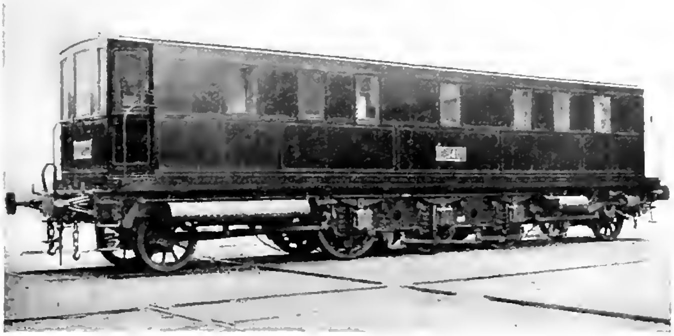

Fig. 12. Midi Railway, France. Experimental locomotive. Motors geared with quill drive.

axle flexibly supported and geared to a quill surrounding that axle.

Three of these locomotives, those shown in Figs. 9, 11 and 12, were accepted by the railroad company. The other three were rejected after experimental service, as not meeting the contract in some particular or as developing characteristics which made them inoperative. To each of the three manufacturers whose sample locomotives were accepted the railroad company has given orders for eight additional locomotives. The interesting thing to note is that the 24 new locomotives are not in any case to be duplicates of the accepted sample. The type of locomotive ordered is to have three driving axles and two trailing axles, each driving axle driven by two motors geared to a quill surrounding the axle and supported flexibly. In other words, after an investigation of the merits of different designs, the railroad company have decided on a geared type of locomotive with twin motors driving through a quill in preference to any type of side rod locomotive.

### Loetschberg Tunnel

In Switzerland the most important recent electrification is the Loetschberg Tunnel, which was put in operation about the middle of the year 1913. The construction of the Loetschberg Tunnel offers a short route from Italy to France through the Simplon and Loetschberg Tunnels and through the Province of Bern. In preparation for this the Bernese Alps Railway has been working for a number of years to provide suitable electric service when the Loetschberg Tunnel should be opened, and which would divert over this line part of the traffic which previously went through the St. Gothard Tunnel by way of Luzerne. As a part of the preparation in 1910 the Bernese Alps Railway received an experimental locomotive shown in Fig. 13. The locomotive weighed 110 tons with 75 tons on drivers. It was an articulated unit equipped with two motors, one upon each half of the locomotive. Each motor drove a jack shaft through a connecting rod having a slope of 11 degrees from the vertical, and this jack shaft in turn was connected to two driving axles through horizontal rods. The writer has no definite information as to the results of the test of this locomotive, but one might anticipate the same troubles which developed on the single motor locomotives equipped with vertical connecting rods which we have previously discussed. A second experimental locomotive was purchased of which the design is shown in Fig. 14. The locomotive is built with two separate three axle trucks and one motor on each truck. The motor is geared to a jack shaft, which in turn is connected to the driving wheels by connecting rods and side rods. The jack shaft is placed so low that the connecting rod makes a very small angle with the horizontal. The motors are placed at the extreme ends of the locomotives, and while no information has been published as to the results of the tests on this type it might be anticipated that the large value of the moment of inertia around the vertical axis would give rise to severe oscillations, and that the locomotive would be hard on the track at high speeds. The result of the tests was the adoption for the final installation of the type of locomotive shown in Fig. 15. It will be noted that several important changes have been made from the experimental type. There are five driving axles instead of six. Three of the drivers are carried in a rigid wheel base and each leading truck carries one idle axle and one driving axle. The driving axles on all three trucks are held parallel to each other and connected by horizontal side rods. The two motors are set close together in the center of the cab and geared to jack shafts, which in turn are connected to the center driving wheel by a Scotch yoke to which the horizontal rods are knuckled. The weight of the locomotive is 235,000 lb. with 172,000 lb. on drivers. The earlier reports indicated very successful and satisfactory operation of this type of locomotive, but as later discussions of this electrification have appeared it is evident that the locomotives have developed some serious defects. Apparently very serious oscillations or vibrations take place in the driving mechanism at certain speeds which are sufficient to break rods, crankshafts and yokes. The cause of these vibrations has been the subject of mathematical investigations by A. Wickert (*Elektrische Kraftbetriebe und Bahnen*, June 14, 1914) and J. Buchli (*Elektrotechnische Zeitschrift*, May

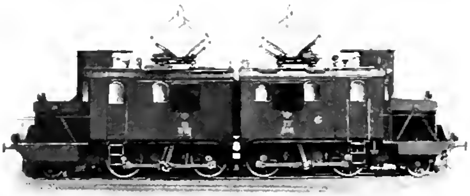

Fig. 13. Loetschberg Tunnel. Experimental locomotive with vertical side rod drive

Fig. 15. Loetschberg Tunnel. Accepted type of locomotive. Motors geared to jack shafts coupled with Scotch yoke and side rods

Fig. 14. Loetschberg Tunnel. Experimental locomotive. Motors geared to jack shafts with side rod drive

28, 1914). Perhaps the clearest statement of the troubles developed can be obtained from the following extract from Buchli's article:

> "The Loetschberg locomotives which have been in regular operation since the middle of last year develop at certain speeds very serious vibrations whose cause has for a long time been unexplained. While some of these locomotives at all speeds up to 75 km. hr. run perfectly steadily in others there appear at speeds between 35 and 42 km. hr. vibrations which in several cases have caused serious defects of the driving gear. By careful adjustment of the bearings one is able to remove the trouble. The adjustment requires labor and time and shortly after the locomotive is put in normal service the trouble occurs again. Similar vibrations as are seen on the Loetschberg locomotives I have also observed on other jack shaft driven locomotives. They appear under some circumstances so serious that the locomotive in question cannot be kept in service. The locomotives of the Pennsylvania Railroad appear to possess this same fault and I do not think I am going too far when I make the statement that every main line electric locomotive built up to this time with side rods and jack shafts shows mechanical vibrations of this character in greater or less degree. It is, therefore, not surprising that the representatives of main line railroad companies are today looking at the side rod drive with some mistrust and that the American construction of drive, the axle motor or the quill drive motor is again coming into prominence."

Both the articles referred to indicate that these vibrations can be attributed to resonance effects of oscillations in the driving system. They also indicate that by the introduction of a proper amount of elasticity in the driving mechanism these oscillations should be diminished or prevented. Along these lines it has been proposed to rebuild one of the Loetschberg locomotives with springs inserted in the gears so as to introduce a certain amount of elasticity between the motors and the yoke. Until some information is published as to the result of this test, it will be impossible to say whether the troubles on this type of locomotive have been eliminated.

The question arises why vibration effects such as are described above do not occur on the driving rod systems of steam locomotives. The fact is that a great deal more accurate adjustment is required on an electric side rod drive than on a steam side rod drive. In the electric locomotive a number of axles, jack shafts and armature shafts have to be lined up and centered very carefully, or the cranks, rods and frame of the locomotive will be subjected to excessive stresses at certain points in the rotation. The same trouble does not appear in the steam locomotive because the terminus of the driving rod system lies in the steam cylinder where the elasticity or cushioning of the steam takes up any inaccuracy in the construction. The trouble we have described on electric locomotives is exaggerated in cases where the heavy rotating members of two independent motors are connected together by a system of rods as in the designs described on the Loetschberg, Wiesenthal, and Silesian locomotives. The motors can be looked on as independent of the wheels and the wheel friction cannot dampen oscillations set up between the two motors.

### Simplon Tunnel

It is of interest to compare, with the results above described, the performance of the equipment of the Simplon Tunnel. This electrification is geographically a continuation of the Loetschberg electrification, as the Simplon electrification meets the Loetschberg at Brig, Switzerland, and extends through the Simplon Tunnel to Iselle in Italy. Four locomotives are in service in the Simplon Tunnel, two each of the types shown in Figs. 16 and 17. There will be noted a general similarity in wheel arrangement and general design between these locomotives and the Loetschberg locomotives. The Simplon locomotives have been in service since 1907 and 1909 respectively, and as far as published reports give any evidence they have not developed any of the troubles which appear to have required investigation on the Loetschberg.

Aside from the fact that one of these electrifications is single-phase and the other three-phase, the important difference as far as mechanical arrangement is concerned seems to be that the motors of the Loetschberg locomotives are larger in weight and horse power than those of the Simplon and being geared to jack shafts the motors run at higher rotative speed for the same locomotive speed. The rotary momentum of the moving parts on the Loetschberg locomotive is therefore far greater than on the Simplon.

### Italian State Railways

The equipment of the Valtellina line in northern Italy has been so often described that it is unnecessary in this article to do more than mention it. The locomotives on this line, one of which is shown in Fig. 18, have been in operation since 1904 and their success has largely led the Italian State Railways to locomotives of this Scotch yoke side rod type. A still more recent and successful type has been fully described in the technical press and is widely used on the Italian State Railways

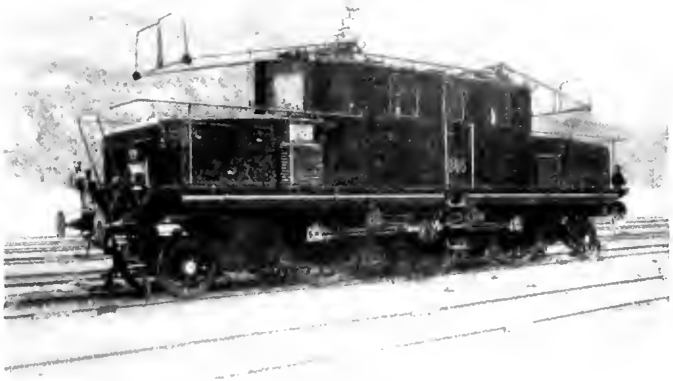

Fig. 16. Simplon Tunnel. Passenger and freight locomotive. Gearless motors coupled with Scotch yoke and side rods

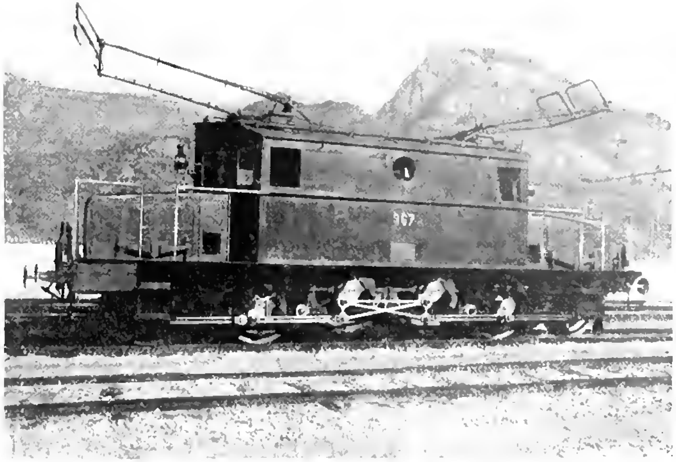

Fig. 17. Simplon Tunnel. Passenger and freight locomotive. Gearless motors with horizontal side rod drive

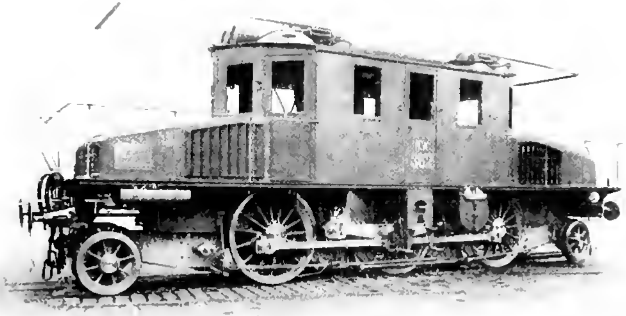

Fig. 18. Valtellina Railway. Passenger locomotive. Gearless motors coupled with Scotch yoke and side rods

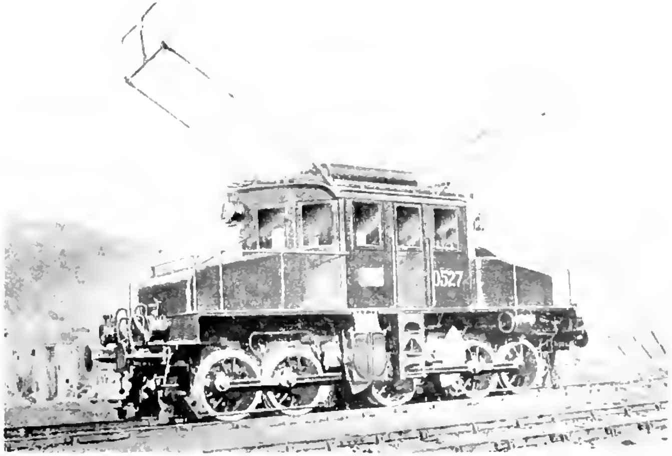

Fig. 19. Italian State Railways. Freight locomotive. Gearless motors coupled with Scotch yoke and side rods

for freight service. This type is known as the Giovi locomotive and weighs 132,000 lb., all on drivers. It has five driving axles and, like the Simplon and Valtellina types, is equipped with two gearless motors set well down between the axles, and driving the middle axle through a Scotch yoke to which the other driving wheels are attached by horizontal side rod. These locomotives are built for a maximum speed of 28 m.p.h. The first of this type was placed in service in 1908 and according to the latest accounts 40 of this type are in service and 25 more on order.

One section of the Italian State Railways, that from Milan to Varese is equipped with direct current, the other Italian installations being three-phase. Fig. 19 shows the latest type of locomotive in service on this section. The locomotive weighs 157,000 lb., of which 102,000 lb. are on drivers. It is equipped with two 1000-h.p. motors placed high in the cab, each connected to a jack shaft through sloping connecting rods and from there to the driving wheels by horizontal side rods. The locomotive is built for a maximum speed of 60 m.p.h. at which the motors have a rotative speed of 350 r.p.m. Five locomotives of this type are in service. No publication of results in operation of these locomotives has appeared since their installation and preliminary tests about two years ago.

### Conclusion

The review of European electric locomotives which we have given above is not exhaustive. It omits a discussion of several important and interesting electrifications and types of locomotives. Among these are the geared side rod locomotives of the Rhaetian Railway in the Engadine, Switzerland, the locomotives of the Mittenwald Railway in the Austrian Tyrol, and the heavy freight locomotives of the Kiruna-Riksgransen line in northern Sweden. Sufficient illustrations have been given, however, to show the difficulties which have been encountered in the development of the direct drive side rod locomotive for high speed service, and to illustrate the fact that European engineering practice is apparently turning away from that type to some form of geared locomotive for medium speed service, and does not yet indicate what will be the finally accepted type of locomotive for high speed passenger service.

It would be very difficult to make any estimate of the investment which has been made in these experimental European electrifications. It is a well known fact that the cost of design, development, construction and testing of a large electric locomotive is a considerable item and sufficient illustrations have been given to show that a large sum must have been spent in the last few years on experimental locomotives.

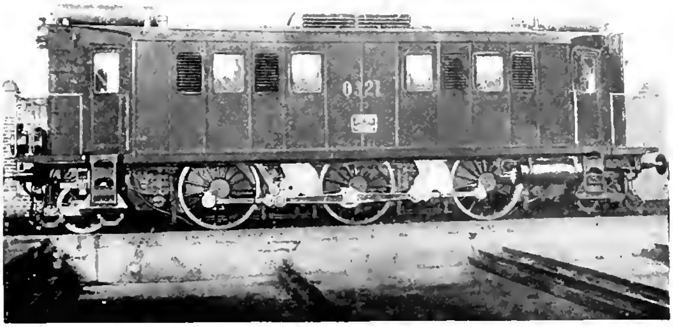

Fig. 20. Italian State Railways. Passenger locomotive with vertical connecting rods, jack shafts and side rod drive

The opinion formed by the writer from this study is that electric locomotive development in America has been more conservative and productive of more economical and satisfactory results than the same development in Europe. We have not been affected by the considerations which have forced spectacular designs on the European engineers, and our initial installations have not been loaded with sample locomotives to the same extent as theirs. Such installations as the Detroit River Tunnel, the Great Northern Cascade Tunnel, the Baltimore & Ohio Tunnel, the Hoosac Tunnel and the Butte, Anaconda & Pacific have shown the geared locomotive to be entirely successful and satisfactory for medium speed service. The development of the gearless motor in locomotive service and its unquestioned success upon the New York Terminal electrification, shows that we have been able to solve the question of high speed passenger service.

# A REVIEW OF AMERICAN STEAM ROAD ELECTRIFICATIONS

By John A. Dewhurst

Railway and Traction Engineering Department, General Electric Company

This article contains a short review of the most important steam road electrifications in America. A great deal of detailed information is given in the tables concerning the physical characteristics and equipment of these roads. The author gives a short explanation of the American and Foreign classification of locomotives.—Editor.

John A. Dewhurst

Steam railroad electrification represents a mutual growth; the electric locomotive not only grew to meet the demands of heavy traction but heavy traction grew, through precisely the same period, to demand results beyond the limitations of the steam locomotive in certain fields of operation. In general, the early development of electric traction was along the lines of the street trolley car, as the unsolved traction problem in cities presented the most attractive field. On the other hand, the conditions of the longer hauls and heavier service of the steam roads did not so favor electricity, and moreover, by that time the steam locomotive had won the place that it still holds and will hold for many years to come.

However, as a result of the enormous growth of the railroads in recent years with the accompanying traffic congestion, the limitations of the steam locomotive have been evident under three principal conditions; first, congested terminals; second, important tunnels; and third, the heavy grades experienced on mountain divisions.

Electric operation has successfully overcome each of these limitations on account of the elimination of smoke and dangerous gases in the first two conditions, and the freedom from the limitations of the steam boiler, giving a greater continuous pulling power, in the third condition involved. In such service the electric locomotive cannot only handle heavier trains but the speed is much greater, this being an important factor in increasing the service capacity of the division.

What can be done by means of electric operation in a congested terminal can be seen at the Grand Central Station at New York City, which is the terminal for both the New York Central & Hudson River Railroad and also for the New York, New Haven & Hartford. Not only are all of the local and through passenger trains of both roads operated electrically out of this station but the suburban passenger service as well; the latter being handled largely by multiple unit motor cars. To economize space the trains are brought into the terminal on two levels, the local and suburban service on the lower level and the limited trains on the upper level.

The Pennsylvania Terminal in New York City is an equally good example of the possibilities of electrification; the problem in this case could never have been solved without the electric locomotive, since the trains must be carried in tubes under the North River directly into the terminal yards. Up to 1912, the Pennsylvania Terminal was in New Jersey, the only communication with New York being by ferry boats.

The first steam road electrification of importance in this country, namely, the Baltimore & Ohio Railroad, was made for the purpose of eliminating the smoke and dangerous gases in the tunnel at Baltimore. Since then there have been four other electrifications installed to overcome the single objection of smoke in the tunnel; namely, the Detroit River Tunnel on the Michigan Central, the St. Clair Tunnel on the Grand Trunk, the Cascade Tunnel on the Great Northern and the Hoosac Tunnel on the Boston & Maine.

In general, where the tunnel is of sufficient length or where it leads directly into a station, the steam locomotive is dropped at a transfer point, the electric locomotive hauling the train through to its destination. In many cases where the tunnel occurs in the middle of an engine division, the electric locomotive is simply coupled to the train ahead of the steam locomotive and the train hauled through with the steam locomotive running light, eliminating practically all of the gases.

---

Two running speeds—first using 4 poles ond using 8-pole connection on motors.

*f* Full field data on first line—tapped field data on second line.

*g* Including 30 motor cars of New York, Westchester and Boston.

*h* These are single trucks each with two GE-229 motors mounted in the usual manner. For switching work one truck is coupled to a locomotive the motors being connected in series with the motors of the main locomotive and controlled as a single unit. This gives a greater tractive effort and a lower speed for switching.

*i* Retired after 15 years' service on account of obsolescence.

*j* One other experimental side rod locomotive not listed.

As an example of the third limitation of the steam locomotive, the Butte, Anaconda & Pacific and the Norfolk & Western may be cited, although in the latter case the existence of a tunnel was an equally important factor. With steam operation on heavy grades, it is often necessary to break up a normal freight train into two or even three sections and haul each section over the heavy grades, using four and sometimes five of the heaviest mountain type locomotives. The service efficiency is naturally low due to the large percentage of idle weight of tenders, etc., and this coupled with the more important factors of the steaming difficulties as well as the low speeds attained, makes this class of service a very attractive field for electric operation.

Several transcontinental railroads are at the present time considering electrifying mountain divisions on account of the greater service obtained by electric operation and the reduction in operating cost.

The accompanying table gives a list of the eleven principal steam road electrifications in America. From this it is seen that approximately 1000 miles of track are electrified, involving 286 locomotives.

The system of operation or of distribution to the locomotives differs widely, there being six of these roads that use direct current, three single-phase, one three-phase, and one split phase which is a combination of a single-phase distribution and polyphase induction motor operation, obtained by means of a rotating phase converter carried on the locomotive. Both the d-c. and single-phase installations mentioned above use some form of series wound commutator motor on the locomotives, while on the two roads last mentioned the polyphase induction motor is used.

Looking at this from a different standpoint, it is noted that of the total of 286 locomotives listed, 148 are designed for direct current operation, 110 for single-phase, 4 for three-phase, and 24 for split phase. Nearly all of the New Haven single-phase engines are designed to operate on direct current as well since they enter the New York Terminal over common tracks with the New York Central, using 600 volts d-c.

There is one other electrification that rightfully belongs under this classification, although in the strict sense of the word it is not a steam road electrification. This is the Bethlehem Steel Corporation electrification of the Bethlehem-Chile Iron Mines Company in South America. This project involves three 110-ton electric locomotives operating over about 18 miles of track, the system of operation being 2400 volts d-c. These locomotives will derive their power from a substation consisting of two 1000-kw. 2400-volt synchronous motor-generator sets installed in the power house, the main power equipment being Curtis steam turbines. All of this equipment is now being built by the General Electric Company.

Regarding the heading "Classification" of locomotive types in this tabulation, a brief word of explanation might not be amiss. The scheme generally used for electric locomotives, although not standardized, is based on the standard classification of steam locomotives, the wheel arrangement being given first; the general type second; the weight third; and the motor equipment last. The wheel arrangement is based on the principle that every locomotive theoretically has three trucks, a guiding truck at each end and a main driving truck in the middle. Beginning at the head end, the wheels on each truck are counted. Thus the first New York Central type were classified as 484 type, there being a guiding truck of 4 wheels at each end and a main driving truck of 8 wheels in the middle. The common 25 to 60-ton type of electric engine having two swivel trucks, connected through king pins to the locomotive frame, is know as the 404 type, there being no main central truck. Likewise in the Detroit Tunnel or the Great Northern type there are two trucks articulated and considered to be the main locomotive truck, there being no guiding trucks, the classification in this case being 0440. The complete classification then of the first New York Central is 484-E-230-4-GE-84-600; the 484 being the wheel order, the E denoting electric operation, the 230 being the weight in thousand pounds (230,000 lb.), and the last showing that the motor equipment consists of four GE-84 motors wound for 600 volts.

It is interesting to note that the German practice differs from the American in this respect. The American classification denotes the truck arrangement without regard to which wheels are driven and which are idle. The German classification distinguishes between driven and non-driven axles as well as signifying the truck arrangement and also the side rod coupling. Beginning at one end the axles are counted on each truck, idle axles are counted numerically and driven axles are denoted alphabetically. A truck containing two driven axles would be classed "B" if the axles are coupled by side rods or "AA" if they are driven separately, as is generally the case in most American designs. A plus mark between two truck classifications indicates an articulated joint and a dash indicates that there is no articulation. Hence the first New York Central type (484) would be classed as 2-AAAA-2. The new New York Central type (4444) would likewise be classed as AA-AA+AA-AA. The Pennsylvania Terminal locomotive (also 4444) would be classed as a 2-B+B-2 the driving wheels of each truck being coupled by a side rod.

This list does not cover all of the steam road electrifications by any means. There are several electrifications not mentioned in this table that are more extensive in many respects than some of the roads mentioned. They have been classed, however, as either interurban or suburban and do not as a general thing handle through traffic. For instance, the Long Island Railroad, operating out of New York City, controls 825 miles of steam and electrified track, operating 369 motor cars, the system of distribution being by means of a third rail at 600 volts. Likewise the Oakland, Alameda & Berkeley Divisions of the Southern Pacific handle extensive suburban service. The Spokane and Inland Empire Railroad, the Ft. Dodge, Des Moines & Southern, and the Portland, Eugene & Eastern are other important electrifications which come entirely under the classification of interurban roads and would in all probability be operated by electricity if constructed new today. The following is a brief list of some of the more important steam road electrifications and mileage not classed in the previous tabulation.

This list does not include the electrification of all of the early elevated lines in Chicago and New York, and the electrification of the yards of many manufacturing plants, terminal

yards, interurban lines, and street railway systems which were either previously operated by steam or are owned and operated by steam railroads.

Just 34 years have elapsed since the first electric engine, a mere toy today, was constructed, and only 18 years since the first notable steam road electrification. The first electrifications were made more with a view of overcoming certain physical difficulties regardless of expense, but today it is realized that, besides overcoming these difficulties, there are actual economies to be gained in the electric operation of many classes of service. However, to gain the greater economies of operation, it is necessary to make a comparatively great expenditure for equipment, since not only do the electric locomotives cost more than steam units of the same weight but it is necessary to provide substations as well as an efficient distribution system to the locomotives, to say nothing of a power house and transmission lines if power cannot be purchased directly at the substations. This all results in a greatly increased interest charge, and although the actual comparison between steam and electric operation is in favor of the latter, there must be a decided saving to induce conservative financial interests to make the expenditure, or else some other physical advantage as outlined above must be the deciding factor.

160-Ton Electric Locomotive Hauling 4550-Ton Ore Train, Butte, Anaconda and Pacific Railway

# FROM THE CONSULTING ENGINEERING DEPARTMENT OF THE GENERAL ELECTRIC COMPANY

## HOW INSULATION BREAK-DOWN MAY BE CAUSED IN APPARATUS BY THE ADDITION OF STRONGER INSULATION

It is important in combining dielectrics of different permittivities to see that it is properly done; otherwise, the one may weaken the other by causing an unequal division of the stress. As a matter of fact, it is possible to cause break-down in apparatus by the addition of insulation, which is good and dielectrically stronger than the original insulation. That the respective dielective strengths of insulation can not be added directly will be shown in the following:

As an example, take two parallel plates rounded with a 5-cm. radius at the edges and placed 2-cm. apart in air.

(1) Apply 60 kv. (max.) between the plates. The gradient then is approximately 60/2=30 kv. per cm. max. (neglecting flux concentration at edges which is not great on account of the rounded edge). As a gradient of 31 kv. per cm. (max.) is required to rupture air, there is no break-down.

(2) Remove the voltage and insert between the plates a sheet of pressboard 0.2 cm. thick. The constants of pressboard are:

$k_2=4$ Rupturing gradient $=175$ kv. per cm. (max.) $l_2=0.2$ cm. = thickness of pressboard.

For air

$k_1=1$ Rupturing gradient $=31$ kv. per cm. $l_1=1.8$ cm. = thickness of air.

The total insulation is now 0.2 cm. of pressboard and 1.8 cm. of air. The total "strength" added directly is $(1.8\times31)+(0.2\times175)=90.8$. Apply the same voltage as before. Break-down results. The combination is actually weaker than the air alone. The addition of the pressboard because of its higher permittivity has increased the capacity of the combination and, therefore, the total flux and the flux density in the air. The gradient in the air has also been increased because of the greater flux through the air.

The combination may be considered as two condensers in series. Let $c_1=$ the capacity of the air condenser, $c_2=$ the capacity of pressboard condenser. $e_1=$ the voltage across the air condenser, $e_2=$ the voltage across the pressboard condenser, $A$ a constant including the area of the plates, and $e=$ the total applied voltage.

The total flux is

$$\psi=c_1e_1=c_2e_2$$

$$\psi=\frac{k_1A}{l_1}e_1=\frac{k_2A}{l_2}e_2$$

therefore,

$$\frac{k_1}{l_1}e_1=\frac{k_2}{l_2}e_2$$

$$e=e_2+e_1$$

$$\frac{k_1}{l_1}e_1=\frac{k_2}{l_2}(e-e_1)$$

$$e_1\left(\frac{k_1}{l_1}+\frac{k_2}{l_2}\right)=\frac{k_2}{l_2}e$$

$$e_1=\frac{\frac{k_2}{l_2}e}{k_1\ l_1+k_2\ l_2}=\frac{l_1k_2\,e}{k_1l_2+k_2l_1}=58.4$$

$$e_2=60-58.4=1.6$$

$$g_1=\frac{e_1}{l_1}=\frac{k_2\,e}{k_1l_2+k_2l_1}$$

$$\text{Then } g_1=\frac{4\times60}{(1\times0.2)+4\times1.8)}$$

$$=32.5 \text{ kv. per cm. (max.)}$$

The air breaks down since $g_1$ is in this case higher than the critical gradient value that causes the rupture of air. As the broken-down air is conducting, most of the applied voltage is then placed on the pressboard. Thus, after the air ruptures, the gradient on the pressboard is:

$$g'_2=\frac{60}{0.2}=300 \text{ kv. per cm. (max.)}$$

This is much greater than the rupturing gradient of pressboard and consequently the material then breaks down. Therefore, the 2 cm. space, which is safe with air alone, is broken down by the addition of stronger insulating material of higher permittivity.

By properly arranging insulations of different permittivities, or specific capacities, the stress may be greatly reduced in many designs.

The case discussed above is an exaggerated example of conditions often met in practice. In many power stations, little bluish needle-like discharges, (called "static") may be noticed around generator coils, bushings, etc. This "static" is simply over-stressed or broken-down air but, unlike the conditions in the example, the solid dielectric is so thick that very little added stress is put upon it by the broken-down air. Damage may be caused in the course of time, however, by local heating, chemical bombardment, etc.

GENERAL ELECTRIC REVIEW

## THE PATHS OF PROGRESS

In this issue we conclude a series of articles by Dr. Saul Dushman entitled "Recent Views on Matter and Energy." All of our readers who have read these contributions must have been struck by the boldness of many of the speculative theories that have recently been propounded, as well as by the fact that we seem to be on the verge of great developments in the realm of scientific thought.

The ultimate constitution of matter has been the plaything of profound thinkers for generations and the origin of energy has been no less a subject for speculative theorizing, but it has been left to the scientific minds of this generation to attempt to propound a monistic theory to account for all natural phenomena. The atomic theory originally propounded to account for the mysteries of the structure of matter was developed into an electron theory to explain electrical phenomena, and now, as a product of modern scientific thought, we have the quantum theory which is an atomic theory of energy. Thus it seems likely that we shall ultimately not only fully develop, but we may prove by patient research and experimental work, a common theory for both energy and matter which may be broad enough to include all natural phenomena. Should this be accomplished it is highly probable that all natural phenomena will be found to be governed by a few simple laws, and that the complexity of many of our scientific theories in the past has been caused by a lack of knowledge of the simple laws that govern the movements and "habits" of the ultimate "something" of which both energy and matter are born.

Such a simplification of theories would undoubtedly lead to great progress in scientific discovery and ultimately to enormous industrial developments in a multitude of different directions, and it is for this reason that all engineers and professional men in general should try to follow the trend of modern scientific thought. The series of articles referred to were written with the idea of giving a general understanding, in simple language, of some modern scientific speculations that may ultimately have a far-reaching industrial influence. We believe that there is too generally a tendency to consider all higher scientific reasoning to be beyond so simple an interpretation that the ordinary lay mind can derive any benefit following it. In reality this is very far from the truth. While it is true that it takes a great mind to translate scientific thought into simple terms, it is also true that many men have devoted much time to this task.

Scientific developments and discoveries have been almost entirely derived in the first place from speculative imaginations. All theories must be imagined before they can be propounded, tested, and proved or disproved; indeed, speculative imagination can almost be said to be the root of all progress. Those who take no trouble to familiarize themselves with the speculative imaginings of modern scientific minds are, we believe losing much that would lead to valuable inspirations that might be applied to their own work, no matter what its nature. In these days of specialists there is too marked a tendency to think a general understanding of the activities of others as of little value.

Imagination is the seed of all originality and in these days of competition there is more and more need of original thought in all industrial activities. The type of reasoning displayed in developing scientific theories by such men as Kelvin, Planck, etc., might well be imitated in many walks of engineering and business life. The imagination should be given full range and any theory arrived at should be tested till some are found that will bear the fruit desired. We believe that a careful study of the work accomplished by those great minds engaged in scientific research might give great inspiration and lead to an added efficiency in the reasoning powers of all men.

# WORKMEN'S COMPENSATION

By James O. Carr

Law Department, General Electric Company

Workmen's compensation laws are one of the products of modern conditions, and the laws throughout the union are many and varied, no less than twenty-four states having adopted laws compensating workmen for industrial accidents. No one claims that these laws are perfect and it is likely that many modifications, based on experience gained from their working, will be adopted from time to time. The author deals in a very interesting manner with many phases of the different laws already in force and discusses the pros and cons of their practical working.—Editor.

One of the most remarkable reform movements in the industrial world of the United States in recent years is that which has had for its object the enactment of laws requiring the payment of compensation to workmen who are injured in the course of their employment. The theory upon which this movement has proceeded is that the workman should be compensated for disabilities resulting from industrial accidents regardless of the question of fault, and that the financial burdens of such accidents should be borne by the industry in general rather than by the workers alone.

While this principle has been in force in some of the European countries for many years yet it is only within the past five years that the matter has been taken up actively in the United States.

A law was enacted in the State of Massachusetts in 1907 permitting employer and employee to agree on a plan of compensation and the State of Montana passed a compensation act relating to the coal industry in 1909, yet neither seemed to accomplish the desired result and little or no progress was made thereunder. It really received its initial impetus in 1909 when a commission was appointed by the Legislature of the State of New York to investigate the whole subject.

During the year 1910, two compensation laws were passed in the State of New York, one elective and one compulsory, but early in the year 1911 the compulsory law was declared unconstitutional by the Court of Appeals of the State of New York, upon the ground that it took the property of employers without due process of law. During the year 1911, compensation laws were passed in the States of California, Illinois, Kansas, Massachusetts, Nevada, New Hampshire, New Jersey, Ohio, Washington and Wisconsin, some of which were compulsory and some elective.

Since that time, compensation laws have been passed by other states so that the principle is now in force or soon will be in twenty-four different states. One of the last states to enact a workmen's compensation law was the great State of New York, where the law was passed in the month of December, 1913. That law is in many respects the most liberal to the workman and the most burdensome to the employer of any compensation law passed by the various states. It was passed more or less hurriedly with the idea that the practice of compensating workmen for injuries sustained through industrial accidents should be commenced at once and that an actual trial of the law would show wherein it ought to be amended so as to improve it for the benefit of all concerned. It has been in actual operation since July 1, 1914, and it is already evident that many changes are necessary to make the law more workable.

Many of the most prominent labor leaders in the country have said that the present workmen's compensation law of the State of New York is the best compensation law ever passed in this country. That this is so from the standpoint of the workman is undoubtedly true. Many of the employers feel that the law ought to be less burdensome to them than it is. However, this will undoubtedly be worked out satisfactorily in time.

In most of the states the law is elective, that is, the employer and the employee may elect to accept the provisions of the law or not just as they choose. In the case of the employer who elects not to comply with the provisions of the law, however, all his defenses are taken away in case the workman sues him for damages for personal injuries, so that the employer is almost compelled to accept the provisions of the law rather than to attempt to defend negligence actions and be subjected to the large verdicts which would certainly be rendered against him. If the employee elects not to accept the provisions of the law, he is relegated to the same rights which he had at the time the new law went into effect. In the opinion of many who are conversant with these compensation laws, the workman should only have the rights which existed at common law if he refuses to accept the provisions of the compensation law, the idea being to compel both parties to abide by the principle of compulsory compensation.

In some states the compensation law is compulsory, that is, both employer and employee must abide by the requirements of the law and the employer must pay the compensation therein provided.

The elective laws were passed by many of the states in order to avoid, if possible, any question as to the constitutionality of the law such as was raised at the time the first compulsory law was passed by the State of New York. The new law in many of the states provides that all workmen shall come under its provisions except farm and domestic labor. In other states, the laws are so framed as to cover only those workmen who are engaged in so-called hazardous employments. Where this has been done, however, some means have been found to include nearly all workmen. This very feature is one of the objections to the New York law because it is uncertain what workmen are covered by the law and what ones it does not cover. How much better it is for a workman to be under the protection of the compensation laws can readily be seen. As soon as he is injured, he is, in many of the states, entitled to medical attendance for a period of from two weeks to three months, at the expense of the employer. This also covers hospital treatment, medicine and other requisites. All of this is to be provided by the employer.

If the injury causes temporary disability of more than one week, in some states, and more than two weeks in others, which is called the waiting period, the workman is paid a certain percentage of his average weekly wages, ranging from 50 per cent in some states to 66⅔ per cent in others, so long as the disability continues, subject to certain limitations as to length of disability and amount paid.

In some states, in the event that an accident causes total permanent disability to the workman, he is paid the weekly percentage of his earnings for periods of time ranging from six years to the remainder of his natural life.

If the workman sustains a permanent partial disability, such as the loss of a finger, eye, hand, arm or foot, he is then paid a certain stipulated amount per week for a certain period to compensate him for the loss sustained. In some states he is also paid weekly compensation during the time of disability caused by the permanent injury; but the most satisfactory way seems to be to pay a certain fixed amount which is considered sufficient to compensate for the loss, and this is provided for in the laws of most of the states.

In some states, the workman is compensated for the loss of earning power due to injury. This is likely to prove quite troublesome as time goes on and will lead to complications, as some of the Workmen's Compensation Commissions of the various states seem inclined to hold that if a workman goes back to work and takes a different job which pays less money than he earned at time of injury, he is therefore entitled to compensation for loss of earning power.

If an injury proves fatal, then the widow, children or other dependents are paid a certain percentage of the weekly wages of the deceased workman. In some cases this compensation is paid for the life of the widow if she does not re-marry, and in others, for a certain number of years and not to exceed a certain amount. The compensation to be paid to children usually ceases when they reach the age of eighteen. In addition, many of the states require the employer to pay a certain amount for funeral expenses.

The compensation is paid to the workman in various ways. In New York, for instance, the employer pays the money to the Workmen's Compensation Commission and it in turn pays the injured workman or his dependents. This plan is unwieldy and cumbersome and is not nearly as expeditious as the practice in many other states where the employer makes arrangements to pay the workman direct the amount provided by law pursuant to an agreement made between the parties which is subject to the approval of the Commission. In some states where the principle of state insurance has been put into effect, the compensation is paid direct to the workman from the premiums paid in by the employers. In some states, the compensation must be secured to the workmen either through the medium of insurance in stock or mutual companies, through the medium of a state fund or, if the employer can give satisfactory proof of his financial ability to pay compensation to his employees, he may be permitted to carry his own insurance upon giving a satisfactory bond or depositing sufficient security to guarantee the payment of the compensation. Most employers carry insurance in either stock or mutual companies. Only the employers having a large number of employees can afford to carry their own insurance.

Various methods are adopted for handling disputes between the interested parties so that the workman may receive the compensation to which he is entitled as soon as possible after an accident.

As time goes on, many developments will take place in connection with the practical working out of these laws and we shall have a far better knowledge of them and their beneficial effects or otherwise five years hence.

That the general plan is sound and will work out to the interest of all concerned is probably conceded by all who have given the matter thoughtful consideration. The necessity for such legislation has been more or less forced upon us by the course of human events and by the many changes and developments in the method of carrying on modern industry.

Prior to 1880, the handling of business on a large scale and through the medium of great corporations was practically unknown, except perhaps with respect to railroads and the manufacturing interests in New England. Subsequent to that time, however, by reason of the great improvements in machinery, it became possible to have done by machinery the work which had formerly been done by the individual workman, and in many instances the workman was displaced by machinery. The result of this has been that in every industry the production has been marvelously increased and this feature has been largely instrumental in developing the great manufacturing industries in the United States. While enormous strides were being made in the manufacturing field, there was also a great increase in the number of industrial accidents due to the greater use of machinery and the hazard incident thereto. As a consequence, the burden on society was greatly increased because of the fact that the workman was seldom compensated for disabilities due to accidents occurring in the course of his employment.

In former years, when manufacturing was carried on in a small way by the individual employer, he usually knew most of his employees and took more or less of a personal interest in them and in their welfare. This resulted in a friendly feeling between the employer and the employee and there then existed a bond of human sympathy between them. It is also a fact that in those days the labor union was almost unknown and had little or no influence upon manufacturing operations.

With the development of the industry through the medium of machinery there came another development, that of the labor union, which today has almost a predominating influence in all parts of the country where large bodies of workmen are employed. With these developments and the creation and growth of the large corporations the human element was lost sight of in many ways. The workman was looked upon more and more as a machine rather than an individual. This, of course, was not true in every case, but it is true and must of necessity be so where thousands of workmen are employed in one industry since those in charge of the industry are absolutely unable to be in personal touch with all of the employees. This is also true where the labor unions predominate, because the members of the labor organizations seem to prefer to deal with their employers through the medium of their organizations and this has a tendency to eliminate the personal element.

In the days of small industries, when a workman was in trouble or was incapacitated through injury, he was, in many instances, looked after in some way by his employer who attempted to relieve him and his family from the loss which he was bound to sustain. It is not to be understood that this was so in every instance but it was in many cases. At the same time the employer who was engrossed in accumulating wealth undoubtedly very often overlooked the misfortune of his employee and was inclined to rely upon his legal rights in the event that any claim was made upon him for compensation.

The common law governing the relations of employers and employees in connection with injuries sustained during the course of employment was such that the employer was seldom held legally responsible for injuries which happened to the workman in the day's work. The only way in which the workman could recover money damages from his employer was by proving that the employer was negligent and that he did not fulfill the duty which he owed the employee. It can well be realized how difficult it was for the employee to sustain this burden when he was obliged to prove that he himself was in no way negligent and that his actions did not contribute to the accident; that he did not understand the risk and did not assume it and that the accident was not due to the neligence of some other employee engaged on the work. Prior to the enactment of the Employers Liability Laws, in many states even the superintendent in charge of the work was held in many instances to be a co-employee, so that if for any reason the accident happened through his negligence the employee could not recover.

The law in these respects being so harsh upon the employee and the burden on society caused by industrial accidents having increased so rapidly, it became more and more apparent that there must be some enlargement made of the rights of the employee to recover for accidents sustained in the course of his employment. As a result many of the states have from time to time passed so-called employers liability laws, placing a much greater burden upon the employer and relieving the employee in many ways. Up to the year 1912 these laws had become so drastic so far as the employer was concerned that it was more and more difficult for him to escape the payment of damages to injured workmen regardless of how the accident might have happened. This situation came about in many respects through the work of unscrupulous lawyers who became so skilled in negligence litigation that they could almost always find some means of making the case a question of fact which the Courts have held required the submission of the case to a jury. Within the past ten years the submission of such a case to a jury almost invariably resulted in a verdict for the plaintiff against the defendant. If the defendant was a corporation it was almost a foregone conclusion that the verdict would be a substantial one and that it would eventually be sustained by the Appellate Courts. Juries in the past five years have seemed to lose their reason and judgment when called upon to render verdicts in cases of this character. The amounts awarded by them have been astounding and unreasonable beyond any question. Passion and prejudice have undoubtedly prevailed in a great many cases of this character and have tended to influence the verdict. The defendant, however, has found it almost impossible to demonstrate that such was the case. The slogan has been: "The corporation is rich; it can stand it. Let's give the poor fellow a good substantial verdict."

By reason of this situation the employer who has been looking into the future has tried to establish for his own welfare as well as that of his employees, a system of compensation which would to some extent relieve the employees from the burden of industrial accident and that the employers have succeeded admirably in many cases is a well-known fact. That this should be done from a social standpoint need not be demonstrated. That it should be done from a business standpoint also requires no demonstration. The employee himself was made to realize that it was for his interest to co-operate with his employer along these lines when it became more and more apparent that the lawyers who handle negligence litigation were in almost every instance merely exploiting the injured workman for the purpose of getting the substantial fee which they would obtain in the event of the litigation being successful. The speculative feature of this class of litigation had a tendency to make the plaintiff as well as his lawyers disregard the truth in many instances, the sole object being to endeavor to obtain a verdict against the employer.

Many employers have for years been carrying on their own systems of compensation for injured and killed workmen and their dependents, and have been successful in their efforts in this direction and have succeeded in reducing the annoyance and expense incident to negligence litigation to a minimum and have thereby been able to increase the compensation and relief to the injured employee. Particularly is this true in respect to the employer who has handled his own insurance rather than by having insurance companies protect him through the medium of casualty insurance.

Undoubtedly one of the greatest incentives to the enactment of workmen's compensation laws in the various states has been the methods adopted by casualty companies in conducting their business and in adjusting claims made by employees for injuries sustained by them. The attitude of the insurance companies until very recent years has been that they would not pay anything to the injured workman if it was possible to avoid it, preferring to rely upon their legal defenses in case the workman saw fit to bring a suit. Whenever an accident happened the insurance company intervened between the employer and the employee and the employee was obliged to conduct his negotiations, if any, with the insurance company. Naturally the ordinary workman is not versed in matters of this character and he was at a tremendous disadvantage when attempting to do business with the representatives of the insurance companies. As a result he was imposed upon; he was unable to clearly understand his legal rights, and was made to understand that before he could hope to recover anything he would be obliged to go through a protracted litigation which might extend over a period of years and in the end it was possible and perhaps probable that he would be unsuccessful, in which event he would recover nothing. During all the time that this litigation might continue he would have the worry and annoyance of it and nothing to compensate him for his injury, which in many instances was serious; so that the insurance companies by use of such arguments were in most instances able to effect a settlement for a small amount and get the case disposed of. It is significant that the records show that prior to the time when compensation laws were first enacted in this country the amount disbursed by insurance companies in the way of payment of compensation to injured employees was about 30 per cent of the total premiums, the balance being used by the insurance companies for the payment of their expenses and dividends to their stockholders. Of the 30 per cent probably a large amount was paid over by employees to lawyers and others for assistance rendered by them. It can readily be seen that the real purpose for which insurance was taken out was not to insure the payment of compensation to the injured workmen when the accident was due to the fault of the employer, but rather to relieve the emoloyer from making any payment whatsoever and as a result the workman received a small percentage of the amount to which he was really entitled and in addition considerable feeling was engendered between him and the employer. It was apparent to the manufacturers who where able to look ahead that this state of affairs, coupled with the expense and annoyance incident to the harassing negligence litigation, could not continue much longer and that some remedy should be found which would make both of these things entirely unnecessary, and in addition enable both employer and his employee to work more in harmony with each other, and afford the man who was injured at his work a partial recompensation for the loss which he should sustain. The workmen were also beginning to think along the same lines.

While the employers and employees may both claim the credit for workmen's compensation legislation, yet regardless of the question as to whom the credit belongs it may safely be said that it is one of the greatest steps in promoting social welfare that has occurred in modern times. It may well be termed: "The movement to conserve human life and health through the medium of legislative enactment." As times goes on both the employer and the employee will wonder why the great waste of human life and health which we have endured up to very recent years was permitted to go on unchecked when it was possible to remedy the difficulty so readily. It will also be found after these laws have been enforced for a short time that neither the employer nor the employee would be willing to go back to the old condition of things under any consideration. That it may be classed as paternal legislation is in one sense true, but on the other hand it is agreed that paternal legislation that brings desired results to all parties interested alike is the best kind of legislation that can be enacted. There can be no ground for arguing that such a law is unjust and inequitable, so far as the principle is concerned. In the years gone by the machine in the shop when out of order was shut down and promptly repaired so that it might be again put in use for the purpose for which it was designed and thereby enable the employer to make use of it in turning out his product. In the same way the horse that was used for hauling the freight and other material around the plant when taken sick was promptly attended to by the veterinary. He was fed and cared for, and every effort made to put him in good condition so that he could again resume his work. To be sure no wages were paid to the horse but yet as compensation for the food and care which he received he performed a certain amount of work for the employer. That this condition of affairs should have been overlooked for so many years and these principles not applied to the human machine seems almost startling in the light of present day developments. Why is it that the human machine did not receive equally as good care and treatment as the others? Was it because of selfishness or neglect or failure to consider the true merits of the situation? The answer undoubtedly is that when the human machine became out of order for any reason it could promptly be replaced by another without any trouble or apparent expense, and for that reason the man who was injured in employment was displaced, for the time being in any event, by another workman who was prepared to take up his work, and if the former employee had been so disabled as to be unable to resume his employment then the new one could remain on permanently. In the case of the horse it would cost a substantial sum of money to replace him even temporarily, whereas with the human being it cost nothing, so that the action taken may properly be said to have depended entirely upon the question of cost. Nowadays the employer is finding out that it is money well invested to keep the human machine in proper working order and condition. The benefits derived from his efforts in this direction are manifold. It is seen not only in the workman himself but the benefit redounds to his wife and children and to the public in general which is relieved from any apparent burden so far as he is concerned. If a man is in good physical condition he can naturally do more work and do it better than the man who is ailing and unfit for the employment in which he is engaged. The more and the better production the manufacturer is able to put out the more business he does, the larger his income, and presumably the greater his profits. The saving to the community in general, by reason of the enactment of laws regarding compensation of workmen who are injured in the course of their employment, will more than compensate for any additional expense to which the state may be put in administering such laws. Heretofore a large portion of the time of our courts has been devoted almost exclusively to the conduct of negligence litigation arising out of accidents to employees. In fact the calendars in some of the courts in the larger cities have been almost entirely filled with these negligence actions. Without question the work of the courts in such a state as New York will be so materially decreased by the disappearance of this class of litigation that many of the judges will have time on their hands and some of them could be dispensed with. When the enormous expense that is attendant upon the operation of the courts is realized it will be seen at a glance that a great saving is to be effected. In addition to that, the workman who is seriously injured is not going to be a burden upon himself and his family and upon society in general. He is not going to be made to feel that he is dependent on charity for his existence. He is still going to be able to hold his head up among other men, knowing that so long as he is deprived of his ability to work by reason of the injury sustained in the course of his employment he is going to receive compensation to assist him to a considerable extent in caring for his family during the time of his disability. This feeling of self respect which the workman will have is in itself worth a good deal and will tend to make him in most instances a better citizen. The burden of compensating employees will be borne by the industry and when it is of sufficient amount to be at all appreciable it will be added to the cost of the production, and the consumer, which is the public, will pay for it. In this way society in general pays the expense as it really does in everything else ultimately. The workman who is compensated while injured will, by being able to receive enough to keep his family from want, also be able to keep his children in school and thereby confer an untold benefit upon them. They will not of necessity be obliged to start in work when the wage earner of the family is disabled, whereas they might be obliged to do so much before the intended time if there were not other means of support. Of course it is impossible to have legislation of this character which is not without some drawbacks and subject to much criticism. In many of the states the claim is made that the compensation is too liberal and too far-reaching in that it will be an incentive where the compensation is too high for the injured workman to remain out of employment as long as he possibly can. Of course there may be something in this, particularly if the workman carries his own insurance either through insurance companies or some fraternal organization, for by taking such insurance benefits in conjunction with the compensation paid by the employer he may derive more than the sum which he would receive when working steadily. This, however, is a condition which must be met. In some states the list of dependents is carried to extremes, persons being entitled to compensation as far remote from the injured person as grandparents and grandchildren and nephews and nieces. It is undoubtedly true that the schedule of compensation for partial permanent disability seems in many instances high but time alone will tell how burdensome this may be in the states where such compensation seems to be unduly high. Fortunately this only pertains to a class of accidents which are fewest in number. That an untold amount of good is going to be accomplished by these laws must be admitted without controversy. It is going to have a tendency to cause employers to investigate more carefully their working conditions in order that they may ascertain wherein they may reduce the number of accidents in their factories. Every accident prevented means, theoretically, so many dollars earned, because by reducing the number of accidents the expense incidental thereto will also be diminished. An employer will be warranted in expending money for the purpose of reducing the number of accidents because it will be found to be an excellent investment. The amount of stimulation that has occurred since the beginning of the agitation for workmen's compensation legislation is surprising. Many large manufacturers have been and now are spending thousands of dollars in safeguarding machinery and doing other things to decrease the hazard of the employment and make it safe for the life, limb and health of the employee. Naturally these things have a tendency to improve the efficiency of the workman and his surroundings. One of the great elements which have been found to have a very important bearing upon industrial accidents is the question of lighting and it has been shown that many accidents which could well be prevented have been caused by failure to properly light the place where the employee was performing his work. It has been found a simple proposition in many ways to place these safeguards around the employee and thereby reduce the possibility of accidents and it is undoubtedly due to the fact that it has been so simple and easy to do these things that they have been left undone for so long a period of time. In another respect, outside of compensation for industrial accidents, the employee is bound to derive a substantial benefit. The burden which the employers have had placed upon them has led them to take a much greater interest in the welfare of their employees and has put them in touch with many conditions which were unknown before. Until recent years no special effort has ever been made to fit the work to the man but it has usually been a case of fit the man to the work. The requirements of the compensation laws have given the employer a new incentive and that is to try to see that he has workmen physically able to perform the work for which they are engaged. To this end many of the employers of labor throughout the country have adopted the policy of medical examination which is believed will prove to be of untold benefit to employer and employee alike. It does not mean that the man who is not physically perfect will be shut out or prevented from obtaining employment, but it does mean that more care will be used in the employment of labor and that an effort will be made to place the man at the kind of work which he is physically able to do rather than to place him at the kind of work which he thinks he wants to do but for which he does not know he is physically unfit. Such procedure is bound to be beneficial to both parties because it will tend to improve the efficiency of the employee, thereby benefitting the manufacturer; it will tend to conserve the life and health of the employee, thereby enabling him to perform his duty to society; and by lengthening out his life it will extend the period of his usefulness to his family and the community. Society has much to be thankful for when we consider the amount of suffering and distress that is going to be saved by reason of the enactment into law of the principle of compensating workmen who are injured in the performance of the work incident to their employment and in the years to come the employers and employees will wonder why such a blessing to mankind was not brought into existence many years before.

# PRACTICAL ECONOMIES IN DISTRIBUTION WITH THEIR EFFECT ON THE COMMERCIAL POLICY OF A CENTRAL STATION COMPANY

## DOHERTY MEDAL PAPER—1914

By Harold Goodwin, Jr.*

Assistant Superintendent Distribution, The Philadelphia Electric Company

The content of this article is of great practical value to all those concerned in any way with the distribution of electrical energy through overhead lines (the conditions existing in underground lines are conformable to the same treatment as is used herein for overhead lines). This article is meritorious chiefly because, unlike others, its author has studiously avoided falling into the error of delivering either with an exposition based only on theory or a treatise founded solely on practice. A comparison of the merits of the radial and the tree systems is made; load capacity data of the secondary distributing lines are given in tabular form; and cost data of line materials and their erection are presented, also in tabular form. A careful explanation of the local factors which have to be considered in distribution problems and well-balanced helpful advice supplement the value that can be derived from the tables. Through the courtesy of *Current News* we have been able to publish this excellent article.—Editor.

### INTRODUCTION

The technical press is at present filled with notes on the cost of central station service showing at one end of the system the present low generating costs and at the other the almost fixed charges per customer's service. 'Twixt these there is a great gulf fixed and labeled "Distribution Costs." The central station man goes into competition with the isolated plant and finds his main generating costs much lower, but then he has to add "Distribution Costs" that seem to wither his chances for the business. Mr. P. Junkersfeld, in his report on "Distribution" to the last (1914) midwinter convention of the A.I.E.E., states: "The great importance of the subject of distribution of electrical energy is further indicated by the fact that, in the average central station system in a large city, the fixed charges and operating expense of the distribution system are nearly three times the fixed charges and operating expense of the power house."

Most central stations meter the output of their generating or substations and also sum up the total of customers' meter registrations and compare the two. There is a discrepancy of from 10 to 50 per cent. This is put down as distribution loss; a little is accounted for as transformer core loss and the remainder just entered mentally to the discredit of the distribution engineers.

Yet what is being done to reduce these costs and losses? Eminent engineers are working to increase turbine and generator efficiencies if only by half of one per cent. Practically all transmission systems are in the hands of competent engineers. Others of equal standing in their profession are continually devising means, by combining loads of different characteristics, by which the efficiency of the substations may be raised. These same men lay out, more or less definitely, distribution systems with rules as to voltage and phase of motors, grouping loads on transformers, maximum voltage drop from feeder end to last transformer, etc. Then what?

The operation of the generating stations, transmission systems, and substations is put in the hands of engineers; complete meter and instrument readings are continually taken and the results are checked up against those previously calculated and an efficient condition is thus maintained. But what is done for the efficiency of the system beyond the substation? The general rules on voltage, phase, etc., are given to a "practical man" who knows from experience the "one-hundred-and-one" mechanical details that enter his problem and he proceeds to build primary lines, hang transformers, run secondaries, and supply the current to meters registering with almost absolute accuracy to the fraction of a per cent. General voltage tests are made and the job is said to be a good one. A complaint may come in and the voltage being found a little low a new transformer is hung, or new secondaries are run in a manner which has caused no complaint to the "practical man" at another location and is therefore to him the proper thing.

Some "practical men" have gone further and have investigated their transformers to see that they are properly loaded and have

---

* The writer desires to take occasion to express his appreciation of the excellent distribution work done by the Aerial Line Department of The Philadelphia Electric Company, which has inspired this paper, though it has been done without the confidence of these figures. He also wishes publicly to extend his thanks to Mr. William Foster for his willingness in supplying the assumed figures on costs and to Mr. N. E. Funk and Mr. Clarence W. Fisher for their assistance in the preparation of the article.

thus shown a considerable saving. This showing, with the ability which guided their work, has qualified them for higher positions which they have assumed. They have then written articles showing most beautifully the advantages of grouping load on transformers and the advantages of diversity factor and so forth; they have proceeded to the study of transmission lines and given us no end of valuable information and short cuts on the calculation of these problems. But what have they done to help the man who is still struggling to determine whether he should put a transformer in every block with small secondary wires, or only one in every four blocks with heavy secondary wires?

At this point the young technical graduate has advanced his theories and figured out a superb (!) system with conductors tapered down toward the end of the secondary, giving what he claims to be the ideal system of distribution. Suddenly a large load is to be added at a point where his conductors have been neatly tapered down; it is necessary to renew them and he comes to believe the "practical man" is correct in building with the same size conductor throughout, so he throws his theory to the winds and is lead by the "practical man." Occasionally special cases force themselves upon him and he may figure out what is the economical arrangement.

But as yet no practical man who has acquired the theory, or theoretical man who has learned the practice, has given to his fellow practical workers throughout this country even the most simple and fundamental tables of capacity and economical use of wires, except the N.E. Code rules on the ampere capacity of various sized conductors.

The "Lamp Committees" are now discussing the question of adopting one standard voltage lamp for a given system. Yet who knows for alternating current systems in general whether the range in voltage on the lamps is to be arbitrarily fixed by the committee at a maximum which they consider will still give good service, or whether the actual losses of energy in the distribution system supplying the lamps will not definitely limit the range of voltage at the different services?

It is with this vast and complicated unknown of DISTRIBUTION that this paper will deal. First will be submitted a few comments on primary systems and a preliminary set of tables for guidance of the practical man. Then a study of the fundamentals of the economic side of the situation will be made, pointing out the need for research and testing along certain lines.

Attention will be confined entirely to overhead lines and detailed discussion will only be given the transformer and secondary lines. The methods used in comparing fixed with operating charges are familiar and of course apply equally well to primary and secondary, though the almost infinite complication of the secondary problem is increased seven-fold when the primaries are considered in conjunction with it. There are, however, certain practical limitations, explained later, which enter to exclude the primary from consideration and the solutions are therefore more general than would appear at first sight.

All methods also apply to underground construction and to comparison of overhead and underground structures, though to cover completely only the subject in hand would require such a large volume that consideration of these last two subjects has been omitted entirely.

All figures on costs are altogether approximate and are not supposed to represent the experience of any one company, and are introduced simply to make the results more tangible. It would, of course, be possible to work out the whole problem with algebraic symbols leaving it to anyone interested to substitute true values and solve for the result. It would also have been possible to take these figures from "Data" or other handbooks. But they are simply assumed and are therefore not open for discussion unless their accuracy materially affects the conclusion.

The figures on maximum carrying capacity of wires are derived from Table B, paragraph 18 of the "N.E. Code," 1913 edition. All figures connected with power and voltage loss are based on the familiar formulae:

$$A = \frac{D \times W \times C}{P \times E^2}$$

$$V = P \times B$$

where

$A$ = area of conductor in circular mils.

$D$ = distance one way from source to receiver.

$W$ = load in watts.

$C$ = 2400 for 95 per cent power-factor, single-phase.

= 3380 for 80 per cent power-factor, single-phase.

$P$ = per cent power loss of delivered power.

$E$ = receiver volts.

$V$ = per cent voltage loss.
$B$ = constant given in following table for 60 cycles:

| No. of Wire B.&S. Gauge | Conductor Area Circular Mils | VALUE OF B | |
|---|---|---|---|
| | | 95 Per Cent P-F. | 80 Per Cent P-F. |
| 6 | 26,200 | 1.05 | 1.00 |
| 4 | 41,600 | 1.11 | 1.10 |
| 2 | 66,600 | 1.18 | 1.26 |
| 0 | 106,000 | 1.31 | 1.49 |
| 00 | 133,000 | 1.34 | 1.66 |
| 000 | 168,000 | 1.49 | 1.95 |
| 0000 | 212,000 | 1.62 | 2.09 |

### PRIMARY DISTRIBUTION SYSTEMS

There are two generally accepted alternating current distribution systems which can be considered regardless of the cycles, phase, or voltage so long as the latter is not above the generally accepted standard of 2400 volts. These two systems are the "tree" or "main and branch" system, and the "radial" or "center of distribution" system.

Fig. 1 shows the "center of distribution" system as submitted by Mr. H. B. Gear in Appendix II, to the report of the Distribution Committee to the last (1914) midwinter convention of the A.I.E.E. For this system very good voltage regulation is claimed on account of the radial feeds from the centers $A$, $B$, and $C$. The same writer shows in another diagram that emergency connections between the three circuits must be provided at points where they come close together. In his concluding paragraph he states:

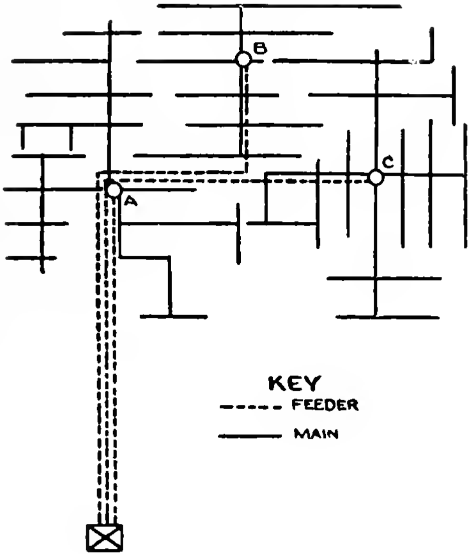

Fig. 1. Radial System of Distribution

"The feeder system must be reinforced as may be necessary from time to time to carry the added load. This involves rearrangement of connections of primary main and many complicated 'cut-overs' which add to the expense very materially."

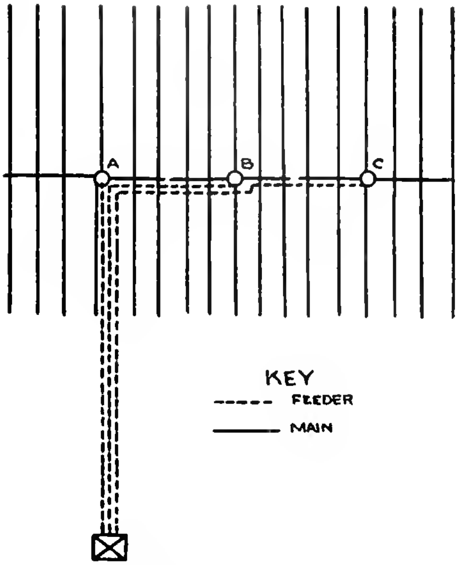

Fig. 2. Main and Branch System of Distribution

We do not doubt this writer's statement.

Now contrast this first method with the "tree" or "main and branch" system shown in Fig. 2, for covering the same section. A rough comparison will show that the wire lengths from the feeding points to the most distant points are not materially different from those in Fig. 1, and therefore the regulation must be almost the same. In fact, it is difficult to see where Fig. 1 has any advantage, so long as there are no diagonal streets.

A comparison can also be drawn on the basis of continuous service which is one, if not the most rigid, requirement at the present time. Suppose trouble occurs and a man goes out to locate and repair it. In the "radial" system he has to go around many corners and look in many places. On the "tree" system he has one straight main to travel and after clearing that, if necessary, he can travel out any branch he finds in trouble, moving quickly to the point in question.

Suppose the main feed "$B$" is in trouble in either system. See how simple it is to "cut-over" the load to "*A*" or "*C*" on the main street in Fig. 2, while in Fig. 1 it would apparently be done in an out-of-the-way corner.

Mr. Gear's opinion has been quoted on the work necessary to introduce a new feeder in Fig. 1. Notice how simple it is in Fig. 2. The breaks may be closed and the main cut into four sections and the new feeder run at a minimum expense.

In Fig. 2 there would probably be another main running directly by the substation. This would have branches on the same streets as *A*, *B*, and *C*. These would be run to meet each other on the same street parallel to the main *A*, *B*, *C*, and in case of trouble on *A*, *B*, and *C* the whole load could temporarily be transferred to the mains nearer the substation.

Consider also the simplicity of the pole line construction in Fig. 2, as compared to the many irregular dead ends and corners to be turned in Fig. 1.

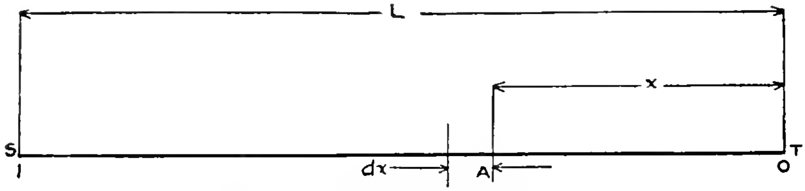

Fig. 3. Electric Circuit with Uniformly Distributed Load

But it is not intended to discuss the primary systems in this paper, so probably enough has been said to allow the assumption later in the calculations that, for all normal loads, the primary should always be present. The cost of its erection can, therefore, in general be neglected.

## LOAD CAPACITY OF SECONDARY DISTRIBUTION LINES

As stated in the introduction, it is proposed to present a set of tables of the capacity of secondary distribution systems for the use of the practical man. These alone will not show whether a given system is economical or not, but they will show the losses in any system and anyone using them may depend on his own judgment for determining the allowable losses until such time as the calculations shown in the latter part of this article have been made.

The three-wire nominal 110/220-volt single-phase secondary system has been assumed with an actual delivery voltage from the main of 112/224 volts which allows for a slight loss in the service wires and house wiring, insuring 110 volts at the lamp socket. The power loss and voltage loss are both assumed at 1 per cent. If it is decided that this is the proper loss to allow for any system the values of loads in the tables are correct; if a different loss is to be allowed the values can easily be multiplied by that per cent. An attempt will be made later to determine what that value is and it should be noted particularly that there is no reason why it should work out to an even per cent, indeed when the tables have once been multiplied it makes little difference in their use how irregular the per cent voltage or power loss may have been.

Tables have been used throughout rather than curves, because there are so few standard sizes of wire on any system that it is believed to be a more simple matter to pick the values from the tables for a few sizes, rather than from a curve covering all sizes.

The distribution of loads covered in the tables are typical:

*First:* Load concentrated at one end of secondary with transformer at opposite end.

*Second:* Uniformly distributed load with transformer at one end.

*Third:* Uniformly distributed load with transformer in center.

Any other loadings can be figured from a combination of these. All loads are given in kilowatts. The uniformly distributed load tables have been carried down to the lower hundreds of feet merely to show how enormously the capacity increases under these conditions though it is an impractical condition on a pole line since services can only be tapped from the mains at poles, which are in the vicinity of 100 feet apart.

It is interesting here to note that if the lamps of various customers are properly rated for the average voltage of the secondary supplying them, it makes no difference in the central station revenue how great the voltage drop, within a long range, since the curve of watts to volts is a straight line for a considerable distance both sides of normal rating. It does make a very considerable difference, however, in the amount of light received and current consumed by the first and last customers, since the lamps of the former will be burning above rating and those of the latter below rating.

The length to be used in calculating both voltage and power loss with a uniformly distributed load is a point of interest. It is generally known that to find the maximum voltage loss, half the greatest distance and the total load are used in the formula. However, it is probably not so well known that to find the *total* power loss only *one-third* of the total length is used. It may therefore be worth while to derive the equations for voltage drop and watts loss in the uniformly loaded circuit represented by Fig. 3.

$ST$ = an electric circuit of uniform resistance.

$S$ = source, and load is distributed uniformly towards "$T$."

$I$ = current at "$S$."

Current at "$T$" $= O$.

$E$ = potential difference between "$S$" and "$T$."

$W$ = total power loss in circuit.

Let

$i$ = current at any point "$A$" at a distance "$x$" from "$T$."

Then

$$i=\frac{I}{L}x.$$

$de$ = volts loss in a section "$dx$."

Let

$r$ = resistance of circuit per unit length.

Then

$$de=irdx.$$

$$E=\int_0^L irdx=\int_0^L \frac{I}{L}rxdx=\frac{Ir}{L}\int_0^L xdx.$$

$$E=\frac{Ir}{L}\left[\frac{x^2}{2}\right]_0^L=\frac{IrL^2}{L2}=Ir\frac{L}{2}.$$

But

$$Lr=R.$$

$$\therefore E=\frac{IR}{2}.$$

Similarly

$dw$ = watts loss in a section "$dx$."

Then

$$dw=i^2rdx.$$

$$W=\frac{I^2r}{L^2}\int_0^L x^2dx=\frac{I^2r}{L^2}\times\frac{L^3}{3}=\frac{I^2rL}{3}.$$

$$\therefore W=\frac{I^2r}{3}.$$

In order to show the method of applying the formula (page 1160 of "Introduction") to the following tables, calculation is here made of the capacity of 500 feet of No. 00 wire at 224 volts delivered with a power loss of one per cent, a power factor of 80 per cent, and with the load concentrated at the opposite end from the transformer.

The formula as given previously reads:

$$A=\frac{D\times W\times C}{P\times E^2}.$$

Since "$W$" is the unknown the formula is transposed for use:

$$W=\frac{A\times P\times E^2}{D\times C}.$$

$A$ = 133,000 circular mils.

$P$ = 1 per cent.

$E$ = 224 volts.

$D$ = 500 feet.

$C$ = 3380.

Then

$$W=\frac{133{,}000\times 1\times (224)^2}{500\times 3380}=3.9 \text{ kilowatts.}$$

This value will be found in Table II.

A similar calculation for 1 per cent maximum voltage loss may be made.

This involves the use of the formula:

$V=P\times B.$

Since "$P$" is the unknown this may be transposed:

$$P=\frac{V}{B}.$$

But

$V$ = 1 per cent.

$B$ = 1.66 (page 1161).

$$P=\frac{1}{1.66}=0.602.$$

$$W=\frac{133{,}000\times 0.602\times (224)^2}{500\times 3380}=2.4 \text{ kilowatts.}$$

This value may be found in Table I.

As noted in the first paragraph these tables are useful for determining the loss under any given conditions. Suppose a 500-foot, No. 00 secondary, similar to that used in the preceding calculations is carrying a load of 12 kw. and it is desired to know the voltage drop. Table I or the foregoing calculations show a load of 2.4 kw. will produce a drop of 1 per cent. Therefore 12 kw. will produce a drop of 12 divided by 2.4, or 5 per cent. The actual voltage drop is then 5 per cent of 224 or 11.2 volts.

The values of "$P$" as used in the foregoing formula are shown in the second column of

Tables I to VI. In the third column is shown the maximum load the circuit will carry without overheating, based on the rating of wires with other than rubber insulation in Table B, paragraph 18 of the "N.E. Code," 1913 edition.

### COST DATA ON DISTRIBUTION LINES

The following figures given in Tables I to VI are dependent on the fundamental electrical properties of wires and are entirely independent of how or when the wires are erected or the cost of erecting them. It is now proposed to consider the costs of erecting wires and their supports with a view to ascertaining the factors which need particular attention. As stated in the introduction, the figures have only the most general foundation in practice and are merely assumed and tabulated in order to show the data which

anyone studying this subject should prepare and also to give a basis for the sample calculations made later.

Table VII shows approximate costs of erected poles when erected singly or in lots up to ten in the same vicinity. It is very evident that, particularly in the smaller sizes which are used largely in local distribution, it is very advantageous to erect a large number at one time. In fact if, in a given section, the load gradually grew so as to call for two 40-ft. poles at a time, erected throughout the year, till seven were standing, it would have been just as cheap to have erected ten in the first place. This means that ten poles could be erected ready for new business

with a chance that three might never be used and still it would cost no more than the other "piece meal" method.

Similar and indeed more striking lessons could be drawn from Table VIII, showing the cost of erected secondary wires. For instance, if the initial financial burden were not too great, and if streets were open so that it would be possible to erect secondaries in a residential section in runs of 1000 ft. at a time instead of 200 ft. at a time, No. 2 wire could be used instead of No. 6 without additional cost. This would mean a tremendous difference in the capacity of the system as can be seen by referring to these two sizes in Table VI for 1000 ft., which shows that

## Table X

## COST IN DOLLARS OF ERECTION OF A TRANSFORMER ON AN ERECTED POLE WITH PRIMARY AND SECONDARY LINES ALREADY ON POLE; ALSO COST OF CHANGING TO ANOTHER SIZE

| Group | Transformer Size Kv-a. | Original Installation | Changing to Group A | Changing to Group B | Changing to Group C |
|---|---|---|---|---|---|
| A | 1 to 10 | $5.50 | $4.00 | $5.00 | $6.00 |
| B | 15 to 25 | 6.50 | 3.50 | 5.00 | 6.00 |
| C | 30 to 50 | 7.00 | 5.00 | 5.00 | 6.00 |

through the 1000 ft. with the transformer in the center the No. 6 wire would carry 6.6 kw. while the No. 2 wire would carry 16.6 kw. This is an increase to 2½ times the capacity without additional expense if one can just look ahead far enough.

On account of the increase in load in any section it may be necessary at any time to replace small wire with a conductor of larger size. It is therefore interesting in this connection to determine how much return can be had for removing the wire which is so expensive to erect. This return is here termed "credit" and is the scrap value of the wire minus the cost of removing it. These credits are shown in Table IX for wire which may still be used over again. The credits run higher for the greater lengths because they might be returned to second-hand stock while the shorter lengths would just be cut down and scrapped. A comparison of this table with Table VIII shows strikingly the results of not building lines large enough at first to carry all load which may arise during the useful life of the wire.

Now that the poles and primary and secondary lines of a distribution system have been considered, it is time to consider the transformer which ties together the primary and the secondary mains. This has properties similar to those of poles and wires in that it costs money as is clearly shown in Table XI. It also shares with the wires in absorbing some of the energy which it transmits. But it goes further than that, absorbing energy whether it is transmitting any or not. This constant drain of energy is called the core loss, and is shown in Table XI for transformers from 1 to 50 kv-a., both in watts and in cost in dollars per annum at ½ cent per kw-hr.

There has been some discussion about the rate at which the core loss should be charged. Some would say that it must take its share of the generating substation and distribution costs, while some would merely charge its coal cost. This latter would appear to be more nearly correct since the core loss totals less than 1 per cent of the peak load and therefore has a negligible effect on the generating capacity. Its effect on the remainder of the system is so distributed over the whole that its effect is absolutely negligible. Judging it by the standards for commercial loads, it has a 100 per cent load factor on the 24-hr. basis and is so distributed that it requires no additional apparatus and it is therefore entitled to the absolute minimum rate.

Table XI also shows the cost of the various sizes of transformers and the cost of erection. From these figures with interest at 6 per cent and depreciation 10 per cent, on the basis of a life of 10 years, the cost of keeping a transformer on the line for a year has been worked out and is shown. Some would like to claim longer life than 10 years, though general experience would not seem to warrant it for the average size pole type transformer. Of course, these figures should be modified by the latest data on each system in making the calculations.

The core loss has been materially reduced in recent years. It probably makes more expensive construction to reduce the loss, and by letting it run higher the transformer should be cheaper. It is therefore the business of the manufacturing companies to obtain a true balance between these factors.

No allowance has been made for maintenance charges against the transformer since many companies have done practically no maintenance work on them and no definite figures, as to the amount necessary or how it will improve the life of the transformer or its capacity, are readily available. However, just a superficial study of the table will show that if 10 years is the true life of a 50-kv-a. transformer, without any maintenance work, work that would improve the life to 15 years could cost as much as $10.00 per year. This is easily enough to pay for most complete lightning protection, purification of the oil, and complete cleaning when out of service and still leave a very wide margin of profit.

Many people familiar with transformers can scarcely tell the difference between a 40 and a 50-kv-a. transformer when they see it on the pole. Yet the last column shows the difference is $8.10 a year. A practical man in choosing whether to put up a 40 or a 50-kv-a. transformer will very likely decide to use the 50, saying: "It will be needed in a couple of years anyway." However, it will cost $16.20 more in that time and it would cost only $6.00 (Table X) to change it. This last column (Table XI) shows that if the average size of transformers on any system could be reduced say from 15 kv-a. to 10 kv-a. it would warrant the expenditure of approximately $6.00 per transformer per annum. This is easily enough to pay for very complete tests and records of every transformer.

In this connection it is not out of place to consider briefly what tests and records are necessary. On small systems with one or two men handling all records it is very generally possible to have one set of records for all. But on larger systems it becomes necessary to have records of customers' loads in the contract department, meter department, and distribution department. Experience has shown the great difficulty of keeping these records up to date, particularly with medium size business places, where different sizes of lamps are kept on hand and used on different evenings according to the season of year and business expected. So it is an open question in the distribution department, with which only we are now concerned, whether it is necessary to keep any record of load except for the larger customers—that is, for the customers whose loads are say one-fourth or one-half of the transformer capacity supplying them. But it is evident from Table XI that it is most necessary to keep records of actual tests, showing that the transformers are working at least up to their rating, and, if they will stand it, above their ratings during the peak. The two factors that determine whether they will stand it or not are the temperature and the regulation. This is a great subject in itself and there is not space here to say more than that one central station has just started some practical in-service tests on this basis and there may be some very interesting results to report in the future.

Table XI

INITIAL COST OF, AND ANNUAL CHARGES AGAINST POLE TYPE TRANSFORMERS

Life, 10 Years; Depreciation, 10 Per Cent; Interest, 6 Per Cent; Total Capital Charges, 16 Per Cent; Energy to Supply Core Loss, ½ Cent per Kw-Hr.

| Kv-a. | COST IN DOLLARS | | | | CORE LOSS | | Total Annual Charges |
|---|---|---|---|---|---|---|---|
| | Original | Erection | Total | Annual | Watts | Cost per Year | |
| 1.0 | $20.00 | $5.50 | $25.50 | $4.10 | 25 | $1.10 | $5.20 |
| 2.0 | 30.00 | 5.50 | 35.50 | 5.70 | 35 | 1.50 | 7.20 |

| 4.0 | 50.00 | 5.50 | 55.50 | 8.90 | 50 | 2.20 | 11.10 |
| 5.0 | 55.00 | 5.50 | 60.50 | 9.70 | 55 | 2.40 | 12.10 |
| 7.5 | 75.00 | 5.50 | 70.50 | 11.30 | 75 | 3.30 | 14.60 |
| 10.0 | 90.00 | 5.50 | 95.50 | 15.30 | 90 | 3.90 | 19.20 |
| 15.0 | 120.00 | 6.50 | 126.50 | 20.20 | 120 | 5.25 | 25.45 |
| 20.0 | 150.00 | 6.50 | 156.50 | 25.00 | 145 | 6.35 | 31.35 |
| 25.0 | 180.00 | 6.50 | 186.50 | 29.80 | 170 | 7.45 | 37.25 |
| 30.0 | 200.00 | 7.00 | 207.00 | 33.00 | 190 | 8.30 | 41.30 |
| 40.0 | 240.00 | 7.00 | 247.00 | 39.50 | 225 | 9.80 | 49.30 |
| 50.0 | 280.00 | 7.00 | 287.00 | 46.00 | 260 | 11.40 | 57.40 |

As a matter of interest and for subsequent use, the copper loss and regulation of transformers are shown in Table XII. The cost of energy for copper loss has been assumed at 2 cents per kw-hr. since it is a peak load. This is discussed more fully in considering rate for energy losses in the secondary (page 1172).

The transformer has been treated in a manner slightly different from that in which the pole and wire costs were treated; that is, its cost per annum has been determined as well as the initial cost. It is now proposed to do the same for secondary wires but, since the previous tables show plainly that it is uneconomical to erect wires in short sections, figures for 1000-ft. sections only have been made up. These are shown in Table XIII.

## PRACTICAL COMBINATION OF DATA FOR ECOMONICAL RESULTS

In the preceding sections of this article the losses in various apparatus and the cost of maintaining it in service have been shown. It is now proposed to combine these to show what is the truly economical design for a secondary distribution system.

This would appear a very complicated problem, and indeed it is. But it is here that the "practical man" comes in to simplify matters. For instance, in considering the question of service to a row of houses by wires run along the rear on brackets from one end, the "practical man" says it is useless to consider running the primary lines in to a transformer placed in the center of the row, no matter how cheap a job it will make, on account of the same objections which have been advanced against the "radial system," and also on account of the life hazard of

### Table XII

### TRANSFORMER REGULATION AND COPPER LOSS AND COST PER YEAR AT 2 CENTS PER KW-HR. FOR FULL LOAD OPERATION 1 HOUR PER DAY

running primary wires open on a row of residences. This is, of course, an extreme case, but it is brother to the case of a moderate size load on a side street; that is, a street that has not been chosen for a primary branch, as in Fig. 2. The practical man says: "Let it cost more, but if any reasonable arrangement can be made, keep the transformers on the main street." Further, the junction pole at a corner would appear to be the ideal place to feed economically in both directions; but objection is rightly made that a junction pole is complicated enough without the transformers; it is already the most difficult to maintain and renew, and it usually of necessity has a street lamp. This limits the transformer poles to those in the center of the block. There may also be some alleys requiring lines and therefore junction poles, so in a block 500 ft. long there may be only two or three poles available for transformers. Considering that there may be separate light and power transformers required, apparently only one pole per block will be available for a lighting transformer, unless sufficient economy by using more can be shown to warrant the shortening of the spans and the erection of an additional pole. Then, the practical man goes further—he says: "Transformers, like all other apparatus on a line, are points of trouble," and he wants as few of them as possible, in order to maintain continuous service, so that one transformer for every two blocks would be much better. Concluding, he thinks that a secondary system, such as shown in Fig. 4, considering the primary lines running on the "main streets" would be ideal, except that the transformers would have to be moved to the pole next to the corner.

So the problem would on the whole appear to be much simplified by the apparent complications of practical conditions.

The most economical condition is, of course, when the sum of the fixed capital and maintenance charges, and the operating charges or cost of the power loss are a minimum. The question of increased or decreased consumption of current by the lamps might at first be thought to influence this problem, but it has no connection. If lamps are supplied rated at exactly the service voltage of each individual customer, it then makes no difference what is the range in voltage from the nearest to the most distant service. If lamps are supplied to all alike of the average voltage on the secondary, then the increase in consumption of some will offset the decrease by others, so far as the central station is concerned. The results of the calculations in Table XIV amply justify this assumption and preclude the necessity of further discussing the ethics of the matter.

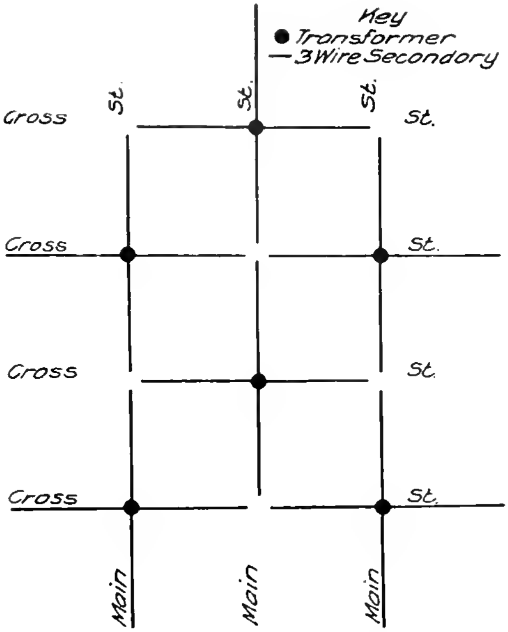

Fig. 4. Ideal Secondary Distribution

It is not proposed here to work out economical conditions for all cases but to give an example of the procedure. The case taken will be that which the forenamed practical considerations would point to as normal. Suppose there is an actual combined running load of 30 kw. in two blocks, each 500 ft. long, making a total length of secondary of 1000 ft. (This is very near the condition on the main business street of a small town or an outlying business street of a large city.) The 30 kw. can just be carried by No. 6 wire without over-heating. The question is, what size wire shall be used to supply the load. The charges for the 30 kv-a. transformer will be fixed. The charges for the wire will be fixed for each size regardless of the length of time the load is in use. The operating costs or power loss in the secondary will vary with the length of time the load is in use, and the copper loss of the transformer is included with it, since it varies in exactly the same manner. It is therefore evident that the answer, i.e., the size of wire, will vary with the length of time the load is in use. Since the load does not come on or go off suddenly or stay at any fixed value, and since it, as well as the time in use, varies throughout the year, a more general answer can be obtained by finding the most economical sizes for each period of use from 1 to 10 hours.

The charge per kw-hr. for energy losses, like the charge for core loss of a transformer, is open for discussion. It is in reality the total cost of supplying current to the class of customers supplied by the secondary line in question, minus the customer or service line and meter charges. The practical way to obtain this, until the whole subject of distribution has been given much more detailed attention than it has received to the present time, is to take the average rate per kw-hr. paid by the customers on a secondary main and subtract the average charges per kw-hr. delivered for service and meter costs. The figure of 2 cents per kw-hr. has been used in Table XIV, but is obviously very low for lighting customers. Any increase in this value would tend to increase the economical size of wire.

Table XIV needs study, rather than comment. It sums up all that has gone before and shows most conclusively that there *is* an economical size of wire to be used for every condition and that this size is not far different from what the practical man is accustomed to use, but is right in the range of commercial practice. In the particular case in hand it is probably not out of the way to assume that the load would be "on" two or three hours per day as the average. The table shows that for this use the best size of secondary is No. 0. No. 00 is so close to the same economy and with better economy if the load should run for four hours, that it is a question indeed if it should not be used.

But while the fact that the most economical size of wire can be exactly determined is of great interest, the final column is of even greater. It shows that if central stations could afford to abandon their present distribution systems and build new ones in accordance with these principles of design, the question of different lamp voltages for different customers would be settled. With the most economical size of wire the range of voltage in the hypothetical case considered is only 2.2 per cent or 1.1 per cent from the average. This is such a small amount that it is negligible, as can be seen by reference to any of the standard candle-power curves published by lamp manufacturers. Such curves show a change of only 3.5 per cent in candle-power for a 1 per cent change in voltage. (A very complete discussion of this subject is given in the report of the Lamp Committee to the Pennsylvania Electric Association, 1913.)

In other words, the central station with lines designed without regard for initial cost and with regard for total economical operation will supply service of which there can be absolutely no complaint.

This does not consider the primary losses which might cause different voltages on the different transformers. Similar calculations can, however, be made for them and it is probable that the results would be similar to those for the secondary and warrant large enough wire to offset the losses. At any rate, a practical remedy is to get a great enough load density so that the primary lengths from the first to the last transformer on a circuit are short, and it is then found with the "tree" system that there is almost no difference of voltage on the different transformers.

In Table XIV the load is fixed at 30 kw. It is interesting as another general problem to determine at what load the advantage turns—say from No. 6 to No. 4 wire, when the loads are in use three hours per day. This is determined in Table XV, which is similar to Table XIV, except that only two sizes of wire are considered, and the time is constant at three hours per day, while the load is varied from 1 to 30 kw.

Table XV shows plainly that with a load of 7½ kw. or less the No. 6 wire is the more economical, while if the load is increased to 10 kw. or above, the No. 4 wire is more economical. It is also interesting to find that the voltage loss for this maximum economical load is only 1.8 per cent or a variation of no more than 0.9 per cent from the mean value. This table should be extended to cover all sizes of wire for actual use, but the principle is the same and extension here is not considered necessary.

Next, it is interesting to consider the practical matter of replacing small wire with larger when the load has increased enough to require it. This will be done by means of the tables on the original cost of wire and credit for removal of wire when replaced by larger. (Tables VIII and IX.)

The case taken for a sample calculation will be that of the erection of No. 6 wire to carry its full capacity of 7½ kw. and later changing it to No. 0 when the load requires. The question is to find how much time must elapse between the original installation and the date of increase, in order to make it economical to erect the No. 6 wire and later change it to No. 0. The No. 6 wire carrying 7½ kv-a. for three hours per day (Table XV) costs $26.20 per year.

A similar secondary of No. 0 wire carrying 7½ kv-a. with a 7½-kv-a. transformer costs $27.45 per year, made up as follows:

| | | |
|---|---|---|
| Fixed charges for transformer........ | | $14.60 |
| Fixed charges for secondary lines.... | | 11.80 |
| Transformer copper loss | 0.120 kw. | |
| Secondary power loss (0.284 per cent)..... | 0.0213 kw. | |
| Total............... | 0.1413 kw. | |
| Cost of 0.1413 kw. 3 hours per day.. | | 1.05 |
| Total........................ | | $27.45 |

| 25.0 | 37.25 | 7.10 | 44.35 | 29.70 | 74.05 | 8.20 | 45.45 | 21.00 | 66.45 |
| 30.0 | 41.30 | 7.10 | 48.40 | 39.30 | 87.70 | 8.20 | 49.50 | 24.00 | 73.50 |

### Table XVI

### SHOWING DERIVATION OF OPERATING COSTS IN TABLE XV, GIVING OPERATING COST FOR TRANSFORMER AND SECONDARY FOR 1 YEAR WITH USE OF 1 HOUR PER DAY. RATE, 2 CENTS PER KW-HR.

| TRANSFORMER | | NO. 6 WIRE POWER LOSS | | | | NO. 4 WIRE POWER LOSS | | | |
|---|---|---|---|---|---|---|---|---|---|
| Size Kv-a. | Copper Loss in Kw. | Per Cent | Kw. | Total Kw. | Cost | Per Cent | Kw. | Total Kw. | Cost |
| 1.0 | 0.030 | 0.15 | 0.0015 | 0.0315 | $0.25 | 0.095 | 0.0010 | 0.031 | $0.20 |
| 2.0 | 0.050 | 0.30 | 0.0060 | 0.056 | 0.40 | 0.19 | 0.0038 | 0.054 | 0.40 |
| 3.0 | 0.070 | 0.45 | 0.0135 | 0.083 | 0.60 | 0.29 | 0.0087 | 0.079 | 0.55 |
| 4.0 | 0.085 | 0.61 | 0.0244 | 0.109 | 0.80 | 0.38 | 0.0152 | 0.100 | 0.75 |
| 5.0 | 0.095 | 0.76 | 0.0380 | 0.133 | 1.00 | 0.48 | 0.0240 | 0.129 | 0.95 |
| 7.5 | 0.120 | 1.14 | 0.0854 | 0.205 | 1.50 | 0.71 | 0.0542 | 0.174 | 1.25 |
| 10.0 | 0.160 | 1.52 | 0.152 | 0.312 | 2.30 | 0.95 | 0.095 | 0.255 | 1.85 |
| 15.0 | 0.220 | 2.28 | 0.342 | 0.662 | 4.80 | 1.43 | 0.214 | 0.434 | 3.15 |
| 20.0 | 0.295 | 3.03 | 0.607 | 0.903 | 6.60 | 1.90 | 0.380 | 0.675 | 4.90 |
| 25.0 | 0.355 | 3.80 | 0.950 | 1.355 | 9.90 | 2.48 | 0.620 | 0.975 | 7.00 |
| 30.0 | 0.430 | 4.55 | 1.37 | 1.80 | 13.10 | 2.86 | 0.860 | 1.090 | 8.00 |

Therefore the No. 0 wire costs but $1.25 more per year than the No. 6 wire.

To change from No. 6 to No. 4 wire and from a 7½ kv-a. to a 30 kv-a. transformer involves charges against the expense account (Tables VIII, IX and X) of,

| | |
|---|---|
| Changing wire | $32.50 |
| Changing transformer | 6.00 |
| Total | $38.50 |

To change from a 7½ kv-a. to a 30 kv-a. transformer in connection with the No. 0 wire costs $6.00. The difference of these charges to expense is $32.50. This figure is to be compared to the difference of $1.25 in operating costs for the period previous to the change. If $32.50 is divided by $1.25 it is found that unless the smaller load is in use over 26 years before the increase comes, it would have been more economical to erect the No. 0 wire originally.

These figures are most startling. Yet they are only extreme in the fact that if any other combination is chosen the period will be longer instead of shorter. They do point out very clearly the necessity of working up tables similar to these, using absolutely the most reliable information at hand, and the extension of all these calculations to cover concentrated and other distributions of loads, as well as the case of uniformly distributed loads here used.

There is another saving that could be made by using several sections of the No. 0 wire together till the load increased to an extent to require separate transformers. This would be equivalent to "closing through" the secondaries on one of the main streets in Fig. 4, and omitting one of the transformers on this street. It could then be sectionalized, in the light of greater information on the load, at a future date. In this connection it is interesting to note that if an extreme load came on at any point the transformer could be placed directly at that point and the load would not affect the general capacity of the secondary in the slightest degree.

## EFFECT OF ECONOMIES ON COMMERCIAL POLICY

The economies that can be practised if the future load is known, as has been shown in the previous sections, are so obvious that the commercial policy that they dictate follows without argument. The engineer can build lines very economically if he is allowed to do it in large sections at a time, and if the curve of the predicted growth of load is known.

Therefore, the first step is to take a large section or even one street for three or four blocks and determine the growth of load and lay out an economical distribution to cover this; then, send the contract agent to secure the first contract. As soon as this has been done build the whole distribution system and leave it to the contract agent to come up to the mark set for him. He will have no excuses of high service costs or length of time to run service, and will simply have to hustle. Incidentally, he will be reduced from his present high place as the man who brings the new life blood into the Company and will become simply a hard-working part of the machine.

It would be possible to write at length on the methods for determining the growth of load curve and the sections of a property first to be treated, but that is a detail that can easily be worked out if the general plan is adopted.

## CONCLUSION

In conclusion, particular attention is drawn to the fact that this is but the beginning of the solution of the great problem of aerial distribution. The problem of underground lines needs treatment in a similar manner, only perhaps more urgently, since the investment is much greater. The comparison of overhead and underground lines is exactly similar, only probably even more startling in some of its results.

Let all concerned in any way in distribution bear these few facts in mind and make all their work and records conform, so that in the near future the rational solution of this ever-present problem of the central station may be reached.

# THE SUCCESSFUL OPERATION OF A TELEPHONE SYSTEM PARALLELING HIGH TENSION POWER LINES

By Charles E. Bennett

Electrical Engineer, Georgia Railway & Power Company

The author describes the successful installation of a telephone line on the towers of the Georgia Railway & Power Company's Tallulah Falls 110,000-volt transmission line. The fine degree of potential balance between the two wires of the telephone line, necessary for satisfactory communication, was obtained by transposing the wires at every tower and by thorough insulation. Drainage coils are connected between the wires and to ground to relieve the line of low frequency high potential stresses, while high frequency surges are discharged through vacuum type lightning arresters, supplemented by horn gaps. A large number of tests were conducted on this line to determine the effects produced by different arrangements of apparatus, and the results are given in the text and in the accompanying oscillograms.—Editor.

The problem of locating private telephone lines on the steel towers of high voltage power lines instead of carrying them on a separate pole line is one that has been under discussion for some time, and many of the larger companies have abandoned the use of a telephone line carried on the towers on account of the many troubles occasioned by this arrangement.

When telephone lines parallel high tension transmission lines they are subjected to influences which may under certain conditions interfere with the proper transmission of speech. This interfering influence is, in all cases, due to the static induction from the high tension transmission line. Under normal operating conditions, i.e., with fairly well balanced three-phase circuits, this influence will be slight; but with abnormal operating conditions on the transmission line, the effect created on a telephone line may increase to such an extent as to become destructive. In addition to these influences the telephone line is subjected to disturbances occasioned by lightning discharges, which, however, are very similar in character to the effects created by abnormal conditions on the transmission line, such as those occasioned by switching with unbalanced phases, arcing grounds, etc.

Under normal operating conditions the effect of the static induction upon the two wires of the telephone line is practically the same, with the result that the two wires will assume a definite potential with regard to earth. With a well insulated and properly transposed metallic line, the potentials of each wire against ground will be nearly alike, and hence there will be no difference of potential between the two wires themselves. In telephone work, however, even the smallest difference of potential between the wires will create a flow of current through the telephone receiver. This current, being alternating, produces a noise in the receiver which may be loud enough to render talking impossible. The higher the voltage of a transmission line and the closer the telephone line to the transmission line, the more prominent will be the noise in the telephone, with a slightly unbalanced telephone line. As this disturbing current is due to a difference of potential, it is obvious that the noise in the receiver is in a measure independent of the absolute value of the voltage of each line to ground, and that it cannot be eliminated unless the voltage on both wires be made exactly alike. This condition, which is termed "balanced," is realized by properly insulating and trans-

Fig. 1. Photograph of a Standard Line Tower of the Georgia Railway & Power Co., Showing the Power Wires and the Telephone Wires and Their Transposition

posing the telephone wires. The larger the number of transpositions per mile, the more nearly will the potential on the wires be equalized; and the better the insulation of the lines, the less will there be a chance for a "leak" (to ground), causing a drop of potential on that particular wire, with the subsequent result of unbalancing the line and rendering it noisy.

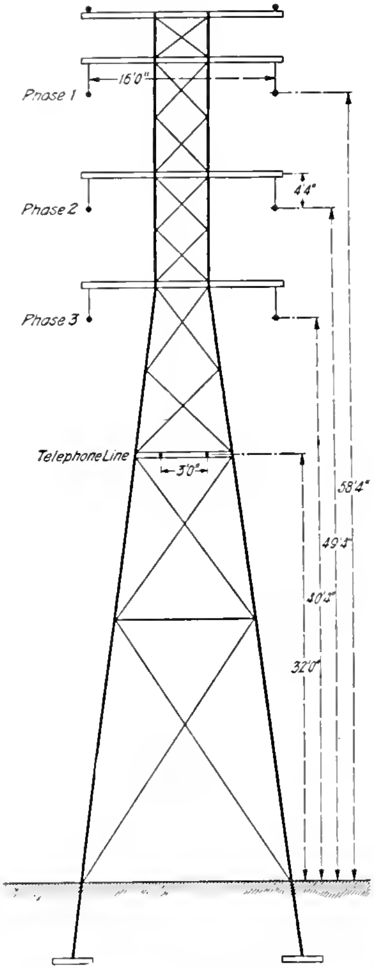

Fig. 2. Dimensioned Drawing Showing the Location of the Power and Telephone Wires on Tower

From the above it will be seen that so far as the noise of the line is concerned it can be kept within any limit, provided the telephone line is properly transposed and well insulated. On the other hand, it will be seen that the existing potential between telephone wires and ground, by reaching high potential values, may not necessarily impair the transmission of speech, but will seriously strain the insulation of the instruments and make their use dangerous.

*The transmission system of the Georgia Railway & Power Company consists of a double 4/0 circuit from Tallulah Falls to Atlanta, a distance of 90 miles, with double 2/0 circuits extending northward to Lindale and southward to Newnan from Atlanta. The line from Atlanta to Lindale is about 75 miles in length, while the line to Newnan is about 40 miles. All of these lines are operated at from 110,000 volts to 120,000 volts at 60 cycles.

This system is paralleled by a single two-wire telephone circuit located about 10 feet (diagonally) below the bottom power conductor and carried on the horizontal angle iron which forms a part of the tower.

The original layout was made with pin insulators of 11,000-volt design, but the many induced surges or steep front waves punctured them with such remarkable rapidity that is was decided more insulation—or puncture-proof quality—was necessary. From a construction standpoint it was found most convenient to re-insulate the line with suspension disks. It has been found that one suspension unit will withstand most of the

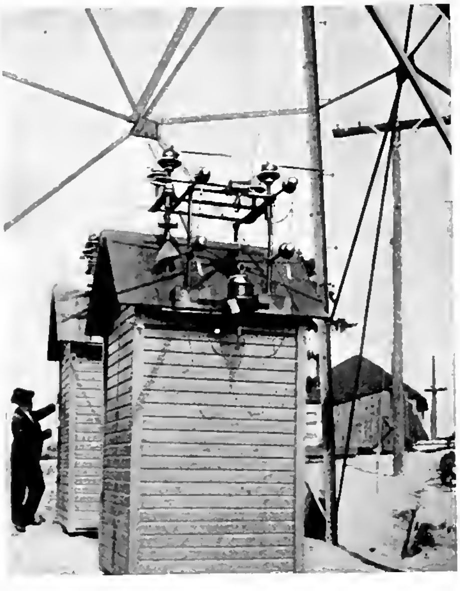

Fig. 3. Telephone Booth Connected, Showing Disconnecting Switch and Horn Gaps

---

* A full description of Tallulah Falls development of the Georgia Railway & Power Company will be found in the June and July, 1914, issues of the REVIEW.

electrical stresses, but in order to secure perfect continuity, two were used. The telephone wires are spaced at three-foot centers, the wire itself being No. 4 copper clad, of 30 per cent conductivity, drawn from 400 lb. ingots in lengths of about half a mile to minimize the number of joints. All joints are made with special "figure eight" splicing sleeves about nine inches long.

The reason for using wire of this size was that it might be strung parallel to the power conductors and still be able to withstand a loading of about three-quarters of an inch of ice without exceeding the elastic limit.

Transpositions are made on all towers, which average about nine or ten to the mile. The wires are supported by suspension insulators on each side of the tower, two insulators being used at each point of support, and transpositions made with long and short loops between the insulators located on opposite sides of the tower. The transpositions are all made with the same clockwise twist, so as to make a running transposition.

Fig. 4. Front View of the Telephone and Its Protective Equipment as Installed

At intervals of four miles, telephone booths are located. They are simply frame buildings of the knockdown type, about four feet square, with a 22,000-volt switch of special construction on the roof. This switch is made with horn gaps to ground, set at approximately three-eights of an inch, and the two poles are operated simultaneously by means of a hand lever inside the booth. An insulated platform is provided in the booth on which the operator may stand while throwing the switch that cuts the station in multiple with the line. This switch is opened as soon as the operator finishes his conversation. In otherwords, the telephones in the booths are only connected to the line during the time they are in actual use, and the equipment is therefore not endangered by surges or lightning along the line, nor is the talking impaired by having a number of stations in multiple.

Fig. 5. Side View of the Apparatus shown in Fig. 4

At numerous places, convenient to working crews, the telephone line is sectionalized to facilitate the location of trouble, and at the intermediate substations 22,000-volt double-pole switches are used for this purpose.

Specially designed receiving and sending equipment is located at the power house and substations, which is standard for all stations. It comprises a horn gap to ground mounted on a bracket at the entrance to the building, and a 50-turn air choke coil; the line then passing through 20,000-volt entrance bushings to the interior, where a specially designed double-pole fused switch is inserted. From this switch the line is connected through a horn gap and vacuum arrester to a one to one

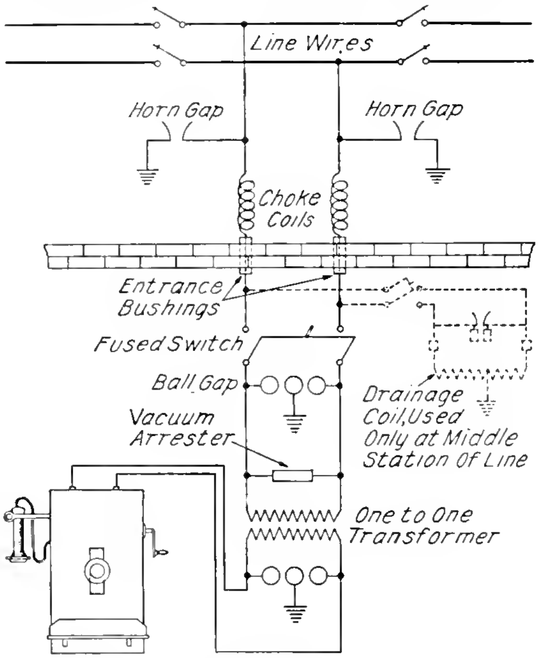

Fig. 6. Connection Diagram of a Telephone Located at a Station

Type Y-109-B insulating transformer, which in turn is connected to the telephone instrument.

The usual way to relieve telephone lines of high potential is to bridge a so-called bleeding or drainage coil across the line. Considerable experimenting was done with drainage coils on this line, and it was found that the ordinary type was not of sufficient carrying capacity. Sizes of 1 kw., 3.5 kw., and 5 kw. were soon destroyed and then a 15 kw. 2200-1100/-220-110 Type H lighting transformer was installed, which has given very good results. The telephone line is connected to the terminals of the 2200-volt winding and the middle point of this winding connected to ground. The secondaries are then left open circuited. This arrangement will offer a high inductive resistance to the talking currents, but a very low ohmic and negligible inductive resistance to the flow of current from the two wires to ground, owing to the fact that the simultaneous discharge from the wires through the coils to ground will neutralize the magnetic effects. This bleeding coil becomes an effective outlet for all low frequency currents induced from the transmission line.

Sudden changes in the transmission line, like switching, arcing grounds, lightning discharges, etc., have all the same effect upon a balanced telephone line, namely, to charge the two wires suddenly to a very high potential. Owing to the rapidity, or in other words, the high frequency with which these charges are induced on a telephone line, the small inductance of the bleeding coil, no matter how accurately balanced, is not sufficient to prevent these charges from flowing to ground, and therefore another apparatus is required which will act as an outlet for these particular disturbances. It has been found that the vacuum type arrester is best suited for this service. This arrester consists of two electrodes enclosed in a partially exhausted metal tube and connected across the line. This arrester is very sensitive to charges of high frequency and will begin to discharge freely as soon as the voltage on the lines reaches about 300 volts. The peculiar advantages of these arresters lie in the fact that the discharge occurs gradually instead of disruptively, and these discharges have no ill

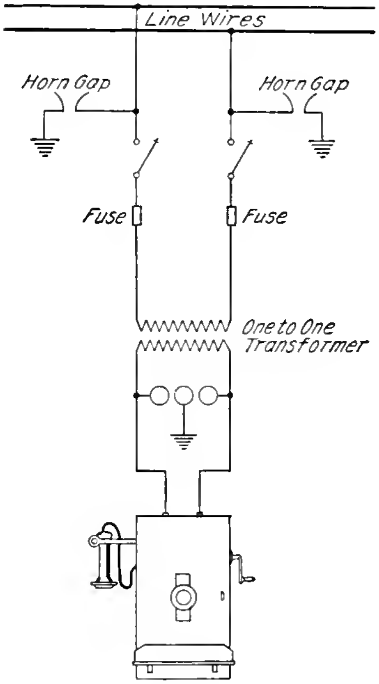

Fig. 7. Connection Diagram of a Telephone Located in a Booth

effect upon the electrodes, leaving the line perfectly clean and balanced. It is advisable to place fuses in circuit to protect this arrester from destruction should the discharges, for some reason or other, exceed the safe value for which it is built. The large gaps or horns, being set at three-eighths of an inch, form a sort of rough protection to all the equipment, should it be subjected to very high momentary potentials.

The station equipment of this system was tested by impressing 60,000 volts on it, which resulted only in the blowing of a fuse.

Calculations were made to determine the potential of the line against ground by use of the following formula, which is offered for those interested in figuring out new lines:

Let $A$, $B$ and $C$ represent the three conductors of a three-phase power circuit, and $S$ and $T$ the conductors of the telephone circuit.

Let $E_0$ be the voltage between each wire of the power circuit and ground.

Let

$r$ = radius of power conductor in inches.
$a$ = distance in inches between $A$ and ground. (Av.)
$b$ = distance in inches between $B$ and ground. (Av.)
$c$ = distance in inches between $C$ and ground. (Av.)
$s$ = distance in inches between $S$ and ground. (Av.)
$t$ = distance in inches between $T$ and ground. (Av.)

Then

$$e_a = E_o \frac{log \frac{a+s}{a-s}}{log \frac{2a-r}{r}}$$

$$e_v = E_o \frac{log \frac{b+s}{b-s}}{log \frac{2b-s}{r}}$$

$$e_c = E_o \frac{log \frac{c+s}{c-s}}{log \frac{2c-r}{r}}$$

and

$$c_s = \sqrt{e_a^2 + c_b^2 + e_c^2 - (e_a e_b + e_a e_c + e_b e_c)}$$

where $e$ is equal to potential of wire $S$ against ground. Potential of wire $T$ against ground may be found by a similar process, substituting $t$ for $s$ in the above formulae. (From Ferguson's "Elements of Electrical Transmission.")

By the use of this formula a theoretical induced potential of 5700 volts for the above line was obtained. Tests have subsequently been made to ascertain the actual value of this induced potential.

With one power line energized (the power conductors being on nine-foot centers in a vertical plane), an induced potential reading of 5600 volts from line to ground was obtained. As the high-voltage system has its neutral grounding at the power house, the voltage between each power line and ground was, of course, 63,500 volts. The current in the drainage coil neutral was 4.47 amperes at the time the above readings were obtained.

In order to ascertain the maximum potentials that could be induced on this line, the following tests were made and results obtained as indicated:

> With the top wire of one power circuit charged, an induced potential reading of 5100 volts was obtained between telephone line and ground.
>
> With the middle wire of one power circuit charged, the induced potential reading was found to be 7200 volts.
>
> With the bottom wire of one power circuit charged, the induced potential reading was found to be 10,000 volts.
>
> With the top wire of each power circuit charged, the induced potential reading was found to be 9300 volts.
>
> With the middle wire of each power circuit charged, the induced potential reading was found to be 13,100 volts.
>
> With the bottom wire of each power circuit charged, the induced potential reading was found to be 18,200 volts.

All of the above readings were taken with a 100 to 1 potential transformer and indicating voltmeter, the drainage coil being disconnected. Tests were then made with the drainage coils connected across the line at Gainesville and Atlanta and three wires of north circuit excited. Figures give current in ground connection of drainage coils.

| Line voltage | 110,000 | 50,000 |
|---|---|---|
| Current in ground connection of drainage coil at Atlanta, Ga. | 1.0 amp. | 0.6 amp. |
| Current in ground connection of drainage coil at Gainesville, Ga. | 2.6 amp. | 1.15 amp. |
| Current in ground connection of drainage coil at Gainesville with drainage coil at Atlanta disconnected from line | 3.55 amp. | 1.50 amp. |

OSCILLOGRAPH RECORDS OF INDUCED WAVES

**Fig. 14.** Upper Curve: Potential of Phase 3 Power Line to Ground. Lower Curve: Induced Potential on Telephone Circuit 5600 volts

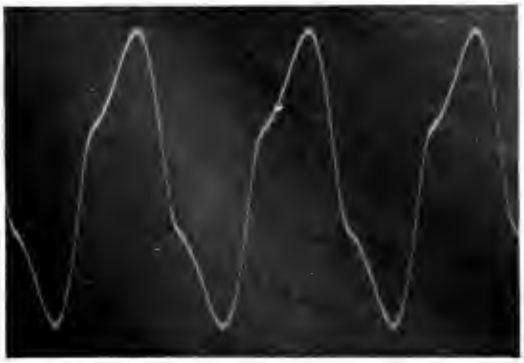

**Fig. 15.** North Circuit Charged. Voltage Curve: Voltage between Telephone Line and Ground 5100 volts

The voltage from telephone line to ground with three wires of the north circuit excited to the line voltage shown, and with drainage coils connected at both Atlanta and Gainesville, was as follows:

| | | |
|---|---|---|
| Line voltage | 110,000 volts | 50,000 volts |
| At Atlanta | 0.0 volts | 0.0 volts |
| At Gainesville | 31.0 volts | 18.0 volts |
| At Tallulah | 234.0 volts | 100.0 volts |

The following figures give the voltage from telephone line to ground with three wires of the north circuit excited to the line voltage shown, and drainage coil connected at Gainesville but disconnected at Atlanta:

| | | |
|---|---|---|
| Line voltage | 110,000 volts | 50,000 volts |
| At Atlanta | 158.0 volts | 70.0 volts |
| At Gainesville | 41.0 volts | 20.0 volts |
| At Tallulah | 240.0 volts | 105.0 volts |

Three drainage coils are now installed on the Atlanta-Tallulah line, one each at Gainesville, Tallulah and Atlanta, and the talking over the line is excellent.

If the following principles are adhered to in the construction of a telephone line, paralleling a high tension line, successful operation should follow:

1. The telephone line should be thoroughly insulated from ground, allowing a liberal factor of safety, as insulation is paramount.

**Fig. 16.*** Potential Wave on Telephone Line with One Circuit of Power Line Charged. Voltage between Telephone and Ground 4500 volts

2. The line should be constructed with as few joints as possible.
3. The ohmic resistance of the line should be as low as possible, so as not to decrease the intensity of the talking waves.
4. A perfect potential balance should be obtained between wires.
5. Transposition should be made at every tower, so as to maintain equal potential between the two telephone wires and ground.

---

* From this oscillograph record, which was taken on a telephone line strung parallel to 110,000-volt power line for a distance of fifty miles but carried on a separate pole line, it can be seen that the number of harmonics is considerably greater than when telephone line is strung on towers carrying power lines.

# THE VENTILATION OF ALLEGHENY SUMMIT TUNNEL, VIRGINIAN RAILWAY

By F. F. Harrington

Engineer of Structures, The Virginian Railway Company

The ventilating equipment for the Allegheny Summit tunnel is located at the eastern portal, and was installed for the purpose of driving the smoke and gases emitted by engines on the upgrade or westbound trip ahead of the train, thus relieving the train crew from the disagreeable and unhealthful effects. Trains in the opposite direction coast on the downgrade, with the locomotive fires banked, and therefore no provision has been made for ventilating the tunnel during the passage of these trains. The plant will ultimately be automatic in operation, and the control apparatus has been built accordingly, although the track circuits have not yet been installed.—Editor.

Allegheny Summit Tunnel is located on the Virginian Railway, 277.6 miles from Norfolk, Va., between Yellow Sulphur and Merrimac.

Princeton, W. Va., 340 miles from Norfolk, Va., is the assembling yard for coal mined at points west and north along the main line and on branch lines. At this point long trains are made up and sent through to tidewater. The maximum eastbound grade from Princeton to Sewalls Point, with two exceptions, is 0.2 per cent compensated for curvature, and the maximum westbound grade between the same two points, with two exceptions, is 0.6 per cent compensated. The exceptions are at Onley Gap and Allegheny Summit, located respectively 3 and 62 miles east of Princeton. A single engine hauls 80 loaded cars of 100,000 pounds capacity from Princeton yard to tidewater without assistance, and the same engine hauls an equal number of empty cars against westbound grades, except at the summits mentioned above. At Allegheny Summit a single pusher engine is used between Whitethorne and Fagg, hauling 80 loaded coal cars eastbound on a maximum 0.6 per cent compensated grade from Whitethorne to the summit, a distance of ten miles, and 80 empty coal cars westbound on a maximum 1.5 per cent compensated grade from Fagg to the summit, a distance of seven miles.

A typical cross section of Allegheny Tunnel is shown in Fig. 3. The alignment is tangent except for about 200 feet at the east end, which is on a two-degree curve, and the grade is 1.22 per cent except for about 1000 feet at the west end, which is on a vertical curve. The total length between portals is 5176 feet and the cross sectional area is 375 square feet. It was lined with timber throughout when constructed in 1908, and afterwards concrete footings were constructed and two sections 50 ft. and 248 ft. long were lined with concrete. The remainder of the tunnel was lined with concrete last year, and as this lining contracted the sectional area and increased the heat considerably, the ventilation of the tunnel was authorized by the management to improve the operating conditions. A brief description of the ventilating plant follows:

The method employed for the ventilation of the tunnel is covered by patents held by Chas. S. Churchill and Chas. C. Wentworth, of Roanoke, Va., who furnished the general plans and specifications for the nozzle and the necessary data for obtaining bids from the fan manufacturers. The plant is illustrated by the accompanying photographs and plans, Figs. 1, 2, and 3, and is located at and connected to the east end of the tunnel. It consists briefly of two large fans operated by electric motors, one set being located on each side of the track. These fans force air through sheet iron ducts between the fans and the nozzle, and then through the nozzle, the reduced opening of which gives a high velocity to the air through the tunnel. The smoke and gases from the westbound engines on the ascending grade are therefore driven ahead, thus cleaning the tunnel and making it cool and comfortable for the trainmen. The eastbound engines, drifting on the descending grade, emit little smoke and gases, and it is not necessary to operate the fans; although this is occasionally done to clear the tunnel after their passage.

The ventilating plant was designed to deliver a volume of 590,000 cu. ft. of air per minute through the nozzle, which has an outlet area of 74 sq. ft.; this corresponding to a velocity of air in the tunnel of about 1600 ft. per minute. A thorough investigation was made of the relative economy of operation by steam and by electricity, and of the construction of a power plant and the purchase of power; it was finally decided to use electric current and purchase power from the Appalachian Power Company, which operates in that locality.

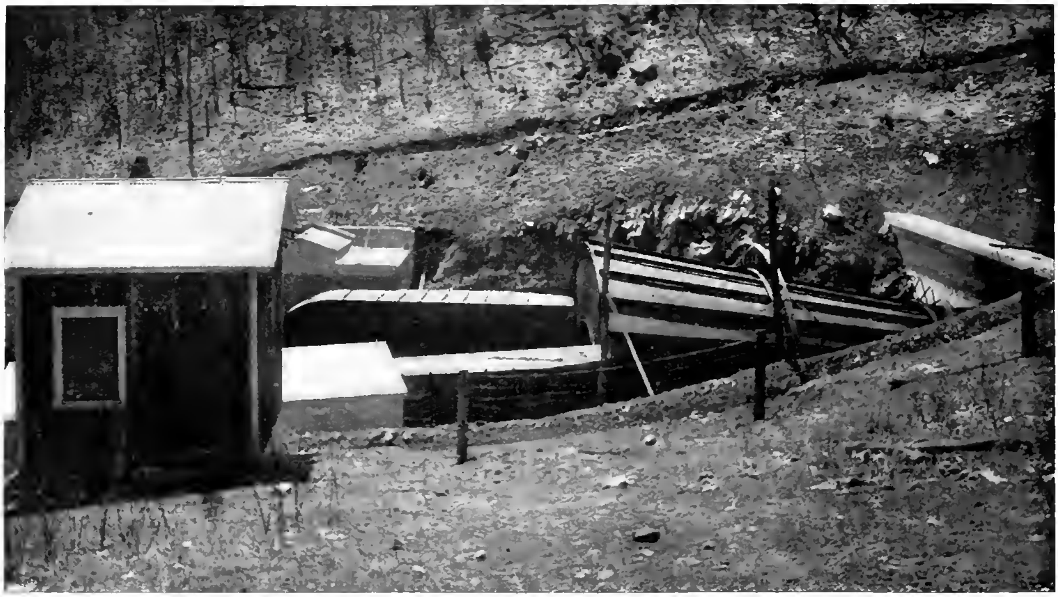
The Appalachian Power Company was organized in 1911 for the purpose of developing the water power of New River and distributing it electrically throughout southwest Virginia and southern West Virginia. It furnishes electric power for the operation of coal mines and other industrial plants in those districts. The high tension transmission lines operate at 88,000 volts and feed substations at various points, where the voltage is lowered for distribution through secondary lines to the various power consumers. A special high tension transmission line was built from Radford, Va., to the east portal of the Allegheny Summit Tunnel, where a substation was constructed which lowers the voltage to 2300 volts for the operation of the ventilating plant. The contract for electric power provides for a primary charge per kilowatt of maximum demand, and a secondary charge for current consumed based on a sliding scale. The maximum demand and the current consumed are determined by suitable meters, and a minimum annual charge is made regardless of the power consumption.

View Showing Position of Ventilating Equipment and Tunnel Portal

The fans are of the multivane type, with single inlet and top horizontal discharge, and were manufactured by the B. F. Sturtevant Company, Hyde Park, Mass. They are constructed of $\frac{7}{8}$ in. steel, $116\frac{1}{2}$ in. in diameter, $80\frac{1}{4}$ in. in width, and deliver through the nozzle 295,000 cu. ft. of air per minute when operating at 195 r.p.m. The induction motors are of the slip-ring type, rated 300 h.p., three-phase, 60-cycle, 2200-volt, 514-r.p.m., and drive the fans by means of Morse silent chains, spaced 5 ft. 6 in. on centers.

The switchboard is arranged with automatic starters for operating the motors from track circuits, but the track circuits have not been installed. The object of the automatic control is to make the plant more reliable and to reduce the cost of operation.

The switchboard consists of one main line control panel and two automatic motor starting panels mounted on pipe supports. The main line control panel consists of two three-pole single-throw oil switches with automatic overload and no-voltage release tripping coils. The incoming line feeds these switches and each controls the current to one of the motor starting panels. On this panel is also mounted an indicating voltmeter and ammeter, which shows the total input to both motors. The motor starting panels each comprise two current limit relays, one main line double-pole oil emersed contractor, and five double-pole contractors which cut out the resistance in the secondary of the motors in balanced steps and thus give equal fluctuations of current in each step. All of the control apparatus is located in the motor house on the north side of the track, and the two three-wire lead-sheathed cables to the motors on south side of track are installed underground in 6-in. conduit. The motors are protected from lightning by choke coils and multigap type lightning arresters.



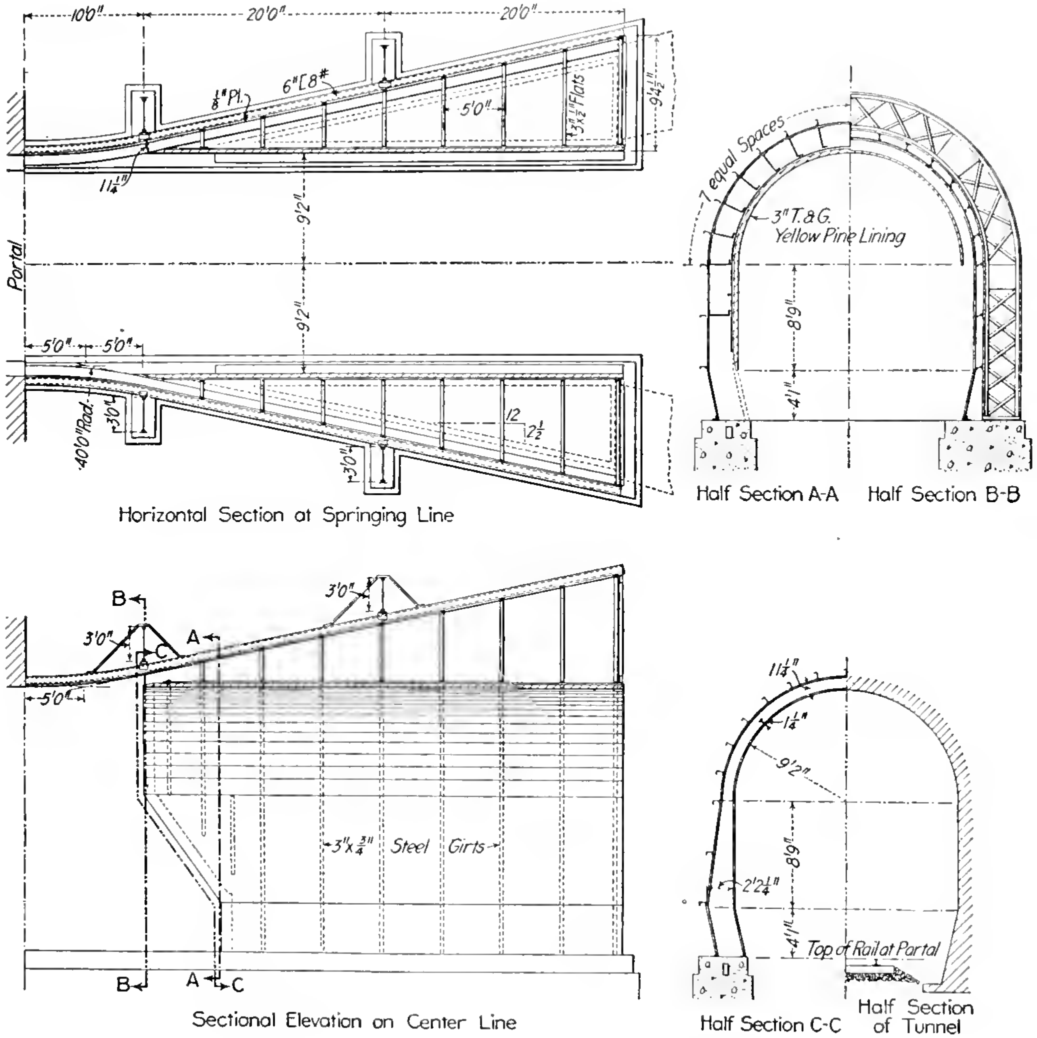
Side View of Ventilating Equipment

The blowing nozzle is constructed of steel, with the exception of the inner lining which is of heart long leaf yellow pine, tongued and grooved and bolted to steel girts. It is made to conform to the dimensions of the tunnel where it connects to the portal, and is 50 ft. long outside the tunnel. The inner lining is also of the same form and dimensions as the tunnel; but the outer lining, made of $\frac{1}{8}$-in. steel plates, is enlarged in the form of a conical surface with cross sections parallel to the inner lining from a point 5 feet from the portal to the face of the nozzle. The minimum distance between the inner and outer linings at a point 10 ft. from the portal is $11\frac{1}{4}$ in.; and the area of the contracted opening is 74 sq. ft. measured on the projection at right angles to the axis of tunnel. The front of the nozzle is provided with openings to which the air ducts from the fan housings are connected. The nozzle is thoroughly braced and is air tight. It was manufactured and erected by the Roanoke Bridge Company, Roanoke, Va.

The air ducts between the fan housing and the nozzle are made of $\frac{1}{8}$-in. sheet steel and braced with angle irons. Particular attention was given to the construction of these ducts and the fan housing in order to prevent excessive vibration from the operation of the fans.

The foundations for the ventilating plant are of concrete and the motor houses are of reinforced concrete and brick. In order to save expense the floors of the motor houses were placed about 8 ft. above the top of the rail, and concrete stairways and lookout platforms are provided for the convenience of the operator. The motor house on the north side of the track is larger than that on the south side, in order to provide room for the switchboard for both motors. The foundations and motor houses were constructed in accordance with plans furnished by the Railway Company.

The ventilating plant was put in operation April 1, 1914. Anemometer tests were made, which showed an average air velocity in excess of the contract requirements and an actual power consumption of about 600 h.p. Train tests indicated that a speed of from 14 to 15 miles per hour could be attained, with the smoke driven ahead of the engines, thus giving good ventilation in the tunnel under ordinary operating conditions. A bulletin has therefore been issued to limit the speed of westbound trains to 14 miles per hour, and at this rate the regular freight trains will not be required to slow down in going through the tunnel. The fans operate only for westbound trains, and the time of running is ordinarily less than ten minutes. A train dispatcher's telephone is installed in the motor house to enable the operator to keep in touch with the train movements in both directions and to communicate with the Appalachian Power Company at Bluefield, through the dispatcher's office at Princeton, in case of current failure or for any other reason. The total cost of the ventilating plant was about $30,000.



Sectional Views of Nozzle and its Relation to Tunnel

# THE ELECTRIC FIELD

By F. W. Peek, Jr.

Consulting Engineer, General Electric Company

All electrical design is dependent primarily upon the characteristics of the electric field surrounding a charged conductor. The magnetic component determines the layout of the iron circuits and the amount of the inductive effects; the electrostatic component determines the question of insulation and the capacity effects. The following article presents, with analyses, the results of experiments to secure a graphical record of the formation of these magnetic and electrostatic components of the normal electric field.—Editor.

In order that electrical energy may flow along a conductor, energy must be stored in the space surrounding the conductor. This energy must be stored in two forms; electromagnetic and electrostatic.

The electromagnetic energy is evinced by the action of the resulting stresses; for instance, the repulsion between two parallel wires carrying current, the attraction of a suspended piece of iron when brought near the wires, or, better yet, if the wires are brought up through a plane of insulating material, and this plane is dusted with iron filings, and gently tapped, the filings will form in eccentric circles about the conductors. These circles picture the direction of the magnetic lines of force of the magnetic field. This field only exists when current is flowing in the conductor. Fig. 1 is an experimental plot of such a field made by placing a sheet of blueprint paper on the plane and exposing to sunlight after the filings had arranged themselves. Such plots of magnetic fields are quite familiar to most of us. In designing the magnetic circuits in apparatus, it is generally of importance to lay them out in such a way that the magnetic flux is uniformly distributed. If the lines are overcrowded in one place it may mean local loss and heating.

If high voltage is placed between two conductors there will be an attraction between them. A suspended piece of dielectric, as a glass fiber, will tend to turn in definite directions at different points around the conductor. If the conductors are brought up through an insulating plane, as before, and the plane is dusted with a dielectric, such as mica filings, and tapped, the filings will form in arcs of circles beginning on one conductor and ending on the other conductor. Such an experimental plot is shown in Fig. 2.* The dielectric field is thus made as tangible as the magnetic field. Insulation breaks down at any point when the dielectric flux density at that point exceeds a given definite value. In high-voltage apparatus it is therefore

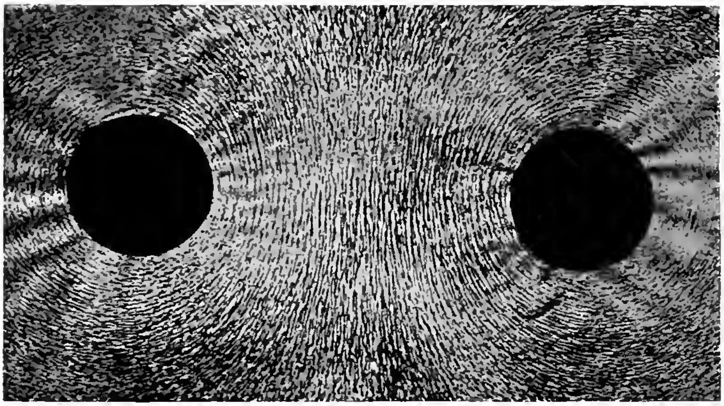


Fig. 1. A Photograph of an Iron-Filing Map of the Magnetic Lines of Force about Two Cylinders

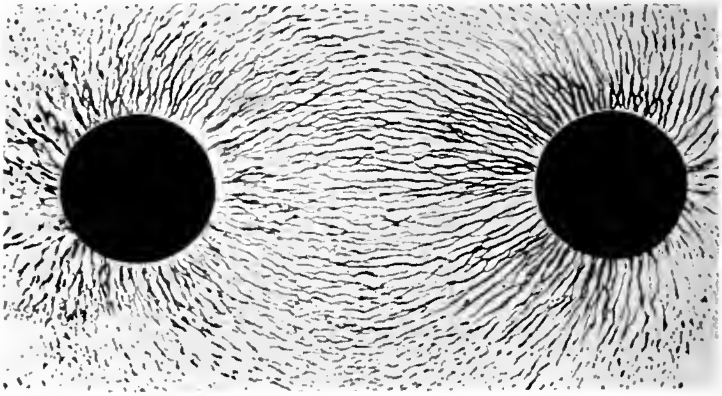

Fig. 2. A Photograph of a Mica-Filing Map of the Dielectric Lines of Force between Two Cylinders

---

* Fig. 2 was made at 10,000 volts. The conductors were 3 cm. in diameter and were at a spacing of 9 cm. between centers.

important to so design the dielectric circuit that the flux density is uniform or in proportion to the breakdown density of the insulations at the different parts of the circuit. In Fig. 2, the density is greatest at the conductor surface and break-down will occur there first. The dielectric flux density at any point is proportional to the volts per cm. (or voltage gradient) at that point. The strength of insulation is generally expressed in terms of the voltage gradient.

Fig. 3 is the superposition of Figs. 1 and 2. It represents graphically the magnetic and dielectric fields in the space surrounding two conductors which are carrying energy. The power is a function of the product of these fields and the angle between them.

Fig. 4 is the mathematical or exact plot corresponding to Fig. 3. In comparing Figs. 3 and 4 only the general direction and relative density of the fields at different points can be considered. The actual number of lines in Fig. 3 have no definite meaning. The dielectric lines of force in Fig. 4 are drawn so that one twenty-fourth of the total flux is included between any two adjacent lines. Due to the dielectric field, points in space surrounding the conductors have definite potentials. If points of a given potential are connected together, a cylindrical surface is formed about the conductor; this surface is called an equipotential surface. Thus, in Fig. 4, the circles represent equipotential surfaces. As a matter of fact, the intersection of an equipotential surface by a plane at right angles to a conductor coincides with a magnetic line of force. The circles of Fig. 4, then, are the plot of the equipotential surfaces and also of the magnetic lines of force. The equipotential surfaces are drawn so that one-twentieth of the voltage is between any two surfaces. For example: If 10,000 volts is placed between the two conductors, one conductor is at +5000 volts, the other at −5000 volts. The circle (∞ radius) midway between is at 0. The potentials in space on the different equipotential surfaces, starting at the positive conductor, are +5000, +4500, +4000, +3500, +3000, +2500, +2000, +1500, +1000, +500, 0, −500, −1000, −1500, −2000, −2500, −3000, −3500, −4000, −4500 and −5000. A very thin insulated metal cylinder may be placed around an equipotential surface without disturbing the field. If this conducting sheet is connected to a source of potential equal to the potential of the surface which it surrounds, the field is still undisturbed. The original conductor may now be removed without disturbing the outer field.

The dielectric lines of force and the equipotential surfaces are at right angles at the points of intersection. The dielectric lines always leave the conductor surfaces at right angles. The equipotential circles have their centers on the line passing through the conductor centers; the dielectric force circles have their centers on the neutral line.

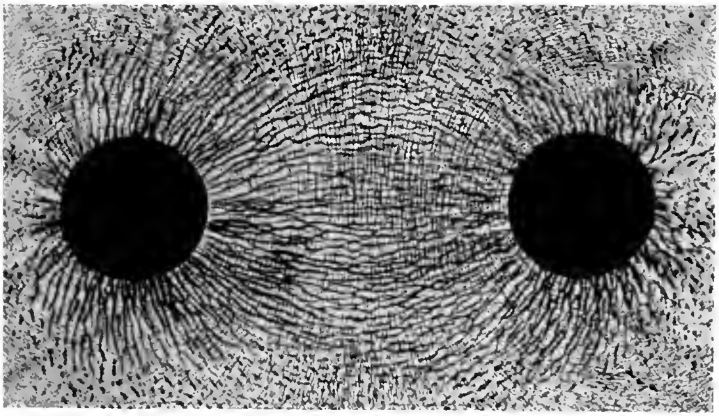

Fig. 3. A Photographic Superposition of Figs. 1 and 2 Representing the Magnetic and Dielectric Fields in the Space Surrounding two Conductors which are Carrying Energy

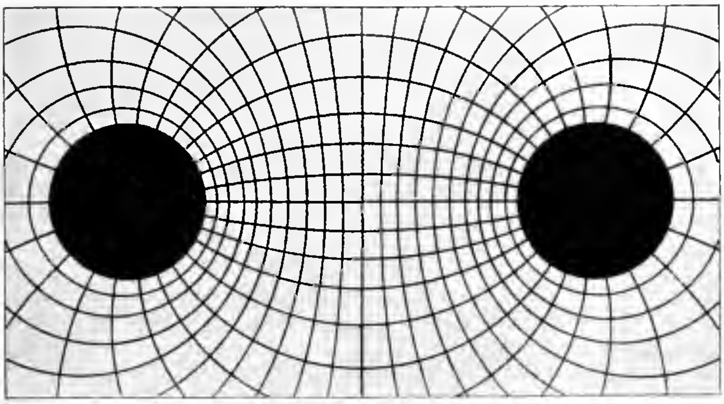

Fig. 4. A Mathematical Plot of Fields shown in Fig. 3

The dielectric and magnetic fields may be treated in a very similar way. For instance, to establish a magnetic field a magnetomotive force is necessary; to establish a dielectric field an electromotive force is necessary. If in a magnetic circuit the same flux passes through varying cross sections, the magnetomotive force will not divide up equally between equal lengths in the circuit. Where the lines are crowded together the magnetomotive force per unit length of the magnetic circuit will be greater than where the lines are not crowded together. The magnetomotive force per unit length of the magnetic circuit is called the magnetizing force. Likewise, for the dielectric circuit where the dielectric flux density is high a greater part of the electromotive force per unit length of circuit is required than at parts where the flux density is low. Electromotive force or voltage per unit length of dielectric circuit is called electrifying force, or *voltage gradient*. If iron or material of high permeability is placed in a magnetic circuit the flux is increased for a given magnetomotive force. If there is an air gap in the circuit the magnetizing force is much greater in the air than in the iron. If a material of high specific capacity or permittivity, as glass, is placed in the dielectric circuit, the dielectric flux is increased. If there is a gap of low permittivity, as air, in the circuit, the voltage gradient is much greater in the air than in the glass.

The dielectric circuit must always be considered in the proper design of high-voltage apparatus. The fields for various other conductors may be plotted with mica filings in the same way.

# SOME NOTES ON BUS AND SWITCH COMPARTMENTS FOR POWER STATIONS

By Emil Bern

Switchboard Engineering Department, General Electric Company

The bus and switch compartments of a station are vital to the continuity of service and safety of the system; and therefore their design deserves the most careful study. This article incorporates a description of certain important advances that have recently been made in apparatus. It states the fundamental rules for determining the dimensions and the construction of fire-proof bus and switch compartments; and it also classifies the different typical designs and discusses their relative merits.—Editor.

Large capacity power stations have outgrown the switchboard having switches, connections and buses supported on the board proper as the electrically operated switches of large capacity are usually installed in the position which is most convenient with respect to high potential buses and heavy connections. The buses and all parts of the switching system must be most carefully protected to avoid short circuits; and at the same time they should be designed to withstand the abnormal conditions caused by short circuits or overloads. For heavy currents at medium high voltages, the objects just named seem to be best accomplished by installing the buses, connections and switches in masonry compartments.

The purpose of this article is to discuss briefly certain typical designs of fire-proof compartments for switching apparatus, based on the familiar type of oil switch illustrated in Fig. 1 and Fig. 2. The construction of the two types of switches is the same, except for the arrangement of the oil vessels and their contacts. In both constructions the walls of the cells are built of brick or concrete and the top and bottom of soapstone slabs. While not shown in the illustrations, there are flame-proof doors in front of the cells. These are hung from steel work at the top so as to swing open easily in case of an explosion in the cell.

### Bus Compartments

Concrete has gained in favor over brick for masonry work and therefore the majority of today's bus and switch compartments are built of concrete. In some cases complete forms are made, usually of wood, and the whole compartment poured. This procedure gives the most substantial construction. It is more often the case, however, that concrete slabs are used set in cement. When this scheme of construction is used, the compartment is so designed that it will require but a small number of different size slabs. Fairly accurate work can be obtained by this method, and the cost of forms is reduced materially.

Where the design of the compartment is not too complicated, and where the desired dimensions agree with the size of bricks available, brick construction is usually the most convenient for smaller compartments. This is especially true in cities where concrete work cannot be handled conveniently on account of lack of space. The shelves or partitions are then usually made of soapstone or slate, but sometimes of concrete. Oftentimes bricks vary considerably in size, which makes accurate work very expensive since close adherence to certain dimensions often necessitates cutting the bricks or making abnormal bonds. For this reason it is usually more satisfactory to cut and drill the buses and connections when installing them than to make them up beforehand from the compartment drawings.

The design of fire-proof bus compartments is usually such as to enclose or to separate the different phases of the buses and connections by masonry. The masonry portions of the compartments must be considered as being at ground potential; therefore, the general dimensions of the compartments are determined primarily by the minimum allowable distance between live parts and ground for the voltages used. This rule has already determined the most important dimensions of bus supports and the switching apparatus.

Fig. 3 shows sections of typical bus compartments with their fundamental dimensions for different voltages based on average capacities and conditions. From the values given in the table any bus compartment can easily be designed. It is, of course, necessary to first determine the dimensions of switches, busbar supports, buses, connections and the clamps for attaching the connections to the buses; and also to take into account mechanical clearance and convenience in installing the material. The compartment shelves are usually made about two inches thick; but sometimes are thicker when made of concrete for large compartments. The thickness of the barriers between phases is determined by the mechanical strength of the structure; this also applies to the thickness of compartment walls. In brick compartments there is very little choice, for the dimensions of the brick usually predetermine them. In concrete structures the thickness of the walls and barriers is generally from three to four inches.

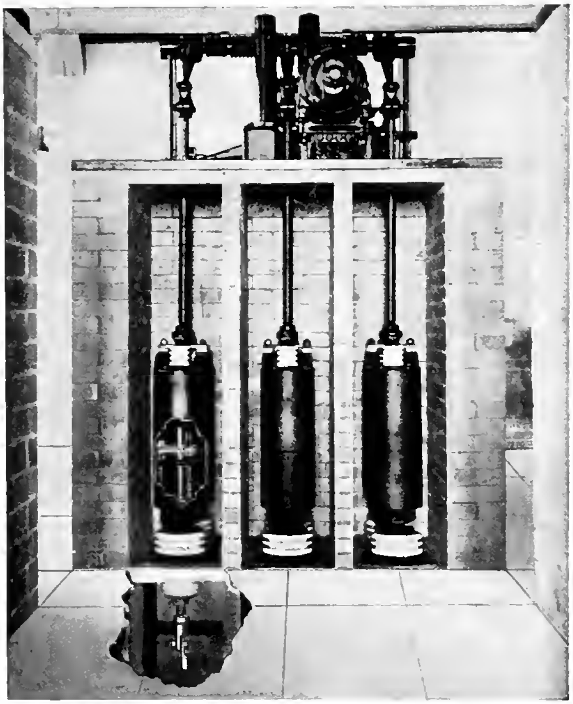

Fig. 1. Bottom-Connected Oil Switch. Parallel Arranged Contacts

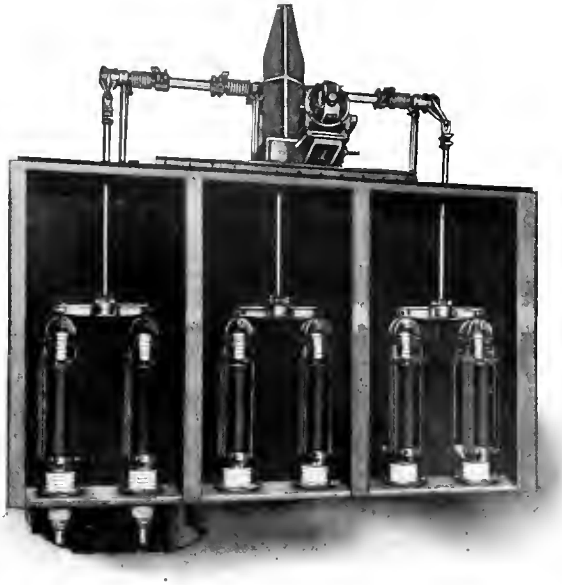

Fig. 2. Bottom-Connected Oil Switch. Tandem Arranged Contacts

### Disconnecting Switches

Several different types of disconnecting switches are used. For voltages up to 3300 they are generally mounted on marble bases without insulators. When provided with insulators they are usually mounted on slate or steel bases. The steel base has the advantage of occupying small space, it preserves the adjustment of the switch, and is less liable to injury during shipment and construction work. Fig. 3 shows several methods of mounting disconnecting switches in compartments.

| Volts | A Ground Dist. | B | C | Volts | A Ground Dist. | B | C |
|---|---|---|---|---|---|---|---|
| 2,500 | 2″ | 9″ | 12″ | 45,000 | 14″ | 34″ | 34″ |
| 6,600 | 3″ | 10½″ | 14″ | 70,000 | 21″ | 45″ | 45″ |
| 15,000 | 3½″ | 12″ | 15″ | 90,000 | 27″ | 56″ | 56″ |
| 22,000 | 6″ | 20″ | 20″ | 110,000 | 33″ | 72″ | 72″ |
| 35,000 | 10″ | 25″ | 25″ | | | | |

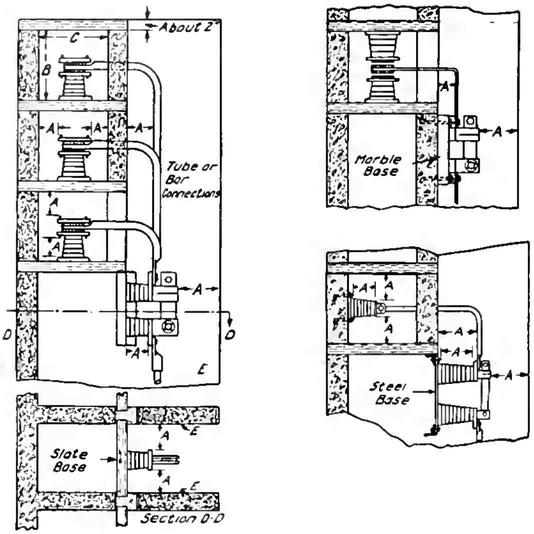

Fig. 3. Dimensioned Sectional Views of Typical Bus Compartments for Various Voltages

Disconnecting switches are occasionally used for isolating horizontal sections of the bus, and in this case are located in the compartments in a straight line with the bus, with the insulators secured either to the shelf or to the back wall of the compartment. If the bus is heavy enough and is securely anchored, it can serve as the hinge and clip for the switch, thus simplifying the construction somewhat. Whatever type of switch is used, care must be taken to see that proper clearance to ground is obtained with the blade in any position.

To withstand, mechanically, stresses incidental to momentary short circuit and heavy overloads, it is necessary that the buses and connections be securely anchored, while at the same time provision must be made for the expansion and the contraction of long buses due to temperature changes. The bus supports may be secured either to the shelves or to the back wall of the compartment, but must be located near openings so as to be accessible for cleaning and inspection. For convenience in joining connections to the bus, the busbars are usually arranged horizontally, i.e. laid on side.

The available space for the switching equipment determines to a great extent the design of the compartments. Sometimes the buses are located on the floor below the oil switches, which construction is very desirable when using bottom-connected switches, provided the disconnecting switches between the oil switches and the bus are located so that a person operating them can see whether the oil switch is open or closed. To meet this condition, and thus eliminate the danger of operating the wrong disconnecting switch, they may be installed in a sub-compartment in the oil-switch cell just above the floor. A door for this sub-compartment, of the same width as the oil switch, helps to determine without question which disconnecting switches belongs to a certain oil switch.

### Buses in the Floor

Fig. 4 shows a simple arrangement of oil switches with sub-compartments, disconnecting switches and the buses installed in the floor. The buses are supported and are accessible from below. Barriers of asbestos lumber or similar material may be provided between the connections of different phases, if considered necessary. If disconnecting switches are required on one side of the oil switch only, the parallel arranged oil switch may be used and installed against the wall, as shown in section A, Fig. 4. With disconnecting switches on both sides of the oil switch, it is possible to arrange all of them in the sub-compartments by providing space back of the oil switch for operating them, or by using the tandem arranged switch as shown

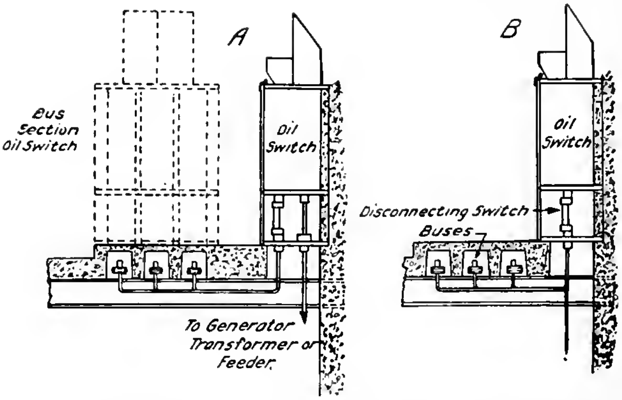

Fig. 4. Two Arrangements for Oil Switches with Disconnecting Switch Sub-Compartments and with Buses in the Floor

in section *B*, Fig. 4. With the first arrangement, a bus-section oil switch may be installed directly over the buses; while with the tandem arranged switches, the construction can be materially improved and made more compact by locating the bus-section oil switch in line with the other switches.

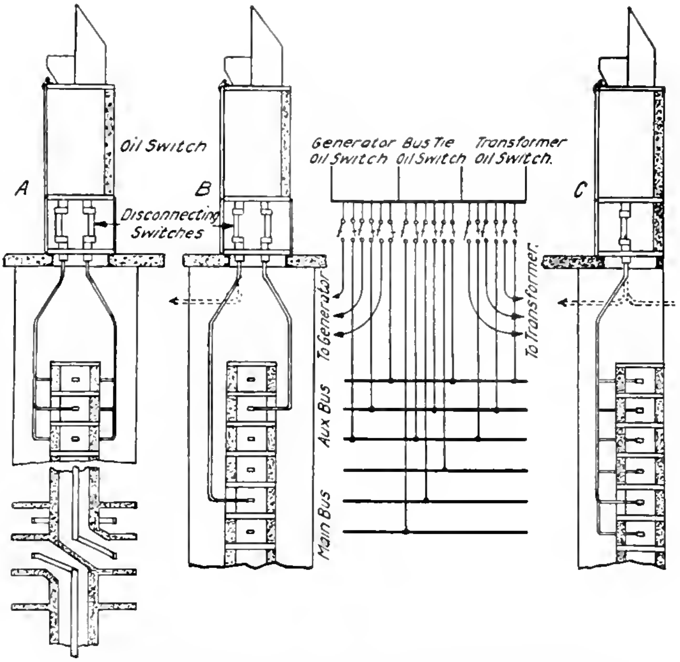

Fig. 5. Standard Arrangements for Oil Switches with Disconnecting Switch Sub-Compartments and with Bus Compartments beneath the floor

**Buses in Compartments Below Oil Switch Floor**

Fig. 5 shows different features of a construction with bus compartments on the floor below the oil switches, and with disconnecting switches arranged in sub-compartments. *A* represents a bus-section switch; and *B*, a bus-tie, generator, or transformer switch connected according to the diagram. *C* shows the application of the tandem arranged oil switch to the same conditions as *A* and *B*. If the room containing the bus compartments is used for other purposes also, it is advisable to provide doors between the barriers to guard against accidental contact with the connections.

**Bus and Switch Compartments on Same Floor**

It is often necessary to install the bus and switch compartments on the same floor, and in some cases this floor is immediately above the transformer compartments, so that the connections between the different elements cannot be made under the floor. A very compact construction of this kind is shown in Fig. 6, which provides for bus-tie, transformer, and generator switches connected the same as in Fig. 5. This construction requires, however, a set of disconnecting switches arranged horizontally in the buses. Passages through the compartments can easily

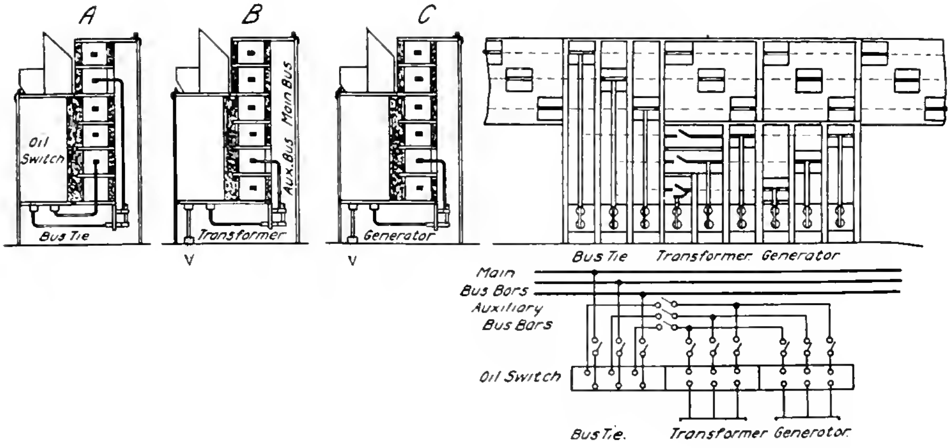

Fig. 6. Arrangements wherein the Switch and Bus Equipments are located on the floor. Electrically these connections are identical to those of Fig. 5

be provided under the main bus, as indicated in the Figure.

Another construction providing the same electrical connections is shown in Fig. 7. Here false floors must be provided over the connections, unless these can be carried through and under the floor. This false floor over the connections between the oil switches and the compartments consists of removable slate slabs resting on vertical brick or concrete barriers between the connections. With this construction it is necessary to provide doors for the compartments as well as for the oil switches. Section *A* shows the construction of a bus-tie connection, section *B* a generator or transformer connection, and the plan view *C* a combination of the above for connecting a generator to its transformer or to the main bus in the same manner as indicated in the diagram of Fig. 6. Section *D* shows how a feeder circuit may be connected to the main bus, and how the instrument transformers may be installed in line with the auxiliary bus compartment if desired. Disconnecting switches may also be accommodated in this compartment for isolating the instrument transformers from the line when energized from the other end.

A bus-section oil switch with disconnecting switches may be installed as illustrated at *E*, but it must, however, be placed at right angles to the main compartment.

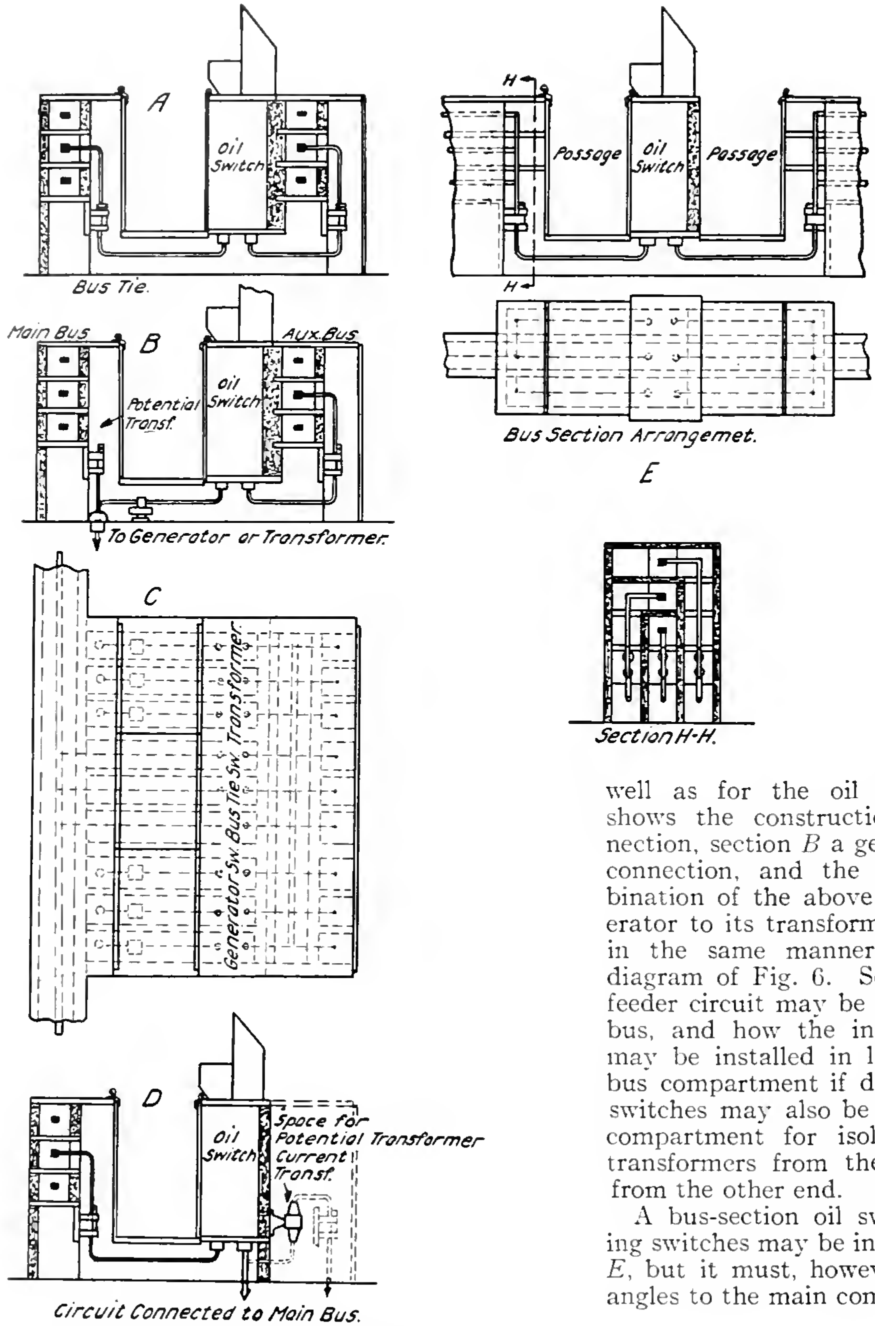

Fig. 7. Arrangements wherein the Switch and Bus Equipments are located on the Floor. A different but equivalent scheme to that shown in Fig. 6

# PRACTICAL EXPERIENCE IN THE OPERATION OF ELECTRICAL MACHINERY

Part III (Nos. 13 to 18 inc.)

By E. C. Parham

Construction Department, General Electric Company

## (13) TRANSFORMER LEADS REVERSED

Fig. 1 is a diagrammatic sketch of the connections for two direct-current generators connected to supply lights and power by three-wire distribution. Between the middle or neutral wire and either outside, the voltage of one dynamo is available (110 volts); between the two outside wires, the voltage available is that of *A* and *B* in series (220 volts). Lamps are connected to adjacent wires and 220-volt motors to the outside wires.

Wherever three wires are run, the neutral should be the middle one, because, as indicated in Fig. 1 (b), should the neutral and one of the outside wires become accidently interchanged some of the lamps are likely to be blown up and 220-volt motors connected to the outside wires will not speed to their rated r.p.m. In Fig. 1 (c) the distributing wires are arranged correctly but the two generators are indicated as having been connected so that their voltages are in opposition instead of in addition. In this case it is still possible to get 110 volts between the middle wire and each outside wire, but the middle wire is no longer a neutral wire; it has become the return wire for the outside wires and has to carry the sum of their currents instead of the difference. Furthermore, the voltage across the outside wires is zero.

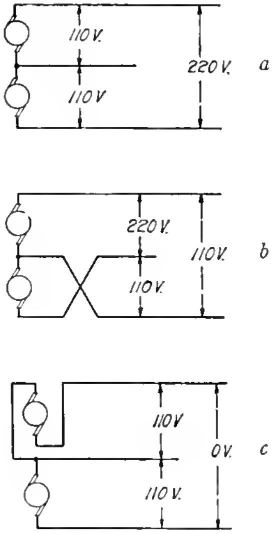

Fig. 1

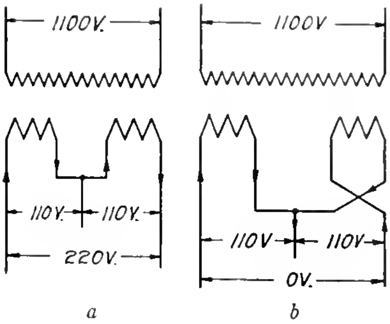

Fig. 2

These sketches are suggested to explain to an operator why he might not be able to start a motor from the outside lines of a recently connected three-wire service when supplied from a single-phase transformer, even though the lamps are operating normally across both 110-volt legs.

Fig. 2 (a) indicates the normal connections of the single primary and double secondary of a single-phase transformer when connected for three-wire secondary supply. It will be noted that the arbitrarily selected current directions are the same, indicating that the e.m.f. of each secondary coil boosts the e.m.f. of the other secondary coil so that the e.m.f. of the outer terminals is the sum of the individual e.m.f's, just as in the case of the d-c. generators of Fig. 1 (a). Fig. 2 (b) indicates the wrong connections to which one operator's trouble was due. One of the secondary leads had been interchanged in bringing it through the bushing. This connection gave the same conditions of voltage distribution as in Fig. 1 (c).

It is important that careful attention should be given when making connections, as in this case, for example, the error might be discovered only after an attempt was made to start a motor between the outside wires or after undue heating of the middle (on account of having to carry the sum of the outside currents instead of the difference) was noted.

### (14) IMPORTANCE OF EQUALIZER

Fig. 3 shows the connections of two generators of which $A_1$ and $A_2$ are armatures, $F_1$ and $F_2$ are series fields, $K_1$ and $K_2$ are individual line switches, and $E_1$ and $E_2$ are equalizer switches.

If $E_1$ and $E_2$ are closed while either machine is carrying the load, part of the current of the loaded machine will pass through the equalizer to and through the series field of the idle machine, the circuit effect of the equalizer being to place the series fields of the two machines in parallel. The closing of the equalizer switches adds to the no-load excitation of the incoming machine and thereby enables this machine to take its share of the load, assuming the correct no-load adjustments to have been made. Within certain limits, the equalizer will prevent one machine from driving the other as a motor in case they should be thrown together when the voltage of the one is considerably below that of the other, since the current through the equalizer and series field of the low-voltage machine increases its excitation. As stated, there is a limit to this automatic regulation because the equalizer possesses resistance and because the excitation due to the equalizing current is only a part of the total excitation of the machine. While the automatic division of the load upon the two machines will be impaired seriously by an unnecessary high-resistance equalizing connection, it is improbable that such an equalizer would cause sudden trouble in the operation of the generators. If the resistance of the interconnection, however, is infinite (caused by the equalizing switches being open), it is a practical certainty that arc-overs or other like troubles will soon occur. Operators, therefore, should be sure that all equalizing switches are closed between the machines that they are about to parallel.

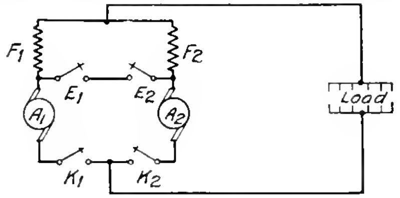

Fig. 3

### (15) SPARKING CAUSED BY LOAD CHANGES

The series field shunts for generators of low and moderate current capacity are made of German silver ribbon; those for heavy current machines are made of cast-iron grids. In either case, the shunts are constructed non-inductively. The scheme of connections employed is indicated in Fig. 4.

A shunt is arranged to have such a resistance that the portion of the armature current which passes through the series field (the portion not "by-passed" or shunted) will be correct to give the desired degree of compounding. The size of the shunt which will be required is determined experimentally since this method of procedure is simple and is satisfactory in most cases.

Among a group of motors which receives its electric energy from one generating source there will occasionally be one or more large motors that are frequently started and stopped, thereby causing sudden large changes in the output of the generator. Under such conditions a generator will require a different type of series field shunt, viz., an inductive shunt. If an non-inductive shunt is used, the self-inductance of the series field winding will force more than a proportionate amount of current through the shunt during a period of sudden increase in load current, and, conversely, it will cause the series field winding to retain more than a proportionate share of the load current during a period of sudden decrease in load current. This unequal rate of change of current in the shunt and series field winding will cause a distortion of the field magnetism. Such a displacement of the flux will probably result in more or less serious sparking at the brushes. A shunt which is non-inductive will not maintain a *constant* proportional division of the current between it and the series field winding (i.e., will not maintain the series field current proportional to the load) during the period of a rapid change of load. Therefore, the condition of widely varying load may prevent a non-inductive shunt from performing its function properly.

When the conditions of the load are sufficiently severe as to make it necessary to overcome this variable division of the load current between the shunt and the series field winding, because of the bad commutation produced thereby, satisfactory operation can be secured by including an inductive element in the shunt. This arrangement is indicated in Fig. 5, in which *F* is the series field, *NS* the non-inductive part of the shunt, and *IS* the inductive portion. This latter consists of copper wire wound on an iron core having an air gap that can be varied to give the desired amount of self-induction. The total ohmic resistance of the inductive and non-inductive parts in series must be such as to give the required degree of compounding for steady currents; the resistance of the inductive part must be adjusted by trial to give sparkless commutation when the load is suddenly varied. Since the inductive part necessarily has some ohmic resistance, a change of taps in this part in order to change its self induction will also change its ohmic resistance and hence the total ohmic resistance of the shunt. Frequently, the whole inductive change can be made by means of the air-gap, which, of course, will not change the ohmic resistance. Final adjustment will require a trial of several combinations of inductive and non-inductive shunt.

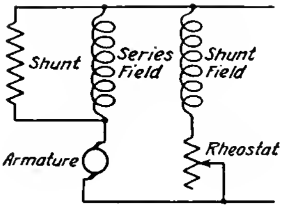

Fig. 4

As a practical illustration of the operation of shunts, reference may be made to an instance where momentary sparking of generators and their tendency to flash over was caused by the starting and the stopping of heavy direct-current motors in a cement mill. An inductive shunt was later obtained and connected in series with the non-inductive shunt, and then the resistance of the latter was decreased until the combined resistance of the two elements, inductive and non-inductive, was the same as the resistance of the original non-inductive shunt alone. In this particular case it was unnecessary to make any adjustments of self-induction in the inductive shunt because by coincidence the amount happened to be correct.

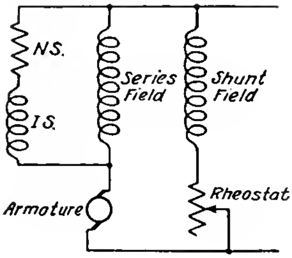

Fig. 5

### (16) REVERSED FIELD COILS

If one or more field coils are reversed on a generator of any type, one result is to lower the voltage obtainable from the armature. In the case of a direct current generator, sparking at the commutator will also suggest the possibility of reversed field coils; in the case of an alternator, however, as there is no commutator, the sparking symptom will be absent. In any case, the magnitude of the effect will depend somewhat on the relation between the number of reversed poles and the total number of poles in the machine.

A large alternator, which was excited from a multi-polar generator, was packed so full of mud and wood as the result of being submerged during a flood that it had to be dismantled for cleaning. The exciter also had been through the same experience. After reassembling, it was impossible to generate normal voltage. Everyone attributed the trouble to dampness and the two machines were baked "almost to death" in a determined effort to dry them. Finally, it was noticed that both machines were about dry and that further drying was not improving the conditions materially. Further, it was observed that there was more sparking at the exciter commutator than formerly. An investigation disclosed a field spool of reversed polarity. This error of assembly was corrected and it was supposed that all trouble had been eliminated. On starting, however, it was found to be impossible to get the alternator voltage much higher than it was before. (The effect upon the exciter voltage could not be observed because there was no direct current voltmeter available.) Then it was suggested that some of the poles of the alternator might be reversed, as in the case of the exciter. This proved to be the case: Out of a total of 32 poles, five poles of reversed polarity were found distributed around the revolving field. The correcting of this fault enabled normal voltage condition to be restored.

### (17) RIDGING OF COMMUTATOR

By ridges on a commutator are meant those alternate high surfaces which remain when intervening grooves are cut in the commutator by the brushes. This may be due to sparking (visible or invisible), to lack of end-play in the armature, to tracking of the brushes (that is, placing the brushes along circumferential lines on the commutator so that certain zones of the surface are not subjected to brush wear), or to excessive brush tension. Sparking which may be so slight that it cannot be seen in a well-lighted room becomes evident in a dark room. This kind of sparking may be due to using the wrong quality of brush. Even with staggered brushes end-play is essential to good permanent commutator operation. The movement can generally be obtained by insuring that the machine is actually level, but if the amount of play is insufficient it should be secured in some way even if it is necessary to turn off the inside end of one of the armature bearings. The brush tension should be no greater than is required, the proper amount being obtained by trial and observation. When the brushes are not properly staggered, even if the commutation is of the best, the unwiped part of the commutator in course of time will stand above the wiped part, unless this tendency is overcome by well-applied sanding of the ridges. If both lubricating and standard brushes are used on a machine, they should be distributed as far as possible so that each kind is correctly staggered in regard to that and the other kind.

Notwithstanding the fact that all ordinary precaution had been taken, the skilled operators of a certain station seemingly found that a ridge on one commutator could not be prevented. It was finally noticed that all the positive brushes were staggered with regard to each other, as were also the negatives; the positive tracked positive, and the negative tracked negative, and the positives were cutting grooves. On re-arranging the brushes correctly on the holders all grooving and ridging stopped.

### LAMPS FLICKERING

The full lines of the diagram in Fig. 6, represent the connections of a two-pole, direct-current armature mounted upon the same shaft with a circular, iron-cored reactance, the two members constituting the main feature of a so-called three-wire generator. The end connections of the reactance are tapped to diametrically opposite points of the armature winding and it is very essential that these points be diametrically opposite. From the center of the reactance is run a wire called the neutral; this neutral, in conjunction with the two outside wires from the generator, constitutes the three-wire distributing line. The reactance is simply a device by means of which the internal neutral, or half-voltage point of the armature, may be reached. Half of the series field winding of the generator is placed in one main, or outside wire, and the remaining half in the other to help balance the voltage when the load becomes unbalanced.

With balanced load, the current in each main is the same and the current in the neutral is zero. The turning off of lamps on one side and not on the other tends to raise the voltage of the more lightly loaded side; this tendency is partly neutralized by the weakened series field on that side acting to lower the voltage. The reactance carries alternating exciting current all the time, and it carries direct current only when the load is unbalanced. In this latter case there is a neutral current and it is equal to the difference between the current in the two mains.

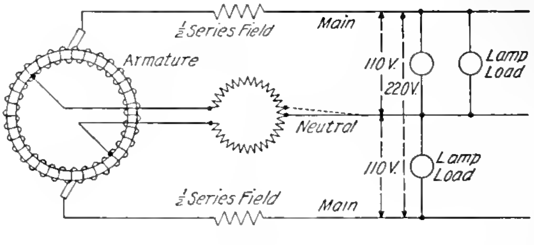

Fig. 6

A case of severe flickering of the lamps furnished with energy by a certain three-wire generator was traced to the tap of the neutral wire on the reactance coil being off center, as shown by the dotted line in Fig. 6.

# RECENT VIEWS ON MATTER AND ENERGY

## Part IV

By Dr. Saul Dushman

Research Laboratory, General Electric Company

In this issue, the last of the series, the author indicates the manner in which the atomic theory of matter has been affected by the atomistic theories of electricity and energy. The result of all the recent investigations and speculations has been to strengthen more firmly the position held by the older theory of the atomic and molecular structure of matter. The greatest interest now centers in the question as to the structure of the atom itself, and in this connection the views of Rutherford and Bohr seem to be in best accord with actual observations.

## ATOMIC THEORY OF MATTER

It is evident from what has been stated so far that the tendency of modern physics is to adopt atomistic views in the explanation of all phenomena. We have an atomic theory of electricity, an atomic theory of energy and we have been familiar for over a century with an atomic theory of matter.

The theory in which Dalton found such a simple explanation of the fundamental laws of chemical combination has, as is well known, been regarded as unnecessary by one school of chemists, while a number of others have adopted the faith of their colleagues, the physicists, and prefer to speak of atoms and molecules rather than of international and reacting weights.

It is not our intention in this paper to enter into any polemical arguments as to which attitude is the more correct. We are here concerned mainly with a recital of experimental facts and a presentation of the theories which have been put forward in explanation.

### Applications of Kinetic Theory of Gases

The first great impetus to the adoption of the atomic and molecular theories of the structure of matter was undoubtedly given by the speculations of Maxwell, Boltzmann and Clausius. The kinetic theory of gases indicated simple relations between the viscosity, heat conductivity and diffusion coefficients of gases; the validity of these relations has been confirmed experimentally.

Similar considerations were extended to the case of solids and liquids, and we have observed that in this manner Boltzmann was able to calculate atomic heats and to account for the law of Dulong and Petit. More recently, the study of the motions of ultra-microscopic particles, such as are present in colloidal solutions has led to results that are in splendid accord with the deductions from the kinetic theory of gases. The number of molecules per gram-mol of any substance has been determined in half a dozen different ways, and it is quite justifiable to state that "today we are counting the number of atoms in a given mass of matter with as much certainty and precision as we can attain in counting the inhabitants in a city. No census is correct to more than one or two parts in a thousand," and there is little probability that the number of molecules in a cubic centimeter of a gas under standard conditions differs by more than that amount from $27.09 \times 10^{18}$.*

### Observations in Support of Atomic and Molecular Theories

The study of radio-active phenomena has given powerful support to these atomic and kinetic conceptions; we see the disintegration of atoms going on under our own eyes, as it were. The spinthariscope is tangible evidence of atoms in motions, and very recently C. T. R. Wilson[1] has succeeded in photographing the tracks of alpha and beta particles as they shoot out spontaneously with immense velocities.[2]

The investigations of J. J. Thomson on positive ions which ought to be mentioned in this connection, have enabled us to measure, independently of other methods, the masses of the positively charged molecules that are repelled from the anode of an ordinary X-ray discharge tube. The method used is practically the same as that used for the

[1] Proc. Roy. Soc. *87*, 277 (1912).

[2] See photographs of the tracks of alpha particles in General Electric Review, July 1913

determination of $e/m$ for the cathode rays.[3] Not only has J. J. Thomson determined in this manner the nature of the different constituents of a gas mixture, but he has also shown that this method of chemical analysis is infinitely more refined than any other method hitherto used.

Similarly S. C. Lind[4] has shown that in the case of chemical reactions produced by alpha particles, the weight of evidence is in favor of the theory that each alpha particle produces one ion by bombardment of molecules and that subsequently these ions react to form neutral molecules.

### Arrangement of Atoms in Crystals

Experimental evidence of the atomic structure of matter has been obtained recently by still another method. It has already been mentioned that considerations based on the quantum theory led to the conclusion that X-rays are merely electromagnetic waves of extremely short wave-length ($10^{-5}$ to $10^{-9}$ cm). To measure these wave-lengths in the usual manner by means of a ruled diffraction grating was therefore out of question. It occurred to Laue that in the regular arrangements of atoms in a crystal we have gratings whose lines are naturally "ruled" so closely that their distances are of the same order of magnitude as the wave-lengths of X-rays. On passing the X-rays though a crystal diffraction patterns were obtained, and from the photographs of these it was found that the observed wave-lengths were of the same magnitude as those calculated.

But within the past year still more interesting results have been obtained by Bragg and Bragg,[5] who have used this method to determine the structure of crystals. We can now see, as it were, the manner in which the atoms in a crystal of rock salt or zinc blende are arranged, and we can even tell whether these atoms are at rest or vibrating about some position of equilibrium. Thus, we find that in a crystal of *NaCl*, the sodium and chlorine atoms are arranged in the form of a cubical lattice-work with chlorine and sodium atoms situated in alternate corners, so that for example "the sodium atom has six neighboring chlorine atoms equally close with which it might pair off to form a molecule of *NaCl*." In the case of the diamond the results obtained are equally striking. Every carbon atom is found to be united to four neighbors in a perfectly symmetrical way, while six carbon atoms are linked into a ring similar to that used to represent the benzene molecule. These results are among the most interesting that have been obtained in recent years.[6]

In view of these observations, the stereochemical models of the organic chemist are endowed with an even greater degree of approximate reality than was hitherto dreamed of.

We are getting a glimpse, as it were, into the innermost structure of the molecules, and are learning daily more and more about the manner in which their constituent atoms are bound together.

### Structure of the Atom. Theories of J. J. Thomson and Stark

But not only do we know something about the *structure of the molecule*, we are also in a fair way to knowing something about the *structure of the atom*, the unit out of which molecules are built up. We have learned already that the atoms must contain electrons. The obvious conclusion is that besides electrons the atom contains also a positively charged residue or nucleus. In what manner are these electrons and nucleus related to each other, and to the properties of the resulting atom? Here we touch upon the most fundamental problem of physics as well as chemistry.

Of the many attempts that have been made in recent years to formulate a theory as to the structure of the atom, those of J. J. Thomson and of Stark are among the most important. Here we can only mention these theories very briefly.[7]

According to Thomson the atom consists of a positively charged outer sphere with the electrons arranged uniformly on one or more spherical shells inside. By means of this theory it is possible to account for the fact that the properties of the elements are periodic functions of the atomic weight; also, for the existence of certain valency relations.

Stark's theory lays most emphasis on the existence of so-called valency electrons. He

---

[3] The beam of positive rays is passed through magnetic and electrostatic fields acting at right angles to each other and to the path of the rays. From the photograph obtained when the deflected beam strikes a senstitive plate, it is possible to calculate $e/m$; consequently, if there is more than one kind of ion, its presence is revealed by a separate streak on the plate. See Proc. Roy. Soc. 89, pp. 1–20, 1913, for full details, also a recent monograph on "Positive Ions" by J. J. Thomson.

imagines that a chemical combination between two atoms "represents not a direct attraction of one atom for the other, but a simultaneous attraction of both atoms for the same electron which thus forms a bond between the atoms." On this theory, "the energy of chemical combination represents the change in the potential energy of the valency electrons connecting the atoms which takes place when they transfer some of their lines of force from the electro-positive to the electro-negative atom. It will be the greater the less the attraction of the former atom for an electron, and the greater the attraction of the latter."

By far the most important contribution that has yet been made to this subject is, however, contained in a series of papers by N. Bohr[8] that appeared during the latter half of the past year.

### Interpenetration of Atoms

To understand the arguments advanced by this writer, it is necessary to refer to a number of experiments that were carried out in Rutherford's laboratory and which led him to a new conception of the structure of the atom.

Rutherford and Geiger found that when the alpha particles from radium or other radio-active substance met a thin gold leaf, most of these passed though the metal with only slight deflection, but now and then one of these particles was completely deflected around so that it returned towards the side of the source. This phenomenon, known as the scattering of alpha particles, was found to obey the same laws as the repulsion of one electric charge in motion by another charge of similar sign at rest.

The moving alpha particle carries a positive charge which is twice as great as that of the electron. It is in fact the same as the helium atom with two positive charges.

From the amount of scattering suffered by some of these particles, the conclusion was drawn that at some point in their paths these particles *pass through the very intense electrostatic field caused by a positive charge whose magnitude is approximately equal to one-half the atomic weight of the metal through which the scattering occurs.* Furthermore, the conclusion was drawn that the alpha particle must approach the repelling positive charge (or nucleus) *within a distance which is infinitesimal as compared with the radius of the atom.* While the radius of an atom is about $10^{-8}$ cm., the experiments on the scattering of alpha particles by hydrogen showed that the former must have approached the hydrogen nucleus so closely that their centers were only $1.7 \times 10^{-13}$ cm. apart. In other words, it was necessary to conclude that the *alpha particle penetrated within the atom of the other metal.*

### Rutherford's Atom Model

These results led Rutherford to assume a structure of the atom which is quite different from that of J. J. Thomson. According to the former "the atom must be assumed to consist of a positively charged nucleus surrounded by a system of electrons which are kept together by attractive forces from the nucleus. This nucleus is assumed to be the seat of the *essential part of the mass of the atom, and to have linear dimensions exceedingly small compared with the linear dimensions of the whole atom.*" Furthermore, as the magnitude of the positive charge in this nucleus corresponds to half the atomic weight, it is necessary to assume that the number of electrons rotating about the nucleus is equal to one-half the atomic weight.

The difference between the atom models of Rutherford and Thomson may be illustrated by means of the diagrams shown in Fig. 1.

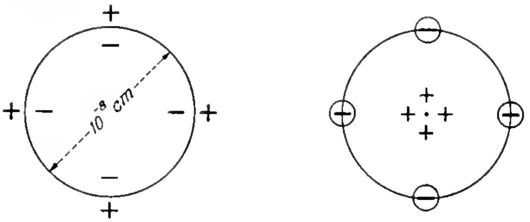

Fig. 1

In this connection it is worth noting that as a result of experiments on the scattering of X-rays, Barkla was led some years earlier to conclude that the number of electrons in the atom must be equal to one-half the atomic weight.

### Bohr's Theory of the Structure of Atoms and Molecules

While the experimental results thus pointed towards a nuclear structure of the atom, it was found that there are apparently good theoretical reasons for assuming that such an atom would be quite unstable. According to the classical electro-dynamics an electron rotating about a positive charge would very quickly radiate its energy in the form of

---

[8] Phil. Mag. 26, 1–25; 476–502; 857–875 (1913).

electromagnetic waves, its orbit would grow smaller and smaller, with increasing speed, until finally the electron struck the positive nucleus. No such objections could, however, be raised against the model of Thomson.

But according to Bohr the difficulties in the way of assuming Rutherford's atom model disappear when account is taken of the fact that the classical electro-dynamics has been found inadequate in describing the behavior of systems of atomic size. "By the introduction of Planck's constant $h$, the question of the stable configurations of the electrons in the atoms is essentially changed," and it *is on the basis of Planck's theory of energy* that Bohr builds up a theory of the structure of atoms and molecules.

The principal assumptions made by him are as follows:

(1) That the electrons revolve in circular orbits about the positive nucleus, with an angular momentum which is the same for all the electrons in the atom. That is, for each electron, $mvr = h/2\pi$, where $m$ denotes the mass, $v$ the velocity, and $r$ the radius; or the angular momentum is equal to Planck's constant divided by $2\pi$.

(2) That in the stationary state the dynamical equilibrium of such a system can be discussed by the help of the ordinary mechanics. In other words, the relation between the frequency of rotation ($\nu$), the average kinetic energy of the electron, and the radius of the orbit ($r$) can be calculated by the laws of ordinary dynamics.

(3) That in the stationary orbit no energy is radiated. This is contrary to the classical electro-dynamics. When, however, in consequence of emission or absorption of energy, the frequency changes, the problem is no longer one that can be dealt with by ordinary dynamics. During the latter process there is an emission or absorption of a *homogeneous* radiation, whose frequency ($\nu$) is the average of the frequencies of rotation before and after the energy change. The amount of energy radiated or absorbed is then equal to some integral multiple of $h\nu$.

From these assumptions Bohr deduces a number of interesting results. Assuming, as known, the values of the elementary charge $e$, the mass of the electron $m$, and Planck's constant $h$, he calculates the radius of the electronic orbit to be equal to that of the atom and the frequency of the energy radiated to be about the same magnitude as the frequency of ordinary visible radiation.

Furthermore, he calculates the ionization voltage, that is, the work required to expel an electron from an atom, and obtains a result that is in agreement with observed values.

Bohr also shows that his theory enables him to account for the well-known laws of Balmer and Rydberg connecting the frequencies of the lines in the line-spectra of the ordinary elements. He finds

$$\nu = \frac{2\pi^2 me^4}{h^3}\left(\frac{1}{a^2} - \frac{1}{b^2}\right)$$

where $a$ and $b$ are integers and the other letters have the usual significance. The quantity before the bracket should be equal to the Rydberg constant of which the observed value is $3.29 \times 10^{15}$. Bohr's calculated value is $3.26 \times 10^{15}$.

### Nuclear Charge. Atomic Number

On the basis of the above assumptions, Bohr also shows that the configuration of any system of electrons, i.e., the frequency and linear dimensions of the rings, is completely determined when the nuclear charge and the number of electrons in the different rings are given. Corresponding, however, to different distributions of electrons in the rings, there will, in general, be more than one configuration satisfying the conditions of angular momentum and stability. The physical and chemical properties thus depend upon the number of electrons, or nuclear charge, and the mode of arrangement of these electrons. The experimental evidence supports the hypothesis that *the nuclear charge* of the *atom of any element corresponds to the position of the element in the series of increasing atomic weights.* Thus, the oxygen atom being eighth in the series, should have a nuclear charge of eight unit charges and eight electrons.

The periodic table of the elements thus assumes a new significance. The order of the elements in this table corresponds to the number of unit positive charges of the nucleus. According to Bohr's theory, *the physical and chemical properties of the atom depend upon the magnitude of this nuclear number;* since, however, any given number of electrons may often assume different configurations it is possible for two or more elements to exist having the same nuclear charge, that is, *the same place in the periodic table*, but possessing *different atomic weights*.

This is quite in accord with the conclusions reached by Soddy and Fajans independently, from a consideration of the transformations that occur in the radio-active elements. The discussion of these deductions is, however, reserved for a subsequent paragraph.

Again, according to Bohr's theory the emission of characteristic X-rays is accounted for as being due to the removal of an electron from an inner ring. On the other hand, the radio-active changes depend upon transformations occurring within the nucleus itself. The formation of a helium atom from an alpha particle is a case of the actual formation of an atom from a positive nucleus and two electrons.

### Bohr's Theory of the Method of Formation of a Hydrogen Molecule

Bohr gives a very interesting picture of the manner in which two hydrogen atoms form a molecule. The hydrogen atom has the simplest imaginable structure; it consists of a nucleus of unit positive charge and one electron revolving round it. "The nuclei of two such atoms repel each other. The revolving electrons of two atoms close together, if rotating in the same direction, constitute two parallel currents of electricity, and these attract one another and arrive in the same plane." The molecule thus consists of the electrons that revolve like the governor-balls of an engine about an axis formed by the two nuclei. Bohr calculates the energy that would be liberated in the process of combination of the atoms and obtains a result in substantial agreement with the value previously calculated by I. Langmuir.[9]

If the value of a theory is to be measured by the number of observations it correlates and by its suggestiveness then Bohr's theory of the structure of atoms and molecules is one of the most important contributions to scientific literature that has been made in recent years.

### Other Theories of Atomic Structure

J. J. Thomson[10] and, more recently, Peddie[11] have suggested other atom models. According to the former, the intra-atomic forces need not necessarily obey the observed electrostatic laws, and he assumes that the forces acting upon an electron in the atom are, firstly, a radial repulsive force, varying inversely as the cube of the distance from the center and diffused uniformly throughout the whole of the atom, and secondly, a radial attractive force, varying inversely as the square of the distance from the center and *confined to a limited number of radial tubes in the atom.* On the basis of this theory Thomson is able to account for the relation between velocity of emission of electrons and frequency of incident radiation as demanded by the quantum theory; and he is also able to account for Balmer's law.

Professor Peddie would also explain the variation in properties of atoms and molecules in a similar manner as due to structural conditions within the atom rather than to the failure of the ordinary dynamical equations in the case of such systems, and along with Thomson he postulates regions of attractive force alternating with regions of repulsive force.

Bohr's theory has, however, proven so far to be the most stimulating conception of atomic and molecular structures and while there are, no doubt, a good many difficulties in the way of accepting it as it stands there are very many reasons for believing it to be a much closer approximation to the truth than any other theory.

### High Frequency Spectra of the Elements

Within the present year Moseley, working at Manchester University, has followed up these speculations of Bohr by actually determining the magnitude of the nuclear charge of the atoms of most of the elements. When the atoms of any element are bombarded by electrons traveling at high velocity, they emit characteristic X-rays. Bohr showed that there is a definite relation between the charge on the nucleus of these atoms and the frequency of the characteristic X-rays emitted. Moseley, therefore, made the different elements anti-cathodes in an X-ray tube, thus bombarding them in succession with cathode rays, and then measured the wave-length of the X-rays emitted. For this purpose he made use of Bragg's method of reflecting the rays from a rock-salt crystal and photographing the resulting diffraction pattern. Knowing the distances between the atoms of the rock-salt cyrstal and the angle at which the X-rays are reflected from the surface of the crystal, it is possible to calculate their frequencies.

In this manner Moseley found that the relation between $\nu$, the frequency of the X-rays emitted by the bombarded element and $N$, the charge on the nucleus, is given by the formula:

$$\nu = A(N-B)^2$$

[9] J. Amer. Chem. Soc. *34*, 860 (1912), also Phil. Mag., Jan., 1914.

[10] Phil. Mag. *26*, 792–799, (1913).

[11] Phil. Mag. *27*, 257–268, (1914).

where $A$ and $B$ are constants for each set of characteristic rays. He has determined in this manner the *atomic numbers* of all the elements from aluminum, 13, to gold, 79. There appear to be only three elements in this range which have not been discovered by the chemist. The atomic weight thus appears to have vastly less importance than the atomic number. In fact, as stated above, there may exist two or more elements having different atomic weights but exactly the same atomic number.

### Isotopic Elements

By examining the very high frequency radiation (gamma rays) emitted by radium $B$ and by bombarding lead with beta rays from radium $B$, Rutherford has found that both these elements give the same characteristic rays, indicating that they have the same atomic number, 82. Now so far as their chemical and physical properties are concerned, the *two elements behave identically the same; yet the atomic weight of lead is 208, while that of Ra B is about 214.5.*

Lead and radium $B$ are not the only examples of elements that differing in atomic weight yet occupy the same place in the periodic table. Soddy has found a number of similar cases among the other radio-active elements, and he has designated them *isotopes* (occupying the same place). These elements are absolutely inseparable by all chemical methods derived so far; yet they differ in that respect which has hitherto been taken to be the most important characteristic of an element—its atomic weight.

It that is true, then the atomic weight of a so-called element is really the average value of the atomic weights of the isotopes of which it is constituted, and ought to depend upon the particular proportion in which the isotopes happen to be present.

In agreement with this conclusion it has recently been shown by Richards and Lembert[12] that lead from radio-active sources has an atomic weight of 206.6, while ordinary lead has an atomic weight (determined by the same method in parallel analyses) of 207.15. The difference is much greater than any possible experimental error. It must furthermore be observed that both specimens of lead are identical in all other respects. Thus, both give the same ultra-violet spectrum.

### Is Mass Entirely Electromagnetic in Origin?

And now we must mention briefly one more conclusion which is probably more far reaching than any yet deduced. According to Rutherford and Bohr, the nucleus of an atom is infinitesimally small compared with the dimensions of the atom, yet practically the whole mass of the atom is concentrated in this nucleus. Now let us quote Rutherford himself.

"It is well known from the experiments of Sir J. J. Thomson and others, that no positively charged carrier has been observed of mass less than the hydrogen atom. The exceedingly small dimensions found for the hydrogen nucleus add weight to the suggestion that the hydrogen nucleus is the *positive electron*, and *that its mass is entirely electromagnetic in origin.* According to the electromagnetic theory, the electrical mass of a charged body, supposed spherical, is $\frac{2}{3}\frac{e^2}{a}$, where $e$ is the charge and $a$ the radius. The hydrogen nucleus consequently must have a radius about 1/1830 of the electron if its mass is to be explained in this way. There is no experimental evidence at present contrary to such an assumption."[13]

For some time we have been familiar with the idea that the mass of the negative electron is electromagnetic in origin; if the same holds true for the positive electron or hydrogen nucleus, then we are forced to conclude that all matter is really a manifestation of electrical charges in motion.

## CONCLUSION

In the above remarks an attempt has been made to present to the reader in a general and confessedly superficial manner some of those concepts which have been evolved in physical science during the past decade. We have seen that in analogy with the ordinary atomic theory of the structure of matter there has been developed not only an atomic theory of electricity but also one of energy.

These theories are, however, not to be regarded as opposed to views previously held, but rather as an attempt to obtain a deeper comprehension of the innermost mechanism of natural phenomena. In a word, while the physics of the past century dealt with nature microscopically, and emphasized the idea of *continuity*, the physics of the present regards nature microscopically and finds that underneath the apparent continuity there exist distinct *discontinuities.*

For the chemist as well as physicist a knowledge of the investigations which have

---

[12] Jour. Am. Chem. Soc., 36, 1329 (July, 1914).

[13] Phil. Mag., March, p. 494 (1914).

led to these new speculations are of extreme importance. Objection may of course be raised to these speculations because of their obviously hypothetical nature. The argument may be advanced that since the theory of today is apt to be cast aside in favor of the theory of tomorrow, what then is the use of any theory at all? As Royce states:[14]

"If certain general theories are mere conceptual constructions, which today are, and tomorrow are cast into the oven, why dignify them by the name of philosophy? Has science any place for such theories? * * * Why not say, plainly: Such and such phenomena, thus and thus described, have been observed; such and such experiences are to be expected, since the hypotheses, by the terms of which we are required to expect them, have been verified too often to let us regard the agreement with experience as due to merely chance; so much then with reasonable assurance we know; all else is silence—or else is some matter to be tested by another experiment? Why not limit our philosophy of science strictly to such counsel of resignation? Why not substitute, for the old scientific orthodoxy, simply a confession of ignorance and a resolution to devote ourselves to the business of enlarging the bounds of actual empirical knowledge? * * * "Why not 'take the cash and let the credit go?' Why pursue the elusive theoretical unification any further, when what we daily get from our sciences is an increasing wealth of detailed information and of practical guidance?

"As a fact, however, the known answer of our own age to these very obvious comments is a constant multiplication of new efforts towards large and unifying theories."

The scientific investigator overwhelmed with numerous observations and results of experiments in different fields finds an actual need for some unifying conception that will make it easier to understand the manner in which all these varied phenomena are correlated.

The scientific imagination, that uncontrollable product of the human intellect, can no more be stifled by a rule of logic than freedom of thought could be repressed by any theological dogmas. And surely it is worth while to make an error occasionally if the net result be an increased enthusiasm and inspiration to increase further the sum of human knowledge.

In conclusion, the writer wishes to express his sincere appreciation of the kindly interest taken in this paper by both Dr. W. R. Whitney and Dr. I. Langmuir, without whose encouragement and inspiration it would not have been attempted.

[14] Introduction to the translation of Poincare's "Foundations of Science."

# THE ELECTRIFICATION OF CANE-SUGAR FACTORIES

By A. I. M. Winetraub
Engineer, Zaldo & Martinez, Havana

The author here discusses the "steam balance" of a sugar factory, as well as the points of superiority of electric motor drive over steam-engine drive. By "steam balance" is meant that condition obtaining when no more steam is generated than needed for high-pressure cooking and for mechanical power, the exhaust from the latter being sufficient for all the low-pressure cooking purposes. In the economical operation of a cane-sugar factory, the important factor is rather to *maintain* a "steam balance" than simply to *create* it. This can be done only by the use of apparatus which provides a means of regulating a portion of the steam flow to suit momentary conditions. It is shown that the only apparatus possessing this function in a satisfactory degree is a steam turbine of the extraction type coupled to an electric generator. The author also compares steam drive with electric drive for factory power and shows the great saving in favor of the latter method, as well as the reasons for its greater reliability, thus further confirming his conclusions that only by electrification can cane-sugar factories obtain the utmost in reliable operation and financial economy.—Editor.

Another very satisfactory season of electrically operated cane-sugar factories has just been completed in Cuba; and while the previous seasons left very little doubt that proper electrification meant an unqualified success, the present season, beside upholding the past record, strengthens the conviction that the adoption of electric drive practically imposes itself upon cane-sugar factory operation.

Cuba has the distinction of being the pioneer in applying the alternating-current system on a large scale to sugar factories, and the results obtained have been so gratifying and convincing that foreign countries have followed the lead. To-day this system is being introduced in Australia, Hawaii, and other cane growing countries. There is hardly an owner of a sugar factory in Cuba who has not seen at least one of the electrified sugar mills. Of the replies to a circular letter sent to sugar mill owners, 80 per cent were unconditionally in favor of electrification. This statement, made by the interested companies, is in itself a fair proof of the satisfactory features visibly apparent in an electrified factory, but the engineer can obtain more than a superficial proof by a careful analysis of the conditions.

The advantages obtained by the electrification of a cane-sugar factory are, of course, not limited to fuel economy only, although this latter has been proved to be in itself a very considerable item. As will be shown herewith, there are other gains equally important and far reaching in insuring uninterrupted efficient operation at a reduced cost of production.

No matter whether an electrical equipment is being selected for a new sugar house or whether the problem involves the electrification of an already existing steam-driven factory, the first and foremost consideration should be that of creating and maintaining a *steam balance*. The *steam balance* in a sugar factory may be defined as the condition under which live steam will be generated to an extent only sufficient to furnish the required mechanical drive and that ordinarily necessary for the high-pressure cooking apparatus, the exhaust from which after deducting condensation losses will be just enough for the ultimate evaporation and concentration of the entire dilute.

In an already existing steam-driven factory, with probably an upset steam balance, there is another very important consideration, viz., that of designing an equipment which will produce and maintain the steam balance with such an expenditure of money that the combined interest and depreciation of the new *and superseded plant* will be more than covered by the total economy thus secured.

There still are a few makers of sugar factory machinery who, although admitting that in an existing steam-driven factory electrification can show a great decrease in the cost of production, are skeptical about the application of electricity to newly designed factories. The main argument they advance is that a steam balance can be created in a new steam-driven factory when properly designed.

While it may be true that a steam balance can so be created, it will be shown in the following that an electrical equipment having properly designed turbine-generators is the only one which will *maintain* the balance. Furthermore, such advantages as reliability, ease of control, cleanliness, low cost of installed equipment, economy of lubrication, flexibility of installation, reduced operating expenses, reduced repair expenses, maintenance of cooking apparatus in an efficient state, and others can only be obtained by the use of an adequate electrical equipment.

In an ordinary sugar factory, the initial steam pressure at the engine is about 75 lb. gauge per square inch and the exhaust about 8 lb. gauge per square inch. In expanding one pound of steam from this initial to exhaust pressure, the engines will use up therefore 918,000 — 835,000 or 83,000 ft-lb., leaving theoretically available in the exhaust (assuming no condensation) 835,000 ft-lb., which is over ten times the energy used for mechanical drive. Usually the available heat in the exhaust steam of a sugar factory is at least seven and a half times that used by the steam engine to do the mechanical work, and with ample heat protective covering may be even eight times that amount. This fact therefore must not be lost sight of, viz., that by far the greatest portion of the heat energy contained in the live steam appears in the exhaust and is not used for mechanical drive. After a steam balance design has been arranged to give, with a certain steam consumption of engines, the required heat for evaporation in the form of exhaust steam, every additional heat unit used in excess for mechanical drive in the cylinders of the steam engines necessitates the release of eight heat units into the exhaust. These of course will be wasted if the balance of the steam requirements has been reached before.

With a lack of steam balance it is sometimes necessary to employ live steam for cooking and, at others, to waste exhaust steam. This means taking no advantage of the heat units in the steam for mechanical drive in the former case and wasting heat units in the exhaust in the latter case.

It would be a comparatively easy matter to obtain a steam balance for any sugar house if the milling and evaporating conditions were uniform and constant. This, unfortunately, is not found to be so in practice for both the mechanical drive, with the corresponding exhaust steam production, and the requirements of evaporation vary due to field, yard, and factory circumstances, and, what is worse, the variations are independent of each other and may not occur at the same time.

Let us assume that, at a certain period "B," the crushing and milling engines in a steam-driven factory are operating at full load and are producing an exhaust which is just sufficient for the evaporation of the juice extracted and diluted some time before, say at period "A," which is now being evaporated at period "B." If, for any reason, at period "C," the milling capacity in tons per hour is reduced, the quantity of exhaust steam is also reduced due to the lessened mechanical load, and is therefore insufficient for the dilute obtained at period "B." In this case live steam would have to be employed for evaporation. On the other hand if, at period "C", the load increased there would be an excess of exhaust steam for evaporating the dilute from the cane crushed at period "B," which would result in a consequent waste of exhaust steam.

A still better illustration of this condition is available in a cane-sugar factory where several tandem grinding rolls are operating.

The change-over from operating one or two of these sets at a time may mean an excess or a lack of exhaust steam for evaporating the dilute accumulated before the change-over, and the steam balance, if such existed previously, is thereby upset.

It has been suggested that low-pressure turbine-generators be installed to utilize the exhaust steam from milling engines and to have electric motors drive the pumps and other mechanical appliances about the factory. While this arrangement appears to be satisfactory to a certain extent, it implies the use of large condensers in connection with the turbine-generators and involves the feature of evaporating the dilute by means of live steam; for with such an arrangement there would be no exhaust steam available for cooking. This would call for a complete revolution in the manufacture and operation of cooking apparatus. The suggestion of utilizing the exhaust steam in low-pressure turbines has been originated mainly because of the desire for creating and maintaining a steam balance.

There have also been other suggestions to eliminate the difficulties attending an excess of exhaust steam, most of which apparently disregard the fact that instead of attempting to utilize in one way or another the heat contained in an excess of exhaust it is naturally more logical *not to produce this excess of exhaust steam.*

The problem of obtaining maximum fuel economy can unquestionably be solved with such an equipment as will give:

(1) Sufficient exhaust steam for cooking at all times.

(2) A variable supply of exhaust steam.

(3) A control of exhaust steam production to give only the needed exhaust.

(4) An automatic governing device to make the exhaust production directly proportional to the cooking requirements.

It requires no special effort to see that a sugar house which is equipped to fulfill these conditions will take care of all requirements and will at the same time secure a steam balance with its consequent ideal fuel economy.

Extraction-type steam turbines have been used quite extensively in electric power plants for furnishing electric light and power and, at the same time, supplying exhaust steam for general heating purposes. The conditions in a sugar factory are not materially different from those just mentioned and there is absolutely no reason why such an arrangement when suitably adapted to a sugar house should not give ideal results.

Fig. 1 is a diagram illustrating the principle involved in accomplishing the desired end. The letters *A* illustrate extraction-type steam turbine-generators which have their exhaust lines connected to a common condenser. An extraction connection is shown from the first stage of each turbine leading into a common exhaust receiver. The crushers and mills are in this case steam-driven and their exhaust is also led to the common exhaust receiver. Between the first stages of the turbines and the common exhaust receiver there are installed automatically operated valves *B*, which are interlocked with the valves *C*. Valves *B* and *C* are set in such a manner that when the pressure in the exhaust receiver is maintained at 6 to 8 lb. per square inch or higher, valve *B* is shut and *C* is wide open.

With such an arrangement, let us assume that the crushing and milling engines are furnishing sufficient exhaust for the assumed cooking requirements, and that the turbines are operating fully condensing which gives high fuel economy. When the demand for exhaust steam in the cooking apparatus is greater than can be supplied by the crushing and milling engines, the pressure in the exhaust main drops and automatically opens valve *B* and closes valve *C* until the pressure in the main exhaust pipe is again 6 to 8 lb. At this time, valve *B* again closes and the turbine again operates condensing.

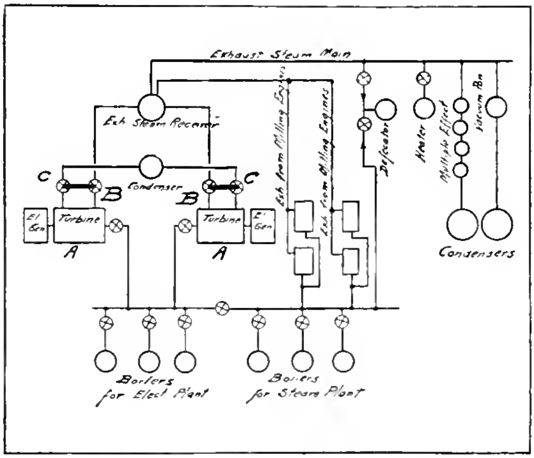

Fig. 1. A Diagram showing an Ideal Arrangement for the Utilization of Steam in an Electrified Cane-Sugar Factory

Valves *B* and *C* can be designed in such a manner as to afford a partially opened *B* valve with a correspondingly partially closed *C* valve. Then, the turbine will operate non-condensing only to the extent of that portion of the steam which passes through the first stage and is then extracted for cooking, while the remainder of the steam taken by the turbine passes through to the condenser and effects a correspondingly economical consumption.

Since the exhaust steam from operating the crusher and grinding rolls is never sufficient for the entire evaporation of the dilute, it is advisable, in a sugar factory where the crushers and rolls proper are to be electrically operated, to have one non-extraction turbine-generator exclusively for the mills and crushers and to have another one or two turbine-generators of the extraction type to compensate for the lack or excess of exhaust steam as described. The non-extraction turbine-generator should have a capacity equal to about 50 per cent of the total mechanical drive in the factory and should operate non-condensing, its exhaust steam being carried into the exhaust receiver just as in the case of the steam-driven crushers and mills.

The turbines operate normally non-condensing, feeding their exhaust steam into the exhaust pipe line for evaporation of the dilute. When the quantity of exhaust steam exceeds the requirements, the pressure in the exhaust line rises and operates a valve which diverts the excess exhaust steam into the condenser. If the quantity of exhaust steam from the turbine is insufficient for the cooking requirements, the pressure in the exhaust pipe line drops and the valve is operated automatically in such a manner that more exhaust steam is fed into the exhaust line and less is diverted into the condenser. When all the steam exhausted from the turbine is required in the exhaust pipe line, the valve opens wide, the condenser connection is automatically shut, and the turbine operates non-condensing.

Fortunately, when operating entirely non-condensing, with as low a steam pressure as the 80 lb. per square inch that is available in most sugar mills, and exhausting at about 6 to 8 lb., the steam turbine consumes over twice as much steam as when exhausting into a 26-in. vacuum. This is decidedly a favorable feature in the operation of a sugar factory, for the arrangement described can furnish the factory with enough exhaust steam to fulfill its maximum requirements and, when not as much is required, the portion of steam that is not needed is condensed and effects the operating efficiency corresponding to the vacuum in the condenser.

The proper control of the electrically-driven air and injection pumps, that serve the auxiliary condenser which operates in connection with the extraction turbines, can be obtained by automatic starting and stopping devices that are governed by the valves *B* and *C*. Similar arrangements can be made in case the exhaust from the turbines should be carried to the central condenser, or manually by means of signals operated by the valves *B* and *C*.

In the suggested layout the feature which will undoubtedly arrest the engineers' attention is the one pertaining to the operation of the extraction turbine at times under a vacuum with the consequent necessitated use of a condenser and additional cooling water.

If it is remembered, however, that the vacuum may be as low as 25-in. and still give decided advantages and, above all, that the turbine condenser is an emergency equipment which is to operate only when the steam balance is endangered, and, if it is further remembered, that the condenser is to take care of only a part of the steam input to the turbine, it will be readily appreciated that the size of the condenser, the water it requires, and the attention to its auxiliaries are of very little importance compared with the enormous advantages to be derived.

It must always be kept in mind that when steam is extracted in the manner suggested, from the first stage of a turbine, it has been used efficiently in the first stage for producing power, and the steam which passes through the remaining stages has been used on the regular condensing basis of efficiency and therefore the arrangement when taken as a whole is very efficient.

Knowing that the condenser's duty is mostly to condense the excess of exhaust steam and this on the basis of vacuum efficiency, it will at once appear that the quantity of steam to be taken care of and therefore the condenser required are not of alarming proportions.

In most cases, it will probably be possible to connect the vacuum end of the extraction turbine to the main condenser of the sugar factory so that the additional requirements would be reduced to pumping only a little more cooling water and operating the air pump a little faster.

To correct for a steam balance in a 1000-bag per day sugar factory which consumed about 80,000 lb. of live steam per hour and which was unbalanced to the extent of wasting as much as 18,000 lb. of exhaust per hour, it has been found that with the installation of only a 300-kw. extraction turbine the otherwise wasted exhaust steam could be made available to evaporate, in the effects and vacuum pans, some 30,000 lb. of maceration water* which in the case under consideration meant over 20 per cent maceration on cane.† In this case some 350 horse power of steam engines could be replaced by electric motors which would eliminate that amount of unnecessary exhaust, there being an excess of exhaust steam in the factory; and a steam balance could be obtained with an extraction of almost 5,000 lb. of steam from the turbine.

With this turbine, requiring about 12,000 lb. of steam at the throttle (80 lb. initial, 6 lb. back pressure) and operating with 5,000 lb. extraction, the size of the condenser for 26 in. vacuum need therefore be of a capacity to take care of only 7,000 lb. of steam per hour, which is indeed not of a size to give any serious concern.

It is to be noted in the diagram of the suggested arrangement of steam-driven crushing and milling engines, Fig. 1, that the boilers operating the extraction turbine-generators (and which are intended for all mechanical drive excepting the mill drivers proper) are shown to be separate from the boilers intended for the milling engines proper. This of course does not mean that new boilers are required in an already existing steam-driven factory that is to be electrified, or that additional boilers than would otherwise be required are needed for a new plant to be installed along the lines suggested.

---

* To best explain the expression "maceration water" it is deemed advisable to quote the following from authorities on the subject:

"When water is poured on the bagasse the residual juice in the bagasse is diluted, and after recrushing the bagasse to its former content of juice, it will contain the same amount of dilute, but therefore less saccharine, causing less loss of sugar, so that maceration considerably improves the juice extraction. (H. C. Prinsen Geerligs, 1909, "Cane Sugar and its Manufacture.")"

"At the present time two schemes are employed in washing out sugar from the bagasse; in the one which is sometimes distinguished as imbibition, water preferably hot is sprayed on the bagasse as it leaves one mill; in the other known as maceration the partly exhausted bagasse is drawn through a bath kept with diluted juice which has already been extracted. (Noel Deerr, 1905, "Sugar and the Sugar Cane.")"

† The degree of extraction is often conveyed by speaking of the percentage of maceration water as compared to the total weight of cane ground. In this case "20 per cent maceration on cane" means that the weight of water added was 20 per cent of the total weight of the cane ground.

Generally speaking of the total boiler capacity of a cane-sugar factory, 50 per cent furnishes steam for the mills proper and 50 per cent for the other drivers about the plant; and it is possible to divide the total intended capacity of the boilers into batteries so that each may take care of their apportioned duties.

The most likely reason causing a drop in boiler pressure is the variable load on the crushing and milling engines and if the boilers feeding them are separate from the other drivers, the load on which is practically constant, there will be the consequent advantage of constant steam pressure to the turbine-generator that is to operate the electric motors, a feature which is by all means desirable.

It is of course appreciated that with a variable load on the mills proper the quantity of bagasse and its quality are variable and therefore this has a bearing on the pressure of the boilers assigned to the electric drive, but it is practicable indeed to arrange for the bagasse supply in such a manner that constant pressure may be maintained on the "electric" boilers with a constant fuel supply.

It has been claimed in this paper that the steam balance can be *maintained* only with a properly designed turbine-generator equipment.

In no sugar factory will conditions remain absolutely invariable from crop to crop as regards steam consumption, and a steam balance once created in such a factory has a tendency to be upset by the addition or deduction of machinery.

If, instead of using turbine-generators of the extraction type, we should attempt to use compound or triple expansion units with the intermediate or low-pressure cylinders acting as "stages" in the same manner as the stages of an extraction turbine, it would perhaps be possible to make arrangements in such a manner that, in accordance with demanded requirements, the intermediate and low pressure cylinders may be by-passed and steam thereby be exhausted at a higher or lower pressure for cooking or even below atmosphere to the condenser. This, however, would mean driving the pistons of the corresponding cylinders "dry," or without steam at times, a feature which is by no means advisable.

As can be seen, the variable quantity of low-pressure steam is not obtainable therefore with a piston-type steam driver and the steam balance which has as a basis just this condition is only obtainable from a stage-type rotary steam unit with an extraction arrangement such as the Curtis extraction-type turbine.

The manager of an important factory in Cuba which has an output of about 150,000 bags of sugar per season calculated that interruptions in his mill represent $6.00 per minute, or over $8000 per actual milling day. This should amply indicate the importance of uninterrupted operation in a sugar factory and it only remains to show that the electric motor affords protection against such interruptions.

Excluding the mill drivers proper, crystalizers, and centrifugals, the most important drive in a sugar factory is practically that required for pumping only. All pumping, with the exception of that for masse-cuite and molasses, can and should be done by centrifugal pumps due to their lack of valves and reciprocating motion. Pump interruptions are due mainly to the sticking or breaking of valves and to the failing of the cylinder lubricating system. The centrifugal pump eliminates these difficulties entirely because it has no valves and does not require internal lubrication. The advantages to be derived from using high-speed pumps of this type are therefore obvious. The benefits of simplicity and reliability which are obtained by the use of centrifugal pumps are easily augmented by the adoption of electric motor drive. Furthermore, an electric motor would be the logical selection for driving a centrifugal pump, since both are naturally high-speed machines and can be coupled together directly.

As to the application of electric motors to the pumping of masse-cuite and molasses, steam troubles are avoided inasmuch as no complicated oiling system or close attention is required with electric motors; and this of course also holds true for the other drives about the factory, such as crystalizers, centrifugals, blowers, conveyors, air pumps, etc.

With the advent of the new rotary air pump, the application of the electric motor becomes still more universal; and there is really no drive where the electric motor could not show superior operating characteristics, a decreased measure of attention required, and a greater degree of continuity of operation.

From a very carefully controlled sugar factory in Cuba producing 1100 bags of sugar of 325 lb. each per day of 23 hours, a careful analysis of the results furnished the following data.

The total cost of the extra fuel purchased during the crop season of 160 days was $20,000.

The live and exhaust steam piping *for the small engines and pump connections only* was found to have over 7500 square feet of radiating surface and the value of fuel being taken at 25 cents per million B.t.u. or about $7.00 per ton of coal equivalent, it was calculated that over $4,000 was lost in radiation and condensation per crop, which represents 20 per cent of the amount spent for extra fuel.

The piping mentioned takes care of approximately 1500 h.p. in engines and assuming, when electrified, a wiring loss of 2½ per cent, which is indeed reasonable when considering a properly distributed alternating-current installation, we have a loss of 37.5 h.p.

With a consumption of 25 lb. of steam per horse power hour lost, the steam loss per season of 160 days of 23 hours each would be 3,450,000 lb. of steam.

Assuming that with $7.00 worth of fuel we can produce 19,000 lb. steam ($7.00 per ton of coal), the cost of the lost power would be

$$\frac{3,450,000\times 7}{19000}=\$1270$$

Considered against the $4000 this shows a difference of $2730 which represents a saving of over 13½ per cent of the purchase of extra fuel.

On the basis of conditions as found in the sugar factory referred to, further comparison has been made relative to the labor and incidental material expense.

| | Steam | Electric | |
|---|---|---|---|
| Labor expense during crop, per day.... | $65.19 | $26.55 | |
| Labor exp. lay-by, end of crop, per day | 2.79 | 0.28 | |
| Labor expense pumping station....... | 3.33 | 0.00 | |
| | $71.31 | $26.83 | |
| Or, a total for 160 days | $11,409.60 | $4292.80 | |
| Labor balance in favor of electric drive... | | | $7116.80 |

The lay-by labor expenses at the end of the crop are due to dismounting the machinery and coating it with non-rusting material to protect it while standing idle for 200 days.

The labor expense of the pumping station is due to the fact that, in the case of this steam sugar factory, it is necessary to have a small pumping station at a distance of one mile from the factory, a condition which applies to practically all sugar mills in Cuba.

The time lost in starting the engines when stopped on dead center, in slow acceleration, and in other general features which would cause complete shut down of the mills proper can be assumed to be four minutes daily at $6.00 per minute, or a total of $3,840 for a crop of 160 days. This item is not chargeable to the "electric" column.

| | Steam | Electric | |
|---|---|---|---|
| Material for repairing pipe coverings per crop day.... | $1.25 | $0.06 | |
| Material for piston packing, lubricators, spares, etc., per crop day.... | 19.87 | 1.10 | |
| Paint, painting tools and labor per crop day....... | 1.20 | 0.12 | |
| Oil and grease per crop day....... | 13.83 | 2.50 | |
| Cotton waste per crop day....... | 1.87 | 0.60 | |
| Repairs and oil at pumping station per crop day.... | 0.25 | 0.10 | |
| | $38.27 | $4.48 | |
| Or, a total for 160 days | $6,123.20 | $716.80 | |
| Material balance in favor of electric drive. | | | $5,406.40 |

To resume, we have in favor of electrified sugar factories the following items:

| | |
|---|---|
| (A) Saving in transmission losses................ | $ 2,730.00 |
| (B) Saving in labor..... | 7,116.80 |
| (C) Saving in incidental material............. | 5,406.40 |
| (D) Saving, interruptions | 3,840.00 |
| Total.... | $19,093.20 per crop. |

The values given in the "steam" column are amounts actually spent in the sugar factory under consideration, while the ones in the "electric" column are computed values from carefully analyzed obtainable conditions during a crop of 160 days with an assumed electrical layout and quite liberal help. It should be noted that the comparison is made on the basis of all drives other than for mills proper, which latter have in this case been assumed to be steam driven. Remembering now that the factory makes 1100 bags of sugar per day or about 175,000 bags per season, the saving just mentioned, which it must be recalled is *exclusive of fuel economy*, represents almost 11 cents per bag of sugar or over 2 per cent of the average value at which a bag of sugar was sold in Cuba during the last crop.

The fact must not be lost sight of that these data as obtained apply to an exceptionally well managed factory and that the advantages of an electric drive over the average steam drive will be decidedly greater than the ones just shown.

The exhaust steam from a turbine-generator contains no oil, as is the case with the reciprocating engine; and, if turbine-generators are used in a cane-sugar factory, the heating coils and the calandria of the evaporating apparatus will receive no heat-insulating oil coatings. It is well known that the efficiency of the cooking apparatus in cane-sugar factories is greatly impaired by such scales, the transfer of heat from the exhaust steam to the liquor being greatly diminshed. Any arrangement which will avoid the forming of such scales and which will maintain the heating surfaces in a maximum heat transmitting condition must be productive of economy not only in time and fuel but also in maintenance cost of the heating apparatus.

With a properly designed, well constructed and installed turbine-generator equipment, it is undoubtedly possible to obtain at least an additional ¼ per cent yield due to the possibility of increased maceration; and in the mill under consideration an 11¼ per cent yield could be obtained instead of an 11 per cent. This represents an increased revenue of 2¼ per cent which, translated into dollars and cents on the basis of last crop's average prices (3¾ reales per arroba; i.e., approximately 2 cents per lb.), means an extra income of $19,775. Outside of the saving in fuel it may be expected therefore that a proper electrification of this mill should produce a saving of about $40,000, which in itself is indeed a respectable sum to pay for interest and depreciation on an electrified mill to cover the new and superseded machinery.

# NOTES ON THE USE OF THERMO-ELECTRIC APPARATUS IN HIGH FREQUENCY SYSTEMS*

## PART II

By August Hund
Research Laboratory, General Electric Company

This article is a continuation of one which appeared under the same title in the October, 1914, issue of the Review. The present installment deals with different combinations of thermo-elements, such as the thermo-cross and the three-thermo-cross methods, which provide sensitive means of determining the reasonance curve and the logarithmic decrement of a circuit.—Editor.

The actual dissipation of energy in *A*, Fig. 9, is

$$W = V.I_2 \tag{31}$$

If only the thermo-couples *I* and *III* are used, the deflection of the galvanometer will be

$$\begin{aligned}\alpha &= K\ .\ I_v\ .\ I \\ &= K^1(V+V_1)\left(I_2+\frac{I_v}{2}\right) \qquad (32)\\ &= K^1\left[V.\,I_2+\left(V_1.I_2+\frac{I_v}{2}(V+V_1)\right)\right]\end{aligned}$$

This shows that the indicated energy is larger by the quantity

$$K^1\left(V_1\ .\ I_2+\frac{(V+V_1)I_v}{2}\right)$$

Since

$$I_v = \frac{V+V_1}{R}$$

we obtain the expression for the deflection of the wattmeter as follows:

$$\alpha = K^1\left\{VI_2+\left[V_1.I_2+\frac{R.I_v^2}{2}\right]\right\} \tag{33}$$

The correction factor, $\left[V_1.I_2+\frac{R.I_v^2}{2}\right]$, must be separately determined for each value of the energy to be measured. This can be done automatically by the addition of the two thermo-couples, *II* and *IV*, as shown in Fig. 9. The thermo-couples *I* and *III* would measure the energy according to equation (33). The thermo-couple *IV* measures the energy $V_1\ I_2$; and the thermo-couple *II*, if made half as sensitive as the other thermo-couples, will measure the energy $\frac{R.I_v^2}{2}$. Then

---

*ERRATUM.—*The title for Fig. 6 which occurred in Part I of this article, GENERAL ELECTRIC REVIEW, October, page 986 should have read as follows:*

*"Fig. 6. The Thermo-couple system shown in Fig. 2 shunted to measure heavy currents. When a proper value of self-inductance is used in the two branches, the system will give accurate readings at any frequency."*

by properly connecting these thermo-couples, as shown in Fig. 9, the actual energy can be measured directly.

The following is a description of a recent application of the thermo-cross bridge to the measurement of resonance and to the determination of the logarithmic decrement. This determination has usually been carried out by the method of Bjerkness, in which either the self-induction or the capacity of the circuit is varied until the current becomes a maximum at resonance. Such a Bjerkness curve is represented by the expression

$$\int_0^\infty i_2^2\, dt = \textit{function}\ (\lambda) \qquad (34)$$

where $\lambda$ is the wave length and $i_2$ the instantaneous value of the current in the resonator circuit. It is essential that the energy of the oscillator circuit (Fig. 10) be kept absolutely constant since any variation in it affects the current indicator in the resonator circuit. In order to overcome this objectionable feature, L. Mandelstam, N. Papalexi and others* worked out an improvement by causing both the oscillator and the resonator currents to act on the indicator.

Their resonance curve is represented by

$$\int_0^\infty i_1.i_2\, dt = \textit{function}\ (\lambda) \qquad (35)$$

where $i_1$ and $i_2$ are the instantaneous values of the current in the oscillator and resonator circuits, respectively. These are defined by the equations

$$i_1 = Io_1 \epsilon^{-\delta_1 t}\ \sin\ (2\ \pi\ ft + \Psi_1)$$

$$i_2 = Io_2 \epsilon^{-\delta_2 t}\ \sin\ (2\ \pi\ ft + \Psi_2).$$

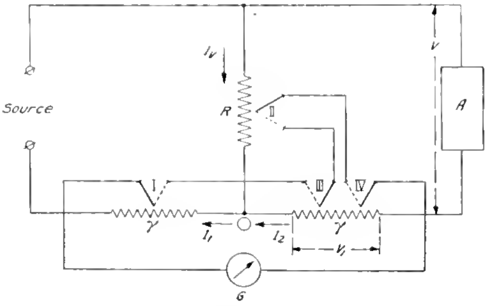

Fig. 9. A Scheme of Connections which is an Improvement over that shown in Fig. 8

In the theory, as worked out by Mandelstam and Papalexi, it is shown that resonance takes place when

$$\int_0^\infty i_1.i_2\, dt = 0,$$

at which time the currents $i_1$ and $i_2$ have a phase displacement of about $\Psi_1 - \Psi_2 = 90$ degrees with respect to each other. The resonance curve reaches its maximum for a definite amount of tuning, which is dependent on the decrement of the resonator and oscillator circuit. Since this is a zero-method, it is inherently independent of the energy variations in the oscillator circuit, and is obviously therefore preferable to the previously described Bjerkness method. In place of the short-circuit-ring-dynamometer, which is used for the current indicator in the Mandelstam and Papalexi method, a thermo-cross bridge may be substituted, thus procuring a considerably higher sensibility in range, accuracy and ease in manipulation.

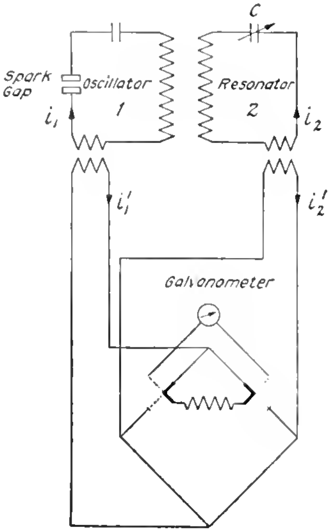

Fig. 10. A Scheme of Connections for Applying the Thermo-Cross Bridge to Determine the Resonance Curve of Circuit 1 and to Measure the Logarithmic Decrements of Circuits 1 and 2

In order to illustrate this method the diagram of connections is given in Fig. 10. The currents $i_1^1$ and $i_2^1$ have practically the same phase difference as $i_1$ and $i_2$ of the oscillator and resonator circuits (if the coupling induct-

*L. Mandelstam and N. Papalexi, Ann. d. Phys., 33, 1910,
M. Dieckman, Diss. Strassburg, 1907,
H. Rohmann, Diss. Strassburg, 1911,
L. Kann, Phys. Z., 12, 1911,
L. Isakow, Phys. Z., 12, 1911.

ances are small). The galvanometer deflection $\alpha$ becomes

$$\alpha = k \int_0^\infty i_1^1 . i_2^1 \, dt$$

$$= k^1 \int_0^\infty i_1 . i_2 \, dt \qquad (36)$$

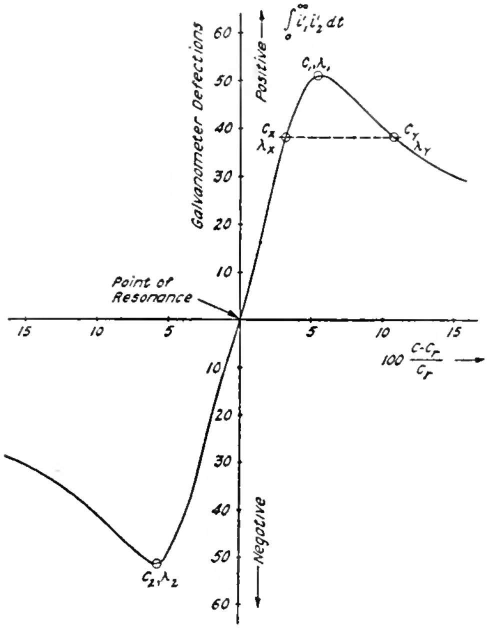

**Fig. 11. A Resonance Curve taken with the Method Shown in Fig. 10**

since

$$\int_0^\infty \left(\frac{i_1+i_2}{2}\right)^2 dt - \int_0^\infty \left(\frac{i_1-i_2}{2}\right)^2 dt = \int_0^\infty i_1 . i_2 \, dt.$$

A representative resonance curve as obtained by this method is given in Fig. 11. The deflections of the galvanometer are plotted against $100 \dfrac{C-C_r}{C_r}$, where $C_r$ is the value of the capacity at resonance and $C$ is the value of the capacity when the resonator circuit is not in tune with the oscillator. It will be noted that the curve is very slanting at the point of resonance. It is evident, therefore, that this method is very sensitive since a very small change in the capacity $C$ corresponds to a considerable variation in the integral value

$$\int_0^\infty i_1^1 . i_2^1 \, dt.$$

Another combination of thermo-elements which can be used for measuring the

$$\int_0^\infty i_1 . i_2 \, dt$$

values of two oscillating circuits is due to M. Dieckman†, who arranged three thermo-crosses as shown in Fig. 12. In this method the thermo-elements *I*, *II* and *III* are connected in series with a galvanometer, and the connections are so made that the effects of *I* and *II* are additive and *III* is subtractive. The electromotive force of each thermo-element is as follows:

*I* is directly proportional to $n_1^2 i_1^2$
*II* is directly proportional to $n_2^2 . i_2^2$
*III* is directly proportional to $(n_1 i_1 + n_2 i_2)^2$.

The values of $n_1$ and $n_2$ depend upon the ratio of the coupling turns in the oscillator and resonator circuits, respectively. With these connections one is able to obtain galvanometer deflections which are proportional to

$$\int_0^\infty i_1 . i_2 \, dt,$$

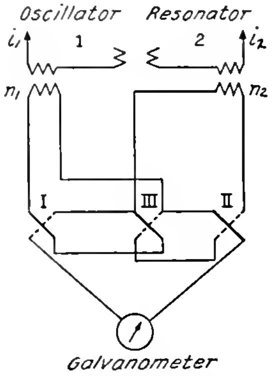

**Fig. 12. A Scheme of Connections using a Combination of Three Thermo-Couples to Determine the Resonance Curve of Circuit 1 and to Measure the Logarithmic Decrements of Circuits 1 and 2**

since

$$\alpha = k \left[ \int_0^\infty n_1^2 . i_1^2 \, dt + \int_0^\infty n_2^2 . i_2^2 \, dt - \int_0^\infty (n_1 . i_1 + n_1 \, i_2)^2 \, dt \right] \qquad (37)$$

where $\alpha$ is the galvanometer deflection and $k$ is a constant.

---

† M. Dieckman, l. c.

The curve marked

$$\text{“}\int_0^\infty i_1 . i_2\, dt\text{”}$$

in Fig. 13 is plotted from the results obtained by this method. The abscissae are degrees on the scale of the condenser which is inserted in the resonator circuit and the ordinates are deflections of the galvanometer. The Bjerkness curve,

$$\int_0^\infty i_2^2\, dt,$$

is also shown in Fig. 13 in order to facilitate comparison between the two methods. This latter resonance curve is the plot of data as secured by means of an ordinary thermocouple, such as is shown in Fig. 2. The couple was inserted in a separate circuit which was loosely coupled to the resonator. It is well to note that the maximum point of the Bjerkness curve comes at exactly the same abscissa as the zero point of the

$$\int_0^\infty i_1 . i_2\, dt \text{ curve.}$$

In this section a short discussion on the measurement of the logarithmic decrement will be given in order to point out the wide field of application of the thermo-cross bridge and the three-thermo-couple method. The sum of the logarithmic decrements may be computed from an ordinary resonance curve, such as the

$$\int_0^\infty i_2^2\, dt$$

curve of Fig. 13, from the formula

$$\begin{aligned}\triangle_1+\triangle_2 &= \pi . \frac{C_r-C}{C}\sqrt{\frac{I_{2\,eff}^{\,2}}{I_{2\,r\,eff}^{\,2}-I_{2\,eff}^{\,2}}}\\ &= \pi . \frac{C_r-C}{C}\sqrt{\frac{\alpha}{\alpha_r-\alpha}} \qquad (38)\end{aligned}$$

In this formula $\triangle_1$ and $\triangle_2$ are the logarithmic decrements of the circuits *1* and *2* respectively of Fig. 12, $\alpha$ is the deflection of the galvanometer which is proportional to

$$\int_0^\infty i^2\, dt$$

and corresponds to the value $C$ of the capacity which is in circuit *2*, and $\alpha_r$ corresponds to $C_r$ at which value the circuit *2* is in resonance with circuit *1*. If the corresponding wave lengths $\lambda$ and $\lambda_r$ be introduced, equation (38) would become

$$\triangle_1+\triangle_2 = 2\,\pi . \frac{\lambda_r-\lambda}{\lambda}\sqrt{\frac{\alpha}{\alpha_r-\alpha}} \qquad (38a)$$

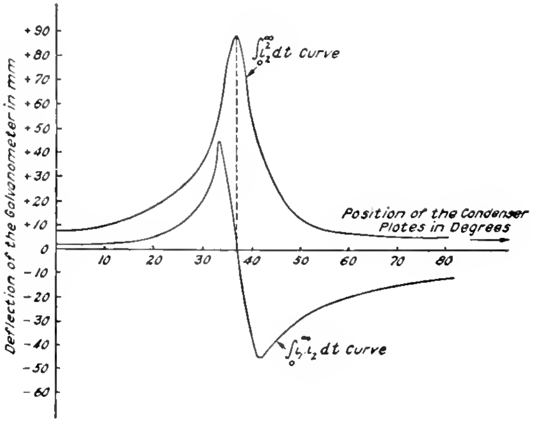

**Fig. 13.** **In this Fig., Curve** $\int_0^\infty i_1 i_2\, dt$, **which is taken according to the Method shown in Fig. 12, is shown compared with Curve** $\int_0^\infty i_2^2\, dt$, **which is plotted from data obtained by the Ordinary Bjerkness Method**

If the logarithmic decrements are to be determined from the

$$\int_0^\infty i_1 . i_2\, dt$$

curve in Fig. 13 for the two maximum integral values, the following formulae may be used

$$\left.\begin{aligned}\triangle_1+\triangle_2 &= \pi . \frac{C_1-C_r}{C_1}\\ &= \pi . \frac{C_r-C_2}{C_2}\\ &= 2\pi . \frac{\lambda_1-\lambda_r}{\lambda_1}\\ &= 2\pi . \frac{\lambda_r-\lambda_2}{\lambda_2}\end{aligned}\right\} \qquad (39)$$

In this case $\lambda_r$ and $C_r$ are the values of circuit *2* at resonance, for which condition

$$\int_0^\infty i_1 . i_2\, dt = 0,$$

$\lambda_1$ and $C_1$ are the values of wave length and capacity respectively at maximum positive deflection of the galvanometer, while $\lambda_2$ and $C_2$ are the corresponding values at maximum negative deflection of the galvanometer (see Fig. 11). If the extreme parts of the

$$\int_0^\infty i_1 \, . \, i_2 \, dt$$

curve are too flat and the corresponding wave lengths and capacities can only be approximately determined, the following formulae may be used

$$\triangle_1 + \triangle_2 = \pi . \sqrt{\left(\frac{C_x - C_r}{C_x}\right)\left(\frac{C_y - C_r}{C_y}\right)} = 2\pi \sqrt{\left(\frac{\lambda_x - \lambda_r}{\lambda_x}\right)\left(\frac{\lambda_y - \lambda_r}{\lambda_y}\right)} \tag{40}$$

where $C_x$ and $C_y$ are the values for the capacity and $\lambda_x$ and $\lambda_y$ are the values for the wave length. All these values correspond to the intersection of the

$$\int_0^\infty i_1 \, . \, i_2 \, dt$$

curve with any line parallel to the abscissa, such as is shown in Fig. 11. In this case it is convenient to plot the galvanometer deflections against the capacity or the wave length of the resonator circuit.

# APPLICATION OF POWER APPARATUS TO RAILWAY SIGNALING

## Part III

By H. M. Jacobs

Signal Accessories Department, General Electric Company

This article is the last of a series of three on the subject of railway signal power apparatus. The first, or introductory article, described in a general way the underlying principles of the various systems in common use, and the second dealt only with electrically controlled signals for both automatic block work along the right-of-way, and for interlockings at stations, terminals, crossovers, etc. The present article describes a few installations on some of the leading roads of the East and Central West, dealing particularly with the equipment at certain interlocking towers that has been put in service within the past three years.—Editor.

It may be said with a degree of certainty that the sole thought in the mind of the average traveler relative to movements of trains is the desire to reach his destination safely and on schedule time; but to a technical man, or one interested in railroading, some knowledge about the great organization of trained workmen who devote their energies to the accomplishment of these ends, and of the vast amount of equipment involved, adds interest to the journey.

The demand for a reduction in train schedules and better service has increased tremendously the responsibilities of the signal department of the various railroads, and railway signaling may now be rightly considered a science in itself. It is manifestly to the advantage of any road to establish certain standards, as this will minimize the amount of supplies to be carried in its storehouses, and reduce the first cost because of the ability to purchase in large quantities and to duplicate orders.

Each road, in solving its own problems, has thus evolved its own standards, until we now have almost as many standards as there are railroads. The Railway Signal Association, composed of men in the employ of signal departments of railroads and representatives of manufacturers interested, was formed to bring about a crystalization in standardization, to obtain an economical and satisfactory product, and to establish a certain excellence in manufacture to meet the exacting requirements.

There are, however, certain standards to which the various roads hold tenaciously; and it should be so, for each is dependent on its particular traffic requirements, the system of signaling installed, the available power for power-operated systems, and other elements too numerous to mention here. It is beyond the scope of this article to deal with signal requirements and standards; only the power equipment accessory to the operation of the signal system will be considered.

A few of the more recent installations of the past three years are described here, and in addition the equipment for some installations not yet placed in service and others installed to handle a problem not encountered in ordinary power service.

### NEW YORK CENTRAL & HUDSON RIVER RAILROAD CO.

The automatic signals and track circuits on the New York Central are operated from storage batteries arranged in duplicate groups at each location and so connected to a charging switch (previously described) that while one group is supplying power to the signals the other may be connected to a series charging line, in series with similar groups at other locations. Power stations, located at points where commercial power is available, supply these lines at a voltage of from 350 to 600, as conditions require, and maintain a constant current of 5 amperes. A single-panel switchboard controls the generator and the two feeders, but the current in each line is maintained at the proper charging value by means of series plate-type rheostats. These rheostats are mounted in some instances on the wall and in others on the back of a separate panel which also provides starting and control apparatus for the motor. The station is protected by choke coils and Type ME lightning arresters on each line, and the same kind of arresters are attached to the return wire at mile intervals.

At the electric interlockings there are required three distinct batteries, one floating on the charging circuit and two in duplicate; the main or machine battery to deliver 110 to 142 volts for operating the signal and switch motors, the lock and indicator batteries 12 volts, and separate track batteries 2 volts for supplying power to each track circuit within the limits of the interlocking. These batteries are charged in series, or separately in various combinations, from specially designed mercury arc rectifiers having a high and low voltage tube. The low voltage batteries alone may be charged from the high voltage tube in series with a variable resistance.

The New York Central uses the type of switchboard recently standardized by the Railway Signal Association for charging under the conditions just described, as well as the line charging panel and the motor and line control panel. The rectifier is a slight modification of the standard panel arranged to obtain the double voltage range.

The most recent installation, shown in Fig. 1, is the interlocking near Rome, N. Y. Directly back of the motor-generator set is the two-way line charging panel for the signals on either side of the interlocking limits. The single feeder panel is for future signaling over the Rome, Watertown & Ogdensburg Railroad. The rectifier panel stands at the left of the four-panel board adjacent to the motor and line control panel. The two interlocking control panels are at the right.

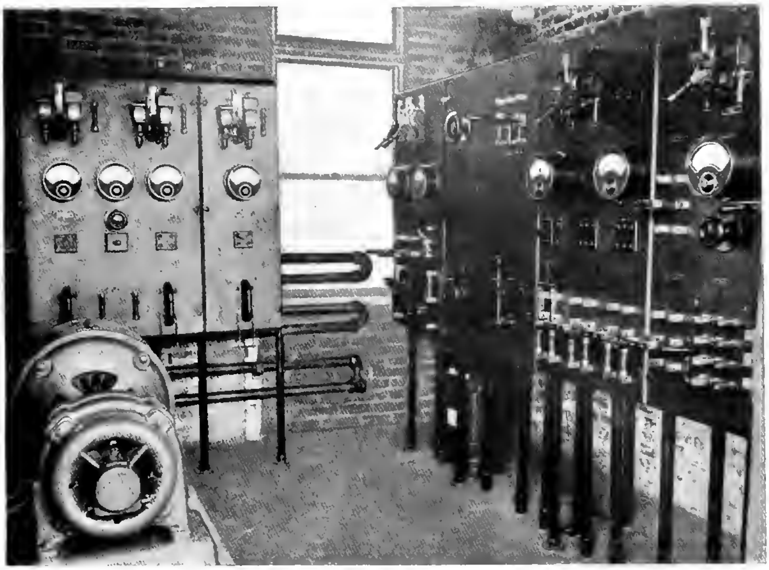

Fig. 1. Power Station, Electric Interlocking, near Rome, N. Y.
New York Central

Short interruptions of the power supply or minor breakdown of part of the charging equipment at one of the 600-volt line charging stations causes little or no concern, but continued failure or destruction of the station would be a serious matter. To provide against this emergency the railroad has fitted up a baggage car as a portable substation. It contains a single cylinder 6-kw., 600-volt gasolene-engine-generator set, a 600-volt d-c. to 110-volt d-c. motor-generator set, a three-panel switchboard, and complete substation equipment. The car may be run on a siding and the charging line temporarily tied in.

## BOSTON & ALBANY RAILROAD

A little over a year and one-half ago, the Boston & Albany put in service an installation of d-c. automatic signals and interlocking at Worcester, Mass. The top floor of the signal tower contains the interlocking machine, the ground floor the five-panel switchboard, power units and relay rack, and the basement the storage batteries. Three-phase, 60-cycle, 440-volt power from a commercial source is delivered to the switchboard for the induction motors of the two sets and for a 10-kw., 440/220-volt single-phase step-down transformer that is connected to a mercury arc rectifier for charging the main 65-cell lead-type storage battery for the interlocking machine. The rectifier equipment is unique in that it is mounted on a 90-inch three-section panel containing instruments and switching equipment to match the rest of the switchboard. The interlocking battery is not furnished in duplicate and must therefore be charged during operation. A fixed resistance may be cut into circuit to draw from the rectifier sufficient current to maintain the arc on low fluctuations of load when circumstances require that the interlocking machine be operated directly from the rectifier. As it is not advisable to raise the voltage on the interlocking machine to the high value necessary to complete the battery charge, an end cell switch has been installed.

Fig. 2. Railway Signal Battery Charging Apparatus Installed in Baggage Car for Emergency Use. New York Central & Hudson River Railroad

One panel contains station lighting switches and 10 battery charging switches for the track circuits within the limits of the interlocking. The local track batteries are charged from the rectifier, and the track and motor batteries on either side of the interlocking are charged in series, similarly to the method of the New York Central & Hudson River Railroad previously described, from a 550-volt d-c. railway source controlled from a switchboard at Jamesville, a few miles away. The charging line is carried through the d-p. d-t. lever switches on the right-hand panel, simply looping through the station. In case of failure of this source these switches may be thrown down onto an emergency generator circuit, the charging being controlled on this panel by the generator and two rheostats, one in each line feeder extending in opposite directions from the station. This generator is one unit of a three-unit emergency set, the other two units being an induction motor and a 110/175-volt d-c. generator to supplant the rectifier.

One panel controls the charging of the duplicate lock and indicator batteries from a small two-unit motor-generator set not shown in Fig. 3.

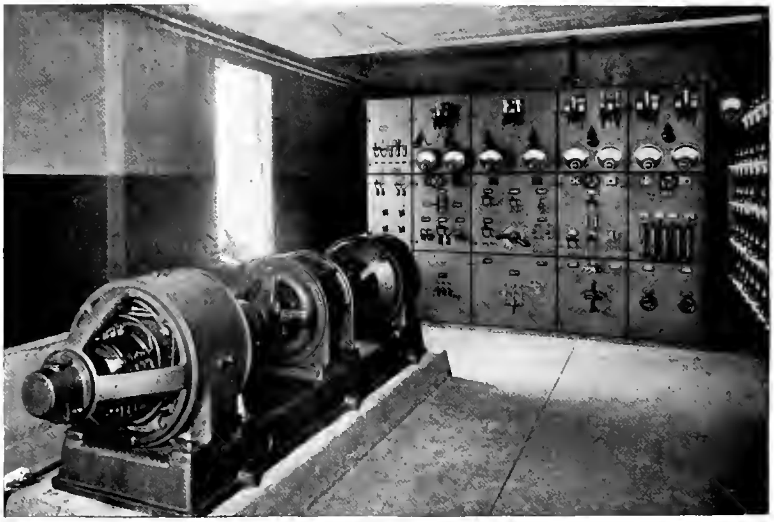

Fig. 3. Power Equipment for Direct Current Signaling Installation on the Boston & Albany Railroad, Worcester, Mass.

The commercial supply is practically immune from a prolonged failure, and as the provision for emergency is so complete and the switching arrangement so flexible, the possibility of a total failure is most remote.

### LAKE SHORE & MICHIGAN SOUTHERN RAILWAY

The Lake Shore & Michigan Southern Railway recently placed in service a battery charging equipment for the automatic interlocking plant at Toledo, Ohio, the switchboard of which is rather unique. Two mercury arc rectifier equipments are provided, the panels of which match and line up with the switching panel, and the switching arrangement is such that the batteries may be charged in every conceivable combination.

The battery equipment consists of one main 55-cell interlocking battery, two duplicate 6-cell group track batteries, two duplicate 10-cell group lock and indicator batteries, and a variable (20 to 90 cells) Edison portable battery. Under normal conditions the portable batteries will be charged from one rectifier and the main battery from the other. The track batteries and lock and indicator batteries are connected to d-p. d-t. battery transfer switches in such a way that the discharge circuits can never be broken. The batteries connected in the charging sides of these switches may be charged simultaneously either separately or in series with either the main battery or the portable batteries; or it is possible to charge alone either the track batteries, the lock and indicator batteries, or a small number of portable batteries from the low voltage tube on one of the rectifiers. This condition so seldom arises that it was deemed unnecessary to provide two tubes on both rectifiers. A six-pole throw-over switch is provided to interchange connections from the high voltage to the low voltage tube on the rectifier to meet this special condition.

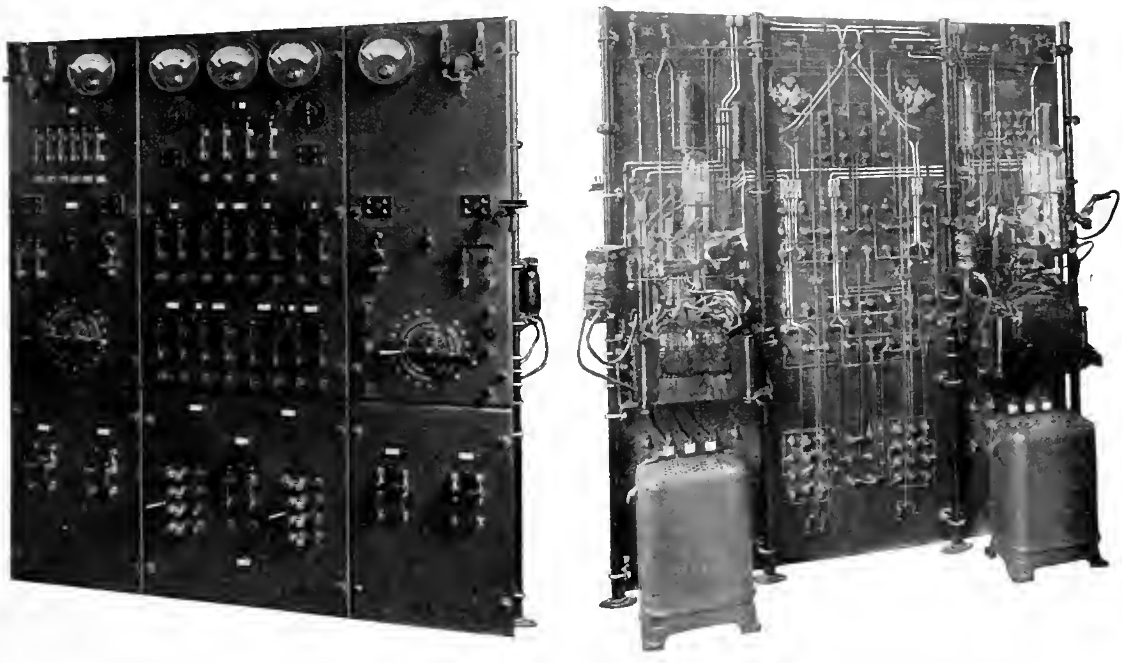

**Fig. 4. Single-Phase Mercury Arc Rectifier and Battery Feeder Switchboard for Charging Signal Batteries, Lake Shore & Michigan Southern Railroad, Toledo, Ohio**

The switchboard also provides four 220-volt single-phase a-c. lighting circuits, each supplying a number of transformers having secondary taps to provide 10, 11, 12, 13, 14 or 15 volts for lighting the signals.

### PENNSYLVANIA RAILROAD COMPANY

The Pennsylvania Railroad has recently completed an installation of automatic block signals on the main line between New York and Pittsburgh, and between Philadelphia and Washington. This comprises a total of 895 track miles equipped with alternating- current automatic block signals, and 91.2 track miles changed from direct-current to alternating-current automatic signals. Over this distance the signals are fed from a transmission line supplied at intervals from the company's power plants, the spacing between plants being determined approximately by the load of the intervening sections of the line. Each station has sufficient capacity to feed in both directions to adjacent stations. Under normal conditions each station may be operated at half-load feeding in one direction, or only alternate stations may supply power in both directions, the other stations being for emergency service. The line is further sectionalized at each signal location in such a way that should a short circuit occur the faulty section may be cut out and power fed to the remainder from the two adjacent stations, thus making all signals operative.

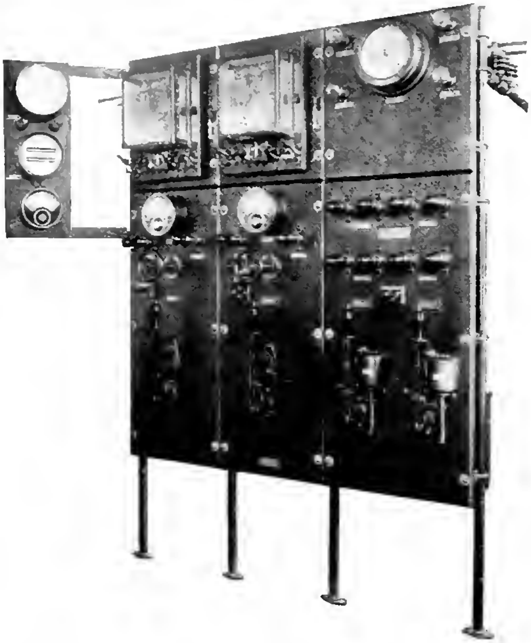

**Fig. 5. Switchboard for Controlling Two 240-volt Single-Phase Generators and Two 3300-volt Single-Phase Feeders for Alternating Current Signaling System, Pennsylvania Railroad**

It is important to note a high degree of standardization throughout the whole system. In 18 stations the steam-engine-driven units are all 35-kv-a., 220-volt, single-phase, 60-cycle generators. The feeder panels with one exception are all arranged to feed in two directions. Fourteen stations have two generating units each with individual generator control panels, four stations have one unit and generator panel, and one station has a 25 kv-a. gasolene-engine-driven unit with generator panel and one-way feeder panel, the equipment of all panels for similar duty being identical. Fig. 5 illustrates a two-generator, two-way feeder switchboard, and Fig. 6 the installation at the station operated by the gasolene engine-driven unit. In order to minimize the responsibility of the operator each exciter has its own voltage regulator, so that synchronizing is simplified as much as possible. The power generated at 220 volts is stepped up to 3300 volts before going to the switchboard. Power circuits are made and broken on oil switches, and plug type disconnecting switches are mounted on the panels. All parts customarily exposed, whether low tension or high tension, are either completely covered by asbestos lumber cases or bushings securely clamped, so that it is impossible for the operator to come in contact with any live part, at either front or back of board. When the movements of the semaphore blades are retarded by weight of sleet or snow, and it is advisable to hasten the movements, the line voltage is boosted 10 per cent without readjustment of the voltage regulators by opening a small lever switch at the side of the regulator base. Aluminum cell static dischargers are connected to the lines where they leave the station.

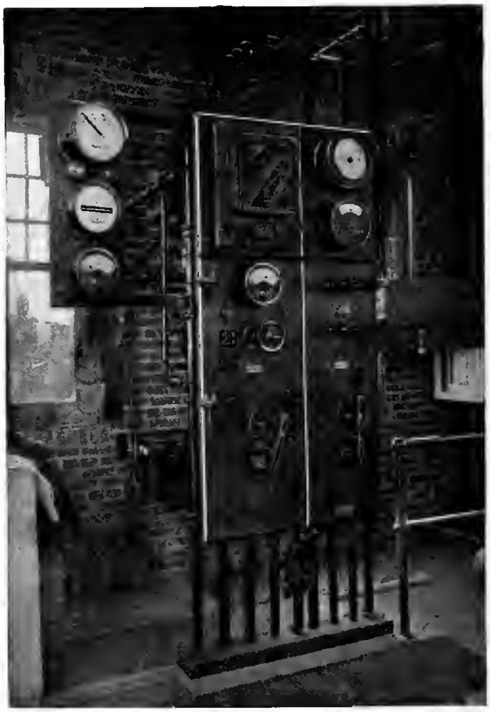

**Fig. 6. Railway Signal Power Station Installation, Pennsylvania Railroad**

The transmission lines consist of two No. 4 or No. 6 B.&S. gauge copper wires heavily insulated and embedded in asphaltum pitch in wooden trunking approximately two feet under ground. The sectionalizing outfit at each signal location consists of an iron mechanism case enclosing a d-p. d-t. non-automatic oil switch, a short-circuit indicating relay, a 3300/110-volt, 600-watt or 1000-watt transformer, and two primary plug cutouts. The transformer is connected to the middle terminals of the oil switch, the two throws of which are independent, so that when both sides are closed the transformer is connected across the line feeding through; or the transformer may be fed from either side with the other side open, or cut off entirely by opening both sides. The short-circuit indicating relay is connected in series with the line of the normal power supply side, and when actuated by heavy overload or short circuit the armature plunger will latch up and give a permanent indication until restored to normal by an attendant. When a short circuit occurs in any section, the relays in every sectionalizing outfit between the generating station and the faulty section will be actuated by the abnormal current and indicate by the position of the plunger that trouble is beyond. An attendant will then open the outgoing side of the oil switch in the last sectionalizing case giving the indication, and the incoming side of the oil switch in the next adjacent sectionalizing case, in order to cut free the faulty section, after which power may be supplied to the remainder of the line from power stations on the two ends. It is thus evident how in a very short time a faulty section may be cut free with minimum interruption to the system. The relays in the outfits adjacent to an interlocking tower have their auxiliary contacts connected to an indicating lamp in the tower, to assist in locating the trouble.

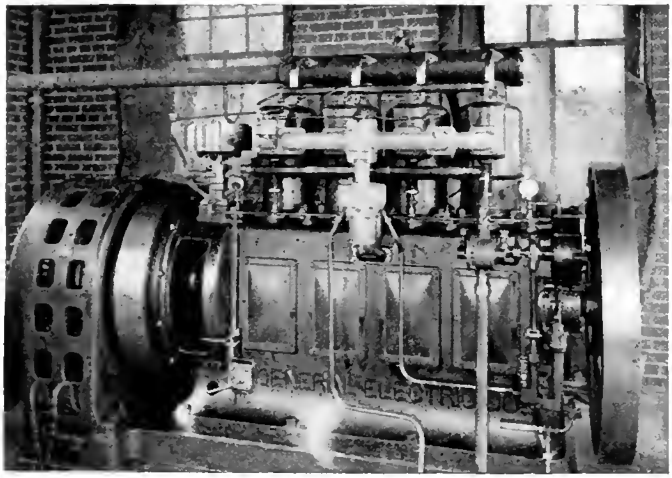

Fig. 7. Gasolene Engine Set in Power House, Pennsylvania Railroad

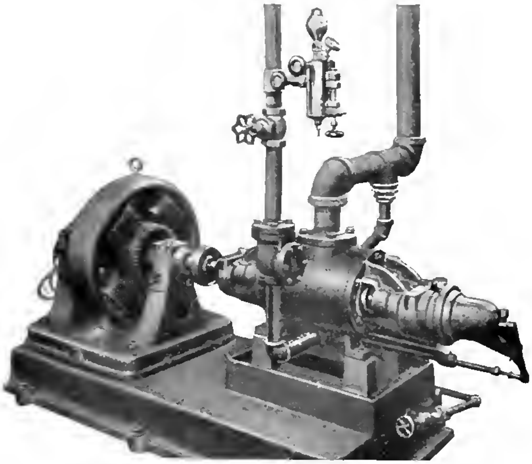

Fig. 8. Turbine-Driven Self-Excited Alternator, Pennsylvania Railroad

At Monmouth Junction, N. J., the Pennsylvania Railroad has installed two small steam turbine-driven alternating-current generators, 5-kv-a., 110-volts, single-phase self-excited. A duplicate set is installed at the North Philadelphia station, and a fourth, similar in every way, except for operation on compressed air, is in service at Rahway, N. J. These units are only 6 ft. 3 in. long, 28¾ in. wide and 36¾ in. high.

## CENTRAL RAILROAD OF NEW JERSEY

The accompanying illustration (Fig. 9) is typical of ten installations on the Central Railroad of New Jersey made during the past two years by the Union Switch & Signal Company, and indicates the standard for battery charging service for the particular kind of signaling installed.

The motor-generator sets (in duplicate) are arranged for d-c.—a-c. or a-c.—d-c. conversion, depending on the particular kind of commercial power available. The generators are 45-ampere, 20/50-volt shunt wound machines, for charging Edison A-6 225-ampere-hour storage batteries. The interlocking battery consists of two duplicate groups of 16 cells each, and the track batteries of two duplicate groups of 12 cells each. Each track battery is subdivided into six groups of two cells each, discharged in multiple and charged in series. The twelve groups of track batteries (six on charge and six on discharge) are so connected to the 13-blade charging switch that the multiple-series discharging groups are connected in series to the charging circuit and the series charging group in multiple-series to the track circuit on each throw of the switch without interrupting the track circuit supply. The four-pole double-throw transfer switch likewise interchanges the interlocking batteries without interruption. The interlocking battery may be charged separately or in series with the charging group of track batteries, and the latter may be charged separately through small fixed resistance by a very simple switching equipment. By means of turn button type ammeter switches one ammeter serves to indicate both the charge and discharge currents of both sets of batteries without conflict.

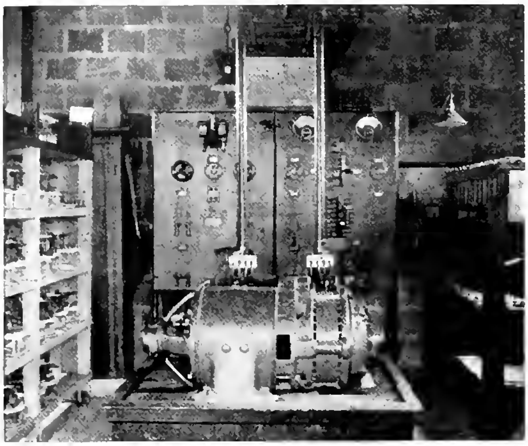

Fig. 9. Battery Charging Equipment, Central Railroad of New Jersey

The more recent installation in the Jersey City Terminal yards provides a-c. track circuits and lighting in towers "A" and "B," while direct current for charging the interlocking batteries is supplied from a mercury arc rectifier. Alternating current is supplied normally from a 575-volt source through either one of two duplicate 575/110-volt transformers and distributed to the various lighting and track circuits. Emergency a-c. supply is available at 2200 volts. This is stepped down to 575 volts, and a transfer equipment consisting of two double-pole contactors and a control relay provides for automatically supplying power therefrom without noticeable interruption upon failure of the normal source, and automatic resumption upon its return. All this control equipment is mounted on a panel 76 in. high and 32 in. wide. The arrangement in tower "C" is somewhat different. The accompanying illustration, Fig. 11, shows only an a-c. feeder panel with transfer equipment similar to that in towers "A" and "B."

### CHICAGO, MILWAUKEE & ST. PAUL RAILWAY

The Chicago, Milwaukee & St. Paul Railway has recently put in service the last 40 miles of a 458-mile alternating-current automatic block signal installation, on which construction work was begun in 1912. This comprises five separate divisions, all double

Fig. 10. Signal Tower, Central Railroad of New Jersey

track, with ten substations, viz., Savanna to Elgin, Ill., having three substations; Lake to Rondout, one substation; Milwaukee to North La Crosse, three substations; Bridge Switch to Hastings, two substations; and Minneapolis to Hopkins, one station. From these stations 543 automatic signals and 96 semi-automatic signals are supplied. All stations receive their power from 60-cycle commercial source, and with one exception all stations on any one division are supplied from the same system so that the load between stations may be picked up by either station without interruption or danger of interference between two unsynchronized power systems. Magnetic locks are provided on the oil switch at the Savanna station and on the oil switch feeding to Savanna in the Forreston two-circuit station, to make connection between these two stations impossible, as the supply sources here are two independent systems.

The panels are all 90 in. high and of natural black slate, with the exception of the station at Sparta, which is blue Vermont marble to match and line up with an existing board. Power is metered and controlled at the voltage received. The panel equipment consists of a single-phase watthour meter, an automatic oil switch with time-limit overload trip for each feeder, and a voltmeter for the bus.

Transformers are located in the outgoing feeder circuits to step-up from the receiving voltage to 4400 volts for transmission. A spare transformer, equal in capacity to that of the heaviest feeder, is installed in each station, together with primary and secondary switching equipment.

The stations on the ends of the section are single feeder, and the intermediate stations double feeder, and of such capacity that the total load may be carried by alternate stations if desired. Emergency operation is thus provided under all conditions, in a manner similar to that on the Pennsylvania Railroad already described.

With the exception of the Portage station, the commercial power supply seldom, if ever, fails. In order to guard against rather frequent interruption at the Portage plant, an auxiliary equipment has been furnished, which consists of a two-unit motor-generator set, the motor being of the synchronous type driving an a-c. generator to charge a 90-cell Edison storage battery. The switchboard and set are furnished with such automatic control equipment that upon failure of the a-c. power supply, the set will run from the storage battery, supplying the signal line from the a-c. machine at normal voltage and frequency without interruption. A synchronizing equipment is provided so that upon resumption of the commercial supply the a-c. machine may be synchronized and operation resumed as before. This equipment has been in satisfactory operation for over nine months.

The Chicago, Milwaukee & St. Paul Railway is particularly fortunate in having ample and satisfactory commercial power available and has carried out the idea of standardizing power apparatus to a very high degree.

### NEW YORK, NEW HAVEN & HARTFORD RAILROAD

Directly across the tracks from the Boston & Albany installation described is the interlocking tower and power plant controlling the alternating-current signals and interlocking on the New York, New Haven & Hartford Railroad. The tower is of pleasing architectural design, is of concrete construction and three stories high. The upper story contains the interlocking machine, the ground floor the switchboard duplicate power units and relay racks, and the basement the storage batteries and transformers for the incoming line.

The switchboard consists of two induction motor panels, two d-c. panels, a storage battery panel, two a-c. generator panels, and the synchronizing and speed regulator equipment. The three units comprising the duplicate motor-generator sets are a three-phase, 60-cycle, 440-volt induction motor, a 7½-kv-a., single-phase, 60-cycle, 440-volt self-excited alternating-current generator, and a 10-h.p., 90/160-volt shunt wound d-c. machine. Only one set is in operation at a time, the other being held in reserve.

Under normal conditions the motor supplied from the commercial power source drives the set, the signal circuits being supplied from the a-c. generator, while the d-c. machine either charges or floats on the storage battery. Upon failure of the commercial power supply the d-c. machine automatically acts as the motor of the set, operating from the storage battery. Speed is held constant by an automatic speed regulator. The battery has capacity sufficient to thus operate the system one-hour. Upon resumption of power, it is unnecessary to synchronize the motor, as it is of the induction type.

### DELAWARE, LACKAWANNA & WESTERN RAILROAD

A little less than two years ago, the Delaware, Lackawanna & Western Railroad put in service an electro-pneumatic interlocking plant at Montclair, N. J. The power plant shown in the illustration is located in the basement of the signal tower and consists of two duplicate induction motor-driven air compressors, duplicate sets of Edison A-10 batteries for the interlocking and for track circuits, three motor-generator sets for battery charging, and a switchboard to control all.

Fig. 11. "The Yankee" passing Signal Tower at Worcester, Mass. N. Y., N. H., & H. R.R.

The air compressors are each of 100 cu. ft. per minute capacity and of the four-cylinder two-stage type, and are driven through double-herringbone gears by three-phase, 60-cycle, 1800-r.p.m. induction motors starting on external resistance in the rotor circuit and controlled from the switchboard.

The motor-generator sets are of unit frame construction. The motors are three-phase 60-cycle, 220-volt machines, and the shunt wound generators are rated for 75 amperes, 15 volts.

The main batteries for the interlocking are arranged in two duplicate sets of 16 cells each, and the track batteries in duplicate sets of two groups, four cells per group, or a total of eight cells per set. The two duplicate sets of main battery are so connected that, when interchanging them from charge to discharge and vice versa, the discharge circuit is never interrupted. The track batteries are so connected to a five-pole double-throw switch that the two component groups of the charging set are in series and those of the discharging set in multiple; and by reversing the position of the switch the duty of the two sets of batteries, as well as the connections, are interchanged without disturbance to the discharge line.

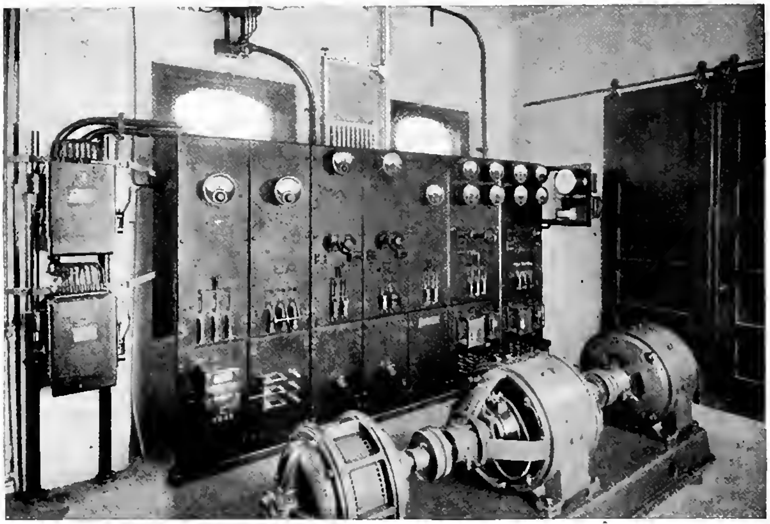

Fig. 12. Power Equipment for Alternating Current Signaling Installation on New York, New Haven & Hartford Railroad, Worcester, Mass.

The switchboard is so arranged that, by running all three motor-generator sets at the same time, the track batteries may be charged from any one, and the main battery from the other two connected in series; but should any one set be disabled the main battery may be charged from the remaining two, and when the charge is complete the track batteries may be charged from either one of these. Thus by alternating the times of charge the two sets of batteries may be charged one at a time from the two motor-generator sets, so that the disability of the other set will not cripple the system.

With the exception of the air compressor governor, which is located on the wall, the automatic starting equipment is all mounted on the switchboard. The air governor is set for operation between 80 and 90 pounds per square inch. A six-pole double-throw lever switch connects one or the other of the compressors to the operating circuits.

### LONG ISLAND RAILROAD

The recent electro-pneumatic a-c. signal installation on the Long Island Railroad at Jamaica, N. Y., requires four separate interlocking towers, all of which receive a-c. power at 2200 volts, 25 cycles, which is transformed to 220 volts for delivery to the switchboard. The compressed air for operating the switches and signals is obtained from the company's car shops at Morris Park, near tower "R."

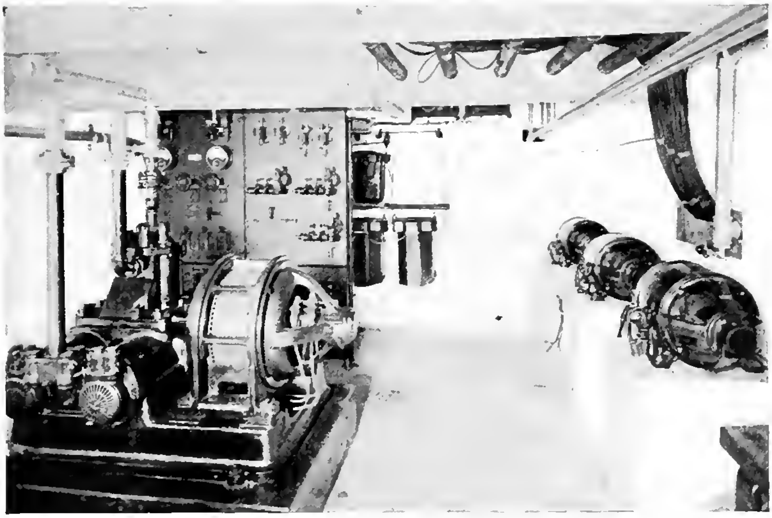

Fig. 12a Power Station in Electro-Pneumatic Interlocking Tower, Delaware, Lackawanna & Western Railroad

Both steam and electric trains pass through the interlocking, but by far the greater number are electric, as the lines to New York and Brooklyn are electrified. 500-volt d-c. propulsion current is supplied from the insulated third rail.

In each of the two small towers, "R" and "MP," the motor-generator set for charging the duplicate 7-cell lead type interlocking battery consists of a 220-volt, single-phase, 25-cycle induction motor and a 25-volt, 25-ampere shunt wound d-c. generator. The switchboard distributes at 220 volts single-phase to the induction motor and to the track circuits, and from the latter further transformation is made at each track section to a lower voltage. It also supplies one of two duplicate transformers for the signal lighting circuits through the upper contacts of a relay held in by energy from the a-c. circuit. Upon failure of the a-c. supply this relay connects the lighting circuits to the d-c. storage battery.

At each of the two larger towers "J" and "JE" the switchboard distributes at 220 volts single-phase to the motor, track circuits and lights. On account of the more extensive distribution of the lighting feeders, it is not feasible to supply them at low voltage as from the two smaller towers. To provide the feature of having emergency power available for the lighting circuits when desired, the motor of the set is made of the synchronous type, excited from the d-c. machine, and upon failure of the a-c. supply the d-c. machine will run as a motor from the storage battery and the a-c. machine as a single-phase generator, supplying only the lighting circuits. To govern this emergency action a master relay energized from the a-c. source having upper and lower contacts, an automatic starting equipment and two field rheostats for the d-c. machine, are required. The connections to the two rheostats, are interchanged by the master relay, one rheostat being in circuit when the machine is generating and the other—for governing the speed of the set—when motoring.

The control circuits are so connected through the relay contacts and a third blade of the lighting switches that should the a-c. power fail in the daytime, when the two lighting switches are open, the set will come to a standstill if charging the batteries, or remain at a standstill if in this condition. When the lighting switches are closed, the set, if charging the battery, will continue to run from the battery; but, if the set is at a standstill, the automatic starting equipment will immediately become active and start the set, throwing power on the lighting circuits from the a-c. machine within a very few seconds.

Fig. 13. "JE" Tower, Long Island R.R., Jamaica, N. Y.

The automatic equipment is arranged so that upon reversal of the set the lighting circuits are cut free from the 220-volt bus, otherwise the set would become overloaded and pump back on the supply line. A switch is provided in the starting control circuit so that the set may be started at any time desired.

The switchboards and sets in the two larger towers are exactly the same in design and arrangement, the only difference being in capacity of equipment, to provide in one a normal charging rate of 40 amperes and in the other 60 amperes.

### SOUTHERN RAILWAY

The General Railway Signal Company have now under construction four signal installations on the Southern Railway which require seven substations and two power stations. Four of the substations: Lynchburg, Va., Morristown, Tenn., Howell and Gainesville, Ga., are exact duplicates, receiving the power from commercial sources at 2200 volts, three-phase, 60-cycle and delivering 30 kv-a. at 4400 volts, three-phase, The substation at Coster, Tenn., receives power at 220 volts and delivers 30-kv-a. at 4400 volts, three-phase, 60-cycle. The two remaining substations are "outdoor type," that is, a steel switch house is located at the foot of a pole structure supporting the transmission line and houses the switchboard, instruments, meters and instrument transformers. The power transformers, disconnecting switches, choke coils and lightning arresters are supported on the pole structure. The power houses at Monroe and Whittles, Va., are exact duplicates except in capacity.

In these nine stations standardization has been strenuously adhered to. One power station has a capacity of 50 kv-a., three-phase, and the other power station and six substations 30-kv-a., three-phase; the remaining substation, connected temporarily single-phase, will ultimately be the same.

All stations bear a similarity in layout and arrangement of apparatus. Disconnecting switches are provided at the low tension side of power transformers and at the line side of the high tension apparatus. The automatic oil switch, ground detector, current and potential transformers for the meter instruments, inverse time-limit overload relay, choke coils and lightning arresters are connected in the 4400-volt circuit in the order given. One potential transformer is between the power transformer and the oil switch to indicate whether power is available from the supply.

The switchboards of the four duplicate substations consist of two panels 90 in. high, each of two sections of natural black slate mounted on pipe supports and surmounted by the ground detector. Two incandescent lamps in goose neck brackets afford ample illumination for the horizontal edgewise instruments directly beneath. Current may be read in any phase on the one ammeter by a three-way ammeter switch, and a short-circuiting switch is provided to protect the instrument against the heavy starting load. Switches are provided for station lighting. The watthour meter is mounted on the subbase.

The two power house switchboards each consist of three panels similar in height of sections, material and mounting to the four substation switchboards. The high tension feeder equipment and its comparative arrangement in the circuit is identical with that in the substation feeders. As the generator voltage is 220, the triple-pole fused main switch acts as a disconnecting switch for the low tension side of the power transformer. A voltage regulator and the customary equipment for controlling the generator and its exciter are provided.

The substation switchboard at the Coster power house consists of two panels 90 in. high, each of three sections of blue Vermont marble mounted on angle iron supports to match and line up with the existing power switchboard. The equipment is identical with the two power-house switchboards, except for the omission of the regulator and panel, rheostat handwheel, exciter switch and exciter instruments, with the consequent reduction in width of the low tension panel.

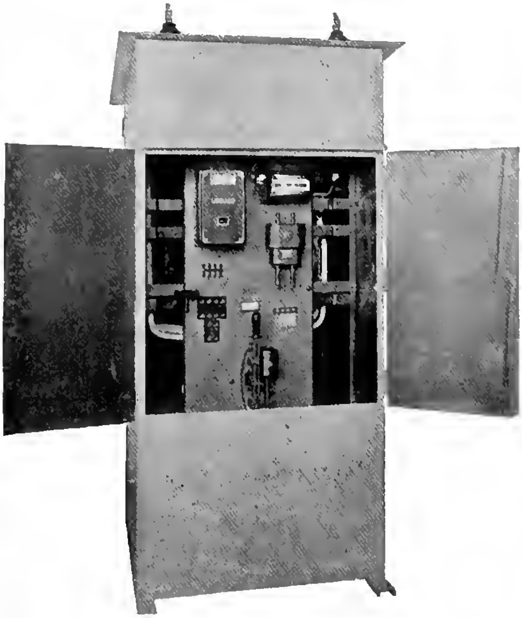

**Fig. 14. Front View of Outdoor Substation, Three-Phase, 4400-Volt Railway Signal Line, Southern Railway**

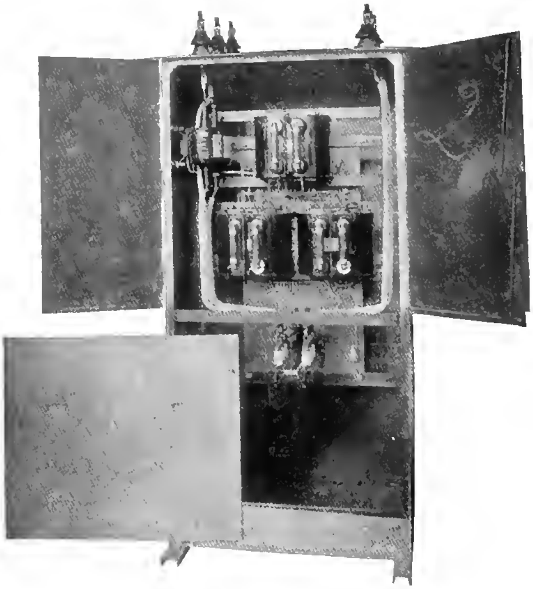

**Fig. 15. Back View of Outdoor Substation shown in Fig. 14**

Figs. 14 and 15 show front and rear views of the first outdoor type substation of this particular class for railway signal purposes. Two of these stations are to be installed, one at Inman, S. C., and the other at Austell, Ga. They are duplicates except that the latter is temporarily connected single-phase, although the full three-phase equipment is furnished so that it may be made three-phase in a few moments by slight changes in the instrument transformer secondary circuits. The equipment is the same as that for the other substations, except that no provision is made for reading current. The instrument transformers and high tension connections are clearly shown in the back view. A lamp with key socket provides ample light for reading instruments.

### SIGNALING ON INTERURBAN LINES

Hand-controlled lamp signals for turnouts and sidings and stretches of single track have been in use for some time, as well as the automatic permissive signals so common on single track portions of the city lines which permit movement of any number of cars in only one direction until the section is clear before allowing a movement in the opposite direction. These, however, place no restriction on the spacing between cars and give no indication as to the condition of the track ahead.

Interurban service is akin to railroad service in that it requires heavier rolling stock, increased speed and a definite time schedule to be maintained under all conditions of weather. Such rapid strides have been made in the development of interurban equipment in the past few years that automatic block signaling has become not only a refinement, but a necessity.

The latter half of the year 1913, saw a great many extensive signal installations on interurban roads, notably the lines in Ohio, Indiana and Illinois, on the Scranton & Binghamton line in Pennsylvania, and on the New York State Railways near Rochester and Syracuse.

In nearly every instance the switchboards, power transformers and switching equipment are installed in the same substation with the rotary converters that supply the motive power. Power is taken from the mains supplying the rotary converters (usually 370 volts, 25 cycles) and stepped up through duplicate transformers to 2200 volts for distribution to the 2200/110-volt transformers supplying the block sections. In some instances the transmission voltage is 4400.

In most cases the switchboards are 90 in. high and of two or three sections, slate or marble, to match the existing switchboard. Where unnecessary to line up with existing boards, 48 in. panels on 76 in. supports are usually furnished. The controlling equipment for a two-circuit-feeder panel usually consists of two fused lever switches supplying the step-up transformers, two oil switches with inverse time-limit overload relays and alarm bell attachment, two current transformers and ammeters with an illuminating lamp, and an alarm bell to give notice of an open oil switch.

Boards installed at the end of the signaled territory are only single-circuit, but in those cases where the signaling will be extended at some future time the boards in many instances have been made of ample size to contain the equipment for two circuits, although equipment for only one circuit is furnished.

On many switchboards that have the ammeter connected in the supply side of the step-up transformer, it has been necessary to furnish a switch to short circuit the ammeter on energizing the line because of the heavy momentary rush which sometimes occurs when connecting the transformer—particularly a low frequency transformer—to the supply line under load. To eliminate this trouble and get away from an oil switch which has a rupturing capacity far in excess of what is required on such low capacity circuits a switchboard has been developed and built for the Union Switch & Signal Company, for an installation on the Scranton & Binghamton road. The double-pole circuit breaker in the low tension side furnishes ample overload protection, and ordinary outdoor type plug cutouts guard against possible trouble from the outside. The low tension sides of the duplicate transformers are connected to the d-p. d-t. lever switch and the high tension sides to the plug switches and only one pair of plugs furnished, so that the inactive transformer will be dead. For two circuits either duplicate panels or a panel with double this equipment would be furnished.

## NEW YORK, WESTCHESTER & BOSTON RAILWAY

The New York, Westchester & Boston Railway, connecting White Plains and New Rochelle with New York City, is the only strictly suburban electric railroad built from the ground up without an old road bed as a basis. It consists of a four-track section approximately seven miles in length connecting with the four main tracks of the Harlem River branch of the New York, New Haven & Hartford Railroad system near 174th Street, New York City, and extending northward to Columbus Avenue, Mount Vernon, where it separates into two double-track lines, one continuing northward to White Plains, 9.4 miles, and the other eastward to New Rochelle, 2 miles, where it again connects with the New Haven system.

Transportation systems in New York City are universally direct-current furnished by substations; this road, however, from its connections with the New Haven system and the successful operation of the installation there existing, naturally installed the same system. Power is purchased from the New Haven power house at Cos Cob, Conn., the connection being made at the end of the New Rochelle branch sixteen miles distant. The transmission is three-phase, 11,000 volts, the conductors being carried on the extended posts of the steel compound catenary structures. Though only one phase is used for propulsion, the three-phase circuit is carried from the point of supply to the machine shops, elevator motors, pumps, and substation for the signal system.

On steam roads either direct- or alternating-current signal circuits may be selected; on roads having direct-current for propulsion using both rails for both propulsion and signal current, the latter must be alternating; but on roads using alternating-current for both propulsion and signaling, employing both rails for both circuits, the frequency of the latter must not be a low harmonic of the former. This is necessary because of the fact that the signal relays must be selective as to frequency. Suppose the propulsion current to be 25-cycle and the signal current

60-cycle, each supplied from a different source. Now if the former should rise to 30 cycles, or the latter drop to 50 cycles, the frequency of the signal circuits would be just twice that of the propulsion circuit and serious trouble result from false signal indications. To obviate such difficulties and maintain a certain fixed ratio between the frequencies of the two circuits, a motor-generator set supplied from the same source is necessary.

Ordinary fiber-insulated rail joints at the ends of the blocks serve to isolate the track circuits in each block; but to permit the continuous flow of the return propulsion current impedance bonds are installed in pairs at each block end across the two rails, one on each side of the insulated joints. These are coils wound on an iron core, with the middle taps of the coils of each pair connected together. They are enclosed in an iron case mounted between the rails with the top practically flush with the surface of the ballast. An installation is shown in Fig. 8 of the first article of this series (December, 1913). The propulsion current passes into both ends of one bond, through the common wire, and into the two rails of the other block through the two ends of the other bond; and thus, by setting up neutralizing magnetic fields in each bond, passes across the block section with a negligible energy loss. As the signal current flows in opposite directions in the two rails, it flows through the bond from end to end, and as the bond is highly inductive, a choking effect is introduced which permits only a negligible portion to pass through, shunting practically all the track circuit current through the track relays.

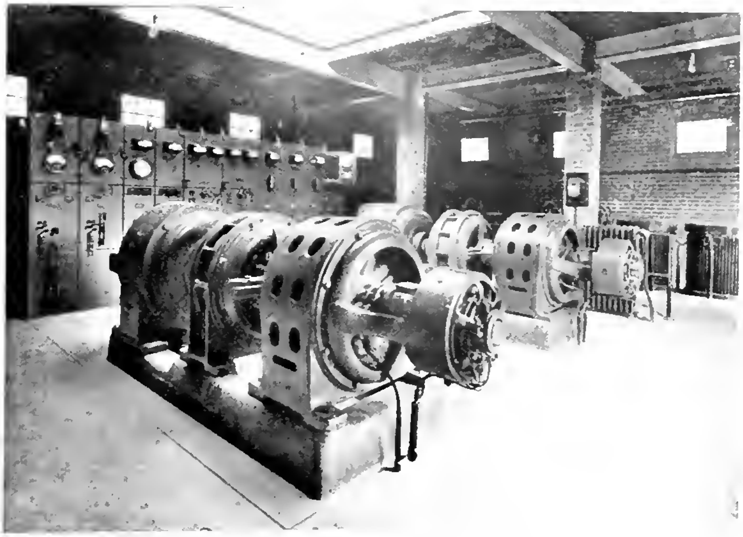

**Fig. 17.** Interior View of Signal Substation shown in Fig. 16

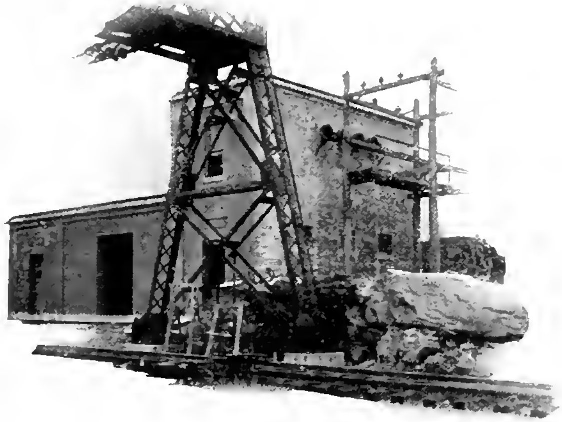

**Fig. 16.** Exterior of New York, Westchester & Boston Rwy. Signal Substation, Columbus Ave., Mt. Vernon, N. Y.

The signal substation at Columbus Avenue, Mount Vernon, is a brick structure of one story, with a high tension gallery at one end for the entrance of the two three-phase, 11,000-volt duplicate lines. Only four wires are brought into the building, as the completing wire for each set of lines comes from the grounded tracks. The gallery contains the high tension multigap lightning arresters, disconnecting switches, choke coils, a d-p. d-t. disconnecting switch for selecting operation between the two pair of lines, high tension series inverse time-limit, overload relays for tripping the two main oil switches downstairs, and high tension instrument transformers, all insulated to stand a surge potential of 30,000 volts. Surges are frequently set up by disturbances on the propulsion circuit and the phases are badly unbalanced because the voltage regulators on the Cos Cob generators regulate on the "propulsion" phase, which necessarily fluctuates greatly.

The ground floor of the substation is divided into three parts, viz., the high voltage section directly under the gallery containing the two line switches and duplicate banks of step-down transformers, the operating room, containing the switchboard and duplicate motor-generator sets, and the battery room.

From the disconnecting switch in the gallery selecting between the two incoming lines, all the apparatus is in duplicate. One complete equipment consists of a small panel for a d-p. s-t. oil switch (double-pole because one leg of the three-phase circuit is grounded); three delta-connected transformers stepping down from 11,000 to 440 volts; a four-unit motor-generator set consisting of 75-h.p., Form K induction motor, a 10-pole, 37-kv-a., 2200-volt, 60-cycle single-phase alternating-current generator with 3-kw., 125-volt exciter, and a direct current machine to operate between 110 and 160 volts as a generator to charge the storage battery, and 110 to 90 volts as a 75-h.p. motor; and controlling equipment for each machine on the switchboard. One set is of sufficient capacity to take care of the probable ultimate requirements of the road, so that the other may be always kept as a spare.

Under normal conditions the d-c. machine is either charging or floating on the battery. Upon failure of the power supply, the low voltage trip attachment opens the main line oil switch, cutting off the induction motor, whereupon the d-c. machine acts as the motor of the set. The speed regulator on the d-c. machine and the voltage regulator on the a-c. machine are so nicely adjusted that a failure and subsequent resumption of supply power produces no noticeable effect on the signal supply. Upon resumption of power the operator closes the main line switch (it being unnecessary to synchronize as the motor is of the induction type), and the operation is resumed, the d-c. machine charging at a greater rate because of the depleted condition of the battery.

The switchboard consists of d-c. generator-motor panel, induction motor panel, and a-c. generator panel, each in duplicate, and the three twin-circuit feeder panels. The d-c. panels each have a starting switch for starting the set from the storage battery, although it is usually started from half voltage taps on the transformers through double-pole, double-throw lever switch on the motor panel. The d-c. panels also have circuit breaker, double reading ammeter, line switch and rheostat handwheel for regulating the charging. On the back of each panel is another rheostat that is cut into circuit by the speed regulator when the d-c. machine is motoring, but this is set to maintain proper speed under full load.

The battery is of sufficient capacity to drive the set under full load for 25 minutes, beginning with a full charge, before the voltage falls to 90. When it reaches this value a circuit breaker located on the back of the board and calibrated to trip out at 90 volts, or under, will open the circuit in order to save the battery from destruction. This precaution is hardly necessary, for failures have been at most only of few minutes' duration.

The generator panels also provide exciter control, and the speed regulator relays and contactor equipment are mounted on the subbases. The three feeder panels feed in all three directions from the junction point, each supplying twin single-phase lines through a d-p. d-t. oil switch having a common trip coil. The duplicate signal mains carried on the extended posts of the catenary bridges supply step-down transformers for the signals and track circuits. The lines are run in pairs so that should one become grounded or defective, or require repairs at any point, that portion between the two adjacent sectionalizing outfits may be cut out and operation continued through the other.

The seven interlocking plants are all built along similar lines. Direct current for operating the switches and interlocking functions is furnished from a 110-volt storage battery. The switchboard, Fig. 17, taking power at 110 volts, 60-cycle, single-phase from duplicate transformers supplied from the signal transmission line for furnishing power to the track circuits and lights on either side of the tower controls the small motor-generator set for charging the battery by continuous floating.

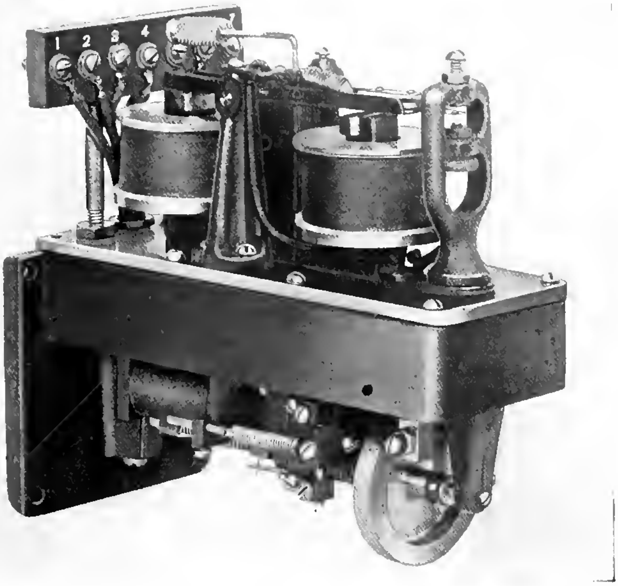
# FROM THE CONSULTING ENGINEERING DEPARTMENT OF THE GENERAL ELECTRIC COMPANY

## FAULTY-FEEDER LOCALIZER

In the operation of a high-tension electrical system, it frequently happens that a single wire arcs to ground. This arc may be caused by lightning, weak insulation, or some remote disturbance on the system. Unless this arc is extinguished it will very quickly cause considerable damage such as burning off the wire, breaking an insulator, or arcing to the other phase wires, thus causing a short circuit (a non-grounded neutral system is here assumed). It is the function of the arcing-ground suppressor to promptly extinguish this arc before damage results.

Suppose the fault to be of permanent nature. If there are a number of feeders connected to the bus there is no way of telling on which one the arc has occurred. The faulty-feeder localizer is designed to select the faulty feeder and light the corresponding indicating lamp, thus giving this important information to the station operator. With this knowledge the operator can substitute a good feeder for the faulty one, cut off the defective feeder, open the switch of the arcing-ground suppressor and the system has been returned to its normal operation without even a momentary delay to any substation. (This assumes that the insulation of the system is high enough to stand operation with one-phase wire grounded for a short time.) It should be noted that while the faulty-feeder localizer and arcing ground suppressor form an ideal combination either device may be operated independently.

The localizer consists of a set of interconnected relays (one relay for each feeder). These relays have two coils each, the pulls of each coil of the pair are balanced against each other, and the only relay which operates is the one in which an unbalancing occurs. By properly connecting up the relays, they are made independent of all load current, no matter how unbalanced. A time-limit device is added to the relay to make it independent of momentary surges. These two parts form a unit and there is one unit for each feeder. The relays are mounted on the back of a panel. This panel carries on its front the indicating lights and also the switches necessary for retaining the balanced condition of the relays under different operating conditions. This balancing operation is very simple. If a feeder is in service its corresponding relay switch is placed in the upper position. If the feeder is out of service the relay switch is thrown down.



Faulty-Feeder Localizer

The relays are operated from the feeder current transformers. It is necessary to have a current transformer in every high-tension wire of every cable on which it is desired to operate the localizers. The transformers in a single feeder have to be of the same type and ratio; however, it is not necessary for transformers on different lines to be similar. It is possible to use either the meter transformers or the overload relay transformers (provided a complete set is installed on each feeder) without interfering with either of these devices. An alternate arrangement is to install separate current transformers for the localizer.

The localizer is not intended to prevent a fault developing and consequently, will not do so. It only indicates the defective line after the fault has developed. A. H. D.

# QUESTION AND ANSWER SECTION

The purpose of this department of the Review is two-fold.

First, it enables all subscribers to avail themselves of the consulting service of a highly specialized corps of engineering experts, or of such other authority as the problem may require. This service provides for answers by mail with as little delay as possible of such questions as come within the scope of the Review.

Second, it publishes for the benefit of all Review readers questions and answers of general interest and of educational value. When the original question deals with only one phase of an interesting subject, the editor may feel warranted in discussing allied questions so as to provide a more complete treatment of the whole subject.

*To avoid the possibility of an incorrect or incomplete answer, the querist should be particularly careful to include sufficient data to permit of an intelligent understanding of the situation. Address letters of inquiry to the Editor, Question and Answer Section, General Electric Review, Schenectady, New York.*

## Announcement

In the 1914 Annual Index of the General Electric Review, included in this issue, there appears a complete classified index of the Question and Answer material for this year. It is recommended that this index be kept at hand in order that the greatest service to be derived from the solutions of past problems may be conveniently available.—Editor.

### TRANSFORMER: EXPLOSION

**(122) What is the initial cause that later results in an oil-cooled transformer blowing-up or exploding?**

**What is the action following the primary cause that actually produces the explosive effect?**

**What attention is given in the construction of standard transformers to the prevention of explosions?**

The condition which renders favorable the possibility of an explosion within the tank of an oil-cooled transformer is that of an accumulation of hydrocarbon gases and hydrogen mixed with air between the surface of the oil and the transformer cover. Provided no vent is supplied whereby the inflammable gases may escape from the case, an accumulation of them may result from an electric arc or succession of arcs beneath the oil surface.

Although confined, no inflammable mixture of gases and air will explode unless raised to its flash temperature by a flame, spark, etc. Where explosions have occurred, the ignition may be attributed to an arc, or to corona on the conductors or leads, above the oil surface.

Since it is far preferable to avoid the possibility of having an explosion occur and since it has been found impracticable to design a tank to resist a severe explosion should it take place, standard transformers are equipped with "breathers" or gas vents which, besides minimizing the condensation of moisture, permit the escape of the generated gases fast enough to prevent the production of a highly-explosive mixture.

R. K. W.

### CATENARY TROLLEY CONSTRUCTION: STRESS FORMULAE

**(123) Will you please publish or furnish references to a set of formulae from which the stress occurring in the messenger cable and in the trolley wire, as used in catenary construction, may be obtained. It is desired that they apply to a line having hangers about 10 ft. apart and spans varying from 90 to 150 ft., and that they take into account variations of temperature from −20 deg. to +120 deg. F. and at least an 8-lb. wind and a $\frac{1}{2}$ inch ice load, also combinations of these conditions.**

As far as we know, no set of formulae has been arranged that will give exact results when applied to catenary trolley construction. Since the messenger cable has approximately uniform loading only at normal temperature, ordinary transmission line formulae are not strictly correct. They are, however, often used where actual test measurements are not at hand. Useful formulae have been published at various times of which consideration may be given to the following:

*Proceedings A.S.C.E.*, June, 1908—Mr. R. D. Combs.

*Elect. Rwy. Journal*, October, 1908—Mr. R. L. Allen.

*Overhead Electric Power Transmission*, Mr. Alfred Still.

*Handbook on Overhead Line Construction*—N.E.L.A.

C.J.H.

### TURBINES: RELIEF VALVES LOW-PRESSURE END

**(124) What is the reason for not installing relief valves on the low-pressure end of Curtis turbines?**

Any small valve which could be provided on the shell of a large turbine to allow for a discharge into the station could only be considered as a signal or alarm, for it would not be practicable to place in such a position on the machine a valve that would be sufficiently large to be of any material benefit in preventing excessive pressure in the shell. In fact, any small relief valve placed on a large turbine is more liable to prove to be a source of danger than to be one of benefit, for the reason that the station operators might consider this valve would prove to some extent a safeguard in operation which, of course, it could not.

The larger the turbine the greater the degree to which this statement holds true. Operating engineers, realizing this, arrange to install an atmospheric relief valve on the condenser or on a connection between the turbine and the condenser. This valve is made to have sufficient capacity to prevent an excessive pressure being built up in the shell should the condenser fail at any time.

In the case of small turbines it would be practicable, of course, to place a relief valve of ample dimensions on the machine. However, it has been commonly experienced that in practically every case the operator prefers an atmospheric relief valve that can be piped up to discharge out of doors; and, consequently, since it seems best, the uniform practice of not installing low-pressure relief valves on all size Curtis turbines has been adopted.

# QUESTION AND ANSWER INDEX

*Wherever a particular kind of apparatus is concerned, its customary name (noun first) appears in bold faced type. General miscellaneous subjects are indexed with their electrical key words in bold faced type.*

**Arrester, Lightning**: Charging—No. 79 .......... 159
  Desirability for steel mill circuits—No. 88 .......... 338
**Alternator**: Armature reconnected for different voltage—No. 92 .......... 428
  Full-load and no-load flux—No. 106 .......... 771
  Methods of lining up—No. 91 .......... 340
**Battery, Storage**: Storage battery auxiliary vs. overloaded d-c. generator—No. 82 .......... 159
  Use in a-c. installations—No. 85 .......... 160
**Braces, Cross-Arm**: Choice of position—No. 115 .... 1002
**Cable**: Proper size for a certain installation—No. 81 .... 159
**Circuit, D-C.**: Effect on charged dust particles—No. 103 . 508
**Circuits, Trolley**: (Catenary) Stress formulae for construction—No. 123 .......... 1230
  Feeder considerations—No. 119 .......... 1003
**Coils, Choke**: Iron core vs. air core—No. 84 .......... 160
  Reactance formula for various shapes—No. 102 ... 507
**Connections, Three-Phase**: To phase one line with another—No. 78 .......... 159
**Converter, Synchronous**: (Commutating pole) Starting up—No. 77 .......... 80
  Effect of line drop—No. 109 .......... 772
  (Polyphase) Operation on single-phase—No. 118 ... 1003
  (Three-Wire) Derivation of neutral—No. 89 ..... 338
**Current**: Possibility of obtaining from earth—No. 100 ... 506
**Exciter**: Control by automatic voltage regulator—No. 98 . 506
**Feeders**: Trolley circuit considerations—No. 119 ..... 1003
**Generator, Automobile Lighting**: Voltage regulation—No. 114 .......... 932
**Generator, D-C.**: Overloaded generator vs. storage battery auxiliary—No. 82 .......... 159
**Generator, Induction**: Operation—No. 96 .......... 431
**Generator, Turbine**: Case of end thrust trouble—No. 105 . 508
  Integral fan vs. external fan ventilation—No. 110 . 772
**Lamps**: Efficiency of carbon and tungsten—No. 83 ..... 160
**Load**: Average running value for steel mill—No. 80 ..... 159
**Locomotives, Mining**: Deterioration due to low voltage—No. 120 .......... 1003
**Meters, Watthour**: Effect of change of frequency—No. 99 506
**Motors**: Definitions of open and enclosed types (*Later: See Standardization Rules of the A.I.E.E., edition of Aug. 1, 1914, §§93–105*)—No. 86 .......... 338
**Motors, Induction**: Characteristics at half voltage—No. 93 428
  Characteristics of low-speed type—No. 108 ..... 771
  Generator action—No. 104 .......... 508
  Knocking of rotor—No. 97 .......... 431
  Operation of 25-cycle motor on 60-cycle supply—No. 101 .......... 506
**Phasing-Out**: A case of peculiar voltage measurements—No. 121 .......... 1004

Page

**Regulator, Automatic Voltage:** Change from a-c. to d-c. operation—No. 117 .......... 1002
  Control of exciter—No. 98 .......... 506
  Parallel operation of two regulators { No. 107 .... 771
  No. 116 .... 1002

**Regulator, Induction:** (Three-Phase) Operation on single-phase—No. 87 .......... 338

**Resistance:** Temperature coefficient of copper—No. 113 .. 932

**Rod, Lightning:** Question of protection—No. 90 .......... 340

Page

**Switch, Oil:** Connections of circuit opening equipment (*See Erratum, p. 508*)—No. 94 .......... 429
  Purpose of bafflers—No. 95 .......... 431

**Transformer:** Cause and prevention of internal explosion —No. 122 .......... 1230
  Phasing out of small polyphase units—No. 112 .... 932
  Phasing out of large three-phase units—No. 111 .... 931
  Power-factor on short circuit—No. 76 .......... 80

**Turbine:** Relief valve low-pressure end—No. 124 .......... 1230

**Wattmeter, Curve-Drawing:** Installation—No. 75 .......... 80
