Edw Schildhauer

Electrical and Mechanical Engineer, Isthmian Canal Commission

GENERAL ELECTRIC REVIEW

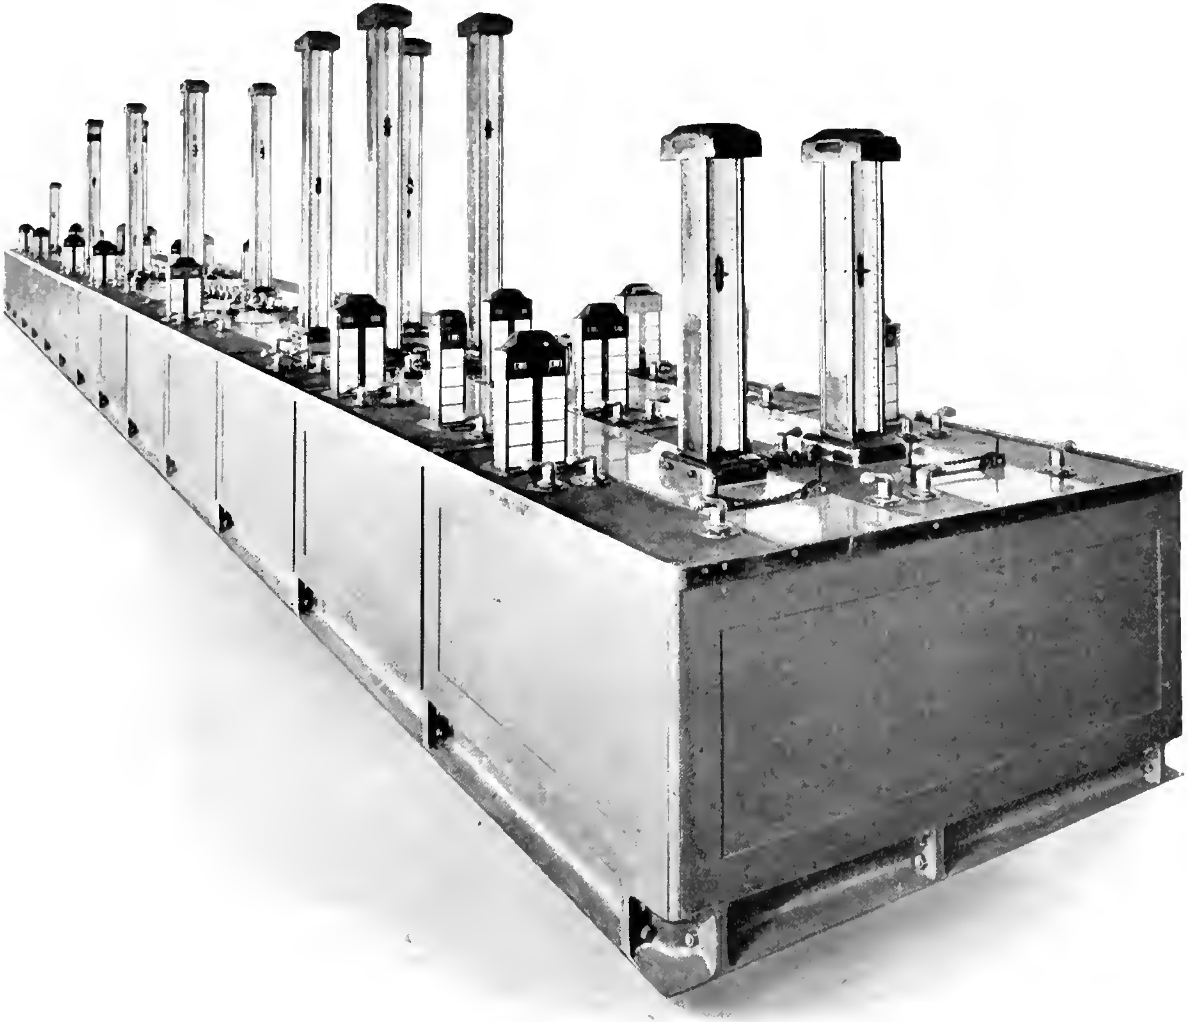
## THE PATHS OF PROGRESS

Considerable space is devoted in this issue to the control features of the Panama Canal. While a great deal has been written on this most notable national undertaking from almost every aspect of the work, we believe little or nothing has been said of this important phase. The undertaking as a whole is the largest of modern engineering undertakings and may prove to have a very far reaching influence on the world's trade so far as the routing of freight is concerned, and as the romantic side, as well as the utilitarian side, has been so thoroughly discussed, our contributions have been confined rather to the technical features of the control apparatus upon which the successful operation of the whole scheme depends.

Mr. Schildhauer, Mechanical and Electrical Engineer, Isthmian Canal Commission, begins his contribution to this issue with a most noteworthy sentence: "The preliminary studies relative to the transmission of power to the required position in the locks showed that the electrical system had decided advantages over hydraulic or air systems." While this statement will not be surprising to those who have followed the trend of modern engineering, it emphasizes the fact that where large forces have to be held under perfect control to render their maximum service and to be as reliable for continuous service as man can make them, electrical control is chosen. Last month we laid stress on the fact that electric energy owed much of its economic value to the ease and cheapness of its transportation, and here we have an excellent example of another of the greatest factors which have led to the extensive adoption of electricity, viz., the ease and the degree of perfection to which it can be controlled. Fire, water and different forms of energy are excellent servants but terrible masters. Whether they are our masters or our servants depend entirely upon the degree of perfection to which we control them.

Mr. W. L. R. Emmet's article on "Power from Mercury Vapor" will undoubtedly attract wide attention. If this process works out as Mr. Emmet predicts, it should prove to be one of the most notable developments since the introduction of the steam engine. The very thought of a new form of prime mover must be fascinating to the scientist and the engineer, and even the speculative chance of such a development maturing into a commercial reality will awaken the interest of the whole engineering world. The results of the experiments that Mr. Emmet is now making will determine the practicability of the combined mercury vapor and steam turbine units, and will decide whether this new development is to take its place in the commercial world. There are many who will view such a radical departure from previous practice with skepticism, but Mr. Emmet's work is based on wide experience in steam turbine practice and on over a year's experimenting with this particular development. The problems involved have been given most careful study, and it would seem that the practical mechanical details are the only things not yet fully matured, as the theoretical over-all efficiency of the combined mercury vapor and steam turbine units can readily be determined.

In our next issue we shall describe the apparatus already built for generating power from mercury vapor, and in the near future we shall hope to give some definite results from the experiments now being carried on and to keep our readers informed of the progress being made in this new development.



Control Board for the Miraflores Locks of the Panama Canal

# AN INSTANCE OF CO-OPERATION

## PANAMA CANAL SWITCHBOARD EQUIPMENT

By J. W. Upp

Manager, Switchboard Department, General Electric Company

Mr. Upp's article is a preface to those that follow in this issue on the Panama work. His story is of special interest as dealing with the human side of this great undertaking—the results obtained in so short a space of time were only made possible by good organization and a splendid spirit of co-operation. This article, coupled with those that follow, ought to give our readers a good idea of this important part of the Panama Canal work, the whole of which is so soon to be completed.—Editor.

The whole world is interested in the Panama Canal as, viewed from any angle, the reasons for the canal itself and the problems relating to its construction have been an absorbing subject. The daily newspapers, the popular magazines and the engineering publications have done their share in keeping our interest alive, and have furnished us with a continuous and ever growing record of accomplishment. The difficulties encountered and the methods of their solution have been so often illustrated and explained that we have all come to feel that keen personal interest that should go with all our great national undertakings. Very little, however, has been written as to the actual means that will be employed to operate the canal after its completion. Thus the collection of articles in this issue of the Review will be of particular value to those who are interested in the plans adopted for the generation and distribution of power and the problems involved in the design and application of the system of "central control" which has been developed and applied to the operation of the lock machinery required for such operation.

Control apparatus was required for thirty-six transformer stations, four substations and one generator station, and for the locks at Gatun, Miraflores and Pedro Miguel. The switchboards for transformer, substations and main stations possess many novel features, but the lock boards for "central control" are of a most unique design. They were to be miniature representations of the locks, chains and gates, and were to provide a ready means of control for operating the machinery of the main apparatus itself; besides indicating every movement and speed of motion of rising stem valves, fender chains and miter gates, and the open or closed positions of cylindrical valves and miter forcing machines. And in addition to this the control switches were to be so interlocked that an improper sequence of operations would be impossible. This part of the work involved upwards of a half million dollars for switchboard material alone.

The specifications for the entire control system were prepared under the supervision of Mr. Edward Schildhauer, electrical and mechanical engineer of the Isthmian Canal Commission, ably assisted by assistant engineers C. B. Larzelere, W. R. McCann, and others, and they will long be used as models of skilled and painstaking engineering where no detail was neglected and every contingency provided for, with all the safeguards that expert engineers could suggest. No specifications could have been more exacting or explicit as to the results to be accomplished, or have given a wider range as to the method of their accomplishment.

After the contract was let, conferences of the Commission's engineers and the manufacturers began, and because there was no previous experience to guide in the selection of designs, these conferences were continued until there was a complete understanding of the requirements, conditions and possible alternatives. These conferences were interwoven with and followed by numerous departmental consultations where factory foremen, designers and engineers were represented. Facilities were discussed and special tools considered. The preliminary plans and models were prepared. These were modified from time to time as no part was considered complete until the model had been critically inspected and tested by the engineers, both of the Commission and the manufacturer, and till all were convinced that the design and operation met every condition which had been foreseen at the time the specifications were written, or which had developed as the details were completed. It was the single aim of all concerned to produce something better, safer and more reliable than anything before undertaken.

By direct conference with the engineers of the Commission and of the manufacturer, at Panama and at the factory, a co-ordinating engineer settled the thousand and one questions which constantly arose in reference to construction, design and delivery. He arranged for special consultations and tests and relieved the departments of endless worry and complication which would have resulted through long distance correspondence.

A separate manufacturing department was organized when the preliminary designs were well under way, which department, although a part of the general organization, was so arranged that its members would not be hampered by other undertakings. The best men in each section were chosen for the Panama work, and their selection has been justified by the results secured.

The Canal Commission was kept in touch with the progress of manufacture by having resident inspectors at the factory, who checked each piece of apparatus as the work moved onward.

The successful completion of this work is a most important indication of the value of co-operation. The customer and manufacturer understood and had confidence in each other and were kept in touch by frequent conferences. Designing engineers and manufacturing departments were in entire accord and were giving mutual assistance; inspectors were checking and testing at times best suited to the convenience of engineers and factory.

The Miraflores control board is shown on pages 4 and 6, the latter being a view of its intricate interlocking rack. These illustrations are sufficiently convincing to prove that the design of the apparatus which they represent would have taxed the ingenuity of any manufacturing organization or its corps of engineers, and they will be viewed with pardonable pride by everyone who has been connected with their specification, design and manufacture. When the first ship goes through the canal, collectively or as individuals they can say, "We helped to make it possible."

# THE CONTROL OF LOCK MACHINERY ON THE PANAMA CANAL

By Edward Schildhauer

Electrical and Mechanical Engineer of the Isthmian Canal Commission

In this excellent article, which is, we believe, the first authentic account that has been published of the control system employed on the locks of the Panama Canal, the author describes the construction of the locks and the machinery essential to their operation. His descriptions of the culverts and the course taken by the water through them, the arrangement and operation of the gate valves and cylindrical valves and of the mitering gates and fender chains, as well as of a number of minor pieces of apparatus such as the rising and disappearing hand rails for the mitering gates, afford the reader a distinct mental picture of the locks and an understanding of the functions of the different pieces of machinery. The most novel feature of the lock machinery, however, consists of the system of remote control and indication which was specified by the Canal Commission and which governed the design and construction of the wonderful interlocking control boards that are described in detail in succeeding articles in this issue. Mr. Schildhauer's intimate association with every detail in the design of these boards makes that part of his article descriptive of the interlocking between control switches for the different machines of special interest.—Editor.

The preliminary studies relative to the transmission of power to the required position in the locks showed that the electrical system had decided advantages over hydraulic or air systems. This will be readily granted when it is known that the flight of locks at Gatun, for instance, extends over a distance of 6152 feet and the principal operating machines are distributed over a distance of 4115 feet.

From an operating standpoint the machinery was placed below the coping of the lock walls, thus affording a clear space for the maneuvering of ships and for protecting the apparatus from the weather without erecting numerous houses.

To control the machines locally meant a large operating force distributed practically along the full length of the locks, which has invariably been the practice heretofore. Such a force would be difficult to co-ordinate into an efficient operating system. The matter therefore resolved itself to centralized control, which reduces the number of operators, operating expense, and liability to accident. Moreover it fixes responsibility.

Another argument for centralized control is the fact that by having all control switches centralized on one switchboard it permits the various control switches to be interlocked in a manner to minimize, if not entirely prevent, the errors of human manipulations. These interlocks will be fully described later, but for the benefit of those who may not be familiar with the various machines in the lock walls, it will be well to enumerate them with their uses.

Water for filling and emptying the locks is conducted through three culverts, one in the middle wall and one in each side wall. The flow of water in these culverts is controlled by rising stem valves. These are located in the culverts at points opposite each end of each lock so that the culvert can be shut off at any desired point for filling a lock with water from above, or upstream, or for emptying it by allowing it to flow out and down to the next lock. Lateral culverts conduct the water from the main culverts, under the lock chambers, and up through openings in the lock floors. Since there are intermediate mitering lock gates for use in locking through short vessels, when the use of a whole lock of 1000 feet would be wasteful of water, rising stem valves are also located in the side wall culverts at points near these intermediate gates. The rising stem valves are installed in pairs; that is, the culvert is divided into two parallel halves at each valve by a vertical wall, and a valve is placed in each half. This arrangement reduces the necessary size of each valve and makes it more easily operated, although each valve is still 8 feet wide by 18 feet high. It is raised and lowered by a 40 h.p. motor requiring one minute for complete opening or closing.

In addition to these pairs of valves in parallel, each pair is duplicated at each change of level from one lock to the next. Thus if the valves cannot be closed at any point on account of an obstruction in the culvert or accident to the machinery, the duplicate pair can be closed. At the upper ends of the culverts at the side walls the duplication is accomplished by three valves in parallel called the guard valves.

The culvert in the middle wall must serve the locks on both sides, and to control this feature cylindrical valves are placed in the lateral culverts that branch out on each side. There are ten of these on each side of the culvert at each lock.

At the upper end of each set of locks there are two valves in the side wall for regulating the height of water between the upper gate and the upper guard gate, as it will be desired to maintain the level of the water between these gates at an elevation intermediate between that of the lake above and that of the upper lock when the upper lock is not at the same level as the lake. These valves are called the auxiliary culvert valves.

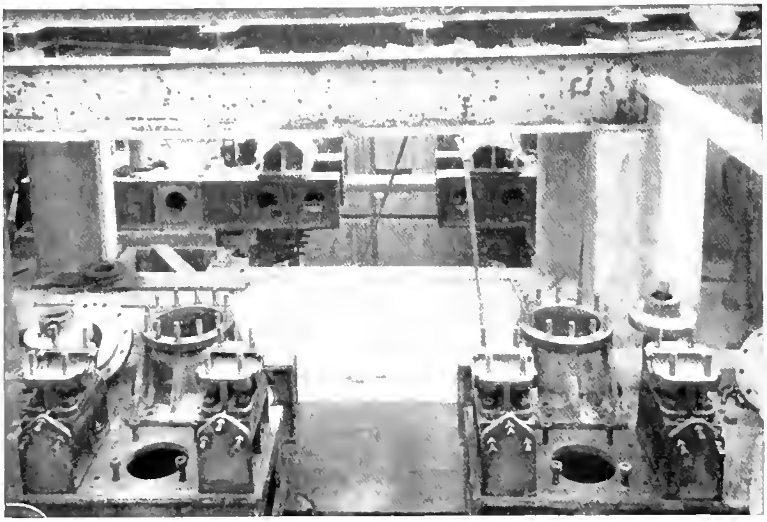

Fig. 1. Miraflores Lower Locks. Rising Stem Gate Valve Machinery Chambers Nos. 442 and 443, West Side Wall. Machinery cleaned preliminary to assembly. July 18, 1913

The mitering gates are opened and closed by a separate motor for each leaf, and the two leaves, when closed in mitered position, are locked together at the top by the miter-forcing machine which is also controlled from the central control house.

Heavy fender chains are stretched across the locks in front of all mitered gates which can be exposed to the upper level and also in front of the guard gates at the lower end. These are maintained in a taut position at all times when the gates behind them are closed, and are lowered when the gates are opened for the passage of a ship. These chains are raised and lowered by a hydraulic cylinder, in a method similar to that followed in hydraulic elevators, with the additional feature that if a ship approaches the gates at a dangerous speed and rams into the chain the chain is paid out from each end with a maximum resistance for gradually stopping a ship before it reaches the gates. Lowering the chain for the legitimate passage of a vessel and raising it again after the vessel has passed are also under the control of the operator at the control house, and each operation of raising or lowering involves the control of two motors; viz. the starting of a large motor driving the main pump supplying water under pressure, and the control of a motor-operated valve which in turn controls the direction of movement of the chain, rising or falling. These two operations are combined in one for the remote control, so that all the operator has to think about is raising or lowering the chain. Each motor is stopped automatically by a limit switch when it has performed its function. This is also true of all motors having remote control, namely, if the operator does not stop a motor when a machine has reached the end of its travel, it is automatically stopped by a limit switch.

On page 9 is a list of motors controlled from the control houses of their respective locks.

Fig. 2. Miraflores Upper Locks, Rising Stem Gate Valve Machine. June 10, 1913

There are many other motors which are not controlled from the control houses, and not included in this list, but their uses should be described briefly before proceeding. One class of these is the hand rail motors. On the top of all mitering gates a foot walk with hand-rails is provided. When the gates are opened and in the recesses provided for them in the lock walls, these hand-rails would interfere with the passing of the towing locomotive, except in the case of the lower guard gates. The hand-rails are therefore made to be raised and lowered. This is done by a motor under the foot walk, controlled from the lock wall. Near the approach to each foot walk a controller is located in the lock wall flush with the surface, this controller being operated by a foot push. If the gates are closed and the hand-rails are down, and a person desires to cross on the gates, he presses the foot push and the hand-rails are raised by their motors. This is true not only of the hand-rails on the nearer gate leaf, but of the hand-rails on the farther leaf as well. After passing across, one can, if he desires, press the foot push on the other side and both hand-rails will be lowered. Or, if he leaves the hand-rails up and the gates are opened by the operator in the control house, they will be automatically lowered so as to be out of the way when the gate is in the recess. When the gates are again closed the hand-rails will automatically rise again if the foot controller has been operated in the meantime. The control of the hand-rails is accomplished by means of the foot controller, a contactor panel in the machinery chamber in the lock wall, and another switch geared to the gate moving machinery which operates the control circuit to produce the automatic lowering and raising when the gates are opened or closed. This geared switch also provides that the hand-rails cannot be raised when the gates are opened, and that no harm

Fig. 3. Miraflores Lower Locks. Rising Stem Gate Valve Machinery Chamber Nos. 442 and 443, West Side Wall All anchor bolts set in concrete with bulkhead frame, guide rails, screws, bearings, wall brackets and subbase in place. July 18, 1913

| Machines and Operation | Motors each Machine and H P. | NUMBER OF MOTORS<br>Gatun | Pedro Miguel | Mira-flores | Total | Total Horse Power |
|---|---|---|---|---|---|---|
| Miter gate, moving, each leaf | 1–25 | 40 | 24 | 28 | 92 | 2300 |
| Miter gate, miter forcing | 1–7 | 20 | 12 | 14 | 46 | 322 |
| Fender chain, main pump | 1–70 | 16 | 16 | 16 | 48 | 3360 |
| Fender chain, operating valve | 1–½ | 16 | 16 | 16 | 48 | 24 |
| Rising stem gate valve | 1–40 | 56 | 24 | 36 | 116 | 4640 |
| Cylindrical valve | 1–7 | 60 | 20 | 40 | 120 | 840 |
| Guard valve | 1–25 | 6 | 6 | 6 | 18 | 450 |
| Auxiliary culvert valve | 1–7 | 4 | 4 | 4 | 12 | 84 |
| Totals | | 218 | 122 | 160 | 500 | 12020 |

results if the foot switch is operated while the gates are in the opened position. Thus it is seen that the hand-rails are provided with remote control, although they are not controlled from the control house.

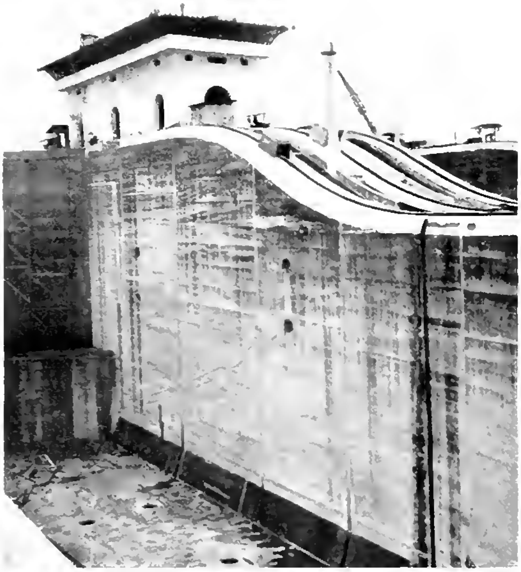

Fig. 4. Control House for Center Wall. Upper Locks at Gatun. Towing track incline between upper and intermediate locks. July 22, 1913

The spillway gates also have remote control, but these gates are entirely separate from the locks, and their control is from a separate and much smaller control board. There are also many motors driving drainage pumps, operated by float switches and starting panels, but these are standard equipment and of no special interest.

The control house is located on the middle wall at a point which affords the best view of the whole lock site, although this view is not depended upon to know the position of the gates or other apparatus, as all are provided with indicators on the control board. At Gatun the control house is located at the lower end of the upper lock, giving a view of the upper locks upstream from the control house and a view of the two lower flights in a downstream direction. At Miraflores the location is the same, that is, at the lower end of the upper pair of locks; but there are only one pair of duplicate locks downstream from the control house, the same as upstream. At Pedro Miguel the control house is at the lower end of the one pair of locks, as this position affords a view of the lower approach wall and at the same time gives the same view of the locks themselves as is obtained for the upper locks in the other cases.

The motors are started and controlled by contactor panels located near them, the contactors of which handle the main motor currents. These contactors are controlled from the control house. The smaller motors, including those for cylindrical valves, auxiliary culvert valves and miter forcing, are started by being thrown directly on the line. Two double pole contactors are used, one for forward and one for reverse. In the case of larger motors for miter gate moving, rising stem valves and guard valves, a starting point with resistance in two legs of the three-phase circuit is provided.

In all cases the contactors are operated from the control house by three wires, one for forward, one for reverse and a common return. In the case of panels having a starting point the period during which the motor remains on the resistance is automatically controlled by a dashpot, so that the starting operation at the control house is the same—

Fig. 5 Gatun Upper Locks. Miter Gate Moving Machine; Structural Steel Girders for towing locomotive track supports in foreground. June, 1912

simply energizing a forward or reverse wire as the case may be.

Indicators are used for all machines to show the operator in the control house the position of each machine at all times. In the case of certain machines, the operation of a motor lasts only a few seconds and the indication of their positions is given by the simple means of red and green lights. Such machines are the cylindrical valves, auxiliary culvert valves, and miter forcing machines. It is never expected in normal operation to stop these machines at an intermediate point in their travel, and only the completed operation is indicated by the red and green lights.

Fig. 6. Miraflores Lower Locks. Miter Gate Moving Machine No. 127. Machine installed complete except short arm and anchor casting on gate leaf. Installation of structural steel in decking commenced. June 20, 1913

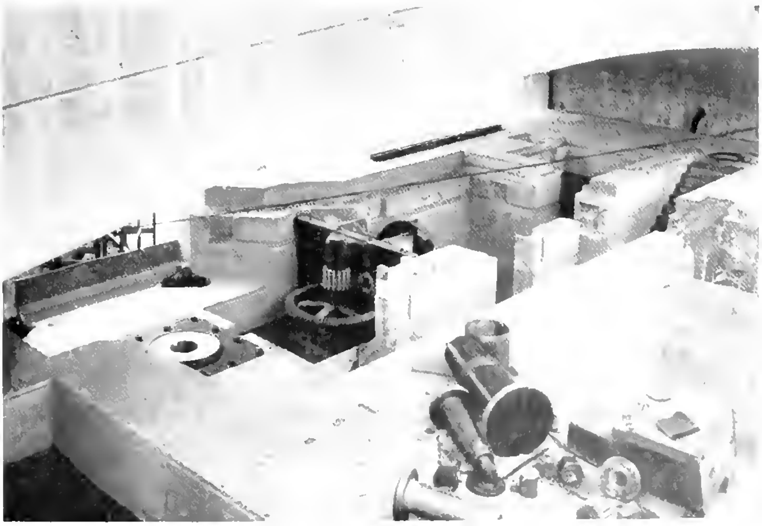

Fig. 7. Miraflores Lower Locks. Miter Gate Moving Machine No. 127, showing center pinplate bulkhead, vertical shaft, 72 in. bevel gear and 64 in. spring center gear in place. West wall, south end. May 11, 1913

For machines of more extended operation which may be stopped at intermediate points of travel, synchronous indicators are used which show at all times the position of the machine, whether in the extremes of travel or at an intermediate point. A complete synchronous indicator consists of a transmitter at the machine in the lock wall and a receiver, or indicator, at the switchboard in the control house. An indicator and a receiver are exactly similar and each consists essentially of a revolving bipolar field or rotor, supplied with alternating current from the same source for excitation. Surrounding each rotor is a stator having a distributed winding similar to that of an induction motor. From three equi-distant points of this winding of a transmitter leads run to three similar points on the winding of the receivers. The alternating current in the rotor of the transmitter (which may be considered stationary for the present), induces currents in the three wires from the stator, the relative values of these currents in the three wires depending upon the position of the field. These currents produce a magnetic flux in the receiver which draws its rotor (free to revolve in this case) into the same angular position as the field of the transmitter. Thus as the transmitter revolves the receiver revolves with it, keeping the same angular position with a very small error. In the case of the transmitter, the rotor is geared to the machine the position of which it is desired to indicate. In the case of the receiver the rotor is geared to a pointer or small model of the machine, or to some other indicating device which it drives. This is the only important difference between a transmitter and a receiver, or indicator.

Fig. 8. Gatun Spillway Gate. One complete gate with operating mechanism. Looking downstream, with gate partly open. July 15, 1913

Synchronous indicators are provided for miter gate moving machines, rising stem valves, guard valves, fender chains, and for water level indication.

The control boards are of a flat top bench board type. Each board is 32 inches high by 54 inches wide. The lengths for the three different boards are as follows:

| | |
|---|---|
| Gatun | 64 feet |
| Pedro Miguel | 36 feet |
| Miraflores | 52 feet |

The handles of the various control switches are above the surface of each board; while the switch, which is of a rotary type, has its contacts beneath the board and is wired from below. In a similar manner the indicators are mounted with the greater part of their mechanism beneath the board, but with the scales and pointers above the board. The visible portions of these indicators are of different forms in order to best indicate their respective machines. The miter gate indicator is nearly flush with the board and consists of a pointer swinging in a horizontal plane and resembling the plan view of a miter gate leaf. All these switches and indicators are located as nearly as possible in the same relative positions occupied by the machines to which they apply. While the board is essentially a control board with indicators, it is made to resemble in a measure a plan view of the locks.

The space immediately below the flat top of the board is occupied by the switch contacts, indicator motors, and connections. Vertical shafts operated by connecting rods from the control switch shafts extend downward past the electrical parts for the operation of the interlocks. These interlocks are in two vertical racks under each edge of the board and some distance below, so that they may be inspected and oiled from a floor which is about seven feet below the floor on which the switchboard stands. The latter floor does not extend across under the board, this space being open so that all parts on the underside of the board are accessible from the floor below. The numerous cables to the control switches and indicators also come to the board from below. Connection boards are provided for the cables, which are led up to them from each side, as are busses for supplying current to the control switches,

Fig. 9. The Gatun Spillway Machinery Tunnel

indicators, and the lamps that illuminate the dials of indicators. The indicators, transmitters and lamps are operated at 110 volts, while the control switches are designed for 220 volts, both circuits supplying 25 cycle alternating current.

In general the two interlock racks contain the necessary interlocks for the switches on their respective sides of the center line of the board; but where interlocking is required between switches on different sides it is accomplished by the aid of cross connecting rods and cranks. The following is a schedule of the interlocking accomplished:

### Fender Chains and Miter Gates

The fender chains are operated from each end by independent machines. The control of each end is interlocked with the control of the miter gate leaf on its side of the lock, so that the chain cannot be lowered until the control switch of the miter gate leaf has been thrown to the opening position. The miter gate cannot be closed again until the control of the fender chain has been thrown to the raising position. In this way the assurance is obtained that the fender chain will always be in the up position to protect the gate when the gate is closed. In order to avoid unnecessary complication, each end of the chain is not interlocked with both gate leaves, but with the leaf on its side of the lock only. As a rule both leaves of a miter gate, as well as both ends of a fender chain, will be operated simultaneously and further interlocking is unnecessary.

### Miter Gates and Miter-Forcing Machine

Each leaf of a miter gate is interlocked with the miter-forcing machine, which locks the leaves together at the top when in the closed position. This interlock is arranged so that the operator must unlock the miter-forcing machine before he opens the gate. Also the miter-forcing machine cannot be closed until the gates are closed.

An electrical interlock is also provided in this case, requiring the gates to be fully closed before the miter-forcing machine can be started in the closing direction, inasmuch as it is important that the first operation be completed before the next operation starts.

### Rising Stem Valves Interlocked With Each Other

Consider, for example, a side wall culvert at Gatun with its principal rising stem valves at each change of level from one lock to the next: The control of these valves is interlocked so that if the valves are opened at one particular point, the valves a lock length upstream or downstream cannot be opened. Thus the operator is limited to equalizing the water between locks and cannot allow water to flow from the upper lock past the middle lock into the lower lock, which operation, if permitted, might flood the lower lock walls and the machinery chambers in them. All rising stem valves occur in pairs side by side, each member of a pair controlling half the opening of the culvert. They may therefore be referred to as pairs. At all points where there is a change of level from one lock to the next, these pairs of valves are further duplicated by a pair in series a short distance away. In regular operation one pair can be left open as a guard pair, and the other pair will, for the time being, be the operating pair and will control the flow of water. Each of the four valves of such a group has independent control. Their control switches are interlocked so that either pair may be opened and left open as guard valves, and the interlocks become effective when the operator tries to open the first valve of the second pair. Either pair may be opened first, at the choice of the operator, the interlock becoming effective when the first valve of the second pair of duplicates is opened. This is done by a system of equalizing levers acting against the ends of the interlock bars, with a certain definite amount of lost motion which is taken up on opening the first pair of valves, thus putting the interlocks in operation on the next pair.

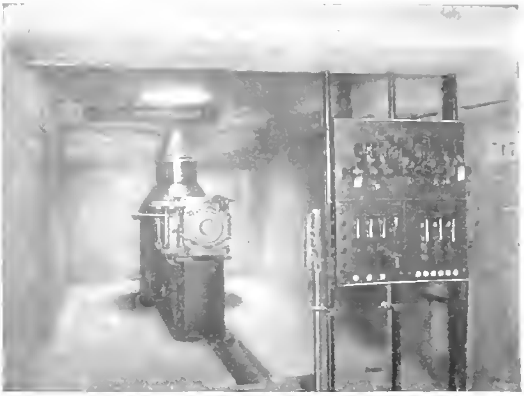

Fig. 10. Cylindrical Valve Machine and Control Panel for Middle Wall, Upper Lock at Miraflores. Chamber walls, floor, and panel partially completed. June 20, 1913

At the upper end of each lock, three guard valves take the place of the duplicate rising stem valves. These perform service exactly similar to the rising stem valves and are similarly interlocked, except that three valves in parallel in this case must conform to the same laws as the two in parallel in the other cases. If necessary to clear the interlocks at one pair of valves in order to open another pair a lock length away, both members of the pair must be closed to accomplish it, and all three must be closed in the case of the guard valves.

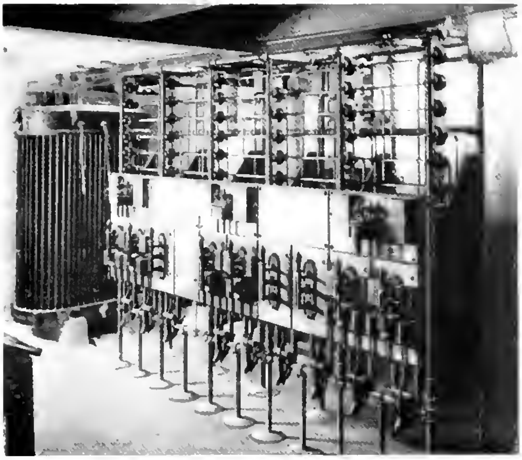

Fig. 11. High Tension Oil Switch Group, Transformer Room Equipment, Pedro Miguel. July 17, 1913

The same interlocking is effected between the successive valves of the middle wall culverts as between those of the side wall.

### Rising Stem Valves "Diagonal" Interlocking

By diagonal interlocking is meant that interlocking which is done between the rising stem valves of the side wall and those of the middle wall a lock length away. The result is interlocking between valves diagonally across a lock when the cylindrical valves are open, this being needed to prevent the flow of water from, say the upper lock by way of a side wall culvert to the middle lock, thence by way of the middle wall culvert to the lower lock, thus allowing an operator through carelessness to flood the lower lock walls. If the cylindrical valves of a certain lock are closed, then this interlock is not needed on rising stem valves of that lock; and furthermore, its existence would interfere with the proper use of the valves of its twin lock on the other side of the middle wall. For this reason this interlock is automatically removed when all ten cylindrical valves are closed on the particular lock in question, and is automatically applied again if one or more of the ten cylindrical valves are opened.

### Rising Stem Valves With Cylindrical Valves

In the use of the middle wall culvert, the cylindrical valves on one side or the other must be opened before the rising stem valves can be opened, and the rising stem valves must be closed first. This interlock is applied in order to require the operator to control the flow of water by means of the rising stem valves rather than the cylindrical valves. The latter perform a complete operation of opening and closing in about ten seconds, and their use in regulating the flows might cause dangerous surging.

Here, as in all other cases of interlocking on rising stem valves, one pair of duplicates may be left open as guard valves, the other pair used as operating valves being subject to interlocking.

The locks in most cases are divided into two parts by the intermediate miter gates. This arrangement divides the ten cylindrical valves into two groups of seven and three, respectively, for the long and short lengths. A selecting lever is provided for the foregoing interlocks, which may be set on "three," "seven," or "ten," respectively; whereupon the corresponding valves are subject to that interlock, and the others of the group of ten are locked closed if three or seven only are to be used. The failure of the operator to make his selection properly in advance will only cause him the trouble of going back and doing so, as the remaining valves are locked closed.

### Interlocks on Cylindrical Valves

The groups of cylindrical valves on opposite sides of the middle wall culvert are interlocked with each other, so that if any valves are opened on one side, all must be closed on the other. This is to prevent careless cross filling between the locks, which operation might be combined with the regular method and produce flooding. However, there may be times when it is desirable to employ cross filling to economize in the use of water from Lake Gatun in the dry season. For this reason this interlock is made removable by the use of a lock and key. The key will be placed in the hands of the chief operator.

### Rising Stem Valves of Side Wall and Miter-Forcing Machine

Interlocks are placed on the control switches of these machines so that the rising stem valves of the side wall, next above or below a miter gate, must be closed while the miter-forcing machine is open. As the miter-forcing machine cannot be closed until the gates are closed, this means that the valves either above or below the gate must remain closed until the gate itself is closed, thus preventing the operator from creating a current of water around the gates while they are open, or being moved in opening or closing. This interlock is not included on the middle wall valves for the reason that they will be used with the locks on either side and must be free for that purpose. Furthermore, the valves of the side wall immediately at the gate which is being moved will be open to equalize water level, and the diagonal interlocking previously described will prevent the opening of the middle wall valves a lock length above or below the gate being moved.

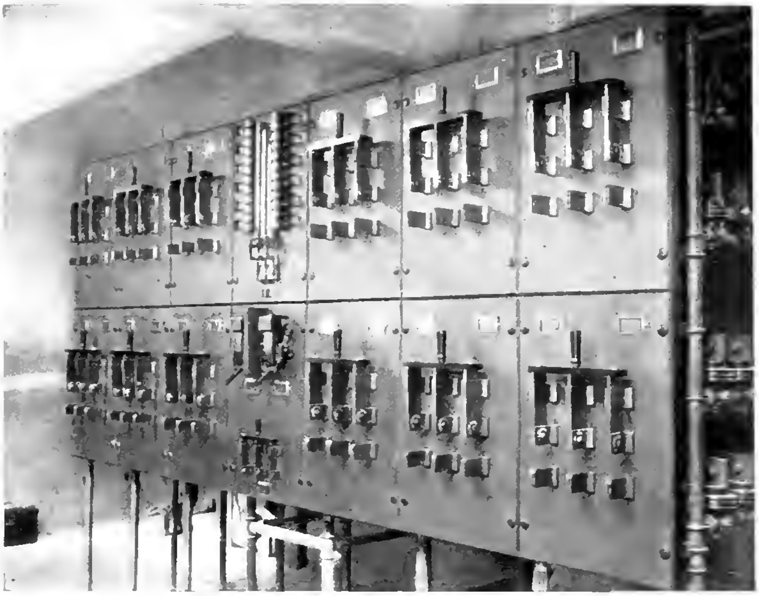

Fig. 12. Low Tension Switchboard, Transformer Room Equipment, Miraflores Lower Lock. July 17, 1913

This interlock between valves and miter-forcing machine is included on the intermediate gates, but is removable by means of a lock and key, because during the passage of large ships these gates must be left open and the valves operated independently of them. This interlock is not applied to the miter-forcing machine of the lower guard gates for the reason that these gates open toward the sea.

There are intermediate rising stem valves in the side walls at each intermediate gate, but no interlocks are applied to these for the reason that they will be used in a more or less irregular manner, and no fixed laws for their operation can be laid down in advance. Moreover, they do not control the water between different lock levels, but only between different sections of the same lock, and there is not the danger from mistakes in operation which exists in the case of the other valves between lock levels. The same is true of the small auxiliary culvert valves, by means of which the space between the upper guard gate and upper main gate is filled and emptied.

The water level indicator has an important bearing on the rate at which the lockage of a ship may be accomplished. It is proposed to limit the filling of the locks to a rate of three feet per minute, which rate may be observed on the indicator. When the water levels between two locks are very nearly equalized, the rate of equalization is slow; it is therefore very important for expeditious lockage that the operation of the lock gates be accomplished just as soon as the water levels above and below the pair of gates are equal. The water level indicators will show these levels to an accuracy of one-twentieth of a foot.

The control connections are arranged in such a manner that each individual machine may be controlled locally. This arrangement provides for emergency operation should the control circuits from the control house be out of order.

The local control was used on September 26th when the first vessel, the tug "Gatun," was passed through the locks at Gatun from the Atlantic Ocean to Gatun lake, and on the following day on its return trip.

# CENTRALIZED CONTROL SYSTEM AND POWER STATION SWITCHBOARDS FOR THE PANAMA CANAL

By E. M. Hewlett

Engineer, Switchboard Department, General Electric Company

The author shows some of the engineering features of this particularly interesting control mechanism. He takes us step by step through the sequence of operations necessary to lock a ship through the canal and brings out some of the most interesting conditions that have to be fulfilled to achieve the results accomplished. This general article will help to a thorough understanding of some of the details that follow.—Editor.

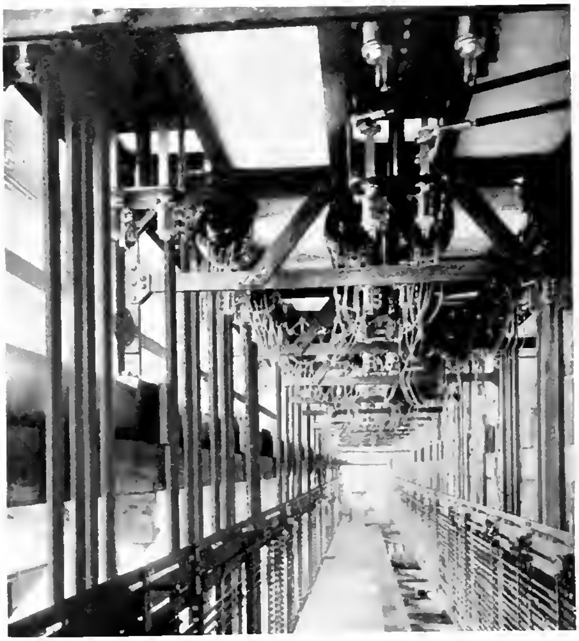
The engineering principles involved in designing and producing the apparatus to control the operation of the locks of the Panama Canal, as well as to give the operator a visual indication of the position of fender chains, gates, valves and other machinery, have necessitated the employment of much creative ability and constructive skill. In bringing this matter to a successful conclusion, it was necessary to carefully weigh and consider numerous problems which had never arisen before.

The importance of meeting in the best possible manner the requirements as laid down by the Isthmian Canal Commission is so obvious as not to require comment. It might be said, however, that these conditions were unusually severe and in many cases highly special.

In the ordinary power scheme of any great size, there exists as a rule the necessity of producing one or more special devices to meet the situation. But such devices are generally to a large extent subsidiary to the main proposition. In the Panama work, such was not the case. Practically every detail in connection with the control boards for the Gatun, Miraflores and Pedro Miguel locks was absolutely new and required special treatment. The switchboards for the distribution of power were also unusual in several respects and came in for their share of careful thought and effort.

It will not be the object of this article to go into much detail concerning the electrical apparatus that has been provided for the canal. In general it may be said that the Isthmian Canal Commission specified what it wished to have accomplished for the lock control and that they, in collaboration with the engineers of the manufacturer, devised the means.

The Commission engineers specified that the lock control boards should be as nearly as possible an operating miniature of the locks themselves, and so arranged that the indicating devices on the control boards would show the positions of the rising stem, and other valves, lock gates, and the water level as it changed in the various locks and in the forebay. It was also specified that in order to pass a vessel through any lock it should be necessary for the control board operator always to maneuver the different operating levers in a definite order corresponding to the pre-determined sequence of operation of the lock machinery necessary to pass the vessel quickly and safely through, and that the operator in control of the east bound channel of the canal must not in any way be able to interfere with the apparatus under the jurisdiction of the operator controlling the west bound channel.



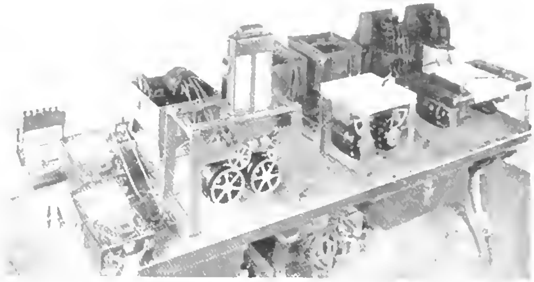
View under Gatun Control Board Showing Control Switches, Position Indicators and Connecting Rods

The imposed conditions have been fully cared for. Each lock control board will indicate to its operator the actual position of the level of the water and of the lock machinery at any instant. Also by a system of horizontal and vertical interlocking bars beneath the control board the control handles are so interlocked that only the proper handle or handles can be operated at any time in the course of a ship's travel through the locks.

The interlocking system forces the attendant to operate the chain fenders, gates and valves always in the proper sequence, and also prevents him from operating these devices in incorrect sequence; for instance, opening a gate when the chain fender is not in position or when the valves are open, etc. There is also an interlocking combination that is used in connection with the intermediate gates which divide the locks into short sections. This arrangement is fitted with a Yale lock and key so that the intermediate gates can be used only when the attendant has unlocked the combination, this also being subject to the general interlocking system. Certain valves are used to cross fill between locks. These also are interlocked so that they can be operated only in proper order and combination to equalize the water between a pair of locks and save water which would otherwise be wasted. This cross filling consists in allowing water from one lock which is full to flow into a lock by its side in the other channel until the level of the water is the same in both locks, thus using a portion of the water over again.

The fact that the control board is a working miniature of the lock which it operates shows the operator the actual condition of gates, height of water, etc., and, consequently, having the whole condition in miniature under his eye he knows what to do next and when to do it; the operator receiving his information as to the movement of the vessel from a towing master. The engineers on the locomotives which take the vessels through the locks, as well as the towing master, can see the position of the gates, but the position of the fender chains are indicated by semaphore arms on the lock walls.

Now let us take a vessel through a set of locks: It proceeds into the lock forebay either under its own power or that of a tug, and comes to a full stop. It will then proceed under the power and control of four electric locomotives two forward to take it along, one on each side, and two others astern, one on each side, to keep the vessel in the middle of the waterway and to stop it when it has reached the proper point, and to prevent it from moving forward too rapidly.



Testing Arrangement for Rising Stem, Chain Fender and Miter Gate Indicators and Transmitters

After the vessel comes to a full stop in the forebay its position is given by the towing master to the switchboard attendant who, by moving a control switch lever, causes the lowering of the fender chain and the miniature fender chain on the control board after the lock gate is in the proper position. The fender chain is stretched across the canal to prevent the vessel from striking the gates if for some reason it should get beyond control. In such an event the fender chain brings the vessel to a full stop.

Now the vessel advances into the lock by means of the electric locomotives. The fender chain is raised and then the massive gates are shut behind, the miniature control board gates in the meantime indicating this movement. When the water on opposite sides of the gates in front of the vessel has been raised or lowered, as the case may be, until the water on both sides is at the same level, as shown on the water level indicators on the control board, these gates are opened and the boat is pulled into the next compartment, and so on.

To assist in performing the necessary locking operations, several kinds of position indicators all working on the same principle and geared to the different pieces of machinery and to the different indicating devices in a suitable way to transmit the signals (or give positions), are employed. The operator is also notified by the towing master of the position of the vessel.

Turning now to the development and distribution of electric power used in connection with the Canal Zone: deviations from standard practice were made necessary because of the extraordinary care required to insure continuity of service and to guard against the rapid deterioration caused by the severe climatic conditions prevalent on the Isthmus. Switchboard fittings, operating coils, etc., could not be used as usually furnished. They had to be made proof against rapid deterioration by the application or impregnation of non-hygroscopic material.

It might be asked: "Why was electricity chosen to operate the Panama Canal locks? Why not water, steam or air?" This is answered by saying that only by the use of electricity would it have been possible to control a set of locks from a central point at each flight of locks, and at the same time to arrange the miniature indicating devices in such a way as to be at all times under the control and observation of the attendant. By the use of electricity it is possible to make a combined control and indicating board, and in no other way could a simple, practicable method of remote operation and indication have been devised, particularly since in some cases the distance between the controlling devices and the operating machinery is greater than 2500 feet.

Another problem was to make the indicating devices as simple as possible and free from a multiplicity of parts which would be likely to get out of order. Appliances with commutators, multiple contacts or ratchet mechanisms were not suitable because of the large numbers of contacts, wires and small pieces in their construction, and also because such devices move step by step and would not continuously register all points of the movements of the main machinery, the indications being only more or less approximately correct according to the number of steps in the indicators.

The solution of this problem is found in the indicating devices now on the Panama control boards, which were developed especially for this undertaking. They are known as position indicators, and, where used in connection with lock machines or water level devices, indicate accurately and continuously every movement.

These remote control devices, which indicate in miniature the position on the switchboard of the water level and the heavier machinery at the locks, are sturdy and simple structures, and consist of pairs of a novel type of galvanometer having a three-phase stator and a single-phase rotor, connected together.

One of the galvanometers is used as a transmitter and is geared to the heavy machinery, the movement of which it indicates, the other galvanometer being used as a receiver and geared to the miniature indicating device on the control board. The three-phase stators are connected in multiple; as are also the single-phase rotors, the latter being excited from a single-phase circuit. The only moving connections in these machines are the two silver collector rings and brushes required for each transmitter and receiver. The heavy machinery whose movement is to be indicated drives the transmitter, and the receiver (through the electrical connections) follows the movement of the transmitter and makes the indicator follow and show the position on the control board of the main device at the lock. The distance over which some of the transmitters operate is more than 2500 feet, but the indications could easily be given over a much greater distance if required.

In some cases it is not necessary to indicate intermediate positions of movement, and here the indications of the open or closed positions are taken care of simply by red and green lamps in the usual manner.

It was of course necessary to assemble and test the several control boards for the various locks and then to take them apart and ship them to Panama where they were re-assembled. To accomplish this with the least trouble the boards were made in sections so arranged that the minimum number of adjustments and parts would be disturbed or removed. The top parts of the boards were made in four foot sections and the interlocking portions in eight foot panels, these being the lengths of units best suited to shipment. This arrangement necessitated very careful work in the layout to establish the dividing lines between parts that could be disconnected at the factory and reconnected at Panama with little trouble.

# LOCK CONTROL BOARDS AND INTERLOCKING SYSTEM FOR THE PANAMA CANAL

By C. H. Hill and C. T. Hentschel

Switchboard Engineering Department, General Electric Company

This article constitutes a description in detail of the control boards that have been built for operating the machinery of the great locks at Panama. The large motors that perform the functions of opening and closing the mitering gates and the many valves that regulate the flow of water are all controlled from this board, as are also many other motors, such as those for the miter-forcing machines, fender chains, etc. Every movement of the mitering gates, fender chains, and rising stem valves is shown by miniature devices in imitation of the respective parts of the lock machinery; while the water level is indicated with great accuracy on vertical scales. The system of interlocking employed between control switches is discussed and illustrated in a very thorough manner, and the reader should have no difficulty in acquiring a complete understanding of the operation of the board.—Editor.

To centralize the control of the large number of machines at any one of the great locks of the Panama Canal, to indicate accurately and at all times the position of this machinery, and to so interlock the control switches that all chance of error in operation is eliminated, presented to the designers of the control boards many problems which were both interesting and difficult.

It is the purpose of this article to describe in some detail the various features of the control boards. There are three such boards, one for the lock at Gatun, one for the lock at Pedro Miguel, and one for the lock at Miraflores. As the board for the Gatun lock is the largest and its design and construction involved all problems incurred, it will be used as a basis for description.

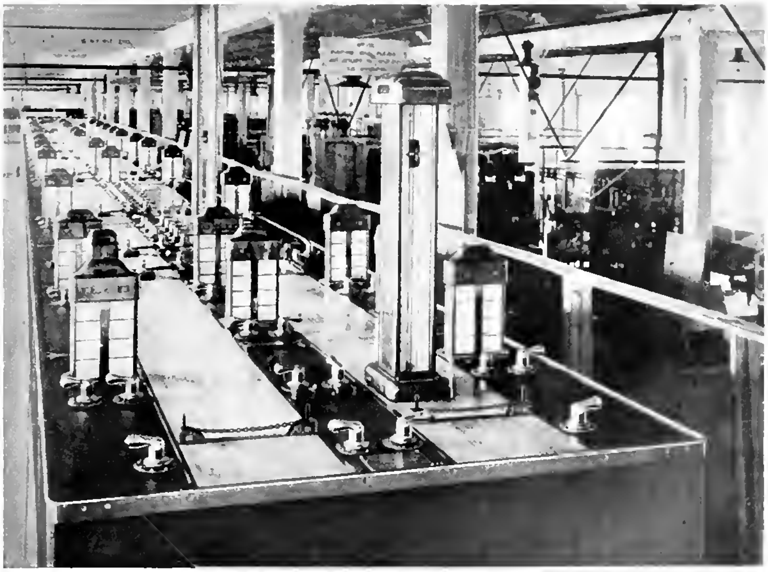


Fig. 1. Control Board for Gatun Lock

It is assumed that the reader, through some of the other articles in this issue, is familiar to some extent with the lock machinery and its use. Therefore, no attempt will be made to describe it here.

### Plan and Construction

The top of the control board (Fig. 1) is, in miniature, a plan of the lock it controls, and the indicating and controlling apparatus located thereon bear relatively the same positions with respect to each other as do the large machines on the locks themselves. The side and center walls of the lock are represented by cast iron plates having neatly matted surfaces with raised edges. Bosses are provided on which are located the various indicators and control switches, and the water is simulated by blue Vermont marble slabs between the metal plates. The outer edge of the board is surrounded by a brass trim rail, which gives a finished appearance, and the sides are enclosed with steel panels which can be readily removed for inspection. The board is supported by a wrought iron framework resting on base castings, which are in turn supported on the operating floor of the control house. Seven feet nine inches below the operating floor is located another floor, these two floors forming a compartment for the interlock racks which are mounted directly in line with the sides of the board above. (Fig. 2.) Back of the interlock racks a space is provided for bringing in and distributing the cables which run from the lock machinery to the control switches and indicating devices. The space between the two divisions of the interlock rack allows easy access to the interlocks and to the various apparatus located underneath the control board. In this space is also provided supports for the busbars, the end bells for the incoming cables, and the fuses for the various circuits.

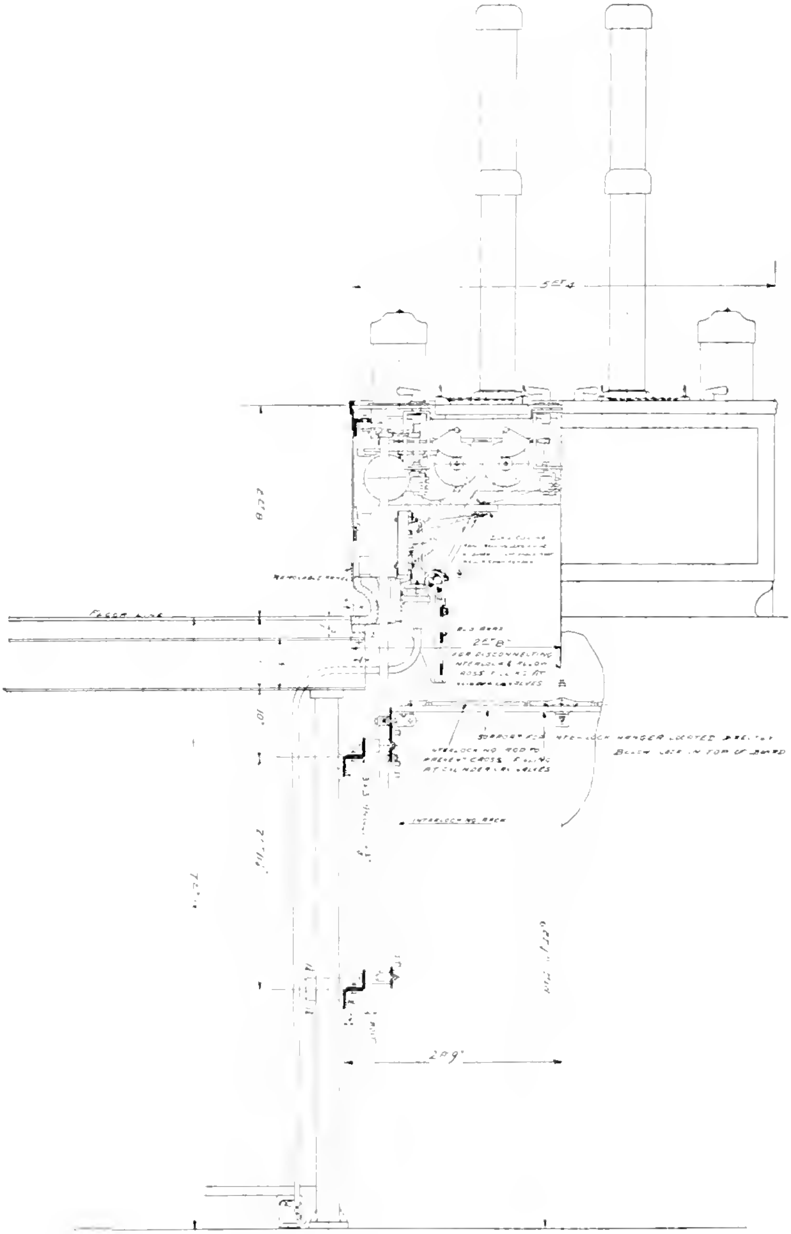

Fig. 2. Section of Lock Control Board

### Indicators

In designing the indicators, efforts were made to represent the actual machines, the operations of which were to be indicated. This was not a difficult matter in the case of the chain fender or the miter gate indicators. The rising stem valve indicators, however, were more of a problem because the valves themselves are located in a culvert and the operating machinery is below the lock wall; yet for the purpose of observation it was necessary to have the indicators project above the surface of the board. To indicate the level of the water, there being no machine to represent, it was necessary to design a gauge which would, like the rising stem valve index, project above the surface of the board.

### Chain Fender Index

The chain fender index, Fig. 3, consists of a small aluminum chain in representation of the large chain, and just as the large chain is lowered into a slot in the bottom of the lock, so the small chain is lowered into a slot in the top of the board. The ends of the miniature chain are fastened to semaphore arms, which are connected by means of adjustable links to arms on segmental gears which mesh with the driving gears on the receiver machines described in other articles in this issue Like the large chain, each end of the index chain operates independent of the other. The distance the large chain has been raised or lowered is judged by that part of the angle through which the semaphore arm on the index has moved, either from the horizontal or the vertical as the case may be. In the different locations on the lock the chain is lifted through varying heights, and in order to allow for this and to make it possible to use one design of index for all positions, the adjustable links mentioned above are provided.

### Miter Gate Index

The miter gate index, Fig. 4, comprises a pair of aluminum leaves or pointers representing a pair of the large miter gates, the leaves being shaped to correspond to the plan view of the top of the gate. The leaves move in a horizontal plane just above the marble slab which represents the water in the lock. The pivot ends are fastened to shafts extending down through the surface of the board, on the under side of which they are geared to the receivers by means of bevel gears (Fig. 5). The shafts are located in the side and center wall castings, and the leaves revolve back over these castings while the gates are traveling to the open position, and when completely opened are covered by shields to give the effect of the gates folding back into recesses in the lock walls. Each leaf operates independently, as does each of the large miter gates.

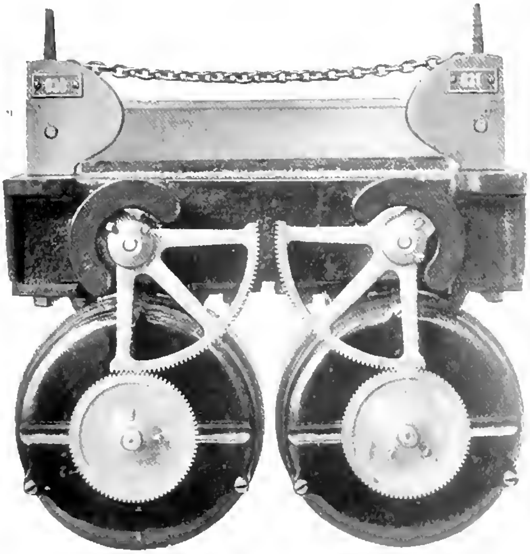

Fig. 3. Chain Fender Index

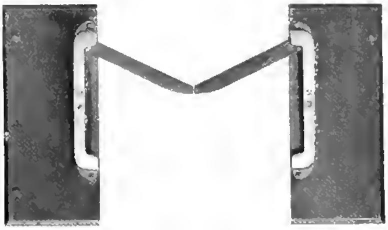

Fig. 4. Miter Gate Index

### Rising Stem Gate Valve Index

As is perhaps already understood, rising stem gate valves usually occur in pairs, and for that reason the indexes for these valves have likewise been made in pairs. These indicators might well be likened to a miniature elevator (Fig. 5), the car being used to indicate the position of the valve gate. The drum for operating the cord which raises and lowers the car is located underneath the board, and is operated by a receiver machine to which the drum is connected through a suitable train of gears. One end of the cord or cable is fastened to the top of the car, the other end being run over an idler at the top of the index and down through the side frame and around the drum to the lower side of the car. This end of the cord is then fastened to a spring, which is in turn fastened to the lower end of the car. The spring keeps a certain tension on the operating cord at all times. Great care had to be exercised in the construction of all bearings so that the cars could be moved with the minimum amount of friction in order that any error due to a lag caused by friction would be eliminated.

Fig. 5. Miter Gate Index

To have the indication visible from various points up and down the board, a novel scheme was resorted to. The under side of the car is equipped with reflectors so arranged as to reflect, parallel to the surface of the board, the light of several incandescent lamps located underneath the board. This light is reflected through openings in the index facing both up and down the board, the openings being closed with opal glass. The reflected light gives a sharp shadow of the bottom edge of the car, all portions of the index above this line being dark and all portions below being illuminated. The illuminated portion shows how far the gate of the valve is open. If the index is dark, the valve is entirely closed; likewise, if the index is illuminated, the valve is entirely open. The one-quarter, one-half and three-quarter positions of the gate are indicated by heavy black lines on the glass. The receivers for all the indicators described above are operated through an angle of approximately one hundred and seventy-eight degrees, as this was found to give the indication within the required accuracy.

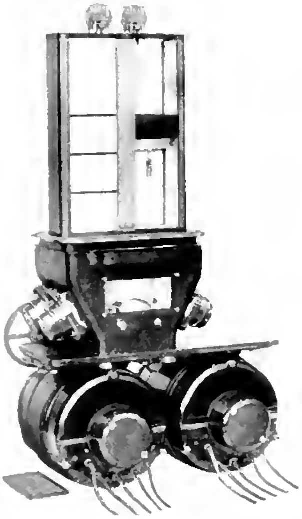

Fig. 6. Open View of Rising Stem Valve Index, Showing Transmissions, Shutter and Illuminating Lamps

### Water Level Indexes

In making up the water level indicator (Fig. 7), however, a much greater accuracy was required. It was found that if the receivers were revolved through not more than one hundred and seventy eight degrees, this accuracy could not be obtained, and it was therefore necessary to make a change and revolve the receiver through ten complete revolutions. While this solved the question of accuracy, it introduced another problem which had to be dealt with; namely, that the rotor of the receiver could be in phase with the rotor of the transmitter in twenty different positions, only one of which would give the correct reading of the level of the water. It was therefore found necessary to provide, in addition to the above receiver, a second receiver which should be operated through one hundred and seventy-eight degrees, the rotor of which could always be depended upon to have the correct position. The index for the fine indication consisted of a hollow cylinder having pointers which moved over the scales of the indicator. The coarse indication consisted of an aluminum ball enamelled red and arranged to operate inside the cylinder of the fine index. The length of the cylinder for the fine index was such that so long as the red ball was within the limits of the cylinder, the fine index could be depended upon to be in the correct position and its reading accurate. The method of operating these indexes was similar to that employed in the rising stem Stoney gate valve indicators described above; but the indication, instead of being accomplished by reflected light, was shown by pointers on the cylinder of the fine index which moved over scales arranged in the four corners of the frame of the indicator. These scales make an angle of forty-five degrees with the axis of the board, so that the level of the water can be observed from various positions up and down or across the control board, through openings in the sides of the indicator facing up and down the board, these sides being enclosed by plain glass and the other two sides of the frame being enclosed with brass panels. The scales are illuminated by tungsten lamps located in both the base and top cap of the indicator. Due to the extreme accuracy required it was deemed advisable to calibrate each indicator with a particular transmitter mechanism and to calibrate each set of scales individually.

Fig. 7. 50 Ft. Water Level Indicator

The specifications required that, the level of the water be indicated to within five-eighths of an inch of the actual level. The indicators as made attain an accuracy somewhat greater than this.

### Miter-forcing Machine Index

The indicators for the miter-forcing machines, which machines force the end surfaces of the gates into alignment (Fig. 8), are not operated by means of position indicator machines, but are only an imitation of the actual machine at the lock, and are operated by the control switch; the intention being to permit the operator to distinguish readily by observation whether the miter-forcing machine was in the open or closed position.

### Cylindrical Valve Indicators

The open and closed position of all cylindrical valves are indicated by means of red and green lamps, the intermediate positions not being indicated in any way.

### Control Switches

The control switches (Fig. 9) are, practically speaking, small controllers, the fingers being at the lower end of the frame, beneath the control board, and insulated by means of hard mica. The contact pieces are located at the end of the operating shaft, and like the contact fingers are insulated from the shaft by hard mica. The portion of the shaft just below the board and above the contacts is square, which provides a means for coupling to the interlocking mechanism, a full description of which will be given later. The handle for the control switch is located on top of the control board and operates through an angle of ninety degrees, and is provided with name plates to show the open, closed and off positions. All handles for control switches are similar in design except those for the chain fender, which are corrugated so that they may be readily distinguished from the control switches for other apparatus located nearby.

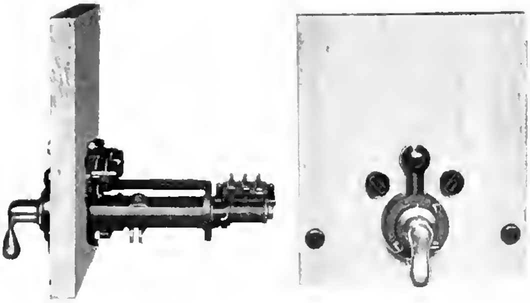

Fig. 8. Miter-forcing Control Switch, Showing Indicating Lamps and Miter-forcing Lamp Indicator

Fig. 9. Double Frame Control Switch

### The Interlock System

In designing the interlock system, the factor of human error had to be reckoned with, and the precautions taken to eliminate the possibility of mistakes by the operator have been carried to a high degree of perfection.

The interlock system takes the form of a bell crank mechanism, as illustrated in Fig. 10, connecting the shaft of the control switch directly to a movable horizontal bar located in the interlock rack, the location of which has been described above. It will be seen that a horizontal connecting rod is used between the cranks on the control switch shaft and the vertical operating shaft. This rod is made with a right-hand thread at one end and a left-hand thread at the other, and provides a ready means for adjust-

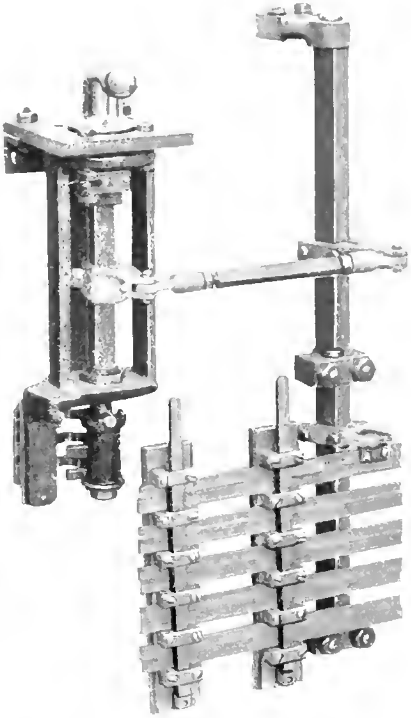

Fig. 10. Control Switch and Interlock Mechanism

ing the throw of the vertical shaft and the meshing of the bevel dogs in the rack.

The rack consists of a rigid frame constructed of three-eighths inch thick steel and having five horizontal members (see Fig. 11). Upon these horizontal members and tying them together are located at convenient intervals a set of vertical straps of three-eighth inch by two inch steel. These carry the brass posts that provide the runways for the horizontal and vertical interlock bars. The posts are firmly riveted to the vertical steel straps, and a one-sixteenth inch brass plate is provided between the posts and steel strap so that the runway is made non-corrosive.

By referring to Fig. 12 it will be seen that the back of the steel strap is grooved and countersunk in such a manner that a key is provided which prevents turning of the posts. Elaborate drill jigs and assembling tools were constructed to make the spacing and alignment of posts perfect. The racks are built in eight foot sections for convenience in shipping, eighteen of them being used in the Gatun control board, making a total length of one hundred and forty-four feet—seventy-two feet for each side of the board.

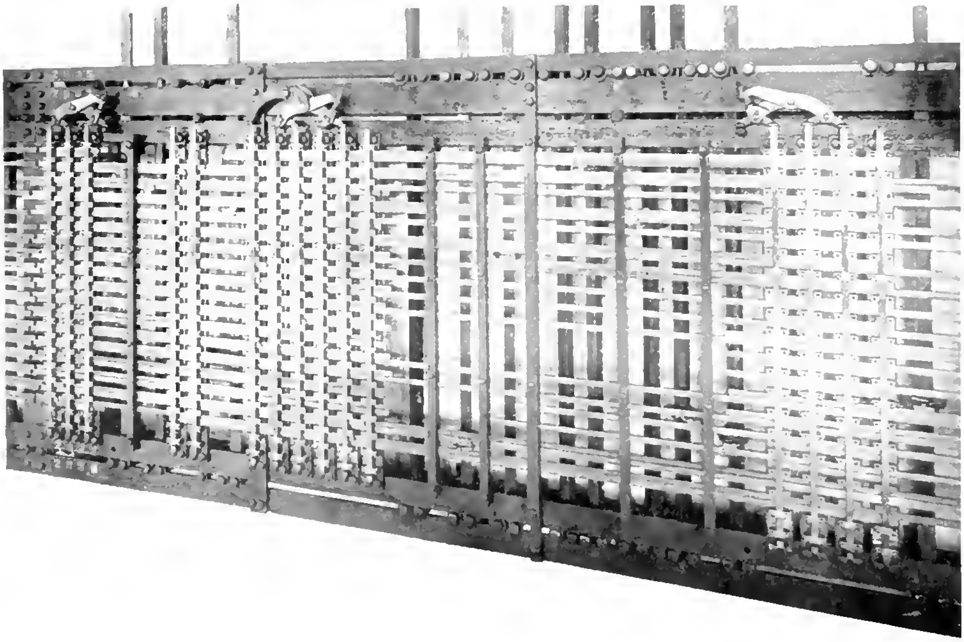

Fig. 11. Section of Interlock Rack Showing Arrangement of Vertical Operating Rods and Method of Interlocking by Means of Adjustable Whiffletrees

They are to be rigidly mounted, by means of heavy angle iron work and suitable spacers, upon the inner faces of the iron columns that carry the operating floor of the control house. Near the upper and lower edges of the racks are located the brass bearings for the vertical operating shafts, which are seven feet long and made of one inch square steel (Fig. 13), the bearing points being turned to a diameter of seven-eighths inch. On the vertical operating shafts are mounted the forked cranks that engage the horizontal interlock bars by means of a pivot block set over a pin block which is firmly riveted to the horizontal bar (Fig. 14). This provides a means of moving the horizontal bar a distance of approximately one and one-half inches by operating the control switch handles through an arc of ninety degrees.

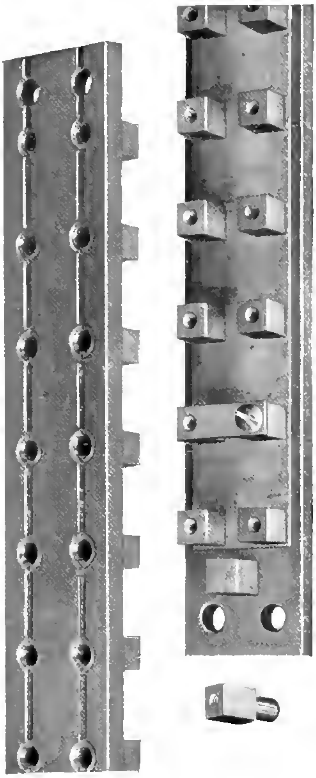

Fig. 12. Runway for Vertical and Horizontal Interlock Bars

The interlock bars are made of hard extruded brass of special shape, as shown in Fig. 15, which also shows a cross section of the bevel dogs. This section was determined upon as the best method of keeping the dogs in line with the axis of the bars when under pressure through being engaged with another dog on a vertical bar. There is a horizontal bar for every switch, but the length of the bars varies considerably, the shortest being about three feet, while the longest are fifty feet.

Fig. 13. Interlock Relieving Clutch and Auxiliary Spring for Intermediate Gates

The interlock system depends in the main on the action of bevel dogs located on the horizontal and vertical bars, these dogs so engaging that the movement of a horizontal bar tends to lift a vertical bar by means of the bevel on the dog. This is plainly illustrated in Fig. 16

The movement transmitted to the vertical dog and its bar is one-quarter inch. Referring to Fig. 17, it will be noted that a second bar has been brought forward and that it is now impossible to move the upper bar because the dog on the lower bar prevents the lifting of the vertical bar; in other words the control switch to which the upper bar is connected cannot be operated until the lower dog is withdrawn. This is the simplest type of interlock employed and forms the basis of the whole scheme.

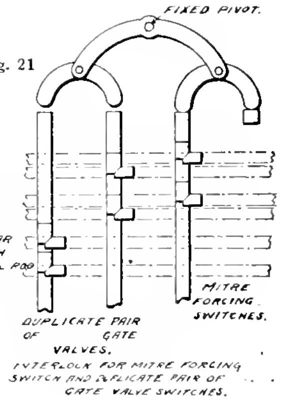

Fig. 22

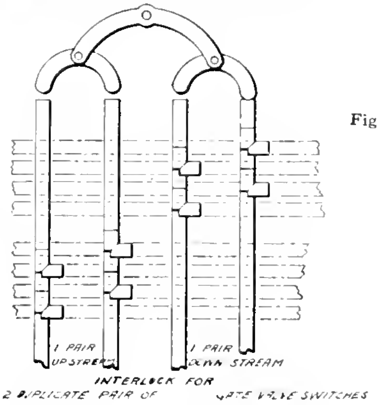

Fig. 20

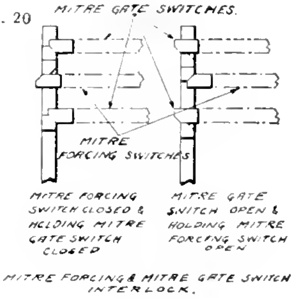

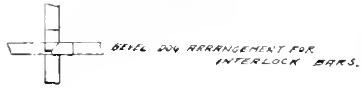

Fig. 16

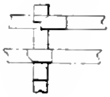

Fig. 17

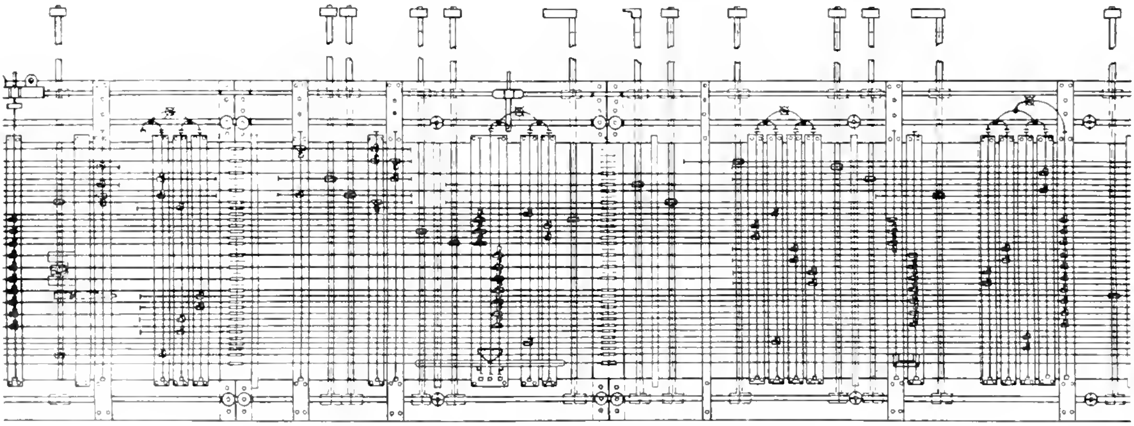

Fig. 18. Section of Detail Chart of Interlocks

Although the functions of the various machines have been described in another article, it will be necessary to touch upon them once more in order to explain how the more intricate interlocking is accomplished. Fig. 18 shows a section of an interlock detail chart covering approximately eleven lineal feet of rack construction, complete with all dogs, vertical shafts, etc., while Fig. 19 shows a section of rack.

### Interlocking of Chain Fenders and Miter Gate Switches

The interlock here prevents the chain being lowered until adjacent miter gates have been opened, and conversely, prevents the gates being closed before the chain has been raised. The gates are thus protected from damage by moving vessels. The interlock is accomplished by means of the simple arrangement shown in Fig. 20. This occurs sixteen times on the Gatun locks.

### Miter Gate and Miter-forcing Switches

These are interlocked in such fashion that miter-forcing switches must be opened before miter gate switches can be opened, and vice versa, miter gate switches must be closed before miter-forcing switches can be closed. The arrangement of dogs for this interlocking is shown in Fig. 20, and is used twenty times.

### Miter-forcing Switches and Rising Stem Valve Switches

Here the object of the interlocking is to prevent the opening of the rising stem valves with the attending flow of water while adjacent miter gates are moving into either opening or closing positions. The locking is here applied to the miter-forcing switches and these are locked with rising stem valves on the side walls only.

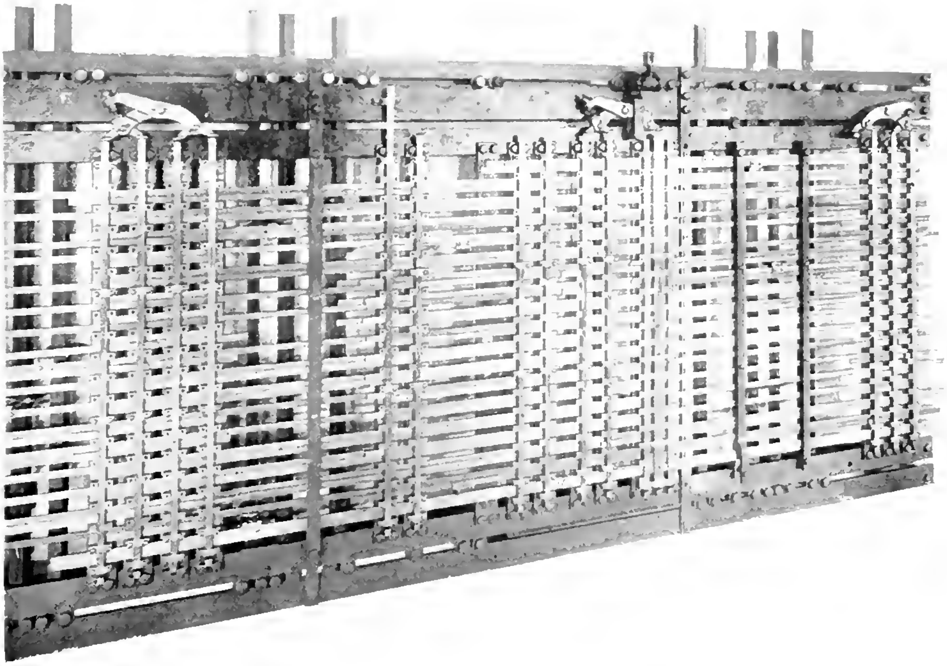

Fig. 19. Another Section of Interlock Rack

It will be noted from Fig. 21 that by operating the miter-forcing switch first, the second of a duplicate pair of rising stem valves is held closed; vice versa, if the two rising stem valves are opened, the miter-forcing switch is closed.

A novel arrangement of rocking levers, conveniently called whiffletrees on account of their resemblance to that familiar contrivance used on horse drawn vehicles, is applied here. Its function is to make the sequence of operation of the two pairs of rising stem valves selective so that either

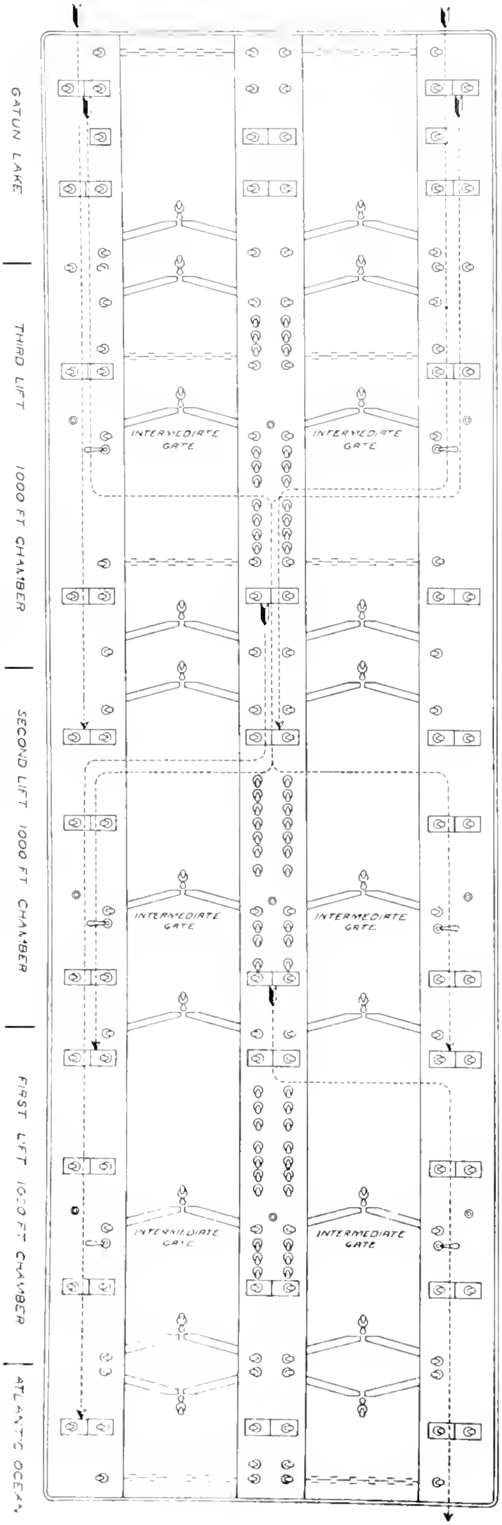

Fig. 23. Plan of Gatun Control Board

pair can be opened first, this pair being the guard pair while the second pair is the operating pair—no water flowing until the second pair is opened. The whiffletrees are equipped with a screw attachment permitting of close adjustment on the lift of the vertical bars.

It will be noted that one of the four points of the whiffletree mechanism is resting on a fixed stop, while the next point is closely in touch with the top of the vertical bar connected to a pair of rising stem valve switches. The other two points are raised one-quarter inch from the top of vertical bars connected to a pair of rising stem valve switches and a miter-forcing switch. If the latter two bars are raised, all available room is taken up and the third bar is held down; in other words, the two switches connected to that bar cannot be opened. This interlock is repeated twelve times on the Gatun board.

### Intermediate Miter Gates

The thousand foot levels are divided into two unequal sections by intermediate miter gates to permit handling small vessels without incurring the waste of water that would result from operating the vessels in the large chambers. These gates are equipped with the same interlocks as those on other gates, but provision has been made to remove all interlocks in case a large vessel is to be passed through.

The method employed here consists of dividing the shaft and installing a clutch arrangement, the lever of which is governed by a Yale lock on top of the board. The turning of a key removes the interlock and permits the gates to be thrown open, thus providing a clear thousand foot level. Fig. 13 shows this clutch.

### Rising Stem Valves

Rising stem valves are located in series in the side and middle wall culverts and are used to intercept the flow of water at proper intervals and shunt it into the various lock chambers. The culverts open into the ocean at the lower ends, and special precautions are necessary to prevent the opening of all valves in series.

The interlocking is here accomplished by the arrangement of dogs and whiffletrees shown in Fig. 22, where four vertical bars each bearing two dogs engage the horizontal operating bars of four pairs of rising stem valve switches. It will be noted that any pair can be selected for operation at will and that three pairs can be opened; the fourth pair is, however, locked closed because all the space between the whiffletrees and the tops of the vertical rods has been taken up. Therefore one of the other three pairs must be closed before the last one can be opened.

Fig. 23 shows a plan view of the control board and the relative location of the various switches. Here it is shown that the flow of water in the culverts is intercepted at eight points exclusive of the intermediate rising stem valves adjacent to the intermediate gates, which are not interlocked.

The interlock described above occurs three times in each culvert and confines the operator to the equalizing of water between levels.

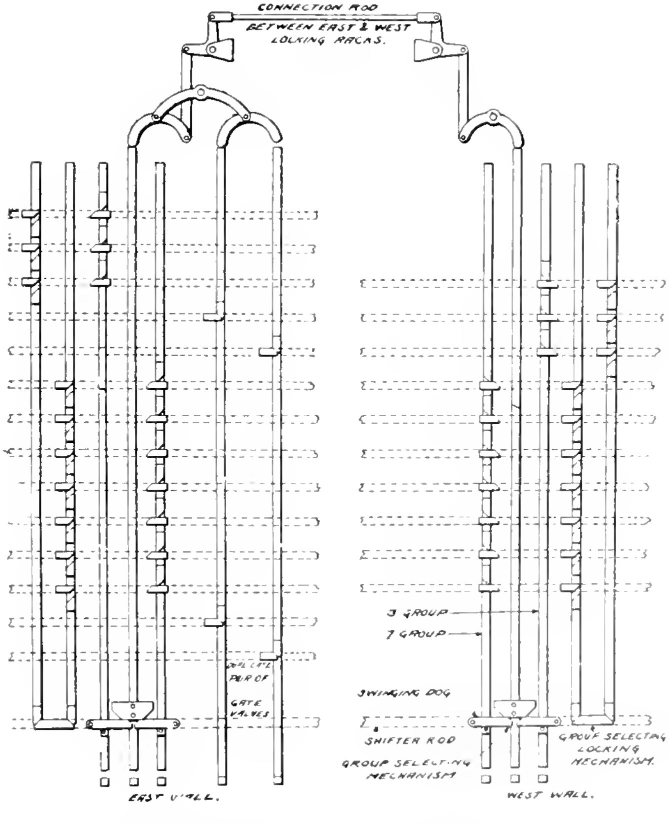

**Fig. 24.** Interlock for 10 Cylindrical Valves on East and 10 on West of Center Culvert and One Pair of Rising Stem Valves Upstream or Downstream with Group Selecting Mechanism and Interlock

### Cylindrical Valve Switches

There are sixty of these located on the middle wall and they control the cylindrical valves which permit of filling and emptying the various lock chambers from the middle wall culvert. Twenty of these switches constitute the equipment for a thousand foot level, ten for each side east and west. They are interlocked so that if one side is opened, the other side is locked closed, and the opening of one switch on a side will lock the opposite ten. Fig. 24 shows the locking system employed here with the necessary connection to the opposite rack. Here is also shown the mechanism for removing the cross locking, which is desirable in cases where two vessels come abreast in opposite basins on the same lift. A large quantity of water can be saved by using part of the water that would be wasted in lowering one vessel and allowing the chambers to equalize by opening both sets of cylindrical valves. The removal of this interlock is accomplished by means of a Yale lock placed on top of the board, the bolt of which holds a toggle extended when locked, but allows it to collapse when unlocked. (Fig. 25.)

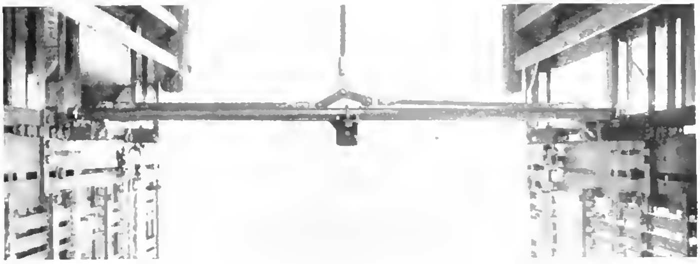

**Fig. 25.** Interlock Cutout Mechanism for Cylindrical Valves

### Cylindrical Valves and Center Wall Rising Stem Valves

Cylindrical valves are not designed to operate against a head of water, and they are therefore interlocked with middle wall rising stem valves so that a set of cylindrical valves must be opened on either side before the second pair of a duplicate pair of rising stem valves on the middle wall can be opened either up or down stream. (Fig. 26, page 26.)

### Group Selecting Levers for Cylindrical Valves

On each side wall and close to the three intermediate gates will be found three control levers. These are used in connection with groups of three and seven cylindrical valves above and below these gates. The handles have three positions, allowing three, seven or ten valves to be used. When the intermediate gates are opened, this handle is placed at the "ten" position.

Assuming that a short vessel is being passed downstream, it would first pass into a chamber having three cylindrical valves. The group-selecting lever would then be placed on the "three" position, which would permit of opening three valves above the intermediate gate but would lock closed the seven valves below it. After the vessel has been passed below the gate, the handle may be reversed, releasing the seven and locking the three switches. (Fig. 24.) The operator, however, is not confined to this operation, but may shunt the water from the upper to the third chamber. In fact, the whole method of using the group-selecting levers is left to his judgment.

### Cross Interlocking of Rising Stem Valves on Side and Middle Walls and Cylindrical Valves

Referring to Fig. 23 and following the dotted line from the culvert entrance through the culvert, through an open set of cylindrical valves, on through the center wall culvert, to and past a lower pair of middle wall rising stem valves into a lower chamber, it will be seen that it is possible to allow lake water to flow and flood this chamber. To prevent this, interlocks have been applied between these rising stem valve switches and cylindrical valve switches so that if a set of ten cylindrical valve switches on either side and a duplicate pair of rising stem valves on the respective side wall are open, the second pair of a lower duplicate pair of rising stem valves on the middle wall is locked closed; and vice versa, if the middle wall duplicate pair of rising stem valves are open and cylindrical valves are open, the last pair of the upper or lower duplicate pair of side wall rising stem valves is locked closed. Again, if all these rising stem valves are open, the cylindrical valves are locked closed.

The development of the interlock system was one of the most complicated problems encountered in connection with the Panama control boards and it was given the closest attention because the final layout of no part of the control board could be determined until the interlocking had been completely taken care of. This was made even more difficult by the fact that all the interlocking had to be shown on a chart and approved by the Commission before detail work could proceed.

The whiffletree mechanism was particularly helpful because it provided in each case the means of accomplishing with four vertical bars what would ordinarily have taken sixteen bars. For checking and final tryout, a separate sheet called the "when sheet" was prepared, which showed the interlocking between one switch and any other.

### Shipping

In designing the board, consideration had to be given to the fact that it had to be fully assembled and tried out at the factory; and further, to make its installation at the Isthmus simple, it had to be shipped with as little dis-assembling as possible. To accomplish this, the board itself was arranged to come apart in four-foot sections, while the interlock was arranged to come apart in eight-foot sections. (Fig. 7.) The top sections are shipped complete with the control switches; the indexes, however, are removed and shipped separately, with the exception of those for the mitering gates. Each section of the interlock rack is shipped complete and can be easily coupled together when re-erected on the Isthmus.

### Climatic Conditions

Another point which had to be given very careful study and thought was the selection of the material of which the board and the various devices were to be constructed because of the peculiar climatic conditions existing on the Isthmus. All bearings had to be made of non-corrosive material, and wherever steel or iron was employed it was necessary to thoroughly coat it with red lead before giving it the finishing coat of paint. All insulating material had to be non-hygroscopic. Even the cords for operating the rising stem gate valve indicators and the water level indicators were selected only after a number of samples of the highest grade silk line had been sent to the Isthmus and subjected to the climatic conditions for a considerable period to determine whether they would be suitable for the work. Anything in the nature of a metallic wire or cable could not have been used.

**Interesting Facts**

The total weight of the three boards will be approximately thirty-nine tons. To accomplish the interlocking, something over two and one-quarter miles of special interlocking rod was required. To connect the various control switches and indicators to the lock machinery will require about eleven hundred miles of control wire, this control wire being made up in five and eight conductor cables. The total number of position indicator machines used in connection with the board and the transmitters at the lock machinery is seven hundred and thirty-two. The total number of control switches required are four hundred and sixty-four. The total number of indicating lamps is about three hundred and eighty, and there are four hundred and fifty-two illuminating lamps. The control is operated at 220 volts, 25 cycles and the indication at 110 volts, 25 cycles.

# POSITION INDICATOR SYSTEM AND MACHINES FOR THE PANAMA CANAL LOCKS

By E. H. Jacobs and H. M. Stevens

Switchboard Engineering Department, General Electric Company

This article consists of a description of the transmitting and receiving devices that were evolved to show at the control board the water level and the movements and positions of the different gates, valves and other pieces of machinery that come into action in passing vessels through the locks. These devices are essentially transformers with movable cores, the stators being connected together at three points of the winding and the rotors excited with single-phase alternating current from a common source. All of the transmitters and receivers are similar, with the exception of those for the water level indicators, where the degree of accuracy required made necessary the use of two machines, geared together with a ratio of approximately 20:1. The methods employed for connecting the transmitters and receivers to the lock machinery and the indicating devices, respectively, are shown in the illustrations in most cases.—Editor.

The care with which the various details in connection with the operation of the Panama Canal lock machinery were determined, as well as the means provided to allow the operators of the control boards to know at all times the position of the lock machinery, are partly shown by the following description of some of the control indicating features.

The Isthmian Canal Commission's specifications required that, in so far as practicable, the devices used to indicate the position of the miter gates, rising stem valves guard valves, chain fenders, and water level be small models of the machines, and that the indication be progressive and synchronous with the movement of the machines. As the distance through which the synchronous movement of the indicators has to be transmitted is, in some cases, approximately 3000 ft., it can be readily seen that mechanical transmission of power from the machines to the indicators on the switchboard would be almost impossible, and therefore it was decided that only an electrical equipment could be satisfactorily used. As the result of considerable experimenting, the requirements were finally met by an arrangement known as a synchronous indicator and consisting of two machines, each having a stator and a rotor. One machine is mechanically operated by the lock machines and mounted either on or near them, and a second motor of the same type, electrically connected to the first, mounted at the control board and mechanically connected to a position indicator. The motor attached to the lock machine is known as the transmitter and the one driving the position indicator as the receiver. Both the transmitter and receiver stators are arranged with a three-phase winding, a lead from each phase being brought out (see Fig. 1) and the corresponding leads permanently connected together, but not connected to a source of power. The stator coils are energized entirely by induction from the rotor. The rotors are bi-polar and designed to be energized from a 110-volt, 25-cycle, single-phase source, the rotors of both transmitter and receiver being connected to the same circuit.

The movement of the transmitter rotor, which is mechanically operated by the lock machine, produces a field in the transmitter stator which polarizes it in the direction of the rotor axis and induces voltage in the stator coils. This voltage is transmitted by a three-phase connection to the receiver stator coils and it duplicates in them the same polarity and voltage conditions developed in the transmitter stator, but in the reverse direction. The rotor of the receiver, being energized in the same direction as that of the transmitter, is reacted upon by the polarized stator until their magnetic axes coincide and the rotors of the transmitter and receiver are in the same relative position. With the rotors in this position, there is no current flowing in the three-phase tie between the stators. Any difference in the position of transmitter and receiver rotors causes a difference of potential between them with a consequent flow of current and resultant torque which moves the receiver rotor to the same relative position as that of the transmitter rotor. The torque increases rapidly with increase in angular difference between the rotors, and, as the magnetic reluctance and the flux through the stator winding are uniform, the receiver rotor follows closely and smoothly the movement of the transmitter rotor. Thus a movement is imparted to the position indicator identical with the movement of the lock machine, although on a scale reduced to the requirements of the control board. It should be noted, in the following description of the arrangement for each lock machine, that this arrangement of position indicator control gives a sufficient accuracy of indication with considerably less than one revolution of the transmitter, with the exception of the water-level indicator which requires an accuracy of one-tenth of one per cent.

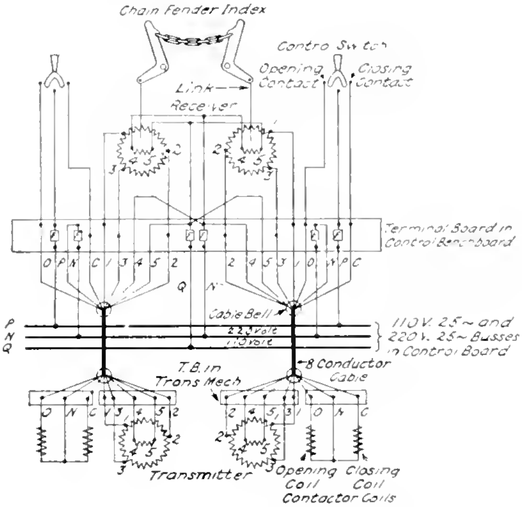

Fig. 1. Wiring for Control Switches and Position Indicators for Chain Fenders. This wiring is typical of wiring for all position indicators

Indication is given on the control boards of the main lock machinery and of the various water levels. The lock machinery consists of the miter gates, the gate valves or rising-stem valves, the chain fenders, and the guard valves.

The miter gates consist of two vertical leaves pivoted on the lock walls, with a motor-driven mechanism for operating each leaf. Each leaf of the gate is operated independently of the other, so that indication must be given of the movement of each leaf. Figs. 2 and 3 show the transmitting mechanism. The vertical operating shaft of the transmitter mechanism is connected to the operating machine and makes approximately 37 revolutions during a complete operation of the gate. The operating shaft is threaded and carries a nut on which is mounted a rack. The rack engages a gear on the motor shaft. This arrangement gives a gear ratio of approximately 75 to 1, the motor revolving 178 degrees while the operating shaft is making 37 revolutions.

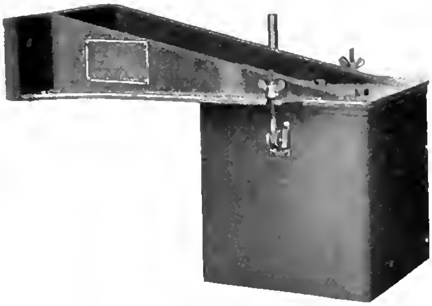

Fig. 2. Miter Gate Transmitter, Closed

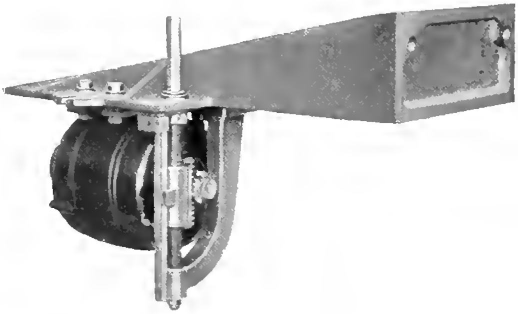

Fig. 3. Miter Gate Transmitter, Cover Removed

The position indicators for both leaves of a gate are mounted as a complete unit on the control board. The indication is given by two aluminum arms which are geared to the motors under the board, and which swing horizontally showing the location of the gates as they would appear to an observer directly above them. (See Figs. 4 and 5, page 21.)

A rising-stem valve consists of a gate carried in vertical guides with a machine for raising or lowering it in order to open or close a duct in the lock wall. The gate is 8 feet wide and has to rise 18 feet to reach the full-open position. The operating power is supplied by a motor driving two vertical screws. Figs. 4 and 5 show the position-indicator transmitter for a rising stem valve. The transmitter motor revolves approximately 178 deg. for a complete operation. The transmitter is driven by a shaft (not shown in illustrations) which makes 497 revolutions, so that the gear reduction is approximately 1000 to 1. The gearing is similar to that used on the miter gate transmitters. A screw with sixteen threads per inch is driven by a gear and pinion. The gear and pinion give approximately 6 to 1 reduction. The screw carries a nut and rack which drive a gear on the motor shaft. Eighty turns of the screw give 5 in. linear travel of the nut and rack, and as the gear on the motor shaft is 3¼ in. diameter it makes about 175 degrees revolution for a complete operation.

There are two ducts in parallel in each wall of the locks with the valves occurring in pairs, although their operation is independent. The position indicators are also built in pairs. The indicator, Fig. 6 (and Fig. 6, page 22), consists of a stack or box with a vertical partition dividing it into two compartments. Each compartment is 3 in. wide by 9 in. high by 2 in. thick. The front and back are fitted with ground glass which is marked with black lines for the ¼, ½ and ¾ positions. A small aluminum cage moves up and down in each compartment in the same manner as the cage of an elevator. Lamps in the bottom illuminate the ground-glass front and back as high as the bottom of the cage, this preventing the light from going above, so that the illuminated portion of the glass corresponds to the amount of opening of the valve. The cage shuts off the light completely when down and is raised into the metal cover for the full open position. The cage is raised and lowered by a continuous cord running over an idler at the top of the stack and over a drum at the bottom. The drum is driven by the motor through gearing. To prevent the cord slipping on the drum, the drum is threaded and several turns of the cord wound around it. A phosphor-bronze spring keeps the cord under uniform tension.

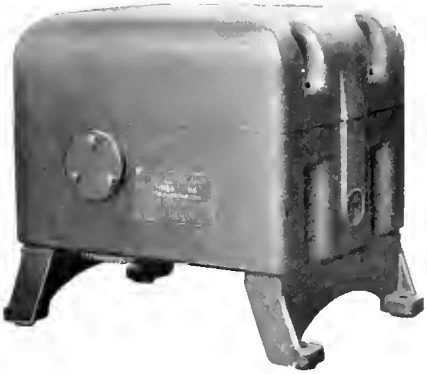

**Fig. 4.** Rising Stem Valve Transmitter, Closed

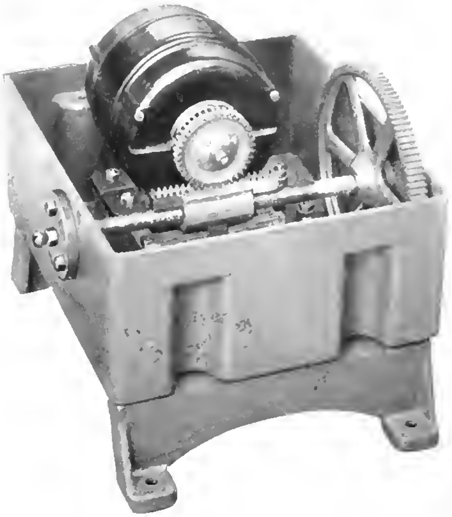

**Fig. 5.** Rising Stem Valve Transmitter, Cover Removed

The guard valves are situated at the upper end of the middle wall of each flight of locks. The machinery for operating them differs from that used for the rising stem valves, but the indication on the control board is the same.

In front of the lock gates are immense chains which are raised to prevent the gates from being rammed by a vessel. Each end of the chain is raised by a hydraulic piston, each piston being controlled independently.

The position-indicator transmitter, Figs. 7 and 8, is driven by the shaft that operates the limit switch which in turn controls the stroke of the piston. The operation of the transmitter is similar to the rising stem and miter-gate transmitters, the only difference being in the mounting and gear ratios. The indication on the board is given by a miniature chain, each end of which is connected through a crank and gearing to a receiver motor. As the receiver motors revolve, the chain is lifted out of a slot in the control board and is stretched straight. The arms which raise the chain are extended so that they form semaphores, giving an additional indication. (See Fig. 3, page 21.)

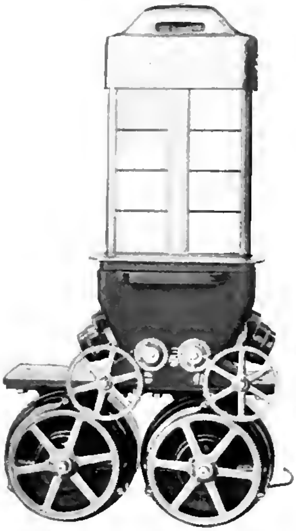

Fig. 6. Rising Stem Valve Indicator

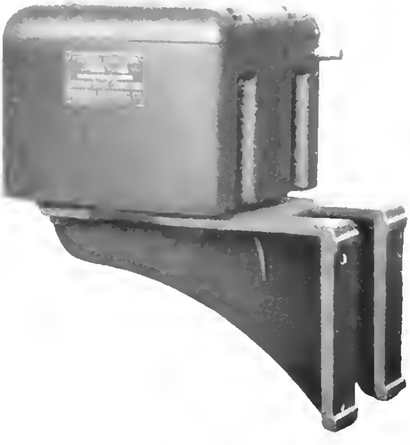

Fig. 7. Chain Fender Transmitter, Closed

The specifications covering the indications for the lock machinery, that is, for the miter gates, valves and chain fenders, required that the indicators show within 3 per cent the actual positions of the main machines. The specifications for the water level indicators, however, required that the indication be within one-twentieth of a foot of the actual water level. For a 50-foot range in water level this necessitated an indication within one-tenth of 1 per cent. To insure of the indicating apparatus being self-synchronizing, it was necessary to give the full range of indication with less than a 180-degree revolution of the indicating motor. As the inherent lag of the receiving motor behind the transmitter motor amounts to about $1\frac{1}{2}$ per cent in 180 degrees, it was impossible to give the required accuracy with one motor. A design was adopted by which an approximate indication is given by one motor, making a 178-degree revolution for the complete range, while accurate indication is given by another motor making ten revolutions for its complete range. The accurate or fine indication will be either correct or one or more turns of the receiver motor away from the correct position. If the pointer giving fine indication is a turn of the motor away from the pointer giving the approximate indication it is apparent to the operator, and the fine indicator can be returned to its correct position by turning the motor by hand. The motor making ten revolutions is thus acting as a vernier for the approximate or coarse indication.

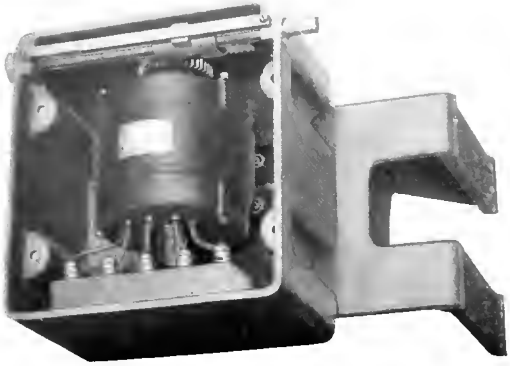

Fig. 8. Chain Fender Transmitter, Cover Removed

The water-level indicator or index is a vertical stack $5\frac{1}{2}$ inches square, the height depending on the length of the scale plates, with clear glass forming two sides. Each side has two graduated scale plates arranged so that the water level may be read from almost any position. The graduation is on a scale of 1 in. to the foot, requiring a scale plate 50 in. long for a 50-foot range of water level. The receiver motors are mounted underneath. The motor for coarse indication drives a threaded drum through light gearing. A continuous cord with several turns around the drum is carried up one side of the stack, over an idler at the top, returning down the center of the stack to the drum. A small aluminum ball, enameled red, is carried by the cord. The motor for fine indication drives two drums on a single shaft, with two cords running up to the top, over idlers, and back to the drums. A vertical aluminum tube 2 in. in diameter and 4 in. long is carried by the two cords, with small pieces of the tube bent out to form a pointer for each scale plate. This arrangement allows the small aluminum ball, giving the coarse indication, to move freely and independently through the tube. When the fine indication is correct the aluminum ball is inside the tube. If the fine indication is $\frac{1}{2}$ turn of the rotor (or more) away from the correct position the red ball is exposed above or below the tube, showing that the fine indication is not correct. Enameled silk cords are used to carry the pointers. Samples of this cord were sent to the Isthmus and, after being exposed to the severe climatic conditions, showed that they would last for a long time without renewal. Illuminating lamps are mounted in top and bottom of the index with glass reflectors to concentrate the light on the scale plates. The index is shown in Fig. 7, page 22.

**Fig. 9. Water-Level Transmitter with Float, Weight and Belt**

Figs. 10 and 11 show the water-level transmitter. Wells 36 in. square are provided in the lock walls to take the float. Communication between the lock and the float is made by a small opening at the bottom of the well which will dampen surges. The float is a welded steel box 30 in. square by $9\frac{1}{2}$ inches deep. It weighs 200 lb. and has a draft of 6 inches. A phosphor-bronze belt $2\frac{1}{4}$ inches wide by 0.010 in. thick transmits the movement of the float to a sheave on the transmitter mechanism. The sheave is studded with pins and the belt punched to fit these, to prevent slipping. A 30 lb. weight is fastened to the belt after it passes over the sheave. As it requires about 1 lb. pull on the belt to turn the transmitter, error at this point is almost eliminated, for 1 lb. pull on the belt lifts the float only $\frac{1}{32}$ in. The error due to transferring the belt from one side of the sheave to the other is partially compensated for by the displacement of the float. The variation in temperature is slight, so that the total error in transmitting the movement of the float will be not over $\frac{3}{16}$ in. on a 50-foot range. The sheave is 6 ft. in circumference with pins spaced 3 in. apart, or a total of 24 pins. This gives $6\frac{1}{3}$ revolutions of the sheave for 50 ft. travel of the belt. The sheave is carried in ball bearings with oil cups for lubrication and pet cocks at the bottom to allow water which may work into the bearings to be drawn off. The remainder of the transmitter consists only of the two motors, the gearing and the enclosing box.

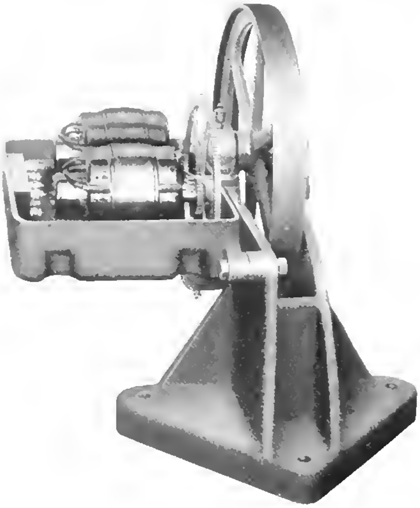

**Fig. 10. Water-Level Transmitter, Cover Removed**

# SWITCHING, DISCONNECTING, AND BUS ARRANGEMENT FOR A-C. POWER CIRCUITS

## PANAMA CANAL LOCKS

By E. H. Jacobs and H. M. Stevens

Switchboard Engineering Department, General Electric Company

On the switchboards described in this article, the thorough insulation of all live parts was made a special feature, in accordance with specifications issued by the Canal Commission. The busbars are located in fireproof compartments, the connections passing through porcelain bushings in the walls of these compartments, and all conductors insulated. The oil switches and disconnecting switches are in a measure combined, and the outside contacts surrounded by an insulating shield. An interlock is provided to prevent the closing or opening of the disconnecting switches when the oil switches are closed. Non-corrosive metal was used for all moving parts, and special insulation for the solenoid and trip coils, owing to the climatic conditions on the Isthmus.—Editor.

The Isthmian Canal Commission specifications covering the high-tension apparatus require that safety to life be considered of paramount importance. The insulation of all live parts was considered advisable and the arrangement used to accomplish this purpose is novel and also of especial interest, in view of the general tendency to more thoroughly eliminate the possibility of station attendants coming in contact with the current-carrying parts of switching apparatus and connections.

The busbars are of solid copper rod and are placed in fireproof compartments. See Fig. 2. The connections to the busses are also of solid copper rod and are of sizes such as will make a very rigid construction. These rods pass through porcelain bushings, cemented into the bus compartment wall, and are threaded into terminals which are clamped to the bus.

All high-tension leads are thoroughly insulated after they are installed. For the oil switches and air-break disconnecting switches, an arrangement was designed which allows the live parts at these points to be completely covered. Fig. 1 shows the arrangement for the 2300-volt hand-operated oil switches and disconnecting switches.

A rigid pipe framework supports vertical metal guides which carry the oil-switch operating mechanism and a slate base, the latter forming a section of the switchboard panel. A lever and toggle mechanism is provided, by means of which the oil switch and all other parts carried on the guides may be raised or lowered. Above the oil switch is a stationary base, mounted on the pipe framework, which carries the disconnecting-switch studs. These are mounted in porcelain insulators of the same design as those used in the oil switch and are arranged to be clamped to a metal supporting base. The disconnecting-switch studs are similar in design to the oil-switch studs, i.e., the high-tension leads are connected to the tops of the disconnecting-switch studs and the bottom

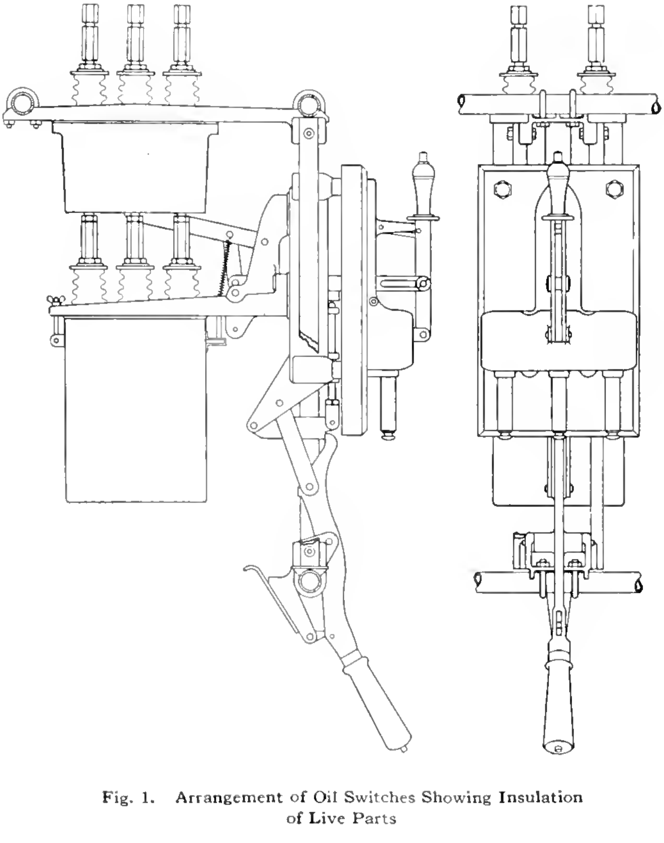

Fig. 1. Arrangement of Oil Switches Showing Insulation of Live Parts

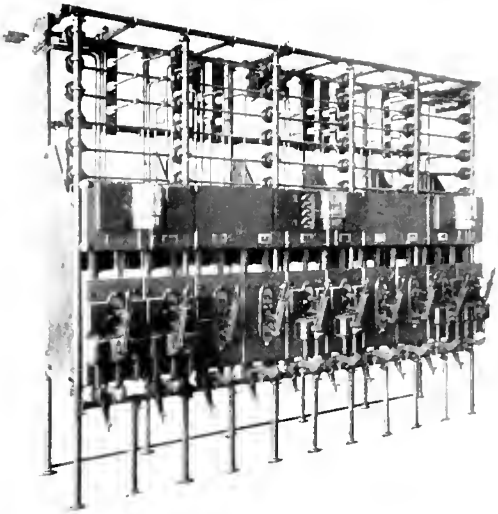

Fig. 3. 2300-Volt Transformer Switchboard for Panama Canal Locks, Showing Oil Switch Disconnecting Switches and Oil Switch Panels

of each stud is equipped with a flared finger contact. On the top of each oil-switch stud is mounted a short wedge-shaped contact blade. When the oil switch is raised, these blades engage the flared contacts on the bottom of the disconnecting-switch studs which, in the closed position, form extensions of the oil-switch studs. Moulded insulating shields completely surround each disconnecting switch contact, except at the bottom. At this point, the shields extend so far below the contact fingers that these are sufficiently insulated to prevent accidental contact, whether the disconnecting switch is open or closed. After being installed, all live parts, not covered by moulded shields or porcelain insulators, are thoroughly taped so that, with the oil switch raised and the disconnecting switch closed, all live metal parts are completely protected. When the oil switch is lowered, contact is broken at each disconnecting-switch stud, so that the oil switch is completely isolated from the circuit. The mechanism for raising and lowering the oil switch consists of a lever and toggle joint, the toggle being just over-center when the oil switch is in the raised position. This arrangement gives sufficient power to force the disconnecting switch contacts together, and always raises the switch to a fixed height, at which point it is latched. An interlock is provided which prevents the oil switch from being either raised or lowered unless the oil-switch contacts are open. This is necessary to guard against the circuit being closed or opened by the disconnecting-switch contacts. An interlock is also used in some instances to make two single-throw switches into a double-throw switch, and to prevent both switches being closed at the same time. Fig. 3 shows the front of a bank of panels equipped with these switches, and Fig. 4 shows a back view of the same arrangement.

For remote-control solenoid-operated switches, the same form of disconnecting switches are used; but the solenoid for operating the switches is mounted rigidly on a concrete-cell structure, and the connecting mechanism to the oil switch is provided with a vertical slotted link, which allows the oil switch to be raised and lowered by hand

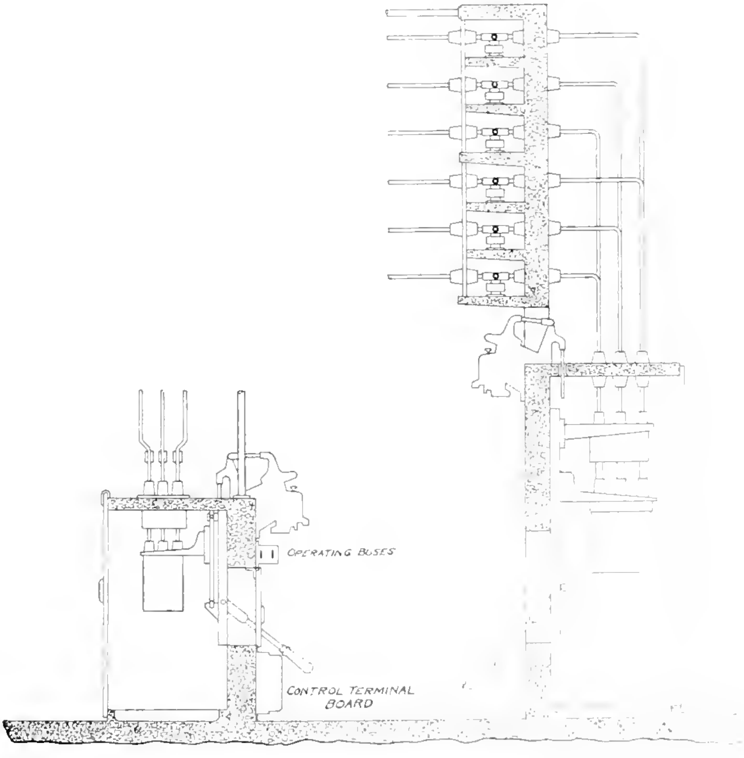

Fig. 2. Bus Compartments, Connections and Oil Switch Arrangement, 2300 Volts

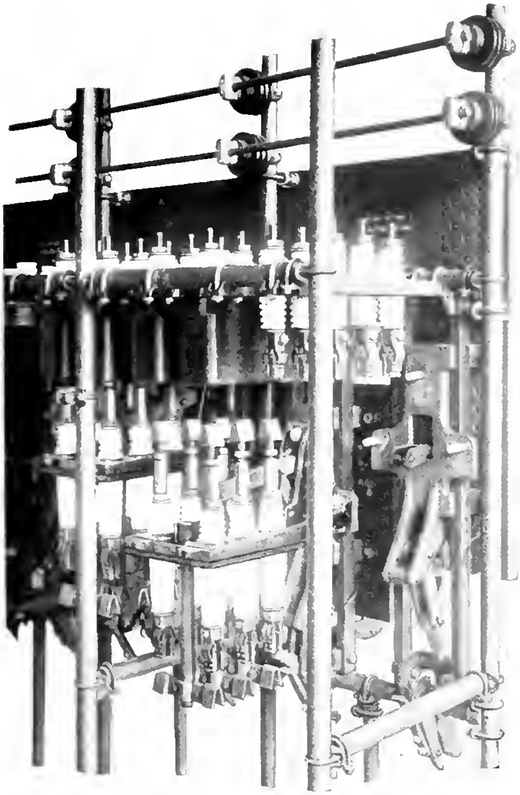

Fig. 4. Back View of Fig. 3

without being disconnected from the solenoid mechanism. A mechanical interlock is also arranged to prevent the raising or lowering of the oil switch while in the closed position. Fig. 5 shows a solenoid-operated switch with the switch in the lowered position. Fig. 6 shows the switch in the raised position, with one of the insulating shields removed from the disconnecting-switch contacts. The disconnecting device for the cell-mounted oil switches is, in the case of the smaller type oil switches, arranged as a part of the cell top, the disconnecting being done in the cell and the disconnecting switch insulators acting in the capacity of bushings through the cell top. The disconnecting device for the larger type cell-mounted oil switches is supported on a metal frame, similar in design to the top frame of the oil switch, and the whole is entirely enclosed in the switch cell, additional bushings being used in the cell top. In each case the oil switches are raised and lowered by means of a handle extending through the back of the cell. It may also be of interest to note that the oil-switch solenoid-control bus is mounted in a small closed compartment on the back wall of the switch cell, and that the leads from the bus to the switchboard and to the solenoids are also entirely enclosed.

Owing to the climatic conditions on the Isthmus, it was necessary to use non-corrosive metal for the moving parts of the operating mechanisms and special insulation for the solenoid and trip coils.

# SWITCHBOARDS AND DISTRIBUTION SYSTEM FOR THE PANAMA CANAL

By S. W. Mauger and Emil Bern

Switchboard Engineering Department, General Electric Company

For the generation and distribution of power for operating and lighting the Panama Canal, there have been erected two power stations and four substations. The power stations, one of which is a steam-electric plant (now held in reserve) and the other a hydro-electric plant, are located respectively at Miraflores and Gatun, while the substations are located at Cristobal, Gatun, Miraflores and Balboa. Alternating current is generated at 2200 volts and transformed at the Gatun substation to 44,000 volts and transmitted to the other substations, where it is re-transformed to lower potentials for local use. Wiring diagrams are included in the article which show the general system of transmission and distribution, and the arrangement of the transformers in the lock walls that supply low voltage current to the lock motors and towing locomotives. Descriptions are also given of the more important features of construction involved in the power station switchboards and control apparatus.—Editor.

In the operation of the great locks of the Panama Canal there is involved the necessity of generating and distributing electric current. The word "operation" is used above in the broadest sense, covering the control of the motors actually operating the lock devices, the locomotives for towing the vessels through the locks, the lights for the locks and government buildings, and the motors for the various duties not directly connected with the lock operation.

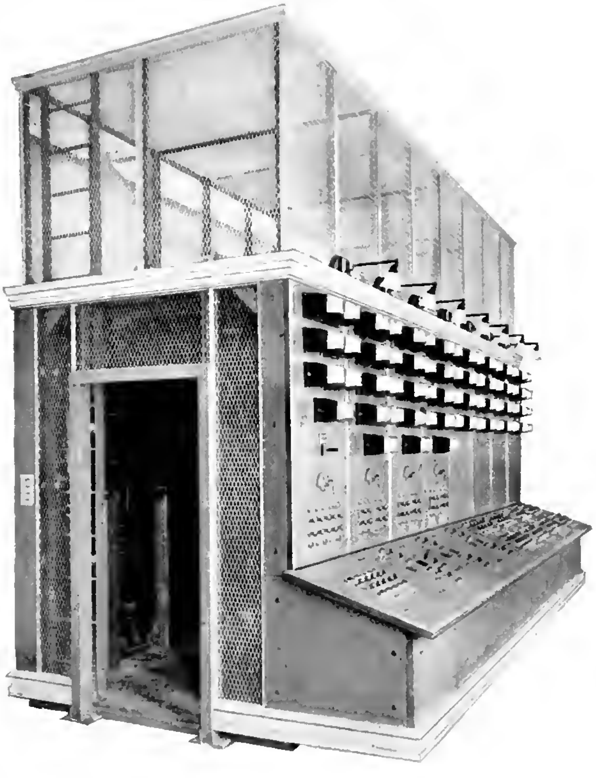

**Fig. 1. Instrument and Control Benchboard for Gatun Hydro-Electric Station, with Gallery for Field Rheostats**

Besides the usual requirements for operation, which are to some extent different from those found in the ordinary systems of power distribution, there are the severe conditions imposed by climate, the necessity of continuous service, in spite of being so far away from the manufacturer of electrical supplies, and the importance of having all parts as near "fool-proof" as possible. All this has entailed a great deal of study and care on the part of the Isthmian Canal Commission engineers in preparing the specifications, and on the part of the manufacturer in building the apparatus to meet these conditions.

The power distribution system is composed of:

1. A 2200-volt hydro-electric power plant at the Gatun dam spillway.
2. A steam-electric power plant at Miraflores erected a few years ago to supply power for construction work, but which will now be held for emergency conditions.
3. A double 44,000-volt transmission line across the Isthmus, connecting Cristobal and Balboa with the two power plants.
4. Four 44,000/2200-volt substations, stepping down at Cristobal and Balboa, and up or down at Gatun and Miraflores, depending upon which of the two plants supplies the power.
5. Thirty-six 2200 240-volt transmission stations for power, traction, and light at the Gatun, Pedro Miguel, and Miraflores locks.
6. Three 2200 220 110-volt transformer stations for the index and control boards at the three locks.
7. Similar stations to (6) at Cristobal and Balboa for coal handling plants, machine shops, and dry dock.

The Gatun hydro-electric station is located at the dam of the artificial Gatun Lake, so that the water from the wheels, together with that from the spillways, discharge into the original channel of the Chagres River. The present installation consists of three 2000-kw., 2200-volt, 25-cycle, three-phase General Electric alternators direct connected to 250 r.p.m. vertical Pelton-Francis reaction-type waterwheels provided with direct-connected exciters, as well as two induction motor-driven exciters with a generator voltage regulator. The station plans anticipate the possibility of three additional generators, should the Panama Railroad be electrified and its traffic be increased to require that amount of power. All switches for the control of machines and 2200-volt feeders are electrically operated (including rheostats, exciters, and field switches) by a storage battery, which also provides emergency lighting for the station through automatic transfer switches in case of failure of the alternating current lighting source.

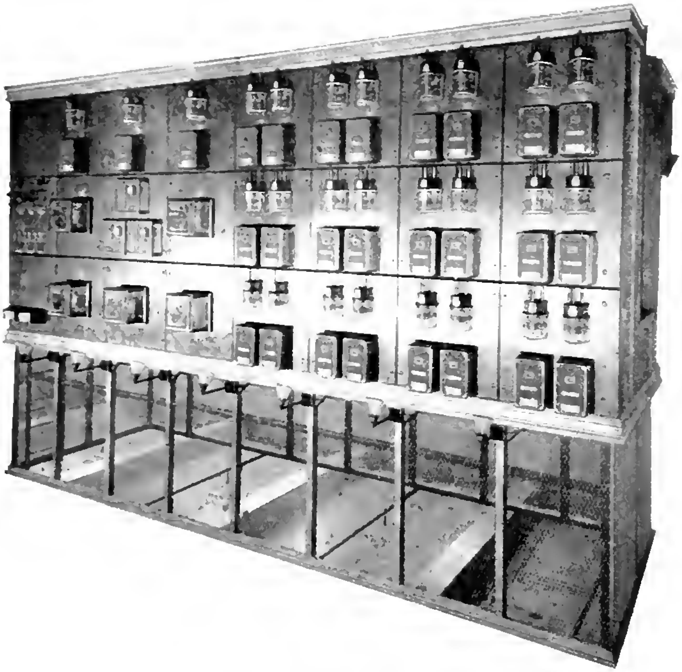

Fig 2. Meter and Relay Panels of Benchboard for Gatun Hydro-Electric Station

The system of connection is a double bus, double-switch scheme, with provision for completely disconnecting either oil switch for cleaning or repair without interrupting the circuit. The generator and feeder oil switches are all solenoid-operated and installed in concrete cells, above which are the concrete compartments for the two sets of busses. The busses and connections consist of copper rods firmly supported, which, after assembling, are covered by several layers of varnished cambric and asbestos tape. The bus compartments as well as all the oil-switch cells are enclosed by asbestos doors, and in a similar manner all current and potential transformers are protected.

The instrument and control board, shown in Figs. 1 and 2, is built of natural black slate, as are all the switchboards for this power system. It is totally enclosed by means of grille work, with doors at each end; a metal moulding surrounding the structure at the top and bottom giving a massive, yet artistic appearance to the whole. A novel feature of this construction is the gallery provided above the board proper for the electrically operated generator and exciter rheostats. This gallery is enclosed by grille work, and is accessible by means of a ladder inside the switchboard structure. On and above the bench are placed the control and instrument equipments requiring the attention of the operator, while the rear panels contain the relays, watthour meters, curve-drawing instruments, and the control battery equipment, including 'the automatic transfer switches for emergency lighting. Testing links are provided on the rear side of the panels so that connections can easily be made inside the board for testing the instruments, meters, and relays.

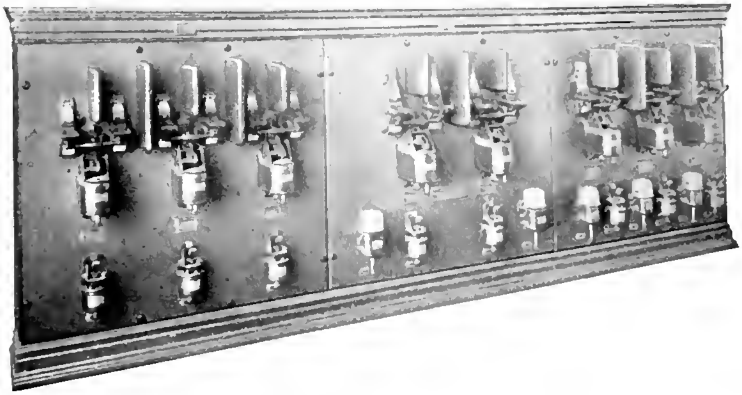

Fig. 3. 125-Volt Exciter and Field Switchboard for Gatun Hydro-Electric Station

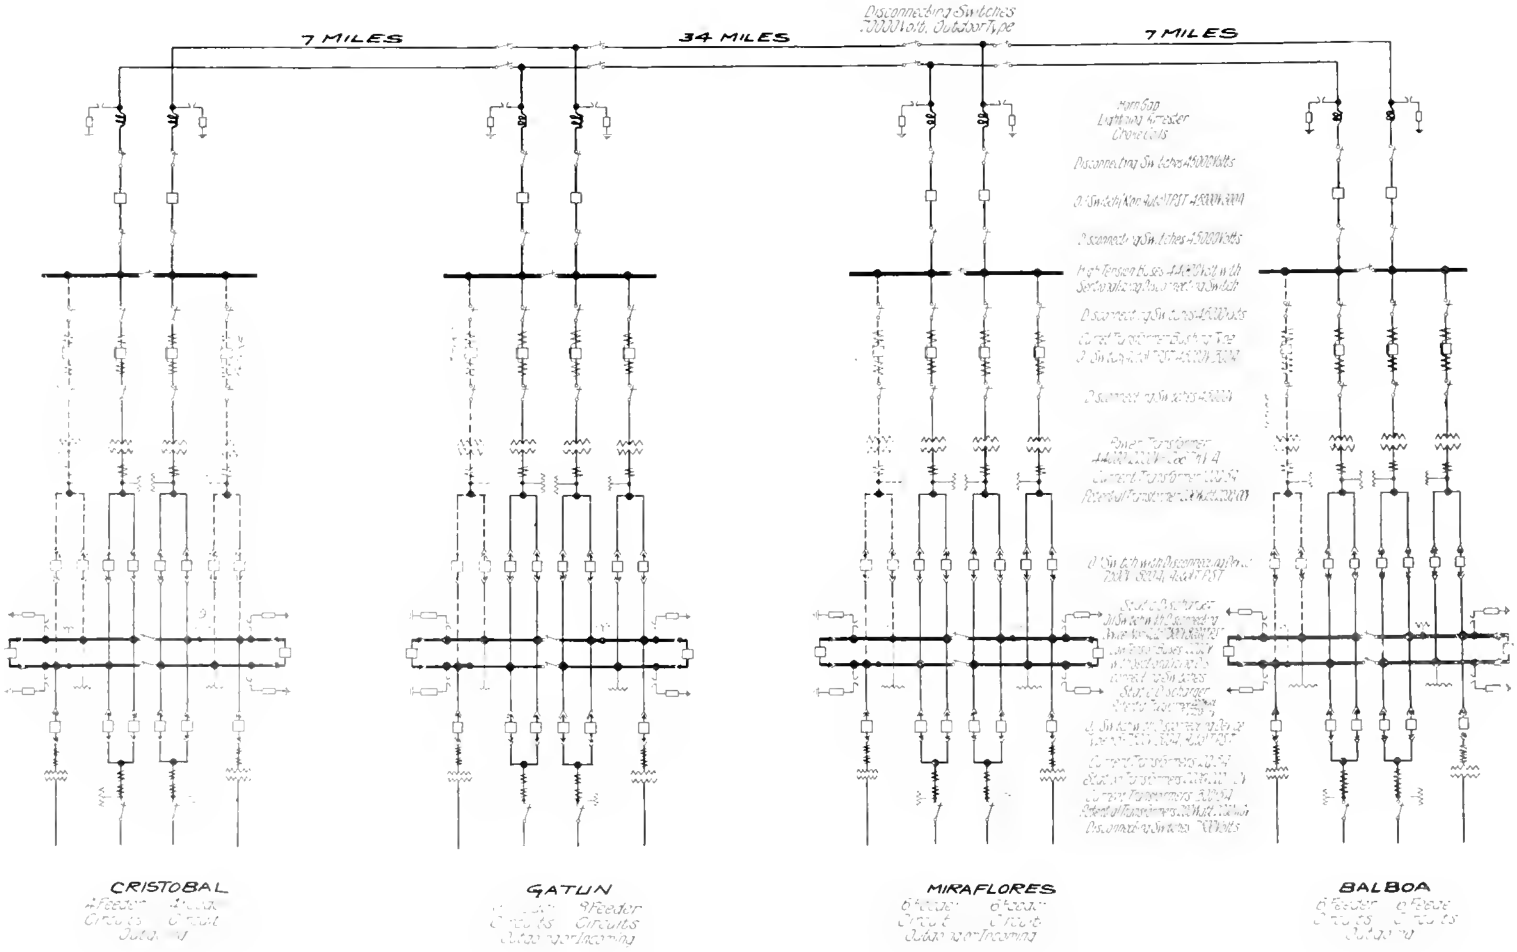

Fig. 4. Single Line Diagram of the Four Substations with High Tension Transmission Line Across the Isthmus

The field switches for the generators and the circuit breakers for the exciters are electrically operated and are mounted on a separate board, shown in Fig. 3. This eliminates the exciter busses and the main leads from the switchboard, but still leaves the control of the exciter equipment in the hands of the operator at the bench.

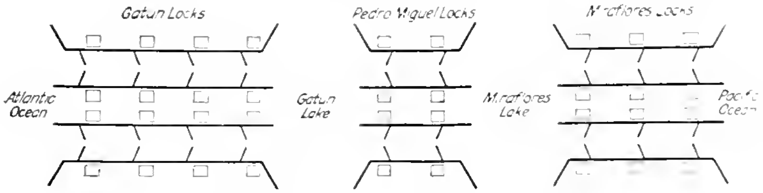

**Fig. 5.** Location of the Thirty-Six 2200 240 Volt Transformer Stations in the Concrete Walls of the Different Locks. For Simplicity the Main Gates only are Indicated

The 2200-volt feeders from this station connect with the incoming feeders in the Gatun substation, and thereby feed the whole transmission system as indicated by Fig. 4, which is a single-line diagram of the four substations with transformers and duplicate 44,000-volt transmission lines across the Isthmus.

These two three-phase transmission lines consist of No. 00 copper cables with ground conductors of the same size and material, all supported by steel towers placed on both sides of the relocated Panama Railroad. The duplicate steel towers on each side of the railroad are tied together by skeleton steel bridges, some twenty-four feet above the tracks, from which catenary trolleys may easily be suspended should the railroad be electrified.

The four substations are almost identical in size and equipment, although the number of 2200-volt feeders is somewhat different, as noted in Fig. 4. The Cristobal and Balboa stations have only outgoing feeders, as they are distributing stations for power to coal handling plants, dry docks, machine shops, etc., where the current is again transformed from 2200 volts to the most suitable voltage for the local conditions. The Gatun and Miraflores stations both receive and distribute 2200-volt current. As already stated, the Gatun substation normally feeds the entire transmission system from the hydro-electric plant; and from the 2200-volt busses in this substation the current for operating the Gatun locks is also distributed. The Miraflores substation is similarly arranged in order that it may, under emergency conditions, feed the transmission system from the

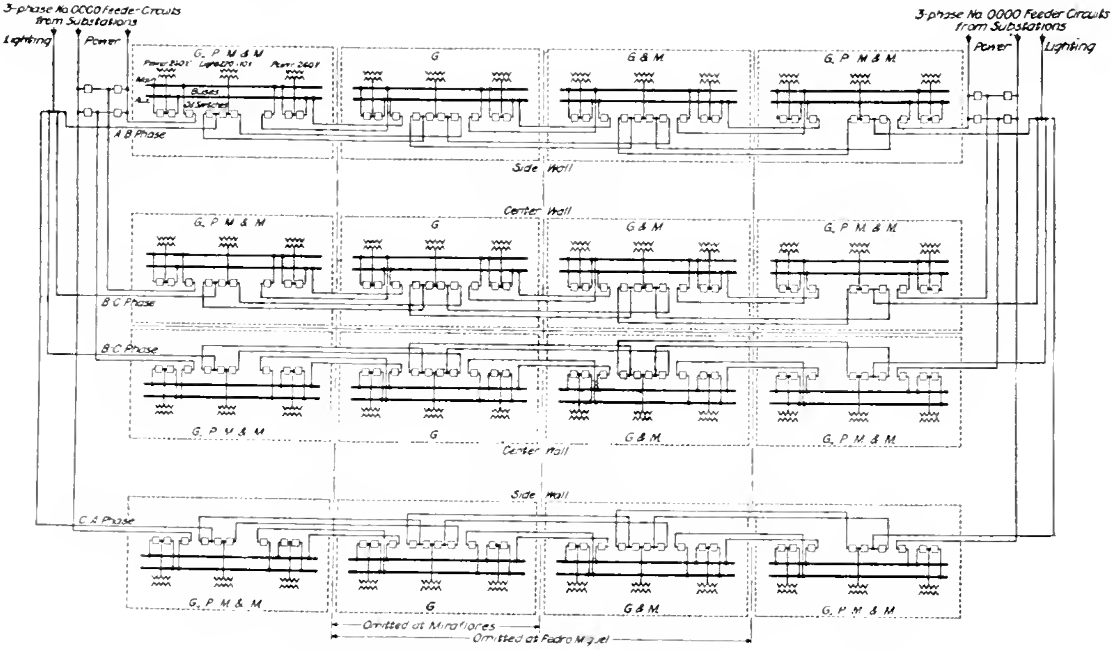

Fig. 6. Single Line Diagram of 2200-Volt Connections for the Thirty-Six 2200/240 Volt Transformer Stations. G indicates stations at Gatun Locks, PM at Pedro Miguel, and M at Miraflores

steam-electric plant, and also supply the current for operating the Miraflores and Pedro Miguel locks.

Each of the four stations is laid out to control four three-phase, 2667 kv-a., 44,000/2200-volt, self-cooled, radiator type, step-up or step-down transformers; all of these will, however, not be installed at present. There are also provided duplicate three-phase 35 kw., 2200/220/110-volt transformers for lighting, auxiliary power, and mercury rectifier for the control battery. The double-bus, double-switch system with disconnecting devices for the oil switches is used on the 2200-volt side; and, with the addition of bus-tie and bus-section switches, the flexibility of a ring bus has been obtained. To each section of the bus is connected a three-phase aluminum cell static discharger, because of the lead-covered cable forming part of the distributing system. The 44,000-volt lines are protected by aluminum cell lightning arresters and choke coils. All oil switches are solenoid-operated; those on the 2200-volt circuits being interchangeable with and arranged in concrete cells in a manner similar to the switches in the hydro-electric station. The high-tension switches on the transformers and line circuits are of the sliding-wedge, tank type, and all 44,000-volt busses and connections consist of copper tubing suspended from the station steel work.

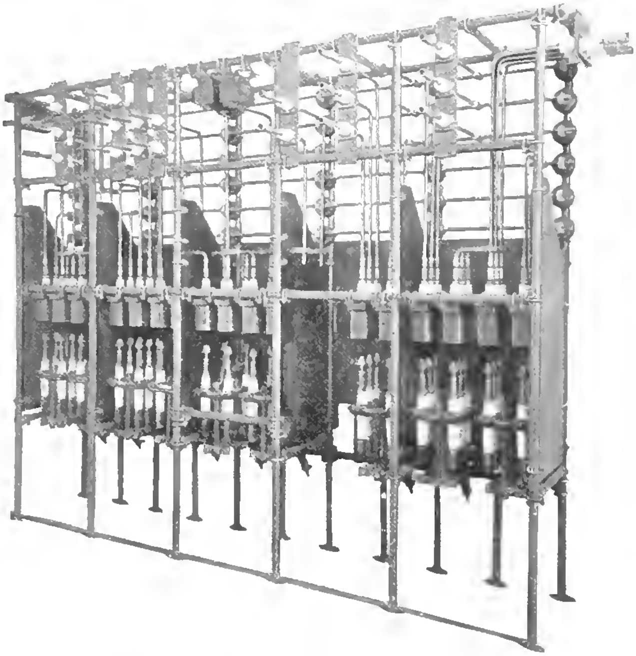

Fig. 8. Rear View of 2200-Volt Transformer Switchboard. Disconnecting devices open and oil switch cans removed

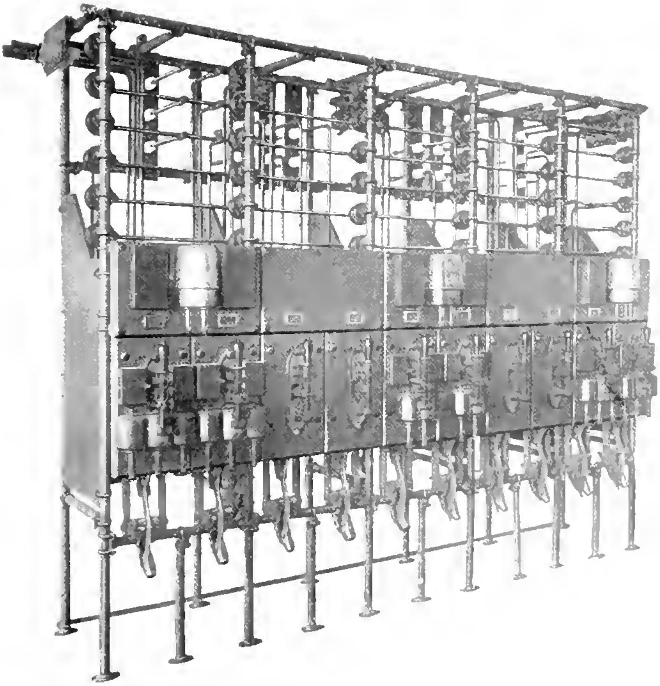

Fig. 7. One of the 2200-Volt Transformer Switchboards for the Locks. Elevated floor and grille work not shown

The switchboards for these substations are of the vertical type, consisting of three-section panels 24 in. wide. The control apparatus and mimic connections are symmetrically arranged on the middle section of the panels. A plain metal moulding finishes the top and bottom, as on the benchboard, Fig. 1. The rear of the board is enclosed by means of grille work, with doors at each end.

The motors for the lock machinery and towing locomotives require about 240-volt, three-phase current. On account of the great distances and the comparatively low potential, it is necessary to transform this current from the 2200-volt system in the immediate vicinity where it is to be used; therefore, a number of transformer stations are arranged in the concrete walls of the different locks approximately as shown in Fig. 5. Each of these stations contain duplicate 200 kw., three-phase, 2200/240-volt transformers for power; and one 25 kw., single-phase, 2200/220/110-volt transformer for lighting. Even here the double-bus, double-switch system is used, as shown in Fig. 6, which represents a single line diagram of the 2200-volt connections for the thirty-six transformer stations at the three locks. Without going into superfluous duplication, the Commission's engineers have evidently looked far into emergency conditions in planning the most flexible system on which testing, cleaning, and repairs can be performed without interruption of service. These transformer stations, while normally fed from the 2200-volt busses in the 14,000/2200-volt substations, can also be operated from the power plants; the ones at Gatun locks from the Gatun hydro-electric station, and the ones at Miraflores and Pedro Miguel locks from the Miraflores emergency steam plant. On account of the limited space for these stations in the concrete walls, the switchboards had, of course, to be very compact. Each station contains a high-tension and a low-tension board facing each other. Figs. 7 and 8 show front and back views of a 2200-volt switchboard as assembled at the factory with busses and connections in place. After installation the busses and connections, which consist of copper rods, are wrapped with varnished cambric and asbestos tape. The oil switches used on the switchboard illustrated in Figs. 7 and 8 are shown in Fig. 8 in open position, and disconnected from their circuits. Mechanical interlocks are provided, so that each set of two switches acts as a double-throw switch on the two sets of busses to which it is connected. Asbestos barriers are also installed between the different circuits as a safety precaution when working on a switch adjacent to a live circuit.

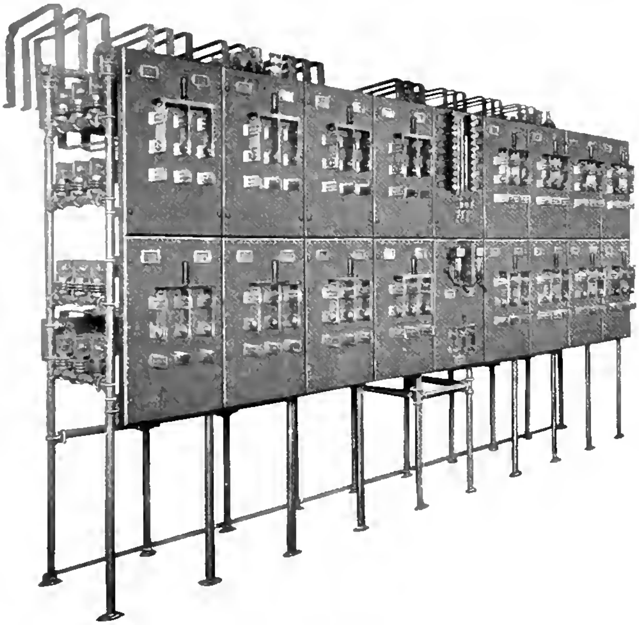

Fig. 9. A Low Tension Switchboard for Power, Traction and Light. Elevated floor and grille work not shown

The low-tension boards, one of which is illustrated in Fig. 9, are also equipped with duplicate sets of busses connected to the 240-volt secondaries of the two power transformers. By means of the triple-pole, double-throw lever switches any of the several power and track feeders can be connected to either transformer. From the hinge studs of the lever switches, the feeder circuits pass through link fuses mounted on slate bases back

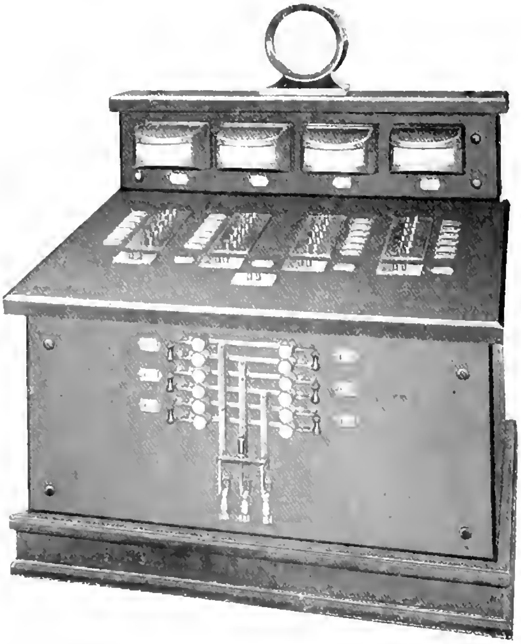

Fig. 10. Control Board for Exterior Lighting of Locks. Installed in the central control station at each lock

of the busses; and from the fuses, copper connections are made to the cable bells in which terminate the lead covered cables leading to the motors. The cable bells for the circuits connected to the lower row of switches are placed below the fuse bases, while those for the upper row are arranged on the wall just back of the board; and to these the copper connections run overhead, as shown in the upper part of the illustration. The center panel in this board is for lighting, and connects to the 220/110-volt three-wire secondary of the single-phase transformer. On this panel are also mounted two double-pole hand or electrically operated switches for the exterior lighting at the locks. For operating these switches in the several transformer stations, there is installed in the central control station at each of the three locks a small benchboard of the type shown in Fig. 10. The small control switches on this benchboard operate these lighting switches, either singly or in groups. The four ammeters at the top of the boards indicate the current in the four 2200-volt power feeders which supply each set of locks, as indicated in Fig. 6.

# NOTES ON PRODUCTION OF THE PANAMA CANAL SWITCHBOARDS

By W. B. Connolly

Switchboard Department, General Electric Company

This, the concluding contribution to our group of Panama articles, deals with some of the special features met with in this undertaking. Much of this special work was necessitated by the climatic conditions in the Canal Zone. Some of the special precautions that had to be taken against corrosion of metal parts and against the deterioration of insulation are cited. The article is concluded with a list of the quantities of the various materials used.—Editor.

As there were so many conditions peculiar to the Panama work which had to be followed throughout, it will be of interest to enumerate some of the most important. For instance, all small metal parts had to be non-corrosive, and were either made of copper, brass, bronze, Monel metal, or of sherardized iron or steel. All iron or steel parts had to be brush-painted with two coats of red lead and one coat of "egg shell" paint. No bolts, tie rods, studs or other threaded parts could be put through the sherardizing process without first being "undercut," to make allowance for the deposits. As far as possible, everything had to be moisture-proof, which meant that all solenoid, relay, circuit breaker, current transformer, and other coils had to be specially impregnated with non-hygroscopic compounds. Mica was largely used instead of fiber, and in many instances, such as potential and current transformer covers, cell doors, relay terminal blocks and barriers, cabinets, etc., asbestos lumber, specially treated, was used.

In the construction of the oil switches, disconnecting devices, operating levers, valve operating mechanisms, transmitters and indicators—such bearing surfaces as would have been in iron or steel were brass bushed. Bearing pins were made of Tobin bronze. Wherever possible, springs were made up of phosphor bronze. Small moulded parts were boiled in paraffine. Iron and steel parts, too long for sherardizing, such as tie rods, rolled metal sections, etc., were copper plated.

All gears, drums and idlers were cut from brass or aluminum. Structural steel members of frameworks, too cumbersome for non-corrosive treatment, were thoroughly "red-leaded."

Over forty of the fifty-eight thousand feet of copper rod and bar was machine bent and formed, insuring perfect uniformity of multiple parts. Instrument lead covers were made up of a special rawhide fiber, saturated with an insulating varnish.

Perfect alignment of all parts on the three lock control boards was absolutely imperative. The import of this condition can better be realized when it is recalled that in order to "condense" the boards to the Commission's requirements, certain clearances in and about the network of cross levers, shafts, control switches, motors, gears, etc., had been estimated down to three-sixteenths of an inch. The Commission wanted the Gatun board to be about 65 ft. whereas the permissible layout showed 81 ft. To settle this point satisfactorily with the canal engineers, it became necessary to make a full scale top view drawing, which was so large (81 ft.) that it was mounted on two rollers. To insure the unusual alignment necessary, all component frames were drilled, machined, hot-riveted to gauge.

The degree of accuracy called for in the government specifications was so exacting that much of the work on the position indexes and transmitters had to be done with watchmakers' precision. To meet these and other rigid requirements of interchangeability, necessitated the making of extremely accurate jigs, tools and templates.

It is interesting to note that some seventeen hundred and fifty drawings were made. This means about nine thousand detail part numbers, many of which again subdivide, totalling to something over twenty-two thousand individual parts entering in various quantities into the work. Up to November 1, 1913, seventy-three carloads of switchboard material had been shipped to Panama. The following list of approximate quantities will give some idea of the extent of the undertaking.

| | |
|---|---|
| Special slate bases | 1,300 |
| Small castings | 160,000 |
| Screw machine parts | 1,200,000 |
| Copper rod and bar | ft. 58,000 |
| Asbestos lumber | sq. ft. 9,000 |
| New patterns | 650 |
| New jigs, templates, tools, etc. | 625 |
| Porcelain parts | 18,000 |
| Special bus supports | 6,800 |
| Gal. pipe (framework) | ft. 21,000 |
| Special gears | 2,300 |
| Special indicator motors | 730 |
| Special instruments | 642 |
| Miscellaneous sherardized pieces | 300,000 |
| Cases for boxing | 4,150 |

# POWER FROM MERCURY VAPOR

By W. L. R. Emmet

Consulting Engineer, General Electric Company

The author states the general formula for obtaining the theoretical limits of efficiency in any thermodynamic process, and then cites the limits existing in actual commercial practice in the case of the steam engine, continuing to show the higher limits which can be obtained by the use of mercury vapor. Some important data concerning mercury vapor are given, and this is followed by the methods applied in the process of deriving power from mercury vapor. Both the advantages and disadvantages of the process are discussed. The apparatus used for generating power from mercury vapor will be described and illustrated in our February issue.
—Editor.

The theoretical limit of efficiency in a thermo-dynamic process is the ratio of the temperature range embraced by the process to the maximum absolute temperature used, $\frac{T-T_1}{T}$. In all processes available for commercial power development, the lower limit is fixed by the temperature of the cooling water available, and is therefore not susceptible of variation. The possible upper limit is the temperature which can be produced by our fuel when burned with air, which in practice is about 2700 deg. F.

The purpose of the process here described is to utilize some of the energy available in ranges above that which can conveniently be utilized with steam. The theoretical efficiency of steam processes can be increased by using higher pressures, but since with rise of temperature the increase of pressure is very rapid, and since the steam turbine has limitations in the efficient use of high pressure, prospects of gain in this direction are not very attractive.

Mercury boils at 677 deg. F. at atmospheric pressure and condenses in a 28 in. vacuum at 457 deg. F. It is therefore well adapted at least by pressure and temperature conditions for use in a temperature cycle above that now used by steam. Its use to greatly increase the temperature range available and so to increase efficiency is the object of the development here described.

Before going further, the writer desires to explain that the broad principle involved in this process was suggested to him by Mr. Chas. S. Bradley, who proposed and patented a process in which he intended to use certain other substances of high boiling point and relatively high vapor density. Consideration of the possibilities suggested by Mr. Bradley led the writer to study the characteristics of mercury, and from this study and a long course of experimenting the plans of procedure here shown and explained have been evolved. A set of apparatus suited to the production of about 100 h.p. has been nearly completed and it is hoped that experiments on a scale and of a character approaching commercial conditions may be made within a month or two. Anything so completely novel and so essentially complicated is naturally liable to delays, so that the prospect of successful tests cannot be confidently predicted. Since the process has been talked about and since a good deal of interest has been expressed, the writer has thought best to record his expectations and to make explanation of the plans which have so far been formed.

In studying the thermo-dynamic possibilities of a substance like mercury, we proceed exactly as we do in the case of steam, and for the sake of convenience it may be well to give here some data relating to the subject.

Boiling point of mercury at atmospheric pressure, 677 deg. F. (358 deg. C.).

Boiling point of mercury at 28 in. vacuum, 457 deg. F. (236 deg. C.).

Vapor density is in the ratio of atomic weight and absolute temperature; as compared with water it is therefore 6.56 times as great at the boiling point and 6.8 times as great at 28 in. vacuum.

Specific heat of mercury liquid, 0.0373.

Specific heat of mercury gas (constant pressure), 0.0248.

(According to Kurbatoff; Z. Phys. Chem. 43, 104, 1903.)

### Latent Heat of Vaporization

At 25 lb. abs. $r = 117$ B.t.u.
At 15 lb. abs. $r = 118$ B.t.u.
At 28 in. vacuum, $r = 121$ B.t.u.
At 29 in. vacuum $r = 121.5$ B.t.u.

(Calculated from formulæ by Kurbatoff.)

The boiling point of mercury at various pressures is shown by an accompanying curve, and curves are also given showing the energy theoretically available from mercury vapor within various pressure ranges. These curves are calculated from Rankine's formula:

$$E = 778\left(Q_1 - Q_2\left[1 + \log.\frac{Q_1}{Q_2}\right] + \frac{x_1 r_1}{Q_1}[Q_1 - Q_2]\right)$$

$E$ = energy in ft. lbs.
$Q$ and $Q$ = heat of liquid.
$X$ = dryness factor.
$r$ = latent heat.

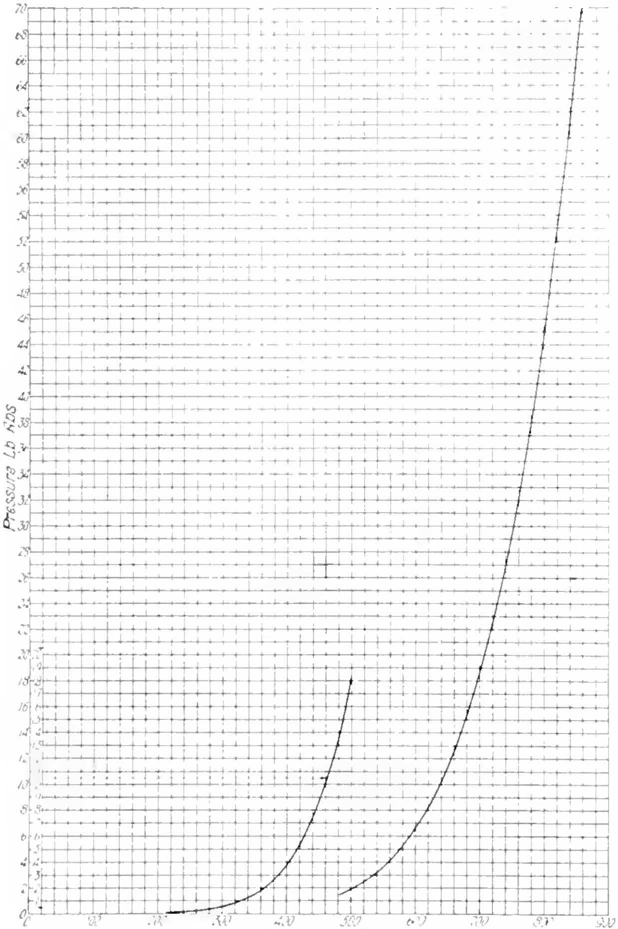

Fig. 1. Curve showing Boiling Point of Mercury at Various Pressures

The data above stated may not have been as accurately determined as that which is available for steam calculations, but its substantial accuracy is indicated by the fact that in our experiments the measured flow of vapor through nozzles has closely checked the calculations.

The method applied in this process may be stated briefly as follows: Mercury is vaporized in a boiler heated by a furnace of ordinary type. From this boiler, it passes at a pressure near or not much above the atmosphere, to the nozzles of a turbine which drives a generator or other utilizer of power. From this turbine it passes to a condensing boiler where it is condensed on the outer surface of tubes which contain water, and this water is vaporized by the heat delivered, and the steam produced is used to drive other turbines or for any other purpose. This condensing boiler is preferably placed at a level above the mercury boiler, so that the condensed liquid will run back into the mercury boiler by gravity without the aid of a pump. Since the mercury vapor is much hotter than the steam, the gases will normally leave the mercury boiler at higher temperatures than they have in leaving a steam boiler. To utilize this excess heat, in the gases, it is proposed to convey them, first, after leaving the mercury boiler through a heater which raises the returning liquid near the boiling point, second, through a superheater which superheats the steam delivered by the condensing boiler, and third, through an economizer which heats the feed water for the condensing boiler and so reduces the gases to the lowest practicable flue temperature.

By careful study and experimental development, which will be explained later, means have been devised for reducing the amount of mercury used, for effectively preventing its loss or dissipation, and for immediately detecting any failure in such prevention.

The disadvantages of mercury for such a process are: First; that it is very expensive, its cost being about 60 cents per lb. Second; that it is poisonous and is capable of pervading the atmosphere in a very finely divided state in the neighborhood of places where the vapor can escape. Third; there are certain difficulties in confining both the vapor and the liquid, although these, with proper methods, are not serious.

Mercury's advantages as a thermo-dynamic fluid for the purpose desired are many. First; its boiling points at desired pressures are convenient. Second; its high specific gravity makes possible the use of gravity feed, sealing of valve stems, etc., by gravity and centrifugal sealing of turbine packings. Third; at the temperatures used it is completely neutral to air, water, iron, and such organic substances as it may come in contact with. Fourth; it carries nothing in solution which can adhere to or affect heating surfaces; consequently the interior of boiler is always perfectly clean. Fifth; its vapor density is so high that it gives a very low spouting velocity, and consequently a very simple type of turbine can be used. Sixth; it does not wet the surface of turbine blades and consequently gives apparently no erosion. It is believed that the action between the vapor with its accompanying liquid and the blade surface will conduce to a high economy in a turbine, although no positive data on this subject has yet been obtained. Seventh; its volume at convenient condensing temperatures is such that it can be used in turbines without excessive bucket heights. One of the greatest limits of design in steam turbines is the large area required for the efficient discharge of the low pressure steam. With mercury vapor, this difficulty does not exist. Eighth; delivering its heat at the temperature and in the manner which it does, the condensing boiler in which this heat is used to make steam is very small and simple as compared with a steam boiler. Steam boilers transmit an average of about 6 watts per sq. in. with an average temperature difference of about 1100 deg. F. A surface condenser transmits 18 watts per sq. in. with 20 deg. F. temperature difference. The mercury boiler is about equivalent in dimensions to a surface condenser, and since there is no high temperature involved, there will be no possibility of scaling or burning.

Thus in this process we have low pressure and a clean boiler interior at the hot end, and small and perfectly distributed temperature differences at the low temperature end of the process where steam is made. High temperature, unequal distribution of heat, and the necessity for large heating surface constitute the principal difficulties of boiler construction. All of these are overcome in this method of making steam.

In this process the mercury vapor acts automatically as a conveyor of heat from the fire to the condensing steam boiler. If, through loss of load or other reasons, the mercury turbine admission is shut off, the vapor by-passes through a safety valve provided for the purpose, so that all the heat delivered to the mercury is immediately put into the steam boiler, except the fraction which is converted into power by the turbine.

Thus the fireman in this process will maintain steam pressure just as he now does. The steam produced will be used just as it now is in existing apparatus, and the output of the mercury turbines will be simply a by-product which is additional to the power which is now obtained. Studies have indicated that if this process works out as expected, the apparatus described can, in many cases, be put into the building space now occupied by steam boilers, so that the act of changing existing steam plants to this process should retain in use most of the existing investment.

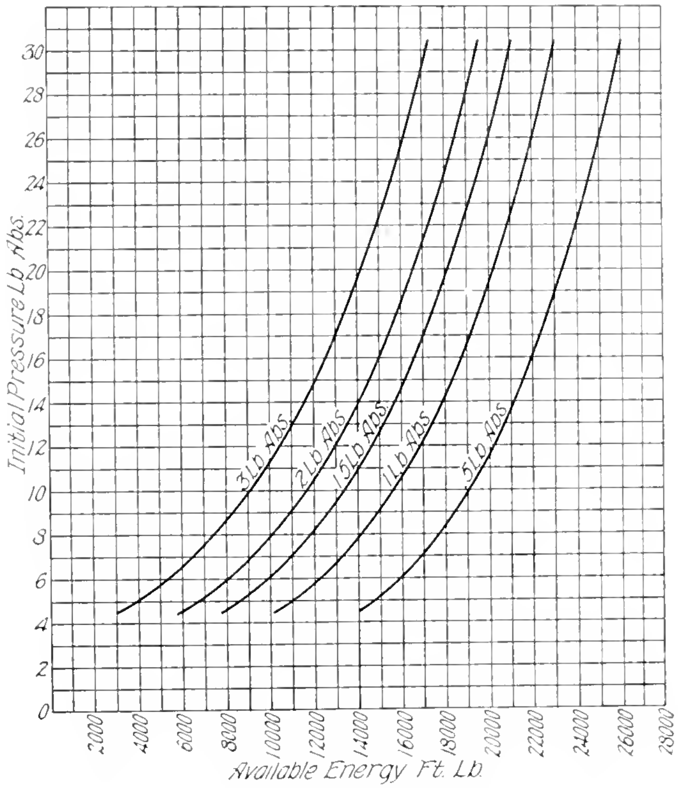

Fig. 2. **Energy Theoretically Available from Mercury Vapor within Various Pressure Ranges**

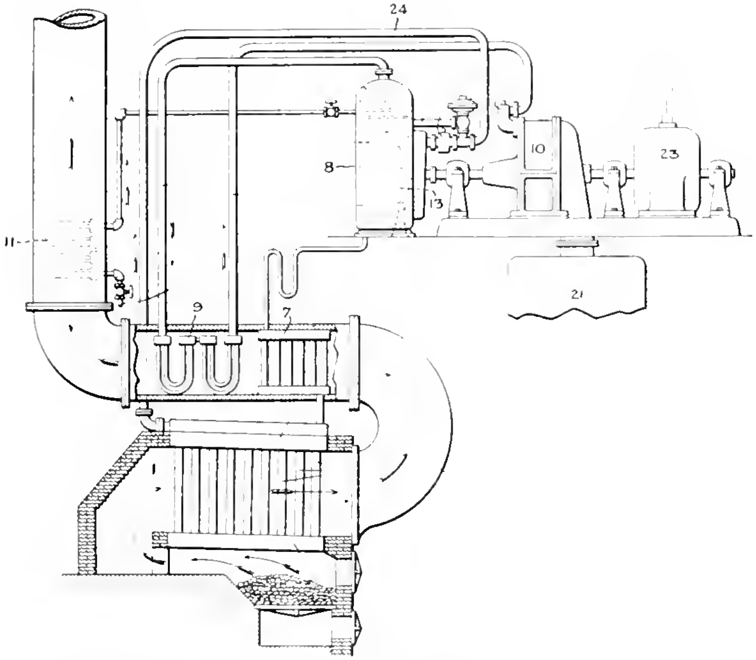
Before entering into the details of experiments or of the methods by which it is hoped to accomplish these results, it may be well to state the degrees of economy which should be accomplished if this development succeeds. Assuming heat deliveries to surfaces exposed equal to those in steam boilers under equivalent conditions of temperature difference, gas velocity, and radiation, and assuming a turbine efficiency equal to that of steam under equivalent velocity conditions, the calculation shows that in an efficient modern power station, the same amount of steam can be delivered to the turbines at the same superheat, thus giving the same turbine output, and that in addition about 66 per cent of the power so delivered can be delivered by mercury turbines, the fuel required being only about 15 per cent greater than that which would be used with the steam alone. Thus the gain in capacity of an existing station would be approximately 66 per cent and the gain of output per pound of fuel would be about 44 per cent. This calculation is based upon a mercury vapor pressure 10 lb. above the atmosphere and a vacuum of 28.5 in. at the steam turbine outlet.



| | | | |
|---|---|---|---|
| 1 | Mercury Boiler | 11 | Feed Water Economizer |
| 7 | Heater for Liquid Mercury | 13 | Mercury Turbine |
| | Condenser Boiler | 21 | Steam Turbine Condenser |
| | Superheater for Steam | | Electric Generator |
| 10 | Steam Turbine | 24 | Mercury Vapor Pipe |

Fig. 3. Diagrammatic View of Apparatus to Generate Power from Mercury Vapor

About 10 lb. of mercury would be evaporated for each pound of steam produced, the steam pressure being about 175 lb. gauge, superheat 150 deg., and the final temperature after the gas leaves economizer being about 300 deg. The vacuum in both steam and mercury turbines can be maintained by the same air pump, means being employed to separate all mercury vapor from the air in a suitable cooler. The vapor velocity would be about 1200 ft. per second, requiring only one turbine wheel

Since the mercury process can be super-imposed upon a non-condensing steam process as well as upon a condensing steam process, it is obvious that with the mercury combination the non-condensing plant can be made almost as economical as the best existing condensing plants, the percentage of output added by the mercury in such cases being greater than that which would be added by the use of condensers. It is also obvious that where the mercury process is added where steam is less economically used than in modern power stations, the gain will be relatively greater. The purpose of the process is to replace steam boilers wherever they are used and to obtain power from mercury turbines as a by-product.

Experimental data indicates that not more than $10 worth of liquid mercury per kilowatt output of mercury turbine will be required for such a process, and it is probable that with suitable arrangements, this amount can be considerably reduced. The general application of such a process would require immense quantities of mercury, but inquiry has indicated that the sources of supply are such that the largest conceivable demand for such a purpose would not permanently increase the price.

In the experimental applications of this process which have so far been made, the vapor has been produced in heating elements similar to those proposed for an actual boiler under the most severe condition of heat delivery by gas flow and radiation. The vapor has been carried from such boiler elements to a nozzle and this nozzle has been exhausted into a condenser from which the liquid was drained back into the boiler by gravity, the vacuum being maintained in the condenser by an air pump.

In these experiments, pressures and amounts of liquid condensed were measured, and these measurements show that the flow of vapor through the nozzle was in agreement with calculations from the data above stated.

In all the tests which have been made with these experimental elements, there has not been a trace of chemical action upon the mercury or steel, although air, water, oil, and various kinds of dirt have been present in considerable quantities, and although very extreme temperatures have at times been used.

Investigation of the conditions of heat transference and circulation in the production of mercury vapor has involved much labor in study and experimenting, and through this work certain data has been collected which in combination with known data concerning the action in different parts of steam boilers has been applied to the design of a boiler of considerable size which is now nearly completed. This boiler would appear to be the only part of the process which involves any difficulty, and it is hardly fair to expect that it will be in every respect satisfactory or in accordance with calculations, although the evidences in its favor seem to be very strong, and although every detail which enters into it has been the subject of successful experimenting. It is believed, however, that any difficulties which may arise can be corrected and that this process is practicable for approximately such results as have been stated. A turbine of suitable design has also been produced and a condensing boiler with all the auxiliary apparatus necessary to the trial of the process as it might be applied commercially.

# MECHANICAL REFRIGERATION

## WITH SPECIAL REFERENCE TO SMALL PLANTS

## PART II

By R. F. Massa

Manager of the General Refrigerating Department, H. W. Johns-Manville Company

Part I of this article, which appeared in the December issue, covered in a broad manner the generation of "cold," the method of calculating the necessary size of the generating machine for a given requirement, and gave a description of the common types of generating machines. The present part of the article, which takes up the utilization of the "cold" generated, explains the method of calculating, designing, and laying out drinking-water systems, refrigerators, and pipe mains. It concludes with a digest of the commercial systems of ice manufacture.—Editor.

### DRINKING WATER SYSTEMS

In a drinking-water cooling system, refrigeration must be supplied for three purposes:

First: To cool the water actually supplied to and drawn from the system.

Second: To absorb the heat flowing into the water as it circulates through the insulated mains.

Third: To overcome the friction loss of the water in the pipes.

Of these three, the heat inflow through the piping is very frequently the largest item. It follows, therefore, that the piping system should be as short as it can be made. This often results in better economy being secured by establishing more than one center for cooling and distributing the water.

It is understood, of course, that in practically all cases it is necessary to keep the water circulating in order to deliver it at satisfactory temperatures at the fountains. This involves arranging the piping system in loops. In some cases, however, the water can pass through a series of fountains and then, when it has warmed to the upper limit of palatability, a second refrigerating machine can be placed in the line to pull down the temperature again.

It is occasionally possible to arrange a system without loop circulation by simply bleeding away enough water at the dead end to keep the temperature at a satisfactory level. The cases where this arrangement can be used, however, are comparatively rare.

The information as to how to lay out a cooling system follows:

It will be necessary to determine the location of the water source, the temperature of the water supplied, and also the temperature desired at the fountains. This latter will usually be fifty to fifty-five degrees. Lower temperatures are, in general, too cool; temperatures above sixty degrees are unsatisfactory.

The location of the fountains should also be determined approximately, and some indication should be made of whatever barriers there may be to various possible piping arrangements, such as, streets, railway rights of way, etc.

The number of persons to be served at each fountain should be known approximately or assumed, and the quantity of water each person will use. This varies through comparatively wide limits. Usually, however, the amount runs from one to two gallons per person per day, the larger figure being taken from results in a large steel works. In schools, the figure will often run as low as one-half gallon per person.

A tentative lay out may now be made of the piping system, and the size of the pipe to be used may be assumed. The heat inflow through the piping system can now be calculated, assuming the insulation to be used and the approximate atmospheric temperatures.

The amount of water to be circulated through the system is determined by the rise of temperature permissible in the circuit. Having calculated the heat inflow, the quantity of water to be circulated may be determined if, say, a five-degree rise is decided upon as satisfactory.

It now becomes possible to calculate the velocity of the water and, by reference to a pipe friction table, the friction head may be calculated. If the assumed pipe sizes are such that the friction head is excessive, larger pipe must, of course, be substituted and the calculation repeated. In the same way, if a smaller size pipe would not run the friction up too high, the pipe size should be reduced on account of the reduced heat inflow that will follow.

One other consideration is of importance in determining the size of pipe. This is, the pipe should be sufficiently large that the opening or the closing of one fountain on the line will not cause an appreciable change in the pressure on any other fountain which may be running. In addition to the size of the pipe being sufficient for this purpose, it is necessary to have some storage of water in the line, either in the way of an air chamber or an elevated open tank to maintain the pressure. Storage is important also in order to take care of the variable demand which occurs in a great many cases, as, for instance, in schools at the noon hour and between classes, and at the noon hour in factories.

The selection of a proper drinking fountain is of great importance in refrigerated water systems. The preferable design, from the point of view of the refrigerating engineer, is one in which the largest portion of the water flowing is drunk. From this point of view, the so-called bubbler type, which operates continuously, is much less satisfactory than those in which a jet of water, about the size of a lead pencil, rises to a steady height upon the opening of a spring faucet. In this latter kind of fountain the larger part of the water flowing will often be drunk; whereas, in the former designs, by far the larger part of the water is wasted.

## DESIGN OF REFRIGERATORS

### Disposition of Cooling Surfaces

No attempt will be made to describe all of the many arrangements of refrigerated compartments found in service. The intention is to point out some of the more important things to be considered in determining the design of a box.

It is desirable in a refrigerator to produce not only a low temperature, but a relatively dry atmosphere. To secure a box of satisfactory dryness it is necessary to have a relatively low temperature in the refrigerant. The air which passes over the cooling surfaces is practically in a saturated condition when it leaves them. If it is to be "dry", at the temperature required in the box, it must therefore have been cooled well below the box temperature. For instance, in a box held at 35 deg. F. the brine should be run at a temperature of about 20 to 25 deg. F. It is further desirable to so locate the cooling surface that the frost in melting will pass

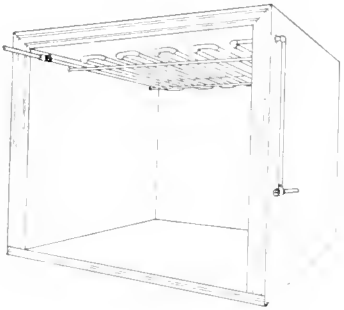

Fig. 15

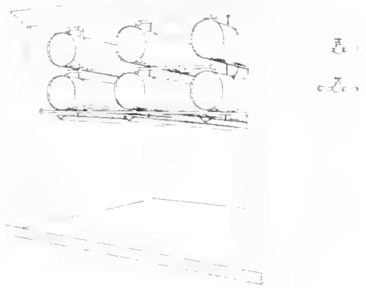

Fig 16

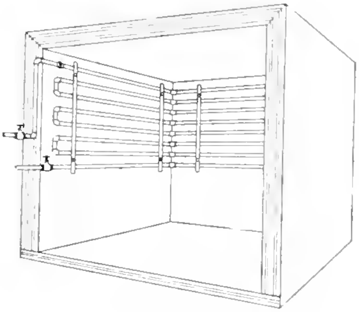

Fig. 17

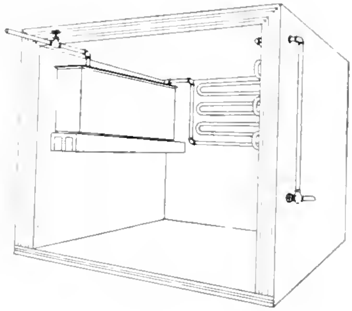

Fig. 18

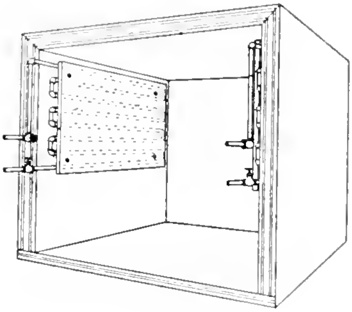

Fig. 19

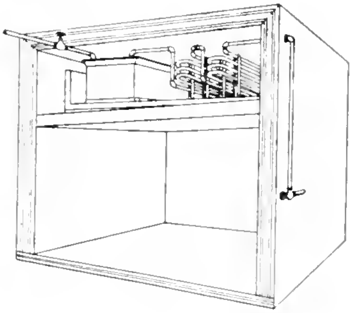

Fig. 20

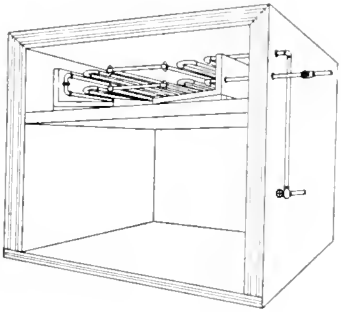

Fig. 21

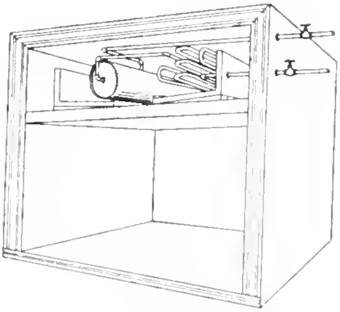

Fig. 22

Various Cooling-Pipe and Tank Arrangements in Refrigerators out of the box quickly and not remain to be re-absorbed by the air in the box.

The following arrangements of cooling surface in refrigerators are the ones commonly used. In Fig. 15 the coils are arranged overhead, but directly in the compartment to be cooled. This is one of the most efficient ways in which cooling surfaces can be arranged, so far as the cooling effect alone is concerned. It is not in general a good arrangement, however, since any frost melting from the coils drips onto the goods.

A modified form of this arrangement gives excellent results. This is illustrated in Fig. 16, in which closed cylindrical brine tanks are arranged horizontally and carried from the roof of the box. Drip from melting frost is caught in the insulated troughs shown. These troughs may be made quite narrow as all of the drip runs to the center line of the tank before it falls. It is advisable to insulate the drip troughs because they are apt to become cold enough while the box is shut that moisture will condense on them when the box is opened again, with the result of some little dripping in case they are not insulated.

The arrangement shown in Fig. 17, with the cooling surfaces on the wall, is to be preferred to the ceiling arrangement, so far as drip is concerned. It has the disadvantage that goods placed close to the wall are apt to be over-chilled, while goods near the center of the compartment are not cooled quickly enough. It also wastes floor space, because it is not practicable to pack goods close to the coils on account of possible over-chilling, also because of the liability of retarding the air circulation. The wall arrangement of cooling surfaces is, nevertheless, often the most practicable method.

Fig. 18 indicates a modified form of wall coil arrangement, where a brine storage tank is used to assist in maintaining the temperature when the machine is shut down.

A further modification is often introduced as shown in Fig. 19, in which a partition or baffle plate is used in front of the coils.

The best type of box arrangement is that embodied in the various refrigerator sections shown in Figs. 20, 21 and 22. In all of these designs the cooling surface is separated from the storage space and is so arranged as to secure an active circulation of the air over the coils and through the compartments.

In all of these designs the one point calling for the greatest care is that the air passages shall be as direct as possible and be of ample size. The force causing the air to circulate, viz., the difference in weight, due to difference in temperature and density between the column of air in the coil compartment and that in the storage compartment, is so extremely small that any slight interference is a serious matter. An extra turn in the passage or a slight reduction in the size of the passage will produce a marked effect. A good rule to follow is to make the passage as large as possible without allowing drip to reach the storage compartment. This will work out in many cases to give a ratio of one to eight or nine between the area of the passage and the floor area of the compartment, but even one to six is just that much better if it can be secured.

The matter of proportioning the size of the air passage is of much less importance where the air is circulated by fans. Forced circulation is not usual, however, except in large storage refrigerators.

It is important in arranging cooling surfaces, especially in small and frequently opened boxes, to avoid undue cooling of walls or ceilings that are exposed to currents of warm air when the door is opened. Moisture from the incoming air deposits on these surfaces, causing the offensive so-called "sweating" of the box. This is most often seen on the storage compartment side of non-insulated coil compartment floors or partitions, and also occurs on walls or ceilings where the cooling pipes are set very close to these surfaces. The obvious and effective cure is to insulate the partition between coil compartments and storage compartments, and to keep cooling surfaces well away from the walls or ceilings, e.g., 3 in. to 8 in., depending upon the temperature of the brine.

### Calculating Necessary Cooling Surface

No hard and fast rule can be given regarding the proper amount of cooling surface for compartments of various sizes, since the design and arrangement of the cooling surface and the freedom with which the air circulates over it greatly affect the amount required. As a guide, however, and where the conditions are such as to permit good circulation of the air, the following formula will give good results. It will be understood, of course, that the refrigeration required in the given room has been determined as indicated in the section on "Calculating Machine Capacities."

The cooling surface required, in square feet, per ton of refrigeration equals $\frac{4700}{T-t}$, where *T* equals the temperature desired in the compartment, and *t* equals the average temperature of the brine.

### Incidental Notes on Refrigerators

(a) *Drawers:* In restaurant kitchens and elsewhere, it is sometimes convenient to have a box fitted with a number of refrigerated drawers. Here the heat leakage is very great, due to the slides invariably being only partially closed and to the poor insulation of the drawers. Where it is at all possible to do so, it is best to arrange an insulated door to cover the entire drawer space.

(b) *Ante-Rooms:* In storage rooms of medium or large size, the air interchange caused by the opening of doors is reduced to a minimum by arranging an ante-room or entry with double doors. This arrangement permits the outer door to be closed before the door to the storage room proper is opened. Where two rooms are side by side, it is often possible to reduce the air interchange by treating the one as the ante-room of the other, having but one door open to the outside air.

(c) *Doors:* Special note should be made as to the design of doors for refrigerated rooms or boxes. There is a common idea that a refrigerator door should be beveled, but as a matter of fact no more certain means of insuring air leakage could be devised.

A perfectly fitted beveled door, if hung accurately, could perhaps be made tight in the beginning, but in service it at once begins to sag, since a refrigerator door is always heavy. It immediately becomes impossible to force it to a tight seat and continuous air leakage begins.

A refrigerator compartment door is most readily made tight by having a flat surface on the door come up against a corresponding surface on the frame, with a soft gasket of some kind between them.

There are several well-made refrigerator doors on the market at prices low enough to make it of doubtful economy to attempt the home-made article.

### Arrangement of Brine Mains

In laying out mains to carry brine from the refrigerating machine to the refrigerator, there are a few simple points which require consideration.

For the convenience of the pipe-covering man, the flow and return lines should be placed sufficiently far apart to enable him to cover each pipe without cutting the covering or else they should lie side by side so as to be covered together.

A common difficulty experienced in brine systems of refrigeration, where the cooling coils in several compartments are fed from the same main, is that when a change of adjustment is made in the valve controlling the flow of brine through one coil it upsets the adjustment of the whole system. This is due to the mains or the pump being too small or both. A similar action is observed when the opening of a faucet on a water pipe checks the flow from other open faucets on the line.

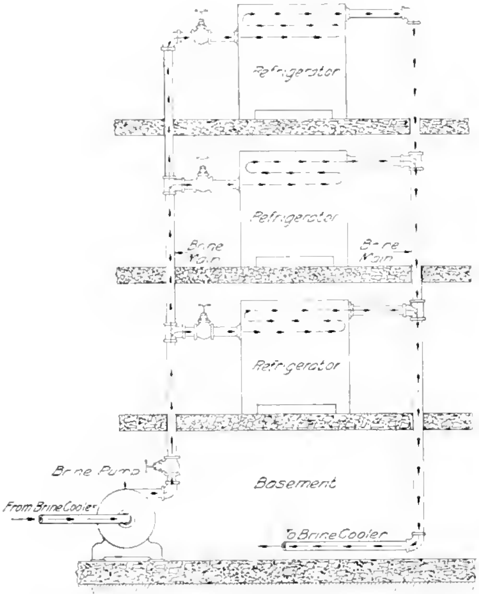

Fig. 23. A Method of Laying Out Brine Mains Which May Cause the Draining of the Top Cooling Coils

The ideal cross-sectional area of the brine mains is as nearly as possible equal to the combined cross-sectional area of all the coils which they serve at any one time.

Even with this proportion, however, it is not possible to absolutely insure that the lower coils will not rob the upper ones, or even drain them completely where the system is piped as shown in Fig. 23.

A most effective, even if somewhat expensive method of overcoming this difficulty, is by the addition of a third main, as indicated in Fig. 24. In this arrangement it is not possible for one coil to rob another to the point of draining it.

## ICE MAKING

### Physics of Ice Making

If the following physical facts are kept in mind, in considering methods of making ice, the results obtainable may be better understood or predicted.

(1) Chemically pure water will freeze solid and clear.

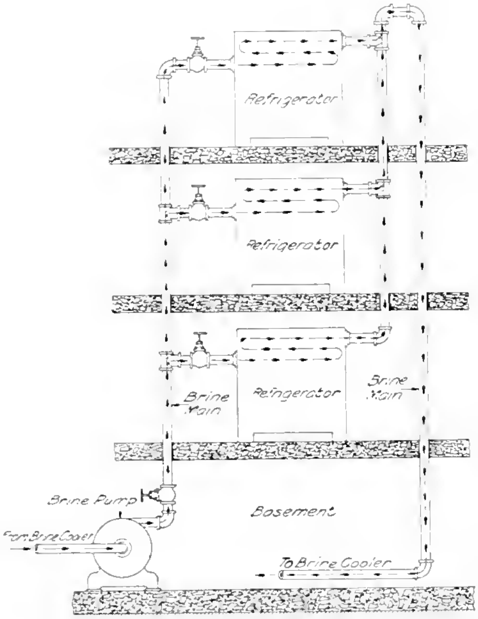

Fig. 24. A Method of Laying Out Brine Mains Designed to Prevent the Possible Draining of the Top Cooling Coils

(2) Water containing impurities in solution tends in freezing to force these impurities out of solution. The slower the process of freezing the more completely is the purification effected.

(3) Ice forming in still water sends out long slender crystals which increase in number and size, forming a mesh work that gradually becomes a solid mass.

(4) Agitation of water during freezing aids in the separation of impurities and facilitates the forming of solid, clear ice.

(5) Practically all natural waters contain more or less organic or inorganic material in solution and invariably contain air. These substances as they pass out of solution during the freezing process tend to make the ice formed opaque, those that are light tending to rise and collect near the surface and the heavier ones tending to sink.

(6) The rate of freezing of ice decreases directly with the thickness already frozen. Therefore, the time required to freeze increases in proportion to the square of the thickness to be frozen. In the formation of natural ice the freezing is from the top down and the impurities which are frozen out of solution fall. This and the motion of the water, especially in quiet running streams, tends to make natural ice freeze transparent American manufacturers of ice have always tried to duplicate this clearness.

### Distilled Water Ice Making

The method first adopted in this country was to use distilled water. From a sanitary point of view such ice would be theoretically ideal.

Practical difficulties, however, make it almost impossible to produce pure ice in this way. Some of these difficulties are:

(1) The removal of oil from distilled water. Engine cylinders are lubricated by allowing oil to drip into the steam supply, and some, if not all, of this oil is ultimately carried out in the exhaust. It is very difficult to remove the oil, and it is practically impossible to remove it if any organic oil is present.

(2) The lack of assurance that the filters are in proper condition. This assurance is often impossible to obtain, since this apparatus is ordinarily used throughout the season without overhauling.

(3) The possibility of contamination in the storage tank where the distilled water is held and usually "pre-cooled" to as near 32 degrees as possible before passing to the freezing cans, thus saving time in the freezing process in the tank.

(4) The possible contamination from handling the cans and the wooden covers over them. These covers form the top of the freezing tank in which the cans of water are immersed in cold brine for freezing, and are tramped over by the ice harvester with the consequent possibility of dirt getting into the cans.

### Plate System of Ice Making

A second system of ice making in common use in this country is the "plate system." In this process the ice is formed on vertical steel plates. Natural or raw water is used and the bath is agitated by various methods. The ice thus produced is very clear and dense.

In this system when the ice is formed to the desired thickness, usually about 12 inches, it is loosened from the freezing plate by various thawing arrangements in different forms of the apparatus. The ice plates, often nine feet by sixteen feet by twelve inches in thickness, are lifted from the tanks by overhead cranes and carried to a table where they are cut to commercial size.

While the plate process is usually very slow on account of the fact that the freezing is from one side only, it is largely employed because it permits the using of an economical steam engine. In the old style, distilled water, ice-making plant the amount of steam that must be provided in order to get sufficient distilled water to fill the ice cans was more than an economical engine would use in driving the refrigerating machine to freeze this ice. There is therefore with this type of plant nothing to be gained by installing an economical engine.

### Raw Water Can Ice Making

One modified form of the above systems now coming into considerable favor is arranged so that stationary cans are filled with raw water, which is constantly agitated by air bubbling up through the water. When the freezing has progressed part way, the remaining water is drawn off and replaced by fresh water, thus removing most of the impurities that have been frozen out of solution. Fig. 25 is a diagram of the freezing chamber of a representative installation of this type.

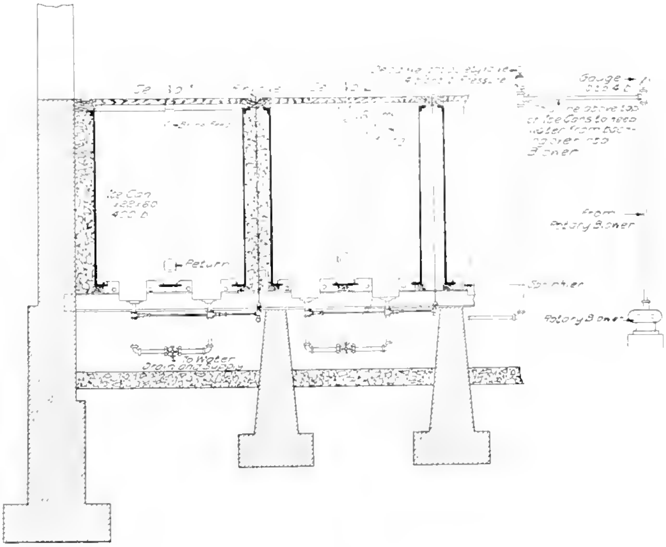

Fig. 25. Sectional View of the Freezing Chamber of a Stationary Can Ice Plant for Making Clear Ice from Raw Water

### General

Various other modifications of these systems of ice making have been and are being developed. All of them depend, however, upon the series of physical facts noted at the beginning of this section.

## RELATIVE ECONOMY OF MECHANICAL AND ICE REFRIGERATION

### Cost of Ice

In determining the cost of refrigeration by ice, account must be taken not only of the cost of the ice, but of meltage, of uncertain ice harvest, of the amount of ice left over at the end of the season, and of that which freezes together in the storage and becomes therefore practically useless.

Regarding the meltage, this may run anywhere up to fifty per cent of the total ice harvest. As to what will be the quantity of ice left over at the end of the season it is impossible to make estimate. In many cases, however, it is a very large item.

The loss by the ice freezing together in the storage can be reduced to a very small quantity if the ice is properly packed with distance strips between the ice cakes. Proper packing is much more readily carried out, however, where artificial ice is stored than where natural ice is held, and a mechanically-cooled ice storage is less subject to this difficulty, since the temperature is, of course, held constantly below the melting point of ice.

### Items Making up Cost of Mechanical Refrigeration

The cost of refrigeration produced mechanically is made up of power, water, oil, refrigerant (usually ammonia), labor and attendance, insurance and interest and depreciation on the investment. The figures on these items vary between wide limits. The following figures, however, will be of interest as they are taken from the annual costs of an ice manufacturing company having a capacity of 1500 tons per day in plants ranging in size from 50 to 100 tons per day each.

| | | |
|---|---|---|
| Coal | $0.40 | per ton of ice produced |
| Labor | .50 | " " " " " |
| Ammonia | .10 | " " " " " |
| Water | .05 | " " " " " |
| Wasted power, oil, etc. | .10 | " " " " " |
| Total | $1.15 | " " " " " |

# A MINIATURE ELECTRIC NIGHT LAMP

By John T. H. Dempster

Research Laboratory, General Electric Company

In this article the author defines the field of this new device, describes its construction, names its electrical characteristics, and furnishes figures on its cost of operation.—Editor.

With the advent of electric light the need for a small low candle-power lamp has been felt. Up to the present time this has not been successfully met. To fill the need of a small electric light, which could be applied to the ordinary distribution voltage and yet be of sufficiently low watt consumption to create a wide-spread use as a night light, a combination transformer and drawn-wire tungsten lamp has been developed.

It is well known that hospitals and sick rooms demand a lamp of low candle-power in order that the nurse or attendant may seek assurance as to the patient's comfort in the matter of bedclothes, ventilation, or temperature of the room, all without the disturbance incident to the operation of switches and the glare of high power lamps. There is a wide field for such a miniature lamp, however, that has been previously handicapped by the much greater total current consumption of the previously lowest candle-power lamp that has been available to be burned directly on the service voltage.

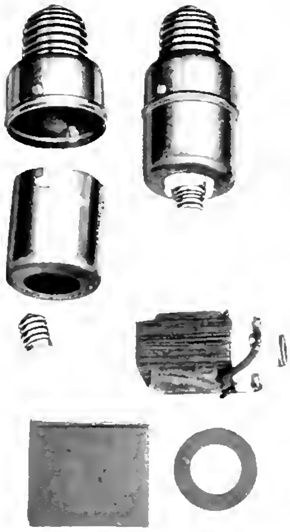

Fig. 1. Exploded and Assembled View of Night Lamp

In a residence, such as the average flat or cottage, a night lamp burning in the hall, bathroom, sitting room, or at the cellar stairs during the evening or all night is a convenience to be tried to realize its value fully.

In the matter of cost of operation, a small lamp such as has been heretofore available, taking about 20 watts, would, if used as a night lamp burning 10 hours per day for 30 days, cost in the neighborhood of 50 to 60 cents per month, figured according to the prevailing rate for energy. This is a prohibitive figure for the ordinary householder, and would not tend to make universal the use of electric service during the night.

However, the device herein described will, at a cost of only a few cents per month, sufficiently light the rooms in an ordinary house throughout the night to permit a person's safely passing to and fro. As an example of an average house, the installation would probably be as follows: one lamp located at each of the following places; the name and number-plate on front door, front hall, bathroom, one bedroom, and cellar or rear stairs, making in all five lamps. The energy required for the five transformers and lamps would be about 6 watts, and for 30 days at four hours per night would cost about 7 cents. For a 10-hour night service the cost would only amount to about 18 cents per month. Such a low cost of operation for light in so many places warrants the all night use and makes a pleasure of what would otherwise be a burdensome luxury.

The complete device consists of a miniature transformer contained within a brass shell and adapted to screwing into the standard lamp socket in place of the usual incandescent lamp. The shell carries at the other end a candelabra socket to take miniature plain or frosted lamps which are ordinarily rated at about one candle-power.

The miniature transformer is wound to operate on 60-cycle alternating current circuits of 100 to 125 volts. It is well insulated, of course, and has a shell-type laminated iron core working at moderate magnetic density. The windings operate at an ordinary current density, are separately insulated, and have a ratio of 10 to 1. The temperature rise of the transformer in operation is barely perceptible, being usually only about one or two degrees, which proves the high economy of the device. At no load the average energy taken by the transformer is about 1/5 of a watt; and when loaded with a lamp giving about one candle-power, the input is about $1\frac{1}{4}$ watts.

The device fills a long felt want for a very small light unit which can be operated alone or in groups without having to recourse to wasteful dead resistances or several lamps in series to consume the average 110 volts of the lighting circuit.

# NOTES ON INTERNATIONAL STANDARDIZATION OF ELECTRICAL MACHINERY

By A. R. Everest

Chief A-C. Designing Engineer, The British Thomson-Houston Company

On the 10th of last month the Institution of Electrical Engineers (of Great Britain) held a meeting at Birmingham, at which International Standardization was the subject under discussion. On this occasion Mr. A. R. Everest, who was a delegate at the recent Berlin Conference of the International Electrotechnical Commission, contributed the following paper which sets forth particularly clearly the objects in view and the extent to which these objects have been accomplished. As explained by Mr. Everest, there was complete international agreement in the matter of standardizing temperature values which shall be regarded as representing approved practice for continuous operation, but which shall never be exceeded. The prospective international ambient temperature of reference is 40 deg. By deducting this value of 40 deg. from the standardized values for permissible observable temperature given in the table in Mr. Everest's article, we obtain values for the limiting temperature rise to which the international rating of any machine will correspond. As soon as this value of 40 deg. for the ambient temperature of reference is officially adopted by the I.E.C., a machine can be stated to have an international rating of, for example, 1000 kw. when, with an ambient temperature of 40 deg., a load of 1000 kw., will not occasion higher "observable" temperatures than those set forth in the table in Mr. Everest's article.—Editor.

In order to properly discuss the work of the International Electrotechnical Commission it is necessary to clearly distinguish between an "international standard of quality" and an "international rating" for machines.

The rating of a machine is the output for which it is sold and which is marked on its name plate (rating plate). This output is the "rated output" of the machine.

(*a*) *I.E.C. Standard of Quality.* If the rated output of a machine is such that when working under the particular cooling conditions for which it is designed the machine keeps within the I.E.C. limits of temperature, this machine, for its particular application, conforms to I.E.C. Standard of Quality.

The I.E.C. Standard of Quality is valuable particularly for important individual and special applications. Various machines in this class from different sources would still not be directly comparable since they would not have equal temperature rise if primarily intended for different conditions.

(*b*) *I.E.C. Rating.* If the rated output of the machine is such that *when working under the I.E.C. standard conditions of cooling,* the machine keeps within I.E.C. limits of temperature, the rating of this machine is the I.E.C. Rating.

Thus the I.E.C. Rating establishes temperature rise as well as maximum temperature. All machines with the I.E.C. Rating would be directly comparable amongst themselves since they would all have the same temperature rise at their rated output.

The rules adopted at the recent I.E.C. meeting in Berlin establish the I.E.C. Standard of Quality (as regards temperature) for electrical machinery.

Agreement was not reached upon the further question of an I.E.C. Rating, due to differences of opinion regarding the value for cooling air temperature.

Before referring further to this feature it may be well to briefly review that part of the work which has been completed by the I.E.C.

These rules are the outcome of deliberations in the various National Committees and at the meetings of the Special Committee on Rating held in Paris, Zurich and in Berlin prior to the Plenary Meeting.

The rules so far adopted are based on considerations of the highest safe temperatures for various insulating materials, the joint effect of time and temperature, also probable difference between observable temperature and maximum internal temperature.

From these considerations international agreement was reached regarding permissible limits of temperature for various insulating materials employed in modern electrical machinery.

In connection with these permissible temperature limits, rules are provided regarding the proper determination of the temperature of the cooling air, a knowledge of which is necessary to ascertain the temperature rise which must not be exceeded at the rated load of the machine.

Finally rules are provided dealing with differences which may exist between the temperature rise on test and under service conditions due to variations in cooling temperature, and barometric conditions.

Thus the I.E.C. Standard of Quality has now been established as regards temperature, and therefore life, for any machine working under the conditions for which it is sold.

### Method by which Temperature is to be Observed

(1) While the hottest internal temperature at any point affects the life of the insulation affected, the I.E.C. does not consider

it feasible to make this the subject of ordinary commercial investigation. Information obtained from laboratory investigations with exploring coils and thermo-couples built into specially prepared machines appears to justify the conclusion that for modern machines wound for not more than 4000 volts or for transformer coils for not more than 10,000 volts, the hottest internal spot will not exceed the temperature *observed by ordinary methods* by more than ten degrees C. Accordingly the limiting *observable* temperatures permitted which are shown in the table on this page apply to measurements by rise of resistance of the winding (wherever practicable) together with the use of thermometers, the highest reading found being always considered.

Electrical thermometers and thermo-couples applied to any accessible part of a completed machine are classed with thermometers.

### The Question of Overloads

(2) A great deal of confusion exists between different countries at present concerning the relation between the so called "full load" rating of a machine and the highest load it is actually expected to carry. Further, the various overloads are rated for different lengths of time and in some cases are not allowed at all when the machine has been heated up by its ordinary "full load."

The I.E.C. has decided that any machine intended for continuous service should be ordered, designed, and rated for the highest load it is expected to carry, and that it should be capable of carrying this rated load continuously without exceeding the temperature limits of the table given herewith. No overloads are permissible beyond this rated load.

In the case of a machine subject to peak loads in excess of the ordinary load; if the peak endures for more than a short time it must be included in the rating. But if the peak load is to be endured for brief periods only, the rating must be sufficiently above the ordinary load to give a continuous thermal capacity equivalent to that required on the brief peak loads without exceeding the permissible temperature limits.

### Intermittent Service

(3) A machine for intermittent service may for the purpose of test have either a continuous rating which is thermally equivalent, or a "short time" rating which, when starting cold, and running at rated load for the specified time, shall not at the end of that time occasion temperatures in excess of those allowed by the table.

### Permissible Limits of Observable Temperature

(4) Upon these considerations the I.E.C. decided to standardize limiting values for temperature which should apply to "observable temperatures" measured by the means and methods specified and which should be set with due allowance for such excess internal temperatures above those "observable," as would be associated with the approved methods of test.

The temperatures were to be such as might be endured continuously without prejudice to a reasonably long life, but they were to be limits which *must not be exceeded.*

Accordingly values have been standardized as shown in the following table.

### LIMITS OF "OBSERVABLE" TEMPERATURE ADOPTED BY THE I.E.C. SEPTEMBER, 1913

| | |
|---|---|
| Non-impregnated cotton | 80 deg. C. |
| Impregnated cotton or paper (general) | 90 deg. C. |
| Impregnated cotton single layer field coils stationary or moving | 95 deg. C. |
| Impregnated cotton stationary coils solidly impregnated throughout | 95 deg. C. |
| Impregnated cotton rotor and stator windings having the slot portion solidly impregnated or moulded | 95 deg. C. |
| Enamelled wire (without cotton) | 105 deg. C. |
| Mica, micanite, asbestos (general) | 115 deg. C. |
| Mica, micanite single layer field coils stationary or moving | 120 deg. C. |
| Mica, micanite stationary coils solidly impregnated or moulded | 120 deg. C. |
| Windings permanently short circuited { Insulated | 100 deg. C. |
| Windings permanently short circuited { Non-insulated | 110 deg. C. |
| Commutators, slip rings | 90 deg. C. |
| Bearings | 80 deg. C. |

NOTE. When the insulation is composed of several different insulating materials the lowest of the temperatures corresponding to the various insulations employed must be taken as the temperature limit. The insulation even when forming a support is always considered as part of the winding.

(Material employed in small quantity in the construction and not relied upon continuously as a support for the insulating material is not regarded as part of the insulation under this rule.)

### Statement of Cooling Air Temperature

(5) Permissible limits of temperature are useless to the designer except in conjunction with information regarding the cooling temperature, since the difference between these two values is the "temperature rise" which the machine may create when carrying its rated load.

Hitherto in the I.E.C. proceedings as well as in the various national rules, the value mentioned as cooling air temperature has been the "ordinary" or average value. Obviously such value cannot be used directly in connection with a table of limiting temperatures "which must never be exceeded."

The corresponding value of air temperature employed must be the highest which is likely to occur.

The British and United States committees agreed in recommending that in future 40 deg. C. should be taken as the reference air temperature, instead of 25 deg. C. as hitherto indicated in the national rules.

(Unfortunately some confusion arose because the reason for this sudden jump from 25 deg. C. to 40 deg. C. on the part of the British and United States committees was not explicitly given.)

The I.E.C. rules now require that the maximum and not the average temperature of cooling air shall be stated, but agreement was not reached regarding an International Standard Reference Air Temperature. This will be referred to again in the section under "I.E.C. Rating."

### Correction for Room Temperature at Test

(6) Extended investigations made by the United States National Committee show that the variation in temperature rise with a given load when tested with cooling air at different temperatures is a small and uncertain quantity, sometimes positive, sometimes negative, according to the characteristics of the particular machine.

The I.E.C. decided that no correction shall be made in practice for such difference between conditions of test and of final service.

### Corrections for Difference of Altitude

(7) No correction is to be made for variation in the cooling properties of the air at a given temperature at altitudes not exceeding 1000 meters.

For higher altitudes it is recognized that a correction is necessary but the I.E.C. is not yet in a position to furnish an official correction factor.

### "I.E.C. Rating" for Machines

(8) Although the I.E.C. states that "wherever possible the temperature of the cooling air shall be stated and the machine constructed for this cooling condition," it is also proposed to establish a value which shall be taken as maximum temperature of the cooling air when no specific information is available. Probably more than 90 per cent of all the machines sold come under this class and the establishment of an International Reference for Air Temperature in connection with the table of limiting temperatures already provided would at once fix the temperature rise permissible at rated load, and in connection with the rulings given regarding overload would completely establish the capacity of any machine sold with "I.E.C. rating."

With such uniform rating adopted, a buyer of standard machines could compare without misunderstanding or possibility of mistake, tenders received from various makers even from different countries. He would know that all the machines offered would carry their rated loads continuously with the same temperature rise (and also with uniformity in other characteristics such as commutation as far as these might be defined by the I.E.C. rules).

It is evidently desirable that the I.E.C. Rating shall also be the domestic standard rating of the same machine in the countries in which they are produced. The Reference Air Temperature must then be set at such value as *shall not be exceeded by the hottest conditions likely to occur in service at any time of the year in any temperate climate.*

At Berlin a majority of the delegates including those from Great Britain and the United States desired to set this reference temperature at 40 deg. C. but a minority desired 35 deg. C.

Examination of the meteorological records for various temperate countries, including Great Britain, Germany and the temperate part of the United States, shows that 35 deg. C. is not sufficiently high to cover even the highest *outdoor* shade temperatures which are occasionally recorded, so that with a temperature rise based on the 35 deg. C. assumption the limiting temperatures of the I.E.C. table would certainly be exceeded at times. But such is contrary to the express conditions under which the limiting temperatures were adopted by the I.E.C.

In order to justify a *nominal* "maximum" temperature for cooling air which would exclude the highest peaks occasionally occurring, it would be necessary to reduce all the values shown in the table of permissible limiting temperatures by a margin sufficient to allow for such occasional peaks.

This proposition was suggested at Berlin but was not accepted by those desiring the lower reference temperature. Finally this entire question was referred back to the various national committees, and it is to be hoped that an early settlement will be reached, as upon this question hangs in reality the whole problem of international standardization in the rating of electrical machinery.

# THE ENGINEERING PROBLEM OF ELECTRIFICATION

By A. H. Armstrong

Assistant Engineer, Railway and Traction Department, General Electric Company

This is an important contribution to electric railway literature, and, owing to the author's reputation, should attract a great deal of attention. He analyzes the three systems which would be considered for main line electrification, viz., the single-phase alternating current, split-phase alternating current, and high voltage direct current systems, and shows the present standing of each as regards their use on important roads. The list of railways using single-phase and high voltage direct current are impressive, and the fact that so many systems originally equipped with single-phase have now changed to higher voltage direct current, and that no high voltage direct current installations have been changed to any other system speaks more eloquently than words for the good inherent qualities of the high voltage direct current apparatus. The illustration showing the comparative size of the split-phase alternating current and the 2400 volt direct current locomotive will speak more convincingly than many paragraphs of text. The efficiency of the different systems is reviewed from many different standpoints. This paper was read before the Canadian Society of Civil Engineers in Montreal on December 18, 1913.—Editor.

The broad question of whether electrification will show an attractive return upon the large capital investment required can best be determined by a detailed investigation of the local conditions obtaining in any given case. Any estimate of a general character is at best more or less misleading when applied to a specific problem. The electric locomotive possesses many operating characteristics not shared by the steam engine and its introduction opens up possibilities in operating methods that may make it desirable to effect sweeping changes in train operation as now carried on with steam engines. Until one or more engine divisions are electrically operated, perhaps we may not fully appreciate what it means to the railway operator to be relieved of many of the limitations of the steam locomotive.

For example, given an electric locomotive capable of hauling an 800 ton passenger train at sixty miles per hour on level track and without assisting locomotives, haul the same train up gradients of 2 per cent at a speed of twenty-five miles per hour, it is possible to make radical improvements in schedule. When it is considered furthermore that such an electric locomotive requires no stops for fuel and water and can operate 1200 miles or more between inspections, it is evident that electrification calls for considerable readjustment of steam railway traditions.

Failure to fully grasp the possibilities of electrical operation may result in running up the first cost of proposed electrification to an extravagant total upon which no adequate return is possible. So much local color is required to intelligently discuss the question of "will it pay to electrify," that no attempt will be made in this paper to discuss the financial aspect of the matter. The several important installations now under construction and the even larger projects upon which favorable decision has been reached, all point to the fact that electrification must be attractive in some instances at least. There are, however, certain fundamental data governing the operation of all electric locomotives and it is the purpose of this paper to discuss some of the engineering questions involved.

At the outset, it is found that the electrical engineer has perfected several types of locomotives and different methods of distributing electric power to them, thus giving rise to what is known as several different "systems of operation." The term "system" is generally applied to the combination of locomotive and trolley or third rail distribution as the question of power generation and transmission is common to all. While it is true that the single-phase and split-phase locomotives call for a supply of single-phase 25 cycle power, it is only in isolated instances that this kind of electric power can be economically generated and used exclusively by the railway company. Large power installations are now so well equipped to give attractive power rates over extended areas and economical electric power production is so completely an industry in itself, that local conditions must be very favorable to justify the installation of a separate power house devoted exclusively to railway load. Even should such a separate installation be made, it may be considered sound engineering to look to future possibilities and install apparatus similar to that in neighboring systems where the frequency and voltage are standardized. Different frequencies are not as serious as conflicting track gauges, but they do involve the burden of expense and loss in efficiency of frequency changing sets which it may some day be found expedient to install in order to tie the two systems together. Hence the statement is again made that the generation and transmission of power offers the same problem without regard to the system of electrification favored.

It is proposed to replace the steam engine with a type of motive power that offers superior advantages in the hauling of heavy trains. In other words, the electric locomotive itself constitutes the main argument in favor of electrification, and no marked excellence of distribution system can offset the failure of the electric motive power. The steam locomotive it is proposed to replace is a highly developed machine of great reliability and the result of the experience born of a great many failures. It cannot be too strongly emphasized therefore that the electric motive power is the controlling factor in main line electrification, a point of view that is sometimes overlooked.

The three electric systems considered for main line electrification are as follows:

1. Single-phase—alternating current.
2. Split-phase–alternating current.
3. High voltage—direct current.

The single-phase commutating motor has been in operation upon interurban electric railways for some years, and a study of the history of these installations reveals some of the fundamental reasons why this type of motive power has not been more generally adopted. It has been found that the initial expense and cost of upkeep of rolling stock equipped with single-phase commutating motors is fully double that of cars having the same seating capacity and equipped with direct current motors. No new installations have been made for the past two years, and the several single-phase roads are being changed over to direct current as fast as financial conditions will permit. Following is a list of the single-phase installations and on those roads starred the single-phase motors have been replaced with the direct current type.

The introduction of the single-phase system was a result of the success of suburban and interurban electric railway operation and the extension of these lines over large areas, thus bringing into prominence the question of economical power distribution. It was recognized that a voltage higher than the com-

## SINGLE-PHASE RAILWAY INSTALLATIONS IN UNITED STATES AND CANADA

| Name of Railway | Year |
|---|---|
| Indianapolis & Cincinnati | 1904 |
| * Atlanta Northern Ry. | 1905 |
| * Illinois Traction Co. | 1905 |
| Long Island R. R.—Sea Cliff Division | 1905 |
| San Francisco, Vallejo & Napa Valley, California | 1905 |
| * Warren & Jamestown | 1905 |
| Westmoreland County Traction, Derby to Latrobe, Pa. | 1905 |
| Spokane & Inland Empire R. R. | 1906 |

* Changed from alternating current to direct current motors.

monly accepted standard of 600 volts was desirable upon the trolley in order to minimize the cost of installing feeder copper and substations. While the single-phase motor was being developed and installed upon interurban railways careful attention was also being given to the question of the possibility of using direct current motor equipments at higher voltages and resulted in the installation of the first 1200 volt road, the Indianapolis & Louisville Traction Railway, operated in 1907. The success attending this operation lead to other similar installations at both 1200 and 1500 volts until it is now generally recognized that the high voltage direct current system is without a competitor for all classes of suburban and interurban electric railways. It is a safe prediction to make that no more single-phase motor equipments will be placed in operation in this country on new roads unless these roads virtually form an extension of existing systems.

Following is listed the several high voltage direct current installations in the United States and Canada.

The history of the battle of the systems and the elimination of the single-phase motor as being unsuitable for the equipment of light electric railways has an important bearing upon the selection of systems for main line electrification. The limitations of the single-phase motor that lead to its failure in the interurban railway field do not appear to be lessened when considering it for locomotive equipment with the result that it is in use on but three of the twelve roads that are truly representative of electrified steam roads operating large electric locomotives.

There are other electrified steam lines but the service on them more nearly approaches that of high class electric interurban railways.

### HIGH VOLTAGE DIRECT CURRENT RAILWAY INSTALLATIONS IN UNITED STATES AND CANADA

| Road | Voltage | No. of Equipments | Date |
|---|---|---|---|
| Indianapolis & Louisville Trac. Ry. Co., Scottsburg, Indiana | 1200 | 13 | Oct., 1907 |
| Central California Traction Co., Stockton, California | 1200 | 22 | June, 1908 |
| Pittsburg, Harmony, Butler & New Castle Ry., Bidenau, Pa. | 1200 | 30 | July, 1908 |
| Washington, Baltimore & Annapolis Elec. Ry., Baltimore, Md. | 1200 | 47 | Feb., 1910 |
| Milwaukee Elec. Ry. & Lt. Co., Milwaukee, Wis. | 1200 | 32 | Mar., 1910 |

| Pennsylvania Terminal | 1910 | Side rod | Direct current | 600 |
| Butte, Anaconda & Pacific | 1913 | Geared | Direct current | 2400 |
| * Canadian Northern | 1914 | Geared | Direct current | 2400 |
| * Canadian Pacific | 1914 | Geared | Direct current | 2400 |

* Under construction.

Also there are interurban systems where electric locomotives of considerable capacity are operated, but the class of service does not approach the exacting demands of main line passenger and freight operation. The above table, however, comprises converted steam lines where the service consists of hauling main line passenger and freight trains behind electric locomotives of large capacity.

It is a noteworthy fact that the use of the single-phase motor has not extended beyond the two original roads installing this type of equipment, the Grand Trunk and New York, New Haven & Hartford (including Hoosac Tunnel) whereas direct current motors have been universally adopted in all the more recent electrifications with the single exception of the proposed split-phase installation on the Norfolk & Western Railway.

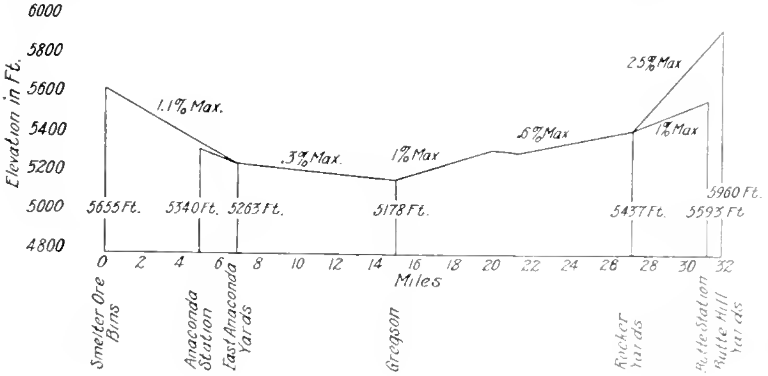

Fig. 1. Profile of Butte, Anaconda & Pacific Railway

The so-called "split-phase" system is a comparatively new comer in the electric traction field and it has not yet been subjected to the test of actual operation. The proposed system offers many attractive features, however, and it is worthy of careful study in order to understand its fitness for heavy electric railway service. From experimental tests made, it seems reasonably certain that the split-phase locomotive can meet the demands of commercial operation with satisfactory reliability.

The split-phase locomotive was first described by E. F. W. Alexanderson, and reference is made to his articles for a full understanding of its underlying principles.*

Confronted with the problem of main line electrification and the demand for a distributing system which would provide for the economical distribution of large units of power over an extended area, the need of higher direct current voltage was appreciated and resulted in the first installation of 2400 volts direct current upon the Butte, Anaconda & Pacific Railway, first operated May 28th of this year. This installation marks an epoch in electric railway progress, as its success offers substantial proof that direct current motor equipments can be constructed at a reasonable cost and operated in an efficient and reliable manner with trolley potentials as high as 2400 volts.

It has been characteristic of the installations operating at 1200 and 1500 volts that

---

* A.I.E.E. Proceedings, 1911, Induction Machines for Heavy Single-Phase Motor Service. G. E. REVIEW, October, 1913 "The Split-Phase Locomotive."

the reliability of the direct current motive power has been in no way impaired by reason of using a higher trolley voltage, in fact, the maintenance of 1200 volt motor equipments shows no increase over that of 600 volt equipments. A brush life of over 150,000 miles gives evidence of good commutator performance with practically no wear and the increased insulation and creepage distance provided has been ample to ensure reliability and low cost of maintenance.

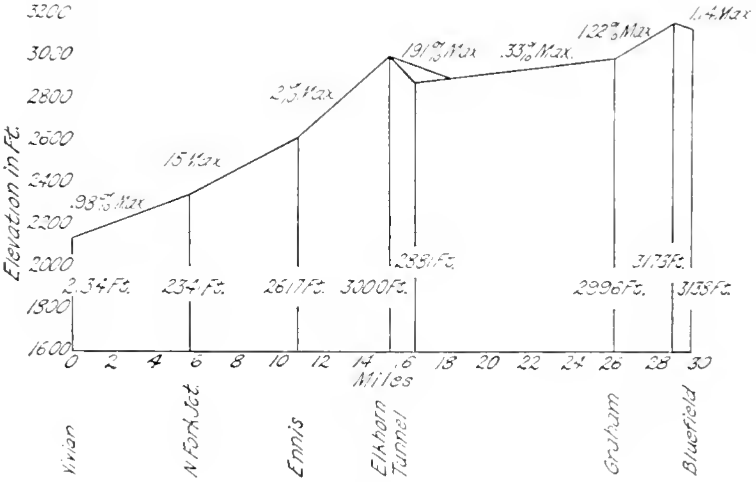

Fig. 2. Profile of Norfolk & Western Railway—Elkhorn Division

The transition from 1200 to 2400 volts direct current has also resulted in completely successful operation at this potential. The operating record of the Butte, Anaconda & Pacific 2400 volt direct current system has been truly remarkable and can best be expressed by quotation from letter published in the Electric Railway Journal by Mr. H. A. Gallwey, General Manager.

"To the Editors:

"In reply to your inquiry I would say that on Oct. 1, 1913, the Butte, Anaconda & Pacific Railway established regular electric passenger service between Butte and Anaconda. For approximately four months previous to this the freight service between East Anaconda yards and the smelter had been handled electrically. During this period electric locomotives have made approximately 55,000 miles and have delivered to the smelter about 1,500,000 tons of ore. Since starting the electric service there has been no failure of any of the electric apparatus and no delay in any way attributable to electric operation.

"The substation at Anaconda has been in continual service twenty-four hours a day with no more than ordinary care and without replacement of any parts. The locomotives have been operated by the steam locomotive enginemen and have been maintained by the regular shop force with the addition of one man experienced in electric operation. They have met every requirement and there has been no failure or replacement of locomotive parts.

"The overhead contact system has been highly successful, and there have been no failures and no accidents. The wear of the contact wire is inappreciable. The original pantograph rollers on the locomotives are still in use and show very slight wear notwithstanding the severe conditions imposed by the smoke and soot deposited on the wire from the steam locomotives during the several months of construction. Our experience up to the present time indicates the complete success of our electrification and justifies the existing optimism and enthusiasm for heavy railroad electrification.

"(Signed) H. A. Gallwey,
"General Manager."

The success of high voltage direct current installations has not been marred by a single instance of failure due to fundamental defect in the type of apparatus used, and justifies the conclusion that the 2400 volt, 1200 volt and the 600 volt direct current equipments are all part of the same general direct current system, and that the only difference is the need of more insulation in one case than in the other. The 2400 volt direct current installation of the Butte, Anaconda & Pacific cannot be looked upon therefore as in any way constituting a new "system" of electrification, but rather as a natural development along the lines of higher voltage of the same well known direct current system which has rendered such excellent account of itself in the past on all our city and practically all of our suburban and interurban electric lines. This has an important bearing upon the general electrification of the steam roads, as it places the status of the direct current system as applied to such service.

Fully appreciating the grave responsibility of selecting a type of motive power for a proposed electrification that holds promise of special fitness for the immediate service contemplated and also is capable of meeting the demands of unlimited future extensions, this paper will briefly touch upon the comparative characteristics of the split-phase and 2400 volt direct current systems of operation. The choice seems to lie between split-phase and direct current inasmuch as the history of the single-phase motor equipment does not seem to justify its further consideration for heavy electric railroading.

The general scheme of distribution to the split-phase locomotive is shown in Fig. 5 which has special application to western railways where 60 cycle power supply is universally standardized. A corresponding diagram of the 2400 volt direct current system is shown in Fig. 6, this also being adapted to 60 cycle power supply.

Starting first with a comparison of the two types of locomotives it is necessary to make some general assumption as regards service conditions in order to draw conclusions as to relative locomotive characteristics. The electric locomotive is capable of being constructed in very large units, but convenience in shopping and simplicity in construction both point to a unit of approximately 100 tons total weight on drivers. These 100 ton units can be coupled together and operated as a single locomotive of any desired capacity, though probably a two unit locomotive weighing 200 tons and giving a starting tractive effort of 120,000 lb. is as large as the draft gear will stand.

Experience with steam locomotive practice seems to point to a locomotive rating on ruling grade that calls for a tractive effort corresponding to approximately 18 per cent coefficient of adhesion on drivers. Thus the conditions obtaining upon a 2 per cent ruling gradient will be as follows:

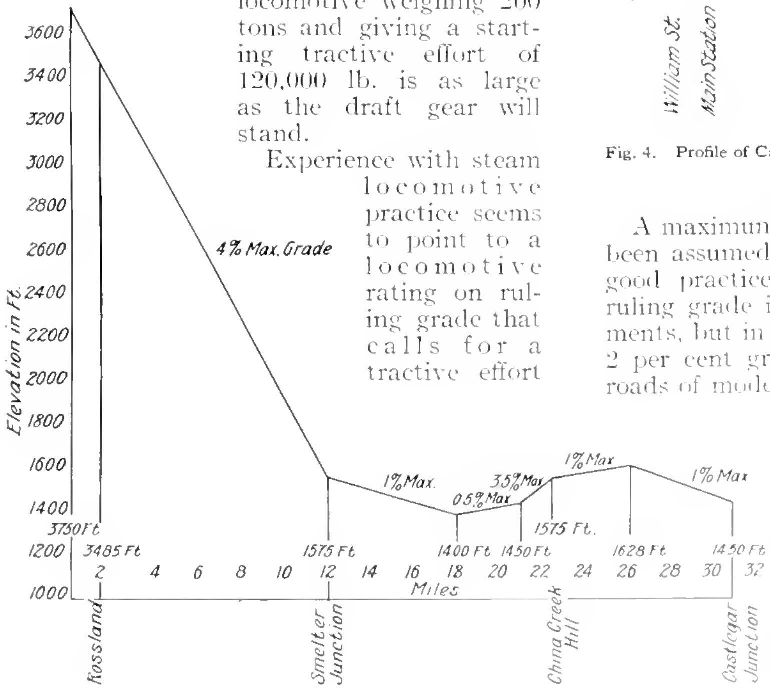

Fig. 3. Profile of Canadian Pacific Railway—Rossland Subdivision

| | |
|---|---|
| Tractive effort due to 2 per cent grade | 40 lb. |
| Tractive effort due to train resistance | 6 lb. |
| Tractive effort due to curve resistance | 2 lb. |
| Total per ton | 48 lb. |

| | |
|---|---|
| Total weight on drivers | 200,000 lb. |
| Rating at 18 per cent coefficient of adhesion | 36,000 lb. |
| Gross train weight | 750 tons |
| Trailing train weight | 650 tons |
| Speed | 15 m.p.h. |
| Net output at drivers | 1450 h.p. |

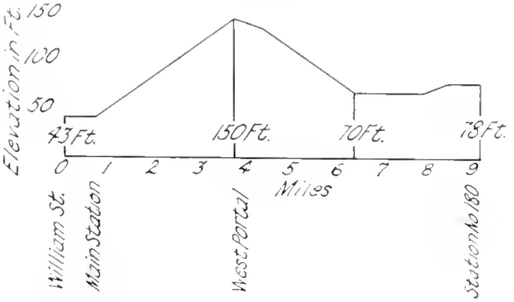

Fig. 4. Profile of Canadian Northern Railway—Montreal Tunnel & Terminal Electrification

A maximum load of 50,000 lb. per axle has been assumed as being within acceptance of good practice. The question of speed on ruling grade is one subject to local requirements, but in general a speed of 15 m.p.h. on 2 per cent grade is as high as desirable on roads of moderate tonnage.

As ruling grade generally extends unbroken over comparatively short distances, it is possible to take advantage of this fact in electric locomotive design and proportion the motive power for a continuous capacity of say 16 per cent coefficient of adhesion without danger of exceeding safe temperature limits in operation. The continuous capacity of the 100 ton unit would therefore be 32,000 lb. tractive effort at somewhat more than 15 miles per hour, based upon 16 per cent coefficient of adhesion of the weight upon the drivers.

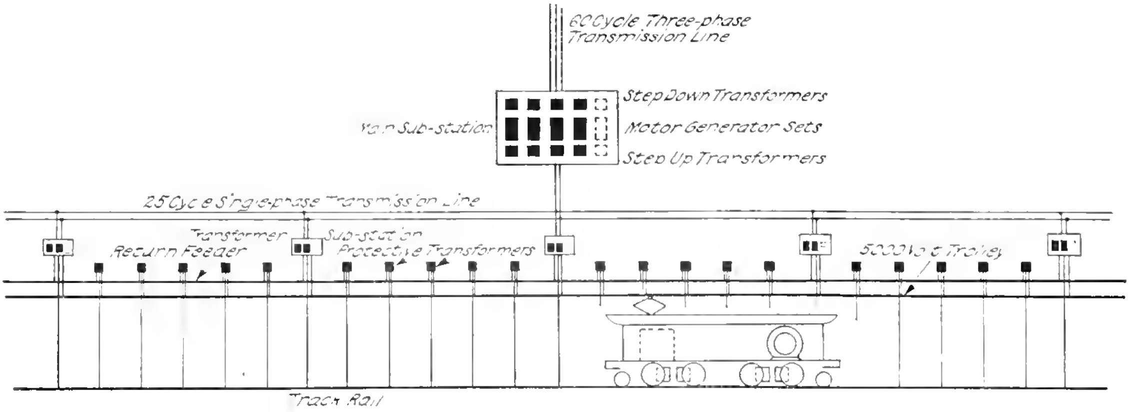

Fig. 5. General Scheme of Split-phase Alternating Current System

Owing to the moderate speeds at which a freight locomotive will operate, it is entirely feasible to consider a construction wherein the motors are geared direct to the driving axles by twin gearing, in this respect following the practice of the Detroit Tunnel, Cascade and B. A. P. locomotive which has proven very successful.

For the purpose of this comparison, it is assumed that both split-phase and direct current locomotives will be of similar construction and employ twin geared motors of equal weight and efficiency. A comparison of weight distribution in the two types of locomotives is presented herewith. See page 69.

As the direct current locomotive of 100 tons carries no ballast, it is evident that the 40,000 lb. comprising the phase converter and transformer of the split-phase locomotive must be carried on idle wheels together with the additional weight of cab and running gear required to carry this excess weight. The net result is a split-phase locomotive of fully 35 per cent more weight than a direct current locomotive of equal capacity and of similar construction. This weight comparison is based upon the assumption that 50,000 lb. per axle constitutes the limit allowable, thus forcing the introduction of guiding axles to carry the excess weight of the split-phase equipment. For locomotive construction of less capacity, permitting the split-phase to come within axle weight limits, both types of locomotives would comprise four axles with no guiding wheels and the split-phase locomotive may not total more than 20 per cent more weight than the equivalent direct current type.

It is evident that the split-phase locomotive is not only considerably heavier for equal capacity, but also more complicated and inefficient than the direct current locomotive.

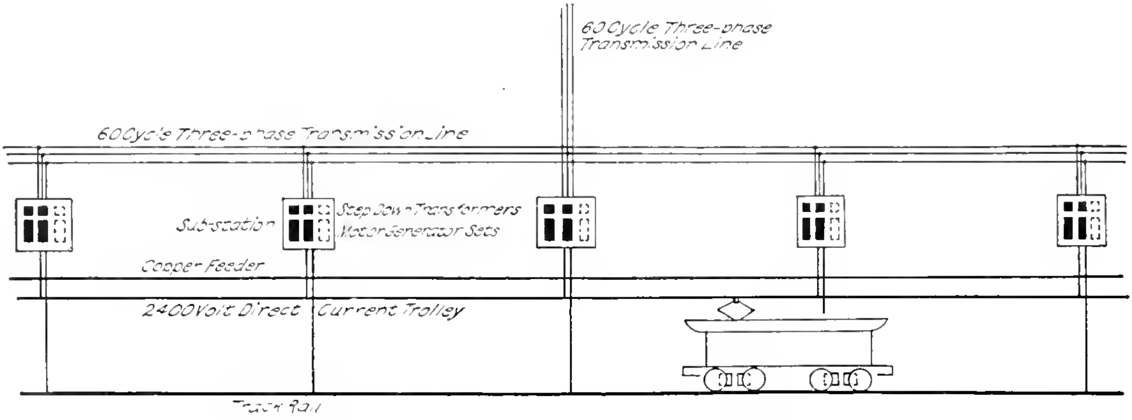

Fig. 6. General Scheme of 2400 Volt Direct Current System

The power from the trolley must in turn pass through transformer, phase converter, control, motors and gears. The efficiency of the complete locomotive in operation will depend upon its output and hence in the following comparison, efficiency has been computed for operation on both ruling grade and level track. The average efficiency of a day's run will obviously lie somewhere between these values, assuming that portion of the run when the locomotive is taking power.

### COMPARATIVE WEIGHT OF LOCOMOTIVE
CONTINUOUS CAPACITY, 32,000 LB. 15 M. P. H.

| | Split-Phase | 2400 Volts Direct Current |
|---|---|---|
| Four motors | 44,000 lb. | 44,000 lb. |
| Control apparatus complete | 17,000 lb. | 27,000 lb. |
| Air compressor | 4,000 lb. | 4,000 lb. |
| Air brake equipment | 3,000 lb. | 3,000 lb. |
| Miscellaneous | 2,000 lb. | 2,000 lb. |
| Phase converter | 22,000 lb. | . |
| Transformer | 18,000 lb. | . |
| Cab and running gear | 160,000 lb. | 120,000 lb. |
| Total | 270,000 lb. | 200,000 lb. |

### FREIGHT LOCOMOTIVE EFFICIENCY
DETAILED COMPARISON

| | SPLIT-PHASE | | 2400 VOLTS DIRECT CURRENT | |
|---|---|---|---|---|
| | Ruling Grade | Level | Ruling Grade | Level |
| | Per Cent | | Per Cent | |
| Motors and gears | 89.3 | 86.0 | 89.3 | 86.0 |
| Blower | 97.8 | 95.8 | 97.9 | 95.9 |
| Starting resistances | 98.6 | 98.0 | 99.2 | 99.4 |
| Phase converter | 96.3 | 94.7 | | |
| Transformer | 98.0 | 97.0 | | |
| Wheel correction | 98.0 | 98.0 | | |
| Weight efficiency | 95.0 | 97.0 | | |
| Combined efficiency | 75.7 | 70.5 | 86.6 | 82.0 |
| Average of grade and level | 73.1 | | 84.3 | |

*Motor and gears* are assumed to be of equal efficiency for both split-phase and direct current, as the advantage of one type motor over the other will be small at best and will not materially affect the values given.

*Blower efficiency* is based upon the fan blower required to cool the motors and auxiliaries taking 30 kw. split-phase and 25 kw. direct current.

*Starting resistances* consume a portion of the power required to start the train, and efficiency of the locomotive is based upon the assumption that the train is started from rest once in two hours. This starting resistance loss is greater with the split-phase than with the direct current locomotive, being twice as large up to speeds of 15 miles per hour on ruling grade and four times as large up to speeds of 30 miles per hour on level track.

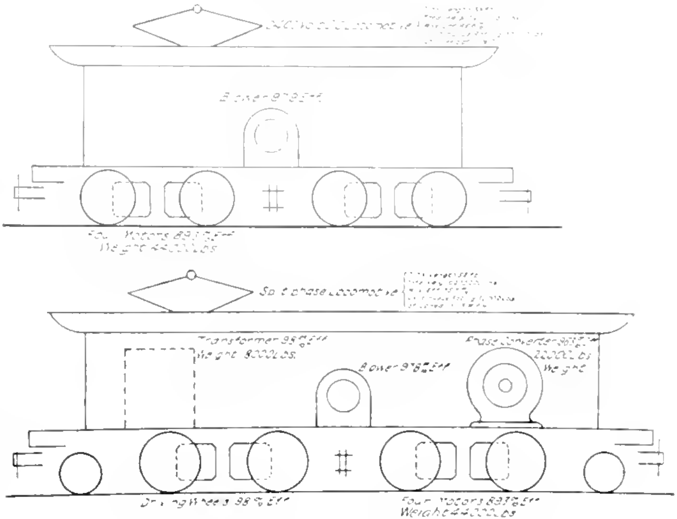

Fig. 7. Comparative Elevations of Split-phase and 2400 Volt Direct Current Locomotives of Equal Capacity

*Phase converter* efficiency is determined by assuming that the capacity of the converter will approximate 75 per cent of that of the four motors it controls.

*Transformer* efficiency values given require no comment.

*Wheel correction* is determined as follows:

Induction motors run at nearly synchronous speed, the slip being proportional to the total secondary non-inductive resistance, hence all wheels upon the same locomotive must be very closely of the same diameter in order to ensure equal loading of the several motors. When one pair of wheels is turned, all must be turned equally. This would not be a very serious handicap were it not for the fact that several locomotives will operate in the same train thus necessitating equal wheel diameters on all such locomotives. It is therefore evident that all locomotives must be interchangeable and any group of two or more be capable of running in the same train or the operating department will be seriously handicapped.

The diameter of new and turned wheels may vary fully 4 per cent, an amount sufficient to cause a prohibitive load distribution between motors. Hence it is proposed to install a variable secondary resistance and so adjust this resistance in the several motor secondaries that all wheel peripheral speeds will conform to the average diameter of new and worn wheels. This will entail an average loss of say 2 per cent when operation has continued long enough to require turning wheels to the minimum diameter allowable. Direct current motors have such a variable speed characteristic as to require no adjustment for varying wheel diameters.

*Weight efficiency* is a relative value based upon comparison with the direct current locomotives taken at 100 per cent.

### COMPARATIVE WEIGHT EFFICIENCY
#### FREIGHT LOCOMOTIVES

| | Split-Phase | 2400 Volts Direct Current |
|---|---|---|
| Rated t.e. on ruling grade | 36,000 lb. | 36,000 lb. |
| Gross train weight | 750 tons | 750 tons |
| Trailing train weight | 615 tons | 650 tons |
| Per cent trailing to gross | 82% | 86.7% |
| Weight efficiency | 94.7% | 100% |

On level track it is assumed that pushing locomotives will be dropped and train weight per road locomotive will be double the ruling grade values. On this basis the split-phase locomotive weight efficiency will be 97 per cent for level track runs. Both values of split-phase locomotive weight efficiency are based upon the assumption that locomotives will be loaded to 100 per cent capacity on ruling grades. As such will not always be possible in regular operation it is evident that the values quoted above will be lower under actual service conditions.

The combined efficiency of the complete locomotive shows that the split-phase freight locomotive will demand 15 per cent more power input from the trolley than a direct current locomotive of equal hauling capacity and similar mechanical drive.

For passenger service it is reasonable to expect the locomotive running gear to be so constructed as to permit maximum speeds approaching 75 miles per hour without danger of derailment or exceeding safe limits of motor and drive construction. Neither of the forms of construction in Fig. 7 are well adapted for very high speeds, and to secure good running qualities it is probably necessary to adopt different types of construction for freight and passenger locomotives however desirable it may be from an operating standpoint to have them interchangeable.

With direct current motors several forms of construction are available that will all operate successfully at high speeds. The most efficient construction is unquestionably to mount the motor armatures upon the driving axles and eliminate the losses, weight and complications of any form of mechanical drive. It is assumed in this comparison that gearless construction will be adopted for direct current high speed passenger locomotives.

The split-phase locomotive motor is of the multiphase induction type and not adapted to gearless construction except by the introduction of quills and springs. This form of construction has not been so successful in operation as to justify considering its general adoption. It is assumed therefore that in order to get a locomotive of good riding qualities at high speeds, it is necessary to resort to side rod drive from a jack shaft and house the motors in the cab. In this comparison it is assumed that motors drive the jack shaft through gears rather than by rods as offering a lighter form of construction requiring less space. The same form of drive is equally available with direct current motors, but gearless construction offers great advantages such as extreme simplicity, accessibility and high efficiency so that comparison will be based upon geared side rod split-phase and gearless direct current motor locomotives.

It appears reasonable to expect the efficiency of mixed passenger and freight locomotive operation to approximate 85 per cent for direct current and not much exceeding 68 to 70 per cent for split-phase locomotives.

### PASSENGER LOCOMOTIVE EFFICIENCY
#### DETAILED COMPARISON

| | SPLIT-PHASE | | 2400 VOLTS DIRECT CURRENT | |
|---|---|---|---|---|
| | Ruling Grade | Level | Ruling Grade | Level |
| | Per Cent | | Per Cent | |
| Motors and gears | 89.3 | 83.0 | 87.5 | 94.0 |
| Blower | 97.8 | 84.8 | 97.9 | 95.5 |
| Starting resistances | 98.6 | 97.8 | 99.2 | 99.3 |
| Phase converter | 96.3 | 94.0 | .. | |
| Transformer | 98.0 | 96.0 | | |
| Wheel correction | 98.0 | 98.0 | | |
| Weight efficiency | 92.5 | 92.5 | | |
| Jack shaft | 97.0 | 93.0 | | |
| Side rods | 97.0 | 93.0 | | |
| Combined efficiency | 69.3 | 54.5 | 85.0 | 89.2 |
| Average of grade and level | 61.9 | | 87.1 | |

This efficiency in each case is based upon that portion of the run during which power is delivered to the locomotive. If transformer, phase converter and blower are kept running during coasting periods or when standing, the standby losses thus introduced will seriously reduce the all day efficiency in commercial operation. It is evident that such standby losses are much greater in the split-phase than in the direct current locomotive and the 20 per cent saving in power for mixed freight and passenger service credited to the direct current motive power may be materially increased in actual service.

Before concluding the general discussion of the locomotive it is necessary to touch upon the question of braking. One of the strongest arguments advanced for the adoption of the induction motor locomotive is that this type of motor offers an ideal electric brake by reversing its function on down grade and returning power to the trolley circuit. A regenerative braking method of control has been perfected for use with the direct current motor which offers even greater advantages in service operation than induction motor braking. Just as the direct current locomotive is the more efficient in hauling a given trailing tonnage so also it will return to the system a larger percentage of the mechanical power given the locomotive by the descending train. Hence whatever claims are advanced for regenerative electric braking with the split-phase locomotives are even more applicable to the direct current type.

Referring again to Figs. 5 and 6, showing the general plan of distribution respectively for the split-phase and direct current systems, it is of interest to compare the two in order to see how much of the split-phase locomotive loss is recouped by its more efficient distribution system. The following comparison is therefore submitted.

### EFFICIENCY OF DISTRIBUTION SYSTEM
#### DETAIL COMPARISON

| | Split-Phase | 2400 Volts Direct Current |
|---|---|---|
| | Per Cent | Per Cent |
| Step-down transformers | 97.5 | 96.5 |
| Motor-generator sets | 87.0 | 81.0 |
| Step-up transformers | 97.5 | |
| Railway transmission line | 96.0 | 96.0 |
| Line transformers | 96.0 | |
| Protective transformers | 96.0 | |
| Trolley, track and feeders | 96.0 | 88.0 |
| Combined efficiency | 70.5 | 66.0 |

Protective transformers appearing in above table are for the purpose of neutralizing the inductive disturbance caused by single-phase trolley upon neighboring telephone, telegraph and signal circuits.

There is every reason to expect that the split-phase system will demand fully 15 per cent more power input than the direct current system of 2400 volts for equal trailing tonnage movement, actual figures depending upon the proportion of freight and passenger tonnage. This figure is based upon 60 cycle power supply for the reason that many of the immediate electrification projects under construction or contemplated are located in territories where this frequency is firmly established.

### TOTAL EFFICIENCY
#### DISTRIBUTION SYSTEM AND LOCOMOTIVE

| | Split-Phase | 2400 Volts Direct Current |
|---|---|---|
| | Per Cent | Per Cent |
| FREIGHT SERVICE | | |
| Distribution | 70.5 | 66.0 |
| Locomotives | 73.1 | 84.3 |
| Combined efficiency | 51.5 | 55.7 |
| PASSENGER SERVICE | | |
| Distribution | 70.5 | 66.0 |
| Locomotives | 61.9 | 87.1 |
| Combined efficiency | 43.6 | 57.5 |

Where 25 cycles is available, single-phase power may be taken direct from the three-phase supply provided phase and voltage balance is maintained by suitably located substations containing step down transformers and phase converters. Direct current supply will be more efficiently obtained through rotary converters in place of motor-generator sets. The efficiency of the distribution system, as given above, will therefore need correction for 25 cycle power supply but will result in no material change in the relative efficiency figures quoted for the two systems.

Installing a power house to generate single-phase current at 25 cycles or less introduces all the serious handicaps encountered in single-phase generation as well as raises questions of general expediency and adequate return on the capital invested in a power plant devoted to supplying railway load only. Advocates of single-phase trolley distribution have sometimes failed to fully consider the question of power supply available as having any bearing upon the broad question of electrification. Not every railway is so situated by reason of character of load, cheap fuel or other favoring local conditions as to justify the large expenditure for a generating station containing ample reserve capacity. The somewhat higher efficiency of the distributing system alone in cases where single-phase power is available is so relatively unimportant that it may be looked upon as a special condition applying only to favored and restricted localities.

A study of the general plan of distribution as given in Figs. 5 and 6 discloses the fact that where 60 cycle power supply is available at attractive rates, the general statement can be safely made that the total amount of electrical apparatus is greater and therefore the first cost higher and efficiency lower with the split-phase than with the direct current locomotive system. Nor is this statement modified to any extent in the event that power supply is obtained from a 25 cycle three-phase source, as it will be the exception rather than the rule that any power company will be found willing to furnish single-phase power from its balanced three-phase circuit when the pernicious effect upon the general distribution system of a violently fluctuating low power-factor single-phase load is fully understood. Some corrective device like a phase converter must be introduced and its first cost and efficiency are both comparable to the rotary converters which are permissible with 25 cycle supply to secure direct current. It would seem therefore that the complication of the split-phase locomotive system renders it inherently more expensive to install and less efficient to operate. This is due largely to the fact that substations containing moving machinery are required both on the ground and also in the locomotive cab itself.

The single-phase trolley circuit, irrespective of the type of locomotive it may supply, constitutes in itself a most serious handicap to the adoption of any type of alternating current locomotive. Neighboring circuits of all kinds are practically put out of commission by static and inductive disturbances unless adequate protective measures are introduced. No method of complete protection has as yet been perfected although many schemes have been proposed that are partially successful. The elaborate and expensive apparatus now being installed upon one of our most important single-phase railways will soon be in operation and it is expected to give relief from the present serious condition obtaining. As the inductive interference of the single-phase trolley is proportional to the intensity of the current and distance it is transmitted, it is to be expected that a maximum disturbance will result in the case of mountain grade divisions where the current input to trains approaching 3000 tons gross weight is several times that thus far met with in any single-phase trolley installation now operating. No cost estimate of single-phase trolley systems is therefore complete without including a liberal allowance for telephone and telegraph protective devices. This cost will probably not be less than $2500.00 per mile of route and may even greatly exceed this figure. Even with such an expenditure, no assurance is at hand that hazard to employees and interference with service will be entirely eliminated, and until more exact knowledge of this whole situation is available, single-phase trolley interference constitutes a most serious handicap to the adoption of any alternating current locomotive system of operation.

This paper is largely devoted to a comparison of alternating and direct current motor locomotives, as lack of appreciation of the fundamental facts involved has perhaps been the basis of the false hopes raised as to the possible advantages resulting from the installation of the single-phase trolley. It surely does look attractive to install a system employing 15,000 volts on the trolley, no feeder copper and no rotating substation apparatus. But investigation and experience discloses the fact that the single-phase trolley is a decided menace to neighboring circuits, feeder copper is required for return circuit, substations are comparable as to first cost and efficiency with direct current substations and finally, the alternating current locomotive of the most promising type, the so-called split-phase combination of induction motors, transformer and phase converter is heavy, expensive, complicated and inefficient to a degree that would not be tolerated in direct current construction. Assuming that the favorable results of factory experiments are borne out in the success of later commercial operation, there appear to be no controlling advantages of alternating current locomotive traction which cannot be secured at less expense and with greater reliability in operation with direct current motive power.

Until the adoption of the inter-pole motor construction made it entirely practicable to build direct current motors for high potentials, there was some justification for considering alternating trolley systems as offering the best means of changing from steam to electric motive power at a reasonable first cost. The high voltage direct current motor has now been developed, built and proven completely successful under the most exacting service conditions. The trolley potential has been raised to 2400 volts which seems sufficiently high to ensure a distribution system of reasonable first cost and not too high to handicap the locomotive as regards its first cost, reliability and operating efficiency. Experimental results already obtained with direct current apparatus tested at potentials higher than 2400 volts indicate that no constructive difficulties apparently exist and the installation of a higher voltage becomes an economic question rather than an engineering problem.

With 2400 volts direct current both protected third rail construction and multiple unit car operation are feasible. The third rail offers advantages in accessibility and low cost of maintenance on single track roads and multiple unit car operation is without question the proper way to take care of local traffic. Furthermore, 2400 volt equipments can be successfully operated upon the lower voltage terminal zone that local restrictions may make necessary.

It is popularly supposed among electrical engineers that the cause of electric traction is retarded by an openly expressed divergence of views as to the relative merits of different systems of electrification. The opinion is advanced on the contrary that a free presentation of the facts available, but not always made public, will do much to clarify the situation. No one contributing cause has done more to hurt the electric railway industry than the failure of the single-phase system to make good the too optimistic claims of its early advocates, and no such open presentation of installation and operating costs has ever been made public on any alternating current installation in operation in this country or abroad, as has been published by Mr. B. F. Wood in a paper before the A.I.E.E. on the West Jersey & Seashore Railway.

This paper has been purposely restricted to a discussion of engineering questions entering into the electrification problem as having a fundamental bearing upon the all important matter of first cost and cost of operation. Such estimates are readily prepared for any local conditions obtaining provided there is no serious conflict of engineering opinion regarding engineering details as exist today. The direct current motor is fully able to meet all the requirements of the heaviest passenger and freight train operation as proved by the entirely successful installations now running and which afford the convincing facts upon which statements of cost and operation are based. No such condition exists with any alternating locomotive system and such operating facts as are obtainable are not of such a nature as to inspire confidence in selecting such a system to meet the exacting requirements of heavy electric railroading. The engineering facts presented herewith are offered with the purpose in view of clearing the engineering atmosphere preparatory to the serious work that seems to lie immediately before us, that is the problem of where and to what extent it will pay to replace the steam engine by the electric locomotive.

# THE ELECTRIFICATION OF CANE SUGAR FACTORIES

By A. I. M. Winetraub

Engineer, Zaldo & Martinez, Havana

In the August, 1913, issue of the Review we published an article, "Electricity Applied to the Manufacture of Sugar," by Mr. P. S. Smith, which presented an interesting description of the principal features in sugar manufacture and gave the reasons for the growing tendency to equip or re-equip all machines requiring mechanical drives with electric motors. The present article is an excellent continuation of the former, in that it constitutes a conclusive mathematical proof of the savings to be made by electric drive over steam drive. The author confines himself entirely to those improvements that may be made in fuel economy, and only names some of the other benefits which are co-incident with the installation of an electric drive.—**Editor.**

The extensive application of electricity in sugar factories during the last three or four years has given complete satisfaction, and present indications point to the belief that its use in this industry will become so general that the lack of complete electric drive will be a proof of a sugar factory's inefficiency. Its absence may even contribute toward the exclusion from the competitive field of those factories not so equipped.

The promiscuous adaptation of electric motors for pumping and general mechanical drive without a systematic study of the individual requirements for each factory may, however, not result in ultimate fuel economy. The engineer entrusted with the problem of electrifying a sugar factory must be therefore extremely careful in analyzing the particular requirements of that factory, that he may suitably devise for it such an equipment as will give the desired economy.

Until a very short time ago the problem of sugar making was strictly a problem of industrial chemistry and the installation of machinery was looked at from the chemist's point of view. He needed steam for a certain evaporation; he wanted enough of it, and there was nothing that so fully answered his requirements as the old pump working with steam unexpansively. At that time and before the mechanical engineer had devoted his attention to this industry, the juice extraction from the sugar cane was as low as 50 or 60 per cent, and it is reasonable to expect that under such prevailing conditions the bagasse should have given all the steam required and that the amount of steam exhausted to the atmosphere need not have been given any concern.

With the advent of ingenious machines, however, extracting as much as 80 or 85 per cent of the cane juice, the bagasse did not prove in practice to be sufficient, and additional fuel had to be purchased to generate the steam needed for cooking, for this greater extraction now meant much greater evaporation and much larger pumping and driving machinery. The exhaust steam from such machines was greatly in excess of that needed for cooking, with the result that exhaust steam with its contained heat was allowed to go to waste. The logical sequence of such conditions was the seeking of machinery, the exhaust steam from which would balance the cooking requirements, and therefore the most efficient known method of applying power, the electric motor, was called into service.

An actual example will best serve to show the fuel economy obtainable from a proper electrification outside of other adjunct advantages consequent to electric drive, such as reduced labor and maintenance, elimination of shut-downs, increased output, etc. These are all apparent and are productive of ultimate economy in the cost of production. The calculations in the following example do not include all the refinements in the art of sugar making, but such assumptions as have been made approach very nearly to actual practice. The example is worked out mainly with the idea of showing how important it is for the electrical engineer to make his calculations intelligently, and at the same time illustrates the manner in which they are to be made.

Assume a mill of 70 tons per hour grinding capacity, or roughly 100,000 bags of sugar of 325 lb. each per season of 100 days, operating 23 hours per day with a sugar yield of $10\frac{1}{2}$ per cent from the cane. The dry bagasse being 13 per cent of the weight of the cane, and the extraction 80 per cent of the weight of the cane we have:

| | |
|---|---|
| Dry bagasse per hour . . . . . | 9.1 tons |
| Juice . . . . . . . . . . | 56.0 tons |
| Loss in moisture of bagasse . . . | 4.9 tons |
| Total . | 70.0 tons |

The gross thermal value of the moist bagasse has been determined and given as 3767 B.t.u. by Geerlings and as 3920 B.t.u. by Deerr. To be conservative in our deductions, let us assume the latter value to hold good for the bagasse obtained.

The thermal efficiency of boilers, having the high flue temperature of those used in an ordinary mill, being only 55 per cent, we have the result that each pound of bagasse actually delivers in the shape of steam $3920 \times 0.55$ or 2156 B.t.u. (Deerr). For 14 tons of bagasse we have

$14 \times 2000 \times 2156 = 60.5 \times 10^6$ B.t.u. in steam available from the bagasse.

The approximate amount of heat required to cook the juice after dilution can be calculated as follows: The average density of the raw juice, before dilution water is added, is 20 degrees Brix. This is generally reduced to 17 deg. Brix before it is defecated, and, therefore, the added water is $\frac{20}{17} - 1$ or 18 per cent of the weight of the juice which was assumed to be 56 tons. The added water being 10 tons we have the total weight of the juice to be defecated, cooked, and reduced to sugar equal to 66 tons at 17 deg. Brix.

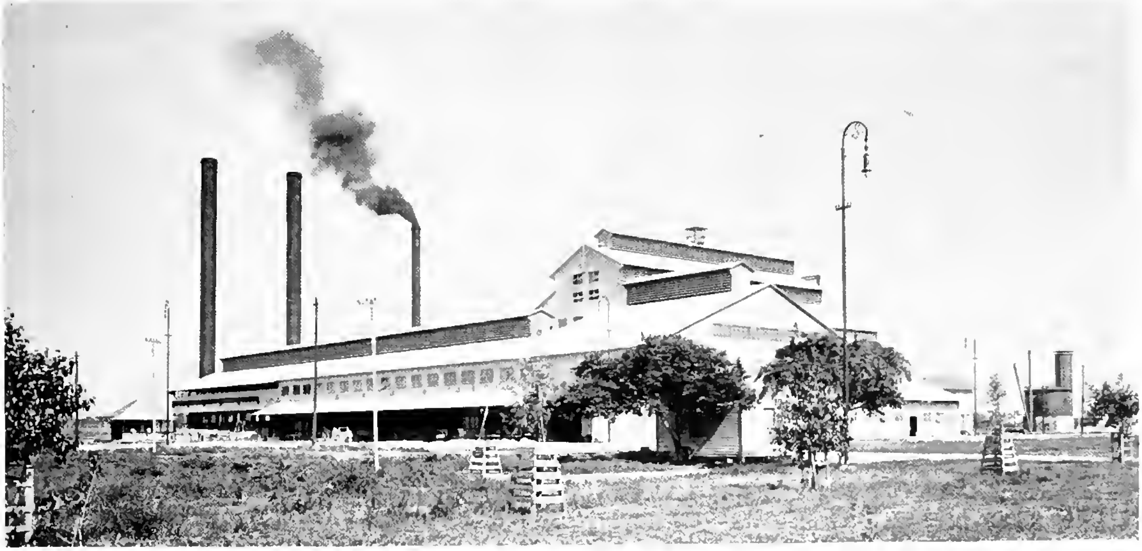

Fig. 1. The Ingenio Las Delicias San Manuel Sugar Co., Cuba, which is equipped with nearly 1500 h.p. in electric motors

The temperature of the juice is raised to 100 deg. F. from the original 70 deg. F. by the B.t.u. contained in the water of condensation, and this heat is therefore not to be considered as there are sufficient B.t.u. contained in the condenser water to do this work.

The juice is then heated from 100 deg. F. to 208 deg. F. in heaters, and the heat required is

$66 \times 2000 \times (208 - 100) = 14.2 \times 10^6$ effective B.t.u. This heat is supplied by exhaust steam at 6 to 8 lb. per sq. in. pressure, but as the steam in cooling gives up only its latent heat or 952 B.t.u. while the heat in the admitted steam is 1152 B.t.u. this work requires

$$\frac{1152 \times 14.2 \times 10^6}{952} = 17.2 \times 10^6 \text{ actual B.t.u.}$$

which is 28.5 per cent of the heat in the steam evolved by burning the bagasse.

In the quadruple-effect evaporator, the density of the defecated juice is changed from 17 to 55 deg. Brix, and the water to be evaporated for this concentration is

$$2000\left[0.90 \times 66 - \left(0.90 \times 66 \times \frac{17}{55}\right)\right]$$

or 82,000 lb.

In practice 3.7 lb. of water are evaporated by one pound of steam at 6 to 8 lb. pressure in a quadruple-effect evaporator. Therefore, 22,700 lb. of steam are required, which at 1152 B.t.u. represents $25.6 \times 10^6$ B.t.u. or $42\frac{1}{2}$ per cent of the steam generated by the bagasse. The remaining substance termed "meladura" $\left(0.90 \times 66 \times \frac{17}{55} \times 2000 \text{ lb. or } 36{,}800 \text{ lb.}\right)$ is to be reduced ultimately from 55 to 95 deg. Brix, and the water to be evaporated is therefore

$$\left(36{,}800 - 36{,}800 \times \frac{55}{95}\right) \text{or } 15{,}500 \text{ lb.}$$

Assuming this operation to be done in a vacuum pan under high vacuum and with exhaust steam, the steam required is proportional to that of the multiple-effect evaporator or

$$\frac{3.7}{4}\times 15{,}500\times 1152 = 16.5\times 10^6 \text{ B.t.u. or } 27.3$$

per cent of the steam generated by the bagasse.

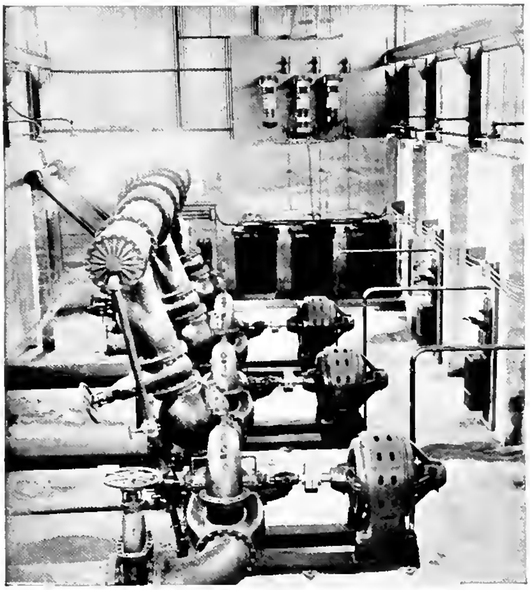

Fig. 2. Direct-connected, Motor-driven Centrifugal Pumps Providing Injection Water for Vacuum Pans and Multiple-Effect Evaporators

Assume now that the extraction gives a first yield amounting to 9 per cent of the cane or 12,600 lb. per hour when the "massecuite" as above is $36{,}800\times\frac{55}{95}$. We then have as molasses

$21{,}400-12{,}600$ or 8,800 lb. per hour.

This molasses is to be diluted say from 88 deg. Brix to 50 deg. Brix, and then further concentrated to 92 deg. Brix in the vacuum pan. The dilution water is $\frac{88}{50}-1$ or 76 per cent water by weight. Therefore, there are 15,500 lb. of liquor to be concentrated to 92 deg. Brix and the water to be evaporated is

$$15{,}500-15{,}500\times\frac{50}{92} \text{ or } 7050 \text{ lb.}$$

The heat required is, calculating as above,

$$\frac{3.7}{4}\times 7050\times 1152 = 7.5\times 10^6 \text{ B.t.u. or } 12.4 \text{ per}$$

cent of the steam generated by the bagasse. The total heat required for heating and evaporation, in terms of heat evolved from the burning of the bagasse is, therefore:

| | | Per Cent |
|---|---|---|
| Heating and defecating . | $17.2\times 10^6$ B.t.u. = | 28.5 |
| Evaporating in effect . . | $25.6\times 10^6$ B.t.u. = | 42.5 |
| Evaporating in vacuum pan . . . . . . . | $16.5\times 10^6$ B.t.u. = | 27.3 |
| Evaporating of molasses . | $7.5\times 10^6$ B.t.u. = | 12.4 |
| Assumed losses in condensation . . . . . . | $6.1\times 10^6$ B.t.u. = | 10.0 |
| Total . . . . . . | $72.9\times 10^6$ B.t.u. = | 120.7 |

or 20.7 per cent more than the actual steam generated by the bagasse. Analyzing this in dollars and cents, we have for the case under consideration the following result. 20.7 per cent × 14 tons = 2.9 tons of extra bagasse required per hour for cooking the "dilute" obtained from grinding 70 tons of cane per hour.

The average pound of coal contains 14,000 B.t.u., so that if bagasse possesses 3920 B.t.u. the ratio between coal and bagasse is 3.6, and the extra coal required per hour is, therefore,

$$\frac{2.9}{3.6} = 0.81 \text{ tons of coal per hour.}$$

Where wood is used as fuel, the ratio is obtained on the basis of the heat contained in the variety of wood used.

Operating the mill 100 days per season, 23 hours per day, and assuming that 14,000 B.t.u. in wood cost $7.00 per ton, the mill would spend per season for extra fuel needed to evaporate the water from the dilute,

$$0.81\times 100\times 23\times 7 = \$13{,}000.$$

Fig. 3. Back-geared Motors Driving Crystallizer Countershafts by a Chain Drive

This sum is greatly exceeded in mills of this size and extraction, indicating that money is spent for steam other than that required for cooking purposes, and it is probable that the most of this steam is freely exhausted into the atmosphere.

By the proper use of an electrical equipment, the difference can actually be saved.

Remembering now that the thermal efficiency of the steam engine, or that the percentage of actual B.t.u. required for the transformation of heat units into mechanical units is very low, and that nearly all the heat units put into the engine at the higher pressure are still contained in the low-pressure exhaust and therefore available for cooking, and assuming 8 or 9 per cent of the B.t.u. required for actual mechanical drive, which has been shown by practice to be a reasonable value, we would have the total heat required to be generated in the shape of steam to run the plant. This amounts to $79 \times 10^6$ B.t.u. or 130.7 per cent of the heat generated by the bagasse.

Each boiler horse power delivers 33,300 B.t.u. per hour. Therefore, the boiler capacity in this case, a 70-ton-per-hour mill, should be 2360 boiler horse power, or 34 boiler horse power per ton of cane ground per hour. As a matter of fact, the boilers installed and operating are nearer 45 and 50 boiler horse power per ton of cane per hour, which is a figure that has been found in actual practice to be in excess of the requirements of a factory equipped with a suitable electric drive.

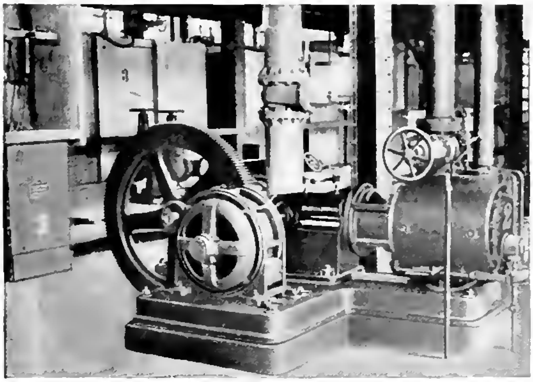

Fig. 4. One of Five Motor-driven Vacuum Pumps Installed in a Sugar Factory

In the electrifying of a sugar factory, i.e., changing its drive from steam to electric, it is apparent therefore that this excess boiler capacity can be used as a spare, with a consequent more efficient boiler operation which will also reduce the cost of repairs and increase the life of the boilers. The problem of electrification, from the modern mechanical or electrical engineer's point of view, is not to diminish the cost of steam required for cooking but to install such machinery as will not give an exhaust in excess of that needed for cooking. If additional machinery is required for mechanical drive or other purposes, it should be of such a type as to consume the least amount of steam and to waste the least or give no exhaust to the atmosphere.

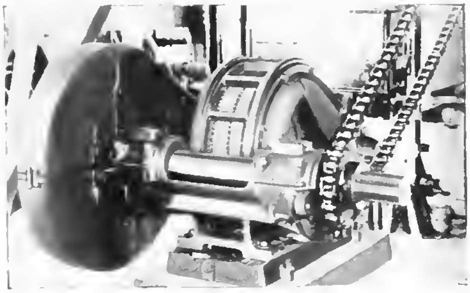

Fig. 5. Back-geared Motor and Chain Drive for a Countershaft Belted to Two Massecuite Pumps, Four Molasses Pumps and a Screw Conveyor

The mechanical power installation for the plant under consideration must, therefore, be proportioned in such a manner that its exhaust will be capable of furnishing the required $72.9 \times 10^6$ B.t.u. per hour. Any exhaust in excess of this represents wasted money; and the mill which shows a continuous stream of exhaust gives an indication of being operated uneconomically. Many a mill owner claims he has steam to spare, that he requires no improvements, and as a proof of it he points to the free exhaust, forgetting that he paid good money to obtain the 1152 B.t.u. contained in the exhaust steam at 6 lb. pressure, or that his extraction is so poor that he cannot use all the heat contained in the bagasse.

Now let us suppose that we have carefully analyzed the power requirements of each mechanical drive in terms of input, and that after considering the proportionate time of operation of each machine, i.e., the load-factor, the power requirements, in engines for crushers, mills, pumps, mechanical drive, electric lighting and power, tool shops, etc., are 28 brake horse power* per ton of cane ground per hour or a total of 1960 brake horse power for a 70-ton-per-hour sugar house. The steam consumption of the various steam engines must now be considered

---

* This figure is in agreement with the 8 or 9 per cent of the heat required for cooking, as previously mentioned.

as guaranteed by the manufacturers, and the equipment must be proportioned accordingly. An average steam engine of the Corliss type in a sugar house, running non-condensing and with 6 to 8 lb. back pressure, consumes approximately 28 lb. steam per indicated horse power hour, and with a general gross efficiency of brake to indicated horse power of 85 per cent the actual steam required would be $\frac{28}{0.85}$ or 33 lb. per brake horse power hour. As the heat contained in the exhaust is 1152 B.t.u. the heat of the steam exhausted by each brake horse power is

$$1152 \times 33 = 38{,}000 \text{ B.t.u.}$$

Fig. 6. Inclined Track at Ingenio San Manuel Sugar Co., Cuba, to take care of the wood fuel needed to help the bagasse in the process of evaporation, and for which the bagasse alone is insufficient

Therefore, the necessary capacity of steam engine equipment for the needed exhaust is as follows:

$$\frac{72.9 \times 10^6}{38{,}000} = 1{,}920 \text{ brake h.p.}$$

With an equipment of 1960 brake h.p. in engines consuming 33 lb. of steam per brake h.p. hour, we see that we would have in this case very nearly only the actual amount of exhaust necessary for evaporation and thus no steam would be wasted. This, therefore, constitutes as near an ideal arrangement as is possible for this particular installation because the only fuel expense is that necessary for obtaining the heat required in concentrating the liquor and for which work the bagasse is not sufficient.

Assume now that instead of having 1960 brake h.p. in engines all consuming 33 lb. of steam per brake horse power hour, we had say 30 per cent of the total brake horse power requirements in pumps, hydraulic machinery, etc., using in the neighborhood of 100 lb. of steam per actual brake horse power hour, which consumption is by no means high in non-expanding steam engines.

With this latter arrangement we would have

$$0.70 \times 1960 \times 1152 \times 33 = 52.1 \times 10^6 \text{ B.t.u.}$$
$$0.30 \times 1960 \times 1152 \times 100 = 67.7 \times 10^6 \text{ B.t.u.}$$

Total heat available in the exhaust $119.8 \times 10^6$ B.t.u.

As we only require $72.9 \times 10^6$ B.t.u. the extra fuel is spent for obtaining

$$(119.8 - 72.9) \times 10^6 = 46.9 \times 10^6 \text{ B.t.u.}$$

By the installation of a suitable and duly proportioned electrical equipment, it is entirely feasible to save these $46.9 \times 10^6$ B.t.u., the value of which can be estimated as follows.

One pound of bagasse contains 3920 B.t.u.; the coal equivalent compared with bagasse is 3.6, as has been shown; the cost of coal equivalent is assumed at $7.00 per ton. Assume a 23-hour-per-day operation and a 100-day season.

Then:

$$\frac{46.9 \times 10^6 \times 23 \times 100 \times 7}{3920 \times 3.6 \times 2000} = \$27{,}000 \text{ can be}$$

saved in a mill of 70 tons per hour grinding capacity. A newly built factory of this size, without the use of a suitable electric drive, will then actually lose at the rate of $27,000 per season of 100 days.

Assuming now that for electrifying an old sugar house the interest on the investment for the change-over would represent yearly the sum of $7000, the sugar mill owner would actually have a yearly profit of approximately $20,000. This is apart from the interest on the electric motor investment, and is exclusive of the other very important coincident advantages which will save, as will be demonstrated in a later article, as much as and even more than the value of economized fuel.

Analyzing this result from another point of view, it will be apparent that from the value of the saved fuel alone and without considering the other advantages, the change-over from steam to electricity, in an old mill, would pay for itself in three or four years.

# FROM THE CONSULTING ENGINEERING DEPARTMENT OF THE GENERAL ELECTRIC COMPANY

## MAGNESIUM METAL

The value of magnesium as an alloy with copper and zinc has been known for some time. Recently the extremely light construction desirable for airships and other machines has brought aluminum-magnesium alloys into prominence, and it has been found that for castings an alloy of aluminum with 10 per cent magnesium is preferable to pure aluminum for practically all purposes, as it is harder, stiffer, casts better, takes a better polish and is materially stronger, so that lighter constructions are permissible. Aluminum-magnesium alloys, with magnesium contents varying from a few per cent to 50 per cent have been introduced some time ago under the trade name "magnalium," but were limited by the high price of magnesium.

Magnesium metal is now on the market at approximately $1.40 per pound, which is quite reasonable considering the bulk of the material, due to the low specific gravity which is 1.75. This renders it practical to consider magnesium-aluminum alloy for various electric machines.

Magnesium metal, as now offered on the market, analyzes 99.8 per cent magnesium and 0.2 per cent iron. The properties of this metal have been found as follows, which is practically what has been previously found for pure magnesium:

Resistivity at 22 deg. C....... 4.55 microhms
Conductivity at 22 deg. C. . . 38.1 per cent
Temperature coefficient at 22 deg. C., 0.00380
Temperature coefficient at 0 deg. C., 0.00412
Tensile strength, lb. per sq. in........30,000
Elastic limit, lb. per sq. in......below 10,000
Shearing strength.....................15,600

J. D. B.

## CHARACTERISTICS OF NON-ARCING METALS

The purpose of this investigation was to determine the a-c. voltage necessary to establish an arc between two clean metal cylinders, after the intervening gap has been broken down by a static spark. The results, at first, did not seem to be at all consistent and finally it was found that the data taken depended to a marked extent on the particular reactance used to limit the short circuit current when the dynamic arc held. This lead to the suspicion that power-factor had an important relation to the holding a-c. voltage, and that all reactances used must not be saturated.

The nearer the voltage and current are in phase, the higher the voltage required to establish the arc. Unit power-factor curves are irregular, as should be expected. Theoretically, the voltage and current should be zero at the same time and the arc should break, but a finite curve is obtained, due probably to a time displacement between the current and the vapor stream of the metal and also to the slight reactance of the transformers and resistance circuit.

At the very small gaps, say from 0.01 in. to 0.1 in., the dielectric strength of the air is a predominating factor, while for the larger gaps the condition of the arc stream and the formation of more vapor is more effective. Hence, the increase and decrease of voltage, as shown by the curves.

From the data it seems that, for copper, brass and wrought iron, the minimum voltage required depends more on the angle of lag of the current than it does on the material under test. However, the curves for carbon and graphite seem to give much lower average values.

These results partly explain why titanium lamps would not operate on some circuits until the maximum reactance of the lamp was used. For example, on one 50 lamp system standard connections were wholly inadequate; that is, the power-factor of the system was too high and, under those conditions, the available voltage was not high enough to maintain the arc.

The same seems to hold for a system of magnetite lamps; that is, if the stability gained by station reactance is partly balanced by the capacity of a section of cable, the operation of the lamps is generally unsatisfactory. Perhaps some have noticed this on our local lighting circuits.

H. D. B.

## QUESTION AND ANSWER SECTION

The Q. and A. Section has been started with the sole object of increasing the practical usefulness of the REVIEW; and in order that it may be made of real value, we invite correspondence from any of our readers who are looking for information on any technical matter in the field covered by this magazine and which they think we can furnish.

Where possible the answers to such inquiries will be the work of this office; where desirable we shall obtain our authority from that engineering or commercial person in the General Electric Company's organization best fitted for handling the particular subject. We hope our readers will not hesitate to avail themselves of the expert engineering opinion which should be made available through this section of the REVIEW. Information on matters of general importance and interest will be published here; questions of interest solely to the querist will be handled by mail.

Sketches should accompany questions in all cases where this is necessary to give us complete and accurate information on the point at issue. Scale drafts will be made up here from correspondent's rough pencil sketches. Questions must be accompanied with the name and address of the sender, although these will not necessarily be for publication, and should be addressed to the Editor, Q. and A. Section, GENERAL ELECTRIC REVIEW, Schenectady, N. Y.

### INSTALLATION OF A CURVE-DRAWING WATTMETER

**(75) It is desired to install, in a system already in operation, a curve-drawing wattmeter connected according to the accompanying wiring diagram (Fig. 1). There is at present one curve-drawing wattmeter, one watthour meter, and one voltmeter. The potential for these is taken from two 200-watt potential transformers and it is intended to use the same source for the added curve-drawing wattmeter. The current coils are intended to be connected to another set of current transformers, as shown in the diagram.**

We would say that the proposed arrangement would seem to be permissible. However, an accurate estimate of the errors involved can not be given without the ratio and specification numbers of the potential transformers, the ratio and specifition numbers of the current transformers, the specifications or serial numbers of the relays, their type, form, etc., the frequency of the circuit, and the power-factor limits of the output power from the 2000 kv-a. transformers into the 2300-volt busses.

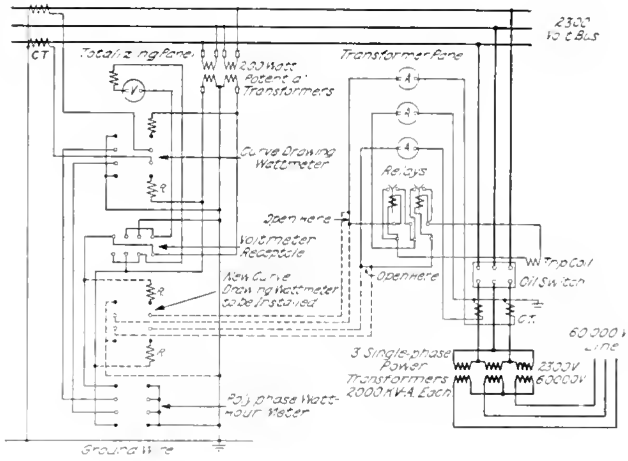

Fig. 1

L.T.R.

### POWER-FACTOR OF TRANSFORMER ON SHORT CIRCUIT

**(76) What are the internal characteristics affecting the power-factor of a transformer on short circuit; and what would be the value of the power-factor for, say, full-load current and also 150 per cent full-load current, both of course, at reduced voltage?**

The power-factor of a transformer on short circuit depends upon the ratio of its resistance to its impedance; and would be the same at full-load current and at 150 per cent full-load current. The actual value for this is subject to such wide variation that it would hardly be safe to answer by giving one definite figure, because it varies with the size, voltage, frequency, and type of the transformer. For instance, in one type it may be as low as 0.10 and in another type it may be as high as 0.75.

R.K.W.

### STARTING UP COMMUTATING-POLE ROTARY CONVERTERS

**(77) Why is it necessary to raise the direct-current brushes on a compound-wound commutating-pole rotary converter when starting from the alternating-current side?**

As is well known, there is at the starting of a rotary converter not equipped with commutating poles more or less sparking at the brushes due to the alternating field which induces voltage in the coils short circuited by the brushes. When commutating poles are added, a certain amount of magnetic material is thereby placed over the coils which are short circuited by brushes. This decreases the magnetic reluctance, and the induced voltage due to the alternating flux is increased. This induced voltage becomes effective between those adjacent commutator bars short circuited by the brushes with the consequent result of burning the brushes and commutator. The brushes are raised, therefore, to avoid the short circuit and burning. Incidentally also this operation decreases the starting current. When starting all the brushes are raised except two narrow ones, one positive and one negative, which remain down for excitation. The main field circuit is opened to give higher starting torque and less starting current.

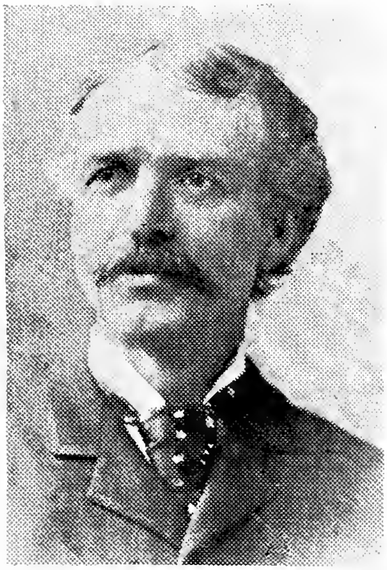
# IN MEMORIAM

## DANIEL MOODY BARTON

The sudden death of Daniel M. Barton, which occurred Monday, December 8, 1913, at his residence in Schenectady, N. Y., after an illness of only five days, removes a prominent employee from the organization of the General Electric Company. He is survived by his wife, who was Miss Lucinda Hill; a daughter, Mrs. Robert E. Nivison, and three grandchildren. He also leaves a brother, Silas A. Barton of Waltham, Mass., and a sister, Miss Vila Barton of Northampton, Mass.



D. M. BARTON

Daniel Moody Barton was born in the town of Ware, Hampshire County, Mass., in the year 1843, the son of Silas D. and Eliza Johnson Barton. There he spent most of his youth up to the age of nineteen, when together with his brothers, Henry and Silas A., he enlisted in the army. He served through the Civil War in the 10th Regiment of Massachusetts Volunteers, which fought at Fredericksburg and Gettysburg. After his return from the war, he became a dry goods merchant in Meriden, Conn., and Fall River, Mass., following which he removed to Lynn, Mass., where he pursued the occupations of bookkeeper and newsdealer.

In 1883 the Thomson-Houston Electric Company was formed by citizens of Lynn, one of the leading spirits being Silas A. Barton. Three years later Daniel M. Barton entered the employ of that company and became its first Production Manager, under E. W. Rice, Jr., Superintendent. During his administration of that office, inspired by the first large railway contract secured by the company, for electrifying the West End Street Railway, Boston, he devised and inaugurated some novel and successful systems of scheduling, regulating and expediting production, which attracted wide attention.

In 1891, the purchasing for the company, including that of its allied companies, was centralized in what was termed a Purchasing Bureau, located at Boston, with Silas A. Barton, Manager; F. W. Webster, Purchasing Agent; E. D. Floyd, Assistant Purchasing Agent. In 1893, D. M. Barton became Assistant Purchasing Agent of the General Electric Company, which was formed the previous year. With the removal of the offices to Schenectady, after it was decided early in 1894 to make that city the headquarters of the company, Mr. Barton was appointed Purchasing Agent, this title being changed to General Purchasing Agent some years later, which position he filled ably and loyally up to the time of his death.

Daniel M. Barton was a true christian gentleman, exceptionally devoted to his home and family; endowed by nature with deep human sympathies, which he extended to all, his kind hearted impulses and sunny disposition, coupled with a stern integrity and a scrupulous sense of justice, made his character a respected and lovable one. His death will cause a keen sense of personal loss, not only to his business associates, but also to his many friends in the industrial world.

## MATTHEW MAURY CORBIN

Matthew Maury Corbin, who died suddenly on August 24th at Charlestown, W. Va., was born near Fredericksburg, Va., in 1873. At the age of 21 he was graduated from the Virginia Military Institute in Civil Engineering, class of 1894, immediately following which he successfully completed a two years' special course in applied electricity at Johns Hopkins University. He taught school for a year in Southern Maryland and was later employed by the Bailey Switch and Signalling Company to assist in laying out their electric signalling system.

M. M. CORBIN

At the age of 25 he was commissioned Second Lieutenant, 1st Regiment, U. S. Volunteer Engineers, which was organized on the outbreak of the Spanish-American War in 1898 by the late General Eugene Griffin under the direction of President McKinley. He was promoted in the field to First Lieutenant and was at one time commanding officer of the Island of Ponce, Porto Rico, when that island was put under military jurisdiction.

At the end of the war, Lieutenant Corbin was given an opportunity to remain in the Government service, but he resigned and entered the General Electric Company's testing department, from which he was subsequently transferred to the Railway and Traction Engineering Department, under Mr. W. B. Potter. He served the Company in Schenectady, Cincinnati, Philadelphia and San Francisco, being a specialist in the electrification of steam railways.

J. C. CALISCH

Mr. Corbin was married in 1906 to Mary Anderson Rinehart of Plainfield, N. J. He is survived by his wife and two children.

### J. C. CALISCH

J. C. Calisch, special agent of the railway department of the General Electric Company, died in New York on November 28th from septic pneumonia.

Mr. Calisch entered the New York office of the Edison General Electric Company in 1890 and remained with this company when it was merged with the General Electric Company in 1892. In 1895, Mr. Calisch was appointed manager of the Pittsburgh office, and in 1899 manager of the Buffalo office. In 1906 he resigned to become vice-president and general manager of the Buffalo & Lake Erie Traction Company. In 1912 he returned to the General Electric Company, and since then has been located in New York as a special agent to look after certain large assigned customers.

### J. H. RYAN

J. H. Ryan, special sales agent for the Chicago office of the General Electric Company, died in one of the hospitals of that city on October 22nd.

Mr. Ryan was graduated from Cornell University in 1909, and after spending some time in the testing department of the General Electric Company, was transferred to the Chicago district in November, 1910, where he was employed as salesman's assistant. In February, 1912, Mr. Ryan was put in charge of sales to certain large interests in Chicago, which position he ably filled up to the time of his death.

GENERAL ELECTRIC REVIEW

## THE PATHS OF PROGRESS

With the beginning of a new year it is not uncommon to review the progress made during the last twelve months, but this is not always easy, and even when well done is seldom satisfactory. At best we touch those achievements which are the most apparent, and as size alone makes some developments so conspicuous, we are apt to lay too much stress on the large and to pay too little attention to the apparently small. It is often these small developments that lead to future progress and upon which the larger achievements are built, although it takes some time for their influence to be felt. However, the building of a power station larger than any yet constructed, and the manufacture of generating and transforming apparatus of immense proportions are notable steps taken along the paths of progress, as one of the chief objects of increased size in this direction is the securing of increased efficiency. The steady decrease in the number of pounds of material used in producing a kilowatt of energy is alone ample evidence that we are advancing. The article which we publish in this number, entitled "Some Notable Electrical Developments in 1913" cites numerous instances of progress in several different directions.

If time and space were available to thoroughly analyze the advances made during the last twelve months, there is little doubt but that the foundations which led to them could, in a very great number of instances, be traced to the research, testing, and other laboratories, where pioneer work is being done all the time, and here again the pioneer work which counts for so much eventually is often apparently insignificant at the time the work is being actually done. The choice of suitable materials and the development of new materials and ways and means of working them are among the important undertakings in this direction. There are so many notable things done today that could not have been done a few years ago, owing to the lack of suitable material and a lack of knowledge in the way to handle them, that the work constantly going on along these lines must be regarded as most important.

The strides made during 1913 in increasing the efficiency of the incandescent lamp will make the year notable for some time to come, and it would take a bold mind to predict the final result that the introduction of the use of gases in incandescent lamps may lead to.

In this issue we publish a paper by Dr. Coolidge on a new and more powerful form of X-ray tube. This work again is the product of the research laboratory of a large manufacturing firm, and bears an eloquent tribute to the nature of work undertaken. It would seem that this particular development may pave the way for further progress along these lines, and it is not unreasonable to believe that it may lead to some spectacular discoveries in that region of the spectrum lying between the X-rays and the gamma rays from radium. The work already accomplished with these rays, especially the discovery of radium, forms one of the most fascinating chapters in scientific research; and if Dr. Coolidge's work should lead to the writing of "known" on that portion of the spectrum hitherto marked unknown, it would indeed be a most notable achievement and a matter for the most whole-hearted congratulation. Such work will be heralded with great joy all over the world and it is not unreasonable to suppose that it may be the foundation stone for future work and future progress along lines that the whole scientific world, and especially the medical contingent, are deeply interested in.

Hydro-Electric Development at Keokuk on the Mississippi River, Showing Dam, Power House and Ship Lock

# THE MISSISSIPPI RIVER HYDRO-ELECTRIC DEVELOPMENT AT KEOKUK, IOWA

## PART I

By Eric A. Lof

Power and Mining Engineering Department, General Electric Company

The completion of this immense hydro-electric development was one of the notable achievements of the year 1913. The construction of the dam and the foundation for the power house was fraught with difficulties, principal of which were the heavy spring floods with their destructive ice jams, that all but defeated the project. The success of the undertaking is as much a credit to the courage and progressiveness of the civil engineer as it is a record of accomplishment for his fellow workman in the electrical field. In this article the author has given us a very satisfying description of the entire development; the present instalment including a historical sketch of the project, and full and well illustrated descriptions of the dam, power house, ship canal, and hydro-electric and electrical equipments (the latter only in part). The concluding instalment, which will appear in our April issue, will deal with the power-limiting reactances, switching arrangements (including control boards), transmission lines, and the St. Louis substation.—Editor.

The huge hydro-electric development of the Mississippi River Power Company at Keokuk, Iowa, is one of the largest that has ever been undertaken in this country and unquestionably ranks highest among the plants of its kind in the world. It is located at the foot of the Des Moines Rapids, a dam having been constructed across the river between the cities of Keokuk, Iowa and Hamilton, Illinois, and the power house erected on the Iowa side.

### Historical Review of Development

The history of the project of developing power from the Des Moines Rapids dates back as far as 1848, but no success attended the various attempts until in 1899, when a final effort was made by the citizens of Keokuk and Hamilton. The Keokuk and Hamilton Water Power Company was organized with a capital of about $2500, which was raised by the sale of stock. The city councils of Keokuk and Hamilton were applied to for help, and by unanimous consent of the citizens $7500 was appropriated and turned over to the promoting company, every cent of which has been paid back to the city treasuries. With these funds at their disposal further investigations were carried on, and Congress was applied to for a franchise, which was granted early in 1905 after a thorough investigation to safeguard the rights of the people. In the early part of 1910 sufficient capital had been assured, and the actual work on the construction was started on January 5, 1910, just thirty days before the franchise expired. The Mississippi River Power Company was formed in the spring of 1911 to succeed the old Keokuk and Hamilton Water Power Company, and is now the owner of the entire plant and equipment. Current was delivered to St. Louis on July 1, 1913, as provided by contract made long before this water-power development was even an assured project. The total cost of the development was approximately $25,000,000.

"Sacred to the Memory of Keokuk, Distinguished Sue Chief, Born at Rock Island in 1788, Died in April, 1848"

### General Features of the Plant

The ultimate capacity of this development will be 300,000 horse power. The present power house installation comprises only one-half of the ultimate equipment, although the sub-structure of the building is complete for the second section, which will be erected as soon as the demand for additional power warrants it.

The electric power will be used mainly for manufacturing and agricultural purposes. The power zone is expected to cover a territory around Keokuk having a radius of about 200 miles and a population of over five million people according to the latest census report. The cities of Keokuk, Fort Madison, and Burlington in Iowa; Hamilton, Quincy and Alton in Illinois; and Hannibal and St. Louis in Missouri, are in the territory receiving power from this system.

Several transmission lines have been erected, one 110,000 volt line covering the territory along the river as far south as St. Louis, 144 miles from Keokuk; one 66,000 volt line from Meppen to Alton; two 33,000 volt lines, one to Hannibal and one to Quincy; and one 11,000 volt line covering the territory up the river to Burlington. The bulk of the power is at present disposed of in St. Louis, where 60,000 horse power is contracted for on a 99-year lease. All the power will be disposed of wholesale to large consumers, independent distributing companies, who may tap the main transmission lines through conveniently located substations.

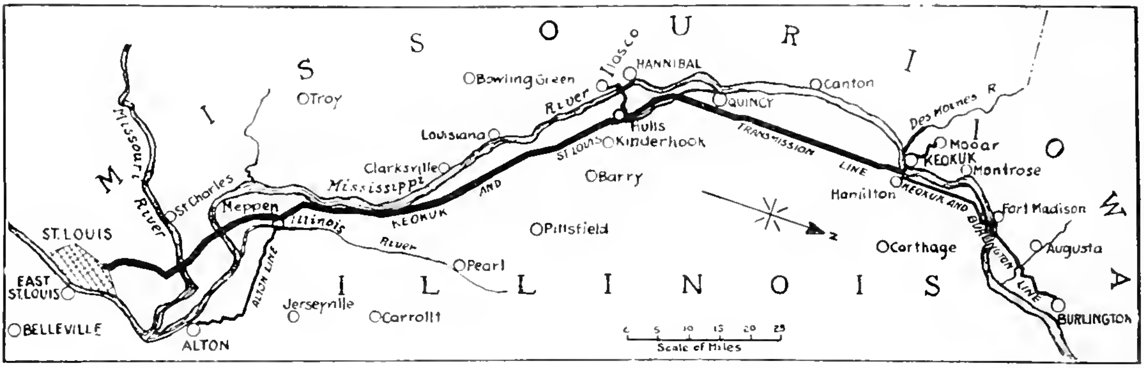

Fig. 1. Map of Country Served by Keokuk Development

The plant consists of the dam across the river, the power house, a navigation lock and dry dock, a retaining wall for protecting the railroad tracks, and an ice fender—all one concrete mass with a total linear length of 2½ miles.

One of the restrictions made by the Government when granting the franchise was that a deep waterway must be maintained, the old locks, dry dock and canal being submerged under many feet of water with the new development. A lock and dry dock had therefore to be built by the water power company and ceded free of cost to the Government, which will have complete ownership of them. The lock, which is 400 feet long and 110 feet wide, is one of the largest in existence, the width being the same as that of the Panama locks. Power for operating both the lock and dry dock, as well as the machine shops, is also furnished free from a separate turbine-driven air compressor plant built by the Company and turned over to the government.

Fig. 2. Timber Cofferdam for Power House Resisting Ice Jam, March 24, 1912. Cofferdam 25½ feet high

### Dam

The dam is of the gravity type, built of mass concrete without reinforcement and keyed down into the limestone bottom of the river about five feet. The structure, including the east and west abutments, has a total length of 4649 feet, a width of 29 feet at the top and 42 feet at the bottom, and a height from the bottom averaging about 53 feet. It comprises 119 equal spans, consisting of arches supported on piers between which the spillway sections are placed. The structure therefore acts both as a bridge and dam, with the water flowing over the spillways beneath the arches. The piers are 6 feet wide and the spillway sections 30 feet long and about 32 feet high.

In designing this dam the extreme variations in the stream flow of the river had naturally to be provided for, this varying from a minimum of 20,000 cubic feet per second to a maximum of 372,500 cubic feet, according to records taken during the last twenty years. While the normal operating head is 32 feet, this will vary from 21 to 39 feet from high to low water.

Fig. 3. View of Dam and Gate Crane

It was also necessary to limit the water level above the dam to prevent flooding of such land as had not been included in the flowage lands. The height of the spillway has therefore been designed to take care of the limit of the upper level. Furthermore, in order to keep the water above the dam at a constant level with smaller flow, steel gates have been provided on top of all the spillways. In extreme high water periods these gates will all be open, while at lower stages a suffi-

Fig. 4. Downstream Side of Dam

cient number will be closed to maintain the pool above the dam at the proper level.

The spillway gates are built of steel truss framework faced with steel plates, and they are raised or lowered by means of two electrically operated derricks, traveling on a track on top of the dam. Two standard gauge railroad tracks previously used for construction are also located on the dam and serve the above mentioned gates.

Fig. 5. First Boats to go Through New Lock. June 12, 1913

The erection of this dam across the Mississippi River at Keokuk has formed a lake which covers an area of approximately 43,000 acres. It extends 65 miles upstream to Burlington, Iowa, and varies in width from one to three miles. Navigation for this distance, which formerly was very difficult during low water periods, has therefore been greatly benefited.

### Power House

The power house is located some distance from the Iowa shore, the intervening space forming the forebay. It lies almost parallel with the river, and the water runs through the intakes and draft tubes nearly at right angles to the river flow, resuming its normal direction in the tail race, which is excavated in the river bed from the upper end of the power house along its entire length and for some distance beyond the downstream end.

The total length of the power house will be 1708 feet, of which the portion normally submerged is now completed. It consists essentially of two distinct parts, the substructure and the super-structure. The former not only serves as a foundation for the present part of the power house superstructure, but is in reality the hydraulic structure of the building. It has been completed to its full height on the forebay side for the entire plant, including the future extension, while on the river side the downstream half has been built above high water. It includes, however, the draft tube openings for the future units.

The width of the building is 132 ft. 10 in., and the total height 177 ft. 6 in., of which the height of the substructure to the generator floor is 70 feet and to the transformer floor 78 feet. The height of the generator room is 68 feet, which gives ample head-room for the traveling cranes, and makes it possible to take out the turbine runners with their shafts and carry them to the repair shop at the end of the generator room.

To gain head, and in order that the draft tubes might always be covered with water, the power house foundation has been extended down in the bed-rock of the river about 25 feet below the limestone bottom. The substructure is built entirely of concrete, the intake, scroll chambers and draft tubes being moulded in. It contains 211,400 cubic yards of concrete, or 13,400 cubic yards more than was used for the dam.

The superstructure is a reinforced concrete building of imposing design, containing four floors. The generator room is located on the main floor along the river side. The exciter sets and transformers are installed in compartments in the center of the building, while the gateroom occupies the shore side of the building. The floor level for the exciter, transformer and gaterooms is 8 feet higher than the floor of the generator room.

For the low tension switches, busbars and reactances, there are provided two narrow mezzanine floors in the center of the building.

Except at the ends, where additions are built out over the generator room to accommodate offices and store rooms, the fourth floor extends for the entire length of the building on the shoreward side only. This floor contains the switchboard control room, the 110,000 volt switches, busbars and lightning arresters.

The floors are supported partly on steel trusses and partly on concrete beams, interconnecting four rows of columns which rest on the sub-structure and extend to the roof. The floors and roof are of reinforced concrete slabs, a large portion of the floors being covered with red tile, while the roof is covered with tar and gravel. Window sashes and frames are all of steel, the windows being electrically operated. The lower part of the interior walls are painted dark green, while the finish of the upper part is white or cream. The entire exterior surface of the building is finished with white cement wash.

## HYDRAULIC EQUIPMENT

### Intakes and Scroll Chambers

From the forebay the water enters each turbine through four intakes converging into a scroll chamber moulded in the concrete around the turbine. The design of this spiral-formed scroll chamber and the intakes has been made very carefully in order to insure an equal velocity and force of the water all around the circumference of the wheel and thus obtain the highest efficiency possible. Three of the intakes for each turbine are entirely separate from the fourth, uniting in a common passage, some distance from the scroll chamber for passing the water to the further side of the wheel, while the fourth intake supplies the water to the nearest side. The scroll chamber has an average diameter of 39 feet and a height of 22 feet.

The outer openings of the intakes, which are 7½ feet wide by 22 feet high, are provided with steel gates sliding in cast iron guides. For raising these gates, as well as the screens, a 75-ton traveling crane is provided, running the full length of the gate house. For lowering the gates, however, there are separate brake mechanisms for each gate.

### Draft Tubes

The water from the turbines is discharged to the tail race through concrete draft tubes. These are about 60 feet long, gradually curved from a vertical to a horizontal direction. The foundations at their outlets are about 25 feet below the normal river bed. The draft tubes have a diameter of 18 feet at the wheels, but their cross section changes from a circular section at this point to an oval shape at the outlet; the tail race openings measuring 22 feet 8 inches in height by 40 feet 2 inches in width. This enlargement and change in shape is calculated to reduce the discharge velocity of the water

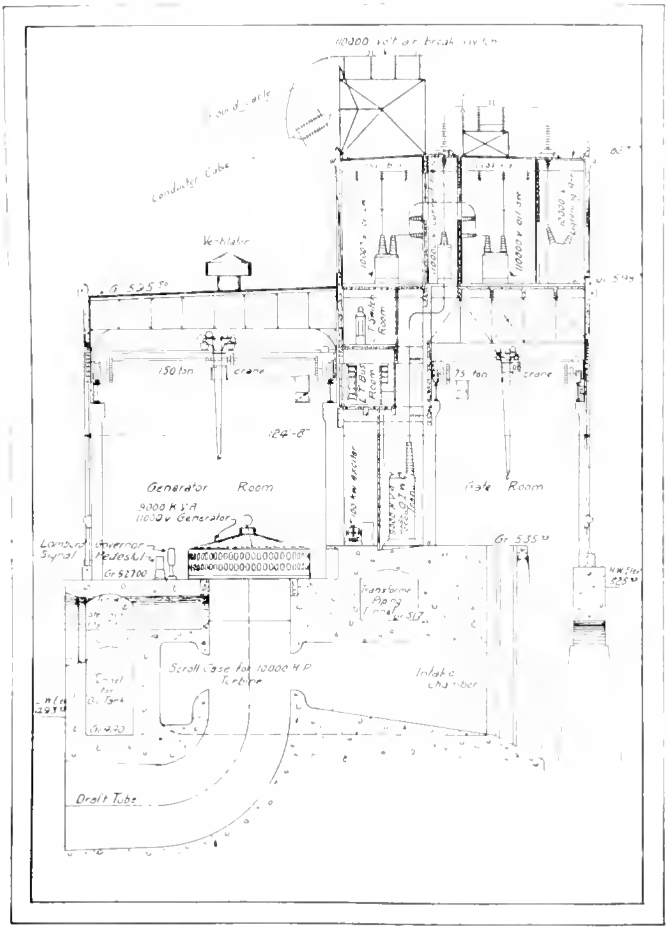

Fig. 6. Sectional Elevation of Power House

to four feet per second at the outlet into the tail race.

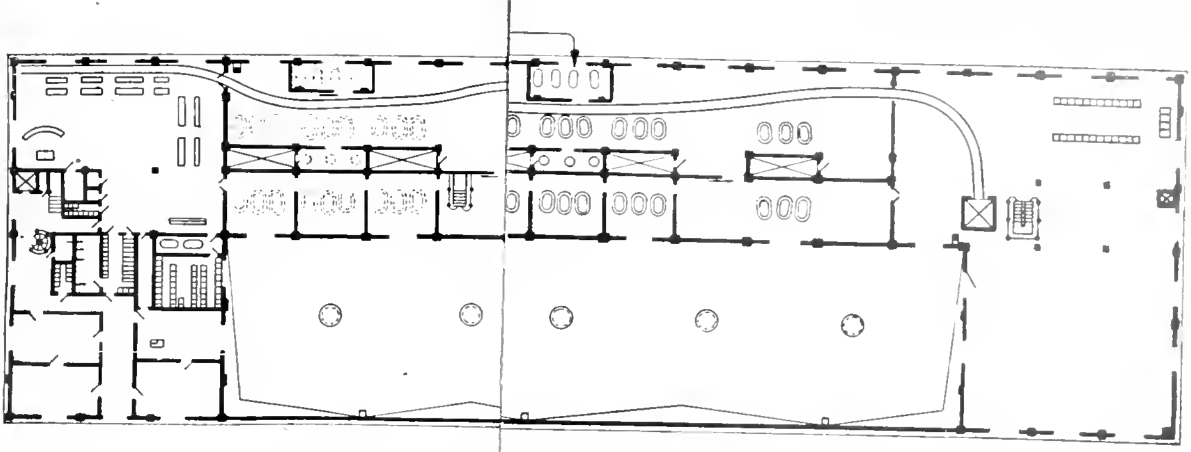
Fig. 7. Looking South Through Gate Room, Showing Gate Mechanisms in Place August 4, 1913

### Main Turbines

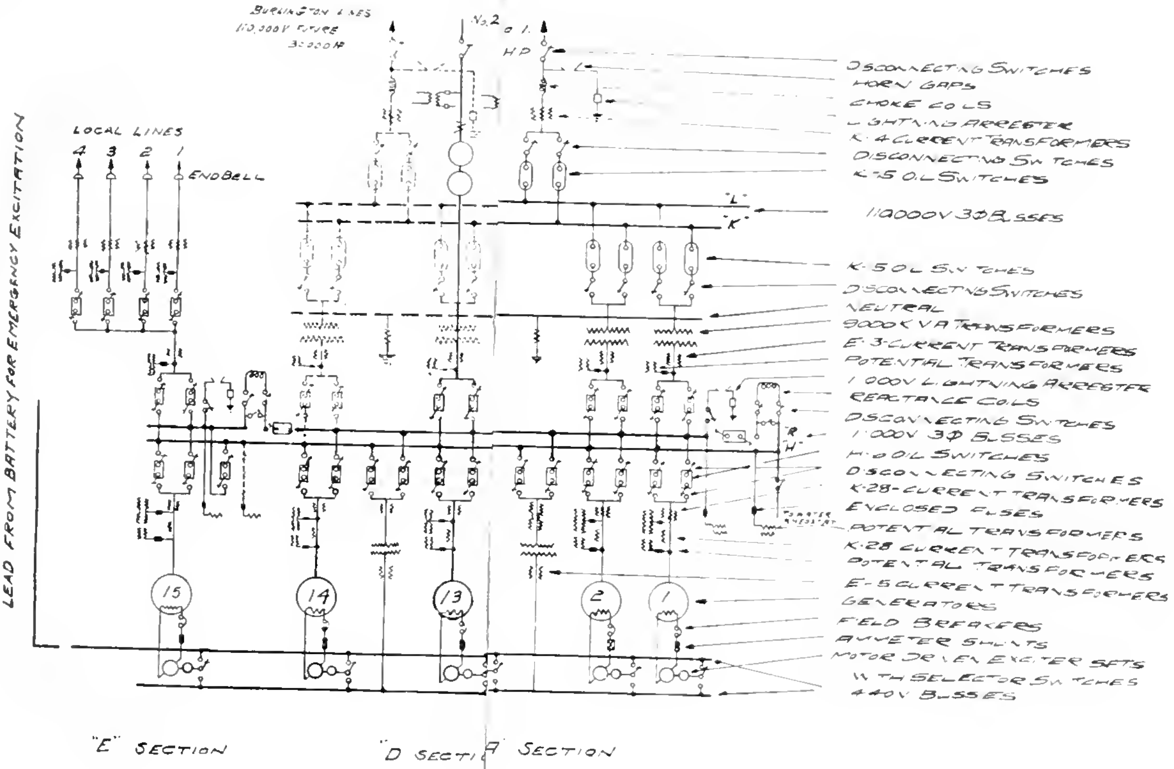
The initial installation comprises fifteen main turbines of the vertical single runner Francis type. They have a normal rating of 10,000 h.p. based on a head of 32 feet. Their design is, however, such that they will operate efficiently with a head varying from 21 to 39 feet. The actual speed is 57.7 r.p.m., the specific speed 338, and the maximum efficiency at normal head about 88 per cent.

The turbine itself is placed at the bottom of a large concrete-encased steel cylinder called the pit liner. Bolted to the upper and lower ends of this steel shell are large cast iron rings, weighing 30 to 40 tons each, which support the entire weight of the unit, or approximately one million pounds. Each turbine has twenty cast steel guide vanes, which are placed just below the pit

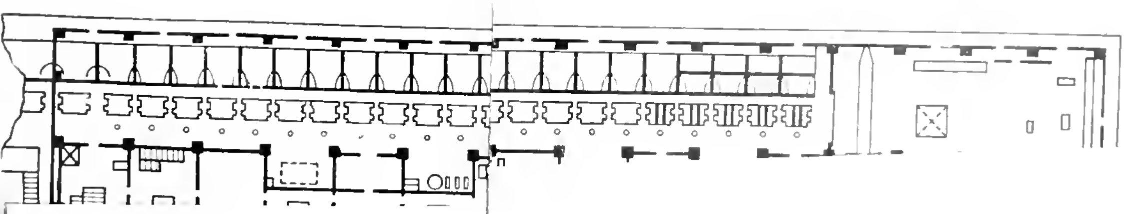
Fig. 8. Generator Room



Fi uture Installations



③



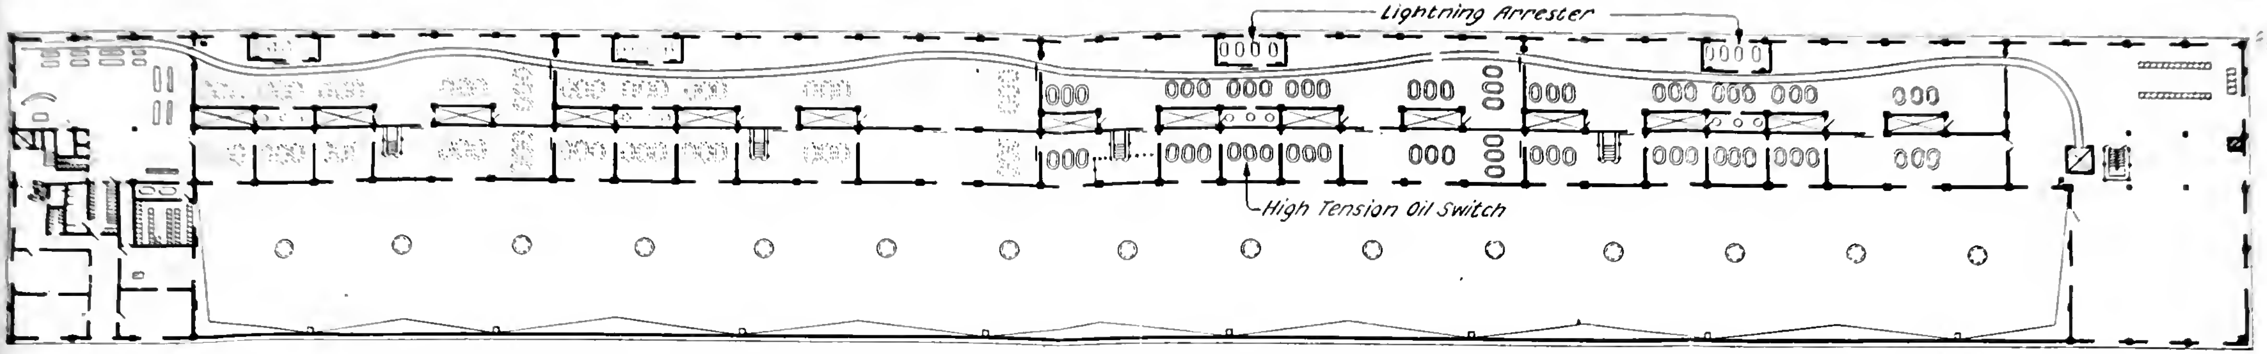


Fig. 6a. Plan of Fourth Floor of Power House, Showing Location of High Tension Switches and Lightning Arresters. Dotted Units Indicate Future Installations

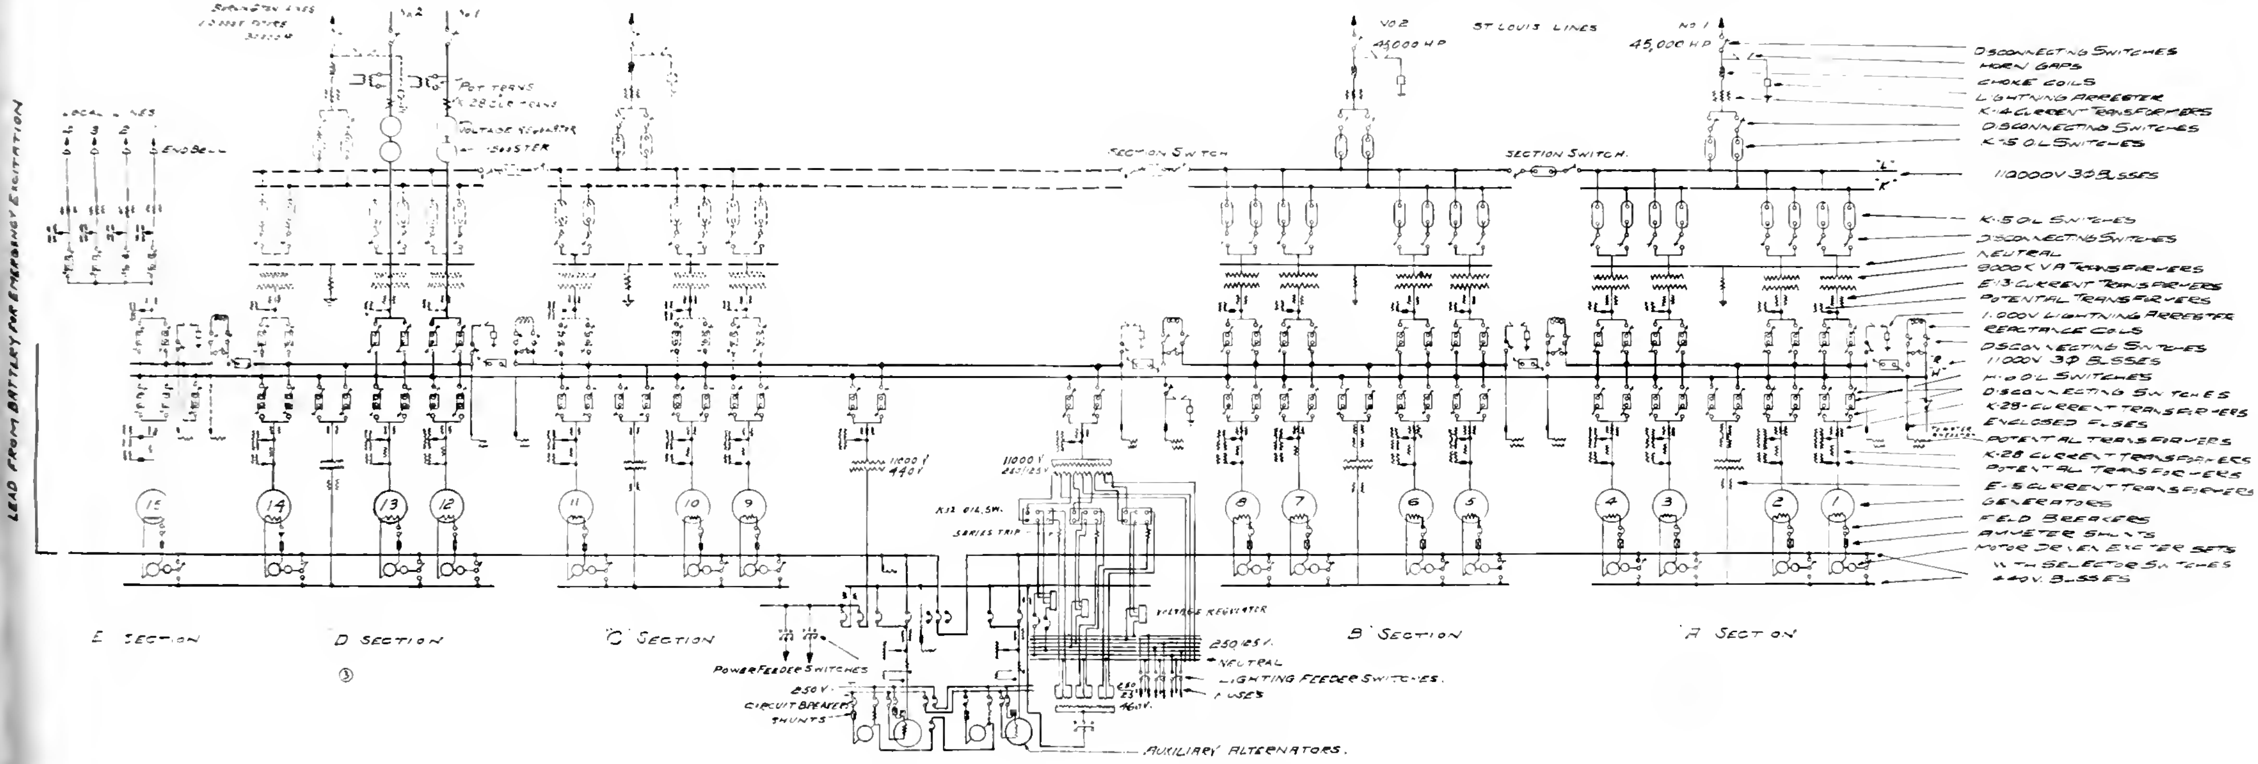

Fig. 6b. Diagram of Connections. Dotted Portions Indicate Future Extensions

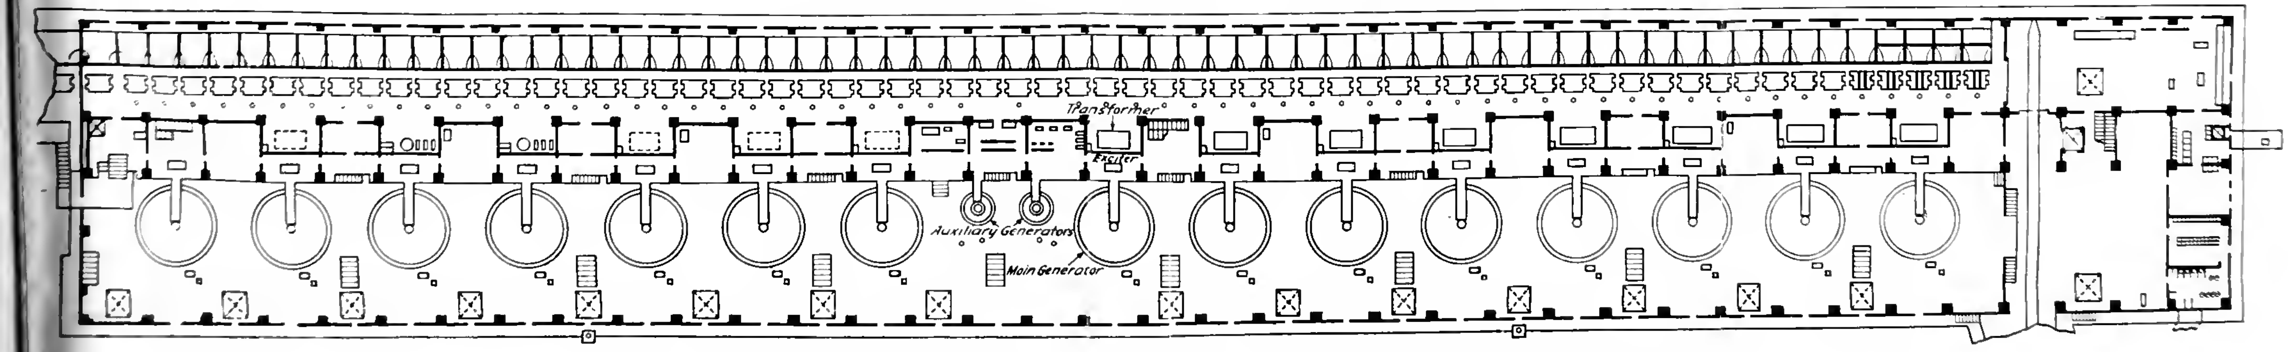

Fig. 6c. Plan of Generator Floor, and Elevated Floor on which are Mounted the Exciters, Transformers and Gate Mechanisms

liner cylinder between two heavy cast iron foundation rings, which are separated by 8-inch bolts.

Each runner has 16 vanes, the outside diameter at the bottom being approximately 17 ft. and at the top 12½ ft., the length being 11 ft. The runner is mounted on a forged steel shaft, which has a diameter of 25 inches and is coupled to the generator shaft above. The weight of each runner alone is 64 tons, while the weight of the total revolving element, including the water thrust and the generator field, is 275 tons. This weight is carried by a thrust bearing at the top of the wheel and below the generator, the bearing being supported from the upper foundation ring. Two guide bearings are also provided for each turbine unit.

Two different kinds of thrust bearings are used. Twelve of the units are equipped with the Standard Roller Bearing Company's combination oil-pressure and roller bearing. Under normal operation oil is forced between the two bearing faces at a 225 pound pressure, separating these by a thin film of oil, on which the revolving element is supported. However, if for any reason the oil pressure or supply should fail, the upper bearing plate will settle down on a set of oil-immersed steel rollers, which will then carry the weight of the rotating element without interrupting the operation. The three remaining thrust bearings are of the Kingsbury type, and require lubrication at only atmospheric pressure.

For lubricating the pressure type thrust bearings, each unit is provided with a separate triplex oil pump, chain driven from the governor shafts and having a capacity of 150 gallons per minute at 225 lb. pressure. A central oil supply system for the thrust bearings is also installed to be used in case of emergency. This consists of two motor-driven triplex oil pressure pumps, located in the main pump room and piped to the different bearings.

The lubricating oil for the guide bearings is furnished either by two waterwheel-driven or two motor-driven pumps. The oil is pumped to large tanks, whence it flows by gravity to the bearings and thence to reservoirs under the lower bearings. From the reservoirs it is pumped to the filtering and central supply tanks. Provisions are also made so that the oil can be simultaneously pumped directly to the bearings and the gravity tanks.

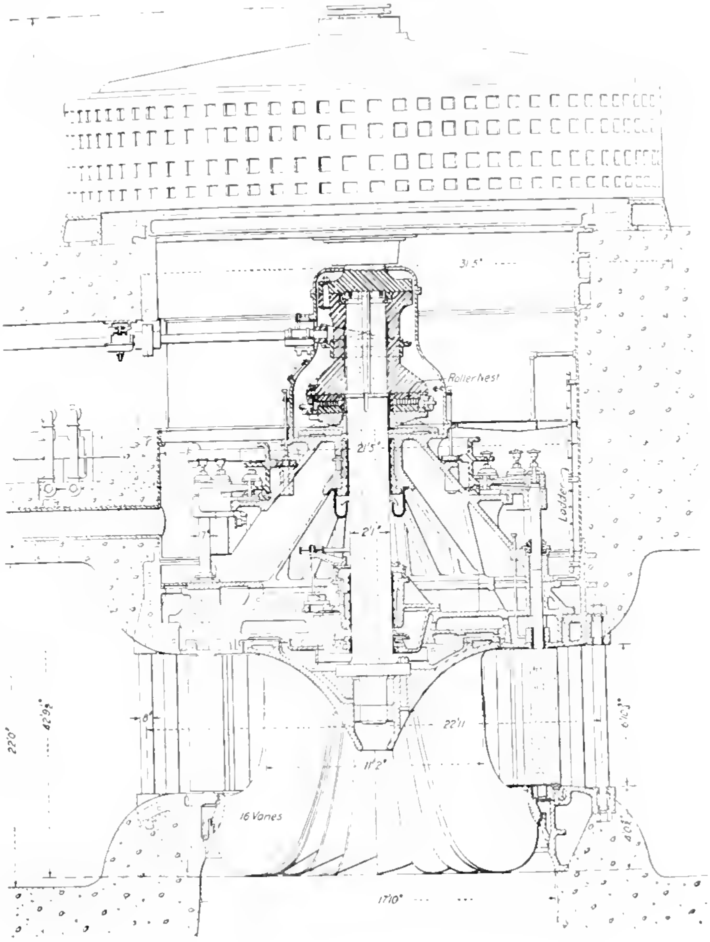

Fig. 9. Sectional Elevation of Turbine Showing Thrust Bearing and Connection to Generator Shaft

Revolving indicators, designed on the principle of water meters, are inserted in the piping leading to the guide bearings of each unit. These indicators are so adjusted that a certain number of revolutions correspond to a certain quantity of oil. Thermometers are also inserted in the in and outgoing oil supply pipes for each unit.

### Auxiliary Turbines

In addition to the main units there are two smaller turbines for driving the auxiliary generators furnishing power to the motor-driven exciters. These turbines, which are also of the vertical type, have a capacity of 2200 h.p. and a speed of 125 r.p.m.

**Governors**

The regulation of each turbine is accomplished by a specially designed Lombard oil-pressure governor, the balanced guide vanes being controlled through an exposed operating mechanism from the actuators, which are located on the generator floor in front of each unit. The operating mechanism consists of a rocker ring, which is carried on ball bearings and which is connected by links to the cranks on the guide vane stems. The rocker ring is operated by means of piston rods from two high-pressure regulating cylinders, which, together with the relay valves, are located on the thrust bearing floor. Under 200 lb. oil pressure these cylinders will develop 250,000 ft. lb., and the oil pressure is furnished by a separate induction motor-driven triplex pump for each unit. This pump and motor, as well as the accumulator and receiving tanks are also installed on the thrust bearing floor. By means of an automatic control arrangement the pump is started up if the pressure falls below 140 lb., and continues to run until it has reached 180 lb. The speed control element and the anti-racing devices are installed in the governor pedestals on the main floor, and the governor fly balls are driven mechanically from a counter shaft which is geared direct to the turbine shaft. On the governor pedestals are further mounted various gauges indicating the oil pressure, the gate opening, and the speed, while provisions are made so that the automatic regulation can be changed over to hand control if desired. The governor mechanism is also equipped with a motor connected electrically to the control switchboard, in order that the switchboard operator shall be

Fig. 10. Looking South Through Machinery Tunnel

able to control the speed of any unit when synchronizing.

The governors are guaranteed to maintain the speed steady within one-half of one per cent, and on decrease to load to bring the speed to normal within five seconds.

## ELECTRICAL EQUIPMENT

### System of Connections

The system of connections has been laid out with a view of securing the greatest flexibility and reliability, and double sets of busbars are therefore installed on both the high and low tension sides. As seen from the wiring diagram, one of the low tension buses runs continuous for the full length of the station, and this set will normally be used for forming a ring-connection or for transfer purposes in case of emergency. The generators will be normally connected to the other bus, which is divided into five sections, with current-limiting reactances and sectionalizing switches inserted between sections.

Both high-tension buses are divided into two sections, the operating bus being provided with sectionalizing switches; and while these will be open under normal operation, they afford means of paralleling the sections if desired. The other set is intended for transfer of the transformers within the respective sections only.

The two 110,000 volt outgoing St. Louis circuits are connected to sections "A" and "B," while the two 11,000 volt Burlington circuits are fed from section "D." The station and local service is taken from sections "C" and "E." However, when the demand for power increases, it is the intention to run two 110,000 volt lines from sections "C" and "D." In this manner the generators and transformers feeding each outgoing line will be on a separate section, insuring against trouble caused by short circuits or surges spreading from one section to the other.

### Arrangement of Apparatus

The fifteen main generators are located directly above the turbines and are spaced along the generator room 48 feet apart, measured between the center lines of the units. The two auxiliary generators are installed between main units Nos. 8 and 9. These auxiliary generators are equipped with direct-connected exciters mounted on top of the units, while the individual exciters for the main generators are motor-driven; the sets being installed in compartments on the same floor level as the gate house floor, eight feet above the generator room floor. These exciter compartments are entirely open towards the generator room, and openings are furthermore provided in the partitions between the compartments, thus affording a continuous passage through the whole length of what may be termed the exciter gallery. The auxiliary exciter, lighting and power transformers, as well as the auxiliary switchboards, are also located in compartments on this gallery, facing the generator room.

The large main transformers are installed on the same floor level and back of the exciter sets in compartments opening towards the gate house. The low-tension busbars and oil switches are located above these compartments, as shown in the cross-section.

Fig. 11. Step Bearing for Unit No. 1

The high-tension room occupies almost the entire top floor of the gate room section of the building. Its floor is at the same elevation as the roof of the generator room, and it is divided into a number of compartments, or rather rooms, for separating the various high tension switches, lightning arresters, connections, etc. The outgoing lines run through roof bushings to the roof structure to which the long river spans are anchored. These roof structures also support the line disconnecting switches and the lightning arrester horn gaps, while the arrester tanks are installed on the high-tension switch room floor.

The control switchboards are located in a large room at the south end of the high-tension switch room floor—a position which ultimately will be in the center of the building when this has been extended to its full length. This room is entirely shut off from the generator room; but, by descending a short flight of stairs to an inspection gallery, a view of the entire generator floor is obtained. All the pumps for water, vacuum and air compressor systems, are located in tunnel below the transformers.

**Main Generators**

As previously mentioned, the present installation comprises fifteen main units. They are of the three-phase, twenty-five cycle, vertical revolving field type, having 52 poles and operating at a normal speed of 57.7 revolutions per minute. They have a maximum continuous rating of 9000 kv-a. at 11,000 volts, and when operating at 80 per cent power-factor the temperature rise will not exceed 50 deg. C. on the armature winding measured by resistance or temperature coils placed in the armature slots between the top and bottom coils; 50 deg. C. on the field winding measured by resistance; or 50 deg. C. on all other parts measured by thermometer.

The machines are designed for a high internal reactance, limiting the instantaneous short circuit current to about five times the normal value. At the same time they have an inherent regulation of approximately 8 per cent at unity power-factor and 20 per cent at 80 per cent power-factor.

The guaranteed efficiencies were as given in the following table, while actual tests after installation indicated even somewhat higher values:

| | Full Load | 3/4 Load | 1/2 Load |
|---|---|---|---|
| 9000 kv-a., 1.0 power-factor | 96.3 | 95.9 | 94.6 |
| 7200 kw., 0.8 power-factor | 95 | 94.5 | 93 |

The required maximum excitation is 85 kw. at 250 volts.

The armature winding consists of form-wound interchangeable coils of the barrel type, heavily insulated with both mica and varnished cambric. They are Y-connected, but the neutral is not brought out to the terminal board.

The field spider is made of cast iron with the field rim of cast steel. The pole pieces are securely bolted to the rim and the whole construction is designed to withstand a 100 per cent over speed. The flywheel effect ($WR^2$) of the revolving field is approximately 20,000,000 pound-feet.

The two collector rings are mounted on the shaft extension above the top brackets. Bridges with handrails are built to the exciter gallery, thus facilitating the inspection and adjustment of the collector ring brushes. These bridges also serve as a support for the field leads, which run in conduit underneath the bridge directly from the exciters to the collector rings.

Two guide bearings are provided for each generator, one above and one below the rotating field. The shaft is a hollow steel forging 27 inches in diameter, with a forged coupling, 57 inches in diameter, on the lower end for bolting to the combined coupling and thrust block on the waterwheel shaft.

For ventilating the machine, the movement of the air is brought about by the natural fanning action of the revolving field, holes being provided in the field spider rim between the poles to secure a uniform ventilation of the field coils. The air is drawn through the openings in the top cover of the frame and from the pit below, and is discharged through holes in the sides of the frame after having been forced through the ventilating ducts in the core.

Each generator is equipped with a pneumatically operated brake, consisting of eight sets of brake cylinders with shoes which work against the lower surface of the revolving field rim. These brakes are designed to bring the whole rotating element to rest in from five to ten minutes, against the water leakage which may be expected to leak through the gates. The piping to the cylinders has been laid out so that a failure to any of the sets will not affect and cripple the others.

The outside diameter of the generator frame is 31 ft. 5 in., and of the revolving field 25 ft. 5 in., while the height of the unit at the center is 11 ft. 3 in. The net weight of the stator is 221,000 lb., of the base 165,000 lb., and of the rotor and shaft 228,000 lb., the total being 614,000 lb.

### System of Excitation

The system of excitation is of unusual interest, being quite out of the ordinary. In order to obtain the greatest flexibility, each generating unit is provided with a separate exciter. These are motor-driven and operate at a much higher speed than would have been possible with direct connected units, which results in a more economical arrangement. The exciter sets receive their driving power normally from an entirely independent source, consisting of two auxiliary waterwheel-driven alternators feeding into a set of busbars which run the full length of the station; sectionalizing switches being provided only in the middle so that if desired the bus can be divided into two sections with one auxiliary alternator connected to each. Provisions are also made so that the exciter sets can be fed from the main bus, four step-down transformers being provided for this purpose. They connect the main bus with a second auxiliary exciter bus, which is sectionalized in four groups with one transformer for each group. Connections can also be established, in case of emergency, with one of the duplicate storage batteries which ordinarily are used for the operation of the oil switches.

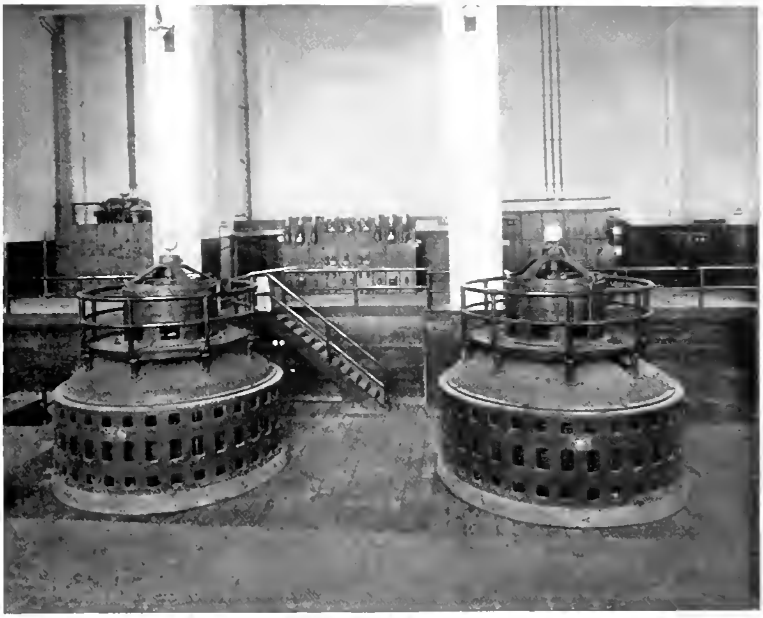

Fig. 12. Auxiliary Alternators Nos. 1 and 2. June 10, 1913

The two auxiliary alternators are equipped with individual direct connected exciters, and TA regulators serve to keep the auxiliary bus voltage constant. Besides supplying the exciter sets, energy is also normally taken from this bus for the power and lighting required for the station service, although provisions are made so that it can also be taken from the main bus.

The field current is conducted directly from the motor-driven exciters to their respective generators, the commutator brushes of the former simply being connected to the collector ring brushes of the latter, with solenoid operated field switches inserted in one of the leads. The regulation is accomplished by adjusting the fields of the individual exciters, thus eliminating large field rheostats and energy losses in the main field circuits. Each exciter is provided with its own TA regulator, and parallel operation with compensation for cross currents is obtained by means of current and potential transformers which are installed in the generator leads and connected 90 degrees out of phase with each other. If cross-currents tend to flow between the generators, the regulators will reduce these by strengthening or weakening the field of the affected generators.

The two auxiliary alternators are of the vertical type direct connected to waterwheels. They have a maximum continuous rating of 2000 kv-a. at 460 volts and operate normally at 125 r.p.m. Their general design is the same as for the main units, with the exception that each is equipped with a direct connected exciter mounted on the upper bearing bracket so that the machines can be started as self-contained units. The upper bearing bracket also supports a Standard roller thrust bearing which carries the weight of the total revolving element, including the waterwheel runner and the water thrust.

Under test these auxiliary generators showed a temperature rise well within 50 deg. C. and an efficiency of 95.1 per cent, both based on the full load of 1600 kw. at 80 per cent power-factor. At full load, with unity power-factor, the inherent regulation is approximately 8 per cent. Each unit requires a maximum excitation of about 30 kw. at 250 volts, and motor-driven field rheostats are provided so that the voltage may be adjusted from the control switchboard.

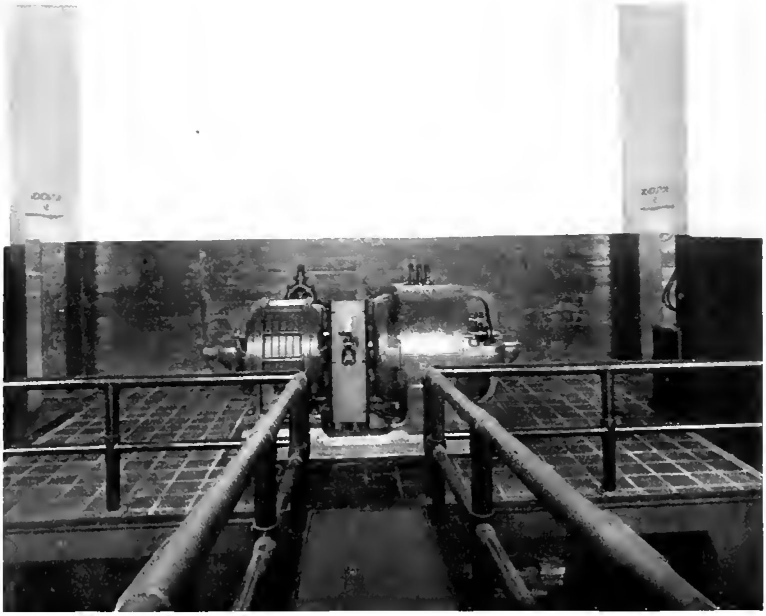

Fig. 13. Exciter Set for Unit No. 12. June 19, 1913

The direct connected exciters for these units are of the compound-wound, commutating pole type. They have a normal rating of 60 kw. at 250 volts, and each exciter is therefore capable of exciting both the machines in case one of the exciters should be disabled. Connections and switching arrangement are provided to accomplish this, and also to make it possible to operate the two exciters in parallel if desired.

The total weight of each auxiliary generator is 127,000 lb. and of each exciter 15,000 lb.; the combined weight of the rotating elements being 42,500 lb. The diameter is 13 ft. 8 in. and the over-all height from the floor to the top of the exciter, 13 ft. 3 in.

Each of the exciter sets for the main units consists of a six-pole 100 kw., 250 volt-shunt-wound commutating pole generator mounted on the same base with and driven by a four-pole 25 cycle, 3-phase, 440 volt squirrel-cage induction motor, the set operating at a synchronous speed of 750 revolutions per minute.

The sets are designed to operate at 25 per cent overload for 2 hours, and with a full-load efficiency of 84.2 per cent. The starting is accomplished through a starting compensator. Provision is made for overload or low-voltage tripping, although not used at present. The total weight of each set is approximately 11,500 lb.

The four transformers for supplying power for the exciter sets from the main bus are of the three-phase, oil insulated and water-cooled shell type construction. They have a continuous rating of 600 kv-a. with a temperature rise not exceeding 40 deg. C., based on a cooling water supply of 6 gallons per minute at 15 deg. C. They also have a 2-hour overload capacity of 750 kv-a. with a rise of 55 deg. C. based on a water supply of 7.5 gallons per minute.

The high-tension winding consists of five coil groups, five in series for 11,000 volts, and five in parallel for 2200 volts. Similarly, the low-tension winding consists of four groups to be connected in series for 440 volts, in series-parallel for 220 volts, and in parallel for 110 volts. No other taps are provided and both the high and low tension windings are connected in delta. The high tension winding has been submitted to a one-minute test of 22,000 volts from primary to secondary and core, and across the full winding, while the low tension winding has been tested at 4000 volts for one minute between the secondary winding and core.

The full load efficiency is 97 per cent and the regulation at 100 per cent power-factor 2.3 per cent.

The cooling coils are of wrought iron, and the connections to oil piping and vacuum system are provided for these units as for the main transformers. Each unit occupies a floor space of 7 ft. by 4 ft. 2 in. and an over-all height of 12 ft. 10 in. The total weight including the oil is 25,200 lb.

Fig. 14. 9000 Kv-a. Transformer. June 3, 1913

**Main Transformers**

There are nine three-phase oil-insulated water-cooled transformers of the shell type construction, one of which is for spare. They have a maximum continuous rating of 9000 kv-a. with a temperature rise not exceeding 50 deg. C. This rise is based on an ingoing water quantity of 46 gallons per minute at a temperature of 27 deg. C.

The low-tension 11,000 volt winding is delta-connected and the high-tension 110,000 volt winding Y-connected, with the neutral brought out and dead-grounded. For bringing out the leads four high-tension and three low-tension bushings are therefore provided in the cover. No taps are provided in either winding.

The high voltage winding is very heavily insulated and has been submitted to a one-minute high potential test of 250,000 volts from primary to secondary and core, and across the full winding, while the high-tension bushings have been tested at 450,000 volts. A similar test at 22,000 volts has been applied between the low tension winding and the core.

The efficiency of the transformers at normal load is approximately 98.5 per cent. The regulation at unity power-factor, 1.3 per cent and the reactance 5.7 per cent.

The supporting framework which holds the core and coils together, is built of structural I-beams, channels and angles. The tanks are made of boiler plate reinforced by numerous ribs and designed to withstand atmospheric pressure. On account of their large size they had to be made in two sections, an upper and a lower, which were riveted together after their arrival at the plant. The top covers are provided with gaskets, making the transformers practically air-tight. However, a four inch overflow pipe is provided and sealed with oil paper gaskets. In general, the design is such that the cover, core and leads can be lifted out of the tanks without detaching any parts, while the whole unit rests on a wheeled truck which permits moving of the transformer from its compartment out into the gate house where it may be handled by the crane.

Fig. 15. Exciter Transformer

The cooling coils are of the $1\frac{1}{2}$ inch wrought iron pipe, each coil being made up in three sections, the total length being 1834 feet.

They are designed to withstand a water pressure of 500 lb. per sq. in. The water for cooling purposes is pumped from the gate house by motor-driven centrifugal pumps, after which it is filtered and led to the cooling coils. A duplicate system of piping is provided, the valves and visible discharge nozzles being mounted back of the transformer compartments on the walls facing the generator room.

Each transformer requires about 10,000 gallons of insulating oil, and a complete piping system with pumping equipments has been installed for handling this between the cars, tanks and the various transformers. Large storage tanks for both filtered and unfiltered oil are installed in separate compartments in the lower tunnel below high tail race water level, the tanks being imbedded in sand as a fire protection.

There are 12 storage tanks for transformer oil, six for the good and six for the bad oil. Two oil treating outfits with the necessary pumps, filters, drying ovens, etc., are provided for filtering the oil. These are at present of the portable type, but piping arrangements are made so that permanent equipments can be installed. Connections are provided at the bottom of the transformers for filling or emptying the oil. At the bottom of the tank is also a quick acting valve accessible from the generator room, which allows the transformer oil to be quickly discharged either into the storage tanks in the sub-structure or directly into the tail race in case of emergency.

Each transformer is provided with an oil gauge and a thermometer of the capillary tube type.

Each transformer occupies a floor space of approximately 9 ft. by 16 ft. The height to the top of the cover is 18 ft. 6 in. and to the top of the high-tension leads 24 ft. 3 in. The weight of the complete unit including the oil is 246,000 lb.

# POWER FROM MERCURY VAPOR

## Part II

### By W. L. R. Emmet

Consulting Engineer, General Electric Company

This paper relates to a process by which it is expected to accomplish a very large saving of fuel in the practical production of power. In our January issue Mr. Emmet gave a general outline of the theoretical considerations governing the application of mercury vapor as a means of generating power. In his present article he deals with the practical aspects of this development. He cites some of the first experiments made and tells of the later designs of apparatus that give promise of success. Some of the mechanical details described are of very great interest and much ingenuity has been displayed in solving such problems as guarding against leaky joints. The article is concluded by a brief resumé of the proposed methods of commercial application. The paper was presented before the Schenectady Section of the A.I.E.E. at its December meeting.—Editor.

With a view to developing a design for a mercury boiler which would produce the vapor with practicable methods of firing, without destructive temperatures in the steel and with a small total amount of mercury in use, much experimenting was done to determine the behavior of mercury under boiler conditions.

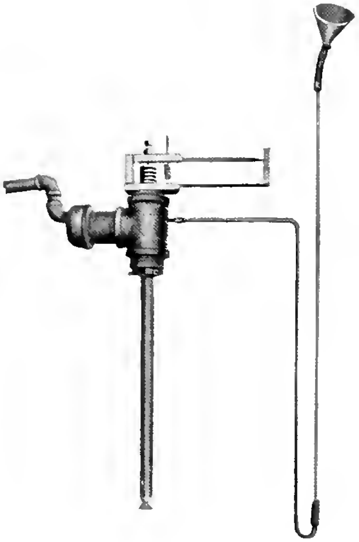

Fig. 1. First Experimental Mercury Boiler Tube

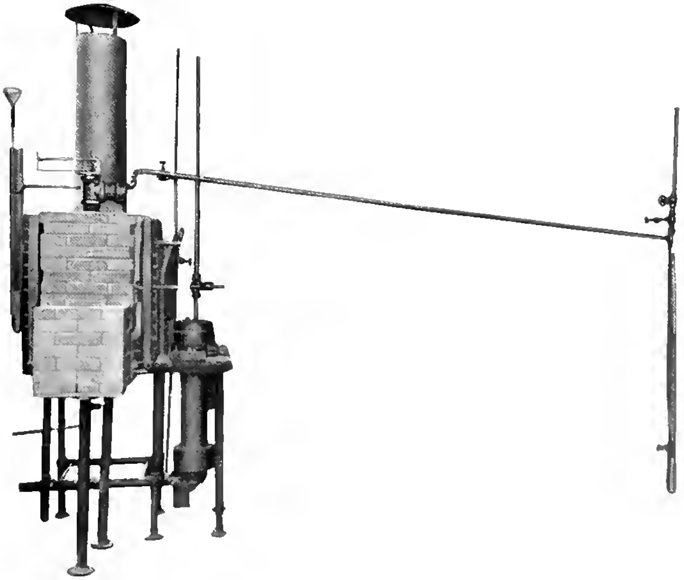

Fig 1a. Mercury Boiler Tube of Fig. 1 Encased in Brick Setting

The first experiments made were with tubes containing solid cores, with a small clearance between the core and the tube and a central hole in the core provided for circulation of the liquid. The apparatus used in this experiment is shown by Fig. 1. A rod was carried downward through the central duct and projected out through a packing as shown. The relative expansion of this rod and of the outer walls of the tube was indicated by a multiplying lever as shown, which afforded an accurate measure of the average temperature difference between the outer walls, which constitute the heating surface, and the liquid which was flowing in contact with the rod. This tube was subjected to various heating conditions and curves were plotted which compared rates of vapor flow with temperature difference. Some unexpected results were encountered and the nature of the action was investigated by boiling mercury between concentric glass tubes having an annular clearance about equivalent to that used in the steel tubes. These experiments showed that to absorb a large amount of heat with a small temperature difference between the heated surface and the liquid, it was necessary to provide for a very free circulation of the liquid so that a large amount of liquid could flow. The size of the central hole had a very positive effect upon the vapor capacity of the tube.

Since the mercury does not wet the heating surfaces, the tendency is for the vapor to fill a space between the liquid and the heating surface and thus to prevent heat removal. The way to get effective action in a mercury boiler is to create conditions by which so much liquid will circulate in hot parts that very little vapor will be formed until the heated liquid reaches the upper parts of the tubes, where the pressure is relieved and where the heat stored begins to be released in vapor.

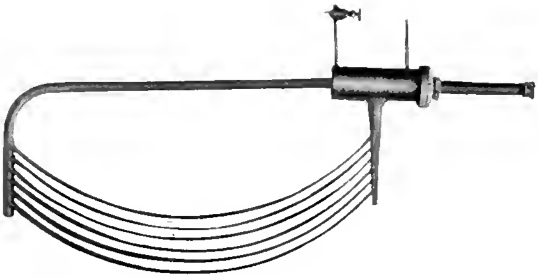

Fig. 2. Second Experimental Mercury Boiler Tube

Difficulties with temperature differences are only encountered in the hottest parts of the boiler where radiation plays an important part. With the low rates of heat transference which prevail through a greater part of the surface, extremely narrow spaces can be provided for the circulation of liquid and for the release of the vapor which is formed.

Having obtained by experiments data concerning possible rates of heat transference, a boiler was built in which the heating surface was made up of round tubes with concentric cores. The tubes were expanded into a horizontal sheet which formed the bottom of a box, and arrangements were made by which the central ducts in the cores always received a supply of liquid. The tubes in this boiler were rather thin, and in experimenting with it, it was found that at the hot end the expanded joints in the tube sheet became loose, the temperature differences imposing

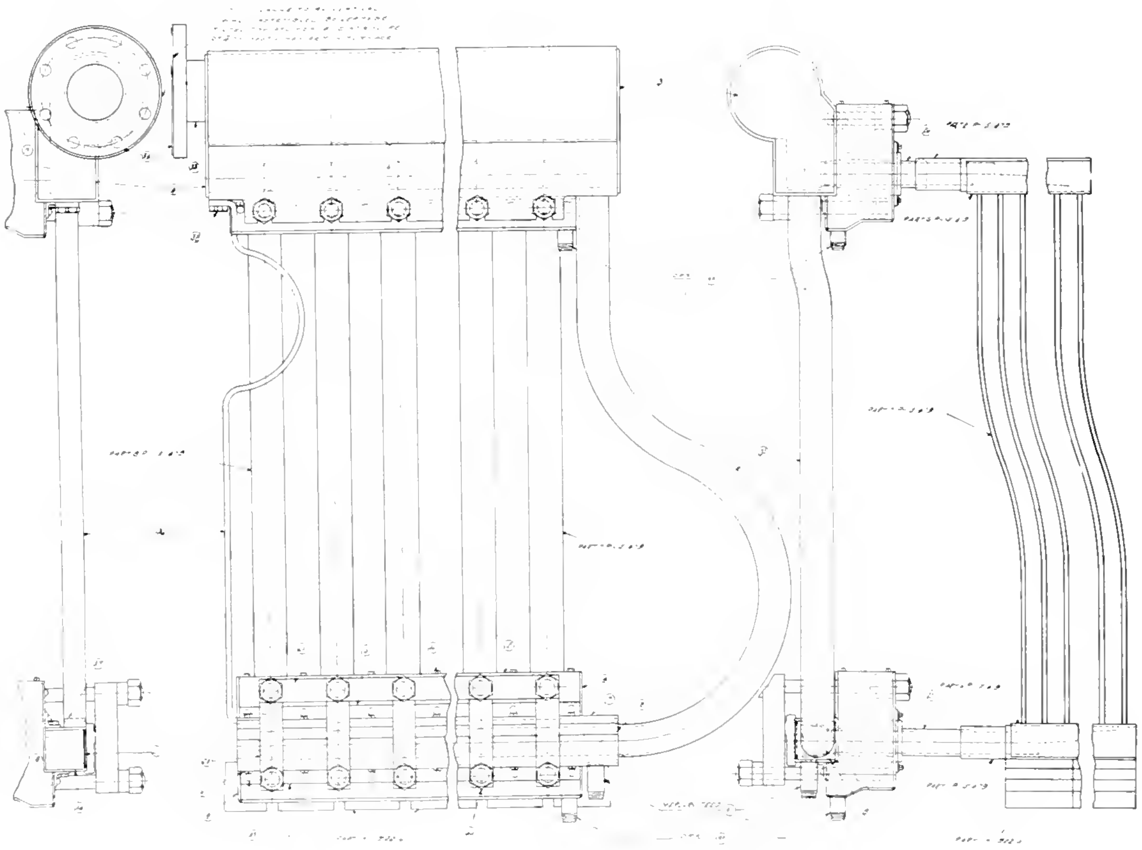

Fig. 3. Assembly of Experimental Mercury Boiler

strains which exceeded the elastic limit of the metal. This trouble could have been corrected by acetylene welding these joints; but this would have involved various changes and difficulties, and since trouble was also encountered in making the bolted joints of the box vacuum tight, it was decided to abandon this boiler and build another on an entirely different principle, which had been in the meantime devised and experimented with. The construction of this new boiler is shown by Fig. 3, and the experimental unit used to determine its characteristics is shown by Fig. 2.

This boiler is made up of a number of heating units each consisting of an upper and a lower header which are connected together by curved flattened tubes. The flattening is to reduce the space which must be filled with liquid mercury, without diminishing the

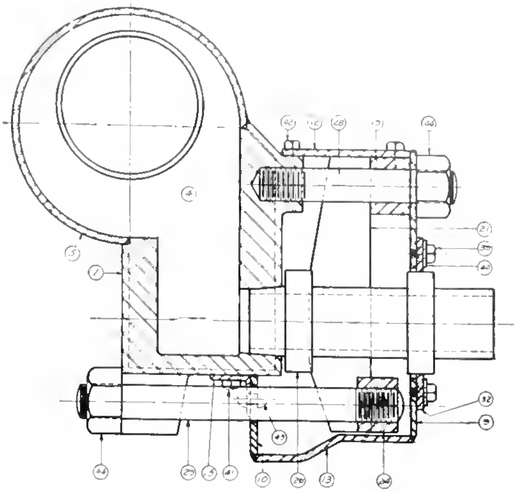

Fig. 5. Sectional View of Upper Main Header, Mercury Boiler

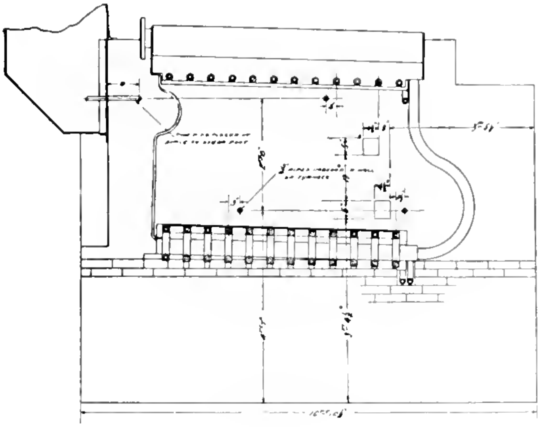

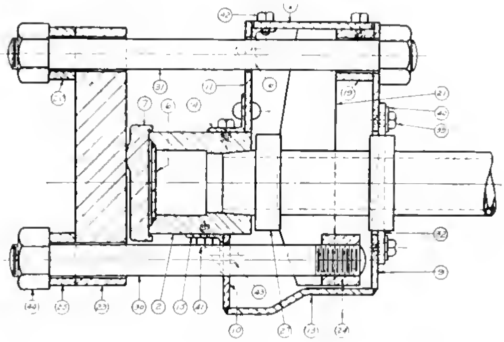

Fig. 6. Sectional View of Lower Main Header, Mercury Boiler

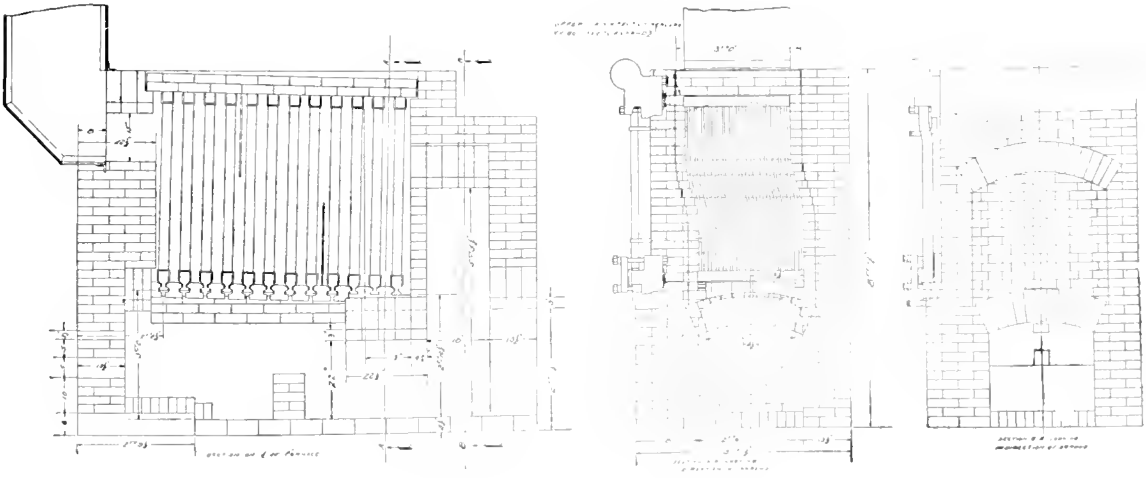

Fig. 4. Mercury Boiler Setting

surface. The curvature is to prevent mechanical strains through unequal expansion caused by irregular heating. These flattened tubes are connected into the headers by acetylene welded joints. The tubes are first welded from the inside into channel-shaped pieces; these channels, with the set of tubes connecting them, are then annealed so as to release all strains incident to the welding. After annealing, they are tested with high pressure air, suitable clamps being used to confine the air in the channels. If the welded sheets will stand the anneal and the subsequent pressure test, it is assumed that they will be reliable for service, since in service they will be subject to uniform temperature conditions and will be practically free from mechanical strains. These channel pieces are then welded to steel headers so that the whole unit becomes perfectly tight and capable of standing a high pressure. The headers of these units terminate in taper nozzles, which fit into taper holes in the bus header at the bottom and into a vapor chest at the top. A curved liquid duct connects the vapor chest to the bottom header at the hot end, so that the heating units which are exposed to the greatest heat receive the most direct supply of liquid. In these hot units, a larger internal space will be allowed than in the units which occupy the cold part of the boiler, so that the colder part will not carry an unnecessary amount of liquid.

Fig. 7. Mercury Boiler and Turbine as Erected in Power House

If these heating units will remain tight, and the success of experiments indicate that they will, it will be impossible for liquid mercury or vapor to escape except at the joints where these headers connect to the bus headers and to the vapor chest, or at the joints through which the vapor is conveyed to the turbine. To guard against loss through leakage in such places, arrangements have been made by which the sets of joints at the top and bottom of the boiler are enclosed in boxes which are practically air tight, the bolts used in tightening these joints extending outside of the boxes in such a manner that a leaky joint can be drawn up. These boxes are connected by ducts to a condensing cooler in which a low pressure is maintained by the suction from the base of the stack or from any other sufficiently exhausted place. This suction will maintain within the boxes a pressure lower than any of the pressures which surround them, so that there will be a constant indraft of air through such leaks as may exist and a flow of all the liquid or vapor which may escape into the cooler. In this cooler it will be carried through passages over water pipes until all the vapor is condensed and nothing but cool air and gas is discharged. In a similar manner, any joints in the system which might possibly be subject to leakage can be enclosed by boxes and connected to this same cooler. By this means, all possible leakage except that which may occur in heating units will be effectively caught.

In case there should be loss of mercury in any of the heating units, means are provided by which such loss can be quickly discovered before any large amount has escaped. The feed of each boiler is so arranged that it is governed automatically by the difference of pressure between the lower header from which liquid circulates and the pressure in the vapor chest, this being the force necessary to produce sufficient circulation. At the back of the valve which admits the feed there is a reserve chamber, to which connections are provided so that the level of liquid in this reserve chamber is visible to the fireman.

In case loss of this liquid is apparent, the doors will be opened, the fire drawn, and the liquid drained out of the boiler into a receiving tank. The boiler can then be tested with air pressure and the leaky elements replaced, the construction being such that any one of these elements can be taken out without disturbing the others.

The arrangements of the turbine have also been improved as the result of experience. The first turbine arranged was made from an old experimental steam turbine and had many joints which were difficult to keep vacuum tight. The new experimental turbine has only one joint, arranged in a manner which has been experimented with and which will avoid leakage.

The condensing boiler used in the experiment now in preparation is made from a standard high pressure feed heater having a water space at the top and bottom connected by tubes in the manner customarily used in such devices. This boiler has apparently worked satisfactorily and produced steam from mercury vapor in the manner expected. It is not, however, considered a suitable design for the purpose, since the temperature differences impose a strain on the expanded tube sheets. It is thought that tubes attached at one end with concentric circulation after the manner of the Nicholaus boiler will afford the most satisfactory method for such condensers. Since no violent temperature differences will exist, it is believed that these condensing boilers can be made practically free from deterioration and entirely free from leakage.

As has been said, the turbine is provided with a centrifugal packing and is kept sealed by a constant admission of liquid mercury from a suitable level in the condensing boiler. The turbine is also provided with a throttle valve which can be used in governing, and with a by-pass valve which allows the vapor to pass directly to the condensing boiler in case the admission to the turbine is shut off.

### Proposed Method of Commercial Application

The plan which has been considered for commercially applying this process is to produce a simple type of unit suitable for installation in the same floor space occupied by a standard 500 h.p. steam boiler. This unit would be so proportioned that the steam output of the condensing boiler would equal that obtainable from the standard 500 h.p. boiler. For each of these boiler units, a separate turbine and generator would be provided, the nature of this process being such that there is no loss of efficiency involved in such multiplication of generating units.

Since it would never be desirable to operate these mercury-driven generating units alone, the generators could be made either of the induction or synchronous type, completely enclosed, with an air supply from some clean outside source. Their circuits would run to the main switchboard, they would need no attendance, and the space around them would not have to be kept either cool or clean, although it would generally be possible to get them within an enclosure which would not be exposed to the fire room dirt. By such means a single set of parts or combinations of a few standard parts could be made to cover a very wide demand, and this would greatly simplify the commercial introduction of such a process.

Without the acetylene welding process, a satisfactory mercury boiler design would be very much more difficult to arrive at. The manufacture of such boilers as are here described would involve a very large amount of acetylene welding, requiring great care and a considerable expense.

The possible cost of the commercial application of such a process has not been carefully studied. It has, however, been roughly estimated that if existing stations were converted to this method, the cost per kilowatt of added power would not exceed the present cost per kilowatt of well designed steam stations, not including the cost of real estate. Thus this process, if successful, would greatly extend the capacity of existing stations and postpone the building of new stations; the saving would about cover the real estate values, and the gain in fuel economy over that of the best existing plants should be about 45 per cent.

Such a process, with the most efficient oil firing of boilers, ought to give a fuel economy very near to that which is commercially obtainable by Diesel engines, and its mechanical simplicity and freedom from the probability of deterioration should give it a very decided advantage over the Diesel engine. While it is not wise to make definite predictions about anything so radically new, it certainly appears to the writer that this process is worthy of very careful study.

# A POWERFUL RÖNTGEN RAY TUBE WITH A PURE ELECTRON DISCHARGE

By W. D. Coolidge

Research Laboratory, General Electric Company

This article relates to the development of a new tube for the production of Röntgen rays. Briefly, the device consists of a tube exhausted of all gases to the extreme possible limit, in which is supported the cathode so arranged that it may be heated electrically; an electrically conducting cylinder or ring connected to the heated cathode, and so located with reference to it as to focus the cathode rays on the target; and the anti-cathode, or target. The advantages of the tube are complete and immediate control of the intensity and the penetrating power of the Röntgen rays; continuous operation without change in the intensity or character of the rays; absence of fluorescence of the glass; and the realization of homogeneous primary Röntgen rays of any desired penetrating power. This article was abstracted for the Review by the author from his paper in the December number of the *Physical Review*.—Editor.

## § 1. INTRODUCTION

A consideration of the limitations of a Röntgen tube of the ordinary type showed that they were for the most part incident to the use of gas and that they could, therefore, be made to disappear if a tube could be operated with a very much higher vacuum. In this case, of course, the electrons constituting the cathode ray stream would have to be supplied in some other way than by bombardment of the cathode by positive ions.

The work of Richardson and others on the emission of electrons from hot bodies suggested that the electrons might be produced by simply heating the cathode. But the values of the thermionic currents obtained by different observers had varied between wide limits, so much so as to suggest that a Röntgen tube based upon this principle might be as unstable in resistance as is the standard tube. Moreover, the fact that the substances usually worked with, platinum and carbon, are so difficult to completely free from gas, suggested strongly that with the cleaner conditions (greater freedom from gas) that could be realized by the use of tungsten, the thermionic currents might cease altogether. Some experiments by Dr. Irving Langmuir, however, on the thermionic currents between two tungsten filaments in a highly evacuated space were very reassuring. According to his observations, after a certain high degree of exhaustion had been reached the thermionic currents increased, up to a certain limiting value, as the tube became freer and freer from gas.

The idea of using a hot cathode in a Röntgen tube was not new, but, so far as the writer could learn, the principle had never been successfully applied in a vacuum good enough so that positive ions did not play an essential role.

Wehnelt & Trenkle had used a hot lime cathode for the production of very soft Röntgen rays, working with voltages from 400 to 1000. Wehnelt, in another article, describes the use of his lime cathode in a Braun tube, and here he says that it is not advisable to employ more than 1000 volts, as otherwise cathode rays come off from that part of the platinum which is bare, giving bad disintegration. As the platinum is heated only to dull redness, this obviously means that there is sufficient gas in the tube to furnish positive ions which bombard the platinum and so cause it to emit electrons. For it has been shown that platinum, unless heated almost to its melting-point, will not yield an appreciable thermionic current*. Apart from this fact, of course, the Röntgen rays produced by voltages as low as 1000 are too "soft" for the ordinary applications.

Lilienfeld & Rosenthal had described a Röntgen tube whose penetrating power is, they say, independent of vacuum. The main aluminum cathode and the platinum anti-cathode are shaped and located like the electrodes in the ordinary Röntgen tube. Besides these, it has an anode and an auxiliary hot cathode. Current from a low voltage source passes from the hot cathode to the anode, and this current furnishes the positive ions which by their bombardment of the main cathode liberate electrons from it. Their tube is dependent for its operation on the presence of positive ions, for without these there is no means provided for getting electrons out from the main, or aluminum cathode. Lilienfeld concludes, from his extended experiments in tube exhaustion, that

---

* H. A. Wilson concluded a paper upon this subject, in 1903, with the following statement: "It is probable that a pure platinum wire heated in a perfect vacuum would not discharge any electricity at all, either positive or negative, to an extent appreciable on a galvanometer."

the complete removal of all gas from tube and electrodes would not do away with positive ions. There would, according to this view, be no such thing as a pure electron discharge. Lilienfeld's work in exhausting the gas from the tube itself and from the glass seems to have been excellent, but according to the experience of the writer, none of his electrodes were sufficiently freed from gas to justify the conclusions drawn. Working even with tungsten electrodes in a tube so designed that the electrodes could be heated in place to very high temperatures, the writer has had the positive ion effects persist for hours, disappearing completely, however, as the electrodes become sufficiently freed from gas.

The work of Dr. Langmuir had shown that a hot tungsten cathode in a very high vacuum could be made to continuously yield a supply of electrons at a rate determined by the temperature.

Further work showed that very high voltages, up to at least 100,000, in no wise affect this rate of emission. For application to the fields of radiography and fluoroscopy, it was necessary to develop a satisfactory method of focusing. And, finally, the large amounts of energy transformed into heat in a Röntgen tube render imperative the use of a very heavy target, and this made it necessary to develop methods for sufficiently freeing large masses of metal from gas.

The result of efforts in this direction has been entirely successful, and tubes have been made, based upon this principle, which are free from most of the limitations of tubes of the ordinary type.

## § 2. GENERAL DESCRIPTION

The structural features of the new tube which differ from those of a tube of the ordinary type are the following:

The pressure, instead of being, as in the ordinary tube, a few microns†, is as low as it has been possible to make it; that is, not more than a few hundredths of a micron.

The cathode consists of a body which can be electrically heated (such as a tungsten or tantalum filament) and, suitably located with reference to this portion, an electrically conducting ring or cylinder, consisting preferably of molybdenum, tungsten or other refractory metal. The ring or cylinder is connected either to the heated portion of the cathode, or to an external source of current by means of which its potential may be brought to any desired value with respect to the heated portion. The heated portion of the cathode serves as the source of electrons, while the ring or cylinder assists in so shaping the electrical field in the neighborhood of the cathode that the desired degree of focusing of the cathode-ray stream upon the target shall result.

The anti-cathode, or target, functions at the same time as anode.

## § 3. THEORY OF OPERATION

As will be seen from the characteristics of the tube (in §5) it gives no evidence of positive ions. This makes the theory of its operation exceedingly simple.

The discharge appears to be purely thermionic in character.

The rate of emission of electrons from the filament appears to be in accord with Richardson's Law, which says that the maximum thermionic current which can be drawn from a hot filament is

$$i=a\sqrt{T}\quad e^{-\frac{b}{T}}$$

where $T$ is the absolute temperature, $e$ is the base of the natural system of logarithms, and $a$ and $b$ are constants.

In the particular tube described in detail in this paper, over the range of temperatures and voltages included in the curves shown in Figs. 4, 5 and 6, this simple law accounts perfectly for the conductivity of the tube.

## § 4. DETAILED DESCRIPTION OF TUBE NO. 147

This description relates to tube No. 147, which was used in getting the data for the following curves. Fig. 1 shows a complete assembly, while Fig. 2 shows an enlarged detail of the cathode and of the front end of the target.

### The Cathode

In the diagram, 25 is a tungsten filament in the shape of a flat, closely wound spiral. It consists of a wire 0.216 mm. in diameter and 33.4 mm. long, with 5½ convolutions, the outermost of which has a diameter of 3.5 mm. It is electrically welded to the ends of two heavy molybdenum wires 14 and 15, to the other extremities of which are welded the two copper wires 16 and 17. These in turn are welded to the platinum wires 18 and 19. The molybdenum wires are sealed directly into a piece of special glass, 12, which

---

† A micron is 0.001 mm.

has essentially the same temperature coefficient of expansion as molybdenum. This first seal is simply to insure a rigid support for the hot filament, the outer seal being the one relied upon for vacuum tightness. The outer end, 13, of the support tube, is of German glass like the bulb itself, and it is therefore necessary to interpose at *S* a series of intermediate glasses to take care of the difference in expansion coefficients between 12 and 13. The small glass tube, 20, prevents short-circuiting of the copper wires, 16 and 17.

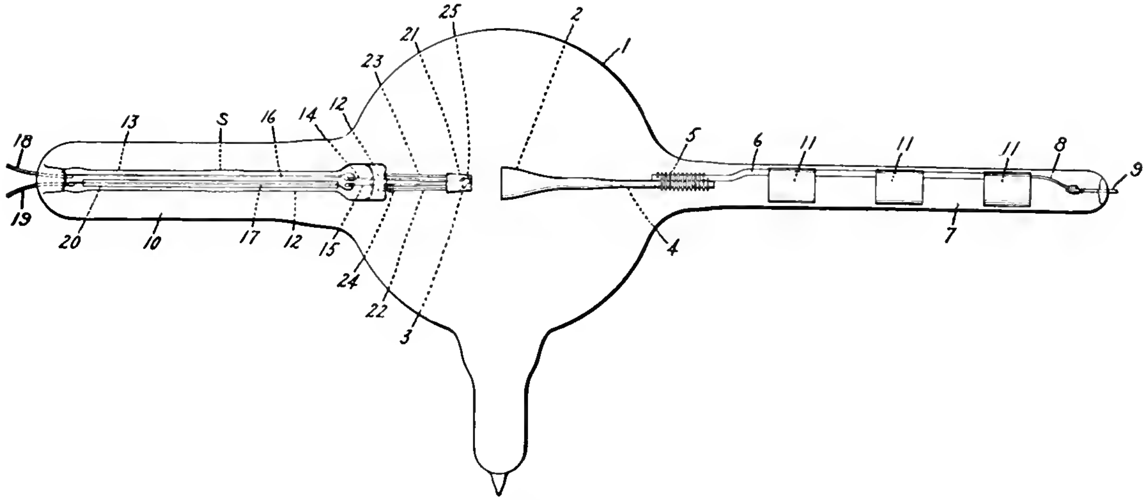

Fig. 1. Experimental Röntgen Ray Tube

The filament is heated by current from a small storage battery which is well insulated electrically from the ground. In the circuit are placed an ammeter and an adjustable rheostat, and by means of the latter the filament current can be regulated, by very fine steps, from 3 to 5 amperes. Over this current range the potential drop through the filament varies from 1.8 to 4.6 volts and the filament temperature from 1890 to 2540 degrees absolute.

### The Focusing Device

This consists of a cylindrical tube of molybdenum, 21. It is 6.3 mm. inside diameter and is mounted so as to be concentric with the tungsten filament, and so that its inner end projects about 0.5 mm. beyond the plane of the latter. It is supported by the two stout molybdenum wires, 22 and 23, which are sealed into the end of the glass tube, 12. It is metallically connected to one of the filament leads, at 24.

Besides acting as a focusing device, it also prevents any discharge from the back of the heated portion of the cathode.

### The Anti-cathode or Target

The anti-cathode, or target, 2, which also serves as anode, consists of a single piece of wrought tungsten, having at the end facing the cathode a diameter of 1.9 cms. (Its weight is about 100 gms.) By means of a molybdenum wire, 5, it is firmly bound to the molybdenum support, 6. This support is made up of a rectangular strip, and riveted to this are three split rings, 11, 11, 11, all of molybdenum. The split rings fit snugly in the glass anode arm, 7. They serve the double purpose of properly supporting the anode and of conducting heat away from the rectangular strip, and so preventing too much heat flow to the seal of the lead-in wire, 9.

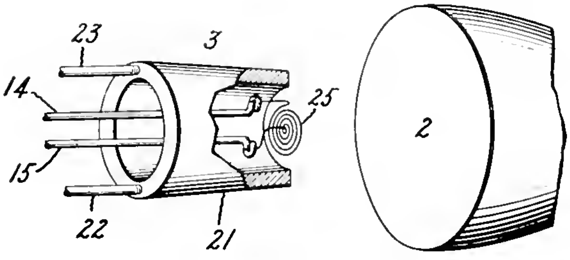

Fig. 2. Enlarged View of Cathode and Front End of Target

### The Bulb

This is of German glass and is about 18 cm. in diameter.

**The Exhaust**

This is as thorough as possible.

For the earlier tubes, mercury pumps were used, with a liquid air-trap between the tube and pump to eliminate mercury vapor. The whole tube, while connected to the pump, was in an oven and was heated at intervals to 470 deg. C. Between heating operations the tube was operated with as heavy discharge currents as the condition of its vacuum would permit. For hours the tube would show the characteristics of an ordinary Röntgen tube, and in many cases a several days application of the above treatment was required to entirely eliminate these characteristics and to realize an essentially pure electron discharge.

The exhaust time has been greatly reduced in two ways. The massive tungsten anode is given a preliminary firing to a very high temperature in a tungsten-tube vacuum furnace*. The molybdenum support is also fired, to a somewhat lower temperature, in the same manner. In the second place, a Gaede molecular pump has been substituted for the mercury pumps and, at the same time, a very large and short connection has been adopted between the tube and pump.

In the later stages of the exhaust a very heavy discharge current is maintained continuously on the tube for perhaps an hour, the temperature of the bulb being kept from rising too high by the use of a fan.

The pressure in the finished tube is very low, certainly not more than a few hundredths of a micron and probably much less than this.

**Connections and Method of Operating**

The tube was connected as shown in the diagram, Fig. 3, in which *T* is the tube; *B* is a small storage battery; *A* is an ammeter; *R* is an adjustable rheostat which can be controlled from behind the lead screen which shields the operator from the Röntgen rays; *S* is an adjustable spark gap with pointed electrodes, which can also be operated from behind the lead screen; and *M* is a milli-ampere-meter which can be read from behind the screen.

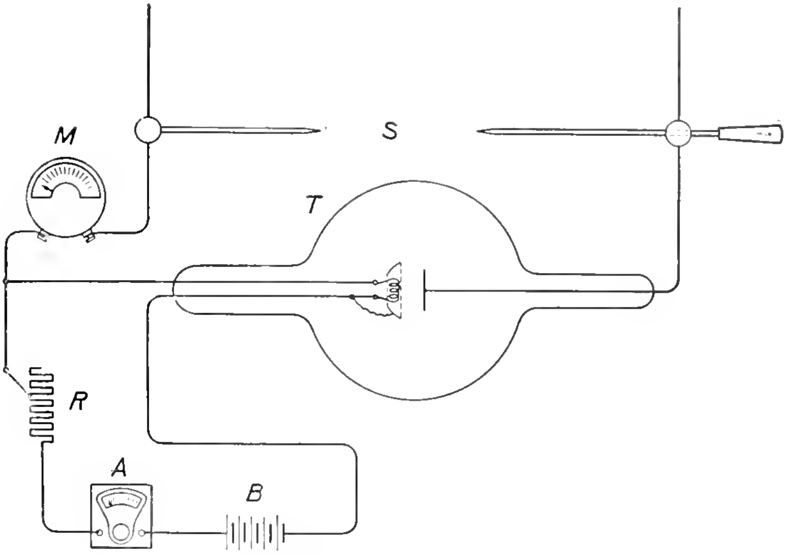

Fig. 3. Diagram of Connections

As the high potential is connected to the battery circuit it is necessary that the latter shall be thoroughly insulated from the ground.

As a high potential source, a 10 kw. Snook machine, made by the Röntgen Apparatus Co., was used. This consists of a rotary converter driven from the direct-current end and delivering alternating current at 150 volts and 60 cycles per second to a closed magnetic circuit step-up transformer with oil insulation. From the secondary of this transformer the high-voltage current is passed through a mechanical rectifying switch (which is direct connected to the shaft of the rotary) and the milli-ampere-meter, *M*, to the tube. The output of the transformer is controlled by a variable resistance in the primary circuit.

## § 5. CHARACTERISTICS OF THE TUBE

*A. No Discharge Current Unless Filament is Heated.*

Unless the filament is heated, the tube shows no conductivity in either direction, even with voltages as high as 100,000.

---

* A description of this furnace will be published in the near future. The heating element consists of a tungsten tube 2.5 cm. inside diameter and 30 cm. long. This is fastened in an upright position and, by means of suitable terminals, is connected to a 100 kw. transformer. The heating element is placed in a water-cooled metal cylinder, and the space within connected to a pump which maintains, with the furnace at its highest temperature, a vacuum of a few microns.

*B. Tube Allows Current to Pass in Only One Direction.*

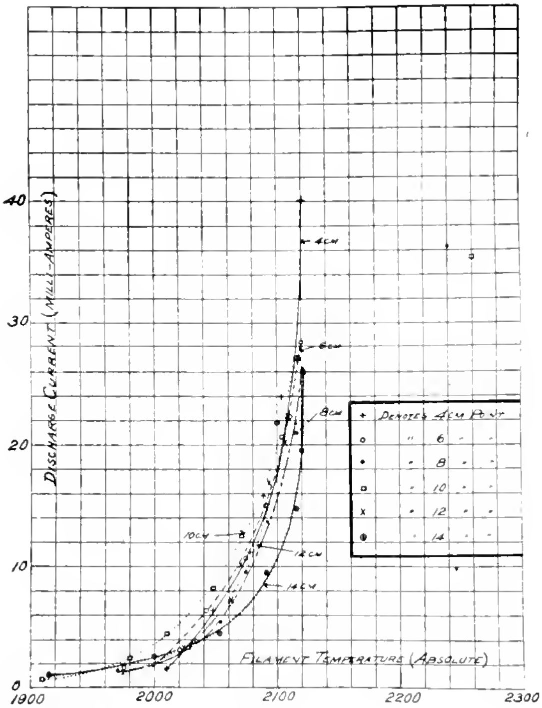

Fig. 4

The tube suppresses any current in the direction which does not make the hot filament cathode. It is therefore capable of rectifying its own current when supplied from an alternating source.

In the case of a focusing tube, however, the use of alternating current will very considerably lower the maximum allowable energy input, for as soon as the target becomes heated at the focal spot to a temperature approximating that of the filament, the tube will cease to completely rectify as the temperature of the focal spot rises, and will allow more and more current to pass in the wrong direction. This, to be sure, will not cause either a harmful vacuum change or a metallic deposit on the bulb, as it would in the case of the ordinary tube, but it will give rise to needless heating of the bulb where it is bombarded by the cathode rays from the target, and to disturbing Röntgen rays emanating from the glass at this point. In the case of a tube which does not focus, but in which the cathode rays bombard the entire surface of the anode, the allowable energy input which the tube will completely rectify can be increased to any desired amount by simply increasing the surface of the anode.

*C. Discharge Current Determined Primarily by Filament Temperature.*

With a given design, the amount of discharge current which can be passed through the tube is determined primarily by the temperature of the filament, and responds instantly to changes in the same in either direction.

The effect of both temperature and voltage on the discharge current, in the case of the tube illustrated in Fig. 1, may be seen by referring to Fig. 4. The different curves obtained for different voltages, expressed in terms of the equivalent parallel spark gap, are seen to lie very close together, showing that over the range of voltages employed, the magnitude of the discharge current is practically independent of voltage. This shows that the current in these experiments was always the saturation value.

Richardson's Law, stated in §3, may also be written in the following form:

$$log_{10} \frac{i}{T} = b \frac{.434}{T} - log_{10}\, a$$

which is the equation of a straight line.

If then the values of log $\frac{i}{T}$ and $\frac{.434}{T}$, corresponding to the curves in Fig. 4, are plotted, they should lie along straight lines, provided the conduction in the tube, between the voltage limits used, follows Richardson's Law.

Reference to the plots, Figs. 5 and 6, will show that the points are clearly represented by straight lines.

If the temperature of the filament is low, only a small number of electrons escape from it and, consequently, only a small discharge current (the saturation current) can be sent through the tube. Increasing the impressed voltage above that needed for this current value causes no further increase in current. It simply increases the velocity of the cathode rays and hence the penetrating power of the Röntgen rays.

*D. Penetrating Power of Rontgen Rays Determined by Voltage Across Tube Terminals.*

The penetrating power of the Röntgen rays coming from the tube increases with the potential-difference between tube terminals.

With the tube excited from a variable potential source, such as the transformer, it did not seem safe to predict that, with the same equivalent spark gap, the rays would show, photographically, the same penetrating power as those from a standard tube. But upon making the experiment, using a Benoist penetrometer, it was found that they did.

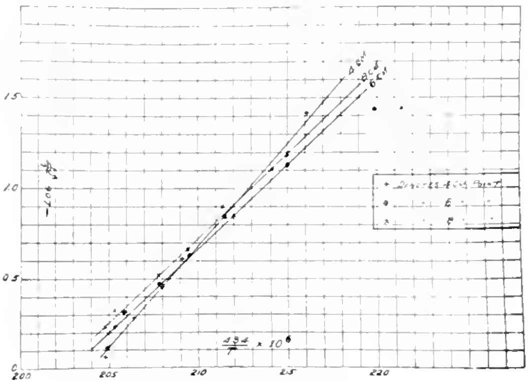

FIG. 5

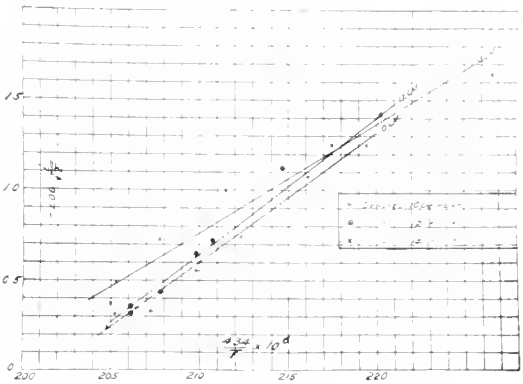

FIG 6.

*E. Capable of Continuous Operation Without Change of Characteristics.*

That the tube may be operated continuously without exhibiting an appreciable change in characteristics, is shown by the following experiment on Tube No. 147, illustrated in Fig. 1.

The filament current was set at 4.1 amperes. This gave a discharge current of 25 milliamperes. The impressed voltage was then set at a point where the tube showed a 7 cm. equivalent spark gap.

The tube was then run continuously, with no adjustment of any kind, for 50 minutes. The readings of discharge current and equivalent spark gap, taken every two minutes, are given in Table II.

TABLE II

| Time | Discharge Current (Milli-Amperes) | Equivalent Spark Gap (Cm.) |
|---|---|---|
| 11:48 A.M. | 25 | 7.0 |
| :50 | 25 | 7.0 |
| :52 | 25 | 6.9 |
| :54 | 25 | 6.5 |
| :56 | 25 | 6.5 |
| 12:00 P.M. | 25 | 6.7 |
| :02 | 25 | 6.9 |
| :04 | 25 | 6.5 |
| :06 | 24 | 6.4 |
| :08 | 24 | 6.5 |
| :10 | 24 | 6.5 |
| :12 | 23 | 6.6 |
| :14 | 25 | 7.0 |
| :16 | 25 | 6.8 |
| :18 | 24 | 6.8 |
| :20 | 25 | 6.9 |
| :23½ | 23 | 6.7 |
| :26 | 23 | 6.9 |
| :28 | 25 | 6.9 |
| :30 | 25 | 6.9 |
| :32 | 25 | 7.0 |
| :34 | 24 | 6.9 |
| :36 | 25 | 7.0 |
| :38 | 24 | 7.1 |

*F. Sharpness of Focus.*

Other conditions remaining the same, the greater the distance between the filament and the front (end facing the target) of the molybdenum tube, the sharper will be the focus.

*G. Fixity of Position of Focal Spot.*

The focal spot on the anode does not wander, but remains perfectly fixed in position. This is in sharp contrast to the ordinary Röntgen tube in which the focal spot does move about, and often so rapidly as to be noticeable even during the shortest radiographic exposures. The effect of movement of the focal spot is, of course, to cause in the radiograph or on the screen, a blurring of all lines except those parallel to the direction of motion. In the earlier stages of exhaustion, while the new tube is being operated with a relatively poor vacuum, the focal spot may dance about, but as the electrodes and the glass become freer from gas the motility of the focal spot decreases and finally disappears completely. Its disappearance goes hand in hand with the disappearance of fluorescence of the glass, discussed in section J. Movement of the focal spot appears to be due to the action of positive ions in disturbing the distribution of static charge on the glass walls of the tube.

*H. Tube not Sensitive to Considerable Changes in Gas Pressure.*

The gas pressure within the tube is so low that it can increase several-fold, and apparently decrease without limit, without appreciably affecting the other characteristics.

*I. Capable of Continuous Operation With High Energy Input.*

Owing to the fact that the tungsten target can run at such a high temperature, large amounts of energy can be continuously radiated.

*J. No Fluorescence of Glass.*

When operating properly the tube shows no fluorescence of the glass at any point. Corresponding to this, there is an absence of the usual strong local heating of the anterior hemisphere. The absence of fluorescence and of local heating seem to point to the fact that there is no bombardment of the glass by secondary cathode rays sent out from the target. This is in striking contradistinction to what takes place in an ordinary Röntgen tube, where, in the case of a platinum target, it has been found that there are about three-fourths as many electrons leaving the target, and going to the glass as secondary cathode rays, as there are bombarding it, in the form of primary cathode rays. This elimination of secondary cathode ray bombardment prevents the production of a large part of the useless and disturbing Röntgen rays which emanate from the glass in the case of the ordinary tube.

The simple explanation appears to be based upon the fact that the large number of positive ions present in an ordinary Röntgen tube is here lacking. The inner surface of the glass becomes strongly negatively charged, when the tube is first operated, and, not being able to attract an appreciable number of positive ions, remains so. The presence of this negative charge upon the glass prevents further electrons, either in the shape of primary or secondary cathode rays, from going there.

*K. Identity of Starting and Running Voltage.*

The starting or break-down voltage of the tube is the same as the running voltage. This is very different from the state of affairs in the ordinary tube in which the break-down voltage is much the higher of the two. The explanation of this difference is as follows: In the ordinary tube the number of ions present when the circuit is closed is exceedingly small, being only that due to natural ionization causes, such as radio-active matter in the surroundings. After the discharge circuit is closed, the number of ions increases, by collision, very rapidly, and the voltage across the tube terminals falls in consequence. In the case of the new tube, on the other hand, the full supply of electrons is there the instant the discharge circuit is closed, and even before this, and the available number is not changed by the discharge current.

*L. Permits of Realization of Homogeneous Bundle of Primary Rontgen Rays.*

The tube must permit of the realization of a strong homogeneous bundle of primary Röntgen rays of any desired penetrating power. For this purpose it should clearly be excited from a source of constant potential. The result should be attained even though the discharge is intermittent.

*M. No Heating of Cathode by Discharge Current and no Evidence of Cathodic Disintegration.*

At the high vacuum and with the relatively gas-free electrodes of the new tube there is no evidence of any bombardment of the cathode. On the pump, in the earlier stages of gas removal, when a discharge can be made to pass through the tube without the heating current in the filament, the latter is seen to be strongly locally heated by the discharge current, as from bombardment by positive ions. But when the exhaustion has been completed and the tube is operated with the cathode hot, a voltmeter and ammeter in the filament circuit show no change even when a very heavy discharge is sent through the tube. Positive ion bombardment, if it existed to an appreciable extent, would raise the temperature, and hence the resistance of the tungsten filament, and would therefore be indicated by the instruments. If it were very local and considerable, it would be further indicated by a melting through of the filament at the point in question. The resistance change and local disintegration of the filament have been observed in only those cases where the vacuum, as shown by other effects such as fluorescence of the glass, has been poor.

Disintegration of the cathode would also manifest itself in blackening of the bulb. Even after running for several hours, the deposit on the bulb is very slight, and what there is may well be entirely accounted for by vaporization of tungsten at the focal spot on the target.

*N. The Size of Focal Spot on the Target the Factor Limiting Allowable Energy Input.*

Of the many factors limiting the allowable energy input in the ordinary tube, but one remains in the case of the new tube. With sharp focusing and above a certain energy input the tube resistance is unstable, dropping suddenly to perhaps a small fraction of its original value returning instantly to the old value, however, upon stopping the discharge or upon lowering it to the limiting value. The cause of this phenomenon appears to be as follows:

With a very high energy input and sharp focusing, the surface of the target melts at the focal spot and volatilizes. Owing to the fact that this tungsten vapor is produced at the focal spot, all of the primary cathode rays pass through it and, by collision, ionize it. This, of course, decreases the tube resistance. The larger the focal spot the greater is the allowable current. The design of the target also has a great deal to do with the allowable current value, as the face of a thin target is vaporized with a much lower energy input than a relatively thick one. For very short excitation of the tube, the allowable energy input is somewhat larger than for longer periods; but an input which can be carried for a few seconds can be carried indefinitely.

## § 6. DANGER CONNECTED WITH USE OF TUBE

There has been in the old tube a certain element of safety in that it could not be run continuously with a very heavy energy input. The new tube, even when focusing sharply, can be operated, for example, on a 7 cm. parallel spark gap with currents as high as 25 milli-amperes for hours at a time, and without the slightest attention.

For most purposes, other than fluoroscopic or radiographic work, there is no advantage in having the tube focused. In case it is not, the above mentioned energy input limitation falls away and the tube can apparently be designed for any energy input whatsoever. This permits, in this field, of the use of much greater Röntgen ray intensities than have heretofore been realized.

In the light of the above, it will be seen that the precautions which have been shown by years of experience to be sufficient for work with the old tube are not necessarily sufficient for the user of the new one.

## § 7. SUMMARY

In the foregoing, a new and powerful Röntgen-ray tube has been described. It differs in principle from the ordinary type in that the discharge current is purely thermionic in character. Both the tube and the electrodes are as thoroughly freed from gas as possible, and all of the characteristics seem to indicate that positive ions play no appreciable role.

The tube allows current to pass in only one direction and can, therefore, be operated from either direct or alternating current.

The intensity and the penetrating power of the Röntgen rays produced are both under the complete control of the operator, and each can be instantly increased or decreased independently of the other.

The tube can be operated continuously for hours, with either high or low-discharge currents, without showing an appreciable change in either the intensity or the penetrating power of the resulting radiations.

The tube in operation shows no fluorescence of the glass and no local heating of the anterior hemisphere.

The tube permits of the realization of intense homogeneous primary Röntgen rays of any desired penetrating power.

It is a pleasure to the author in closing, to express his appreciation of the services of Mr. Leonard Dempster, who has assisted him throughout this work.

# ELECTRIC RAILWAY SYSTEMS

By C. E. Eveleth

Railway and Traction Engineering Department, General Electric Company

The introduction of this article (based on a lecture delivered in New York City) acquaints one with the rapid growth which has been made in the application of electricity to traction, its present surprising magnitude, and some of the reasons which have brought about the extensive electrifications. At this point, the author makes a novel distinction between the "Science" and the "Art" of electric railroading, devoting the remainder of his article to the latter division of the subject. Starting with the power supply, he traces through to the rolling stock the different features and items which influence the choice and affect the maintenance of the systems that are to be considered.—Editor.

When considering the subject of electric railway systems it is well to bear in mind that only twenty-six years have passed since the first electric motors propelling street cars in Richmond startled the people by the terrifying flashes at the overhead collector and from the motor brushes. As in any radically new enterprise the pioneers were called upon to bear the brunt of development and to overcome what appeared to be almost insurmountable difficulties. The improvements made in the various elements were so rapid that soon the electric motors not only displaced horses as motive power but also lead to the extension of the field of city transportation. Then there followed the development of many thousands of miles of interurban electric lines, which have brought the outlying farms close to the cities in almost every locality east of the Mississippi river. This network is being steadily extended and will eventually cover the entire country as the density of population increases. The effect of the inter-communication so afforded is incalculable, both from an economic and sociological standpoint.

It is interesting to know, in these days when so much is heard about the increased cost of living, that such elements in our daily lives as are served by electricity have steadily decreased in cost, and today we ride farther for a nickel and have more electric light illumination for less money than ever before. Is it not significant to learn that the only divisions of one of our large eastern steam railroads where the net earnings per passenger car mile are holding their own are on the portions operated electrically, while on those divisions not so operated the net earnings are only a fraction of what they were seven or eight years ago and are decreasing at an alarming rate?

We sometimes ask: when will our railroads be operated electrically? In a recent lecture by Steinmetz, the statement was made that there is more aggregate horse power in electric motors operating cars and locomotives today than the aggregate horse power capacity of all of the steam passenger locomotives used for transportation in this country. Based upon this, we can fairly say that electrification is here now. The day has not yet arrived when the universal electrification of our steam railroads can be economically accomplished, but the decreasing cost of power and the lower cost of electric equipment for rolling stock is gradually extending the field where the application of electricity to transportation is justified and will eventually permit electricity to replace steam on all important railroad divisions.

At present we are using electricity to accomplish results unattainable with steam engines, notwithstanding the magnificent accomplishments which the steam engine designer has achieved with the Mallet locomotive, oil-fired boilers and the use of super-heated steam. Of all known agents, electricity is the most convenient means of distributing power and its application to transportation successfully overcomes widely different limiting conditions. On some railroad divisions about one twentieth of the gross ton mileage is used for hauling the coal to supply the steam locomotives with fuel: on other sections, the speed on going up grade is limited by the boiler capacity of the engines. The operation in descending these same grades is frequently hazardous, owing to the possibility of the loss of air for the air brakes, or danger from over-heated brake shoes and wheel tires. Applying electric locomotives to these conditions, in many instances, eliminates entirely the freight tonnage required to haul fuel. We are able to increase the speed of freight trains up grade to the maximum safe or economic limit, and by the use of regeneration we not only lessen the danger from failure of air for the brakes and the heating of tires and brake shoes, but are able to actually recover a material portion of the energy given up by a train descending a mountain and utilize this power for ascending trains. We are able to overcome the difficulties incident to bad water found in desert regions on one hand, and to more quickly transport the suburbanite on the other. Other limiting conditions which can only be met by electric traction are the elimination of smoke, the better utilization of space in city terminals by the use of different track levels, the elimination of round houses, turn tables and the saving of time required by steam locomotives while going for water and cleaning fires.

There are two broad divisions of the subject under consideration; one might be called the "Science of Electric Railroading," and the other the "Art of Electric Railroading."

The "Science" has to do with all the fundamental details which enter into the present development and includes the work of improvements and invention, which are necessary to broaden the field of electric traction. This includes developments in insulation, designs of generating, transmission, conversion and rolling stock equipment parts, the solution of problems of current collection, the mechanical structure of locomotives for high speeds, and the many elements which go to make up a successful and economical system of control for the electric power from the prime movers to the train wheels. There are thousands of men employed in the development of the science of electric railroading, and it is to these men that we shall be indebted for the final victories of the electrification.

The "Art" of electric railroading includes the analysis of conditions and the selection and application of the available elements to a specific problem as well as the operation and maintenance of the finished system.

It is the problem of the electrical engineer to so select and balance all the elements of power generation, transmission, and consumption in such a manner as to deliver the desired quality and quantity of transportation with the greatest reliability and the lowest cost.

As set forth, the problem seems simple, but experience has indicated that very different conclusions are reached, both as to the methods which should be applied and the anticipated results. The problem is, in fact, extremely complex; so much so that it is almost impossible to retain in mind the many elements which must be simultaneously considered to reach a justifiable conclusion. Frequently one sees results cited, which, on analysis, are found to disregard entirely elements of the greatest importance.

A better comprehension of the situation can be obtained by outlining some of the elements which must be equated. We will assume that the problem as to schedules, train capacities, grades, etc., both for the present and future, has been accurately set forth. For conditions requiring the use of motor-car trains and locomotive operation, there are available for consideration direct current and single-phase equipments or possibly single-phase for the motor cars and split phase for the locomotives, with a further possibility of three-phase, if the problem involves the use of locomotives only. To reach the proper conclusion every element from the prime movers to the train wheels must be considered.

### Power Supply

In some sections of the country, in the Carolinas, Michigan, Montana, Washington, Oregon and California, for instance, we find networks of power distribution which range from five hundred to two or three thousand miles of transmission circuits in each system. Generally in such localities, it is more economical for a railroad to buy than to manufacture its own power, since this requires less capital expenditure, and the power companies which have the benefit of diversified load factor, can, generally, manufacture power for less cost. Where such conditions exist the frequency of the primary distribution is established by these systems. Where it is necessary for the railway to build its own power house, the question of frequency with its bearing on the power already available in the territory to be served and the demands of the particular rolling stock selected must be carefully investigated. Comparisons must be made between single-phase and three-phase power generation, due weight being given to the elements of initial cost, efficiency, power-factor and protective appliances. Some of the problems such as the desirable size of power house units, their overload capacity, etc., is common to all systems.

### Distribution System

This is the simplest element in the chain and can generally be worked out on its economic merits as regards the selection of voltage, size of conductors and the character of installation to conform to the distance of transmissions and permissible line regulations for the various systems.

### Secondary Distribution and Substations

The location and capacity of substations must be considered jointly with the secondary power distributions to the trains. This involves the selection of voltage; the determination of the permissible potential drops; provisions for the mitigation of inductive interference with telephones and telegraphs for the single-phase and three-phase systems, or the consideration of the possibility of electrolytic difficulties in case of the direct current, both for normal operation and for conditions of short circuits; the selection of third rail or overhead trolley; the affect of atmospheric conditions such as lightning, snow and sleet; examination of the reliability of the elements chosen and decisions regarding the amount of line to be incapacitated when local repairs must be made. The selection of substation apparatus will be different for each system and will further vary with the frequency of power supply. The advisability of using transformers or auto-transformers with questions of capacity and regulation must be considered for the alternating-current systems; and with direct current, there are questions of the relative merits of motor-generator sets, rotary converters or motor converters with the determination of their normal and overload capacities and regulation. To make these different elements comparable, the selection of apparatus must be so balanced as to yield the same degree of insurance in case of the failure of individual elements or abnormal congestion of traffic, due to any cause.

### Rolling Stock

This item is by far the most important, as the proper selection of these elements is vital to the success of the system. Here we are at once confronted with the consideration of the inherent features and costs of the various kinds of apparatus available and due consideration must be given the relative values of constant versus variable speed, features involving the starting characteristics, efficiency of motors, conversion devices, control and driving mechanisms, effects of inherent characteristics on power load factors, electrical power-factors, etc.; in addition, the desirability of regeneration and emergency braking require consideration, if mountain work is involved.

After having determined the first costs and rates of depreciation of each of the above elements, there remain two important items for consideration. The first is the analysis of power consumption, which can be carried through with reasonable accuracy for the particular conditions under consideration. The second is the problem of the determination of the operating and maintenance costs, which is more difficult. It is in these elements that the results of practice are most often lacking, and the value of an individual's judgment will depend on his general experience, and on his ability to deduce from available data information which can be applied, when properly modified, to meet the specific problem in hand.

### General

The assembly of these elements in the order of their relative merits is the problem before the engineer who is called upon to select a system for a particular application. It is not surprising that different results are reached by different investigators, due to the different weights assigned to the elements or difference in the degree of optimism towards some of the unproved features. Very often it is surprising to find how little difference there is in the initial costs of the various systems, as some of the elements tend to offset each other. For example: the high cost of single-phase rolling stock equipment frequently offsets the greater cost of direct-current substations, while the additional weight of the single-phase equipments offsets the greater conversion losses of the direct-current substations, resulting in both the cost and power consumptions of the two systems being almost identical. Consequently with a greater quantity of rolling stock, the tendency is for the moderate voltage direct-current systems to be lowest in cost and cheapest to operate, while with few rolling stock elements the tendency is to relatively favor the higher voltage systems. For suburban electrifications a moderate direct-current voltage is generally the most economical, while for single track infrequent service, higher voltages are desirable.

A discussion of electric railway systems would not be complete without consideration of the Standardization of Systems. There is no doubt but that standard third rail and overhead trolley clearances are necessary to avoid serious interference with bridge girders, station platforms and various structures existing along main railway rights of way. About seven years ago, the Germanic countries headed by Prussia, adopted certain arbitrary standards that all main railways should be equipped with fifteen thousand volt single-phase trolleys operated at sixteen and two-thirds cycles. At that time there was no experience available to justify such a selection, but it was believed by those in power to be desirable to have all efforts expended in one direction, and, furthermore, it was deemed necessary for military reasons. Since then, it has developed that the limitations imposed are very adverse to economical motor car operation, that inductive interference with telephones and telegraphs under certain conditions are extremely serious, and the low frequency involves difficult mechanical problems and practically bars out forever an economical design of induction motor for certain classes of service. These limitations are arousing some dissatisfaction in Germany; the Italian engineers have decided that three-phase is better suited to their conditions and the majority of engineers in England, Australia, Canada, France and Russia seem to favor direct current.

In this country we have done well to avoid a limitation such as an arbitrary standard system of electrification would impose, since it leaves us free to work in every direction whether it be single-phase, three-phase, split phase, moderate or high voltage direct current, the mercury rectifier systems, or in any other direction which may be entirely unknown to us today. Arbitrary standardization of a system would mean limited development or stagnation.

Electrification of railways is desirable, not only from the standpoint of superior transportation, but on account of improvement in land values and the comfort and safety of travel. Although electrification is economically justified for many conditions there are to-day no known systems sufficiently low in cost to permit universal use of electricity for railroads and we must, therefore, have a free hand in order to achieve the ultimate general application which we believe will come.

# SOME SALIENT FEATURES OF RECENT 60-CYCLE SYNCHRONOUS CONVERTERS

By J. L. Burnham

Direct Current Engineering Department, General Electric Company

When the first sixty-cycle synchronous converters were brought out, they were regarded as rather sensitive pieces of apparatus. The improvements which have been made in recent designs have, however, placed them on a par with their twenty-five-cycle prototypes. What these changes are, how they came to be made, and their effects on the characteristics of the machines constitute the principal points covered in this article.—Editor.

The confidence that has been gained for the 60-cycle converter as a reliable piece of apparatus is due principally to improvements in mechanical details which permit of higher surface speeds. The adoption of commutating poles has also aided materially in its satisfactory operation, particularly in the larger sizes. Aside from improvements in the converter itself, the generally better present conditions for operation, such as larger transmission lines, more uniform frequency of power supply, and better and more complete protection, have an important influence on the increase of reliability of service. Those more important factors in the design and manufacture of synchronous converters that contribute to its present success will be here considered.

Safety against flashing at the commutator has been increased by providing more distance between brushes of opposite polarity. This is particularly true when this distance is as small as is obtained for 60-cycle converters, if heretofore considered allowable commutator speeds are employed. For instance, a speed of 4500 ft. per minute gives a distance of 7½ in. between centers of brushes of opposite polarity. The distance between the nearest points of brush-holders is less than 7½ in., which is admittedly small for 600 volts. To add 1½ in. to this distance would increase the commutator speed proportionately and would give a speed of 5500 ft. per minute (which is now considered conservative). Nine inches between brushes would increase the safety against flashing in a much greater proportion than the 22 per cent increase in speed, as the distance between brush-holders is increased in a much greater proportion.

With the improved design of commutator to stand higher speeds, the sequence of operations of manufacture and assembly of bars and the treatment of mica has received much attention, so that the finished commutator requires much less seasoning to fix the bars permanently. It is now quite generally recognized that commutators for 60-cycle converters must hold perfectly true and smooth to secure successful operation.

The proper proportioning of thickness of mica between commutator segments to voltage per bar has been proven in practice to give operation at higher voltage between bars equal in reliability to that obtained with lower voltage between bars. With 20 per cent greater voltage and 30 per cent more mica between bars than was formerly used (with also the same size and speed of commutator) there is practically no difference in the tendency to flash under adverse conditions. The tendency to spark is less with the smaller number of segments and the commutator is easier to build, therefore, usually better.

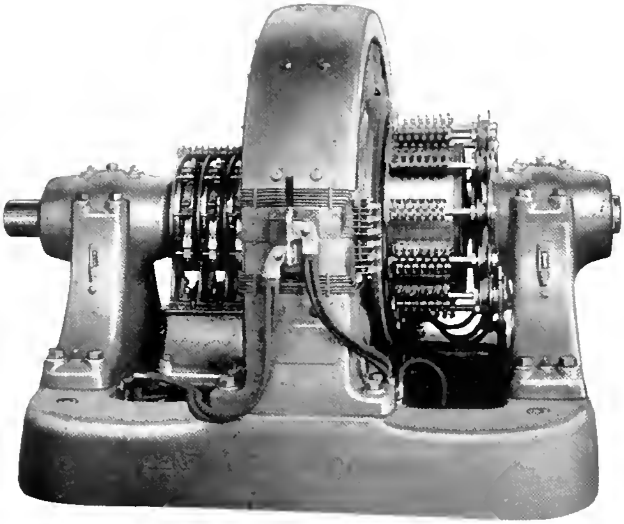

Fig. 1. 12 Pole, 500 Kw., 600 R.P.M., 575 Volt Rotary Converter without Commutating Poles

With the ability to build longer high-speed commutators, it became possible to increase the output per pole, that is, to increase the r.p.m. for a given size of unit. In recent machines the output per pole has been increased beyond the inherent commutating ability, so that commutating poles are necessary.

An interesting comparison to show the development in the past ten years is given in Figs. 1, 2 and 3. These machines all have 12 poles and run at 600 r.p.m. The one in Fig. 2 is capable of delivering twice the output of the machine in Fig. 1, and represents about the maximum output per pole as limited by commutation without commutating poles. The converter in Fig. 3 is able to carry three times as much load as the converter in Fig. 1, and represents present good practice in regard to the limiting features, namely: commutator length and speed, and commutating ability with commutating poles. The converter in Fig. 1 has 95 per cent more pounds of material per kilowatt than the commutating pole machine in Fig. 3. The one in Fig. 2 has 50 per cent more material per kilowatt than the one in Fig. 3.

This comparison also shows how armature surface speeds have been made greater with proportionately greater pole pitch, or spacing. The more recent designs in Figs. 2 and 3 have approximately 40 per cent higher surface speeds than the older one in Fig. 1. This allows of a 40 per cent greater distance between adjacent pole tips, without changing the ratio of pole arc to pole pitch, which reduces the amount of magnetic fringe flux cutting the armature conductors in the neutral space undergoing commutation. The resulting smaller voltage between commutator segments, under and near the brushes, allows of more latitude in brush position with less cause for sparking, due to the short-circuit current from the armature coils passing through the brushes during commutation. Also there will be a less possibility of flashing over in the event of heavy sparking due to excessive load, or

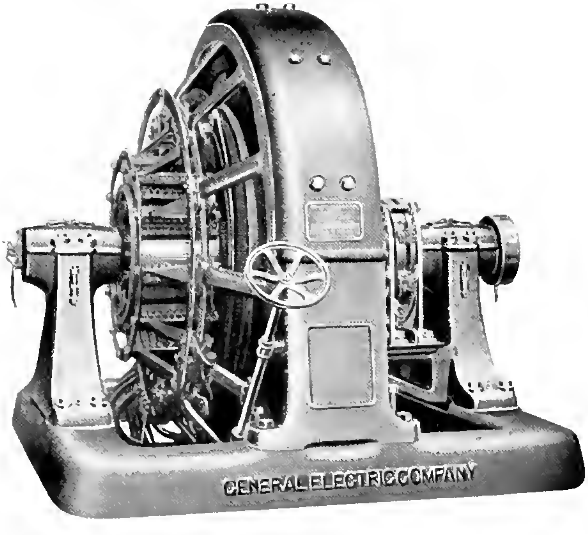

Fig. 2. 12 Pole, 1000 Kw., 600 R.P.M., 600 Volt Rotary Converter without Commutating poles

unusual disturbances for the lower voltage between the commutator bars, near the brushes, would have less ability to maintain the incipient arcs. Since the ratio of pole arc to pole pitch is unchanged, the ratio of maximum volts per bar to average volts per bar is also unchanged.

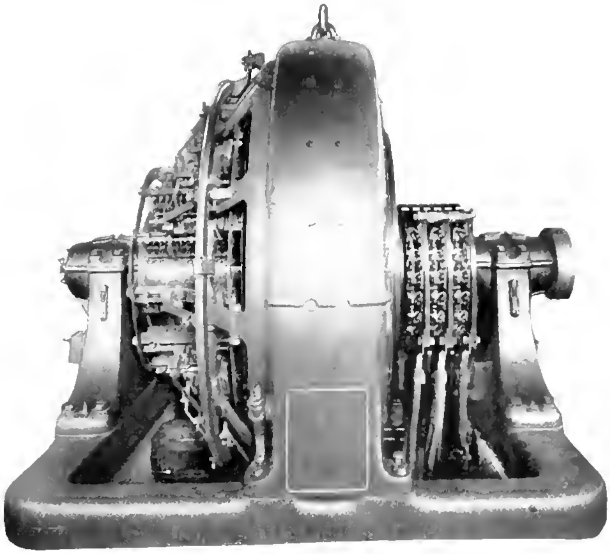

Fig. 3. 12 Pole, 1500 Kw., 600 R.P.M., 600 Volt Rotary Converter with Commutating Poles

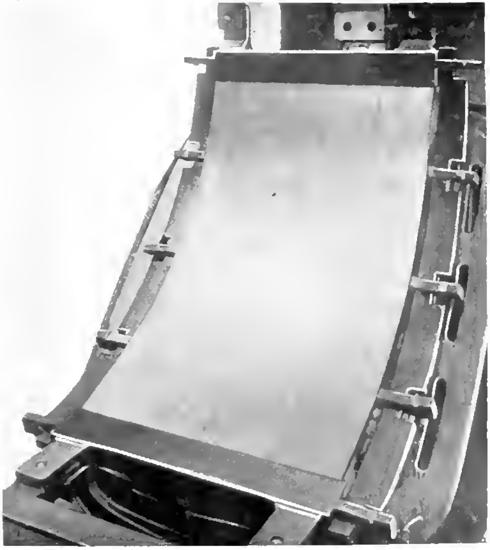

Fig. 5. A Welded-Joint Pole Damper

This comparison is based on 600-volt converters. The same comparison might be made with the 300-volt converters showing the even greater increase in output per pole, which has been made possible by the use of ventilating vanes fastened to the commutator bars. With the lower voltages, the possibility of flashing is so much less that the vanes do not add any material risk of damage in the case of a short-circuit or other disturbance that might cause flashing. The danger to the attendant is eliminated by enclosing the vanes, as shown in Fig. 4, by a circular trough, which also serves to direct the cooling air more effectively past the vanes.

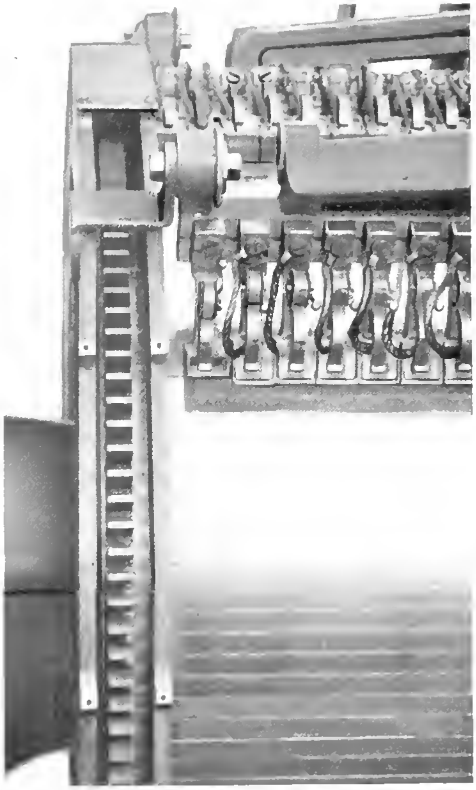

Fig 4 Partial View of a Commutator Equipped with Ventilating Vanes and Protecting Trough, latter partially removed

An average example of the gain in cooling surface by the addition of vanes to a commutator would be about as follows:

Commutator bar 0.4 in. wide, 25 in. long, cooling surface 10 sq. in. A vane $4\frac{1}{4}$ in. wide by 2 in. high by $\frac{1}{8}$ in. thick would add about 5.6 sq. in. of radiating surface. The cooling surface of the commutator would be increased over 50 per cent by the vanes which, with their protecting cover, occupy about 8 per cent of the commutator length.

With commutating poles, it is necessary to raise the direct-current brushes in order to avoid sparking when starting a converter with alternating current. The rigging for raising all of the brushes by the movement of one lever is shown in Fig. 8. The current required to start a commutating-pole converter with brushes raised is less than required by converters without commutating poles with brushes down, and all sparking is of course eliminated.

To obtain quick changes in field strength, to correspond with changes of load for good commutation with commutating poles, the polepiece dampers have been modified so that they will not enclose the commutating pole. To compensate for the omission of the connection of the bridges between adjacent poles, the dampers are made of lower resistance and much attention has been given to the making of all joints so they will remain permanent. There are three methods of making the joints in pole dampers, now in use: (1) by welding, Fig. 5; (2) by casting, Fig. 6; and (3) by a slight taper, Fig. 7, carefully fitting and drawing them sufficiently together by a nut to expand the copper, or brass.

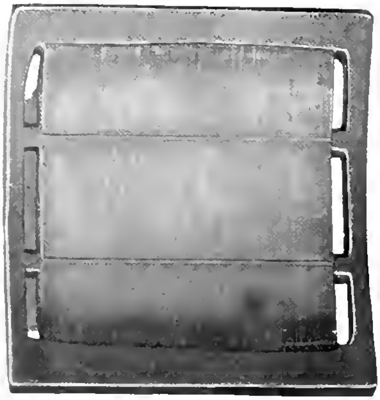

Fig. 6. A Cast Pole Damper

To avoid overloading some of the brushes, greater care is now taken to insure uniform resistance from the commutator to the bus-ring through each brush, when the greater number of brushes per arm are required. A busbar, to which all of the brush leads are connected, is mounted on each bracket and is connected to the main bus-ring. This construction is shown in Fig. 3. For a similar reason, it is also specially desirable to have the armature windings thoroughly equalized, Fig. 8, to insure uniform commutation and equal distribution of heating.

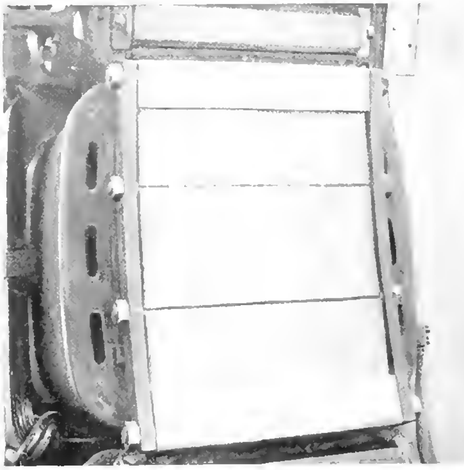

Fig. 7. A Taper-Joint Pole Damper

The machine illustrated in Figs. 3 and 8 is operating very successfully under unusually severe conditions. It transforms power received at the end of a 100,000-volt, 153-mile line, which is subject to direct strokes of lightning and other interruptions usual to such long-distance, high-voltage transmissions.

# ELECTRIC PROPULSION ON THE U.S.S. JUPITER

By W. L. R. Emmet

Consulting Engineer, General Electric Company

The author gives some interesting data comparing the Cyclops, Neptune and Jupiter, which are equipped respectively with reciprocating engines, turbines with helical gearing, and turbines in conjunction with two induction motors. The trials referred to were not the official trials, but only preliminary trials. We hope to be able to give our readers the results of the official trials when these have been run. This paper was read before the Society of Naval Architects and Marine Engineers in New York on December 11, 1913. Editor.

The contract for propelling machinery of the U. S. Collier Jupiter was awarded by the Government to the General Electric Company in June, 1911. The designs had been made during the previous year when it was expected that the ship would be built in a private yard. The ship was built at the Mare Island Navy Yard, and was put in commission September 15, 1913. Since that time she has made a number of trial runs in San Francisco Bay and at sea, but she has not yet had her official trials.

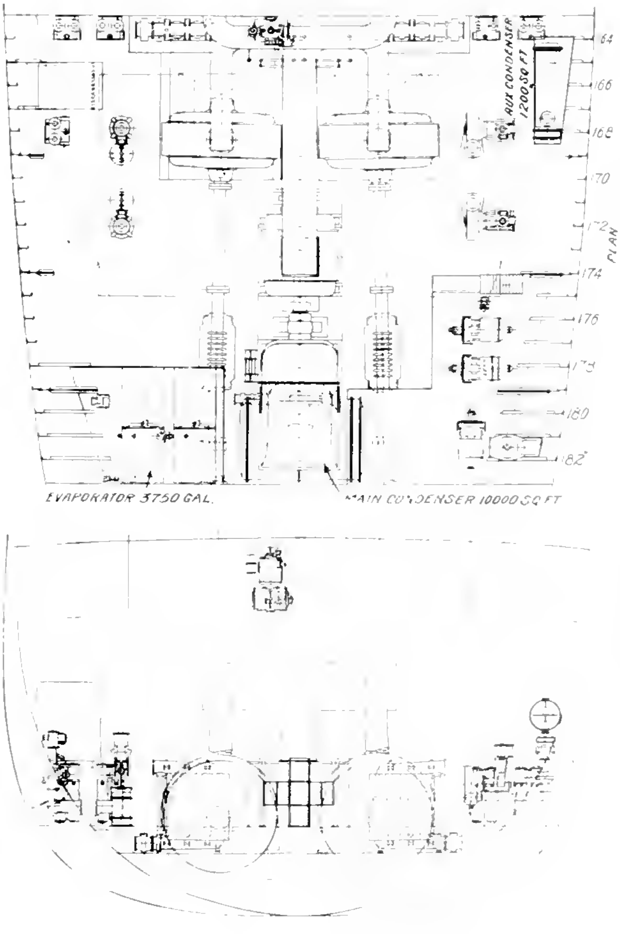

Fig. 1. Arrangement of Machinery

The Jupiter is a very large vessel of about 20,000 tons displacement, and is designed to carry about 12,000 tons of coal and oil. The length of her deck over her cargo space is occupied by a line of derricks, which must add considerably to the weight and wind resistance of the ship.

She is a sister ship of the colliers Cyclops and Neptune. The Cyclops was equipped with reciprocating engines and has been in operation for some years. The Neptune was equipped with turbines connected to the propellers by helical gearing.

The Jupiter is equipped with one turbine generating unit and two induction motors, one driving each of the propeller shafts. There is also a board carrying switches and instruments.

A comparison of the equipment of these three vessels is given by Table I on page 123.

The character of the apparatus installed in the Jupiter is shown by the accompanying cuts. It is all of a type commonly used in the electrical industry and need not be described in detail here. There is only one feature about the generating unit which is different from the type of units ordinarily used for electrical purposes; that is, that the governor is so designed that it can be set to hold any desired speed through a wide range, the adjustment of the governor being the normal method of speed variation used in this vessel. The ship can also, if desired, be controlled by the throttle, so that the governor is simply a convenience and in no sense a limitation.

The windings of the generator, which carry the alternating current, are on the stationary part and are insulated with non-combustible material. The generator drives its own ventilating air by powerful impellers attached to the ends of the rotor. This air is delivered from the top of the generator through a duct which connects to the space from which the fire room blowers take their air supply. The heated air from the motors also passes out of the engine room through similar ducts. The revolving parts of motors are connected to water-cooled resistances through collector rings, and means are provided by which these collector rings can be short circuited so that the rotor circuits are closed upon themselves. Such a condition, with the resistances cut out, is the normal state of efficient operation, the resistances being used only for the purpose of giving a large torque in reversing. The vessel can be operated with the resistances continuously in circuit. With this connection, the immediate movement of either motor in either direction is very convenient, and this method of operation is normally used in maneuvering in narrow waters or about wharves. The ship can, however, be maneuvered and reversed without the use of the resistance; and while this method has not yet been fully experimented with, it is thought that her reversal, even without the resistance, will be about as effective as that of vessels having existing types of equipment.

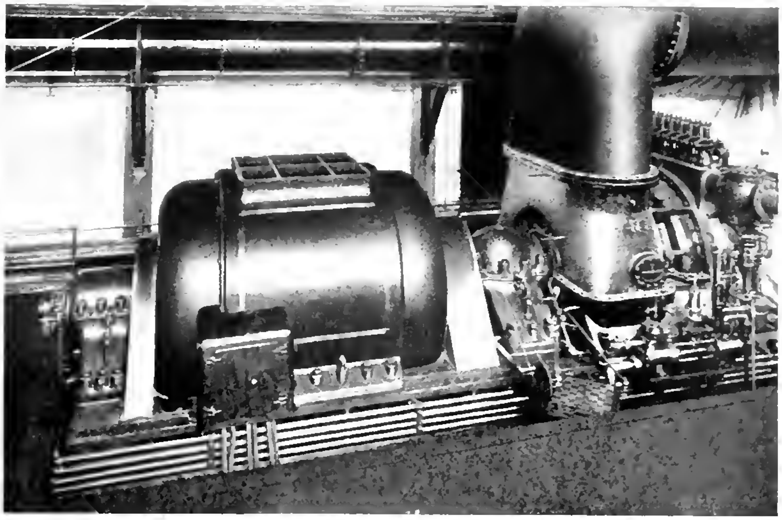

Fig. 2. Generating Unit

Since the Jupiter apparatus was designed, a method of designing induction motors has been developed which will give all the desired characteristics for reversal without the use of external resistance. Such motors will have squirrel-cage rotors, which are of a simpler character than the definite wound rotors now used. While the method of control and operation of the Jupiter is extremely quick and simple, the operations necessary with this new type of motor will be simpler still. With this new method it will be extremely easy to accomplish all the operations of speed control or reversal of either propeller from the bridge if desired.

When the first tests of the Jupiter operation were made she had been lying at the Navy Yard dock for four months, so that her bottom was in a very foul condition. Her speed in that condition was something like 25 per cent below normal. This produced abnormal electrical conditions, since the low frequency made necessary the use of higher magnetic densities than are desirable. Many of the conditions of these runs were very unfavorable. A large proportion of the crew were green men; in one fireroom watch a large proportion of the fireroom force were seasick. A great deal of boiler compound was used in the boilers, and the priming was excessive. The condensed water was much discolored by boiler compound, and water was at frequent intervals forced from the valve packings.

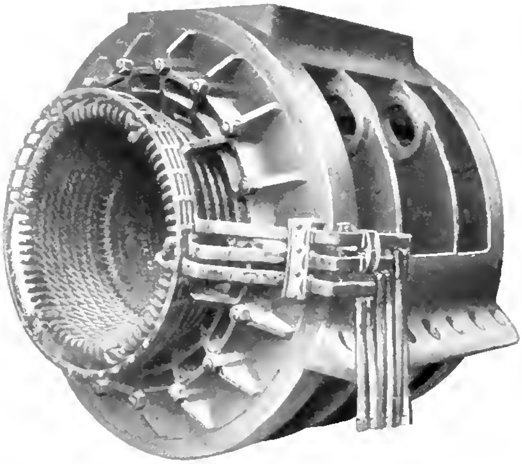

Fig. 3. Stator Frame and Windings of Generator

The operation of the apparatus during these runs was exactly in accordance with expectations. The turbine ran with a very perfect

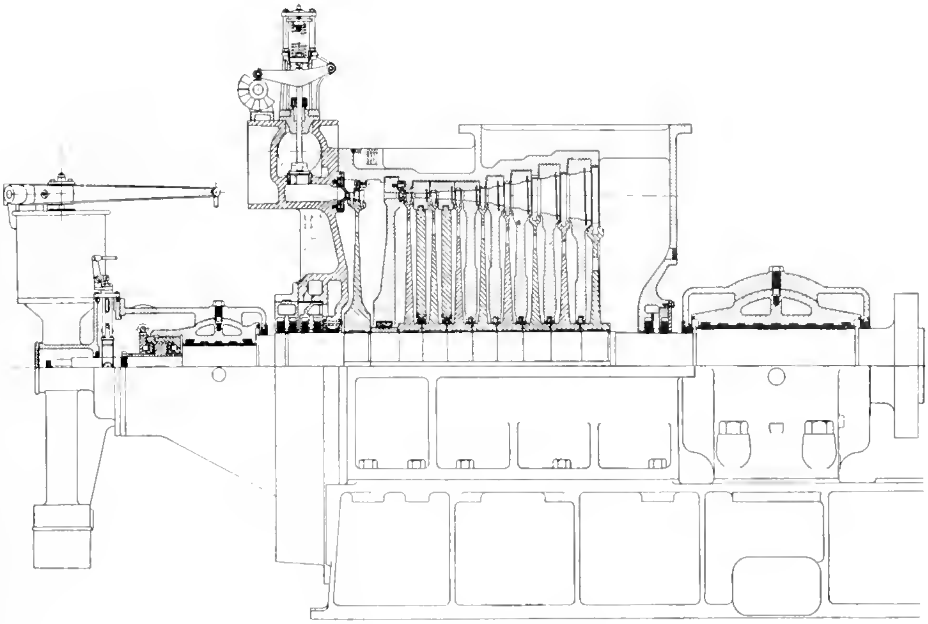

Fig. 4 Cross-Section of Turbine

balance, and ran just as steadily in rough water as in smooth. The governor held its speed perfectly. The lifting of propellers to the surface at no time caused any perceptible speed variation. The only effect of such lifting of propellers was a fall of current on the instruments showing a diminution of power delivered to the propellers. Examination of the turbine after several such runs had been made showed it to be in perfect condition, and free from rust, scale or dirt.

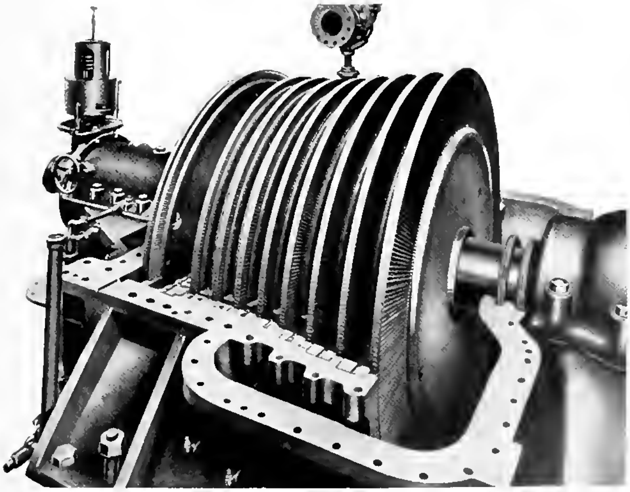

Fig. 5. Turbine for U. S. Collier "Jupiter" Mid-Bearing Cap and Top Intermediate Holder. Intermediates and Nozzles Removed

After this period of preliminary trials, the ship was docked, and since that time she has made a set of standardization runs and a 48-hour unofficial trial with a clean bottom. On this 48-hour trial the ship averaged 14.78 knots, the average power delivered by the generator was 5000 kw., corresponding to about 6300 h.p. The average revolutions of the propeller were 115. The Cyclops in her official 48-hour run made 14.61 knots with an average of 6705 i.h.p.

The power required by the Jupiter in this 48-hour run is somewhat less than would be expected from the Cyclops performances, and the slip of the propellers is also less than was expected. It has been suggested that this difference might, in some degree, be attributable to the fact that in the Jupiter the torque delivered to the propellers is continuous, while with the reciprocating engines the impulses are intermittent. Careful investigation would be necessary to ascertain whether there could be anything in such a theory. It has also been suggested that there would be some advantage in the fact that the

Jupiter's propellers were entirely free from racing, but since some of these tests were made in quite smooth water, this could hardly have had any effect. If no advantage is gained through these causes, it would certainly seem that the performance of the Jupiter's propellers is very creditable to Captain Dyson, who designed them.

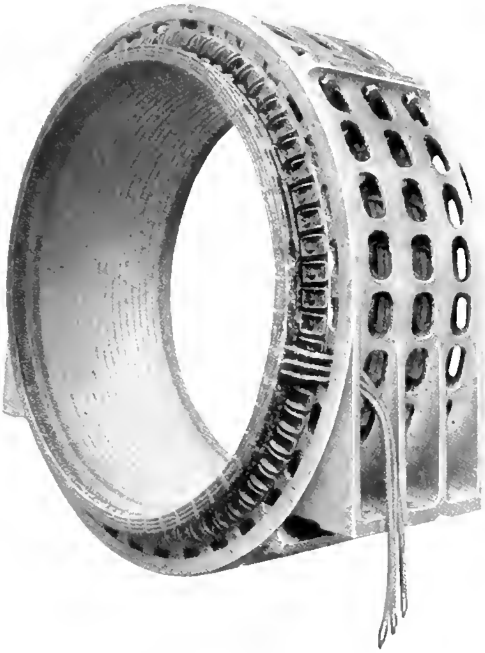

Fig. 6. Stator for Motor

Through a misunderstanding, the steam pipe on board the Jupiter was made much too small, so that the normal pressure at the turbine cannot be attained. The vessel will not give her best performances until this is corrected, and until an effective separator is put between the boilers and the turbine so that the efficiency of the turbine will not be affected by priming. It is believed that when these changes are made, the Jupiter can, if desired, be operated at a much higher speed than that which has been attained, and that her economy will prove to be far better than that of any vessel afloat.

The steam consumption of the Jupiter turbine and the efficiency of all of her apparatus has been determined by exhaustive tests at Schenectady, and is also accurately known through knowledge of the performances of other similar apparatus. These results are shown by the accompanying curve, and they cannot fail to be accomplished in the ship herself when all conditions are normal.

Since the preliminary trials above mentioned, the Jupiter turbine has been injured through the breaking of a half-inch tap bolt, which held the section of stationary buckets used in the first stage of this machine. On account of this trouble her official trial has been postponed, and it is hoped that the steam pipe will be changed and a separator put in before the official trial is made. A section of stationary buckets held by these bolts is the only detachable part in this turbine. Tap bolts are subject to the danger of breaking under such conditions, and we have had trouble with such method of attachment in other turbines. The matter in this case was, however, unfortunately overlooked. The trouble is easily corrected, and the accident has no significant bearing upon the demonstration which this ship has made. While this bolt destroyed all the buckets in the first stage, the turbine was still capable of operation. The turbine was taken apart because it was seen that the economy was not normal. By taking out the bolt which was adrift and clearing the damaged parts which might interfere, the ship could still have been operated indefinitely at normal speed with a very fair economy. Such arrangements could be made in a few hours.

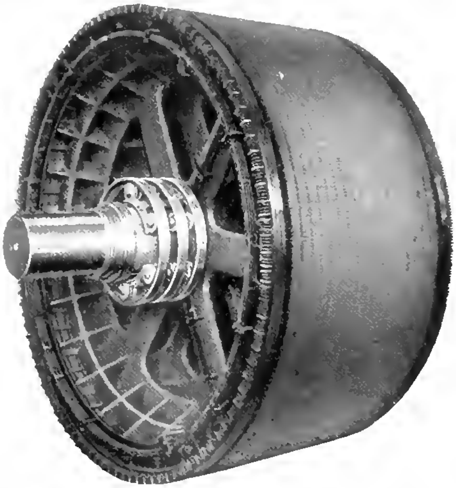

Fig. 7. Rotor for Motor

Four years ago I presented my first paper on Electric Ship Propulsion to this Society.

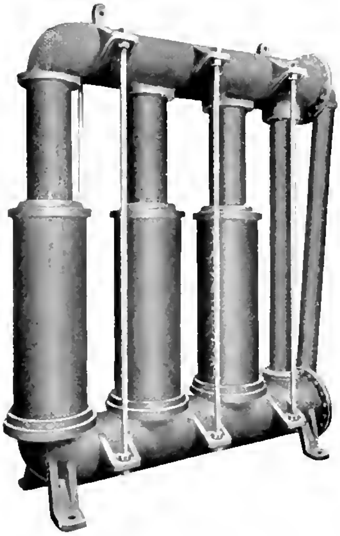

Fig. 8. Water-Cooled Rheostat

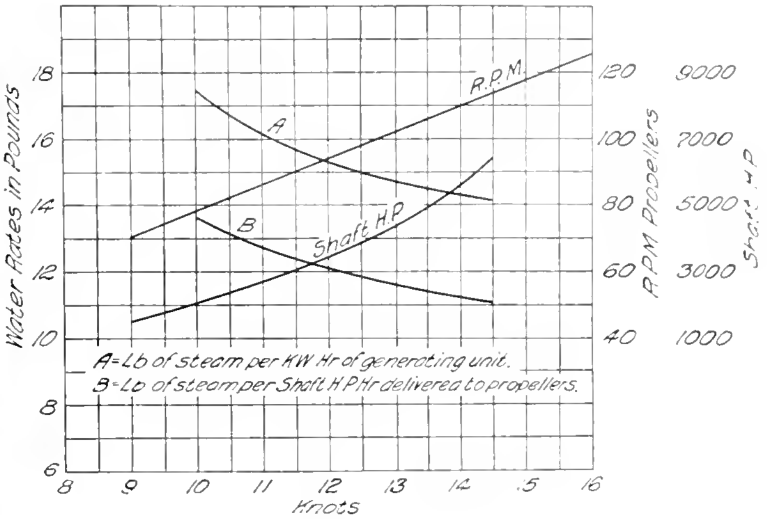

Fig. 9. Water Rates U. S. S. "Jupiter"—Conditions 190 Lb. Gauge, 28.5 In. Vacuum, No Superheat

A year before that I had designed an equipment for the battleship Wyoming, and a proposal had been made to the Government in which my designs were embodied. Since that time I have submitted several designs to the Government relating to equipments of battleships which have been built. My last design applied to a case like that of the Pennsylvania, and was submitted last spring. My estimates as to the results of this equipment as compared with those which will be accomplished by the equipment which is being put into the battleship Pennsylvania are shown by Table II.

With reasonable allowances for steam required outside of the main turbines, it would appear that this ship, which is provided with 12 boilers, could, with the turbo-electric

## TABLE I

| | Cyclops | Jupiter | Neptune |
|---|---|---|---|
| Displacement, tons | 20,000 | 20,000 | 20,000 |
| I.h.p. at 14 knots | 5600 | . . | . . . . |
| Engine or turbine speed at 14 knots | 88 r.p.m. | 2000 r.p.m. | 1250 r.p.m. |
| Propeller r.p.m. at 14 knots | 88 | 110 | 135 |
| Weight driving machinery, tons | 280 | 156 | |
| Character driving machinery | 2 triple expansion engines | 1 turbo-generator and 2 motors | 2 turbines each with gearing |
| Steam consumption in lb. per s.p.h. hr. | 14 (estimated) | 11.2 (tested) | |
| Speed maintained on 48 hr. trial | 14.6 knots | | 13.9 knots |

## TABLE II

| | R.P.M. 21 Knots | H.P. Required 21 Knots | Pounds of Steam per Hr. Turbines Alone 21 Knots | Pounds of Steam per Hr. Turbines Alone 15 Knots | Weight of Driving Machinery in Tons |
|---|---|---|---|---|---|
| Turbine drive with geared cruising turbines as adopted | 222 | 31,700 | 374,000 | 106,000 | 749 |
| Turbo-electric drive | 160 | 29,200 | 305,000 | 91,000 | 598 |

equipment, operate equally well with 10 boilers. If two boilers were omitted, the whole weight saving would be 266 tons.

If my first design for a warship made over four years ago had been accepted by the Navy Department, the vessel produced would have been very greatly superior in respect to economy, reliability, weight, simplicity, and cruising radius to any ship now afloat, and ever since that time my case has been steadily strengthening through the great improvements which have been made in high-speed turbines.

Since the Jupiter has been put in operation, much interest has been aroused among ship owners and ship builders, and it is probable that equipments for several large vessels will, within a short time be contracted for. If such a beginning can be made, the practical results accomplished will soon develop great activities.

# DIAGRAMS OF THE POLYPHASE COMMUTATOR MOTOR

By Dr. H. Meyer-Delius

Induction Motor Department, General Electric Company

In this article, the theory of the polyphase commutator motor is developed. First the theory of the d-c. motor is outlined, and it is shown that the same principles apply to the polyphase motor, with the only difference that due to the alternating nature of the current a reactance drop has to be added to the ohmic drop. Making use of elementary geometrical relations of vectors, the author develops a diagram for the polyphase series motor, by means of which the current, power-factor, speed, torque and efficiency can be determined for different values of load. It is shown how this diagram can be drawn after the reactance and the resistance of the motor have been determined either by test or calculation. The diagram is finally applied to the brush-shifting series motor invented by Prof. Goerges of Germany, the commercial application of which has only recently become possible, as a result of a better understanding of alternating current commutation.—Editor.

The torque of any electric motor is produced by the reaction of the magnetic field on the current flowing in the armature conductors. Fig. 1 shows diagrammatically the connections of a normal d-c. motor. The field winding, *F*, excites the field. The main current, passing through the brushes and commutator into the rotor winding, produces with the action of the field the mechanical torque which drives the motor. When the rotor revolves, the rotor conductors cut the field and a counter e.m.f. is induced between the brushes which is proportional to the number of revolutions. The counter e.m.f. times the current represents the electrical energy taken from the line equivalent to the mechanical energy delivered at the shaft. (Losses neglected.)

This same principle holds exactly with a-c. commutator machines. The only difference is that, due to the pulsation of the currents, reactance voltages appear, which cause phase displacements of currents and voltages, rendering the phenomena more complicated than with d-c. machines. In order to avoid too large phase displacements, the reactance voltage should be kept as small as possible. In d-c. machines the armature field is steady and does little harm outside the commutation zones; in a-c. commutator machines the armature field must be neutralized, because the reactance voltage induced by this strong field would be prohibitively large. This could be effected by a compensating winding on the stator connected in series with the rotor. The compensating winding is a true duplicate of the armature winding, completely neutralizing the armature ampere turns along the whole circumference. This arrangement is shown in Fig. 2, drawn for quarter phase current. Besides the second phase we

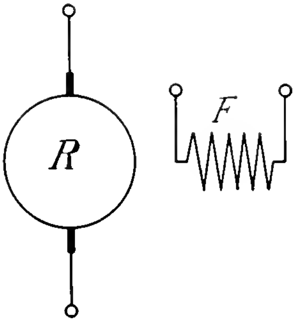

Fig. 1. Connection Diagram of a D-C. Motor

have added to the d-c. diagram of Fig. 1, only the compensating winding $C_1$ and $C_2$. The rotor is the unchanged d-c. armature. Since the stator field is excited by a-c. current, the stator iron must be laminated. The compensating winding, like the rotor winding, is distributed over the whole circumference in small slots, so that the stator of the a-c. commutator motor has generally the appearance of that of a normal induction motor. The field windings $F_1$ and $F_2$ may be placed in special big slots producing distinct poles as in a d-c. machine, or they may be distributed in the same small slots with the compensating winding. In the latter case a distributed field of more or less sine shape is produced, as in normal induction motors, In this case the field and compensating winding are of the same type and may also be converted into one winding. But in order to separate the actions of the field and compensating winding more clearly, we will assume a separate field winding, as shown in Fig. 2.

We will now study the actions of the different windings. Fig. 3 shows in a simplified manner the windings and magnetic paths of the commutator motor of Fig. 2 in the axis of one phase. $S$ indicates the stator and $R$ the rotor iron. Between the main terminals $T_1$ lie the compensating winding $C_1$ on the stator and the rotor winding $D$ on the rotor, which are connected in series over the brushes $B$ on the commutator. The compensating winding is wound with the same number of turns as the rotor winding, but in the inverted sense, so that a current flowing through both windings does not produce any flux in the magnetic circuit $SR$. The compensating winding neutralizes the armature field completely.

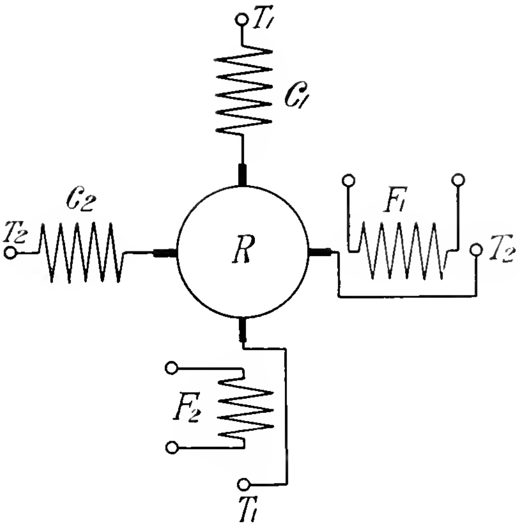

Fig. 2. Connection Diagram of a Polyphase Commutator Motor

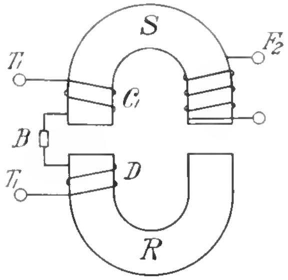

Fig. 3. Simplified Connection Diagram of a Polyphase Commutator Motor

The field winding $F_2$ is wound separately on the stator. If we connect $F_2$ to an a-c. voltage, a field is excited in $SR$. This field induces equal and opposed voltages in the compensating and rotor windings, so that no voltage appears between the main terminals $T_1$. For the motor this means that at standstill a field excited by the field winding produces no difference of potential between the main terminals, since the transformation voltages induced by the main field in compensating and rotor windings necessarily balance each other at the main terminals. Thus we do not at all need to introduce these transformation voltages in the diagrams or calculations. Now if we turn the rotor, a rotation voltage is produced by the main field in the rotor winding, which does not appear in the steady compensating winding and which therefore shows up at the main terminals. Just as in d-c. machines, this rotation voltage is at each instant proportional to the number of revolutions and the strength of the field. It is therefore in phase with and of the same frequency as the main field. The intensity of this voltage is entirely independent of the frequency of the applied current and is proportional to only the speed of the rotor and the intensity of the main field. This is the characteristic difference between the commutator motor and the induction motor. In the latter the rotor voltage is dependent upon the line frequency as well as upon the speed.

The only other voltage appearing at the main terminals is the impedance drop in the compensating and rotor winding. Fig. 4 shows the voltage diagram of the motor. The following voltages appear at the terminals:

1. $e_r$: the rotation voltage. It has the same phase and frequency as the field. Its intensity is proportional to the intensity of the field and the number of revolutions, and is independent of the line frequency.

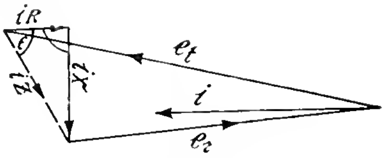

Fig. 4. Voltage Diagram of a Polyphase Commutator Motor

2. $i\times R$: the ohmic drop in the conductors carrying the main current. Its phase is opposed to that of the current and its intensity proportional to the current.

3. $i\times X$: The leakage reactance drop in the conductors carrying the main current. Its phase is 90 deg. behind the current. Its intensity is proportional to the current and the impressed line frequency and independent of the speed of the motor, correct commutation being assumed for the sake of simplicity. (See article, "The Commutator as Frequency Changer," GENERAL ELECTRIC REVIEW, Dec., 1913.)

These three voltages must balance the impressed line tension $e_t$. The resultant of the latter two voltages, the ohmic and reactance drop, is the impedance drop $i\times Z$. With the line frequency constant, the reactance drop is proportional to only the current, as is the ohmic drop. The impedance triangle therefore has a constant shape, and the third side—the impedance drop, $iZ$—is proportional to the current and has a constant phase displacement from it. Let the constant angle between the impedance and ohmic drop be $\epsilon\left(tan\ \epsilon=\frac{X}{R}\right)$.

Compare with the above diagram the voltage diagram of a d-c. motor as shown in Fig. 5. $e_r$ represents the rotation voltage and $i\times R$ the ohmic drop. These two voltages must balance the line tension $e_t$. All tensions are in phase and all possible operating conditions are covered by the plain algebraic equation:

$$e_r+i\times R=e_t$$

The difference between the terminal voltage and the rotation voltage drives the current over the resistance $R$. With increasing speed the current becomes smaller and smaller, because the rotation voltage grows, until the developed torque, which is proportional to current times field, is the same as the counter torque of the driven machine.

The only new voltage in the a-c. diagram is the leakage reactance drop $i\times X$, which throws the total drop $i\times Z$ considerably ($\epsilon°$) out of phase with the ohmic drop of the d-c. diagram. The algebraic d-c. equation becomes with a-c. a geometrical vector equation:

$$\overline{e_r}+\overline{i\times Z}=\overline{e_t},$$

because the three voltages are no longer necessarily in phase with each other. But the general character of the equation is unchanged. The difference between the terminal voltage and the rotation voltage drives the current over the impedance $Z$. With increasing speed the current becomes smaller and smaller until the developed torque is the same as the counter torque of the driven machine. The motor torque is now proportional to the current times field times the cosine of the angle of phase displacement between current and field.

Just as in a d-c. motor we obtain a series motor if the field is excited by the main current, a shunt motor if the field is excited by the terminal voltage, and a compound motor if the field is excited by both at the same time, so in an a-c. motor we obtain the same characteristics with the same connections. For each type of motor we will study the electrical relations between the three voltages of the diagram regarding phase and intensity for different loads. These electrical relations will give geometrical relations between the corresponding vectors in the diagram. These geometrical relations will show that the end of the impedance vector, $Q$, must move on a geometrical locus with varying load. This locus will enable us to find for each load the line current in intensity and phase, the torque at the shaft, the speed, the input and output, and the efficiency of the motor.

Fig. 5. Voltage Diagram of a D-C. Motor

## THE SERIES MOTOR

The connections are shown in Fig. 6. The field $F_1$ is excited by the main current $i_1$ and is therefore in phase with and proportional to it (no saturation of the iron assumed). But we can use as well the current $i_2$ or any combination of the currents $i_1$ and $i_2$ for the excitation of the field $F_1$, as is shown in Fig. 7. The phase of the resultant field $F_1$ is shifted from the phase of the main current $i_1$ over an angle which is determined by the relation of the number of turns of the two exciting windings. This angle, which we will call $\beta$, is constant for all loads. Since the rotation voltage is in phase with the field, it has a constant phase displacement $\beta$ from the main current. We found before that the impedance vector, which includes the impedance of the field winding in the series motor, has also a constant phase shift ($\epsilon^\circ$) from the current. Thus the impedance drop and the rotation voltage have also a constant phase displacement from each other. Therefore in the diagram of Fig. 8 the angle $\delta$ between $i \times Z$ and $e_r$ is constant ($\delta = 180 - \epsilon - \beta$). The end of the impedance vector $Q$ must move therefore on a circle, in which the terminal tension $OE$ as chord subtends the angle $\delta$. This is the desired locus for the end point of the impedance vector.

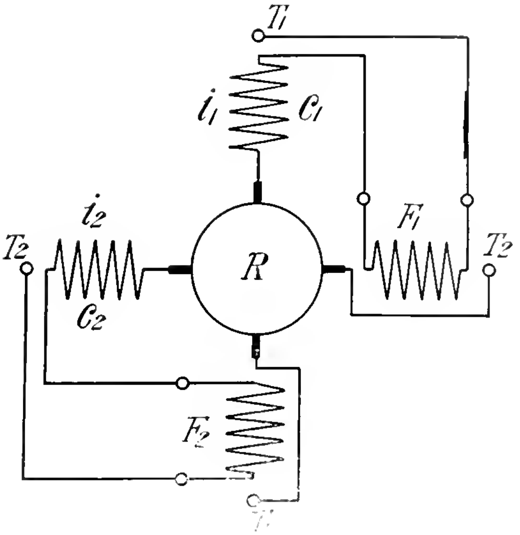

Fig. 6. Connection Diagram of a Polyphase Series Motor

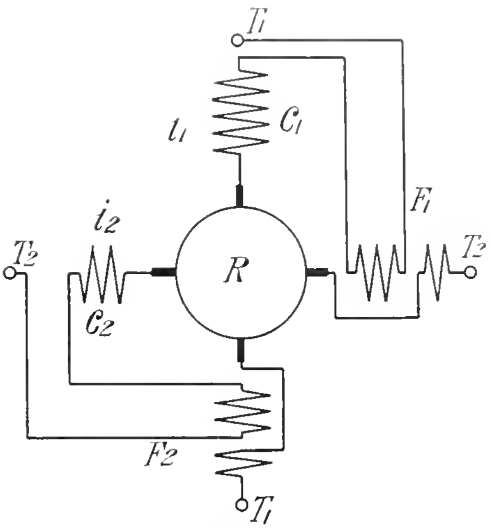

Fig. 7. Connection Diagram of a Series Motor with Phase Combination on the Exciting Winding

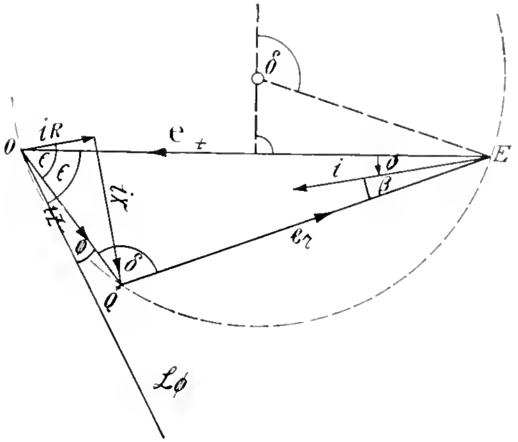

Fig. 8. Circular Diagram of a Series Motor Showing Current and Power-Factor

### Current and Power-factor

Since the impedance drop is proportional to the current, we measure the current by the same vector $OQ$. This vector is lagging $(180 - \epsilon)$ degrees behind the current. If we draw a line $L\phi$ through $O$, which forms the same angle with the terminal voltage (see Fig. 8), we can measure the phase shift $\phi$ of the current from the terminal voltage by the angle between this line $L\phi$ and the impedance vector $OQ$.

### The Speed

The rotation voltage is proportional to the speed times the field, which is again proportional to the current.

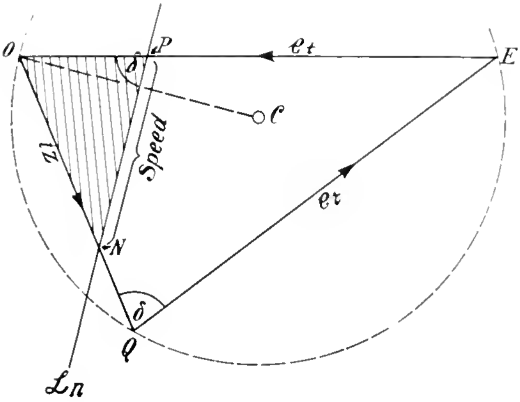

Fig. 9. The Speed in the Diagram of a Series Motor

$e_r = QE = n \times i$, where $n$ indicates the number of revolutions. The impedance drop, $OQ$, is proportional to the current;

$$\underline{i \times Z} = OQ = i$$

thus $$\frac{e_r}{i \times Z} = \frac{QE}{OQ} = n \qquad \text{(See Fig. 9)}$$

Draw a line $L_n$ through an arbitrary point $P$ on $OE$ under the angle $\delta$. This line $L_n$ may cut $OQ$ in $N$. $\Delta OPN$ is similar to $\Delta OQE$, because two angles are equal.

$$\frac{QE}{OQ} = \frac{NP}{OP} = n$$

If $Q$ moves on the circle, the vector $OQ$ cuts off from the line $L_n$ a portion $PN$, which is proportional to the speed, the denominator $OP$ of the above ratio $\frac{NP}{OP}$ remaining constant. The point $P$ may be chosen so that the number of revolutions appear on $L_n$ in a convenient scale.

### Input and Output

The input is proportional to the watt component of the current. If we draw a line $L_1$ through $O$ at right angles to the power-factor line $L\phi$ (see Fig. 10), we could measure the input by a line $QW$ through $Q$ perpendicular to $L_1$, which would represent the watt component of the current.

To obtain the output, we have to deduct the losses in the motor from the input. There are the $I^2R$, core and friction losses. The core loss is nearly proportional to the square of the field, or in this case to the square of the current, so that we may unite the $I^2R$ and core losses and take both proportional to the square of the current.

Draw the line $OCT$ through the center $C$ of the circle. $\Delta OQT$ is a rectangular triangle. Draw the perpendicular to $OT$ through $Q$, which cuts $OT$ in $S$. We find

$$\frac{OS}{OQ} = \frac{OQ}{OT} \text{ or}$$

$$(OQ)^2 = OS \times OT = I^2$$

If $Q$ moves on the circle, $OS$ is always proportional to the square of the current or to the $I^2R$ and core losses.

Prolong $QS$ until it cuts $L_1$ in $U$. If $Q$ moves on the circle, the triangle $QWU$ is always of the same shape and therefore $\frac{QU}{QW}$ is a constant relation. $QW$ represented the input, and $QU$ is therefore also proportional to the input. The triangle $OSU$ is always of the same shape, $\frac{US}{OS}$ is therefore a constant relation, and $SU$ is also proportional to the losses. If we draw an arbitrary line through $O$, which may cut $QU$ in $V^1$, $UV^1$ is also proportional to the losses. If $QU$ (= the input) and $UV^1$ (= the losses) are drawn to the same scale, $QV^1$ will represent the output. We find the right scale at standstill, where the output is zero and the input equals the losses. $QE$ represents the rotation voltage, which is zero at standstill. $Q$ falls in $E$. The input is $EU_s$, which at the same time must represent the losses. $OE$ is therefore the output line. For our former load point, $Q$, the input is pro-

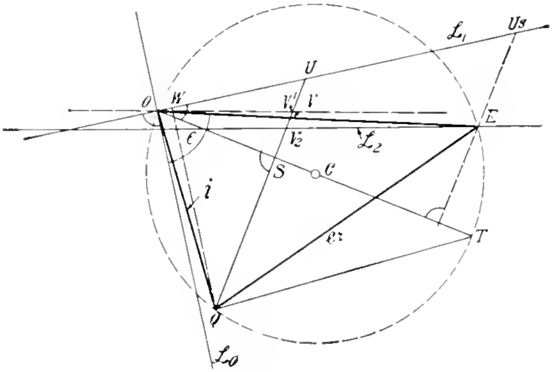

Fig. 10. Input and Output in the Diagram of a Series Motor

portional to $QU$ and the output to $QV$ in the same scale.

So far we have neglected the friction and windage loss. This loss has a complicated relation to the speed, which makes it impossible to introduce it exactly in a diagram. Since it is a small part of the losses a rough approximation will do, at least in the normal speed range. At standstill this loss is zero, so the output line must go through point $E$. We draw a straight line $L_2$ through $E$, which gives at normal speed the right friction loss, $VV_2$ and measure the output only up to this line $L_2$.

### The Torque

The torque is proportional to the current times the field times the cosine of the angle of phase shift between them. This angle is $\beta$, which we found is a constant angle. The field is proportional to the current. The torque therefore varies with the square of the current, just as in a d-c. series motor. It could be represented in the diagram by the same line $UV$, as the losses varying with the square of the current. This distance being rather small for the normal speed range, we had better take the distance $OU$ on $L_1$, which is proportional to $UV$, to indicate the torque.

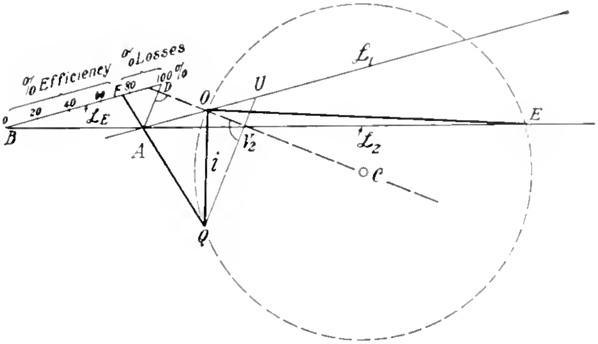

Fig. 11. The Efficiency in the Diagram of a Series Motor

### The Efficiency

$$\text{The efficiency} = \frac{\text{output}}{\text{input}} = \frac{QV_2}{QU}$$

See Fig. 11. Prolong the output line $L_2$ beyond the intersection $VA$ with the input line $L_1$. In an arbitrary point $B$ on $L_2$ draw a line $L_e$ parallel to $L_1$ and through $A$ a parallel to $QU$. The two parallels cut themselves in $D$. Further prolong $QA$, until it cuts $L_e$ in $F$.

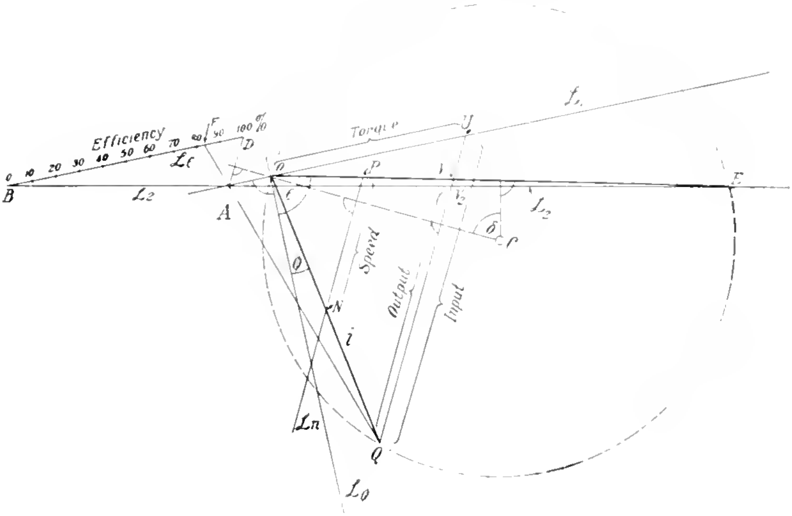

Fig. 12. The Complete Diagram for a Series Motor

It is

1. $\Delta\, AQU$ similar to $\Delta\, FAD$
2. $\Delta\, AV_2U$ similar to $\Delta\, BAD$

$$\text{from 1 we have } \frac{QU}{AU} = \frac{AD}{FD}$$

$$\text{from 2 we have } \frac{V_2U}{AU} = \frac{AD}{BD}$$

Equation 2 divided by 1:

$$\frac{V_2U}{QU} = \frac{FD}{BD} = \frac{\text{losses}}{\text{input}}$$

Therefore

$$\frac{BF}{BD} = \frac{\text{output}}{\text{input}} = \text{efficiency}$$

For $Q$ moving on the circle, the point $F$ moves on the line $L_e$. $BF$ represents the efficiency, because the denominator $BD$ of the relation $\frac{BF}{BD}$ remains constant.

$B$ may be be chosen on $L_2$ so that the efficiency appears to a convenient scale. *

---

* An analytic derivation of similar loss and efficiency lines may be found in the book of E. Arnold, die Wechselstromtachnik, volume 1, page 118 ff.

### The Complete Diagram

For the construction of the diagram the following data are required:

*1.* The impedance as obtained, for instance, by a standstill test. The standstill current $i_{st}=\frac{e_t}{Z}$. The power-factor = cos $\epsilon$ at standstill gives angle $\epsilon$. It is also $\tan\epsilon=\frac{X}{R}$.

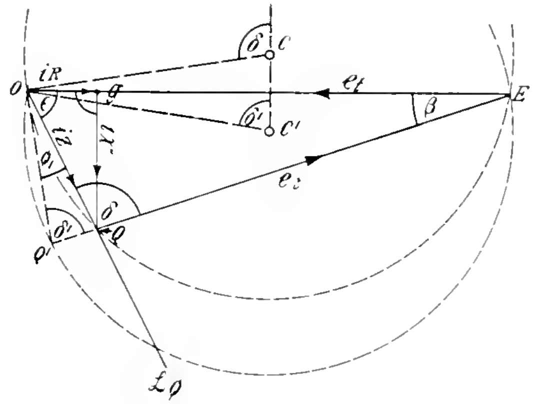

Fig. 13. Influence of the Angle $\delta$ on the Power-Factor of a Series Motor

Make $OE=i_{st}$ (Fig. 12) and draw $L\phi$, the power-factor line, through $O$ under angle $\epsilon$ and at right angles to $L\phi$, the input line $L_1$.

*2.* The phase displacement between the field and current, angle $\beta$. This gives $\delta=180-\epsilon-\beta$. Draw the circle, in which $OE$ as chord subtends angle $\delta$. Draw $OQ$, the current for normal load.

*Speed:* At a convenient point $P$ on $OE$ draw $L_n$, the speed line, perpendicular to $\overline{OC}$. $PN$, representing the normal speed, gives the speed scale.

*Output:* Draw $QU$ perpendicular to $OC$. $QU$, representing the input, gives the watt scale. Make $VV_2$ equal to the friction and windage losses and draw the output line $L_2$ by connecting $E$ with $V_2$.

*Torque:* $OU$ gives the torque scale.

*Efficiency:* $L_1$ and $L_2$ intersect in $A$. Draw $AD$ perpendicular to $OC$, choose $B$ on $L_2$ at a convenient point and draw $L_e$ parallel to $L_1$. Divide $BD$ in 100 parts, to indicate the efficiency at the intersection $F$ of $QA$ and $L_e$.

We are now able to look over the operating conditions of the motor completely and we shall see how similar they are to those of the d-c. series motor. In Fig. 13 just that load point $Q$ is shown at which the power-factor is unity, $Q$ falls on the power-factor line $L\phi$. The reactance voltage is balanced by a component of the rotation voltage $e_r$. Resolve $e_r=QE$ into the watt component $GE$ and the wattless component $QG$. The latter balances the reactance tension $iX$ completely, and we have the plain d-c. diagram, $OGEO$.

But the balancing rotation tension $QG$ is proportional not only to the current as the reactance voltage, but also to the speed. Therefore for lower speeds it is too small and the power-factor becomes lagging. For higher speeds it is too large and the power-factor becomes leading. In the neighborhood of the unity power-factor point the differences are small and the power-factor is nearly unity, and current, speed, torque and efficiency are exactly the same as in a corresponding d-c. machine.

For a given current the speed is determined by the strength of the watt field or the number of turns of the field winding. The power-factor is given by the strength of the wattless field, or by the angle $\beta$. For larger $\beta$ the power-factor becomes better; $\delta=180-\epsilon-\beta$ becomes smaller and the circle bulges higher, as shown in the dotted circle of Fig. 13. For a properly chosen $\beta$, the power-factor is approximately unity over a rather large speed range.

Though the reactance voltage produces a lagging current at lower speeds, it gives the a-c. motor a decided advantage over the d-c. motor at starting. At standstill the rotation voltage is zero and the full reactance voltage throttles away the main part of the terminal tension. The standstill current is therefore still moderate, and no starting resistances or transformers are necessary.

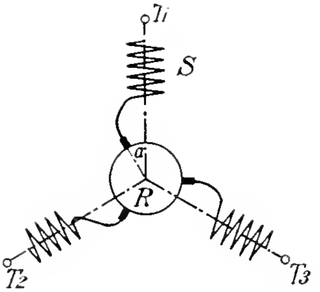

Fig. 14. Connection Diagram of a Brush Shifting Series Motor

In a d-c. motor the standstill current would be prohibitively large and starting resistances are always required. This fact makes the controlling apparatus for a-c. motors very simple.

We will apply the above diagram to a special practical type invented by Prof. Goerges, of Germany. The motor was exhibited in 1891 in Frankfurt a/M, Germany. But only recently have the conditions at the a-c. commutator been sufficiently cleared so that such a motor could be designed to operate with sparkless commutation; which was, of course, necessary before a market could be opened for it.

The connections for three-phase current are shown in Fig. 14. The stator is an entirely normal induction motor stator with one three-phase winding distributed in small slots and connected in Y. The Y point is formed by the rotor winding, which is connected in series with the stator winding over three equally spaced brushes sliding on the commutator. The rotor is an entirely normal d-c. rotor. The brushes are mounted on a movable brush yoke so that any brush position may be obtained.

Just as in a normal induction motor the stator winding excites a nearly uniform sine shaped field, and so does the similar rotor winding. Therefore the field resultant from the stator and rotor ampere turns is also of sine shape, whatever the brush position may be, so that practically no disturbing local fields appear.

Let us suppose the ampere turns of stator and rotor to be exactly equal in strength, and let us put the brushes in the same axis as the corresponding stator winding. The stator winding completely neutralizes the rotor winding over the whole circumference; no field is excited, and the stator winding acts as a plain compensating winding.

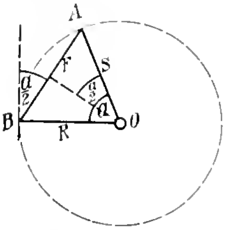

Fig. 15. Vector Diagram for Rotor and Stator Ampere Turns of a Brush Shifting Series Motor

Let us now shift the brushes over a certain angle $\alpha$, as shown in Fig. 14. Stator and rotor ampere turns no longer balance each other and the resultant ampere turns excite a field of sine shape, as we have seen before, proportional to the current and the angle of brush shift. A torque is developed by the field reacting on the current in the rotor winding. The motor is a plain series motor. A constant current assumed, the field increases with larger brush shifts. As in a d-c. motor the speed varies nearly inversely proportional to the field. The brush shift therefore controls the speed in a very simple manner without any auxiliary controlling apparatus.

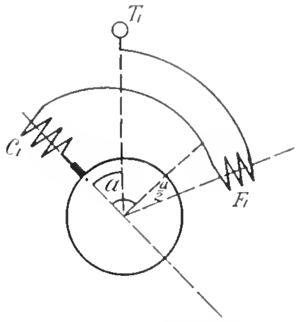

Fig. 16. Separation of Compensating and Field Winding in a Brush Shifting Series Motor

If the brushes are shifted over 180 deg., stator and rotor ampere turns are again in the same axis; instead of bucking, they act in the same sense. The torque is zero and the motor takes only a very small current from the line, since the impedance of the two windings in series is very large. This position is therefore well suited for connecting the motor to the line. By shifting the brushes forward, torque gradually develops until the motor starts and comes to the desired speed.

To develop the circle diagram for this motor we resolve the stator winding into two components, the compensating and the exciting winding. Since the stator and rotor ampere turns have uniform sine shape, they may be represented by vectors, as in Fig. 15. $S$ is the stator ampere turns, $R$ those of the rotor, shifted from the former by the brush shift angle $\alpha$. We resolve the stator vector $AO$ into the compensating ampere turns $BO$, equal and opposed to the rotor ampere turns, and into the field winding $AB$. Fig. 16 shows the two corresponding windings on the stator for one phase, $C_1$ the compensating, $F_1$ the field winding. We see that the field winding has a shift of $\frac{\alpha}{2}$ degrees. In our diagram we have called this angle $\beta$; therefore

$$\beta = \frac{\alpha}{2}$$

An impedance test at standstill gives the standstill current, and angle $\epsilon$ for this brush position. By finding $\delta = 180 - \epsilon - \beta = 180 - \epsilon - \frac{\alpha}{2}$ and constructing the circle diagram in the above indicated way, all desired data can be obtained from the diagram for all speeds. This method, repeated for several brush shifts, will show the features of the motor in all possible operating conditions.

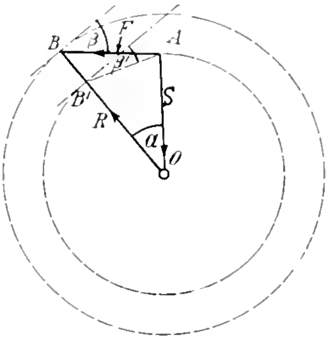

Fig. 17. Influence of the Strength of the Rotor Ampere Turns on the Angle $\beta$

It will be found that a motor designed in this way has not a very good power-factor for normal load and speed. We have seen above that to improve the power-factor the angle $\beta$ must be increased. This can easily be effected in the following way.

We see from Fig. 15 that the strength of the field winding is proportional to the angle of brush shift, at least for smaller angles, where the sine is approximately proportional to the angle itself. To increase $\beta$, the phase of the field winding $AB$ must be shifted without changing the brush shift or angle $\alpha$. This can be effected by increasing the rotor ampere turns with unchanged stator ampere turns, as shown in Fig. 17.

For the lower speeds the power-factor must drop, because we would need too large a wattless field to balance the reactance drop at the low speed. The necessary increase of the rotor ampere turns would be incomparatively large, and the size and cost of the motor would grow too much and the efficiency would drop. For smaller brush shifts or angles $\alpha$, which give the higher torques at higher speeds, the above method is very effective and only a small increase of the rotor ampere turns is necessary to obtain a high power-factor over a rather large speed range without affecting the size and cost of the motor.

The brush shifting series motor is only an example, to show how the diagram developed above may be applied to practical motors. Other polyphase series motors may be dealt with in the same way. The separation of the compensating winding and the field winding simplifies the electrical conditions in imagination and calculation, because all transformation voltages disappear. The remaining rotation voltage and impedance drop bring the a-c. motor near the d-c. motor in character, the principles of the latter having long been well known.

---

# SOME NOTABLE ELECTRICAL DEVELOPMENTS OF 1913

By John Liston

Publication Bureau, General Electric Company

The electrical manufacturing industry is one of extreme mutability and in no other line has there been required such continuous variation in design and construction methods. This is clearly shown in the following article, although a majority of the installations referred to do not indicate fundamental changes, but rather a logical and progressive development of apparatus already in successful operation.—Editor.

Owing to the vast extent of the developments which have characterized the electrical industry during the past year, it is difficult to select for special reference apparatus or installations which will serve as typical instances of recent advancement in the electrical art.

The following review will, therefore, be limited to brief reference to certain examples of 1913 apparatus and installations which are notable either for size or unique design, and indicate the achievements and tendencies of electrical manufacture for the year.

### Water Power Development

Pre-eminent among the notable hydroelectrical installations of the year is the huge power station at Keokuk, Iowa, which is the largest plant of its kind in the world, both on account of the extent of the engineering work involved during its construction and the volume of electrical energy which it is designed ultimately to develop. Its construction work included the building of a dam, power house, lock, dry-dock and ice fender, which combined constitute a concrete monolith with a total linear measurement of about 2½ miles. The power house itself is over 1700 ft. in length, and will, when completed, have 30 vertical shaft turbo-generators, the driving wheels of which under the normal head of about 32 ft. will develop an aggregate of 300,000 horse-power. A full description of this development is given in an article by Mr. E. A. Lof, beginning on page 85.

A water power plant which indicates the trend of electrical development for the year 1913 in a more striking manner than that of the equipment at Keokuk, is found in the hydro-electric development of the Pacific Light and Power Corporation of Los Angeles, Cal., on the Big Creek River, at a distance of about 200 miles northeast from Los Angeles. The two power stations are practically identical in their system of operation and the amount of their output, and a brief outline of the equipment of No. 1 station will serve to indicate the advance in the construction of electrical apparatus which this development involves.

The main equipment represents an increase in the size of units over all previous hydro-electric installations. The waterwheels are the largest impulse type turbines ever constructed, and they drive generators which have in turn a greater output than any hydraulically operated generators yet placed in service. At a speed of 375 r.p.m. these generators deliver an output of 17,500 kv-a. at 6600 volts, 50 cycles. The transformers, which are rated at 4500 kv-a. and operate at 150,000 volts, are also the largest units that have so far been produced for this voltage.

This development is essentially a high head plant, the water drop between the intake and the waterwheels being 2146 ft. The water is projected against the waterwheel buckets in a stream of 5½ in. diameter, at a velocity of about 300 ft. per second.

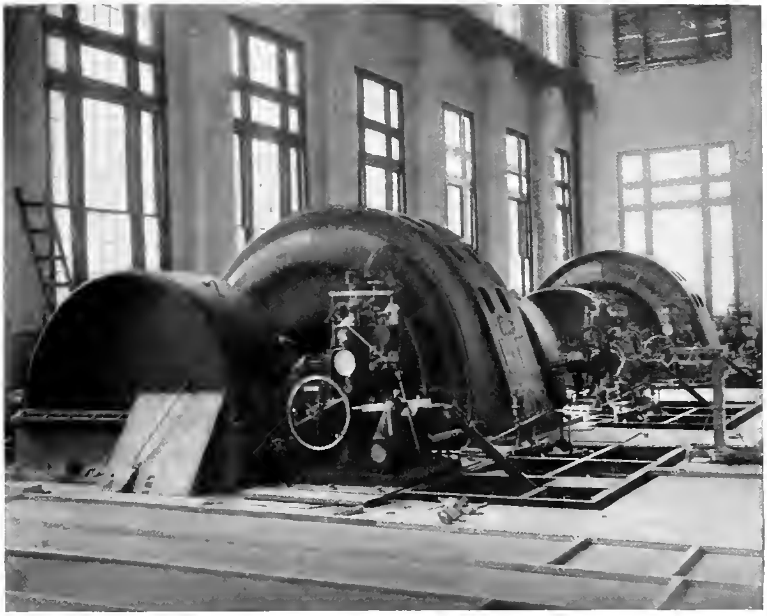

Fig. 1. 17,500 Kv-a. Generator Sets, Pacific Light and Power Corporation

This installation is also notable for the length of the transmission line, which consists of two sets of conductors carried on separate steel towers, the two lines running parallel (spaced 80 ft. apart) for 241 miles. The lines terminate at the Eagle Rock substation near Los Angeles, where the current is again transformed and utilized for lighting and railway service.

This power station has still another feature of unusual interest, necessitated by the high potential and extreme length of the transmission circuits. In order to compensate for line fluctuations and to insure proper regulation at the distribution point, the substation has been equipped with two 15,000 kv-a. synchronous condensers, which are the largest machines of this type ever used.

### Transformers

Since transformers were first manufactured for commercial service, each succeeding year has seen an increase in the physical size and electrical capacity of power transformers. This increase, which has been most notable during the past decade, was the result of, and coincident with, the development of enormous water power plants and central stations. With the consequent increase in voltage, necessitated by continual efforts to secure economical current transmission over great distances, there arose the imperative demand for transformer improvement. Of all the problems presented in transmission, that of the transformer is the most complex, and yet that problem has been successfully solved by the manufacturers in ample time to keep well ahead of the ever advancing demand. The year 1913 has witnessed the successful installation of numerous transformers which represent a distinct advance over previous practice. During that period the unit capacity has reached 15,000 kv-a. and the maximum potential 150,000 volts.

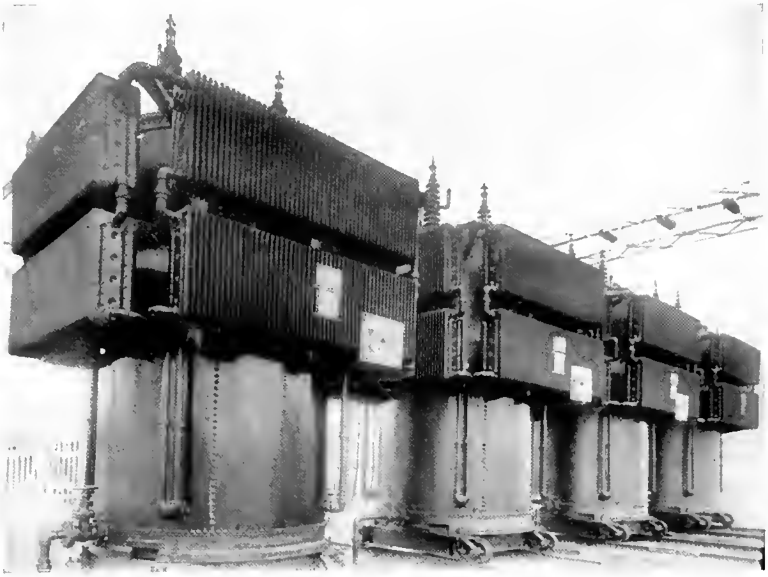

Fig. 2. High-Voltage, Self-Cooling Transformers, Out-of-Doors Type

One of the most radical designs consists of a relatively large self-cooled oil-insulated transformer, a number of units of this type, in capacities up to 3000 kv-a., having been constructed for use on a 100,000 volt transmission line. These units are entirely self-contained and are equipped with external pressed steel radiators, which are designed for automatic circulation and cooling of the oil; the internal arrangements being practically the same as those of the water-cooled type. By this means the benefits of the small self-cooled type have been incorporated with practically all the advantages heretofore available only in the large water-cooled type. A number of these transformers equipped with pressed steel radiators are at present being built for the Isthmian Canal Commission for use on the Panama Canal power system.

The use of transformers for out-of-door service has been given a strong impetus during the past year by the performance of various units of this type, which have withstood all sorts of climatic conditions. Several units of 3000 kv-a. for 140,000 volt lines, as well as others of 7500 kv-a. for 120,000 volt lines, have been installed. Experience has demonstrated that neither size nor voltage, nor climate is a bar to the successful operation of properly designed transformers out-of-doors.

### Electric Mine Hoists

One of the most important developments of the year in the application of electricity to mining service consists of the electrically driven automatic hoist recently designed for the Inspiration Consolidated Copper Mining Company of Miami, Ariz. This

Fig. 3. 4500 Kw., 150,000 Volt Transformer

electrical equipment is designed for the relatively low hoisting speed of 750 ft. per minute, and for automatic operation, although an emergency equipment for hand operation is also provided. The hoisting will be done at the rate of 1000 tons per hour from each of two shafts having a depth of 630 feet. The two balanced hoists are each independently driven by a 750 h.p., 575 volt direct current motor, to which current is supplied from a flywheel motor-generator set consisting of two 500 kw. generators driven by a 750 h.p. induction motor. The arrangement of this hoisting set represents a distinct advance in mining service, due to the immense tonnage which can be brought to the surface by the set, and the saving effected in the operation of large skips, which are automatically filled at the bottom of the shaft from storage bins and automatically dumped at the surface. This set is the largest automatic hoisting outfit in the United States, and the attendance actually required is limited to the starting and stopping of the motors at the beginning and ending of the operating periods, which will average about 14 hours per day, and an occasional inspection and renewal of the lubricant.

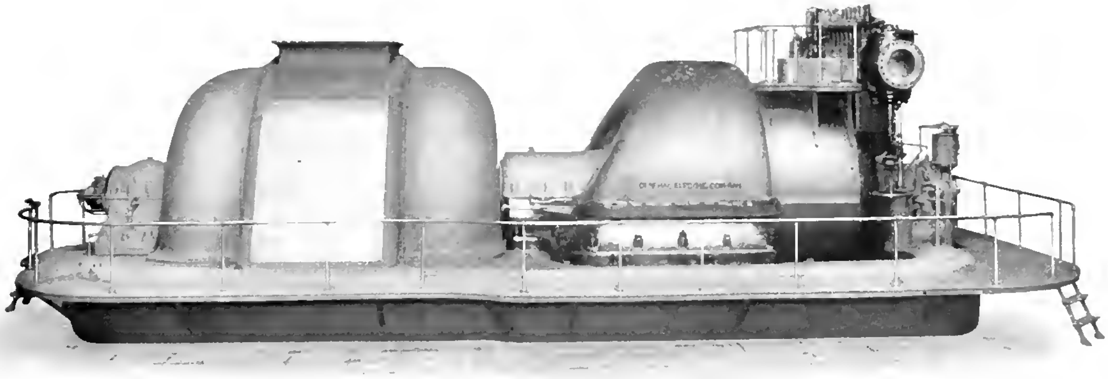

Fig. 4. 12,500 Kw. Horizontal Curtis Steam Turbine

These hoisting equipments are, however, dwarfed by the mammoth duplicate hoisting sets recently shipped to the gold mines of the Rand in South Africa, one for the Crown Mines, Ltd., and the other for the Modderfontein Gold Mining Co., Ltd. These are the largest mining hoists in the world, each set consisting of two 2000 h.p. motors installed one at each end of the hoist and direct connected to the hoist shaft. Each motor is over 16 ft. in diameter, and operates at 53½ r.p.m. Current is supplied to each set at 1000 volts, and the motors are connected in series. Current for their operation is received from the Victoria Falls and Transvaal Power Company's lines at 2000 volts, and is transmitted to the hoist motors through a motor-generator set consisting of two 1650 kw. generators driven by a 5000 h.p. motor. No flywheel is used.

An idea of the service conditions under which these motors operate may be gained from the fact that they hoist 8 tons per trip from a maximum depth of 3540 ft., at a speed of 3500 ft. per minute, which is equivalent to about 40 miles per hour; and during the hoisting cycle the load varies as much as 12,500 h.p. in a period of 30 seconds, the maximum positive load reaching 9000 h.p.

In view of their unusual size (the total weight aggregating 90 tons), it was necessary to ship these equipments in sections, and to reassemble them at the mines.

### Curtis Turbines

During the past year the development of the Curtis steam turbine has not been marked by any change of type or any radical departure from previous practice. Considerable advance has been made in the efficiencies obtained in the improvement of details, and in the size of units constructed and contracted for.

In general, the tendency has been in the direction of higher rotative speeds, and improvements in nozzles and buckets, both in arrangement and material. The earliest Curtis turbines generally consisted of a small number of stages, each containing several rows of moving and stationary buckets; subsequently, the number of stages was increased and the number of rotating rows of buckets in each decreased. This tendency has continued.

The design of the buckets and nozzles has not changed except in regard to detail. Various metals are employed, depending on the stresses and other requirements in each case. Curtis turbines that have been completed during the year and accurately tested show an efficiency superior to anything heretofore produced.

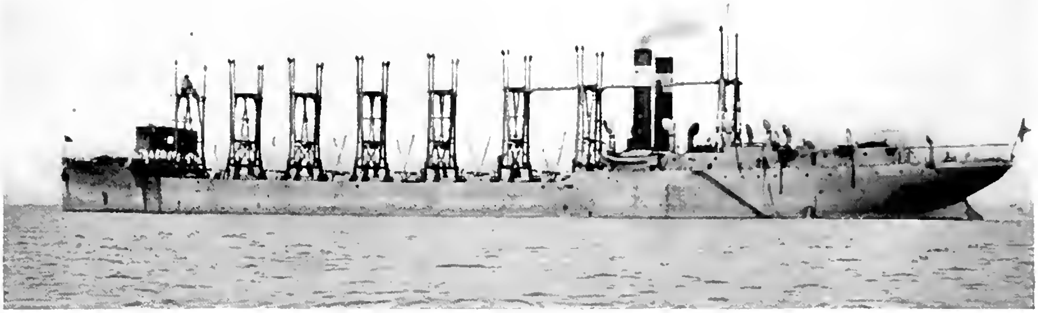

Fig. 5. U. S. S. Jupiter

A number of large horizontal units, ranging from 10,000 kw. to 20,000 kw. in capacity, have been completed and shipped, while other machines of 30,000 kw. and 35,000 kw. output are at present under construction. These latter are the largest turbine sets ever contracted for by any manufacturer, and consist of single self-contained units, the steam end and generator in each case being direct-connected and mounted on a common bed plate.

### Electric Ship Propulsion

The advantages of the electric propulsion of ships is exemplified in the equipment of the United States collier *Jupiter*, the power plant of which includes a Curtis steam turbo-generator, and two induction motors for driving the twin screws. The *Jupiter* has a displacement of 20,000 tons and is the first large vessel to be so equipped.

In comparison with her sister ship *Cyclops*, which is provided with reciprocating engines, the *Jupiter* showed a notable improvement in steam economy. By operating the turbine at about 2000 r.p.m., and the driving motors at 110 r.p.m., economical and efficient speeds were obtained for both prime movers and propellers. For a speed of 14.8 knots a turbine output of 6800 h.p. was required.

The adoption of electric drive has not only simplified the maneuvering and speed control of the ship, but has also materially reduced the weight of the power plant hitherto required for the development of corresponding energy by means of marine engines.

### Generators

During the year 1913 there has been developed a complete line of engine-driven generators with commutating poles for lighting and power service, this type of generator being the last to receive the benefits of the commutating pole feature. There has also been developed a new and original design of

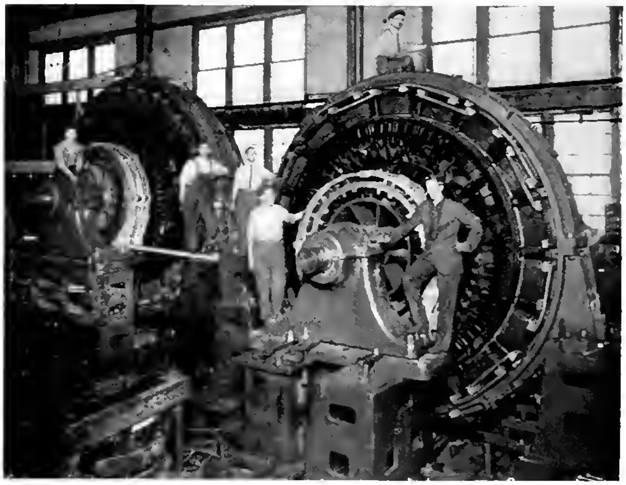

Fig. 6. Two 4000 Kw., 600 Volt Synchronous Converters for Commonwealth Edison Company in Test

revolving compensator for producing the neutral for three-wire service. This compensator is self-contained with the armature, and requires the use of but one collector ring for obtaining the neutral. It will supersede the oil type of separate oil-cooled compensator.

During the past year work was started on eleven 5200 kw. direct current generators for the Southern Aluminum Company, to be used for the refinement of aluminum. These machines are 26-pole, 170 r.p.m., 520 volt units, designed for waterwheel drive and capable of withstanding 75 per cent over speed. They are probably the largest d-c. machines that have been constructed.

### Motor-Generators

For supplying current to the 1200 and 2400 volt railway installations, special motor-generator sets have been required, and it is probable that in the near future higher voltages will be used for this apparatus which will involve the development of direct current generators for potentials up to 5000 volts.

### Synchronous Converters

In the design of synchronous converters, the year 1913 witnessed a steady reduction in the amount of space required for a given capacity in this type of machine; and for lighting service there have recently been constructed units having an output of 3000 kw. which occupy the same space as former units rated at 2000 kw. For railway work 4000 kw. converters have recently been successfully mounted on foundations originally provided for 2000 kw. units. These improvements have been rendered possible by the utilization of commutating poles, combined with an increase in speed; and in the case of the machines for lighting service, in a special arrangement for cooling the commutators, consisting of projections on the ends of the commutator bars which provide additional surface for heat radiation and augment the cooling effect by increased air circulation. The 4000 kw., 600 volt commutating pole rotary converters built in 1913 for the Commonwealth Edison Company of Chicago are of greater capacity than any previously built. For electrolytic work there was constructed a 2500 kw., 500 volt, 50 cycle machine, which is the largest of its type.

The reliability of the modern rotary converter, even when operating under extremely adverse conditions, is indicated by the success with which a 1500 kw., 60 cycle, 600 volt unit, installed at the end of a long 110,000 volt transmission line passing over mountain ranges at a high altitude and subjected to frequent and severe disturbances from lightning, has operated during the past year. Notwithstanding these operating conditions, this machine was run successfully for a large part of the year without a single breakdown.

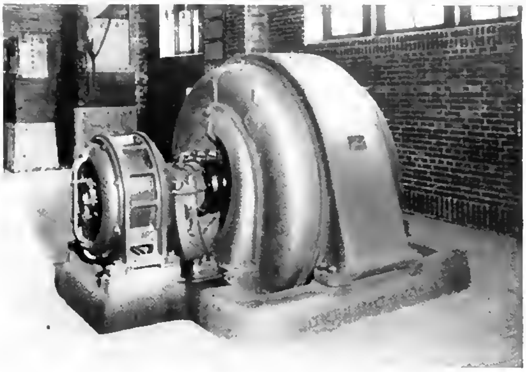

Fig. 7. 1000 Kv-a. Synchronous Condenser with 35 H.P. Starting Motor, United Electric Light and Power Company, 187th Street Substation

### Synchronous Condensers

Interesting as an example of special construction is a totally enclosed 1000 kv-a. synchronous condenser set which was designed to secure noiseless operation. The set is installed in a small substation located between two apartment houses in New York City, where any appreciable noise would be objectionable; but by the use of solid end shields and forced ventilation from below the floor line, the set has been entirely successful in meeting the requirements of noiseless operation.

### High Voltage D-C. Railway Electrification

The most conspicuous advance in railway engineering during 1913 has undoubtedly been the rapid development of the high voltage direct current system. Four steam railroads have now adopted 2400 volt direct current in the United States and Canada, one of which is already in operation; namely, the Butte, Anaconda & Pacific Railway. The others are the Michigan United Traction Company, which is contemplating the operation of 92 miles of 2400 volt interurban railway, part of which is now operated by steam. This road will see the first installation of 2400 volts collected from third rail, and also the first use of 2400 volts on multiple unit motor cars. The third road is the Canadian Northern Railway, which has ordered seven 2400 volt locomotives for hauling transcontinental trains into the Montreal terminal. The present electrification includes about nine route miles from the Montreal terminal through the tunnel under Mt. Royal to outlying suburbs. Eight multiple unit motor cars for interurban traffic are also to be equipped for this road. The fourth 2400 volt road is the Canadian Pacific Railway, which is preparing to electrify about 22 miles of mountain grade section between Castlegar and Rossman in western Canada.

Fig. 8. 2400 Volt Locomotive Hauling Ore Train, Butte, Anaconda and Pacific R. R.

All of these electrifications will employ high tension a-c. for distribution to substations, where the energy will be converted to 2400 volts d-c. by two 1200 volt generators connected in series.

Among the railways which have recently adopted high voltage direct current service are the Victorian Railways, Melbourne, Australia, and South Manchurian Railways, Manchuria, China. The Victorian Railways include about 325 miles of track, over which the traffic is now handled by steam trains. The potential to be employed on the trolley in this installation is 1500 volts d-c. The electrical equipment will require 400 motor cars. This electrification is by far the most extensive steam road conversion ever attempted.

It should be noted that the trend towards high voltage direct current railways is not considered to be a new system, but the natural development of the standard 600 volt system which has given satisfaction in practically every city in the country. The requirements for long interurban railways, however, require a higher trolley voltage, and for these systems 1200 and 1500 volts are commonly used. The heavy freight and passenger roads now operated by steam require a still higher voltage on account of the great distances and the heavy power requirements.

The 1200 volt system was adopted by a large majority of the newly built interurban systems in 1913, and by many other roads formerly operated on single-phase or 600 volt direct current. At the close of the year there were thirty railways in the United States and Canada which had standardized on high voltage direct current operation, the additions during 1913 totaling fourteen railways with an aggregate trackage of about 2000 miles.

One of the notable accomplishments of the year is the supplying of 16 new high speed

Fig. 9. Looking West from Flinders Street, Melbourne. Victorian Government Railways

passenger locomotives to the New York Central & Hudson River Railroad. These locomotives anticipate the extension of the system to Albany.

### Storage Battery Locomotive

For some time past the storage battery type of locomotive has been used for internal transportation in commercial and manufacturing plants, and a considerable number were used with notable success in the tunnel construction work of the Catskill aqueduct. But it was not until 1913 that the advantages of this type of locomotive were fully recognized for mine haulage. The first equipment so used consisted of a 4-ton haulage locomotive which was placed in service in the Glendower Colliery of the Philadelphia & Reading Coal & Iron Company of Pottsville, Pa. Its success in coal mine haulage resulted in other installations for similar work, and the size of the locomotives was increased until at the end of the year ten ton units were being manufactured.

### Locomotives

In the trolley type of locomotive there has been no notable increase in size during the past year, and the improvements which have been made are along the lines of perfection of details. The most important features in recent types are the use of commutating poles on all sizes of driving motors and the use of ball bearings for the motor shafts.

The most striking development in locomotives of this general type is found in the 40-ton units which are being constructed for hauling ships through the locks of the Panama Canal. These are solid body 4-wheel units, arranged for control from either end, and are driven by alternating current, three-phase, 220 volt, 25 cycle motors. The hauling speed is two miles per hour, the returning speed five miles per hour, and the draw-bar pull 34,000 pounds. For the hauling operation the locomotives are provided with pinions which run in mesh with a rack located in the center of the haulage track. Four locomotives will be utilized for handling a ship, but only two of these do the actual hauling. These two are located on the lock walls, one on each side of the fore part of the ship, while the remaining two locomotives are similarly placed at some distance to the rear, where they serve to steady the ship during its progress through the lock.

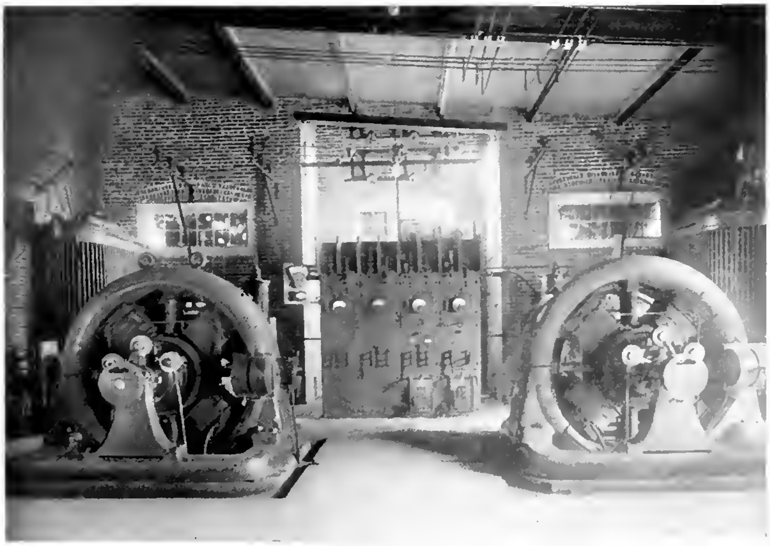

Fig. 10. Pittsburgh and Butler Street Railway, 1200 Volt Substation at Mars. Two 300 Kv-a. 1200 Volt Synchronous Converters, Transformers and Switchboards

The towing cables are wound on a friction drum mounted on the locomotives and independently motor-operated. These drums are so adjusted that sudden excessive strains, which might serve to break or injure the cable, are avoided by an automatic compensation of the drum friction.

Fig. 12. 835 Kv-a. 2300 Volt Sine Wave Generator, and 450 H.P., 440 Volt Motor. United Electric Light and Power Company, New York City

### Motors

For the operation of the Panama locks and concomitant machinery, about 1500 motors are required, and a large percentage of these were completed during the year. They are not notable for size, but the climatic conditions imposed insulation guarantees which involved radical departures from standard detail construction.

### Testing Set

Another relatively small machine may be cited as an instance of special work for the year. It consists of a motor-generator testing set for the United Electric Light & Power Company of New York City, in which a 450 h.p., 440 volt, 750 r.p.m. induction motor drives an 835 kv-a., 2200 volt sine wave generator.

### Switchboards

The development of switchboard apparatus kept pace with the demands imposed by the increasing transmission potentials and capacities which characterized the hydro-electric developments of the year. In the manufacture of switching apparatus the principal improvements consist of changes in design and construction details, which will render the switching equipment more accessible for inspection and repair. This matter is one which has become of considerable importance, due to the increasing size of the switching units.

The 100 amp., 130,000 volt solenoid-operated, triple-pole, single-throw oil switches supplied for outdoor service on the transmission system of the Utah Light & Power Company may be cited as an indication of this tendency. They are among the largest switching units developed during the year, and, except for the heavy casings which are required to insure safety for the moving elements in outdoor service, they are similar in construction and operation to the 150,000 volt units which were provided during the year for indoor use.

Conspicuous among the switchboard installations for the past year are the control boards for the Panama Canal Locks which have operating and indicating features which are unique in switchboard construction. There are three of these boards, all of which have been completed and which will be installed respectively at the locks at Gatun, Miraflores, and Pedro Miguel. These boards are arranged practically as miniatures of the locks themselves, and the various indicating devices are designed to operate in synchronism with the main machinery so that every change in the water level, the movements of the valves, lock gates, guard chains, etc., are simultaneously shown on the control board. The switches on these boards are so interlocked that an improper sequence of operations is impossible.

### Arc Lamps

No fundamental changes in arc lamps were made during 1913, but there was a steady increase in efficiencies obtained and improvements in mechanical detail. In the case of the flame arc lamp there were numerous new installations, the most important being the addition of 6000 lamps to the street lighting system of Chicago, which now has 10,000 flame arc lamps in service. This is the largest single flame arc lamp installation.

Early in the year there was completed at Cincinnati, Ohio, an equipment which indicates the extent to which combined unit series arc rectifiers are being used for supplying arc lighting circuits. There are 118 75-

light, 4-ampere double-tube sets in this installation, serving 6800 luminous arc lamps.

The ornamental luminous arc lamp, which first came into prominence in 1912, became increasingly popular during the past year, and among the numerous cities which utilized them for street illumination are: Boston and Cambridge, Mass., Buffalo and Schenectady, N. Y., Dubuque, Iowa; Toledo, Ohio; Chattanooga, Tenn.; Washington, D. C. and a number of cities in Canada. The largest installation is found in Providence, R. I., where 1500 lamps of this type are used.

**Incandescent Lamps**

Perhaps the most radical improvement in electric lighting during the year 1913 is represented by that type of mazda incandescent lamp, in which the filament is surrounded by a gas instead of a vacuum. In this lamp the previous effective candle-power possible with a given energy consumption has been more than doubled. Lamps of this type which have so far been developed commercially are largely high candle-power units. It cannot be doubted that the general introduction of this lamp will have a far-reaching influence on the problem of effective and economical lighting of streets and large areas, for which its evident advantages render it especially available.

# CHURCH LIGHTING

By A. L. Powell

Edison Lamp Works, Harrison, N. J.

The matter that is the subject of this article is one which is only just beginning to receive the attention it deserves and, of course, there has been but very little material published upon this type of illumination. As the author points out, the lack of activity in improving church lighting is due, without doubt, to the fact that of the total hours comprising the week but a very few of them are spent at church and still fewer there during the evening when artificial illumination is necessary. This condition has been used to a great extent as an excuse to condone the lack of progressiveness along these lines. Poorly lighted architecture and strained vision demand an improvement. The following article gives directions as to how these changes should be made in churches varying from the Gothic to the modern type, furnishes the reasons governing the selection of the units and their location, and presents photographs showing the resulting lighting effects.—Editor.

From a lighting standpoint, our churches and our homes are very closely related, for in this class of illumination the artistic element is far above the consideration of efficiency. When the term *artistic* is used in its broadest sense, eye protection is assured, for nothing can be artistic that is not thoroughly comfortable. This leads to another thought, which involves a very broad statement. If our homes were as poorly lighted as many of our churches, it would soon have a serious effect on our vision; but as we are in the church for only two or three hours each week, the matter is not given sufficient thought.

In a great number of churches very little attention has been paid to the proper protection of the eye; the fixtures used are very rarely in architectural unity with the building and the efficiency of light utilization is entirely neglected. For these reasons, and the fact that there is so much work to be done, church lighting is one of the most interesting problems now confronting the illuminating engineer. He must, however, cooperate with the architect and bear out the latter's ideas with respect to location of units, type of fixture, and relative distribution of light in the various portions of the structure.

### Necessity for Good Illumination

It is true that the Gothic churches of the middle ages had a very low intensity of illumination, but in those days little light was needed, for most of the worshippers were unable to read or else knew the services by heart. These masterpieces of architecture were, however, well lighted to bring out the beauties of the building. By day, light filtered through immense stained glass windows and the beams of colored light, in vivid contrast to the dark woodwork, presented an impressive picture. Very little light was effective in the upper part of the room and the lofty vaulted ceilings seemed still higher. At night, although the light sources—candles or oil lamps—were not far from the floor, and hence often in the line of vision, the brilliancy was so low as to make them relatively unobjectionable. The flickering shadows cast by these units increased the majesty and solemnity of the structure.

Now, however, practically everyone reads, and a light suitable for reading is required. In the church, in contrast to the theater or assembly hall, the lights are turned on the entire time that the congregation is present, and particular attention must be paid to the arrangement of lighting units, concealing the lamps from view or equipping them with diffusing glassware. Frequently it is quite difficult to conceal the light sources on account of the construction of the church, but in any event glare must be avoided.

The light must come from an angle such that the eyebrows shade the eye, else headache and drowsiness will result. It is often wondered why the men are affected with drowsiness so much more than are the ladies at church services. This can be easily explained by remembering that the ladies usually wear their hats in church, the projecting brims of which furnish an eye-shade.

We must make the churches comfortable to everyone, and if care is taken in selecting and locating the lighting fixtures these edifices can be very satisfactorily lighted, for they seldom have brilliant interior finishes to cause glaring reflections, while the ceilings are usually high, thus permitting hanging the lamps above the angle of vision.

### Requirements for a Church Illuminant

The light, first of all, must be easy to maintain, for as a rule the sexton, who has charge of the entire building, is not of a mechanical turn of mind; second, it must not be too large, i.e., too high candle-power, for frequently architectural considerations demand a number of small units; third, its color quality must approach that of daylight, for millinery and gowns of many colors will be lighted; and lastly, it must be easy to control, as quite often it is desired to use the church in the absence of the caretaker.

These facts seem to indicate that the incandescent lamp is the logical illuminant, for it fulfills the demands outlined, and as the mazda lamp is the most efficient of the incandescent sources, the following discussion will be based on the use of this unit.

### Methods to Avoid in Designing a Church Layout

Most chandeliers are bad for two reasons—(a) they have no architectural significance, and (b) they are usually loaded with clusters of bare lamps, sending the light directly into the eyes.

Studded lights around the capitals of the pillars, along the beams and on the corbels are also objectionable, for it is almost impossible to avoid annoying images. While this system sometimes brings out the architectural beauties of the building, one very strong objection is that a lamp will burn out now and then, and, as there are so many sources, the decrease in illumination due to the few outages will not be noticed, and the lamps will not be replaced until a considerable number are out. Each burned out or black lamp will make a break in the continuity and spoil the effect sought. The use of this system will occasionally produce freak effects; for instance, a row of small lamps around the capital of a pillar may give the appearance of an open space and leave the roof and its arches without visible means of support. The efficiency of this system is low and renewal cost high. Decorative lighting around the pulpit and organ is particularly serious, for anyone giving attention to the speaker must look at these bright spots.

### Classes of Churches

Churches may be divided into two main groups: ritualistic and evangelical. In general this applies to both the architecture and the lighting arrangements.

The ritualistic church is usually Gothic in construction, while the evangelical, though a great number are Gothic, modified or pure, has a tendency toward the Renaissance or some more recent period.

In the first class, the amount of reading required is relatively little, as a large percentage of the congregation is familiar with the responses, prayers, etc., while in the latter the form of worship is more varied, and text which is not so familiar is used. It is a well known psychological fact that the most brightly lighted portion of any area attracts the attention, and as the service in the ritualistic church is centered about the altar, this must be put in prominence by a relatively high illumination. In the other group, the minister or speaker symbolically demands the highest intensity of light.

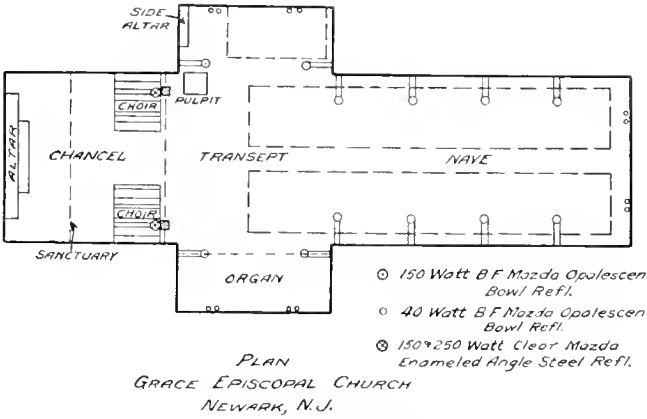

Fig. 1. Floor Plan of a Lighting Layout for a Church Built on Gothic Lines

### Ritualistic Churches

The characteristic arrangement of a Gothic church without side aisles is shown in Fig. 1. The nave contains the pews, while the transept at one side has the organ (in the church under discussion, mounted on a balcony) and at the other side a small altar which is used as a chapel for even-song and the like. The chancel is divided into the choir and the sanctuary.

The nave and transept can usually be lighted by direct overhead units, either concealed from the eyes of the congregation, or on lines conforming with the architecture. The ritualistic churches of the Basilica type present a slightly different problem for illumination, and can be treated by the methods described under evangelical churches.

On account of the elaborate ritual held in the sanctuary, this must be the most brightly lighted portion of the church, and yet no lights should be visible, for the congregation faces in that direction. In the Gothic structure, there is usually an excellent opportunity for locating the units behind the chancel arch. Angle steel or mirrored glass individual, or glass trough reflectors and clear lamps are applicable. The various distributions afforded by the large holophane D'Olier asymmetrical reflectors, simplify the problem remarkably.

The sanctuary should have plenty of light to bring out its decorative value, and yet the altar should not be uniformly bright, for shadow effects are then lost and the elaborately carved portions appear flat and dull, with consequent absence of detail. It is usually better to light the altar from the sides, simulating the daylight values, rather than from the top. Light coming from both sides can be made to avoid deep shadows, without entirely annuling them.

Fig. 2. Night Photograph Showing Lighting Effect in the Church Whose Plan is Given in Fig. 1

The lamps should be so arranged that the choir stalls are well illuminated, and it is often desirable to have the units on several switches, so that various intensities of light can be secured to meet the demands of the different portions of the services.

In a number of churches, the candles have been replaced with imitation candlesticks and all frosted candelabra lamps. In most services, however, the candle has a symbolistic value and it is sometimes a question whether the substitution is in good taste.

Having roughly outlined the principles to be observed in lighting this class of church, an example of their application is of interest. Fig. 2 is a night photograph of the interior of Grace Church (Episcopal), Newark, N. J. The floor plan is shown in Fig. 1.

The building is of the early English period of the Gothic, and being without the side aisles the hammer-beams offer a logical place from which to suspend lighting fixtures. Bowl frosted mazda lamps are used with "Alba" bowl reflectors, hung sixteen feet from the floor by a simple brush brass chain suspension.

The appearance by day is very pleasing, and when lighted the diffusion is excellent and the distribution satisfactory. The lines of the unit are quite severe, bearing out the Gothic idea, and the placement of the lights does not violate the architectural continuity.

An illumination test gave the following results: Average intensity in nave, approximately 1.3 foot-candles with a power consumption of 0.4 watt per square foot. It is true that the illuminating efficiency is not so very high, but it must be remembered that a large part of the light flux is transmitted by the reflector and serves to illuminate, to a low intensity, the rather darkly decorated ceiling which has low reflective power. This slight illumination of the ceiling is an essential point, for no matter how brightly the reading or working plane is illuminated, if the ceiling is dark the room presents a gloomy appearance.

The unit used here would also be applicable in a Gothic structure with side aisles, the lamps being hung from the apex of the arches between the supporting pillars. A proportionally larger lamp should be used on account of the greater area per outlet to be illuminated.

A white leaded glass shade of the "Monolux" type with trefoil decoration could have been used in place of the pressed opalescent bowl with equally good results.

Still another method might have been employed in this particular building, namely, focusing prismatic reflectors and clear mazda lamps on short brackets on the sides of the hammer-beams toward the altar. The illuminating efficiency would have been greater and the lights concealed from the congregation; but the ceiling would have been rather dull and no decorative value added.

A glance at the illustration will show that the sanctuary is the most brightly lighted portion of the church. Behind the chancel arch and on each side at the points "X" are two D'Olier enameled steel angle reflectors, hung pendant; the lower lamps being 150 watt and the upper 250 watt clear mazdas. The choir stalls are well lighted (average intensity 3.0 foot-candles), and the vertical illumination on the rear wall, about three feet to the left of the altar, varied as follows:

3 feet above the floor, 1.1 foot-candles
6 feet above the floor, 1.2 foot-candles
9 feet above the floor, 1.25 foot-candles
12 feet above the floor, 1.3 foot-candles

The horizontal illumination at the base of the altar was 1.2 foot-candles.

### Evangelical Churches

Since the ceilings of many of these buildings are light in color and not as steep as those which have just been discussed, there is much more latitude in the choice of lighting equipment. In the pure Gothic church, indirect systems of illumination are quite out of the question, but in the modified Gothic structure with a smooth ceiling, light in color, or in the Basilica, the scheme is often quite feasible. Again, the non-ritualistic church is often in the form of a large hall, and to light these the problem is quite simple, as the location of units is not fixed by the architecture.

Gorgeous lighting is particularly out of place, for any attempt at pageantry is to be deplored. While the light units should be in architectural conformity, utility of the lighting should be given consideration. By this is meant: 1st. Use every precaution to prevent eye strain, which leads to drowsiness and attendant discomfort. We do not go to church to be annoyed and yet the writer's experience has been that in most churches unprotected lamps are continually in the line of vision, distracting attention and irritating the congregation.

2nd. Ocular comfort having been secured, enough light should be provided in all parts of the room for easy reading. Experience has shown that if there is no annoying glare or bad contrast, an intensity of from 0.75 to 1.5 foot-candles is sufficient for reading at short intervals, as for instance during the singing of a hymn or psalter responses.

Fig. 3 shows a night view of a church which infringes all the rules laid down for good church lighting, and, yet, while this is an extreme case, the installation is characteristic of many others. The first criticism is that there seems to be absolutely no place in partial shadow on which the eye can momentarily rest; a uniform brightness prevails and gives one the impression of entering into a flood of light. This is aggravated by the fact that there is really a greater wattage used than is necessary, namely, 1.1 watts per square foot, with no diffusing enclosing globes. Second, medium size (60 watt, large bulb) clear lamps are used with a very flat milk glass shade, which does not protect the eye in the least. These are used at the groins and bases of the main arches, one at each cross beam, making it almost impossible to avoid being in the line of vision. Third, so-called decorative brackets are used at each side of the pulpit and choir loft, which, although equipped with diffusing shades, are in a direct line with the speaker and anyone sitting slightly to the side of the room. Fourth, a rather hideous chandelier of brass and mirrored glass is suspended from the crossing. This is a relic of the days of kerosene lamps and was converted to electricity when the church was wired. As there are usually a few of its lamps burned out, it detracts from rather than adds to the general appearance of the building.

Contrast this picture with a few of the installations which are in accord with the requirements mentioned above. These may suggest some new ideas which will aid in the advancement of the art of good illumination.

Fig. 4 is a night view of the interior of the Methodist Episcopal Church of North Adams. The building is of modified Gothic construction with light colored wall and ceiling. The mazda monolux semi-indirect fixture is used. This is of spectro-white glass, leaded together, and is of Gothic design. It is forty inches in diameter, with a brass

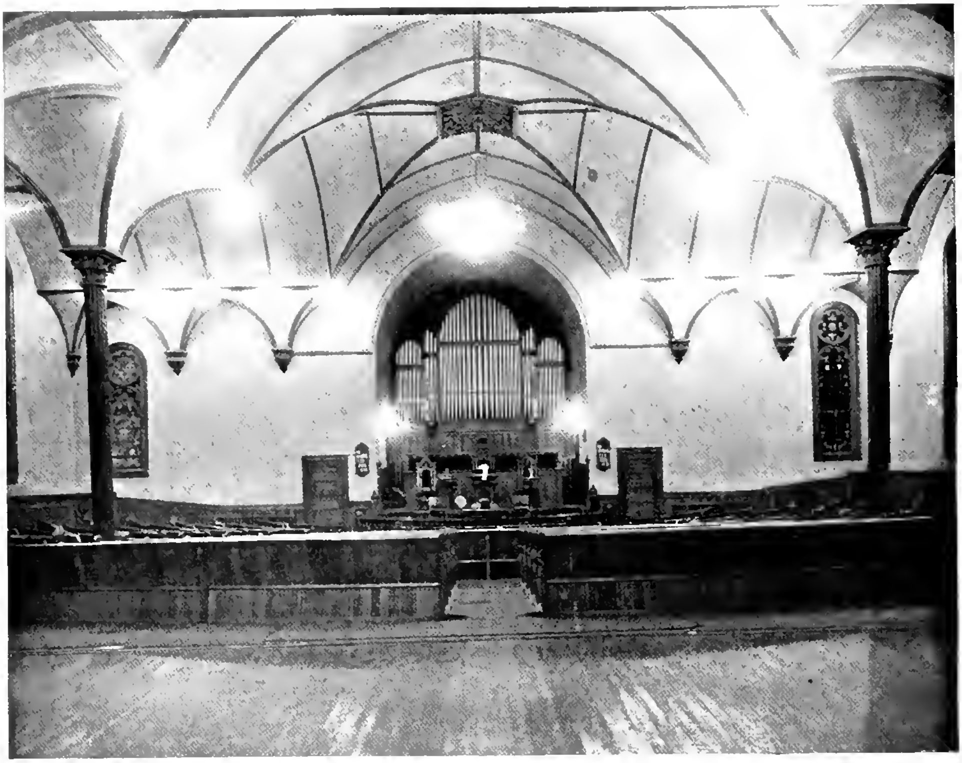

Fig. 3. An Example of Poor Lighting. The Lamps are in the Line of Vision and Produce a Uniform Brilliancy

Fig. 4. A Church of Modified Gothic Design Lighted by Semi-Indirect Units

Fig. 5. A Church Lighted by Totally Indirect Lighting Units

Fig. 6. An Example of Good Lighting in a Church of Colonial Design

chain suspension 15 feet in length which brings the lamps 28 feet above the floor. Five units are used with three 250 and three 150 watt clear mazda lamps in each. Considering the total floor area, the power consumption is 0.8 watt per square foot. An illumination test (corrected for voltage variation) showed the average intensity to be about 1.5 foot-candles with the units clean. The depreciation, due to the collection of dust in seven months' service without cleaning, was 14 per cent.

Fig 5 is an interior night view of the Delaware Avenue M. E. Church, Buffalo, New York. Totally indirect lighting units are used. Silvered one-piece glass reflectors and clear mazda lamps are used, and are concealed within large composition fixtures of Gothic type. The system is effective and the writer found the character of the lighting pleasant, with no discomfort such as is often experienced while at services.

The data on this particular installation is as follows: ceiling height to peak, 45 feet; at sides, 32 feet; auditorium, exclusive of balcony, 39 by 97 feet; three units with five 250 watt mazda each. Two balconies 15 by 97 feet each. Above these, six units with five 100 watt mazda each, and below ten units with one 150 watt mazda each. One watt per square foot, considering large units only. Designing engineer estimated an average intensity of illumination in the center of the church of three foot-candles.

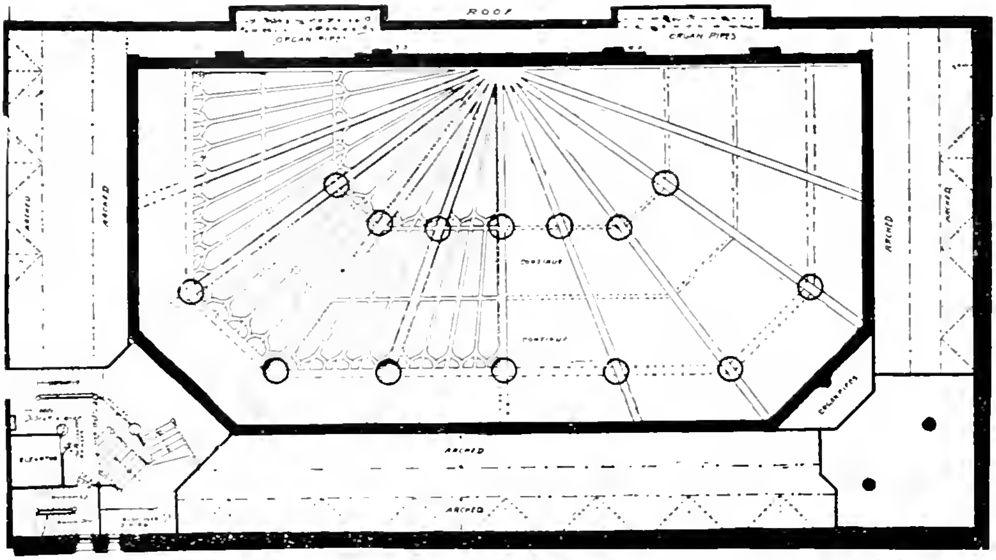

Fig. 7. Floor Plan of the Church Shown in Fig. 9. Location of Lighting Units Marked by Circles

The First Reformed Church, Port Richmond, S. I., N. Y., has recently installed a new lighting system. Fig. 6 shows a night view of the installation. The building is of the Colonial type of architecture, the church proper being a rectangular room with a flat ceiling and a relatively low balcony at the sides and rear. The ceiling decoration was such that there was a rosette at each of the four corners, at the approximate location of the outlets, for a symmetrical five-lamp arrangement. At the center was a ventilating hood, from which was suspended a chandelier. The ceiling is papered white with a bronze decoration. At each of the four rosettes and the center outlet was installed a 500 watt clear mazda lamp with a hemispherically shaped opalescent glass dish suspended by chains, the arrangement thus furnishing semi-indirect illumination. Watts per square foot = 0.9.

From the ceiling below the balcony were suspended bowl shaped opalescent glass reflectors and 60 watt bowl frosted mazda lamps, these being equally spaced. The church was formerly lighted with carbon lamps, and the installation of the combination of semi-indirect and direct lighting with mazda lamps showed a considerable saving of power, at the same time increasing the illumination remarkably and presenting a very attractive appearance as well as avoiding glare. The light is very evenly distributed and shadow is minimized. The old kerosene brackets were retained, although never used, for the congregation feels that these fixtures are in excellent conformity with the architecture, and also that they are of considerable historic interest, being a part of the original equipment.

A church in New York state, now under construction, is planning to install a rather novel, yet logical and efficient system of direct illumination. The auditorium ceiling is shaped somewhat like an open fan, as indicated roughly in Fig. 7, rising from the rear toward the front. From equally spaced points on this roof will be suspended 400 watt mazda lamps, with angle type fixtures, such as shown in Fig. 8. This is of leaded opalescent glass, and gives an asymmetrical distribution of light. Arranged as shown in Fig. 9, most of the light is directed toward the pulpit, and yet through the white diffusing glass there will be sufficient transmitted light for the portion of the balcony under the units, and the rear portion of the main floor. The lines of maximum light flux are such that there will be no glare effect, and the lamps will be well out of the angle of vision. The fixture will have a hinged stem to permit easy re-lamping, for sections of the glass ceiling above the church are to be made removable. To clean and renew lamps it will be a simple matter to reach through the opening with a hook, pull up the unit and turn it about the joint mentioned.

### Other Requirements

Having briefly discussed the general illumination of the auditorium, chancel, etc., it might be well to give a little attention to the other factors which often are to be considered. In many respects the demands of a church are similar to those of a theater, and it is advisable, if the cost is not prohibitive, to install dimmers both on the main and chancel circuits. During the sermon the dimming of the lights produces an effect which is very desirable.

Another similarity is the necessity for pocket outlets. In many churches entertainments are given, some of which require the use of a stereopticon. A pocket should be provided for this purpose with sufficient capacity for the lantern. At other times decorative lighting is called into play, as for instance at Christmas, when a tree might be illuminated by small lamps. A receptacle on the rostrum or stage is very convenient on such occasions. Many pastors use notes, and a floor plug with reading lamp answers the demand for a strong localized light.

### Windows

Most churches have at least one elaborate stained art glass memorial window. By day this is a thing of beauty, but at night, when viewed by reflected rather than transmitted light, it appears as a dark, dull space. In most cases it is not difficult to illuminate the window. Weatherproof type, enamel steel, angle reflectors with clear lamps, or tubular lamps with cylindrical reflectors, have proven of use. In most cases it is necessary to make a point by point illumination calculation to determine the type of unit and its location for the even distribution of light, and this can often be supplemented by some slight experimentation to determine the final result.

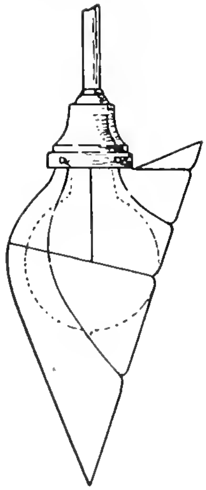

Fig. 8. Holder and Shade for the 400-watt Lamps in the Church Shown in Fig. 9

As a general rule, the window should be evenly illuminated, and it is bad practice to have the position of the light source visible through the glass. Sometimes, however, there is a point in the design which logically demands a higher intensity of light, as, for example, the sky in a landscape scene, and these features must be given attention.

Light of a color approximately daylight must be used, to prevent distortion of the colors of the glass.

### Choir

In the Evangelical church, this occasionally presents a problem. It is often located at the front, and the light from the main auditorium units is both low in intensity and from the wrong direction.

The practice has been to a great extent to place a few brackets on the organ and shield the lamps with some sort of diffusing shade. These units are continually in the vision of the congregation and are extremely annoying. One solution is to place the lamps in recessed boxes in the overhanging portion of the organ, and diffuse the light through glass plates. If the organ structure will not permit of this, recourse has been made to bowl shaped steel reflectors painted on the outside to harmonize with the organ finish, and used on brackets. While these are not especially decorative, a strong light is provided on the books of the choir, and as the reflectors are opaque, the eyes of the audience are protected. Reading lamps on music racks, as in the orchestra pit of a theater, are also applicable and possess many advantages.

A local lamp is, of course, provided for the organist, and in many instances it is advisable to have a low candle-power lamp below the keyboard to illuminate the pedals. These lamps should be readily controlled for use during rehearsals.

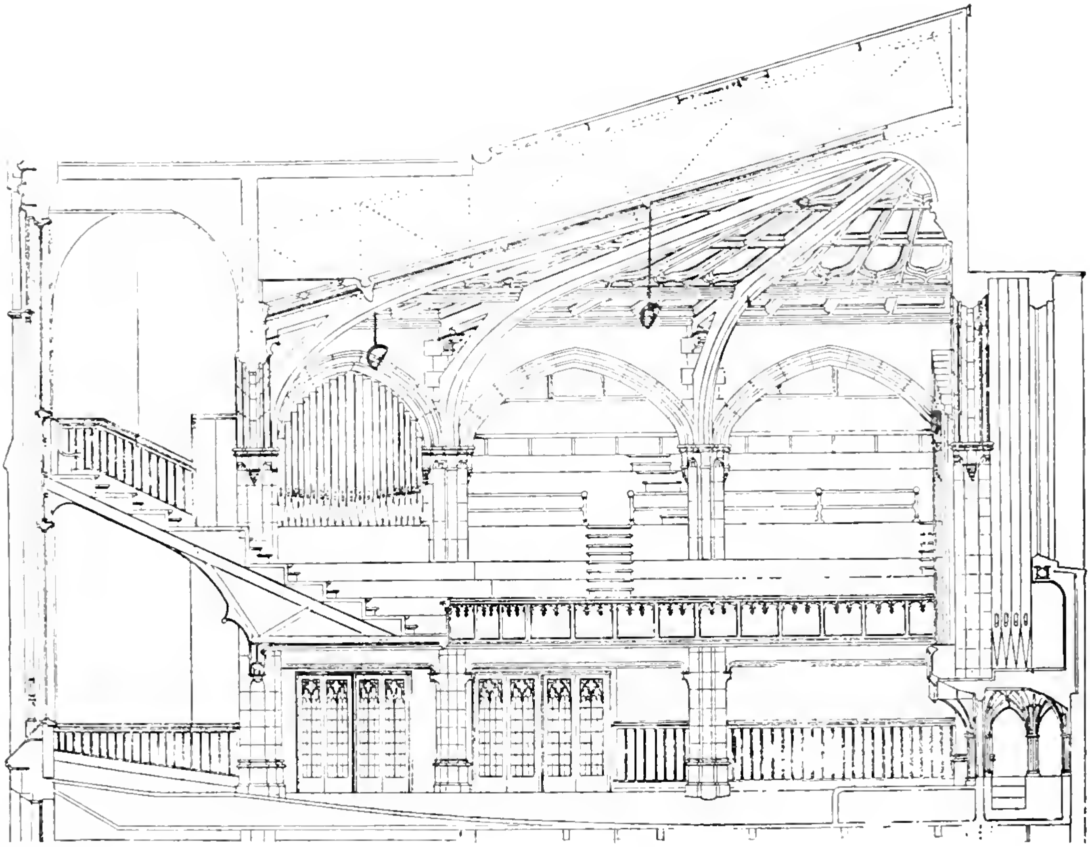

Fig. 9. Sectional Elevation of a Church having an Inclined Floor and Ceiling Suspended Lighting Units

**Exterior**

In conclusion, it might be well to mention some of the recent innovations along this phase of church lighting—illuminated signs, crosses, and bulletin boards are becoming quite widely used. Installations of ornamental street lighting are often made directly about the church, which have the effect of attracting attention, with the result that the chance pedestrian is often induced to attend the service.

# PUBLIC SERVICE AND PUBLIC OPINION

By William McClellan

Consulting Engineer, New York

Mr. McClellan, who was for some years Engineer of the Public Service Commission of New York, has had such broad experience in the relationship between the public service corporation and the public that his views on this important subject are of much value. He points out very frankly the sins of the past, and states that though a Public Service Corporation should have no objection in dealing with the public through a commission, this condition ought to be unnecessary, for frankness and honesty on both sides is the real desideratum. The author looks to a better understanding in the future than there has been in the past. This paper was read by Mr. McClellan before the Eastern New York Section of the N.E.L.A. at their annual meeting at Lake George last fall.—Editor.

Every business needs the support of public opinion. Where there is competition, the need is quickly perceived and the support is striven for. Merchants of commodities know another kind of competition, that of disuse. The overcoming of this type of competition they call "creating a market." This is our kind of competition, and we, the public utilities, need the support of public opinion to overcome it. It has taken most of us a long time to realize this, but, with a few exceptions, we recognize it now. Our obtuseness in the past, however, has left us with a sorry burden, for we do not simply lack the support of public opinion but find that that which does exist is adverse to our welfare. We are in the class which the community does not trust, along with the ice man and the watering milkman, and the short-weight coal man. How can we change our condition and get the support of public opinion?

When I consider our circumstances, I am not at all hopeless. I simply try to recognize a problem and then seek the solution. And the problem must be solved if the business is to become entirely satisfactory. Merely dodging an answer never removes a really vital question.

Distrust and consequent regulation did not arise out of vindictiveness. By forgetting or ignoring the force of public opinion, we brought it all upon ourselves. I prefer to think of the public not as wanting to "get us," not as consciously unfair, but as simply insisting on certain rights which have so frequently been denied it in the past. The public must deal with us, and if it prefers to deal through Commissions, there can be no reasonable objection on our part. Fortunately, there is little objection; and education with patience will remove whatever difficulties loom up great at the time.

How shall we gain the much needed support of public opinion? Naturally, it must be gained in such a way that we may keep it. It is the foundation of our business. Unless we build on it, the results may be very disastrous. There are examples enough now to show what is sure to happen in the way of repudiation, virtual confiscation, and even total loss, if public opinion is continually flaunted. There are also examples to prove that in times of stress public opinion is the inner line of fortification which secures a company against annihilation by political and other opportunists.

We may put this differently. Public opinion will support us only on the basis of an enduring confidence. It must have faith in us, which means we must keep faith with it. This involves a sincerity which is not merely a business policy but a state of being. For many of us, it means a complete change of mental attitude, a decided shift of position. Mere promise or protestation will not do. Every action, every statement, every interview, every contract, every negotiation, not only by the chiefs but also by every employee, must be based on a confidence-begetting sincerity. A simple slip, a single case of double-dealing, too much shrewdness, or one attempt to "put something over," can easily undermine a confidence which has been built up by years of effort and thousands of dollars of expense. How shall we start? What are some of the cardinal points?

In the first place, if we have not already done so, we must clean house. We cannot be sincere if we have anything to hide. We ought to know how much property we have, and what it is worth on some basis. We ought to know the cost of doing business, and whether it is as low as our circumstances will permit. We ought to know the condition of our property, and whether it is being handled so as to be continuously in a state of 100 per cent operating efficiency. We know better than anyone else that rate-making is not a matter of scientific accuracy; but, nevertheless, it should not be a matter of grape-vine growth. We ought, therefore, to make sure that each particular group of rates is internally consistent on some basis. We ought to be able to give some explanation of their peculiar forms. If we are accumulating various funds and accounts, we ought to be able to give an adequate reason for them. We ought to know just what profit we are making, and whether we could square this with public opinion. We have no business to be criminally prosperous.

Such a house-cleaning will be dictated by enlightened self-interest. Public regulation ought not to be able to do more than we can do ourselves. In a few cases, it is demagogic; usually, it is prompted by honest intentions but is accomplished in an ignorant and inexperienced manner. Unfortunately, in the past, it has been too frequently found, on the examination of many companies, to be a mess of greater ignorance and planless operation. Information was not available until it was dug out by the regulators. After many a regulation, in spite of some unpalatable orders perhaps, the company has hardly recognized itself in the light of the information given to it by the investigation. Moreover, there are not many examples of ruin caused by regulation.

Having cleaned house, and with nothing to hide, we ought to be accessible. The prepared-food people have shown us the way. They cleaned house, and then invited the public to come and see how clean it was. Their business is something like ours. Both of us are in a business which the public can do for itself, if it wants to, though in different ways. As a matter of fact, the public went into business with us when it gave us a franchise. We thought it was a free gift, but we were somewhat blind and misled. Again enlightened self-interest would want the public to be acquainted with us. Our officers, therefore, high and low, should be easily accessible. Offices should be arranged so that there is an atmosphere of ease and welcome. The limit of authority of under officials and employees to make adjustments in accordance with well-established principles should be set as wide as possible. Information and explanation should be given with great freedom. The public has the right to understand the basis on which it is paying for service, and it is to our interest that they should. It is easy for a merchant who has one price for a particular article to get the confidence of his patrons. It will be just as easy for us, if we can make our customers understand that we really have one price for each particular kind of service.

Proper relations with, and fair treatment of, our employees are powerful aids to the good-will of the public. It is often forgotten that employees are part of the public, that they live in all sections of our territory, that they are frequently asked questions about this and that feature of our often perplexing methods; and that, therefore, they have much opportunity to mold public opinion. The sincerity of the company can be impressed on them in several ways, not with the idea of buying their loyalty and good-will but of inducing these valuable assets. They should never be asked to do anything which could not be justified publicly if necessary. They should understand that nothing is going on in any part of the company that need be concealed, and that their own work is to be carried on in the same manner. They should be taught the ideals of the company, and that they are expected to have a large part in the realization of these ideals. All questions of hours, remuneration, and other working conditions should be open for discussion at any time between the persons involved. Whatever the outcome, it should be capable of explanation from the standpoint of the business as a whole. They should be dignified by being treated as freely contracting parties with the company, and not as a species of valuable beast of burden which must be controlled and cared for. A certain amount of welfare work is desirable, insofar as it does not replace a proper increase in remuneration. This question of the employee has received too much attention of one kind and not enough of the right kind. They are our outposts in the public and have tremendous force in specific cases and in general influence.

A constructive policy in relation to social and community progress is essential in gaining public opinion. I believe that a public service company is the most important factor in the development of a community. To believe this and act accordingly is to realize the responsibility of our franchises. Have you ever thought about this "free gift" of franchises? The community wanted to give them to us and hoped that we would take them. They thought that we were going to make a lot of money through them; but that was not the reason that we got them. The community also expected to benefit greatly from the gift. Therefore, in proportion as it benefits, so will we gain their good opinion. This means adequate and satisfactory service, and extension of lines promptly so as to aid the growth of the community in area and development. Under such a policy, I believe rates will adjust themselves on account of the enlightened self-interest of the company. High rates and largest profits seldom go together.

This constructive policy will show itself in some broader phases of community life. Legislation of various kinds will not be opposed unless it is inherently wrong. When opposition is necessary, it will be done publicly; and in the hope of enlisting the intelligent sympathy of the community. The company, regarding itself as a good citizen, will be in active sympathy with all uplift movements, such as hospitals, and safety plans for the public and its employees. It will contribute from its funds, but especially by its knowledge and intelligent effort, so far as sound business and social policy will permit. The presentation of a pulmotor to a hospital, or of expenses to an injured employee are good actions in themselves. How they will affect public opinion depends upon whether or not the actions flow from a consistent business policy.

In our own state, perhaps the most shining example of a lack of constructive policy is shown by our treatment of the conservation of water power. Public opinion regards the water powers of the state as great and valuable resources. Attempts are made to develop these resources and the public service companies of the state are found in opposition. There is some indication that this opposition is organized in the sense that it proceeds from national and state committees representing the companies. In the resentment which is called forth, it is not perceived by public opinion that the opposition is almost entirely against the method and not against the principle. This must be charged, however, to the lack of constructive effort on our part. Surely as business men, we know that the easiest method to beat a bad scheme is to provide a good one. In times past, when public opinion was quite inattentive to such matters, other methods were available, but not now. Opposition to such projects as these has a far reaching influence in our local business relations. Why should not the public service men of this state stand out in the broad light and acknowledge that the state has valuable water powers which could be developed? Why should these men not offer their wide experience in devising proper plans by which the developments could be made so as to give the state as a whole the benefits and profits to which it is justly entitled, and, at the same time, protect investments of all kinds already made? Why should not a bill be offered which the public service men could work for openly, in the light of day? I know that there would be much misunderstanding by the public. They have never been accustomed to seeing us play such a part. But, if it is right, we ought to have the courage to attempt it. A dozen public service men, known in as many communities as men of probity, ability and experience, standing as directors of a campaign of education, going directly to the public of their own communities, hiding nothing, using no subterfuges, might have a long pull to the finish, but would discount failure at the start. And the collateral benefits from such a campaign would be very great. Public opinion is now active and thinking about our affairs. We must reckon with it; or, finally, lose out.

Advertising, I have put last where I think it should be. After we have done everything else which is necessary, we can talk about it. I believe in advertising and plenty of it. This is not the place to discuss methods, where there are so many. As a matter of fact, everything that we do should be advertising, that is, turning the people to us. Advertising which is mere protestation or exaggerated promise is ruinous, in the end; and is likely to result in nothing but a cynical smile. Simplicity, truthfulness, and sincerity count here as elsewhere.

After all, does not our whole argument mean that we must take the public into a real partnership? In a peculiar sense, they have been contributors to our enterprise. A franchise is a necessity in order to have a public service business and yet there has been little disposition to allow a company to value it. May this not be regarded as the equity of the public in the business? Are not all the attempts made by the public to regulate our business to be regarded as an attempt to assert this partnership? May it not be that its very obstinacy arises from our past stubbornness in regarding our business as entirely private, to be operated as we saw fit. The total disregard by the public, in the past, of its interest in our business is as much responsible for the present condition as our misunderstanding of the relations which should exist. While the change is taking place, there is great danger that the dominance of capital will be exchanged for the dominance of the public. Both are bad, because they are both naturally self-seeking.

The hope of a proper balance is in the operating man, from President to common laborer. His part is to teach each of his partners to respect the rights of the other. The "Company" can no longer be synonymous with "Capital" but must mean the three-strand partnership of capital, labor and the public.

# THE DESIGN OF AN OSCILLATION TRANSFORMER

By S. Thomson

Consulting Engineering Department, General Electric Company

The following is a direct quotation from the conclusion of this article: "Oscillation transformers have recently come into use for testing insulators, as they offer a cheap means of obtaining a very high voltage. Experience shows that the high frequency discharge can find defects in insulators which have passed the standard 60 cycle tests." Thus we are acquainted with the fact that there is a new commercial field for the oscillation transformer in which it bids fair to supplant the apparatus used at present. The article furnishes a description of the various parts of such a transformer, the explanation of the electrical factors entering into its design, information relating to the materials to be used, and a liberal amount of data for its calculation.—Editor.

An oscillation transformer, sometimes called a Tesla coil, is an apparatus for obtaining very high electrical potentials by means of the well known phenomena of resonance. There are two windings which are coupled inductively, as in the ordinary transformer, but the step-up in voltage is not obtained by adjusting the ratio of primary to secondary turns, but by the free oscillation of the secondary under the influence of high frequency impulses inductively communicated from the primary, which build up in this manner a standing wave of high potential. The frequency supplied by the primary winding is adjusted to correspond to the natural period of free oscillation of the secondary. By such means very high potentials are obtained at the terminals of the secondary or high tension coil. As will be readily seen, these have nothing to do with the ratio of turns. An air core is always used, as at the high frequencies employed the eddy current losses and screening effect would be excessive, even in a finely laminated iron core.

Fig. 1 gives the essential parts of an oscillation transformer circuit. $A$ is a coil of fine wire wound on an insulating cylinder or frame work, with its ends brought out to spark-gap terminals; $B$ a coil of a few turns of heavy wire wound, on a wooden frame, concentrically with coil $A$, which constitutes with $A$ the oscillation transformer proper; $C$ a condenser of proper voltage and capacity; $D$ a ball gap; $E$ an iron core transformer, preferably of high reactance, supplying a voltage of 10,000 to 20,000; $F$ an air or open iron cored reactance; and $G$ the alternating current supply.

### I. The Oscillating Circuit

In designing an oscillation transformer the first thing which we must consider is the oscillating circuit $BCD$. Here originates the high frequency discharge which operates the coil. Let us assume that we are going to build an apparatus to supply a high potential discharge at a certain frequency. We must then arrange to produce this frequency in the circuit $BCD$ by the discharge of condenser $C$ through the coil $B$ and the ball gap $D$. The frequency of discharge of such a circuit, when it is of negligible resistance, is determined by the product of its inductance and capacity according to the well known formula:

$$f = \frac{1}{2\pi\sqrt{LC}}$$

The inductance and resistance of the circuit, including that of coil $B$, must be comparatively low if we wish to obtain the best results and have it free from arcing in the ball gap, which occurs when the circuit has too much inductance. Coil $B$ is therefore usually made of a few turns (5 to 10) of heavy wire, and the remainder of the circuit also of heavy wire and as short as possible. For a large apparatus it is advisable to use an air blast on the ball gap, or some form of rotary gap to prevent overheating by the discharge, and a dynamic arc instead of the desired interrupted discharge. Thus, as we are confined within rather narrow limits as to the amount of inductance in the circuit, we must obtain the frequency desired by regulating the capacity of the condenser.

In order to obtain maximum power with a given frequency the condenser should be operated at as high a voltage as possible. In all cases we must have enough power to overcome the losses in the coil $A$ when operating at a voltage sufficient to break down the maximum spark gap which we wish to use.

To summarize: high power coupled with high frequency means the use of a high voltage on our condenser $C$. If, however, we are not particular about the frequency, but wish simply high power, the condenser should be of the largest possible capacity, and be operated at 10,000 to 20,000 volts. Higher voltages make the condenser undesirably bulky, and with voltages below 10,000 the ball gap must be set so small that it does not get good ventilation and has a tendency to overheat and arc. However, as low a voltage as 5000 can be used with small coils.

### II. The High Tension Coil

Since the frequency has already been determined by the constants of our low tension circuit, we must make the high tension coil of such dimensions that its natural period of free oscillation will correspond to this impressed frequency. Here we are dealing largely with distributed inductance and capacity, and therefore the frequency of such a coil is:

$$\frac{1}{4\sqrt{LC}}$$

The capacity of the terminals themselves must, of course, be taken into account. It is a difficult matter to calculate beforehand just what the natural period of such a coil will be, as it depends not only upon the constants of the coil itself, but upon the degree of coupling with the low tension coil and the inductance of this coil. The best plan, therefore, is either to wind a coil which previous data shows to be a little too large and then adjust it by testing and removing the few turns that are unnecessary, or to provide an adjustable condenser in the low tension circuit.

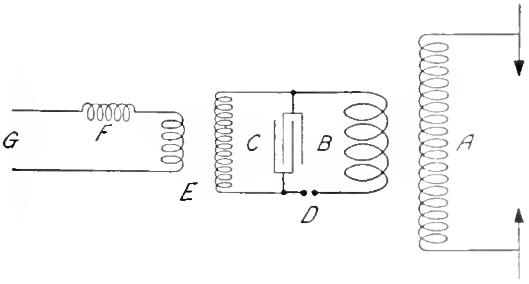

**Fig. 1. Diagram of Connections of Oscillation Transformer**

The greatest problem in winding the high tension coil is that of insulation, especially in the larger coils. Hard rubber has proved to be the best material of which to build the frame work which supports the coil. The following table gives the creepage distance between small wires over the surface of several materials immersed in number six oil as compared with the corresponding jump in air between needle points of a 150,000 cycle discharge.

| | Creepage under oil | Spark in air |
|---|---|---|
| Oiled pressboard | 6 in. | 15½ in. |
| Porcelain | 6 in. | 17½ in. |
| Hard rubber | 6 in. | 21 in. |

Paraffined wood, stressed with the grain under oil, in time breaks down below the surface, and there are formed small charred paths under stresses with as low as 8 inches air needle gap for a 6 inch creepage path. The coil should therefore be wound in a single layer and the supporting frame work built of hard rubber, allowing a creepage distance between ends under oil equal to the desired spark between needle points in air. This provides a factor of safety of more than three which is ample.

The next thing that interests us is the spacing between the high tension and the low tension coils. It has been found by experience that the diameter of the high tension coil should be from one-half to one-third of its length, although this is simply an arbitrary rule. The low tension coil is usually placed outside of the high tension coil, concentric and co-axial with it. This arrangement combines in one the insulation between primary and secondary, and the insulation to ground. The spacing between high and low tension coils depends upon the dielectric strength of oil, and on whether we wish to connect the coils together at one end, in the middle or keep them entirely isolated.

In the case of end connection, the low tension coil is built in the conical form, the total stress coming across the insulation at the opposite end. With the middle connection, or the isolated condition (which is the most common), the low tension coil takes a cylindrical form, and the voltage stress is distributed one-half at each end. The choice between these connections depends upon the way the coil is to be used and the available space, etc.

Having chosen the connection to be used, we must know the dielectric strength of transil oil against a high frequency discharge.

A number of tests have shown that the relative jumping distances, between needle points in air and in number six oil of a high frequency discharge, is 25 or 30 to one. Choosing a factor of safety of somewhat more than two,* a good rule to follow is to allow an inch spacing in oil for every foot of spark in air. This may be all at one end or distributed between the ends as described above, according to the connection used.†

The copper wire used in the high tension coil should be from 0.016 to 0.032 inch in diameter. This is of low enough resistance not to damp unduly the oscillating discharge, and yet is small enough so that we can wind 15 to 30 turns to the inch, according to the insulation used. It may even be used bare and wound in a spiral groove turned in the surface of the supporting frame, which is, perhaps, the best method; or it may be heavily insulated and wound as closely as possible. The latter method is the easiest to carry out, but does not give quite so good a coil, owing to the fact that the insulation losses are somewhat greater in the fibrous insulation than in clear oil. A double cotton covering is not sufficient, except for coils of the smallest size, as the stresses between adjacent turns may reach thousands of volts in the larger coils.

Triple cotton covered enameled wire has been used very successfully on coils giving sparks up to 24 inches. For larger coils we may use sextuple or octuple cotton covered wire. An enamel coating is approximately equal to two cotton coverings. The cotton covering becomes saturated with oil and provides essentially an oil insulation. It is advisable to separate the 15 or 20 turns at each end of the coil by two or three times the normal spacing, as abnormal stresses are liable to occur here.

### III. Tank and Terminals

The two co-axial coils of the oscillation transformer should be immersed in an oil-tight wooden tank under a sufficient depth of well dried oil. The form of the tank will depend upon the size and placing of the coils (vertical or horizontal). A metal or metal lined tank introduces a much more difficult insulation problem but is much more easily made oil tight.

The terminals of the high tension coil are usually brought out beyond the ends of the low tension coil by means of flexible wires through suitable porcelain, hard rubber, or oil filled bushings in the wooden tank cover. If we use the arrangement with one terminal grounded, one bushing only is required, and a vertical position of the coils is probably the best. This arrangement is most suitable for very large coils.

All the metal parts of the terminals which are exposed to the air should be made with surfaces having as large a radius of curvature as possible to keep the losses by corona at a minimum.

### IV. The Transformer

The transformer which is used to supply the low tension circuit should be made preferably of the open core construction for two reasons:

1st. The high magnetizing current of such a transformer would supply the heavy leading current taken by the condenser, thus reducing the current drawn from the power source and greatly improving the power-factor.

2nd. The high reactance limits the short circuit current when the ball gap discharges. If we wish to use an ordinary low reactance transformer to charge the condenser, an open core or air cored reactance coil must be inserted in series with the low tension side of the transformer. The reactance should be adjusted to give maximum power-factor, in order to take minimum current from the power source when the coil is operating.

Experience with wireless apparatus has shown that the best frequency of alternating current with which to operate a high frequency oscillating circuit is in the vicinity of 500 cycles per second. With this we get 1000 discharges across the ball gap in a second, which is about as high as it can be run without excessive heating and arcing. The larger the number of condenser discharges in a given time, the more powerful is the high tension discharge. We see, therefore, that it is advisable to use the highest available frequency up to 500 cycles, although 60 cycles will be very satisfactory for most uses.

The high tension winding of the supply transformer should always be grounded at one end to fix its potential with respect to ground, and thus eliminate breakdowns to ground caused by the grounding of one terminal of the high tension coil of the oscillation transformer, and a resulting breakdown from the other terminal to the low tension coil, and thence to ground.

---

* This is purposely made low to act as a relief gap.

† Full spacing at both ends should be allowed when the coils are isolated.

### General

Below are given the characteristics of a number of coils which have been built.

| | No. 1 | No. 2 | No. 3 |
|---|---|---|---|
| Spark length | 14 in. | 24 in. | 48 in. |
| Frequency (approx.) | 200,000 cycles | 150,000 cycles | 100,000 cycles |
| Condenser volts | 13,000 | 13,000 | 20,000 |
| Supply volts | 110 | 110 | 220 |
| Supply amp. | 18 | 70 | 100 |
| Supply kw. | ¾ | 3 | 12 |

Oscillation transformers have recently come into use for testing insulators, as they offer a cheap means of obtaining a very high voltage. Experience shows that the high frequency discharge can find defects in insulators which have passed the standard 60 cycle tests.

When a high potential test of an insulator is made with this apparatus, the natural period of oscillation of the high tension coil is lowered by introducing at its terminals an extra capacity—the insulator. This, therefore, throws it somewhat out of resonance with the impressed frequency, the more so as the size or number of insulators in parallel is increased. In such a case means should be provided for increasing the capacity of the operating condenser in order to bring the circuits back into resonance. With most coils, however, one or two insulators can be tested in parallel without any condenser adjustment.

A means has been found of regulating the voltage by adjusting the primary spark gap.

## INTERNATIONAL ELECTRICAL CONGRESS

San Francisco, 1915

The International *Electrical* Congress is to be held at San Francisco, September 13 to 18, 1915, under the auspices of the American Institute of Electrical Engineers by authority of the International Electrotechnical Commission, and during the Panama-Pacific International Exposition. Dr. C. P. Steinmetz has accepted the Honorary Presidency of the Congress. The deliberations of the Congress will be divided among twelve sections which will deal exclusively with electricity and electrical practice. There will probably be about 250 papers. The first membership invitations will be issued in February or March, 1914.

Attention is drawn to the distinction between this Electrical Congress and the International *Engineering* Congress which will be held at San Francisco during the week immediately following the electrical congress. The engineering congress is supported by the Societies of Civil, Mechanical and Marine Engineers and by the Institutes of Mining and Electrical Engineers, as well as by prominent Pacific Coast engineers who are actively engaged in organizing it. This Congress will deal with engineering in a general sense, electrical engineering subjects being limited to one of the eleven sections and including about twelve papers treating more particularly applications of electricity in engineering work.

The meeting of the International Electrotechnical Commission will be held during the week preceding that of Electrical Congress.

# FROM THE CONSULTING ENGINEERING DEPARTMENT OF THE GENERAL ELECTRIC COMPANY

## PERMEABILITY OF LIQUID AIR

It frequently happens that various schemes are proposed to utilize the magnetic properties of liquid air, including its use as the magnetic circuit of a transformer core. These suggestions doubtless grow out of the statement that liquid oxygen $O_2$ is strongly magnetic. This statement is perfectly true but is correct from the standpoint of the physicist, rather than that of the engineer, as liquid $O_2$ is strongly paramagnetic only as opposite to diamagnetic.

The permeability of liquid $O_2$ is about 1.004, or 0.4 per cent more magnetic than air and is, therefore, not to be considered as a substitute for the ferromagnetic metals. There is no reason to suppose that the magnetic values of liquid $O_2$ and $O_2$ gas are the same for equal weights, as between the two there exists wide differences of temperatures and physical conditions in general.

J.D.B.

## IRON CONDUCTORS AS A PROTECTION AGAINST HIGH FREQUENCY DISTURBANCES

Although skin effect and other high frequency phenomena in iron conductors is pretty thoroughly understood, there seems to be a general misconception as to the value of iron in affording protection to apparatus from line disturbances. A partial acquaintance with the phenomena that takes place in iron conductors at high frequencies leads to the false conclusion that such a conductor affords considerable protection from line disturbances. After a careful perusal of all the available data, the question arises as to whether it affords appreciable protection or not.

A discussion of the relative merits of an ordinary copper choke coil and one made of soft iron conductor will perhaps throw some light on the subject. It is assumed that the coil is to be placed in the high tension side of a transmission line, in series with the station apparatus, for the purpose of choking back high frequency disturbances and forcing them through the protective apparatus.

There is a certain critical frequency between $10^4$ and $10^5$ cycles which is destructive to station apparatus, and this article deals only with frequencies between these limits. Chapters VI, VII, VIII and IX of Dr. Steinmetz's "Transient Phenomena" cover the entire field thoroughly in a theoretical way, and if actual research data is desired, a reference to Mr. E. F. W. Alexanderson's "Magnetic Properties of Iron at Frequencies up to 200,000" A.I.E.E., 1911, Part III, page 2433, would be of benefit.

It is well known that a copper choke coil does not give a sufficient degree of protection to station apparatus. Although it may choke back the greater part of the high frequency energy, enough seeps through before the protective apparatus is brought into play to start up destructive oscillations. To prevent this seeping an iron coil must have an appreciable increase in effective resistance and internal reactance at high frequencies over one of copper, and the high frequency hysteresis losses should be much more than at the commercial frequencies. Even at low frequencies there is considerable skin effect in iron conductors; that is, the current flows only in the outer shell of the conductor and thus only a small volume of a solid conductor would have hysteresis loss. It must be remembered that in most cases the high frequency current is superimposed upon the commercial current in the form of a path in the outermost shell of the conductor, its depth of penetration being much less than that of the lower frequency. There would thus be a very small volume of iron to produce hysteresis loss, and for this reason the loss is not so pronounced as would be supposed. This is shown in Mr. Alexanderson's article. There is, however, a considerable increase in effective resistance and internal reactance at high frequency. These factors vary as the square root of the frequency, but the coil reactance varies directly as the frequency, and thus at high frequencies is much greater than the internal resistance and reactance.

It seems then, that an ordinary copper coil with an increased number of turns would be more effective in holding back disturbances than would one made of iron.

J.D.B.

## QUESTION AND ANSWER SECTION

The Q. and A. Section has been started with the sole object of increasing the practical usefulness of the REVIEW; and in order that it may be made of real value, we invite correspondence from any of our readers who are looking for information on any technical matter in the field covered by this magazine and which they think we can furnish.

Where possible the answers to such inquiries will be the work of this office; where desirable we shall obtain our authority from that engineering or commercial person in the General Electric Company's organization best fitted for handling the particular subject. We hope our readers will not hesitate to avail themselves of the expert engineering opinion which should be made available through this section of the REVIEW. Information on matters of general importance and interest will be published here; questions of interest solely to the querist will be handled by mail.

Sketches should accompany questions in all cases where this is necessary to give us complete and accurate information on the point at issue. Scale drafts will be made up here from correspondent's rough pencil sketches. Questions must be accompanied with the name and address of the sender, although these will not necessarily be for publication, and should be addressed to the Editor, Q. and A. Section, GENERAL ELECTRIC REVIEW, Schenectady, N. Y.

### THREE-PHASE CONNECTIONS

(78) How many correct but different combinations are there of connecting the leads of a three-phase generator to the bus?

Six. Assuming the generator to be represented by the symbol (a), the bus by (b), and their leads by the numbers 1, 2, and 3, the various ways follow:

First:
1 on (a) to 1 on (b)
2 on (a) to 2 on (b)
3 on (a) to 3 on (b)

Second:
1 on (a) to 2 on (b)
2 on (a) to 3 on (b)
3 on (a) to 1 on (b)

Third:
1 on (a) to 3 on (b)
2 on (a) to 1 on (b)
3 on (a) to 2 on (b)

Fourth:
1 on (a) to 3 on (b)
2 on (a) to 2 on (b)
3 on (a) to 1 on (b)

Fifth:
1 on (a) to 2 on (b)
2 on (a) to 1 on (b)
3 on (a) to 3 on (b)

Sixth:
1 on (a) to 1 on (b)
2 on (a) to 3 on (b)
3 on (a) to 2 on (b)

The phase rotation in the first three methods is opposite to that in the last three.

R.E.D.

### LIGHTNING ARRESTER CHARGING

(79) A certain aluminum lightning-arrester equipment for a 17,000-volt ungrounded system has the usual four tank connections, with the exception that there is no transfer device for charging, and the ground tank never becomes a line tank. The arresters are charged by merely inserting a conductor between each horn gap, taken one at a time. Will this method of charging keep the arresters in good operating condition?

This method of charging is absolutely wrong and will probably result in damage before long. It has been tried, but has failed to keep the films in good condition. (Closing one gap at a time when the films are in poor condition and when there is any disturbance on the system is somewhat like an arcing ground.) The method is to be condemned from every standpoint.

E.E.F.C.

### STEEL MILL, RUNNING LOAD

(80) What is considered good practice when figuring motor loads in steel mills? Assume 1000 h.p. of motors (name-plate rating), varying in size from 10 to 75 h.p., located around a mill on roll tables, cranes, shears, etc. They in no case carry full horse-power and are not all working at the same time. What would be an average horse-power load to use in figuring generator or transformer capacity?

An average horse-power load for figuring the generator or transformer capacity for motors operating roll tables, cranes, shears, etc., may be obtained by taking from 25 to 33 per cent of the total horse-power of the motors.

G.M.B.

### PROPER SIZE OF CABLE

(81) What would be the proper size of cable to carry current to the following?

1600 h.p. a-c. 2200-volt motor (roll-drive), 80 per cent p-f., 500 ft. distant from generator.

1200 h.p. under the same conditions.

200 h.p., 70 ft. distant; otherwise under the same conditions.

The generator voltage is in all cases 2300 volts.

1600 h.p., 2200 volts, 80 per cent p-f., 500 feet from 2300-volt generator,—750,000 circular mils.

1200 h.p., under the same conditions,—400,000 circular mils.

200 h.p., 70 ft., otherwise under the same conditions,—No. 4 B.&S.

In each of the above cases the cables are capable of carrying 50 per cent overload for 2 hours.

G.M.B.

### STORAGE BATTERY AUXILIARY *versus* OVERLOADED GENERATOR

(82) Is it considered good practice to use storage batteries to aid direct-current generators in carrying a peak load, or, if the excess load is not too great, to allow the generators to supply the peak load alone?

The only statement that can be made in answer to this question is the general one that if the overloads are not too great and are not of too long duration the generator should be allowed to supply the demand. It would be necessary to know, however, the magnitude and time-characteristics of the load and the size of the generators before the values of the limits "too great" and "too long" can be set.

G.M.B.

### EFFICIENCY OF CARBON AND TUNGSTEN LAMPS

**(83) What is the actual measured efficiency in watts per horizontal candle-power of 16 and 32 candle-power carbon and tungsten filament lamps of 110 and 220 volts?**

On account of the present rating, neither the carbon filament nor the tungsten filament lamps give exactly 16 or 32 candle-power, but those which give the nearest to these figures have been selected and following is a table showing the results of measurements made on these lamps.

| | Hor. C-P. | Watts | W.P.C. | Rated Life |
|---|---|---|---|---|
| *Carbon Filament* | | | | |
| 110 volts.... | 16.83 | 50 | 2.97 | 700 |
| | 33.66 | 100 | 2.97 | 600 |
| 220 volts.... | 16.26 | 60 | 3.69 | 750 |
| | 32.52 | 120 | 3.69 | 750 |
| *Tungsten Filament* | | | | |
| 110 volts.... | 16.0 | 20 | 1.25 | 1000 |
| | 34.2 | 40 | 1.17 | 1000 |
| 220 volts.... | 18.0 | 25 | 1.40 | 1000 |
| | 30.5 | 40 | 1.31 | 1000 |

### IRON CORE *versus* AIR CORE CHOKE COILS

**(84) Some discussion recently brought out the fact that low-voltage coils such as are used in telephone work are provided with an iron core. Choke coils, however, on higher voltages are not provided with an iron core, probably due to the transformer action if this were done.**

**A certain installation has a choke coil in a protection panel operating in series with a lightning arrester. This coil has 50 turns of No. 5 wire and is caring for approximately 10 h.p. on 500 volts direct current. Considerable trouble has been experienced, however, due to line surging when a lightning storm is in the vicinity.**

**I would be pleased to have you explain in detail why a choke coil with an iron core would not be allowable on 500 volts direct current, and why the same is permissible on a lower voltage, and also give us some remedy for preventing this surging.**

Iron cores are not used in lightning choke coils because the thickness of lamination of the ordinary iron is great enough to permit serious eddy currents to flow in the iron. As a result of the eddy currents the use of iron is worse than none at all, due to the fact that a counter-magnetomotive force is set up. Placing iron in the lightning choke coil is almost equivalent to diminishing the area of the cross-section of the choke coil by the area of the cross-section of the iron used. If very thin laminated iron is used the high frequency eddy currents can be diminished and the iron becomes useful. It is difficult, however, to insulate the turns from the iron and the lightning is liable to jump from the end turn to the iron and back again to the coil, thus shunting out the turns of the choke coil.

Iron is not used in a current-limiting reactance for the simple reason that the iron saturates on short-circuit current and thus becomes ineffective at the time when it is most needed to limit the current. On the other hand, when the permeability is least needed, viz., at normal or low loads, it is high and produces poor regulation on the line.

Choke coils in telephone circuits are used in different ways, and the writer cannot decide what is the function of the choke coil, as mentioned in this question. Where continuous induction is to be guarded against, drainage coils are used, in which the inductance from line to line is very high but the inductance from line to ground is very low.

Complete protection for 500-volt direct-current circuits can be obtained by using d-c. aluminum arresters. These arresters will shunt out high-frequency surges of lightning and will also take the electromagnetic kick which comes from opening an accidental short-circuit.

E.E.F.C.

### A-C. INSTALLATIONS WITH STORAGE BATTERIES

**(85) Will you please publish some information regarding the following use of storage batteries in connection with alternating-current installations? The purpose of the batteries is to deliver at peak-load hours the energy which they have stored up during the night and at other periods of light load.**

We do not believe that there are many such installations. Storage batteries are, of course, widely used in hotel plants and other isolated plants for the purposes mentioned, but such installations are nearly all direct-current. The storage batteries as used by central stations in modern practice are not generally discharged at peak load, but are kept floating on the line almost fully charged as a reserve, being discharged only in case of an emergency. This practice obtains on account of the fact that the efficiency of the storage battery is only 60 to 65 per cent, i.e., output divided by input.

When used in connection with alternating-current installations and charged and discharged by a motor-generator, the losses in the motor-generator are, say, 12 to 15 per cent during charging and 12 to 15 per cent during discharging, i.e., a total of 25 to 30 per cent is involved in addition to the loss in the storage battery itself, so that such a system is not generally employed in large plants. There are some cases, viz., steel mill drives, mine hoists, etc., where extremely high peak loads of very short duration are frequently encountered. A few such installations employ alternating current: one at the U.S. steel mills at Gary, where a split-pole rotary converter is used to transform the alternating current to direct current and vice versa. Another installation is at the Kolar gold fields, Mysore, India, where 25-cycle alternating current from a transmission line is fed through small motor-generators into a storage battery which supplies larger motor-generators, that in turn generate 50-cycle alternating current. In this form the power is transmitted to a number of electrically operated mine hoists. This plant is regulated so that the storage batteries take a constant load for the 24 hours in spite of the very widely varying load on the hoisting circuit.

The Boston Edison Company has recently made an installation of storage batteries in connection with alternating-current lighting distribution, but here the storage battery is used largely as a reserve and it is not intended to be discharged very much at peak loads.

# GENERAL ELECTRIC REVIEW

## THE PATHS OF PROGRESS

A history of artificial illumination would make a most interesting study. If such a history were written it would reveal the fact that the industry of lighting, and especially that of electric lighting, like most of our modern industries, has developed more during the last two or three decades than during an equal number of centuries previous to this period. During the last century, and especially during the latter part, our modes of living have changed enormously, and the changes have been brought about in the main by the work of the scientist and the engineer. We believe that amid all the advances and development made in this most progressive period of man's history, no industry has been so progressive as the electric lighting industry It was born scarcely thirty years ago, and has grown to such proportions that it is hard for the human mind to comprehend the vastness of the industry as it stands to-day. We might take our readers through a bewildering mass of figures to show this growth. The number of incandescent lamps in use, the number made every day, the number of towns and the number of people using electric light are all figures that could be compiled with a greater or less degree of accuracy by the patient statistician; but such figures would in reality mean very little to the average mind. Some would be so enormous that we might either multiply or divide them by ten or even a hundred, and the difference would mean little to most of us. If we want a real comparison in this matter, we must compare "what was" with "what is." A careful comparison of this sort is hard to make, as written histories mostly deal with kings and queens, the rise and fall of governments, of battles, of conquests and defeats, and most, at least, make little mention of the conquests made by the gentler men of science; but Macauley in his "History of England" does devote a most interesting chapter to "The state of England in 1685," in which the following paragraph concerning the lighting of London occurs.

"It ought to be noticed that, in the last year of the reign of Charles the Second began a great change in the police of London, a change which has, perhaps, added as much to the happiness of the body of the people as revolutions of much greater fame. An ingenious projector, named Edward Heming, obtained letters patent conveying to him, for a term of years, the exclusive right of lighting up London. He undertook, for a moderate consideration, to place a light before every tenth door, on moonless nights, from Michaelmas to Lady Day, and from six to twelve of the clock. Those who now see the capital all the year around, from dusk to dawn, blazing with a splendor besides which the illuminations of LaHogue and Blenheim would have looked pale, may perhaps smile to think of Heming's lanterns, which glimmered feebly before one house in ten during a small part of one night in three. But such was not the feeling of his contemporaries. His scheme was enthusiastically applauded, and furiously attacked. The friends of improvement extolled him as the greatest of all the benefactors of his city. What, they asked, were the boasted inventions of Archimedes, when compared with the achievement of the man who had turned the nocturnal shades into noon-day? In spite of these eloquent eulogies the cause of darkness was not left undefended. There were fools in that age who opposed the introduction of what was called the new light as strenuously as fools in our age have opposed the introduction of vaccination and railroads, as strenuously as the fools of an age anterior to the dawn of history, doubtless, opposed the introduction of the plough and of alphabetical writing. Many years after the date of Heming's patent there were extensive districts in which no lamp was seen."

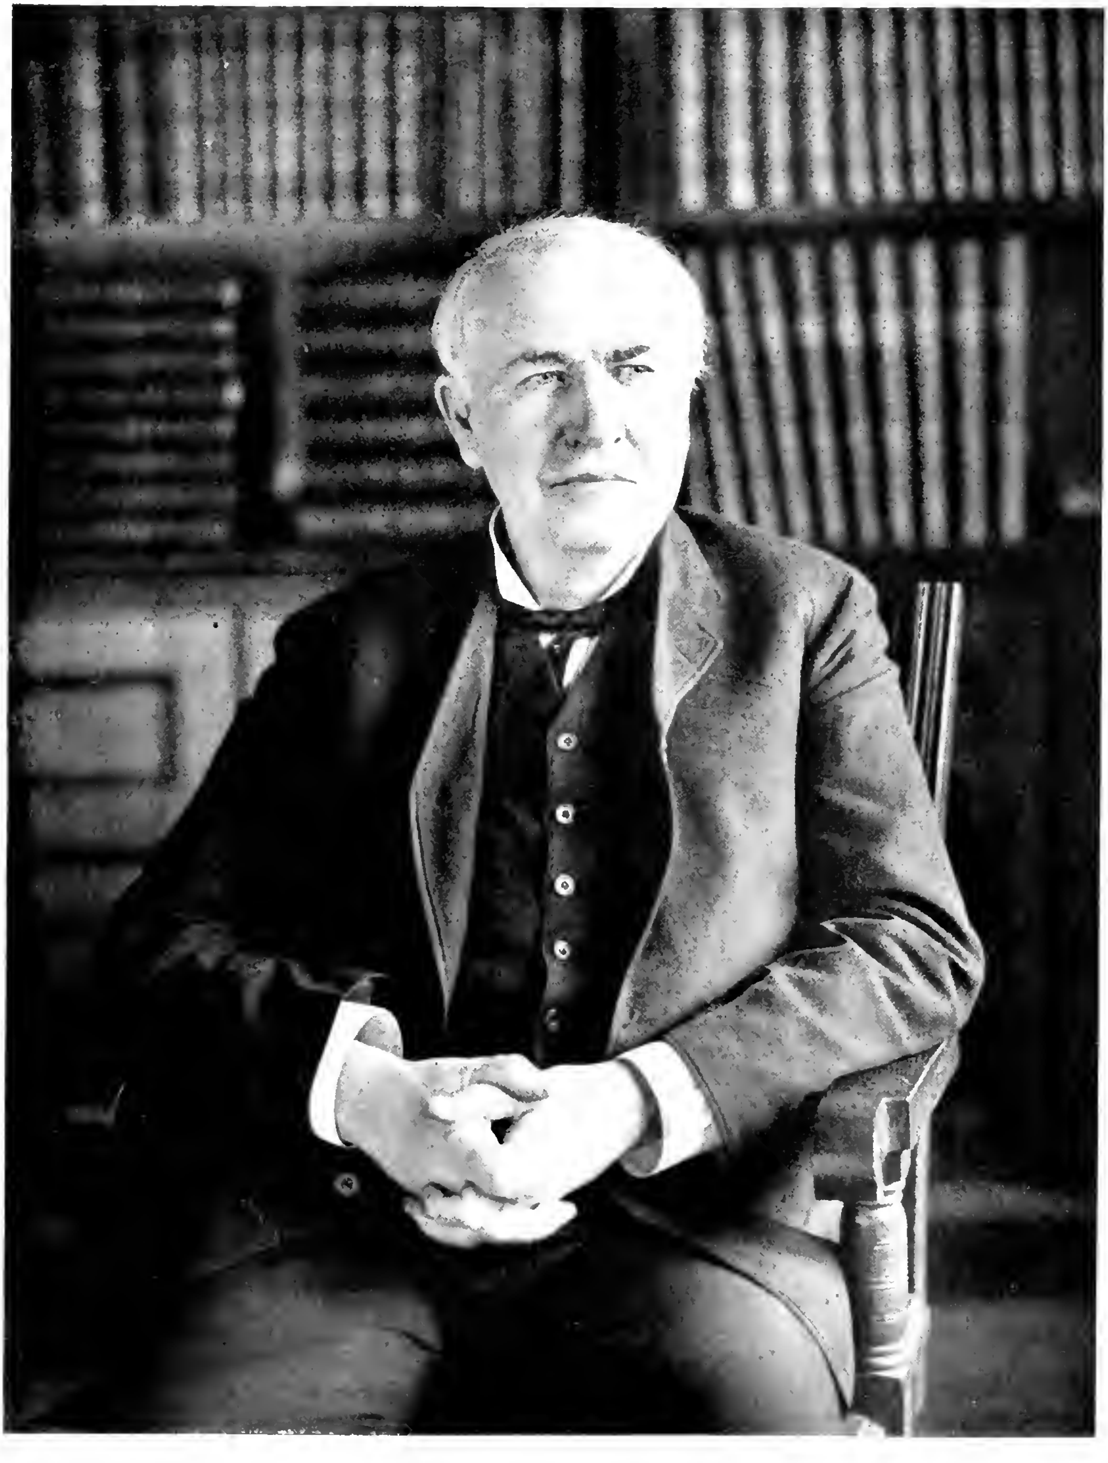
If the reader, after perusing this paragraph concerning the conditions as they existed some 229 years ago, walks down any of the main streets of any large modern city, he can form a good mental picture of the progress made. We should naturally expect great progress in so long a period, but if a similar paragraph were written describing accurately the state of things a hundred years or even only 30 years ago, the picture would be hardly less impressive, as it is in the last quarter of a century that the greatest strides in the lighting industry have been made.

It is interesting to spend some time in considering the word "light" itself. It is used so commonly, but what does it mean? It may be used in so broad a way as to make it meaningless and confusing to the lay mind, or it may be used in so narrow a sense as to limit its meaning beyond the point of usefulness to the scientific mind. The limits to its meaning have not yet been defined. If the word light is to include only that bare octave of energy vibrations in ether that affect the human eye, then the ultra violet light used in photography is not light but something else; and similarly the infra red just beyond the wave length to which the eye is sensitive is not light but something else, and the exact limit would vary with different eyes. There is no excuse for confining the word light to these narrow limits unless our definition of the word is to state that it is only to include those vibrations to which the average eye is sensitive. Should this be done, then what would be light to some eyes would not be light to others, as our range of perception differs; so this is hardly satisfactory. On the other hand, if no such limit is set, the meaning of the word light is extended indefinitely, perhaps too indefinitely, and light includes both visible and invisible energy radiations extending in both ways to the extreme limits of the spectrum, and the term light then includes all the energy radiation of the spectrum, embracing hertzian rays, radiant heat, visible light, ultra violet and x-rays, and so on up to the highest limits of the spectrum including the gamma rays from radium. As no definition of "light" seems quite clear, perhaps the best way is to be paradoxical and talk of "visible light" and "invisible light." It is some years ago now that Professor Sylvanus Thomson published his most interesting lectures, entitled "Light, Visible and Invisible," and there seems even now little ground for quarreling with this title.

If space permitted, we should like to deal with some of the problems, both scientific and commercial, of the lighting industry, but the subject is so vast that an attempt to cover even a small part of it in so short an editorial would be futile; but it is interesting to note in passing that these problems are so many and so varied that the progress made in the past, great as it has been, is small when compared with the work that is left to be done. Our most efficient illuminant, although a vast improvement on our best of a few years ago, is still woefully inefficient when compared with theoretical possibilities.

The science of light is perhaps the broadest of all the sciences; it includes so much, embracing as it does so many of the physical phenomena. We have learned much in the past, but still the study of light seems almost like a groping in the dark. It is true that our modern scientific conceptions occasionally give a glimmer of hope, and that such conceptions as our modern views on the nature of matter and the properties of the electron seem bound to broaden our scope of scientific research and achievements; but at the same time there is a tremendous field left as yet untrodden, and much building to be done right down on the foundations of the science of light that were laid by the immortal Newton. Such brilliant minds as Sir Thomas Young, Clerk Maxwell and Helmholtz, including such men of modern times as Lord Kelvin and J. J. Thomson, have broadened these foundations, but we have yet to learn the answer to that question which seems well nigh like the riddle of the universe: What is ether?

Fortunately, the scientific mind seems to be fed and stimulated on difficulties to be overcome, so it is rather an encouragement than otherwise to know that in spite of the brilliant work done in the past there is still more to be done; and that of the problems, both scientific and commercial, facing the electric lighting industry of to-day, it might be said, as of the charms of Cleopatra, that "age cannot wither" nor custom stale their "infinite variety."



Thomas A. Edison

Whose reminiscences form a contribution to this issue

# MR. EDISON'S REMINISCENCES

The Editor went to see Mr. Edison at his famous laboratory at Orange, N. J., for the purpose of [illegible] his reminiscences in regard to the beginning of the electric light business. The following is the substance of the interview. Mr. Edison kindly read and personally corrected the manuscript. It may interest our readers to know that Mr. Edison corrected this manuscript on February 11th, 1914, the sixty-seventh anniversary of his birth.—EDITOR.

Electric lighting is a broad subject and it is no easy task to furnish an article to preface so large a special issue of the REVIEW devoted to it. As this issue contains many articles covering widely different phases of the present day industry, and as prophecy is difficult and often dangerous I shall, in the main, confine myself to some of the earlier phases of the industry around the time that it was born.

Those of us that were actively interested in this great industry at the time of its birth are very few now compared with the number of younger men that have entered this field since the industry has been on a commercial basis. It is hard for the later comers to realize the conditions that existed then, as practically speaking, nothing was known of the electric circuit as we know it today. Everything had to be learned.

After a great deal of work had been done, the arc lamp was put on a more or less commercial basis, and this was the first commercially successful system of electric lighting, but it was suitable for exterior illumination only. I realized at the outset that the arc lamp could not be made suitable for general interior illumination. It was too large a source of light for ordinary house illumination and it was too bright, having a bad effect upon the eyes. I could see at this early date that the big field for electric lighting was the interior illumination of houses and that for every arc lamp burning in the streets there would, some day, be a thousand smaller electric lights burning in dwellings, office buildings, and factories. For this interior illumination it was necessary to obtain smaller units which could be used in exactly the same way as the gas lamps to which the people in general had become thoroughly accustomed at this time. The problem that faced me was how to obtain a small electric unit.

The younger men of today can't possibly realize the situation as it was then. We were literally working in a new unknown continent of thought. In these early days around 1877 and 1878, everyone who was working on the electric lighting problem had thoroughly made up their minds that the subdivision of the electric current was an impossibility. Men talked about it and wrote about it as an impossibility, and eminent scientists proved it to be impossible by mathematics and by logic, and indeed with our knowledge of electrical matters as it stood at that date it did seem an impossibility; but in July, 1878, I conceived my first idea of the low tension multiple arc system for the distribution of electricity for light, heat and power purposes.

I fully realized at this time that the problem was a gigantic one and that its solution would involve an immense amount of study, experimental work and commercial figuring. I started my task by reading an enormous amount of literature and studied everything I could find on the subject, investigating all systems of lighting, including gas, and taking into special consideration the commercial features. I made up my mind that the whole thing had to be done in one certain way or not at all, and then I started experimenting to discover and perfect the devices for this pre-determined system.

The problem was a broad and fundamental one, requiring the development of a complete system which I realized from the first must be analogous to the gas system of illumination then in use.

There was no previous work to serve as a guide. Everything had to be done first hand, so I settled down to take the gas system as a model and to make a system of electric light that could compete with it on a commercial basis.

The lamp was the key to the whole situation. I must invent an electric lamp about the same candle-power as the gas lamp then in use, which must be reasonably cheap and the cost of copper to feed it must be small. It must be durable and capable of burning at full incandescence and at full candle-power for a great number of hours; and over and above this, it must be made independent of all other lamps on the system.

A complete system of distribution for electricity had to be evolved, and as I had to compete with the gas system this must be commercially efficient and economical, and the net-work of conductors must be capable of being fed from many different points. A commercially sound net-work of distribution had to permit of being placed under or above ground and must be accessible at all points and be capable of being tapped anywhere.

I had to devise a system of metering electricity in the same way as gas was metered, so that I could measure the amount of electricity used by each consumer. These meters must be accurate so that we could charge correctly for the current used, and also they must be cheap to make and easy to read and keep in working order.

Means and ways had also to be devised for maintaining an even voltage everywhere on the system. The lamps nearest the dynamo had to take the same current as the lamps farthest away. The burning out or breaking of lamps must not affect those remaining in the circuit, and means had to be provided to prevent violent fluctuations of current.

One of the largest problems of all was that I had to build dynamos more efficient and larger than any then made. Many electrical people stated that the internal resistance of the armature should be equal to the external resistance, and said that that was Ohm's law; but I made up my mind that I wanted to sell all the electricity I made and not waste half in the machine, so I made my internal resistance small and got out 90 per cent salable energy, and these electrical people found that Ohm's law still held good. There were so many other improvements to be made in the dynamo to suit my system of electric lighting that I cannot enter into a description of them in so short an article.

Over and above all these things, many other devices had to be invented and perfected, such as devices to prevent excessive currents, proper switching gear, lamp holders, chandeliers, and all manner of details that were necessary to make a complete system of electric lighting that could compete successfully with the gas system. Such was the work to be done in the early part of 1878. The task was enormous, but we put our shoulders to the wheel, and in a year and a half we had a system of electric lighting that was a success. During this period, I had upwards of one hundred energetic men working hard on all the details.

One question concerning this early system has often been asked, namely: "Why did I fix 110 volts as a standard pressure for the carbon filament lamp?" The answer to this is that I based my judgment on the best I thought we could do in the way of reducing the cost of copper and the difficulties we had in making filaments stable at high voltage. I thought that 110 volts would be sufficient to insure the commercial introduction of the system, and 110 volts is still the standard.

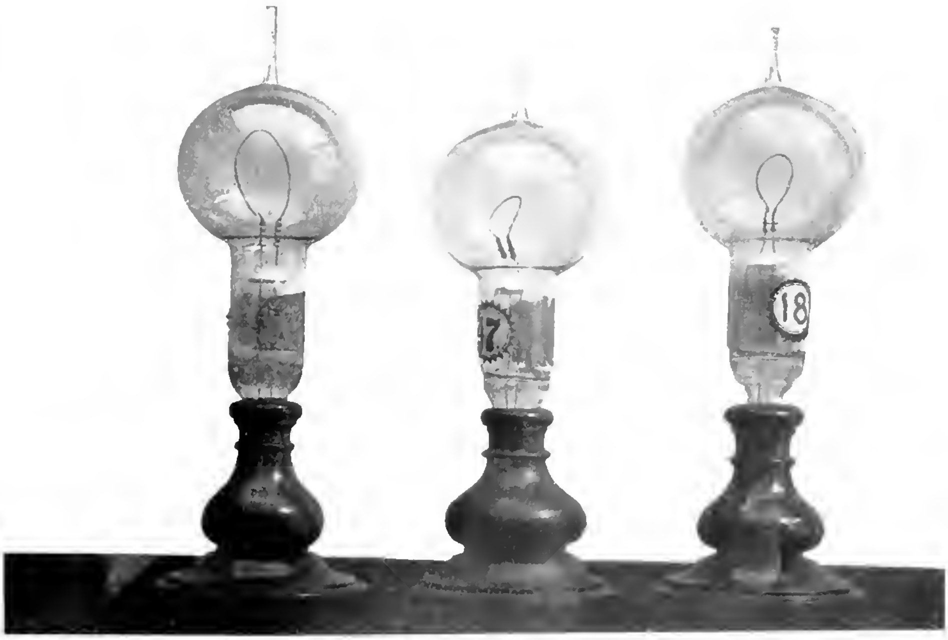
A detailed account of the work done in evolving this first system of incandescent lighting would fill volumes; but as I have already stated, the lamp was the key to the whole situation so a few remarks on this point of the work seems essential. The development of the first practical commercial incandescent lamp involved an enormous amount of experimental work. The first things I tried were filaments of metal, and finally long lengths of metal coiled to get high resistance and small radiating surface with varying degrees of success. Many of these experiments were made both in air and in vacuum. The results of these experiments proved to my entire satisfaction that the successful incandescent lamp must consist of a filament of high resistance, with a small radiating surface, and that such a filament must be contained in as nearly a perfect vacuum as we could make. I therefore proceeded to improve our apparatus for making a good vacuum and when I had accomplished this, success seemed certain. After all our experiments had been made to find the best material for the filament, I came back to carbon on account of the ease of getting a high resistance with a small radiating surface, and after innumerable trials, finally, on October 21, 1879, I carbonized a piece of cotton sewing thread bent into a loop, and this was sealed into a glass globe from which the air had been exhausted up to one millionth part of an atmosphere. This was the birth of the first commercial electric lamp. The sub-division of the electric current was an accomplished fact.

A patent taken out by me on Jan. 27, 1880, numbered 223,898, covered practically all of the salient features of the carbon lamp as made today, and the results that I arrived at were obtained because I had determined that I wanted to compete with gas and I worked all branches of the system to effect the desired result.

Many other people have worked on the incandescent lamp since this date, but I still believe in the great future of the carbon lamp. There are certain phenomena which work against high economy, but I believe that in time these defects will be surmounted and carbon will be the filament par excellence.

In conclusion, I would say that I am often asked to prophesy as to what artificial light may be developed in the future, but I have an objection to prophesies, as none of us knows very much; but it is certain that there are many things as yet untried that may give results as yet unthought of. A great deal of interest has been taken in what is known as cold light, namely, phosphorescence and fluorescence, but the chief objection to this is that it does not seem to suit the eyes of mammals. It is interesting to note here that there are still more streets lighted in New York City with gas than there are with electricity; but I believe that electric light will extend and will gradually supersede all forms of illumination, and that in the future even the country districts will be lighted electrically. If we consider the illumination of any large town, we may divide it into a central or thickly populated business district, with a residential district beyond this, and again a suburban district beyond the residential zone, with highways radiating into the country and leading to other towns. The illumination of all of these sections had to be considered, and it seems to me that all could be illuminated successfully with incandescent lamps, let us say with units of 100 candle-power spaced closely together in the business section and smaller units more widely separated where less light is required, while the country highways might be lighted in the same manner, only with smaller units. All our streets, parks, residences, public buildings, and stores, as well as our factories, will ultimately use electric light. From my own experience, I have found in my factories, where we use 100 candle-power mazda lamps with plenty of them, that we get no shadows and it appears to be the best form of lighting for our works.

There is certainly one good feature about electric light on which we will all agree, that is, that it is about the only thing that has decreased in cost during the last twenty years.



Some of Edison's Early Incandescent Lamps

[illegible]

LIGHT AND LIBERTY

# LIGHT

By Dr. W. R. Whitney

Director of the Research Laboratory, General Electric Company

This article by Dr. Whitney is one of great interest on the general subject of light and its artificial production. He shows that some of our theories and logic are apt to hinder experimentation in profitable directions, and that persistence and optimism are more likely to be rewarded with results than a conservatism born of a knowledge of supposed limitations. The author shows that we are still far from an artificial light for commercial purposes anything like approaching to daylight but he is optimistic as to the future.—Editor.

Dr. W. R. Whitney

My contribution to this symposium on light, I prefer to make general rather than specific. The real work of the research laboratory on the subject is naturally largely confined to the safe and sane applications of what we may call "contiguous reagents" to the problem. By contiguous reagents, I mean such theories of light, of radiation, of conduction, of molecules, of ions, of electrons, etc., as, without too great lapses of time or loan of effort, may be made practically useful, and such materials and principles as seem to promise improvement on present systems. In other words, we do not wander much afield. A theory might be advanced that ultra violet light could be generated more economically than white light and that by suitable yet-to-be-discovered-and-therefore-not-apparently-contiguous reagents, its effects would become visible and therefore useful. But this would not correspond to present methods of study. The research work of the past has been conservative. The incandescent lamp has been repeatedly improved by the application of refined methods, while the general reagents of a glass bulb with an incandescent filament has not been departed from. Practically all promising chemical elements have been tested as filaments in this way and in almost no other way. The arc lamp work has been along the line of continued study of the phenomena which existed in the very first arc that was ever observed. From the charcoal arc of Sir Humphrey Davy to the most recent type of arc lamp, the path has been narrow and the steps small. Substitution of one material for another produced by gradual stages the luminous arcs of today, in which often four or more chemical ingredients are found useful to carry out four or more different physical or chemical processes, all necessary to the lamp.

A general treatment of this research work is unnecessary, and specific treatment can better be given by others.

In this connection, though, there is a point which is always of interest to me: this is the apparent instability of our conclusions when we attempt, as it were, to put limits upon Nature. It seems rather as though Nature rewarded the patient, persistent and optimistic student in marked defiance of what was earlier learned as laws and logic. The trouble is, of course, with us, our laws and our logic. Like our theories, they are strictly useful only when they force us to a trial. All of them are often harmful when they stand in the way of experiment. When Auer von Welsbach made the osmium lamp, he had plenty of laws and logic showing the uselessness of attempting to make a superior incandescent filament of any other metals. Later, when Werner von Bolton, further advancing the art, made the first tantalum filament, he had good reasons to believe that no more promising metal existed. Similar ideas prevailed regarding tungsten when the apparent limit of its efficiency was one watt per candlepower. Alexander Siemens wrote as follows, only last spring, of the one watt lamp: "These results, taken together with the high temperature at which the tungsten lamp works, make it very doubtful whether it will be possible to construct a much more economical glow lamp, so that the consumer will have to look, for further economy, to the improvement and cheapening of the electric supply." The half-watt-per-candle lamp, which was already operating in the laboratory at that time, denied this allegation. Surely the increase of 50 per cent which the nitrogen introduction has effected in the economy of the glow lamp, has come because undue weight was not given to laws, logic and theories which apparently forbade it. There are still plenty of theories pointing onward. The good ones aim towards yet higher efficiencies, longer life, and better color.

Perhaps they ought to be valued more in proportion to their reach than their reason. Maybe this is technical pragmatism.

Therefore, in writing an article like this, I may be permitted to wander from the contiguous reagents and look at artificial light production from a distance.

What relation do our present best lamps bear to the best theoretically obtainable? This is a difficult question. I think it is fair to say that we do not know exactly how much electrical energy is theoretically just sufficient to give us one candle-power. Suppose this were known to be 0.05 w.p.c. We might say that because we are actually using half a watt per candle-power in our best incandescent lamp, our best present lamp would then be about 10 per cent light efficiency, and we might still expect a tenfold improvement. During the past twenty years the value of the ideal (consumption per candle-power) first dropped from 0.22 to 0.11, and then from 0.11 to 0.04 or 0.05, as investigators have continued their work, so that the actual improvements have had to be recalculated on a new basis, leaving us really still far from efficient electric lights. It has often been pointed out that we ought ultimately to expect to reach at least as great an efficiency for practical lamps as we can obtain with any known materials for brief periods of time. We can show for a few minutes, for example, a much greater efficiency than our best lamps exhibit during their much longer lives. It seems as though the difficulties which stand in the way of perpetuating temporary very favorable light efficiencies are more easily overcome than the kind of difficulties we know less about. It is this kind of difficulty that is partly overcome in the nitrogen tungsten lamp where the rate of evaporation of the metal at the temperature of operation is greatly reduced by the simple presence of nitrogen. In accord with this reasoning, one might say that a specific consumption of about 0.25 w.p.c. was in sight. That is, this is about the limits at which a tungsten filament will last at least a short time. This is twice as efficient as our best incandescent lamp and about four times as efficient as the standard mazda vacuum lamp. It is, however, at best not better than 25 per cent ideal efficiency.

An interesting point deserves consideration in this connection. It may well be stated that there are those who believe that there is no great object in making very much more efficient lamps. This condition will doubtless not always exist, but it is quite evident in some places today. Suppose, for example, that all the light needed for a dwelling could be produced at 0.25 w.p.c., and that people were satisfied with 100 c-p. in the house.

Assume, again, that the rate for power were 5c. per kw-hr. and that the lamps were burned 5 hours per night, 30 nights per month. The income to the power station would be 18¾ cents per month. This might mean that the lighting company could not afford to install the meters and read them. What this foreshadows is not that the higher efficiency lamps will be less eagerly sought and introduced, but that electric energy will be more freely used for still other purposes. There is little danger of a limit to power consumption being reached so long as the electric current is not generally used for heating.

While the advances of the past half century in production of light may seem considerable to our worm's-eye view, it is probably really only because of the proximity. No one has produced any considerable light that would be mistaken for daylight. You couldn't fool a half grown pumpkin with it. The energy which comes from the sunlight filtering through our atmosphere on a bright day can be measured as energy, and it amounts to approximately one horse power per square yard. If we arranged our best artificial light so that a horse power of radiant energy fell upon a square yard of earth during the night, would the grass grow at the daylight rate? Certainly not! It would scarcely grow at all. It might grow as much in a whole summer of nights as in one summer's day.

Growing lettuce, when given plenty of electric light, can be kept awake at night and will even grow a little, but tomatoes insist on sleeping and decline to grow under such conditions. It is said in general that "one hour of sunlight will accomplish more in the way of growth than several nights of arc light." In fact, we are still so near the tallow dip and so far from daylight that it is almost inconceivable that an artificial daylight should ever be asked for. We are so accustomed to the changes in color which take place all around us, when we pass from daylight to lamp light, that we seldom even think of it. Our incandescent lamps still give a light that, at its best, would never be mistaken for the feeblest ray of good daylight. A bird's-eye view makes the advance seem slight. A layman might even think we were not trying to imitate daylight at all, but fire light instead. He would be flattering us. I believe the future will be richer in artificial daylight, but the contiguous reagents may seem a little remote. McFarlan Moore, who has perfected a vacuum tube lamp to be used by dyers and color matchers, has produced light which closely resembles daylight, but at a cost and under conditions which seem to make its present use for ordinary illumination prohibitive. By screening the other ordinary light sources with colored screens, a truly white light is available, but thus far the cost also precludes its general use. In other words, there is yet no artificial daylight commercially producible. There can be little doubt that it would be used if obtainable at several times the cost of our present night lights, so that there is some uncultivated field here in artificial light production. While efforts will evidently be continually expended towards cheapening our present lighting methods, it seems also certain that investigation of ways of producing a cheap light which will resemble daylight will receive additional attention. According to the pragmatic doctrine, this is only true when it is made good, and "generalizations in Nature are never strictly true, not even this one."

There is being so much work done in fields not at first apparently closely allied to light, that no little interest is attached to thinking of the inter-relationships. It has been but a short step to follow the investigators who have mapped the spectra of hot bodies or of fire-flies, and those who exposed to our view previously unknown spectral fields even ten times as extensive as our visible spectrum from violet to red. Infra-red and ultra violet rays were to be expected. Prof. Langley practically photographed the sun's spectrum below the red of the ordinarily visible part to wave lengths of 0.005 mm., or over a range ten times as great as the visible portion of light. In this new field were also all sorts of absorption lines and bands like the Frauenhofer lines of the visible spectrum. These are to be looked for in all further extensions of light or ether vibrations. But what an inconceivable field for research must exist in the range where wave lengths pass from 0.0003 mm. of ultra violet light to the 0.000000001 mm., which are now attributed to X-rays; or where the infra red ether vibrations extend upward in the wireless rays to miles in length.

So even if the scientists do not agree in considering the word "light" to cover all radiations in the hypothetical ether, we are still handling a "contiguous reagent" of light when we are operating a wireless station or an X-ray tube. It is certain that the physicist, chemist and electrician are to gain more from the coördination of scientific work in these fields than in any other now known, and this for years to come. I need only, in a layman's way, point for example to the interpretation of spectral lines such as are now found in the mapped regions and as will be found and utilized from X-ray to wireless waves, together with their bearings on the composition of chemical atoms or the unlimited refinement of wireless signalling, to indicate the possibilities.

If one considers light as all radiations of whatever wave length in the ether, he has also a nice way of co-relating all those evidently connected phenomena of "emission" and "convection" while keeping his picture clear. He has a sort of filter which separates all the relevant materials into those which pass and those which are held by the theory. For example, the energy lost from a hot body in air is emitted in part as radiation in ether waves and as convection in the air. In the emanation of radium, polonium, etc., and in all the phenomena of electrical discharges through gases and in X-ray tubes, when we are not dealing with tangible emitted moving masses, as in the case of cathode rays, vaporizing metal, alpha particles, etc., we are dealing with ether vibrations, as in the X-rays proper and the gamma rays. When we know that to the latter may be attributed the velocity of light, and to the former always lower velocities, less penetrability, etc., we have made further steps easier. In going backward in thought from the ether vibration of any kind or color, we find its pedigree shows the chemical atom as its grandparents, with the negative electron its dam and the positive ion its sire. Or, putting it in another way; all the radiations in the ether which I am here wanting to call "light" and which vary from gamma radium rays to wireless waves, are born of the electrons and all are called into being by changes in the velocity of electrons. The family tree of blood relationship helps account for the inherited characteristics in each case.

The absorption of light by a body or material—that is, its opacity—is due to the transfer of the energy of the ether vibrations to something in the body which can transform it into other energy forms. At present we see no good reason, for example, why ordinary light should pass readily through a quantity of lead when this lead is one of the components of a sheet of glass, while it will not pass through the same thickness of lead when in the form of sheet metal.

When we learned that the continuous spectrum, on passing through sodium vapor, lost that part of the yellow light which sodium produces when heated to luminescence, the Frauenhofer dark lines of the solar spectrum were better understood, but the opacity of materials in general was not.

In the case of X-ray light there is greater simplicity. Here the absorption or opacity seems to be determined entirely by the atoms of the material. A substance of high atomic weight is, in general, more opaque to X-rays than one of low atomic weight, and the opacity is proportional to the number of atoms per volume of material. The opacity of an atom is retained in whatever compound it may be found. The lead in lead glass is as opaque as the same lead in white paint or sheet metal. The diamond differs from graphite in opacity to X-rays only slightly and this just as would be expected from the difference in gravity. The heavier diamond is more opaque in the same thickness, because the carbon atoms are more concentrated; the opacity here is proportional to the density. On the other hand, carbon being of low atomic weight, is in all cases more transparent to these rays than most of the other chemical elements. This simplicity, when realized as occurring in all compounds, makes one realize that at present X-rays in this respect are much simpler than ordinary light. The absorption of homogeneous X-rays is an atomic property, and the absorption of a compound, or its opacity, is that of its components for the corresponding concentration. For example, solid sulphur and carbon, when superposed, exhibit the same degree of opacity as the corresponding quantity of carbon bisulphide, though this latter is transparent to ordinary light, and the components are opaque. Something in the atom, and not a property of the molecule itself, nor the material as a whole, takes up the energy of the X light—absorbs it.

It would lead from light to darkness to take up the question of opacity of material to ordinary light, but the recent discoveries of the laws of opacity of X-rays and the gamma rays of radium are encouragingly simple, and they doubtless will greatly aid in the understanding of the relations of ordinary light and light absorbing matters.

# THE PROBLEM OF LIGHT-PRODUCTION

By Dr. Edward P. Hyde

Director of the Physical Laboratory, National Lamp Works of General Electric Co.

The many different aspects from which light can be studied are mentioned, but the author chiefly confines his article to the physical properties of light-giving sources which are important in the production of light. The sensitivity curve of the eye is given and explained. The author then sets out to answer four fundamental questions concerning the problem of light production, viz: (1) What are the extreme values of luminous efficiency possible for monochromatic light, for white light, and for black body radiation? (2) What are the actual values of luminous efficiency for ordinary illuminants in comparison with the values theoretically obtainable, and what are the causes of these relatively low efficiencies? (3) What are the possible ways in which commercial illuminants of higher efficiency may be developed? (4) What other considerations than luminous efficiency enter in determining the most satisfactory illuminant?—Editor.

Dr. E. P. Hyde

LIGHT is a sensation. By extension the term is also applied to the radiant energy emitted by a luminous source, which, transmitted through the ether in electro-magnetic waves and impinging on the retina of the eye, produces those retinal changes which are forwarded through the medium of the optic nerve to the brain cells and call forth the sensation of light. And whether we focus our attention on the last step of the process, and inquire into the phenomena and the mechanism of the phenomena which occur in the cells of the brain and of the nerve fibrils, or investigate the propagation of radiant energy through empty and matter-weighted space, or whether we study these phenomena which are exhibited in the process of emission of radiant energy by luminous sources, the problem is equally interesting.

In the present article we shall center our attention on this last problem—the emission of radiant energy by luminous sources; but in the consideration of this we shall avoid these esoteric questions which have to do with theories and speculations regarding the mechanism of emission and shall concern ourselves principally with those established and measurable physical properties of light-giving sources which are of importance in the problem of lighting. It is, of course, impossible to refrain from traversing the complete circuit from the oscillating electrons to the physiological phenomena involved in vision, for a study of the light-giving properties of luminous sources hangs upon the response in the human eye and brain to those radiations emitted by the source. The problem of light production is indeed the problem of the correspondence between physiological sensibility and physical excitation.

Our first inquiry then, must be into the degree of response of the retina to radiation of varying wave-lengths or color. Complete information on this point under ordinary conditions is given by the curve in Fig. 1, which is ordinarily called the *sensibility curve* of the eye. This curve is obtained from experimental data on the quantities of energy per second in the different portions of the spectrum required to produce the same luminosity, i.e., the same intensity of sensation. The reciprocals of these quantities of energy are thus plotted as the ordinates of the curve of Fig. 1, corresponding to the different wave-lengths, $\lambda$, expressed in thousandths of a millimeter. This curve shows that if a lamp emitted only orange-colored light of wave length 0.00061 mm. (or 0.61 $\mu$) it would have a candle-power of only one-half that of a lamp which emitted the same quantity of energy per second, but which confined its radiation to yellowish-green light of wave-length 0.000545 mm. (0.545 $\mu$). It also expresses the fact that all radiation of longer wave-length than 0.7 $\mu$ and all radiation of shorter wave-length than 0.43 $\mu$ produces little or no visual response, and so this region of the spectrum, taken roughly between 0.43 $\mu$ and 0.7 $\mu$, is defined as the visible region of the spectrum, or more concisely as the visible spectrum. The average eye can see light between the somewhat broader limits of 0.8 $\mu$ and 0.83 $\mu$, but owing to the uncertainty of these limits and to the feebleness of the sensation near these extreme limits the practical limits taken are somewhat narrower. Unfortunately these are not always taken the same by different writers and so I shall define my limits in the following discussion as otherwise inconsistencies may arise.

With these facts regarding the sensibility of the eye before us we are prepared to discuss several questions regarding the radiating properties of matter which are of prime importance in lighting. And perhaps it will be well to confine this limited article to an attempt to answer four fundamental questions in the problem of light production.

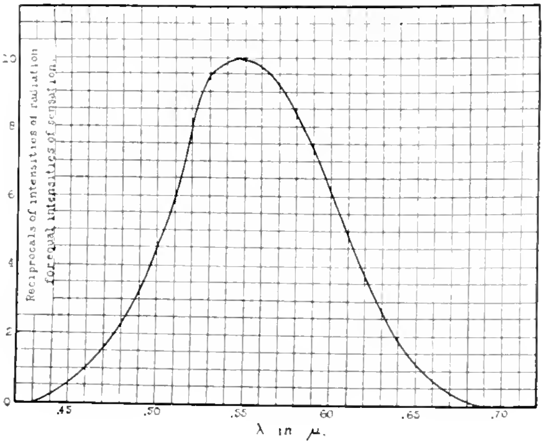


Fig. 1

*a. What are the extreme values of luminous efficiency possible for monochromatic light, for white light, and for black body radiation?* By "luminous efficiency" is here meant the ratio of the rate of luminous radiation measured in lumens, to the rate of energy consumption or transformation, measured in watts supplied to the lamp. From a consideration of Fig. 1 it is seen at once that the highest possible luminous efficiency attainable would be secured if all the energy supplied to a lamp were radiated in yellow-green light of wave-length 0.545 $\mu$. The efficiency of such a lamp would be of the order of magnitude of 800 lumens per watt, or about fifteen times the efficiency of the most efficient light source in current use. It is interesting to note in passing that although we do not know what internal energy reactions are involved in producing the glow of the ordinary fire-fly, looked at merely from the standpoint of radiation the fire-fly has a luminous efficiency of probably more than 95 per cent of the highest attainable efficiency.

If all the energy supplied to a lamp were radiated in the visible spectrum (between $\lambda = 0.76\ \mu$ and $\lambda = 0.38\ \mu$) and if the radiation were distributed throughout the visible spectrum in the way to produce white light the luminous efficiency would be approximately 300 lumens per watt, or about 40 per cent of the efficiency of the monochromatic radiator. In this case it is supposed that all the energy supplied to the lamp is radiated within the visible spectrum, none being radiated in the long infra-red or heat waves.

Finally what would be the highest possible efficiency of a black body radiator at the most favorable temperature? We can think of a black body as represented fairly accurately at ordinary temperatures of operation by a carbon filament. If the carbon filament could have its temperature increased indefinitely without subliming or melting, at what temperature would it attain to the highest possible efficiency and what would be the luminous efficiency at that temperature? It is easy to prove that this temperature would be very closely that of the sun or 5000-6000 deg. C., that the color of the light would be white, and that the luminous efficiency would be approximately 125 lumens per watt, or about 15 per cent of the highest possible efficiency of monochromatic radiation.

*b. What are the actual values of luminous efficiency for ordinary illuminants in comparison with the values theoretically obtainable, and what are the causes of these relatively low efficiencies?* The luminous efficiencies of ordinary illuminants are all far below the maximum luminous efficiency of monochromatic radiation, viz., 800 lumens per watt; moreover, they are all below the maximum luminous efficiency of the black body at 5000-6000 deg. C., which we have just seen to be approximately 125 lumens per watt. It is not the intention in this article to dwell long on the actual values of luminous efficiency of commercial illuminants, but rather to call attention to the relation between these values and the maximum values theoretically possible, and even more particularly to explain some of the phenomena which enter in determining the relatively low efficiencies, and to indicate the possible ways in which commercial illuminants may be developed in efficiency. It may be well, however, before proceeding to this discussion to give approximate values of luminous efficiency for some of the more common illuminants in their relation to the maximum values theoretically obtainable. Such data taken from published investigations are given in Table 1.

The matter of interest in the physics of light-production in connection with the luminous efficiencies of ordinary illuminants is the considerations of the factors which enter to determine these efficiencies. The electric incandescent lamp furnishes an interesting illustration. A definite amount of energy per second is supplied electrically to the terminals of the lamp. A part of this is transformed into heat by the $I^2R$ loss in the leading-in wires and junctions; the remainder is transformed into heat by the passage of the current through the high-resistance filament. That which is transformed into heat by the $I^2R$ loss in the leading-in wires is completely lost, as far as its direct influence on the luminous efficiency of the lamp is concerned. This loss in the ordinary types of lamps manufactured at the present time is negligibly small, amounting in most cases to less than 1 per cent.

**TABLE I.***

**Values of Luminous Efficiency**

| Sources | Values of Luminous Efficiency in Lumens per Watt | Relative Values in Luminous Efficiency in Terms of that of Monochromatic Radiation at Wave-Length 0.545 |
|---|---|---|
| Monochromatic radiation ($\lambda = 0.545\ \mu$) . | 800 | 100 Per cent |
| White light of maximum efficiency . | 300 | 40 Per cent |
| Black body at temperature of maximum efficiency 5000-6000 deg. C. | 125 | 15 Per cent |
| *Quartz mercury arc | 50-60 | 6-7½ Per cent |
| Luminous and flame arcs . . | 40-60 | 5-7½ Per cent |
| Glass mercury arc | 12-24 | 1½-3 Per cent |
| 0.5 Watt-per-candle gas-filled mazda lamp . . | 16 | 2 Per cent |
| D-c. open carbon arc | 16 | 2 Per cent |
| Nernst glower | 5 | 0.6 Per cent |

The energy which is transformed into heat in the filament is dissipated in various ways, only a small part of it ultimately becoming available for the production of light. A part of the energy is dissipated by conduction and convection by the gases in the bulb in cases where the vacuum is not high, but this loss in a good lamp is entirely negligible. Another portion of the energy is dissipated through heat conduction by the leading-in and anchoring wires. Thus, owing to the high temperature of the filament compared with that of the leading-in and supporting wires with which it comes into contact, there is a continual heat conduction away from the filament at these points, thus cooling the filament locally and decreasing its luminous efficiency.

The remainder of the energy transformed in the filament is radiated, the spectral distribution depending upon the temperature of the filament. Only that portion which is radiated in waves within the limits of wave-length of the visible spectrum is productive of light. As stated above, the loss due to conduction and convection by the gas in a normal lamp must be negligibly small. It is quite a simple matter, however, to show what a saving is effected in the case of an ordinary incandescent lamp through the use of an evacuated bulb. If a lamp is constructed having a filament of some material, such as platinum, which can be operated either in air or in a vacuum, the difference in power supplied to the lamp when evacuated and when filled with air (the temperature of the filament being the same in the two cases) is under certain conditions quite large. Thus a platinum filament of 0.1 mm. diameter and 15 cm. length, mounted in a pear-shaped bulb of 8 cm. maximum diameter and 13 cm. length, when operated at a temperature of approximately 1700 deg. abs. (Centigrade+273 deg.), requires 4.75 watts when the bulb is evacuated, and 24.3 watts when filled with air at atmospheric pressure. In other words, the loss by convection and conduction of the gas is 400 per cent of the total power required to operate the filament in a vacuum.

The relative magnitude of this loss, which in the case cited is quite large, must be understood to depend on at least four factors: (1) the diameter of the filament, (2) the temperature of the filament, (3) the emissive power of the filament material, and (4) the nature of the surrounding gas. In the new gas-filled mazda lamp these factors enter in such a way that the relative magnitude of the gaseous conduction losses is small, as otherwise the gain in efficiency owing to the higher temperature of operation of the filament would be largely offset by the loss in efficiency occasioned by the gaseous conduction.

---

* This table of values of luminous efficiency needs some explanation to prevent possible misunderstanding. It is to be understood, of course, that the first three values given are for ideal sources never realized in practice, and are, moreover, estimates which may be in error by 25 per cent or even more.

Also the values given for arc lamps are subject to much uncertainty. This is particularly true of the value for the quartz mercury arc. Values of 60 lumens per watt have been recorded for the quartz lamp omitting all consideration of the ballast resistance, etc., but the values obtained in ordinary commercial lamps on ordinary circuits are very much smaller than those given in the table. As our interest in the present article, however, relates rather to the physical explanation of the relatively low efficiencies obtained in the various ordinary methods of light-production at their best than to a practical consideration of lamps in ordinary use it seems advisable to present the highest values obtainable with the quartz arc under the most favorable conditions, and omitting any consideration of losses in ballast resistance, etc.

The losses by conduction at the leading-in and anchoring wires in the ordinary electric incandescent lamps have been variously estimated, the published values ranging from an almost negligible quantity to as high as 25 or 50 per cent in various types of standard lamps. Attempts at direct measurement of the energy radiated seem to indicate comparatively high figures for the thermal conduction losses, whereas the conclusion from practical experience in lamp manufacture points to rather small losses. Measurements by a new direct method gave for these losses for normal carbon, tantalum and tungsten lamps values in all cases of the order of magnitude of 5 per cent, which would seem to be more consistent with the experience of lamp manufacturers than the much larger losses found by other investigators.

If then the losses by convection and conduction amount to but a small percentage of the total energy supplied to the filament, explanation of the relatively low luminous efficiency of the lamp must be sought in the spectral distribution of the radiated energy.

In a similar way the losses in other types of lamps may be analyzed, though not so simply as in the incandescent lamp. In the d-c. open arc the luminous efficiency of the crater, which is at a temperature of 3800-4000 deg. abs. is probably 70 or 80 lumens per watt, but owing to the many losses the net efficiency is only about 16 lumens per watt. Also in the low pressure arc the efficiency of the luminous vapor is quite high but the losses at the terminals are great and so reduce the net efficiency. Except in the case of the electric incandescent lamp there is much energy supplied to the lamps which is not transformed into radiation. But in all the lamps the actual efficiency of the radiant energy is relatively low compared with the maximum efficiency of 800 lumens per watt of monchromatic radiation, though the disparity, especially in the case of such lamps as the quartz mercury arc, would be much less if all the losses except that due to infrared radiation were eliminated.

c. *What are the possible ways in which commercial illuminants of higher efficiency may be developed*? From the preceding consideration it immediately follows that the efficiency of commercial illuminants may be increased theoretically in three possible ways. Thus net efficiency would be increased if the energy losses due to thermal conduction and convection could be eliminated or reduced. It would also be increased if the temperature of operation could be raised without reducing seriously the effective life of the lamp. Finally it would be increased if substances could be found which would radiate relatively more energy in the visible region of the spectrum even at temperatures of operation such as are ordinarily found in similar illuminants in present use.

Regarding the first possibility, there is little to be gained in the electric incandescent lamp in which the efficiency loss owing to the cooling effect at the leading-in and supporting wires amounts only to a few per cent. Much gain has been made in the low pressure arc, such as the Moore nitrogen tube by greatly lengthening the tube and thereby reducing very considerably the relative magnitude of the losses at the electrodes. These losses enter most largely in gas lamps, as in the open gas burner or in the Bunsen flame in conjunction with an incandescent mantle, and though it is impossible to eliminate these losses it is not inconceivable that they might be reduced.

Regarding the second possibility, it is of course very well known that increase in temperature increases the relative amount of energy radiated in the visible region of the spectrum, and also produces a different distribution of energy in the visible spectrum, the two factors combining to increase very materially the luminous efficiency as the result of a relatively small increase in temperature. Thus in the case of the new gas-filled mazda lamp the reduced sublimation owing to the pressure of the gas permits an increase from about 2000 deg. C. to about 2550 deg. C., or approximately 550 deg. in the temperature of operation with a corresponding increase of more than 100 per cent in the luminous efficiency.

Similarly the substitution of quartz or other highly refractive material in the place of glass in the mercury arc has made possible a somewhat higher temperature of operation and a much higher efficiency; and it is not impossible that still further improvement in illuminants may be produced in this way.

The third possibility referred to above is in many ways the most promising. No material substance radiates precisely like the ideal radiator or black body, and the deviations for materials used in commercial illuminants are practically without exception in the direction of increasing the luminous efficiency. Even in metallic filament electric incandescent lamps an appreciable increment to the efficiency is to be ascribed to this cause commonly known as *selective radiation.* The relatively high efficiency of the flame arc is also ascribable to this cause, and the peculiar radiating properties of the ceria-thoria mixture used in the incandescent gas mantle account for the efficiency of this type of lamp.

It has been customary in the past to distinguish between *temperature radiation*, as exhibited ideally in the black body, and illustrated in the carbon and metallic filament lamps, and *luminescence* as exhibited in fluorescence and electro- and chemi-luminescence and illustrated in the flame arcs and the low pressure arcs such as the Cooper-Hewitt lamp and the Moore tube. This distinction is not now so universally insisted upon as in the past, but whether the distinction is real or artificial the practical fact remains that much development in commercial illuminants has proceeded from the utilization of certain radiating substances which under certain conditions of excitation emit radiant energy favorable to high luminous efficiency. With the increasing knowledge which is being acquired regarding the radiating properties of matter I look to the development of lamps based on the principle of highly selective emission as the most promising field in the invention of the illuminants of the future.

*d. What other considerations than luminous efficiency enter in determining the most satisfactory illuminant?* Much has been said regarding the luminous efficiency of illuminants—not from the viewpoint of a comparative study of the efficiencies of lamps and of the variations in these efficiencies under varying conditions, such as that of varying voltage, but rather as a basis for the consideration of the problem of light-production. The first requirement of an illuminant is that it give light, and therefore luminous efficiency enters as a factor of the first importance; but there are other requirements to be demanded of a light source of almost equal if not fully equal importance.

Efficiency has been defined as "the ratio of satisfactoriness to cost, and not the reciprocal of cost." Thus far in considering luminous efficiency we have been dealing only with the denominator of the fraction. We come now to the numerator, but we are restricted to a mere mention of some of the more important properties which an illuminant should possess to be satisfactory. These properties, of course, will in some cases vary with the uses to which the illuminant will be put: such a property is that of *quality* of light. We have seen that the most efficient source would be one radiating all its energy in the yellow-green region of the spectrum, but a yellow-green monochromatic light would be most unsatisfactory for many purposes. The quality of light from an illuminant is a very important element in determining the utility of that illuminant under different conditions, and so the quality of light from an illuminant has come to be looked upon as one of its most important characteristics.

We have seen that the energy radiated in the infra-red and ultra-violet regions of the spectrum is ineffective as regards both the magnitude and the quality of the luminous flux, and yet no one knows positively the bane or blessing that would ensue from the elimination of the radiation in these regions of the spectrum. Infra-red radiation is probably of considerable importance in plant life, and ultra-violet radiation is a well-recognized germicide; it would be difficult to forecast the result of eliminating these radiations from our natural and artificial illuminants.

Brightness of a source, or the candle-power per unit area, is an important characteristic of an illuminant, and there are minor characteristics, such as divisibility into small units, hardiness, convenience of operation, and others, all of which influence the satisfactoriness of an illuminant in practice.

The solution of the problem of light-production must take cognizance of all these desiderata, and the development of improved illuminants must be guided by the requirements which increased knowledge imposes as the result of observation and experiment. The correct evaluation of these requirements comes within the province of the rapidly developing science of illumination.

# EFFICIENCY OF ILLUMINANTS

By Dr. Charles P. Steinmetz

Chief Consulting Engineer, General Electric Company

The author begins his article with the statement that efficiency of the light source is the first and most important factor in any problem of illumination; for undesirable qualities, if present, can always be got rid of by a sacrifice of efficiency, and thus efficiency is the dominating factor in economical light production. The only correct comparison of light efficiencies is on the basis of the total light flux of the illuminants, expressed in mean spherical candle-powers or in lumens. Some very interesting data on the efficiencies of the electric illuminants at present available are given in the form of tables; the first table grouping the lamps according to types, and in order from the least efficient to the most efficient units of the several types; the second table giving the relative efficiencies of the illuminants of the first table, also in order from the least efficient to the most efficient, but irrespective of the capacity of the illuminants; while the third, fourth and fifth tables compare respectively the efficiencies of 300 watt and 500 watt illuminants, and the relative efficiencies of the various sizes of illuminants.—Editor.

Dr. C. P. Steinmetz

When considering problems of illumination, whether it be lighting of indoor places, or of the streets of a city, the first and most important question is the efficiency of the source of light, or the illuminant.

Efficiency is not the only factor, but other features come in as essentials of a satisfactory illumination, such as:

The quality or color of the light; that is, how nearly white it is, or whether it is off color towards the yellow or the green.

The size of the lighting unit, as determining uniformity and diffusion of the illumination.

The glare or absence of glare of the illuminant; that is, the intrinsic brilliancy of the light source.

The steadiness of the light, and its sensitivity to fluctuation of voltage or current.

The characteristic of the electric circuit required for the operation, as determining the amount of station apparatus, such as constant current transformers, voltage regulators, etc.

The cost of maintenance and renewal, such as trimming, length of life of the arc lamp electrodes, useful life of the incandescent lamps, etc.

However, all this is secondary to efficiency, because defects in any of the above enumerated features can be overcome by a sacrifice of efficiency:

While a light source which is free of glare would be preferable even if of slightly lower efficiency, its inferiority in efficiency must not be much, as a light source can be freed of glare with a slight decrease of efficiency, by a diffusing globe.

Higher cost of maintenance and renewal balance against lower cost of power in the more efficient illuminant, etc.

Thus, while the other features of a satisfactory economical illuminant must be considered and balanced against light efficiency, the efficiency is economically the dominating factor.

In judging of the efficiency of light sources, two procedures are feasible:

We may secure and photometrically test all the commercially available illuminants, and base our judgment thereon. This would be the proper and only feasible way in solving an illuminating engineering problem, as when designing the illumination for a building, store, streets of a city, etc.

Such procedure would fail, however, when considering the larger problem of the development of the art of illumination, and of the possibilities of the various illuminants, as when dealing with the question whether the new high efficiency incandescent lamp will replace the arc lamp, or whether the arc lamp as well as the incandescent lamp will both find definite fields of usefulness. Questions of this character can not be decided by the comparison of existing types of lamps, as these types merely represent the industrial requirements of the preceding years, and a general judgment on the possibilities of the various illuminants would almost certainly be erroneous and misleading, if based only on existing commercial types. It would for instance not include the effect of the gas-filled mazda lamp or of the titanium lamp, neither of which is yet a standard commercial product.

Thus, in judging on the possibilities of the various types of illuminants, we must go beyond the mere comparison of existing commercial lamps, and must base our judgment on the efficiency characteristics of the light giving radiator—lamp filament or arc stream—as derived from the photometric tests of lamps in commercial existence or in development.

In comparing light efficiencies, only the total light flux given by the source of light can be considered, and will in the following be given in mean spherical candle-powers (msph. c-p.), as the mean spherical candle-power is a more familiar unit than the lumen (one lumen = 4 $\pi$ msph. c-p.).

The candle-power 10 deg. below the horizontal, which is of importance in street lighting, and the mean hemispherical candle-power, which is of importance in indoor lighting, are not measures of the light flux of the illuminant, and have no direct relation to efficiency, but they represent the distribution of the light flux as affected by the type of reflector, globe, etc. Comparisons based on 10 deg. c-p. or mean hemispherical c-p. characterize just as much the efficiency of the design of globe or reflector as the light flux, and thus when used in the efficiency comparison of light production, would be misleading. For instance, a European quartz mercury lamp gives 10 deg. below the horizontal the same c-p. per watt as the mazda lamp, but gives four times the mean hemispherical candle-power of the mazda lamp: its total light flux, however, or its msph. c-p. per watt, are only twice that of the mazda lamp. By a suitable reflector, the mean hemispherical c-p. of the same mazda lamp could be increased by 50 per cent, or by another reflector the 10 deg. c-p. of the mercury lamp made more than twice that of the mazda lamp, etc. Thus, depending on the reflector used, we would get all kinds of comparisons of these two lamps, when using 10 deg. or mean hemispherical c-p. No reflector, however, can change the total light flux, or the msph. c-p. of the light giving source, and with the same light flux and equally good design of reflector, the 10 deg. c-p. and the mean hemispherical c-p. would be closely the same also, so that the total light flux is the characteristic of the illuminant which best determines its efficiency for all uses.

Table I gives a collection of efficiency data of the various available illuminants.

The fourth column gives the msph. c-p. per watt of commercial lamps, as based on photometric tests. Therefrom, and from other tests, are derived in column 1 the specific consumption in watts per msph. c-p., and in column 2 the efficiency in msph. c-p. per watt, of the light source proper, that is, the filament, arc or vapor stream. The values in column 2 usually are higher than those in column 4, by the amount of light which in the commercial lamp is lost in reflectors, obstructed (in the arc lamp) by the operating mechanism, etc. The efficiencies given in column 2 can in general not be realized, since in directing the light flux for the distribution required by the use of illuminants—downwards in indoor lighting, and with a maximum about 10 deg. below the horizontal in street lighting—a loss of light occurs in reflectors, globes, etc. This loss is assumed equal to 20 per cent in the incandescent lamps, and 22 per cent in the arc lamps. These values represent about average conditions met with properly designed light distributors. Column 3 then gives the *available efficiency*, that is, the efficiency of the light flux directed for the contemplated use, or the "useful light flux" available with suitable reflector, etc. Columns 5 and 6 give the mean hemispherical candle-power—indoor lighting—and the candle-power 10 deg. below the horizontal—street lighting—of the lamp per watt, as given by test or estimated as available with suitable reflector, etc.

It is obvious that general efficiency comparisons of the various classes of illuminants must be based on the values in column 3, as these values represent the usefully available light flux in msph. c-p. per watt. All the following tables, except where otherwise stated, are therefore based on the values in column 3 of Table I.

A difficulty exists in comparing flame carbon arcs with each other and with other illuminants, insofar as flame carbons have no typical efficiency, but their efficiency depends on the amount of impregnation. With increasing impregnation, the efficiency increases, but other defects make themselves gradually more and more felt, as slagging and sticking, etching of the glassware, lesser steadiness, etc. In the tables are given the best values found in test, though commercial flame carbons of different types and makes are as a rule lower by from 20 to 50 per cent.

Table II gives the relative efficiency of the various illuminants of Table I, arranged in the order of their efficiency, from the least efficient to the most efficient, irrespective of the size of the illuminant.

The limitation of this table naturally is, that the efficiency of illuminants varies with the size, or watt consumption, in a different manner for different illuminants. Thus the efficiency of incandescent lamps remains approximately constant over a wide range of sizes, while that of arc lamps increases with increasing, and decreases with decreasing watt consumption. A smaller unit of arc lamp would therefore take a lower position, and a larger unit a higher position in the table.

As 300 watts and 500 watts are representative power consumption of medium and of large light units, in Table III and Table IV are given the efficiencies of available 300 and 500 watt illuminants, in order of their efficiency, from the lowest to the highest.

Table V then gives comparison of the watt consumption of the different types of illuminants required to produce respectively 200, 300, 400, 500 and 1000 available msph. c-p. The values in this table are also arranged in order from the lowest efficiency, that is, the highest watt consumption, to the highest efficiency, that is, lowest watt consumption.

Many interesting conclusions can be drawn from these tables.

For instance, in Table V, 400 c-p. seems about the dividing line between high efficiency and low efficiency illuminants: The a-c. and the d-c. arc and the mazda lamp do not go beyond 400 c-p., while the flame carbon arcs, the titanium lamp and the gas-filled mazda lamp do not go below 400 c-p., and can not be produced efficiently in smaller units.

### TABLE I. LIGHT SOURCES

| | RADIATOR | | Available Efficiency; Mean Sph. C-p. per Watt (Inclusive Reflector)* | LAMPS | | |
|---|---|---|---|---|---|---|
| | Specific Consumption Watts per Mean Sph. C-p. | Efficiency; Mean Sph. C-p. per Watt | | Mean Sph. C-p. per Watt | Mean Hemisph. C-p. per Watt | 10° C-p. per Watt |
| INCANDESCENT LAMPS | | | | | | |

* Loss by reflector assumed 20 per cent for incandescent, 22 per cent for arc lamps.

It is interesting to note that the 6.6 amp. a-c. series enclosed carbon arc lamp, which has done practically all street lighting of America for many years, and has done it fairly satisfactorily, and which is still today the most widely used street illuminant throughout the country, does not even reach 200 c-p., but, as seen from Table II, gives only 175 available msph. c-p. About 400 c-p., or more than twice as much, is the lowest c-p. at which the gas-filled mazda lamp can be efficiently built (300 watts), while the 300 watt 4 amp. magnetite arc, which has been most successful in replacing the carbon arc in street lighting, gives an available 300 c-p., and the lowest titanium arc unit, of 220 watts, gives about 400 c-p. From this, it seems that the smallest units at which these high efficiency illuminants can be built are the industrially most important ones in street illumination, and even these are rather larger candle-powers than necessary for general street illumination in towns and cities. There is a general desire for more light, but more still is the desire for cheaper lighting, and there is a much greater appreciation of getting a reasonable increase of illumination—50 to 100 per cent—at a reduced cost to the city, than there is of getting much more light at the same price; while even a very great increase of light, if accompanied by an increased cost, is rarely acceptable in street lighting, except in special cases of decorative lighting, of white way lighting, etc., and such special application naturally represents only a small part of the country's lighting. This is well illustrated by the experience of the arc lighting industry: when the arc lighting engineers became so interested in "large units" as to lose some interest in the low power high efficiency arcs and began to push the big luminous or flame arcs, the replacement of the 175 c-p. enclosed carbon arc by low power luminous arcs, which had been going on rapidly before, practically stopped, and the country turned to the mazda lamp, which offered lower power and therefore cheaper units.

Very interesting is the appearance, in the gas-filled mazda lamp, of the first incandescent lamp with an efficiency within the range of the modern arcs; as seen, more particularly in Table II, there is a considerable number of illuminants with efficiencies of one to one and a half candles per watt, which may be classed as "medium efficiency illuminants." The gas-filled mazda lamp falls in this group, between the different sizes and efficiencies of the magnetite arc; and cost of maintenance and replacement, quality or color of the light, etc., then become

**TABLE II. RELATIVE EFFICIENCY OF ILLUMINANTS**

**(Irrespective of Size, in Available Mean Sph. C-P. per Watt)**

| | Available Mean Sph. C-p. per Watt | (Street Lighting) 10° C-p. per Watt | Available Mean Sph. C-p. |
|---|---|---|---|
| 3.1 watt per h. c-p. carbon filament | 0.21 | 0.4 | Any |
| 2.5 watt per h. c-p. gem filament | 0.26 | 0.5 | Any |

| 480 watt 6.6 amp. series enclosed d-c. carbon arc | 0.62 | 1.0 | 300 |
| 1 watt per h. c-p. mazda lamp | 0.64 | 1.25 | Any |
| 500 watt d-c. "intensified" carbon arc | 0.78 | | |
| 4 amp. 300 watt d-c. standard magnetite arc | 1.0 | 2.2 | 300 |
| Neon Moore tube | 1.1 | | |
| 0.5 watt per h. c-p. gas-filled mazda lamp | 1.28 | 2.5 | above 350 |
| 4 amp. 300 watt d-c. special magnetite arc | 1.4 | 3.0 | (420) |
| 6.6 amp. 500 watt d-c. standard magnetite arc | 1.5 | 3.2 | 750 |
| Mercury lamp in glass tube, best values | 1.55 | | |
| 6.6 amp. 500 watt d-c. special magnetite arc | 1.7 | 3.6 | 850 |
| 220 watt a-c. titanium arc | 1.9 | 4.0 | 420 |
| 300 watt yellow flame arc, best values | 1.95 | 4.0 | [585] |
| 500 watt white flame arc, best values | 1.95 | 4.0 | [975] |
| Mercury lamp in quartz tube, best values | 2.0 | | |
| Experimental 350 watt a-c. titanium arc | 2.7 | 5.4 | (950) |
| Melting tungsten in vacuum | 2.88 | | |
| 500 watt yellow flame arc, best values | 3.1 | 6.2 | [1550] |
| Experimental 500 watt a-c. titanium arc | 3.6 | 7.0 | (1800) |
| Titanium arc, best values (high power) | 5.2 | | |

factors in the selection between these illuminants.

The group of illuminants below one candle per watt, comprising the various carbon arcs and vacuum incandescent lamps, is hardly of much further industrial value in street illumination, while on the other hand, in the yellow flame arc and in the titanium arc, efficiencies can be reached which no incandescent lamp can ever approach, and the latter illuminants, within their field of application, therefore still remain unrivaled in efficiency.

### TABLE III. EFFICIENCY OF 300 WATT ILLUMINANTS

| | Available Mean Sph. C-p. per Watt | Available Mean Sph. C-p. |
|---|---|---|
| Mazda lamp (1 watt per h. c-p.) | 0.64 | 190 |
| Standard 4 amp. d-c. magnetite arc | 1.0 | 300 |

# MODERN THEORIES OF LIGHT

By Dr. Saul Dushman

Research Laboratory, General Electric Company

Dr. Dushman starts his valuable contribution to this issue by giving a brief review of the more important work that has been done in the past in building up our modern theories of light. He then passes to a discussion of the laws of radiation, which deal with energy distribution, at any temperature, as a function of the wave length; the formulae of Raleigh, Wein and Plank being given and discussed at length. The author shows that some sort of quantum theory is absolutely necessary to explain experimental facts, and proceeds to show the application of such a theory. In his conclusion he quotes Professor Millikan to show that there is no reason why we should not be able to assign some such structure to ether as will help in explaining many of the hardest problems before the scientific world.—Editor.

## INTRODUCTION

Dr. S. Dushman

BEFORE entering upon the discussion of the latest views that are held by scientists regarding the nature of light, it may not be out of place to consider briefly the different stages in the evolution of a theory of light which marked the progress of science from the middle of the seventeenth century to within the last few years.

Newton was the first one to formulate a theory of light based on definite experimental facts. Reasoning from ordinary observations on shadows he developed the idea "that light consists of exceedingly minute particles shot out from a luminous body, and causing the sensation of sight when impinging on the retina." This was a genuine corpuscular theory of light. Its great merit consisted in giving a logical explanation of reflection and refraction. It left, however, unexplained an ever-increasing number of phenomena, such as the colors exhibited by thin films, polarization and diffraction.

In 1678, Huygens suggested the wave theory, but his ideas remained dormant until Young, early in the nineteenth century, used the theory to explain interference, while Fresnel, by assuming the transverse character of light waves, was able to explain the polarization of light. These advances established the wave theory of light on a sound experimental basis.

Finally, Maxwell in 1873 propounded the electro-magnetic theory. The great achievement of this theory consisted in correlating electro-magnetic and light phenomena by demonstrating that both kinds of effects are due to waves transmitted through a hypothetical medium, the ether; and that electro-magnetic and ordinary light waves differ only in respect to wave-lengths.

The conclusions foreseen by Maxwell were, as is well known, experimentally confirmed about fifteen years later by Hertz, who succeeded in reproducing with electro-magnetic waves all the phenomena exhibited by light waves; while subsequently to Hertz, Lebedew, and then Nichols and Hull, showed that light exerts a pressure which is equal to that calculated by Maxwell on the basis of his theory, and *half of that prophesied* on the basis of any corpuscular theory.

Long before this, it had been shown that the ordinary visible spectrum is only a small portion of a much larger spectrum which extends on both sides of that portion that affects us as light. Extending towards the region of shorter wave-length we have the ultra-violet and Schumann rays, while beyond the red end of the visible spectrum we have the infra-red radiations which are manifested by their heating effect.

The following table gives the wave lengths of the different groups of radiations as they have been determined by different observers:

| Radiation | Wave-Length in Cms. |
|---|---|
| Schumann waves | $10^{-5}$ to $2\times10^{-5}$ |
| Ultra-violet | $2\times10^{-5}$ to $4\times10^{-5}$ |
| Violet . | $4\times10^{-5}$ |
| Green . | $5\times10^{-5}$ |
| Red | $6\times10^{-5}$ to $7.5\times10^{-5}$ |
| Infra-red (heat waves) | $7.5\times10^{-5}$ to $6\times10^{-3}$ |
| Longest heat waves so far isolated | $6\times10^{-3}$ |
| Shortest electromagnetic waves . | $6\times10^{-1}$ |
| Electromagnetic waves used in wireless telegraphy . . . | $5\times10^{4}$ to $3\times10^{5}$ |

It is seen that the visible spectrum comprises barely one octave of a range of electromagnetic radiations which extend from $10^{-5}$ to $3 \times 10^5$ cms. and higher. These radiations differ only with regard to the detectors that are used to determine their presence, and show gradual variation in properties with progressive increase in wave-length. There exists, it is true, a rather large gap between the shortest electromagnetic waves and longest heat rays, but this is probably due, on the one hand, to the inherent difficulty encountered in making an oscillator of very small dimensions, and on the other hand, to the difficulty of isolating longer heat waves.

Up to twelve or thirteen years ago this essentially Maxwellian conception of light radiation had been found to be self-sufficient, and physicists in general had been assuring themselves that the great discoveries in science had been made and the last word had been said upon the mechanism of light radiation. All future work was to be merely in elaboration of Maxwell's fundamental equations.

But this self-complacency was not destined to endure very long. In 1901 Planck published a paper in which he showed that the ordinary electro-dynamical methods of dealing with radiation did not lead to results in agreement with experimental data on the relation between energy distribution and wave-length as obtained from the measurements on the spectra exhibited by heated bodies. The discussion thus started by Planck struck at the most fundamental concepts of the electromagnetic theory. But the revolutionary effect of Planck's work did not cease there; it was found subsequently by Einstein, Nernst, and others, that similar considerations had to be applied to explain rapidly accumulating observations in other fields of physics. It was found that an absolutely continuous emission and absorption of radiant energy, such as was assumed by Maxwell is incompatible with the newer discoveries. Here then we have the origin of an atomic structure of energy, of the theory of light quanta, which has been the subject of so much discussion in recent years. It has been thought that a consideration of some of the experimental data leading to a quantum theory of radiation and a brief exposition of various other phenomena that have lent additional importance to this theory might not be uninteresting.

## RADIATION LAWS

If a solid or liquid is heated to a high enough temperature it emits light. This light may be resolved into a continuous spectrum and the distribution of radiant energy with wave-length measured by means of an instrument like the bolometer.* It is found that the curve giving the relation between intensity of radiant energy and wave length depends in general upon the nature of the body and also on the temperature to which the body is heated. But it has also been deduced theoretically and shown to be true, experimentally, that under certain conditions the thermal radiation emitted by a body is a function of the temperature only and independent of the material used as radiator. Balfour Stewart and Kirchhoff independently arrived at the conclusion that the radiation within a uniformly heated enclosure depends on the temperature of the enclosure and on nothing else. A body having the characteristics of such an enclosure would completely absorb all the radiation falling on it. Kirchhoff was thus led to the conception of what he termed a "black body" or full radiator, since every other material would absorb, and therefore emit, at any given temperature less energy than a "black body." No substance is known which is a perfect "black body" in this sense, although some materials such as lamp-black approach it quite closely, while platinum and white oxides depart to quite an extent from black body radiation. But, as was pointed out by Kirchhoff, it is perfectly possible to determine the laws of such radiation by using the radiation emitted from an enclosed space that is maintained at a uniform temperature.

Such experiments were carried out during the years 1897–1901 by Lummer and Pringsheim. They measured not only the variation in the total amount of radiant energy with the temperature, but also the variation in distribution of energy, at a given temperature, with the wave-length. Their results are shown in Fig. 1 where the ordinates are intensities, or emissive powers (which are proportional), and the abscissae are wave-lengths.†

As the temperature of a full radiator rises it first gives out heat waves only. When the temperature exceeds 600 deg. C., the radiations below 0.76 $\mu$ become intense enough to affect the retina of the eye. As the tempera-

---

* A good description of this instrument as originally devised by Langley and subsequently improved by Lummer and Kurlbaum is given in Preston's Theory of Heat, Chapter VI.

† 1 $\mu = 10^{-4}$ cm. The visible spectrum is comprised between the values 0.4 $\mu$ and 0.76 $\mu$.

ture increases still more the body is said to vary from a dull red heat through cherry red, and orange, up to a bright white heat. This occurs at about 1500 deg. C. It will be noted that by far the largest portion of the spectrum is found in the infra-red region; but, as the temperature is increased the position of the wave-length at which the maximum emissivity occurs shifts towards the region of shorter wave-lengths. This is the cause of the gradual change in color of the body from red to white.

These experiments also confirmed some mathematical relations which had been deduced from the electromagnetic theory of light. In Fig. 1, the area contained between any curve and the $\mu$-axis is proportional to the total amount of radiant energy emitted by a full radiator at the corresponding temperature. If $E_\lambda$ denote the energy comprised between wave-lengths $\lambda$ and $\lambda + d\lambda$, then $E$, the total amount of energy emitted, is given by the relation

[*] $$E = \int_0^\infty E_\lambda \, d\lambda \tag{1}$$

About 1879, Stefan concluded from certain measurements of Tyndall that $E$ varies as the fourth power of the absolute temperature. This law was subsequently deduced by Boltzmann from thermodynamic consideration on the basis of the electromagnetic theory of light. The measurements of Lummer and Pringsheim, as well as later determination, have led to the following expression for the *Stefan-Boltzmann radiation law:*

$$E = 5.6 \times 10^{-5} \, (T^4 - T_0^4) \tag{2}$$

where $E$ is expressed in (ergs cm.$^2$) per sec.

If $E$ is denoted in watts per cm.$^2$,

$$E = 5.6 \times 10^{-12} \, (T^4 - T_0^4) \tag{2a}$$

In this equation $T$ denotes the temperature (absolute degrees Centigrade) of the radiator, and $T_0$ the temperature of the body receiving radiations.

A further advance in the theoretical treatment of this subject was made by Wien. "Starting with the well-grounded assumptions that (1) according to the electromagnetic theory the pressure of the radiation was equal to the energy in unit volume, (2) that the second law of thermodynamics, and (3) that Doppler's principle were applicable, and by postulating the existence of walls, enclosing radiant energy, that were completely black and others that were completely reflecting and diffusing, Wien was led to the conclusion that when the temperature increases, the wave length of every monochromatic radiation diminishes in such a way that the product of the temperature and the wave length is a constant,[†]" i.e.,

$$\lambda \, T = \lambda_0 \, T_0.$$

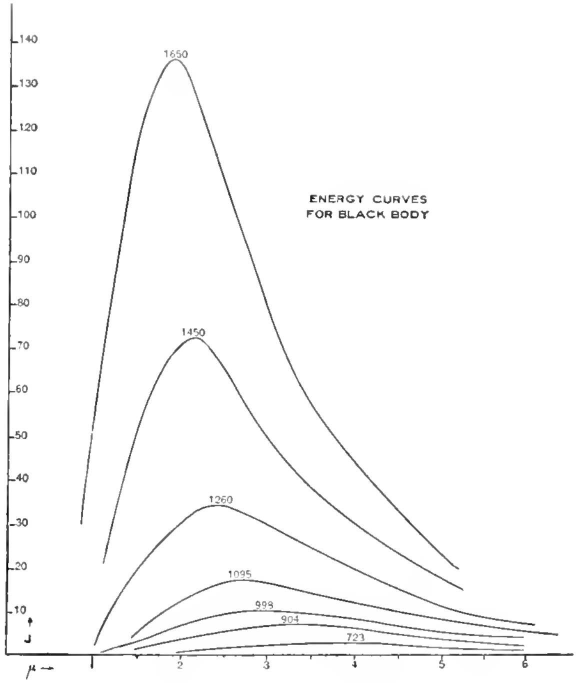

**Fig. 1.** Energy Distribution in Black Body Radiation

Hence for the wave-length of maximum energy, $\lambda_m$

$$\lambda_m T = \text{const.} \equiv A \tag{3}$$

Combining this with the Stefan-Boltzmann relation, Wien was led to the other relation that

$$E_{max.} \; T^{-5} = \text{const.} \equiv B \tag{4}$$

where $E_{max.}$ denotes the energy corresponding to the wave-length $\lambda_m$ and $T$ is the absolute temperature of the radiator.

Equation (3) is also known as the "*displacement law.*" Careful measurements have shown that the value of the constant $A$ is 0.29 (very closely) where $\lambda$ is measured in cms. and $T$ in absolute degrees centigrade, while $B$ is about $2190 \times 10^{-17}$.

Neither of these laws gives us any information, however, about the actual distribution of energy at any temperature as a function of the wave-length. In the notation of

---

[*] $E_\lambda$ is therefore the derivative of $E$ with respect to $\lambda$. Similarly $E_\nu$ may be designated the derivative of $E$ with respect to $\nu$, where $\nu$ denotes the frequency of radiation.

[†] Optical Pyrometry—Waidner & Burgess.

mathematics, it still remained an open question as to the nature of the function $f$ in the relation $E_\lambda = f(\lambda, T)$ that could most closely represent the experimental data.

### FORMULAE FOR THE LAW OF DISTRIBUTION

Three solutions have been suggested and each is of extreme importance. The first is that of Rayleigh:

$$E_\lambda = ck\,T\,\lambda^{-4} \tag{5}$$

The second is that of Wien

$$E_\lambda = c^2 h\,\lambda^{-5}\,e^{\frac{-ch}{k\lambda T}} \tag{6}$$

while the third is that of Planck

$$E_\lambda = c^2 h\,\lambda^{-5}\,\frac{1}{e^{\frac{ch}{k\lambda T}} - 1} \tag{7}$$

Written in terms of the frequency $\nu$, instead of the wave-length $\lambda$, these equations become

$$E_\nu = c^{-2}\nu^2 kT \qquad \text{(Rayleigh)} \tag{5a}$$

$$E_\nu = c^{-2}h\nu^3\,e^{\frac{-h\nu}{kT}} \qquad \text{(Wien)} \tag{6a}$$

$$E_\nu = c^{-2}h\nu^3\,\frac{1}{e^{\frac{h\nu}{kT}} - 1} \qquad \text{(Planck)} \tag{7a}$$

In these formulae, $c$ denotes the velocity of light, and $k$ and $h$ are universal constants, while $e$ denotes the base of the natural system of logarithms. The products $c^2h$ and $ch/k$ are usually denoted by $c_1$ and $c_2$ respectively, so that $k = \frac{c_1}{c_2 c}$ while $h = \frac{c_1}{c^2}$.

The actual measurements of Lummer and Pringsheim and others show that of these three formulae, that of Planck is the only one that is valid over the whole range of the spectrum.

Wien's equation is applicable only at low values of $\lambda T$, while Rayleigh's equation fits the experiments only at high values of $\lambda T$. Other formulae have been suggested from time to time, but the above three are the only ones that are important. The equations of Rayleigh and Wien were deduced by perfectly logical arguments from the fundamental principles of dynamics; the equation of Planck was derived by making assumptions that are in absolute contradiction with these fundamental principles. The fact that the latter formula agrees with the experimental results while the equations of Rayleigh and Wien do not agree would be startling enough in itself without its further bearing on other physical phenomena. But the theory of Planck becomes of vast importance because it leads to a new conception of the mechanism by which light energy is transmitted. Now what about the considerations which have led to these different formulae?

It is obvious that the radiation emitted by a perfect radiator may be regarded from two points of view: Firstly, it may be considered as a body at *constant temperature*, to which, therefore, the considerations used in ordinary thermodynamics must be immediately applicable. Secondly, regarded as a source of electromagnetic waves, it ought to be possible to apply to these radiations the equations derived from the fundamental principles of electrodynamics. When the conclusions based on these kinds of arguments are combined, the results ought to be formula which express $E$ as a function of $\lambda$ and $T$.

### PRINCIPLE OF EQUI-PARTITION OF ENERGY

Now let us consider the manner in which the energy of a system and its temperature are related. The kinetic theory shows that in the case of gases such a relation may be arrived at by purely dynamical methods.

If $N$ denote the number of molecules in a gram-molar weight of a gas; $V$ the volume at pressure $P$ and temp. $T$, then

$$PV = RT = NkT \tag{8}$$

where $R$ and $k$ are universal constants.

The values of these constants according to the most recent determinations (Millikan, Phys. Rev. 2, 147, 1913) are as follows:

$N = 6.06 \times 10^{22}$ molecules per gram-molecule
$k = 1.37 \times 10^{-16}$ ergs per degree.
$R = 8.30 \times 10^{7}$ ergs per gram-molecule per degree,
$= 1.99$ calories per gram-molecule per degree.

Furthermore, the average kinetic energy $K$ of the $N$ molecules is calculated as

$$K = \frac{3}{2}\,RT = \frac{3}{2}\,NkT = 3\,T \text{ calories} \tag{9}$$

Thus, the average kinetic energy of each molecule is $\frac{1}{2}kT$ for each of the three directions in which it can move, or the average kinetic energy of a gram-molecule is $T$ calories for each of the three "degrees of movability."

If, now, the only effect of an increase in temperature on a mass of gas maintained at constant volume is to increase the kinetic energy of agitation of the molecules, then the heat capacity at constant volume per gram-molecule ought to be $\frac{3}{2}$ $R$; that is, 2.98 calories. This is actually found to be the case for monatomic gases, that is, those in which the molecules consist of individual atoms. The conclusion is therefore drawn that any rotational energy which molecules may possess adds nothing to the total amount of kinetic energy, which is important in the consideration of the specific heat of gases.

In the case of diatomic gases, Boltzmann considered the molecule as having a dumb-bell sort of structure. Such a molecule may be assumed to have five degrees of movability; for not only can the molecule as a whole move in three different directions, but the atoms within the molecule can rotate in two directions which are at right angles to the axis of the dumb-bell. If the average kinetic energy of the molecule is $^1{}_2kT$ for each degree of movability, more generally known as degree of freedom, the heat capacity per gram-molecule of a diatomic gas ought to be $\frac{5}{2}$ $R$. This deduction was again found to be in agreement with experimental data.

But not only was Boltzmann able in this manner to calculate the specific heats of gases; he also applied the same considerations to solids and thus arrived at an explanation of the Dulong and Petit law. According to this law the product of specific heat and atomic weight in the case of elements in the solid state is a constant which has a value of about 6 calories. This law had been derived empirically at the beginning of the nineteenth century; but until Boltzmann enunciated his theory, there appeared to be no reasonable explanation of such a relation. His argument was to this effect:

Consider an elementary substance in the solid state in equilibrium with its vapor. Assume for the sake of simplicity that the vapor is monatomic. We know that this is actually true in the case of metals like mercury, zinc and cadmium, whose densities in the vapor state have been measured. Now the energy of the atom in the solid state must depend upon the vibration of this atom about a position of equilibrium. It also follows from the fundamental principles of dynamics that in the case of any such source of periodic vibrations, an oscillator, the average kinetic energy is equal to the average potential energy. But from fundamental dynamical considerations it is evident that the only conditions under which thermal equilibrium can exist between the atoms in the solid phase and those in the gaseous is that the average kinetic energy of the atom in each state should be the same, and since the average energy of an atom in the gas is $\frac{3}{2}$ $kT$, it follows that the total energy per atom in the solid is $3kT$, or $3RT$ per gram atom. Consequently the atomic heat must be $3R$, that is 5.96 calories.

Boltzmann embodied these conclusions in a general law which he together with Maxwell deduced from fundamental dynamical considerations. This law is known as the *principle of equi-partition of energy*, and states that for any system in equilibrium the total energy is divided equally among the different degrees of freedom of the system. The number of degrees of freedom corresponds to the total number of terms required to define exactly the state of the system at any instant. Thus in the case of a monatomic gas, the molecule possesses three degrees of freedom, since its velocities in each of three directions must be known in order to define its energy at any instant. Similarly a diatomic molecule may be said to possess five degrees of freedom because it requires three terms to express its position in space and two other terms to express the position of each atom with reference to the center of equilibrium of the molecule.

To sum up the above discussion it is concluded from the fundamental principles of ordinary dynamics that in any system at equilibrium, the average energy is $^1{}_2kT$ for each degree of freedom. This therefore answers the question as to the relation between energy and temperature.

### RAYLEIGH'S FORMULA

Turning to the considerations of radiation as an electro-magnetic phenomenon, we may consider as Planck does, that the radiation is produced by means of linear oscillators, similar to those used in the production of Hertzian waves, which emit linear harmonic vibrations.*

The equations of electrodynamics lead to the following relation between the energy $U_\nu$ of the oscillator of frequency $\nu$ and the

---

* During the decade that has elapsed since Planck first enunciated his radiation theory, the rapidly growing experimental evidence in favor of the electron theory has led to the conclusion that the oscillators postulated by Planck probably have their physical counterparts in the atomic structures. According to the most recent speculations (N. Bohr, Phil. Mag., July, September, and November, 1913), the atom is assumed to consist of a positively charged nucleus of very small dimensions and one or more electrons describing closed orbits around the nucleus. Such a system would produce the effect of an oscillating charge and thus give rise to linear harmonic vibrations.

intensity $E_\nu$ of the radiation emitted (or absorbed) by it.

$$U_\nu = \frac{c^2}{\nu^2} E_\nu \qquad (10)$$

where $c$ denotes the velocity of light.

Now consider an enclosure surrounded by absolutely opaque walls and containing black body radiation of the same nature as that emitted by a body at the temperature $T$. The radiation emitted by the oscillators is in thermal equilibrium with the walls of the enclosure and any bodies contained in it. According to the principle of equi-partition of energy the average energy of each oscillator must be the same, that is, independent of the frequency, and equal to that of a body with two degrees of freedom. This is evident if one considers the oscillator from the electronic point of view as an electron rotating about a positive nucleus. To define the position of such an electron at any instant requires only two terms.

Consequently, the average energy of the oscillator must be

$$U_\nu = kT \qquad (11)$$

Combining (10) and (11) we obtain the Rayleigh equation

$$E_\nu = \frac{\nu^2}{c^2} kT \qquad (12)$$

In other words, the principle of equi-partition of energy leads to the conclusion that the intensity of the radiation at any temperature increases with the square of the frequency. Now this is evidently not in accord with the experiments of Lummer and Pringsheim as shown diagrammatically in Fig. 1. Actually the Rayleigh equation agrees with the experiments for low values of $\nu$, but instead of $E_\nu$ increasing indefinitely with increase in $\nu$ (as demanded by the above equation) the experiments show that $E_\nu$ passes through a maximum and then *decreases with further increase* in frequency.

The argument may be put in another form. The total energy emitted at any temperature $T$ is

$$E = \int^{\infty} E_\nu d\nu$$

Substituting for $E_\nu$ from equation (12) it is evident that at any temperature $E$ must be infinitely great. But we know from the experimental confirmation of the Stefan-Boltzmann law that such is not the case. Thus, whichever way we look at the matter, the principle of equi-paritition of energy when applied to black body radiation leads to values of $E$ that are only partly in accord with actual determination. The question therefore arises: Why should the agreement between Rayleigh's formula and experiment hold only for large values of $\lambda T$? The only assumption made in the above argument is that the principle of equi-partition of energy is always valid. Evidently the assumption is justified for a certain upper range of values of $\lambda T$ and not for lower values, and yet the principle of equi-partition of energy is as valid as the fundamental dynamical equations from which it was deduced by perfectly logical methods. Why then the disagreement?

### WIEN'S FORMULA

Mention has already been made of the Wien displacement law. Since the law agrees with experiment it is obvious that there is every justification for the validity of assumptions from which it was deduced. Carrying the argument still further, Wien showed that any distribution formula must be of the general form

$$E_\nu = \frac{\nu^3}{c^2} F\left(\frac{T}{\nu}\right) \qquad (13)$$

This, then, must be the general form which a distribution formula must satisfy in order to be in accord with the three following principles, for each of which there is every experimental evidence:

(1) The existence of radiation pressure whose magnitude is calculable from electrodynamic equations,

(2) The second law of thermodynamics,

(3) The Doppler principle of the change in wave-length of a ray with change in position of the source.

But the above equations still left undetermined the form of the function $F\left(\frac{T}{\nu}\right)$. Wien, therefore, made two additional assumptions, namely (1) that the velocities of gas molecules follow the Maxwell distribution law; and (2) that the frequency of the vibrations emitted by a molecule depends only on its temperature. He thus obtained a law of energy distribution of the form

$$E_\lambda = c_1 \lambda^{-5} e^{-\frac{c_2}{\lambda T}} \qquad (14)$$

or

$$E_\nu = \frac{\nu^3 c_1}{c^4} e^{\frac{-c_2 \nu}{cT}} \qquad (15)$$

This equation was found to be in accord with experiment only for low values of $\lambda T$. Thus it is applicable in the visible region of the spectrum at lower values of $T$; but gives too low values of $E_\nu$ in the infra-red region and at higher temperatures.

### PLANCK'S THEORY

The failure of both the Rayleigh and Wien equations to account for experimental data showed conclusively that ordinary methods were not applicable in attacking this problem. Since, however, the method of reasoning adopted in arriving at the Rayleigh equation was perfectly logical, the only conclusion to be drawn was that the fundamental principles upon which the argument was based are not of as general validity as supposed.

Now for a number of years a gradually increasing number of facts had led many physicists to question the general validity of the principle of equipartition of energy. For one thing, while the law of Dulong and Petit is pretty generally true, the number of exceptions to it had been accumulating during the past century. Thus it was known that carbon, boron, and silicon have atomic heats lower than 6; but it was also observed that the atomic heats of these elements increased with temperature, and at high enough temperatures they behave "normally." Furthermore, the molecular heats of some diatomic gases like chlorine and bromine are nearly a calorie too high even at ordinary temperatures, and they become even greater at higher temperatures.

To explain these facts it would be necessary to assume that the number of degrees of freedom of a carbon atom or chlorine molecule increases gradually with the temperature. But the Boltzmann concept leaves no room for such a transition stage. An atom or molecule must possess a certain integral number of degrees of freedom; a degree of movability in any definite manner is either absent or present. There can be *no gradual acquisition* by any body of a degree of freedom. The conception of integral degrees of freedom thus presents many difficulties. Furthermore, it has been shown above that in the realm of radiant phenomena similar difficulties are met with. The principle of equi-partition of energy can therefore not be of as general validity as hitherto assumed. But this principle was deduced from the fundamental laws of dynamics, and is therefore just as valid as the latter. Here then was a Gordianknot that appeared as difficult tountie as the one of classical fame. It remained for Planck to apply to this case a similar remedy.

Planck starts out with denying the general validity of the principle of equi-partition but makes use of the fundamental electrodynamical equations in deducing his radiation formula. Doubt may be cast upon the theory, therefore, because of its assumptions; but that the conclusions from his assumptions are in excellent accord with experiment is undeniable. Furthermore, the fact that his arguments have been successfully extended into regions undreamt of when the theory was enunciated gives the latter the most prominent place in contemporary physics.

Planck's theory of complete radiations contains three groups of assumptions: Firstly, he asumes that there exists in the enclosure linear oscillators similar to those used in the production of Hertzian waves but of molecular dimensions, so that the frequencies of the harmonic vibrations emitted by them are of the order of magnitude of those present in the radiation from a black body. As in the previous section, the relation between $E_\nu$, the intensity of the radiation of frequency $\nu$ and the mean energy of the oscillator, $U_\nu$ is

$$U_\nu = \frac{c^2}{\nu^2} E_\nu \tag{10}$$

If there are present in the enclosure $N$ oscillators of frequency $\nu$, each having a mean energy $U_\nu$, the total energy is $NU_\nu$.

Now, as we have seen above, the principle of equi-partition of energy would demand for each oscillator an average energy of $kT$, equation (11), and the combination of this with equation (10) leads to the Rayleigh equation. This equation would ascribe to each oscillator an average energy *greater* than that found experimentally. The fact, however, that the Rayleigh equation holds for large values of $T$ shows that the average energy approximates more and more to $kT$ as the temperature is increased.

This leads Planck to make the second of his assumptions: that an oscillator cannot take up energy continuously, but *discontinuously in multiples of a unit quantum* $\delta$. As the temperature increases, the value of this multiple, $n\delta$, approximates more and more nearly to $kT$. The problem therefore to be solved is this: What is the average energy of an oscillator when it can take up or give out only a definite fraction, $\frac{\delta}{kT}$ of this at any instant? The theory of probability leads to the relation.

$$U_\nu = \frac{\delta}{e^{\frac{\delta}{kT}} - 1} \tag{16}$$

Combining this with (10)

$$E_\nu = \frac{\nu^2}{c^2} \frac{\delta}{e^{\frac{\delta}{kT}} - 1} \qquad (17)$$

For $\delta = 0$, this equation becomes the same as the Rayleigh equation, as we would expect, since the theory of Planck differs from that of Rayleigh in the fact that the former assumes a discontinuous variation of energy in an oscillator, while Rayleigh assumes the variation to be continuous.

The similarity of equation (17) with Wien's formula leads to the third and last assumption made by Planck. He assumes that the unit quantum which the oscillator can emit or absorb is proportional to its frequency, $\nu$; that is,

$$\delta = h\,\nu$$

where $h$ is a universal constant.

Substituting $h\nu$ for $\delta$ in equation (17) leads to the Planck equation, which is the most satisfactory formula over the complete range of radiations: From the experimental values of the constants $c_1$ and $c_2$ in the Wien equation it is possible to calculate the value of $h$. As a result of very accurate experiments on the determination of the elementary electric charge, Prof. Millikan assigns to this constant a value of $6.62 \times 10^{-27}$ erg. sec.

The obvious weakness in this argument is the fact that while Planck denies validity to the principle of equi-partitions of energy and consequently the fundamental dynamical equations upon which this principle is based, he yet assumes the validity of the electrodynamical equations, which are also deduced from these fundamental equations.

The same difficulty arises when one tries to obtain a physical representation of Planck's theory. We know that a wave-theory of radiation is absolutely necessary to represent all the other phenomena exhibited by radiant energy; that furthermore the phenomena of static fields and alternating currents of high and low frequency show that the wave theory represents the facts accurately in these cases.

Nevertheless, the agreement between the Planck equation and the experimental results of Lummer and Pringsheim and others lead inevitably to the necessity of assuming that the emission and absorption of radiant energy occurs in multiples of a definite quantum,

We cannot do better than quote Prof. Millikan in this connection:

"Planck has appreciated fully from the beginning the above-mentioned weakness in the method of development of his equation, and within a year he has modified his statement of his theory in the endeavor to meet this objection. The theory as outlined above implies that, since energy is always contained in the oscillator in exact multiples of an energy unit, both the absorption and emission of energy by the oscillator must take place in units—that is discontinuously. Planck now assumes that emission alone takes place discontinuously, while the absorption process is continuous. At the instant at which a quantity of energy $h\,\nu$ has been absorbed, an oscillator has a chance of emitting the whole of its unit, a chance which, however, it does not necessarily take. If it in this way misses fire, it has no other chance until the absorbed energy has risen to $2h\nu$, when it has again the chance of throwing out its 2 whole units, but nothing less. If again it misses fire, its energy rises to $3h\nu$, $4h\nu$, etc. The ratio between the chance of not emitting when crossing a multiple of $h\nu$, and the chance of emitting, is assumed to be proportional to the intensity of the radiation which is falling upon the oscillator."

Einstein has termed the quantity of energy $h\nu$ a *light-quantum*. It is evident that "this view of light-emission and absorption requires a complete reversal of our conceptions of the structure of light." According to the view which has hitherto prevailed, the light from any source spreads out uniformly round the source and any recipient of energy can take up continuously that fraction of the total energy which falls on it. According to the newer concepts, the light is emitted discontinuously *in time*, in amounts which correspond to multiples of $h\nu$. We have here, therefore, a sort of *atomistic theory of energy*. How such a theory can be reconciled with the ordinary wave theory it is as yet impossible to state, but there is no doubt that a fusion of the two points of view must occur.

## FURTHER APPLICATIONS OF THE QUANTUM THEORY

That some sort of quantum theory is absolutely necessary is emphasized by the existence of a large number of phenomena that have been observed during the past decade, and the explanation of which is only possible, at least, at present, on the basis of some kind of quantum theory.

First of all we have the specific heat relations of different elementary substances at very low temperatures such as those of liquid hydrogen. It has been mentioned previously that some elements of low atomic weight such as carbon, boron and silicon, obey the Dulong and Petit law only at very much higher temperatures. Now Nernst and other investigators have observed that at sufficiently low temperatures all the elements begin to exhibit atomic heats lower than 6, and that as the temperature decreases the atomic heats decrease and tend to become equal to zero at the absolute zero. Furthermore, the lower the atomic weight the higher the temperature at which this low atomic heat begins to appear. What is the explanation of these facts?

According to Einstein the observations are quite in accordance with what one would expect by applying the arguments of Planck to atomic vibrators. There are good reasons for assuming that the longer heat waves emitted by solid bodies are due to vibrations of the atoms themselves. Now assume that an atomic vibrator can absorb and emit heat energy only in multiples of a unit quantum $h\nu$ where $\nu$ is the frequency of the vibrator. Since the atom can receive or emit at the maximum $3kT$ calories (as shown previously), it is evident from the analogy between the Planck oscillator and Einstein's vibrating atom that the average energy of an atom will be given by an equation of the form

$$U_\nu = \frac{3h\nu}{e^{\frac{h\nu}{kT}} - 1} \qquad (18)$$

The only difference between this equation and (16), outside of the substitution of $h\nu$ for $\delta$ in the latter is due to the fact that the linear oscillator considered in deriving equation (16) has only two degrees of freedom, while that considered above has six degrees of freedom.

The average energy per gram atom may be denoted by $W$ where

$$W = \frac{3h\nu N}{e^{\frac{h\nu}{kT}} - 1} = \frac{3R\frac{h\nu}{k}}{e^{\frac{h\nu}{kT}} - 1} \qquad (19)$$

At very high temperatures, where $T$ is large compared to $\frac{h\nu}{k}$, equation (19) becomes

$$W = 3\,RT = 6\,T \text{ calories.}$$

But this is the Dulong and Petit law, and it is seen that this law has the same validity in the realm of specific heats as the Rayleigh equation in that of black-body radiation.

Differentiating (19) we obtain the equation for the atomic heat at constant volume namely

$$\frac{dW}{dT} = 3R \frac{e^{\frac{h\nu}{kT}}\left(\frac{h\nu}{kT}\right)^2}{\left(e^{\frac{h\nu}{kT}} - 1\right)^2} \qquad (20)$$

Now the actual specific heat determinations of Nernst and of those working with him, are found to be in accord with the results that are to be expected from (20). The curves showing the variation in atomic heat with temperature are all of the type indicated by (20). It is true that with increased accuracy in the measurements it has been found necessary to modify the right-hand side of equation (20) by adding more terms corresponding to different values of $\nu$, but the general character of the results remains the same. The necessity for discarding the principle of equi-partition of energy and assuming that each atom can take up energy only in multiples of a definite quantum $h\nu$ is apparently essential for an understanding of the specific heat phenomena at low temperatures.

Another set of phenomena to which the quantum theory has been applied successfully is that comprised under the heading of photo-electric effect. For a long time it has been known that when ultra-violet light strikes a metal surface electrons are emitted from the latter with a speed which is independent of the intensity of illumination, but depends only upon the frequency of the incident (monochromatic) lights. The number of electrons emitted increases, however, with the intensity of the illuminating source. In the case of highly electro-positive metals like sodium and potassium light of even lower frequency than ultra-violet causes the emission of electrons.

On the basis of the quantum theory it is possible to deduce a relation between the frequency of the incident light and the velocity of the ejected electron.

Denote the initial velocity of the electron leaving the surface by $v$ and let $m$ be its mass. Let $P$ denote the work required to carry an electron through the surface of the metal. The energy for this emission must be obtained from the incident light, and on the basis of the quantum theory this must be equal to $h\nu$. Consequently

$$\tfrac{1}{2}\,mv^2 = h\nu - P \qquad (21)$$

Denoting by $V$ the potential difference through which the electron must pass to acquire a velocity $v$, and combining (21) with the relation,

$$V\epsilon = \tfrac{1}{2} mv^2, \qquad (22)$$

where $\epsilon$ denotes the charge on an electron, we obtain the relation

$$V = \frac{h\nu}{\epsilon} - \frac{P}{\epsilon} \qquad (23)$$

By measuring $V$ for different values of $\nu$, it is evidently possible to test this conclusion. In the actual experiments it is more convenient to determine the minimum positive potential which it is necessary to apply to the illuminated surface in order to cut down the electron emission to zero. Such measurements are difficult to obtain with any degree of accuracy, and it is only within this year that excellent experimental confirmation of equation (23) has been obtained. At the meeting of the American Physical Society held in Chicago, November 29, 1913, Prof. Millikan announced that he had obtained such confirmation over a large range of frequencies, the observed value of $h/\epsilon$ being within five per cent of that calculated from other data.

A phenomenon closely related to the photo-electric effect is the ejection of electrons from surfaces bombarded by X-rays, and it has been shown that in this case also the velocity of the emitted electrons is proportional to the potential difference between the electrodes of the tube which produces the rays, that is, the "harder" the X-rays, the greater the velocity of the emitted electrons. Assuming, therefore, that the X-ray transfers a quantum of energy from the electron bombarding the anode to the electron emitted from the surface upon which the X-ray impinges, it is possible to calculate the frequency of the latter.

The calculation is similar to that of the emission velocities of photo-electrons. We have

$$V\epsilon = h\nu = \frac{hc}{\lambda} \qquad (24)$$

as in equation (23). If $V = 40{,}000$ volts

$$^{*}\lambda = \frac{hc}{V\epsilon} = \frac{6.62\times10^{-27}\times3\times10^{10}}{4.774\times10^{-10}\times\dfrac{40{,}000}{300}} = 3\times10^{-9}\text{cm.}$$

This is the order of magnitude of the wave-lengths which have been obtained by measuring the diffraction patterns produced by letting X-rays pass through crystals.

There is a still further similarity between the emission of electrons by X-rays and by ultra-violet light. Besides the normal photo-electric effects mentioned above, there exists a selective photo-electric effect which is characterized by the fact that at a certain frequency of the incident illumination there is emitted an abnormal number of electrons. The frequency at which this maximum emission occurs is characteristic of the substance illuminated and decreases with decrease in atomic weight. Similarly there exists a selective X-ray effect, so that at a certain definite voltage in the exciting tube, corresponding to rays of a definite hardness, there occurs an abnormal emission of electrons from the surface upon which the X-rays impinge, and here also the frequency of X-rays required to produce this abnormal emission is nearly proportional to the atomic weight of the excited substance.

We find therefore *a complete parallelism between the phenomena exhibited by X-rays and ultra-violet light.* But while the lowest wave-length so far measured in the ultra-violet is about $10^{-5}$ cm., the above measurements show that hard X-rays are electromagnetic waves with wave-lengths of the order of magnitude of $3\times10^{-9}$ cm. To produce X-rays with a wave-length of $3\times10^{-6}$ cm. would require potentials of about 40 volts, and recent work has shown that even with voltages as low as this it is possible to obtain qualitative indication of the production of X-rays. In other words, there is a gradual transition from ultra-violet and Shumann rays, which have a wave length of $10^{-5}$ cm., to hard X-rays having a wave length of $10^{-9}$ cm., and finally to the gamma rays which are nothing else but extremely hard X-rays.

There is still another point to be observed in this connection. While the application of the quantum theory to radiation and specific heats suggests emission and absorption of energy that is discontinuous with respect *to time*, the observations on emission of electrons by X-rays and ultra-violet light lead to the conclusion that the discontinuity exists here with respect *to space*. In other words, in order to account for the fact that the X-ray carries over unimpaired the energy of the electron that produced it to another electron that is emitted by it, it is necessary to assume that the amount of energy represented by it keeps together as an entity or quantum throughout the different transformations. A corpuscular theory of X-rays such as originally suggested by Professor

---

* $\epsilon = 4.774\times10^{-10}$ electrostatic units, $h = 6.62\times10^{-27}$ erg. sec. and $c = 3\times10^{10}$ cm. To convert volts to electrostatic units it is necessary to divide by 300.

Bragg accounts for this fact very well; but such a theory is obviously not in accord with the diffraction experiments of Lane and the analogies exhibited by ultra-violet light and X-rays. To reconcile these apparently conflicting facts, it is necessary to assume for X-rays some form of "spotted-wave" theory, but as yet no physicist has dared to propose such a theory.

### CONCLUSION

We have attempted in the above remarks to show that in the case of at least four distinct lines of investigation the necessity has arisen for assuming an atomistic structure of energy in order to explain the purely experimental facts. In each case that has been considered, the same factor *h occurs* and the *unit quantity of energy*, *hν* plays a fundamental part. Whether this quantum represents a discontinuity in the rate of emission of energy as one class of investigators seems to think or whether it is more nearly in accord with a sort of corpuscular-wave theory is still a debatable question.

Regarding, therefore, the exact manner in which the electromagnetic wave theory of light will have to be modified in order to account for the above experimental results, there is as yet no agreement among the greatest living physicists to whom we look for guidance in such matters. The fact remains that while a wave theory is absolutely necessary in order to account for diffraction and interference phenomena, some sort of quantum theory is just as necessary in order to account for the laws of radiation, specific heat relations at low temperatures and the emission of electrons by X-rays and ultra-violet light That the two points of view are not absolutely incompatible seems to be the prevailing impression. As Prof. Millikan writes:

"I see no reason *a priori* for denying the possibility of assigning such a structure to the ether as will permit of a localization of radiant energy in space, or of its emission in exact multiples of something if necessary, without violating the laws of interference. That no one has yet been able to do this can scarcely be taken as a demonstration that it cannot be done. Fifty years ago we knew that such a thing as an atom existed, but we knew absolutely nothing about its structure, and it was customary to assume that it had none. Today, we know a great deal about the structure of the atom, but the position formerly occupied by it has been assumed by that thing which we call the ether. We know that there is a vehicle for the transmission of electro-magnetic energy, but we know nothing whatever about its structure, and it has been customary to assume that it has none. To deny the existence of this vehicle, which we have been in the habit of calling the ether, and to use the word "vacuum" to denote all the properties heretofore assigned to it by the experimentalists, namely, those of transmitting electro-magnetic disturbances, is a bit of sophistry in which he is little interested. We seem to be on the eve of learning something more about the properties of this vehicle, call it by what name you will, than we have known heretofore. Certainly there has never been a time when physics offered such task to its followers as now, nor ever a time when it needed more and better brains applied to these tasks."*

# THE SPECTROSCOPE

### By Professor Elihu Thomson

In leading up to the subject of spectrum analysis, with which the author is mainly concerned in this contribution, mention is made of the identical nature of all electromagnetic waves in the hypothetical ether; and that of this entire range only about one octave is visible to the human eye. Probable reasons are advanced for this narrow range of sensitiveness. Brief mention is made of the discovery by Newton of the solar spectrum, and of its further investigation by Fraunhofer, the discoverer of the dark lines therein which bear his name. The interpretation to be placed on the regular occurrence of these lines is given, and the great significance that attaches to them in many fields of investigation is outlined. In certain modifications of the spectroscope the degree of precision and care necessary in their construction, and the skill and patience required in their manipulation, are seldom equalled in any other line of human endeavor.—Editor.

Prof. Elihu Thomson

OUR vision depends upon the perception by the eye of a limited range of waves or wave lengths in the ether. These are the light waves. They are ether waves of the same general nature as the wave disturbances used in wireless transmission and particularly the Hertzian waves given out by an electric oscillator. Heat radiation is of the same nature, but of too low pitch to be visible. Ultra violet rays and Roentgen rays are similar, but in this case the pitch is too high; the waves are too short to affect the eye. They are all energy waves and are physically identical electro-magnetic waves in the ether such as Maxwell first studied.

The probable reason for our not being able to perceive by the eye, lower or coarser waves than the red and shorter or higher pitch waves than the violet in the spectrum, is that vision would not be helped but probably hindered by light waves of greater range, inasmuch as many white objects as now seen would be dark or black under the higher rays, and many transparent media such as glass would be opaque. This condition has been strongly emphasized by the experiments of Dr. R. W. Wood in photographing with invisible rays. Objects would be similarly false in their effect and therefore misinterpreted if waves lower than the red were visible. Besides, since ultra violet rays are absorbed by the tissues of the eye, such tissues being opaque to them, there could be no need of retinal sensitiveness to them. Acuity of perception of objects also, according to an optical law, is less with the lower red rays than with those higher in the spectrum, so that perception by rays lower than red would, if it existed, be actually detrimental to vision. While, therefore, electromagnetic waves identical in nature with visible waves, may be produced in frequencies from the lowest up to Hertzian waves of millions and billions per second, and while the series may extend up to low invisible heat waves and may pass through and beyond the visible rays, to the ultra violet and lastly to Roentgen rays, out of this enormous range of pitch of identical waves only about one octave is visible. Evolution has determined the range so visible as best suited to the needs of the organism. The light waves are simply those wave lengths of electric ether vibration—energy waves, heat waves, or Hertzian waves, if one chooses to so designate them, which in the slow process of evolution of the eye have been selected for vision, or to which sight has adapted itself as conducive to the most comprehensive, acute, and perfect delineation of the objects in nature around us and with which we are directly concerned. This visual range is from about 400 millions of millions frequency up to about double that figure. Investigations show that the velocity of light, about 186,000 miles per second, holds good from the lowest to the very highest pitch of these waves.

When the visible waves reach the eye, in all wave lengths from low red to violet, and in proper proportion as in sun light, the light perceived is white, i.e., we call it white, but the sensation of white is also produced by combination of waves in which are only a fraction of the whole range. The explanation would take us too far into the theories of color perception. Suffice it to say that our perception of objects by sight depends on varying intensities and combinations of wave lengths giving shades and color, shadows and high lights. The eye itself is unable to discover whether an object is red, for example, because it reflects, transmits, or diffuses red rays only, or whether it is red merely because of an absence of green in the light from the body. Most colored objects, lights or pigments, or dyes, owe their color to a complex mixture of waves. Any instrument which deals with the light waves of different pitch so that they can be noted separately or successively is a spectroscope. A spectroscope provided with means for measuring the separation of the colors, or the value of the wave lengths of the rays, is a spectrometer. A spectrograph is a spectroscope with a camera attachment, whereby the peculiarities of the spectrum may be recorded on a sensitive plate photographically. The spectra of stars not visible to the eye may thus be recorded if the exposure given to the plate is long enough.

When Sir Isaac Newton, in about 1670, received the beam of sunlight entering through a hole in the shutter in a darkened room, upon a prism of glass and noted that the white light was separated or analysed into a band or spectrum of colors on a screen beyond, he was indeed using a crude form of spectroscope to discover the composite nature of the sun's light. The spectrum he saw was, of course, very imperfect, as owing to the shape of the opening in the shutter the colors overlapped and were not pure. Later a narrow slit was used instead, and Fraunhofer, himself a skilled optician, using such a slit and a far more perfectly made prism than was available in Newton's time, made a fundamental discovery. This was in 1814, when on examining solar light the dark lines in the solar spectrum were for the first time seen. They are known as the Fraunhofer lines. At first only the more evident of these lines were noted at intervals in the range of colors where light appeared to be missing—gaps in an otherwise complete set of waves from red to violet.

The interpretation of these lines, of which there are many thousands, came later when they were identified in position with the bright lines of metallic vapors in flames. With this advance there was born the science of spectrum analysis, or spectroscopy.

It had long been known that various metallic salts and the metals themselves would color an alcohol or bunsen burner flame in a way characteristic of the substance; but in the hand of Herchel, Brewster and others the spectra of such flames were seen to be bright lines chiefly occupying definite positions in relation to one another and having the colors which belonged to the position in the spectrum where they were found. The radiation was thus seen to be selective. Colored solutions, such as dyes, were also investigated and here again were noted dark or absorption bands crossing the spectrum or covering a portion of its length, indicating the color of the solution to be due to the absence of certain wave lengths. These spectra are called absorption spectra. The yellow sodium lines, called the D lines, at first puzzled the investigators from their almost constant appearance. The problem was solved when it was recognized that the spectroscope would detect almost infinitesimal amounts of some metals, and that sodium was everywhere present.

The salt spray from the ocean, drying up, would leave an imperceptible speck of sodium chloride which would be easily detected in a flame before the slit of a spectroscope. The science of spectrum analysis grew out of the recognition of the exceeding delicacy of the method, so small were the quantities of chemical substances capable of detection. In the hands of Kirchoff and Bunsen the foundations of chemical analysis by examination of the light emitted by hot vapors was laid. One of the most important steps in this development was the recognition of the fact that the dark lines of Fraunhofer were a case of absorption by vapor of the light from the same substance which would produce bright lines in the same position if hot enough. In other words cooler vapor absorbs the same wave lengths of light that it emits when hot enough to be luminous. Thus the *dark* D lines in the solar spectrum are due to sodium in the outer layers of the sun's atmosphere, through which shines the intense white light of the body of the sun below, the sodium vapor absorbing the light and being, as it were, opaque to light of the particular wave length.

The Fraunhofer lines then are absorption lines in a spectrum due to the fact that the light-giving surface of the sun is surrounded by innumerable elements in a state of vapor, cooler than the lower layers of the sun and each absorbing waves of just those wave pitches as would be given out if they were vaporized in an arc or spark. Doubtless if an opaque screen could be inserted between these vapors and the intensely luminous solar body below them, they would then give out a bright line spectrum if hot enough. Indeed, the bright line spectrum can be noted at the edge of the sun when the luminous body of the sun is covered by the moon in a total solar eclipse.

Our space does not permit following the gradual improvements in the spectroscope as an instrument and its application to the many fields of research or industry. We may note the extended use now made of the instrument, particularly in the form of spectrographs in modern astronomy. By it the chemical constitution, state of condensation, and temperatures of the stars and nebulae are indicated. Our own star, the sun, has yielded a rich and continued harvest to the spectroscopist. The great storms or sun spots area of the sun are shown to involve the motion of heated gases at enormous speeds. The protuberances at the edge of the sun, or solar prominences, are shown to be due to enormous jets, or vast outbursts of incandescent hydrogen. Recently in the hands of Dr. G. E. Hale, the instrument has been made to yield not only a knowledge of the condition of the sun's outer atmosphere at various levels, but has enabled him to demonstrate that stupendous electric effects accompany sun spots—motion of great vortices of electrons, and the magnetic fields produced thereby—utilizing the recently discovered Zeeman effect, or the influence of strong magnetic fields on the spectral lines given out by incandescent vapors.

According to conditions discovered by Zeeman, lines that would be ordinarily single, are doubled, trebled and polarized, in accordance with the direction of the magnetic field with respect to the course of the light beam traversing it from the incandescent vapors subjected to the field.

The displacement of spectrum lines known as the Doppler effect tells us of motion of the most distant stars towards or from us and gives us the speed of each motion. It even discloses motion of companion stars which are so close to each other and so distant that they never can be seen separately. This is the great class of stars known as "spectroscopic binaries. The Doppler effect gives us knowledge of the rates of rotation of the sun and planets. The spectra given by the stars enables them to be separated into great classes, according to their apparent temperature, their composition and inferentially their age. We obtain an inkling of what goes on in those remarkable bodies, temporary stars which suddenly brighten, and afterward gradually fade away. Helium gas was first known to exist by the spectroscope. It was seen that certain gas lines, not due to any gas on the earth, were present in the solar spectrum. Recently this gas has been discovered in small amounts in certain minerals and is now known to be a product of radium in its disintegration. The name coronium is given to another supposed gas, probably the lightest of them all, which gives certain lines in the outer layers of the sun's corona, but of which there is hardly a suspicion of its existence on the earth.

Investigation by the spectroscope of the colors of substances is very valuable in determining their nature. The coloring matter of the animal fluids, such as the bile or the blood, the colors of plants, the various dyes, colors of solutions and of pigments are investigated by their absorption spectra, and much valuable assistance so obtained in their identification, and much light also thrown on their more intimate chemical constitution. Spectroscopic measures of refraction and dispersion of light, even by colorless bodies, assists greatly in an understanding of their composition and molecular arrangement. The spectroscope combined with a photometer enables true values of the luminous effects of different lights to be obtained regardless of color; as the intensities of the several colors are individually compared by photometric methods. Hence we have an instrument, the spectro-photometer, as a modification of the spectroscope.

In like manner, spectro-thermometry allows the temperature of radiating bodies to be determined from an examination of their spectra. It is found that the temperature of a hot body considered as black body radiation is connected directly by a simple law with the wave length emission at maximum intensity or maximum energy in the waves. In a red hot body this maximum is of course in the red. As the temperature of the body is raised its light becomes whiter owing to the gradual addition of the higher rays of the spectrum and their growing intensity relatively to the lower rays. Hence, the product of the absolute temperature by the wave length of the emitted rays of greatest energy tends to be a constant. For the very high temperatures of incandescent tungsten filaments, it is important to possess a means for estimating at convenience the temperature of the filament from the nature of the light emitted.

The outlook for the future knowledge to be gained as to the intimate constitution of the chemical atom, and the relations of the elements to one another, is very promising. And much of this advance is to be expected from spectroscopic study and data now being accumulated. Each element is, when radiating light, characterized by what at first appears to be almost a haphazard set of spectral lines without relation to one another.

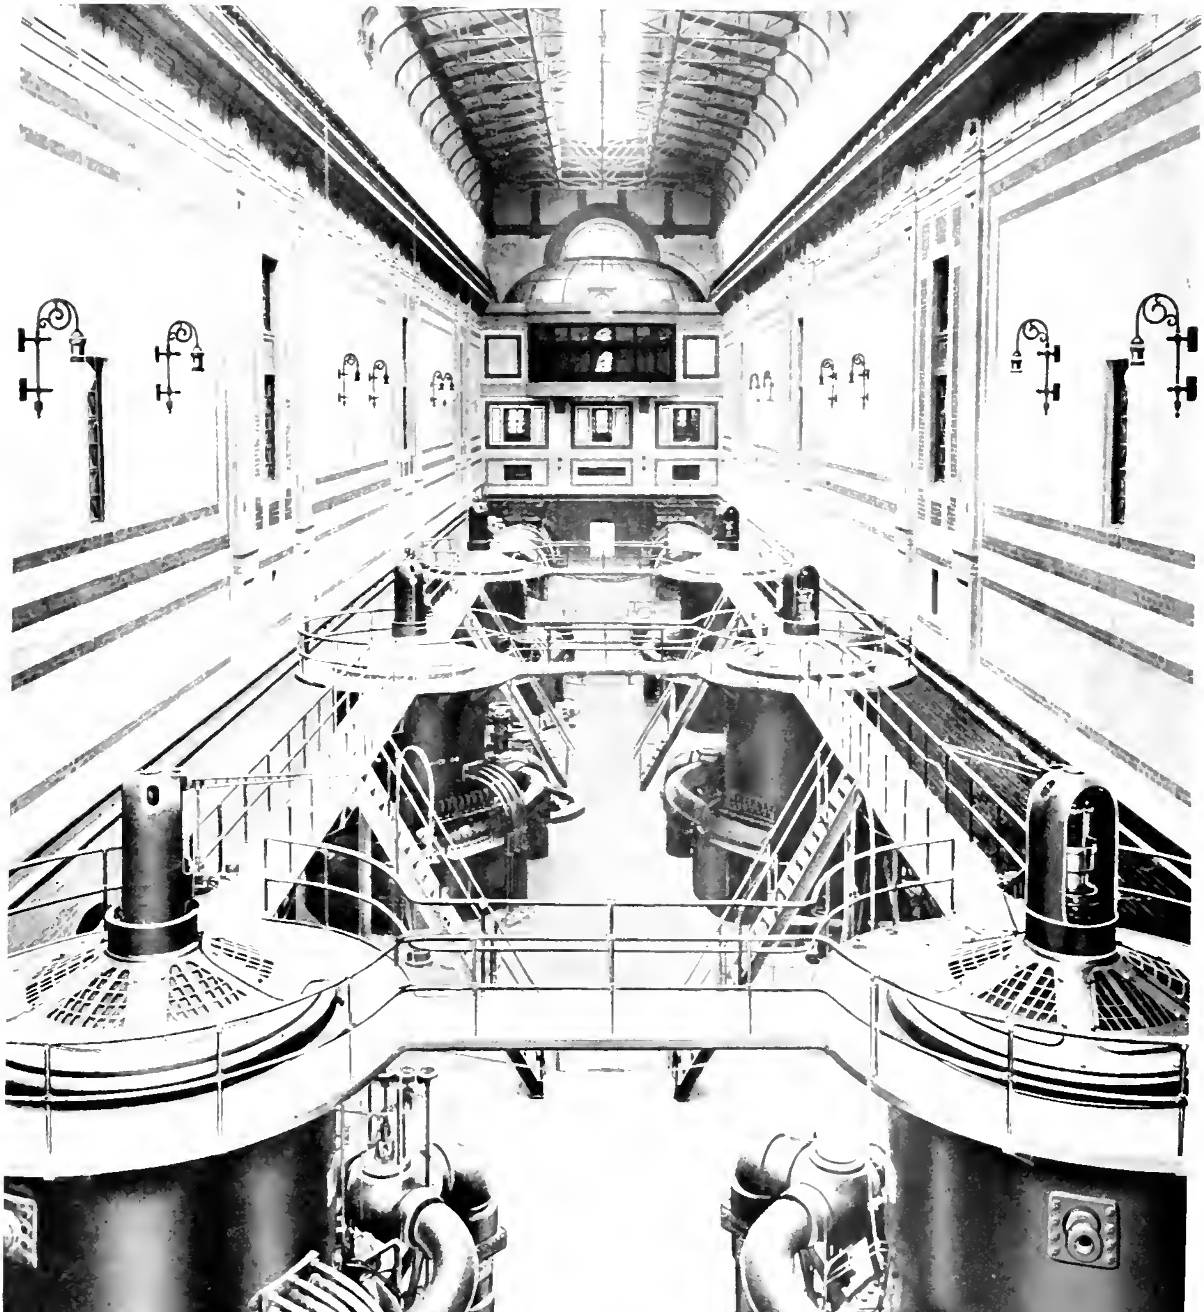
Recent work, however, discovers in them series related in wave lengths by mathematical laws and that the apparent haphazard character is probably only the result of our lack of knowledge of how to interpret our results. Doubtless, indeed, all the lines given out by an element are related according to some unknown laws and when these are discovered, we will at last possess an idea of the innate character of a so-called element and its relation to all the others. One difficulty is that the lines which appear in the visible spectrum are only a part of those which are present if we could as easily investigate the extension below the red, the infra-red region, and likewise could map the spectrum lines far beyond the violet end of the spectrum, as in the ultra violet. The field is so very large and the vastness of the already accumulated data such that progress must be slow or gradual.

The problems will be solved by persistent study, and perhaps by some great generalization the task will be simplified. Even the apparently simplest spectrum, such as that of hydrogen, when closely examined, is found to be quite complex. Furthermore, the spectrum emitted is largely governed by the conditions under which it is produced; temperature, pressure, electric state, etc.

Nevertheless, in the observation of spectra and the discovery of laws relating thereto lies the key to the structure of atoms, the number and orbits of electrons and other conditions.

The spectroscope is, however, so modern an instrument that it is remarkable how much has already been added to our knowledge by its use. All light from whatever source, including phosphoresence and fluorescence, come under its scrutiny. All media transmitting or in any way modifying light, such as the atmosphere, liquids, glass, minerals, color stuffs, dyes, pigments, are examined and yield valuable knowledge. Sometimes, the gain is in pure science or theoretical knowledge, or it may be highly practical, as in the study of glass for optical uses, or of colors for their identification.

The spectroscope, including the various forms of spectrometers and spectrographs, has many forms from the simple prism instruments commonly employed in the ordinary work, to the delicately ruled gratings of Rowland and the elaborately constructed interferometers and echelons of Michelson in which the resolving power or capacity to separate close lines in a spectrum is carried to the limit of possibility. For investigations of the Zeeman effect mentioned above the powers of these latter instruments are needed. They are based on the principle of optical interference, and their construction has demanded a degree of manipulative skill and care which is rarely to be found in any other human undertaking. The work of construction and adjustment of a small watch is ordinarily considered a delicate matter, but bears no comparison to the patience and skill, as well as extreme care required in the work of ruling a large grating for a diffraction spectroscope. Errors are forbidden and cannot be repaired. The work as a whole must be practically perfect or the instrument is useless. The manipulation of interferometers is a task of exceeding delicacy, demanding the highest skill and exhaustless patience.



WATERSIDE STATION No. 2, NEW YORK EDISON CO.

# THE CENTRAL STATION IDEA

By Joseph B. McCall

President, National Electric Light Association
and
President, Philadelphia Electric Company

It has been many years now since a centralized generation of power for a large district was first advocated by a few far-sighted engineers. In those days the plan was impracticable of execution, however, because of the insufficiently developed apparatus for the purpose. Now, with the enormously increased size of generating units having correspondingly higher efficiencies, and with the complementary high-voltage transformers and transmission lines, the day has arrived when the most economical means of securing power is to obtain it from a *central station*. This unified supply of power for a district from a single source briefly constitutes the "Central Station Idea." The following article, explaining this up-to-the-minute idea thoroughly, should be highly appreciated.—Editor.

J. B. McCall

GREAT ideas developed enthusiastically to a practical working basis are responsible for nearly all of the great modern business successes and now we have the *Central Station Idea.*

Although manufacturing development has been more or less "marking time," during the past twelve months, the *Central Station Idea* has been striding forward in "seven-league boots."

The *Central Station Idea*, the purchasing of power in large or small units from great, centrally-operated generating stations with numerous interconnected substations as opposed to the private plant is growing very fast in this country. This is a very good thing for the people as a whole, because the *Central Station Idea* was born of economy and fostered by efficiency; it is the very last word in economical and efficient power supply.

It is a great satisfaction to merchandise a product such as electricity, which is an actual benefit to the individual and the public at large, a commodity which is not merely desirable from the standpoint of the purchaser but which is also a mighty agency for producing the greater efficiency, the increased comfort and the better health of our nation. The magazine *Public Service* touched upon this subject in a very apt way not long ago:

"It is characteristic, perhaps, of the present day disposition to measure all success or achievement by the standard of dollars and cents, that in nearly every estimate of the vast advantages resulting from the use of electricity in the industries, the humanitarian side of the question has been either ignored entirely or dismissed with mention so slight as to be entirely out of proportion to its importance.

Without detracting in any way from the commercial value of electricity, as an agency in manufacture, it may be said from the standpoint of the world at large that its most beneficent influence has been wrought in improvement of labor conditions among the employees of the factories where it is used. Other causes, it is true, have contributed to these improved conditions, and much credit is due to the owners and managers of modern factories; but without the aid of electricity there would not have been the revolution in factory conditions that has been witnessed in the last few years.

In addition to these advantages from the labor standpoint, the public also gains greatly by the reduced prices of the cost of manufactured goods resulting from reduced cost of production through the use of electricity."

The development of the *Central Station Idea* has, of course, been an integral part of the development of the electrical industry which has made such wonderful strides during the present century. From an engineering standpoint, the art has developed to an extent almost beyond the dreams of even the technical mind. During the past thirteen years huge generating units have been produced, along with other pieces of apparatus, which show gratifying increases in efficiency; transmission problems have been overcome, permitting the carrying of great quantities of energy for long distances; consequent improvements in transforming and distributing devices over larger areas have taken place; a greater and more diversified use of the energy has been generated, whether in the nature of scientifically designed lighting installations for the smallest residence or the largest commercial building or for some unique and useful power application. The supplying of power for street railway purposes by the central station is becoming general practice, this being so because the diversity factors of the two branches of the industry permit the greater use of the dollar invested in generating apparatus, with consequent economies; and the era of the electrification of steam railways is at hand, the current for which should be, and probably will be, supplied by the central station, for the same reasons that apply to the street railway transportation.

The result of the development of this *Central Station Idea* shows a reduction in costs, a reduction in rates and an increase in income; greater, stronger and more staple business, attracting a constantly increasing class of investors. The advances and improvements have, however, not all been material in character. The industry, as a whole, has taken a livelier interest and has taken a different stand on all questions involving the welfare and safety of the employe, as shown by the incorporation of beneficial organizations, saving fund societies, service annuity benefits, etc., forming thereby a closer, stronger, more co-operative relation between the employer and employe, and effecting permanent organizations which will inevitably insure better service to the public.

The brief span of the present century has also witnessed the establishment of governmental regulation by state commissions, and the industry recognizes that such regulation, as to rates and service, coupled with protection to our business, permitting a reasonable profit for service and effort, is acceptable and desirable to all concerned, maintaining as should be the purpose of such legislation an equitable, fair and just consideration of the rights of both parties, the public and the corporation.

Recent figures show that the requirements for the electrical industry of the country, during the present year, will be over a million dollars a day and it is the feeling of financial men, who are charged with the responsibility of furnishing money for these requirements, that the securities of utility companies will be more desirable as investments under governmental regulation than they are without it, and that a larger and a wider market for these securities will be created wherever governmental regulation is found.

We have reason, therefore, to be very optimistic as to the future of the central station industry. We believe the time will come when, in every community, the *Central Station Idea* will be recognized as an economic fact, when there will be a central station source of supply for all electrical energy furnished for any purpose whatsoever, and it is not beyond probability that future years will see vast trunk lines transporting energy over many miles of territory and connecting large centers of population throughout the country.

# THE COMMERCIAL METERING OF ELECTRICAL ENERGY

By J. W. Lieb, Jr.

Vice-President, New York Edison Company

The accurate metering of all the energy generated by a central station, both that used by the operating company and that supplied to the individual consumer, is of fundamental importance to all operating companies. Mr. Lieb analyzes the essential features for a satisfactory metering system and discusses at length the most important items; the matters of testing and inspection of meters being dealt with in detail. The author shows how a good system of inspection can reduce the number of complaint tests, and gives figures showing what has been accomplished in this direction in the case of the New York Edison Company. It will be noted that the ratio of complaint tests to the total number of meters is astonishingly small, and is being still further reduced. The development of a meter testing force is among the other interesting subjects discussed in this able article.—Editor.

J. W. Lieb, Jr.

THE proper metering by the electricity supply company of the energy generated in its power stations, and delivered to its customers, is one of its most important functions. We shall endeavor to analyze the more important factors involved in the conduct of a typical metering system, without attempting on the one hand to cover the subject too broadly, or on the other hand entering into a discussion of innumerable minor details. Briefly, the important essentials of a good system of commercial metering are as follows:

(1) Metering accurately and completely all the energy generated, thus providing basic data for the operating and accounting systems.

(2) Metering accurately and completely all the energy consumed for company purposes on the system and in the substations.

(3) Metering accurately and completely the energy delivered to the consumer so that each shall receive a proper bill and the company receive its rightful revenue.

The importance of properly metering all generated energy and all energy used for the company's own service so as to provide proper operating and statistical data is obvious and does not require amplification. From the technical standpoint the metering of the energy in generating stations and substations does not ordinarily introduce any unusual or difficult problem which cannot be handled by an adequate system for taking care of the operation of meters on the customers' premises.

The third requirement considers the metering of all of the energy delivered to the customer and involves many factors to which it will be necessary to refer in some detail. Some of the more important elements to be considered in the operation of a meter department are:

The selection of the proper types of meters and their approval by the regulating authority.

Assignment of the proper type and capacity of meter to the individual installation.

A proper system of tests and inspections.
Inspection on installation.
Periodic tests.
Inspection to detect tampering.
Office test.
Consumers complaint test.
Public Service Commission complaint tests.
Methods of settlement of complaints.
Standards.
Organization of Department.
Record and statistics.

The determination of the acceptability of any new type of meter has been greatly simplified by the establishment of the Code for Electricity Meters. The code was issued jointly by the meter committees of the National Electric Light Association and the Association of Edison Electric Illuminating Companies, the membership of these two committees, from the standpoint of central station service, representing the large majority of meters in service in the country. The specifications of the code have been approved by the leading manufacturers of meters, and it has come to be regarded as a generally acceptable set of specifications for watthour meters by the manufacturers and users, and it serves as a criterion by which any manufacturer can evaluate his own product and judge of the acceptability of a new design of meter before it is formally presented for adoption. Recent rules and regulations of public service commissions have freely embodied wholly or in part the specifications of the code, notably the rules of both the First and Second District Commissions of the State of New York.

The assignment of the meter to any consumer's installation, whether done by the contract agent or representative of a service department, should be in accordance with definite rules, often somewhat empirical in their provisions, but carefully prepared by the company's meter engineer who is familiar with the performance characteristics of the types of meters used and the local characteristics of the services and installations. Such rules usually assign meters of a capacity equivalent to 100 per cent of the total connected installation for such service as window lighting, signs, air compressors, and for emergency or construction service, in order to protect the meter against overloads. Correspondingly, the rules usually assign meters of a capacity of 50 per cent or even less of the total connected installation equivalent for apartment or detached residence lighting, the contemporaneous use of the total installation in such cases being infrequent and of short duration. Between the 100 and 50 per cent classes of meter assignment there will be of course various intermediate classes depending on the nature of the installation and the service.

In Fig. 1 is shown a comparison of the meter assignment rules of an electricity supply company, the "normal" load test of the meter in terms of the connected installation prescribed for meter tests by one public service commission, and the "active" meter load as specified by another public service commission.

The initial test of any meter on the part of the electricity supply company is the laboratory test. This test is quite distinct from the investigations conducted to determine originally the acceptability of a type, but is a test of each individual meter to determine its acceptance or rejection as received from the manufacturer. The test follows a closely maintained routine of, (1) comparison of meter accuracy with standard instruments; (2) measuring the adjustment ranges, magnet and compensators; (3) phase to phase relations in the case of inductive loads; (4) determination of current and potential transformer ratios, and shunt resistance, where such apparatus is auxiliary to the meter; (5) finally the inspection of the mechanical construction of the meter and the gear train to check the constants and gear ratios.

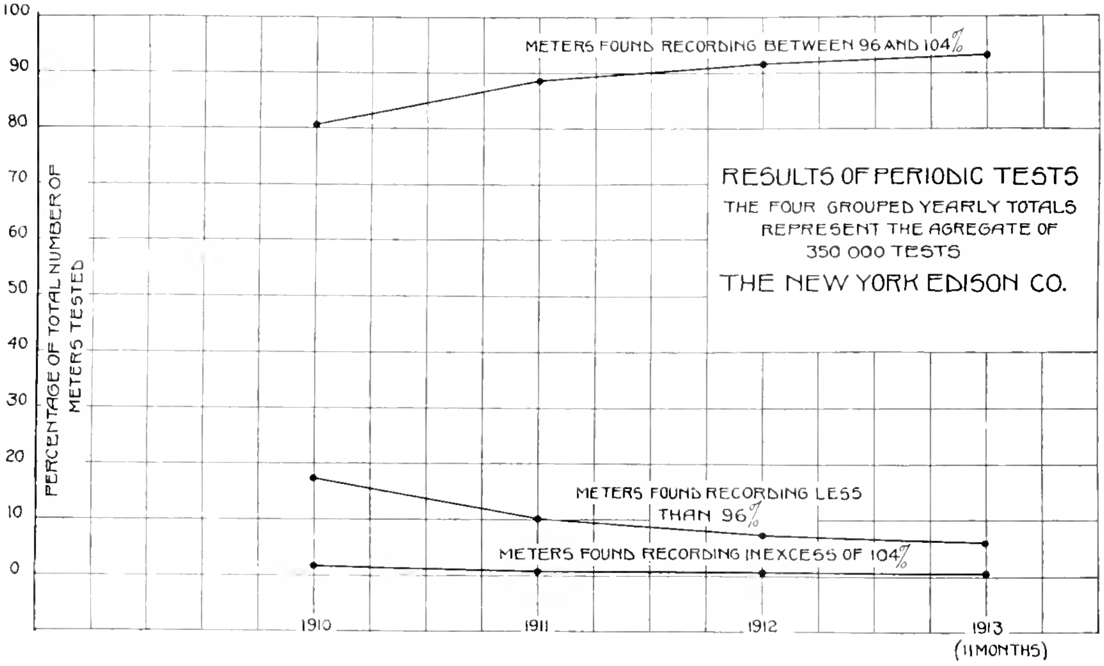


Fig. 1

With the completion of the meter installation in the customers' premises and usually within forty-eight hours thereafter a meter man should inspect and approve the work of the wiring or installation department, if the latter includes in its work also the setting of the meter. This inspection is to insure that the meter is in good operating condition, properly connected, and that the location is such as to insure the best possible metering conditions. In no sense is this inspection an accuracy check, although at this time such a test may be ordered at the discretion of the inspector. The detailed inspection immediately after installation includes the following:

(1) The examination of the general conditions of location that could affect the operation of the meter or affect the permanence of its calibration, i.e., excessive vibration, dust of any character, chemical fumes, dampness, proximity to stray fields or abnormally high or low temperatures.

(2) The setting and installation are inspected to prevent the placing in service of meters, their setting out of alignment, insecure fastening, incorrect connection or insufficient provision for future testing. At this time the possibility of the consumers, being able to divert unmetered current should also be covered by the inspection.

(3) The translating devices and their use in connection with the capacity and type of each meter are considered and the assignment of the meter as installed for the service approved or ordered changed.

(4) Notification to the accounting department as soon as the meter has been installed and connected with detailed information for placing the meter on the meter indexer's binder.

A proper system of service tests means primarily some basic schedule for periodic testing which constitutes the bulk of the work of the meter department. The periodic testing schedule of the public service commission of the First District of the State of New York is quoted in full below and is advanced as a typical example:

> "All direct-current meters installed upon consumers' premises shall be periodically tested according to the following schedule:
>
> Meters up to and including 25 amperes rated capacity shall be tested at least once in every 18 months;
>
> Meters exceeding 25 amperes up to and including 500 amperes rated capacity shall be tested at least once in every 12 months;
>
> Meters exceeding 500 amperes rated capacity shall be tested at least once in every 6 months.
>
> All types of alternating current induction meters shall be periodically tested as follows:
>
> Single-phase meters up to and including 25 amperes rated capacity shall be tested at least once in every 30 months;
>
> Single-phase meters exceeding 25 amperes rated capacity shall be tested at least once in every 24 months;
>
> Polyphase meters up to and including 150 amperes rated capacity shall be tested at least once in every 24 months;
>
> Polyphase meters exceeding 150 amperes rated capacity shall be tested at least once in every 12 months."

Supplementing a routine testing schedule such as the above, there may be special groups of meters tested at shorter intervals because an intimate knowledge of local conditions makes more frequent tests advisable, such, for instance, as meters set for emergency, temporary, or construction work. In many localities these constitute an appreciable and important group of meters measuring a considerable revenue, subject to severe and varying conditions and in service for limited periods. Meters for any class of service and of any capacity which from the records of the billing department show for continued periods a registration considerably higher than the average meter of the same capacity, can profitably be tested at shorter periods than those specified in the ordinary schedule of periodic tests.

Another group of meters which it is advisable to test at intervals shorter than those prescribed by the routine schedule of tests consists of meters whose monthly registration would raise a suspicion of tampering on the part of the consumer. An abnormal or sudden variation in consumption may be indicative of tampering and still not serve as a basis for legal procedure. Disregarding the legal aspects of the matter, however, the tampering may be such as to cause the meter to under-record, obviously reducing the consumer's bill, or to intentionally over-record so that the complaint test—which is even in such cases often insisted upon by the consumer—may show a fast meter, establishing an improper claim for a false rebate. This fake rebate claim might be for a part or all of the elapsed period back to the last previous test. With a meter in either condition, it is evident that frequent tests break up into short periods the time over which loss would occur from a slow meter and reduce the period for which an improper rebate might be claimed.

The foregoing paragraph leads naturally to the consideration of methods for detecting tampering. The obvious ones are, first, a periodic inspection survey of all meters and services. This method is, for a large system, expensive and likely to prove ineffectual. Second, all employees requiring access to services should be instructed to note and report immediately any evidence of tampering. Such inspections are infrequent and are not instigated by reasons having to do directly with tampering, so that this method is not complete. The third and most logical method of attacking the evil is through the constantly recurring weekly or monthly records of consumption handled by the meter indexers and bookkeepers. The bookkeepers should be instructed to watch carefully the monthly consumption and report any sudden or abnormal variation, any variation from normal may mean high or low or backward registration, or lack of registration. The report should take the form of a request for a careful inspection of the meter by a trained meter man. These inspections will result in repairs to damaged meters, the elimination of non-recording meters, and the correction of conditions which facilitate tampering, and the continued surveillance of premises where chronic tampering is likely to be practiced.

It is possible, of course, that many inspections thus called for by irregularities in the record noted by the bookkeeper may be due to perfectly natural and legitimate causes. Speaking for one large lighting system, however, it can be stated that these inspections and checks are justified by the irregular conditions frequently discovered and corrected, and the expense is amply warranted by the stoppage of losses.

These inquiry inspections just described form in themselves the source for a large number of tests known as office tests, a term defined by the First District Public Service Commission as follows:

> "An office meter test is a test of an electric meter by an electric corporation upon the premises where the meter is installed, by the direction of the corporation itself, of an officer or of an employee, that a special test be made."

A third but most essential single group of meter tests is composed of the complaint tests. The nature, volume and trend of these tests

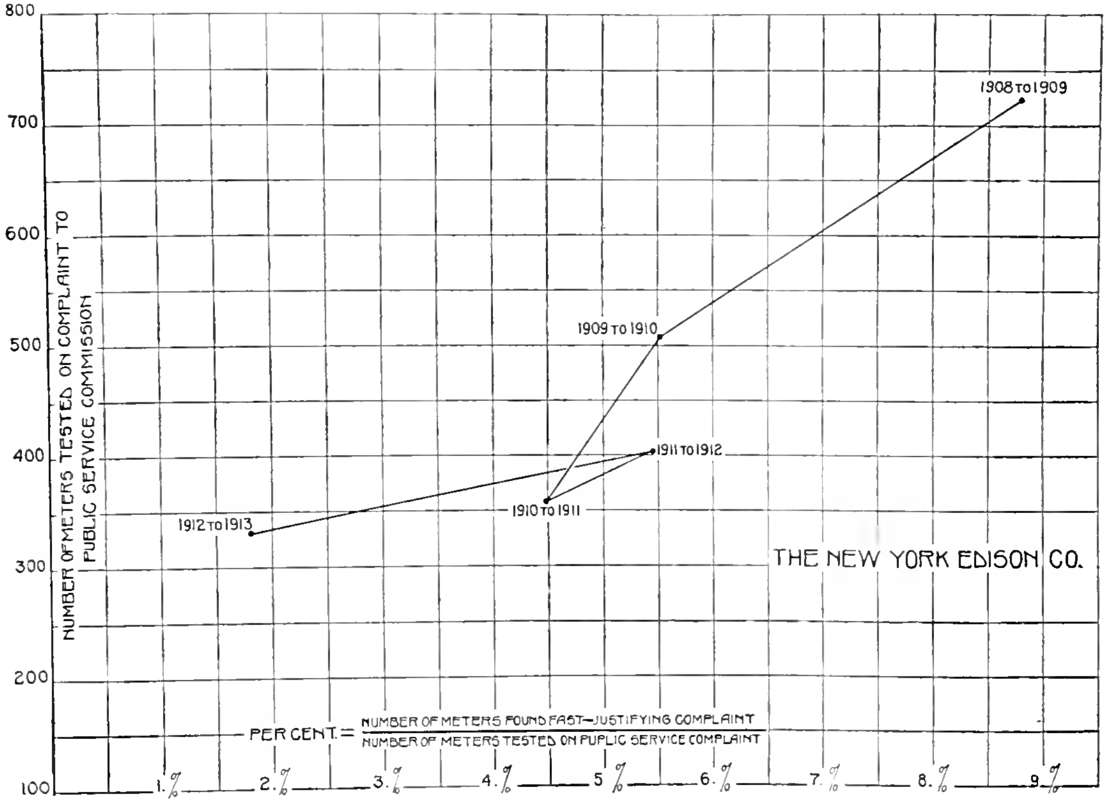

Fig. 2

afford a general index of the operating condition of the meters on any system. Fast meters obviously will cause complaints by the consumers, but complaints may also arise from meters which are allowed to become slow or defective and then suddenly brought to accurate condition as a result of a periodic or office test. The complaint tests, while all of the same character as to technical details, may be of very different significance in their origin and the interpretation of the results obtained. The lighting companies are as a rule ready at all times to make complaint tests of meters or detailed investigations of any consumer's installation without charge. Complaint tests may, therefore, be made by the company on direct complaint of the customer, often in the presence of his representative expert; by the public service commission on complaint to it; or by the city authorities on complaint to them.

A few years ago there was current a general impression of suspicion on the part of the public toward all metering devices and the electric meter shared to a large extent the prevalent distrust of the gas meter. This impression is confirmed by the fact that the public service commissions when first established directed their activities to a great extent to the investigation of metering matters, consideration of the performance of the types in current use, methods of maintenance and test, and the checking of standards. The consumers at first took advantage liberally of the new facilities afforded by the establishment of the commissions to ascertain the condition of their own meters.

The considerable demands made at first upon the commissions in this direction have gradually decreased and the number of complaint tests which they are now called upon to make has been reduced to a very moderate routine. This can be ascribed to at least two causes: First, the formulation and wide dissemination of the Code for Electricity Meters, and second, its general approval and acceptance by all interested parties. The code represented the best meter practice of the country and presented meter data and performance according to the highest possible

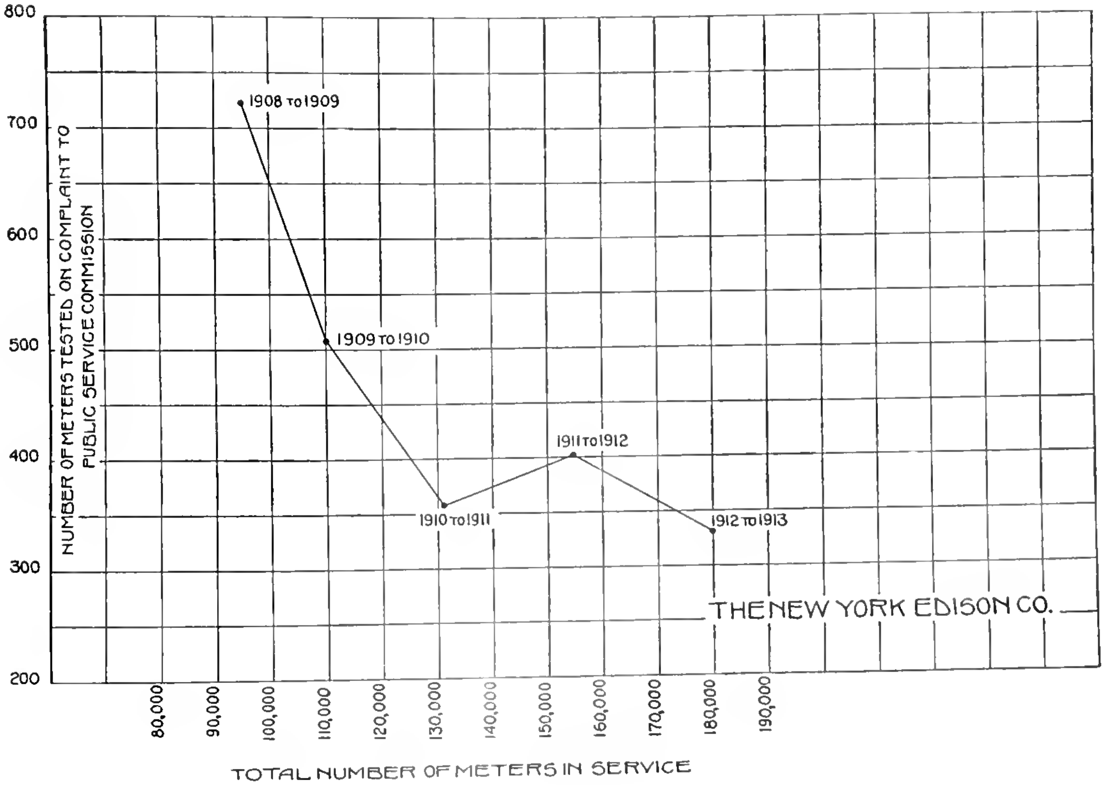

Fig. 3

standards, and it became available at an opportune time for the use of the public service commissions. A careful consideration by their engineers of the data contained in the code, the basis on which it was compiled, and its authoritative character assure them of its thoroughness and practicability meeting every reasonable requirement as measured by the highest performance standards.

The other cause which has tended to dispel the attitude of suspicion toward electric metering on the part of the public service commissions and the public has been the gradual appreciation by them of the high plane on which the lighting companies have practically without exception endeavored to maintain the metering of their product and the large expense and effort expended to insure accuracy for the individual consumer, avoiding all overcharge and irregular registration and securing to the company its just revenue.

Definite figures are now available which show conclusively the marked diminution in the number of complaint tests of meters made by the Public Service Commission for the First District on the circuits of The New York Edison Company. In analyzing the curves shown, it may be well to state the conditions under which complaint tests of meters are made by the public service commission on the consumer's premises and the testing fees charged by them.

The schedule for these charges is as follows:

SCALE OF FEES FOR TESTING METERS

| Amperes Rated Capacity | Fee |
|---|---|
| 10 or less | $1.50 |
| Over 10 but less than 15 | 2.00 |
| Over 15 but less than 25 | 2.50 |
| Over 25 but less than 50 | 4.00 |
| And for each additional 25 amperes or fraction thereof 50 cents. | |

If the meter is found fast to the prejudice of the consumer—the public service commission law fixing the limit at plus four per cent—the lighting company pays the cost of test; but if the meter is found accurate, below the four per cent limit, or is found slow, the consumer pays for the test.

It is fair to assume that, if fast meters recording to the prejudice of the consumer exist in any appreciable number, they would certainly appear among the complaint tests applied for to the commission, as the consumer is not likely to risk paying the charge for a test unless he believed that his meter was over-recording. This is particularly true in view of the fact that the consumer is aware that the company itself is willing to test his meter at any time without any charge whatsoever.

The data tabulated below and the curves in Figs. 2 and 3 show the decrease in number of public service commission tests during the last few years, as well as the marked decrease both in number and extent of inaccuracy of the so-called "justified" complaints. The figures are grouped in yearly periods from August to July, as the first tests of this character under commission jurisdiction were made in August, 1908.

PUBLIC SERVICE COMMISSION COMPLAINT METER TESTS
NEW YORK EDISON COMPANY SERVICE

| | Total Number of P.S.C. Tests | Number of Meters Found Fast (+4 Per Cent and Above) | Per Cent of Fast Meters |
|---|---|---|---|
| August, 1908, to July, 1909 (incl.) | 722 | 64 | 8.8 |
| August, 1909, to July, 1910 (incl.) | 507 | 28 | 5.5 |
| August, 1910, to July, 1911 (incl.) | 357 | 16 | 4.5 |
| August, 1911, to July, 1912 (incl.) | 403 | 22 | 5.4 |
| August, 1912, to July, 1913 (incl.) | 331 | 6 | 1.8 |

RATIO OF PUBLIC SERVICE COMMISSION COMPLAINT TESTS TO TOTAL NUMBER OF METERS IN SERVICE

| | Total Number of P.S.C. Tests | Total Number of Meters in Service | Per Cent |
|---|---|---|---|
| August, 1908, to July, 1909 (incl.) | 722 | 95,000 | 0.75 |
| August, 1909, to July, 1910 (incl.) | 507 | 110,000 | 0.46 |
| August, 1910, to July, 1911 (incl.) | 357 | 131,000 | 0.27 |
| August, 1911, to July, 1912 (incl.) | 403 | 155,000 | 0.26 |
| August, 1912, to July, 1913 (incl.) | 331 | 180,000 | 0.18 |

Continuing the consideration of tests made by the commissions it is to be noted that while specifications for the acceptance of types of meters and the frequency and methods of making periodic tests are prescribed in much detail, the methods or bases of settlements with the consumer where a meter is found fast have been left to the companies. The settlement in actual money that is to be refunded to the consumer is really what interests him. There are no laws or operating rules and regulations of the commissions which prescribe in a definite manner the bases of settlement with the consumer for a fast meter. It is left largely to the discretion of the company whether the allowance shall be for the full period back to the last test of record, or half the period, or half the rate of allowance to be extended over the full period shall be considered in adjusting the refund to the consumer.

The accuracy of the work done by the meter department is, of course, entirely dependent on the instruments used as standards and the system for maintaining their accuracy through periodic comparison with fundamental standards. The manufacture of instruments of precision and the methods of standardization have made great progress within the past few years, and high grade portable instruments are now available at a reasonable cost, making it possible to apply precision methods and primary standards in the field which were formerly available only for use in the standardizing laboratory. In order to eliminate every possible source of error in the standards, securing the highest degree of accuracy, it is necessary to provide, as a matter of routine, for systematic comparisons and careful checks. In Fig. 4 will be found a diagrammatic representation of the standardizing and check system developed by the New York Edison Company. It is only necessary to add that the system is supplemented by a complete set of records so that it is possible to refer to the accuracy condition of an instrument at any time in terms of the Company's fundamental standards.

In considering meter maintenance on a large system it is necessary to provide for conducting the operating details on a large scale. The work involved in conducting, as in one case we have in mind, three hundred thousand meter tests and inspections annually involves not only the work of the meter indexer and installation workman, but the gathering, training, maintaining and directing of a complete and efficient organization. A typical organization in the case of one of our large electricity supply companies is outlined in Fig. 5. Thoroughly competent meter testers are not obtainable as are skilled watch-makers, for instance, in answer to advertisements. It is necessary for each company to train them for its own work. Testing equipments, complete in their details from the standard instrument to the load box, of proper shape and weight for local conditions, are not available as a purchasable unit, but must be put together and adapted to the local conditions. As a result of the consolidation of outlying companies and the extension of the territory served, which has been going on for some time past in the central station industry, it is necessary to arrange for geographically located district headquarters which must be correlated under the supervision of the centrally located headquarters or department.

young men with technical or mathematical training in the technical school or college. Graduates of our technical schools and universities do not as a rule become permanent employees of the meter department, as they have open to them more lucrative positions, owing to their broader technical knowledge, and they regard the service in the meter department only as giving them a practical knowledge of testing methods. The man who enters the meter service with a less complete educational equipment is more apt to stay in the department, where he is brought into contact with other departments in the company's organization and obtains familiarity with the many kinds of apparatus and devices connected through the meters to the company's supply mains. These employees, therefore, if they profit by their opportunities for acquiring broad knowledge and experience, readily fit themselves for work of greater responsibility with higher emoluments in other departments of the company, or in other branches of electrical work.

Where geographical districts are used as parts of the large system, the training of the

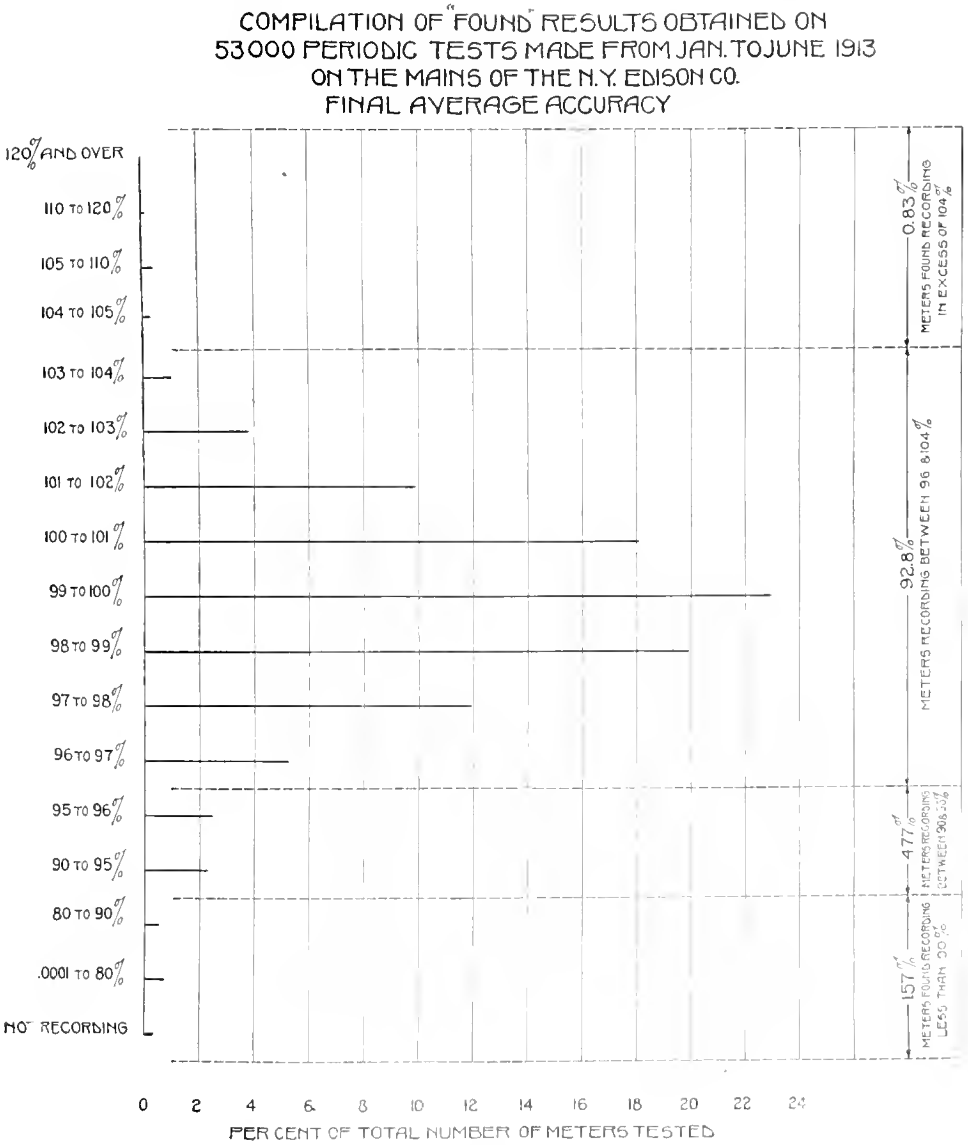

Fig. 6

men, the formulation of the methods of test, and the standardization of equipment should be carried out in every detail on a uniform standard, so that comparable efficiency may be obtained from the several units. The continual development of new meters and testing devices requires a constant process of investigation and improvement, so that the meters and their maintenance shall be conducted so as to obtain the highest possible accuracy at a reasonable cost.

The records of the meter tests are important from a commercial and legal aspect, constituting a signed and dated record of the condition of the apparatus on the readings of which the consumer is billed, and they constitute an index of the performance of the meter as an individual piece of electrical apparatus. To fulfill the former requirement, the meter test records, like any other reference data, to be of maximum value should be readily accessible and immediately available to those desiring to consult them. They should, therefore, be carefully filed and indexed in accordance with a system dictated by local conditions, either according to the consumer's name and address, or by the meter serial number.

From the standpoint of technical test data the records serve as a continuous running index or source of information on such matters as the suitability of certain types of meters for distinct classes of service, the performance of the various component parts of the meters, the methods of test in use when the meters were last tested, the accuracy of the standardizing of the instruments used, and the competence and personal equation of the men who made the test. The records of "found" accuracy on meter tests should therefore be carefully tabulated, scrutinized and analyzed before they are filed and lose their identity, in the aggregation of a day's or month's work. This may be illustrated by referring to Fig. 6, giving curves showing the metering conditions, and their gradual improvement is shown by the records of "found" results on periodic tests in the case of the New York Edison system, condensed for plotting in yearly totals. The results shown are based on the "final average accuracy" as prescribed by the First District Public Service Commission rules and composed of a composite of the accuracy of each meter at three loads, 10 per cent load, "normal" load and 100 per cent load, which as a single figure index of the performance of the meter throughout its entire range is probably as fair and representative a figure as can be obtained.

The load at which the meter is to be tested as the "normal" load under this plan is obtained by operating the meter under the various service conditions at the following percentages of the total connected installation:

CLASSIFICATION OF INSTALLATION TO BE USED IN TESTING METERS AT "NORMAL" LOAD

| | | Per Cent |
|---|---|---|
| A | Residence and apartment lighting | 25 |
| B | Elevator service | 40 |
| C | Factories (individual drive), church and offices | 45 |
| D | Factories (shaft drive), theaters, club entrances, hallways and general store lighting | 60 |
| E | Saloons, restaurants, pumps, air compressors, ice machines and moving picture theaters | 70 |
| F | Sign and window lighting and blowers | 100 |

*Final Average Accuracy*—After the accuracies at the three loads, namely, 10 per cent of meter capacity, "normal" load, and 100 per cent of meter capacity have been obtained, the *final average accuracy* is obtained from these three figures by multiplying the result of the test at normal load by three, and adding the results of the tests at 10 per cent capacity and 100 per cent capacity, and then dividing the total by five.

In curve No. 6 is shown the improvement in the results obtained in the periodic meter tests on the New York Edison system from 1910 to date:

Referring again to the data on the public service commission complaint tests it should be borne in mind that the results of the commission tests are checked by a contemporaneous test made by the lighting company's representative, the two groups of testers using different sets of instruments, maintained by different systems of standardization. The two sets of instruments are placed in series, the results obtained by the public service commission testers, checked as above, serving as the official record of the test. It should be observed that it is sometimes impossible to obtain the customer's consumption by a direct reading from the meter, owing to the fact that the meter was burnt out or became inoperative or "non-recording" from some other cause. In this case the consumer is rendered a so-called prorated bill, with the fact of its being prorated clearly indicated on its face. The prorating is obtained by a careful comparison of the readings of the meter during the previous months and for the similar period of the preceding year and represents the best judgment of the company as to what the consumption may have been during the period in question. In case the consumer raises any question as to the amount so "estimated" by the company, the matter is adjusted on such a basis as may be entirely acceptable to the consumer.

Looking at the matter from a commercial standpoint, it will be seen that questions of contract, rates, and classification of service, etc. are questions of the commercial policy of the company conforming to well established business laws, commission regulation, or company policy which are alike for each consumer. The introduction of the electric meter by the lighting company in the consumer's premises and the successive rendering of bills to the consumer month by month, based on the readings of the meter, may constitute a source of suspicion and question on the part of the consumer, which if allowed to remain may seriously impair the good will of the consuming public. It is, of course, the earnest desire of the lighting companies to eliminate all such questions, and to this end the supply meters must be kept up to the highest standard of accuracy. There must be constantly available a system of records so that the consumer, or his technical representative, may be satisfied by personal investigation and inquiry that the meters used by the company are of the proper type and so maintained as to accurately show the energy used by the consumer. While questions as to rates and conditions of service may arise in the relations of the consumer with the company, his continued good will and satisfaction with the service is largely based on the fact, either accepted by him or demonstrated to his satisfaction, that his individual consumption is being properly metered and correctly billed.

# A PLEA FOR THE STANDARDIZATION OF FREQUENCIES

By C. W. Stone

Manager, Lighting Department, General Electric Company

The author points out that there are as many as five different frequencies in use in this country today, although there has never been an excuse for more than two of them, 25 and 60 cycles. The latter frequency possesses decided advantages for incandescent and arc lighting circuits, and affords the manufacturer a greater range of speed and a more economical design for his generators and motors. The lower frequency was justified a number of years ago, when the operation of synchronous converters on 60 cycle circuits was far from satisfactory; but now that these machines have been improved to the point where their performance is entirely satisfactory at the higher frequency, it would seem that all parties concerned—the public, the operating companies, and the manufacturers—would be benefited by the gradual adoption of 60 cycles as standard.—Editor.

C. W. Stone

THE frequencies used in this country for the distribution of alternating current are 25, 40, 50 and 60 cycles, 125 and 133 cycles having practically disappeared. There are a few cases of 33 cycles.

There seems to be little excuse for any frequency other than the two most commonly used: namely, 25 and 60 cycles. Both 40 and 50 cycles are compromise frequencies which, if standardized before the wide development of both 25 and 60 cycles, would probably have been a more natural general frequency to use, 50 cycles being preferable. As matters are at present, however, 50 cycles is only used in a few isolated cases. Forty cycles is used more generally, but only in such limited areas as represented by the power companies in the Mohawk Valley, and in isolated mill installations. It is the opinion of the writer, therefore, that both 40 and 50 cycles should be discouraged.

True economic principles are not presented by adopting a system of distribution for some installation which would make it impossible to connect, either in emergencies or ultimately for good, with some other source of power, except through expensive and inefficient frequency changers.

Twenty-five cycles was adopted a number of years ago, as it seemed to be a frequency best suited to the classes of apparatus then available for transforming from alternating current to direct current, and as the larger lighting and power companies were using direct current primarily as their main load, and also as direct current was universally used for railways. The principal consideration in determining the frequency was the class of apparatus available for transforming alternating into direct current.

Conditions today are different, and the result is that 60 cycles is the frequency most generally used. This frequency is more generally applicable to all the varied conditions met with in the distribution of power than 25 cycles. More speeds are available with 60 cycles than with 25 cycles; for example, 1500 revolutions per minute is the highest possible speed for 25 cycles, whereas 3600 revolutions and intermediate speeds are available with 60 cycles.

The question of speed affects not only the driven apparatus, but also the generating apparatus. This is particularly true with steam turbine-driven machines, for with a speed of 1500 revolutions per minute, especially with turbines of less than 10,000 kw. the machines are more costly, less efficient, and require more floor space than those designed for 60 cycle operation.

Motors for 25 cycles are more expensive to build than 60 cycle motors. They are more bulky and less efficient, and have no better operating characteristics; and this same condition exists in the design of 25 and 60 cycle transformers.

The higher inductance of 60 cycle apparatus has a tendency to dampen out disturbances originating in the lines feeding them, this being particularly true with very high voltages.

Synchronous converters, which are used almost universally in this country for transforming from alternating to direct current, are now designed for operation on 60 cycle systems, and can be considered very reliable and efficient pieces of machinery under almost all conditions of service.

In the opinion of the writer, there has been a more general use of motor-generators in railway work, for transforming alternating current to direct current on 60 cycle systems, than was necessary. It would probably always be better to use motor-generator sets where it was thought inadvisable to install rotary converters on a 60 cycle system, however, than it would be to install frequency changer sets for 25 cycle apparatus which would be used exclusively for railway purposes, as the first cost would be lower and the overall operating efficiencies considerably higher.

As fuel becomes more expensive, there will be a still greater tendency to concentrate the production of power in larger systems, and to gradually eliminate all isolated power plants. It is obvious, therefore, that a frequency which makes it possible to tie in with the existing companies nearby, and to use the existing motors, etc., of the installation without paying for the losses incident to the use of frequency changers, represents a frequency having universal advantages.

We can consider, therefore, that in the course of time all the frequencies now used, other than those generally used, will eventually be eliminated, and consequently 25 and 60 cycles will be by far the most universal.

While 25 cycles is generated for lighting purposes in some localities, it is probable that it will never be generally used, whereas 60 cycles is almost universal and is destined to be the common frequency for such purposes. There are many reasons for this conclusion which are probably too well known to require discussion in this short article.

It is history that all power companies organized for lighting and power purposes, using direct current for general distribution, found that direct current, while of advantage in congested localities, was not suitable for use in the less densely populated districts, because of the expensive transmission lines required to eliminate the high losses. In consequence they adopted alternating current for all outlying districts, and almost universally selected 60 cycles, except in the early stages of the art, where higher frequencies were used; but today nearly all of these installations have been changed to a lower frequency.

It is also true that the growth of most places, while at first concentrated in certain districts, after a certain saturation is reached have to extend further from the center, and consequently into a district or zone requiring alternating current. Thus it is quite common to find that the alternating current load is increasing far more rapidly than the direct current, and, as pointed out before, the frequency most generally used for this service is 60 cycles.

Another reason for this increase in alternating current is that the growth in population necessitates more industries, and usually these are not built in the congested districts but in the suburbs, in the district fed by the alternating current systems. In cases where these manufacturing concerns require direct current for their purposes, synchronous converters are usually used for transforming.

Where railway companies, instead of increasing their own generating equipment, are now either purchasing power from the water power companies or central stations in their vicinity, or will do so in the future, they require direct current as a rule, and in consequence have no interest in the frequency of the supply system. The power companies furnishing this energy certainly cannot afford to install 25 cycle apparatus in their stations for this purpose alone; nor can they afford to throw away the power necessary for the operation of frequency changer sets, involving as it does energy losses of 10 per cent or more—usually more—as well as the interest and depreciation on the apparatus, the buildings, and the control equipment, and the labor involved in operation. In addition, the peak capacity of the stations is increased almost in proportion to the increased losses due to the operation of frequency changers.

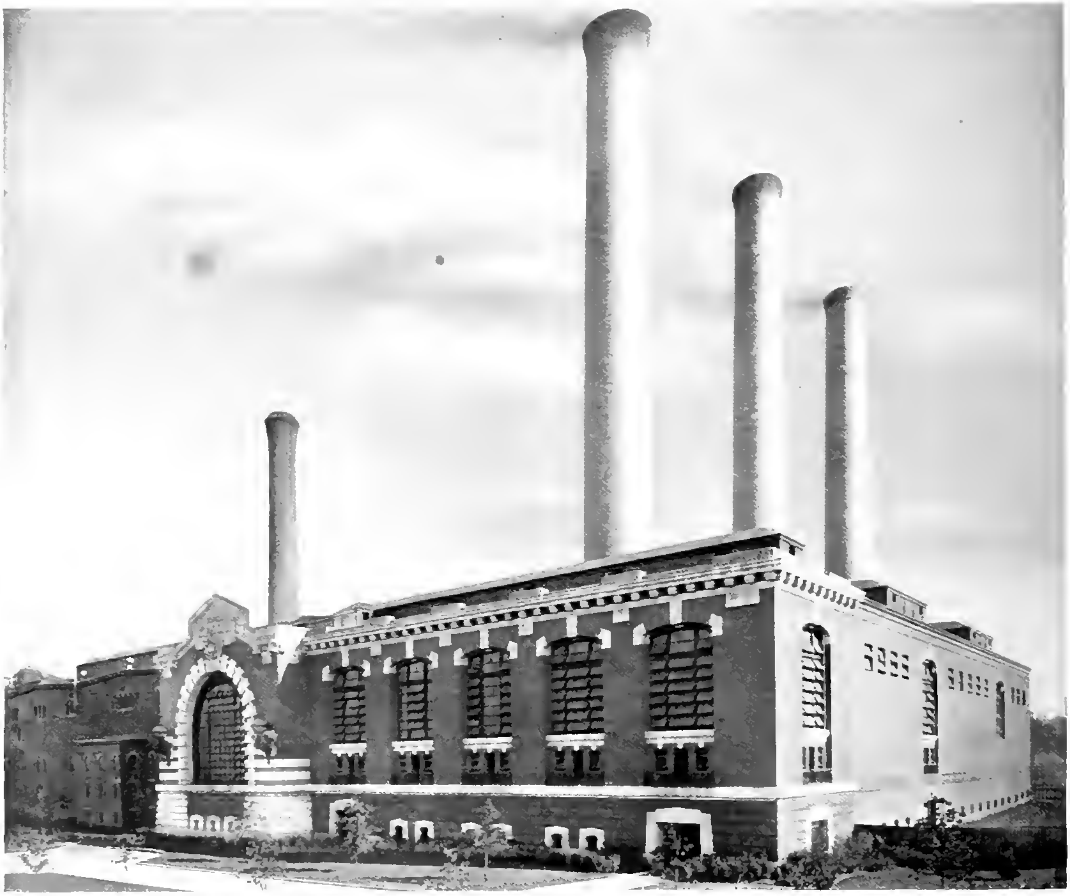
Another feature which should be considered is that the cost of apparatus is greatly affected by the multiplicity of its parts. This is true not only in first cost, but in maintenance cost. Take, for instance, a line of alternating current motors. Manufacturers are now forced to develop a complete line of motors for 25, 40, 50 and 60 cycles, each size usually for about ten voltages, and generally two or more speeds; each size of motor at each frequency, at each potential, being designed for enclosed, semi-enclosed, vertical, horizontal and other miscellaneous methods of operation—the entire line being duplicated over and over again due to the frequency.

This certainly is not a particularly economical manufacturing condition, and in consequence is reflected in the cost of all motors. If, therefore, the motors could be confined to simply 25 and 60 cycles, or preferably 60 cycles alone, great economies would result.

Transformers are another class of apparatus falling in this category. We have air blast, oil-cooled, oil-and-water-cooled, forced oil-cooled and other modifications of these designs, all arranged for many different voltages, and all the various frequencies duplicated in capacity for all the different conditions.

If all operating companies would, when it is necessary to increase the capacity of their stations, install 60 cycle machines in their outlying substations instead of 25 cycle apparatus, and further, as the demands of the central portions of their systems require additional equipments, remove the 25 cycle machines from the outlying stations to the main stations, or exchange them for new and larger 60 cycle machines, there would be a gradual elimination of 25 cycle apparatus. This would consequently increase the requirements for 60 cycle apparatus, which in the course of time would result in such a preponderance of 60 cycle apparatus that 25 cycles would appear only as an incidental frequency, and would have little bearing upon the cost of other apparatus. This could be done without in any way seriously affecting the operation of existing companies and their systems. Greater economies would result in feeder investment from such method of operation, and a considerable simplification in the operation of the systems.

From the foregoing it would seem that a determined effort should be made by all interested, in particular the operating companies, to eliminate as far as possible the further extension of 25 cycle systems, confining, as far as possible, all of their increased demands to the 60 cycle systems.



POWER HOUSE OF THE EDISON ELECTRIC ILLUMINATING COMPANY, BOSTON

# A REVIEW OF SYSTEMS OF TRANSMISSION AND DISTRIBUTION FOR LIGHTING SERVICE

By H. R. Summerhayes

Assistant Engineer, Lighting Department, General Electric Company

The main reason for the great number of systems of distribution that are in use today will be found in the rapid growth of the companies supplying electric lighting and power, and the demands made upon them; progress in the industry; differences of opinion among engineers; and the variety of purposes for which electrical energy is used. The author gives us a historical sketch of the development of each of the fundamental systems—direct current and alternating current—and shows how conditions in some of our larger cities have brought about a combination of the two. Each of the common methods of distribution is then shown diagrammatically and discussed in detail with particular reference to copper consumption, regulation, and its suitability for lighting and power.— Editor.

**H. R. Summerhayes**

In considering the methods of transmission and distribution of electrical energy for lighting and power in cities, the observer is at once impressed with the great diversity of methods and systems. In many of our large cities, 25 and 60 cycle current is transmitted to substations, and 60 cycle and direct current distribution systems are in operation side by side; and there is often presented the additional complication at some stations of 600 volt direct current supply for street railway service and 500 volt ungrounded power circuits for motors.

These conditions are due to various causes, among which may be assigned rapid growth and transition in the systems themselves and in the demand upon them; progress in electrical art; difference of opinion among engineers as to the relative advantages and disadvantages of different systems; and the great variety of purposes for which electrical energy is used.

Since most of the vast growth of these systems has taken place within a third of a century—and the progress of electrical science and industry has been so rapid that it has been difficult even for engineers active in the profession to keep abreast of ever changing practice—it may be of interest to trace the development of some of these systems from the earlier stages.

## DIRECT CURRENT

In 1879 and 1880 the Brush and Thomson-Houston open coil dynamos for series arc street lighting were introduced, and at about the same time came Edison's twin inventions of the high resistance incandescent lamp and the constant potential distributing system of feeders and mains, with lamps connected in parallel. These inventions form the basis of all the direct current lighting networks, and are in use today with changes only in detail.

In 1881 the first Edison plant for the supply of electric current to the public for lighting was established at Appleton, Wisconsin. The Pearl Street generating station of 2000 lights capacity, supplying a system of 50 miles of wires, was inaugurated in New York in 1882. A 3000-light Edison plant was started in the early part of 1882 in London. In the same year also, the Edison three-wire system made its appearance, using 220 volts across the outer wires, with 110 volt lamps connected between the outer wires and neutral, this arrangement requiring only 40 per cent of the copper of a 110 volt two-wire system. Thus the economical area of the system was greatly extended and the growth of the industry was rapid. Before the end of 1882 over 125 electric lighting plants, with a total capacity of about 25,000 lamps, had been installed on the Edison system, and by 1891 the total capacity of Edison direct current stations was over one and a quarter million lamps.

During the eighties, direct current systems were installed in many cities, including Boston, Chicago, Philadelphia, Brooklyn and others. The early direct current development abroad paralleled closely American methods, but later the lamp voltage was raised from 110 to 220 volts on most of the English and many of the Continental systems; so that the standard lamp pressure in England is now 200 to 220 volts, and the three-wire systems are operated there at 460 to 500 volts across the outers, as compared to 240-300 volts in American practice.

It is difficult to understand this divergence, although both systems possess advantages. American engineers claim that the 15 to 2 per cent inherent superiority of the 11 volt lamp in life or efficiency over the 220 volt lamp more than compensates for the saving in copper, which is the chief advantage of the English system.

We should not forget, however, in these days of unified electric systems, an incidental advantage of the higher voltage, namely, that of utilizing the 500 volt generator for street railway supply as well as lighting.

The railway voltage in England is frequently 500, and a station supplying both lighting and railway service may contain five machines, two for railway, two for lighting, and one spare. All of these are shunt wound for lighting service, at 480 volts, and are provided with an auxiliary series winding which is cut in by switches when the machine is used for railway supply.

Three-wire systems with 220 volt lamps have never been widely used in this country. The only two prominent instances are Richmond, Va., and Providence, R. I. Five-wire systems permitting the use of 550 volt generators, with balancer sets consisting of four machines so arranged as to obtain three intermediate wires between the outers and giving a lamp pressure of 110 volts between adjacent wires, were used to a limited extent abroad, but have mostly been discontinued. Notable examples were Vienna and Paris. The complication and difficulty of balancing on these systems outweighed the saving in copper.

The first Edison systems in this country were laid out for incandescent lighting; but within two years motors were connected, at first for 110 volts, but soon afterwards the present practice was established of using 220 volt motors connected across the outers, thus minimizing the unbalancing of voltage. Constant potential direct current arc lamps came into use in the early nineties, and thus, with the motor service, made the three-wire network a universal reservoir for all classes of power and light.

In some places where the power load was large as compared to the lighting, it was found expedient to install separate 500-volt two-wire power circuits; but in most large cities the combined power and lighting service gives excellent results.

The generators were at first belt-driven from engines, but the advantage of direct-connected units was early recognized and such machines were installed in large plants.

The small economical area of distribution required that stations be within a mile or less of each other for a dense load, and the result was that some of our larger cities soon contained several steam generating stations connected to a common network. As it was not always possible to locate the station conveniently with respect to a supply of condensing water, the exhaust steam was frequently sold for heating service. The next step was the installation of storage batteries to insure continuity of service; this being followed still later by the replacement of many of the early engine-driven generators by rotary converters or motor generators supplied from a-c. power transmitted from a central generating station.

In its essentials, the Edison three-wire system remains the same as at first introduced. Many of the original Edison tubes still survive in the mains of the network, but are supplanted by cables in the feeders and trunk mains. Cables are used for new work. The principal changes have taken place in the generating apparatus, and more recently in the lamps.

### ALTERNATING CURRENT

The first commercial alternating current plants in this country were installed in Greenburg, Pa., and Buffalo, N. Y. The alternating current systems were taken up and rapidly developed by Westinghouse, Stanley, Thomson and Houston and others. A single-phase frequency of 125 or 133 cycles was used in those early plants; the current being generated usually at 1100 or 1200 volts, single-phase. Lamps of 50 volts were used, for the 110 volt lamp as then made did not have a long life on alternating current.

These high frequencies appeared desirable on account of the transformers being much cheaper than those for low frequencies. Also the small belt-driven generators used in those days were less expensive if made for high frequencies. House to house transformers were at first used, that is, very small transformers having sufficient capacity to light only one or two houses.

These systems had an immediate application in small cities where direct current was not then established, and in the residential parts of large cities where the business districts were already supplied by direct current. An established direct current system with the advantages of efficient variable speed motors for elevators, etc., and continuity of service guaranteed by storage batteries, has seldom been displaced by alternating current.

A short time later a great impetus was given to alternating current progress by the development of the polyphase system and of the polyphase induction motor possessing the now well known advantages of high efficiency, good starting torque and simplicity of construction, absence of commutators, etc.

It was found desirable to use a lower frequency for the polyphase system, as the advantages possessed by the motor at low frequency outweighed the somewhat greater cost of transformers. Furthermore, while small belt-driven generators had been cheaper at high frequency, the tendency in the art was toward the use of direct-connected generators of lower speed, for which the lower frequency was more advantageous. Sixty cycles was established as standard practice in this country for general power and lighting service in the early nineties.

A prominent instance of one of the first alternating current installations to use 60 cycles was at St. Louis, where 1200 volt single-phase distribution was adopted with the 1200 volt feeders running from the station to transformers located at various points in the district supplied. These transformers had a three-wire secondary and supplied a three-wire low tension network which was interconnected like a d-c. network.

This frequency was also used in several of the early high tension transmissions from water power; but for the important Niagara Falls plant an international commission of engineers in 1895 recommended 25 cycles on account of the lower charging currents on a transmission network, and the adaptability of this frequency for use with synchronous converters and alternating current railway motors. A few plants at compromise frequencies, such as the Mechanicville station at 38 cycles, and some of the Western plants at 50 cycles, were installed for transmission work, and an effort was made to introduce 40 cycles as a universal frequency possessing the advantages of both 25 and 60 cycles; but it was found instead to have the disadvantages of both. It was not high enough for a-c. arc lamps and too high for synchronous converters of those days and for a-c. commutator motors.

Thus 25 and 60 cycles have survived as the standard frequencies in this country, each occupying a well defined territory of usefulness which is its own by right of superiority, with a broad stretch of debatable ground between for work where one or the other frequency possesses points of advantage.

In English and Continental practice a number of frequencies were quite widely used and such odd frequencies as 42 cycles, 33 cycles, 83 cycles and 100 cycles may still be found; but the tendency in foreign practice in recent years has been toward the standard frequency of 50 cycles for general distribution for power and lighting, with 25 cycles in special cases for supplying direct current railway substations, and even lower frequencies such as 15 cycles for a-c. railway work.

With the extension of a-c. lighting systems over larger areas and after familiarity with the terrors of insulating for 1000 volts had bred contempt, it was found desirable to increase the distributing pressure to 2300 volts, which has survived and become standard in this country, and to a large extent abroad.

At about the same time improvements in lamp manufacture enabled 110 volt lamps to displace those of 50 volts, with a consequent improvement in service because of less drop in the wiring from transformers to lamps.

In the early days of polyphase work, two-phase generators and distribution had considerable vogue because it was thought the balancing would be easier on two phases than three; but with the increase in size of plants and the introduction of regulators, less attention was paid to this fancied advantage of two-phase, and three-phase is now generally used on new systems.

### COMBINATION

In the late nineties most of our large cities were equipped with direct current networks in their business centers, sometimes supplied from several steam stations; while alternating current plants of various sizes existed in the residential and outlying districts of these cities. There were frequently several alternating current stations, for franchises had been granted to different companies and sometimes these stations were of different voltages, as 1000 and 2000, and different frequencies, as 125 and 60 cycles. Furthermore, the secondary voltage might be different and motor circuits two-phase or three-phase.

At about this time there began a movement toward the replacement of several small generating stations in a center of population by a single, large central station, located where cheaper coal supply and ample condensing water were available. Several ways were adopted for meeting this problem. In moderate size cities the central station was laid down to generate at a frequency of

60 or $62\frac{1}{2}$ cycles and at a pressure of 4000 volts, using for distribution the 4000/2300 volt four-wire three-phase system. This voltage was sufficiently high to insure economical distribution over fairly large areas, and the system was flexible inasmuch as it enabled 2300 volt single-phase feeders to be taken off from sub-centers of distribution for lighting, with four-wire three-phase feeders going to districts where considerable power was required.

In larger cities where the direct current load was already heavy and where the distances to be covered were considerable, 6600 or 13,200 volt transmission from the central station was adopted, with a frequency either of 25 or 60 cycles, according to the predominance of d-c. load or the views of the engineers with respect to the future sale of current to street railways.

The old generating stations were frequently retained and used for substations, the generators being replaced by motor-generators or rotary converters to feed the d-c. distribution systems. The a-c. distribution was taken care of by substations stepping down from the transmission voltage to 4000/2300 volts four-wire three-phase, or to 2300 volts three-phase. Feeder regulators were generally located in these substations. Where 25 cycles had been adopted it was necessary to install frequency changers in substations or in the main stations for the 60 cycle load, and in some cases this 60 cycle load has since grown to such proportions that it has been found expedient to avoid the losses in the frequency changers by installing 60 cycle turbine-generator units. This explains the situation which exists in many of our larger cities.

On the other hand, many cities which started with 60 cycles, as on the Pacific Coast, have found it unnecessary to use 25 cycles at all, since motor-generators can always be utilized for direct current supply and in late years the 60 cycle synchronous converter has become a successful machine.

Under the subject of "Combination" should be noted the consolidations of the lighting and power systems of towns in suburban districts with the central city system, as in Boston and Chicago, and the conversion of a number of small generating stations into substations containing either transformers, motor-generators or synchronous converters.

It is also interesting to note, as the tendency of the times, the high tension transmission networks in the south and west, covering vast areas with 60,000 volt and 100,000 volt main lines having parallel and branching lines at low voltage, such as 22,000 or 11,000. These networks supply great parts of towns and small communities with lighting and power, and are displacing steam power in mills and incidentally taking care of increasing amounts of farm loads.

Another development which is daily reaching greater proportions comprises networks, such as those in Illinois, connecting a large number of towns by a transmission at 33,000 or 66,000 volts, thus shutting down a number of small inefficient generating stations and getting the benefits of the better economy of a large station, as well as the diversity factor in load, better engineering, and the advantage of economies in management, purchasing, etc. Such networks are usually supplied, not from one station, but from several of the larger and more advantageously situated stations, these replacing a great number of the original small stations.

## STREET LIGHTING

Compared with the multiplicity and uniformity of systems for interior lighting, there have been a great variety of lamps and systems for street lighting. Most of the street lighting in this country has been done on the series constant current system, involving overhead wires and rather high voltages.

Abroad the series constant current system has hardly been used at all, the constant potential system being employed almost exclusively; although sometimes arc lights are run several in series across constant potential mains.*

One reason for this difference in practice is that most of the foreign systems have been underground; while in many places in the narrow streets a high voltage series overhead system would be more dangerous than under the conditions existing here.

The d-c. open arc lamps, run in series from a constant current arc generator, were widely used in this country and are still in use in some places. Alternating current open arcs or series circuits were very little

---

*One exception may be made to this statement however. During the nineties a system was evolved consisting of constant current transformers and mechanical rectifiers, enabling direct current arc lamps to be run in series, the original source of supply being alternating current. These were used in England to a certain extent some years before the mercury arc rectifier and series d-c. system was devised, which is now so widely used in the United States. The mechanical rectifier was efficient but had a rather high maintenance charge and is now not much used.

used on account of their lower efficiency. Constant potential d-c. and a-c. open arc lamps were widely used, not for formal street lighting, but in business districts for auxiliary illumination, advertising, etc. Most of the plain open arc lamps, both a-c. and d-c., were replaced (beginning about 1899) by enclosed arc lamps, on account of the longer carbon life, steadier light, and less time required for trimming. The d-c. series enclosed arcs were run from arc dynamos and the a-c. lamps from constant current transformers. This constant current transformer system with a-c. enclosed arc lamps had and still has a very wide use, but has recently been superseded, largely by luminous arc lamps operated on series circuits supplied by rectifiers and constant current transformers. The use of constant potential flame arc lamps is increasing.

The series incandescent system operated from constant current transformers is undoubtedly the most economical system for districts where brilliant illumination is not required, and has been popular from the first for villages and small towns. The efficiency of this system has been greatly improved and its range extended by the use of mazda lamps, and in the near future, with the gas-filled mazda lamp, the field of this system will approach and overlap that of the series arc lighting system.

Still another system which has recently come into use here is ornamental lighting with clusters of incandescent lamps on poles, these being usually supplied on the constant potential system.

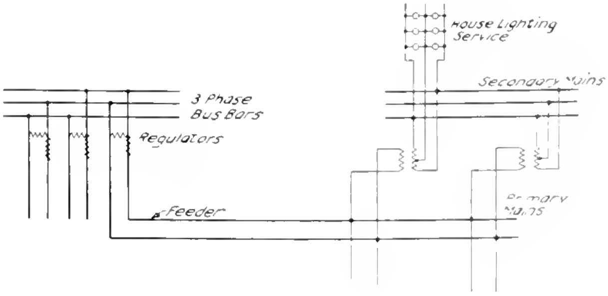


Fig. 1

## DISTRIBUTION SYSTEMS

Assuming that the generation and transmission are already settled, so that with either generating directly at the center of distribution at the distribution voltage, or generating three-phase at a distance and transmitting to the distribution center and there stepping down to the distribution voltage, there are a variety of distribution systems to choose from. A few of these will be discussed.

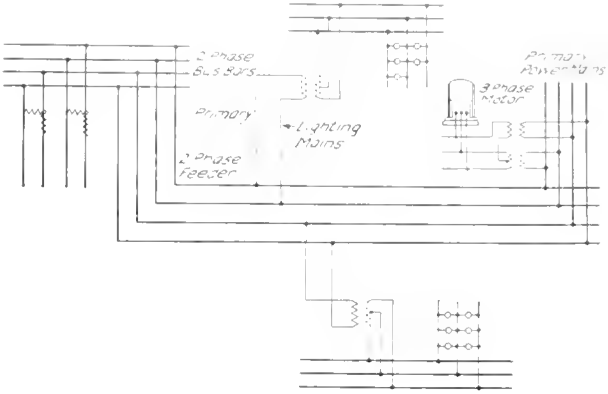

Fig. 2

### Primary Distribution

*Single-Phase Two-Wire* (Fig. 1).

Copper, comparative amount, 100.

For lighting distribution, single-phase feeders are run from the station, these feeders being connected in rotation to the three phases; that is:

Feeder 1 across phase A
Feeder 2 across phase B
Feeder 3 across phase C
Feeder 4 across phase A, etc.

Each feeder runs to a district in the city where several single-phase transformers, located at various points in the district, are tapped off from the feeder. These transformers step down to 110/220 volts for single-phase three-wire lighting networks. The voltage is controlled by feeder regulators.

*Two-Phase Four-Wire System — 2300 Volts* (Fig. 2.)

Copper, 100.

In this case two-phase is available in the station and four-wire feeders are run out, the lighting transformers being distributed equally on the two phases, which may be controlled separately by feeder regulators. The three-wire lighting secondaries supplied from the two phases cannot be interconnected but are usually run in adjoining areas. Where power is required, two low tension wires may be run from one network to the point on the other network where the motor is located.

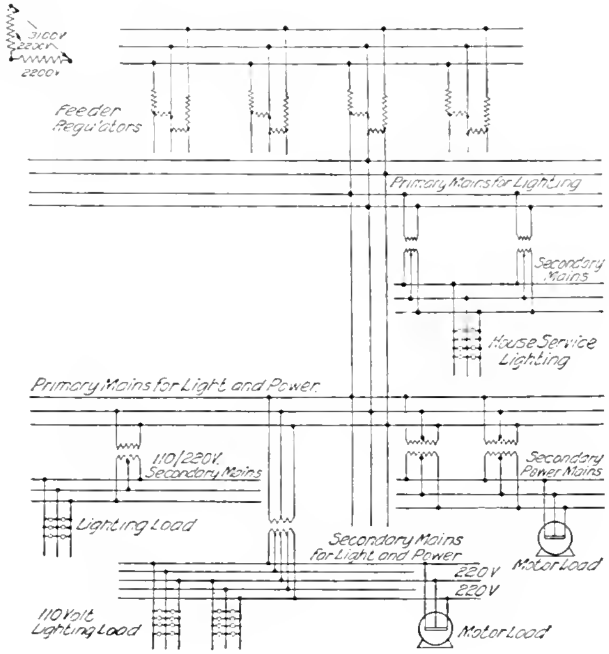

Fig. 3

Or, in the case of large motors, a special transformer bank of two transformers is tapped off the two-phase feeder. The copper economy of this system is not particularly good and the number of wires required are against it as compared to the three-phase system.

*Two-Phase Three-Wire* (Fig. 3).

Copper, 75.

One side of each of the two phases is connected to a common wire which acts as a common return for the two phases. This system has the advantage of employing only three wires and is a polyphase system capable of supplying either power or lighting, but it is very difficult to get good voltage regulation as the load on one phase reacts upon the other. It would not now be recommended for an important distribution system.

*Three-Phase Three-Wire System* (Fig. 4).

Copper, 75.

Three-wire three-phase feeders run out from the station with banks of transformers connected across all three phases for power supply, and single-phase lighting transformers connected at various points and distributed equally on the three phases for lighting supply. This is somewhat more difficult to balance than the two-phase system, but an equal unbalancing of load will not affect the voltage so much. Three-phase regulators may be used. Some companies connect all the lighting across one phase of a three-phase feeder and put a regulator on that phase at the station, sometimes also using the arrangement of transformers shown in Fig. 14. Less frequently the lighting is distributed on two phases, using two regulators. Unless special current transformer arrangements are used in the control of the regulators, this arrangement is likely to prove unsatisfactory.

A widely used combination employs three-phase three-wire feeders to the centers of distribution with single-phase regulators at the station. Single-phase branches are connected to the regulated phase, and a third wire runs from the distribution center only to points where power is needed.

*Three-Phase Four-Wire with Grounded Neutral 2300/4000 Volts* (Fig. 5).

Copper, 29.

This system is used for distribution over large areas in large cities where the density and area are larger than can be economically handled with 2300 volts three-phase. Standard 2200 volt transformers are used

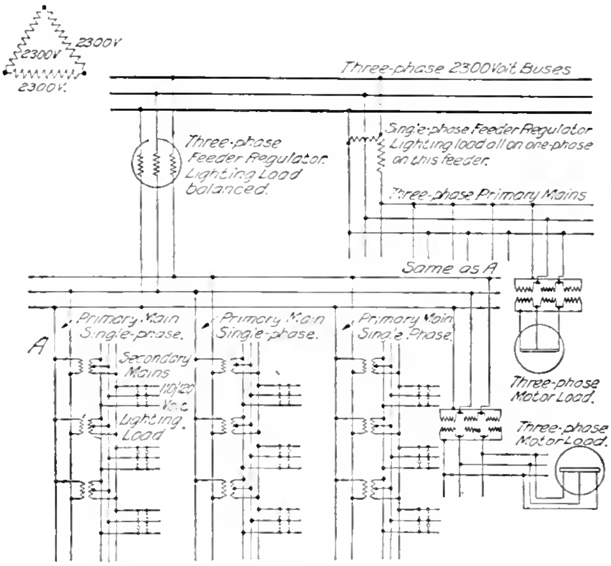

Fig. 4

between phases and neutral. The neutral is usually grounded at the generating station. The feeders run four-wire from the station to the center of the district to be served, whence single-phase branches at 2300 volts are taken off to various parts of the district, these branches being balanced on the three phases; that is, between each phase and neutral.

It is possible to get very good regulation, using a regulator on each phase at the station. This system is widely used in important cities and gives excellent service. Small power users may be supplied from two transformers connected open delta. At points where the load is dense and a large amount of power load divides honors with the lighting load, a three-phase four-wire secondary network may be fed from banks of transformers supplied from the three-phase four-wire primary feeder.

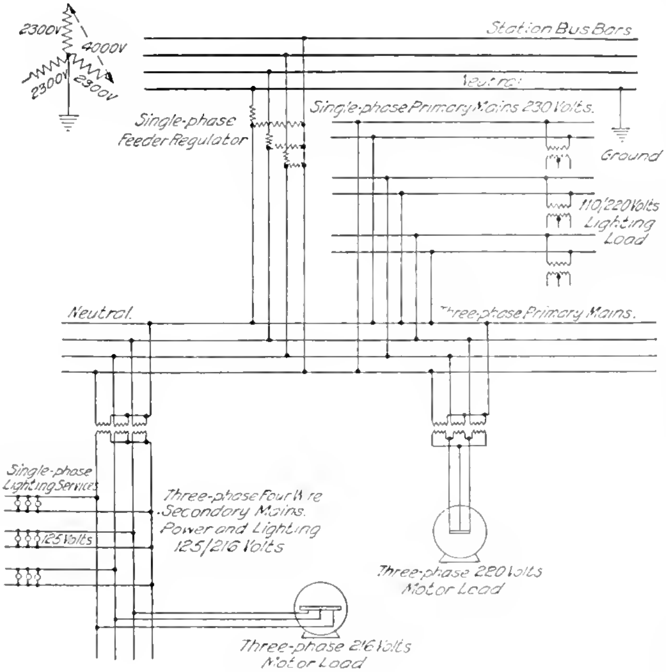

Fig. 5

### Secondary Distribution

*Direct Current Two-Wire System—110 Volts* (Fig. 6).

Copper, 100.

The advantages are simplicity, only two wires, low voltage; and the use of variable speed motors.

This system is limited in application, and is chiefly used in small isolated plants, and in buildings and small vessels. In larger buildings and vessels and for all central station work, the two-wire system has been displaced by the three-wire on account of copper economy.

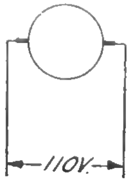

Fig. 6

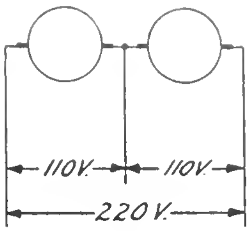

Fig. 7

*Direct Current Three-Wire System—110/220 Volts* (Fig. 7).

Copper, 31.

This is the Edison three-wire system now commonly used on large networks. As installed for underground service with feeders from a number of stations intercepting the network of mains at various points, and the whole network connected together and provided with storage batteries of 20 per cent of the capacity of the system as in our large cities, the continuity of service is unexcelled by any other system. On some of these networks there has not been a complete shut-down for over ten years. The low voltage permits the burning off of short circuits without interruption of service, except locally, and thus insures the localization of faults. Elevator and other variable speed motor service may be supplied. Only three conductors are required, and excellent regulation of voltage is readily accomplished.

*Direct Current Three-Wire System—220/440 Volts* (Fig. 8).

Requires about one-quarter the copper of the 110/220 volt system; that is, comparative copper economy 8. This system possesses all the advantages of the 110/220 system, but has the disadvantage that the 220 volt lamps are about 15 per cent less efficient, or shorter lived, than 110 volt lamps. There is also somewhat greater danger of shocks and more difficulty in insulating heating devices, etc.

*Two-Wire Single-Phase—110 Volts* (Fig. 9).

Copper, 100.

Can only be used for short distances for small amounts of power, and is now chiefly used in branches from secondary mains feeding small residences. Usually, however, all three wires of the secondary mains are connected to the house service.

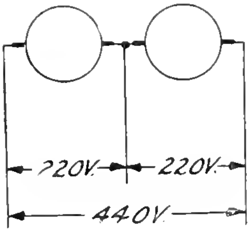

Fig. 8

*Three-Wire Single-Phase — 110/220 Volts* (Fig. 10).

Neutral one-half the size of either outside conductor. Copper, 31.

This system is commonly used on secondary networks or secondary mains for lighting. The mains may be supplied from several transformers, which are in turn connected to primary mains fed from the station. The system is simple, requiring only three conductors, but as it is only single-phase, does not permit the operation of polyphase induction motors.

An extended secondary network of this sort, covering a large territory and fed from a considerable number of transformers, compares very favorably with the direct current network, but has the disadvantage of not being able to use storage batteries, while variable speed motors on this system are not so cheap or efficient as d-c. motors. Furthermore, on account of the reactance drop, the weight of copper would have to be greater than for a d-c. system, and the sizes of conductors would be limited, that is, conductors would have to be laid in multiple for large sizes.

On account of the possibility of a transformer failure, causing other transformer fuses to blow and thus depriving the network of current, such secondary networks are usually subdivided into areas disconnected from each other, the several transformers in each area being fed from one primary feeder. If the areas are all interconnected, some arrangement would have to be made for the disconnection of transformers in the case of transformer failure, to prevent current flowing into the transformer from the network. Another reason for dividing the network into areas is to balance the load on the three phases. The feeder going to each area will be connected to a different phase at the station.

*Four-Wire Two-Phase* (Fig. 11).

Copper, 100.

This system requires the same amount of copper as two single-phase two-wire circuits but involves the complication of four wires. It has the advantage of being able to operate polyphase motors and lighting on the same system.

*Two-Phase Three-Wire* (Fig. 12).

Copper, 75.

This system has a common return for both phases, which accounts for the saving in copper. It has the advantage of permitting operation of polyphase induction motors and lighting on the same system, but it is difficult to regulate the load properly, since the load on one phase may affect the voltage on the other phase. Furthermore, in order to have all the wires capable of carrying overloads equally, the middle wire should be made 40 per cent larger than the others, in which case the copper economy becomes the same as the two-phase four-wire system.

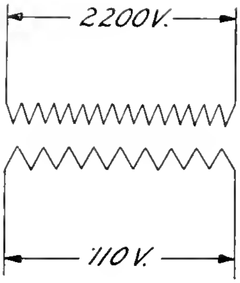

Fig. 9

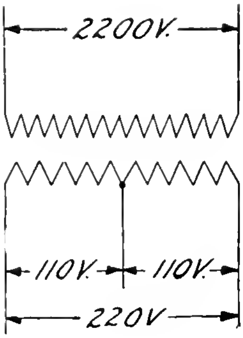

Fig. 10

*Three-Phase Three-Wire System* (Fig. 13).

Copper, 75.

This system is used occasionally for straight power work, or sometimes for combined power and lighting, the lighting load being balancing on the three phases; but since it is rather difficult to balance and not so good in economy as the three-phase four-wire system, it is not much used.

*Three-Wire Single-Phase Lighting with Separate Wire for Three-Phase Power* (Fig. 14).

With a neutral one-half the size of the main conductors, the copper economy for lighting is about 31 and for power 19. The lighting transformer supplying the three-wire system may be made as large as necessary, and if the lighting predominates the power transformers may be comparatively small, the fourth wire for power being run only to those places where power is required. This system obviously possesses a number of advantages and is very commonly used.

*Four-Wire Three-Phase with Grounded Neutral* (Fig 15).

Copper economy, with neutral one-half size, 29.

The lamps are connected between the line and neutral; and the motors across the three lines. It is desirable to use lamps of about 125 volts so that the motor voltage will be 215, or very close to the standard of 220. This system is very flexible and lends itself to the establishment of an extended combined power and lighting network, as the copper economy is good and unbalancing produces less disturbance of voltage than in a three-phase three-wire system. The neutral should be grounded as in the case of Edison three-wire systems. Chicago, Cleveland, Atlantic City and other places contain certain areas supplied by low tension networks of this character.

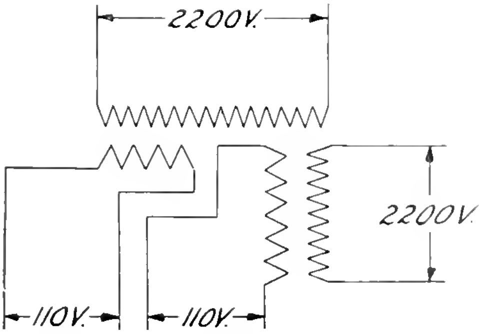

**Fig. 11**

There are a number of plants abroad employing this system in extended networks fed from transformer substations at various points. In all respects except as regards efficient variable speed motors and the continuity of service guaranteed by the storage battery it is practically the equal of a direct current system.

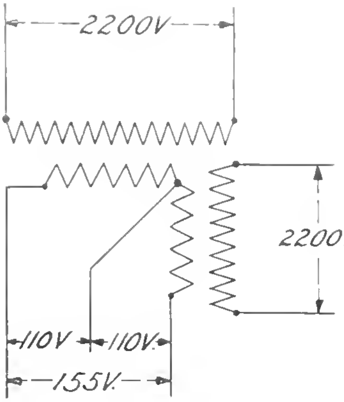

Fig. 12

When considerable areas of such secondary network are interconnected, it is desirable to arrange the transformers so that they will be disconnected from the secondary network in case of reverse current flowing from the network into the transformer; that is, in case of a short circuit in the transformer or feeder.

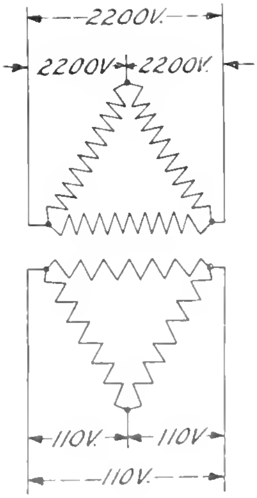

Fig 13

*Four-Wire Three-Phase Secondary Network with Grounded Neutral Supplied by Low Tension Feeders from Substations* (Fig. 16).

This system is largely used abroad, as in Dublin, Ireland; Hendon, Tottenham, and certain districts of London; and also in Shanghai, China. In this system, power is generated three-phase at 3000, 5000 or 11,000 volts and distributed by three-phase high tension feeders to a large number of substations located almost as close together as the stations on a direct current Edison three-wire network. Each substation contains several banks of transformers of large capacity, as compared to the outdoor transformers used in American systems. These substation transformers step-down from 5000 volts to a four-wire three-phase secondary busbar with 200 volts between phases and neutral and 346 volts between phases. From this busbar, 200/346 volt, four-wire, three-phase secondary feeders emanate. In many instances these feeders supply an interconnected network at different points, of which the substation is the center. Practice varies as regards connecting together the low tension networks supplied from the different substations. Usually they are kept separate. These systems are used where the load is fairly dense, or where a direct current network would ordinarily be used in this country.

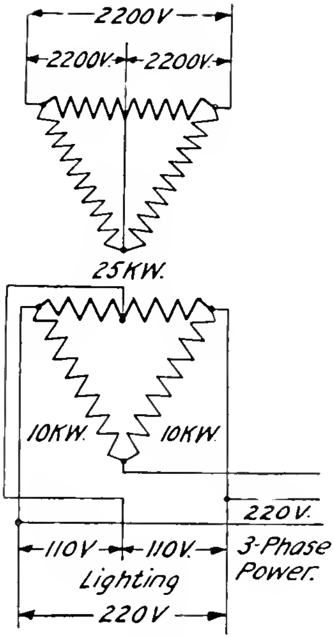

Fig. 14

The chief advantage possessed by this foreign system as compared to the American practice in alternating current distribution is efficiency at light load, since the transformer banks are large and their core losses small per kilowatt; and furthermore, because the number of transformer banks in service may be proportioned to the load. The system, however, requires a large investment in sub-stations and a large maintenance charge for station attendants. In this respect it is similar to the direct current system.

With the present day reliability of transformers and the development of automatic devices, we shall no doubt in the future see an ideal system in which large transformers are grouped in vaults with automatic devices for apportioning the number of transformers to the load and for disconnecting faulty transformers from the network and notifying the operator at central point.

## Regulation of Voltage

The systems of distribution used in this country are all based on the old Edison system of feeders and mains. It is aimed to keep a uniform voltage along the mains; that is to say, so nearly uniform that the variation of lights connected at different points will not be perceptible at different loads, the chief drop of voltage being in the feeders which can be compensated for at

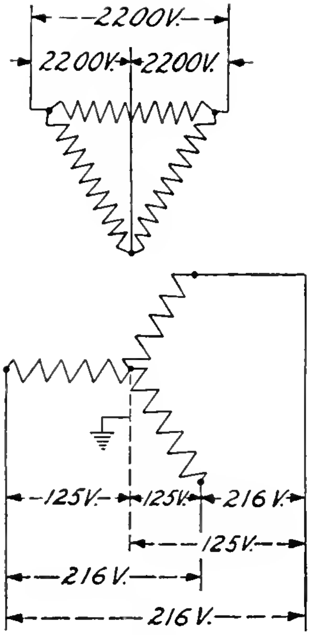

Fig. 15

the station. In the direct current system the drop is compensated for by having several busbars at different voltages on which the feeders may be thrown.

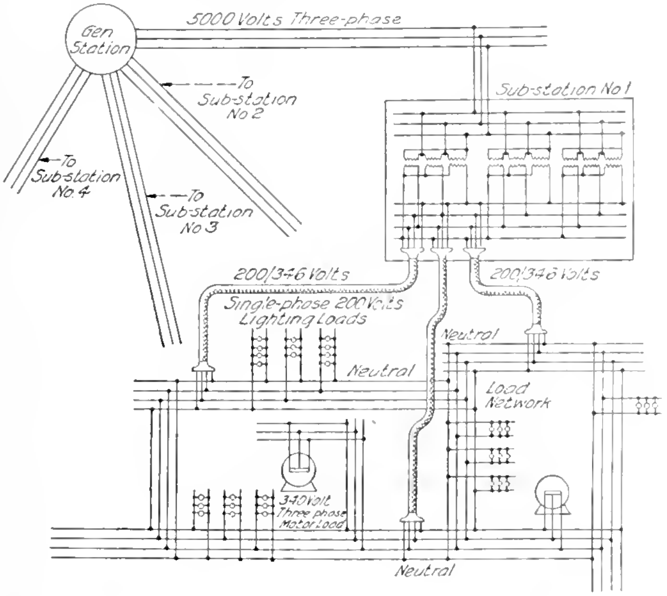

Fig. 16

In the a-c. system the feeders are usually high tension and the transformers may be considered a part of the feeder. Voltage regulators, usually of the induction type, are used to increase the feeder voltage at the station to compensate for the reactive and resistance drop in the feeders and transformers. These are hand operated in small systems and automatically operated by compensating voltmeters in the large systems. The secondary distribution in a-c. systems is laid out so that a very small drop may occur between different parts of the system, from no load to full load.

A variation in voltage of 2 to 3 per cent at the lamps used to be the goal that engineers strived to obtain with carbon lamps. Mazda lamps are less sensitive to slow variations in voltage, so that 4 to 5 per cent variation between minimum and maximum voltage does not mean poor regulation.

# THE EDISON THREE-WIRE SYSTEM

By R. H. Tapscott

Lighting Engineering Department, General Electric Company

Ever since the introduction of the Edison three-wire system, many years ago, it has been the one most commonly employed in secondary distributing systems. After leaving the distributing station, the general layout of all the systems of this type is practically the same, but for the securing of the neutral there have been many methods developed and a considerable number of these are in use today. It is of these that the author principally treats in this article. The advantages and disadvantages of each kind of neutral-producing apparatus are explained, the relative weights and efficiencies of the machines are given, and much valuable instruction is included which it has been found necessary to follow out in order to secure the successful operation of the system.—Editor.

**R. H. Tapscott**

To completely cover the subject of the Edison 3-wire system would mean a history beginning with the original Edison 60-light generator, and leading up through the period of the 125-volt engine-driven double machines to the present day alternating current high-voltage turbines and rotary converters. The feeder and main system of the Edison 3-wire system of today is essentially the same as the feeder and main system of the 2-wire system used with the old 60-light machines of 30 years ago. We will, therefore, consider only the up-to-date equipment, taking the various steps from the generating station to the consumer.

The direct current system is generally used in the congested districts of cities or towns and in hotels or office buildings, owing principally to two reasons:

First: A large portion of the load in either of these cases is the elevator load. The advantage of d-c. elevator motors over a-c. elevator motors is to be found in the ease of control, the perfection of the control equipment, and the increase in torque per ampere of direct current over alternating current. This means that for the same torque the regulation on the a-c. system would be inferior to the regulation on the d-c. system.

Second: The high line drop in a-c. systems due to the self inductance of the large capacity feeders run in close proximity to each other, the drop in the d-c. system being due solely to the resistance of the feeder.

The modern generating station consists of high-speed turbines with high-voltage a-c. generators. Alternating current is used through transformers in the more remote and sparsely settled districts, and through conversion for the d-c. service in the congested districts. In addition to this, in cities where there are more than one generating station, one of which is adjacent to or very near the d-c. load, a d-c. generating station may be advisable which could feed directly through the usual Edison feeders to the 3-wire mains.

Considering the a-c. turbo generators, the transmission to the substations will be 6600 or 13,200 volts, or even slightly higher, and the feeders will either be laid one for each converter or parallel feeders connected to a main bus in the substation. Under either circumstance there will be an auxiliary or emergency bus in the substation so that, when necessary, the feeders can be transferred from one converter to another, or separated from each other and a division of load made on the two busses. There will also be the usual ring bus or ties between substations for emergency service. In laying the mains from the generating station to any particular substation, due to the possibility of interruption to service caused by breaks in water mains or any other local disturbances, the feeders are laid through separate districts, even though this procedure greatly increases their length.

The greatest divergency will exist in the substations, for here we have the greatest amount of apparatus from which to make our selection.

The conversion units may be either synchronous converters or motor-generator sets. Synchronous converters have been almost universally used in preference to motor-generator sets on 25-cycle systems. On 60-cycle systems the motor-generator set has been preferred owing to its greater reliability than the earlier design of 60-cycle synchronous converters, and also owing to its supposed economy in power-factor correction. The present day 60-cycle converters are so reliable that we would not be justified in differentiating between the 25 and 60-cycle systems, but will assume that the synchronous converter would be used for either frequency owing to its higher efficiency. We shall, however, consider both types of units for the purpose of comparison.

If motor-generator sets are to be used, they will be of either the 2-unit or 3-unit type, with synchronous motors. In the 2-unit set we shall have either a 125/250-volt 3-wire generator or a 250-volt generator with a balancer set for obtaining the neutral, or, if a balancer set is not deemed desirable, the neutral may be obtained by means of a battery. The 3-unit set consists of a motor and two 125-volt generators. With this arrangement no other means of deriving the neutral is necessary.

If the synchronous converter were used, it would either be of the 2-wire 250-volt or 3-wire 125/250-volt type, and the voltage would be controlled by means of an induction regulator placed either in the high or low-tension side of the transformer or by a direct-connected synchronous booster, or a synchronous converter with regulating poles may be used. The economy in floor space of all of these synchronous converters, over the older type, has been greatly increased by the addition of commutating poles, thus allowing a considerable increase in speed.

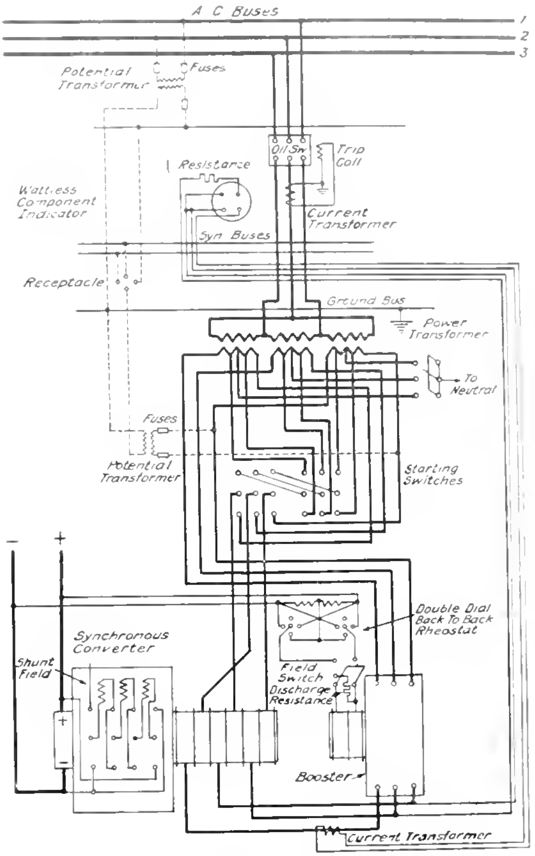

Fig. 1. Complete Diagram of Connections to a 6-Phase 3-Wire Synchronous Converter

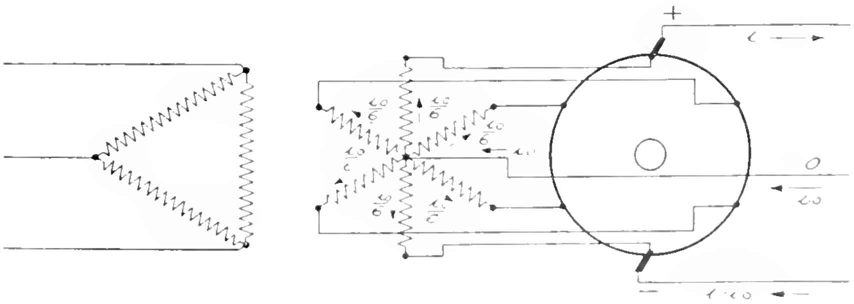

Fig. 1a. Simplified Diagram of Connections shown in Fig. 1

For the 6-phase synchronous converter, the transformers, which would usually be of the 3-phase type instead of three single-phase units, could have their secondaries connected in double delta or in diametrical. The double delta could not be used if the rotaries were of the 3-wire type as there would be no means of obtaining a neutral unless an additional compensator were installed. The advantage of the double delta seems to have been the fact that if one phase of the transformer were damaged, assuming the high tension to be delta connected, the converter could be run at reduced capacity on an open delta connection. As it has been found that if the transformers were diametrically connected in the secondary and delta connected in the primary they can

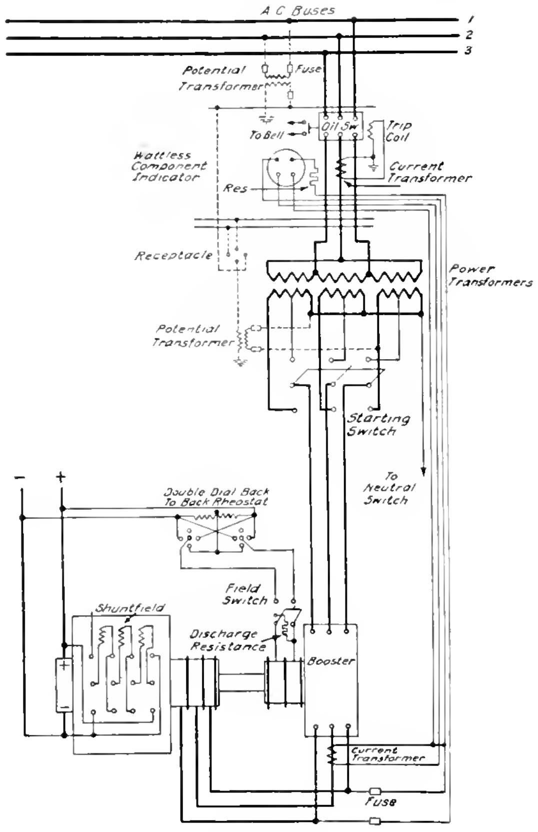

Fig. 2. Complete Diagram of Connections to a 3-Phase 3-Wire Synchronous Converter

also be operated from two phases under these same conditions with the same output, and, further, as this connection must be used for 3-wire service (see Fig. 1) there does not seem to be any further use for the double delta connection of the secondaries.

For the smaller synchronous converters, which would operate 3-phase, the straight Y-connected secondary, Fig. 2, would be satisfactory for 3-wire service if the transformer were of the 3-phase core-type construction. If three single-phase transformers were used, it would be necessary to use the distributed Y-connection, Fig. 2b, in order to neutralize the effect of the direct current in all three transformers.

The balancer sets mentioned could be either of the shunt-wound type for hand regulation or of the compound-wound type for automatic regulation. Figs. 3 and 4 show the connections of both the shunt and compound-wound balancer sets with cross-connected fields. This connection is necessary in order to obtain finer regulation for unbalanced loads.

If a battery is to be used in connection with the substation equipment and the neutral of this battery is grounded, and the neutral of the balancer is also grounded, or if the battery and balancer neutrals are connected together, it will either be necessary to use shunt-wound balancers or to use compound-wound balancers with the series

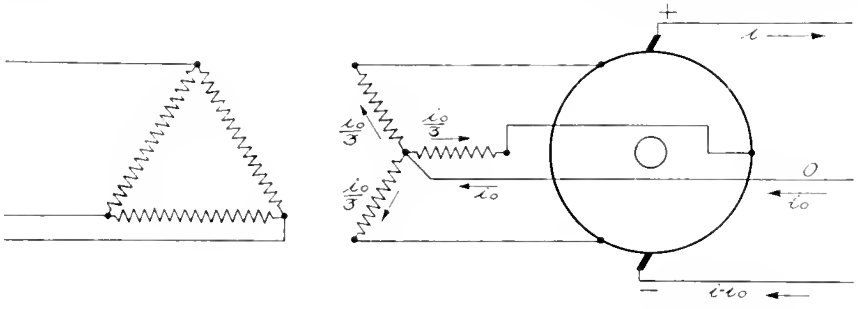

Fig. 2a. Simplified Diagram of the Connections for Using a 3-Phase Core-Type Transformer

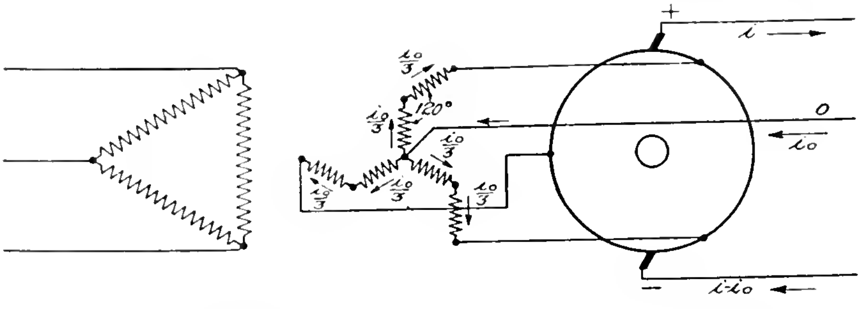

Fig. 2b. Simplified Diagram of Connections for Using Three Single-Phase Transformers

fields connected in series with the neutral wire (see Fig. 5) in order to obviate the possibility of a continuous interchange of current between the batteries and balancer sets, which would, in turn, lead to hunting of the sets.

If a battery is used for obtaining the neutral in connection with a 2-wire synchronous converter or motor-generator set and no balancer sets are used, or in any case where the battery neutral is tied directly into the neutral of the system, or, as is usual, grounded, a 3-unit booster set will be required for charging. This 3-unit set will consist of a motor, usually d-c., and two similar boosters. In order to cut down the initial expense of the boosters, and also to have some method of automatically disconnecting them from the line in case the battery is required for emergency service while it is being charged, an arrangement as shown in Fig. 6 has been used. This emergency may result in the battery being required for the d-c. load due to a shut-down in the conversion units or the main generating station, or it may be the requirement of heavy unbalanced current from the battery owing to trouble on the d-c. system which the other substations are unable to take care of. With this arrangement the 2-unit booster set is employed, and, while charging, the battery neutral is disconnected from the system, and the entire battery equipment charged from the one booster. The relays are so arranged that if the emergency arises, the battery neutral is reconnected to ground and the booster fields weakened, and the booster temporarily short circuited. With this system of relays and circuit breakers, there is no possibility of the battery remaining disconnected from the line when required for emergency service or for heavy unbalanced load.

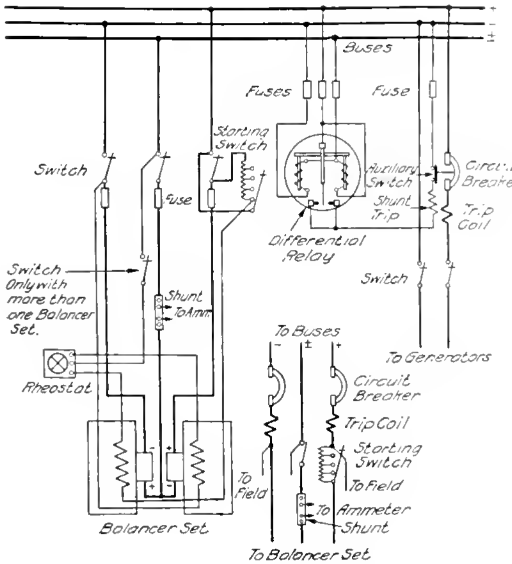

Fig. 3. Complete Diagram of Connections for a Shunt-Wound Balancer Set for Hand Regulation

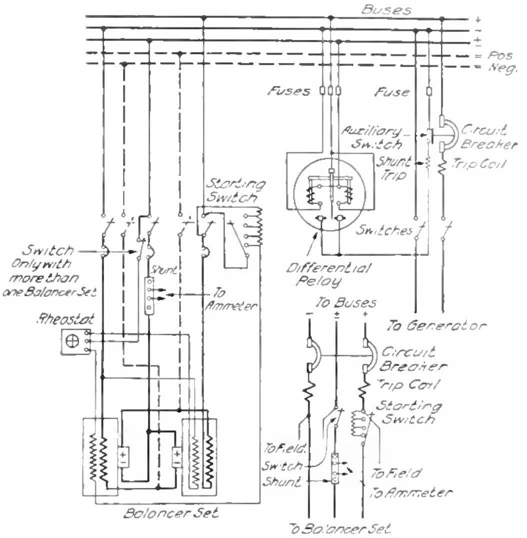

Fig. 4. Complete Diagram of Connections for a Compound-Wound Balancer Set for Automatic Voltage Regulation

To consider the various types of substation apparatus already mentioned from the standpoint of obtaining a neutral, the 3-wire generator either with collector rings and external compensator, or internal compensator and one collector ring, or with additional windings in the armature for deriving a neutral, would not allow of any compensation for the increased IR drop in the heavily loaded feeder, but would actually give the reversed condition due to the internal drop in the compensator and the direct-current armature, that is, the higher voltage will be impressed upon the lightly loaded side of the system instead of on the heavily loaded side. With a 3-unit motor-generator set or two 125-volt generators, compensation or compounding can be obtained on the heavily loaded side of the system, but it must be borne in mind that in obtaining unbalancing from two generators the total capacity is reduced by approximately the amount of unbalancing. In a 3-wire synchronous converter, with the neutral obtained from the neutral of the main transformers, the same condition exists as with the 3-wire generator except that due to the increased size of the transformers, which we may assume are used in place of the compensator of the d-c. generator, the voltage drop is materially reduced, and the voltage will not be decreased on the heavily loaded side of the system as much as with the 3-wire generator. It may happen that this unsuitability of apparatus to compensate for IR drop in the heavily loaded feeder may not be serious, for, with a certain distribution of the neutral in the 3-wire mains, the unbalanced current may be neutralized or taken care of only in a few of the substations. In this case, this unbalancing could be compensated for by small balancer sets in the particular substations where they were required.

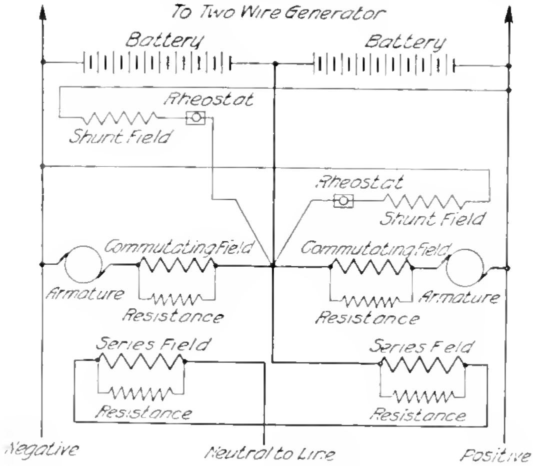

Fig. 5. Diagram of Connections for a Compound-Wound Balancer Set with Neutral Connected to Neutral of Battery

The shunt-wound balancer sets may be controlled by hand through the shunt fields to obtain the necessary increase in voltage required to compensate for the IR drop in the heavily loaded side of the system. With the compound-wound balancer with the cross-connected fields or with the fields connected in the neutral as in Fig. 5, adjustments can be made so that with unbalanced current equal to the ampere rating of the set (this rating should always be stated in neutral amperes) the machines will either compound flat, giving equal voltage on either side of the 3-wire system or may be over-compounded to automatically take care of the IR drop on the heavily loaded side.

In the matter of efficiencies of the various units, the order will be:

Three-wire synchronous converter, synchronous converter with balancer set, 3-wire motor-generator set, synchronous converter with battery, motor-generator set with balancer set, motor-generator set with two generators, motor-generator set with battery.

These efficiencies are calculated at full load with an unbalanced current of 15 per cent. The highest, or 3-wire synchronous converter, would be from about 90.5 to 93.5 per cent for 25 cycle and the lowest, or motor-generator set with battery, from about 85 per cent to 88 per cent.

The order of weights and dimensions will be approximately the same as the efficiencies.

Considering the distribution, this is always of the Edison feeder and main system, the feeders being run from the substation to the various points of distribution where they are tied into the mains of the 3-wire net-work. Customers are invariably fed from the 3-wire mains and not from the feeders, although for large installations, separate feeders are sometimes tied into the 3-wire net-work on customer's premises. Fuses are used in the mains at the various junction boxes or points where the feeders are tied. These are of ample capacity so that they will open only on severe overloads or short circuits. The fuses insure the isolation of a short circuit to a very small section of the net-work.

In some cases the feeders are 3-wire, that is, include the neutral, whereas in other cases the neutral is run on the tree system in order that any unbalancing which may occur will be equalized on the system instead of being returned immediately to the nearest substation for correction. This, as already mentioned, reduces the number of stations from which heavy unbalanced current is required.

The feeders and mains rarely exceed cables of larger cross-section than 1,000,000 circular mils. If mains larger than this are required cables are usually run in multiple. Feeders larger than this are not required, since they are tapped into the net-work at various points which are determined by the loads and regulation required on the 3-wire system. They are usually fed from either two or three separate busses at the substation which are operated at voltages outside the normal, giving a range from low to high, varying usually from about 240 to 300 volts or 120 to 150 volts on either side of the neutral. The feeders contain pressure wires by which the voltage demand of any particular feeder can be determined and the feeders switched from one bus to another as the demand exists. The shifting of a feeder from one bus to another does not change the voltage of the 3-wire net-work in proportion to the difference in bus voltage, but merely causes a shift of load away from or to the other feeders according to whether the voltage of the particular feeder being changed is increased or decreased, with a consequent very slight change in voltage. To supply the three busses in the substation, different machines are connected to the busses as required by the load, or in some cases the machines are operated on one bus and the standby battery is used for an intermediate bus and a booster used for the high bus. There are some cases in which the feeders are very short and the requirements for three busses are not very great, but, in the majority of cases, the 3-bus installation works out to the best advantage.

It is no doubt a common impression that of all public utilities the water supply of our large cities is the most dependable. We will not enter into a direct comparison of the Edison 3-wire system with the water system, for one is usually dependent upon the other, but let us consider the remarkable service and size of some of the 3-wire systems. The net-work is almost self-protecting for, owing to the size of the mains and the fact that any point on them is fed from two directions, a short circuit will almost invariably burn itself out with the large current and low voltage available and will not be re-established on account of the very low puncture point of this voltage. The substations not only have a large spare capacity in conversion units but in most cases an enormous capacity in standby batteries. The generating stations are still larger for here again we have spare units and the total capacity is far greater than the d-c. capacity, since this latter is only for the crowded sections of the city and the main stations must also supply power and light to the more remote districts, also, in some cases, for a considerable portion of the railway load. These are some of the reasons why we hear of such figures on one system as 30 years of service with only two or three complete shut-downs aggregating in all not more than 12 or 13 hours.

As to size, the largest synchronous converter for lighting work that has been built up to the present time is of 3500 kw. with a two hour capacity of 4250 kw. or approximately 210,000 present-day lamps against the original main generator of only 60 lights. The largest substation for Edison service is in the neighborhood of 20,000 kw. as a normal output exclusive of batteries. One of the large operating companies today has a capacity of conversion units in their lighting substations of 275,000 kw. on the overload or two hour basis and a peak load on their 3-wire systems of approximately 135,000 kw. or over 1,000,000 amperes. As a standby, this same system has a battery capacity of about 37,000 kw-hrs. at the one hour rate but, owing to the design of these batteries, the fifteen minute rating will be almost four times this figure, or more than the peak load of the system. In another city we find in round figures 150,000 kw. in conversion units on the two hour basis and a battery of about 22,000 kw-hrs. on the one hour basis.

# SYNCHRONOUS CONVERTERS *versus* MOTOR-GENERATOR SETS FOR LIGHTING SERVICE

By L. B. Bonnett

Lighting Engineering Department, General Electric Company

The higher efficiency of synchronous converters in many instances will make their installation more economical than that of synchronous motor-generator sets, and their unity power-factor operation may raise the power-factor of the system sufficiently for satisfactory operation, even when the a-c. load alone has a large lagging component. In the following article, the author assumes a concrete case of a substation supplying both d-c. and a-c. load, the latter of low power-factor. He then calculates the comparative losses and investment charges, which show an annual saving for this specific case in favor of synchronous converters. At the end are tabulated results of similar calculations for different assumptions of loads and transmission voltage.
—Editor.

L. B. Bonnett

For transforming from 25 cycle power to direct current for Edison light and power systems, it is almost universal practice to use synchronous converters. For 60 cycles there is considerable difference of opinion as to the relative advantages of synchronous converters and motor-generator sets. At one time, 60 cycle converters were decidedly inferior to the 25 cycle units, and many companies standardized the use of motor-generator sets. Of late years, great improvements have been made in 60 cycle converters, and the operating objections to them have been gradually overcome. Many companies, however, still strongly favor motor-generator sets because of the power-factor correction inherent in such sets. It is not the purpose of this article to go into the relative operating advantages, but rather to show that it is often more economical to use synchronous converters, even when combined with an a-c. load of poor power-factor. Their better efficiency may show a saving which more than counterbalances the increased losses in transmission and generators due to the lower power-factor of the system.

This is best shown by some concrete examples. Assume a substation five miles from the generating station supplied with 60 cycle 13,200 volt power through two three-phase 4 0 underground cables.

Fig. 1, curve "A," shows the kilowatts of d-c. load supplied by two 1500 kw. units, only one unit being used from 10:30 o'clock at night until 7:30 o'clock in the morning. Curve "B" shows an a-c. load supplied from the same substation at the power-factor shown by curve "D." For motor-generator sets assume two 1500 kw. shunt wound generators driven by high voltage 0.8 power-factor synchronous motors, and operated with constant excitation so adjusted as to give 0.8 power-factor at approximately normal load. At lower loads, therefore, the corrective kv-a. will be larger than if the excitation were adjusted for 0.8 power-factor at all loads, and it is obtained with small sacrifice in efficiency. For the synchronous converters assume high speed commutating pole shunt wound units with either series boosters or induction regulators for varying the voltage, and three-phase six-phase air blast transformers with suitable blowers, adjusted for approximately unity power-factor at all loads. The efficiencies assumed for various loads cover the complete losses from the high tension side of the transformer to the d-c. load, including the losses in the blower and a small amount for cable loss between the transformer and the converter.

Assuming an efficiency curve for the motor-generator sets, the input at the various points on the load curve is obtained and the difference between the total kilowatt-hours direct current and the total input gives 7980 kilowatt-hours daily loss in conversion. Curve "C," Fig. 1, shows the total kilowatts input to the substation. The wattless component of the a-c. input alone may be obtained from the kilowatts and power-factor. This, counterbalanced by the leading wattless kv-a. given by the motor-generator sets and combined with the kilowatts in curve "C," gives the kv-a. input to the substation (curve "B" on Fig. 2 at the power-factor of curve "E"). From this curve the amperes flowing may be obtained, and the average of the square of the amperes with the resistance of the transmission cables gives the $I^2R$ loss in transmission, which, for this case, equals 2900 kilowatt-hours per day. In the above we have neglected the capacity currents of the cables, as their effect on the comparison would be negligible. Curve "C," Fig. 1, shows that the average load is approximately 5035 kilowatts at an average power-factor of 96.5. This plus the average transmission loss gives 5170 kw. average power generated for this substation. With economical generation, we may assume the generator losses chargeable to this amount of power to be approximately 7 per cent. or 362 kw., which equals 8700 kilowatt-hours daily loss. This gives a total daily loss for the motor-generator substation of 19,580 kilowatt-hours.

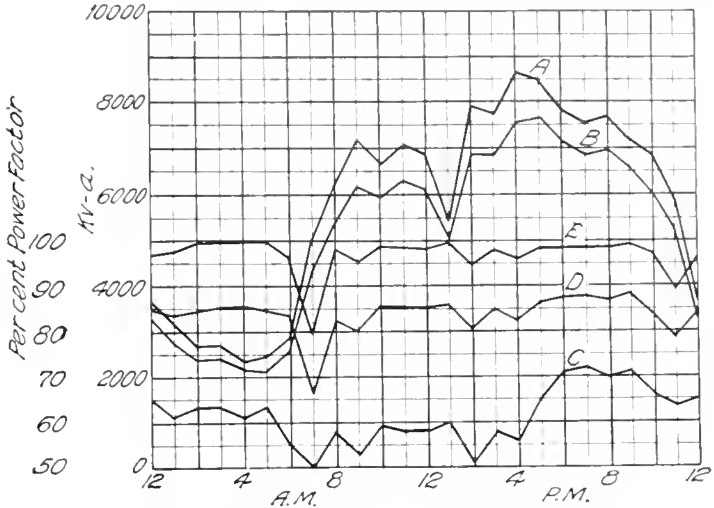

Fig. 2. Comparative Curves

A = Total Kv-a. with Rotary Converters.
B = Total Kv-a. with Motor-Generators.
E = Resultant P-f. of Line with Motor-Generators.
C = P-f. of A-C. Load Alone.
D = Resultant P-f. of Line with Rotary Converters.

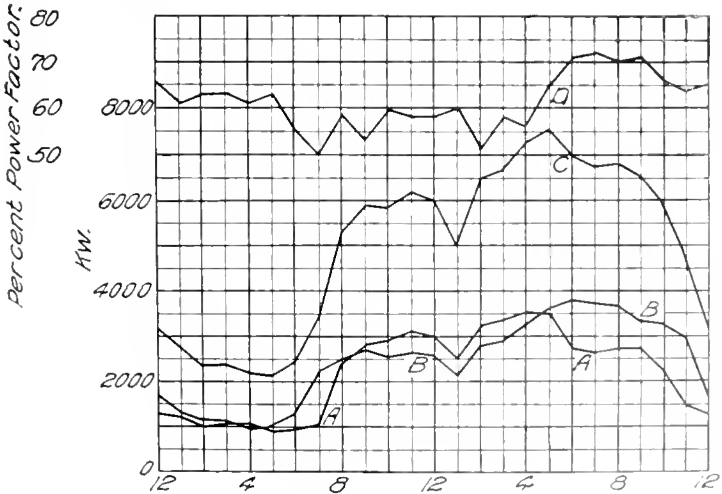

Fig. 1. Load Curve

A = Kw. D-C. Load.
B = Kw. A-C. Load.
C = Total Kw. Input to Substation.
D = Power-factor A-C Load Alone.

The same process of figuring for the converter substation gives a daily loss in the converters of 4880 kilowatt-hours. The total kilowatts input to the substation is slightly less than curve "C," Fig. 1—approximately 2.8 per cent lower, but too near it to show successfully on the small scale used. Fig. 2, curve "A," shows the kv-a. total combined load at the power-factor of curve "D." Based on curve "A" the transmission loss figures to be 3650 kilowatt-hours. Fig. 3 shows the approximate increase in losses of large high speed turbo-generators with constant kilowatt output and varying power-factor. This curve is approximately true only for high speed generators where the variable losses are small compared with the fixed losses. With slow speed generators having a large number of poles, the variable losses, and with them the increase in losses with decreasing power-factor, are relatively greater. The average load with synchronous converters is 4895 kw. at an average power-factor of 83.8 per cent, or 5047 kw. average power generated. Seven per cent of this equals 353 kw. loss. The curve, Fig. 3, however, shows that the losses at 83.8 per cent power-factor are increased 3.7 per cent over that for 96.5 per cent power-factor, making 366 kw. loss. This gives a daily generator loss of 8800 kilowatt-hours, or total losses for the converter substation of 17,330 kilowatt-hours a saving over the use of motor-generators of 2250 kilowatt-hours per day. At one cent per kilowatt-hour this gives a daily saving of $22.50, or $8225 annually in favor of synchronous converters.

The transmission line losses given above are based on the assumption that the same cable is used in both cases. If it is of correct size for the converter substation it could be reduced in the ratio of the peak kv-a. loads or as 8630 is to 7680 (see curves "A" and "B," Fig. 2). Such decrease in size would increase the resistance and therefore the I²R loss inversely in the same ratio. This gives an increase of 360 kilowatt-hours daily loss for the motor-generator station, which amounts to $1315 annually, making a total annual saving in favor of the synchronous converters of $9540.

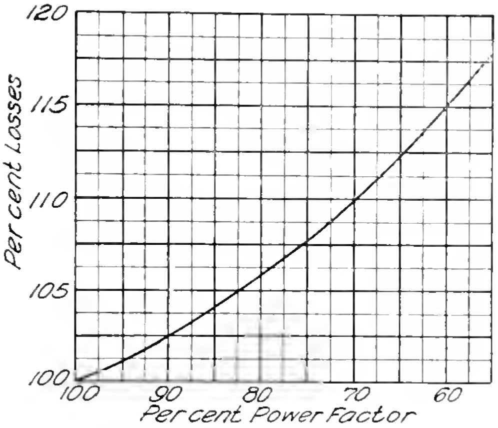

**Fig. 3. Comparative Curve**
Increase in Losses in Turbo-Generators.
Constant Kw. Output at Varying Power-factor.

Assuming a cable and duct cost of $15 per kv-a. for the five mile line, the increased cable required by the greater (by 950 kv-a.) peak of the synchronous converter station would be capitalized at $14,250. The generators and equipment from them to the busses must also have 950 kv-a. increased capacity, which at $10 per kv-a. is $9500; making an increased investment for the synchronous converter station of $23,750.

Considering all the losses, there is a difference in favor of the converter of 139 kw. in peak kilowatts generated. Power house equipment to generate this increased load, if capitalized at $100 a kilowatt, would amount to $13,900. Deducting this from the previous figure for increased investment, we have a total increased investment for the converter station of $9850. Interest and depreciation at 20 per cent equals $1970 annual charge. Subtracting this from the annual saving in losses leaves $7570 net annual saving in favor of the installation of synchronous converters. The foregoing assumes that motor-generator sets and synchronous converter equipments have the same cost, although, in general, the latter will be cheaper.

Reference to Fig. 4 shows that the efficiency curve of 4000 volt or 2300 volt motor-generator sets is higher than that of 13,200 volt sets and compares more favorably with that of synchronous converters. The second section of Table 1 shows results from assuming the same loads as before, but with lower voltage transmission. The transmission copper is assumed to be such as to give the same loss as in the case of the converter station. This case shows a net annual saving of only $620.

For 22,000 volt transmission, the efficiency curves of Fig. 4 show that results would be approximately the same as in the case of 13,200 volt transmission.

For still another case we will assume a 13,200 volt transmission consisting of four 3/0 cables with an a-c. load of twice that shown on curve "B," Fig. 1, or approximately twice the d-c. load. This shows a saving of $2390 annually for synchronous converters. The resulting power-factor of the system is of course not so high, the average being 86.9 per cent for the motor-generator station and 75.9 per cent for the converter station. At first glance this may seem low from an operating standpoint, but with the voltage of the feeders going out from the substation suitably controlled, the question of drop from the generating station to the substation becomes of less importance.

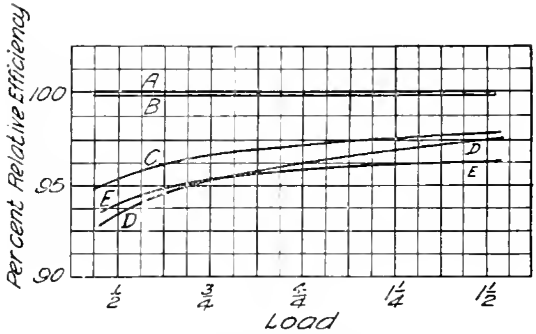

**Fig. 4. Relative Efficiencies**
*A* = Basis = Converter with 13,200 Volt Transformer.
*B* = Converter with 22,000 Volt Transformer.
*C* = 0.8 Power-factor M.G. Set, 2300 or 4000 Volt.
*E* = 0.8 Power-factor M.G. Set, 2300 or 4000 Volt with 22,000 Volt Transformers.
*D* = 0.8 Power-factor M.G. Set, 13,200 or 6600 Volts.

The load curves shown have a high load factor, but it would seem that a poorer load factor would show a greater saving for the converters as their efficiency does not drop as rapidly with light loads as that of motor-generator sets. This article is not intended as an argument that synchronous converters are always more economical than motor-generator sets, but it endeavors to show that each individual case should be investigated on its own merits.

TABLE I—SUMMARY

| TRANSMISSION VOLTAGE | 13.200 | | 4000 OR 2300 | | 13.200 | | 22.000 | |

# EXTENSION OF LIGHTING SERVICE THROUGH THE SOCIETY FOR ELECTRICAL DEVELOPMENT

By J. Robert Crouse

Manager of Sales, National Lamp Works, General Electric Company

Ever since the time when there sprung up several individuals who made the same kind of article, to be sold in the same district, sales competition has existed. The manufacturing company, the natural outcome of the individual manufacturer, continued this policy of jealous competition until at the present day each company while seeking to attract the attention of the public to its own particular wares is put to a by no means inconsiderable expense in educating the public to the usefulness of such devices in general. It is inefficient that each company should individually carry on this general educational work, for it could be much better accomplished by a single collective organization. In the electrical industry this organization is the Society for Electrical Development, which, with the earnest cooperation of central stations, manufacturers, jobbers, dealers and contractors, will carry on the educational work for the benefit of all and then leave its component parts to compete upon a rational basis. The following article explains the commercial conditions prompting the formation of this Society, defines its functions, shows how it is supported, and tells of its reception.—Editor.

J. Robert Crouse

PERHAPS the best way to introduce this subject is to quote from the notable address of Mr. Samuel Insull, delivered at Camp Co-operation, Association Island, September 4, 1913.

"At that time (referring to the very early years) the business of producing and distributing energy was mainly for the purpose of producing light, principally through the medium of the incandescent lamp. The business of supplying power was, so to speak, a by-product; just as much a by-product of the electric lighting business of that day as coke and tar and ammonia are by-products of the gas business of today. And notwithstanding that the incandescent lamp business has grown so that a hundred millions of lamps are consumed in this country in a year, today the electric lighting end of our business has become very largely a by-product. That side of our business which, thirty, twenty, even ten years ago, was the main portion of our business, was the portion of our business from which we got the necessary returns in order to pay a return to those investing their capital in our business, I say notwithstanding its importance as late as ten years ago, today, in looking to the future, I think that it is perfectly safe to say that the lighting end of the business is the by-product side of the business. If the business represented by the manufacturers here, of manufacturing lamps, is to increase by any such leaps and bounds as it has increased in the last ten years, the lighting business must become still further a by-product of the business, and, for the main basis, for a return on our investment we must look to the power business."

Mr. Insull, elsewhere in this address, states that the amount of energy used for incandescent lighting, as far as they have been able to check it, is from not more than 27 per cent under the best conditions, to 45 per cent under not as good local conditions, of the current produced at the station.

It seems to me that this statement from so authoritative a source is a sufficiently clear exposition of the evolution of the lighting business from the dominating activity in the early days to what Mr. Insull calls a by-product at the present time. A necessary deduction from this is that the interests of all who are engaged in the lighting branch of the industry are intimately and necessarily tied up with the progress of the other branches in heating and power work. Accordingly, while we, in the lighting business, must necessarily spend most of our energy along the line of perfecting and extending the lighting service, the conditions before recited should make a successful appeal for our sympathetic interest and active cooperation along broad lines of market development for all classes of service.

The principles involved in this trade movement are briefly covered as follows:

There are always some underlying, basic principles governing all change and progress, whether in the field of research, engineering, manufacturing or merchandising. These principles are of the same essential quality as the axioms in mathematics or refined statements of particular relations, such as $C=E/R$ in our electrical business. Such principles do not depend for their truth or power upon minority or majority assent, and when once fairly stated are assured of final acceptance, since essential progress must be made in harmony with them.

The progress in our electrical business during thirty years, notwithstanding the fact that less than thirty per cent of the population is electrically served, has been one of the wonders of the world; its contributions to the comfort, happiness and efficiency of our modern life are so great that we wonder how a preceding generation did without it. We may justly feel proud of such a magnificent business, which in every department of its development is so worthy of our best thought and effort.

The efforts of those engaged in the fields of research, engineering and manufacturing have shown the most marked results, since, while enjoying the stimulus of the friendly rivalry of other men and organizations, they have been free from the sort of competition which makes the accomplishment of useful results expensive and difficult. It is a matter of common observation that rapid progress has been made in discovery and research, in efficient engineering adaptation of discovery to practical manufacture, and in improved products tending to better the conditions of generation, construction and distribution.

However, in the field of selling and distribution we are challenged by the cold fact that no essential progress, meaning by this a decreasing ratio of sales expense to sales, has been generally accomplished. Not only this, but there is a prevailing opinion among the manufacturers, jobbers, dealers and contractors that the ratio of sales expense to sales tends to increase. The annual reports of some of the largest electrical manufacturers makes specific mention of this tendency as a fact in their operation. Among central stations this is doubtless less true, since by common consent they are properly monopolistic for the best results and are competitive only with other methods of furnishing service for light, heat, power, etc.

Our electrical business, technical in its very nature, has doubtless for that reason placed less emphasis in the past on aggressive selling and distributing effort—witness the fact that the first commercial papers in the National Electric Light Association appeared only so recently as 1905 and national advertising by individual companies began about 1907-1908.

It is estimated that the gross sales, and ratio of sales expense to sales for 1912, in the electrical business, were approximately as indicated in Table I

This $80,000,000 of sales effort, which is equal to one-fifth of the gross sales of all the central stations, is incurred by approximately 5000 central stations, 500 manufacturers, 200 jobbers, 5000 dealers and contractors, a total of 10,700 organizations. It is of special importance to note that $60,000,000 of this $80,000,000 sales effort is incurred by the manufacturers, jobbers, dealers and contractors who operate under complete competitive conditions, at a sales expense ratio of at least fifteen per cent, and tending to increase.

TABLE I

| Branch of Business | Gross Sales 1912 | Per Cent Ratio Sales Expense to Sales | Sales Expense 1912 |
|---|---|---|---|
| Central Stations | $400,000,000 | 5 | $20,000,000 |
| Manufacturers and Jobbers | 300,000,000 | 15 | 45,000,000 |
| Dealers and Contractors | 100,000,000 | 15 | 15,000,000 |
| Total | 800,000,000 | | 80,000,000 |

While Table I and its comments are broad generalizations, the reader is asked to check the principle and its application in his own particular case.

These facts in themselves are a challenge to commercial men which cannot be avoided. They justify the most careful search for causes and investigation of plans for improvement.

Whatever minor causes may be contributory to this failure in more efficient merchandising, the major one, which experience and facts disclose, is competition among these thousands of companies, resulting in expensive duplication of all kinds of sales efforts and failure to co-operate in a definite organized plan in those kinds of endeavor which effectively supplement and vitalize legitimate competition.

This competition consists, to a very great extent, of securing the business held by others and that of natural growth, which we may characterize as the existing market. A very large part of the selling effort is exerted on this existing market and dissipated in commercial friction and lost motion, with a resulting decrease in its creative effect.

The fact is frequently overlooked that the current-consuming devices for light, heat, power and other useful purposes are the only aspects of our business in which the public are or can be interested, while they constitute but a small part of the resulting business from the boilers to the devices the public uses. We are therefore all, without conscious organization, joint sellers of the final service.

This age of business, in which someone has said we live to do business instead of doing business to live, in the best sense, is, in the order of social development, the successor to the period when war, the extreme of competition, was the principal occupation. Business has inherited from this prototype many habits of enmity, antagonism and waste, which only the persistent cultivation of good fellowship, harmony and economy will gradually supplant. The most successful organizations which I have observed have given the greatest attention to the cultivation of harmony among their men, and the spirit of progressive, constructive effort. This same result must measurably follow similar conscious effort by an entire industry, especially one whose existence in its present form depends on the public's good will and appreciation.

The Society for Electrical Development proposes a broad, common organization of our entire industry: central stations, manufacturers, jobbers, dealers and contractors, controlled by a balanced representation from each, but not by any one alone, through which a part of this $80,000,000 of unorganized and competitive sales effort can be more effectively exerted through organized and co-operative effort in promoting and popularizing electrical service. These plans to teach the public to "Do it Electrically," though there are many more than can at once be undertaken, have been worked out and endorsed as entirely practical by many prominent men in our business.

The Society proposes at the start that a minimum of $200,000, or but one-fourth of one per cent of this $80,000,000 of competitive sales expense, be co-operatively expended. The basis of subscription is for manufacturers, and central stations, one-fifteenth of one per cent of gross sales, and one-twentieth of one per cent for jobbers, dealers and contractors, amounting, for illustration, in the case of the former, to $66.67 per $100,000 or $666.67 per $1,000,000 of gross business, and in the latter to $50 per $100,000 or $500 per $1,000,000 of gross business, the subscription being on an annual basis. This means in the case of a company having a fifteen per cent sales expense account, but one three-hundredth of their sales appropriations. There are few organizations which cannot locate competitive expenses of doubtful value equal to the Society's subscription. While individual subscriptions are comparatively small and in no sense burdensome, yet general co-operation in the movement will make a fund of $500,000 per annum available for progressive and aggressive market cultivation along these new lines.

This Society creates the organization and the fund through which some of our dollars can co-operate with the good will of us all in broad effective activity for the expansion of the market, while we continue with the most of our dollars to compete for our fair share.

This plan means real progress in the direction of more efficient distribution of electrical service through joint cultivation of our common market, the great preoccupied, incredulous, money-spending public, a result which our present systems neither accomplish nor promise ever to achieve on the old lines.

The plan presents a new kind of consolidation for sales efficiency through the means of a better balance of competitive and co-operative effort to which the popular thought will not now nor in the future take exception.

The plan means that electrical men, identified with this most wonderful of all businesses, will demonstrate for themselves, and by example for others, the true principles which underlie progress in more efficient sales distribution, through the creative cultivation of the market. The plan lends dignity to the art of selling, synonymous in the best sense with service, and marks a further point in the age now happily passing, when the selling spirit was symbolized in the economist's expression *Caveat Emptor*, "Let the buyer beware."

The limits of this article will not permit a discussion in detail of the plans of the Society for Electrical Development, further than to state that they cover broadly many lines of specialized activity in advertising, publicity, demonstration, etc., to teach the public to "Do it Electrically," which may be indicated by the following headings.

1. National Campaign of Advertising.
2. National Electrical Press Bureau.
3. Advertising Service through Agencies.
4. New Business Departments of the Technical Press.
5. School of Electrical Salesmanship.
6. Field Men to stimulate and develop local co-operation.

7. Field Men among Allied Trades, such as Architects, Builders and Contractors.

8. Campaigns of suitable Commercial Literature to Different Trades.

9. Special Prizes for Commercial Work, from which resulted, for instance, the Solicitor's Hand-Book which has been widely circulated.

This trade movement has received the endorsement of a group of men of [illegible] and international reputation (recently widely distributed in pamphlet form) as well as by practically all of the National Electrical Associations, so that, while its ideals for commercial progress are along such advanced lines, their practicability is well evidenced by these endorsements of both expert and general opinion.

---

# SERVICE TO THE SMALL CONSUMER

## By S. E. Doane

Chief Engineer, National Lamp Works, General Electric Company

It is rather startling to learn that many European central stations include, at a profit, customers that have a connected load of only 15 or 20 watts, one company in fact carrying several thousand such consumers. Using these examples, the author recommends that our American central stations and supply dealers develop this field which has been so long neglected in this country.—Editor.

S. E. Doane

IT IS but natural that we, who are of the electrical industry, should come to regard the electric light as an almost universal illuminant when, as a matter of fact, the incandescent electric lamp is limited in its application to a relatively small part of the total field of artificial illumination. In the first place, about half of the population of this country is not within reach of central station service. This necessarily, to a great extent, excludes them from the advantages and conveniences of the incandescent electric light. In the second place, of the remaining part of the population residing in districts within reach of the central station service, but a small proportion is using electric service principally because our central stations have not generally as yet developed methods of rendering electric service to the smallest possible customers on a profitable basis. The central stations, entering the lighting field at a somewhat late date with methods of service which, to say the least, were not inexpensive, looked particularly toward the larger consumers as the profitable and desirable part of their load. In fact, it was not many years ago that some central stations doubted the possibility of serving even the larger residential lighting customers at a profit, while others regarded all residential lighting as a rather undesirable class of business. In consequence, they preferred to devote their attention to the larger commercial users of light and power.

The feeling that the small customers could be served only at a loss served to center the interest of the central station on the customers of larger size to such an extent that, until very recently, in this country very little has been done to reduce the cost involved in rendering service to the small consumers. The small customer, if served at all, must be served cheaply and, to serve the small customer cheaply, but at the same time profitably, the cost of service must be reduced to its lowest possible value.

The central stations in this country have not generally felt the immediate need of soliciting and developing the business of the very small consumers. Abroad, however, conditions have been somewhat different and the central stations have, for various reasons, found it desirable to give the smaller, and as we believed less profitable, consumers their most careful attention. It is not surprising, therefore, that we should find developed abroad methods for handling small customers' business which have served to render such business profitable and desirable from the central-station standpoint. The problem has been studied carefully from every angle and the details have been worked out with nicety; not only as to systems of charging and methods by which the expense of the wiring is financed for the very small customers, in order to remove some of the initial burden from their shoulders, but as to the method of billing, accounting and collecting which have all been modified with the particular object of reducing the expense involved in handling the accounts of these very small customers.

The results of the investigation by the foreign stations have placed them in a position where they do not simply tolerate the small customer, but where they actually solicit his business. Electric light is being extended into the homes of the poorest classes and the smallest possible customers using but one or two lamps of perhaps 15 or 20 watts each are being served by the central station at a profit. In fact, in Milan the average connected load of some 25,000 small customers is but 1.83 lamps, averaging about 22 watts per customer. It is needless to say that if our own methods of serving small customers were developed to this extent the thousands upon thousands of lighting customers, who are today within easy reach of the central station service and who because of the present methods of handling lighting business have been unable to avail themselves of the convenience and safety of electric light, would constitute one of the most important and profitable fields of electrical development open to us today.

Some of the systems and methods developed abroad for handling the very small customer's business are so unique that at first sight they may appear to be of more theoretical than practical value. However, the central stations abroad are actually obtaining today a not inconsiderable part of their revenue from the lighting business of the smallest possible class and the methods which they have developed are thoroughly practical and produce results.

The more progressive central stations in this country are already realizing the enormous possibilities which lie before them in rendering service to the thousands and thousands of small customers within easy reach of their existing lines. Within the year much will be heard of the foreign developments and practice. The report of the author's extended investigation of this subject abroad has already been presented to the National Electric Light Association's committee "Wiring of Existing Buildings" (of which he is a member), and the results of this investigation will be published in the very near future. Some of our own central stations are beginning to develop and devise means for opening up this enormous field and others will undoubtedly follow in increasing numbers. This extension of electric service to the smallest possible lighting customers will not only serve to increase the sale of electrical energy but the addition of this new business to the central station lines will open up a new field for the sale of wiring material and electrical supplies, and thus prove of broad benefit to the electrical industry.

Let us therefore do our utmost to bring about the extension of electric service to every possible customer within reach of central station service; let us enable these customers to discard their obsolete, dangerous and inconvenient lighting equipment, and in the future to "Do It Electrically."

# SOME RECENT DEVELOPMENTS IN CENTRAL STATION AND SUBSTATION EQUIPMENT

By J. R. Werth

Lighting Department, General Electric Company

In this article the author has selected for discussion some of the more important developments that have been made recently in the design and construction of switchboards, motors and generators. The reasons that brought about these improvements are pointed out and the manner of their accomplishment described and illustrated. The principal features relate to the standardization of switchboard panels, cast copper field coils, connection of end rings to rotor bars, forced oiling system for starting large machines, mica tape insulation of coils, and cooling vanes for commutator.—Editor.

J. R. Werth

To the central station man continuity of service is, in all probability, "the chiefest of virtues." Substation and central station equipment has in recent years been manufactured not only to secure reliability of service, but also with the aim of improvement along the lines of simplicity, safety and convenience of operation. It is the object of this article to give a few random examples showing how some of these features have been secured.

### Switchboards

The switchboard has often been called the brain of the central station and, as the problems of generation, distribution and control are different in each case, the "brain" must obviously be a little different for each installation. A switchboard inherently consists of so many separate items that it might seem almost a hopeless task to standardize and catalogue the various panels so that a suitable board could be selected by catalogue number to meet more than a few requirements. Until recently this was a fact. Now, however, it is possible to obtain for use on d-c. systems up to 600 volts and on a-c. systems up to 2300 volts complete switchboards for large or small stations made up completely of so-called "standard unit" panels which can be ordered direct from a publication by catalogue number. To accomplish this it has been necessary to standardize many thousands of separate and distinct panels which can be used in a very great number of combinations.

A type of switchboard manufactured by this system is shown in Fig. 1. It was built to fill a rush order, the previous equipment having been destroyed by fire. The elapsed time between the placing of this order and its fulfillment was in weeks what under the usual system would have been as many months.

The fact that a switchboard, for example, to control three rotary converters cannot be selected by simply multiplying by three the equipment listed for one rotary converter and that the problem of the selection of the correct number of voltage and current

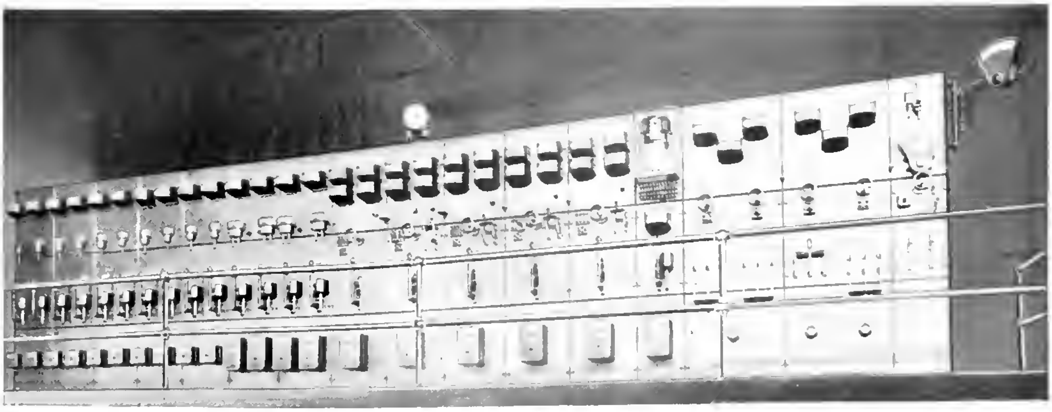

Fig. 1. A switchboard which was furnished in a remarkably short time because of being ordered on the "Standard-Unit Plan"

transformers varies according to the number of machines or feeders to be controlled, increase the difficulty of successfully listing these panels to meet every emergency. Therefore, a relatively enormous amount of work must be done in order to secure what, from the central station man's viewpoint, must be an extremely simple result.

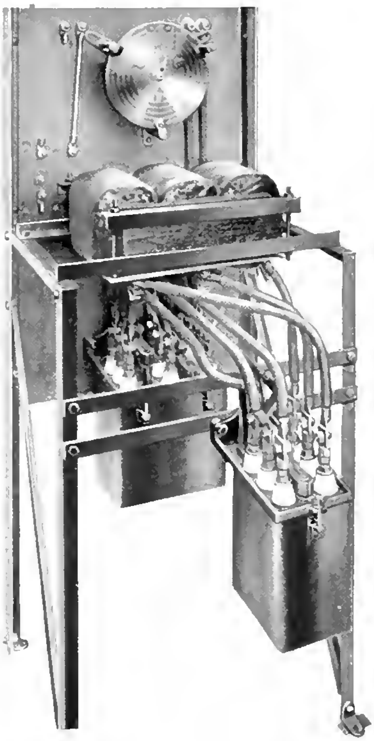

Fig. 2. 2200 Volt, 123 Amp., 470 Kv-a. Synchronous Motor Panel

The rupturing limits of oil switches shown in the tables may be of interest to some engineers. This information should apparently render the selection of the correct switch an easy matter. These tables have sometimes been used inadvisedly, not bearing in mind the fact that the selection of the proper oil switch depends directly on the available power which may feed into the short circuit at the instant when the switch is opened, and that the ratio between the kv-a. bus capacity and the "available power behind the short" depends on the system of connections, the protection afforded by other switches, the short circuit characteristics of the generators, and the resistance and reactance of the transformers and feeders.

For example, one central station company went exhaustively into the question of the proper equipment for a 500 kw. rotary substation. They ordered K-12 switches. A little later they decided to install in a different part of the city another 500 kw. substation. Here they also selected K-12 switches. In the first case, their selection was correct because the substation was one of several, all of which were connected to one 6600 volt feeder. In the second case, however, the selection of K-12 switches was wrong and the cheaper and smaller K-5 switch was subsequently substituted. It was amply large, due to the fact that a single feeder ran from the power station to this and only to this particular substation. By setting the large H-3 switch, at the power house end of this particular feeder, at the proper tripping value as regarded current and time, solely to meet the requirements of its one substation, a selective action between the switches was obtained.

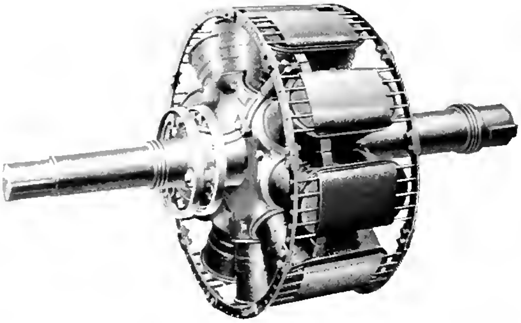

Fig. 3. Completely Assembled Field of a Synchronous Motor. The copper bars comprising the pole-face winding are tightly riveted to the sectionalized end rings

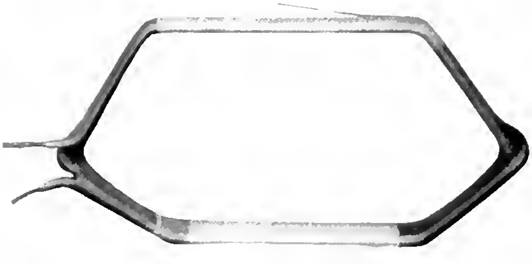

Fig. 4. Armature Coil Insulated with Mica Tape and Protected from Corona by a Tin Foil Covering

Under heavy short circuits, the H-3 switch at the power station would trip out and thereby relieve the K-5 switch at the substation of the duty of rupturing an arc beyond its capacity.

Fig. 2 shows an advance along the lines of simplicity and convenience. It represents the back view of a panel which controls a 470 kv-a. synchronous motor. Its unusual feature is the placing of the starting coils of the synchronous motor on the back of the panel instead of having them isolated, as has been previously customary for units of this size.

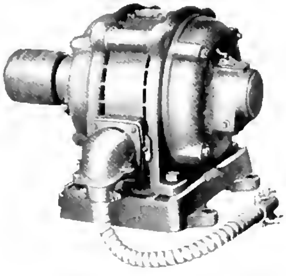

Fig. 5. A Five Horse-Power Induction Motor with Universal Terminal Box for Conduit Wiring

### Motor-Generators

Squirrel cage windings on synchronous motors were formerly built with the bars soldered to the end-rings of the squirrel cage. When a surge on the system caused pulsation and a rush of current through the bars, the solder would often melt and run out and the integrity of the electrical contact be destroyed. Fig. 3 shows a squirrel cage winding in which the bars are riveted to the end-rings, brass to brass, thus avoiding the necessity of using any solder. Not a single complaint has been received of poor contact at this point since this practice has been followed. The photograph also shows the fact that the squirrel cage has been divided into as many sections as there are poles. The advantage of this is that when it is desired to remove a damaged pole, that part of the squirrel cage belonging to that particular pole may be unbolted.

A much desired improvement in the ability of armature coils to maintain their insulating qualities is illustrated in Fig. 4.

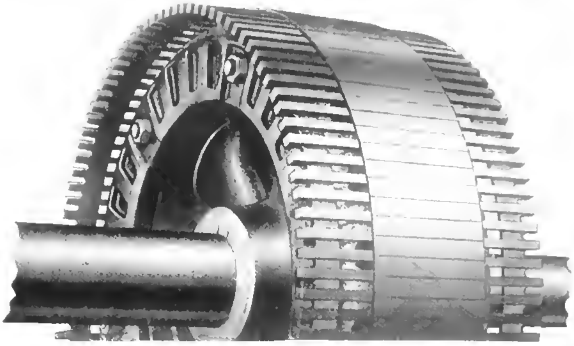

Fig. 6. A Squirrel Cage Rotor with Welded End Rings

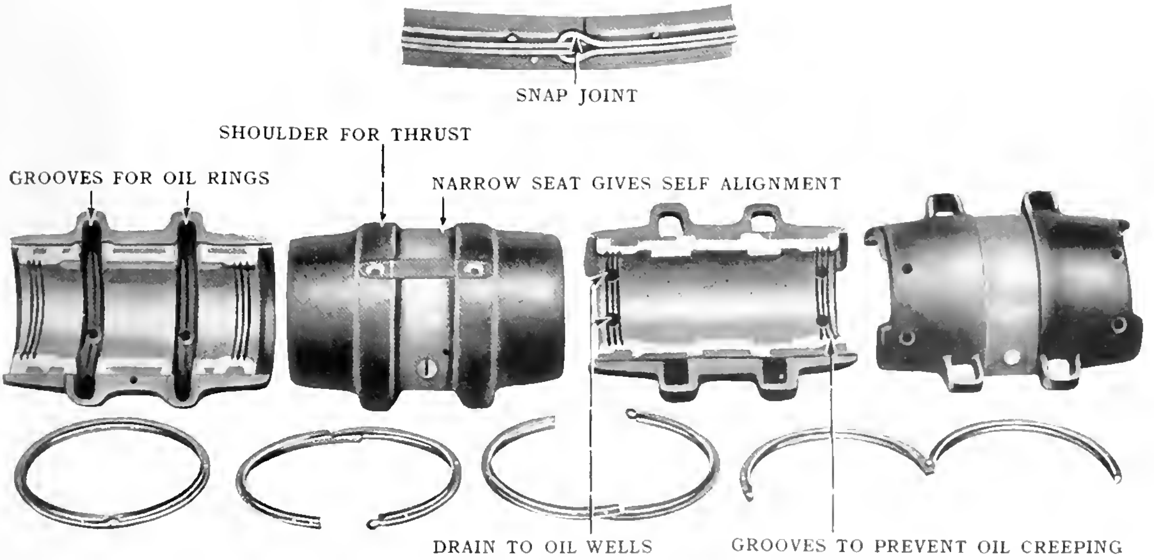

Fig. 7. This cut shows the Construction of Bearings and Snap Oil Rings

The use of mica tape has for several years proved advantageous. High-voltage armatures of 11,000 volts and above often tend to break down at the corners or bends of the windings. The mechanical strain is greater there, but, in the opinion of many engineers, it is inadvisable to appreciably thicken the insulation at that point in an endeavor to compensate for the tendency to break down. Thickened insulation acts like an extra blanket and keeps in the heat instead of permitting it to be radiated. The greater dielectric strength of mica suggested the use of solid sheets of it as a covering for the armature coil. This construction has been used by some manufacturers, but by others it has been considered as open to the objection that it piles up and thickens the insulation at the corners or bends of the windings, and also that a defect in the mica may go all the way through the solid sheets.

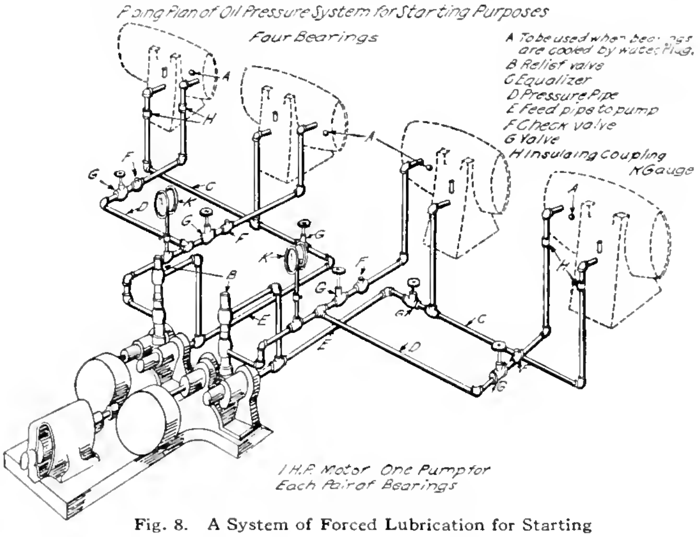

Fig. 8. A System of Forced Lubrication for Starting

On the other hand, by the use of mica tape wound on by hand, in a strip about $\frac{3}{4}$ of an inch wide, the strip being composed of many small overlapping pieces, the probability will be that a defect in one small piece will be offset by being covered by the overlapping piece which contains no imperfection.

Another characteristic of certain high-voltage windings which, in the past, has tended to shorten their useful life, has been the presence of corona. The mechanical and chemical action has often resulted in high-voltage armature windings being pitted and honeycombed so that when a sudden rise in voltage occurred on the system, the dielectric strength of the insulation would not be great enough to stand the increased strain and the armature coils would break down. The illustration, Fig. 4, shows an armature coil wound with tin foil from end to end of the armature slot, the ends of the foil being grounded on the armature core. A careful examination of many armature coils so treated has shown that the effect has been to eliminate the corona and give the coil a useful life of two to three times as long as it formerly possessed.

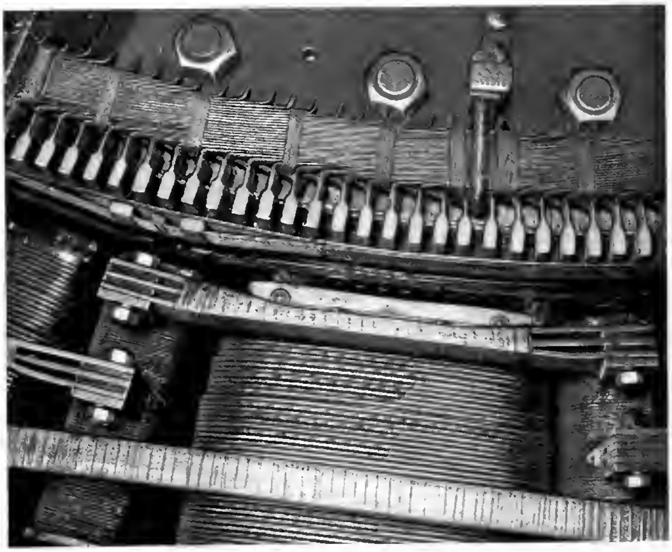

Fig. 9. A 2000 Kw., 250 Volt Direct Current Generator Equalized on Every Slot

Motor-generator exciter sets generally employ a squirrel cage induction motor as the driving unit. The exciter set is such a vital part of the central station that any improvement tending to increase its reliability is most welcome. The electric welding of rotor bars to the rotor end-rings as shown in Fig. 6 is an interesting advance in the art of perfecting the electrical circuit in the rotor, since it practically eliminates the chance of a high-resistance joint.

The universal terminal box for induction motors shown in Fig. 5 is made in sizes suitable for 2-inch conduits and below and is so obvious a convenience that it hardly needs comment.

To any one who has performed the somewhat tedious job of removing one of the old types of oil ring from a bearing, the snap oil rings with the hinge joint illustrated in Fig. 7 will appeal as distinctly a time saver.

A complete oiling system for the four bearings of a very large motor-generator set to insure easy starting is indicated by the diagram in Fig. 8. The writer has seen a large three-unit frequency changer set consisting of two synchronous machines, with an auxiliary motor used solely for starting, in which the starting motor was about two-thirds the size of the main units. The large starting motor was required because of the enormous torque necessary to "break" the shaft from its bearings after the set had been shut down several hours.

With a subsequent installation of the oiling system as shown, a small ¾ h.p. motor driving an oil pump forced the oil between the shaft and the bearings of the large set, floating the shaft on a film of oil, and the set was started without the use of a special induction starting motor, thereby saving valuable floor space and avoiding a continuous loss of energy necessary to keep the starting motor revolving 24 hours a day after its useful functions had been completed. After the set has started to revolve, sufficient lubrication is secured by use of the usual oil rings.

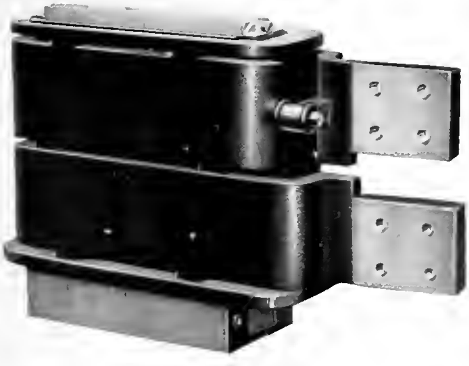

Fig. 10. Commutating Pole Piece with a Two-Turn High-Conductivity Cast Copper Coil

The direct-current end of larger motor-generators has, in some recent cases, been equipped with cast copper series field coils as shown in Fig. 10. The attractive features of this construction are its practical indestructibility and the economy of space with the resulting improvement of ventilation.

On direct-current armatures, inequalities in the magnetic circuits and different resistances in the multiple circuits running from the commutator bars through the brushes and studs to a common bus ring, will obviously cause cross currents, which, if excessive, will result in objectionable sparking at the commutator. Therefore for many years equalizers or miniature bus rings connecting equi-potential conductors have been used on the back of direct-current armatures, running from about every fourth slot to the corresponding slot under every alternate pole. Fig. 9 shows an amplification of this idea. Instead of being equalized on every fourth slot, this armature is equalized on every slot, and the resulting improvement in commutation has justified the additional labor.

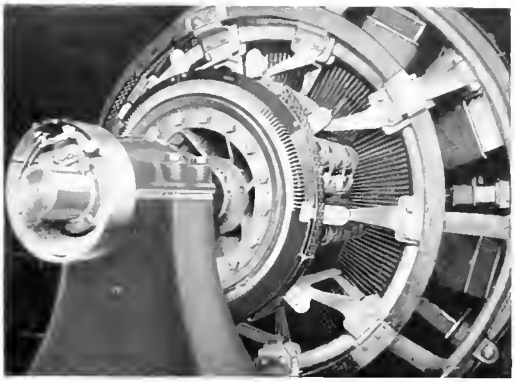

Fig. 11. Cooling Vanes on End of Commutator Protective Covering Partially Removed

The use of high-current-density brushes and improved ventilation of commutators has been the means of shortening the active commutator length. Fig. 11 shows the ventilating vanes on the outer edge of a commutator. The protecting covers, which in the photograph have been partially removed, are in practice placed over the ventilating vanes in order to afford the needed protection to the attendant.

The whole or partial disassembling of a large motor-generator often consumes valuable time, particularly if the direct-current brush rigging is supported from the pillow block or the magnetic frame. Fig. 12 illustrates an interesting mechanical improvement in that the brush rigging is supported from the base of the set. This

## RUPTURING LIMITS OF TYPE "F" OIL SWITCHES

Since it is obviously impossible to define limits of capacity which are applicable to every installation, the ratings given in these tables are based on the assumption that the switch will be connected directly to the buses and will be subject to maximum short circuit conditions. If, however, an intervening transmission line or transformer introduces sufficient reactance or resistance in the circuit, or if the generators have favorable short circuit characteristics, the switch can be given a much higher rating.

Refer all doubtful cases to the manufacturers with complete information including system of connections, size and characteristics of apparatus and line. Definite recommendations will then be given.

CLASS "A" SYSTEMS—All systems excepting those in Class B.

CLASS "B" SYSTEMS—Systems in which one or more generating units are turbo-driven, the reactance of any one of which with its connections to the buses is less than 8 per cent.

### SWITCHES FOR USE WITH SWITCHBOARDS

| SWITCH | | | KV-A. RATING OF BUS INCLUDING OVERLOADS OF ONE HOUR OR MORE | | | |

† ‡ See top of opposite page.

† For single-phase multiply above by 0.75; for quarter-phase multiply above by 1.50; for single-phase switches to three-phase buses use three-phase ratings; for switches used on line voltages less than that for which ratings are given, use kv-a. capacity corresponding to nearest voltage rating; the capacity of switches for intermediate voltages may be obtained by proportion.

Remote control switches are recommended for voltages above 3300

‡ Use of K13 oil switch for circuits 751-3300 volts.

The use of the K13 oil switch on circuits of 751 to 3300 volts, inclusive, is subject to the following limitations irrespective of the bus capacity of the station.

1. It is not to be used for railway service.
2. It is not to be used anywhere on a system, the maximum capacity of which exceeds 20,000 kv-a. (except as outlined in Clause 6) or in the line of any system subject to severe voltage disturbances.
3. It is not to be used anywhere in a generating station whose maximum capacity exceeds 2600 kv-a.
4. For systems 2600 to 5600 kv-a maximum generating capacity, it may be used in substations, providing a higher duty switch is interposed between it and the main station bus.
5. For systems of 5000 to 20,000 kv-a. maximum generating capacity, it may be used only under the following conditions:
   - (a) In a substation, providing transformer capacity not exceeding 750 kv-a. is interposed between the K13 switch and the line.
   - (b) On a substation feeder, providing a higher duty switch is interposed between the K13 switch and the substation bus.
6. When considering switches for connection to buses fed from the low-voltage units of motor-generator sets, the capacity of the system supplying energy to the motor-generator sets need not be considered. In such cases the sum of the rated capacities of the generator units of the motor-generator sets must needs come within the limits given in the above table to allow the use of the K13 switch.

A Form H switch is one for mounting in cells of masonry.

A Form K switch is one designed primarily for mounting on pipe framework. It has a removable iron cover.

permits the easy removal of the pillow block cover or the lifting of the upper half of the magnet frame, without disturbing the arrangement of the brush rigging in any way.

It is hoped that the scattered examples here mentioned of the various improvements may prove of interest to the central station man.

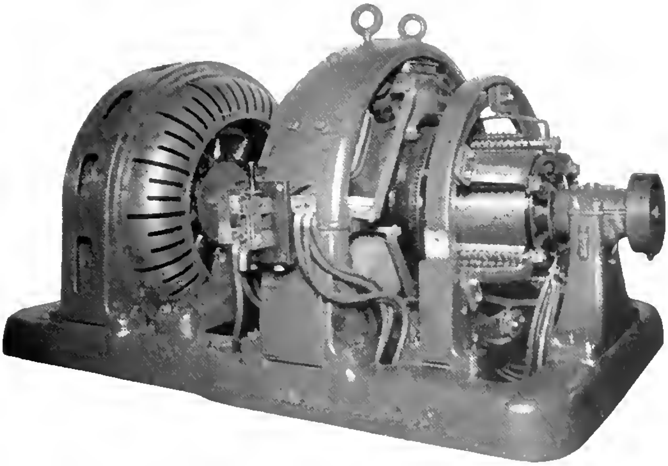

Fig. 12. A Synchronous Motor-Generator Set of Recent Design. The independent support of the brush rigging is clearly shown

# THE PROGRESS OF THE LIGHTING INDUSTRY

By E. P. Edwards

Assistant Manager, Lighting Department, General Electric Company

Seldom have we seen a more brief and at the same time comprehensive review of the epoch-making events which have made possible the present-day commercial generation and utilization of electricity than that which composes the first part of this article. The author proceeds to show that these advances have been but stepping-stones toward the realization of that long-predicted economical system of production and distribution of electricity—the *Central Station Method*. In connection with the latter section of this article we would call the reader's attention to the article, "The Central Station Idea" on page 201.—Editor.

**E. P. Edwards**

ARTIFICIAL illumination dates back to prehistoric times. Vegetable and animal oils were burned, through the medium of a wick, in open lamps until 1747, when Argand, a Swiss, invented his enclosed lamp embodying the fundamental principle of all modern oil-burning lamps.

Mineral oils were not introduced as illuminants until 1853.

The gas era began with the discovery of gas by Murdock, an Englishman, in 1779, thus securing a start of just 100 years over the first successful "incandescent" electric light.*

The discovery of electricity, however, antedates the achievements of Argand and Murdock by twenty-three centuries, as Thales of Miletus, a Greek, is reported to have noted in the year 600 B.C. the fact that amber and jet, when subjected to friction, possessed the power of attracting leaves, straw and feathers. It is quite certain that Thales did not realize the import of his discovery; at least he made no known use of it—did not even give it a name. On the other hand, it is certain that he possessed an equal knowledge with ourselves as to what electricity is, for we do not know today.

It was not until 1600 A.D. that a study of the phenomena of this unknown force was undertaken by Gilbert, an Englishman, on a scientific basis, and he first used the word "electrica," from which is derived "electricity," to denote substances possessing properties similar to amber, the Greek name for which is electron.

Otto von Guericke, a German, in 1663 built the first electrical machine capable of transforming mechanical into electrical energy. It consisted of a globe of sulphur fixed on an axis and rotated by a winch. Electrostatic current was produced, the machine being excited by the friction of the operator's hands held against the revolving globe.

Benjamin Franklin deserves an exalted place in the ranks of electrical engineers. It was he who demonstrated, about 1750, the identity of lightning discharges and the electric spark, invented the lightning rod, and contributed much other useful knowledge bearing on electrical phenomena.

The next step worthy of note was made by Volta, an Italian, in 1799. In this year he invented the voltaic pile and produced electric current by means of it.

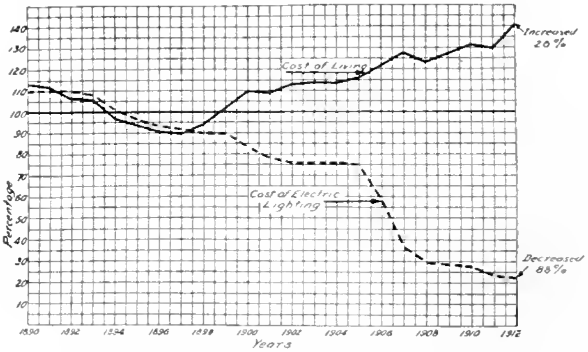

Fig. 1. Curve Sheet showing how the Cost of Electric Lighting has Rapidly Decreased while the Cost of Living has been Steadily Increasing

Sir Humphrey Davy, an Englishman, in 1808, working with a voltaic battery of 2000 plates, produced an electric arc between two carbonized wooden rods, and this was, properly speaking, the first incandescent lamp, and was, of course, the first arc light.

Oersted, a Dane, and Davy were the pioneer discoverers of the magnetic action

---

* Note.—The arc lamp is, of course, an incandescent lamp, but the term "incandescent" is commercially used to distinguish Edison's development from the arc lamp.

of the electric current about 1820; but William Sturgeon, an Englishman, was the first to bring out an electro-magnet, which was further perfected by Henry, an American, and first used in telegraphy.

The remarkable invention by Faraday, an Englishman, in 1831, of a mechanical generator capable of producing kinetic electricity, paved the way of modern electrical development. His machine consisted of a copper disk rotated between the poles of a permanent horseshoe magnet. The principles laid down by Faraday, as a result of his experiments, were fundamentally the same as those upon which we are now working.

In 1844 Foucault, a Frenchman, was successful in substituting carbon taken from gas retorts for the soft wood carbon used by Davy, and while his discoveries represented a step in advance, it did not make possible successful competition between the new form of illuminant and gas, oil or tallow.

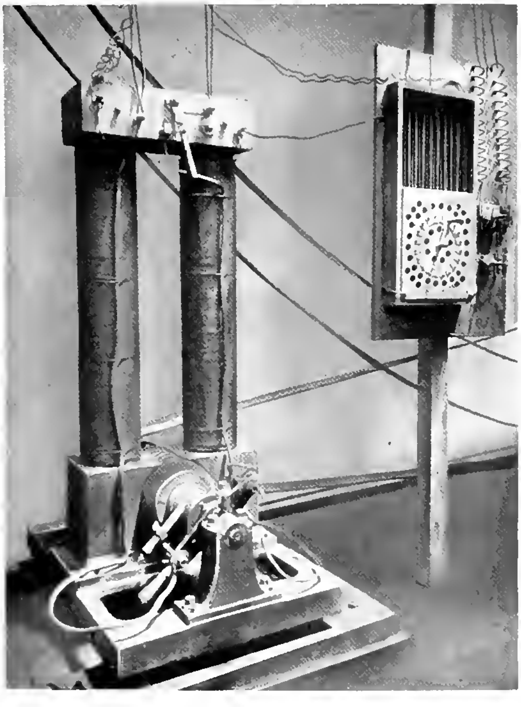

Fig. 2. One of Edison's First Generators

Credit for the next step in the development of the arc light belongs to Thomas Wright, an Englishman, who, in 1845, devised a lamp in which the carbons could be automatically adjusted.

In the next twenty-five years progress was slow but sure, the steps being marked by the invention of the drum wound armature in 1856, by Siemens, a German, the enunciation of the electro-magnetic theory of light in 1865, by Clerk Maxwell, an Englishman, and the development of the dynamo in 1870, by Grammes, a Belgian. The latter's inventions form the basis of present day electrical engineering.

Fig. 3. Exterior of an Early Central Station Lighting Plant, Appleton, Wis. Capacity 250 Lights or Approximately 11 Kw Interior View shown in Fig. 2. Page 256

Commercial dynamos, intended for producing electric light, were first built about the year 1866, but electric lighting was not established on a successful commercial basis until C. F. Brush, an American, brought out his series arc-lighting system in about the year 1878. This development in conjunction with the famous electric candles of Paul Jablochkov, a Russian officer, invented in 1876, are generally conceded to be the foundation stones of the arc-lighting industry. Jablochkov is also credited with being among the first to suggest the use of transformers, and while he, together with de Meriteus, Mordey, Gordon, Brush and others, took out patents on transformers, it was not until 1883 that Goulard and Gibbs, following this line of thought, introduced the first practical system making use of transformers. The first installation of a series arc-lighting system was made in Cleveland, Ohio, in 1879.

In 1883 arc-lighting companies began to take contracts for city street lighting, charging one dollar per lamp per night for the service: the units used being capable of producing 2000 candle-power.

The Thomson-Houston arc-lighting system was introduced about 1881, the first machine being of 25-light capacity.

Fig. 4. Interior View of the Fisk Street Station of the Commonwealth Edison Company, Chicago. Approximate Capacity 110,000 Kw.

While the arc lamp was fairly satisfactory for outdoor use, it obviously was not adapted to the needs of the individual consumer, and inventors as far back as Sir Humphrey Davy's time were working with the object in view of perfecting the small individual unit.

The first English patent on an incandescent electric lamp was taken out by DeMoleyns in 1841. In 1845, J. W. Star of Cincinnati, Ohio, took out a patent in England in the name of his attorney, King, covering a lamp consisting of a strip of graphite mounted in a vacuum. The first American patent was taken out in 1858 by Gardner & Blossom.

Many others were working along similar lines, notably Swan & Stearns in England, but Thomas Alva Edison was the first man to construct a commercially practical incandescent lamp. He proceeded on the theory that a successful lamp must be enclosed in a globe from which the air had been exhausted, fused at all joints, durable, and still cheap enough to be thrown away when broken. The first lamps of this character that were manufactured were sold for $1.50 each, and consumed about fifteen times the amount of energy for the same amount of light that is consumed by the modern lamp.

Edison employed various substances in his early experiments, notably platinum. The lamp which he brought out in 1879 employed a filament of carbonized bristol board cut in the shape of a horseshoe, enclosed in an exhausted glass bulb. Later on Edison used bamboo and many other substances for his filaments.

Edison's inventions marked the beginning of the era of incandescent lighting and the principles of his first carbon filament lamp are still embodied in the modern incandescent lamp.

Fox in England, and Edison in America, are credited with being the first two men who realized the commercial possibility of establishing public distributing stations. There is some conflict as to the exact date of establishment of the first of these plants. Four installations are worthy of note: the arc-lighting system in Cleveland in 1879; a public supply station erected by Edison in Pearl Street, New York, in 1881; another plant located in London in 1882, and the Edison plant at Appleton, Wis., installed during the same year. This last mentioned plant had a capacity of two hundred and fifty 10-candle-power, direct-current incandescent lamps. For all practical purposes we may say, therefore, that commercial arc lighting and incandescent lighting were introduced at the same time, and only thirty-four years ago.

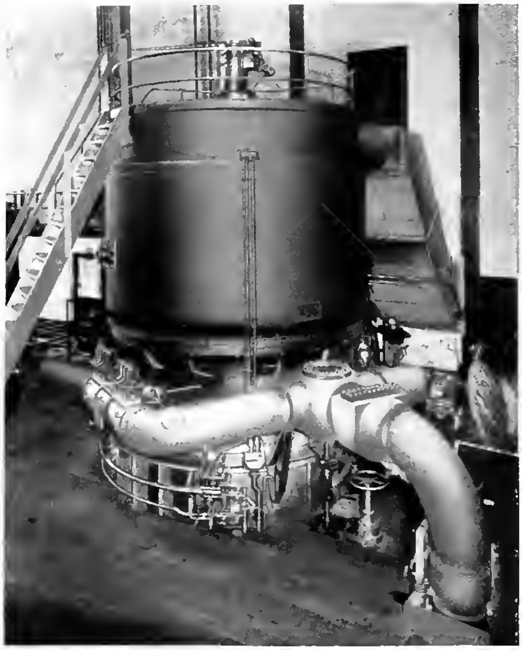

Fig. 6. Curtis-Turbine-Driven 20,000 Kw. Generator in the New York Edison Company Plant

It is obvious, from a historical review of the progress of the art, that the early investigators were bending all of their energy toward the development of electric light. It was not until 1873 that the fact was discovered that a dynamo of the Gramme type could be used as a motor, and it was not until between the years 1880 and 1884 that advantage was taken of this discovery, its possibilities realized, and electric power utilized for traction purposes.

Electric lighting, therefore, was the goal at the start and still is the "opening wedge" for electrical progress.

The first public-service stations were known as "lighting companies" and the large majority of them are so designated at the present time. The National Electric Light Association was organized in 1885 at Chicago, its original membership being of a very miscellaneous character, including manufacturing companies supplying electrical apparatus, fixture concerns, carbon and copper companies, isolated plant operators and a few central station representatives, all sharing in its management and direction. As the industry grew the Association was reorganized along its present lines, the voting membership being confined to central station companies. At the present time the membership, made up of various classes, is about 12,250, making it the largest organization of its character in the world, and numbering in its ranks central stations, manufacturing concerns, officials and other employes of these companies, and a large number of college and university professors; it has numerous affiliations throughout the country and members from all over the world.

The functions of the central station and the National Electric Light Association are much broader than the name implies; they are vitally concerned with the power problem, as a very large proportion of the output from central stations is used for power purposes, and the Association devotes a large part of its time to a study of this phase of the business, while still retaining its original name.

Today we find central stations in this country to the number of approximately 6000, furnishing current for lighting alone, equivalent to more than one hundred million 16-candle-power lamps—an average of more than one lamp per capita of our population.

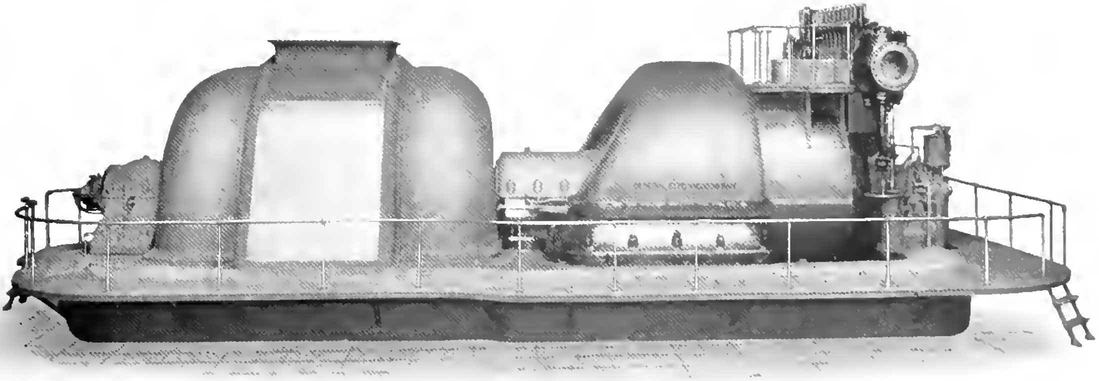

Fig. 6. Seventy Million Candle-power from One Machine. Typical Large Curtis Turbine Now Built in Sizes of 35,000 Kw. and Smaller

In addition to these public service lighting companies, there are about 1300 electric railway distributing stations and over 100,000 isolated plants in the United States generating electrical energy for both light and power purposes.

The aggregate continuous capacity of electrical generators installed in our central stations approximates twelve million kilowatts, with a daily output of seventy-five million kilowatt-hours. Statistics of isolated plants would greatly magnify these figures.

The investment represented in electrical generating stations and machinery amounts to over two and one-quarter billions of dollars. No accurate figures are available showing the grand total invested in the electrical industry. The statisticians have not been able to keep abreast of the rapid progress that has been made, and references to the latest encyclopedia will demonstrate that development is outstripping contemporaneous history by leaps and bounds.

Since the first central-station generator of twenty-five hundred candle-power capacity was built, there has been developed the modern single unit of seventy million candle-power capacity based on the specific consumption of the latest gas-filled tungsten lamps, and also individual plants with a capacity of 110,000 kw.

The steam turbine has made these large individual units possible and revolutionized the industry; conversely, electricity has made the turbine possible. Hero is credited with its first invention, 130 B.C., but the turbine did not begin to compete with, nor supplant, the steam engine until the principles employed by Parsons, Curtis and DeLaval were brought into their present high state of efficiency, through the efforts of the prominent engineers of the day, and this only within the last decade.

During the early stages of development, plants were installed only in the cities and larger towns where it was considered that the expense would be warranted. At the present time practically every "live" town of 1000 or more inhabitants has its own plant, or is served from some nearby station. Many towns of smaller population also have electric service. Electricity is not generally in use outside of these centers of population, but the time is rapidly approaching when it will be. The development of larger units makes possible economic concentration; smaller plants are giving way to substations served from a central generating point by means of transmission lines, which are rapidly networking the country. Our first so-called high-tension transmission lines, 4000 volts, were installed in about 1890 in Oregon, Colorado and California. They were of from ten to twenty miles in length. Today we have transmission lines two hundred and fifty miles long and with an operating pressure of one hundred and forty thousand volts. This practice of centralization is rapidly coming into vogue for many very good reasons, viz.:

1st. It is now possible to distribute power economically.
2nd. Because of the diversified nature of the load it is possible to reduce the cost and size of power-house equipment.
3rd. It is possible to operate the system with a better load-factor.
4th. The purchasing of apparatus, supplies and spare parts through a central source is of decided economic advantage.
5th. The centralization of the management, engineering and operating forces reduces the overhead expense.
6th. It is possible to serve certain classes of customers that the small independent plant cannot afford to serve.
7th. The consolidation of interests makes it possible to finance improvements, substitute new for obsolete apparatus and extend service into new territory.
8th. Better regulation and better protection can be provided for.
9th. And above all concentration can bring and has brought down the cost to the consumer far beyond what is possible with the relatively small independent or isolated plant.

The fact can be easily demonstrated that electricity is not in any sense responsible for the increased cost of living. The converse is true, as is aptly shown in Fig. 1.

Electricity is the cheapest, most convenient and safest form of energy, and it is used in practically every branch of art, industry and science. Electrical machinery can now be purchased for about one-fifth or one-quarter of what it cost in the early days and is far more efficient.

The same statement holds true of lamps and electrical supplies generally.

The first carbon lamps consumed from seven to eight watts per candle-power of light and had a relatively short life; the specific consumption of the latest carbon lamp is three and one-tenth watts per candle. Metallized filament lamps are a marked improvement over the carbon type, but the most satisfactory lamp so far developed employs the metal tungsten filament, the gas-filled mazda lamp of this type having a specific consumption of one-half watt per candle.

New uses are being found for electricity every day, and the history of its progress written five years hence will disclose many more remarkable developments that are not now even dreamed of.

# THE COMMERCIAL VALUE OF ELECTRICITY

By J. E. Kearns

Lighting Department, General Electric Company

Electricity is becoming more and more to be regarded as a commodity, in spite of its being intangible physically, for it performs much the same functions as other utilities commonly classed as commodities. In order that there be a demand for a commodity it must have a commercial value. The author of this article shows, in a historical manner, how electricity has advanced from its early stages of application to become a public utility almost as indispensable to a city as its water supply.—Editor.

J. E. Kearns

The criterion of today is commercialism. What does this mean with respect to electricity and electric service?

Any commodity, to have a real commercial value, first, must be useful, second, must have a market sufficiently broad to warrant its development, and third, must be manufactured on a basis and at a cost that will create and stimulate a requirement, until it eventually becomes a necessity.

Commerce, in its broad sense, means the distribution of products (manufactured or otherwise) affecting individuals, companies, corporations and countries, with a view of supplying their demands on a more efficient and economical basis. This gives a very broad market for most products; so broad that many articles are transported thousands of miles before being consumed.

These developments depend upon several conditions, e.g., upon a market for the commodity and the local conditions surrounding its production, such as the soil and climate, the presence of natural resources, and the cost of labor, but to a far greater extent upon the freedom and security of communication.

Very few of us treat and consider electricity as a commercial commodity, because the general idea of a commodity is that of something material. While electricity cannot strictly be considered as a material, its property as a medium for the transfer of energy legitimately places it in the category of commodities.

It is interesting to note that this commodity, representing today billions of dollars, has been of commercial value for only about one half of a century and that during this time its development, leading to the invention of the telegraph and ocean cables, has been the prime factor in making United States one of the leading nations in commerce.

The early commercial application of electricity was to supply power for lighting purposes, and its success in this field gradually led to its almost innumerable uses of today. This condition has been made possible only by the careful, consistent and indefatigable efforts of prominent engineers to develop the art and to improve the design of the generating units, converting machinery, transmission lines and distributing systems.

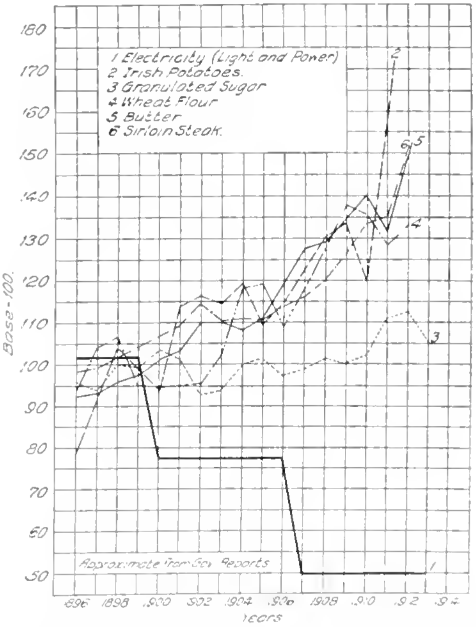

Fig. 1. Curves showing the Decrease in the Cost of Electric Light and Power and the Increase in the Cost of the More Common Staple Food Articles During the Past 18 Years

During the early stages of progress, the developments and extensions of electric energy were confined to communities of sufficient size to warrant the installation of a central station and, for a period of twenty years, the energies of engineers, bankers and promoters were confined to the improvement of the segregated plant; but, today, this condition is being gradually supplanted by a more conservative, effective and efficient method of distribution, namely, that of grouping towns and serving them from a central point of distribution.

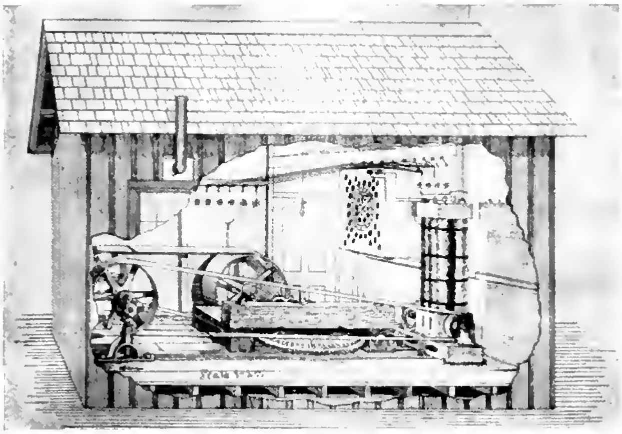

Fig. 2. Interior View of the First Central Station Lighting Plant, Appleton, Wis Capacity 250 Lights or Approximately 11 Kw. Exterior shown in Fig. 3, Page 251

This system of conservation has been made possible through the development of suitable generating equipment, distributing transformers, transmission lines and local substations for serving the smaller communities.

The generating equipment for such a system will usually consist of steam turbo-generators or, in cases where warranted, waterwheel generators supplemented by a steam turbine relay equipment, since there are very few localities where the water supply can be entirely relied upon. In this station would also be installed step-up transformers, protective apparatus and suitable switching equipments, together with whatever other apparatus is required for local distribution.

The transmission system would probably be of some reasonably high voltage, say, from 33,000 to 140,000, depending upon local conditions, and use suitable primary and secondary conductors carried on wooden poles or steel towers of approved cross-arm construction.

The local substation may consist of one of two types, the indoor type which is necessitated where revolving machinery is required, or the outdoor type which is used where stationary apparatus only is installed, such as transformers, etc.

This system appears to be quite complicated when compared with the first complete installation, which consisted of one generator, some simple switching equipment and a short transmission system. But, even as simple as this method may have been, it required considerable care and attention to insure its operation. The present system of distribution is made quite simple and effective by load dispatching which is taken care of by telephone orders for starting and stopping the machines and operating the switches, and, further, by the remote control of rotating substation apparatus from the main station.

Through the stages of progress, as may be suspected, many changes and improvements have been made. At the present day, we have single turbo-generator units of 35,000 kw. capacity as contrasted against the first "Jumbo" machine, of 700-lights capacity, exhibited at the Paris Exposition in 1881 where its size excited wonder and caused considerable excitement. This great gap is just as wide when we compare the old one-mile distributing system with that of the 250-mile system of today.

The unfortunate part of all this gradual improvement is the fact that it has developed nothing that could be called standard for this commodity, and it seems that the next logical step for the manufacturer and user is to improve the standards, paying particular attention to capacity, frequency, voltage and heating. It is further extremely desirable to dispense with the use of the multiplicity of transformer taps for voltage regulation and to use instead some regulating device. It seems only fair to mention here that the users are beginning to appreciate the value of standardization with respect to price and delivery, also with respect to its important bearing on their overhead charges. It is apparent, therefore, that the manufacturers also should put forth their keenest efforts to assist the public service companies' endeavors and make them, as they should be, mutual endeavors.

The inherent characteristics of electricity make it adaptable for innumerable and ever-increasing uses, as it is the only form of energy that can be produced economically in large quantities and be distributed great distances with but little loss for use in extremely small units. Many comparative values are available to prove this.

The commercial application of these characteristics has led to important electrical inventions and developments, which add to the comforts of life. Its safety at low potentials creates a demand for application where other commodities would be a menace to property and life.

It can safely be stated that if it were not for the great diversity factor of electricity its price per kilowatt would not be as low as it is today, namely, 50 per cent less than it was a few years ago; while most other commodities have shown a gradual increase in price. The time is not far off when it will be necessary to increase the price of the generating and distributing equipments, owing to requirements in design and complicated operation developed because of the increased demands of the public for safer operating machines, while the cost per kilowatt to the consumer of the energy will tend to remain about the same, due to an increased diversity factor.

This situation some might construe as being impossible due to competition, the keenness of which sometimes necessitates the sale of a commodity at a loss. This condition is gradually and surely disappearing, owing to the development of our high-speed electric-driven machine tools, by means of which the production of a commodity may be limited to existing conditions. To try to establish competition, as it existed in the past, would be maleficent, as it is directly contrary to the present economic system of production. The forcing of the price of a commodity below its finished cost must eventually mean ruin to the industry; therefore, the only logical step is co-operation and standardization, as this will mean not only an improvement in the products but a total lower cost which paves the way for increased consumption of the commodity and in turn means more business and gradual increase and continuity of prosperity.

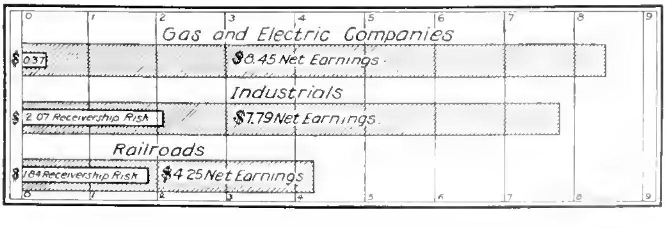

**Fig. 3.*** Comparative Safety of Gas and Electric and Other Forms of Investment

Just such co-operation as that mentioned has given electricity the great commercial and economic value it has today, for without it many of the inhabitants of small communities would not be enjoying its advantages, industrially, socially or otherwise. Co-operation of this sort has also been the vital force in the advancement and growth of everything in nature, and why, at this period, should the political aspirations of individuals or parties be allowed to destroy a natural and healthful commercial growth?

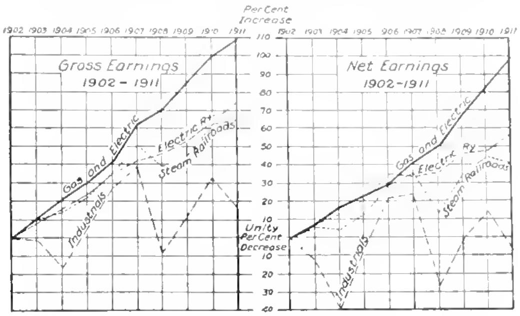

**Fig. 4 *** The Steady Increase in Gas and Electric Earnings as Compared with Railways and Industrials

As a further proof of the value of such co-operation, one has only to refer to the relative safety with which investments may be made in public utility securities. It is interesting to note that, during the past decade, the railroads have increased their capital stock only about 50 per cent, while the public utility corporations have more than doubled their capitalization during the same period. The primary value is represented by the fact that, even during periods of depression, earnings from the sale of electric energy have shown a gradual increase, in spite of reduced rates to the consumer, while the income from other industries was subject to sharp fluctuations.

Due to its intrinsic value, the popularity of this type of investment is gradually increasing, with the result that the public utility corporations will be able to finance future developments at a much lower cost, and this, of course, will be profitable to the communities served by giving them better service at a lower cost.

---

* Figs 3 and 4 copyrighted by Henry L. Doherty & Co., New York.

The commercial value of electricity has developed beyond all expectations until now it forms one of life's most vital commodities, but, while requiring the utmost skill and talent for its production, it is the cheapest commodity available today. So important has this energy become (having reached a point where it is now an absolute necessity) and so diversified its uses, it is safe to predict that a universal failure in its production for ten days would cause untold suffering and business stagnation.

This shows how great is the value of continuity of service to a large community like New York or Chicago, which is made possible only by the care in the design and economic operation of the machinery and which represents a value that is often unjustly slighted in public appraisals.

Intelligent management in the electrical field by developing through co-operation, by removing obsolete and inefficient apparatus, by replacing the small wasteful plant by a properly-designed service station, and by conserving the natural resources has been able to place electric energy within the reach of all, and to enable the public utility corporations to deliver this energy for commercial welfare and individual benefit at a minimum cost to the consumer and at fair profit to the producer.

# SERIES MERCURY-ARC RECTIFIERS

By C. M. Green

Engineer, Rectifier Department, General Electric Company

The main division of this article describes the functions of the various component parts of a mercury-arc rectifier, viz., tube, constant-current transformer, reactance coil, exciting transformers, means of cooling, static dischargers, and panel board. The second section deals in a historical way with the commercial development of the rectifier. The good and bad points of the early rectifier outfits are described, and then the improvements which led to the elimination of these bad points are taken up step by step. The article concludes with some very pertinent suggestions as to how to avoid certain kinds of trouble in underground distribution systems, and also for the adjustment of the lamps themselves that they may be protected from burn-outs by a misapplied high voltage.—Editor.

C. M. Green

The constant-current mercury-arc rectifier is a device for obtaining constant direct current suitable for the operation of series direct-current arc lamps of either of the open or enclosed type from a single-phase constant potential supply which may be taken from a polyphase system. The apparatus has been designed to use all of the commercial frequencies from 25 to 140 cycles, and all the voltages which are in use today up to 13,200 volts primary.

There has been developed a series rectifier, having a capacity of 8500 volts, 6.6 amperes, which will operate from a three-phase supply, but which has not been put on the market for the simple reason that the single-phase rectifier answers all commercial requirements and is less complicated and expensive to build.

The arc, formerly called arch light, was discovered by Sir Humphrey Davy in the year 1820, and was operated from batteries. The cost of electricity from this source was so excessive, however, that it could not compete with other illuminants, and, as a result, remained a laboratory experiment for over half a century.

Charles F. Brush gave to the world the first complete series arc lighting system and many of the Brush arc generators and lamps are still in active service. The generators are, however, of relatively small capacity, the maximum size being 76.8 kw., 8000 volts, and 9.6 amperes, with an efficiency at full load of about 84 per cent.

During the past twenty years the whole system of generation and distribution of electrical energy has changed. In the early days the plants, whether water power or steam, were of comparatively small capacity and distributed over a comparatively small area; whereas, today the bulk of electrical energy is generated in large central stations by means of turbo-alternators and is transmitted long distances at high voltage to the many places where it is desired to be used.

During the early transition period many of the Brush arc generators were motor-driven, having an efficiency between terminals of about 75 per cent, whereas, the modern rectifier has an efficiency of approximately 92 per cent with a full-load power-factor of 65 per cent.

The direct-current arc has been invariably a more efficient means for the conversion of electrical energy into light than the alternating-current arc, and the rectifier is the latest apparatus used for the conversion of alternating to constant direct current for the operation of arc lamps.

## THEORY OF THE MERCURY ARC RECTIFIER

The theory is generally well known, but those who desire further information regarding this subject should refer to the article by Dr. W. R. Whitney on "Theory of the Mercury Arc Rectifier" in the December, 1911, issue of the GENERAL ELECTRIC REVIEW, also to the article by F. Parkman Coffin on "Physical Phenomena of the Mercury Arc Rectifier" in the October, 1913, issue of the GENERAL ELECTRIC REVIEW.

## FUNCTIONS OF VARIOUS PARTS OF THE RECTIFIER

The rectifier outfit may be divided into the following parts:

### Rectifier Tube

For rectifying the current, there is a tube which consists of an exhausted glass vessel containing two anodes, cathode, and two starting anodes, the cathode and starting anode arms being filled with mercury. The mercury arc permits the current to flow with comparatively little resistance in one direction, about 25 volts drop, and offers practically an infinite resistance in the opposite direction. A diagrammatic section of such a tube is shown in Fig. 1.

### Constant-Current Transformer

A constant-current transformer supplies constant alternating current, for rectification, from a constant-potential alternating-current source. Changes in voltage and current are obtained by varying the relative position of primary and secondary coils on the core, which also varies the impedance between primary and secondary of the transformer. The lower the load, the greater the distance between coils and the higher the impedance; and, as the load increases, the coils come together with a reduction in the impedance and increase in the power-factor. It also insulates the primary from the arc-lighting circuit, which is very essential because the circuits are more or less subject to arcing grounds, crosses with other circuits, etc.

### Reactance Coil

Reactance is used to store energy during the high part of the wave that it may be returned to the circuit during the low part of the wave.

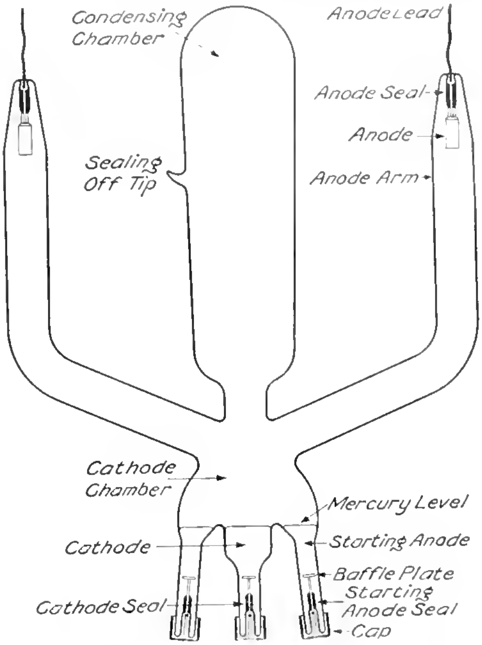

Fig. 1. A Diagrammatic Section of a Rectifier Tube Listing Its Various Parts

During the interval that the arc is running in both anode arms of the tube the reactance carries the entire load, its functions being similar to the flywheel of an engine.

### Exciting Transformer

This is a specially designed, highly insulated transformer with high reactance between primary and secondary coils so that the latter will stand short circuiting without injury. It has also a d-c. reactance to perform the same functions as the main reactance. This transformer contains no moving parts and, besides its fundamental purpose, serves to insulate the supply from the load circuit.

### Means for Cooling the Rectifier Tube

Tubes in the early outfits were cooled by means of an air blast from a blower, usually arranged as shown in Fig. 2. Fig. 3 shows the front of a rectifier board but the blower arrangement is not shown. These outfits were later changed from single to two tubes in series. Later the method of cooling was changed to that of submerging the tube in oil, the oil being water cooled, which is the present standard method.

### Static Dischargers

These are connected between the anode and cathode of the rectifier tube to protect the tube and remainder of the apparatus in case of trouble. In other words, during normal operation of the tube gases are apparently given off, and after shut down these gases are re-absorbed by the graphite anodes. When an old tube is started up cold the anodes run hot, the gases are driven out and apparently prevent the arc from transferring normally from anode to anode, similar to water in the cylinder of an engine. Then, the discharge from the reactance and secondary coils of the transformer may produce a discharge, when the voltage between anode and cathode reaches from 25,000 to 30,000 volts, as shown by needle points. Of course with oil-cooled tubes this cannot occur when static dischargers are added. They also have been installed at a number of stations using air-cooled tubes.

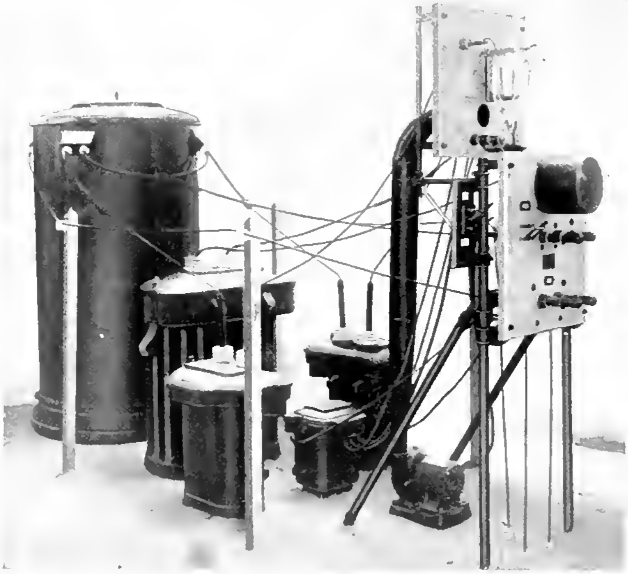

Fig. 2. An Early Mercury Arc Rectifier Outfit Showing Motor and Blower for Air Cooling the Tube

### Panel Board

This board at present has the following equipment, primary switch and fuses, load and short-circuiting switches, ammeter, and shaking handle.

## COMMERCIAL DEVELOPMENT OF THE SERIES RECTIFIER

The first commercial rectifier outfit was operated by Dr. Steinmetz for the purpose of running a few magnetite arc lamps on the streets of Schenectady above Union College in 1903 and 1904.

Feb. 22, 1905, 100 magnetite lamps were operated for a period of eight hours on a single tube and, with the addition of resistance in the circuit, or an all resistance load, the load on the tube was increased to 10,000 volts, 4 amp., or 40 kw.; on a tube with a little larger arms to 10,000 volts, 6.6 amp., or 66 kw.

In December, 1905, there were started at Portland, Oregon, some 75-light 4-ampere rectifier outfits. Considerable difficulty was experienced with the operation of the tubes during the following summer, for the temperature of the air reached about 100 deg. F. The capacity of the motors, driving the blowers for cooling the tubes, was gradually increased to 2 h.p. per tube. The difficulty was finally overcome by changing the sets from single tube to two tubes in series. In other words, it was found by factory tests that tubes, which would operate at 85 deg. but not at 90 deg. F. on 75 lamps, would operate up to 110 deg. F. when connected two in series and would give a guaranteed life of 400 hours.

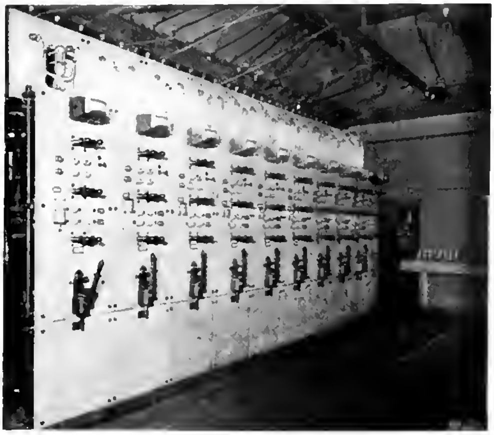

Fig. 3. An Early Installation of Ten Air-Cooled Rectifier Tubes and Switch Panels

In 1907 the method of cooling the tubes was changed from air to oil, the oil being water-cooled, which, combined with a partial consolidation of the apparatus, made a material improvement in the outfit.

In 1910 the various parts of the rectifier outfit, with the exception of the panel board, were all combined into a single piece of apparatus, and the panel board installed in front or elsewhere. Figs. 4 and 5 illustrate combined outfits.

### 50-Light, 6.6 Amp. Single-Tube Outfits

The load conditions on the tube were not quite as severe as with 75 lights, 4 amperes, but the first outfits were changed over from air to oil-cooled tubes, on account of unsatisfactory operation, and are still operating single tube. However, since conditions in a great many parts of the country made it impossible to keep the oil temperature down to 85 deg. F., many of these sets have been a constant source of annoyance, and their manufacture has therefore been discontinued. Some of the sets which have given excessive trouble have been changed over from single tube to two tubes in series.

It was assumed that water no hotter than 70 deg. F. would be used for cooling the oil so that an oil temperature of from 85 to 90 deg. could be maintained, but later developments showed that the city water of St. Louis, Montreal, New Haven, Bridgeport, Conn., and a number of other places would reach 85 deg. F. in summer, and, with the air up around 100 deg., it would be impossible to keep the oil down to 85 or 90 deg. F.

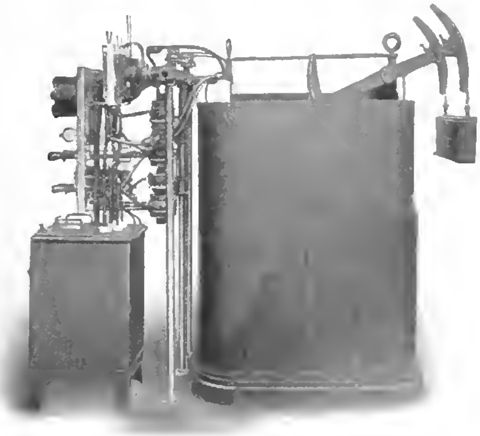

Fig. 4 A Later Rectifier Outfit than that shown in Fig. 2

### 50-Light, 4 Amp., Single-Tube Outfit, Oil Temperature 90 Deg. F.

In Texas, and some other parts of the country, water was not available to keep the oil at 90 deg. or below, and it was necessary to use ice. This, of course, was a decided handicap, and the outfits were changed over from single tube to two tubes in series, since which time their operation has been thoroughly satisfactory.

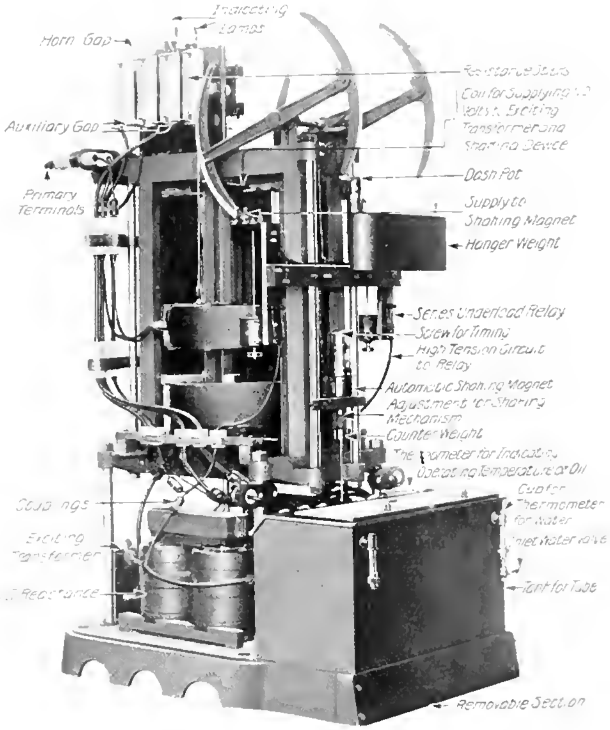

Fig. 5. A Complete Rectifier Outfit, Except for the Casing, of the Latest Type

There is an outfit which has been operating for over six months in Dallas, Texas, with tube tank 40 in. high and no cooling coils. It is a 50-light, 4-ampere, two-tubes-in-series outfit. This is a great advance over the use of ice in the old single-tube outfits.

### 50-Light, 4-Amp., 2-Tubes-in-Series Outfit

The operation of all these outfits (consisting of those which have been made by changing single-tube outfits to two-tubes-in-series outfits and others which have been built up new in the latter form) has been invariably so satisfactory and the tube life so much greater than guaranteed that it very strongly points to the fact that, where customers are obtaining their guaranteed average life of 400 hours, or even 600 hours, on failed tubes covering a period of six months, it would be a profitable investment for them to change over their old outfits from single tube to two tubes in series. This will result in a material reduction in expense of tube renewals, which reduction, in comparison with the expense of renewals on the single-tube outfits, ordinarily speaking will pay for the cost of changing over the outfits from single tube to two tubes in series in two to three years. This is in addition to the material improvement in their operation, fewer interruptions in service, etc.

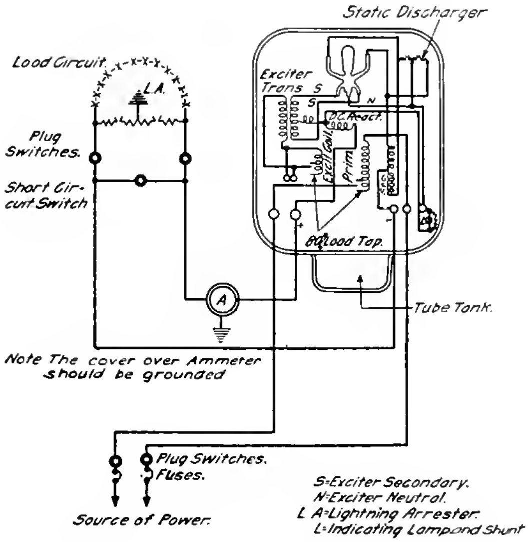

Fig. 6. Diagram of Connections of a Single-Tube Rectifier System

### Connections

The first connections sent out on the single-tube outfits are the standard connections of today; reactance between cathode of tube and line. Fig. 6 shows the connections for a single-tube rectifier.

Some companies made the statement in 1906 that they did not see the necessity for placing the reactance next to the cathode of the tube, as originally called for. There had been, however, no tests made up to that time to determine which was the better connection; and, as an intermediate step, quite a number of outfits were tried out with the reactance connected next to the center of the secondary of the transformer, thus simplifying and reducing the wiring. Later experiments showed that these outfits were sensitive to arcing grounds on the positive side of the line, crosses with other lines, as well as sensitive to inductive effects of high-voltage transmission lines in the near vicinity; whereas, with standard connections, these were not appreciable. Consequently those users, who have had difficulty with their outfits dropping load and with the cathode spot jump-over into the starting anode, have changed the connections so as to have the reactance between line and cathode of tube with a marked improvement in the service.

### Two-Tubes-in-Series Rectifier

The early outfits had no reactance between line and tube. A very marked improvement in service has been found by dividing the reactance and placing half of it between line and cathode of tube, or half next to each cathode. Fig. 7 shows the connections of a two-tubes-in-series rectifier.

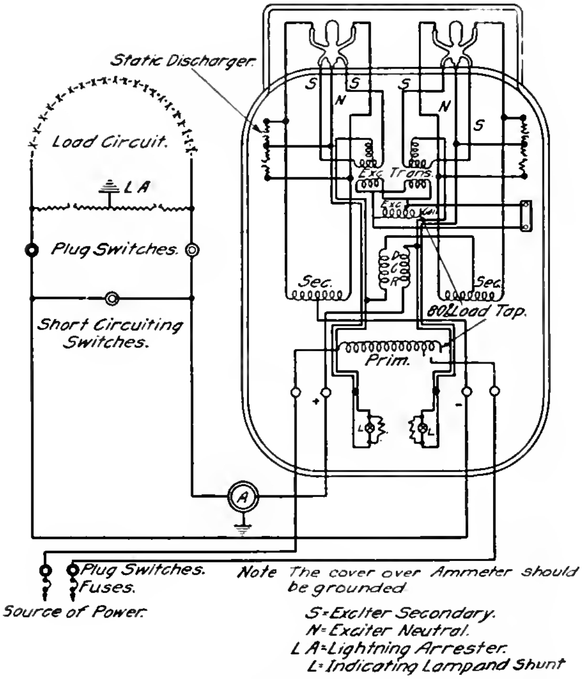

Fig. 7. Diagram of Connections of a Two-Tubes-in-Series Rectifier System

### Rectifier Tube Development

The lava bushing form of tube has undergone some minor changes. The punched iron anode form of tube is a later development and has shown a marked improvement over the former as it is less liable to damage in shipment and as it gives better satisfaction in service, both with air and water cooling. Fig. 8 shows both these tubes.

It is impossible to form a correct opinion of the comparative merits of different forms of rectifier tubes without a careful investigation of the tube life covering a large number of tubes and extending over several years time.

### Duplicate Two-Tubes-in-Series Rectifier

This new outfit was developed in 1913 in order to overcome the objection of the large central stations to the interruptions that occurred during the lighting hours when a tube had to be replaced. These interruptions amounted to about a one 5-minute period in two months service. The outfit has given satisfactory results, the spare tube taking the load in case of trouble.

The tank has been so designed that it can be used with either the old segregated outfits or the later combined units, or with the regularly designed outfit. See Fig. 9 for detailed internal construction of tank with oil removed.

### Connections

As the name implies, duplicate two tubes in series, it is simply a two-tubes-in-series outfit with duplicate tubes, two tubes being connected in parallel, either one of which may operate. For connections see Fig. 10.

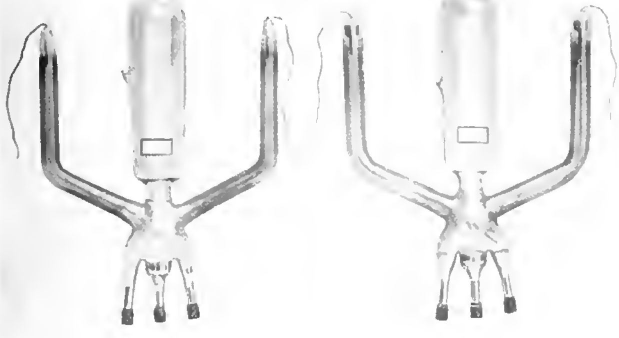

Fig. 8. Two Types of Rectifier Tubes. Tube with Lava Bushing Anode on the Left; Tube with Punched Iron Anode on the Right

### Voltmeter for Measuring Potential on Arc Lighting Circuits

There has been developed an arc-circuit indicator which is a high-grade, high-reading voltmeter and which is very useful in keeping track of the load on the circuits, also, for the purpose of locating grounds, and measuring the insulation resistance of the circuit to ground, etc. Such instruments should be obtained having a maximum scale reading of approximately 50 per cent above rated voltage of the rectifier, which is its open-circuit voltage.

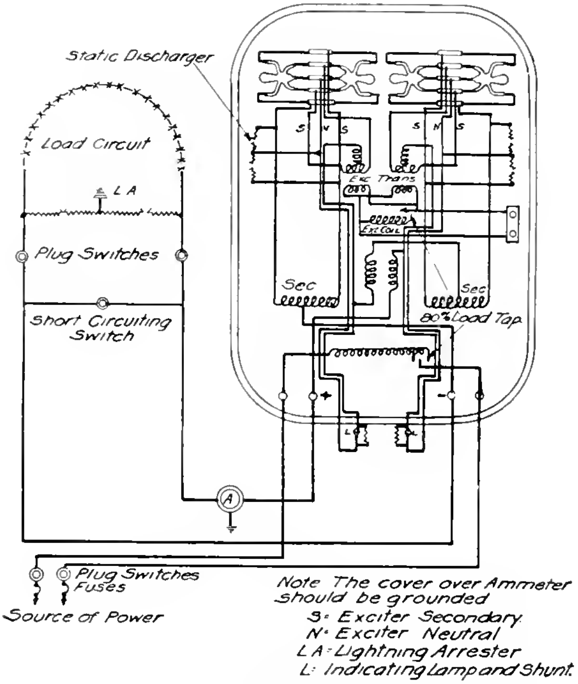
Fig. 9. Tube Tank for Duplicate Two-Tubes-in-Series Mercury-Arc Rectifier, Showing Internal Construction of Tank. No Oil

### Underground Cables

There has been a very steady increase in the number of circuits which are run underground, in comparison with those which have been run overhead; and, occasionally, in putting in these former circuits difficulty has been experienced principally due to the two following causes.

First: Insufficient dielectric strength of the cable, which in accordance with the recommendations of the A.I.E.E. should be called upon to stand a test of double the open-circuit voltage of the rectifier, which is practically three times its rated voltage.

Second: In installing and occasionally in repairing underground cables, the lead sheath on the same is not bonded where the cable is opened to go into the station or up to a lamp. The lead sheath on the single-conductor cable is similar to the secondary of a series or current transformer, and, if this lead sheath is left open, in case of surges on the circuit, there is liable to to be an appreciable voltage generated between the open terminals. This may seriously interfere with the operation of the apparatus, break down the cable, and in certain instances may produce arcing between the lead covering on the cable and other conductors, which might ignite the explosive mixture of gas frequently found in man-holes.



Note The cover over Ammeter should be grounded
S = Exciter Secondary
N = Exciter Neutral

L = Indicating Lamp and Shunt

Fig. 10. Diagram of Connections of a Duplicate Two-Tubes-in-Series Rectifier System

Arcing grounds and crosses with other circuits invariably interfere with the operation of any electrical apparatus, but, if the circuits are kept in good condition and will stand the insulation test as called for by the A.I.E.E., satisfactory service is invariably obtained.

### Lamps

The rectifier has introduced new problems in arc-lamp design, which were not necessary when operated from direct constant-current generators. When these machines flashed they required a very appreciable time to build up and allowed the electrodes or cut-out contacts in the lamp to come together long before the generator would supply its normal current. The same is not true of the rectifiers. These in case of flashing will frequently supply current to the circuit before the electrodes or cutouts in all the lamps get together, and, as a result, the insulation of some lamp may be broken down, or the shunt winding burned out. This difficulty has been taken care of in some forms of d-c. series lamps by inserting an additional automatic cutout, and in the magnetite lamps by keeping the distance between the carbon and copper contacts between $\frac{1}{32}$ in. minimum and $\frac{3}{64}$ in. maximum. As the lamps operate, the carbon contacts slowly burn away, and after a time the distance may become so great that it ceases to act as a spark gap, and consequently the insulation of the lamp may be broken down or the shunt winding burned out. When these latter adjustments have been made the trouble will cease.

# THE IMMEDIATE FUTURE OF THE HALF-WATT MAZDA LAMP

By L. A. Hawkins

Engineer, Research Laboratory, General Electric Company

The author does not attempt to predict what will be the eventual field of the gas-filled mazda lamp, but rather, by a consideration of the characteristics of the lamp, to determine the general directions of the development of this field. The gas-filled mazda does not manifest its wonderful efficiency until relatively high current values (large diameter filament) are reached, and it is probable that the first commercial lamps will be made for currents in excess of five amperes. For the multiple house circuits of 110–125 volts in general use, this would mean lamps of over 600 c-p., which are entirely unfit for average residence lighting. The most obvious field for the new lamp at present is series incandescent street lighting, replacing the old lamps on existing 6.6 and 7.5 ampere circuits. On a-c. circuits better efficiency would be obtainable by the use of 20 ampere lamps supplied with current from a compensator. The author states that the probable net result of the advent of this lamp in the arc lamp field will be to produce better arc lamps, and both types will co-operate in furnishing better lighting systems for all conditions.—Editor.

L. A. Hawkins

THE announcement last summer by the General Electric Company that an incandescent lamp had been produced with a specific consumption of one-half watt per candle naturally gave rise to much speculation upon the effect this new lamp would have on electric lighting. Since then, the characteristics of the new lamp have been fully described by Langmuir and Orange,* but speculation continues and some misapprehensions are manifest. Therefore it may be worth while to devote a few minutes to a consideration of the probable immediate future of the new gas-filled mazda lamp.

It would be equally presumptuous and futile to attempt to anticipate developments by mapping out the metes and bounds of that portion of the field of electric lighting which the gas-filled mazda lamp will eventually occupy. It is not the purpose of this paper to make any such attempt, but rather, by considering some of the well established characteristics and peculiarities of the lamp, to try to determine the general direction of probable development which may affect that development.

When a gas-filled lamp is compared with a vacuum lamp, its most striking characteristic, aside from its higher efficiency and higher intrinsic brilliancy, is that its efficiency varies with the size of the filament. In vacuum lamps the efficiency at a given filament temperature is independent of the diameter of the filament, except for the relatively slight effect on loss through leads. In gas-filled lamps the diameter of the filament is an important factor in determining the efficiency. The reason for this is that at a given temperature the wasted energy, i.e., the heat lost by conduction in the gas, is practically independent of the filament diameter, while the useful or radiant energy is proportional to the surface, and therefore to the diameter of the filament. Langmuir † gives the specific consumption of a tungsten filament at 2800 deg. absolute in nitrogen at atmospheric pressure as 1.54, 0.74 and 0.50 watt per candle for filaments of 1, 5, and 50 mils dia. respectively. It is clear from these figures that the large filament has in nitrogen an advantage over the small filament which it does not have in vacuum. Nor do these figures tell the whole story. A 5 mil filament at 0.74 watt per candle and a 50 mil filament at 0.50 watt per candle, though running at the same temperature, will not have equal lives. The larger filament should outlast the smaller several times. In order to get a comparison based on equal lives the specific consumption of the smaller filament must be raised or that of the larger lowered. The difference in efficiency will then be more marked.

The gas-filled lamp is thus at its best in large sizes, and it is therefore in large sizes that the first commercial development should be looked for. Large size means large filament diameter and that means large current. The filament can and should be coiled in a close helix, so as to give the effect of a larger diameter, but the permissible diameter of the helix is limited, because, if it is made too great in proportion to the diameter of the filament, the filament will sag rapidly early in the life of the lamp and

---

* *Proc. A.I.E.E.*, Oct. 1913.

G. E. Review, Oct. and Dec., 1913.

† *Proc. A.I.E.E.*, Oct., 1913.

the efficiency will fall correspondingly. Therefore, even though the filament is wound in a helix, the specific consumption is relatively so much greater in low current lamps that the first commercial lamps, except for special purposes, will naturally be designed for currents above, rather than below, 5 amperes. For multiple circuits of 110 to 125 volts, this means lamps of over 600 watts, in which specific consumptions of 0.75 down to 0.6 w.p.c. in the larger sizes can be looked for.

Lamps of such wattage and candle-power are so far removed from the sizes of lamps adapted for house-lighting that it is not to be expected that the gas-filled lamp will be scaled down in the near future to house-size.

But there are other circuits on which the high efficiency mazda of more than 5 amperes is immediately applicable. Most street series incandescent circuits now carry 6.6 or 7.5 amperes, and on such circuits the new lamp can be substituted directly for the old and reduce the specific consumption to about 0.7 w.p.c.

A better efficiency is obtainable on alternating current circuits by using a lamp of 20 amperes or more, with a compensator to transform the current to the proper amount. With such a lamp a life of well over 1000 hr. can be obtained at a specific consumption measured on the primary side of the compensator of not more than 0.5 watt per candle.

This combination of a high current lamp and compensator has several advantages over a lower current lamp designed for direct connection in the circuit, other than its higher efficiency, amounting to at least 30 per cent more light for the same wattage. In the first place, on a series circuit, some kind of shunt protection is necessary to take care of burnt out lamps, and a shunt reactance is one of the simplest forms of such protection. This, in effect, is what the compensator is. Secondly, since these new lamps run much nearer the melting point of the filament than do the vacuum lamps they are more sensitive to excess current. The compensator can be designed to reduce the current rise in the lamp for a given rise in the series circuit. Even if the compensator is not designed to give this effect, the greater mass of the large filament, with its time lag in temperature, makes it less sensitive to sudden rises of current than is the lamp with the smaller filament. This time lag is very noticeable when current is thrown on or off a 20 ampere lamp. There is a very appreciable interval before the lamp reaches full luminosity or falls below incandescence.

On the basis of equal life, the large filament runs at a somewhat higher temperature than the smaller filament and therefore gives a somewhat whiter light, but this difference would not ordinarily be noticeable except where direct comparison is possible.

The 20 ampere lamp, with its high efficiency, high intrinsic brilliancy, and relatively white light, enters directly into the arc lamp field. Its efficiency is about three times that of the enclosed a-c. arc of 6.6 amperes, which still lights more miles of street than any other lamp, and is on the same order as that of the luminous arc. In connection with relative efficiencies, it should be remembered that it has been the practice to rate incandescent lamps in watts per mean horizontal candle-power, the measurements being taken on the bare lamp, while arc lamps are usually measured complete with casing, reflector and outer globe and rated in watts per mean hemispherical candle-power. In making comparisons care should be taken to reduce efficiencies to the same basis.

The 20 ampere half-watt mazda seems certain to find a field in street lighting. It can in the present state of its development be made efficiently in sizes as small as 300 watts, 600 candle-power, or even smaller by resorting to special expedients to prevent excessive heat loss through the leads when the filament length is reduced below that corresponding to 15 volts. There is no upper limit to the candle-power and wattage.

In connection with outdoor applications, one point is of interest and importance. The bulbs of nitrogen-filled lamps run much hotter than those of vacuum lamps. Temperatures approaching 200 deg. C. or even higher are to be expected. The reason is that, whereas in the vacuum lamp much the greater part of the energy in the filament is radiated directly through the bulb without heating it, in the nitrogen-filled lamp much the greater part of the energy is taken up by the gas as heat and so delivered to the bulb, with the result that the top of the lamp especially runs very hot. Now when cold water is suddenly thrown on an ordinary glass bulb at 200 deg. C. the bulb cracks. Therefore, for outdoor use it is necessary either to make the bulbs of special low-expansion glass that can when hot withstand a sudden cold shower, or so carefully to house the lamp as to prevent the access of water.

Housing is not a disadvantage for the larger lamps, since the intrinsic brilliancy is so high that a diffusing outer globe is desirable to prevent glare, and for the 20 ampere lamps the compensator must be housed anyway. In the design of the housing, however, it is necessary to provide adequate ventilation. A lamp which will last 1500 hours if properly ventilated will not last 50 hours if the ventilation is insufficient. This is because overheating of the glass sets free water vapor within the lamp which attacks the filament and rapidly spreads a dense black deposit over the bulb. Therefore if the lamps within it are to have a reasonably long life, the housing must be designed with a knowledge of the lamp requirements and its temperature limitations.

It is often asked what effect the half-watt mazda will have on arc lamps. In all probability its effect will be to make better arc lamps. The high efficiency, brilliancy, steadiness, relatively white light, and low cost of maintenance, will make the new lamp a dangerous competitor of the arc lamps; but the case of the arc lamp is far from hopeless. Half a watt per candle is a higher specific consumption than that of the most efficient arc lamps today, and in the race for still better efficiencies the arc lamp has the great advantage that, whereas at about 0.2 watt per candle a tungsten filament reaches its melting point, there is no such fixed limitation on the efficiency of the arc. In brilliancy the arc has a slight, but very little advantage. The slight relative unsteadiness of the arc is not a disadvantage in the eyes of some, who see in it a snap and vivacity which is lacking in the steady though brilliant incandescent lamp. The half-watt mazda, while much more nearly white than the one-watt per candle mazda, is not so white as the luminous arc or the white flame carbon arc. Further increase in arc lamp efficiencies will lower the cost of maintenance per candlepower, and, especially where the cost of power is high, will give the arc lamp a decided advantage.

Thus it is altogether probable that the net result of the advent of the new lamp in the arc lamp field will be that better incandescents and better arcs will co-operate in furnishing better street lighting systems for all conditions. In some cases those conditions will best be met by the mazda, and in others by the arc.

Another field in which the arc lamp must expect competition from the half-watt mazda is in projector, stereopticon, headlight, and searchlight work. The intrinsic brilliancy and high degree of concentration of filament which can be employed in the new lamp adapt it peculiarly for such applications, and should enable it to share this field with the arc.

In so far as the foregoing comments are in the nature of prophesy, they are properly subject to distrust. Prophesy was never more dangerous than in the art of electric lighting today, in which developments are following each other with unprecedented celerity. Other gases than nitrogen are giving excellent test results and may soon be in production. Other developments in arcs or incandescents may at any time disturb the balance of power and bring predictions to naught. One thing alone is certain: The art of electric lighting is advancing more rapidly than ever before, and in its progress will surely bring more and better light to everyone and ultimate benefit to all who are interested in the generation and use of electric energy.

# THE QUARTZ MERCURY ARC LAMP

By Dr. E. Weintraub

Director of the Research Laboratory, Lynn General Electric Company

A description is first given of the quartz mercury arc lamp as developed by the German firm of Heraeus. The principal characteristics of this lamp are discussed, such as the limitation of the current value imposed by the size of the mercury reservoirs, or heat radiating surfaces, and the initial instability of the arc when put in operation. The author then proceeds with a description of the quartz mercury arc lamp as made by the General Electric Company, and relates in detail some of the most interesting features connected with its development, such as the production of a satisfactory glass seal and of a suitable material for a solid anode. The article is concluded by a discussion of the efficiency of the quartz lamp as an illuminant.—Editor.

Dr. E. Weintraub

The quartz mercury arc lamp is distinguished from its predecessor, the glass mercury arc lamp, by the fact that a considerably larger amount of energy is concentrated in a given space, and by the concomitant features of a higher potential drop per unit length, a higher mercury vapor pressure, and a higher temperature. The greater concentration of energy leads to a greater efficiency of light production. This greater concentration of energy is made possible by the use of quartz as an envelope, a material which has a considerably higher melting-point than even the most refractory glass at present at our disposal.

The pioneer commercial work on the quartz mercury arc lamp is due to the Heraeus firm in Germany. It is therefore proper to begin this article by a description of the lamp they have developed and put upon a commercial basis.

### Heraeus 220 Volt Lamp

Fig. 1 represents the 220-volt d-c. 3.5 ampere type of lamp, which has had so far the widest application. The lamp consists of a tube connected at the ends to two mercury-filled reservoirs. One of these mercury reservoirs serves as an anode, the other as a cathode. It will be noticed that the arc tube is shaped differently near the reservoirs: toward the anode reservoir, the arc tube is shaped in the form of a sloping roof; near the cathode reservoir, the tube takes the form of a narrow thick-walled contraction. To the reservoirs are attached small, thick-walled quartz tubes which carry metallic conductors for the introduction of the current. The tube is exhausted to a fair vacuum.

Externally the lamp differs from the familiar glass lamp by the shortness of the light-giving tube, and the absence of a "condensing chamber." In this 220-volt type, the light-giving tube is only about 5 in. long.

The "ground joints" are attached to the reservoirs. It is not possible to seal metallic conductors into quartz in a manner similar to that common in exhausted glass vessels. A metallic conductor with a coefficient of expansion near that of quartz is found in a certain alloy of nickel and steel, but as the melting-point of this alloy is too low, and sealing it into quartz is impossible, recourse is taken here to a ground joint between a conical nickel steel plug and quartz. As one ground joint is not perfectly vacuum tight, two such ground joints in series are used and a seal of liquid mercury is placed on the top of the upper ground joint. On the whole, these ground joints if properly made are satisfactory so long as they are not exposed to any considerable temperature rise. This limitation has the disadvantage of reducing the number of possible designs of the lamp.

The mercury reservoirs are of a very large size as compared to the arc tube. The necessity of these large size reservoirs is best explained by referring to the volt-ampere curves of the quartz mercury arc lamp given in Fig. 2. It will be seen from these curves that when a certain current is reached, the voltage rises very steeply. The quartz lamps for reasons of light efficiency operate on that part of the volt-ampere curve which is practically parallel to the axis of the ordinates. In other words, the *quartz lamp under its operating conditions is a constant current device*, and no matter what the impressed voltage or the resistance in series, a current above a certain maximum value cannot be forced through the arc.

*This constant current value depends mainly on the size of the mercury reservoirs*, or, perhaps, more exactly on the rate at which heat can be dissipated from their surfaces. The three curves in Fig. 2 are obtained by varying the size of these reservoirs. In order to force even a current of 3.5 amperes, the size of the reservoirs has to be very large, in fact, much larger even than that actually used. Such large reservoirs are bulky and expensive, and in order to obtain a sufficient rate of heat dissipation, it was found preferable to attach metallic wings to the reservoirs; the heat dissipation is then regulated by the size of these wings, by their distance apart, and, of course, also by the size of the reservoirs to which they are attached.

The heat generated at the anode is greater than that at the cathode, and if no precautions were taken the anode mercury would distill over into the cathode. One way of preventing this would be to increase the heat dissipation at the anode over that at the cathode by increasing the surface. However, a complete balance could not be obtained by this rough means, and in the commercial type this is accomplished in an automatic way by the different shaping of the tube near the electrodes. The cathode reservoir is connected to the light-giving tube by a contracted part, in such a way that, during the operation of the arc, the mercury stands in this contracted space. The narrow column of mercury thus introduced between the arc and the reservoir conducts the heat away with difficulty, and this tends to increase the rate of vaporization of mercury as compared to that at the anode, where the mercury surface exposed is large and the heat generated at the anode spot is conducted away freely by the large mass of mercury. Should at any time the amount of mercury vaporized at the anode be larger than that at the cathode, more mercury will accumulate in the narrow cathode tube; the heat conductivity from the cathode spot will thereby be reduced and the amount of vapor generated at the cathode automatically increased. By these means, continuous operation is made possible.

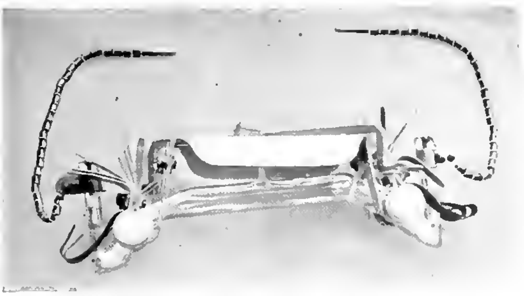

Fig. 1. 220 Volt, 35 Ampere D-C. Quartz Mercury Lamp, made by Heraeus, Germany

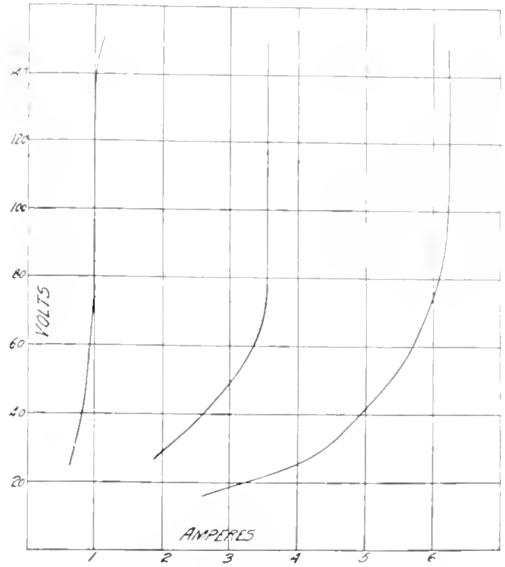

Fig. 2. Volt-Ampere Curves of Quartz Mercury Arc Lamp of Fig. 1

### Operation Characteristics of the Lamp

When conditions of equilibrium are reached, this particular type of lamp runs at 3.5 amperes and about 170 volts on a 220 volt circuit. The current is determined by the construction, especially the size of reservoirs, as pointed out above. The voltage is determined by the series resistance and can be varied at will. This voltage is, of course, equal to the impressed voltage minus the IR drop in the resistance—in this case, about 14 ohms.

Referring to the volt-ampere curve, Fig. 2, it will be seen that the volts across the arc rise rapidly with the current and it would seem as if a steadying series resistance were unnecessary. That such a resistance is indispensable is due to the fact that the instantaneous variation of voltage with current change is in the opposite sense from the permanent one. A decrease of current causes an instantaneous increase of arc voltage, which changes into a decrease only after some time. In other words, the instantaneous characteristics of the quartz mercury arc are the same as those of an ordinary arc.

The current and voltage values given above correspond to the final equilibrium reached by the lamp only some time after starting, when the mercury reservoirs are warm and the dissipation of heat is equal to the input. Immediately after starting, the resistance of the arc is low and the voltage drop is only about 30 volts. With a resistance of 14 ohms in series, this means that an initial current of about 15 amperes is flowing, a current more than four times the final equilibrium value.

*The high value of the initial current is characteristic of the quartz mercury arc lamp.* As the tube and its electrodes warm up, the current diminishes and the voltage rises. The time taken by the tube to get into equilibrium is about 15 minutes.

During this interval of time, the appearance of the arc also changes in a characteristic manner. At first the arc fills the whole cross section of the tube uniformly, but as the temperature and the pressure rise the luminous arc detaches itself from the walls of the tube and finally occupies only a small central portion.

### Other Types of the Heraeus Lamp

Besides this 220-volt, 3.5 ampere, d-c. lamp, the Heraeus firm has developed a 110-volt, 4-ampere type and a 220-volt, 1.5 ampere lamp. The first differs from the 220-volt type only in that the light-giving portion of the tube is much shorter, or about 1½ in. in length. The arc consumes about 75-80 volts. The smaller current type has smaller mercury reservoirs.

The Heraeus firm have also developed an alternating current lamp, but have not yet introduced it into commercial use to any extent.

As is probably familiar to the reader, the mercury arc is essentially uni-polar, and is not directly suitable for use on alternating current circuits of moderate voltage. By arranging connections similar to those of the mercury arc rectifier, it is, however, possible to have a mercury arc run on alternating current. The Heraeus a-c. lamp has two mercury anodes and one mercury cathode, and compensator connections with a neutral connected to the cathode.

It is to be expected that difficulties would be caused by arcing between the anodes, which takes place very readily when the anodes are made of mercury.

It will be observed that all the Heraeus lamps are multiple lamps. This is because the quartz mercury arc lamp is not suitable for series or constant current circuits without special arrangements. The cause of this is again the peculiar volt-ampere characteristic. The rapid rise of the voltage curve for even very small changes of current means that even small fluctuations either in the circuit or in the outside temperature (the latter changing the conditions of heat dissipation), would mean large changes of energy input into the tube, which in turn would mean rapid increase of temperature with further rise in voltage, etc., until destruction of the tube took place.

### General Electric Quartz Mercury Arc Lamp

The development of this lamp is the result of work carried out in the Lynn research laboratory of the General Electric Company.

The first problem attacked and solved was that of introducing current into exhausted quartz vessels, not by means of ground joints but by means of metallic wires sealed in in a vacuum tight manner.

In principle, the method used is that of interposing between the quartz and a suitable metallic wire different glasses of variable coefficients of expansion. The coefficient of expansion of quartz is in the neighborhood of $0.5 \times 10^{-6}$; the coefficient of expansion of platinum, which is the metal used in glass seals, is in the neighborhood of $9.0 \times 10^{-6}$. The glass with the lowest coefficient of expansion on the market has an expansion of about $3.5 \times 10^{-6}$.

To make possible the connection of this low expansion glass with lead glass, six intermediate glasses were necessary, these glasses being obtained from the glass factories.

To connect quartz to the low expansion glass, glasses were needed with intermediate coefficients of expansion. After considerable work, glasses filling the requirements were prepared, and it was found that four such "intermediates" were necessary to produce a reliable joint. In all, ten different glasses were therefore necessary to enable one to seal in platinum wire. This large number of intermediates made the method expensive, and it was also found that the reliability of the joints between the low expansion glass and lead glass was not sufficient for shop use.

Fortunately, we soon made the other and equally important discovery that tungsten wire could be sealed into the low expansion glass in a vacuum tight manner. The number of intermediate glasses was, therefore, reduced to only four, and tests on a large number of these seals have shown them to be reliable. They stand higher temperatures than any other vacuum seal, and, due to the higher electrical conductivity of tungsten, can carry more current for a given cross section. The tungsten leading-in wire, in combination with low expansion or heat-resisting glass, is also being used in a new type of rectifier and bids fair to become of importance in the field of gas-filled mazda lamps. These "graded" seals are not only cheaper than the ground joints, but they permit certain designs of tube that would be impossible with the ground joints.

The use of these graded seals, capable of withstanding relatively high temperatures, suggested at once the replacement of the mercury anode used in the Heraeus quartz lamp by a solid anode.

The solid material to be used as an anode in the quartz mercury arc lamp must have a very high melting point and a very low vapor tension. It must have a high melting point in order to withstand not only the normal temperature developed at the anode by the lamp current, but also the much higher temperature produced by the initial current, which is many times larger than the equilibrium current. The material must have a low vapor tension, because it would otherwise slowly volatilize and blacken the tube, especially in the neighborhood of the anode, a blackening which is the more serious as the light-giving section of the tube is short. Materials fulfilling these requirements were not known until recently, and among those available now, tungsten and tantalum are the best.

Fig. 3. Graded Glass Seals with Tungsten Leading-in Wire

The use of a solid anode has numerous advantages. Mercury vapor is now evolved only at one electrode, i.e., the cathode, so that the vapor pressure for the same current and the same size mercury reservoir is greatly reduced. Of course, balancing of the vaporization of mercury at the two electrodes is no more needed since no mercury is evolved at the anode; therefore the peculiar narrow space near the cathode can be dispensed with, thereby still further reducing the vapor pressure. This means that for the same current a much smaller mercury reservoir can be used and no wings are necessary.

Fig. 4. Anode formed of Tungsten Wire Wound into Flat Spiral

The elimination of the mercury anode reservoir, the reduction in size of the mercury cathode reservoir, and the elimination of the heavy quartz tubes used in the ground joints has reduced the amount of quartz and the amount of labor necessary to shape the tube to from one-third to one-half that of the corresponding device of the Heraeus type.

The peculiar difficulty of forcing large currents through the quartz mercury arc lamps was referred to above. This difficulty is greatly reduced in the case of the General Electric type of lamp. The volt-ampere curve has still the same characteristic in that the volts rise very rapidly when a certain current is reached, but, with a reasonably sized mercury cathode reservoir, currents as high as 6 or 7 amperes can be easily forced into the arc as against the 3.5 or 4 amperes of the Heraeus type. Still larger currents can be obtained if wings or a small condensing chamber are provided.

The General Electric type of lamp shares with the Heraeus type of lamp the slight disadvantage of large initial current; but, due to the smallness of the mercury reservoir, the time necessary to reach equilibrium is reduced.

Fig. 3 shows the graded seal with the tungsten leading-in wire. Fig. 4 shows the tungsten anode usually made from wire wound into a flat spiral. Fig. 5 shows the 110-volt, 4-ampere, horizontal type and Fig. 6 shows the 220-volt, 3.5 ampere, horizontal type, which were developed first to correspond to the units of the Heraeus lamp.

The cathode mercury reservoir is either horizontal or vertical. The graded seal with the tungsten leading-in wire is in the form of a drop seal on the cathode. The tungsten leading-in wire and the tungsten anode used are formed of one piece. The arc tube is shaped in the form of a sloping roof near the cathode, mainly for the purpose of steadying the arc.

Fig. 5. 110 Volt, 4 Amp., Horizontal Quartz Mercury Arc Lamp

Fig. 6. 220 Volt, 3.5 Amp., Horizontal Quartz Mercury Arc Lamp

Fig. 8. Alternating Current Quartz Mercury Arc Lamp. This lamp differs from the d-c. lamp in having two tungsten anodes instead of only one

Two types of mechanism have been developed for starting the arc. One consists of a shunt coil which starts the arc by tilting the tube; as soon as the arc is started, the circuit of the shunt coil is interrupted automatically. For the other type of mechanism, the tube is slightly modified in such a way that the mercury makes contact with the anode before the arc is started. A series coil is used which by tilting the tube starts the arc.

The design of the General Electric type of lamp lends itself readily to the construction of a vertical type which is more suitable for street and park illumination on account of its better light distribution. Such a type is shown in Fig. 7, together with the mechanism used, which is placed underneath the lamp so as to produce a unit suitable for ornamental lighting. In the Heraeus type of lamp, the construction of a vertical lamp is connected with such difficulties that it has never been attempted.

A very considerable advance was also made possible in the construction of an alternating current lamp. We saw that the Heraeus alternating current lamp was costly and

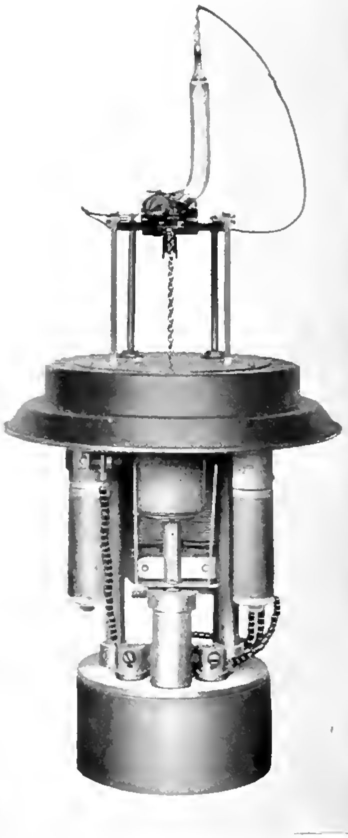

Fig. 7. Vertical Type Quartz Mercury Arc Lamp

offered difficulties in operation. The elimination of the mercury anodes has reduced the tendency to arcing to such an extent and has made the construction of the tube so simple that the General Electric alternating current quartz lamp is just as practical and satisfactory in operation as the direct current lamp. The construction will be seen in Fig. 8; it differs from the d-c. lamp only by the use of two tungsten anodes instead of one.

### Efficiency of the Quartz Lamp as an Illuminant

The horizontal type of quartz lamp has to be provided with a reflector above it and both the horizontal and vertical lamps have to be surrounded by a globe in order to cut out the harmful rays that penetrate through the quartz. In this respect, the quartz mercury arc lamp is in no way different from any other arc lamp. See Fig. 1 for reflector, and Fig. 9 for the general appearance of the General Electric horizontal lamp.

The use of the reflector and the globe causes a certain loss of the light flux and there is a certain amount of energy dissipated in the resistance in series with the arc. Taking all these losses of flux and energy into consideration, the General Electric 220-volt lamp, 3.5 ampere type, has a mean spherical specific consumption of 0.6 watt per candle, while the 110-volt, 4-ampere, type has a specific consumption of 0.75 watt per candle.

The life of the tubes is long. One thousand to ten thousand hours are the extreme limits, with an average of about three thousand.

Recent work done in the Lynn Laboratory and which can be only referred to here has led to a considerable increase in these efficiency figures. The 110-volt lamp has by this means given a consumption of 0.5 watt per mean spherical candle, and in the 220-volt type a corresponding improvement has been obtained. Lamps now on life test show that the life of these "high efficiency" lamps will not be materially less than that of the older type.

# THE MANUFACTURE OF DRAWN WIRE TUNGSTEN LAMPS

By J. W. Howell

Edison Lamp Works, Harrison, N. J.

The incandescent electric lamp is the most widely used of all electrical devices, and although requiring the most exacting methods in its manufacture, is one of the simplest in its elements; yet it is surprising to find how little of an authentic nature has been written on the manufacture of incandescent lamps—possibly the most fascinating branch of the electrical industry. This article should therefore prove of much general interest; for the author has clearly outlined, with the assistance of some excellent photographs, each step in the manufacture of the mazda lamp, from the reduction of the tungsten ore and blowing of the bulbs to the final operation of "sealing-off" and testing.—Editor.

J. W. Howell

There are few persons, other than those directly associated with the production of incandescent electric lamps, who realize to what immense proportions this branch of the industry has developed, or who have a well-formed conception of the operations and difficulties involved in lamp manufacture, or of the methods that have been inaugurated for dealing with them. The purpose of this article is to present a short description of each of the principal steps in the manufacture of the high efficiency drawn wire mazda lamps that have now been on the market for some time.

Some idea of the magnitude of the business is conveyed by the fact that 120,000,000 incandescent lamps were made and sold in the United States in 1913.

Four factories contribute to the manufacture of incandescent lamps; namely, the glass works, in which the bulb and other glass parts are made; the filament factory; the base factory; and the lamp factory, in which the parts are assembled and the lamps made.

The glassware, consisting of the bulbs and tubes, is made by several manufacturers. The bulbs are blown in moulds by manual labor, requiring a high degree of skill, and their manufacture alone is a large industry. The glass employed for these parts must be of fine and constant quality and made to the same formula; for tubing from one factory must often be used with bulbs from another, and unless all factories use the same formula and maintain the same quality, this could not be successfully done. The glass is the same as that used for the finest cut glass; in fact, one factory which makes large numbers of lamp bulbs also makes cut glass articles of the highest quality—and American cut glass is the finest made.

The heart of the lamp is the filament. The filament gives the light, and light-giving is the whole function of the lamp. The other parts of the lamp perform necessary but subordinate functions; they support the filament, enclose it, protect it and lead electricity to it. The failure of any one of these other parts to perform its function will destroy the usefulness of the lamp, but only the filament is manifest in the operation of the lamp. Most of the great improvements in the energy consumption of the lamp have been brought about by filament improvements.

Edison's first commercial lamps (sixteen candle-power) were known as "8 to the horse power." Now, the mazda sixteen candle lamp would be 38 to the horse power, and would have a longer useful life than Edison's "8 to the horse power" lamp. With the same life it would operate with one-fifth the energy needed by Edison's first lamp, or with the same energy per candle it would last 50,000 times as long; so the lamp today may be said to be 50,000 times as good as Edison's first commercial lamp.

The mazda lamp with its filament of drawn tungsten wire is now superseding all other lamps. The production of this filament is due to the persistence of Dr. W. D. Coolidge in sticking to a problem which was generally considered impossible of solution. In the early stages of the development of the drawn tungsten wire, its production was attended with the greatest difficulty. At first a piece of a few feet long was a wonder, but now a piece a mile long and of absolutely uniform diameter is commonplace. It can be made far more accurately and of more uniform quality than the old carbon filament. The raw material used in the filament factory is a concentrated ore of tungsten, from which

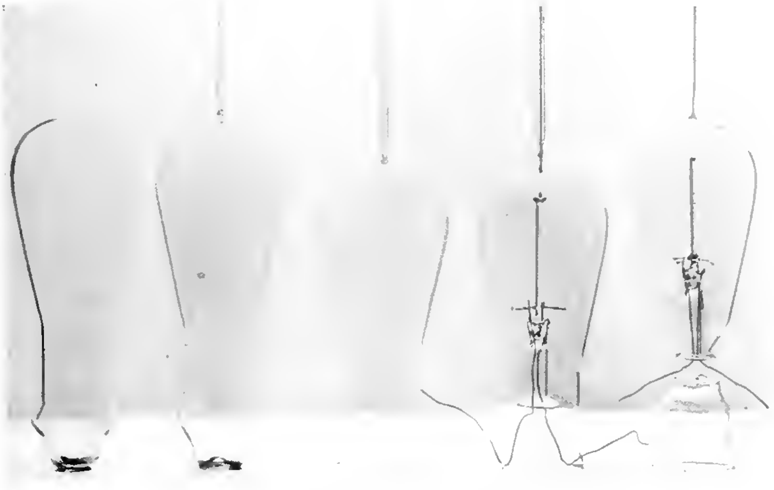

Fig. 2. Illustrating Different Steps in the Manufacture of Drawn Wire Mazda Lamps

pure tungstic oxide, a fine grained yellow powder, is obtained. This is "doped" and reduced to tungsten metal by hydrogen in an electric furnace; the metal produced being in powder form, rather coarse grained, gray in color, and very heavy. This tungsten powder is formed into ingots about ¼ in. square and 6 in. long by pressure alone, no binder being used. The pressure, which is very great, is applied transversely and compacts the tungsten so that the ingot can be handled. It is then placed in an electric furnace in an atmosphere of hydrogen and heated to a white heat, the effect of this heat being to compact and strengthen the ingot and make it a good conductor of electricity. The ingot is then placed in an atmosphere of hydrogen and heated to near the melting point, long enough to thoroughly sinter the ingot. The ingot now has a high luster, and the powder particles of which it is composed are welded together quite firmly. The square ingot now goes to a swaging machine. It is heated to white heat, taken out into the open air and swaged. During this operation a cloud of tungstic oxide rises from the ingot. The ingot is re-heated and swaged several times before the square ingot becomes round. The heating and swaging are continued until the ingot is changed to a rod, three one-hundredths of an inch in diameter and thirty feet long. Before this, when the rod is about six one-hundredths of an inch in diameter, it begins to have a fibrous structure. At three one-hundredths it has a well developed fibrous structure, but can easily be broken by bending back and forth once or twice.

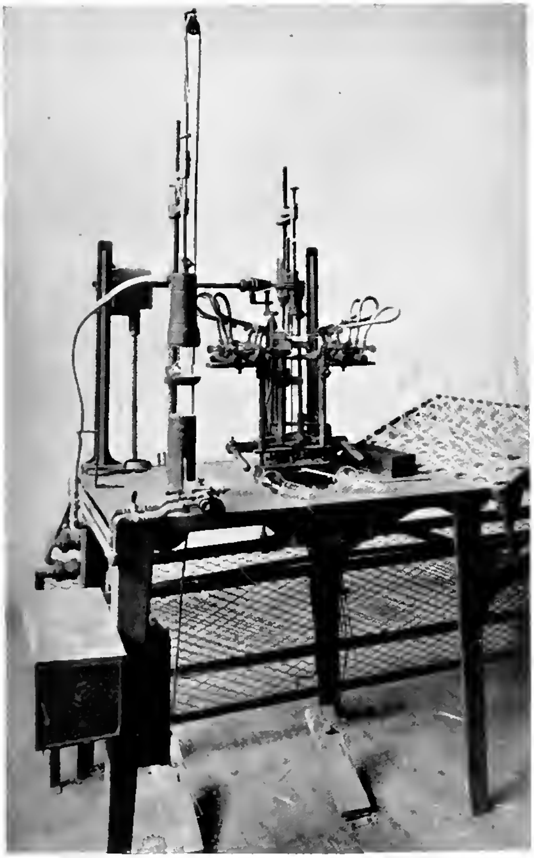

Fig. 1. Tubulating Machine

From thirty mils the rod or wire is reduced in size by hot drawing through diamond dies. The wire is heated to a bright red heat and is still red hot after passing through the die. This degree of heating is continued until the wire is only three mils in diameter, which is about the size of the filament in a 100 volt, 100 watt lamp. Below this, the temperature of drawing is reduced and the last drafts of any wire are made below red heat. The wire is now quite ductile and the last drafts may be made cold if desired. During this drawing the wire is lubricated with graphite, which forms a coating and prevents oxidation of the wire. It also lubricates the wire when it passes through the die. The last draft is made through a very perfect die which reduces the diameter of the wire very slightly, and in this way very long pieces are made which are the same size throughout.

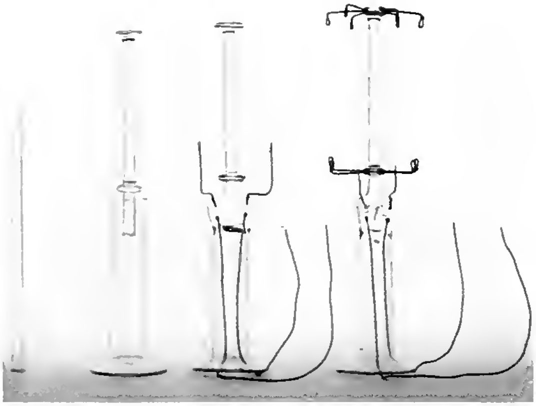

Fig. 3. Illustrating the Several Steps in the Construction of the Filament-Supporting Stem

The size of the wire down to three mils is determined by micrometer, but below this it is determined by weighing a standard length of wire; and the size is not expressed in mils but in normal amperes, which is the amperes required by the wire in a vacuum at a certain watts per candle. The filament in a regular ten watt lamp is about three-quarters of a mil in diameter, which is probably the finest wire ever produced by straight drawing. At a recent industrial exposition, a wire manufacturer exhibited some wire one and a half mils in diameter as a marvel of wire drawing.

Bulbs, tubing, filaments and bases are the raw materials used in the lamp factory. Bulbs as received are shown in Fig. 2. The round end of the bulb is smooth, the neck being long and its end ragged. The first operation on the bulb is "tubulating," by which the small tube is attached to the center of the round end of the bulb.

Fig. 1 shows a tubulating machine. The bulb is first placed in the holder on the left, where a fine jet of gas strikes the center of the round end and heats it red hot in a spot. Air pressure admitted inside the bulb blows out the hot glass at this spot and makes a small round hole, the size of this hole being regulated by the air pressure; the higher this pressure, the smaller the hole.

The bulb is then transferred to the tubulating machine proper, which holds the tube so that its end registers with the hole in the bulb. Gas fires heat the parts to the fusion point and they are melted together in such a way that the tube and hole are left open.

Fig. 2 shows a tubulated bulb. The structure which supports the filament is called a stem, and when the filament is on the stem, the whole is called a mount. Fig. 3 shows the stem construction and Fig. 4 a stem-making machine. The stem-making machine is fed with a short piece of glass tube, two leading-in wires, and a glass cane or hub.

The head of this machine rotates. In the second position the tube has a flare made on its upper end; in the next position a second operator puts the lead-in wires and hub in position; then the lower end of the glass tube is melted down upon the lead-in wires and hub, and when so melted the parts are

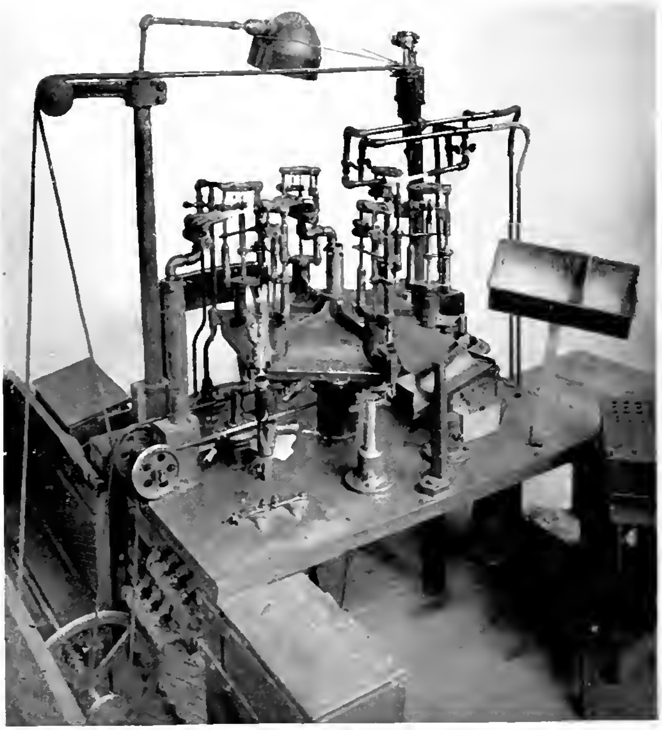

Fig. 4. Stem Making Machine

squeezed together, making a seal about the wires which is air tight.

The wire hooks, which support the filament, are then stuck in the glass hubs. Copper wires have been used for hooks in the smaller sizes of lamps and tungsten wires in the larger sizes, but tungsten wires are now supplanting the copper wires in all sizes. The stem is now ready to receive the filament.

In order to make a lamp of the desired voltage, candle-power and efficiency, the filament must be of exactly the right diameter, and must be cut exactly the right length. Sizes suitable for all standard types of lamps are carried in stock, all very carefully measured and labeled. To get the right length for the desired voltage, the wire is wound on an adjustable form which determines the length of each piece very accurately. The winding of the filament on the supports is done by hand. The operator draws a filament, already cut to length, from the form, attaches one end to a lead-in wire, winds the filament on the supports and attaches the other end to the other lead-in wire. The supports are then bent to space them properly and to put the right tension on the filament. The completed mount is shown in Fig. 3.

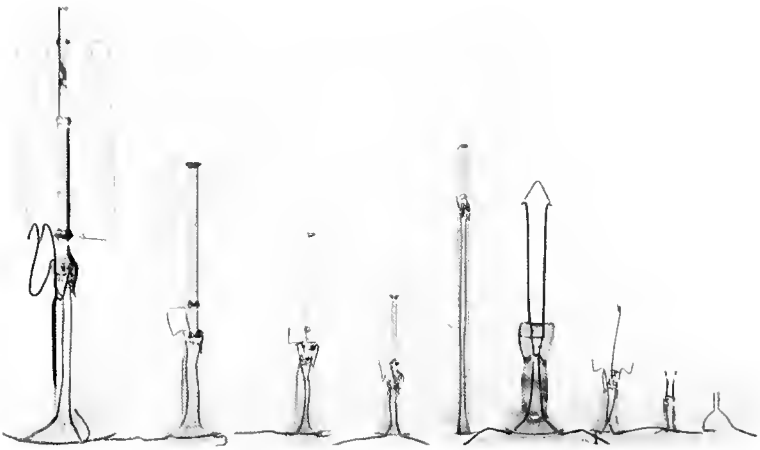

Fig. 6. Mounts and Filament Shapes

Where concentration of the light is desired, or where it is desired to put a long filament in a small bulb, the filament is wound on a mandrel to form a helix, with the coils slightly separated, as shown in Fig. 6.

The attaching of the filament to the lead-in wires is an important operation. Thin filaments are inserted in tubes formed in the end of the lead-in wires and the parts squeezed together. Large filaments are fused to the lead-in wires, and in both cases the material of the lead-in wires is a matter of great importance.

When the mounts are ready they are assembled with the bulbs already prepared. This assembly is done in the sealing-in operation, which is performed on the sealing-in machine shown in Fig. 5. This machine supports the bulb in a rotary holder, and supports the mount inside of the bulb in its proper position. The assembled

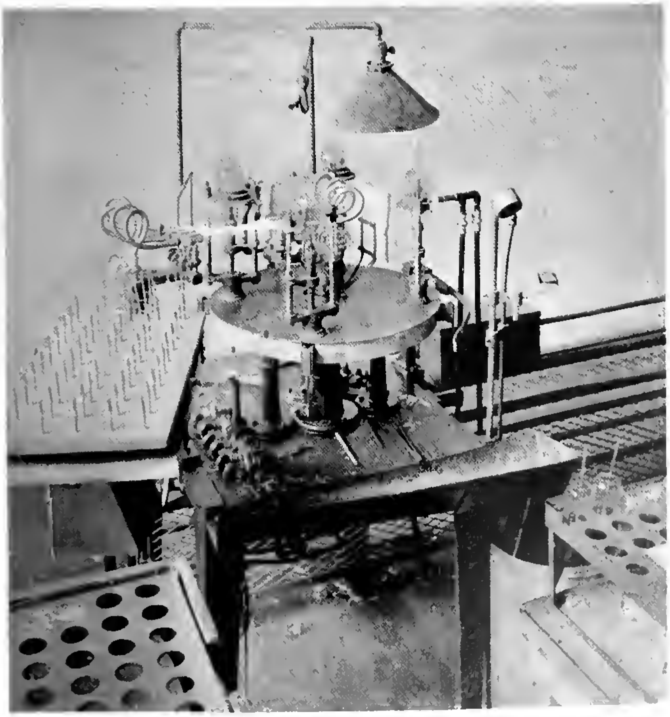

Fig. 5. Sealing-in Machine

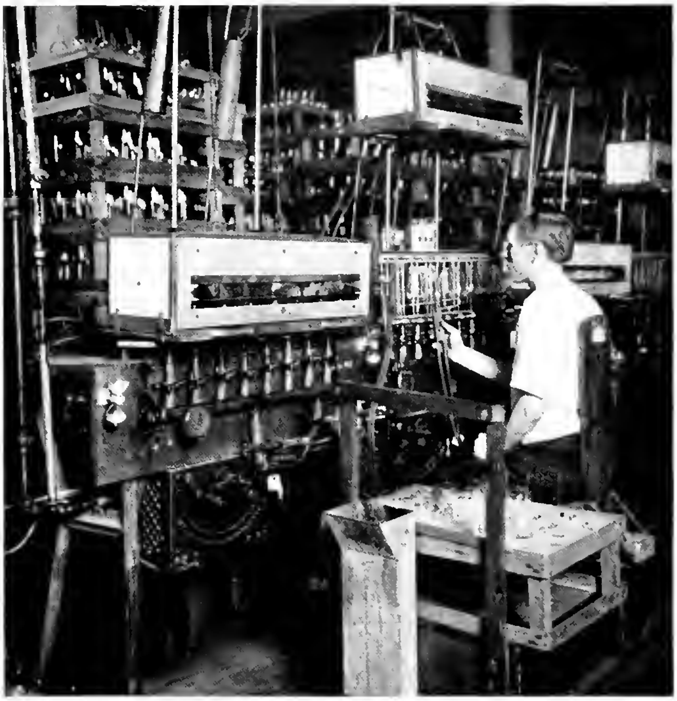

Fig. 7. Exhaust Table

parts are acted upon by three sets of gas fires; the first gently heating the neck of the bulb and the flare at bottom of mount; the second heating these parts until the neck of the bulb softens, and the glass sinks downward and inward until the neck of the bulb touches the flare and the two are sealed together. The third set, which are thin sharp fires, melts the neck of the bulb below the seal, thus cutting off the surplus glass. While the glass is still soft, the operator centers the mount in the bulb, and the assembling is complete. Fig. 2 shows the stages of the work in this operation.

The lamp is now ready for exhaustion. Fig. 7 shows an exhaust table. Its essential elements are a preliminary vacuum pump, a final vacuum pump, a manifold containing a chemical dryer with connections for pumps and lamps, a heater for heating the lamps, and electric connections by which the lamp may be lighted up or tested by induction coil for vacuum. The lamp is connected to the pump by slipping the tube which has been attached to the round end of the bulb into a rubber connection on the manifold. Where this tube is attached to the bulb, it is reduced in diameter, or contracted. This contraction limits the passage of the air, gases and vapors from the lamp, and is an important factor in the time needed to exhaust a lamp; but it aids the sealing off of the lamp and the appearance of the tip left on the bulb.

During exhaustion the lamps are heated. This heat frees the glass of absorbed gases and vapors so that the pumps and chemical dryer can remove them from the lamp. The exhaustion is continued for a certain time, which has been determined by experience, or until the induction coil test shows the vacuum to be good. This time is much longer for large lamps than for small ones.

The lamp is sealed off by melting the glass tube at its contraction close to the bulb; this melting closing the tube completely and sealing up the tip left

Fig. 8. Basing Machine

on the lamp so that it is perfectly air tight. The lamp is now ready for basing, sorting, cleaning, packing and shipping.

Inspections are very important in the lamp factory; imperfections or defects must be discovered as soon as they appear and before other work is done on the lamp, which would increase its value and consequently the loss if the defect is serious. A defective stem, if discovered right after the stem is made, causes at most the loss of the stem; but if not discovered until the stem is sealed in a lamp, may cause the loss of the lamp. So the work is carefully inspected after each operation by skilled inspectors, and all defective parts are rejected.

### Breakage

The lamp parts are fragile and many pieces are broken in the various stages of manufacture. The handling of these broken parts, and parts rejected by inspectors, so as to salvage as much as possible, is an important part of a factory superintendent's duty; in fact, a good idea of the competence of a factory superintendent may be obtained by inspecting his breakage department and his breakage cost item. All broken and rejected parts are taken to a breakage department, where competent operators salvage as much as possible, and return the repaired and saved parts to the factory departments.

Breakage is an expense which benefits nobody; it is made the subject of special work and reports, and each factory superintendent knows that his record depends on his success in keeping this expense within the proper limits.

Every successful lamp factory must maintain a life test department, for the quality of lamps can be learned only by a life test. These tests must be made at a known efficiency, and must be carried on long enough to determine the full value of the lamp. This means continuing a test until the lamp has failed, or deteriorated to a degree which tells the whole value of the lamp. Lamps should be life tested at their normal voltage, or a voltage so little in excess of that voltage that no very abnormal conditions are created. This voltage during the test must be held as constant as possible, and automatic voltage regulation of the utmost refinement is used for this purpose. Also, as lamps of many different voltages must be tested, suitable lines must be provided. These lines differ in voltage by only one volt, and to maintain all these lines constant, necessitates the use of transformers and compensators of the most careful design and construction, and conductors of large size.

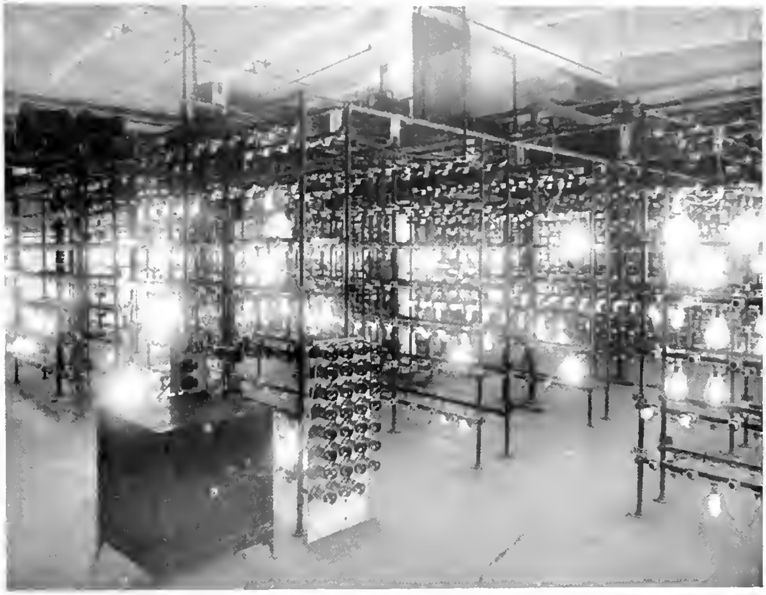

Fig. 9. Life Test

Before putting a lamp on test, it is carefully photometered and measured at exactly the voltage of the line on which it is to be tested, and subsequent measurements of candle-power and efficiency are all made at this same voltage. Satisfactory life tests require at least four hundred hours if the lamps are good. Burning lamps at higher voltages to get quicker results has been found unsatisfactory. Life tests are made frequently and at regular intervals on the regular product of each factory, in order to know the quality of the work done in each, and also in order to detect and correct any error which may be made in the factory. Life tests are also made on experimental lamps, and no change in method of manufacture can be made until repeated tests have demonstrated its value.

# CHARACTERISTICS OF MAZDA LAMPS

By Evan J. Edwards

National Lamp Works, General Electric Company

Mr. Edwards notes in the early part of his article that the term characteristics, as applied to incandescent lamps, refers to the relation existing between voltage, current, and candle-power and all dependent relations, while the relations which involve time, such as candle-power life curves, are termed performance. The characteristics as generally used by the illuminating engineer are usually only considered in an approximate manner, but the scientist and lamp manufacturer need more accurate data than can be obtained by approximate calculations. The author has given formulæ, curves and tables worked out to a great degree of accuracy, which should be of much value to the specialist interested in this work. The author wishes to acknowledge the valuable assistance rendered him in the preparation of this article, and in the experimental work involved, by Mr. C. L. Dows, his assistant.—Editor.

Evan J. Edwards

IT IS well known that several variations result from changing the voltage applied to incandescent lamps and that for a given filament material all the relations are fairly definite, and expressible with fair accuracy by simple exponential equations. These equations are extensively used by illuminating engineers and approximate values for the exponents have become a matter of almost common knowledge among them. Many data have been published * and nearly all the recent figures given agree within an accuracy sufficient for the purposes of illumination calculations, where, as a rule, transpositions are made over only short ranges of voltage and are needed only to a relatively low precision.

The particular type of construction used in the lamp and the normal efficiency taken as a basis affect the values of the exponents as ordinarily defined, but usually not to a sufficient degree to make it necessary for the illuminating engineer to revise his data every time slight changes are made in the manufacture of a lamp or the efficiency at labeled voltages.

There is, however, a need for data of the highest precision, notably in the case of the lamp designer who must make a table of manufacturing data which does not include any avoidable directional errors. Exact methods are also necessary in many special cases where computations are applied over wide ranges of voltage, such as for quick force testing of lamps, or the applications of considerable over-voltage for photographic work. The lamp manufacturer must obtain these relations to the highest possible degree of precision always for his latest product, and there can be little doubt but that these data will find a wider field of application.

The name "characteristic" has come to be applied to the relations existing between voltage, current and candle-power and all dependent relations, leaving the term "performance" to cover the relations which involve time, such as candle-power life curves. The former relations only will be considered in this article and, since they are all similar in that they can be approximately expressed as simple exponential equations, only one will be considered in the general discussion.

If the intensity values are obtained through a range of voltage, that is, considering that voltage is the independent variable and candle-power the dependent variable, the result may be expressed approximately by the equation

$$c\text{-}p. = Ce^k$$

where $C$ would be a constant depending on the size of the lamp and $k$ a constant depending on the filament material. It is seen that, if the candle-power and voltage values are expressed in terms of their ratio to normal, the constant drops out and the equation becomes

$$c\text{-}p. = e^k.$$

The exact relation, however, cannot be expressed by this simple equation where $k$ is taken as a constant for all ranges, and therefore, for accurate work, it is necessary to use a graph or to obtain an equation which more nearly coincides with the experi-

*Cady:—Electrical Review and Western Electrician, November 25th, 1911.

Edwards:—Journal of the Association of Engineering Societies—Volume XLVIII., No. 4.

Note:—For other sources note references under above article by Mr. Cady.

mental values. There are many ways in which this can be done, but for the lamp man and illuminating engineer, it seems most convenient to retain the above simple form of equation, and to consider $k$ as a variable and a function of the voltage. The chief reason for adopting a variable-exponent form of equation is that it makes all computations very easy, using the log-log slide rule with which the raising to powers and extracting of roots is similar to the ordinary slide rule processes of multiplying and dividing. The part of the equation designated as $k$, then, is different for different percentages of normal voltages to which the reductions are made, and may be said to be defined always as the ratio of the logarithms to normal, that is, $k$ at any per cent volts is equal to the ratio

$$\frac{\log\text{ (ratio of c-p. to normal)}}{\log\text{ (ratio of voltage to normal)}}$$

A graph of this ratio plotted with per cent normal volts provides data for all transformations with absolute freedom from directional error, provided that the efficiency for which the lamp is considered normal has not changed.

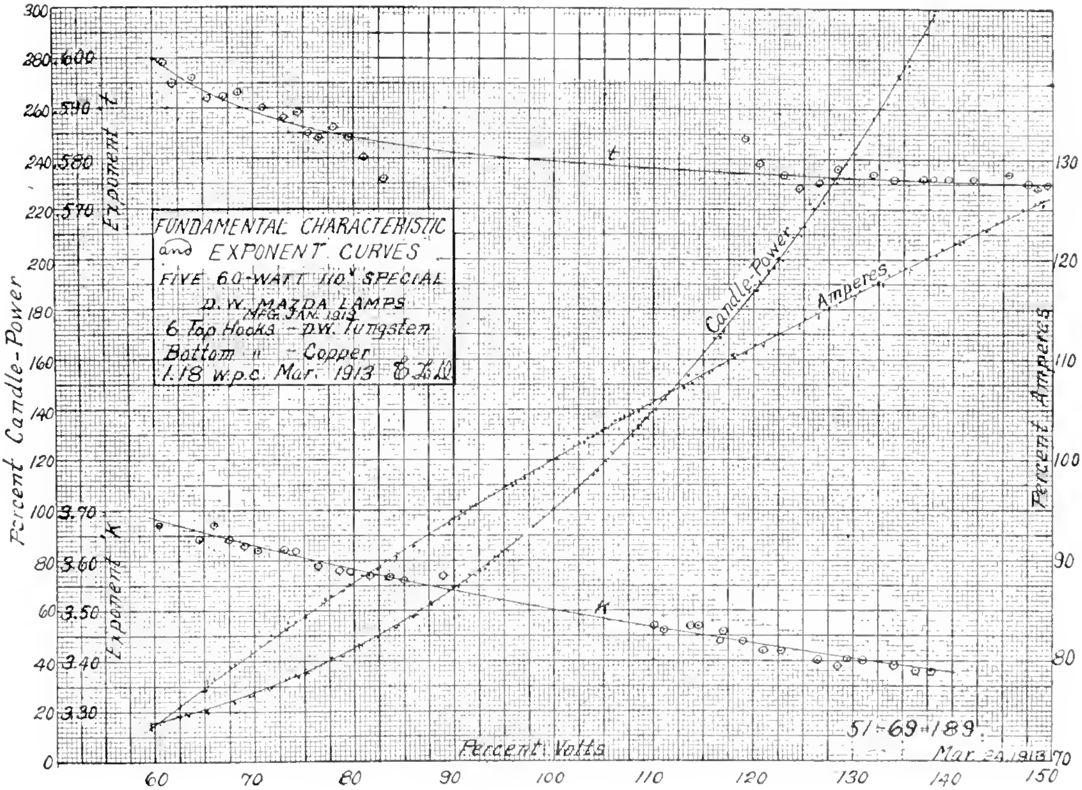

Fig. 1. Fundamental Characteristic and Exponent Curves for Mazda Lamps

As the voltage of the lamp is varied, the candle-power, the wattage, the current, the resistance and the efficiency all undergo changes. In using characteristic data it may be seen that there are fifteen combinations of the variables and that each combination may be expressed with either of the two variables as the independent one. Therefore, if all possible combinations are to be provided, thirty exponents would have to be available. Of all these relations, but two are fundamental. All the others may be derived by the use of very simple mathematical relations.

Since the greater percentage of incandescent lamps are operated or intended to be operated at a specified voltage and on a circuit of supposed constant voltage, it seems proper to consider voltage the fundamental independent variable. Candle-power and current are taken as the two fundamental dependent variables. All the other exponents may be derived from these two fundamental relations. In Table I will be found a list of those most commonly used, with their definitions in terms of the fundamentals.

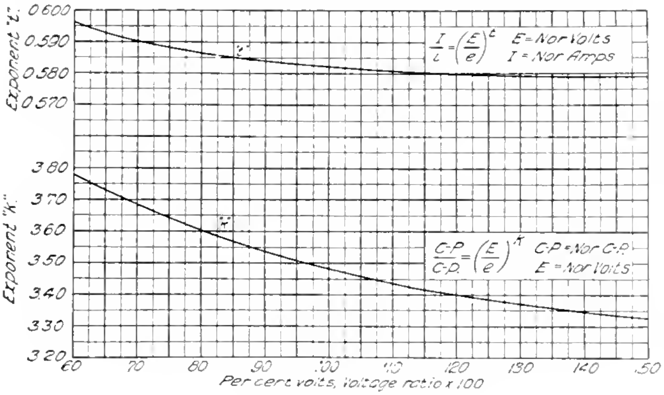

Fig. 2. "k" and "t" Curves for Mazda Lamps

The process of obtaining the values of the characteristic exponents is repeated at least as often as once each year by the laboratory with which the authors are connected and every detail of the work has become standardized. In order to furnish an idea as to the precision to which the figures are known, some of the more essential processes will be shown in detail. The lamps are first aged and then readings are taken on a highest precision photometer from 50 to 150 per cent normal voltage. Current readings are also taken over this range. Then by plotting a short range of volts with watts-per-candle, the voltage for assumed normal efficiency is obtained, after which all values are reduced to terms of ratio to normal. Next, the values are all recorded on very accurate cross section paper, a point for each observation on each of the groups of lamps entering the test. A sample of this sheet is shown in photographic reproduction in Fig. 1. It will be seen that the best representative curves have been drawn and the corresponding $k$ and $t$ values obtained and plotted. The points have been enlarged and the lines widened on this sample sheet in order to show more plainly in the reproduction; about 50 per cent of the points have been obliterated by the curves. The advantage of this method is apparent in that each sheet serves as a complete record and report of the test.

TABLE I

| Dependent Variable | Independent Variable | Symbol | Definition | Value |
|---|---|---|---|---|
| Candle-power... | Volts | $k$ | Taken as fundamental | 3.48 |
| Amperes . | Volts | $t$ | Taken as fundamental | 0.582 |
| Lumens-per-watt. | Volts | $g$ | $g=k-(1+t)$ | 1.90 |
| Watts ... | Volts | $n$ | $n=1+t$ | 1.58 |
| Ohms.... | Volts | $q$ | $q=1-t$ | 0.418 |
| Candle-power... | Amperes | $y$ | $y=k/t$ | 5.98 |
| Lumens-per-watt | Amperes | $j$ | $j=\frac{k-(1+t)}{t}$ | 3.26 |
| Ohms.... | Amperes | $m$ | $m=\frac{1-t}{t}$ | 0.718 |

After a sufficient number of separate tests have been completed, final conclusions for $k$ and $t$ are recorded on a separate sheet which becomes standard for the laboratories until further change is made necessary. Fig. 2 shows the present standardized $k$ and $t$ curves for mazda lamps. They are given on the basis of a normal specific consumption of 1.10 watts-per-horizontal-candle-power, which at present applies to the regular 40-watt multiple lamp. All tables and characteristic curves are now derived from these standardized fundamentals.

Fig. 3 shows a set of characteristic curves which are based on the curves of Fig. 2. It will be seen that voltage is considered as the independent variable and that the fundamental dependent variables, candle-power and current, together with the other dependent relations, watts, ohms, and watts-per-candle, are plotted against voltage. This form has been found the most convenient for everyday use.

The curves of Fig. 3 apply strictly to the regular multiple lamps up to and including the 100-watt size. For the high-wattage multiple lamps and the street-series line, where the cooling of the filament at supports is great, the characteristics are changed a measurable amount. The tendency of the cooling effect is to lower slightly the values of $k$ and $t$. The exponent $k$ on a 1.10 w.p.c. basis may go as low as 3.40 at 100 per cent normal volts in individual cases and the corresponding values of $t$ have been found as low as 0.56, but it is rather surprising to find how well the figures apply to all sizes and designs.

Fig. 4 shows the error which results from the use of the constant normal exponent, i.e., the use over all ranges of voltage of the values of *k* and *t* at 100 per cent normal volts as taken from the curves of Fig. 2. It is seen that for a range of 10 per cent above and below normal voltage the error in candle-power and watts-per-candle does not exceed 0.6 per cent and that the error in amperes due to the use of the constant exponent is practically negligible. For wide ranges in voltage, however, the error becomes great and the variable exponents must be considered.

It has been noted that the curves of Figs. 2 and 3 apply only when the normal values are taken as those for which the curves were obtained. However, the fundamental *k* and *t* curves can readily be transferred to any other normal efficiency basis; and it is, of course, necessary to transform all sheets to the same basis for comparison. In order to change to another efficiency basis it is necessary to first obtain the old-basis voltage corresponding to the new-basis efficiency; this value now becomes the new normal value. The voltage scale is now changed by referring the "old volts" to this new normal value. In like manner new scales of amperes and candle-power are formed, and from these new relations *k* and *t* may be calculated.

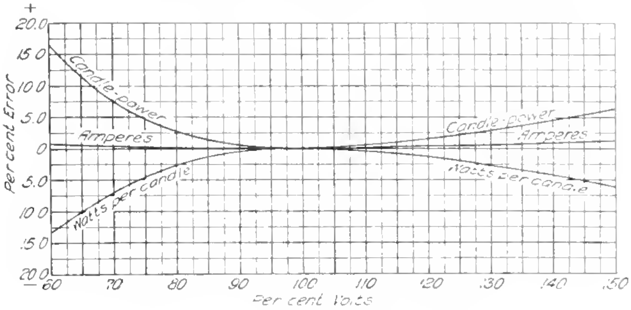

**Fig. 3.** Characteristic Curves for Mazda Lamps

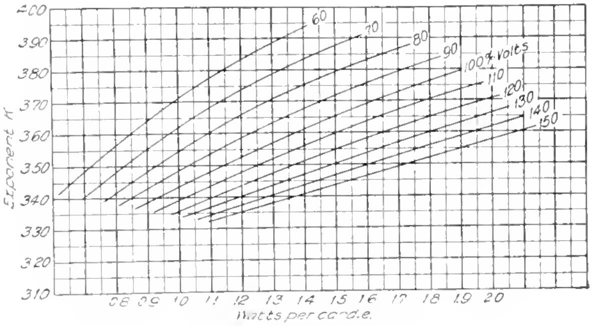

**Fig. 4.** Curves of Error Due to Use of Constant Normal Exponent

The families of curves shown in Figs. 5 and 6 furnish a ready means of making the conversions for the fundamental relations of Fig. 2. The values of *k* and *t* may be read directly at 60, 70, 80 per cent volts, etc., for any desired watts-per-candle within the range given. The values of *k* or *t* and per cent volts are now plotted and the *k* and *t* curves at the new efficiency obtained.

It should be noted that the watts-per-candle figures used in this discussion are watts-per-horizontal-candle-power for regular lamps, having a spherical reduction factor of 0.78.

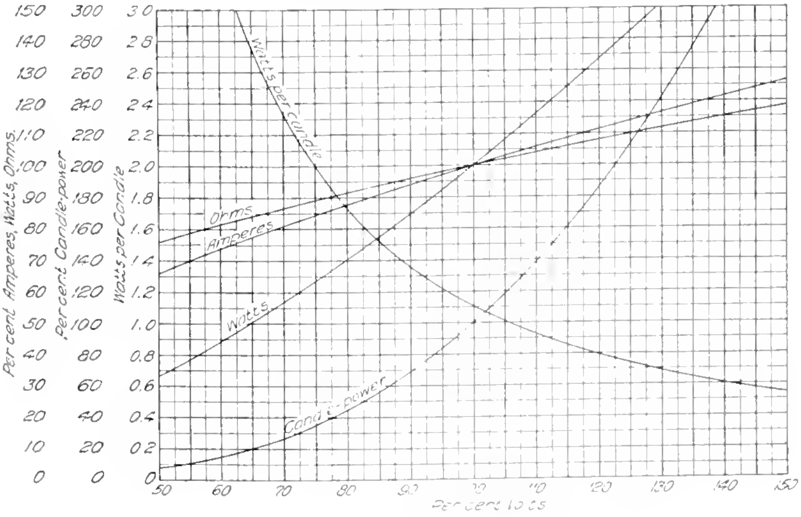

**Fig. 5.** Curves from which "k" Curves may be Obtained for any Desired Normal Watts-per-Candle Basis

Therefore, the true basis for the normal point is 1.41 watts-per-mean-spherical-candle-power, or 8.91 lumens-per-watt.

In conclusion it may be said that the data of this paper are given as being accurately representative of the present-day mazda lamp. They should not be considered as refined measurements on a few lamps, but rather as new conclusions from accumulated progressive data taken over a period of several years. The methods outlined are recommended as being convenient and proper. They are the survivors in a laboratory where the question of characteristic relations has necessarily been given an unusual amount of attention.

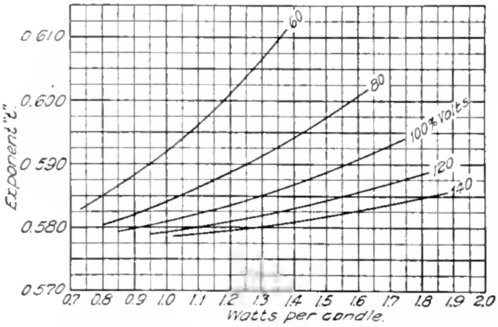

Fig. 6. Curves from which "t" Curves may be obtained for any Desired Normal Watts-per-candle Basis

# SOME INSTANCES ILLUSTRATING THE INFLUENCE OF RESEARCH AND DEVELOPMENT UPON THE MANUFACTURE OF INCANDESCENT LAMPS

### By J. E. Randall

Consulting Engineer and Manager of Lamp Development Department,
National Lamp Works, General Electric Company

This article first lists in a clear and concise manner the principal improvements which have been made in the incandescent lamp since its earliest days. (Detailed descriptions of the individual steps which have been made have, of course, been given before in separate articles but, unfortunately for a clear survey, these have all been widely scattered as regards the time and place of their publication.) A very unique analysis is then made as to the source of each improvement, and due credit is given to the type of mind which produced it. As the conclusion of this analysis, the author shows that it is due to the collective efforts of three types of minds—research, development, and manufacturing—that the present-day lamp has reached its state of low cost and high efficiency.—Editor.

J. E. Randall

In the history of the incandescent electric lamp the twelve factors in development, mentioned below, stand out prominently because of their influence upon the industry:

1. *The long slender filament*, an idea that permitted the use of small lamp units upon the 110-volt circuit which has now become practically universal. Furthermore, the idea made possible, in the simplest way, the complete independence of each unit so far as concerns turning its light on or off.

Viewed from the present, the idea of "multiple-burning" lamps, the conception of the conditions necessary thereto, and, finally, the production of a filament sufficiently tenuous to meet the electrical requirements, yet sufficiently rugged to endure the knocks, must be regarded as the evidences of superior genius.

If Mr. Edison had given to the world nothing more than the idea of the "multiple burning" lamp, he should be ranked among its benefactors.

2. *The "treated filament."*

The idea of covering the carbon skeleton of a cotton thread with a coating of graphitic carbon, reduced from a hydro-carbon, was probably evolved for the purpose of producing more uniform filaments. This purpose was hardly accomplished. The real result was a surface which could be maintained at a higher temperature than had been possible with "raw carbon."

3. *The use of cellulose as a material from which to make a carbon filament "base."*

This development really caused an advance in uniformity and quality.

4. *Embedding the "knots" or joints between the copper and the platinum of the lead wires.*

Only those who made lamps before the general use of this device appreciate its value to the industry.

5. *The "flange seal."*

This device, now universally used, appeals only to those who have made lamps.

6. *Blowing bulbs in moulds.*

If today it were necessary to make bulbs by the "free-hand" method, incandescent lamps might be used to light exposition buildings, but would not be the universal light.

7. *Perfection of vacuum chemically.*

This idea, in conjunction with the moulded bulb, has had great influence upon the price of lamps.

8. *The metallized carbon filament.*

9. *The tantalum wire filament.*

10. *The "squirted tungsten" filament.*

Each of these three (8, 9 and 10) contributed a good share toward more efficient light.

11. *The filament of drawn tungsten wire.*

This is considered to be one of the greatest steps in the march of the industry. Drawn wire has justly entitled the tungsten filament lamp to the name, "The lamp of universal use."

12. *The lamp having a gas, at a pressure of approximately an atmosphere, within its bulb.*

This development puts the incandescent lamp upon a basis of equal competition with all other commercially used illuminants, so far as concerns efficiency. It has made available a satisfactory large lamp unit.

These twelve factors in development do not exhaust the list of those that are noteworthy, but they will serve to illustrate the subject to be discussed.

Numbers 4, 5 and 6 may be said to have been conceived, to have been developed, and to have been commercialized in the lamp factory. Unquestionably, all the others were conceived in the laboratories devoted to experiments.

Numbers 1 and 2 were conceived at a period in the history of the art when the distinction between a "laboratory" and a "lamp factory" was so hazy that even those employed in them called them, indifferently, by either name. These two ideas, then, were conceived, developed, and commercialized in a laboratory, or in a factory, whichever name one may choose to house the organization and the equipment employed in their utilization.

All of the others, seven in number, should be credited to laboratories; if we designate as a laboratory that portion of the industry that expends its effort in experiment rather than in production.

Cellulose came from the laboratory of a chemist.

Chemical exhaust came from an Italian who was really a scientist outside of the lamp industry.

Metallized carbon came from a research laboratory.

Tantalum wire came from a research laboratory.

Squirted tungsten came from an experimentalist who had never undertaken to make more than a few experimental lamps.

Drawn tungsten wire came from a research laboratory.

The lamp filled with nitrogen came from a research laboratory.

Some of the individuals credited with the seven factors were connected with the lamp industry, but they would not be called makers of lamps.

The succession in which these twelve factors have been mentioned is very nearly the temporal succession in which they were first proposed. It will be noticed that the last four have come since the industry had been brought to a well organized state, not only in this, but in other countries.

These four were conceived within the organization of laboratories equipped for the scientific investigation of problems dealing with illuminants.

Each one of the four added at least one new factor to our store of scientific knowledge.

Numbers 4, 5 and 6 were really new methods of using information or devices that already existed.

These two groups of factors illustrate the mental differences between the men who conceived them: one group comes from the minds of men trained to co-ordinate unrelated phenomena in such a way as to demonstrate new possibilities; the other group comes from the minds of men trained to apply existing knowledge to a betterment of methods.

A third kind of mind essential to manufacturing success is that found in men who can systematically and economically use better methods.

These three kinds of minds—research, development and manufacturing—illustrate, in a definite way, coordinate specialization of effort.

The incandescent lamp industry today feels the impulse of their cooperation.

There are three fields of effort—research, development and manufacture—lying side by side and overlapping somewhat at their boundaries through which new ideas in incandescent electric lamps are passed to the users of lamps, as the pigskin is passed by a team on the gridiron.

# THE FIELD OF THE GAS-FILLED MAZDA LAMP

By S. H. Blake

Engineer, Supply Department, General Electric Company

The advent of a really worthy illuminant into practical use always means a readjustment of established lighting practice, and in this article the prospective field and scope of the new gas-filled incandescent lamp are considered. As is now pretty well known, the gas-filled lamp shows its best performance at present when made for large current values (not appreciably below twenty amperes), which fact renders it highly suitable for series connection. The use of the high current lamp will in most all cases necessitate special wiring, fixtures, etc.; but the gain in efficiency and sturdiness should justify the change. The lamp is attractive from almost every standpoint, and, in addition to its use for street lighting, should prove immensely popular for the lighting of large interiors, doorways, etc.—Editor.

S. H. Blake

The advent of a radically new illuminant into practical use always means that there must be a readjustment of established lighting practice in order to make room for the new comer. Such a transition is now commencing, owing to the recent appearance of the wonderful gas-filled mazda lamp. It is interesting to consider briefly the prospective field and scope of this new light source in its present state of development.

It is very difficult to compare directly and to classify the various methods of producing artificial light, owing to the many varying factors that must be considered and weighed as to their relative importance. Furthermore, the particular qualities that make a certain light source well suited for some purposes make it entirely unsuitable for other equally important applications. The gas-filled mazda lamp, however, is strikingly attractive from almost every standpoint, as it embodies in one unit the desirable qualities of the incandescent lamp, namely, steadiness of light, constant color value, cleanliness in operation and low maintenance labor cost, etc., together with high efficiency and good quality of light when compared with the present standard practical arc lighting units.

Owing to the fact that the gas-filled mazda lamp in its present form gives its highest efficiencies when it is made for about twenty amperes, or more, the fact at once becomes apparent that this new lamp is highly suited for series connection. The only practical method of operating such high current lamps on *direct current* constant potential circuits will be to connect them in series-multiple, whereas for alternating current constant potential connection they may be operated either in series-multiple or from individual or group step-down transformers or compensators. If the lamps are made suitable for direct, single connection across one hundred and ten volts a-c. or d-c. constant potential, they will operate at a very appreciably lower efficiency than when made for high currents.

Even a casual consideration of the few essential characteristics mentioned will indicate that there are really two types of gas-filled mazda lamps with a well defined line of demarcation between them.

First, there is the *real* gas-filled mazda lamp, as we may call it, operating at high current and low voltage, the efficiency of which compares favorably with that of the magnetite arc lamp; and, second, there is the low current gas-filled mazda lamp which is practically an improved mazda lamp operating, to be sure, at attractive efficiency, but not, at the moment, in the same class with the high current lamp. In fact the only excuse for the low current type is that it can be operated on existing circuits without auxiliary devices, whereas the practical economical use of the high current lamp will involve the design and production of new apparatus and fixtures, as well as some changes in connections and practice.

For example, if it is desired to operate a 20 ampere gas-filled mazda lamp from a 110-volt constant potential circuit it will either be necessary to connect several of them in series, the number being dependent upon the candle-power of the lamps, or else if the circuit is alternating current a small transformer or compensator can be used to step the voltage down to the correct value for the lamp. Such a transformer or compensator should be preferably mounted with the lamp itself. The whole combination should have a cover or casing to give it a pleasing and finished appearance and to protect the lamp, socket and windings from weather conditions when used out-of-doors. Arrangements should also be provided for attaching suitable reflectors and provision should be made for a globe-holding device, as not only will diffusing globes sometimes be desirable but the hot glass bulb of the lamp should be properly protected from possible fracture due to rain, snow or sleet. It is also important that this whole structure be well ventilated so as to keep the interior parts as cool as possible. Thus, it is at once evident that special fixtures, etc., are necessary to properly use high current gas-filled lamps in actual service. If it is desired to use the 20 ampere lamps on existing series street lighting circuits, it becomes at once apparent that either the street wiring suitable for 7.5 and 6.6 amperes will have to be replaced with heavier wire, to say nothing of the rewinding of current regulating devices; or else individual series transformers or compensators will have to be used, as with the multiple lamp, involving complete fixtures, etc.

The use of these transforming devices for running multiple and series gas-filled lamps will, of course, lower the operating efficiency of the lamps and also reduce the power-factor slightly; but the greater efficiency of the high current lamp makes it well worth while to use it in this way instead of using the low current lamp without transformers. This procedure is further influenced by the fact that the large, rugged filament of the high current lamp should be expected to give longer and more reliable service than the thinner filament of the low current lamp.

It is significant to note that even the low current gas-filled mazda lamp compares very favorably with the multiple arc lamp, particularly on d-c., as the ballast resistance necessary to make such arcs stable on constant potential greatly reduces the input watts per candle efficiency, whereas no such loss is necessary in operating the gas-filled mazda lamp. To a less degree the efficiency of the a-c. multiple arc lamp is lowered by the losses in the ballast reactance, but the power-factor of such lamps is about 30 per cent lower than that of the gas-filled mazda lamp. In this field it is, therefore, probable that the gas-filled mazda lamp will become supreme except where conditions of severe vibration and rough handling make an incandescent lamp unsuitable, and in cases where the penetrating powers of the rays from the yellow flame lamp make it more effective.

For constant current connection the arc lamp is not handicapped to the same extent that it is for multiple operation, and before it can be predicted with any degree of accuracy just how far the gas-filled mazda lamp is liable to encroach into the field of series street lighting now practically dominated by the arc lamp, it will be necessary to determine by actual experience whether the gas-filled mazda lamp is inherently rugged and reliable enough to economically withstand the very trying conditions of this truly American method of operating street lamps.

The gas-filled mazda lamp will apparently meet European conditions better than it does ours in this country, owing to various causes. The practice in large cities abroad is to light the city proper with high candle-power units, generally arc lamps operating two or three in series on 110 volts or 4, 5 or 6 in series on 220 volts constant potential. These lamps are hung very high, quite close together and often are directly over the center of the streets. High candle-power gas-filled mazda lamps should work out well under such conditions, as they throw a bountiful amount of light directly below the lamp. The steadiness of the gas-filled mazda lamp is another great point in its favor from the European standpoint, while its yellowish white quality of light will be much superior to the light of the yellow flame lamps that are now used there so extensively.

The perfect steadiness of the gas-filled mazda lamp will also be a very decided point in its favor in this country, particularly for the lighting of large interiors, doorways and in front of buildings. For street illumination it will be an interesting study to watch the progress it makes against the magnetite lamp, which is undoubtedly a remarkable lamp for street lighting due to its beautiful white color, its ideal light distribution, and its low cost of maintenance. The "life" of the gas-filled mazda lamp will largely determine its success in this field, for the cost of even one renewal will be a relatively large part of the yearly maintenance cost of one magnetite lamp.

As to flame, quartz, titanium and other high efficiency lamps the introduction of the gas-filled mazda lamp instead of tending to discourage their further development should greatly aid to still more perfect them. Even now the efficiencies that it is possible to obtain with some of these lamps are twice as good as the best that can be secured with the gas-filled mazda lamp. The general effect of the gas-filled mazda lamp on such other lamp developments will probably be to enhance the relative commercial importance of the qualities of steadiness and constancy of color values and to redouble the efforts already being made to obtain still higher efficiencies. These several qualities will be sought in arc lamps by using higher currents and smaller diameter electrodes.

It would be entirely premature at this time to try to analyze the probable cost of operation and maintenance of the gas-filled mazda lamp compared with other lamps for equal illumination of streets, but it is not unlikely that such a comparison would show that the titanium and flame lamps are the most economical, practical illuminants at high cost of power and the magnetite and gas-filled mazda lamps when the cost of power is low.

# IMPROVEMENTS IN THE MAGNETITE ARC

By C. A. B. Halvorson, Jr.

Designing Engineer, Arc Lamp Department, General Electric Company

Efficiency is the keynote of this article. As the author points out, it is along this line that improvements in luminous arc lamps are to be expected, since in operation and maintenance they have already reached a high degree of perfection. Preparatory to describing what is being done to increase the efficiency, a thorough exposition is given of the proper method of rating lamps, in order to clarify much of the confusion which exists in comparing lamps of different types. After this phase of the subject has been placed on a rational basis, the means which are to be employed in bettering the present day high efficiencies are described and the amount of the improvement given.—Editor.

C. A. B. Halvorson, Jr.

THERE are in use, at the present time, in the neighborhood of 200,000 luminous arc lamps, including both the pendant and ornamental types. By far the majority of these are 310-watt lamps operating at 4 amperes, 75 volts at the arc. It is but natural that the users of these lamps, as well as those contemplating the purchase of new street-lighting units, should be vitally interested in the future possibilities of the luminous arc, principally from an efficiency view-point; since from an operating and maintenance view-point, the luminous arc lamp leaves but little to be desired. Moreover, due to the pure white color and the characteristic distribution of the light, the luminous arc is more effective physiologically than the other lighting units designed for street illumination.

With regard to efficiency, so much misunderstanding exists at the present time as to the comparative rating of street illuminants that, before describing certain improvements in the luminous arc, which is the principal object of this article, a brief review and discussion of the several methods employed may be of interest.

In incandescent lamp work the following practice is customary:

"The mean horizontal candle-power has been adopted by long practice as the conventional measure of the performance of an incandescent lamp. This, of course, originated through the need of a simple comparison of one lamp with another of the same type, before the necessity of comparing lamps of different types arose. It is a very useful unit, if properly used; but under present conditions should be accompanied by a reduction factor, from which the mean spherical candle-power (and hence the total lumens) can be figured. Lamp manufacturers usually give with the candle-power rating of a lamp either the reduction factor, mean spherical candle-power, or total lumens."*

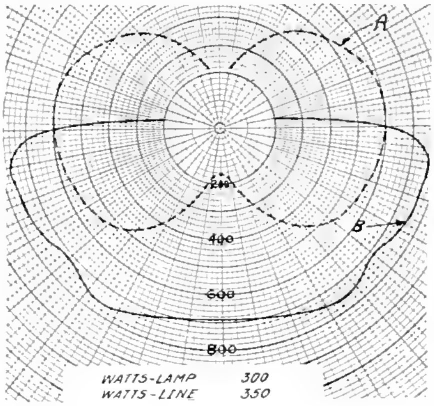

Fig. 1

| | A | B |
|---|---|---|
| Mean Horizontal C.P. | 600 | 600 |
| Watts per Mean Horizontal C.P. | 0.50 | 0.58 |
| Mean Spherical C.P. | 510 | 411 |
| Watts per Mean Spherical C.P. | 0.59 | 0.85 |
| Mean Spherical C.P. per Watt | 1.70 | 1.17 |
| Mean Hemispherical C.P. | 518 | 733 |
| Watts per Mean Hemispherical C.P. | 0.58 | 0.48 |
| Mean Hemispherical C.P. per Watt | 1.73 | 2.10 |

---

* Quoted from "Interpretation of Photometric Curves," G. H. Stickney, General Electric Review, November, 1912.

It should be noted that ratings given under this method cover only the lamp itself, or, to state it in another way, the raw material; however, from these data the engineer can design suitable fixtures or complete lighting units to meet any specific requirements.

Thus, if an incandescent lamp, giving the characteristic light distribution curve shown in Fig. 1 as curve A, is rated at 0.5 watt per mean horizontal candle-power and consumes 300 watts, the mean horizontal candle-power is found to be 600. The spherical reduction factor of such a lamp would be 0.85; consequently, the mean spherical candle-power would be 510 and the specific consumption 0.59 watt per mean spherical candle-power. It is perfectly clear, however, that such a distribution curve is not suited to the majority of cases met with in street lighting and that the original light distribution must of necessity be modified by proper devices designed to redirect into the lower hemisphere that light found above the horizontal (curve B, Fig. 1). Therefore, a further increase in the specific consumption of watts per mean spherical candle-power would occur due to unavoidable losses in auxiliary devices, etc. Now, the spherical reduction factor has been changed to 0.68, there being practically no light above the horizontal, and consequently the just rating will give a specific consumption of 0.85 watt per mean spherical candle-power instead of 0.5 watt per mean horizontal candle-power, which was the original rating.

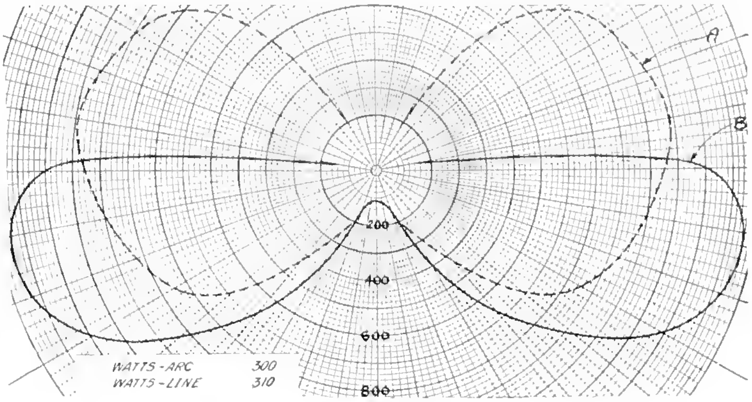

Fig. 2

| | A | B |
|---|---|---|
| Mean Spherical C.P. | 763 | 607 |
| Watts per Mean Spherical C.P. | 0.39 | 0.51 |
| Mean Spherical C.P. per Watt | 2.54 | 1.96 |
| Mean Hemispherical C.P. | 711 | 1035 |
| Watts per Mean Hemispherical C.P. | 0.42 | 0.30 |
| Mean Hemispherical C.P. per Watt | 2.37 | 3.33 |

Fig. 3. Arrangement of Electrodes and Form of Arc Employed for Data of Fig. 2

In arc lamp work, on account of the close relations existing between the lamp mechanism and the arc, it always has been customary to consider only the distribution curve of the complete unit equipped with proper devices and glassware to give some desired result. Thus, it is evident that the losses, due to the redirection of the light, etc., are always included in the resultant distribution curve.

Fig. 2, curve B, shows a characteristic distribution curve of a luminous or magnetite arc lamp. It is very unfair to the light source in so far as the spherical rating is concerned, since curve A indicates the characteristic light distribution curve of the luminous arc *per se*, or, as we may say, of the raw material from which the illuminating unit as a whole is developed or designed.

The arrangement of arc and electrodes for obtaining curve A, Fig. 2, is indicated in Fig. 3, the lamp mechanism being used without any auxiliary devices. From the foregoing, it is apparent that in order to compare dissimilar units for some specific purpose, it is first necessary to obtain the light *source values;* i.e., all lighting units must be reduced to the simplest form, which, in the case of the luminous arc lamp, would be the lamp mechanism operating an electric arc drawn between a pair of vertical electrodes surrounded with a globe to keep out transverse air currents, as these would affect the operation of the arc.

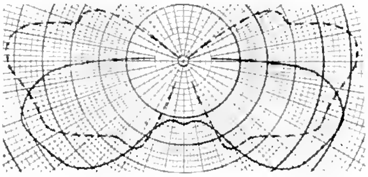

Fig. 4

The distribution of light in a vertical plane from such an arc arrangement, Fig. 3, is shown in Fig. 2, curve A. Such a distribution curve may now be compared with curve A, Fig. 1, since they are both made under similar conditions representing the performance of the bare light sources or, we may say, the raw material. However, it is perfectly obvious that complete lighting units giving curves with these characteristics, would be of little value in the design of ordinary low-intensity street illumination where an extended distribution is desirable, but, on the other hand, are of the utmost importance in the design of "White Way" or ornamental street lighting.

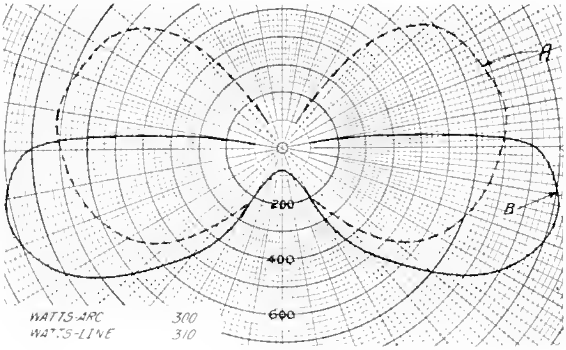

Fig. 5

| | A | B |
|---|---|---|
| Mean Spherical C.P. | 572 | 412 |
| Watts per Mean Spherical C.P. | 0.52 | 0.75 |
| Mean Spherical C.P. per Watt | 1.91 | 1.33 |
| Mean Hemispherical C.P. | 532 | 735 |
| Watts per Mean Hemispherical C.P | 0.56 | 0.42 |
| Mean Hemispherical C.P. per Watt | 1.77 | 2.37 |

As an illustration of this, refer to Fig. 4, where two curves, A and B, are shown. The former represents the characteristic light distribution from an ornamental luminous arc lamp with a clear globe and the latter shows the characteristic distribution of the same kind of arc consuming the same amount of energy, but in the pendant luminous arc lamp such as is used ordinarily in American cities. It is clear from these curves that merely giving the mean spherical ratings in both cases would be unfair to one of the lamps and that in order to intelligently select the proper lighting unit for some specific purpose, the distribution curves should be given in addition to the values in any one of the various ratings now in common use.

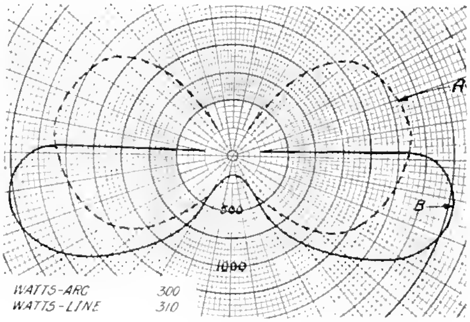

Fig. 6

| | A | B |
|---|---|---|
| Mean Spherical C.P. | 1141 | 844 |
| Watts per Mean Spherical C.P. | 0.26 | 0.37 |
| Mean Spherical C.P. per Watt | 3.80 | 2.72 |
| Mean Hemispherical C.P. | 1065 | 1477 |
| Watts per Mean Hemispherical C.P. | 0.28 | 0.21 |
| Mean Hemispherical C.P. per Watt | 3.55 | 4.76 |

During the past few years a vast amount of research work has been done in attempts to increase the efficiency of the magnetite arc. Two lines of endeavor have been followed. One line of experimental work has been directed toward the production of an electrode which would support an arc of higher efficiency; while the other line has been directed toward the production of luminous arcs of maximum efficiency, without regard to the utilization of these electrodes in standard lamps. Both lines of endeavor are nearing completion, with the result that in a short time electrodes should be available which will operate in luminous arc lamps and which will support an arc giving an efficiency of from approximately 2.0 to 2.5 spherical candles per watt (see Figs. 2 and 5).

It may be noted that there is considerable difference between the values given for the two curves, but they are of the same order and Fig. 5 shows what has been obtained from electrodes in actual commercial service. The same may be said also of Fig. 2, although as yet this particular electrode has been subjected to less commercial operating experience. It will be observed in Fig. 2, curve A, that the specific consumption is 0.42 watt per mean spherical candle-power. With the proper arrangement, the upward light can be redirected to between 10 and 15 degrees below the horizontal, with a maximum value of 1360 candle-power, and a specific consumption of 0.30 watt per mean hemispherical candle-power, or an efficiency of 3.33 mean hemispherical candle-power per watt. The value of such a distribution curve, in the design of street illumination, is immediately apparent; but little light is given directly below the lamp, while the maximum values, which are at the most advantageous angles for street illumination, show an efficiency of 4.4 candle-power per watt.

There is no reason why electrodes supporting arcs of even greater efficiency cannot be used with a modified lamp mechanism. Fig. 6, curve A, shows the distribution of light from one of these extremely efficient arcs where a maximum of 1600 candle-power is easily obtainable at 300 watts. With the proper arrangement, a maximum of over 2000 candle-power at 10 to 15 degrees below the horizontal may be obtained. Such efficiencies as 4 to 5 mean hemispherical candle-power per watt, or specific consumptions of 0.2 to 0.25 watt per mean hemispherical candle-power, are not immediately available commercially, but may be regarded as reasonably sure of attainment and are indicative of what may be expected of the luminous arc lamp within a comparatively short time.

However, the commercial gain in efficiencies already made, Fig. 7, curves A and B, assure the future of the luminous arc lamp, for, with the inherent advantages of superior light distribution and unexcelled color, it is extremely doubtful if any competitive illuminant will be found within the immediate future to supersede it. In this connection it is interesting to note what Dr. Steinmetz says with regard to the requirements of street lighting:

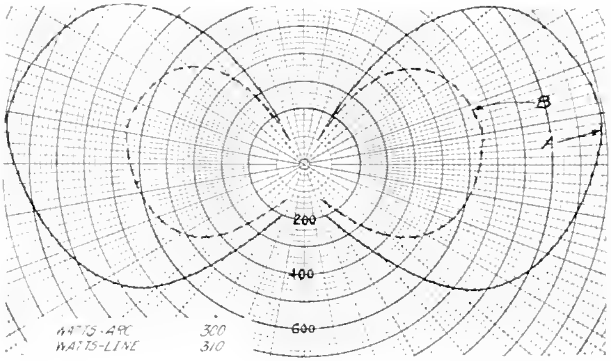

Fig. 7

| | A | B |
|---|---|---|
| Mean Spherical C.P. . . . | 763 | 458 |
| Watts per Mean Spherical C.P. | 0.39 | 0.65 |
| Mean Spherical C.P. per Watt | 2.54 | 1.53 |
| Mean Hemispherical C.P. . | 711 | 426 |
| Watts per Mean Hemispherical C.P. | 0.42 | 0.70 |
| Mean Hemispherical C.P. per Watt | 2.37 | 1.42 |

"It is a physiological and pyschological phenomenon, and as such cannot well be expressed numerically, except in general, that, where low intensity illumination is contemplated, as in most of the street lighting, the white color has a material advantage in physiological efficiency."†

"The success which has attended the ornamental luminous arc lamp, principally on account of its pearl white color and high efficiency, promises to be augmented by these improvements in electrodes which make possible a large reduction in the energy required per unit, necessary to produce certain desired effects now-a-days considered so essential to the success of spectacular or so-called White Way lighting."‡

---

# THE FLICKER OF INCANDESCENT LAMPS ON ALTERNATING CURRENT CIRCUITS AND STROBOSCOPIC EFFECTS

### By Dr. Irving Langmuir

Dr. Langmuir's contribution to this issue is an able article on the complex phenomenon of flicker. This phenomenon is influenced by the intensity of fluctuation and the frequency of an a-c. circuit and by a number of physiological factors. The most important consideration from a commercial standpoint regarding flicker is the determination of how a lamp will behave on a given circuit. Formulæ are given in this article which will enable a ready determination to be made of the behavior of different types of lamps on any circuit, special attention being paid to the modern gas-filled lamp. It is interesting to note that under ordinary conditions the effect of a helical winding is to decrease the candle-power fluctuation in about the ratio of 1.4 to 1, and that with a similar filament in gas the effect is much greater than with a helical winding in vacuum. Owing to our incomplete knowledge of this subject, we believe that Dr. Langmuir's article with his formulæ and tables, will be of much interest and value to the illuminating engineer.—Editor.

Dr. Irving Langmuir

SINCE the introduction of metal filament lamps, the flicker that occurs when low wattage lamps are run on 25 cycle alternating current has attracted considerable attention and has often been experimentally investigated.

The flicker is a physiological effect caused by the fluctuations in the intensity of the light source. If the frequency is either too high or too low, no flicker will be observed, even though the candle-power of the source may vary through a fairly wide range. Furthermore, the perception of flicker depends to a marked degree on the intensity of the illumination and on its distribution. Flicker can often be observed in the light thrown by a lamp on a large white wall, although by looking directly at the lamp or at objects near it, no flicker will be noticed.

The variations in intensity of a fluctuating light source produce, besides the flicker, other striking effects observable when the eyes are moved from one object to another, or an illuminated object is moved across the field of vision. This motion gives rise to a stroboscopic effect characterized by the production of a series of multiple images. Frequency in this case has very little effect, except that with very high frequency a more rapid motion is necessary to make the separate images distinct from one another.

Flicker, therefore, is a complex phenomenon dependent not only on the magnitude of the intensity fluctuations, but on the frequency of the alternating current and a number of physiological or psychological factors.

In any discussion of the flicker of incandescent lamps, however, the first element to be considered should be the actual magnitude of the fluctuations in the intensity of the light. This fluctuation completely determines the degree of stroboscopic effect obtainable and at least allows comparison to be made between the flicker produced by different types of lamps operating on current of the same frequency.

The ease and accuracy with which the candle-power fluctuation may be calculated from simple thermal data, seems to have been generally overlooked by most of those interested in the technical side of the question. Several years ago the writer developed some simple equations by which the fluctuation could be calculated from the ordinary characteristics of lamps and from the specific heat of the material of the filament. Since then, O. M. Corbino has published a series of papers on the theory of "periodic temperature fluctuations of metallic filaments heated by alternating currents" (see Physik. Zeitschrift *11*, 413, 1910, and *12*, 292, 1911). Corbino has made elaborate experiments to test his equations and to determine the various thermal constants involved.

The object of the present paper is to call the attention of lighting engineers to some of the most important of Corbino's formulas and to modify and simplify these in such a way that they may be of more direct application to lighting problems. The simplified formulas will then be used to calculate the magnitude of the candle-power fluctuation in various types of lamps with especial reference to gas-filled lamps.

The heating effect of a sine wave alternating current varies periodically according to a sine wave of double the frequency of the current. During the part of the cycle in which there is low energy input, the filament temperature falls, since the radiated energy exceeds the input. During the time of high input, the temperature rises, as more energy is supplied than can be radiated. The temperature of the filament therefore rises and falls with double the frequency of the alternating current. The magnitude of the temperature fluctuation evidently depends on the manner in which the resistance and radiating properties vary with the temperature and also on the heat capacity of the filament. From a knowledge of these factors, the temperature variations and from this the candle-power fluctuation may be calculated.

### Derivation of Formulas

Let us consider the temperature fluctuations in a lamp filament supplied by alternating current of the frequency $f$.

Let $e$ = instantaneous potential applied to the lamp

$i$ = instantaneous current

$r$ = instantaneous resistance

$w$ = instantaneous heat dissipation from filament in watts

$T$ = instantaneous temperature of filament (absolute scale)

$c$ = specific heat of the material of the filament

$m$ = mass of the filament

$\theta$ = variation in the temperature of the filament from its mean value $t$.

We will consider that the applied potential is a pure sine wave.

$$(1) \qquad e = e_0 \; sin \; \omega t$$

where $\omega = 2\pi f$

The power input into the filament is $e^2\ r$, and this must equal the sum of the radiated power and that necessary to raise the temperature of the filament.

$$\frac{e^2}{r} = w + mc\,\frac{d\theta}{dt}$$

or

$$(3) \qquad rmc\,\frac{d\theta}{dt} = e^2 - wr$$

It has been found that both the energy radiated and the resistance of tungsten lamp can be expressed as a power of the absolute temperature of the filament.

That is, we can place as a very close approximation

$$(5) \qquad r = r_0\left(\frac{T}{T_0}\right)^{n_R}$$

$$(6) \qquad w = w_0\left(\frac{T}{T_0}\right)^{n_W}$$

where $r_0$ and $w_0$ are respectively the resistance and wattage at the temperature $T_0$, the average temperature of the filament.

If we assume that the variations in $r$ and $w$ are relatively small, we may place

$$(7) \qquad r = r_0\left(1 + \frac{n_R}{T}\,\theta\right)$$

$$(8) \qquad w = w_0\left(1 + \frac{n_W}{T}\,\theta\right)$$

We can now substitute these values in (3). However, since we assume the variation in $r$ to be very small, we may put $r_0$ in place of $r$ in the first member of the equation, although in the second member, which consists in a small difference between two relatively large quantities, we use the values given by (7) and (8). We thus obtain, by neglecting second order terms,

$$r_0 mc\frac{d\theta}{dt} = e_0^2 \; sin^2 \; \omega t - w_0 r_0\left(1 + \frac{n_R + n_W}{T}\,\theta\right)$$

The solution of this equation (excluding transient phenomena) is of the form

$$(9) \qquad \theta = \theta_0 \cos\,(2\;\omega t - \psi)$$

where

$$(10) \qquad \theta_0 = \frac{1}{\sqrt{\left(\frac{n_R + n_W}{T}\right)^2 + \left(\frac{2\,c\,m\,\omega}{w_0}\right)^2}}$$

We thus see that the variation in the temperature of the wire is a simple harmonic function having twice the frequency of the applied e.m.f. The amplitude is given by (10).

The two terms under the radical sign in equation (10) are of very unequal magnitude. The value of $n_W$ for tungsten in a vacuum is about 4.7, while $n_R$ is 1.2. For tungsten filaments in gases, $n_W$ is less than 4.7, except in hydrogen, where it may become as great as 10. In any practical lamp, however, $n_W + n_R$ will never exceed about 6. The temperature of the filament of any practical lamp will be at least 2000 deg. K (absolute temperature), and the term $\left(\frac{n_R + n_W}{T}\right)^2$ will thus never exceed 0.000009. The second term under the radical must always be greatly in excess of this; otherwise the fundamental assumptions made in the derivation of the equation are not fulfilled and the equation ceases to be of value. This is apparent from the following considerations:

If the second term were small compared to the first, then the equation would reduce to

$$\theta_0 = \frac{T}{n_W + n_R}$$

This would give a value of $\theta_0$ of at least 330 deg., so the total variation of temperature would be over 660 deg. With such a temperature range as this, the power ($w_0$) radiated from the filament would vary in about the ratio of 1 to 3.5, so that equation (8) would not be even approximately fulfilled.

It can be readily shown that if $\theta_0$ is to be as small as 100 deg., the second term in the radical must be about 10 times as great as the first, and that to neglect the first term entirely, would make an error in $\theta_0$ of less than 5 per cent.

Since the flicker in ordinary lamps is caused by a temperature variation with a range much less than 200, it is evident that we can neglect the first term under the radical, in the applications of this formula.

Equation (10) therefore assumes the very simple form

$$(11) \qquad \theta_0 = \frac{w_0}{2\ cm\omega} = \frac{w_0}{4\ \pi fcm}$$

The candle-power ($H$) of a filament is related to its temperature ($T$), by the equation

$$(12) \qquad \log H = A - \frac{11230}{T}$$

where $A$ is a constant characteristic of the filament.

Let us now calculate the candle-power fluctuation that would be produced by the periodic change in temperature of amplitude $\theta_0$.

For small variations in temperature equation (12) can be written

$$(13) \qquad \triangle \log H = \frac{11230}{T^2} \triangle T$$

If we let $\triangle T$ represent the total fluctuation in temperature, then $\triangle T = 2\ \theta_0$ and $\triangle \log H$ becomes

$$\log \frac{H_{max.}}{H_{min.}}$$

If we change to natural in place of common logarithms and consider such small fluctuations of temperature that the relative change of light intensity is also small, then we have

$$(14) \qquad ln \frac{H_{max.}}{H_{min.}} = \frac{H_{max.} - H_{min.}}{H_{mean.}}$$

This is the measure of the relative change in candle-power and will serve as the best measure of the candle-power fluctuation. Since, however, the candle-power of a filament varies extremely rapidly with its temperature equation (14) will cease to hold for larger temperature fluctuations, although (13) may still be very accurate. It will be better, therefore, for us to adopt the following definition of the relative candle-power fluctuation ($F$):

$$(15) \qquad F = ln \frac{H_{max.}}{H_{min.}} = 2.30 \log \frac{H_{max.}}{H_{min.}}$$

Combining this with (13) and remembering that $\triangle T = 2\ \theta_0$ we obtain

$$(16) \qquad F = \frac{51600}{T^2}\ \theta_0$$

Combining this with (11), we obtain

$$(17) \qquad F = 4100 \frac{w_0}{f cm\ T^2}$$

### Application of Formula to Flicker of Tungsten Lamps

To apply this formula to the calculation of the candle-power fluctuations of tungsten lamps, we need first to know the specific heat of tungsten at the operating temperatures of lamp filaments. Corbino has determined this quantity from measurements on lamp filaments and obtains the value 0.0425 calories per gram per degree at 1500 deg. C. His temperature measurements above this temperature were probably not reliable, but he has experimentally determined the quantity $\frac{CT}{n_R}$ up to the normal operating temperature. Combining Corbino's data with our data for $\frac{n_R}{T}$ at the normal operating temperature, we obtain 0.049 calories per gram per degree, or

$C = 0.205$ watt seconds per gram per degree. Equation (17) thus becomes

$$(18) \qquad F = 20000 \frac{w_0}{fmT^2}$$

This equation gives the relative candle-power fluctuation of any tungsten lamp in terms of the power consumption ($w_0$), the frequency ($f$), the mass of the filament ($m$), and the absolute temperature of the filament ($T$). The equation holds equally as well for gas-filled lamps as for vacuum lamps.

We see that the fluctuation, $F$, is inversely proportional to the frequency of the alternating current and directly proportional to the power consumption. The introduction of gases into lamps therefore tends to increase the candle-power fluctuation since it increases the power consumption at any given temperature. On the other hand, winding the filament into a tight helix tends to decrease the fluctuation, since it decreases the ratio of power to mass of filament.

The practical application of the formula (18) therefore requires data characteristic of the particular type of lamp under consideration. We will therefore discuss its application under the following headings:

### Lamps with Filaments in Vacuum

The loss of energy from filaments in vacuum occurs almost entirely by radiation. The power consumption is approximately proportional to the 4.7 power of the absolute temperature. From equation (18), we thus see that the candle-power fluctuations in such lamps increase with 2.7 power of the temperature.

In tungsten lamps running at 1.0 watt per candle, the temperature of the filament is about 2400 deg. K, and the power consumption is about 0.54 watt per cm. for a filament 1 mil in diameter. The mass of a filament 1 mil in diameter is 0.098 mg. per cm. of length.

Substituting these data in (18), we obtain the following formula, which gives the relative candle-power fluctuation of a tungsten lamp at 1 watt per candle in terms of the frequency of the current and the diameter ($d$) of the wire in mils.

$$F = \frac{19.2}{fd} \tag{19}$$

For most purposes, it is more convenient to have a formula which involves only quantities directly measurable on the lamp.

The current necessary to maintain a filament at 2400 deg. K. is 0.197 $d^{3/2}$ amperes, where $d$ is the diameter in mils. From this and the data previously given, we get the relations: ($l$ = length in cm.)

$i = 0.197\ d^{3/2}$

$w_0 = 0.54\ dl$

$m = 98 \times 10^{-6}\ d^2l$ (grams)

From these three equations, we can readily obtain

$$\frac{w_0}{m} = \frac{5500}{d} = \frac{1860}{i^{2/3}}$$

Substituting this in (18) together with $T = 2400$ gives

$$F = \frac{6.48}{fi^{2/3}} \tag{20}$$

This gives the relative candle-power fluctuation in tungsten lamps with filaments in vacuum operating at one watt per candle. When the lamps are run at any other specific consumption, the constant 6.48 should be replaced by a quantity which depends on the operating temperature. Thus we find the fluctuation ($F$) can be expressed by the formula:

$$F = \frac{A}{fi^{2/3}} \tag{21}$$

The following table gives the values of $A$ for different specific consumptions and temperatures:

TABLE I

| Watts per Candle | Temperature | A |
|---|---|---|
| 3.0 | 2050°K | 3.64 |
| 2.0 | 2160 | 4.22 |
| 1.5 | 2250 | 5.05 |
| 1.25 | 2315 | 5.62 |
| 1.00 | 2400 | 6.48 |
| 0.80 | 2490 | 7.40 |
| 0.50 | 2730 | 10.56 |
| 0.30 | 3050 | 15.60 |

### Effect of Helical Winding

A straight filament of length $l$ and diameter $d$ has a mass $m$ and requires a power $w_0$ to maintain it at a temperature $T_0$. If this filament is now wound into a tightly coiled helix, the mass remains unchanged, but the power consumption to maintain the wire at $T_0$ decreases materially, since the wire now radiates only from those parts that lie on the outer surface of the helix. The effect of helical winding is to decrease the ratio $\frac{w_0}{m}$ and therefore, by equation (17), to decrease the candle-power fluctuation in the same ratio. It is evident that the greatest possible reduction thus obtainable with filaments in vacuum by winding into a helix would be in the ratio $\pi$:1. Practically, however, the effect would be much less than this. Under ordinary conditions the effect of helical winding is to decrease the candle-power fluctuation in about the ratio 1.4:1.

With filaments in gas, the effect of helical winding is much greater than in vacuum, for not only the radiated energy but also the heat carried from the filament by convection, is decreased by concentrating the filament into a smaller space.

### Candle-Power Fluctuations of Straight Filaments in Gases

We see from equation (15) that the presence of gas increases $F$ in the same ratio as it increases the wattage at a given temperature.

In general, for a filament of any given diameter in a given gas, $F$ will be given by an equation of the form (derived from 107).

$$F = \frac{\text{constant}}{fd} \quad \frac{w'}{w_0}$$

where $w'/w_0$ is the ratio in which the power is increased by the presence of the gas. For straight filaments in nitrogen, the writer has already published (Trans. A.I.E.E. for 1913, p. 1912) a table of the specific consumption of filaments in nitrogen at various temperatures as compared with that in vacuum. From these data the following table (II) is prepared of the function $\frac{\text{const}}{d} \frac{w'}{w_0}$ which, for convenience, we will call $\beta$.

The relative candle-power fluctuation is thus equal to

$$F = \frac{\beta}{f}$$

TABLE II—VALUE OF $\beta$ FOR STRAIGHT FILAMENTS IN NITROGEN AT ATMOSPHERIC PRESSURE

| Temp. of Filament | Watts per Candle in Vacuum | Diam. 1 Mil | Diam. 2 Mil | Diam. 5 Mil | Diam. 10 Mil | Diam. 20 Mil |
|---|---|---|---|---|---|---|
| 2400 | 1.00 | 92 | 30 | 7.8 | 3.0 | 1.3 |
| 2600 | 0.63 | 94 | 32 | 8.6 | 3.4 | 1.5 |
| 2800 | 0.45 | 98 | 34 | 9.4 | 4.0 | 1.7 |
| 3000 | 0.33 | 102 | 36 | 10.2 | 4.4 | 2.0 |

Table III gives similar data for straight tungsten filaments in hydrogen at two different pressures, 100 mm. and 760 mm.

TABLE III—VALUES OF $\beta$ FOR STRAIGHT TUNGSTEN FILAMENTS IN HYDROGEN

| Temp. of Filament | Watts per Candle in Vacuum | 760 MM. OF $H_2$ |  | 100 MM. OF $H_2$ |
|---|---|---|---|---|
|  |  | Diam. 1 Mil | Diam. 2.8 Mil | Diam. 2.8 Mil |
| 2000 | 3.4 | 340 | 64 | 46 |
| 2200 | 1.7 | 370 | 70 | 50 |
| 2400 | 1.0 | 410 | 78 | 66 |
| 2600 | 0.63 | 520 | 96 | 90 |
| 2800 | 0.45 | 620 | 118 | 132 |
| 3000 | 0.33 | 780 | 146 | 176 |
| 3200 | 0.26 | 1000 | 188 | 260 |
| 3400 | 0.21 | 1200 | 226 | 360 |

This has been calculated from data on the power consumption of tungsten wires in hydrogen, published in the *Physical Review* (Vol. 34, p. 418, 1912), and from other similar data more recently obtained in this laboratory. It is interesting to note that the fluctuations are greater when the lower pressure of hydrogen is used.

As an example of the use of these tables, let us calculate the candle-power fluctuation of a 5 mil tungsten wire in nitrogen when run at the temperature equal to that of a filament running at 0.45 watts per candle in a vacuum. We see from Table I that $\beta = 9.4$ and therefore

$$F = \frac{9.4}{f}$$

With a 60 cycle current, $F$ would thus be 0.157. This means that the candle-power would vary periodically (120 cycles per second) with an amplitude of approximately 7.8 per cent. The ratio of the extremes in candle-power would be 1.078:0.922, or 1.17.

It is evident from Table III that the amount of fluctuation that can be obtained with straight filaments in gases, especially hydrogen, is enormously great.

For example, for a one mil wire run at 3000 in hydrogen at atmospheric pressure, we have

$$F = \frac{780}{f}$$

Thus, with a frequency of 3900 cycles, the relative candle-power fluctuation would be 0.2; that is, the candle-power would vary between extremes 0.9 to 1.1 of the mean candle-power. With a frequency of 780 cycles, the value of $F$ would be unity. Since we defined $F$ as $\Delta ln\ H$ and since $ln\ 2.72$ is unity, we see that the value $F = 1$ corresponds to a change in candle-power in the ratio of 1:2.72.

With currents of such high frequency of course the flicker would not be noticed, but with a rotating mirror, the stroboscopic effect would be very apparent.

A qualitative study of the stroboscopic effects obtained with tungsten lamps and of the effects caused by the introduction of gases, has been made by C. F. Lorenz (*Electrical World*, Nov. 30, 1912). The results obtained seem to be in general accord with the equations derived in the present paper.

### Experimental Determination of Candle-Power Fluctuations

The equations already given should render it possible to calculate accurately the relative candle-power fluctuations in any type of incandescent lamp run on alternating current.

The greatest source of uncertainty is due to lack of extensive experimental data on the specific heat of tungsten at high temperatures. The error that could creep into our equation from this source would hardly exceed 5 or 10 per cent.

It was thought well, however, to put the equations to a practical test by making an actual determination of the candle-power fluctuation on a couple of lamps.

For this purpose an eight-pole synchronous motor was fitted up with a rotating sector consisting of a disk with eight teeth along its circumference. The space between the teeth was made equal to the width of the teeth. This rotating sector was set up in front of the opening of a portable Weber photometer, which was sighted on the test lamp. By running the synchronous motor from the same alternating current supply as that used for the test lamp, it was possible to determine the candle-power of the lamp at any part of the cycle. The rotating sector was shifted in front of the photometer so that first a maximum and then a minimum reading was obtained, each reading corresponding to the average candle-power during one-half of a cycle of temperature fluctuation, the two half cycles being displaced 180 degrees in phase.

Two test lamps were studied.

The first lamp was a standard tungsten lamp having the following characteristics when run on direct current at its rated voltage:

28 volts
0.453 ampere
9.3 candle-power
12.7 watts
1.37 watts per candle.

This lamp was photometered through the rotating sector when running at 28 volts on 29 cycle alternating current.

In shifting the phase by moving the rotating sector, the ratio of the maximum to the minimum candle-power was found to be 1.23 as the average of a number of closely agreeing determinations. The maximum and minimum values thus measured are not the true maximum and minimum, but are averages during two half cycles. It can be readily shown that the maximum variation in candle-power is ½ π, or 1.57 times the average variation during one half cycle. The value of $F$ is thus found to be

$$F=\frac{\pi}{2}\ ln\ 1.23=0.324$$

This means that the relative candle-power fluctuation is 0.324 of the mean candle-power. Or, more accurately, from equation (15), the ratio of the true maximum candle-power to the minimum is 1.38, or again, if we take 9.2 to represent the normal candle-power of the lamp, the instantaneous candle-power varies between the limits 7.8 and 10.8.

Let us now compare this result with that calculated from our equations. Since the lamp was a regular tungsten lamp with exhausted bulb, we can calculate $F$ from equation (21), taking the proper value of $A$ from Table I.

As the lamp was running at 1.37 watts per candle, we interpolate between the values for $A$ given for 1.25 and 1.50 watt per candle, and find $A=5.3$. Substituting this, together with $f=29$ cycles and $i=0.453$ amp. in equation (21), we obtain

$$F=0.31$$

This value is in first class agreement with that found by direct photometer measurement, namely, $F=0.325$.

The second lamp tested was a 6.8 ampere nitrogen filled lamp. The characteristics on direct current were

19.1 volts
6.80 amperes
237 candle-power
130 watts
0.54 watts per candle.
Temperature of filament 2850 deg. K.

This lamp was photometered through the rotating sector when running at 19.1 volts on 26 cycles alternating current. The ratio of the average maximum to the average minimum reading was 1.07. This gives, for $F$

$$F=\frac{\pi}{2}\ ln\ 1.07=0.104$$

With this lamp no flicker was observable, and it was only with difficulty that any stroboscopic effect could be detected by watching strips of white paper pasted onto the rotating sector.

The calculation of $F$ may be carried out as follows: The specific consumption of a filament in a vacuum at 2850 deg. is 0.42 watt per candle (see Table III), as against 0.54 watt per candle for the test lamp which had a helical filament in nitrogen. At constant filament temperature (therefore constant resistance), the current taken by a lamp must be proportional to the square root of the wattage. Therefore, if the nitrogen in this lamp had been pumped out, while the filament temperature was maintained constant, the current would have been decreased in the ratio $\sqrt{54} : \sqrt{42} = 1.13$. We have seen that the effect of helical winding is to decrease the wattage consumed by a given length of wire in the ratio 1.41:1. The ratio of the current taken by a straight to that of helically wound wire in vacuum is therefore $\sqrt{1.41} = 1.19$. Hence the ratio of the current in the nitrogen filled lamp to that which would be required to heat the same wire to the same temperature in vacuum after uncoiling it, is

$$\frac{1.13}{1.18} : 1, \text{ or } 0.95$$

The wattage is therefore less in the ratio $(0.95)^2:1$ or 0.90. Therefore, if we calculate from equation (21) the relative candle-power fluctuation for a filament taking 6.8 amperes at 2850 deg. K. in vacuum and multiply the result by 0.90, we obtain the calculated value

$$F = 0.9 \frac{11.5}{2.6 \times 5.8^{2/3}} = 0.123$$

The value of $F$ may also be obtained more directly (by equation 18) from the weight of the filament. In the nitrogen lamp used in the above test, the weight of the filament ($m$) was found to be 0.101 gram. Substituting this together with $w_0 = 130$, $f = 26$ and $T_0 = 2850$ in (18) we obtain

$$F = 0.127$$

Both these calculated results are in satisfactory agreement with the value 0.104 obtained experimentally.

### Candle-Power Fluctuations in Commercial Tungsten Lamps

The experimental tests having shown that the equations give results in agreement with observations, we may now calculate the candle-power fluctuation of various standard tungsten lamps run at their normal voltages on alternating currents of various frequencies. These results are given in the two tables (IV and V).

TABLE IV—CANDLE-POWER FLUCTUATIONS ($F$) FOR 110 VOLT TUNGSTEN LAMPS WITH EXHAUSTED BULBS

| Watts | Amperes | Watts per Candle | F |  |  |
|---|---|---|---|---|---|
|  |  |  | 25 Cycles | 40 Cycles | 60 Cycles |
| 10 | 0.091 | 1.30 | 1.08 | 0.68 | 0.45 |
| 15 | 0.136 | 1.25 | 0.87 | 0.54 | 0.36 |
| 20 | 0.182 | 1.17 | 0.72 | 0.45 | 0.30 |
| 25 | 0.228 | 1.14 | 0.64 | 0.40 | 0.27 |
| 40 | 0.363 | 1.10 | 0.48 | 0.30 | 0.20 |
| 60 | 0.545 | 1.07 | 0.37 | 0.23 | 0.15 |
| 100 | 0.91 | 1.02 | 0.27 | 0.17 | 0.11 |
| 150 | 1.36 | 0.90 | 0.22 | 0.14 | 0.09 |
| 250 | 2.27 | 0.90 | 0.16 | 0.10 | 0.07 |
| 500 | 4.55 | 0.90 | 0.10 | 0.06 | 0.04 |

TABLE V—CANDLE-POWER FLUCTUATIONS ($F$) FOR NITROGEN FILLED TUNGSTEN LAMPS WITH HELICAL FILAMENTS

| Amperes | Watts per Candle | F |  |  |
|---|---|---|---|---|
|  |  | 25 Cycles | 40 Cycles | 60 Cycles |
| 3.0 | 0.9 | 0.25 | 0.15 | 0.10 |
| 5.0 | 0.7 | 0.14 | 0.08 | 0.06 |
| 6.6 | 0.6 | 0.11 | 0.07 | 0.05 |
| 10.0 | 0.55 | 0.08 | 0.05 | 0.04 |
| 20.0 | 0.40 | 0.05 | 0.03 | 0.02 |

If the values of $F$ given in these tables be multiplied by 100, the result will express the candle-power fluctuation directly in per cent.

It is seen at a glance from these tables that the candle-power fluctuations in the nitrogen filled lamps are negligible. Thus a 5.0 ampere nitrogen filled lamp on 25 cycles shows a total fluctuation of candle-power of only 14 per cent, an amount too small to be observable, being less than that of a 250 watt vacuum lamp.

A Good Example of Modern Illumination

# PRESENT TENDENCIES IN STREET LIGHTING

By Dr. Louis Bell

Consulting Engineer, Boston

Dr. Louis Bell shows in this article that the present tendencies of street lighting are hard to define, owing to the transition stage through which we are passing, and it is pointed out that other considerations besides specific consumption, such as steadiness and cost of maintenance and supplies, are important factors in determining the selection of lamps for street lighting. The size of units, the spacing, and the type of lamp should be selected with due reference to the specific requirements of the individual locality. The author deals amusingly with the real purpose of street lighting. The article is concluded with a few remarks concerning the inefficiency of some of the modern types of lamps which are being considered for street lighting purposes.—Editor.

Dr. Louis Bell

Just at the present time we are passing through a transition period in street lighting. The old order of things is passing away and it is by no means certain what will come out of the turmoil of change. In street lighting, as everywhere else, a steady movement toward higher efficiency is going on and yet one cannot be safe in predicting off-hand that the only criterion by which illuminants for street lighting are to be judged will be specific consumption. Ten years ago street lighting in this country was, so far as electrical illuminants are concerned, chiefly a matter of enclosed arc lamps, either d-c. or a-c. and series incandescent lamps such as had been used for a decade previously. The introduction of the enclosed arc did not make for light-giving efficiency, for it was perfectly well known to those acquainted with the facts, even at the time mentioned, that the enclosed arc showed something like twice the specific consumption of the open arcs which had preceded it when the latter were properly run with a good grade of carbons. From the mere standpoint of watts per candle the change to the enclosed arc was a step backwards.

The choice of the new illuminant depended then upon something altogether outside the efficiency. To push the analysis a little further, the fundamental advantage of the enclosed lamp was its great steadiness compared with the open arcs as commonly operated. There has never been to the writer's knowledge a circuit of first class open arcs, in the European sense of the description, regularly operated on this side of the Atlantic, on account not so much of the cost of trimming in labor, but from the fact that the necessary grade of carbons has never been readily obtainable in this country and can be imported only at large expense. Open arcs such as are found in Vienna today would have kept the enclosed lamps from even a look-in at the street lighting business; but taking conditions as they were, the man on the street liked the new lamp because it possessed conspicuously a quality which its predecessor lacked. The enclosed lamp was, moreover, desirable from the standpoint of the central station as somewhat cheaper and more convenient to operate, and its use was therefore pushed by that sort of psychological appeal which good salesmen have always been able to make. If an article has certain clear and conspicuous points of merit the insistent iteration of these to the exclusion of all other matters by merely crowding them out usually produces an effect.

About five years ago, with the introduction of the metallic filament lamp things took on a new aspect. It was perfectly obvious to the engineer that these lamps were immensely more efficient as light producers than the enclosed arcs, and as soon as they became available in reasonably large sizes a process of substitution began. It was preceded, however, by another movement, also psychologically interesting. The matter of distribution of light by small units suddenly came to the front. It had been seriously considered when the old carbon lamps were available, but these were too inefficient to allow the plan to be tried on an effective scale. With incandescent lamps more efficient than the arcs, the call for better distribution by a multiplicity of small units was vigorously raised. In some respects the demand was very reasonable, for if there is any one thing in which American cities have sinned, from the standpoint of good lighting, it has been in the use of arcs at a spacing so wide as to reduce the minimum between lamps to a quantity which for seeing purposes is practically negligible.

The first fruit of the new movement was the tungsten cluster, very beautiful and effective in its proper place, but frequently most ineffective and entirely unsuited to its environment. The place of tungsten clusters is where a moderately strong illumination only is required, where an appropriation sufficient to place the posts rather close together is available, and above all where decorative fixtures harmonize with artistic surroundings. A beautifully and symmetrically built business street, with buildings not too high, can be lighted by tungsten clusters with wonderfully effective results; but the same fixtures placed on a shabby straggling street with dirty gutters and slovenly sidewalks deserves almost to be classed as a practical joke. The same criterion holds good with respect to the boulevard type of arc introduced to compete with the tungsten cluster where the retention of arc lights seemed for one reason or another desirable.

The move in the direction of smaller units than the arc lamps furnished was on the whole a healthy one, since it enabled pretty good lighting to be maintained in streets where the requisite number of arcs for their proper utilization would be out of the question. It seems to be a tendency of the human mind, however, to follow an apparently reasonable idea with unreasonable pertinacity, hurrying along the broad highway until it dwindles into a footpath and finally terminates in a squirrel track which runs up a tree. Hence came extreme examples of sub-division of units such as may be found in Toronto, where of late there has been a storm of protest against lack of light. The fact is that in the last resort the choice of illuminants comes down to a matter of psychology which cannot be reasoned out on theoretical principles beforehand. People almost universally like a brilliant effect, particularly in the center of a city. They like brilliant lights, even glaring ones. This perhaps may be an inheritance from the time when their savage progenitors danced around the camp fire in the days when fire making was an art new to man; but whatever the cause, the fact remains that the ordinary person, the man on the street, would not be satisfied with artificial moonlight even if he could get it. One cannot, therefore, push the subdivision of units too far, nor can he by any amount of preaching persuade his fellows not to like the glitter and snap of a brilliantly lighted room or street.

Fundamentally street lighting is, and was, a police measure, introduced nearly two hundred and fifty years ago as a defense against brigandage. Such remains its function up to the present time to a very considerable degree. All of a city that is at all thickly inhabited, requires a certain effective amount of lighting for police purposes, enough to enable the guardian of the peace to distinguish between a worthy burgher late home from his club, and a gentleman with a jimmy sneaking around for a chance to pry open a window. Within that part of a city in which the traffic is dense and in streets largely used at night, something a good deal more effective is required, enough to enable one to distinguish faces, read addresses, dodge automobiles and keep from tripping over projecting paving stones. Finally, there is a certain amount of outlying territory in which lights are desirable for the guidance of traffic rather than for illumination, merely as markers of the way to prevent pedestrians from wandering into the gutters and inebriated chauffers from trying to climb telegraph poles alongside the road. It is perhaps in this minor lighting that the interesting theory of silhouetting finds application.

There are, then, many distinct phases of street lighting and it is perfectly safe to say that no one system of illumination can meet all of them equally well in the utilitarian sense, let alone in the artistic sense. And now we have the gas-filled lamp coming into the field, and improvements in arcs to meet the new competition are undoubtedly on the road. It is something of a feat to improve the efficiency of the incandescent lamp by 30 or 40 per cent, but this change is by no means as great from the dollars and cents standpoint as was the change from the carbon lamps to the first metallic filaments. People who expect that the cost of street lighting is going to be cut in two by the "half watt lamp" are due to be grievously disappointed. In the first place the gas-filled lamp as it appears at present does not run very close to 0.5 watt per candle-power except in sizes which bring it into direct competition with flame arcs at 0.2 or 0.3 watt per candle-power, and long-burning at that. The first effect of the new comer ought to be the complete wiping out of the whole tribe of open and enclosed carbon arcs, except the intensified arcs invaluable in color discriminations. They can advantageously be replaced by the medium sized gas-filled lamps, even if these are worked at 0.6 or 0.7 watt per candle instead of at 0.5.

In the smaller metallic filament lamps the gain in efficiency is worth taking, particularly on account of the improved color of the lamp. In the actual saving of energy the gain is not impressive so far as the present outlook for the smaller lamps goes. In a 100 c-p. lamp, for example, on all night service, the gain would be from present figures something like 100 kw. hours—worth saving, but by no means revolutionary. Very possibly higher efficiencies of the metallic filament lamp may come into sight, but there is absolutely no chance for the wholesale saving in energy that was brought about by the abandonment of the carbon filament lamp. Meanwhile, where brilliant lighting is desirable and the new incandescent has to make a frontal attack on the flame arc, the battle will not be an easy one to win. The writer saw long-burning flame arcs, very fine and steady, in Paris, which were actually doing a little better than 0.2 watt per m.l.h. c-p., in units taking less than 500 watts. There is a great gap left yet between this and the efficiency of any lamp that depends on an incandescent filament. Unless it should prove possible to make very revolutionary improvement in the incandescent filament, far beyond anything as yet promised, the best of the arcs can save enough energy to hold their own for some time to come. The writer will, however, be much disappointed if the gas-filled lamp or some successor in business does not within two or three years make the enclosed arc as hard to find as a whale oil lamp.

---

# A NOTABLE DEVELOPMENT IN ORNAMENTAL STREET LIGHTING

By Walter C. Allen

Electrical Engineer of the District of Columbia

There has recently been installed in the central section of the city of Washington, D. C., a luminous arc lighting system which possesses a number of unique features, these principally being the result of the special ornamental design of lamp adopted. The following article briefly reviews the steps which led up to the new system, shows the locations of the lamps on maps, describes in detail the construction of the poles and the special diffusing globes which are employed, and furnishes some very interesting figures on both the investment and the maintenance cost of the installation.—Editor.

Walter C. Allen

Three years ago, after experimenting with various kinds of illuminants, a system of improved lighting with incandescent electric lamps was adopted for the principal avenues and boulevards of the District of Columbia. Since then, over sixteen hundred such units have been installed and are now in successful and satisfactory operation on more than eighteen miles of streets. This method, however, has not been extended to the heart of the business section of the city, nor to that portion of Pennsylvania Avenue connecting the Legislative and the Executive groups of buildings, where a higher intensity of illumination appears desirable. Any system of lighting for this broad, well-known avenue must be efficient in operation, pleasing in design and in keeping with the dignity of the capital city of the nation. After a careful study of the conditions, supplemented by experiments with sample installations, it is believed that the approved plan described below meets all the requirements.

Before entering into the details of this unique system, a brief reference to the history of the lighting of this avenue may be of interest.

The first definite plan for any extended lighting system, as far as the official records show, was adopted seventy-one years ago, when Congress appropriated $2500.00, in 1842, for erecting and lighting lamps on Pennsylvania Avenue between the Capitol and the "President's Square." Although the records are silent as to the kind of lamps, they must have been some form of oil lamp, as it was not until July, 1848, that the first gas light company to operate in the District of Columbia was granted its charter by Congress, followed the next month by another act authorizing the laying of gas pipes and the erecting of one hundred lamp posts in this thoroughfare. The lighting of these lamps, as well as those in and around the Capitol and the President's house and grounds, was paid for by the general government and was placed under the jurisdiction of the Commissioner of Public Buildings, a Federal officer. The lighting of other public streets was maintained by local taxation as a municipal function of the corporation of Washington City. This arrangement, which applied to other kinds of improvements and which gave a national character to Pennsylvania Avenue, continued for about twenty-five years, when changes in the relations between the Federal Government and the Municipality were inaugurated, resulting in the present form of government by commission, with general authority over all the public streets.

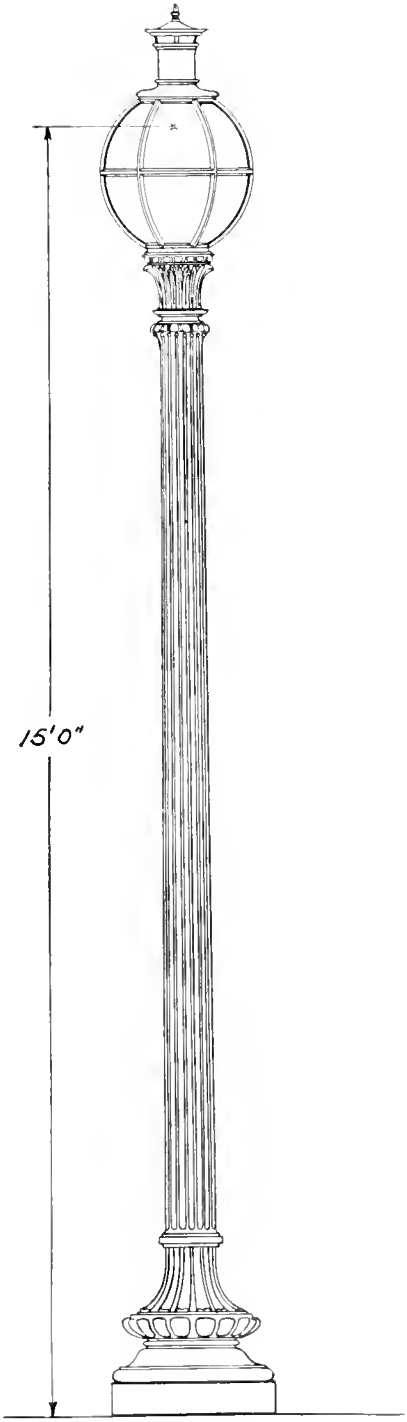

**Fig. 1.** Drawing showing the Ornamental Type of Diffusing Globe and Pole Used in the Installation Described

For the thirty-eight years, from 1848 to 1886, gas was the only illuminant used for the lighting of Pennsylvania Avenue, although experimental installations of electric arc lamps were made on that and other streets from time to time during 1884 and 1885. In October, 1886, a contract was entered into between the District of Columbia and the Potomac Electric Power Company for electric arc street lighting at the rate of 65 cents per lamp per night ($248.20 per lamp per year) on a sunset-sunrise schedule; and twenty-four such lamps were erected on the south side of this avenue. At that time, 123 gas lamps at $20.00 each per annum were used to light the street on a moonlight schedule, totalling 2600 hours.

When the enclosed arc lamp was perfected and after thorough tests with experimental installations, the old open series lamps were replaced in 1902 with multiple enclosed lamps, and these are now being supplanted by lamps of the type described in this article.

Before the adoption of this plan, several other methods of improving the lighting of Pennsylvania Avenue were considered. One involved the erection on "isles of safety" of two rows of standards in the roadway close to the outer rails of the street car tracks, supplemented by lamps at the curb lines among the trees. This plan was described in an illustrated article in the "*Illuminating Engineer* (N.Y.) for January, 1909, (Vol. 3, No. 2). It was formally referred to the Commission of Fine Arts in 1911, whose report states that:

> "Members of the Commission are personally familiar with a large number of the instances, both abroad and in this country, illustrated in the paper

accompanying the report on the plan, and each of the members has independently reached the opinion that in every case of long straight avenues the appearance of the streets has suffered materially from the presence of the posts in the midst of the street. Therefore, in spite of the fact that such a method of lighting has been tried in many important thoroughfares, it is believed that lamps on tall posts, with isles of safety in connection, near the middle of the roadway, would confuse and seriously injure the appearance of Pennsylvania Avenue, the most important vista in the Capital. Another consideration, which is both practical and aesthetic, is that the presence of these posts and islands in the roadway would interfere with the best handling of parades."

Fig. 2. Photograph showing the Ventilator, Diffusing Globe and Casing Containing the Lamp Mechanism of One of the Units

The elimination of a roadway plan of lighting practically fixed the position of the posts at the curb in line with the trees. In 1912, experiments with both tungsten and luminous arc lamps were made with posts in this position on a portion of the Avenue, resulting in the adoption of the system herein described.

### Lamps

The greatest interest in the technical features of this installation centers around the lamp itself and its novel treatment. The standard 6.6-ampere luminous arc lamp of the General Electric Company, fully described in the issues of December, 1911, and November, 1912, of the GENERAL ELECTRIC REVIEW, is used for this purpose, equipped, however, with special parts to adapt it to its unusual method of installation. The standard form of globe used by the makers of the lamp has been replaced by an elongated spherical-ribbed frame holding segments of alabaster glass. The main insulator on which the lamp mechanism rests is enclosed in the ornamental cast-iron casing, instead of being exposed as in the standard forms. Trimming is done in the usual manner by removing the spun-metal ventilator and raising the upper fume box and insulator on the specially constructed flat slide rod. The lamp mechanism is so adjusted in the frame that the shadow cast by the rod is thrown on one of the ribs, and as it is not greater than the width of the rib the globe is left absolutely shadowless. By this operation, access is also given to the interior of the globe for cleaning and adjustment of the upper parts, while the terminals and lower coils are reached through a door in the ornamental iron casing. More room for working around the lamp may readily be obtained by removing the upper half of the ribbed frame, Fig. 3. Figs. 5 and 6 show the details very clearly.

Fig. 3. View showing the manner in which the Globe Can be Dismantled for Cleaning. Transparent glass is here used only to show the lamp

**Ribbed Frame and Glass**

After many experiments in various metals, the General Electric Company found that aluminum gave the best results in casting the ribbed frame, which is made in two hemispheres, an upper and a lower. It is not a true sphere, being described about two centers two inches apart, see Fig. 7. It is not insulated from the post, but rests upon the cast-iron casing, and is rigidly held to it by three set screws. Fig. 4 shows the dowel pin on the inside of the casing, used to hold the lamp mechanism in its proper position. The glass, known as "polycase alabaster," is specially designed for use with luminous arc lamps and is made by the Gleason-Tiebout Glass Company of Brooklyn, N. Y. Difficulties in manufacturing moulded segments of glass of this character made it necessary to first blow the glass as a sphere to the proper diameter, approximately 23 inches, grind the top and bottom openings to size, and then cut the globe in segments to fit the ribbed frame. As far as is known, this is the first instance where it has been possible, on an extended scale, to fit blown glass to cast metal frames with any degree of accuracy. The inner surfaces of the ribs are lined with felt and the glass is held against them by equalizing spring fasteners shown very clearly in Figs. 7 and 8. This fastener is so designed that the pressure is distributed equally on all panes, besides providing for irregularities in thickness and allowing for expansion and contraction. The glass segments are inserted from the inside of the frame, and can readily be replaced while in position on the post.

Two densities of glass are used, "medium" in the upper half and "light" in the lower

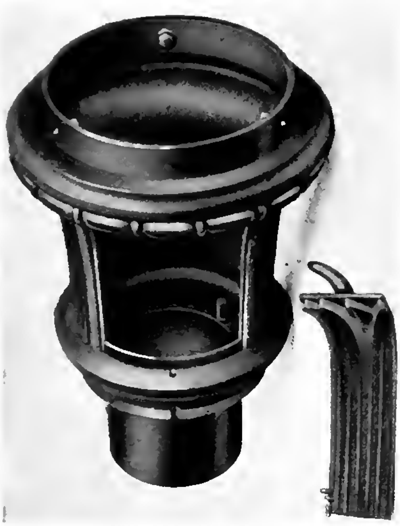

Fig. 4. Casing Container of the Lamp Mechanism

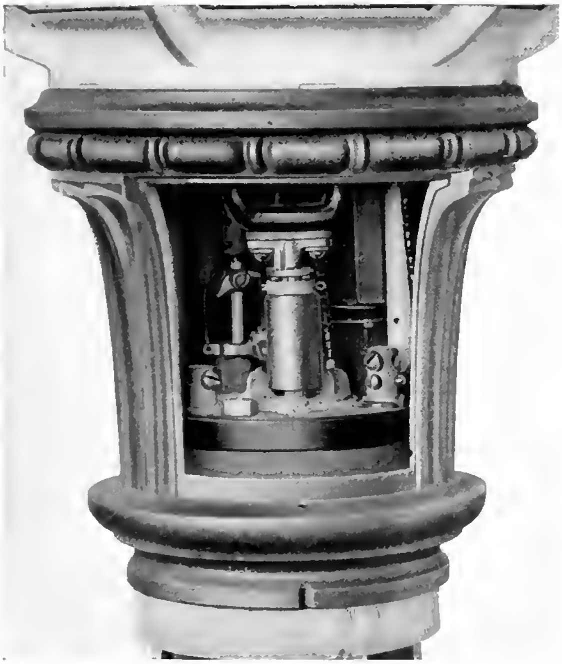

Fig. 5. View of the Lamp Casing Mounted at the Top of the Pole, Door Removed to show the Lamp Mechanism

half of the frame, both of which give such perfect diffusion that no shadows, no portion of the lamp mechanism, and not even the arc itself are visible. When the lamp is in operation, the glass becomes a luminous surface radiating a powerful, yet soft light, without glare.

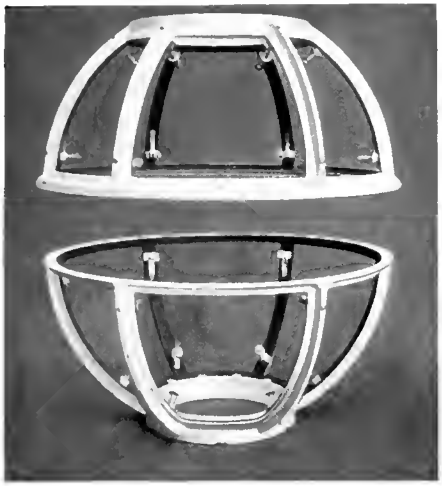

Fig. 7. The Two Semi-spherical Halves of the Globe Frame Located According to their Respective Centers

Fig. 8. The Means Used for Holding the Glass in the Frame of the Globe

### Insulation

Insulators of special General Electric waterproof compound, instead of the standard glazed porcelain, are used between the lamp mechanism and the top of the cast-iron post. These are tested at 20,000 to 25,000 volts. As stated above, they are placed within the iron casing. A specially shaped ring of the same composition is placed on the top of the aluminum frame to insulate the spun metal ventilator and upper fume box from the post. A cylindrical lining of mica, the sides of which are $\frac{3}{16}$-inch thick, is placed around that portion of the mechanism within the cast-iron casing.

### Posts

The posts were designed by James Rush Marshall and Albert L. Harris, of the firm of Hornblower & Marshall, architects, of Washington, D. C., and follow the lines of the posts, also designed by them, that are used in the improved incandescent electric lighting system of that city and which have been so favorably commented upon. See Fig. 1. For description of this incandescent electric lighting system, see the *Illuminating Engineer*, N. Y., for January, 1912, Vol. VI., No. 11.

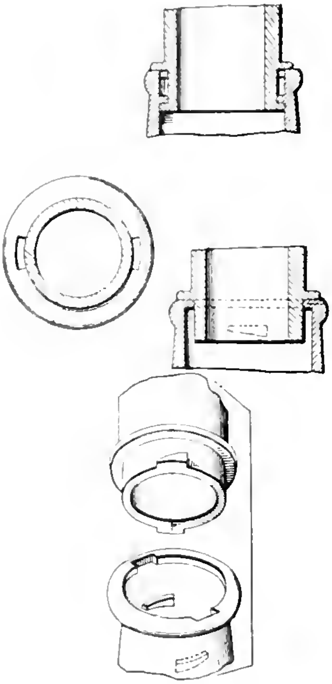

Fig. 9. Drawing showing the Method of Fastening the Lamp Pole to the Base

In casting the posts for the Pennsylvania Avenue installation, the Union Foundry Company, of Anniston, Alabama, used a very ingenious device, patented by them, for locking the shaft to the base. (See Fig. 9, which is reproduced from the Patent Office

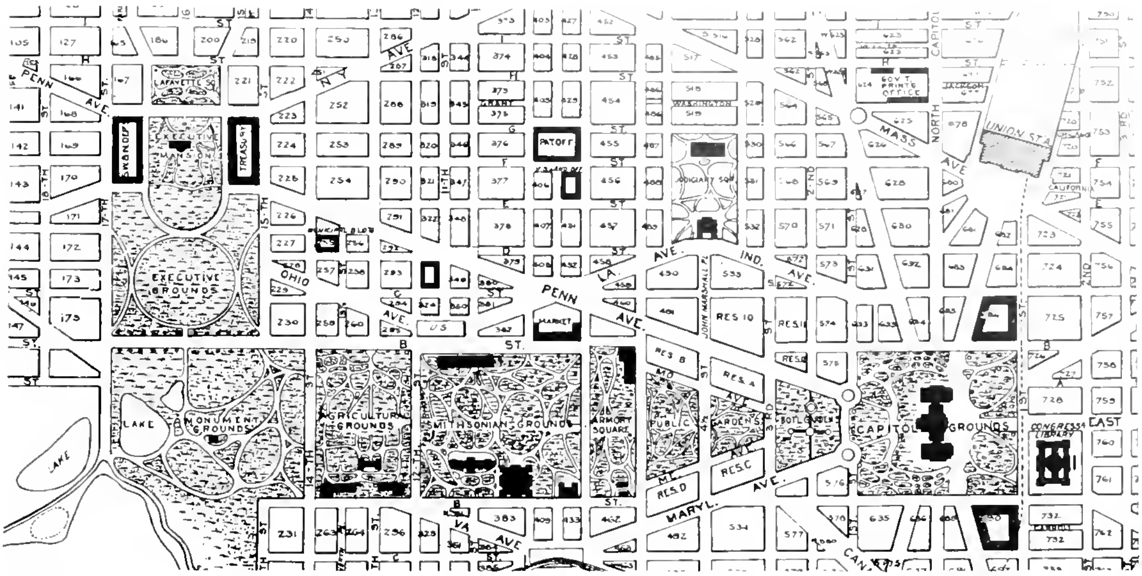

Fig. 10. Map of the Federal Government Section of the City of Washington showing that portion of Pennsylvania Avenue which is Lighted by the New System

drawings.) By a single turn of the shaft after inserting it in the top of the base the two are locked firmly together. This method obviates the necessity for bolts or set-screws to hold the two parts together, and greatly facilitates the erection of the posts.

Full-size plaster models were made by John J. Early, sculptor, of Washington, D.C., from the architects' drawings, with several types of lamp casings and globes, among them the standard design of the General Electric Company, a one-piece globe, and a spherical ribbed frame. From the study of these several combinations the final design was evolved. The accepted models were then sent to the foundry, and from them, as guides, the patterns were made.

The section of the city covered by this improved lighting installation is that portion of Pennsylvania Avenue which is shown in Fig. 10. Fig. 11 illustrates to scale the manner in which the intersecting streets form open spaces, and shows the typical arrangement and spacing of the posts.

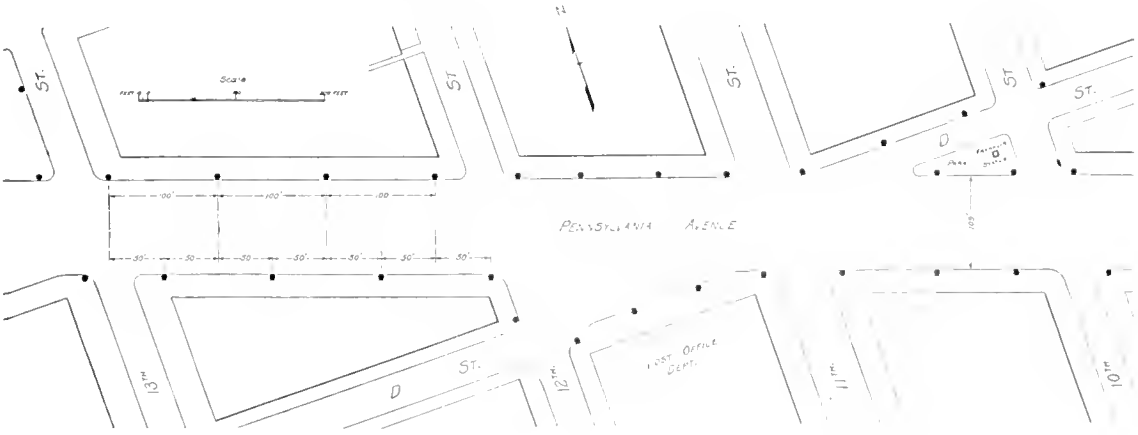

Fig. 11. A Scale Drawing showing the Location of the Lamps in the Neighborhood of the Post-Office Department

Fig. 12. Two Views of Pennsylvania Avenue Taken Toward the Treasury Building showing the Appearance of the Lighting Units as Installed

Along the unbroken length of the avenue, the distance between curbs is 109 feet; this is increased to as much as 200 feet at the open space in front of the Post Office Department building where the usual triangular parking is omitted. (See Fig. 11.) As these numerous open spaces are in reality a part of the avenue proper, the improved lighting has been carried around them, an average spacing of 100 feet between posts being maintained both on the main throughfare and on the offsets.

The cable for this installation is single conductor No. 8 B.&S. gauge copper, insulated with 8/32-inch varnished cambric and protected by a ⅛-inch lead sheath. The conduits into which it is drawn were laid many years ago, and are in the roadway within three feet of the curb on both sides of the street. The cable is carried up the post to the lamp terminals without breaking the lead covering, no cut-out being used in the base of the post. Two circuits are used, with the lamps on the two sides of the street connected alternately thereto. With this arrangement, it will be possible to burn half of the lamps after midnight and still give a sufficient and fairly uniform illumination.

The following figures refer to the main avenue only; the offsets are not included:

Length of roadway on center line, 6356 feet.
Width of roadway, 109 feet.
Square feet of roadway, 692,804.
Number of lamps, 123.
Total watts at 520 each, 63,960.
Annual maintenance cost ($97.50 each), $11,992.50.
Watts per linear foot, 10.06.
Watts per square foot, 0.0923.
Cost to maintain per linear foot, 1.886.
Cost to maintain per square foot, $0.0173.

The exact figures of the cost of installation are not at hand; they are estimated to be $170.00 per unit, exclusive of the posts, ribbed frames, glass and special parts, which are furnished by the municipality and cost as follows:

| | |
|---|---|
| Cast-iron post...................... | $26.90 |
| Cast aluminum ribbed spherical frame | 37.50 |
| Special parts...................... | 3.00 |
| | $67.40 |

The installation of cables, erection of posts, etc., is made by the Potomac Electric Power Company at its own expense, which company also maintains the lamps at the rate of $97.50 each per annum, less $4.40 deducted as interest and depreciation on the municipally owned posts, in accordance with the Acts of Congress establishing rates for street lighting in the District of Columbia.

Fig. 13. A Near View of One of the Lighting Units

Everyone connected with the development and installation of this lighting system has shown a lively interest in making it an ornament to the Capital City and a model for other municipalities, and to them the thanks of the citizens and officials of the District of Columbia are due.

# AN EXAMPLE OF A MODERN ARC-LIGHTING SYSTEM APPLIED TO THE LIGHTING OF BOULEVARDS

By G. N. Chamberlin

Engineer, Arc Lamp Department, General Electric Company

The immense advantage of the luminous arc-lighting system in congested districts has been firmly established. The mushroom-like growth of popularity with which the "White Ways" have been received attest this fact. This article shows that its use in the more thinly populated sections promises to meet with equal success, and describes an example of such an installation.—Editor.

G. N. Chamberlin

THE employment of the ornamental luminous arc for the lighting of principal business thoroughfares has been met with such favor that, as a natural consequence, its use is now being rapidly extended to the lesser populated areas. The suitable illumination of public highways has not as a rule been given the careful consideration that it deserves. When such large sums are spent in the building and up-keep of parkways, boulevards, and shore drives, it is thoroughly in keeping that the lighting units should be of the same high order of excellence.

The following example will clearly illustrate the immense improvement in lighting which can be secured along such highways.

At the expiration of the contract for boulevard lighting, the engineers of the Massachusetts Metropolitan Park Commission, being familiar with the excellent illumination obtained from the luminous arc, approached the Lynn Gas & Electric Company relative to the illumination of that section of the North Shore Boulevard from the Bath House, Lynn, to Monument Square, Swampscott, a distance along the ocean front of about two miles. A thorough consideration of the subject resulted in a contract which provided for the installation and maintenance of forty lamps by the Lynn Gas & Electric Company.

The lighting system previously employed consisted of gasolene mantle lamps, two on a pole. The poles were about 12 ft. high and the lamps were equipped with large clear globes arranged in the usual manner. Fig. 3 shows a portion of this boulevard at

Fig. 1. The Method Used in Filling the Lamps of the Old Gasolene-Mantle Lighting System

Fig. 2. View showing the Laying of the Ducts through which the Luminous Arc Lamps are Supplied with Current

Fig. 3. A Day View of One Section of the Boulevard taken before the Installation of the Electric Units

Fig. 4. A Night Photograph showing a Portion of the Boulevard as Lighted by the New Luminous-Arc System

Fig. 5. A Day View showing the Location of the Luminous-Arc Units Furnishing the Lighting shown in Fig. 4

the time the old lamps were used. The mantles were rated at 32 c-p. each but, under service conditions, some were found to run as low as 15 c-p. and a number of tests showed an average of about 25 c-p. per mantle. Each lamp contained a small reservoir which held only enough gasolene for one night's burning. The method used in filling these reservoirs is shown in Fig. 1.

The light given by these lamps was, however, thoroughly inadequate for either the automobilist or pedestrian. Photometric tests made in the center-line of the street with a Sharp-Miller photometer gave an average of 0.03 foot-candles opposite the lamp and an intensity halfway between the lamps far below the reading limits of the instrument.

The new lamps which were turned on for the first time Christmas night, 1913, are of the ornamental luminous arc type, operating on a 4.0-ampere rectifier circuit and consuming about 300 watts each. The arc is placed 18 ft. from the ground, and the lamps are spaced from 200 to 300 ft. apart on the shore side of the Boulevard. A light-diffusing globe is used which distributes a well-diffused and pleasing white light. Fig. 6 shows a complete unit installed. These tall, slender poles with a single globe at the top are in no way conspicuous but, when attention is directed to them, they are found to be artistic in design, harmonizing perfectly with the beautiful stretch of boulevard maintained by the Commonwealth of Massachusetts.

The work on this installation was started Dec. 3rd, and completed Dec. 23rd. Some idea as to the method of underground construction used can be obtained from Fig. 2. Fig. 5 shows a section of the Shore Drive with the luminous units installed.*

Fig. 4 is a night view of the roadway and promenade. Photometric tests, made under similar conditions to those with the old gasolene lamps previously mentioned, show for the luminous arcs 0.37 foot-candles in the center of the road opposite the lamps and 0.008 foot-candles halfway between the lamps. This is about twelve times the illumination secured from the gasolene mantle lamps; and it is rather interesting to note that this increased illumination is being furnished at less cost than that of the previous gasolene installation. Although the roadway

Fig. 6. A Complete Luminous-Arc Unit as Installed in the Boulevard Lighting System

---

* It will be noted that at the time of writing this article sufficient time had not elapsed to allow of removing the old units.

presents a dark, poor reflecting surface, the single units are of sufficient intensity to make use of the now generally understood silhouette principle of lighting.

The promenade is of granolithic construction having a better reflecting surface and shows figures in excellent relief.

A very pleasing sight, since the installation of these arc units, is the white crests of the breakers along the beach. The intrinsic brilliancy of the light source is also noticeably low and does not interfere with the ocean view from the residences on the opposite side of the Shore Drive.

From the results now being obtained, it would seem certain that the ornamental luminous arc lamp can be used as economically and efficiently for this class of work as for the illumination of the more densely populated areas.

---

# SOME SPECIAL FIELDS OF INCANDESCENT LIGHTING

By G. H. Stickney

Assistant to Sales Manager, Edison Lamp Works, General Electric Company

In making a survey of the fields of incandescent lighting, we find that they naturally divide themselves into two classes; viz.; those that require an individual treatment in order to conform to artistic requirements, and in which ornamentation is largely the governing factor; and those which can be more or less standardized in practice and in which utility is the first essential. In designing installations of the first class the case must be worked out on its own merits; precedent, where there is any, counting for little, and standardization being reduced to collection of descriptions of existing installations. In the second class, however, where decorative effects are of secondary importance, the results from several similar installations can be averaged, and the data so obtained, with possibly slight modifications, can be used for future work. Fortunately, most of our lighting problems belong to the second class and are becoming to a certain extent standardized. Some of the more important branches of lighting in this class that are fast becoming standardized, such as street car lighting and the use of concentrated filament, with parabolic reflectors and lens systems, are reviewed in the latter part of the article.—Editor.

G. H. Stickney

The problem of extending the application of incandescent lamps by securing their right use in existing fields and determining applications in new fields is exceedingly interesting, especially at the present time when improvements of great value are succeeding each other with astounding rapidity. These remarkable improvements, along with the increased interest of the public—for good lighting is its own best advertiser—has brought about wonderful changes, influencing every human activity of work or play.

The popularity and extended use of an illuminant depends upon its being applied in such a manner as to give the greatest service and satisfaction to its users. On this account it has been found profitable by manufacturers of illuminants to expend considerable sums in studying the requirements of the various fields of illumination, in order that their customers may be properly informed as to the best selection, equipment and arrangement of lamps.

With the present practice of concealing the wiring, changes in lamp locations are expensive, and it is important that an effective arrangement of lamps be determined before the structure is completed. This presents quite a contrast to the custom of ten or fifteen years ago, when it was the practice to add the lighting to a completed structure, so that comparatively little trouble and expense were involved in later changes.

While in the past there have been master architects and engineers who have acquired wonderful facility in the use of lighting units, each one has held his methods as his personal stock in trade, to be kept secret as far as possible for his own benefit. The result was that, in a very large proportion of installations, the arrangement of lights was not such as to give the best effect, and there was a tendency on the part of the rank and file to follow such rule-of-thumb methods as happened to be known. With the twentieth century has come the new idea of co-operation and this is having a remarkable effect in improving the practice in the design of lighting installations.

In undertaking such installation designs, we find that lighting problems naturally arrange themselves into two classes; first, that in which individual treatment is required to conform to artistic requirements; and second, that in which the practice can be more or less standardized.

The first class includes those problems in which decorative effect is the predominating feature. Although in most cases of this sort the actual distribution of light follows fairly definite and well-known methods, individual treatment is necessary principally with regard to the ornamental design of fixtures and, to a certain extent, in carefully proportioning the illumination factors for the particular conditions. Unquestionably this element of individuality is sometimes abused in the effort to produce something different from what has already been done well, without regard to whether it meets the particular conditions better or worse than the usual practice.

In recording the practice in regard to any such special effects, it has been necessary to use what is sometimes called the "case system," in which particular installations are described, since the experience in completed installations cannot be interpreted directly in designing new ones.

In the majority of lighting installations, however, utility is the first essential, and ornamental features, while they should not be neglected, have to be restricted for the sake of economy. So, in studying the practice for these problems of the second class with the idea of improving future installations, the results obtained in a number of similar successful installations can, to a certain extent, be averaged and constants thereby determined, standardizing the practice for that particular type of work. We have sometimes called this method of treatment the "method of averages." For example, if by experiment or observation, we find a particular arrangement of lighting units especially advantageous for the lighting of weave rooms of a certain type, this arrangement can be standardized and used with very slight modifications for future work. This method is particularly applicable for classes of lighting where the individual installation is small but the number of similar installations very large. While a single installation might not warrant the expense of expert study, the class does if the results can be made available in such a way as to improve the practice. An interesting example of work along this line was an investigation carried on under the direction of the writer in endeavoring to improve the lighting of ordinary small stores such as are found in all communities. In the course of this investigation the lighting of approximately 800 such stores was examined and record made of the principal simple constants and features peculiar to this class.* Since a a large number of small store installations are planned by those not familiar with the technical terms and methods often employed in illuminating engineering, it was important that the results be expressed in as simple English as possible, and it was found practicable to express the quantity elements in terms of the electric power per square foot required by standard mazda lamps equipped with efficient reflecting devices. It is, of course, to be anticipated that some of these quantitative values will be affected by changes in the efficiency of lamps as well as by the constantly rising standard of lighting, and that the values may have to be revised from time to time. On the other hand, the tendency of these two variables is to compensate for each other so that the data will not become obsolete as soon as might otherwise be expected.

Commercial, industrial and street lighting are, in a similar way, being more or less rapidly standardized with regard to their particular sub-classes, especially where conditions are sufficiently established to warrant standardization.

Probably one of the most important and one of the most difficult elements to standardize is that of quantity, since this is determined as a compromise between useful effect and cost; and it is largely for this reason that the method of averaging results in a number of successful installations becomes so valuable.

A special problem in lighting which is exciting considerable attention and interest at the present time is the lighting of street railway cars. Until very recently all street railway cars were lighted by means of bare, low-efficiency carbon-filament incandescent lamps. Owing to the rough service, excessive voltage variation and low cost of power, practically no advance in car-lighting was made until the drawn wire tungsten-filament demonstrated its ability to withstand these severe conditions. The conspicuous advantages offered by the mazda lamp were the narrower range of light-intensity variation with fluctuating voltage and a very considerable saving in power. The 23 watt mazda

---

* See Law-Powell paper on "The Lighting of Small Stores." Trans. Illuminating Engineering Society, 1912.

has recently been substituted for the 64 watt carbon lamp by a considerable number of street railways. This gives a small increase in illumination delivered with a considerable reduction in power consumption. A study of the problem of car lighting, however, showed that the light could be more efficiently distributed and the illumination made more pleasant to the passengers by the use of prismatic or translucent reflectors; and if, at the same time, a smaller number of lamps of higher power could be used, the cost to the operating company could be considerably reduced, both as to reflector equipment and lamp maintenance. Investigations and tests have been made on the cars of the Bay State Street Railways, as well as on those of a number of other street railway companies. This has resulted in the development of a new method of car lighting which is being adopted especially with regard to new equipments, where an expense for re-wiring will not be involved. *

As an example of new fields of incandescent lighting made possible by the drawn wire tungsten filament, we have the so-called "concentrated filament" lamp applications, in which the lamp is used in connection with a parabolic reflector or lens system in the production of beams of light. The new feature here involved is the possibility of making an incandescent lamp in which the filament is coiled into a small space, approximating a point, a feature which has not been practicable with any of the former types of filaments. Since an approximate point source has very conspicuous advantages for such lens and reflector work in securing a very much higher degree of utilization of light, its importance will be recognized.

Formerly the arc was the only electric illuminant which met these requirements economically, and while today the electric arc gives a degree of concentration and brilliancy that has not yet been equalled by the mazda, it has limitations due to the fact that it is essentially a high-power unit and requires mechanism and skilled attention to keep the light source accurately at the focal point.

The first important application of the concentrated filament lamp has been in automobile headlights and small searchlights, which are now considerably used. The locomotive headlight is another application which is assuming considerable importance, and much study is being given to the determination of the requirements for this service. Up to the present time there have been two distinct practices: one which demanded a high-power headlight, and the other a low-power one, which is little more than a marker. The former has seemed to be desirable on single-track railroads without block signals, while the latter has been used on roads having block signals and two or more tracks. Certain objections have arisen to the use of high-power headlights on the latter class of roads because of the blinding effect of an opposing headlight on the engineer and its interference with the reading of signals. Investigations have not gone far enough to determine a practice to standardize, but it is apparent that in a large majority of cases, a headlight of intermediate power will be required. Since the proper solution of this problem involves the safety of a large number of people transported by the railroads on night trains, as well as large property interests, the problem warrants careful and extended study, and it is probable that within the next year the standardization will be fairly definite.

Another class of lighting which will be largely extended by the use of the concentrated filament mazda lamp is that in connection with small and moderate sized stereopticons and small moving picture machines, in which the simplicity and economy possible with this lamp will greatly extend its use. To what extent the mazda lamp will compete with the arc on the larger machines remains for future development, but investigations are now being carried on covering these and many other lens applications. Here again the individual installation is relatively small, but the aggregate use likely to be very wide and extended.

These few examples suggest the enormous amount of work yet to be done to standardize the lighting practice. There are many other fields not mentioned which are demanding study and attention, both for the sake of extending the business and securing better living conditions.

# INTERIOR ILLUMINATION

By A. L. Powell

Edison Lamp Works, General Electric Company

In this article the author divides the several kinds of lighting in vogue today into two distinct classes, as was done by Mr. G. H. Stickney in his article beginning on page 315; one class embracing those cases where ornamentation is the first consideration, and the other covering those installations where light efficiency is of prime importance. Those cases coming under the first class are the only ones considered in this article. All artificial illumination is accomplished by one of three methods of distribution, viz., direct, semi-indirect, and totally indirect; the main characteristics of each of which are herein enumerated. As examples of lighting installations that demand special attention from the decorative standpoint, the author has selected for discussion the illumination of art galleries, drafting rooms, hotels and stores, and states for each case the requirements in such matters as intensity, diffusion, direction, distribution, color, and steadiness of the light. Incidentally, economy should always be considered, but never to the extent of sacrificing correct illumination for lower cost of illumination.—Editor.

A. L. Powell

THIS very broad subject is logically divided into two quite distinct classes: One, in which the decorative element and artistic effect of the completed installation demand primary consideration, and where efficiency in terms of light effective on a certain area is of secondary importance. This class of illumination includes church, library, residence and store lighting, and will be the particular phase treated in this article. The other class is industrial lighting, where efficiency of light utilization must be investigated first and the architectural features are practically eliminated. This special division is discussed in another article in this issue.

The systems of illumination may be classified in two fashions:

First, as to arrangement of lighting units producing general illumination, local illumination, localized general illumination, or a combination of two. Most problems of decorative interior lighting are solved by general illumination; that is, the system is designed to give approximately even illumination over the entire working space, or room area. Of course special cases arise which demand local lighting in conjunction with the general illumination, as, for instance, in illuminating the walls of an art gallery with small angle steel or mirrored glass reflectors, or in lighting the music rack of a piano in the residence.

Second, as to the method of supplying illumination to the working plane. The three systems in common use are termed, direct, semi-direct and totally indirect. All three systems are applicable for interior illumination, although each has its limitations, advantages and disadvantages.

*Direct Lighting:* Ordinarily this system results when the lighting device is so arranged that it is quite evident that over half of the emitted lighting flux is directed downward or to the side, reaching the surfaces to be illuminated without being reflected by the walls or ceiling. As this system, when properly designed, is the most efficient and was the primal method of utilizing light, and as the color of surroundings has less effect on the resultant illumination, it is the method most frequently met in practice. This classification would include clear or frosted bare lamps, lamps totally enclosed by diffusing media, and lamps with reflectors, either opaque or translucent, which direct the light downward.

*Semi-indirect:* This system employs a diffusing or translucent device to direct most of the light to the walls or ceiling to be redirected for use, a part of the light being diffused through the glass.

It has been the practice of some engineers to use the term "indirect" for fixtures which have a very dense translucent reflector below the lamp, with less than 15 per cent of the resultant illumination direct from the lighting unit. The claim is that the brightness of the fixture does not exceed the brightness of the ceiling; therefore the efficiency of the eye is as good as under a totally indirect system. However, the layman is prone to look at the lighting equipment from a decorative standpoint, and these units would therefore be termed "semi-indirect."

Another point which would prevent the adoption of this 15 per cent factor is that the classification might have to be confirmed by an illumination test in the room where the unit is installed, for an equipment which might be just on the border line if installed in a room with a very light ceiling, would be indirect under this classification. Then, if the ceiling became dirty, reducing the indirect component of the illumination, the direct portion might be more than 15 per cent, as specified. Thus, the system would become some other type than indirect.

*Totally Indirect Lighting:* With this system all the light emitted by the fixture is projected to the ceilings or walls and thence reflected to the objects to be lighted. Cove lighting falls under this class, and also those equipments which conceal the light source by interposing an opaque reflector between it and the working plane.

The indirect systems are only economically applicable for use in rooms in light finishes, and, generally speaking, they are less efficient than the direct systems. They have marked advantages, however, in very even distribution of light, absence of glare, and minimization of shadows.

While there are many splendid examples of totally indirect lighting, the semi-indirect seems to meet with almost universal favor; it possesses all the advantages of the totally indirect and has, in addition, several good features: First, the place where the light originates is readily detected by the layman (which is a natural condition, for during a long period of years man has grown used to seeing the source of light, either in its full brilliancy or shaded); second, the fixture does not show up as a dark spot against a white background; third, it is possible to make the units of etched and tinted glass, which are really things of beauty; and fourth, the semi-indirect is under most conditions a little more efficient than the totally indirect system.

Whatever system is adopted, the relation of the lighting to the architecture should be given much consideration. This is a feature which in the past has sometimes been neglected. Now, however, the introduction of many types of diffusing and directing media has drawn the attention of everyone to the great possibilities for effects which may be secured with the aid of artificial lighting. Direction and color of light play such an important part in the design of an interior, that a simple means of investigating the effects produced by any given system is desirable. Many lighting engineers have constructed boxes arranged somewhat in the form of a miniature theatre, with means for directing the light from above, below, at the sides, etc., and also means for changing the color. In this box are placed various pieces of ornaments, pilasters, friezes, etc., and the direction of light is varied. The play of the shadows and high lights is remarkable and often startling in its variations. Then a portion of colored decoration is placed in position and mixtures of various colored lights introduced until the desired result is secured. Slight experimentation along this line may often save much time and expense to the designer.

It is obviously impossible to discuss all classes of interiors, but a few types have been chosen and a brief summary of their requirements is outlined, accompanied by a few illustrations showing the method employed to carry out the ideas embodied in the text.

The classes outlined are widely diversified and the illustrations show the use of quite different systems, as it is desirable to demonstrate in as brief a manner as possible the wide range of application of illuminating devices.

### Art Gallery Lighting

Three factors which are prominent in the correct lighting of art exhibits are: (a) direction of light; (b) color of light; (c) intensity.

(a): When lighting paintings the light source should be arranged to throw practically all of its light on the exhibit and none in the eye. This must strike the work at such angles that it is not directly reflected into the eye, and yet it must cover completely the surface to be illuminated.

In lighting statuary, it is necessary that the units be located so that daylight is simulated, and corresponding shadows formed. Horrible distortions often result from the incorrect placing of lighting units around a piece of statuary.

(b): The color must be approximately that of average daylight, to avoid distortion of the paintings, for we see objects by reflected light and regardless of the color of the surface. If the same color is not present in the light source, the object appears black, or, in other words, reflects no light. For example, a red apple appears black under a pure blue light.

(c): The intensity of light must be such that all the important parts are readily discernible. This requirement varies with the

Fig. 1. A Good Method of Low-Intensity Direct Illumination, Especially Suited to Art Gallery Lighting

Fig. 2. A Well-designed Semi-indirect System for Lighting a Drafting Room

Fig. 3. An Example of Good Lighting in a Department Store

Fig. 4. An Excellent Method of Lighting a Dining Room, Semi-indirect Units being Employed

nature of the exhibition. For instance, a delicate pen and ink sketch demands a higher intensity of illumination than an impressionistic painting, for the discerning of detail is of more importance. Again, a picture in light colors will require less light effective on it than one in dark tones, for it will reflect more light proportionately. This discrimination is only of use where individual lamps light individual paintings; otherwise the intensity of light on the picture walls must be sufficiently high to light the dullest painting to the correct intensity.

In general, a painting gallery should have a relatively low intensity, 1 to 2 foot-candles, of well diffused general illumination. This is necessary to prevent contrast, to facilitate passage about the room, and to provide light for the reading of catalogues, etc.

The exhibition walls should be the most brightly lighted portion of the room. They should have an intensity of from 5 to 10 foot-candles, depending on the character of the exhibition, as explained above. One method of obtaining this, which gives excellent results, is the use of correctly designed, properly located, asymmetric reflectors. Individual angle steel, aluminum interior finish, one piece mirrored glass, or sectional mirrored glass trough reflectors are found in general use.

A little calculation, supplemented by experimentation, is necessary for satisfactory service, always bearing in mind, in the art gallery, to avoid direct reflections from the cover glasses or glazed surfaces.

Quite frequently the galleries themselves are works of art, and the lighting must therefore be designed to be consistent with the period of decoration of the building, thus assuring architectural conformity.

Fig. 1 shows a commercial art gallery with a low intensity of general illumination from direct lighting units. The walls are illuminated by small lamps in specially designed trough reflectors.

### Drafting Room Lighting

The ideal condition is an even distribution of well diffused light of high intensity; there should be no objectionable shadows. These requirements may be met with the following systems:

(a) Semi-indirect or totally indirect illumination, undoubtedly, gives the best satisfaction. With these systems, sharp shadows are avoided, glaring light sources are not visible, and the light is well diffused. When a semi-indirect system is used, the glass should be quite dense and have a low intrinsic brilliancy; the walls should be light in color, and the ceiling pure white. The installation should be maintained in good condition to obtain maximum efficiency. From 5 to 9 foot-candles intensity is required. The power necessary to produce this illumination will vary widely with the conditions of the reflecting surfaces.

Fig. 2 shows the application of a semi-indirect system to an engineering drafting room.

(b) Direct general illumination with a high intensity, 6 to 10 foot-candles, with very closely spaced bowl-shaped reflectors and bowl frosted lamps.

Due note must be taken of the arrangement of boards relative to the windows, locating the lamps so that, as far as possible, the direction of artificial light is the same as that of daylight. Lamps must be hung well out of the angles of vision, and every effort made to avoid glare.

(c) A system which is quite frequently found is the use of diffuse general illumination, using 1 to 2 foot-candles, supplemented by a local lamp for each drawing board. This unit may be one of several varieties, fixed or movable, attached to the wall or to the drawing board, with opaque or diffusing reflector and various sizes of lamps. In any case, it is open to the usual objections of local lamps; namely, liability of glaring reflection, loss of time in shifting the lamps, and a relatively high maintenance cost.

Tracing may often be satisfactorily accomplished by having the top of the tracing table made of etched glass, and lamps with suitable reflectors placed below the glass, illuminating the work from beneath rather than above.

### Hotel Lighting

This is one of the fields where the decorative element is a dominant feature. As a result of this, the practice varies widely, and it is therefore only possible to delineate a few of the important points.

The marquise is usually outlined with low wattage all-frosted lamps, or clear regular lamps in opalescent caps. This furnishes adequate illumination for the reception of guests, and also serves as an advertising medium. The entrances are often illuminated by lantern type fixtures with clusters of lamps, the design of the fixture harmonizing with the period of the building.

The lobby is the portion of the structure which exhibits the most novelty in its lighting, and direct, semi-indirect or totally indirect systems in elaborate forms have all found application.

The crystal chandelier and glass wall fixture, or candle-stick, central units and wall brackets with candelabrum lamps, find wall brackets with candelabra lamps, find much favor in the ball room, and produce the sparkling, cheery illumination which is so desirable here.

The parlors, writing rooms, and the like are usually illuminated to a very low intensity by decorative portable or local lamps, as privacy is desirable here, and lights concentrated at various points seem to produce this effect.

Corridors should be illuminated with efficient units, as these lamps are burned continuously.

For bedrooms, side wall brackets equipped with 25-watt bowl frosted lamps and diffusing reflectors should be located at the sides of the dresser and chiffonier. A central diffusing ceiling unit is also desirable for furnishing general illumination.

Fig. 5 shows a bedroom illuminated by a totally-indirect lighting fixture. The distribution of light is even and the appearance pleasing.

Two systems are in general use in the dining rooms: One provides a moderate intensity of general illumination (see Fig. 4, showing the application of this system using a very shallow opalescent dish as a semi-indirect lighting unit); the other system supplies a very low intensity of general illumination, which is supplemented by lights on each table. Low wattage, all frosted mazda lamps with decorative silk or glass shades are applicable here. This arrangement is usually to be preferred, as it creates the air of coziness and comfort so desirable in rooms of this nature.

Utility of lighting is of much more importance than artistic appearance, in the service departments, kitchens, pantries, etc. A high intensity of illumination will increase the efficiency of the service by facilitating cooking, reducing breakage, and, primarily, promoting cleanliness. Enameled steel reflectors with clear mazda lamps, since they are efficient and sanitary, find application here.

### Store Lighting

There must be the correct quality and quantity of light to insure advantageous

Fig. 5. A Pleasing Light Distribution in a Bed Room secured by a Totally Indirect Unit

presentation of goods, and there must be no discomfort arising from the lighting system.

In general, we may divide stores into three classes: Ordinary small stores, large dry-goods and department stores, and high grade shops.

In the small stores, high efficiency of light utilization, low initial cost, low maintenance, and simplicity are the prime factors. Artistic appearance cannot be had cheaply, and the amount spent for light in this case is of necessity low.

On account of this demand for efficiency, the direct lighting system is usually the only one applicable. Reflectors should be chosen to give distributions suitable for the type of store to be illuminated. Some, for instance, require a maximum light on the counters, with less on the side walls; others need the highest intensity on the walls; and some, as the manicuring parlor, demand localized lighting. Considerable data have been published on the subject, giving results of investigations and recommendations.

The department store should have a harmonious system of lighting for the entire building. Efficiency and artistic appearance have more nearly equal weight. Artistic lighting implies good diffusion, and this cannot be obtained with the commercial illuminants without some absorption of light. We must balance the two factors; that is, sacrifice some of the efficiency to obtain good diffusion and a harmonious layout. In general, any floor in a department store requires the same intensity of illumination throughout, except where there are departments requiring special lighting, such as rug racks, cut glass, etc. Therefore, for the sake of appearance, if nothing else, it is best to have one type of unit used throughout the entire floor. It is essential to space the units symmetrically with the bays and columns, and it is also very desirable to hang the lamps at the same height. Suitable diffusing or enclosing globes should be used and the system maintained carefully, as this adds greatly to the appearance of the store.

Fig. 3 shows the use of the one-piece totally enclosing opalescent balls in a department store.

The high grade shop is usually small in size, lavishly furnished, located in some fashionable section, and only the best grade of goods handled. The proprietor is accustomed to spending large sums for rent, equipment and general up-keep, and more money can be spent for individuality of layout. A distinctive lighting system is therefore appropriate. Artistic appearance is the predominating factor and efficiency is secondary consideration. The lighting system should harmonize with the architecture and preferably be designed to be strictly in accord with some predetermined plan.

In concluding an article of this character, a summary of the points which are desirable qualities of good illumination is in order. In brief these are:

*Intensity of Illumination:* That is, the correct amount of light must be supplied on the object to be illuminated.

*Diffusion of Light:* This implies the avoidance of glare in its many forms and the elimination of sharp contrasts.

*Direction of Light:* Important when lighting works of architecture and art, and also objects with overhanging parts likely to cast shadows.

*Distribution of Light:* This quality varies with the nature of the service, some interiors demanding an even illumination; others a concentrated light.

*Color of Light:* Of extreme importance in lighting fabrics, paintings, and the like.

*Steadiness of Light:* This is always an essential if our eyes are to work at maximum efficiency without undue strain. Reliability and continuity of service have much weight in connection with interiors where crowds are likely to congregate, as in the store, assembly hall, and the like.

*Economy:* This factor must always be considered but never to the extent of sacrificing adequate and correct illumination for a low cost of operation.

# THE ILLUMINATION OF ART

By M. Luckiesh

Physical Laboratory, National Electric Lamp Works, General Electric Company, Cleveland, Ohio

This contributor points out that without light there could be no art, and that after the artist has completed his work the results may be either marred or beautified by the quality and direction of the light used to illuminate it. Some of the illustrations show very plainly what incorrect artificial illumination can do to give an incorrect rendering of the artist's work. Correct lighting for paintings in art galleries is one of the difficult subjects dealt with in this article.—Editor.

**M. Luckiesh**

All works of art in the field of sculpture, architecture and painting depend for their expression upon the combination of light, shade and color. Light is essential for the existence of a subject to paint or a form to model. It is therefore the first requisite to art because it illuminates the subjects and as far as vision is concerned it creates them. Light is likewise the final requisite in art because it illuminates the artist's product and here again it has complete control. The artist with his brush or chisel is in reality a mediary who awaits in readiness to transfer a mood or expression of light to a permanent record. He is a link between two lightings. Light then creates art subjects, the artist preserves them, while proper lighting makes these records visible in all their beauty. In fact proper lighting can even overcome certain handicaps which to the artist are insurmountable.

Art in general is badly lighted. This is due to a variety of causes, chief among them being the lack of knowledge regarding the possibilities of lighting. The field of art therefore offered a worthy problem for research. Obviously the method of procedure was to investigate the effect of lighting on light, shade, and color in works of art, for it is in the combining of these factors that the creation of art is found. The distribution of light determines the light and shade in a sculptural work or in a painting. The relative amounts of direct and diffused light determine the character of the shadows in sculpture. Therefore the expression of a sculptured model depends upon the position of the light source and the relative amounts of direct and diffused light. The importance of proper lighting in this branch of fine art is well illustrated in Fig. 1. Here the head of Loacoön, that most expressive work among the antique, is lighted by a single light source from various sides. It is impossible to give empirical rules for the lighting of art because art can not be manufactured nor can the lighting be applied by rule of thumb. Each subject must be studied separately and the lighting should be the result of a combined knowledge of the science of lighting and an appreciation of art. In large exhibits of sculpture a procedure which should prove successful would be to place the works in a long narrow room, lighting them predominantly from one side. Greater control of light would be found in dividing this long room into stalls and controlling the reflecting power of the walls in order to obtain a proper relation of direct and diffused light.

In the lighting of paintings will be found an interesting field for the endeavors of the lighting artist. If possible both the position of the light source and the quality or tint of the light should be carefully determined for each painting. Here it is well to state that the writer's experiments show that each painting should be treated specifically. The limitations of pigments are a source of much trouble for the artist. In fact they present handicaps which the artist alone cannot overcome. The range of brightness in a landscape is usually many times greater than the range obtainable from pigments. That is, the artist's white is not nearly as many times brighter than his black when illuminated by the same light flux density as is necessary in depicting nature. However, by directing more light upon the high lights in a painting than upon the dark portion a great increase in contrast range can be

Fig. 1. Effect of Distribution of Light on Sculpture

secured This is illustrated in Fig. 2. It is evident that different moods are expressed by the painting. It should be borne in mind that the object in lighting is to carry out the artist's hope and intention. Therefore, there is but one mood to be sought. To give the painting a lighting which would tend to create another mood would be assuming that lighting can produce art, which is quite certainly untrue. The lighting will be serving well if it is done in such a manner that the artist's hope is realized. The quality of light is of highest importance because it affects all three factors—light, shade and color. It is well known that the standard illumination for paintings has been daylight. Daylight, however, differs with time and place. Paintings are done in many kinds of daylight varying both in intensity and quality. They are then illuminated by many kinds of daylight and artificial light. If the painting remains a work of art throughout all this abuse then the production of a work of art is a simple matter. But this cannot be; therefore each painting should be treated with a lighting adapted to it. Fig. 7 shows the effect of quality of light on a picture specially painted for the purpose. In one case the mountain has completely disappeared. The most practical scheme resulting from the writer's experiments involves the correction of each picture to daylight appearance by adding to the ordinary artificial light those rays demanded by the picture under consideration. This can be done by the use of colored lamps or glass. The proper proportion can easily be attained by varying the relative sizes of the clear and

colored lamps or by other means. This scheme obviates the necessity for correcting the entire spectrum when for instance there are no blue colors in the painting.

This scheme has recently been applied to a large temporary art exhibit in Cleveland and has met with the approval of all concerned. The lighting of art promises an extensive field of endeavor for the lighting artist. Further it is gratifying to note the growing importance of the lighting specialist, for here he has been permitted to tread on most delicate ground, where as one artist expressed it: "Lighting is everything."

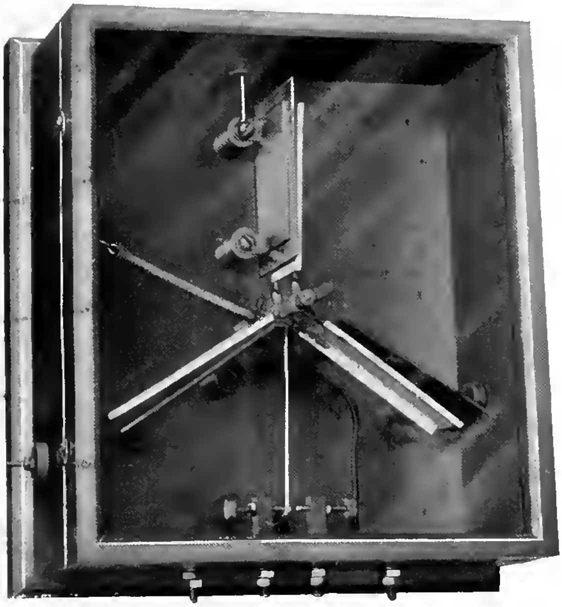
## POTENTIAL INDICATING STATIC RELAY

The protective apparatus laboratory has developed a simple electrostatic relay for indicating potential on high tension circuits. It consists of three stationary brass plates separated by mica and air from three movable plates mounted on a common shaft which is grounded and carries a low voltage contact. The fixed plates are connected through the capacity of standard suspension insulators directly to the high voltage circuits, and by properly choosing the number of insulators the relay can be applied to any circuit above 10,000 volts. It is used either to close the circuit for an indicating device, such as a lamp or bell, or for operating one of the points of the multirecorder.



## VOLT-AMPERE CHARACTERISTICS OF THE VACUUM TUBE

The Geissler tube or luminous glow of the electric discharge in partial vacuum is the most fascinating of all the light sources, but although a vast amount of work has been devoted to it, we have not yet succeeded in developing it into an illuminant which can compete in efficiency with the high efficiency mazda lamp and still less with the high efficiency luminous or flame arc. However, everybody who has ever studied the vacuum glow thinks that there may be and probably are possibilities of efficiency in it which make it unwise to entirely abandon its investigation.

A large amount of study has been given by the Consulting Engineering Department, for a number of years, to the investigation of the electrical and luminous characteristics of the vacuum tube discharge.

The electrical characteristics in many ways differ materially from those of the arc, and of all other conductors. In the Geissler tube, at constant gas pressure and constant temperature, the voltage dissipated is, within a considerable range, approximately independent of the current, that is, the "effective resistance" is inversely proportional to the current.

The voltage dissipated by the Geissler tube, or Moore tube, very greatly depends on the gas pressure. With gradually decreasing gas pressure, that is, increasing vacuum, the voltage dissipated by the tube first decreases, then reaches a minimum, usually between 1 mm. and 0.1 mm. pressure, and then increases again, and the tube becomes unstable, i.e., shows a tendency to arcing.

The tube voltage consists of two components which vary with the pressure in opposite direction: the stream voltage, that is, the voltage consumed by the gas space between the terminals, is proportional to the length of the tube, and decreases with decreasing gas pressure; and the terminal voltage, that is, the voltage dissipated, mainly as heat at the terminals, is independent of the tube length, and increases with decreasing gas pressure. The sum of both voltages, or tube voltage, therefore reaches a minimum at some intermediate gas pressure; at higher pressures the stream voltage predominates, at lower pressures, the terminal voltage.

As the stream voltage is proportional to the tube length, and the terminal voltage independent thereof, the minimum point of the tube voltage, or total voltage, is not at a definite gas pressure, as sometimes assumed, but depends on the length of the tube; it occurs at a lower gas pressure with longer tubes, and at a higher pressure with shorter tubes.

At the minimum voltage point of the tube, with air and similar gases the terminal voltage is usually of the magnitude of about 1000 volts, and the stream voltage about 5 volts per cm. Much lower values are given by some of the noble gases, as argon, neon, etc.

J.L.R.H.

## QUESTION AND ANSWER SECTION

The purpose of this department of the Review is two-fold.

First, it enables all subscribers to avail themselves of the consulting service of a highly specialized corps of engineering experts, or of such other authority as the problem may require. This service provides for answers by mail with as little delay as possible of such questions as come within the scope of the Review.

Second, it publishes for the benefit of all Review readers questions and answers of general interest and of educational value. When the original question deals with only one phase of an interesting subject, the editor may feel warranted in discussing allied questions so as to provide a more complete treatment of the whole subject.

*To avoid the possibility of an incorrect or incomplete answer, the querist should be particularly careful to include sufficient data to permit of an intelligent understanding of the situation. Address letters of inquiry to the Editor, Question and Answer Section, General Electric Review, Schenectady, New York.*

### Announcement

This issue marks the first anniversary of the Q. and A. Section. At the time of beginning this department of the Review we adopted the policy which we believed would best fulfill the requirements of the service offered. We have held tentatively to this practice during the entire year, studying meanwhile how to be of greater benefit to all of our subscribers.

A careful review of the year's work confirms the fact that the original policy was fundamentally a satisfactory one, but we have decided, however, to make a greater distinction between the two functions of the department. An explanation of this new policy is given at the head of the section. It is not a radical departure from our previous practice but is a more definite and extensive one. It will enable us to improve the efficiency of the mail consulting service to the individual subscriber and to increase the attractiveness of the published answers. By including short reading articles or digests of such questions as are worthy, it is hoped that this section will be made one which is eagerly sought for at the coming of each issue.—Editor.

### MOTORS: DEFINITIONS

**(86) Will you kindly furnish definitions and give authority for the following terms?—Open motor, semi-enclosed motor, enclosed motor, totally enclosed motor. Would an induction motor with enclosed slip rings and dust-proof bearings be considered as an enclosed motor?**

We do not believe that at the present time there is any definite rule completely covering the various types. Our understanding in general is, that the open motor is one without any attempt at protection. The semi-enclosed motor is a very broad term and means anything from a partially protected motor to a drip-proof motor. However, we take it to mean more of a mechanical protection than anything else. Enclosed motors or totally enclosed motors mean one and the same thing, but as there are several different types of enclosed motors, each one would have to be specifically mentioned. For instance, there is the entirely enclosed self-contained motor without any external ventilation, there is the enclosed self-ventilated motor, and the enclosed motor with external pressure blower; both of the latter use a pure air intake pipe. There are also motors enclosed against dust and other motors enclosed for protection from moisture and dampness.

An induction motor with enclosed slip rings and dustproof bearings would not be considered an enclosed motor.

In any enclosed motor the rating depends entirely on the system of ventilation used. Therefore, the difficulty of making any simple classification of these various terms can be readily seen.

A.E.A.

### INDUCTION REGULATORS: OPERATION

**(87) Is it possible to operate three-phase, induction, revolving-armature, feeder regulators on single-phase lines?**

Three-phase feeder regulators may be operated on single-phase lines, in which case it is necessary to leave one secondary phase open circuited and to short circuit upon itself the corresponding primary phase, the other two phases, both primary and secondary, being connected in series. When operating single-phase the line current should not be more than about 75 per cent of that when operating three-phase, as otherwise the heating of the short-circuited coils may become excessive. The voltage of the single-phase line may be the same as that between phases of the three-phase line.

M.U.

### LIGHTNING ARRESTERS: DESIRABILITY

**(88) Are lightning arresters considered necessary on 2300-volt alternating-current lines running along steel mill buildings, either for protection against direct lightning or to take care of switching disturbances?**

The danger from lightning on short feeders for steel mill service has never been considered as being very serious. Potential surges, however, resulting from switching and sudden changes of load have frequently broken down apparatus. Since interruptions to steel mill service are of a very serious consequence, on account of the importance of continuous service, it is advisable to install aluminum lightning arresters at the generating stations and on the feeders of the more important mills.

V.E.G.

### ROTARY CONVERTER: 3-WIRE NEUTRAL

**(89) Is it possible to use the transformer or auto-transformer of a rotary converter for deriving the neutral of a three-wire machine, as shown in Fig. 1, instead of bringing out the neutral to slip rings and using a three-wire compensator? What will be the characteristics of the transformer and converter operating on an unbalanced load under these conditions?**

This method is entirely feasible and is commonly employed. It is, however, customary to use transformers rather than auto-transformers for the alternating-current side of rotary converters, as the ratio of transformation is usually too high to make auto-transformers economical. To derive the neutrals of three-wire generators, auto-transformers (sometimes called compensators or balancing coils, when used in this way) are used.

The direct current from the neutral wire divides equally between the three legs of the transformer. The transformer here spoken of is of the three-phase shell type, but three single-phase shell or core-type machines are equally applicable. The following statements apply to each of the preceding transformer installations.

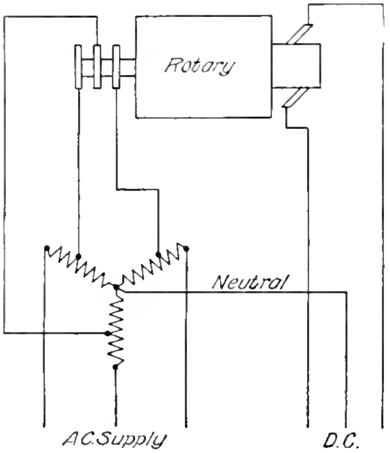


Fig. 1

When the transformer is Y-connected, the flow of direct current gives a biased magnetic condition, increasing the transformer exciting current with a change of wave shape. This increase in exciting current is roughly equal to the direct current (increasing, therefore, with the unbalancing). There is also some additional loss in the transformers due to the increased current density in the windings, and a small increase in iron loss due to the unsymmetrical cycle, since the maximum flux of one polarity is greater than normal.

To eliminate this increase in exciting current and core loss, one of the two following methods must be employed:

(a) The use of the so-called "zigzag" or distributed Y-connection (see Fig. 2). In this connection two separate windings are provided for each phase, one winding of each phase being connected to a similar winding in another phase to form a leg of the Y. The effect of the direct current in one winding is completely neutralized by the direct current in the other winding of the same phase, these currents being equal and opposite. With this connection, the exciting current and core loss are normal.

(b) The use of a three-legged (interlinked magnetic circuit) core-type transformer with a straight Y-connection. (See Fig. 3.) Here equal amounts of direct current flow in the same direction in the windings of the three legs and tend to cause equal fluxes in the same direction in the three legs. These fluxes cannot close in the iron circuit but must close in the air as leakage flux. On account of the high reluctance of the air, the fluxes are cut down to a very small value and therefore have a negligible effect upon the exciting current and core loss. Transformers for use in this service are never built with the straight Y-connection, except in the three-legged core type. For all other constructions, the "zigzag" winding is used.

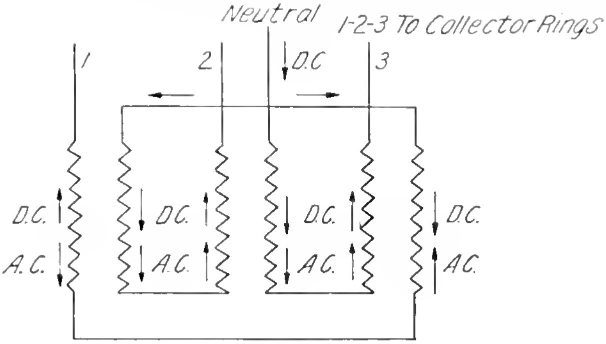

Fig. 3

One feature that may be considered a disadvantage to the use of auto-transformers in deriving the neutral is the fact that if either the a-c. neutral or the d-c. neutral is grounded both are grounded, and this is objectionable. If one side of the d-c. circuit is grounded instead of the neutral, it would successively ground the different a-c. phases.

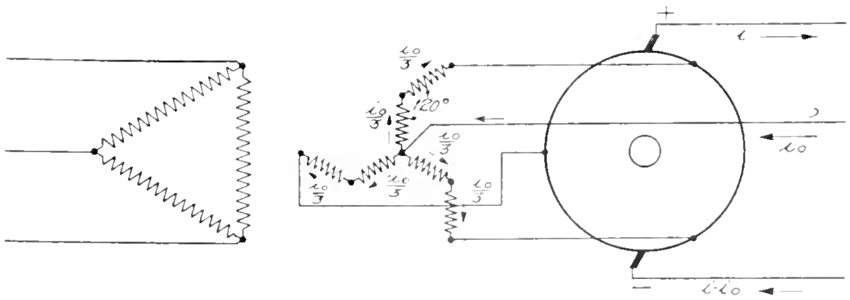

Fig. 2

### LIGHTNING ROD: PROTECTION

**(90) Is the application of a lightning rod to a brick chimney to be recommended?**

A lightning rod on a chimney or on a house is extremely useful in the case of a direct stroke of lightning. When used on a chimney, three small rods spaced 120 degrees, or four at 90 degrees apart are better than one for protecting the chimney from damage. Even an iron wire running down a wooden post gives a high degree of protection as a lightning rod against direct strokes.

E.E.F.C.

### ALTERNATORS: LINING UP

**(91) The revolving fields of two similar alternators are to be mechanically locked together and driven by the same prime-mover. The generators are to be run in parallel. What is the best means of determining the angular location of the fields (relative to each other) that the machines may give the most effective parallel operation?**

There are several methods whose results are indicative of the location desired. All of them require that the leads of one armature be connected through ammeters to the corresponding leads of the other machine; and, also, that there is some facility for shifting the rotative positions of the two rotors, or stators, relative to each other. Since it is more often the case that there is a coupling between the two machines, the methods which are most applicable to this condition will be first taken up.

*Stationary Method*

Assuming that the armatures of the two machines have been connected together as previously described, connect the two fields in series across a direct-current supply, having a quick-break switch in the circuit. When the current through the fields has reached its steady value, after closing the switch, there will be no tendency of the armature ammeters to register a deflection, their needles remaining stationary over the zero of the scale. Now suddenly break the field circuit. Unless the two rotors have been set correctly the first time, the ammeters will show a "kick." This indicates a flow of current in the leads, which is just the condition that it is desired to avoid. Make note, at this time, of the relative position of the two rotors, which is easiest done at the coupling, then shift one of them slightly and repeat the test. Being guided by the succession of positions and their corresponding ammeter readings, the zero-exchange-current position can soon be arrived at.

It is evident, of course, that an alternating-current excitation of the two fields in series will give readings equally as indicative as the direct-current. In the case of the use of alternating current, however, the armature ammeters will always give a deflection until the rotors are correctly placed, at which time they will read zero.

*Rotating Methods*

If undrilled couplings are used between the alternators, the adjustment can be made by drilling two diametral bolt holes in the one half and two corresponding slotted holes in the other half. If the couplings have already been drilled, two diametral holes of one half may be slotted. As a matter of precaution, wedges should be driven in the slotted holes beside the bolts to prevent the rotors from slipping relative to each other, because of the exchange current which will almost certainly occur at first. This construction will permit of the rotors, which should now be bolted together at the couplings, being shifted relative to each other. The machines should now be driven at some certain speed and be excited equally at some certain current. Read the exchange amperes armature, and, if not zero, shut down. Note the position of the two rotors to each other and then shift one a slight amount relative to the other. Drive the machines again, and repeat the test as many times as is necessary to reduce the reading of armature amperes to zero.

If for any reason it is inconvenient or inadvisable to slot the couplings or the rotors are pressed on the same shaft, or some equivalent condition making it impossible to change the position of one rotor relative to the other, the following procedure will furnish satisfactory results.

First, line up the two rotors on the shaft as accurately as possible, mechanically. Driving the machines with low field excitation, read the exchange current on these meters. It is possible that the precautions so far taken, in the lining up of the machines, will have been sufficient. There is, however, quite a possibility that the exchange current may be of such a magnitude as to render parallel operation impossible or inadvisable. This condition may have been caused by an inaccuracy in the mechanical lining-up of the two rotors on the shaft or by the stators not being located in exact similarity. It is always best, under the conditions last assumed, to rectify any irregularity by experimenting with the stator. This is permissible, so far as the results are concerned, for it is immaterial whether the rotor or stator is revolved.

By means of raising one side of the stator and lowering the other, inserting and withdrawing shims beneath the stator feet to accomplish this, the stator may be "revolved" a small amount. If the machine has many poles this small angular displacement will represent a considerable shift of phase, measured in electrical degrees, and may be sufficient to accomplish the purpose desired. It will be more expedient, in case a large movement is required, to entirely remove the sub-base of the generator under consideration and to support it upon a temporary adjustable one, so that greater travel can be accommodated. With these wider spread limits available, the stator may be revolved through a greater angular displacement. Care, at the same time, should be taken that the air-gap around the field is always held uniform. During all these trials, the measurements of armature exchange current should be made at the same field excitation and speed, in order that the value of exchange amperes may be indicative of the angular displacement of the machine. When the position of zero current, or minimum current in all three lines, is arrived at, the angular displacement of the stator, from its normal bed-plate position, should then be measured. This displacement may then be transferred to the rotor, which should now be located by a special offset key, cut for that purpose, and the stator returned to its normal position upon the bed-plate.

GEORGE WESTINGHOUSE

# IN MEMORIAM

George Westinghouse crowded the sixty-eight years of his life full of hard work, noble deeds and kind acts.

He constantly bent his energies to the solution of problems which meant progress to civilization and congenial and helpful employment for his fellow men. To his powerful intellect and well trained mind the most complex and difficult tasks yielded their answers in simple terms. To the achievements of this man in mechanical, electrical and scientific fields the industries of the world will pay homage for generations to come.

The attractiveness and charm of his personality rivalled his genius. His character was most interesting and fascinating because it combined with a powerful intellect and an indefatigable will, keen moral susceptibilities, a chivalrous manner, a quick sense of humor, deep rooted convictions of honor, cordial sympathies and an affectionate disposition.

Those who knew him but slightly admired his manifest genius; those who knew him intimately found their increasing admiration and respect outrun by their affection for him.

In his death mankind loses a benefactor, his industries a wise counsellor, the thousands connected therewith a considerate employer and his associates a loyal friend.

As one who has had the honor of a close friendship with him for more than twenty-five years and has felt the inspiration of his manly qualities, I deem it a great privilege to express in the pages of your journal this brief tribute to his memory.

Charles A. Terry

---

Mr. Terry's tribute will appeal to all who knew Mr. Westinghouse, for all who knew him admired and loved him. His versatility, courage, optimism and zeal for accomplishment were an inspiration to all workers, and his personal magnetism was irresistible. His life's work entitles him to a prominent place in constructive history, and his contributions to industrial progress will be of permanent benefit to mankind. The close of his splendid career will be universally regretted.

E. W. Rice, Jr.

GENERAL ELECTRIC REVIEW

## THE PATHS OF PROGRESS

The paths of progress have been well trodden during the nineteenth century and the first decade of the twentieth. Many illustrious men have come and gone and left their mark; some as scientists, some as engineers, and some as organizers of mighty industries, each playing his part in our march of progress. As we go to press with this issue, we hear with the deepest regret that the unique career of one of these great men, Mr. George Westinghouse, is closed by his death, which occurred in New York City on March 12th. The work that he accomplished during his life will live for generations and the world at large will still continue to profit from the results of his fertile imagination and untiring effort although his labors have been brought to an end. Mr. Westinghouse was a man of remarkable capabilities, and by virtue of his force of character and indomitable courage, these capabilities brought a rich harvest of accomplishments.

It is as an engineer and organizer that he is best known to the world. The results of his labors in the invention, development and perfection of the air brake are known in every country, and the many industrial plants that he has built up and organized remain as a monument to his genius as an organizer of men. The breadth of his work is one of the most remarkable features of his career, he was an active worker in many branches of engineering, but we do not propose to cite examples of his activities, as these have been so thoroughly covered in the daily press.

The career of Mr. Westinghouse as an organizer is of special interest. His work in common with that of others in the same direction has played a very prominent part in the development of the electrical industry, which was born during his lifetime and which he lived to see become one of the greatest industries of modern times. For its present greatness the industry is largely indebted to those who in its early days saw the possibilities in it and had the courage and faith to spend their work and money in developing these possibilities until they became accomplished facts. A quarter of a century ago, most of our largest electrical factories were non-existent. The changes between then and now have resulted, very largely, from the labor of those who have organized and co-ordinated the work of many active men in one useful direction, and among these, one of the most prominent was Mr. George Westinghouse. Where the engineer uses material matter in accomplishing results, the organizer uses men, handling their brains and energy as the artisan handles tools. Without the organizer effective progress is almost impossible. It is the focusing of many different types of minds in one direction, the concentration of different species of skill in a harmonious effort to accomplish a desired result, that leads to efficiency and enables useful work to be done economically and thereby at a profit.

When the early pioneers had shown the rapidly extending scope of the electrical profession and had demonstrated that there was a tremendous field for the upbuilding of profitable undertakings, many more able men entered the field and the growth of the industry was phenomenal. The number of people employed in the manufacture of electrical apparatus and in its operation and maintenance forms no inconsiderable proportion of the industrial population. Most, if not all, of those people are working under conditions that are vastly superior to the ordinary industrial conditions that existed formerly. Mr. Westinghouse, as one of the organizers in the electrical industry, is responsible in a marked measure for its upbuilding. It is impossible to estimate exactly the extent of our indebtedness to an individual, because a great man's work always stimulates the efforts of others, and the influence of his power is felt far beyond his own immediate sphere of action. Mr. Westinghouse has passed beyond our ken, but his work lives on, and all of us, associates and competitors alike, feel that—losers though we are by his death—we shall still continue to be gainers by the example of one whose courage and perseverance has led to so many notable advances along the paths of progress.

# ELECTRIC LIGHTING OF STEAM PASSENGER EQUIPMENT

By C. W. Bender

Manager Commercial Department, National Lamp Works

The advantages of electric lighting for passenger service on trunk line railroads are well known, and the author does not attempt to present any arguments for its use. He has confined himself to a discussion of the systems in common use, which may be classified under three main headings, viz., straight storage, head-end, and axle generator. Each of these systems possesses advantages, and also disadvantages, over the other two systems, and these have been ably analyzed by the author. As adapted by different railroads, each system shows modifications that have been made to fulfill the needs of its special service, and each modified system is fully described and illustrated.—Editor.

The general public, who are continually demanding the use of electric lighting on all steam passenger equipment, do not realize the numerous difficulties to be encountered and overcome before any system employing electric energy as an illuminant can be considered wholly satisfactory.

It should be borne in mind that provision must be made for supplying light regardless of whether the train is in motion or at rest and, in the latter case, during stoppage of short or long duration. Another, though less obvious, difficulty is the necessity of providing means of automatically compensating for the various demands for light occasioned by the changes in length of the day at different seasons, of meeting the variation in conditions of service under which a car may be running and of providing against sudden dark weather at any time of the year. The problem has been studied by many authorities and attacked in many different ways, each of which has purported to eliminate some special difficulty of other methods, though not infrequently introducing drawbacks of equal or greater weight in some unforeseen direction.

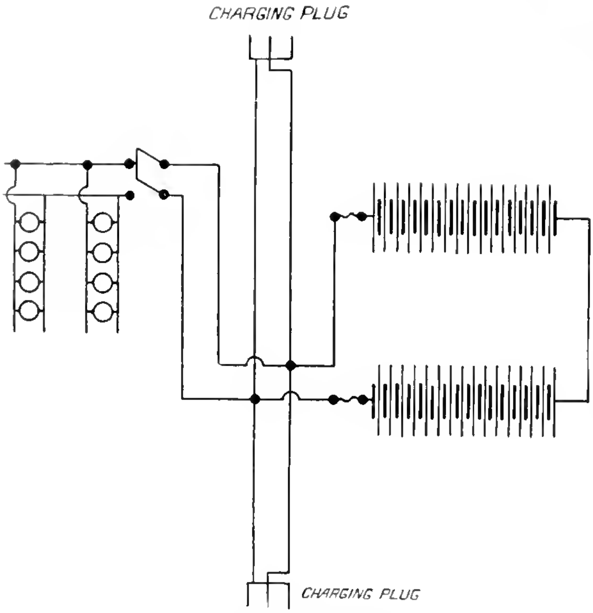

Fig. 1. Straight Storage System—Wiring Arranged for Charging and Discharging Batteries in Series

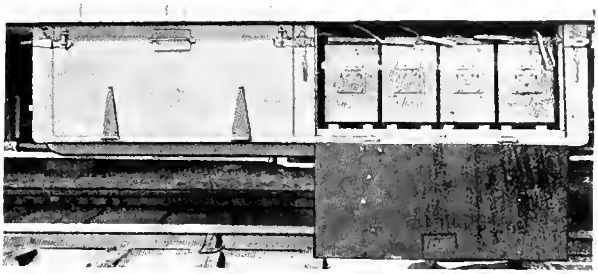

Fig. 2. Storage Battery Mounted on Car

Electric light has the advantage of eliminating open flames in the car, which vitiate the air and produce the unpleasant feeling of nausea. The heat given off from the incandescent lamp is very much less than with gas lighting. This is an item of special importance in the summer months. The discarding of the highly charged gas tanks is a point greatly in favor of electric systems. It is a step toward further safeguarding the traveling public, as statistics show that explosions have resulted disastrously in many wrecks.

Electric lighting lends itself more freely to combined scientific and artistic illumination of passenger equipment. A light source can be controlled by artistic and effectively designed reflectors to govern any condition from the baggage room to the parlor car.

Many engineers have worked on the railway lighting problem for the past 25 years and only within the past five years could it be stated that electric lighting was satisfactory. The improvement has been due not a little to the increased efficiency of incandescent lamps as well as improved train lighting apparatus, such as generators and regulators. The methods used for the electric lighting of passenger equipment today can be classified under three different heads: straight storage, head end, and axle generators.

The straight storage system, as ordinarily installed, consists of 32 cells of 300 ampere hour batteries, which are generally arranged in groups of two cells in double compartment lead lined tanks, the batteries being arranged under the car in special compartment boxes as shown in Fig. 2. It is impractical to change the batteries in a car at the end of each trip except in case of absolute necessity. The cars, therefore, must lay over in the terminal yard a sufficient length of time to charge the batteries. An elaborate and expensive yard wiring system is required in order that the charging circuit can be plugged to the batteries regardless of the position occupied in the yard. Another disadvantage is the fact that a lead storage battery is subject to temperature variations, the capacity dropping off approximately 5/8 per cent for every degree drop in temperature below 70 degrees. It is obvious, therefore, that in extremely cold weather the battery capacity may drop to such a point that sufficient capacity is not available to care for the lighting over a very long trip. With carbon filament lamps, the possibilities of the straight storage battery method of lighting were exceedingly limited, but the advent of the high efficiency mazda lamp, which requires approximately one-third the amount of current consumed by the carbon lamp, had the tendency of raising the number of straight storage battery equipments on the various railroads.

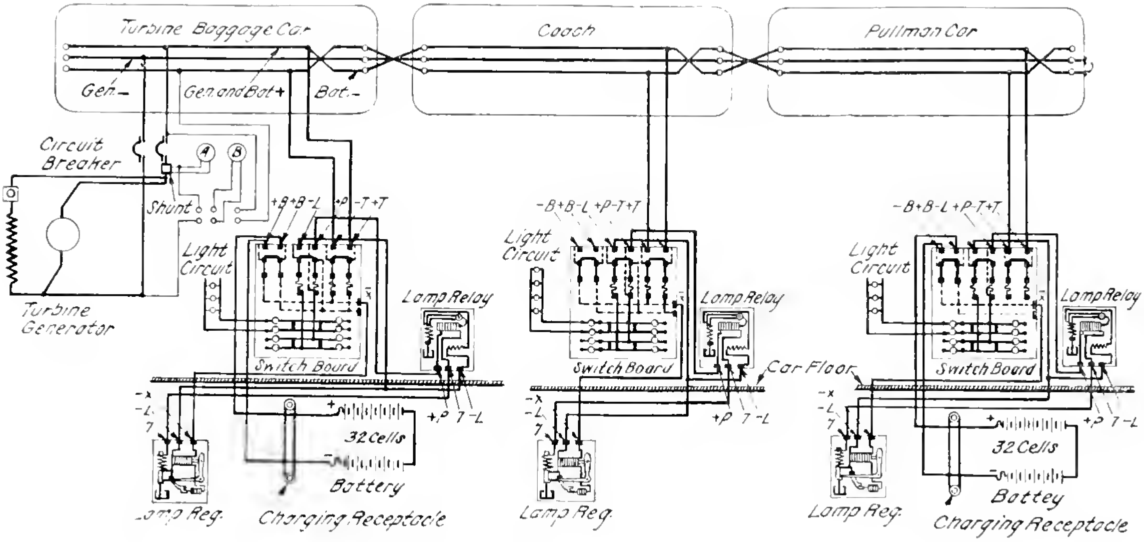

Fig. 3. Wiring Diagram—Baltimore & Ohio Head-end System

There are other disadvantages of the straight storage system, such as a car not being placed on charge at the terminal yard promptly, which introduces the possibility of leaving the batteries standing in a partially charged condition. Again a car going on to another road is subject to the possibility that it will not be properly charged or not charged at all, with the result that the battery is returned badly sulphated. Under these conditions it is often necessary to discard the plates altogether. Another disadvantage is that voltage variation on straight storage battery systems is considerable. A battery of 32 cells when fully charged will give a voltage of approximately 67. This greatly decreases during discharge until it has reached approximately 57 volts, but as the decrease is gradual it is seldom noticeable to the passengers.

## BALTIMORE AND OHIO HEAD-END SYSTEM

This system possesses the special feature of using automatic lamp regulators on each car to maintain a constant lamp voltage. The generator equipment consists of a 20 kw. 100 volt compound wound Curtis turbine generator operating at a speed of about 4500 r.p.m. at 80 pounds steam pressure.

Switchboards with the necessary instruments and overload no-voltage reverse current circuit breakers are provided which, with the generator equipment, are located in a separate compartment at one end of the baggage car. Steam piping is so arranged that either end of the turbine car may be operated towards the locomotive. The batteries consist of 32 cells of 300 ampere-hour capacity and are carried on all the cars of the train except the coaches and express cars. These generally average five batteries on a seven or eight car train.

Each car is provided with an automatic lamp regulator identical with that used for the Gould, Safety, and United States axle generators with a slight modification to adapt it to the larger voltage range met with in this service. The regulators are adjusted to maintain 63 volts on the lamp circuits, 63 volt mazda lamps being used.

The generators are operated at voltages varying from the lamp voltage to 90 volts, depending upon the amount of charging the batteries require. Normal train line voltage is maintained between 70 and 85 volts, thus insuring that the batteries are in a charged condition, or are being charged at all times. When turbines are operating during lighting hours with batteries in a fully charged condition, the voltage is reduced to about the floating point, thus carrying the lamp load entirely on the generators and at the same time preventing overcharging of the batteries.

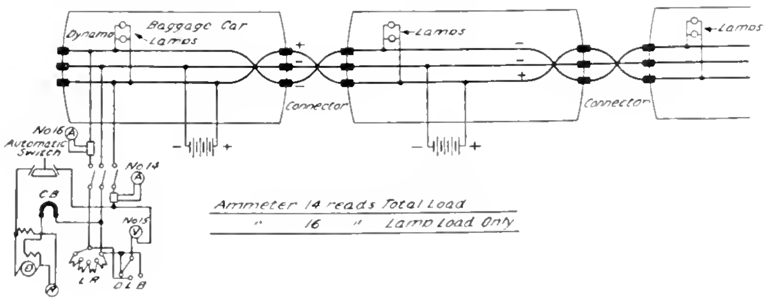

Fig. 4. Head-end System, C., M. and St. P.

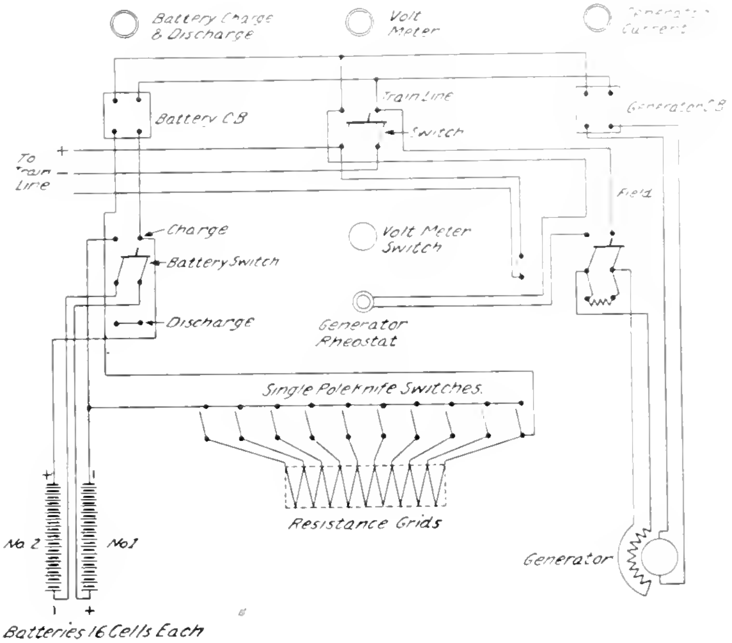

Fig. 5. Head-end System, Harriman Lines

Fig. 3 shows the wiring diagram of this system, from which it will be noted that the center diagram representing the center car is shown minus the batteries. It will also be noted that a pair of conductors are carried from the switchboard of this car to the main train lines, from which they obtain the necessary current for lighting the car.

## CHICAGO, MILWAUKEE & ST. PAUL SYSTEM

In this system the three-wire train line is so divided as to give two separate circuits, the one circuit carrying the batteries and the other carrying the lamps. This is effected by pulling down the loop at the rear of the train and closing the switch in the baggage car, the regular train wire being thus changed from the regular two-wire equipotential system as ordinarily operated, to the two separate two-wire systems having a common conductor, the positive of the three-wire system being used for the common conductor. Between this common positive and what is normally the generator negative, the batteries are connected, while the lamps are placed between the two outer wires and the train line, as is common practice on head-end systems.

A variable resistance is inserted in the lamp circuit, by means of which the electrician may maintain the lamp voltage constant, or the generator voltage may be varied to any desired value for the battery charging.

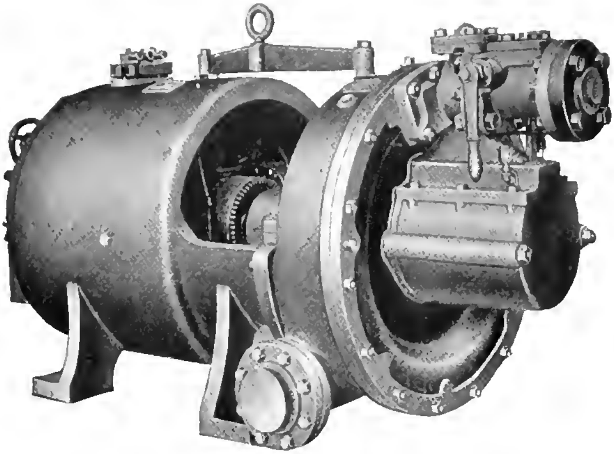

Fig. 6. 35 Kw. Curtis Train Lighting Turbine Baggage Car Type

## HARRIMAN SYSTEM

In the Union Pacific, or Harriman system of head-end lighting, the battery charging is done about midnight, when the lamp load is low. To do this the battery switch is thrown to the charging position. It takes 2.5 volts per cell to charge a battery to full capacity, and, while the train lighting voltage of 64 would not be sufficient to charge 32 cells in series when the battery switch is thrown to the charging position, the battery is cut into two halves of ten cells each and they can easily be charged with the standard lamp voltage of 64 by inserting an iron grid resistance in series with the batteries to keep the charging current from rising to such a high value that it might buckle the battery plates or overload the generator.

As the battery charging proceeds and the current tends to fall off, it may be boosted by cutting out a portion of this grid resistance and raising the impressed voltage of the battery by special single-knife switches located on the generator switchboard.

## HEAD-END SYSTEM

The head-end system of lighting was first attempted with a generator in the baggage car and no batteries, but, by reason of frequent lighting failures due to the train being parted and the locomotive being uncoupled from the train, it was found necessary to place storage batteries on the first and rear cars of the train. Such a system works out satisfactorily, provided the train is never parted and that when locomotives are changed at the division points the transfer is speedily made.

Another difficulty enters into this method of lighting through the possibility of a breakdown of the generator in the baggage car, which would cause a lighting failure of the entire train, and recourse must be had to some auxiliary lighting system; therefore the general practice today of having batteries on practically every car on the train.

Head-end systems are operated on the Harriman Lines, C. B. & Q., C. & N. W., Northern Pacific and Great Northern roads, where the runs are exceptionally long; while in the East the B. & O. is the only road that has continued to use this system.

The C. B. & Q. railroad are operating suburban trains out of Chicago, using a turbine generator placed on the top of the locomotive boiler. No batteries are used in these trains, but the runs are very short with sufficient lay-over at terminal points to properly care for the generator, the cars never being used in any other than this particular service.

All of the roads using head-end systems have adopted 63 volts as standard, i.e., 32 cells of 300 ampere-hour storage battery being used on the various cars.

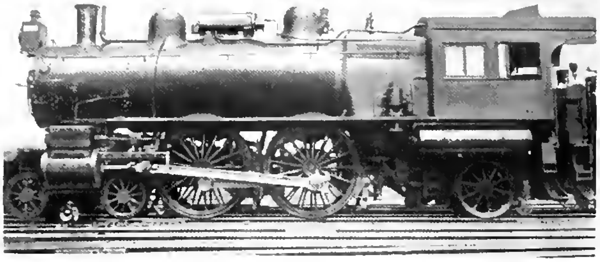

Fig. 7. Side View of Curtis Turbine Generator Mounted on Engine. Pennsylvania Locomotive

One of the difficulties to be overcome with such a system is the fact that to fully charge the 32 cells of battery requires 84 volts to be impressed across the battery, while on discharge in maintaining the lighting circuit the battery will return from 63 to 64 volts. Regulators must therefore be used on the various cars, or an excessive number of lamps will be burned out in the process of battery charging. This is overcome to a certain extent by operating the generator in the baggage car at 72 volts. With an equipotential system of wiring on the cars, and allowing for a drop in the train lines, this will impress approximately 66 volts across the lamps. At night, when very few lamps are burning, the generator voltage is raised to 78. This allows the batteries to be operated at a more nearly charged condition, with few of the lamps being subject to an excess current.

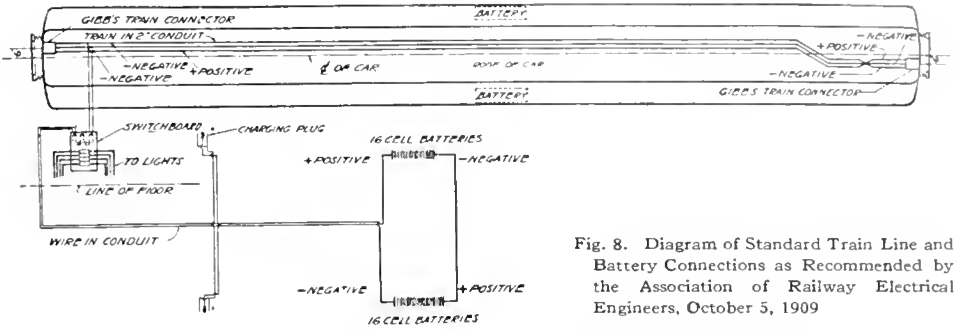

Fig. 8. Diagram of Standard Train Line and Battery Connections as Recommended by the Association of Railway Electrical Engineers, October 5, 1909

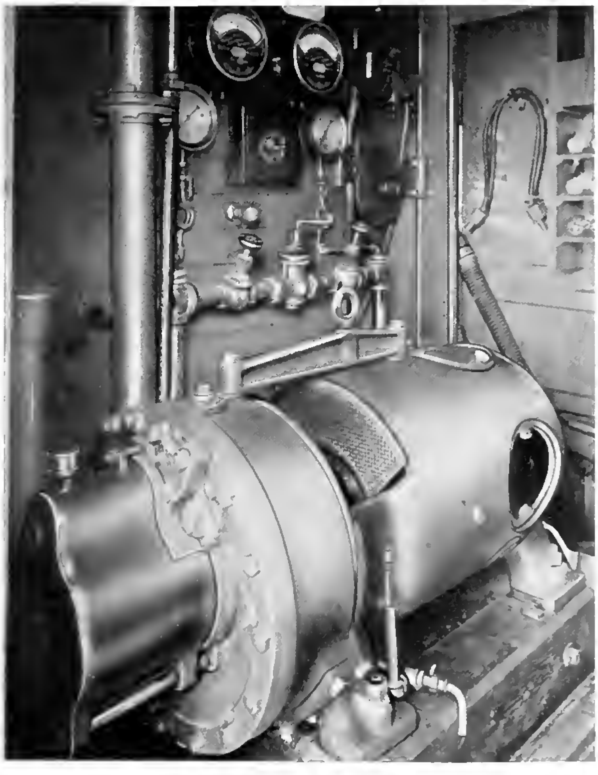

Fig. 9. 15-Kw. Curtis Steam Turbine Train Lighting Set Installed in Composite Car

The more general practice today, however, is to use a regulator on each car, which permits the generator to be operated at the proper voltage for charging batteries, while the resistance, generally a carbon pile affair, reduces the current to the proper amount for the lamp circuits.

### AXLE GENERATOR SYSTEMS

The axle generator system has been greatly improved in the last four or five years, and while still the most expensive system to install, by reason of a generator being required on every car, it has the advantage of being a self-contained unit and therefore the car can be operated on any road with small chance of a lighting failure, as practically all roads have train lighting men who understand the various systems and maintain not only their own but foreign cars passing over their lines.

Furthermore, the axle system does not require the elaborate yard charging facilities that are needed for cars operating on head-end systems, or specially straight storage systems. There are numerous axle-generator systems both in this country and abroad, but space will not permit a description of all of these various types. The following machines are among the most prominent and a description of each will probably be of interest: Consolidated, Gould, Safety, United States, Stone.*

---

* Used in England and Colonies, as well as in some other countries of Europe.

## CONSOLIDATED SYSTEM

### Generator

The generator is of the four-pole, interpole, shunt wound type with cast steel frame, and has a rated continuous capacity of 45 amperes at 60 volts.

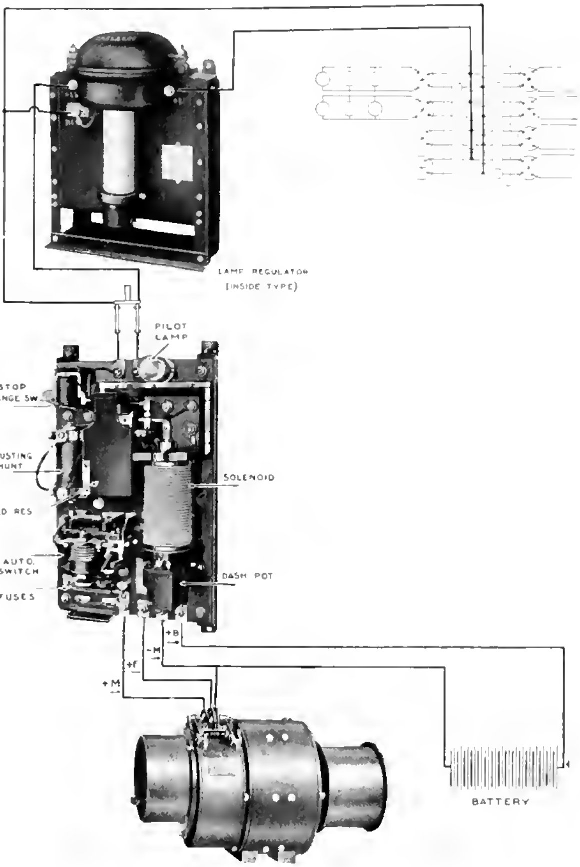

Fig. 10. Showing the Wiring for Connecting the Consolidated Axle Light System, Dynamo with Regulator

The bearings are of the ring oiling type and are carried in the heads, which are secured to the field frame by cap screws. Large oil wells are provided, which are fitted with overflow pipes to prevent overfilling. The armature coils are form wound, and the armature shaft is removable. The brushes, of which there are four sets, are carried in cast brass holders, which in turn are supported by the generator frame.

### Pole Changer

The armature shaft carries a worm operating a cam, which throws a switch when the direction of rotation of the armature is reversed, as is the case when the car is run in a reversed direction. The proper polarity is thus maintained for charging the batteries, regardless of the direction in which the car may be moving.

### Regulator

The Type L regulator consists of a solenoid connected in series with the generator. The solenoid core actuates a rocking contact arm, the contact operating over a series of bars connected to a continuous resistance consisting of metallic grids proportioned to suit the field of the generator.

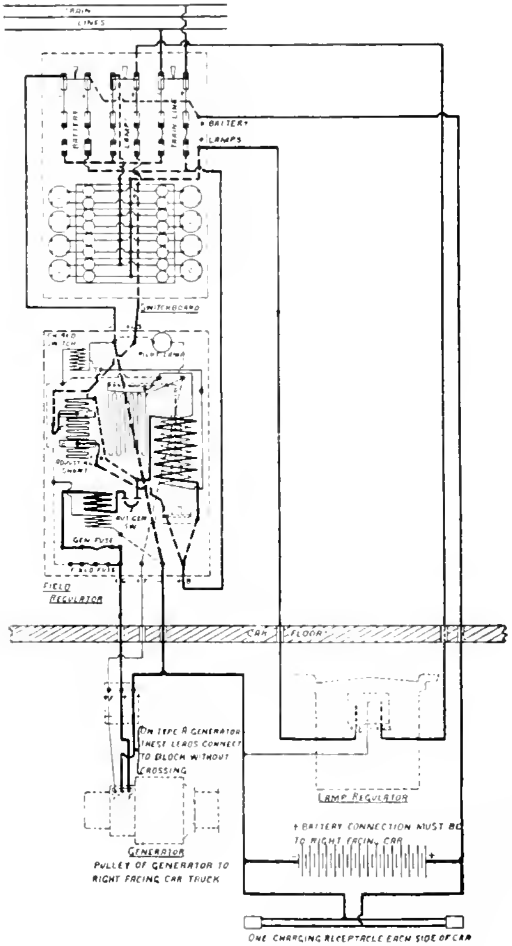

Fig. 11. Wiring Diagram of Complete Equipment with Pullman Switchboard, Dynamo with Regulator

An adjustable shunt is provided, by varying which the amount of current from the generator to lamps can be set at any desired value within the range of one-third to full lamp load. A stop charge switch is also employed for cutting off the generator current when the battery is fully charged. This switch may be adjusted by varying the air gap between the armature and its magnet by means of a graduated cam. The winding of the switch coil is connected across the generator leads, while a second shunt coil is added to the governing solenoid, so that when the first coil closes the switch at some predetermined value the second shunt coil adds additional strength toward drawing up the solenoid core and inserting additional resistance in the generator field, thereby reducing the generator output.

## GOULD SIMPLEX SYSTEM

### Generator

The generator is a multipolar shunt wound machine of the enclosed type, having a cast steel field frame with laminated pole pieces. The bearings are of bronze, the oiling being accomplished by packed oil waste or rings, as desired. The commutator end of the generator is provided with handholes and covers so that the branches are readily accessible.

The leads to the generator brushes and fields and the external leads from the generator are brought to a terminal block in the top casing of the commutator end of the generator. The pole changer is mounted on the shaft directly under the terminal block.

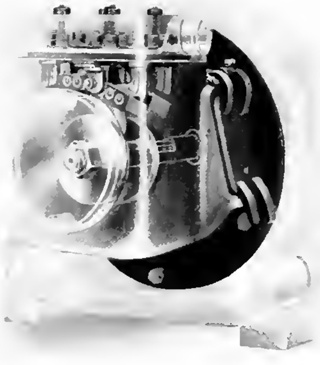

Fig. 12. Gould Pole Changer

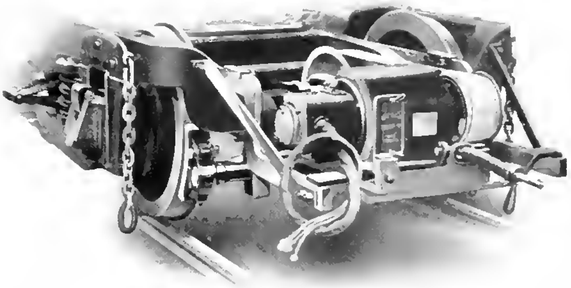
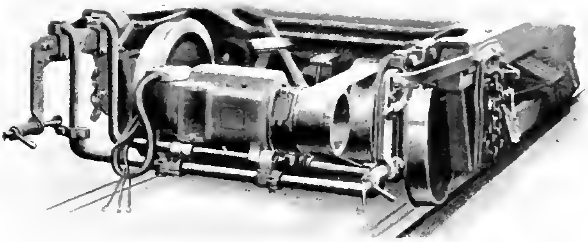
### Pole Changer

The pole changer, a phantom view of which is shown in Fig. 12, is of the mechanically operated type, comprising a double-pole double-throw switch interposed between the brush leads and the external leads of the generator. The switch throwing mechanism comprises an eccentrically drilled weight pivotally mounted on a carrier, the latter being mounted on the armature shaft. The weights have forward and rear projections which act on the front and rear switch blades when the direction of rotation is reversed. When the switch is tripped the throw is completed by a spring toggle, which prevents further contact with the tripping mechanism when the direction of rotation is again reversed. In Fig. 12 the rear projection of the weight is about to throw the switch to a position corresponding to right-hand rotation; should the direction be reversed, the front projection of the weight, coming in contact with the lug on the front switch blade, would throw the switch in the opposite direction, thereby maintaining the proper polarity of the generator leads.





Figs. 13 and 14. Gould Drop Type Suspension

### Generator Suspension

This generator is suspended by means of the link type or the drop type suspension. Views of these are shown in Figs. 13 and 14, in either of which provision is made for alignment of the generator shaft with the car axle and the generator and axle pulleys, while the tension of the chain or belt drive after being set is regulated by springs.

### Automatic Switch

The automatic switch is of the laminated copper contact type with auxiliary carbon break, and is closed against the action of gravity by the lifting of its solenoid core. There are two windings on the solenoid, one a shunt coil across the generator mains, the other a heavy series coil connected in series with the generator mains. When the generator voltage reaches the proper value the shunt coil becomes sufficiently energized to raise the plunger and close the switch. The series coil is then energized and reinforces the action of the shunt coil, assisting in holding the contacts or switch closed. Should the generator speed be decreased and the voltage drop to that of the battery voltage, the latter will tend to discharge through the series coil in an opposite direction, thereby neutralizing the fall of the solenoid, and gravity, reinforced by the switch springs, will cause the switch blades and generator circuit to open. On top of the solenoid plunger are a metal disk and laminated copper brushes which serve to short circuit the series coil of the regulator simultaneously with the operation of the switch. This prevents the current due to the lamp load from exerting an effort to raise the solenoid plunger of the series coil of the regulator, which would increase the resistance in the field circuit and tend to prevent the building up of the generator.

### Generator Regulator

The generator regulation is effected through the compression of carbon pile disks in the generator field circuit. A variable compression of the disks is obtained by the movement of two lever arms, one of which is actuated by the solenoid plunger of a series coil in the battery branch circuit; the other being actuated by the plunger of a shunt coil connected across the generator mains. So long as the battery is not fully charged, the variable compression on the carbon disks, obtained through the lever actuated by the plunger of the series coil, maintains the generator current practically constant by increasing or decreasing the resistance of the carbon pile, should the current tend to increase or decrease from normal.

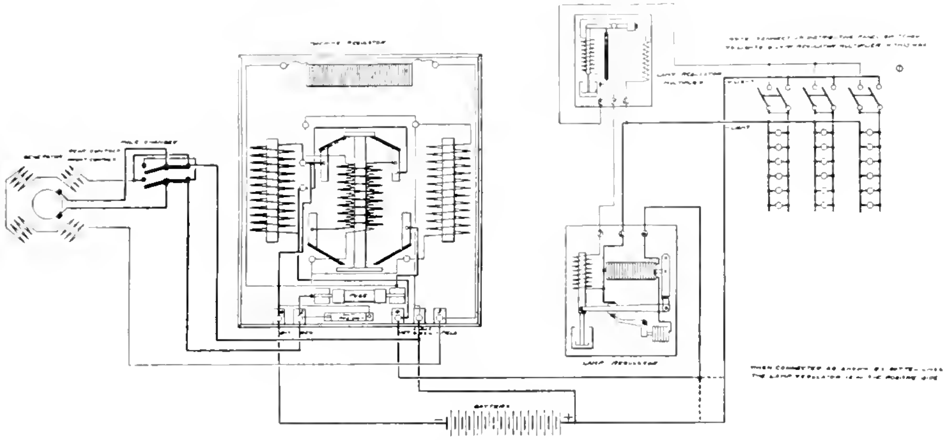


Fig. 15. Wiring Diagram, Gould System

When the battery becomes fully charged, as determined by its attaining a definite limiting voltage, the shunt coil of the regulator becomes sufficiently energized to lift its plunger, thus decreasing the compression of the carbon pile resistance through the movement of the other lever arm. Under this condition the plunger of the series coil is no longer sustained, as the current to the battery is reduced. The control of the field strength, and consequently the voltage, then results from the shunt coil. The current output of the generator is reduced to the value of the current required for the lamps that are burning, the voltage thus corresponding to that of the fully charged battery.

The shunt coil also acts as a prevention against excessive generator voltage, should the battery circuit be broken for any reason. In this event the generator supplies current for the lamps when the speed of the car is at or above the minimum limiting speed.

The solenoid plungers are restrained from oscillation by means of dashpots, while, to ensure the building up of the generator in case of loss of residual magnetism, a resistance unit is connected between the battery and armature circuit, which permits a small amount of current to flow across the armature, breaking down any resistance that may exist.

### Lamp Regulator

Lamp regulation is obtained by pressure exerted upon a series of carbon disks, this pressure being varied inversely with the voltage of the generator. The variable pressure is obtained by a lever arm actuated by a solenoid plunger, the current in the solenoid coil being controlled by an auxiliary regulator, also of the carbon pile type, acting as a multiplier. Thus a very slight increase in voltage of the lamp circuit results in a decided increase in lifting effort on the main plunger, thereby maintaining the lamp voltage and candlepower at approximately constant values, regardless of any variation in generator and battery voltage. The regulator is always in the circuit when the lamps are burning, but the carbon pile resistance is shunted gradually as the battery discharge proceeds.

## SAFETY CAR HEATING & LIGHTING CO.

### Generator

The generator, which is made in 2.6 and 4 kw. sizes, is a multipolar shunt wound machine, with a one-piece steel magnet frame and interchangeable cast iron heads for bolting to commutator or pulley end of the magnet frame. The bearings are of the bushing type, made of bronze, and are alike for both ends of the generator. The bearings are obtainable in either the waste-packed or ring-oiling type, the oil being added through a filling tube in the side of the head, which also acts as an overflow, the low lip of the filling tube determining the proper level of the oil.

The armature is form wound with fireproof insulated wire, the coils being held in slots by hard fiber wedges. The brushes are eight in number (two to each holder), each having a separate trigger with spring tension to maintain the contact with the commutator. Each brush has the usual copper shunt to maintain a good contact with the brush-holders.

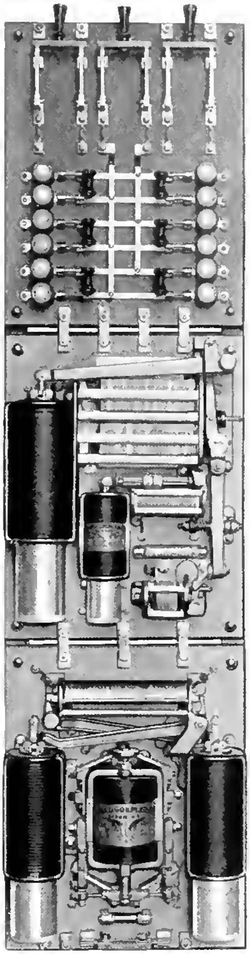

Fig. 16. Simplex Regulator and Distributing Panel

### Pole Changer

The current direction is maintained constant by rotating the brushes through an angle of about 90 deg. whenever the direction of rotation of the armature is changed. The four brush-holders are mounted on an insulated supporting ring which acts as an outer race of a ball bearing, and is slipped over a finished hub on the commutator head and held in place by a snap spring ring. The brush rocker has two stops about 90 deg. apart, with luggage projections cast on the head. While running, the friction of the brushes on the commutator holds the rocker firmly against one of these stops. Reversing the direction of rotation causes the brush rocker to be turned over against the other stop, changing the position of the brushes, but maintaining the same polarity as before.

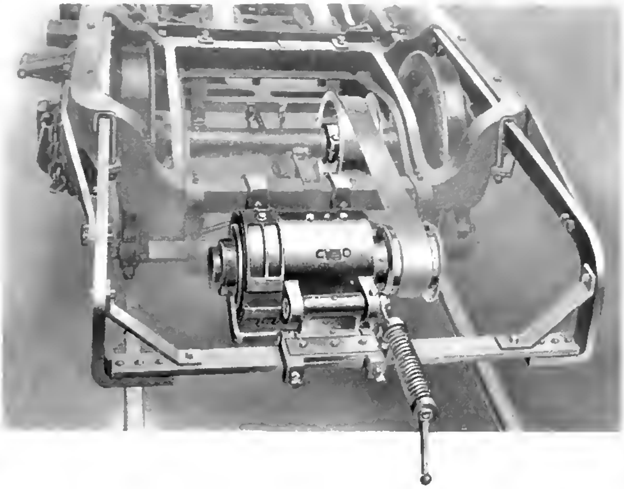

Fig. 17. Dynamo Suspended on Six-Wheel Steel Truck

### Generator Suspension

The generator is supported as shown in Fig. 17. The horizontal shafts by means of which the generator is suspended pass through holes in the projections cast on the field frame, these shafts in turn being supported by links carried by movable pieces resting on heavy horizontal bars. These bars in the case of steel trucks are passed through holes in the end of the truck frame and then bolted.

The dynamo is mounted on the car truck outside the end sill and is driven by a belt from a pulley on the car axle. Fig. 33 shows the general arrangement as applied to a standard form of cast steel truck. The heavy horizontal steel bars from which the dynamo is suspended pass through holes in the end of the steel frame of the truck and are bolted to the frame. The ends of these bars are turned down and securely clamped together by an angle iron, which serves as a brace and supports the tension rod. These bars are further strengthened to prevent lateral motion by braces bolted to the end of the truck. The dynamo is suspended on two horizontal shafts passing through two lugs on each side of the dynamo frame, the two lugs having a long bushing between them. These shafts are supported on each end by links carried by movable pieces resting on top of the horizontal bars. These pieces are adjusted by means of screw bolts to give proper alignment with the car axle, and are held securely, after being adjusted, by means of bolts passing through plates bolted to the supporting bars. A safety chain is attached to the dynamo and the end of the truck, and another safety chain to the dynamo and the angle iron which serves as a brace for the ends of the suspension bars. When the tension spring, which surrounds the tension rod, is compressed by the nut, it tends to pull the horizontal bars and generator away from the truck and give the required tension to the belt. As the vertical center line of the dynamo remains vertical with any movement of the dynamo, the belt tension is the same with either direction of drive.

### Automatic Switch

The automatic switch is of the closed magnetic type, having a fine, or shunt winding, connected across the generator circuit, and another winding connected in series with the circuit. When the generator voltage rises to the proper value, the shunt winding is energized sufficiently to raise the solenoid

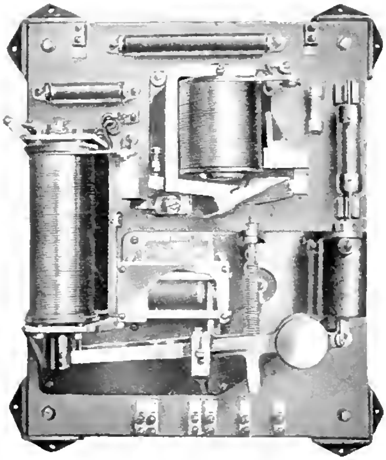

Fig. 18. Dynamo Regulator Panel

and close the heavy laminated contact, when the series coil maintains a firmly closed contact. When the generator voltage drops to that near battery voltage, the battery current, being in the reverse direction, causes the switch to kick out.

### Dynamo Regulator

When the dynamo is at rest the carbon disks in the field are tightly compressed by the pull of a spring so that the resistance is very low. As soon as the armature revolves, current is generated which flows through the field coils, energizing the lifting coil of the main switch. When the voltage is the same as the battery voltage, the main switch closes, connecting into the circuit a series coil which holds the switch firmly closed. As the current rises, a pull is exerted on the plunger of a solenoid magnet and the pressure on the carbons is decreased, thereby increasing the resistance in the field circuit.

## U-S-L SYSTEM

### Generator

This generator is of the multipolar type with a cast steel field frame. The armature is form wound. The bearings are of the ring oiling type. There are two brush-holders, which are accessible through a handhole with removable cover.

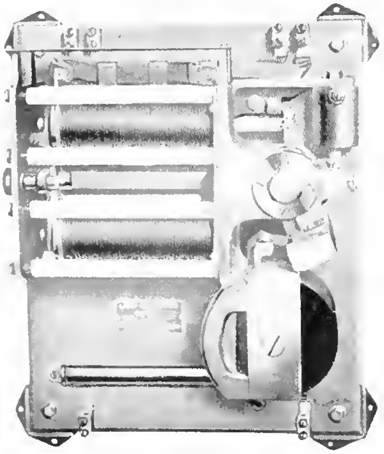

Fig. 19. Lamp Regulator Panel

### Pole Changer

The pole changer consists of a movable wrought iron ring carrying the current contacts, stationary contacts, and the steel plunger which is attached to the armature shaft. The function of the plunger is to engage the movable ring under a train speed of three miles per hour and rotate it so as to maintain the generator in proper relation with the battery. Above a speed of three miles per hour the plunger is disengaged by centrifugal force.

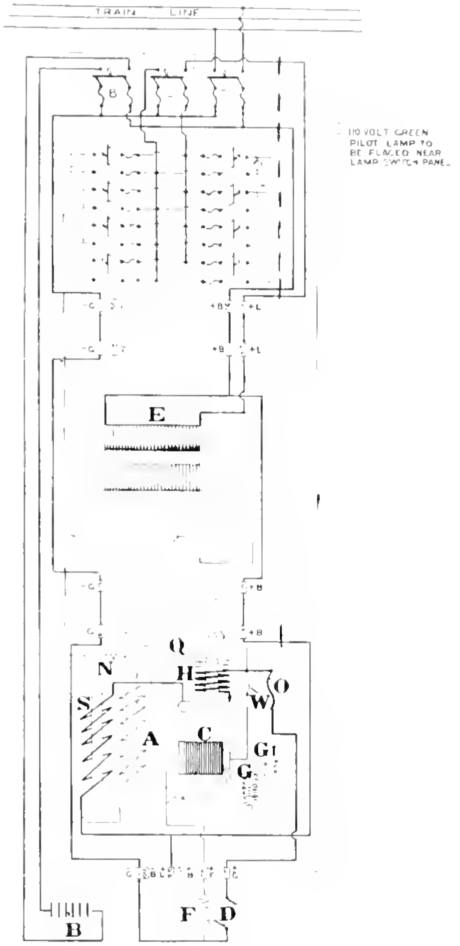

Fig. 20. Wiring Diagram Lamp Regulator in Car

### Drive

The generator is belt-driven, the proper tension being maintained by the use of helical springs attached to the under side of the generator and made adjustable with the suspension.

### Suspension

An overhung suspension is employed. The generator is supported from a $2\frac{5}{16}$ in. shaft which passes through two lugs, the latter being integral parts of the generator frame. Alignment of the machine may be made by shifting the bearings carrying the above mentioned shaft. The weight of the generator is taken directly by spring bars bolted to the truck. Cushion and recoil springs are inserted between these spring bars and a rigid "andle," which is also bolted to the truck.

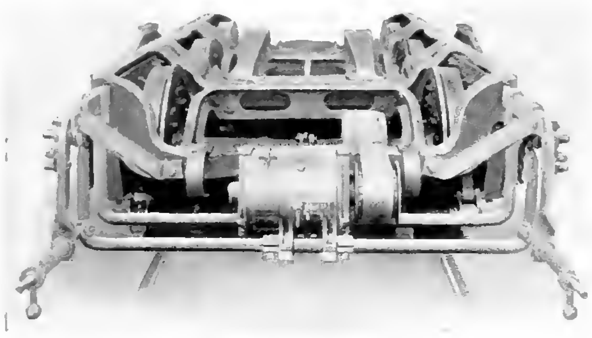

Fig. 21. Generator Mounted on Wide Non-Adjustable Parallel Link Suspension Applied to Steel Truck

### Generator Current Regulator

The current regulator consists of an iron-clad solenoid having a single heavy winding of edgewise wound copper bar connected directly in series with the armature of the generator, and through which the total armature current of the generator flows. The plunger of this solenoid is free to move in a vertical direction through a distance of about ⅜ inch. To the lower end of the plunger is attached a graphite piston which fits a cylinder or dashpot, which in turn forms a part of and is cast integrally with the frame of the solenoid. This dashpot is nearly air-tight and contains no liquids of any kind, the entrapped air and the small clearance between the piston and the walls of the cylinder affording all the damping action necessary to prevent sudden or jerky movements of the plunger. The upper end of the plunger engages a roller, which is attached to the forked end of the horizontal arm of a bell crank lever mounted upon a hub post attached to the panel. The end of the vertical arm of this lever is attached to a thrust plate and carbon terminal block, which latter engages one end of a horizontal pile of carbon disks. The other end of the pile abuts against a solid support. The pile of carbon disks constitutes a variable resistance under the control of the solenoid and is connected directly in series with the field of the generator. The arbor upon which the bell crank lever is mounted is carried through the hollow hub post and slate panel and then bent at right angles behind the panel. The initial pressure on the carbon pile is produced by a weight mounted on the rear horizontal arm of the bell crank. This weight is fixed in value, and its location on the horizontal arm determined in the factory and neither can be altered; but its effectiveness may be altered by changing the angular position of the rear arm of the bell crank lever by means of a knurled nut which, being directly pinned to the arbor passing through the panel and attached to the bell crank by a removable screw, enables one to rotate the arbor and engage the bell crank at different angles

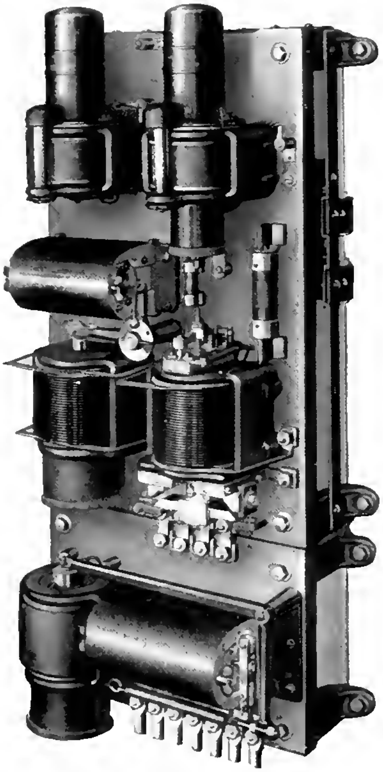

Fig. 22. Generator Regulator Panel with Lamp Regulator Panel Mounted Underneath

by shifting the screw in the knurled nut from one hole to the other.

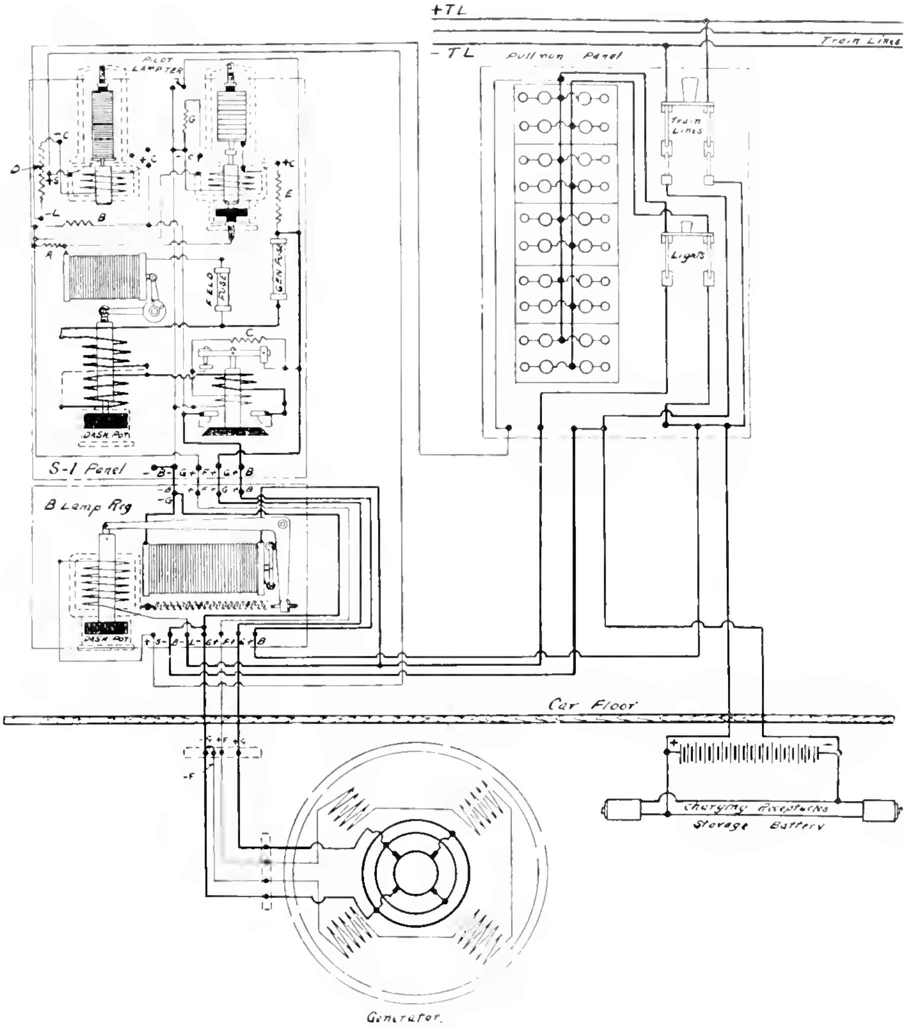

Fig. 23. U-S-L Panel with Lamp Regulator

**The Potential Regulator**

The construction of the potential regulator consists of an iron clad solenoid. It is provided with a single high resistance coil or winding wound on a copper tube, and is connected directly across the generator terminals which, after the automatic switch has closed, are the same as the battery terminals. Within the tube is an upper or fixed plunger and also a lower or movable plunger, the latter being mounted on a pair of parallel motion rods which permit of a frictionless vertical movement of the plunger within the tube. An air dashpot is formed integrally with the lower portion of the solenoid frame and a small graphite piston fitted therein, which is connected to the lower end of the movable plunger by means of a self-aligning connection. The dashpot serves to prevent sudden or jerky movements of the movable plunger. The bottom of the dashpot is made of molded insulating material, threaded and fitted into the dashpot. This insulating cover is provided with a carbon block terminal mounted on a screw, which is threaded through the cover and provided with a lock nut. The frame of the solenoid forms one terminal and the insulated carbon contact attached to the cover forms the other terminal of the resistance which is included in the field circuit of the generator and is normally short-circuited by the contact between the graphite piston and the lower carbon terminal. A brass tail rod is attached to the movable plunger and passes upward through a clearance hole in the stationary plunger. On the upper end of this rod is connected a cross bar, one end of which forms a rigid finger for the attachment of the helical adjusting spring, while the other is formed into a tapper which engages a roller on the end of a small multiplying lever. This lever is fulcrumed on a rigid support attached to the upper part of the solenoid frame. The lever engages a short vertical stud which passes up through the support to which the lever is attached, and supports the lower contact plate on which rests a vertical pile of carbon disks. The disks are confined within a cage whose vertical rungs are attached to the above mentioned support. The rungs are insulated with lava tubes, and thus the carbon pile is insulated from all metal parts with the exception of its lower carbon plate. A bonnet is attached to and insulated from the solenoid frame, and covers and conceals the carbon pile and its operating mechanism. In the top of the bonnet is mounted, by means of a steel adjusting screw provided with a lock nut, a carbon contact block which may engage the upper end of the carbon pile. A pressed cap fits over the top of the bonnet and covers and conceals the upper part of the carbon pile and the upper carbon contact.

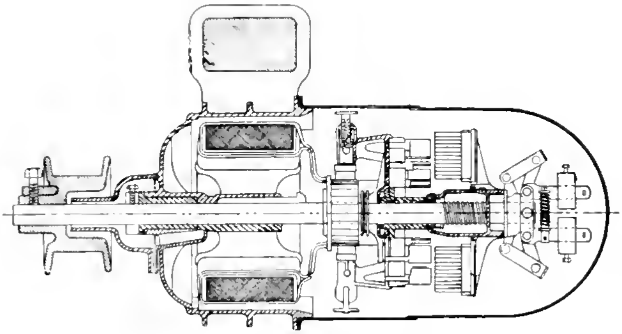

Fig. 24. Stone Axle Dynamo—Longitudinal Section

The action of the small lever provided with a roller is simply to increase the pressure exerted by the movable plunger of the solenoid upon the carbon pile, the dimensions of the lever being such that a multiplying effect of 2 to 1 is secured. The adjusting spring above mentioned is attached, as was stated, to one end of the cross bar fastened to the brass tail rod, and is enclosed within a brass tube mounted in lugs which are cast integrally with the frame of the solenoid. The magnetic pull of the coil is opposed by the weight of the carbon pile, the multiplying lever, and the movable plunger, and also by the tension of the adjusting spring.

## STONE SYSTEM

### Generator

The generator is of the two-pole shunt wound type with a rated continuous capacity of 18 amperes at 25 volts. The armature is of the old Gramme ring hand wound type. The bearings are of the ring oiling type and are carried by supports secured to the generator frame. The oil wells have an overflow pipe.

Two sets of brushes are carried in cast brass holders secured to the generator frame. The polarity is changed by means of a rocking arm and friction gear. Two plungers press against lignum-vitæ blocks on the rear end of the rocking arm by means of a spring engaging it and carrying it around to slots. After the arm is pushed home into the contacts, these plungers fly out free from the rocker arm when the centritugal force, due to the rotation of the armature shaft, is great enough.

The generator is suspended by means of an adjustable link in such a manner as to leave it free to swing. The belt is then adjusted to pull the generator out of the vertical position in which it would naturally hang, thus putting a tension on the belt sufficient to absorb power equivalent to the amount of current required at the speed for which the belt tension is adjusted. It is obvious, therefore, that increasing the speed will cause the belt to slip.

No regulator is used, as it is supposed that the cushioning effect of the batteries, in connection with a small resistance inserted in the lamp circuit and the slipping of the belt is sufficient to maintain the voltage within such limits that the variation in the candle-power of the lamps is not annoying.

The automatic switch is of the fly-ball type and is fastened on the generator shaft. As the speed is increased to a predetermined point, the weights are thrown out due to the centrifugal force and the contacts are made by knife blades being forced into the proper contacts.

Having attained the "cutting-in" speed, the centrifugal force on the governor weights will throw the pole changer to the proper position and cut in the automatic switch.

The generator is then supplying the current, any excess above that required for the lights going to the batteries. If the speed increases above the point at which the automatic switch is thrown in, the belt, if properly adjusted, will begin to slip as the generator is loaded, thus causing the voltage to drop, consequently decreasing the current

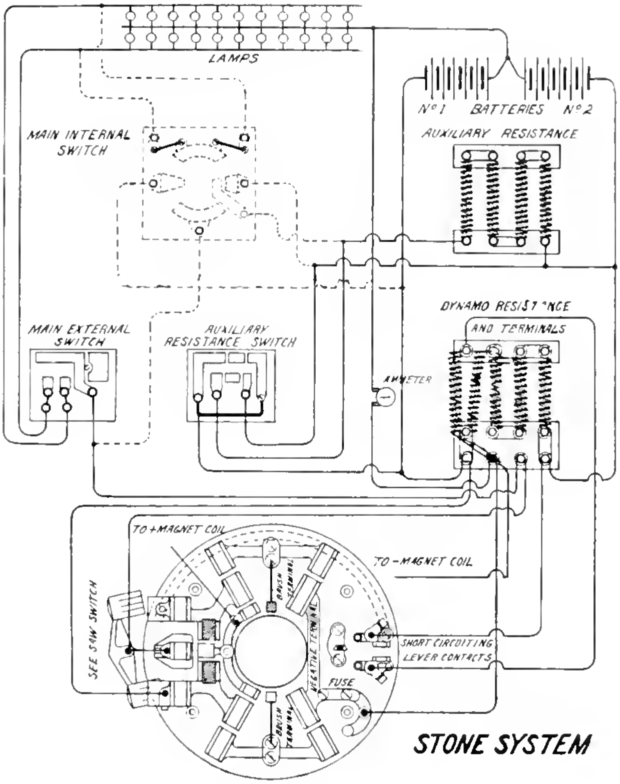

Fig. 25. Wiring Diagram

A question frequently asked is: "What particular system is best adapted to railroad work?" This question is difficult to answer from the fact that no one system is best for all cases; that is, by reason of train schedules, terminal lay-overs, organization, and the frequent interchange of equipment, no one system of lighting would give the most economical operation on all roads. For instance, a system that would be most economical for short runs, such as from Boston to New York and return, with the cars kept permanently on that run, would hardly prove to be the most economical when used in overland runs, such as from Chicago to the Pacific Coast.

Unfortunately, railroads which have adopted the head-end system of lighting are frequently handicapped by reason of the interchange of equipment with other roads, the cars of which do not have the same wiring system.

Where long runs are made, the cars of which are seldom if ever parted from one terminal to another, and no interchange of equipment with other roads is made, the head-end system with one generator taking care of the battery charging and the lighting for the entire train appears to be the most economical. The straight storage system appears to be the most economical for short runs and long lay-overs in terminal yards with no interchange of equipment. An equipment interchange is not troublesome with this system, as the lighting apparatus is a self-contained unit. Again, where cars are subject to transfer to another road, to be gone for some length of time, the axle generator system has proven the most satisfactory

# SOME ADVANTAGES OF THE ELECTRIC HOIST OVER THE STEAM OR AIR HOIST

By K. A. Pauly

Power and Mining Department, General Electric Company

In the introduction of this article the author points out the fact that since electricity can be far more economically distributed than can steam or compressed air it is best adapted to be the motive power in mining. This is especially true when the shafts are widely separated, for individual power generating stations at each shaft are to be avoided for obvious reasons. Attention is then called to the very low operating efficiency of steam and air engines when carrying such a fluctuating load as a hoist. A description of the steam hoist is omitted as it is so well understood, but a brief outline of the main features of the compressed air system is given. A full description of the systems of electric drive of hoists then follows; this covers the salient points of safety, reliability, cost of operation, and first cost. A table of calculated operating costs of the three kinds of hoist drive, covering a wide range of power and fuel costs, is furnished; and an analytical discussion of this table closes the article.—Editor.

As a result of efforts extending over many years, marked improvements have been made in many of the processes connected with the mining industry which have brought about either a reduction in the cost of mining or an increased percentage extraction or both. These advances, however, have been very largely confined to the methods of treating the ore after it has reached the surface. So great, in many cases, has been the reduction in the cost of treatment that the tailings from old concentrating plants and low grade ores from old waste piles, once considered worthless, now have a commercial value.

However, until a comparatively recent date almost no improvements were made in the methods of handling the ore from the face to the surface. This is due to two principal causes, first: the return on investments in improved methods of treating the ore is greater and more susceptible to more accurate determination in advance, and second: electricity affords the only means of making any considerable reductions over the old methods of handling the ore and, until recently, cheap electric power has not been available at most, if any, of the large mining districts. The early applications of electric power to mining were confined to driving locomotives, air compressors for supplying air for drills, small underground haulage engines, small and large pumps, ventilating fans, and the machinery used in treating the ore. The successes attending these early installations and the high cost of maintaining boiler plants for the hoists alone where power is purchased for the other operations have lead mining men, both owners and operators, to interest themselves in the possibilities of electric hoisting; and this article will present briefly some of the advantages of the electric hoist over other types, together with the more important factors which have a bearing on the choice of a particular system of electric hoisting to meet the more important special conditions obtaining at various mines. As the cost of developing power at the mines has an important bearing on the subject it will be discussed first, but in a very general and brief manner.

The conditions obtaining at mines are in general unsuited to the economical development of power. The shafts are scattered, requiring the installation of small steam plants supplying one or two shafts. In the latter case, the steam must often be piped from one thousand to three or four thousand feet. Fuel and labor, except at coal mines, are expensive and frequently of inferior quality. Water in sufficient quantities to supply the boilers is often expensive and frequently contains scale producing impurities, which reduce the boilers' efficiency and shorten their lives, thereby greatly increasing their cost of repairs and maintenance. Seldom is water available in sufficient quantities to permit the use of condensers even with the compressor engines and pumps, much less with the hoists.

These small plants, because of their low load-factor, are high in first cost and are inefficient, especially so when the mine is operated during only one or two shifts (8 hours each) as is frequently the case. In actual test, extending over several days, a boiler plant supplying a mine hoist alone showed the coal consumed during the idle period to be one-half the total coal consumed in generating steam for hoisting. In an effort to keep down the first cost of the boiler house, the boiler capacity is made so small that a large amount of water is carried over to the engines during the acceleration of the hoist, the engine taking steam full stroke for this period. Because of the first cost of piping steam into the mines and of the difficulty in taking care of it after exhausted, seldom, if ever, is any of the underground equipment steam-operated, except the large pumps. Small slope hoists and haulages take air from the drill-supply system and, because the air is necessarily used cold, are extremely inefficient, the useful work not representing over 15 per cent of the power consumed in driving the compressors.

On the other hand, the conditions which obtain in many districts, and which have a bearing on the power problem, are constantly undergoing changes that are favorable to electrification. There is a gradual consolidation of the larger mines into a few companies, which, in turn, absorb those smaller and weaker ones, resulting in a condition which makes the centralization of the development of power not only possible but highly commercial. Further, the increased stability of mining as an industry under these conditions renders a mining load an attractive proposition for investors interested in central station development. Only a very casual examination of the conditions existing, and the developments taking place in a few of the larger mining districts, is necessary to reveal this fact.

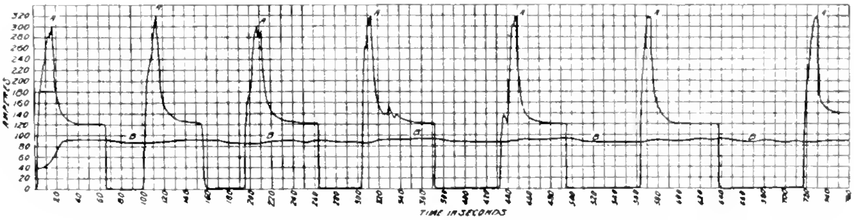

Fig. 1. Curve A, Current Input of Hoist Motor; Curve B, Current Input of Induction Motor of Motor-Generator Set

While these changes have an important bearing on the broad question of the electrification of mines, they affect the hoisting problem more than any other because of the intermittent character of this load. The two important competitors of the electric hoist are the steam hoist and the compressed-air hoist. The steam hoist is too simple to require explanation here, but for the benefit of those not acquainted with the air system a brief description is given.

In its operating characteristics the air hoist is similar to the steam hoist, compressed air from large steam or electrically driven compressors being substituted for steam. An ordinary steam engine may be used to drive the hoist, although the gain in efficiency by substituting a specially designed air engine usually warrants this expense. As a counterpart of the energy stored in the hot water of a steam boiler, large high-pressure storage tanks are provided with each hoist to reduce the momentary fluctuations in the demands for air, and where several hoists are driven from one central compressor plant a large central equalizer in the nature of an hydraulic accumulator is used. In order to improve the efficiency of the air system, which is otherwise very low, the air is reheated to as high a temperature as is practical just prior to admission to the engine. A modification of this system, known as the "dense air system," possesses certain theoretical advantages but, from a practical standpoint, it can seldom if ever be considered as a serious competitor of the simpler low-pressure systems and much less of the electric hoist. It will therefore not be considered here.

Although a great many systems of electric hoisting have been proposed, many of which are to meet special conditions existing at some particular mine, practically all of the installations are included by one of three systems. Of these, the simplest and usually the cheapest, and frequently the most efficient, is the induction motor hoist. In this type the drums are driven by an induction motor, usually through gearing, the speed control being obtained by the insertion of a variable resistance in the rotor circuit. Next in order from the standpoint of first cost is the system in which the hoist is driven by a direct-current motor, either geared or direct connected, the motor being controlled by varying the impressed voltage both in magnitude and polarity by varying the field of the supply generator. The third system is similar to the latter except that a flywheel is added to the motor-generator supplying power to the hoist motor, the speed of the motor-generator being automatically varied in such a manner as to store energy in the flywheel during the light load periods and return it during heavy loads, thereby reducing to a minimum the fluctuations in the central station load due to the hoist. The effectiveness of this system is well illustrated by the curves shown in Fig. 1, which are actual test curves.

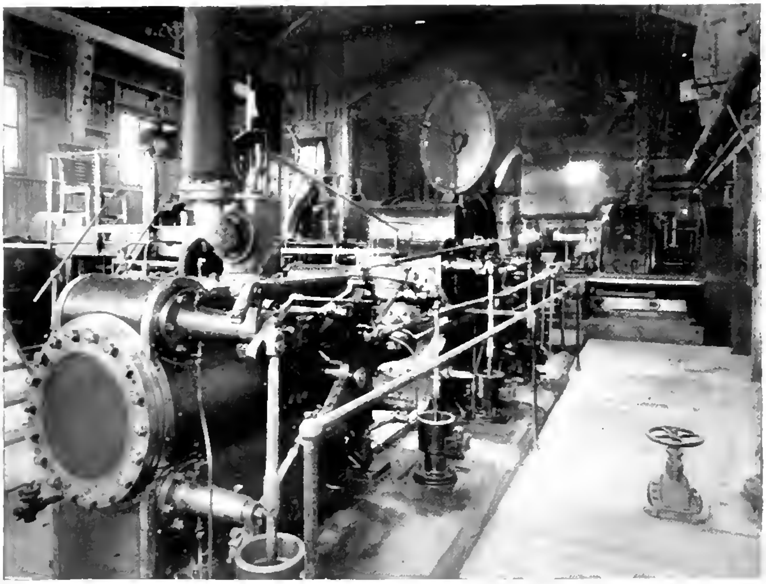

Fig 2. 900 h.p. Induction Motor Replacing Large Corliss Engine on Hoist

Because of the inherent characteristics of the reciprocating engine and the nature of a mine hoist load, an engine driven hoist is very extravagant in the consumption of steam or air. Each cylinder of the hoisting engine must be of sufficient size to handle the total unbalanced load under the most unfavorable position of the cranks, which requires that each cylinder be two times as large as would be necessary were the torque exerted by the engine uniform, as is the case with the electric motor. Steam or air is taken full stroke during acceleration while during the full-speed period the engine runs with a very short and uneconomical cut off. All losses of the engine are obviously high, as compared with its average load due to its large capacity. The steam consumption of a hoisting engine, as a result of these unfavorable conditions, seldom falls below 50 lb. per shaft horse power hour (actual work expended on the material hoisted) and often greatly exceeds this value. Combined with this extremely uneconomical use of steam, the low boiler efficiency due to the fluctuating demands often results in an overall efficiency which seems incredible, but which is confirmed by actual results obtained in practice. Coal consumption of 20 lb. and more per shaft horse power hour is not uncommon.

The consumption of the air engine is materially affected, in addition to the factors pointed out in connection with the steam engine, by the atmospheric temperature and the temperature to which the air is reheated and slightly by the elevation at which the hoist is operated. It is usually in excess of 10,000 cu. ft. of free air per shaft horse power hour.

On the other hand, the torque exerted by an electric motor is independent of the angular position of its rotating member which with its momentary overload capacity when designed for high efficiency at the average load of the cycle makes it especially adapted to meet mine hoisting conditions, advantage being taken of this overload capacity during the accelerating period. While with the systems using direct current motors power is consumed in driving the motor-generator light during idle periods, this is seldom a serious factor although it must be included in estimating the power consumption of an electric hoist driven by a direct current motor when the general supply system is of alternating current.

In discussing the relative merits of the various systems of hoisting, reference is frequently made to their respective efficiencies. Comparisons on this basis may be very misleading and may, unless care is taken, result in erroneous conclusions on the part of the purchaser who in reality is interested only in the relative economies of the several systems, efficiency being but one of several factors affecting economy, which is here used in its broadest sense. The most important factors affecting the economy of a proposed system for hoisting are, in the order of their importance, safety, reliability, cost of operation, and first cost.

Apart from humanitarian considerations an unsafe hoist is uneconomical. Continuity of service is of extreme importance, both because of the inconvenience to a large number of men who may be caught underground and the delay in production occasioned by a shut down, which would be the probable result owing to the small storage capacity that is usually provided. Too careful consideration can not be given these two factors in making a choice between competitive equipments.

The electric hoist has many characteristics which make for safety and reliability. Lowering unbalanced loads can be accomplished against the counter torque of the motor, insuring safe operation under these conditions and relieving the brakes of the severe strains to which they are frequently subjected in the case of the steam hoist. The electric hoist readily lends itself to the application of simple automatic protective devices, which increase the safety and reduce to a minimum the possible abuse of the hoist by carelessness on the part of the engineer. It is true that the electric hoist is liable to interruptions due to failures in the power supply, but little or no more so than is the air hoist depending upon electric power for driving the compressors. As a result of the recent improvements in power station and transmission protective devices and the precautions taken by power companies carrying a mining load, short interruptions are infrequent and long shut-downs seldom if ever occur.

An eminent American mining engineer, who is operating both types of hoists, confirms this in the following statement:

". . . . as to the relative merits of hoisting with electricity as compared with steam, I would say unqualifiedly that the electric hoists are more reliable than steam hoists, granting that you have, of course, a constant and reliable current. The electric hoists are more sensitive to handling, are much easier controlled, and it is easier to apply overwinding and other safety devices to them. The electric hoists give a steady pull on the rope during acceleration and, in fact, during the entire trip. There is none of the flopping of the rope which is apparent in the pull of the steam hoist. We find that for this reason our pulley stands which support the rope between the shaft house and the engine house can be set much farther apart and that the rope never jumps out of the grooves in the carrying sheave."

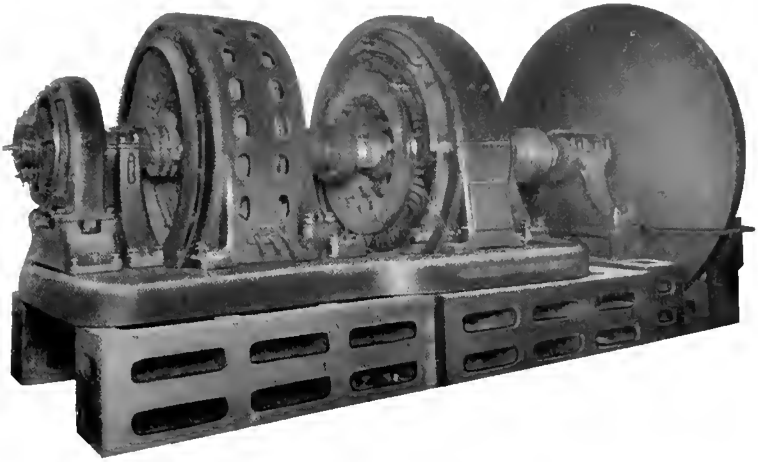

Fig. 3. 1000 kw. Motor-Generator Set with 18-Ton Flywheel for Mine Hoist

Next in order of importance is the cost of operation. Many factors entering into the cost of operating a steam mine hoist are so intimately related to the operating costs of other equipments at the mine that it is extremely difficult in most cases, and impossible in others, to properly separate the hoist costs from the total. The steam for the hoist is frequently taken from boiler plants supplying the air compressors, pumps, etc., which, as a result of a lowering of the boiler efficiency due to the excessive fluctuations in the steam as demanded by the hoist, are charged for at too high a steam cost. The oil waste and supply accounts are seldom segregated. However, the advantage obtained by the electrification of a hoist, because of the reductions in the cost of power made possible by centralization, are so great that a large saving can be shown in its favor even though the steam and repair charges against the steam hoist are somewhat under-estimated by reason of using corresponding costs from plants admittedly operating under more favorable conditions.

In general, the "Operating Cost" is the determining factor in the choice between the several electric systems although frequently the first cost plays an all too important part. A complete discussion of the relative operating costs of the various types of electric hoists is not feasible here, but a brief outline of the general conditions affecting the problem are in order. For long hauls and for slow-speed hoisting for shorter distances where the time required for acceleration is a comparatively small percentage of the total time consumed in making the trip and where the hoist is not required to run at reduced speeds to any considerable extent, the induction motor hoist will give the highest efficiency, but where the opposite conditions prevail the direct current hoist motor and motor-generator without flywheel will show the lower power consumption.

However, as previously pointed out the efficiency or its measure, the power consumption, is only one of the factors affecting the cost of operation for it is true that the most efficient electric hoist may be the most expensive to operate. With both the induction motor and direct current hoist motor and motor-generator without flywheel, all the fluctuations in power required to drive the hoist are reflected back upon the power system. As these variations may be equivalent in magnitude to 300 per cent of the rated load of the hoist motor, if the hoist load is a considerable percentage of the station or feeder load, a considerable excess capacity must be provided to prevent excessive voltage variations. Where power is purchased, provision is made in the rate to protect the power company against loss when supplying a load of this character. The method usually adopted is to base the power rate both on the maximum demand and the energy consumption. Under these conditions it is frequently advisable to install some form of equalizer, usually a flywheel operating in conjunction with the induction motor-generator supplying the hoist motor which, in this case, is of the direct-current type. By means of the flywheel, the speed of which is automatically controlled, the maximum demand is reduced to a minimum, with the result that the reduction in the "demand charge" for power will usually pay for the complete electrical equipment in from three to five years. Often where power is generated locally by the mine operator, the installation of the flywheel motor-generator system is warranted for the same reasons as when the power is purchased, although, of course, greater fluctuations in voltage are permissible

under these conditions than when power is supplied by a public service corporation.

Frequently, an otherwise objectionable hoist-load curve may be materially improved by using conical or cylindrical drums and slightly reducing the maximum rope speed or lengthening the period of acceleration, which may be done without seriously affecting the first cost of the equipment or reducing the shaft output. The high maximum running speed of steam hoists is due to the defect in the steam engine torque curve previously mentioned rather than to production considerations, and, unfortunately, these same high speeds are demanded of the electric hoist which is often looked upon as being inherently slow if a reduction in speed is suggested. It is appreciated that lack of underground storage capacity, or other important considerations in many cases, warrant as high a speed of hoisting as shaft conditions will permit, but frequently a material saving in first cost and operating cost can be made by reducing the speed of an electric hoist without harmful effect. Such a reduction is not possible with the steam hoist because of its irregular torque characteristics.

The determination of the shape of the drum can only be made after a careful investigation of all the special conditions affecting each individual problem, and it is dependent upon so many factors that no general recommendations can be made herein. For the same reason, neither can a complete analysis of the relative costs of operating hoists by steam, compressed air, or electricity be given. However, although the operating conditions vary widely in different localities, those affecting the operating costs produce in the majority of cases about the same relative changes in all of the systems. Bearing this in mind, the figures given in Table I may be taken as typical, although they are based upon hoisting an average of 650 tons per day from an average vertical depth of 1500 ft., assuming the non-productive work one-half the productive work. The estimates are made on the basis of 12,000 B.t.u. coal costing $2, $4 and $6 per ton delivered at the boilers, and power costing (including both demand and energy charge) from ½ c. to 3 c. per kw-hr. In preparing this table, it has been assumed that the particular type of electric hoist best adapted to meet the local conditions has been chosen, thus permitting the treatment of the electric hoist as a system. The air compressors supplying air for the hoists are motor driven, since the cost of so operating the compressors is less under the conditions assumed than if steam driven. The fixed charges are not included as the first cost of the hoisting equipment depends upon many local conditions which can not be taken into consideration. Including these charges will not materially affect the conclusions drawn as, in general, for new installations, the electric hoist can be installed for approximately the first cost of the steam hoist. This statement includes the cost of all of the items chargeable against the hoist, namely; the cost of the boiler plant, piping, additional cost of building to accommodate the steam hoist, for a larger building is required than would be for the electric hoist, etc., and 'it will be found less in all cases than the first cost of the air hoist including in this cost its proper percentage of the compressor plant, piping system, reheating equipment complete and building to house the same, air engine, receivers, and pressure-equalizing equipment. Where the problem is one of replacement, the first cost of the equipment may differ somewhat for the different systems, but the resulting difference in the fixed charges will but slightly affect the results as given.

From an examination of the table, it will be found that only when the cost of power is very low and the cost of fuel high is the compressed air hoist cheaper to operate than the steam hoist; and that in all cases the electric hoist is cheaper to operate than the compressed air hoist and, except where the cost of power is high and the cost of fuel is low, the electric hoist is cheaper to operate than the steam hoist

In summing up it may be stated that the air hoist possesses no advantage over the steam hoist except where fuel is high and power is extremely cheap, and possesses no advantage over the electric hoist under any conditions; that the steam hoist has no advantage over the electric hoist except where fuel is cheap and power is high and then only the advantage of a lower operating cost, while the electric hoist has the advantages of greater safety and reliability, longer life of ropes and brakes, more delicate control under all conditions, and, under practically all actual operating conditions, is operated at a lower cost.

# THE SELECTION OF STEAM TURBINE CONDENSERS

By A. R. Smith

Construction Engineering Department, General Electric Company

In this article the author gives an impartial discussion of the three common types of condensers, viz., the surface condenser, the low jet condenser, and the barometric condenser, and to afford a ready comparison of the different types, has arranged a table which shows at a glance the advantages and disadvantages of each. The question of the best form of drive for the auxiliaries is discussed, with a recommendation for motor drive from an auxiliary non-condensing turbo-generator set. The several types of air pumps, circulating pumps and hot well pumps are described and the merits of each pointed out. The data found in the text and in the form of curves will be of great service in determining the best type of condenser for a given set of conditions.—Editor.

To limit the scope of this article it has been necessary to assume that condensing water is available so as to avoid reference to cooling towers, cooling ponds, spray nozzles, evaporative condensers and the like, which naturally have considerable bearing on the problems as presented.

There are few instances where the installation of condensers is not justifiable. Two common conditions met with in practice which may at first appear to be strictly non-condensing propositions are: first, where a considerable quantity of exhaust steam is required for heating, and second, where the station is purely a "standby" station and economy is of little importance. That a careful investigation of the conditions should be made in such cases will be evident after studying the two following examples.

Let us take a small station containing two 1000 kw. turbines designed for steam extraction for heating, with a condensing water rate of 16 lb., or two non-condensing turbines with a water rate of 34 lb. per kw-hr. Let us further assume that the maximum heating requirements are 34,000 lb. of steam per hour. Now, for a climate requiring seven months heating, the average daily steam required for the coldest month would be about 60 per cent of that for the coldest day and the average for seven months would be 80 per cent of that for the maximum month, or 48 per cent of that for the coldest day.

The curve shown in Fig. 1 is of a typical daily load for a manufacturing plant. The daily load factor here is 54 per cent and the yearly load factor 45 per cent. Because of the entirely different characteristics of the electrical load from that of the heating load, it is obvious that at certain times the electrical output exceeds that which could be obtained as a by-product of the heating, and if condensers were installed 28 per cent of electrical load during the winter, or heating months, could be generated with a turbine water rate of 16 lb. per kw.-hour. Therefore,

$$7 \text{ mo.} \times 30 \text{ days} \times 24 \text{ hr.} \times 45\% \times 28\% \times 1000 \text{ kw.} = 630{,}000 \text{ kw-hr.}$$

$$5 \text{ mo.} \times 30 \text{ days} \times 24 \text{ hr.} \times 15\% \times 1000 \text{ kw.} = 1{,}620{,}000 \text{ kw-hr.}$$

$$\text{Total yearly} \quad 2{,}250{,}000 \text{ kw-hr.}$$

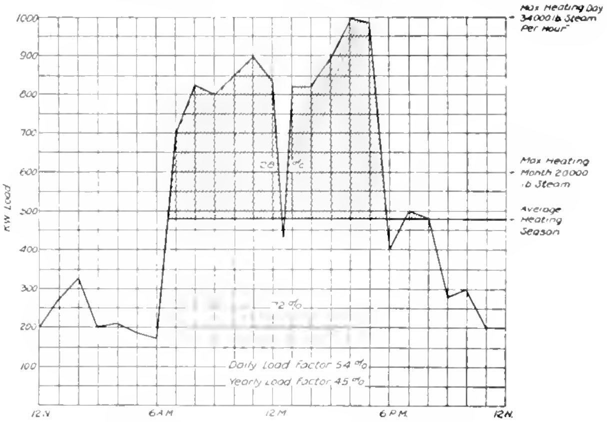

Fig. 1. Characteristic Factory Load Curve Showing Relation Between Electrical Load and Heating Requirements

Now, 34 lb. − 16 lb. = 18 lb. saving per kw.-hr. by running condensing, or 18 × 2,250,000 = 40,500,000 lb. of steam. If steam costs 25 cents per 1000 lb., the yearly saving will be $10,100.00. The steam consumption of the auxiliaries should not exceed 10 per cent of the main turbine steam or 1600 lb. per hour and 87½ per cent of this can be charged to heating the feed water. Therefore,

$$8760 \text{ hr.} \times 12\tfrac{1}{2}\% \times 1600 \text{ lb. per hr.} \times \frac{25 \text{ cts. per 1000 lb.}}{1000} = \$438.00$$

yearly cost of power for auxiliaries. Two condenser equipments installed and including piping would cost approximately $7.50

per kw., or $15,000.00, and the additional building space would cost about $3000, or a total of $18,000. With interest at 6 per cent, depreciation at 4 per cent and maintenance at 2 per cent, the fixed charges would be $2,160.00 a year. The net saving would then be $10,100.00−($438.00+$2,160.00)=$7,502.00.

Considering now the second case, viz., that of a standby station where the yearly output would be so small that the saving in coal due to condensing operation would be negligible: The operation of a turbine condensing practically cuts the water rate in half and proportionally reduces the necessary boiler capacity. It is then a question of balancing the investment for condensers with the investment for boilers.

If condensers were installed, the boiler h.p. would be

$$\frac{1000 \text{ kw.} \times 16 \text{ lb.}}{30 \text{ lb.} \times 1.33\% \text{ rating}} + 50\% \text{ spare} = 600 \text{ h.p.}$$

and if condensers were not installed, the boiler h.p. would be

$$\frac{1000 \text{ kw.} \times 34 \text{ lb.}}{30 \text{ lb.} \times 1.33\% \text{ rating}} + 50\% \text{ spare} = 1280 \text{ h.p.}$$

An increase of 680 boiler h.p. at $20.00 per h.p. installed, would be $13,600.00 against two condensers at $6.50 per kw., or $13,000.00. It is thus apparent that condensers can be installed for practically the same price as additional boilers, when neglecting the extra cost of the building, stack, piping and tunnels, which should ordinarily be in favor of the condensers.

### Types of Condensers

The three common types of condensers are the surface condenser, the low jet condenser, and the barometric condenser. Various trade names are applied to cover modifications in construction, but the merits of the different designs on the market will not be considered here. The essential difference between the low jet and barometric condenser is that the water is pumped away from the former and is pumped to the latter, as will be seen in Figs. 5 and 7.

The one all-important advantage of the surface condenser is that the condensate is saved for re-use as boiler feed. This is really the first consideration in selecting a condenser, unless the available boiler feed water is exceptionally good. With surface condensers it should be possible to re-use 90 per cent of the water evaporated by the boilers, and as the scale-forming matter is deposited during the first evaporation, the only accumulated scale in the boilers will be from the remaining 10 per cent make-up, that is, the amount of boiler scale should be but one-tenth of what would be deposited if surface condensers were not used.

### Surface Condensers

Surface condensers are by far the most commonly used for steam turbines, principally because of the salvage of the condensate. Surface condensers used with sea water will give perfect satisfaction, unless the water is contaminated. Two power houses obtaining circulating water from different parts of the same salt water inlet may show entirely different maintenance costs.

Foreign matter can usually be screened from the water even if it becomes necessary to resort to mechanically cleaned screens. In shallow salt water inlets barnacles, mussels, and shell fish will sometimes spawn after passing the screens and give considerable trouble. Such obstacles can usually be overcome by properly designing the plant.

Besides the reduction of boiler scale due to the re-use of the condensate, there is a small saving in heat. For example, a 28 in. vacuum should give a condensate of about 95 deg. F. which, compared with city water at a temperature of 50 deg. F., means a saving of 45 deg. F. on 90 per cent of the water evaporated, or roughly, 3½ per cent saving in heat. And again, if city water is purchased at a rate of 10 cents a 1000 gal., there is an additional cost of 1.2 cents per 1000 lb. of steam produced.

There are two kinds of surface condenser equipments, one known as the wet vacuum and the other the dry vacuum system. The distinction between the two is that in the former the air pump removes the air and the condensate, and in the latter the air pump removes the dry air, and the hot well pump removes the condensate.

At first glance the wet vacuum system appears to have the advantage, but this is not always true. While the hot well pump is eliminated, the discharge head on the wet air pump is limited and usually a second pump is necessary to lift the water up to the feed water heater, or make-up tank. To make the air pump effective at high vacua, it is essential to lower the temperature of the air below the temperature of the vacuum before removing it from the condenser; but the air and condensate must necessarily be of the same temperature when handled by a single pump, which means a loss of from 5 to 10 deg. F. due to the lower temperature of the condensate. And again, the returned condensate contains more air, which has to be freed in the open feed heater, or in the reboiler if condensate is used for making ice. It is very doubtful if the feed water heater removes all of the air, and the dry vacuum system should have the benefit of the doubt.

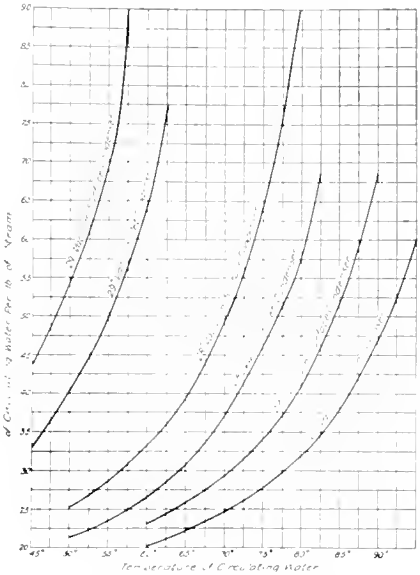

Fig. 2. Curves showing Quantity of Circulating Water Necessary to Produce 27 In., 28 In. and 29 In. Vacuum, Based on Water Leaving Surface Condenser 10° F. Below Temperature of Vacuum and 3° F. Below for Jet Condensers

The above mentioned disadvantages of the wet vacuum system are more or less trivial and for small stations this system is very simple to operate and maintain and has proved in general very satisfactory.

### Barometric and Jet Condensers

A jet condenser whether of the low or barometric type is essentially a chamber where the steam and water come in direct contact. There are many forms on the market, such as horizontal, ejector, injector, eductor, counterflow, etc. and some barometric condensers are arranged so that the sweeping action of the water removes the air and thus makes the air pump unnecessary. Such condensers naturally have restricted water passages to obtain high velocities and generally require some means of opening up such passages to free the condenser of leaves and other material that may accumulate. The pumping head also exceeds that of the type where the cooling water falls over trays.

In choosing between a condenser with an air pump and one without, the merits of each manufacturer's apparatus has to be given consideration. In choosing between a low jet and a barometric condenser, it is largely a question of water levels and design.

### Choice of Condenser as Regards Pumping Head

The amount of circulating water required by a jet or barometric condenser is less than that required by a surface condenser because of the more efficient heat transfer from the steam direct to the water. In the former it is common practice to figure that the outgoing water will be within 3 deg. of the temperature of the vacuum. In the case of the surface condenser it has been customary to figure 13½ deg. F., but the many advances recently made in condenser design indicate that 10 deg. F. is a conservative figure to use. It will be noted from the curves in Fig. 2 that the surface condenser requires considerably more water than the jet condenser as the temperature of the circulating water approximates the temperature of the vacuum sought. However, the power re-

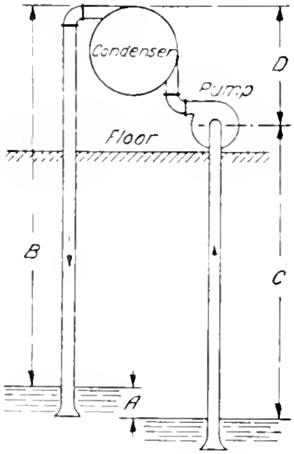

Fig. 3. Diagram of Typical Surface Condenser Installation, where C does not Exceed 22 Ft.

quired for pumping is proportional to the product of the quantity and head, and the following will illustrate how the pumping heads vary.

Referring to Fig. 3 which shows a diagram of a typical surface condenser installation: Dimension C should not exceed 22 ft. (this may be increased slightly by reducing to a minimum the pipe friction) because of the inability of the pump to lift water to a greater height. Should the incoming water level be lower, then the scheme shown in Fig. 4 should be resorted to and the pump may then, if possible, be located so as to be below the water level, to save priming. The pumping head in Fig. 3 will be (A + condenser friction + pipe friction) and the suction lift and static head on the pump are balanced by the siphon formed by the condenser discharge so long as B does not exceed 25 ft. Should B exceed 25 ft., then the pumping head would be

(A + cond. friction + pipe friction + B − 25 ft.)

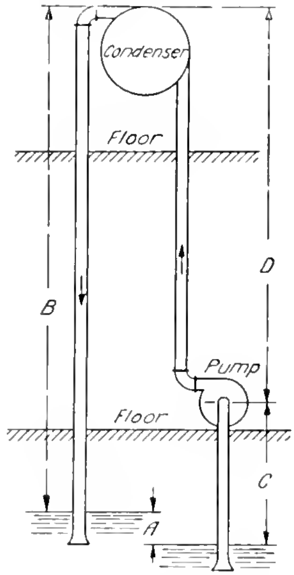

Fig. 4. Surface Condenser Installation for Cases where C is greater than 22 Ft.

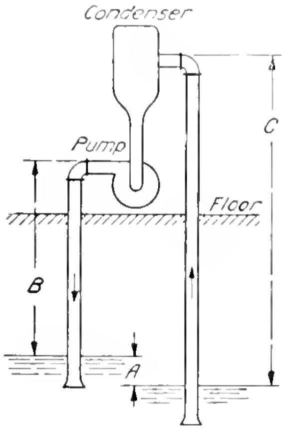

Fig. 5. Diagram of Typical Low Jet Condenser, where C does not exceed 25 Ft.

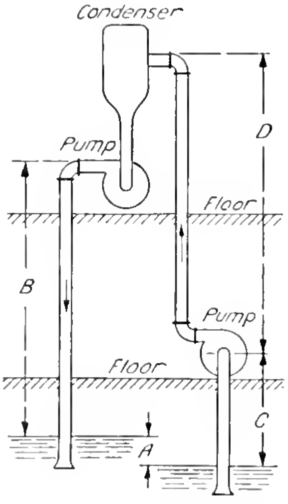

Fig. 6. Diagram of Low Jet Condenser for Cases where C is greater than 25 ft.

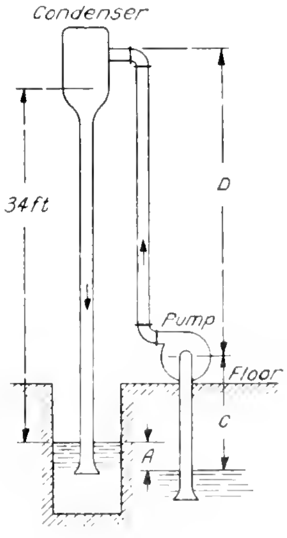

Fig 7. Barometric Condenser in which all the Pumping is Accomplished on One Side with One Pump

Assume a common condition as in Fig. 3, with A = 3 ft., C = 15 ft., cond. friction = 10 ft., pipe friction = 6 ft. Then, the total normal pumping head is 19 ft. Now, if 29 in. vacuum is desired and 50 deg. F. water is available, there would be required 55 lb. of water per lb. of steam (see Fig. 2), or 19 × 55 = 1045 ft. lb.

Now, referring to Fig. 5 showing a diagram of a typical low jet condenser, it will be observed that the dimension C is also limited as the water is lifted by the vacuum in the condenser. Dimension C should not exceed 25 ft. Should this be considerably less than 25 ft. more pumping head is required because the discharge leg on the pump is correspondingly reduced, and the friction in C is increased by the throttle valve to maintain constant flow of water. Therefore, in comparing the jet with the surface condenser under the following assumptions, the conditions are favorable to the jet condenser.

A = 3 ft. C = 25 ft. B = 10 ft. Pipe friction = 6 ft.

Then the total pumping head with 29 in. vacuum is: (29 in. mercury, or 32.8 ft. water − 10 ft.) = 22.8 ft. For a 29 in. vacuum and 50 deg. F. water, 40 lb. of water per lb. of steam is necessary. Therefore, 40 × 22.8 = 912 ft. lb.

Should C be more than 25 ft. and an additional pump be required, as shown in Fig. 6, the problem of regulating the output from two pumps in series is encountered and the barometric condenser shown in Fig. 7 is immediately suggested, where all pumping is accomplished on one side and with one pump.

Let us now compare the power required for the barometric condenser with the foregoing.

Assume A=3 ft., D=30 ft., C=10 ft., pipe friction=10 ft. and 29 in. vacuum in condenser. Then, we have a static pumping head of 30 ft. + 10 ft., or 40 ft.; but this is partly overcome by a vacuum of 29 in. or equivalent 32.8 ft. lift. Still it is not safe to use this without discounting it for leaks and we will credit 28 ft. lift to the vacuum. Therefore, 40−28 ft.=12 ft. static head + 10 ft. friction, or 22 ft. total head. 40 lb. of water × 22 ft.=880 ft. lb.

It is thus apparent that the surface condenser can be used under any conditions of water levels, whereas the low jet condenser is somewhat restricted to a low lift, and that there is little to choose as regards pumping head. The barometric condenser can be adapted to varying water levels and shows a low pumping head; but the conditions on which the calculations are based are rarely met because of high and low water levels at different seasons of the year, which will increase A accordingly, and therefore materially increase the pumping head.

The foregoing examples are given to illustrate the fact that the prevailing and varying water levels are important factors in selecting the type of condenser to be purchased, and it is necessary to make a study in each case of these conditions, providing other considerations do not preclude the use of the jet or barometric condenser.

### Comparative Costs of Condensing Equipments

To show the approximate costs of condensers, including their auxiliaries f.o.b. the factory, curves in Fig. 8 have been made up from average costs of some 150 equipments. The averages for each capacity of turbine are compiled from costs without regard to amount of surface, quantity of water, vacuum maintained, and steam or electric drive. They therefore represent the masses.

It should be borne in mind that the cost of a condenser and its auxiliaries may be considerably more or less than shown on the curves, depending on local conditions and other special considerations.

### Steam *vs.* Electric Auxiliary Drive

Steam driven condenser auxiliaries have been universally recommended in preference to motor drive because any disturbances on the electrical end will not affect the auxiliaries. For example, suppose a short circuit occurs on some outside feeder and the speed and voltage is reduced sufficiently to let the condenser auxiliaries drop out. First, the loss of vacuum on the turbine will necessitate the immediate generation of double the amount of steam; but the boiler room is not prepared for this emergency, and the only alternative is to reduce the load. Second, the vacuum pump has to be started, and third, the circulating pump started and primed. These operations consume considerable time, especially with chaotic periods of interruption. Should there be two turbines on the line, the duration of the interruption is doubled.

The dry vacuum pump and hot well pump can conveniently be made motor driven because the motors are small and can be self starting. An interruption of half an hour of the vacuum pump, or one minute of the hot well pump ought to show but little effect on the vacuum.

It is not an uncommon occurrence to lose the station excitation. With steam driven auxiliaries this does not result in so long an interruption as with motor driven auxiliaries, where the machines not only have to be re-synchronized, but also changed from non-condensing to condensing.

Motor-driven auxiliaries are very desirable in that they are cheaper in first cost and maintenance; they obviate the use of considerable steam and exhaust piping and the expense of maintenance and radiation incident thereto; the motor speeds are conducive to high pump efficiencies, and they are easily started and require little attention when running. To enjoy these advantages without sacrificing continuity of service is possible by feeding the auxiliaries for each turbine off a separate auxiliary turbine driving an exciter and a-c. generator. This may seem like an additional complication, but investigation will show that this auxiliary turbine can be operated at a speed of highest economy and each pump can be operated at the most efficient speed.

The auxiliary turbine can be exhausted into its own feed water heater, thus evolving a comprehensive unit plan station as follows:

| | |
|---|---|
| Main turbine unit (operated condensing) | Supplying all outside load |

Aux. turbine unit (operated non-condensing)
- Exhausting to individual heater
- Supplying excitation to main unit
- Supplying power to
  - Boiler feed pump
  - Circulating pump
  - Air pump
  - Hot well pump

Unless an auxiliary turbine is employed, or steam driven auxiliaries used, there is usually a shortage of exhaust steam for heating the feed water. Take, for example, a case where the turbine is running at half rated load: the steam driven exciter and boiler feed pump would be taking about 5 per cent of the total steam, which would heat the feed water from 75 deg. F. (29 in. vacuum) to 125 deg. F. If the main turbine were carrying full rated load, the condition would be worse as the auxiliary steam would represent only about 3½ per cent and the increase in feed water temperature would be only 35 deg. F. Now, if the condenser auxiliaries are steam driven, the total exhaust steam would be about 15 per cent at half load, and 9 per cent at full load, and the feed temperature in the former case would be 210 deg. with a waste of 1½ per cent of the steam, and at full load it should be 165 deg. F.

## ADVANTAGES OF DIFFERENT TYPES

| Surface | Jet | Barometric |
|---|---|---|
| Re-use of condensate for boiler feed. | Least expensive type of condenser. | Condenser proper not costly but piping to it is expensive. |
| Re-use of condensate for ice production. | Requires less building space. | No possibility of flooding turbine as in the case of a low jet condenser. |
| Readily adapted to the weighing of condensate for tests. | Equipment simpler because hot well pump is not necessary. | Maintenance low. |
| Slightly better vacuum obtainable. | Requires less circulating water than surface condenser. | The use of acidulated water possible. |
| Advantage of low pumping head through siphon action. | Maintenance low. | Requires less circulating water than surface condenser. |
| Less chance of losing vacuum because a drop in vacuum does not affect water supply. | The use of acidulated water possible. | Requires little building space. |
| | | Equipment simple. No hot well pump necessary and in some forms no vacuum pump is required. |

## DISADVANTAGES OF DIFFERENT TYPES

| | | |
|---|---|---|
| First cost high. | Failure of removal pump would flood turbine. Protection is provided by a vacuum breaking float valve. | Long exhaust pipe line to condenser which entails high initial cost and greater possibility of air leaks. |
| Maintenance high. | Waste of condensate. | Loss of vacuum between turbine and condenser which may amount to ½ in. or even more. |
| Requires considerable building space to remove tubes. | | As condenser cone generally extends above roof, it does not lend itself to economical station design when boiler room and turbine room are parallel and contiguous. |
| Acidulated water or water containing foreign matter in large quantities may preclude the use of surface condensers. | | Waste of condensate. |
| More head room necessary to obtain sufficient head on hot well pump. | | |

**Amount of Condensing Surface**

There is at present a wide disparity between the amount of surface recommended for a given condition by the different manufacturers, both here and abroad, and inasmuch as the cost of the surface represents about half of the total cost of the condenser equipment, it is manifestly unfair to compare bids covering different amounts of surface without compensating for it in the prices.

The amount of surface necessary for condensing 1000 lb. of steam at 29 in. vacuum is

$$S = \frac{1000 \text{ lb.} \times \text{latent heat in steam at } 29'' \text{ vac.}}{U \times \left(T - \frac{T_2 + T_1}{2}\right)}$$

where:

$S$ = surface in square feet.

$U$ = B.t.u. transmission per sq. ft. per degree per hr.

$T$ = temp. of vacuum, Fahrenheit.
$T_1$ = temp. of incoming circulating water.
$T_2$ = temp. of outgoing circulating water.

The two uncertain items are $T_2$ and $U$. Now, $T_2$ may vary from 5 deg. to 15 deg. F. below the temperature of the vacuum. It is not safe to figure on 5 deg., although this has been obtained in practice, and it should not reach 15 deg. A temperature of 10 deg. below the vacuum is common and in the writer's opinion can safely be used for the calculation of surface.

On the other hand, it may be better to circulate more water and thereby lower $T_2$ and consequently reduce the amount of surface, but this will be discussed under the subject "Circulating Pumps." The fact remains that "U" is the uncertain quantity, and the one on which the condenser manufacturers disagree.

It has been found that with ordinary condenser tube materials of usual thickness, a transmission of 455 B.t.u. could be obtained with a water velocity of 1.6 ft. per second, and this is materially increased by increasing the water velocity. But the average transmission in a condenser under operating conditions depends on the distribution of steam, the amount of surface used for cooling the air to the pump, the amount of air in the steam, which acts as an insulator, and the condition of cleanliness of the tubes. In the past, the practice has been to figure on an average heat transmission of 350 B.t.u. and now some manufacturers claim that they have in their new designs eliminated most of the idle surface, and can obtain at least 500 B.t.u. transmission. There is no doubt that a perfectly designed condenser will raise the rate of transmission; but it is a question if this increase should not be taken in smaller doses, and it is the writer's opinion that 400 B.t.u. might be safely used until experience has demonstrated that it is safe to take another step forward.

Of course, the purchaser is interested in the guaranteed vacuum, but more particularly in the vacuum that can be maintained in regular service. There are many loop holes, such as air infiltration, moisture or superheat in the exhaust steam and quantity of circulating water, that the purchaser might easily be convinced that the performance was well within the guarantee; but far better results might have been attained with more surface. It is therefore well, in comparing prices, to give due consideration to the amount of surface included, which may readily be done by adding to the lowest price the cost of the additional surface included in the bid containing the greatest amount of surface.

### Air Pumps

There are three general types of air pumps used in connection with condensers. They are the rotative reciprocating pump, the rotary positive displacement pump, and the hydro-centrifugal pump. The reciprocating pump is most commonly used, and is best fitted for steam cylinder drive, although it can readily be adapted for motor drive. The rotary pump is particularly adapted for motor drive and is used almost exclusively on wet vacuum systems. The hydro-centrifugal pump, or one where the impeller projects successive sheets of water, each entrapping a certain amount of air, is best adapted to turbine drive but may also be used with motor drive.

The reciprocating pump, commonly known as the rotative dry vacuum pump, can be used for a wet or dry vacuum system, and requires only about half as much power as a hydro-centrifugal pump. When steam driven the speed can be varied at will, but if motor-driven it may as well be operated at full speed at all loads.

The rotary pump, of which there are many makes, requires water sealing and is therefore best suited for wet vacuum service. The motor drive makes this pump a very compact and simple outfit for moderate size turbines.

The hydro-centrifugal pump is now manufactured in many types, most of which are importations from Europe. It is comparatively new and sold at present largely because of its simplicity. Although it takes about twice the power of a rotative pump, its speed corresponds closely with that of the circulating pump, and thereby makes possible a combination unit of air pump and circulating pump, driven by either a motor or a turbine. Like a circulating pump, it requires priming in starting and some makes are likely to drop the suction when the condenser vacuum gets very low.

The volumetric capacity of the air pump cannot be figured from any theoretical formula, because the amount of air in the steam and the air infiltration are very uncertain quantities. It is quite common to make the volumetric capacity in cubic feet per minute fifty times the cubic feet of condensate per minute, and this represents very good practice. The curves in Fig. 10 show air pump displacement in cubic feet per minute based on 100 r.p.m. for all capacities of turbines. The horizontal line represents the factor "50 times condensate" and various points on both curves show the averages of some fifty condensing outfits.

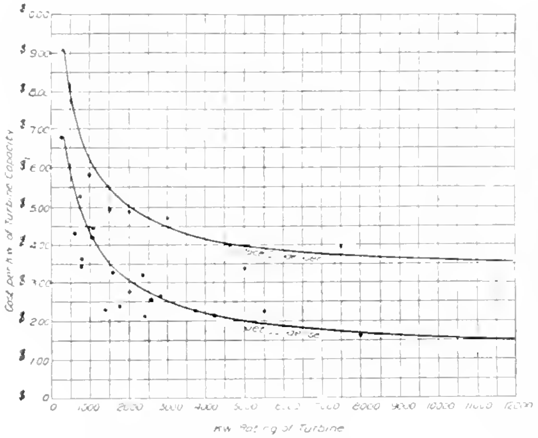

Fig. 8. Curves showing Approximate Cost of Condenser Equipments per Kilowatt of Turbine Capacity

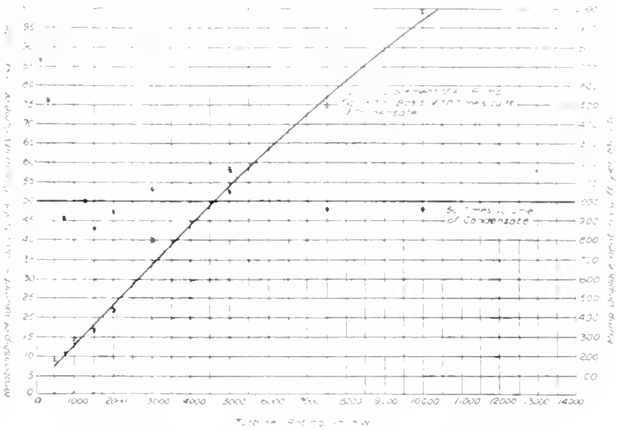

Fig. 10. Curves showing How the Average of Fifty Condenser Propositions Check with Customary Rule of Figuring Air Pump Capacity Fifty Times the Volume of Condensate

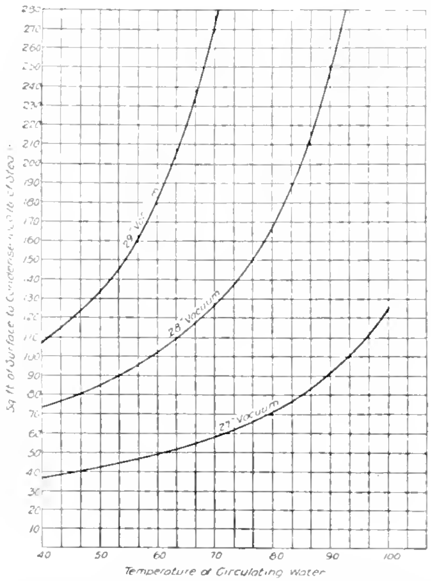

Fig. 9. Curves showing Amount of Surface Necessary to Condense 1000 Lb. of Steam, Based on Transmission of 400 B.t.u. and Water Leaving Condenser at 10 Deg. Below Temperature of Vacuum

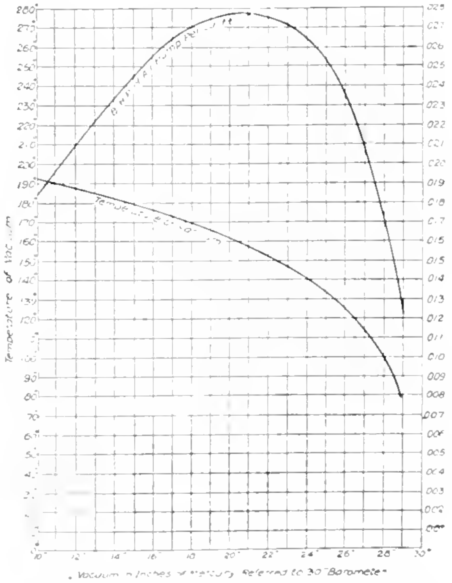

Fig. 11. Curves showing Correspondent Temperature of Vacuum and Brake Horse Power of Air Pump Working Against Vacuum

The power required by different air pumps varies so widely that no curve or tabulation has been worked out showing the horse power for motor drive or steam consumption. The curve shown in Fig. 11 gives the theoretical b.h.p. per cubic foot of air for different vacua, and the actual horse power can be estimated by assuming an efficiency for the pump.

### Circulating Pumps

Circulating pumps are now almost exclusively of the centrifugal type. The volute or turbine form and single or multi-rotor and single or multi-stage developments make these pumps suitable for almost any quantity of water, head and speed. The pumps can advantageously be driven by engines, turbines or motors, although the wide choice of motor speeds often gives the best pump efficiency.

The quantity of circulating water of various temperatures to produce a given vacuum is shown in Fig. 2. As has been pointed out under "Amount of Surface," the surface can be reduced by increasing the quantity of water, but no general rule can be made to show when it is cheaper to pump more water or to increase the surface because of so many factors entering into the cost.

These factors are:

1st. The capacity factor of the turbine. The increased surface represents a fixed charge whether turbine is in operation a part or the whole of the time, while the pumping cost is proportional to the time the turbine is in operation.

2nd. The cost of pumping the water. This is dependent on the head and the cost of motive power.

The cost of motive power is determined by the cost of steam and on the main turbine water rate if motor drive is used.

3rd. The average number of days during the year when the circulating water will reach the temperature on which the calculations are based.

It is apparent that if the condensing equipment is proportioned to give 29 in. vacuum for the highest water temperature, cooler water may produce no higher vacuum because of air leaks, and that less surface and water might have produced the same results. In general, it is well to take the highest average water temperature for about six consecutive weeks during the year and proportion the surface and quantity of water to attain the highest vacuum which appears economical to strive for. One inch increase in vacuum usually means over one pound reduction in the turbine water rate.

The power required by the circulating pump is the largest item of the condenser auxiliaries, and therefore every effort should be made to reduce the pumping head to a minimum. Pump efficiencies as high as 75 per cent are attainable with certain combinations of quantity, head, and speed, and 65 per cent is commonplace. The brake horse power necessary is then:

$$\frac{\text{Head in feet} \times \text{g.p.m.} \times 8.3}{33{,}000 \times 0.65 \text{ eff.}} = \text{b.h.p.}$$

**Hot Well Pump**

The centrifugal pump is now quite universally used for pumping the condensate from surface condensers. The power required to drive the pump would be

$$\frac{(34 \text{ ft. suction} + 25 \text{ ft. discharge}) \times \text{lb. condensate per min.}}{33{,}000 \times .50 \text{ eff.}}$$

Thirty-four feet being equivalent to 30 in. vacuum.

Twenty-five feet discharge being the usual head figured on until actual conditions are known

Fifty per cent efficiency is low due to the small size of the pump.

# THE MISSISSIPPI RIVER HYDRO-ELECTRIC DEVELOPMENT AT KEOKUK, IOWA

## Part II

By Eric A. Lof

Power and Mining Engineering Department, General Electric Company

The first part of this article, published in the February, 1914, issue of the Review, consisted of a brief description of the dam, power house, ship canal, hydraulic equipment, and portions of the electric equipment, including generators, exciters and transformers. The present instalment completes the description of the electrical apparatus of interest in the power house at Keokuk, and then deals in considerable detail with the construction and main features of the five transmission lines, of which the Keokuk-St. Louis line is by far the most important. The St. Louis substation is well described and illustrated and the location of other substations shown by a wiring diagram of the complete system.—Editor.

### Power Limiting Reactances

Power limiting reactances are, as before mentioned, inserted between the low-tension busbar sections to limit to a safe value the rush of current in case of short-circuit. There are twelve reactances in four sets, each having a nominal rating of 240 kv-a., or 8 per cent in terms of the rating of one of the 9000 kv-a. generators. In other words, when the normal current of one generator flows through the reactance, it causes a drop in voltage of 8 per cent of the generator star voltage across the terminals of the reactance coil. As the generators themselves are designed for a high inherent reactance, limiting their short-circuit current to about five times normal full load current, it is obvious that the total current input into a short-circuit somewhere on the low-tension bus will be limited to about 40 times the full load current of one generator. In case of a short-circuit on any of the outgoing lines, the current rush will be still less, owing to the intervention of the transformer reactance in series with the sectionalizing reactances. In any case not more than two sections on either side of the short-circuited one will be affected, and the voltage of these will not fall below 75 per cent of the normal voltage. By means of these sectionalizing reactances it is therefore possible to confine troubles to one section and thus maintain an uninterrupted operation of the other parts of the system.

The reactance coils are provided with tap terminals, so that either 6 or 4 per cent reactances can be obtained when desired. These taps are, however, not used at the present time. The winding consists of one inch copper cable, wound so that both ends of the coil are brought to the outside in order to facilitate their connection to the busbars. The core is of hollow concrete and the winding is mounted on specially selected, kiln dried, resin treated maple sup-

Fig. 17. Reactance Coils in Low Tension Switch Room

ports, fastened to the concrete core by brass studs. The winding is insulated from all metal parts and the concrete core to withstand an insulation test of 33,000 volts for one minute. The temperature rise is limited to 40 deg. C. at normal operating conditions and to 300 deg. C. with fifteen times full load current for one minute. No iron or other magnetic material is used in the construction of these reactances, and furthermore they are sufficiently removed from such materials to maintain a straight voltage characteristic. The spacing between centers of coils is 78 in. and the magnetic clearances 72 in. from the center point and 26 in. from the ends. The reactances are 98 in. high, 56 in. in diameter, and weigh about 9000 lb.

Fig. 18. Completed Section of West High Tension Room, Fourth Floor

## Switching Equipment

The arrangement and sectionalizing of the busbars was described in the February issue of the Review, and a clear understanding of the switching equipment and the system of connections can best be obtained by reference to the general wiring diagram reproduced in that number.

All the switches, with exception of those for sectionalizing the low-tension busbars, are of the non-automatic type. On account of the double busbar arrangement, double generator and transformer switches, as well as line switches, are provided. The generator switches have a capacity of 500 amperes, and the low-tension transformer switches 800 amperes.

The automatic low-tension bus-section switches, which have a capacity of 2000 amperes, are opened by definite time limit relays actuated from current transformers in the outgoing lines and by inverse time limit relays in the main transformer leads. In this manner trouble on one section merely opens the two section switches and thus confines the trouble to the affected section. The relay settings, however, are adjusted to limit currents to values below those which would injure transformers, and also to limit the time during which line currents can supply an excessive arc. An arrangement is also made whereby the opening of the section switches will cause resistance to be inserted in the fields of the exciters for the short-circuited section, reducing the generator voltage to less than half of its normal value. This result is accomplished by special relays which open short-circuits across extra exciter field resistances. By this arrangement a certain class of troubles, such as arcing ground, etc., may be cleared through lack of potential without even causing the synchronous machinery on the system to fall out of step.

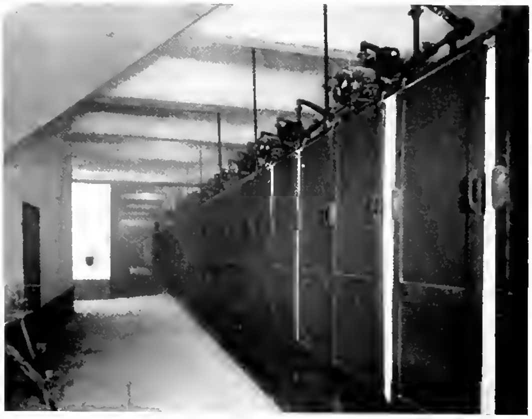

Fig. 19. Looking North Through Low Tension Switch Room

There are in all 74 low-tension oil switches, which are of the H-6, motor-operated type, with 10 in. pots mounted in concrete cells. Disconnecting switches are provided on both sides of every oil switch. These switches are mounted in sub-cells below the oil switches, and are equipped with locking devices to prevent accidental opening. The disconnecting switches for the reactances are mechanically interlocked with the sectionalizing oil switches so that they cannot be opened or closed until the oil switch is first opened.

The high tension switches, of which there are 21, are of the K-15 solenoid-operated type. Each switch has a capacity of 400 amperes, weighs 24,400 lb., occupies a floor space of 6 ft. by 17 ft., and has a height of 10 ft. The tank contains 1375 gallons of oil. Each switch is tested at 330,000 volts. A piping system is provided so that the oil can readily be drawn off to the oil storage tanks in the basement. By means of a track which runs the full length of the high-tension bus room floor, the handling of these switches, in case of repair, is greatly facilitated. All the switch tanks are thoroughly grounded, and a complete ground system with four ground plates is provided throughout the station.

High-tension disconnecting switches are also provided, as indicated on the wiring diagram. The blades of these switches have a length of about 4 ft. They are opened by long wooden rods, which are provided with grounded rings placed above the hand of the operator. When in use these rings are to be connected to the nearest ground bus, thus protecting the operator from danger of static shocks.

Fig. 21. View of Low Tension Bus Compartments

The generator leads consist of 600,000 c.m. single conductor cable, insulated with $\frac{3}{8}$ in. of varnished cambric and with a double braid flameproof covering. They are installed in fiber ducts.

The low-tension buses consist of $\frac{3}{8}$ in. by 3 in. copper bars, mounted on insulator supports and installed in an enclosed bus structure. This structure is built up of $2\frac{1}{2}$ in. molded concrete slabs set on 4 in. concrete barriers. The inside dimensions of each bus compartment are 15 in. by 15 in. and the total length of the compartments is over one mile, requiring over three thousand slabs.

Fig. 20. Looking South Through Low Tension Bus Room

Special provisions for expansion and contraction have been made in the construction of the buses, on account of their length, which is nearly equal to the full length of the station.

Fig. 22. Chief Operator's Room, showing Control Board and Switchboards

The connections from the low tension bus to the step-up transformers are similar to the generator leads, and are also run in fiber conduit.

Each of the two sets of high-tension buses are installed in a separate room. They consist of 2 in. standard iron pipes, bronze painted and spaced 6 ft. apart without any barriers between. They are suspended from the ceiling by 7-unit, 10 in. suspension insulators, dry tested at 440,000 volts. The connections from the high-tension bus to the transformers consist of $1\frac{1}{4}$ in. bronze painted iron pipe, and from the bus to the outgoing lines of $1\frac{1}{4}$ in. copper pipe. The pipes are supported by 6-unit post insulators, and large vertical air shaft passages are provided for the transformer connections.

The roof bushings are of the compound-filled type, tested at 440,000 volts dry and 330,000 volts wet. From these bushings the lines run through the lightning arrester choke coils to disconnecting switches. These switches are of a rotary double-break type, with 12 ft. blades spaced 24 ft. apart. They are opened from the roof by means of a lever, and provided with horns at both ends for breaking the charging current. By means of separate ground switches the lines can readily be grounded when repairs are to be made. Both the choke coils and disconnecting switches are mounted on a roof structure of steel, which also serves as anchor tower for the long river spans.

All the apparatus and their groupings are distinctly labeled throughout the station to avoid as far as possible accidents and mistakes in operation. The piping is painted in different colors to clearly indicate to what class it belongs.

### Operating Room and Control Switchboard

All the apparatus in the station is controlled electrically from an operating room, which is at present located on the fourth floor at the south end of the present building, but which will be in the middle of the station when the extension is completed. The generator room is not visible from the operating room, but by descending a few steps to an inspection balcony a good view is obtained of it.

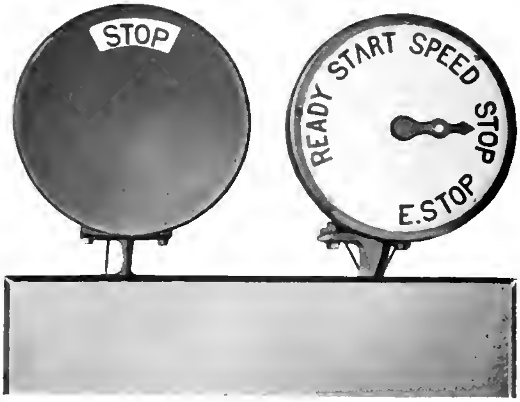

Fig. 23. Receiver and Transmitter for Signalling between Control Board and Generator Room

The operation of the station is completely controlled by a chief dispatcher, who is in telephonic communication with all parts of the system. A special desk is provided for him, on which is mounted the telephone switchboard, while in front of this desk a miniature arc-shaped switchboard is installed which contains a set of mimic busbars showing by means of small indicating lights the open or closed position of all the switches in the station. It also contains graphic voltmeters and ammeters for recording the voltage on each bus section and the current in each of the outgoing lines.

The main control switchboard is divided into six sections corresponding to the bus sections, with an additional section for the auxiliary equipment. The arrangement of these boards is at the present time in the form of an L, although ultimately it will be in the form of a U, with the despatcher board in the center.

The different sections comprise a total of 25 panels, with one panel for each generator and transformer unit and one for the section equipment and each outgoing line. The boards, which are made of black slate, are of the bench-type, with the control switches, indicating lamps, etc., mounted on the bench; while the instruments, generator voltage regulators, etc., are mounted on vertical panels back of the benches. The instrument equipments are as follows:

Fig. 24. Pedestal Containing Transmitter and Receiver, Located near Generator

### Generator and Transformer Panels

3 ammeters, 1200 amp., generator leads.
1 indicating wattmeter, 15,000 kw.
1 watthour meter.
1 wattless component indicator, 7500–0–7500 kv-a.
1 field ammeter, 600 amp.
3 ammeters, 2400 amp., transformer leads.

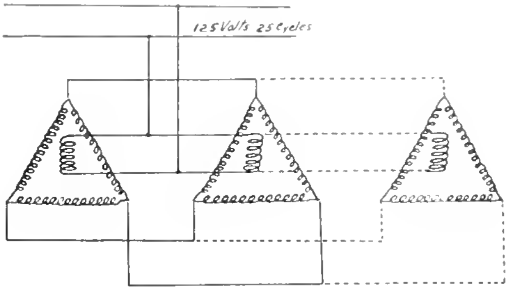

Fig. 25. Diagram of Connections of Transmitter and Receiver

### Section and Line Panels

1 synchronism indicator.
2 voltmeters for buses, 175 volts.
1 voltmeter for generators and transformers, 175 volts.
1 frequency indicator, 25 cycles.
1 generator field voltmeter, 350 volts.
1 transformer neutral ammeter, 600 amp.
1 exciter transformer ammeter, 1000 amp.
3 line ammeters, 1200 amp.
1 exciter transformer watthour meter.

Current and potential transformers are installed in the bus and wiring compartments. Of particular interest are the large 110,000 volt current transformers inserted in the outgoing lines. Transformers are provided with a spark gap to protect them against high voltage surges, etc.

The system for transmitting signals between the switchboard and generating room is quite novel. It is similar to that which will be used on the Panama canal to indicate the position of the lock machinery. The signals will be transmitted by "position indicators," which resemble to some extent small induction motors; these devices being provided with three-phase stator windings and single-phase rotor windings of the shuttle type. For operation, two position indicators are connected in multiple, the rotors being excited from a single-phase 125 volt, 25 cycle source, and the stators by induction. To send a signal, the rotor of one of the indicators is turned to any desired position, and the rotor of the connected machine or machines will assume a like position.

One transmitter and one receiver for each generator are provided on the switchboard, and also on a pedestal, similar to that shown in Fig. 24, located conveniently near each generator. The transmitter on the switchboard is operated through a cable and pulley arrangement by a handle located on the front of the board concentric with the handwheel which operates the field rheostat of the generator. This controlling handle is provided with a pointer which moves over the face of an indicating dial. The dial at the right in Fig. 23 is the receiver. The dial shown at the top of the pedestal is operated by the receiver end of the position indicator, which, as has already been stated, is controlled from the switchboard transmitter. The handle and pointer just below this dial are mechanically connected to the transmitter (located in the pedestal) which controls the receiver at the switchboard. On both the pedestals and benchboard, at each side of the transmitter handle, are located double push button switches which are employed for operating signal lamps, whistles and bells.

The method of signalling is as follows: When the switchboard operator desires to send a signal he turns the handle of the transmitter until its dial indicates the signal he wishes to send. This signal will be indicated on the dial of the receiver in the generator room. He then pushes the button on the right of the handle. This lights a lamp on the generator and blows a whistle in the generator room to attract the attention of the man in charge of the particular machine. As soon as the attendant has read the signal on his receiver, he will turn the handle of the transmitter on the pedestal to the same signal. He will then push the button at the right of the handle, which will extinguish the lamp and cut out the whistle. Next he will push the button at the left of the handle, which operation will light a lamp in the switchboard room and also ring a signal bell indicating to the switchboard man that the generator attendant has received the signal and also just what signal he received. The switchboard operator, after having seen this returned signal, will push the button at the left of the transmitter handle, which will extinguish the lamp and cut out the signal bell. This completes the cycle of sending and receiving a signal.

Double emergency cut-out switches are installed near all the generators, one on the main floor and the other on the exciter gallery. In case of trouble to one of the units it is only necessary to break the glass cover of the cabinet and pull the switch, which operation will close the gates and open both the main generator switch and the field switch, thus entirely disconnecting the unit.

The panels containing the circuit breakers and switches for the auxiliary generators, lighting, and other station service are located on the exciter gallery in the bays opposite the auxiliary generators.

Power for the electrical control of all the oil switches, etc., is obtained from two storage batteries, each consisting of 68 cells having a rating of 320 ampere-hours. For their charging two 15 kw., 750 r.p.m. motor-generator sets are provided.

Feeder regulators are used on several of the local and station circuits. The largest of these are the two three-phase water cooled induction regulators which control the two 3000 kw., 11,000 volt Burlington lines. These regulators have a range of 20 per cent, and their operation is by motors automatically controlled by contact-making voltmeters used in conjunction with line drop compensators. A number of smaller, self-cooled, automatically operated, single-phase regulators are also used for maintaining a constant voltage on the station lighting circuits.

A very complete telephone system has been installed. Nearly one hundred instruments are provided at various points in the station alone, and many others are installed in the substations and in telephone booths along the transmission lines.

### Lightning Arresters

Two sets of electrolytic lightning arresters are provided for the two outgoing 110,000 volt lines. These arresters are installed on the fourth floor, in separate rooms with fire doors, while the choke coils and horn gaps are mounted out-of-doors on the roof structure. The taps for the arresters are taken off between the choke coils and disconnecting switches, and bushings similar to the line entrance bushings are provided for passing the connections through the roof.

Each arrester consists of four tanks, three of which are connected to the line wires through the horn gaps, while the fourth tank is connected between the other three and ground. The arrester gaps are of the double-horn type with charging resistances. The auxiliary horn is mounted above and insulated from the regular horn in such a manner as to intercept the arc if it rises on the regular horn. Enough resistance is connected in series with this auxiliary horn so that the current flow and arc across this gap are always limited to a moderate value. Such a device has several advantages: Since the mechanism is so arranged that the charging is always done through the auxiliary horn, the current rush is limited during the charging and thus troubles from carelessness or ignorance are avoided. It also gives a more uniform charging current. Lightning discharges will pass across the auxiliary gap through the series resistance to the cells. If the discharge is heavy, the resistance offers sufficient impedance to cause the spark to pass to the main horn. This is accomplished with only a slight increase in potential, because the gap is already ionized. If the cells are in a normal condition the spark at the gap is immediately extinguished without any flow of dynamic current. If the cells, through either negligence or some untoward condition, are in poor form, the dynamic current may follow the discharge across the main gap and the arc will rise to the safety horn and be extinguished through a resistance.

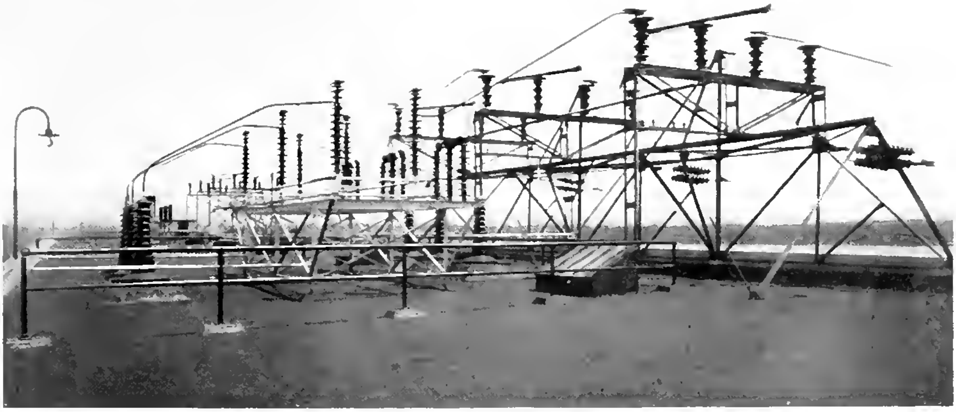

Fig. 26. Roof Structures for 110,000 Volt Line Entrance

Electrolytic lightning arresters are also installed for each of the 11,000 volt bus sections.

### Station Lighting and Service Equipment

The lighting in the generator room is done entirely by 500-watt tungsten lamps, other parts of the station being illuminated by tungsten lamps varying in size from 25 to 500 watts. The current for the lighting is normally taken from the 440 volt a-c. exciter bus, from which it is stepped down to 250/125 volt by means of three 75 kv-a. transformers. Arrangements are also made so that the current may be supplied from the 11,000 volt buses through three 75 kv-a. step-down transformers. Each of the lighting feeders is provided with a 7.5 kv-a. induction regulator for maintaining a constant voltage.

As a protective measure, about one-third of the lights, well distributed in the station, are arranged so that in case of trouble to the supply system they will be automatically switched over to one of the control batteries, which has sufficient capacity to operate them for about one hour.

Diffused illumination in the control room is provided by means of a skylight, which forms the entire ceiling. In order to prevent glare on the instruments it also became necessary to provide amber-colored glass in the windows. At night a diffused illumination is accomplished by tungsten lamps, which are mounted back of the skylight panes.

A complete steam heating system with water tube boilers is installed, and in connection with this there is a steam cleaning plant for waste, which necessarily is used in large quantities in a station of this magnitude.

The auxiliary power for driving the numerous pumps, cranes, etc., in the station is also ordinarily taken from the 440 volt exciter bus; but it may also be supplied from the 11,000 volt main bus through a 500 kw. three-phase, step-down transformer which is provided for this purpose.

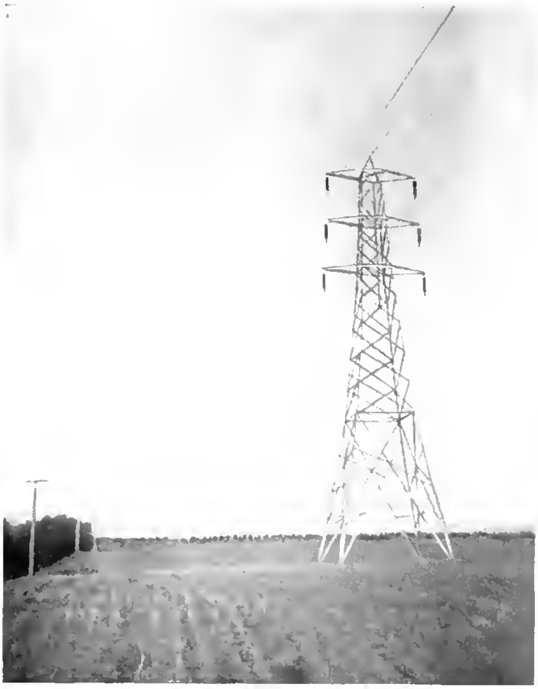

Fig. 27. St. Louis Transmission Line. Cable Strung on Line of Standard Towers

Two 150 ton travelling cranes are installed in the generating room and a 75-ton crane in the gate house.

A complete repair shop is located in the north end of the building, and ample store rooms are provided on both the main floor and the upper floor. Both freight and passenger elevators are provided, and spacious offices are located near the control room in the south end of the building.

There are locker and modern toilet rooms in several parts of the building, and both a vacuum and air pressure system for cleaning. Two complete water systems are installed, one for the transformer cooling, utilizing a pair of 5 in. duplicate headers extending the full length of the building, and the second for the house service.

### Transmission Lines

The bulk of the power is, as before mentioned, transmitted at 110,000 volts to St. Louis, a distance of about 144 miles from Keokuk. Several substations are, however, installed along this line for tapping off branch lines through which power is transmitted to other communities at lower voltages. For local consumption and for the territory north as far as Burlington, a distance of about 37 miles from Keokuk, the power is transmitted at 11,000 volts. A map illustrating the territory served by the various transmission lines was shown on page 86 of the February General Electric Review, while the above table gives the respective lengths and transmission voltages.

| Line | Length in Miles | Voltage |
|---|---|---|
| Keokuk-St. Louis | 143.6 | 110,000 |
| Meppen-Alton | 28.7 | 66,000 |
| Hulls-Ilasco | 8.3 | 33,000 |
| Hulls-Quincy | 19.3 | 33,000 |
| Keokuk-Burlington | 37.0 | 11,000 |
| Keokuk-Mooar | 5.8 | 11,000 |

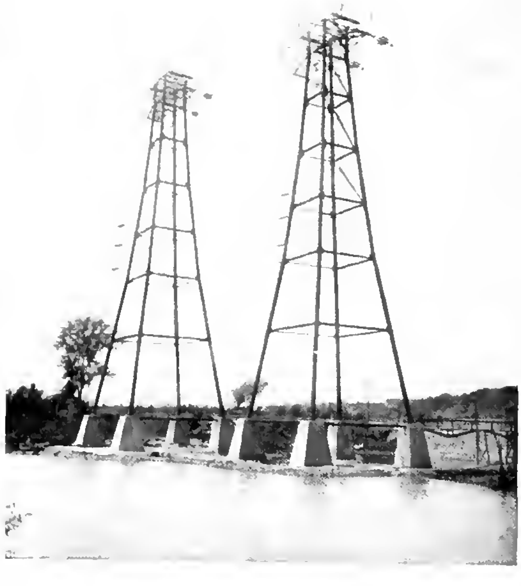

Fig. 28. St. Louis Line, 135 Foot River-Crossing Tower

**Keokuk-St. Louis Line**

This is a double-circuit steel tower line built on a 100 ft. private right-of-way, providing room for another future line. The normal span is approximately 800 feet, while the longest span, which is across the Missouri river, is 3180 ft. Strain towers are used at all angles, on both sides of railroad crossings, and for approximately every tenth tower on tangents.

The towers are all of the four-legged construction, the standard type having a total height of 79 feet and a base measurement of 20 by 20 ft. Its weight is 6800 lb., and it is designed to withstand the weight and side strain of all the conductors under the most severe weather conditions, besides the unbalanced pull caused by the breaking of two of the conductors.

The strain towers, to which the conductors are dead ended, have a total height of 74 ft., a width at the base of 24 by 24 ft., and a weight of 10,500 lb. These towers are designed to withstand the unbalanced pull caused by the breaking of all the seven wires.

Fig. 29. River-Crossing Insulator on Entrance Structure on Power House Roof

The line conductors consist of a 19-strand medium-drawn copper cable having a diameter of 5/8 in. and an area of 300,000 c.m. The three wires of each circuit are arranged in nearly a vertical plane at elevations of respectively 50, 60 and 70 ft. above the ground; the two circuits being suspended on opposite sides of the towers, with a spacing of about 18½ ft. The top wires are slightly closer together than the bottom ones.

Fig. 30. 66,000 Volt Line to Alton, Looking Towards Illinois River Crossing

The cable has an ultimate strength of 14,000 lb., which gives a factor of safety of two under the worst load conditions, which are assumed to be a one-half inch coating of ice, a 60-mile wind, and 0 deg. F. For an 800 foot span, this corresponds to a load of not more than 7000 lb. The corona voltage is approximately 150,000, which gives a wide margin above the normal operating voltage.

The suspension insulators on the standard towers consist of single strings of seven 10 in. disks in series, while at the anchor towers each conductor is fastened rigidly to the structure by two parallel strings, each consisting of eight 10 in. disks. The conductors are looped under the crossarm of the anchor towers. The suspension insulators have been subjected to a rain test of 330,000 volts and a dry test of 440,000 volts.

The ground wire, which is a ½ inch 7-strand galvanized Siemens-Martin steel cable, is mounted at the apex of the towers. Its ultimate strength is 11,000 lb. with a factor of safety of two.

All towers are provided with heavy reinforced concrete foundations. Those for the standard towers extend 6 ft. below ground and weigh about 2 tons per leg, while strain tower foundations extend 8 ft. below ground and weigh approximately 7½ tons per leg.

The transmission line crosses the Mississippi River twice and the Missouri River once, the spans varying from 1950 to 3180 feet, with a minimum clearance to the water surface of 70 feet. At each crossing the two circuits are separated and each circuit, together with a ground wire, is carried on separate towers. The first crossing is at Keokuk, where the span has a length of 2820 feet, extending from the roof structure on the power house to strain towers on the opposite shore, each having a total height of 145 feet and a weight of 88,300 lb.

The second crossing is at Brussels, where the river divides into three channels. Each circuit is carried across on three 160 ft. towers located on islands, the span varying from 1950 to 2400 feet. These towers, which weigh 76,400 lb. each, are only of an intermediate type, and the lines are dead-ended by means of lower anchor towers on the river banks.

The crossing of the Missouri River necessitates one span of 3180 feet and another of 2350 feet. The highest tower, which is located on an island at the midpoint of the crossing, has a total height of 230 ft., while the tower on the higher south bank of the river is 190 ft. high. The former tower weighs 107,400 lb. and the latter 84,700 lb. Both towers are of the intermediate type, the lines being dead-ended to the next ones, which are 60 ft. high and of the anchor type. All these river crossing towers are set on massive concrete foundations resting on bed rock, piles, or earth.

The conductor used for all these long spans consists of a ⅝ in. 19-strand core of special high-tension steel, with an outer stranding of 20 No. 10 B.&S. hard drawn copper wires, making a total diameter of ⅞ inch. They are rigidly fastened to the tower structures by a group of six parallel insulator strings, each consisting of eight 10-inch disks. A system of equalizing levers is provided for dividing the strain equally among the six strings. The ultimate strength of the conductor is 52,000 lb. and of the insulator banks 60,000 lb., which, under the worst load conditions of 24,000 lb., gives a safety factor of more than two. In order to prevent the swinging together of the wires, the conductors are spaced 20 ft. apart in a horizontal plane, with the ground wire above. These ground wires, which are similar to the steel core of the line conductors, serve as supports for the telephone wires and also as runways for the cable cars which are used for the inspection and repair of the spans.

For railroad crossings the conductors are dead-ended at the first two towers on each side of the track, the outside ones of which are of the anchor type. The conductors in these three spans are strung only at half normal tension, and in other respects the N.E.L.A. recommendations for railroad crossings are followed.

Each of the transmission circuits has a capacity of 45,000 h.p., with a voltage drop of 10 per cent and an energy loss of approximately the same amount.

A telephone line parallels the transmission line for the entire distance from Keokuk to St. Louis. It is built on one side of the right-of-way and consists of two No. 8 telephone conductors and a ground wire mounted on 30 ft. cedar poles with a spacing of 125 ft. Houses for the patrolmen are provided every 18 miles and telephone booths every 4 miles. Special precautions have been taken to insulate the telephone lines, and the protective equipment for the telephones consist of drainage coils, vacuum and multigap arresters, and fuses and insulating transformers.

### Meppen-Alton Line

This is a single circuit 66,000 volt line branching out from the main line at the Meppen substation and running as far as Alton, a distance of 28.7 miles. The conductors are supported on H-frame wood structures spaced 300 ft. apart. The structures consist of two cypress poles 6 in. in diameter at the top and 45 ft. high, and a wooden crossarm of two pieces 2 in. by 8 in. by 16 ft. Three No. 2 stranded copper conductors are supported in a horizontal plane by 4-disk suspension insulators and the two $\frac{5}{16}$ inch Siemens-Martin galvanized steel stranded ground wires are carried on the top of the poles. The two No. 8 copper clad telephone wires are supported on brackets on the sides of the poles.

This line crosses the Illinois River, necessitating four spans from 1160 to 1800 ft. in length. Five steel towers are used for these, having a height of 104 ft., a width of 34 by 34 ft. at the base, and weighing 36,800 lb.

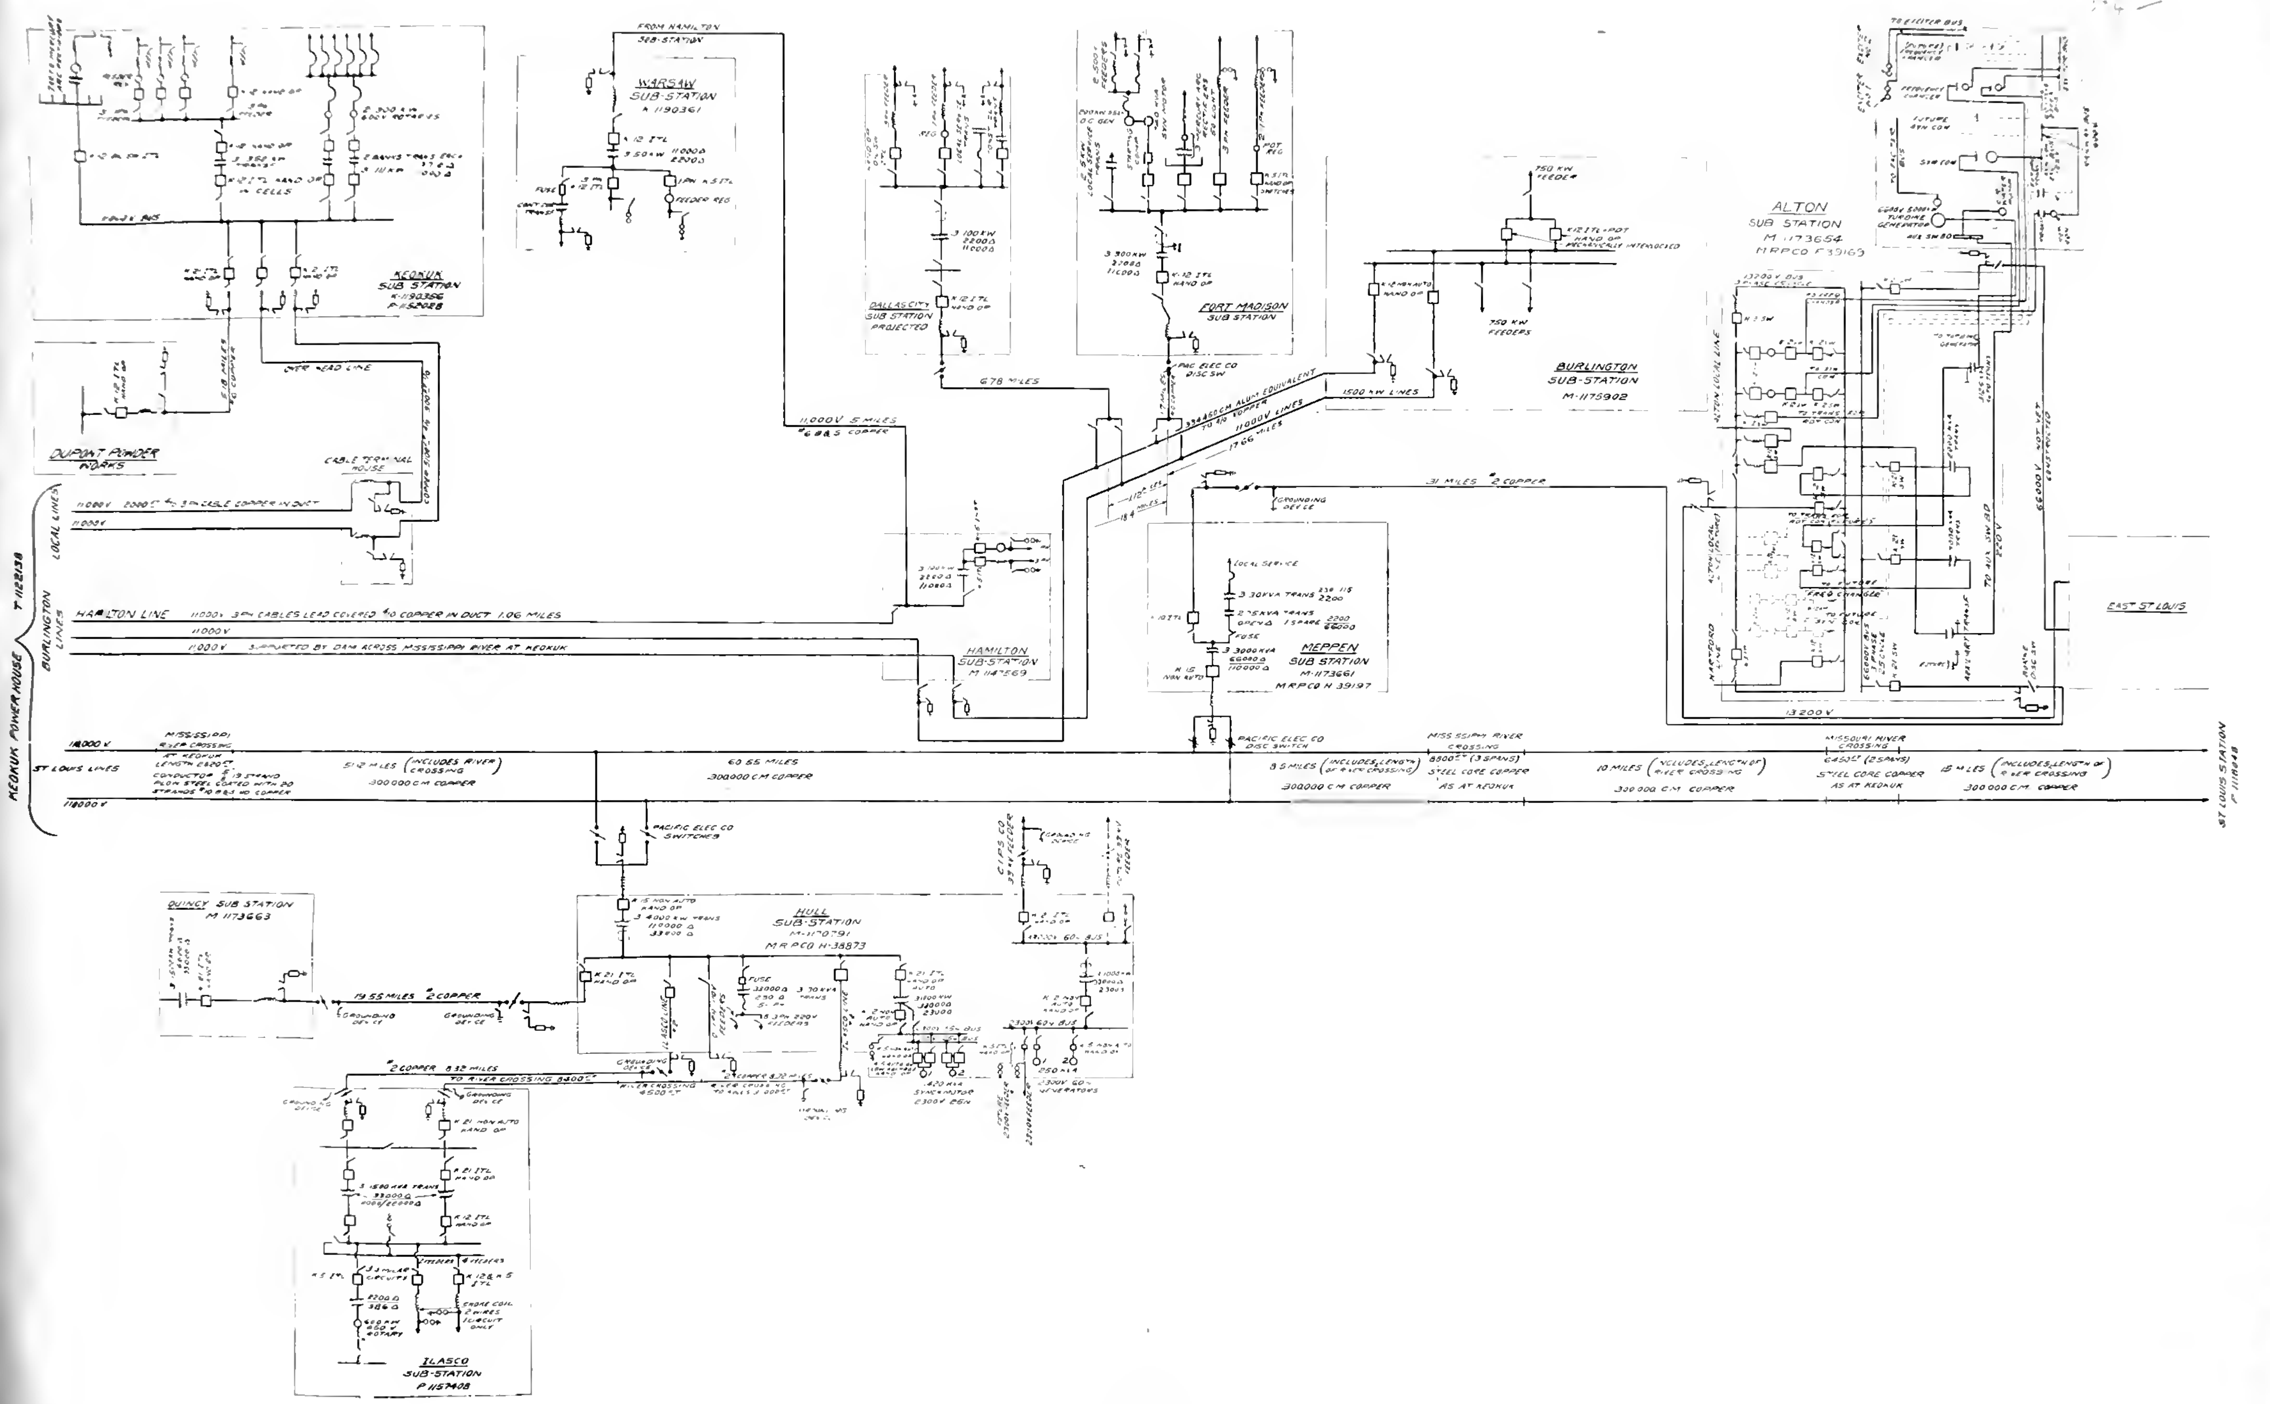

DIAGRAM OF TRANSMISSION LINES AND SUBSTATIONS, KEOKUK HYDRO-ELECTRIC DEVELOPMENT

The line conductors here consist of 5/8 in. Monitor steel strand, supported from the middle crossarm by three parallel 4-disk insulators. The ground and telephone wires are of 3/8 in. high-tension steel, the former being supported from the upper crossarm and the latter from the lower crossarm by two parallel 4-disk strings.

### Hulls-Ilasco Line

The length of this line is 8.3 miles and the transmission voltage 33,000. The line consists of two single circuits of three No. 2 B.&S. stranded hard-drawn copper conductors mounted on pin type insulators on 40 ft. Idaho cedar poles spaced 140 ft. apart. A 1/4 in. galvanized stranded steel ground wire is mounted on the top of the poles, and two No. 8 B.W.G. galvanized iron telephone wires are carried on a crossarm below the two crossarms carrying the line conductors.

This line also crosses the Mississippi River in two spans of 1650 and 2850 ft. lengths. Three steel towers are used for these spans: a 60 ft. tower on the Illinois shore, and two 190 ft. towers, one on King's Island and the other on the Missouri shore. The latter tower is of the anchor type with a base 50 ft. square and a weight of 122,870 lb., while the other 190 ft. tower is of the intermediate type with a base of 42.5 ft. square and a weight of 96,260 lb. The line conductors, which consist of 5/8 in. stranded Monitor steel cores surrounded by twenty No. 10 copper wires, are rigidly supported by 6-string 8-disk insulator groups, as were the river spans of the St. Louis line. Similarly, the two ground wires are of 5/8 in. Monitor steel and serve as supports for the two No. 8 telephone wires.

### Hulls-Quincy Line

This is also a 33,000 volt single circuit branch line with a length of 19.3 miles. The three No. 2 stranded copper wires are carried on pin type insulators on 40 ft. Missouri cypress poles, spaced 140 ft. apart in the country and 125 ft. inside the Quincy city limits. A 1/4 in. Siemens-Martin steel strand ground wire is carried along the top of the poles, except inside the city limits, where it is supported above the poles on a channel iron support.

Two No. 8 hard drawn bare copper wires are used for the telephone circuit, which is carried on crossarms below the conductors, except on the stretches where the line parallels the St. Louis line, in which case it is carried on the telephone poles of that line.

### Keokuk-Burlington Line

This line extends northward from the substation in Hamilton, to which power is fed from the generating station through lead-covered cables carried across the dam in fiber ducts. The distance to Burlington is 37 miles and the transmission voltage is 11,000. The line conductors consist of six 19-strand, 4 0 equivalent aluminum cables carried on pin insulators which are mounted on 40 ft. Idaho cedar poles spaced 140 ft. apart. These poles are provided with three crossarms, two of the line conductors being mounted on the upper and four on the middle while the lower serves for supporting the two No. 8 B.&S. copper wires constituting the telephone circuit. A ground wire of 5/16 in. Siemens-Martin galvanized steel strand is carried above the tops of the poles by 3 in. steel channels. The line is grounded every fifth pole.

### Keokuk-Mooar Line

Power for local distribution in the vicinity of Keokuk is also carried through lead-covered cables from the power station to a cable terminal house on the west side of the railroad tracks. In this building the lead-covered cables are terminated and the lines conveyed overhead from this point.

The Mooar line, for supplying power to the DuPont Powder Works, is of single circuit, 11,000 volt construction and has a length of 5.8 miles. Where it passes through the country, the poles, which are Missouri cypress, have a height of 35 ft. and are spaced 140 ft. apart, while through the city alleys they have a height ranging from 40 to 60 feet with a spacing of 125 ft. The three No. 2 copper conductors are all carried on one crossarm 5 ft. below the No. 6 galvanized steel ground wire, which is carried along the tops of the poles.

No transpositions are made on the 110,000 and 66,000 volt transmission lines, but the 33,000 and 11,000 volt lines are transposed every third mile. All telephone circuits are transposed every fifth pole.

## SUBSTATIONS

### St. Louis Substation

This station, which is by far the largest on the system, was built and is owned and operated by the Electric Company of Missouri, formerly known as the Mississippi River Power Distributing Company. The station has a capacity of 60,000 kw., and the power is distributed to two large customers, the Union Electric Light & Power Company and the United Railways Company. It is a brick structure laid out in the form of a T, with a length of 219 ft., a maximum width of 150 ft., and a height of 60 ft.

Fig. 31. Cooling Basin for Transformer Circulating Water. St. Louis Substation

There are four 110,000 volt incoming circuits, as each of the two Keokuk lines are split up into two circuits about a $^1{}_4$ mile from the station. These circuits enter through roof entrance bushings and connect through line switches with a high-tension bus, which is divided in four sections separated by oil switches, each circuit feeding one section. The low-tension bus is similarly divided into four sections, with an additional connection forming a ring bus. Four transformer banks are provided, one for each section.

The high tension bus is normally sectionized in the middle, while the low tension bus has all the sectionalizing switches open so that there are four separate groups of feeders on the low tension side. Two of these supply the Union Electric Light & Power Company and two the United Railways Company. One group in each pair is tied together on the high-tension bus to one transmission line, so that both these companies have two separate sources of supply all the way back to the generating station. Furthermore, as either line is capable of transmitting the full load of the station, no interruption to service will result in case one line is temporarily out of service.

All the outgoing feeders for the United Railways Company are three-phase, 25 cycle, 13,200 volt circuits. In addition this Company has installed in the substation two 2000 kw., 375 600 volt rotary converters with air blast step-down transformers for supplying power to the territory nearest the substation, and additional space is provided for two future units.

A number of the outgoing lines of the Union Electric Light & Power Company are also three-phase, 25 cycle, 13,200-volt circuits. This Company has, however, installed a 5000 kw., 25 60 cycle frequency changer set with step-down transformers, and space is provided for a future set. The 25 cycle motor is wound for 6600 volts and the 60 cycle generator for 4400 volts, with the neutral brought out. The generator is connected to a double set of 4-wire buses, which supply power to a number of 60 cycle, single-phase outgoing feeders provided with induction regulators. A group of three 3000 kw., single-phase, 60 cycle, 4400 13,200 volt step-up transformers are also provided for supplying 60 cycle power to the territory farthest away from the station.

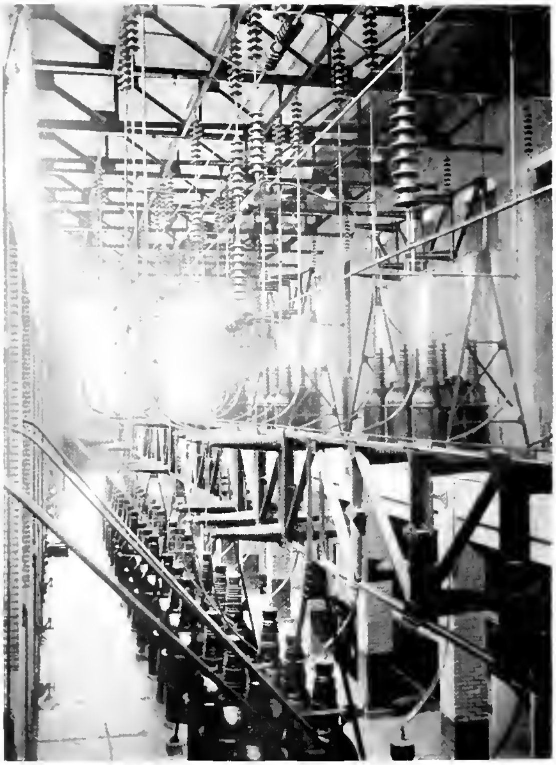

Fig. 32. High Tension Oil Switch Gallery St. Louis Substation

The high-tension apparatus is located in that portion of the building corresponding to the stem of the T, and the rotating machinery in the transept. The four incoming line switches are installed on a gallery, while the high-tension transformer and section switches are placed on the main floor and below the busbars, which are suspended from the roof trusses.

The transformers are placed in compartments along the west side of the high-tension room. These compartments are provided with rolling sheet iron doors in the outside walls, so that in case of repairs the transformers may be carried outside and placed on a transfer truck which runs to the end of the building, where they are taken into the repair room.

Fig. 33. 5000 Kv-a. Transformer in St. Louis Substation

The low-tension oil switches are installed underneath the gallery in the high-tension room, and the buses beneath in the basement, while the control board is located on the gallery facing the machine room.

There are four main transformer banks, each consisting of three 5000 kw., 95,000 13,800 volt, delta-delta connected, single-phase, water-cooled transformers. Each transformer requires about 5000 gallons of oil and weighs complete about 57 tons. A large cooling basin is provided a short distance from the station. It has not been found necessary to use spray, and provision is made simply for the radiation of the heat from the water to the air. Approximately 36 hours is required for the water to circulate through the cooling basin, two motor-driven pumps being provided for pumping the water. The oil drain is piped through a quick-opening valve to an oil tank in the basement. There is one tank for each transformer bank. These tanks are installed in the basement in fireproof compartments provided with iron doors. In order to make sure that these compartments are kept clean, and to obtain better ventilation, their doors are normally held open by weighted chains. These chains are provided with a fusible link which melts in case of fire and closes the door. A filter press is provided for cleaning the oil.

The incoming circuits are anchored to a structural steel roof, which also supports four line disconnecting switches. These switches are of the motor operated type, controlled from the switchboard in the station. Provisions are also made on the roof for grounding the lines by special pull-type grounding switches.

All the high tension switches are of the solenoid-operated type, and the low-tension switches of the motor-operated type. The equipment provides two parallel reverse energy relays in the low-tension leads of every transformer bank. One of these relays, which is of the instantaneous type, trips the middle sectionalizing switches of both the high- and low-tension buses, while the other relay, which has a time element, trips the high-tension line switches. In case of a short-circuit in one of the lines, power will be fed into this both from the generating station at Keokuk and from the Union Electric Light & Power Company's 20,000 kw. steam station in St. Louis. In such a case the bus sectionalizing switches will open first, due to the instantaneous action of their relays, and thereafter the line switch of the faulty line, thus cutting out this line without disturbing the operation of the other. As usually operated, however, the high-tension bus is normally sectionalized in the middle and all the low-tension section switches are open.

The effectiveness of this protective system has been fully demonstrated. During the only case of line trouble which has occurred, a dead short-circuit on the line was handled by the automatic equipment without any interruption whatever in the delivery of the full amount of power being taken at the time by each receiving company.

Disconnecting switches are provided for isolating all the oil switches. The low-tension type is of the ordinary switch blade design, but the high-tension switches are of a special plug-type design, making it possible to reduce the width of the switch room about 36 feet.

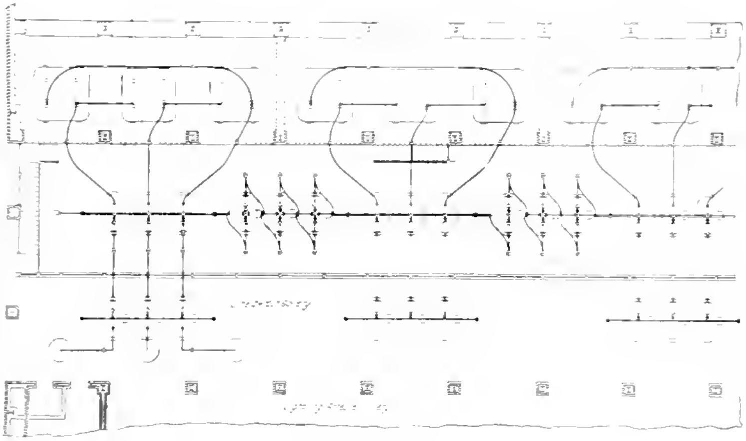

Fig. 34. Partial Plan of St. Louis Substation

These plug-type switches consist of vertical sliding rods with concentric spring contact blocks similar to those of the familiar H-3 oil switches. The rod can be firmly locked in the closed position by means of a bayonet joint.

The high tension busbars consist of 1 in. copper tubing, supported in a vertical plane from the roof trusses by means of suspension insulators comprising eight 10-in. disks, the different sections being separated by strain insulators consisting of ten 10-in. disks. All the high-tension connections are also of 1 in. copper pipe, except the leads from the transformer switches to the transformers, which are of iron pipe.

The low tension main and group buses consist of copper bars mounted on insulators in concrete compartments in the basement. The ring connection for the main bus consists, however, of cables drawn through fiber ducts in the wall back of the bus compartments, this arrangement resulting in a considerable saving of space. All the low-tension connections, furthermore, consist of cable run through fiber ducts in walls and floors, and provided with fireproof coverings in the manholes. The low-tension connections in the transformer compartments are encased in concrete columns, as seen in Fig. 33. This serves both as a support for the leads and as a protective feature. All the outgoing feeder circuits for the city service leave the station through underground lead-covered cables while the county service is supplied through both overhead and underground circuits.

The control switchboard is of the ordinary benchboard construction. In addition to this there are four terminal or meter boards, one for each bus section. These boards are located in the low tension switch room adjacent to the feeder circuits which are to be measured, and graphic-recording and integrating meters are mounted thereon instead of on the benchboard. This reduces the running of a considerable amount of instrument leads to the main switchboard, and results in a great saving in both control wire and conduit. Interconnections are also made between the terminal boards, so that if it is desired at any time to record the output of one board on the meters of another board, this can readily be accomplished.

All the transformer and switch banks, etc., are thoroughly connected to the ground system, which consists of pipes driven into the ground under each building column, with bare copper wires carried around to various parts of the building.

Current for the oil switch operation is obtained from a storage battery, a small motor-generator set being used for charging the battery.

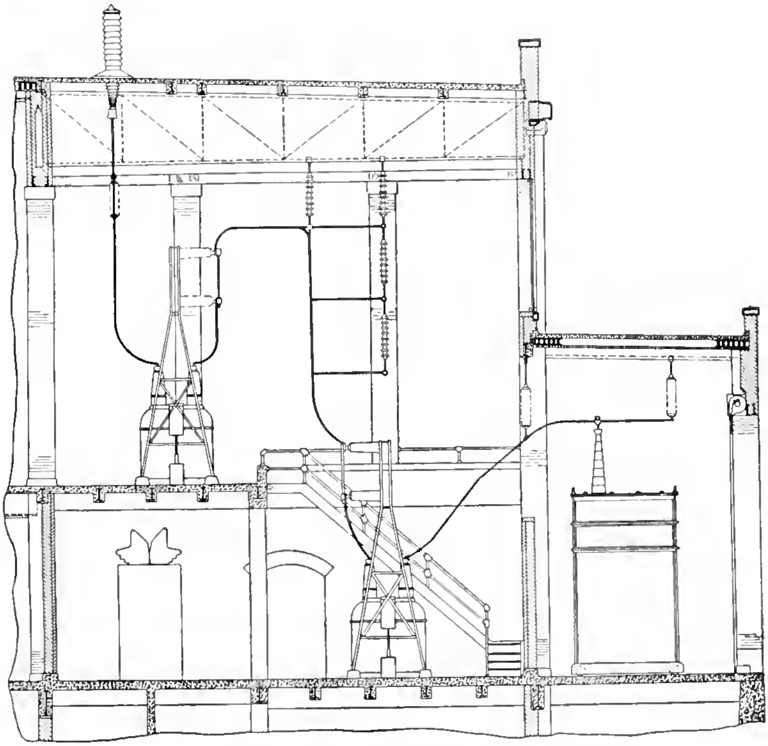

Fig. 35. Sectional Elevation, St. Louis Substation

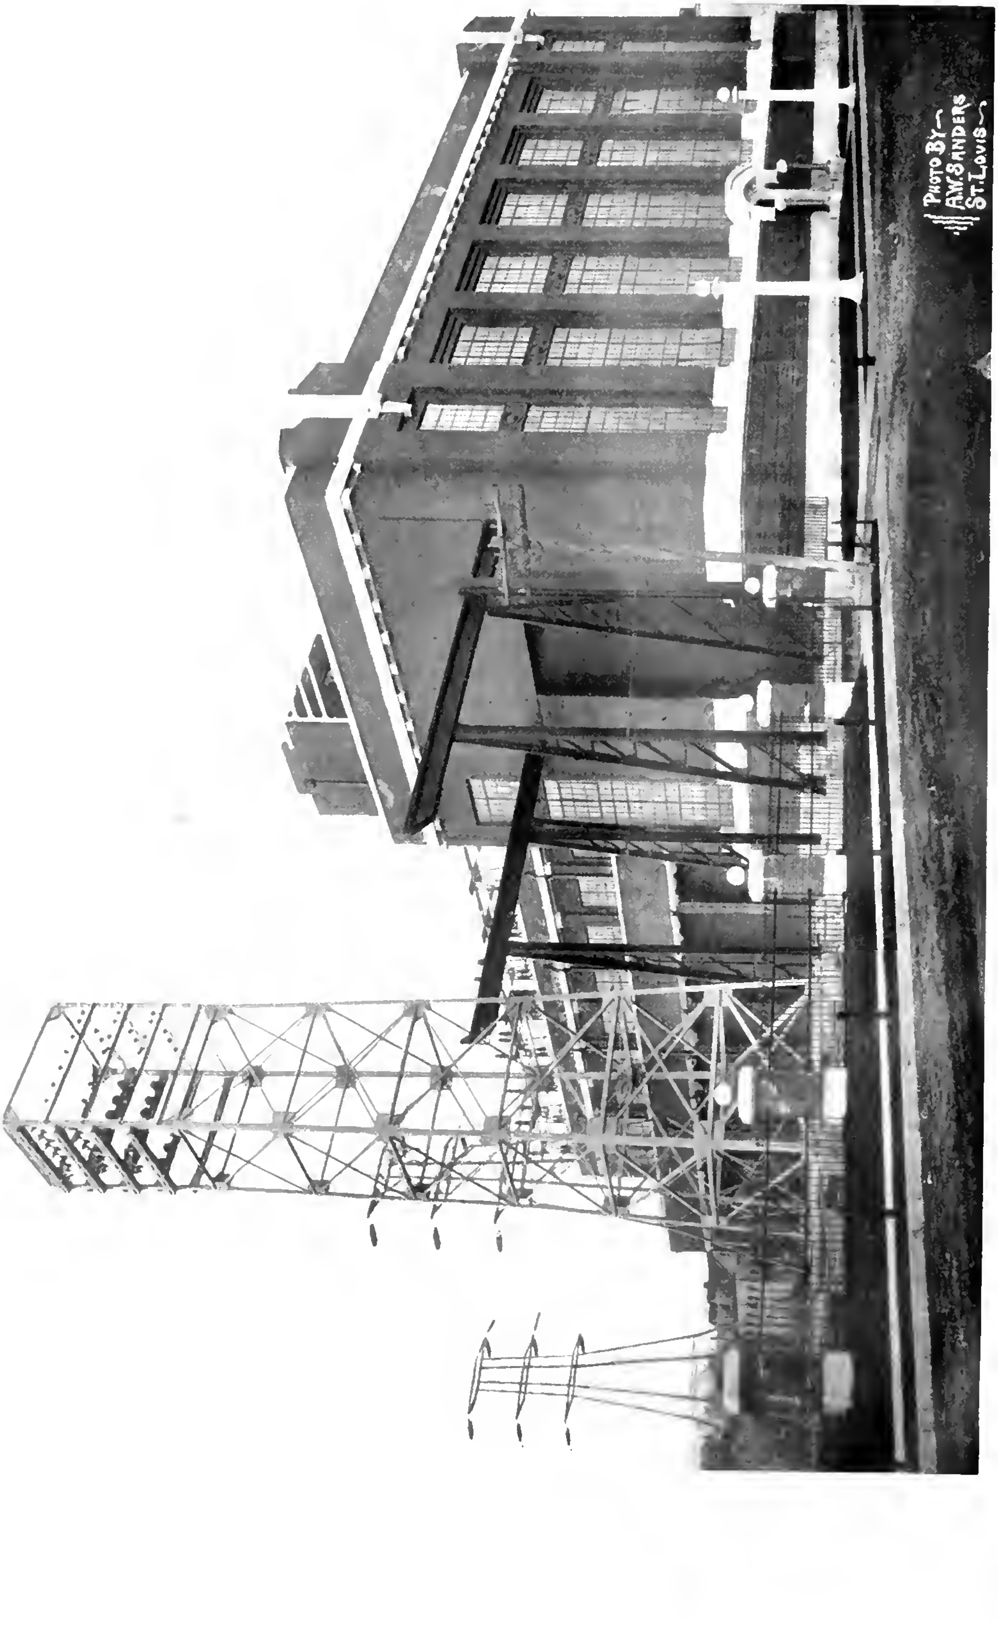
Four electrolytic lightning arresters are provided for the incoming lines. They are of the same design as those for the generating station; the tanks being placed indoors, while the horn gaps and choke coils are mounted on the roof. Each of the four low-tension bus sections is also equipped with an arrester of the electrolytic type.

The auxiliary equipment in the station is very complete. A bank of three 50 kv-a., 13,200-200/110 volt transformers, with one spare unit, is installed for supplying current to the light and power circuits in the station. A large crane is provided for handling the heavy machinery in the low-tension machine room. It can be run out of the building onto a steel trestle, and is also used in connection with the tracks and turntable outside the building to move the large transformers with block and tackle and to pull the transfer trucks along the track. Pumps are provided for draining the basement in case it should get flooded, and a compressed air system is provided for cleaning purposes. This system is quite novel in that the compressed air is carried around the station through the iron pipes which are used for railings in the various rooms and galleries. This has resulted in a material saving in the amount of pipe used.

The design of this station has been carried out under the supervision of Mr. C. S. Ruffner, General Manager of the distributing company.

### Other Substations

There are a large number of other substations which have been built and which are operated by either the Mississippi River



St. Louis Substation

Power Company or their customers. These are located at Meppen, Alton, Hull, Ilasco, Quincy, Hamilton, Warsaw, Fort Madison, Dallas City, Burlington, Keokuk and Du Pont. The equipments and system of connections of these stations are clearly illustrated in the diagram facing page 384.

The construction of this entire plant, with the exception of the St. Louis substation, has been carried out by the Mississippi River Power Company and no work has been contracted for. All the hydraulic design and construction in connection with the dam, lock and power house have been under the personal supervision of the Company's Chief Engineer, Mr. H. L. Cooper, while the Stone & Webster Engineering Corporation has had charge of the installation and erection of all the electrical equipment, including the power station, substation and transmission lines. The plant is now being operated by the Stone & Webster Management Association. With the exception of the transmission line material and a few other minor apparatus, the entire electrical equipment was furnished by the General Electric Company.

# EFFECT OF ELECTRICAL ENGINEERING ON MODERN INDUSTRY

By Charles P. Steinmetz

Chief Consulting Engineer, General Electric Company

This article is divided into two parts. The first section makes prominent the fact that, while the two forms in which energy is transported, viz., in chemical form and in electrical form, are both commercially practical so far as transportation is concerned, electricity alone permits of facile conversion of the energy into those other forms in which it is usually used. Among the examples brought out in the discussion following, to exhibit the influence of this feature upon modern industry, are some which show that, while it is true that the use of electricity adds convenience to all previously existing processes, the manufacture of many products would be commercially impossible without it (this being due to its property of high energy concentration). An exceedingly clear exposition of "load-factor" and "diversity-factor" concludes this section. The second part of the article shows that our modern civilization, and consequently our industries, has been brought about by the transportation of both materials and energy. The former is carried on by railroads and steamships, the latter by electrical distribution systems. The influence of electricity upon our industries is then outlined. This article appeared in the *Journal of the Franklin Institute*, February, 1914.—Editor.

## I.

The use of electricity in modern civilized life is rapidly increasing: in lighting our homes, factories, streets; in industrial power applications; in domestic service, from the fan motor to the electric bell or the heating and cooking device; in transportation: and while no great inroads have yet been made into the field of the steam locomotive, an entire system of electric railroads has sprung up all over the country, fully comparable in size and power demand with the steam railway system; large new industries have developed in electro-chemistry and electro-metallurgy, supplying us with materials unavailable before—as aluminum—or improving the production of other materials—as in copper refining, etc.

All these applications are uses of *energy*. In nearly all, electrical energy is replacing some other form of energy used heretofore: chemical energy of fuel, or mechanical energy of steam or gas engines, etc.

To understand the reasons which enable electrical energy to compete successfully with other forms of energy, which are longer and more familiarly known, we have to look into its characteristics.

Electrical energy can be transported—or, as we usually call it, transmitted—economically over practically any distance. Mechanical energy can be transmitted over a limited distance only, by belt or rope drive, by compressed air, etc.; heat energy may be carried from a central steam heating plant for some hundred feet with moderate efficiency, but there are only two forms of energy which can be transmitted over practically any distance, that is, which in the distance of transmission are limited only by the economical consideration of a source of energy nearer at hand: electrical energy, and the chemical energy of fuel. These two forms of energy thus are the only competitors whenever energy is required at a place distant from any of Nature's stores of energy. Thus, when we study a problem in electric power transmission and consider whether it is more economical to transmit power electrically from the water power or the coal mine or to generate the power by a steam plant at the place of demand, both really are transmission problems; and the question is whether it is more economical to carry energy electrically over the transmission line, or to carry it chemically, as coal by the railroad train or boat, from the source of energy supply to the place of energy demand, where the energy is converted into the form required, as into mechanical energy by the electric motor or by steam boiler and engine or turbine.

Electrical energy and chemical energy both share the simplicity and economy of transmission or transportation, but electrical energy is vastly superior in the ease, simplicity, and efficiency of conversion into any other form of energy, while the conversion of the chemical energy of fuel into other forms of energy is difficult, requiring complicated plants and skilled attendants, and is so limited in efficiency as to make the chemical energy of fuel unavailable for all but very restricted uses: heating and the big, high-power steam plant. Pressing the button turns on the electric light and thereby starts conversion into radiating energy: with chemical energy as source, either special fuels are required—in the candle, kerosene lamp—or a complex gas plant. Closing the switch starts the motor, whether a small fan motor or a 1000-horse power motor supplying the water system of a city or driving the railroad train. With fuel as the source of energy, the boiler plant, the steam engine, or turbine, with their numerous auxiliaries, and skilled attendants, etc., are necessary, and the efficiency is low except in very large units. To appreciate the complexity of the conversion of the chemical energy of fuel, compared with the simplicity of electrical energy conversion, imagine the domestic fan motor with coal as the source of energy: a small steam engine, with boiler and furnace, attached to the fan: to start the fan, we have to make a coal fire and raise steam to drive the engine. This illustrates how utterly unavailable the chemical energy of fuel is for general energy distribution. General energy distribution, therefore, may justly be said to date from the introduction of electric power.

Equally true is the reverse: the conversion of mechanical or other energy into electrical is simple and economical, while the conversion into chemical energy is not. Hence, one of the two large sources of Nature's energy, the water power, was, before the days of electrical engineering, useless except to a very limited extent, since the location of the water power is rarely such that the energy could be used at its source. The water powers thus have really been made available only by the development of electrical transmission.

It is a characteristic of electrical energy that it can be concentrated to an energy density higher than any other form of energy, and results can thus be produced by it which no other form of energy can bring about, or do directly by the brute force of energy, as we may say, which formerly had to be brought about in a roundabout way.

Thus iron can be reduced from its ores by the chemical energy of coal in the blast furnace, but aluminum and calcium can not, as their chemical affinity is higher, and require the higher energy concentration available with electric power. Iron reduced in the blast furnace combines with carbon to cast iron. So calcium combines with carbon in the electric furnace to carbide, the starting material of acetylene, and of cyanamid and the modern fertilizer industry. Platinum can just be melted, and quartz softened, in the hottest flames of combustion: the oxy-acetylene flame and the oxy-hydrogen flame. But in the electric arc platinum and quartz and every existing substance, even tungsten and carbon, can be melted and distilled or sublimed. Thus mighty industries have grown up and many new materials made available to man, as aluminum, silicon, calcium, chromium, the carbides, cyanamid, acetylene, etc.; others produced in a cheaper manner, as alkalies, hypochlorites, phosphorus, magnesium, sodium, etc.

Electricity as such is the most useless form of energy: it is not found in Nature in industrially available quantities, and finds no industrial use as electrical energy, but it is always produced from some other form of energy, and converted into some other form of energy: light, mechanical energy, chemical energy, heat, etc. That is, electrical energy is entirely the connecting link, the intermediary, by which energy is brought from the place where it is found to the place where it is used, or changed from the form in which it is found to the form in which it is used. Thus, on first sight, it appears a roundabout way, when, for instance, in modern electrical ship propulsion an electric generator is placed on the steam turbine, and a motor on the ship propeller, a few feet away, though it is not different from practically every other use of electric energy: a transmission link, superior to any other transmission by the flexibility given by the simplicity and economy of conversion.

The most serious disadvantage of electrical energy is that it can not be stored. It is true, there exists the electric storage battery, and it is used to a large extent as a stand-by battery in high-grade electric distribution systems to give absolute reliability of service, or as a battery floating on a railway circuit to equalize fluctuations of power, or in special applications, as electric automobiles. It does not really store electrical energy, but stores energy by conversion of the electrical into chemical energy, and by reconversion, in discharge, of the chemical into electrical energy.

The economic efficiency of the storage battery—using the term in the broad sense including interest on the plant investment and depreciation—is so low that the storage battery does not come into consideration in the industrial storage of energy—that is, in making the rate of electrical energy consumption independent of that of energy production. We can best realize this by comparing electrical energy with the chemical energy of fuel: the latter can be stored with perfect economy. Thus, when using fuel as the source of energy—in a steam plant—no serious difficulty is met by the industry even if the fuel supply is interrupted for months, as in the case of a supply by water, through the closing of the navigation by ice: we would simply bring in a sufficient coal supply to last until the navigation opens again in spring. But with electrical energy from a water power we could never dream of storing energy by storage battery to last over the two or three months during which the river runs dry and the water power fails.

This means that electrical energy must be consumed at the rate at which it is produced, and the cost of electrical energy thereby becomes dependent on the rate of the energy used. This is not the case with most other forms of energy, as, for instance, the chemical energy of fuel. The price of a ton of coal, as determined by the cost of supplying it, is the same whether I dump the coal into a furnace all at once, or whether I use it up at a uniform rate in a small stove, lasting for weeks. If I consume 2400 cubic feet of gas per day, its cost and thereby its price is the same whether I use the gas at a uniform rate throughout the day, of 100 cubic feet per hour, or whether I use the entire 2400 cubic feet in one hour, nothing in the remaining 23 hours: the gas is produced at whatever rate is most economical, stored in the gas holders and supplied from there at whatever rate it is required for consumption. If, however, I use 240 kilowatt-hours of electrical energy per day, it makes a very great difference in the cost of supplying this energy whether I use it at a uniform rate of 10 kilowatt-hours per hour, or whether I use the entire 240 kilowatt-hours in one hour, nothing in the remaining 23 hours. In the former case, 10 kilowatts of generating machinery are necessary in the steam or hydraulic station producing the electric energy, 10 kilowatts capacity in transmission lines, transformers, substation and distribution lines, to supply the demand. In the latter case, 240 kilowatts of generating machinery, 240 kilowatts of line and transformer capacity are absorbed, and that part of the cost of supplying the electric energy, which consists of interest in investment in the plant, of depreciation, etc.—in short, the fixed cost—is 24 times as high in the latter as in the former case. If the fixed cost approximates half the total cost in a steam plant, or is by far the largest part of the total cost in a hydraulic plant, it follows that in the case of concentrated energy used during a short time the cost of electric energy—and with it the price—will be very much larger—many times, possibly—as in the case of a uniform energy consumption.

Thus, due to the absence of storage, the cost of electrical energy essentially depends on the uniformity of the rate of its use—that is, on the load factor, or the ratio of the average consumption to the maximum consumption.

If I use 240 kilowatt-hours of electrical energy in one hour, nothing during the remaining 23 hours, that part of the cost which is the fixed cost of plant investment and depreciation is 24 times as great as if I used the same amount of energy at a uniform rate throughout the day. In the former case, if somebody else uses 240 kilowatt-hours, but during another hour of the day, the same plant supplies his energy, and the fixed cost thus is cut practically in two—that is, the cost of energy to both of us is materially reduced. Thus, again, the cost of electrical energy, and with it its price, depends on the overlap or not overlap of the use of the energy by different users, the so-called "diversity factor." The greater the diversity factor—that is, the less the different uses overlap and the more their combination, therefore, increases the uniformity of the total energy demand, the "station load factor"—the lower is the energy cost. The cost of electrical energy for lighting, where all the demand comes during the same part of the day, is inherently much higher than the cost for uniform 24-hour service in chemical works, and with the increasing variety of load, with the combination of energy supply for all industrial and domestic purposes, the cost of energy decreases.

Thus, unlike other forms of energy, due to the absence of energy storage, electrical energy can have no definite cost of production, but, even supplied from the same generating station, its cost varies over a wide range, depending on the load factor of the individual use and the diversity factor of the different uses.

This feature, of necessity, must dominate the economical use of electrical energy in industrial, domestic, and transportation service.

## II.

Civilization results in the complete interdependence of all members of society upon each other. Amongst the savages each individual, family, or tribe is independent, produces everything it requires. In the barbarian state some barter develops, followed by trade and commerce with increasing civilization. But up to a fair state of civilization—up to nearly a hundred years ago—all necessities of life were still produced in the immediate neighborhood of the consumer, each group or territory still independent in its existence, and commerce dealing with such things only which were not absolutely necessary for life. All this has now changed, and in our necessities of life, as well as in our luxuries, we depend on a supply from distances of hundreds and thousands of miles: the whole world contributes in the supply of our food, clothing, building materials, etc.

That means, our existence is dependent on an efficient and reliable system of transportation and distribution of all needs of civilized life. Such has been developed during the last century in the system of steam railroads, which, in taking care of the transportation and distribution of commodities, have made modern civilization possible. Civilization means separation of production, in time and in location, from consumption, to secure maximum economy.

The necessities of civilized life consist of two groups: materials and energy. Our transportation system takes care of materials, but can not deal with the supply of energy, and the failure of an efficient energy supply has been and still is the most serious handicap which retards the advance of civilization. The transportation system could deal with the energy supply only in an indirect manner, by the supply of materials as carriers of energy, and when our railroads carry coal it is not the material which we need, but the energy which it carries. But this energy is available only to a very limited extent, as heat, and as mechanical power in big steam units; most of the energy demands of civilized life could not be satisfied by it In any country village far away from the centers of civilization we have no difficulty to have delivered to us any material produced anywhere in the world; but even in the centers of civilization we could not get the energy to run a sewing machine or drive a fan without *electric power*. Thus, just as our steam railways and express companies take care of the transportation and distribution of materials, so civilization requires a system of transmission and distribution of energy, and our electric circuits are beginning to do this; and just as fifty to seventy-five years ago in the steam railroads, steamship lines, etc., the system of transportation and distribution of materials was developed, so we see all around us in the electric transmission systems the development of the system of the world's energy transmission in progress of development When we see local electric distribution systems combining, the big electric systems of our capital cities reaching out over the country, transmission lines interconnecting to networks covering many thousands of square miles, this is not merely the result of the higher economy of cooperation, of mass production, but it is the same process which took place in the steam railroad world some time ago, as a necessary requirement of coordination to carry out their function as carriers and distributors of materials in the case of the railroads, of energy in the case of the electric systems.

We must realize this progress, and the forces which lead to it, so as to understand what is going on, and to assist in the proper development, in avoiding, in the creation of the country's electrical network, whatever mistakes have been made in the development of the country's railway network.

Electricity, thus, is taking over the energy supply required by civilization as the only form of energy which, by its simplicity and economy of conversion, combined with economical transmission, is capable of supplying all the energy demands, from the smallest domestic need to the biggest powers. As we now begin to realize, the economic function of the steam engine is not the energy supply at the place of consumption, from the chemical energy of coal—it is too complicated and inefficient for this—but it is the conversion of chemical energy of coal into electrical energy in bulk, for transmission and distribution to the places of consumption.

If, then, electric power takes the place of steam power in our industries, etc., it is not merely the substitution of the electric motor for the steam engine or turbine. Such would rarely realize the best economy. The method of operation in all our industries, and especially those requiring considerable power, is largely—more than usually realized—determined by the characteristics of the power supply, and what is the most economical method with the steam engine as source of power may be very uneconomical with electric power supply, and electric power supply often permits a far more economical method of operation which was impossible with steam power. Thus the introduction of electricity as the medium of distributing the world's energy demand means a reorganization of our industrial methods, to adapt the same to the new form of power.

For instance, the steam engine requires skilled attendance, and with its boiler plant, auxiliaries, etc., is a complex apparatus, is economical only in large units. Thus, when operating a factory or mill by steam power, one large engine is used, driving by shafts and counter-shafts, by pulleys and belts, and possibly wasting half or more of its energy in the mechanical transmission to the driven machines. But we could not economically place a steam engine at every one of the hundreds of machines in the factory. Substituting electrical power by replacing the engine by one large electric motor would be very uneconomical, as we can place a motor at every driven machine, and these small motors are practically as efficient—within very few per cent—as one big motor would be, and all the belting and shafting, with its waste of energy, inconvenience, and danger, vanishes. With the steam engine as source of power, to run one or two machines only, to complete some work, requires keeping the big engine in operation, and therefore is extremely wasteful. With individual electric motors the economy is practically the same whether only one or two motors are used, or the entire factory is in operation. On the other hand, with the steam engine, it makes no difference in the cost of power whether it is in operation from 8 A.M. to 6 P.M., or from 6 A.M. to 4 P.M. With electric power, in the former case the power demand would overlap with whatever lighting load the same supply circuit carries, but would not in the latter case, and the latter case thus would give a better load factor of the electric circuit, and thereby a lower cost of power. Again, with electric power, if very large power demands could be restricted to the period of light load on the electric supply systems, this would reduce the cost of power. Nothing like this exists with the steam engine.

Electrical energy thus makes the power users economically more dependent upon each other, and thereby exerts a strong force toward industrial coordination—that is, cooperation.

Another illustration of the industrial reorganization required to derive the full benefit of electric power is afforded by the traction problem. Very often a study of the electrification of a railway shows no economical advantage in the replacement of the steam locomotive by the electric locomotive, even when considering only passenger service. At the same time, an electric railway may parallel the same steam railway, offer better service at lower price, and show financially better returns than the steam railway. But so, also, in the early days of steam, the steam engine in place of the horse in front of the stage coach was no success, and still the stage coach has gone and the steam locomotive has conquered; but it did not by replacing the horse, but by developing a system suited to the characteristics of the steam engine. The same repeats now in the relation of steam traction and electric traction. The steam engine is most economical in the largest units, and the economy of steam railway operation depends on the concentration of the load in as few and as large units as possible: therefore, the largest locomotive which can pass through bridges and around curves. Exactly the reverse is the condition of economy of electric traction: the economy depends on the distribution of the load as uniformly as possible in space and in time—that is, small units at frequent intervals—and therefore, while steam traction has gone to larger and larger units, in electric traction even the trailer car, so frequently used in the early days, has practically vanished. Obviously, then, the electric motor can not economically compete with the steam engine under the conditions of maximum economy of steam and minimum economy of electric operation, and electric traction under steam traction conditions shows marked economy only in the case of such heavy service that the maximum permissible train units follow each other at the shortest possible intervals—that is, give maximum uniformity of load—and thus the economic requirements of both forms of power coincide. These two instances may illustrate the changes in industrial operation which the introduction of electric power requires and which are taking place today.

To conclude, then: Electric energy is the only form which is economically suited for general energy transmission and distribution. Civilization depends on the supply of materials and of energy as its two necessities. The supply of materials is taken care of by the transportation system of the world. The supply of energy is being developed by the electrical transmission system, which with regard to energy becomes what the railway system is with regard to materials. Introduction of electric power in place of other forms of power rarely can be mere substitution, but usually requires a change of the methods of power application, a reorganization of the industry, to secure maximum economy.

# THE SMALL OUTDOOR SUBSTATION

By E. B. Merriam

Assistant Engineer, Switchboard Department, General Electric Company

The central stations of the country, in co-operation with the manufacturers of electrical apparatus, have from time to time conducted campaigns for the education of the farmer and the rural resident to the convenience of electricity; but, before any returns can be realized from these efforts, it becomes necessary to supply them with a source of electric power, and at a cost for equipment that will insure a fair return upon the investment. This has been a problem for the manufacturer, and in this article the author describes some of the apparatus that has been developed for tapping off small amounts of power from medium and high voltage transmission lines. Such substations are usually installed out-of-doors to save the cost of a special building, and the designer is confronted with the problem of producing an inexpensive piece of apparatus which at the same time will insure reliable service under severe conditions. More information on the same subject will be found in an article by Mr. Merriam in the August, 1913, issue of the Review.—Editor.

The present rapid increase in the use of small amounts of electricity for purposes of lighting and power in locations heretofore too far distant from the central station and isolated electric plant to be economically feasible, is almost wholly due to the development of the comparatively inexpensive outdoor substation, by which means transmission lines of moderate voltage can be tapped at desired points to obtain the power required. The householder, the owner of farm machinery that has hitherto been operated by hand, and the manager of the small industrial plant outside the previous bounds of central station service insist on those comforts and advantages which can be obtained only through the medium of the electric current. The central station has shown a desire to extend the geographical limits of its activities and obtain additional revenue from the sale of current for such purposes.

The whole question is now, as heretofore, one of installation and upkeep against obtainable revenue, with the added fact that the outdoor substation as now developed cuts down these two latter items to a point sufficiently low to lead one to believe that the use of such substations will greatly increase within a very few years. The mass of data which have been collected and published on this subject proves the point without question.

To the central station this load is highly desirable, adding as it does considerably to diversity and tending to raise the load factor of the system. It may be even said that in many cases a large demand for power can be created by establishing pioneer lines to some few customers at a loss at first. Again it is often possible to create in the minds of some sparsely settled community a co-operative feeling which prompts the citizens to band together and pay some or most of the expense of the installation. This burden will not as a rule be heavy, because one of the underlying principles in the development and construction of outdoor substations is the necessity for producing them at a low price, and also to construct them so that the installation charges will be small. This is one reason why they have not generally been placed on the market sooner, because it has taken considerable time and effort by the manufacturers to produce equipment which, while being low in price, would also be of sufficiently high quality to give continuity of service, and to avoid the introduction of trouble on the transmission line itself.

The equipment has been reduced to the smallest amount consistent with good service; keeping in mind, however, the fact that very seldom will labor skilled in the employment of electrical devices be at hand, and that the apparatus must as a rule perform its functions satisfactorily for a long time with no attention whatever.

The idea of reliability is well brought out by the adaptability of these stations to mining industries where the power is used to drive ventilating fans which require infallible operation or a serious loss of life.

The table on page 398 gives a list of services to which outdoor stations are well adapted.

## Equipment

The wide field just outlined has been opened to operating companies by the development of efficient, reliable and inexpensive outdoor substation equipments. They include outdoor transformers, fuses, switches and other devices recently placed upon the market by electrical manufacturing companies. The equipments, which are shipped complete, permit supplying power from transmission lines operating at pressures up to and including 110,000 volts, the minimum economical sizes of installations for various line voltages being as follows:

| Line Pressure in Volts | Rating of Smallest Economical Substation in Kv-a., Three-Phase |
|---|---|
| 2,300 | 3 |
| 4,600 | 3 |
| 6,600 | 3 |
| 11,000 | 10 |
| 16,500 | 25 |
| 22,000 | 25 |
| 33,000 | 25 |
| 44,000 | 50 |
| 66,000 | 100 |
| 88,000 | 250 |
| 110,000 | 400 |

In general, the equipments consist of the following groups:

1. Primary disconnecting switches, fuses, choke coils, and other protective apparatus.
2. Step-down transformer.
3. Secondary switching and measuring apparatus.
4. Suitable supporting structure.

### Disconnecting Switch

The switch which has been especially adapted for outdoor service under extreme weather conditions is a modified lever switch design. (Fig. 1.) It is provided with a mechanism for raising and lowering the blade in a vertical plane by the rotation of a handle, thus permitting minimum spacing between

### APPLICATIONS OF THE SMALL OUTDOOR SUBSTATION

| Consumers | Applications | Character of Load | Type of Substation |
|---|---|---|---|
| Small towns | Street lighting<br>Commercial lighting<br>Water supply<br>Power<br>Railway<br>Household devices | Similar to urban service | Semi-portable |
| Farms | Outlined in previous papers | Regular intermittent cyclic load | Semi-portable or portable |
| Ice harvesting | Hoists<br>Cutters | Intermittent | Portable |
| Mines and quarries | Cable ways<br>Compressors<br>Crushers<br>Drills<br>Hoists<br>Lighting<br>Locomotives<br>Pumps<br>Ventilating fans | Regular flat load | Semi-portable and portable |
| Pumping installations | Irrigation<br>Refrigeration<br>Water supply | Regular flat load | Semi-portable |

| Contract jobs | Cable ways<br>Compressors<br>Concrete mixers<br>Cranes<br>Dredges<br>Drills<br>Hoists<br>Lighting<br>Locomotives<br>Pumps<br>Shovels | Irregular<br>Intermittent<br>Day and night load | Portable |

the poles, and easy operation. It is equipped with horn type arc deflectors and is designed to permit the operation of one, two or three poles as single-, double-, or triple-pole units. The operating handle, which may be located at any convenient point, is connected to the switch mechanism by bell cranks and gas pipe. It may be locked in either open or closed position by a padlock in a manner similar to that employed for railway track switches and signals.

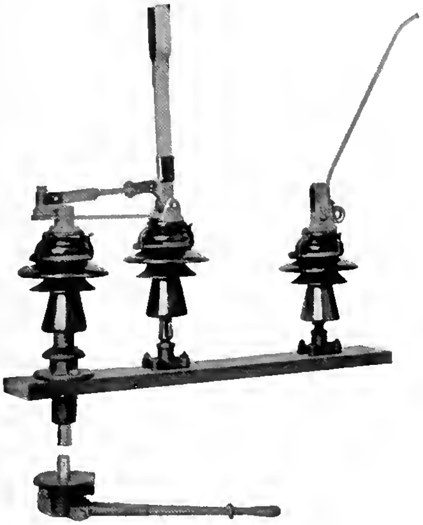

Fig. 1. Single-pole Disconnecting Switch for Outdoor Service on 35,000 Volt Lines

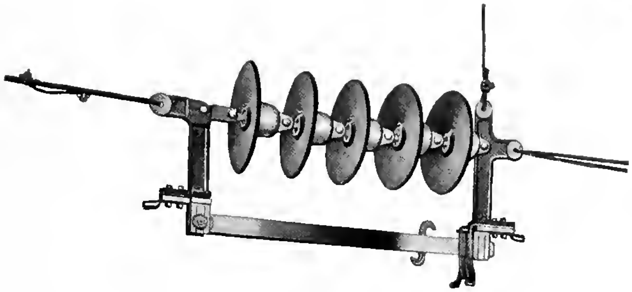

Fig. 3. Disconnecting Switch with Strain Insulators, 300 Amperes, 90,000 Volts

In order to fill the demand for a disconnecting switch that could be mounted outside the power station and operated from the station itself, a motor-operated switch of the above type was developed. (Fig. 2.) Other disconnecting switches suitable for outdoor installations are shown in Figs. 3, 4 and 5.

### Primary Fuses

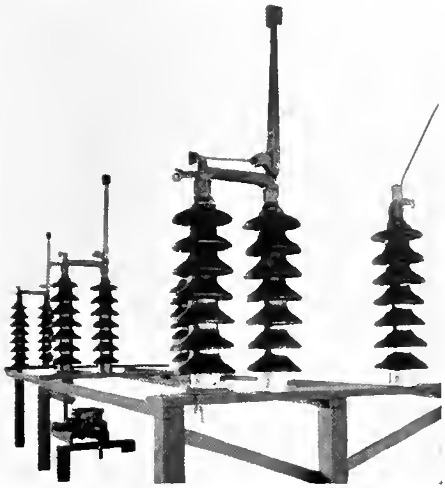

Fig. 2. Triple-pole Disconnecting Switch with Motor-Operating Mechanism for Outdoor Service, 400 Amperes, 100,000 Volts

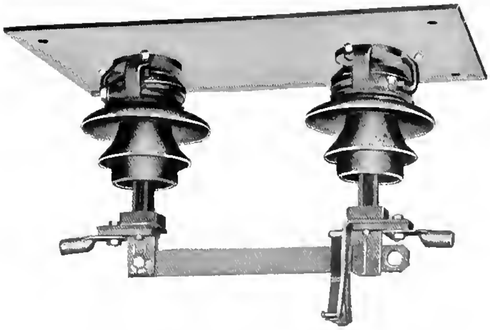

Fig. 4. Disconnecting Switch Underhung on Steel Base for Outdoor Service, 300 Amperes, 35,000 Volts

For vertical mounting, the fuse that is recommended is arranged to swing in clips and operate as a disconnecting switch (Fig. 6) while for horizontal mounting a fuse similar to the above, but without the disconnecting switch feature, is available. These fuses are a modification of the well-known tube expulsion fuse and consist of a holder protected by a weather-proof housing. The holders are closed at one end by a readily removable cap to which is attached the fuse wire. The latter is stretched through the interior of the holder and fastened to the outside at the open end. When overloaded, the fuse wire melts and forms a gas under high pressure which expands rapidly and blows the arc out of the holder. This design is the result of considerable experimental work and practical experience covering a long period of time.

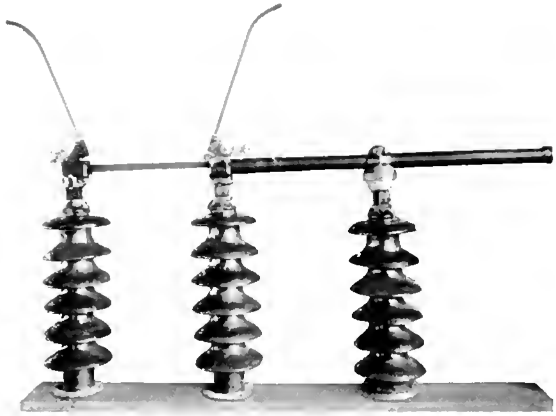

Fig. 5. Single-pole Bolt Type Disconnecting Switch for Outdoor Service, 400 Amperes, 90,000 Volts

Fig. 6. Expulsion Fuse Block showing Fuse in Open Position, 50 Amperes, 15,000 Volts

The vertical fuses can be made up in double or triple-pole units as a disconnecting switch so arranged that all the poles of the unit can be operated at once from the ground by means of a pole, operating rod, or rope. A station layout having this feature is shown in Fig. 7. The vicious and dangerous arcs characteristic of the horn gap render such apparatus unsuitable for fuse protection.

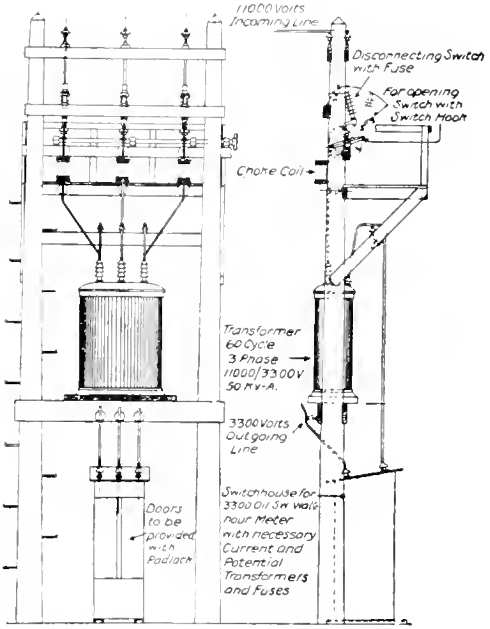

Fig. 7. Arrangement of Switching and Protective Apparatus for Supplying 50 Kv-a., Three-phase, at 3300 Volts from 11,000 Volt Transmission Line. Wooden Pole Construction

### Transformers

The transformers supplied with these equipments are single-phase or three-phase units, oil-insulated and generally self-cooled. They are especially designed for outdoor service under the most severe climatic conditions and are provided with special insulation in order to withstand the arduous character of the service demanded.

Transformers below 25 kv-a. capacity are placed in smooth cast iron tanks. From 25 kv-a. up to 750 kv-a., self-cooled transformers are supplied with corrugated sheet steel tanks, as the largest of these sizes, if made of cast iron, would be too heavy and bulky. From 750 kv-a. to about 2500 kv-a., the necessary radiation surface for self-cooled transformers may be obtained by compounding the corrugation, i.e., by welding together two plain corrugated sheets to form one large corrugation. Another construction, known as the "tubular" or "pipe" tank, consists of a boiler-plate tank having the ends of a double row of vertical steel tubes welded into it at the top and bottom. Transformers above 1500 kv-a. are usually water-cooled.

Transformers for pressures below 17,500 volts have their leads brought out through porcelain bushings set in or underneath the rim around the top of the tank. For pressures above 17,500 volts, the leads are carried vertically upward through the cover and are protected from the weather by petticoated porcelain coverings.

### Choke Coils

Two types of choke coils are available, the hour glass type, which is usually mounted as shown in Fig. 8 and used for stations of 22,000 volts and above, and the suspension type (Fig. 9), which is adaptable for use on small capacity moderate voltage stations.

### Instrument Transformer and Watthour Meter Housing

It is sometimes either desirable or necessary to measure power delivered over lines whose voltage is higher than 6600 volts. Heretofore, where the station is an outdoor one, the general practice has been to use two outdoor weatherproof current transformers and two outdoor potential transformers, and then provide a suitable housing for the outdoor meter.

In order to provide a more compact arrangement, the combined metering and transforming outfit shown in Fig. 8a has been designed. Here the current and potential transformers and watthour meter are arranged in one weatherproof housing, which can be handled as a unit. Only three entrance leads are required. Two of these have two entering cables for the current transformers, which are connected in the outside line of the transmission system. One terminal of each of the two potential transformer primary coils is connected to the incoming current transformer line. The other two terminals are tied together and connected to the necessary wire on the transmission line, which is entered through the third bushing.

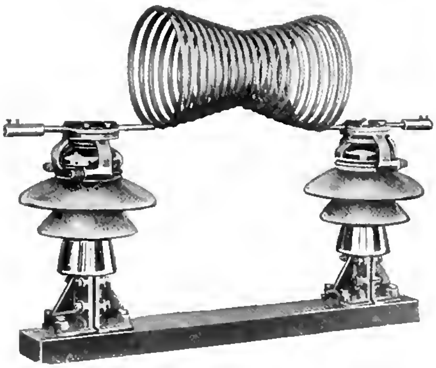

Fig. 8. 200-Ampere Choke Coil, 45,000-Volt Circuit

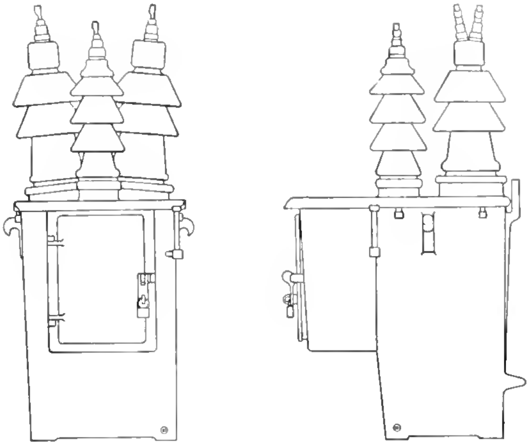

Fig. 8a. Instrument Transformer and Watthour Meter Housing

The secondary equipment is made up from the following elements:

### Secondary Equipment

1. Weatherproof housing.
2. Disconnecting switches.
3. Automatic oil switches or fuses.
4. Watthour meters.
5. Current and potential transformers.
6. Pole type regulators

The oil switches, watthour meters, current and potential transformers require no description, as they are of a standard design. They may be mounted on a steel or slate switchboard and enclosed in a wooden or preferably steel switch house. When no measuring apparatus is required, no housing

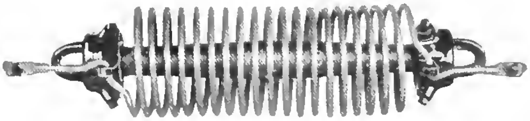

Fig. 9. Suspension Type Choke Coil, 50-100 Amperes, 25,000 Volts

for secondary apparatus is necessary, the load being handled by a pole-type switch and outdoor disconnecting switches.

### Switch Houses

Two types of switch houses have been designed, one for distributing voltages not exceeding 440 volts, where oil switches, current and potential transformers are not necessary, and the other for pressures not exceeding 2300 volts, a service which requires them. The switch house shown in Fig. 10 is for use on the lower voltage distributing circuits. It may be readily mounted at any convenient point. The incoming and outgoing leads pass through bushings fixed in the sides, and the box is provided with a door and padlock for securing the contents against marauders. A lever switch with enclosed fuses mounted on a slate base furnishes both disconnecting facilities and overload protection to the secondary circuit. A watthour meter connected directly to the circuit, without the intervention of current and potential transformers, measures the current supply.

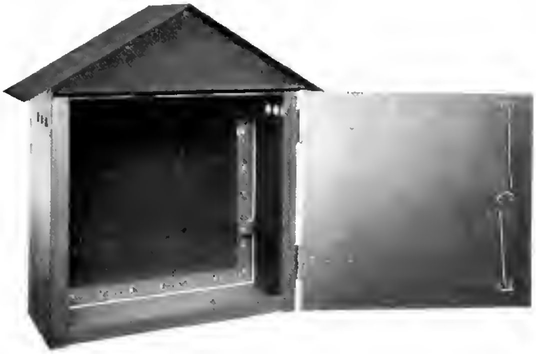

**Fig. 10.** Sheet Steel Switch House for Use on Distributing Circuits of 440 Volts and Lower

The switch house for 2300 volt secondary distribution is shown in Fig. 11. This house is built of sheet steel secured to a structural iron framework mounted on skids to facilitate transportation and provide a foundation. It is provided with padlocked doors at both the front and the rear, which give ready access to all parts. It contains a slate panel on which are mounted the disconnecting switches, automatic series trip oil-switch, and the watthour meter, the latter being provided with conveniently located test terminals. The necessary current and potential transformers are mounted on one of the interior side walls. Ammeters or voltmeters can be easily added to this equipment. The house is also provided with busbars which are fastened to the roof, and to which all of the interior apparatus is connected. Switch houses are shipped completely equipped and wired; in order to place the house in commission it is therefore necessary only to place oil in the oil switches, when they are part of the equipment, and attach the incoming and outgoing lines to the exterior terminals. Switch houses are designed for various standard forms of panels, to provide for single and three-phase commercial lighting, street lighting, three-phase power, and many other standard distribution circuits.

**Fig. 11.** Sheet Steel Switch House for Distributing 25 Kv-a., Three-phase, at 2300 Volts from High Voltage Transmission Line

### Pole Type Regulators

In connection with these equipments, the recently developed pole-type regulators, Fig. 12, may be used to considerable advantage, particularly for constant pressure lighting circuits. The regulator is of the induction type, automatic, entirely self-contained, and has no arcing contacts. It is operated by a small single-phase motor kept in continuous operation and connected to the regular shaft by mechanical means. It is controlled by a voltage relay which operates without the use of arcing contacts. This design of regulator is at present on the market in the 2.3 kv-a., 2300 volt, 60 cycle size only, although other sizes are now being developed. It will control the pressure of a 10 ampere feeder, from 10 per cent above to 10 per cent below normal voltage. The voltage relay is designed for 115 and 230 volt, 60 cycle circuits, and its series resistance is provided with several taps so that any voltage up to 15 per cent above or below normal may be used. It is not designed for line drop compensation, but may be used with a standard external compensator.

### Supporting Structure

The equipments which can be furnished may be divided into three classes, portable, semi-portable and permanent.

Portable equipments for supplying power to contractors, farmers or other consumers, whose apparatus is continually being moved from place to place, may be mounted on wagons, railway cars, floats or drags.

The semi-portable stations are usually of small capacity, where all the apparatus can be placed on a single pole, or a modification where the necessary secondary switching devices, either because of the voltage or current, are elaborate enough to necessitate a housing larger than that adapted to attachment to the pole. In this case a portable house is used.

The permanent structures are used where the size of the outfit requires a framework for the primary switching equipment, or a platform for supporting the transformers, or both. In cases of this kind, the supporting structure may consist of a steel tower, or two or more wooden poles.

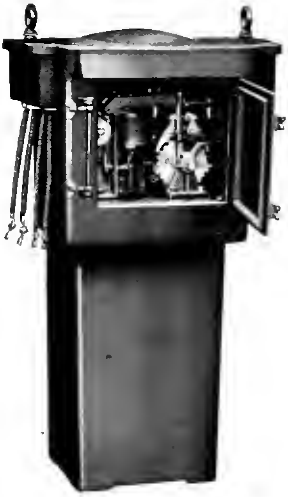

Fig. 12. Small Automatic Feeder Voltage Regulator

Fig. 13. 25 Kw. Transformer and Switching Equipment after Snow Storm. An Installation for Supplying 110-220 Volt Service from a 16,500 Volt Transmission Line

### Arrangement of Apparatus

For single or three-phase stations having a voltage of 6600 to 16,500, with 110 to 440 volt secondary, either two or three-wire, and of a capacity not exceeding 25 kv-a., the apparatus can be arranged as shown in Fig. 13*. In these stations the high tension lines first come to combined disconnecting switches and fuses and then through the transformer. The secondary wiring runs to a small switch house attached near the base of the pole containing a watthour meter and a suitable lever switch with enclosed fuses mounted on a slate panel. In order to adapt stations such as these for 2200 volt secondary distribution, it is only

necessary to substitute for the smaller house the 2300-volt switch house shown in Fig. 11, which contains an automatic oil switch and watthour meter with necessary current and potential transformers. Such stations are classed as semi-portable.

For stations larger than 25 kv-a., where a two or four-pole wooden structure or steel tower is required, a double or triple-pole combined fuse and disconnecting switch unit can be supplied. This unit, as previously described, differs from the single-pole

fuses in that all the fuses can be pulled out at the same time by means of a hook or an operating rod, or a rope running to the foot of the supporting structure. The single-pole units are removed with a hook.

For some stations, where the capacity and secondary voltage render the amount of power greater than that easily handled by a lever switch, it is sometimes necessary to substitute the larger steel house with an oil switch in place of the small switch house attached to the pole. In cases where the voltage does not exceed 440, watthour meters not requiring current transformers can be supplied. Choke coils of the suspension type can, if desired, be supplied for such stations.

Where cheapness is especially desirable, stations up to 150 kv-a. can be constructed for voltages up to and including 35,000, single or three-phase, by using the double or triple-pole vertical type combined disconnecting switch and fuse unit. The arrangement for a two-pole structure is shown in Fig. 7. Secondary distribution can be arranged for either 110, 220, 440 or 2200 volt distribution as described for the 16,500 volt outfits.

For a more substantial layout for installations of a capacity greater than 75 kv-a., with three-phase distribution at 22,000 or 35,000 volts, steel tower mounting is to be preferred. Fig. 14 shows the arrangement of apparatus for such stations. The primary equipment consists of a disconnecting switch, shown in Fig. 1, an outdoor choke coil and a horizontal type fuse. The switch, fuse and choke coil can be supplied as a single unit mounted on a channel iron. This permits one insulator to support the ends of two pieces of apparatus, thus making a very compact unit.

When desired, the switch house can be placed underneath the transformers and the whole lower tower structure enclosed. (Fig. 15.)

It is to be noted that in these installations a low tension bus is provided. The secondary distribution is made through the 2200-volt steel switch house, which has already been described. When the size of the transformers becomes so large that platform mounting would be inadvisable, they can be mounted on the ground as shown in Fig. 16. In all these cases no low tension bus has been provided, for the necessary wiring can in most cases be more advantageously carried on the insulators attached to the steel supporting structure. These layouts are shown in the illustrations, with delta connection on both primary and secondary sides.

The steel tower structures supplied are thoroughly galvanized after all labor is finished. They are easily put together with bolts and nuts that have been sherardized.

### Portable Generating Equipments

There is a wide range of permissible designs of stations for portable use. For supporting or containing the necessary apparatus, wagons, floats, drags, railway boxes, flat cars, or sleds have been used.

In addition to the stations described, which depend for their supply of electricity on a permanent power installation at some convenient point, there has been placed upon the market a line of portable generating equipments. These consist of a gasolene-engine driven generator mounted on a wagon which may be drawn by horses to the point at which power is desired. These equipments are particularly adapted for the following classes of service:

Breakdown auxiliary service.
Temporary peak loads.
Construction work.
During rehabilitation of old stations.
Assisting in new business solicitation.

They should form an efficient and useful auxiliary to all transmission line operators.

### Costs

Approximate costs per kilovolt-ampere of equipments compared with like costs of necessary power transformers are shown in the curves of Figs. 17, 18, 19, and 20. In these are included single and three-phase pole mounted stations for a primary voltage of 15,000 and a distributing voltage of 110, 220 or 2300; and also three-phase wooden and steel tower mounted stations for 35,000-volt lines and 2300-volt distribution.

### Conclusion

The stations described in the above article indicate some of the permissible arrangements of apparatus developed. As the apparatus is adaptable to a multiplicity of combinations for various services, the central station manager is given an opportunity to devise safe and reliable stations, which will permit him, even in isolated communities, to profitably realize on the rapidly awakening tendency to "do it electrically."

# THE EVOLUTION OF RAILWAY MOTOR GEARING

By W. G. Carey

Manager, Railway Supply Sales, General Electric Company

The author traces the development of railway motor gearing from the time that gears and pinions as used on stationary apparatus (where plenty of space was available to permit the use of cast iron) were applied to railway motors, up to the modern gearing which has been developed to meet the severe conditions of up-to-date railway practice. Most of the early part of this work resolved itself into devising means and ways of increasing the life of the pinion to approximate that of the gear. The different methods adopted to produce a harder and more durable pinion are described. The life factors necessary to determine the maintenance cost of different types of pinions are given.—Editor.

The design of the gear equipment of the first small electric railway motors was adapted from established practice in the construction of gear trains in stationary apparatus. Abundant space was available for adequate cast iron gears. With increase in size of motors it became convenient to substitute cast steel for cast iron in order to secure increased strength while conserving interchangeability on existing trucks; and thereafter for many years cast steel gears with machine steel pinions continued to be used in universal practice. The speed reductions from the armature shaft to the axle ranged from about 3 to 1 to 4.78 to 1, and pinions and gears wore out in about these ratios. The obvious advantage of increasing the life of the pinion to approximately that of the gear in order to improve average conditions of mesh and to reduce the cost of frequent renewal of pinions led to early experiments in case-hardening of pinions. In applying this process, practice satisfactory in other arts was followed and little attempt was made to modify, for the special conditions, the process as usually carried out. The first case-hardened pinions exhibited consequently a considerable measure of warping from the heat treatment, which fact involved high cost in rejections in manufacture. Also, this warping and other results of the treatment caused in many cases destructive wear of the companion gear, and the net results were such that no really great interest in any form of heat treatment of gearing was felt until increased size of motors, for which an active demand was arising, made imperative an increase in the strength of materials. The pitch of teeth and width of gear face had been increased to the limit allowed by available space on the trucks, and the strongest cast steel practicable for machine operations was found inadequate; therefore, to meet the severest conditions resort was had to alloy steels with partial success in keeping equipments in service. Experiment to determine the alloy steels best suited for the purpose required, however, a long time and involved heavy expense, and heat-treated carbon steels tried out at the same time afforded excellent results. Painstaking study by manufacturers of railway apparatus, aided by the broad minded co-operation of operating engineers, soon resulted in the determination of suitable material and the development of methods in heat treatment adequate for the severest conditions in present normal practice.

Incidentally, the modification of the material and its heat treatment, together with increased strength, produced considerable increased hardness, and, at least for city service where the strength of untreated gears was still adequate, the old idea of a pinion harder than the gear, tending to equalize the life of the two, was in a measure realized, and within a very short time the untreated pinion was entirely discarded, even for service in which the strength of the heat-treated steels was entirely unnecessary.

Only experiment could determine certainly the effect of the hard pinion on the untreated cast gear, and some curious results developed in special cases. In one of the first installations on a considerable scale the hardened pinions wore out completely in about half the life of the old untreated machine steel pinions, and this proved to be due to the presence in the gear grease of considerable quantities of very hard sand prevalent in the neighborhood, which, getting into the gear case, became embedded in the surface of the soft gear teeth, forming a lap for the rapid destruction of the pinion teeth. On the whole, however, with good methods of lubrication and maintenance of equipment, heat-treated pinions having a hardness not exceeding approximately 300 in the Brinnell scale appear to afford greatly increased life without measurable reduction in the life of an untreated companion gear.

Continued experiment in case-hardening developed means of avoiding most, if not all, of the original trouble of warping in treatment, and the process was applied experimentally on a considerable scale to the cast gears as well as to pinions; and increased life, altogether out of proportion to the increased cost, was immediately obtained. Split gear castings, however, still gave some trouble from warping on account of their irregular sections. At that time split gears were in considerable demand, although the use of solid gears had already commended itself strongly for many reasons. Split gear bolts had always given trouble and it was easier to obtain sound castings in the more regular sections in the solid gear, and these considerations had begun to have a considerable influence in hastening the provision, in repair shops and inspection barns, of wheel presses and other facilities for handling solid gear equipments. In the present state of the art of case-hardening pieces of such size and shape as motor gears, this matter of warping is not so serious a matter, as its control has been greatly improved; but at that time a general readiness to substitute solid gears greatly facilitated the trial of case-hardened gearing on an extensive scale in service.

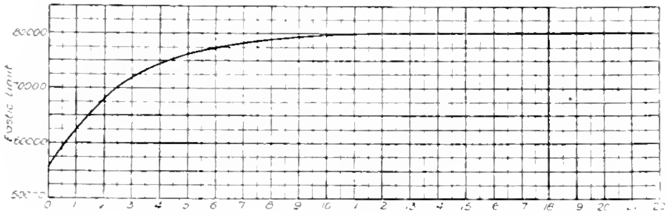

Fig. 1

This material is essentially a low carbon steel with the surface impregnated with additional carbon and heat-treated. The usual practice is to shroud portions not required to be hardened so that only the tooth surfaces are exposed to the "cementing" process, as the incorporation of additional carbon is called. Therefore, only the carburized portion hardens in quenching. It is usual practice to carry the depth of impregnation of carbon in the tooth surface to about the limit of allowable wear, which, in three-pitch gearing, is approximately 1 10 in. This, however, is subject to very definite control and is varied within limits for various conditions.

The surface of case-hardened gear and pinion teeth shows hardness about 95 in the scale of the Shore schleroscope. It is not practicable to measure this material with the Brinnell instrument for the reason that the uncemented core will not stand up under the pressure necessary to effect an indentation, and such pressure also causes deformation of the pressure ball. The schleroscope is also to some extent misleading, as different conditions, such as size of parts tested or method of their support in test, give rise to considerable inaccuracies. In experienced hands the most reliable comparison of hardness of specimens of materials of this class is a file test, though this may be entirely misleading in comparison of different alloy steels. Modern case-hardened carbon steel which gives a schleroscope reading of 95 can just be scratched with a very fine Swiss file.

This class of gearing, because of the price at which it could be marketed, was manifestly a great improvement in economy of operation, wherever it might be found sufficiently strong to withstand the shocks of service. No test, other than that of service, has been devised for determining its resistance to service stresses, but that the limit of its strength is below the requirements of the heaviest modern service appeared probable and has since been demonstrated. In the first days of its use much virtue was attributed to the toughness of the low carbon core, but this toughness cannot manifest itself under stresses on the whole tooth, and a tooth strained beyond its strength breaks short. It is evident that substantially the entire tooth strength must be found in the hardened case, and the factor of safety, even with the enormous elastic limit of this high carbon case, promised to be too low for safety in the heaviest equipments throughout the very long period of its probable service. Although this gearing has been used very conservatively on motors of over 125 h.p., and then only in the light of careful study of operating conditions, the original estimates of strength have been closely borne out. Breakage has occurred in certain carefully watched test equipments after two years of service where wear had hardly begun. This has in some cases undoubtedly been due to fatigue of the case from repeated shocks closely approaching the elastic limit, and in other cases to subsidence of the soft tooth core resulting in cracking of the case.

It is therefore known today that, while with motors of less than about 100 h.p. this type of gearing is sufficiently strong to resist fatigue until worn out in service, its application with heavier equipments can only be advised in the light of a very definite understanding of the conditions of operation. With such heavier equipments, especially in high speed service with rapid acceleration and liability to abnormal shocks such as are produced by commutator flash-overs or line breaks at the collector, the case-hardened gearing appeared and has already been proved to have an inadequate factor of safety.

Attention was then turned to a modification of the homogeneous heat-treated gearing with a view to increasing its hardness to attain increased life and a greater elastic limit, which was essential in order to defer fatigue beyond the extended limit of wear. The physical characteristics of heat treated steels depend upon a considerable number of variable factors in the constitution of the steel, the manner in which it is worked, and methods of treatment. The constitution of the material can only be definitely controlled within certain limits which are well recognized in steel manufacture, and variations in the constitution affect final physical characteristics, though the variations may be corrected in a measure by corresponding variations in treatment. Such methods, if carried to too great a refinement, are prohibitively expensive, and the development of the desired new type of gearing involved a method of analysis and an adjustment of treatment which would be commercially practicable.

The type of heat-treated gearing which had become recognized as a heavy service standard showed elastic limit varying in regular production from eighty to ninety thousand pounds per square inch, although occasionally specimens showed still higher values and certain other specimens with elastic limit varying down to 70,000 lb. per square inch were put into service in the earlier days of this development. Throughout several years a record was kept of mileage and physical characteristics of all specimens broken in a service of known character, and the curve in Fig. 1 shows relation between elastic limit of broken specimens and the time required for fatigue to the breaking point in normal service.

This shows that maximum stresses on the gear teeth, which could be determined in no other way, are equivalent to about 70,000 lb. per square inch in the teeth, since all specimens broken early in service show approximately this value. Higher values are shown to afford longer life, until the specimens broken toward the limit of wear invariably show an elastic limit of approximately 80,000 lb. per square inch, and in no cases have specimens showing higher values broken in service.

With a lower ductility, it was assumed—and it is in all probability true—that a larger factor of safety would be necessary to defer fatigue beyond the limit of wear, and a composition was selected and methods of working and treatment determined which would give an elastic limit of 140,000 to 150,000 lb. This steel shows a hardness approximately 500 in the Brinnell scale, and, while no very definite comparison with hardness of case-hardened gearing is possible, such rough comparison of the Brinnell and schleroscope scales as is possible and the file test indicate the hardness to be approximately 85 per cent of that of case-hardened gearing.

Commercial application of this type of gearing has been made with the greatest care, and it has not yet been trusted in the heaviest service, although since its first commercial use two years ago about 7000 equipments of this gearing have been installed with motors of all power up to 150 h.p. and there is no record of breakage of a single tooth within the limit of wear.

It has been pointed out that various factors had contributed to a marked tendency to substitute solid for split gears. This tendency was manifest in all classes of service, and its wide spread made possible the realization of an old idea of using forged blanks in place of castings for axle gears.

The manifest advantage of forgings in entirely eliminating shrink strains and other faults not altogether avoidable in castings was important, but not all of the desired end. It was practicable to machine steel of a higher carbon content, and the strength and toughness could be greatly enhanced by the operation of forging the blank. The very great diversity of combinations of shape and dimension required involved an enormously expensive development cost and it is probable that this would have long deferred the general substitution of forged for cast solid gears, were it not for the fact that the development of the homogeneous heat-treated types absolutely required forgings, since the desired physical characteristics were unattainable in castings. The cost of manufacture is so far a little higher, but the difference would probably be justified by the certain and invariable integrity of the blank, even with the same life factor. In addition, however, the untreated forged gear shows approximately 20 per cent higher elastic limit and nearly 25 per cent greater hardness, and these characteristics afford an increased life approximately proportional.

Fig. 2
Forged Gear

There are then available in the art today three modern types of gearing, each of which may have its appropriate field, although there may be some difference of opinion as to where and to what extent these fields overlap. The first essential in the selection of a type is adequate strength for positive assurance against breakage within the limit of wear.

There are thousands of motors in operation which are destined to be superseded by more modern machines within the expected life of heat-treated gearing, and in such cases no advantage can be gained by the use, at higher cost, of a type which cannot be worn out within the life of the apparatus; and therefore the untreated forging is clearly the only type to be considered.

Also, many important systems have been completely equipped with case-hardened gearing, and the problem of changing over to another type, unless the two types can be successfully operated together, is a difficult one, and such a change must be effected gradually. Both of these considerations must be taken into account, although in the end practice will be standardized on the basis, first, of safety and then of annual cost of maintenance.

In the meantime, in substituting complete gear equipments of the modern heat-treated steels for untreated gears with heat-treated pinions having hardness of about 250 to 300

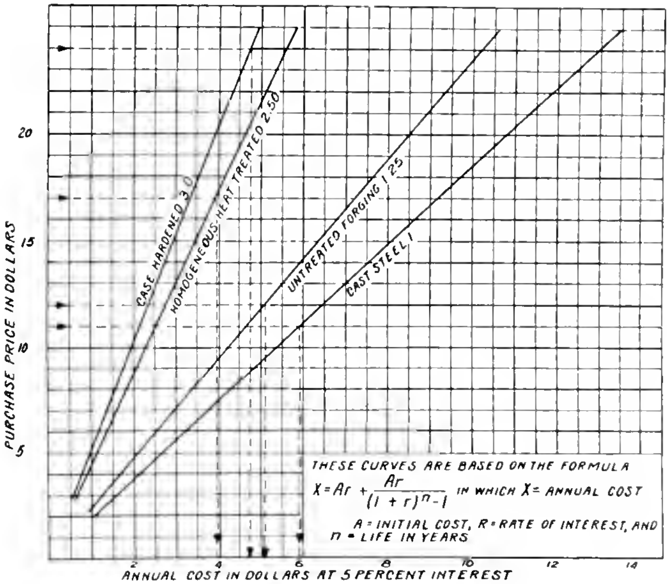

Fig. 3

in the Brinnell scale, it is evident that some trouble will be involved in attempting to maintain the proper combinations, and the result of combining gears and pinions of widely differing hardness under all service conditions is very uncertain. While occasional instances of successful operation of even case-hardened pinions with untreated gears are reported, it is certain that such combinations will generally result in reduced life of the softer member, and in effecting changes in their practice most operators are taking the trouble to provide pinions of only moderate hardness for use with their untreated gears and meshing all new gears of more modern types with pinions of the same types.

For the purpose of estimate of maintenance cost, life factors of different types must be assumed and the following are based upon records of service under widely varying conditions:

| Grade | Life Factor |
|---|---|
| Untreated cast steel | 1 |
| Untreated forged steel | 1.25 |
| Homogeneous heat treated | 2.25 |
| Case hardened | 3 |

These estimated life factors, with cast steel taken as 1, are about proportional to the relative hardness of the respective types, which factor should, and apparently does, reflect fairly closely the average life in service. Based upon these factors and an assumption of 5 per cent interest on investment, the curves in Fig. 3 show a comparison of the respective maintenance costs of the four types here considered, at the prevailing market prices of a representative gear for city service.

The market prices of this gear in the four different types are, respectively: cast steel, $11.00; untreated forging, $12.00; homogeneous heat-treated, $17.00; and case-hardened, $24.00. Following the dotted lines as indicated by arrows from these purchase prices in the ordinates, the respective annual costs will be found to be $5.90 for untreated casting; $5.10 for untreated forging; $3.95 for homogeneous heat-treated, and $4.75 for case-hardened gears.

It has been said that the heat-treated carbon steels now available have proved adequate for the severest conditions in present normal practice. It is known, however, that we are already near the limit of strength of this material, and the added demands of apparatus already projected, and of at least one existing application of somewhat special character, call for an additional factor of safety to maintain strength requisite for service to the limit of wear. Experiment on an extensive scale is being conducted with various alloy steels and various treatments, and encouraging results are promised, particularly with chrome-vanadium. Owing to its narrower base, the strength of the pinion tooth is measurably lower than that of the teeth of its companion gear, and there will undoubtedly be a wide range of applications in which alloy steel pinions may be used with carbon steel gears, and by virtue of an elastic limit of something like 170,000 lb. per square inch, which appears attainable, will equalize the difference and take us another long step in the development of this art in which we are so circumscribed by the fixed dimensions of the trucks.

# CONSTRUCTION AND INSTALLATION OF STAGE LIGHTING EQUIPMENT

By H. H. Reeves

Supply Department, General Electric Company

In the October, 1913, issue of the Review there appeared an article on "The Requirements of Theater Lighting." This article dealt mainly with the various types of lighting required in the different parts of the theater building, with the lamps which are employed to secure those effects, and with the locations of the lamps. The present article describes in detail the best practice in the construction and installation of the equipment which supplies and controls the electricity furnished the lamps. The usual layout of the stage equipment is clearly pictured, and particular attention is directed to those locations for the electrical equipment which produce the most effectiveness in presenting a performance. Wiring diagrams of the main circuits and of convenient arrangements for wiring the switchboard are given. One of the strong points of the article is the suggestion to connect the motion-picture machine to the secondary service lines. In the event of the blowing of the main fuses a possible panic may thus be easily averted, for the audience can be entertained with pictures until normal conditions can be restored.—Editor.

## Introduction

It is not intended that the description of the construction and installation of electrical stage equipment as given in this article is to be regarded as the final word on this subject, for new apparatus is being developed every day and different methods of installation follow each other in rapid succession. However, there are standard types of construction and systems of arrangement of the various pieces of apparatus about the stage in general use today, and the following has been written after a careful study of the situation and represents what the writer believes to be the best practices that are employed in theater construction at the present time. The ideas are not adaptable to theaters of special character, such as hippodromes, etc., but were incorporated with the type of theater in mind which is suited to the average production.

## General

The producing of a play of several acts and scenes, in this day of realism and elaborate detailed settings, necessitates for example the erection and furnishing of an elaborate apartment in a very few minutes. It is no longer an imitation but an actual habitable apartment with real properties, furnishings, etc., and consequently requires specially constructed scenery and equipment. The appliances must be specially designed to be available for instantaneous use and, at the same time, be so constructed as to withstand the necessarily rough handling they experience when in use. The equipment is further taxed by the fact that when it is sent on the road it is subjected to continual shipping and handling by inexperienced and irresponsible parties, and is used on foreign stages under unusual and varied conditions.

The modern theater is equipped with all of the latest mechanical contrivances which tend toward expediency. This has been carried out so far at the Century Theater in New York City that four stages are arranged on a pivot and can be presented to the audience successively. As the stages revolve and one goes behind the proscenium wall the next is brought before the audience. The average theater, however, depends upon movable scenery rather than a movable stage. To facilitate the handling of this scenery, as much of it as possible is kept suspended in a loft above the stage and can therefore be quickly dropped into place and be as easily pulled up out of sight again. This is accomplished by ropes running over pulleys or sheaves fastened to a gridiron structure and then down to a fly gallery on the side wall.

The gridiron (Fig. 3, GI) consists of parallel steel bars ($\frac{3}{4}$ by $2\frac{1}{2}$ inches) spaced approximately two inches apart. Wooden beams are sometimes used where the local ordinance permits. The gridiron should be placed at a height exceeding twice that of the proscenium arch by at least three feet in order to allow the suspended scenes to clear those in use on the floor and in order to allow the free operation of the asbestos curtain. For a standard equipment this should not be less than 65 feet. A greater height than this is advantageous but not necessary for ordinary purposes. Sufficient head room must be provided over the gridiron to conveniently adjust sheaves, ropes, etc.

There is a fly gallery (Fig. 3, FG) on each side of the stage running from the proscenium wall to the rear wall of the theater. These flies are vertically located about halfway between the stage floor and the gridiron, being on a level or a little below the proscenium arch. For standard usage the fly floors should not be less than 27 feet above the stage floor. Their width varies according to the conditions which govern the size of the building, but for standard work they should on no account extend nearer than 4 feet to the

proscenium opening and be less than 50 feet between rails. These fly floors should ordinarily extend to the side walls of the theater but should not be less than 8 feet in width, greater width being desirable.

Along the edge of the fly galleries and at about the height of a man's waist the pin rails are placed (Fig. 3, PR). It is around the pins in these rails that the free ends of the ropes, which suspend the scenes and borders, are tied. Since the pin rails bear the weight of all the suspended pieces, they are subject to considerable strain and should be carefully designed. It is customary to have two lines of pins, one above the other, on the rail with the pins spaced on 8-inch centers in each and staggered so that those on the lower rail come between those on the upper rail. When one tier of flies does not afford sufficient working space it sometimes becomes necessary to introduce a second tier above the first.

All theaters for general productions should have a "paint bridge." This is usually placed at the rear of the stage at a distance of at least one foot from the rear wall so as to permit the "paint frame", on which scenes are mounted to be painted, to pass the bridge upon being raised or lowered. For standard construction the floor of this bridge should be at the height of the fly galleries, and should extend across the stage from fly to fly.

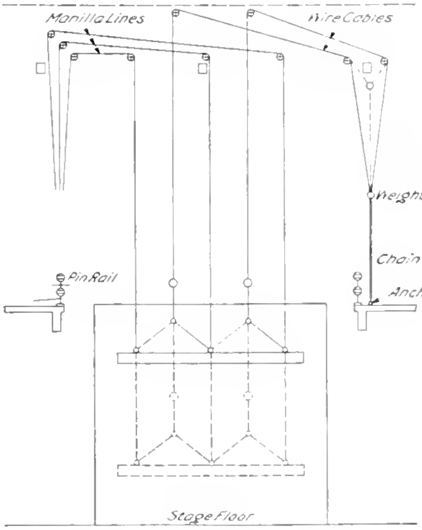

Fig. 4. A Method of Border Suspension

Spot-light bridges (Fig. 3, LB) are used in a large number of modern theaters and extend along the side walls underneath the fly galleries. Lens lamps and similar portable lighting units are operated from these bridges.

### Footlight

A general distribution of light over the stage is obtained by means of footlights (Fig. 3, FL), border-lights, and proscenium-lights, the footlight being the most efficient because of the greater horizontal component of its light distribution. The reflector-hood of the footlight should not project more than 4 or 4½ inches above the stage floor, or it will interfere with the line of sight of that portion of the audience on the lower floor. The reflector should also be designed so that the lamps cannot be seen by those sitting in the back row of the gallery. It is preferable to set the footlight in a concrete trough built in the stage floor as it makes a much more substantial installation and eliminates vibration to a large extent.

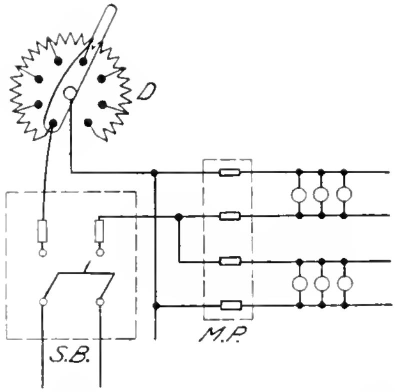

Fig. 5. Diagram showing Multiple Lamp Circuits Separately Fused in the Magazine Panel and Connected to a Dimmer and Switch

The single-row type is used only in the smaller theaters. Of the two forms of double-row footlight, the inverted is much superior to the upright for both electrical and mechanical reasons, the illuminating efficiency being about the same.

The axis of the lamps in both rows should be inclined at an angle of 20 degrees to the vertical, as in this position the maximum of useful light is obtained. The filaments of all the lamps should be as high above the stage level as possible, being limited only by the height of the reflector hood.

The color of the lamps used in the footlight depends largely upon the character of the plays produced, and has been discussed in a previous issue of the Review*.

For standard dramatic use a stage opening 40 feet wide has proved most advantageous, and as this opening is further reduced by the "masking in" of "returns" and "tormentors" the actual working space of the stage is reduced to about 36 feet. On this account the footlight does not necessarily have to extend the full width of the proscenium opening.

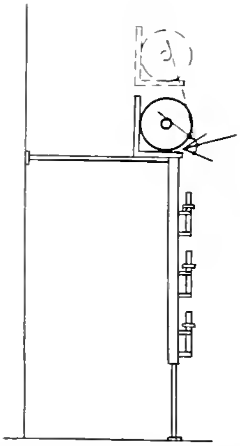

Fig. 7. Diagram showing Dimmer Located Above Horizontal Pipe Supports. Operating Handles at Top of Switchboard

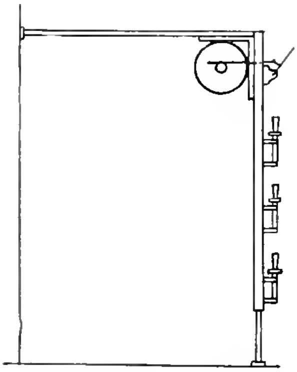

Fig. 8. Diagram showing Dimmer Located Immediately Below Horizontal Pipe Supports. Operating Handles at Top of Switchboard

The splicing box is generally located at the end of the footlight nearest the switchboard.

Very few curved footlights are installed today. This is on account of the difficulties of construction and the poor light distribution obtained, as compared with the straight footlight; and also on account of the difficulty in designing the seating of the auditorium so that the lines of sight from certain sections, viz., the boxes and sides of the balconies, do not bring the lamps of the footlight into view. In case more illumination is required in the

first "entrances" or "tormentor entrances" than is afforded by the footlight the proscenium-light mentioned later can be brought into play.

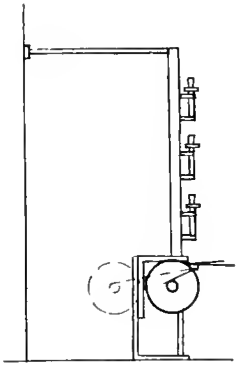

**Fig. 9.** Diagram showing Dimmer Located Between Bottom of Switchboard and the Floor. Operating Handles at Bottom of Switchboard

### Border-lights

Border-lights (Fig. 3, BL) should be suspended from the gridiron by steel cables in such a manner that they can be raised nearly to the gridiron or lowered to within a few feet of the floor according to the position of the scenery and effect desired. Strain insulators should always be used with steel supporting cables. A very good method of suspension, and one which conforms in every respect to the National Electric Code rule, is shown in Fig. 4. The border may be raised and lowered entirely by the manila ropes, while the steel cables, weight, and chains act as a counter-balance and will hold the border in place in case the ropes break. The method shown in Fig. 3 seems simpler, however, and is the one more generally used at the present time. The suspension cables are here carried across and fastened to a counter-weight which slides up and down the side wall in a

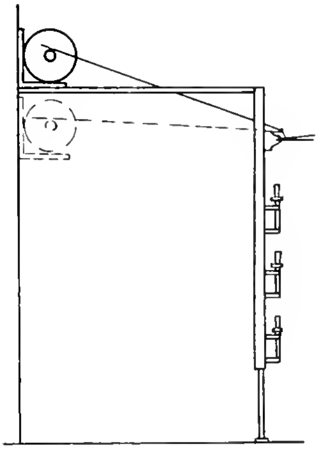

**Fig. 10.** Diagram showing Dimmer Located on Proscenium Wall. Operating Handles at Top of Switchboard

"track." A manila rope is then used to run back to the pin rail and holds counter-weight and border in place. These are so nearly balanced that there is very little weight on this rope. A simple method of supporting the border-light without the expense of a counter-weight track is to run the three (or four) border lines over the loft and head blocks to a "curtain clew" from which is hung a counter-weight (sand bag) and a manila rope line is run from this to the pin rail. A border with two rows of lamps will weigh in the neighborhood of ten pounds per foot and the cable should be selected to give at least a 200 per cent factor of safety.

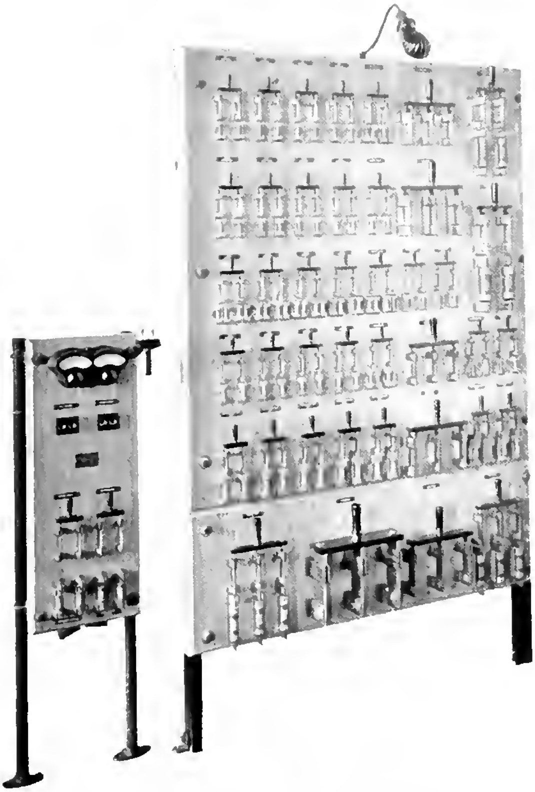

Fig. 12. Front View of a Live-front Stage Switchboard. Small Board at the Left Enables the Mercury Arc Rectifier to be Thrown Onto Either the Moving Picture Machine or Storage Battery for Emergency Lights

The number of borders and whether they are single or double row depends largely upon the size of the theater. In the average theater with a stage 30 to 40 feet deep and a proscenium opening of 30 feet three or four borders of double row construction, spaced 5.5 to 6 feet apart, should be used. In addition to the four borders it is advisable to use a concert border wired in two circuits each having 12 clear 32 c.p. lamps. This concert border (or ceiling strip, as it is sometimes called) is used with small interior sets and for rehearsals. When the interior of a room is shown on the stage, the scenery is often arranged so that it is impossible to lower the long borders, consequently a short ceiling strip is not only advantageous but necessary, especially in large theaters. A paint border is very often hung in the rear of the stage. This is near the paint bridge and is used by the artist in painting scenery.

The arrangement of white and colored lamps used in the footlight is generally followed in the border-light.

The border-light should be two feet longer than the proscenium opening. This does not apply to the first border which should be the same length as the footlight for the same reason.

The splicing boxes are often located on the ends of the borders nearest the switchboard. This arrangement makes it possible to reach readily either the cable or box from the fly galleries and saves a considerable amount of wire and conduit. Sometimes, however, the boxes are placed at the center of the borders in order to keep the cable from interfering with side sets. Inaccessibility is a disadvantage of this arrangement. The position is often determined by local requirements. If the splicing box is at the center of the border, the cable should be run in conduit from the magazine panel to a splicing box or gridiron interconnection box located in the gridiron. This box is used in some installations on account of the convenience of testing the border circuits afforded by an intermediate point between the border and switchboard fuse panel. It is often placed ten feet from the center towards the side of the stage on which the switchboard is located. The cable from this box should be of sufficient length that the border can be lowered to within a few feet of the stage floor. The slack cable is taken up by running it over an inverted U-cradle which is fastened to an extra border line, the latter being run through a sheave set in the gridiron approximately five feet off center. This rigging allows the cable to hang evenly and provides for the working of the cables and borders together. In some localities the requirements call for the cable to be continuous from magazine panel to border splicing box. In this case it is advisable to place pull boxes at suitable distances

(50 to 60 feet). These boxes often have three porcelain knobs so placed that the cable can be run over and between them in such a manner as to prevent its slipping in the conduit.

The most advantageous arrangement, however, seems to be as shown in Fig. 3. The splicing box is on the end of the border nearest the switchboard and the cable runs from here to a splicing box on the edge of the fly floor, being supported near the middle by the cradle. From this box the cable runs in iron conduit along the edge of the fly floor to the proscenium wall and then down to the magazine panel. This arrangement, while saving very little cable if any, removes the weight of all cable from the splicing box and places it on the supporting cradle and attached line. This has an important bearing in eliminating loose connections in the splicing box and is also a much more accessible position for the latter.

### Proscenium-lights and Portable Strip-lights

Proscenium-lights (one on each side of the proscenium opening) are used as an aid to the footlight and first border-light. They are generally of single row construction and are of a length of about one-half the height of the proscenium opening, the lower end being three feet above the stage floor.

Portable strip-lights are used for increasing the local intensity during a scene, and are always wired in one circuit for white lamps.

### Floor Pockets

Every play requires more or less portable lighting apparatus, and to facilitate its use there are, in the floor of the stage, pockets which are connected to the switchboard by means of the permanent theater wiring. The receptacles on the stage are installed on either side opposite the ends of the various borders, but from four to five feet back of the proscenium line towards the side wall. The pockets should, however, be at least three feet from the side wall as scenery is usually stacked against these walls. The Underwriters specify that "plugs for arc and incandescent pockets must not be interchangeable," and consequently it is advisable to install one single arc and one double incandescent pocket opposite each end of each border. Two double pockets should be installed about two feet from the rear wall near the center line.

### Wall Pockets

Wall pockets serve the same purpose as the floor pockets. There is usually one double pocket on each side of the stage mounted on the proscenium wall at a height convenient to the switchboard gallery (about 12 feet above stage floor). There should also be four single pockets on each spot-light bridge, two or three feet above the floor of the bridge. These are frequently mounted along the side wall although sometimes they are placed on the bridge rail.

### Company Service Switches

There are times when the floor and wall pockets are not sufficient to accommodate some certain production and then provision must be made for additional portable lighting units. This is done by using a portable plugging box, or "spider" as it is familiarly termed in stage parlance. If some provision is not made it is perfectly natural to connect the cables from this box directly to the busbars at the back of the board, which is not only a dangerous practice but is harmful to the equipment. This can be obviated by providing company service switches to which the "spider" may be attached. There should be one of these on each side of the proscenium wall at a convenient height from the floor (see Fig. 3, CS). Each should consist of a double-pole single-throw 200 ampere switch mounted on a panel and enclosed in a steel cabinet.

### Magazine Panel

The cables from the footlight, borders, pockets, etc., are brought back to the switchboard fuse panel, or "magazine panel" as it is often called. While all of the switches on the switchboard are fused, the fuse panel is necessary as each switch generally controls several circuits. For example, there is one switch controlling all of the white lights in the first border but, as the National Electric Code states that no set of lamps requiring more than 1320 watts shall be dependent upon one cutout (or fuse), it is necessary to divide the white lamps in the first border into several circuits, fusing each (see Fig. 5). Plug, link, or enclosed fuses may be used, depending upon the local requirements or the preference of the architect. The enclosed fuse can be easily and safely replaced in case of emergency and on this account is more practical from the operator's point of view.

The switchboard fuse panel should be mounted in close proximity to the switchboard, so that the operator or electrician can replace a blown fuse without leaving the vicinity of the board.

**Dimmers**

Dimmers are merely variable resistances which can be inserted in the various lamp circuits for the purpose of varying the intensity. Fig. 6 illustrates one of these. The resistances are usually embedded in soapstone or some kind of insulating compound which is formed in the shape of a disk. Leads are brought out to contact buttons on the surface of this material, and a rotating arm operated by the dimmer handle makes contact on these buttons thus inserting the proper amount of resistance in the lamp circuit. Fig. 5 shows the diagram of connections of a switch, a dimmer, two lamp circuits and their fuses in the switchboard fuse panel

The dimmers are usually mounted above or below the switchboard. Occasionally the

WL —Working Lights
O —Orchestra
F —Fans
S —Spares

dimmers are mounted on a separate panel at one side of the switchboard. This arrangement, however, has rarely been used except in cases where it was impossible to mount them above or below the board. Other arrangements which are sometimes used are shown in Figs. 7, 8, 9, 10, and 11. The dimmer handles are usually mounted in a row above or below the board, depending on the position of the dimmers. In some cases they have been alternated with the switch handles, but this is decidedly poor practice from the standpoint of construction and the majority of stage electricians prefer the segregation of dimmer and switch handles, so far as the operation is concerned.

### Switchboard

The switchboard (Fig. 3, SB) is the vital point of the theater lighting system as it is from here that control is exercised over all the lights of the theater. It is generally located parallel to the proscenium wall, and may be on either side of the stage. The National Electric Code requires 18 inches of clear space between the apparatus on the back of the board and the wall. More space is desirable. It seems to be better practice to mount the board in a switchboard gallery eight to ten feet above the stage floor as this prevents any accidental contact with the board on the part of players or others.

The majority of theater switchboards are made of black slate approximately 72 inches high and of width suitable to accommodate the switches. If the dimmers are mounted beneath the board its top will be somewhat more than 72 inches from the floor. The board is mounted on pipe or angle iron supports, and its bottom should be at least ten inches from the floor.

Switchboards are classified into "live front" and "dead front" types depending upon the position of the switches. Fig. 12 illustrates a live-front board. In the live-front type the switches are located on the front of the board with the fuses in conjunction with the switch clips. In the dead-front type the switches and fuses are mounted in the rear of the main switchboard panel with only the operating mechanism on the face of the board. A "quick make and break mechanism" should be specified with this type of board, otherwise the switch may be held in an arcing position for some time without the operator knowing it.

Almost every conceivable arrangement of switches can be found on existing boards. It seems advisable to group the switches in accordance with their respective functions and in a manner most convenient to the operator, particular attention being given to the symmetry of the layout. Figs. 13, 14 and 15 show ideal arrangements suitable for any theater. When three colors of lamps are used and the master switches are desired along one side of the board, the grouping in Fig. 13 has been used to advantage. This is for a board on the right-hand side of the stage and for one on the left-hand side the arrangement should be reversed in order to bring the master switches nearest the stage. Fig. 14 shows a three-color arrangement with the master switches in the center of the board, and Fig. 15 a similar scheme for four colors. The question of placing the master switches at the side or in the center of the board is one of preference on the part of the operator. The foot and border-light switches, being the ones most often used, are given the preference in laying out a board, and the switches controlling the arc, independent, and house circuits, are then placed in the most consistent manner. The above arrangements followed as closely as possible seem to produce the most successful results.

### Panelboards and Cabinets

Panelboards are located in various parts of the theater for controlling certain sections of the theater lighting. In the majority of theaters a panelboard is located in the box office for controlling all the emergency lights and for the miscellaneous lighting in the front of the theater, such as lounging rooms, smoking rooms, etc. Many theaters constructed recently have offices in the same building, and numerous panelboards are required for the various lighting circuits but this has nothing to do with the theater proper.

### Picture Machine Outlet

Whenever picture-machine booths are installed a picture machine outlet is necessary. This is simply a panel on which is mounted a set of main busbars with main lugs and generally two 100-ampere fused branch switches, the panel being enclosed in a steel cabinet. It is strongly recommended that this be connected to the independent service as the picture machine can then be started in case of any accident to the regular service and the audience thus kept in ignorance of any irregularity and perhaps a panic averted.

### Plugging Cabinets

Plugging cabinets are often installed in the gallery where lens or spot-lamps are used and have as many outlets as the maximum number of lens lamps which will be used at the same time. The capacity should never be less than six arc lamps on account of the wiring, although a four-way plug box is generally sufficient. The receptacles should be similar to those used in the regular floor or wall pockets. The cabinets should conform in construction to the standard panelboard cabinet.

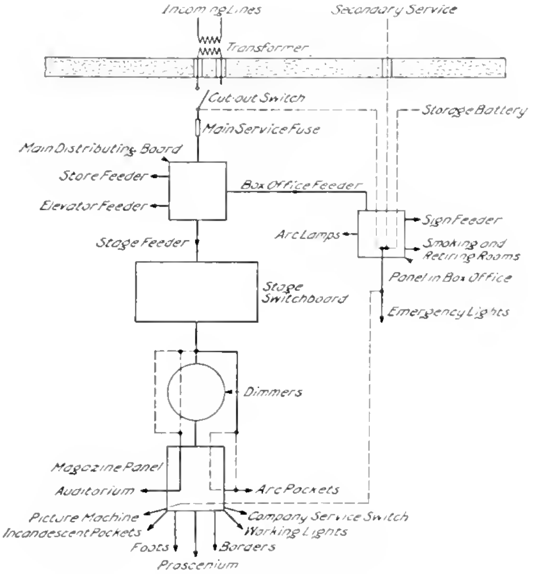

Fig. 16. Complete One-line Diagram of the Lighting Circuits in a Theater

### Service Panel

The service panel is usually located in the basement of the theater and the main incoming lines are brought directly to the fused side of a main switch, the meter loops being provided inside this switch. In the average theater there are two branch circuits from this panel, one to the stage switchboard and the other to the box office panel.

### Control of Theater Lights

Fig. 16 is a one-line diagram giving a general idea of the layout of the various lighting circuits of a theater and the location of the controlling devices. The service is generally brought in at the rear from the secondary of a transformer located on the outside of the building or on an adjacent pole. It then passes through the cutout switch and main service fuse to the main distributing board where it divides, one feeder going to the stage switchboard and the other to the box office. As shown in Fig. 16 the auditorium lighting circuit may be arranged to pass through or around the dimmers as preferred. Also the stage arc light circuit may or may not pass through the magazine panel.

The Board of Underwriters require the installation of a second service, that it may be available to keep the emergency lights burning should some accident cause the blowing of the main service fuse. This second service may take the form of secondary service, a reserve storage battery, or a tap on the main feeder located outside of the main service fuse. All of these circuits are shown in Fig. 16 as dotted lines entering the box office. Local conditions determine which of these schemes will be used. The storage battery is of course to be preferred from the standpoint of safety (although more expensive than either of the other schemes) for the reason that it will furnish light even in the extreme case of the failure of all external power supply. The source used for charging the storage battery is a rectifier, which may be used at any other time for supplying the moving picture machine.

Good practice to-day strongly recommends that the moving picture machine, which is ordinarily supplied from the main switchboard, be fed from the same source as the emergency lights. Then, in case the main service fuse is blown, throwing out all the lights in the theater (except the emergency lights), the picture curtain can be lowered and the audience kept in ignorance of any irregularity and thus a possible panic averted. In the intermission thus gained the trouble can be removed and the interrupted performance continued, thus avoiding the creating of dissatisfaction among the ticket holders.

# NOTES ON INVISIBLE LIGHT

By Dr. W. R. Whitney

Director of the Research Laboratory, General Electric Company

Dr. Whitney prepared these brief notes on invisible light to answer a few of the most frequently asked questions about the radiations given by X-ray tubes and radio-active material. Some of the more important characteristics of the electron are cited and its behavior in different media is stated briefly. The similarity and difference between the emissions from radium and X-ray are touched upon. We hope to publish a longer article dealing more fully with this subject in the near future.—Editor.

The object of these notes is to cover very briefly some of the points of interest in modern electrical theory, particularly with reference to such radiations as are given by X-ray tubes or radioactive material. It may help to review the conceptions of atoms, electrons and ether waves, for the subject is intimately connected with the constitution of matter and of electricity. Formerly the chemical atom was considered the ultimate indivisible particle. While this still has a significance for positively charged matter, another single and much smaller mass has been discovered in the electron. This consists of a negative electrical charge which is always the same in magnitude and to which a mass is attributed of about one eighteen-hundredth that of the hydrogen atom. This magnitude, the sign of the charge, its velocity, etc., have been determined from measurements of the effects of electrostatic and magnetic fields upon it. It is to the motion of these negative charges or electrons through metals that we attribute the flow of current. More is known about their flow across various spaces and within gases than elsewhere. They move with velocities varying with the potential gradient through which they fall. In such places as so-called "hard" X-ray tubes the velocity of the electrons is already known to exceed half that of light. The electrons are capable of passing through thin aluminum foil and even when this is earthed they emerge with their original charges. Material is in general, however, opaque to these electrons.

There seems to be no positive electrons corresponding exactly to the negative ones. The smallest positively charged masses yet known are the atoms of elements from which the negative electrons have escaped. These heavy positively charged particles of matter are well known and they act about as one would expect. They move in electrostatic fields with a velocity much lower and in the opposite direction to the negative. Ponderable matter of the atoms accompany them or constitute them. They do not pass through ordinary matter and are easily filtered out of gases.

Thus we see a differentiation of great importance which we express by saying that electricity exists in ultimate units which are negative charges. Their inertia, i.e., the property which by definition determines mass, make them out to be much smaller than any other particles of which we know.

When these moving negative electrons are stopped by contact with material, then X-rays are set up. It is believed that these light waves are set up by the impact of the electrons on the atoms of matter. These are exceedingly short waves in the ether, otherwise very like light waves. They possess greater penetrability, however, but also affect photographic plates.

These three things, positively charged atoms, negative electrons, and ether waves, are common to radium also; so while no attempt is being made here to cover entirely the properties of either, or the similarity or differences between radium and an X-ray tube, the following rough statements may be of help.

There are three kinds of emissions from radium, viz., alpha, beta and gamma rays. The positively charged atoms of matter from radium are the alpha rays. In the vacuum tube these correspond to the so-called canal rays and were discovered by studying the rays which passed through holes in the cathodes into the space behind the cathode. This is what we would expect if there were any such positively charged particles in a discharge tube.

The negative electrons of radium constitute beta rays and have been well studied. They correspond to the electrons which are shot off from the cathode in an X-ray tube. By their impact upon the anti-cathode or target, the X-rays are produced. Similarly the impact of the beta rays of radium are apparently the cause of the gamma rays of radium, as it is known that the impact of beta rays on solids produces gamma rays. These correspond to the X-rays. Both the gamma rays and the X-rays are ether vibrations of high penetrating power. Their velocity is in each case that of light. It is true that the penetrating power of the gamma rays is greater than that of the ordinary X-rays; but X-rays are of widely different penetrating power, though of the same velocity. The penetrative power should now be under control as it depends on the voltage across the X-ray tube. The hardness of an X-ray tube corresponds to the electromotive force necessary to produce and maintain the current of negative electrons through it, so that if this is made greater the hardness is raised. The greater the hardness the more penetrating are the X-rays produced. Evidently then the application of higher voltages to suitable X-ray tubes should give continually increasing penetrating power of the rays.

# FEEDER REACTANCES

By F. C. Barton

Lighting Engineering Department, General Electric Company

The introduction of the following article presents those reasons which show that feeder reactances should be included in many station equipments to assure the furnishing of an uninterrupted and high-quality service. Their purpose and consequently their advantages, having been covered thus in a general way, the remainder of the article is devoted to a detailed discussion of their disadvantages. These it shows are of a far less serious nature than has been often supposed.—Editor.

Articles on reactances which have appeared in former numbers of the Review have dealt chiefly with those for generators and busses. This type of reactance is certainly a very valuable, in fact, almost a necessary adjunct to the large central station in which the inherent reactance of the generators is comparatively low or in which the total kv-a. generated is very high. At the present date, however, practically all large 60-cycle generators are built with sufficiently high inherent reactance to limit the current on short circuit to not more than ten times normal. In these cases the need for the external generator reactance disappears except for the protection of the generator in case of an internal short circuit, and the need for the bus reactance is diminished, but the demand for a device which will protect the station against the effect of a short circuit on a feeder becomes if anything more pronounced, as where the generators have high inherent reactance it is essential that the currents due to short circuit be held as low as they can be efficiently, because of the effect of such heavy currents on the generator voltage regulation.

The merits of feeder reactances as a step toward that continuous service for which all central station companies are striving are rapidly becoming appreciated, and in modern central stations the practice of installing these protective reactances in feeder circuits is becoming a recognized necessity. Feeder reactances as a contributing factor toward continuity of service fully justify the space they occupy, the losses which they entail, and their cost, for not only do they protect the system of which they are a part from shutdowns due to short circuits in the feeders, but, also, they limit the short circuit current to a point where switching on the short circuited feeder ceases to be a menace. They possess certain disadvantages, which, however, are not as serious as they appear at first sight and which are usually magnified beyond their true proportions. These are:

First. The space required for their installation. Where the reactances are to be installed in the station already built, this is apt to present a rather serious problem; however, if the maximum space available for the installation of reactances is known, it is in most cases possible to design coils which will accommodate themselves to local conditions. The most efficient coil, and also the most economical from a manufacturing standpoint, is one whose diameter is fairly large in relation to its height, but where space limitations prohibit the use of such a coil there remains the alternative of accepting a coil of very slightly lower efficiency and possibly slightly increased price, which will fulfill the space requirements. A three-phase feeder naturally requires three single-phase reactances. These may be installed in any of three general methods, as best suited to the conditions, viz., in the form of a triangle the coils having vertical axes, in a row of coils side by side with the axes vertical, or with coils mounted one above the other with a single common vertical axis. Regardless of which method of mounting is adopted, it is advisable to install the groups of coils in cells or compartments similar in general to the compartments commonly provided for oil switches. Consideration must be given in the layout of such cells or compartments to the dissipation of heat resulting from the energy losses, dealt with later, in the coils. To take care of this heat adequate ventilating facilities must be provided.

Second. The effect on line voltage regulation. The rating of a reactance is based on its apparent watts or kv-a., for example: a single-phase reactance having a rating of 50 kv-a. would have approximately 191 volts drop across its terminals in a circuit carrying 262 amperes, or 3 per cent reactive drop in a 6350 volt circuit of 262 amperes, 6350 volts being the phase to neutral voltage of an 11,000 volt three-phase circuit. This voltage drop is at quadrature with the impressed e.m.f., therefore, the station voltage to overcome the reactive drop will be the $\sqrt{6350^2+191^2}$ or 6352.8 volts, or a rise of 2.8 volts. Expressed in terms of a three-phase circuit of 11,000 volts, the station voltage will have to be raised 4.4 volts to overcome the reactive drop produced by a 3 per cent reactance. The effect of reactances on the regulation of circuits carrying lagging currents is much more pronounced than when carrying current at unity power-factor, as that portion of the total current comprising the wattless component produces a reactive drop or counter e.m.f. which is at right angles to the wattless current or directly opposing the impressed e.m.f. In other words, the drop or counter e.m.f. of the reactance due to the energy current is 90 degrees behind the impressed e.m.f. The resultant station voltage necessary to overcome the effect of the reactance on the regulation being represented by the hypothenuse of a right-angle triangle, the sides of which are the line voltage and the reactance counter e.m.f. whereas the drop or counter e.m.f. due to the wattless component of a current of less than unity power-factor is 90 degrees behind that current or 180 degrees behind the impressed e.m.f., the resultant station voltage necessary to maintain constant line voltage being the straight addition of the drop due to the wattless current and the impressed e.m.f. The problem may be most simply expressed by saying that the voltage drop due to a feeder reactance is at quadrature with the line current, this line current being the resultant of the energy and wattless components, for example: in a circuit carrying power at 70 per cent p-f., the current will be lagging behind the impressed e.m.f. approximately 45 degrees, making a wattless component equal to the energy component. This will produce a drop in phase with the impressed e.m.f. equal to the drop at quadrature with the impressed e.m.f., or a resultant drop of 45 degrees behind the impressed e.m.f. This will be 90 degrees behind the resultant or actual line current. The relations of the various voltages affecting the line regulation and the resulting generator voltages are shown in Fig. 1 in which

$I$ equals actual current.
$I_e$ equals energy component.
$I_w$ equals wattless component.
$E_L$ equals line volts.
$E_{xe}$ equals reactive volts drop due to $I_e$ flowing over the reactance.
$E_{xw}$ equals reactive volts drop due to $I_w$ flowing over the reactance.
$E_x$ equals resultant voltage drop at quadrature with $I$.
$E_g$ equals station voltage.

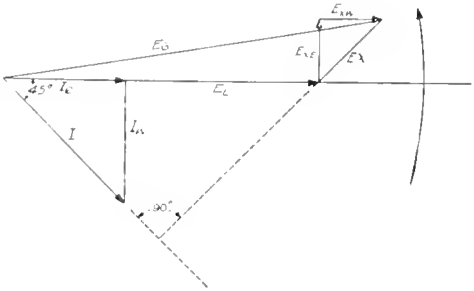

Fig. 1. Vector Diagram of the Voltage and Current Relations as Influenced by the Line, Generator and Reactance Coil

In the foregoing the drop due to resistance is ignored as this quantity is almost negligible.

Third. The energy loss due to resistance and to eddy currents in the copper conductors comprising the coils. These losses vary as the square of the kv-a. transmitted through the reactance, or in the case of the 50 kv-a. referred to above, represent about 2 to 3 kw. per coil when the feeder is carrying 5000 kv-a. or full load. This is equivalent to 0.18 of 1 per cent.

The reactance described, viz., one which produces 3 per cent reactive drop in a 5000 kv-a. feeder operating at 11,000 volts three-phase, will limit the current in a short circuit to 33.3 times normal or 8724 amp. This amount of current represents sufficiently high kv-a. to cause serious disturbances in any but the large systems. Reactances of 5 to 10 per cent are generally recommended for feeders. Such a low value as 3 per cent would be used only in large capacity stations where the ratio of generator capacity to feeder capacity is very large or in conjunction with generator and bus reactances in smaller capacity stations, or when a mixed load of low power-factor makes the voltage regulation of importance.

The preceding paragraph leads to points which must be given consideration when contemplating the installation of feeder reactances. The function of feeder reactances differs from that of generator reactances in that the generator reactances are intended to limit the instantaneous rush of current from a generator on short circuit to a point which will protect it from mechanical injury due to magnetic strains, and also protect the station apparatus and switches in the event of a short circuit occurring inside the station. This current, for the first few cycles following a short circuit, may reach as high as ten times normal in a generator having 10 per cent inherent reactance. If the inherent reactance is but 5 per cent the current may reach a maximum of twenty times normal, which might set up sufficient mechanical strains to destroy the generator windings, or, in the event of several generators feeding a bus which is short-circuited, might produce strains sufficient to destroy the bus structure. After the first few cycles the short circuit current will fall due to generator reaction to from 2 to 4 times normal. With the feeder reactance the impressed potential is maintained and the reactance must be such as to limit the current in a short circuited feeder to a point where it will not produce undue disturbances in the generating station. In other words, it must limit the current to such a point that the station will carry the short-circuited feeder until it is cut off the system without interfering with other feeders or causing the synchronous apparatus in the station and on other feeders to drop out of step. From the foregoing it will be seen that the per cent reactance which is placed in feeder circuits is governed chiefly by the capacity of the generating station to which the feeder is connected, and it must be high enough to prevent excessive voltage drop in the station due to short circuit, but should not be much higher than this point because of the effect as already outlined, upon space requirements, line regulation and energy loss, all of which increase as the per cent reactance or kv-a. capacity of the coil increases.

A secondary function of feeder reactances is to protect the feeder oil switches from the effects of extremely high currents resulting from short circuits. As modern oil switches may be considered as having a rupturing capacity limit of about 500,000 kv-a., it will be seen from this that a reactance of 1 per cent in the 5000 kv-a. feeder previously referred to would limit the short circuit to 500,000 kv-a. or a value sufficient to protect the oil switch against possible injury; therefore, with the 3 per cent reactance, selected for illustration, the kv-a. on short circuits would be limited to approximately 166,000 which gives a large safety factor insuring positive and safe action.

A feeder in some cases may be used as a tie line between generating stations. Tie line reactances perform the same function as bus section reactances, and will usually have a magnitude intermediate between feeder and bus reactances, as the ohmic resistance of the tie line is available, in quadrature with the reactance, to limit the current transferred. The protection of a system will usually be best obtained by a combination of generator bus and feeder reactances.

# FROM THE CONSULTING ENGINEERING DEPARTMENT OF THE GENERAL ELECTRIC COMPANY

## HIGH FREQUENCY MEASUREMENTS

A method has been developed for making energy measurements at high frequency and high voltage, and the apparatus employed involves the use of only hot-wire ammeters and voltmeters. The energy measurements are made by a process of tuning, whereby the wattless components are eliminated so that the energy is represented by the product of the volts and amperes that are measured. In this way, energy measurements have been made as high as 100,000 volts and 100,000 cycles and, in insulation materials, as low as a few watts can be measured at potentials of 20,000 to 30,000 volts. Though the voltages applied to the sample are high, the energy measurements are made at the low-tension end of the oscillation transformer and at voltages within the range of the ordinary hot-wire voltmeter.

It is expected that this measuring apparatus, in combination with the high-frequency alternator, will contribute valuable knowledge of insulation material under high-tension. The results obtained with measurements at high frequency are in many cases startling. Insulators break down at voltages much lower than those for which they are designed and at which they are used at ordinary frequency. Arc-overs occur in air over distances which for ordinary purposes are considered to have an ample margin of safety. For instance, a static voltmeter calibrated for use at 50,000 volts arcs over between the plates at 30,000 volts with 100,000 cycles. Destructive corona discharge appears under circumstances which ordinarily would be no source of trouble. At first there seemed ground to believe that totally different laws apply for dielectric strength at high frequency, but further investigations have shown that the apparent departures are due to secondary phenomena accompanying the high-frequency field. The principal cause is heat generated by dielectric hysteresis and corona. An ordinary insulator breaks down on account of the heat of the corona discharge at the edges of the metallic terminal, and the arc-over in air over long distances is due to corona discharge reaching out in streamers until the whole gap is bridged. Evidently the greater heating of the brush discharge enables it to maintain its conductivity over longer distances, though there is a variety of evidence that indicates that the dielectric strength of air, as well as insulating materials, is substantially the same at high frequency.

It is very difficult to establish a condition under which this can be demonstrated. In order to test insulators at high dielectric strain, they must be immersed in oil to avoid corona at the terminals and even then the heating due to dielectric hysteresis is so great that the insulator is apt to break down before the dielectric strength of the material is reached. Dielectric strength of air was measured between polished spheres of 5 inch diameter and it was found that a gap of 3 inches breaks down at 100,000 volts, which is practically the same as the values found with low frequency. On the other hand, the gap between the two plates 5 inches apart breaks down at 30,000 volts.

Measurements of corona loss at 100,000 cycles have been made and the results agree with the law of corona derived in the investigations of F. W. Peek, Jr. A corona loss of $\frac{1}{2}$ kilowatt at 30,000 volts was found on two wires 0.01 inch in diameter and 40 inches long.

A series of investigations are in progress to measure the dielectric losses and breakdown strength of various insulation materials, as well as parts of finished apparatus.

E.F.W.A.

## QUESTION AND ANSWER SECTION

The purpose of this department of the REVIEW is two-fold.

First, it enables all subscribers to avail themselves of the consulting service of a highly specialized corps of engineering experts, or of such other authority as the problem may require. This service provides for answers by mail with as little delay as possible of such questions as come within the scope of the REVIEW.

Second, it publishes for the benefit of all REVIEW readers questions and answers of general interest and of educational value. When the original question deals with only one phase of an interesting subject, the editor may feel warranted in discussing allied questions so as to provide a more complete treatment of the whole subject.

*To avoid the possibility of an incorrect or incomplete answer, the querist should be particularly careful to include sufficient data to permit of an intelligent understanding of the situation. Address letters of inquiry to the Editor, Question and Answer Section, General Electric Review, Schenectady, New York.*

### ALTERNATOR ARMATURE RECONNECTIONS

**(92) Given an a-c. generator, 1000 kv-a., 2300 volts, three-phase, 60 cycles, 80 poles, 720 slots, armature Y-connected, to reconnect it so as to give the same output at 440 volts, which of the two following methods would be the more practical in regard to its regulation of a load having a power-factor of 0.85: first, to connect the armature in triple parallel △ since there are 240 coils per phase $\frac{2300}{3 \times 1.73} = 440$ or, second, to parallel the three coils per pole per phase and connect the armature △? If this same generator had only 480 slots, that is, only two slots per pole per phase instead of three, what would be the most feasible way of changing its terminal e.m.f. from 2300 to 440 volts?**

It is doubtful if either of the methods suggested for reconnecting the generator for operation at 440 volts would be satisfactory. In the first case, a three-circuit connection on an 80-pole machine is not a very simple matter to accomplish and obtain a properly balanced winding between the three phases of the machine. The other method of connection would result in a heavy circulating current between the three circuits, since the three slots per phase under each pole are 30 electrical degrees out of phase with one another. To make a proper connection and obtain a balanced winding, the machine should be connected Y five circuits per phase for 440 volts, if it is now Y one circuit per phase for 2300 volts. The actual potential obtained with the same field excitation would be 460 volts, but the slight difference would not affect the operation of machine materially. The connection should be made in the same way whether the machine had two or three slots per pole per phase.

T.S.E.

### INDUCTION MOTOR CHARACTERISTICS AT HALF VOLTAGE

**(93) What are the characteristics of an induction motor when running on one-half normal voltage?**

Since the breakdown horse power of an induction motor varies as the square of the applied voltage, the breakdown point with only 50 per cent voltage will be but one-fourth as great. The average motor is designed with a maximum horse-power output of from 2 to $2\frac{1}{2}$ times the normal rating, and to keep this same factor of safety on half voltage the rating would be reduced to one-quarter that of normal.

The starting torque with a squirrel-cage or short-circuited rotor also varies as the square of the voltage, and, in some cases where the static friction is great, the one-fourth torque resulting from the half voltage may be only sufficient to start the machine, therefore allowing no load to be applied at this period.

The efficiency at one-fourth horse power and one-half voltage will be lower than that at normal rating by from 5 to 10 per cent. The friction is the primary factor in thus lowering the efficiency. Since the friction loss is of a constant value, its percentage loss at one-quarter the horse-power rating will be four times that at normal rating. The core loss varies as the 1.6 power of the voltage, which will reduce the core loss watts at one-fourth the horse-power rating to about one-third that at normal. This will therefore give at one-fourth normal load a higher percentage core loss than at normal rated load. With one-half the line voltage at one-quarter the horse-power rating, the line current would be expected to be one-half of normal. Then the percentage copper loss which is $\frac{IR}{E}$ would be the same as at normal. It slightly exceeds this, however, due to a lower apparent efficiency (eff. × p-f.). Therefore, all tendencies are for lower efficiency.

Since the per cent slip varies as the rotor copper loss, the slip at one-half voltage and one-quarter horse-power rating will be slightly greater than the normal full-load slip.

The power-factor is dependent upon the reactance and magnetizing current. With the motor operating at one-half voltage, the percentage reactance will be slightly greater than normal and the percentage magnetizing current will be less. Therefore, the resulting power-factor will be about equal to normal full-load power-factor.

The heating under the condition given will amount to less than one-half load under normal voltage, since the current is one-half normal and the excitation losses less than one-half. However, on a heating basis it will be possible with a 50 per cent drop in voltage to operate the motor up to nearly one-half the normal horse-power rating. The efficiency and speed, however, will fall rapidly, but the power-factor will keep up until the breakdown point is reached, when it will drop off rapidly.

These statements only apply in general, and there may be a variation from them on large and high-torque motors.

C.B.H.

### OIL SWITCH: CONNECTIONS OF CIRCUIT-OPENING EQUIPMENT

**(94) Various methods have been used for connecting the series transformers, relays, and trip coil of an oil switch in order to make it open the line circuit when the load on the line becomes excessive. Direct or alternating current is employed for energizing the trip coil. Please explain the actions which take place when using alternating current for tripping in each type of auxiliary circuit as the result of a single-phase and a three-phase short circuit on the line; also discuss the merits of the different connections.**

There are, it is true, a number of different methods of connecting the tripping device of an oil switch which opens on overload, but only a very few of these afford complete protection. There are several which have been tried with more or less success, and there are others that have been proposed but which have never been adopted because of practical difficulties of application or because of theoretical faults. The following discussion will take up the connections which seem to be most worthy of consideration.

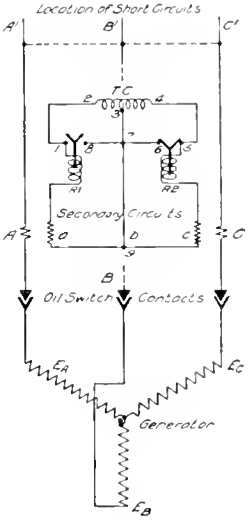

Fig. 1

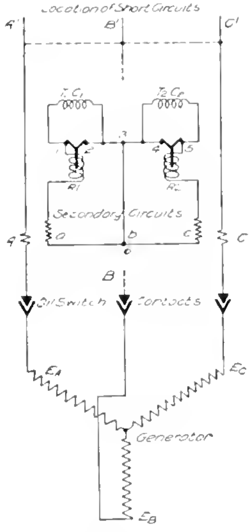

Fig 2

### First Method

The arrangement which at first sight would seem to be the simplest that could be applied is illustrated in Fig. 1. Here the relays are shown closed which is their position during normal operation. In this, and in all the following diagrams, the letters *A*, *B* and *C* will be used to represent the high-tension lines of which *A* and *C* act as the primaries of the series transformers; *a* and *c* the corresponding secondaries of these transformers and *b* the middle secondary wire; $R_1$ and $R_2$ the circuit-opening relays; and *TC* the trip coil when only one coil is used and $T_1C_1$ and $T_2C_2$ the coils when two are used.

This method of connection will fulfill the requirements perfectly in the case of any single-phase short circuit on the line. For instance, in the event of a short circuit at *A'-B'*, the heavy current flowing in *A* and *B* will induce a correspondingly excessive current in *a*, the secondary of the affected series transformer. This current passing through the circuit *a-$R_1$-1-7-6-8-a*, which is the one of lowest resistance and reactance open to it, will cause the solenoid of relay $R_1$ to lift, thus opening that circuit. This action of the relay now forces the entire current to flow through the trip coil *TC*, the circuit being *a-$R_1$-1-2-TC-3-4-5-6-8-a*. The trip coil now being energized opens the oil switch. A short circuit across *B'-C'* would act in a manner corresponding to the one across *A' B'*.

If the short circuit had been across *A' C'*, both relay solenoids would have gone up on account of the heavy current sent through them by the secondary coils *a* and *c* of their respective series transformers. These two secondaries then acting in series will force their entire current through the trip coil *TC*, using the circuit *a-$R_1$-1-2-TC-3-4-$R_2$-c-8-a*. The oil switch is then of course opened by reason of this current through *TC*.

The fault of this method of connections, however, is in the operation of the series transformers under the condition of a three-phase short circuit on the line, i.e., across *A'-B'-C'*.

At this point it will be well to note that the effect on the series transformer secondaries by a single-phase short circuit across *A'-C'*, is by no means the same as that caused by the three-phase short circuit across *A'-B'-C'*.

The difference lies in the phase relation of the currents induced in the secondaries *a* and *c*.

In the case of the single-phase short circuit at *A'-C'*, the voltages $E_A$ and $E_C$ impressed on this single primary circuit combine into a single-phase voltage $E_{A+C}$, which causes a single-phase current $I_{A+C}$ to flow around that circuit, *A-A'-C'-C*. This being the current that flows in the primaries of both series transformers, the e.m.f.'s induced in the secondaries *a* and *c* are in phase and therefore add together directly to cause a single-phase current to flow through the relays and trip coil. Under these conditions, no apparatus is unduly stressed.

When a three-phase short circuit takes place at *A'-B'-C'*, however, the e.m.f.'s $E_A$ and $E_C$ cannot combine to form the single phase e.m.f. $E_{A+C}$ as before, to apply to the circuit *A-A'-C'-C*, for they are maintained individually in their normal relation of 120 degrees apart. This is the result of the short circuit being three-phase, which holds all three primary e.m.f.'s $E_A$, $E_B$ and $E_C$ symmetrically 120 degrees apart.

As a consequence of the primary e.m.f. in *A* being 120 degrees displaced from that in *C*, the induced e.m.f. in *a* is 120 degrees displaced from that in *c*. Therefore, the secondary e.m.f.'s not being in phase, they can never unite to produce a single-phase current in that circuit without a stress at some point.

Previous to the opening of the relays no trouble is experienced, for the two 120-degree-displaced currents of the secondaries flow in independent circuits, viz., *a-$R_1$-1-7-6-8-a* and *c-$R_2$-4-5-6-8-c*. At the moment the relays open, however, the two secondaries of the transformers are restricted to the single circuit *a-$R_1$-1-2-TC-3-4-$R_2$-c-8-a*.

The primaries being 120 degrees apart, whereas the corresponding secondaries form a single-phase circuit, electrically forces the secondaries 30 degrees away from the primaries. The maintaining of this condition, even though it is but momentary, places the series transformers under excessive magnetic strain, since magnetism alone is the connecting link between the primary and secondary circuit.

This excessive magnetic stress on the cores of the series transformers is apt to seriously change their magnetic characteristics and the ratio of the transformers, which will render further operation unsatisfactory. This detrimental action is especially dangerous if high-accuracy instruments and meters are connected to these transformers in addition to the relays.

### Second Method

It has been proposed to overcome the bad features of the first method by using two separate trip coils as shown in Fig. 2. In this case the secondary of each series transformer acts independently of the other upon its own relay and trip coil. When a short circuit occurs across $A'$-$B'$, the secondary $a$, the relay $R_1$, and the trip coil $T_1C_1$ unite in their action to open the switch; in the case of a short circuit across $B'$-$C'$, the corresponding elements $c$, $R_2$ and $T_2C_2$ open the switch; and if a short circuit takes place across $A'$-$C'$, both sides of the secondary circuit act in unison, as in the First Method, to release the latch of the switch. For single-phase short circuits, then, the operation is satisfactory and it remains but to examine the action taking place when a three-phase short circuit takes place.

In the case of the three-phase short circuit, i.e., across $A'$-$B'$-$C'$, the same primary conditions as described in the First Method are, of course, produced. That is, the e.m.f.'s in $A$ and $C$ are 120 degrees apart. Until the relays open, the resulting 120-degree-displaced secondary currents flow independently in their separate relay circuits $a$-$R_1$-$1$-$2$-$3$-$6$-$a$ and $c$-$R_2$-$5$-$4$-$3$-$6$-$c$. Since each series transformer has its own trip coil, their secondaries are not restricted to a single circuit when the relays open. Their two individual circuits are preserved. Therefore, the two separate single-phase currents, one from each secondary, still flow independently of each other, a condition which eliminates the objection found in the first method.

This scheme of connections, therefore, is thoroughly satisfactory so far as its theory of operation is concerned, for it operates as intended in the case of short circuits on any or all the phases. It has not been adopted, however, on account of the cost involved in using two trip coils instead of only one and because of the difficulty of mounting the additional coil in the limited space available on the oil switch.

### Third Method

It might be thought that the objection to the two-coil arrangement could be overcome by the use of a single trip coil having a tap in the center of its winding as shown in Fig. 3. This method does give satisfactory operation when a three-phase short circuit occurs across all the lines or a single-phase short circuit across $A'$-$C'$, for under this condition the tapped coil acts as do the two coils in the Second Method. But, it will not furnish reliable service in the event of a single-phase short circuit either across $A'$-$B'$ or $B'$-$C'$. For example, assume the lines $A$ and $B$ tied together. The excessive current induced in $a$ raises the relay $R_1$, in which position it is shown in Fig. 3. The left-hand half of $TC$, i.e., $2$-$3$, then carries the total current from the secondary $a$. The resulting pull of this half of the trip coil, however, may be insufficient to operate the latch of the oil switch because of the dampening action of the right-hand side, $3$-$4$, of the same coil. Since the two halves of this coil are mounted on the same core, they are linked together magnetically and bear the same relation to each other as the primary and secondary of a transformer. Thus, the current flowing in section $2$-$3$ induces an e.m.f. in section $3$-$4$. This e.m.f. applied to the low resistance and low reactance circuit $4$-$5$-$6$-$7$-$3$, causes a heavy current flow in that circuit. (The action is the same as that of a short-circuited secondary of a transformer.) This current flow partially demagnetizes the core of the trip coil $TC$ and therefore the effective pull of the active section of that coil, i.e., $2$-$3$, is materially reduced. The service rendered by the trip coil in opening the switch is therefore unreliable. The actions taking place in the case of a short circuit across $B'$-$C'$ are similar to those just described.

This feature of unreliable service prohibits the use of this method of connections.

### Fourth Method

In order to secure a construction in which the preceding difficulties would be avoided and which, at the same time, would be sufficiently inexpensive to warrant its adoption, another arrangement has been developed. This is shown in Fig. 4 in diagrammatic form for the sake of clearness. There is but one trip coil and it has a center tap as was used in the Third Method. This construction differs from that of the preceding in the fact that the operation of either or both relays open but one contact, that being $5$-$7$-$6$. This is accomplished by a mechanism of toggle-joints and levers.

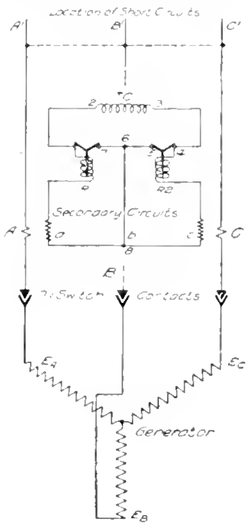

Fig. 3

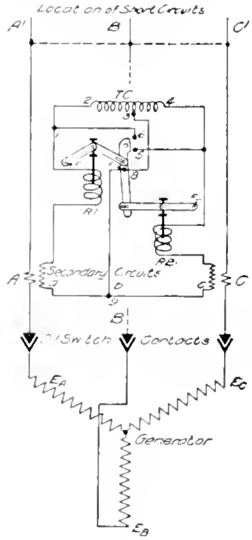

Fig. 4

The only fixed points of the lever system are $F$, and the action of either or both of these relays in opening the contact $5$-$7$-$6$ opens the short circuit around the trip coil.

In the event of a single-phase short circuit between $A'$-$B'$, the relay $R_1$ breaks the links above it upward and opens the contact $5$-$7$-$6$, as shown in Fig. 4. The oil switch is then tripped by the action of the current flowing in the circuit $a$-$R_1$-$1$-$2$-$TC$-$3$-$8$-$9$-$a$. There is no dampening action by the remaining part of the trip coil $3$-$4$, as occurred in the Third Method which also used a tapped trip coil, for this remaining section is not short circuited by a low resistance and therefore cannot act as the short-circuited secondary of a transformer. A short circuit across $B'$-$C'$ has the correspondingly same effect.

A short circuit across $A'$-$C'$ causes the entire trip coil to be used, the single-phase current induced flowing in the circuit $a$-$R_1$-$1$-$2$-$TC$-$4$-$R_2$-$c$-$9$-$a$.

After the relays have operated under the effect of a three-phase short circuit across $A'$-$B'$-$C'$, the conditions existing in the secondary circuit are exactly the same as for the same circumstance in the Third Method and therefore this method is of course equally satisfactory.

This arrangement, fulfilling all the requirements for which it was intended and being cheaper and more convenient of application than the only other satisfactory type, is the one generally used.

D.B.

### OIL SWITCH: USE OF BAFFLERS

**(95) What are the reasons for using bafflers in the oil vessels of motor-operated oil switches?**

The primary reason is to increase the rupturing capacity of the switch. Another reason is to reduce the tendency of the oil to be expelled from the oil vessel on opening the circuit under conditions of heavy overload or short circuit.

Fig. 1

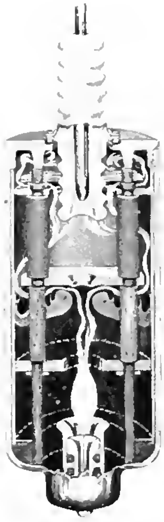

Fig. 2

In detail, the lower or circular section of the baffler tends to prevent the oil in that chamber from leaving, thus assisting in smothering the arc. The only oil exit from this lower chamber being the small hole in the lower baffler plate, the oil which leaves is forced into the path of the arc, thereby cooling it.

Fig. 2 pictures the course of the escape of the generated gases from the oil-filled vessel, as influenced by the baffler, Fig. 1.

The second or triangular baffler and the upper bafflers, by forcing the oil and gases traveling upward around a long and tortuous path on their way to the vent at the top, tend to reduce the velocity of the oil and turn it downward. At the same time, the action permits the gases to escape, which reduces the tendency of the oil to be thrown out of the tank under severe conditions and also prevents high pressure in the upper portion of the tank.

At the same time, the oil is forced back under pressure into the region of the arc which shortens the time of breaking the arc and confines the violent disturbance or explosive effect on short circuit. Consequently, it eliminates to a great extent the flashes due to hot gases and the ejection of the oil from the oil vessels.

### INDUCTION GENERATORS: OPERATION

**(96) Are there any induction generators in use in this country? Are there any such machines driven by exhaust-steam turbines. If so, please state some of their operating details.**

Yes. For instance, the Interborough Rapid Transit Company, New York City, has six or seven of these low-pressure steam-turbine-driven induction-generator sets of 7500 kw. each. Two good points have been claimed for this type of generator. First, it acts somewhat as a storage battery floating on the line, delivering no load when the primary generators are capable of carrying the station demand. This produces a higher station efficiency, for since but a few generators are actually carrying the load they are operating at a high efficiency. Second, it somewhat lowers the impetus or flywheel effect which the generators throw into a short circuit occurring on the line; this because the induction generators depend upon the synchronous generators for their excitation, and with the lowering of the voltage delivered by the synchronous generators the induction machines lose their excitation. Some of the unfavorable points of the induction generator are lower efficiency, poorer regulation, and a larger size machine for the same output.

E.C.S.

### INDUCTION MOTOR: KNOCKING OF ROTOR

**(97) A certain $\frac{1}{8}$ h.p., 60-cycle, 104-volt induction motor produces a knocking sound when running under current. This sound disappears when the current is switched off, although the motor runs at nearly full speed for some time. The bearings are in good condition and the rotor does not rub the stator at any point. A test shows no reversed coils. What is the cause of the sound?**

It is suggested that the operation of the rotor be carefully noted when it is running supplied with current. It would appear that the knocking is due to the rotor and shaft violently oscillating between the bearings, the sound resulting from the shoulders of the shaft bumping against the shoulders of the bearings. Such an action would be quite possible if the rotor is not mounted at the correct position on the shaft.

The correct position of the rotor on the shaft is that at which the action of the field upon the rotor will hold the latter in such a position that the shaft will run freely without its shoulders coming in contact with the shoulders of the bearings. If the rotor is not set in this position, it will seek one bearing when current is applied, bump up against that bearing and be sent to the other bearing. This oscillating action increases in magnitude until it becomes violent. The remedy, of course, is to shift the rotor along the shaft until it becomes central with the field set up by the stator, at which time the knocking will be eliminated.

# INVESTIGATION TO DETERMINE THE EFFECT ON THE PROPAGATION OF ELECTRIC WAVES OF THE TOTAL ECLIPSE OF THE SUN, AUGUST 21, 1914

British Association for the Advancement of Science

The forthcoming total eclipse of the sun affords an exceptional and important opportunity of adding to existing knowledge of the propagation of electric waves through air in sunlight and in darkness, and across the boundaries of illuminated and unilluminated regions. The eclipse will be total along a strip extending from Greenland across Norway, Sweden, Russia and Persia to the mouths of the Indus. In Russia the duration of totality will be little more than two minutes.

There are two main points calling for investigation during the eclipse. In the first place, the propagation of signal-bearing waves through air in the umbra and penumbra will probably obey laws different as regards absorption and refraction from those obeyed in illuminated air. In the second place, the strength, frequency and character of natural electric waves, and of atmospheric discharges, may vary. The variations may occur either because the propagation of natural waves from distant sources is facilitated or impeded by the eclipse, or, possibly, because the production of natural electric waves or atmospheric discharges is for some unknown reason affected by the eclipse.

These points have previously been investigated to only a slight extent. The observers of signals during the solar eclipse of 17th April, 1912, nearly all agreed that the strength of the signals was greater during the eclipse than an hour before or after. There was only one special observation of strays during the same eclipse, when very pronounced and remarkable variations were recorded during the passage of the shadow-cone across Europe.

To investigate the propagation of signals across the umbra it will be necessary to arrange for wireless telegraph stations on either side of the central line of the eclipse to transmit signals at intervals while the umbra passes between them. This transit of the umbra occupies about two minutes. It is thus very desirable that the Scandinavian and Russian stations should transmit frequently throughout several minutes before, during, and after totality. But stations other than those favoured by their proximity to the central line should endeavor to keep a complete record of the variations of signals during the eclipse. Stations in Europe west of the central line and stations in the Mediterranean and in Asia Minor may find noticeable changes in the strength of signals, particularly long distance signals, between the hours of 10 a.m. and 3 p.m., Greenwich time; and it is probable that the stations of India and East Africa, and ships in the Indian Ocean, may feel the effect of the penumbra in the afternoon. On the other hand, ships in the Atlantic, and fixed stations in eastern Canada and the United States, will probably be affected by the penumbra in the early morning. At Montreal the eclipse (partial) is at its greatest phase at 5.52 a.m. Standard Time. It is possible that the eclipse may have some influence even when it is invisible.

The investigation of strays is of as great interest as that of signals. So far as is yet known, the natural electric waves reaching wireless telegraph stations in latitudes higher than 50 deg. appear to travel mostly from the south. Thus the greatest changes produced in strays by the eclipse will probably be experienced at stations in Scandinavia and Russia, to reach which the waves must cross the path of the umbra. At the same time changes of some kind are to be expected in other districts than these, and it is therefore desirable that statistical observations of natural electric waves be made all over the world, and especially at places within an earth quadrant of Southern Russia. It is also desirable that meteorological observations, including those of atmospheric ionization and potential gradient, should be at the disposal of the Committee when considering the records of strays and signals.

The Committee proposes to prepare and circulate special forms for the collection of statistics of signals and strays, especially within the hemisphere likely to be affected by the eclipse; they will endeavor to make provision for the transmission of special signals at times to be indicated on the forms; and they will offer for the consideration of the authorities controlling stations near the central line a simple programme of work. The discussion of the observations, and the comparison with meteorological data, will be carried out by the Committee; and digests of the statistics, together with the conclusions drawn from the analysis, will be published in due course.

This striking picture illustrates forcefully the conditions that exist on the mountain divisions of many of our trunk line railways. Such sections on the right-of-way act to throttle the traffic in each direction, with much loss in time and revenue, and it is the ability of the electric locomotive to cope with the difficulties involved in the expeditious handling of trains on these grades that forms one of the strongest arguments for main line electrification. The reader is referred to the article, "**The Development of Electric Traction**" on page 462.

GENERAL ELECTRIC REVIEW

## THE PATHS OF PROGRESS

The cost of power is one of those subjects of vital importance that is attracting considerable attention just at present. That electric power should be generated and sold as cheaply as possible is essential, as under modern industrial conditions the wheels of industry are getting more and more dependent upon this form of energy every day. But this subject of the cost of power is one which the public can very easily be misled on and fooled into believing that they are paying more for than they ought. There is nothing easier in the world than to deceive people by figures. The bare statement that electrical energy can be produced for less than one cent per kw-hr. at the central station busbar is telling only a very small part of a truth, and immediately makes the uninformed on technical matters wonder why they are paying so much more than this figure for the energy they are consuming. The difference between the cost of production at the central station bus and substation bus and between the cost at the substation bus and at the customer's meter means nothing to the average lay mind. The load factor and the cost of the distributing system are items that are entirely disregarded by those unfamiliar with the subject.

As a rule, the figures cited when talking of the cost of power are based upon very large stations operating under the most favorable conditions which rarely exist. The cost of power is vitally affected by the nature of the load factor, and fortunately, owing to the rapidity with which the use of electric energy is spreading, we may look for an improvement in this direction, but the cost of distribution must under any circumstances always be high.

It would be an interesting study to take a certain number of the best typical central stations with distributing networks of normal dimensions and calculate the cost of power to the consumer at his meter, calculating the cost of energy at the station busbar at zero. Such a set of figures would be a liberal education to some people. The cost of constructing and maintaining a system of energy distribution for a large city is enormous, and these costs are likely to increase rather than decrease since the demands on the public service corporation for a higher class of workmanship are incessant. The fact of whether the light and power wires are carried on poles in our city streets or are laid in expensive conduits under ground must have a marked effect upon the cost of energy delivered.

An appreciable portion of the distributing system and especially that part feeding the residential lighting circuits is only doing active work for a small proportion of the 24 hours, while the heavy overhead charges are working continuously. In spite of the high cost of distributing electrical energy to the consumers, it is immensely cheaper than the transportation of any other form of energy. The cost of electrical energy as paid by the consumers includes the cost of manufacture and transportation, and all the consumer has to do is to turn a switch. If electricity were of such a nature that the consumer could call at the central station and take it away in buckets full, then he could buy it at a figure approaching one cent per kw.-hour, but owing to the service rendered to the consumer by the power company, which includes the manufacture, transportation, metering and controlling of the energy, it is unlikely that rates much lower than those prevailing in many districts at present can be looked for. As a matter of fact, the decrease in the charges for electrical energy that have already been brought about at a time when all the other necessities of life have been increasing at a rapid rate shows what marked progress has been made in the industry of generating and supplying electric power.

# THE LATEST AND LARGEST ELECTRICALLY-OPERATED GOLD DREDGE

By W. H. Gardner and W. M. Shepard

The methods now employed in gold dredging are widely different from those in vogue in the early days, principally because almost all of the gold-bearing surface deposits which have not already been worked out give so low an assay value that the work can only be carried on profitably on a very large scale. The author shows the rapid growth that has been made in the size of the dredges designed for this work, and describes and illustrates in detail the construction, equipment, and operation of the latest dredge—the all-steel electrically-driven Yuba No. 14.—Editor.

## Introduction

Gold dredging is the class of mining that involves the least risk. A dredgable property can be prospected by pits or shafts, if there is not too much water, or by the usual method of drilling. This work, if done under expert supervision, gives with remarkable accuracy the total gold contents of the placer deposit. If the building of the gold dredge is entrusted to a responsible and capable concern, its first action is to study carefully the physical and climatic conditions of the property; and the completed dredge, especially designed to operate efficiently under these conditions, will have an operating cost that can be calculated with reasonable exactness. The value per cubic yard and the cost of recovery per cubic yard thus being known, the profits become practically a known quantity. Were this not the case dredging operators would not so readily spend up to a third of a million dollars for a dredge before actual returns commenced. There is no uncertainty regarding the extent of the vein, nor a continual outlay for exploration and development work, as in a quartz mine. The "ore" is always in sight.

Unfortunately, however, deposits which will lend themselves to the successful operation of a gold dredge are becoming scarce. The richest placers of New Zealand and California are rapidly being worked out. Alaska is a rich and promising field, but inaccessibility and short seasons preclude the successful exploitation of anything but comparatively rich deposits. In South America, Columbia offers a promising field, but difficult prospecting conditions render its development slow. Siberia and the Philippines will eventually prove valuable fields. The whole world is being combed for dredgable deposits, prospecting parties are investigating wild and unexplored regions, but suitable placers are becoming increasingly hard to find. This is largely due to the fact that conditions must be fairly favorable for dredging. Inaccessibility means increased cost; ground running 9 cents per cubic yard being workable at a profit in California, while in some sections of Alaska the costs alone run to 30 cents per cubic yard. The bed rock must be soft, for the heaviest dredge yet built or likely to be built cannot dig hard and massive bedrock, nor recover gold that is highly concentrated in its crevices. Clay is exceedingly difficult to handle, large boulders render operations exceedingly expensive or impossible. As a result, the large dredging companies have turned much of their attention to the problem of handling the extensive low grade properties of more accessible regions, which have favorable conditions. Huge and powerful dredges, having a capacity of 10,000 cubic yards or more per day, have thus been evolved, with their consequent exceedingly low operating cost. Of this type of dredge, the Yuba No. 14 stands to date as the largest, most powerful, and most modern.

The gold dredge is essentially a hull or scow on which is mounted excavating machinery, screening and washing appliances for the recovery of the gold, and an arrangement for depositing the waste material sufficiently far behind the dredge as not to interfere with its flotation and operation. The dredge excavates material at its front end, extracts the gold and deposits the waste material behind it, continually moving forward and carring its own pond with it, thus working any fairly level deposit independent of its elevation or proximity to the river or stream. A continuous influx of fresh water through a ditch, varing from 40 to 200 miner's inches* depending on the kind of ground and the size of the dredge, counterbalances the losses through seepage or evaporation, and serves to settle the suspended clay and silt.

The excavating is done by means of an endless chain of heavy buckets, revolving

---

* A miner's inch is approximately estimated at 1½ cu. ft. per min.

A View of the Yuba Gold Dredge No. 14 in Operation

A View of the Yuba Gold Dredge showing the Digging Ladder Raised over two tumblers mounted at the extremities of a long ladder, the upper tumbler being six sided and acting as a positive driving sprocket for the bucket chain. In modern installations the lower tumbler is round, acting as an idler or sheave. The ladder is suspended at its lower end from a heavy gantry on the bow of the dredge hull, the raising and lowering of the ladder controlling the digging depth. The elevation of this ladder is controlled by a winch, called the ladder hoist winch, situated on the port side of the dredge. The lateral motion of the buckets is secured by swinging the entire dredge on one of the "spuds" as a pivot. This is done by means of lines run from two drums, the "swing winch," on the starboard side, connected through sheaves on the port and starboard bow to "dead men" on the banks. The continuously revolving bucket line is thus swung across the face of the bank for a width of from 190 to 300 feet, and at the extreme lateral limit of the swing the ladder is dropped and the side swing repeated. The revolving buckets thus terrace away the bank until bedrock is reached, when the ladder is raised, the dredge stepped forward by swinging on alternate spuds, and the whole operation recommenced. These spuds, which are single sticks of lumber on the smaller dredges and of structural steel on the larger and more powerful dredges, are at the stern of the dredge and suspended from the stern gantry. On Yuba No. 14, for instance, these spuds weigh over 40 tons each, and are 60 feet long. By alternately raising and dropping these two spuds as the dredge swings, it is stepped ahead much as a stiff-legged man might walk.

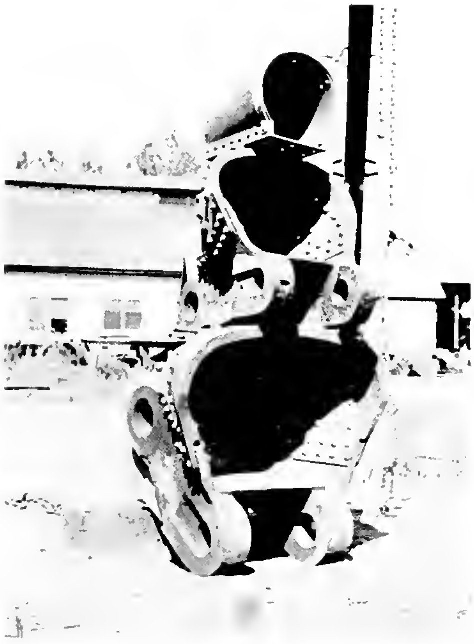

Fig. 1. A Comparison of:
Bucket of First Dredge on Yuba River
7 Cubic Foot Bucket of Early Dredges
15 Cubic Foot Bucket of Yuba No. 13

The ascending buckets, full of gold-bearing material, are dumped over the upper tumbler into a hopper, lined with heavy wearing bars, where it is subjected to high pressure sprays of water. The gravel is then delivered to the screen, a revolving cylinder sloping toward the stern and lined with perforated steel plates, in which it is continuously played upon by jets of water and is completely disintegrated. The sand, fine gravel, and gold particles are washed through the perforations into the distributor under the screen which serves to properly distribute the mass onto the gold saving tables. These are in two banks, an upper and a lower, and are composed of fore and aft and thwart ship sluices, lined with steel shod sugar pine riffles, where the gold is caught and amalgamated by mercury. The waste sand is delivered from the tail sluices at the stern of the dredge, some of it being deposited around the spud points to enable them to obtain a firmer hold, and the remainder dumped at some distance behind the dredge. The boulders and heavy gravel, which do not pass through the perforations, fall from the rear end of the screen into a chute and are thence delivered onto the stacker belt. This endless belt carries the material up a long stacker, which is hung from the stern gantry of the dredge, and is finally dumped far to the stern, forming the extensive "rock piles" characteristic of a dredging field.

All these operations are controlled by three men. The winchman, in the "winch" or operating room above the swing winch, commands a view of the line of buckets and controls the principal motions of the dredge. Two oilers are employed, one of whom attends to the control of the screen and stacker, and they complete the necessary crew for a shift.

The gold dredge became an accredited machine for recovering gold in this country soon after its success in New Zealand. The Continental Dredge, built by Mr. W. P. Hammon in Oroville in 1899, first proved the tremendous possibilities of this method of low-cost extraction. The first dredges were small, although the necessity for using special steels and high-grade material due to the terrific wear and tear on the bucket line was early recognized. At that time a dredge equipped with 9-cubic-foot buckets was considered impossible, and a 16-cubic-foot dredge was undreamed of. Fig 1 shows an old bucket of one of the earliest California dredges, a 7-cubic-foot bucket of the wonderfully successful Yuba Consolidated Gold Fields Company's dredges of a later period, and a 15-cubic-foot bucket of a modern dredge, Yuba No. 13, the immediate predecessor of Yuba No. 14.

The Yuba River, draining a region from which the early output of California gold was largely derived, was considered as a dredging field as early as 1900. While good values were found, the ground was thought too deep to dredge, and it was several years before it was considered possible to construct dredges that could dig deep enough to handle this ground. Yuba No. 1 and No. 2, 7-cubic-foot dredges, were then constructed to dig to a depth of 65 feet. Six more dredges of improved design followed rapidly. The ground was very rich, one of the dredges alone once clearing more than four hundred thousand dollars profit in a single year. Later, four more dredges having somewhat larger hulls were built and added to the fleet. In August, 1911, Yuba No. 13, a 15-cubic-foot dredge with wooden hull, started work and handled an average of 280,000 cubic yards per month at an average operating and maintenance cost of a little over $3\frac{1}{3}$ cents per cubic yard. On the Feather River at Oroville, and on the American River at Folsom, fleets of gold dredges were operating by this time, but in point of extent and value the Yuba River was unequalled.

In 1912 the construction of Yuba No. 14, at present the last word in modern gold dredge construction, was first projected. It was determined to build this dredge entirely of steel, the longer life and practically negligible fire risk being the determining factors. The life of a dredge is limited by the life of its hull, and the steel hull while more expensive increases the life of the dredge from ten years, with a wooden hull, to fifteen years or more. Steel housing and steel gold saving tables were provided to decrease risk of loss by fire and for other reasons. Buckets of 16-cubic-foot capacity each were designed, the expected yardage being 10,000 cubic yards per day. A [illegible] ladder was planned, to enable the dredge to dig 70 feet below water level and reach the deepest bed rock. The latest improvements in electrical equipment and control were incorporated in the plans of the dredge, to help reduce the operating cost to a minimum. An increased area of gold saving tables was provided, to secure the maximum gold recovery. While no experimental features were introduced in the design, the machinery was strengthened in many places. As a result Yuba No. 14 stands as the largest and most advanced gold dredge in the world.

Yuba No. 14 was designed and constructed by the Yuba Construction Company of Marysville, California. It was built on the Yuba River a little further up river than the other dredges operated by the Yuba Consolidated Gold Fields Company, at a total distance of about 14 miles from Marysville. Fig. 2 shows the dredge under construction. A brief description of the engineering and mechanical points of this dredge follow.

### Steel Hull

Perhaps the most important and interesting feature of Yuba No. 14 is its steel hull. This hull is 155 ft. 6 in. long, 58 feet wide with an additional overhang of 5 feet on each side to increase the deck area, and is 11 ft. 6 in. deep. It is made entirely of steel, and is the first steel-hull dredge to have a deck of steel plating. Particular attention has been given to the design of the hull. It has been so constructed that all of the heavy stresses are distributed over a series of fore and aft and transverse trusses. The vertical sides of the hull form the girders which carry the concentrated loads near the edges of the main deck. The bottom of the hull is framed in such a way that the upward pressure of the water is carried to the main fore and aft trusses and to the sides, allowing the hull to be as light as possible and yet giving it at the same time ample strength to withstand the stresses incident to the operation of the dredge. Following out this same scheme, the spuds are directly in line with the fore and aft trusses.

The bow gantry, the truss from which the ladder is suspended, is of particularly heavy steel construction, and the weights of the bow and stern gantry, added to the weight of the hull, show a grand total of 1,562,546 pounds.

The housing, carrying out the general plan of the dredge, is also of steel fireproof construction. It is made up of two sheets of 22 gauge steel between which is a $^1_4$ in. sheet of millboard. This insures absolute fire protection, and gives a maximum insulation, keeping the dredge interior warm in winter and cool in summer. This is an important item, for warm weather in the field is particularly torrid owing to the gravel and sand bars along the river.

### Digging Ladder

The digging ladder, of the plate girder type, is one of the heaviest yet designed, and to enable the dredge to dig 70 feet below water level has a length of 133 ft. 6 in. between tumbler centers. This girder is 10 feet in depth. Not counting the ladder rollers or bucket line, this ladder weighs 125 tons.

### Bucket Line

The bucket line is composed of 87 buckets, connected in an endless chain. The bucket bottoms are of a special nickel-chrome steel, cast with the hoods integral. The lips and bushings are of manganese steel, and the bucket pins are of a specially heat-treated oil-tempered nickel-chrome steel. The wear on the bucket line of a deep digging dredge is very great, and hence only the highest grade steels can be used in its construction. This bucket line complete weighs very nearly 203 tons, a weight of over 4600 lb. per bucket.

### Ladder Hoist Winch

The ladder hoist winch, Fig. 3, is operated by the main motor through a pulley shaft on the main deck, this shaft being also belted to the main bucket drive above. The main digging motor, which is of 400 h.p., is thus used to raise and lower the ladder, and to drive the bucket line.

### Main Drive

The main drive, consisting of the upper tumbler shaft with its two 12-foot-diameter gears, the intermediate shaft which is made in two separate lengths to allow room for

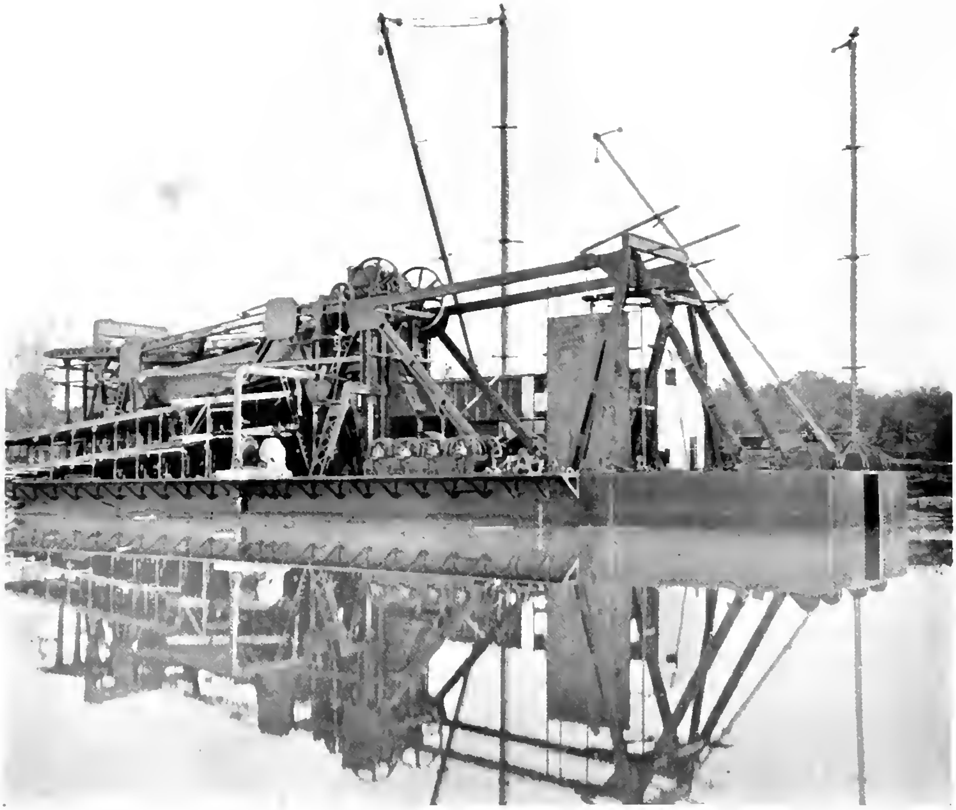

Fig. 2. Yuba Gold Dredge No. 14 Under Construction

the long hopper, and the pulley shaft with its two differential pinions and 12-foot-diameter pulley, is rigidly supported by the steel main gantry and the upper chords of the fore and aft main trusses, this rigidity serving to hold the gears accurately in mesh and to preserve the alignment of the shafting.

### Screen

The screen, a revolving cylinder of perforated high carbon steel plates, is 50 ft. 6 in. in length and 9 ft. in diameter and is stiffened by heavy longitudinal steel angles extending between the supporting tread rings at each end. Fig. 4 shows a part of the drive.

### Gold Saving Tables

The gold saving tables and supports are made entirely of steel, and divided into two separate banks 6 feet apart. In each bank there are fourteen transverse sluices on each side of the dredge. The three upper sluices extend through the side of the house where each one discharges into separate outboard longitudinal sluices that extend to the stern. The other eleven cross sluices discharge into seven inboard longitudinal sluices, the discharge from which is carried about 25 feet astern by overhanging steel tail sluices, or delivered back of the spuds as may be required. The total table area is 7540 square feet.

### Spuds

The two spuds are built up of structural angles and plates, have a cast steel point, are 30 in. by 60 in. in section and 60 feet long, and weigh together 160,800 lb.

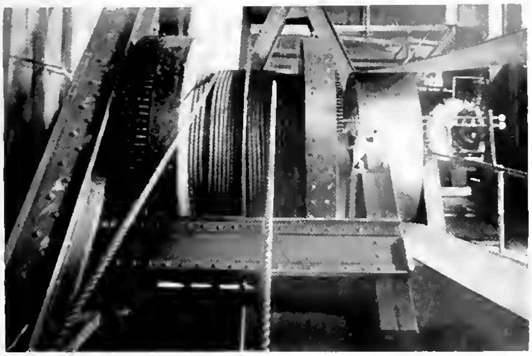

Fig. 3. Ladder Hoist Winch

### Stacker

The stacker is exceptionally long, measuring 137 feet between pulley centers, for when digging to the maximum depth of 70 feet the boulders have to be stacked very high. As is usual, it is of the lattice truss type.

### Swing Winch

The swing winch, Fig. 5, is an eight-drum winch, two of the drums being for spares (lines which are used for repair work and miscellaneous purposes), two for the bow swinging lines, two for the lines that raise the spuds, and two for the stern lines. This winch weighs 41 tons. The design of winches of this type has been worked out particularly well, and in spite of continuous use and hard wear, repairs on such a winch are wonderfully small.

Fig. 4. Screen Drive

### Pumps

Since Yuba No. 14 will not dig with a high bank, as do some of the Natomas Consolidated Dredges, no monitor pump is carried. There are, however, three Yuba construction pumps, one a 14 in. high-pressure horizontal centrifugal pump used for supplying water to the screen, one a 14 in. low-pressure pump used for supplying water to the tables, and

Fig. 5. Eight-Drum Swing Winch

the third, a 6 in., two-stage pump supplying water under a 125-foot head to the dump hopper.

### Operating Levers

By a system of levers the motion of the drums on the swing winch, the speed change on the same winch, and the operation of the main drive clutch, the ladder hoist clutch, the ladder hoist brake, and the main drive brake are all controlled from the winch room, requiring a total of 23 levers (Fig. 6). These are in addition to the control of the main drive and swing winch motors. From the winch room the bucket line can be raised or lowered, stopped or set in motion, the spuds can be raised or lowered, and the dredge moved by either the bow swing, head or stern lines.

Fig. 6. Operating Levers in Winch Room

### Electrical Equipment

The electrical equipment of Yuba No. 14 is of interest in that it represents something of a departure from the equipment heretofore considered standard for California gold dredges. This departure from former practice was made in the light of experience gained in the operation of four dredges of the largest type which were built by the Yuba Construction Company for the Natomas Consolidated of California and one similar dredge built for the Yuba Consolidated Gold Fields.

### Power Supply

Power is supplied by the Pacific Gas & Electric Company and is three-phase, 60 cycle, 4000 volt.

### Shore Cable

The power is brought on board the boat through 750 ft. No. 0 B.&S. gauge, 3-conductor cable, each conductor being stranded and insulated with $\frac{5}{32}$ in. 30 per cent para rubber, conductors twisted together, rounded out with jute and covered with a layer of $\frac{1}{8}$ in. varnished cambric. Over this is a layer of jute and the cable is armored with No. 10 B.W.G. armor put on with short pitch. This cable is insulated for 4500 volts working pressure. The shore cable is brought aboard the dredge on pontoons and enters a switch house on the upper deck near the stern of the dredge, where there is installed an automatic 300 ampere 7500 volt oil switch with hand-operated remote control. The switch is mounted on pipe framework away from the panel carrying the operating lever. There are installed in this switch house two 4400/110 volt, 200 watt potential transformers with fuses and two 150 ampere current transformers. The secondaries of these transformers are connected to indicating instruments mounted in the winch room. From the switch house the current is fed through triple conductor varnished cambric cable in conduit to the primary side of the main transformers. These consist of three 200 kw. oil-cooled transformers, 4000-volt primary and 460/230-volt secondary. In addition to the main transformers, there is installed one 15 kw. 4000-volt primary 230/115-volt secondary oil-cooled transformer to supply lights. From the secondary side of the main transformers various feeder circuits supply the different motors, triple conductor varnished cambric being used in iron conduits.

The control panel for the main drive or digging motor, and for the winch motor, is located in the winch room, as is also the instrument panel. The instrument panel contains the following instruments, which are supplied, as mentioned above, from the instrument transformers located in the entrance switch house: One 5-ampere alternating current ammeter with 150 ampere scale, one 175-volt alternating current voltmeter with 8 point potential receptacle and plug, one alternating current polyphase indicating wattmeter with 1200 kw. scale. The readings of these instruments give the total input to the dredge.

The double-circuit control panel for main drive and winch motors has the following equipment: One 60-ampere alternating current ammeter (winch motor); one 5-ampere alternating current ammeter, 800 ampere scale (main drive motor); one 200 ampere automatic oil switch with double coil series trip (winch motor); one 600-volt 800-ampere automatic oil switch with double coil trip (main drive motor); and two 800-ampere current transformers in main drive motor circuit.

The panels for the pump motors are located on the lower deck, the starting compensators for the pump motors being mounted alongside the panels. These compensators are all provided with inverse time-limit relays. The pump motor panels consist of the following: Two 3-phase 2-circuit motor panels, each panel mounting two 500-volt 200 ampere lever switches controlling the high-pressure, the low-pressure, the 6 in. two-stage, and the vertical pumps.

The stacker and screen motors are controlled from independent panels located in the stern of the dredge, each panel having the following equipment: One 200-ampere automatic oil switch, with 2-coil series trip, and mounting on the front of panel for one reversible type controller. The oil switch operating lever is directly above the controller.

All of the panels are natural black slate mounted on pipe supports.

### Digging or Main Drive Motor

This motor, which is shown in Fig. 7, operates the digging mechanism. It is a 400-h.p., 514 r.p.m., 3-phase, 60-cycle, 440 volt, slip ring, variable-speed induction motor with three bearings, pulley and sliding rails with a master controller and contactor panels, and is provided with resistance good for continuous operation at all speeds from 50 per cent normal to normal.

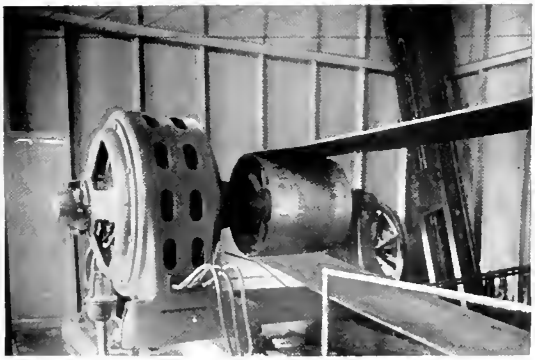

Fig. 7. 400 H.P. Induction Motor Operating Buckets

The contactor equipment, which is shown in Fig. 8, is provided with current limiting relays, which limit the maximum load that the motor can take and so protect both the motor itself and the complete digging mechanism that it drives. This is of considerable importance in keeping down the cost of repairs and preventing loss of time incident to repairs. The digging mechanism is subject at times to sudden and excessive loads and without the current limiting feature provided by the contactor control the only protection would be given by the overload oil switch. Due to the annoyance of having this switch tripping out frequently it is usually set so high as to afford little protection. The current limiting relays also protect the motor and digging mechanism when starting. The winchmen can throw the master controller to the full "on" position and the motor will come up to speed at a predetermined rate, which will not impose excessive stress on any part of the mechanism.

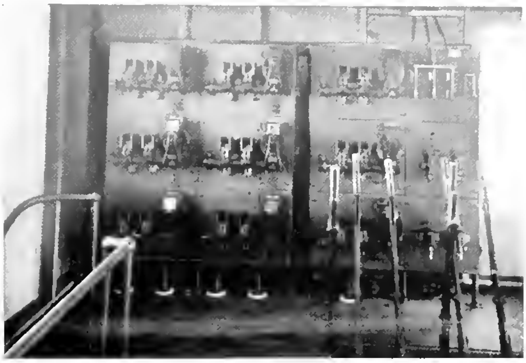

Fig. 8. Contactor Panel for Motor of Fig. 7

### Winch Motor

This motor operates the winch, raises the spuds, and swings the boat, and consists of one 35-h.p., 600-r.p.m., 3-phase, 60-cycle, slip ring, variable-speed induction motor with a controller and resistance for continuous operation at from 50 per cent to full speed. The motor is provided with pulley and base. In a few instances on smaller dredges, motors of intermittent rating were furnished for operating the winch. These motors, however, have not been found suitable for this service, as the winch operates almost continuously.

### Pump Motors

All the pump motors are squirrel-cage motors, the high-pressure pump having a 150-h.p., 600-r.p.m. motor, the low-pressure pump a 75-h.p., 600-r.p.m. motor, the 6 in. two-stage pump a 50-h.p., 1200-r.p.m. motor, and the vertical pump a 10-h.p. vertical motor. These motors are all direct connected to the pumps and, with the exception of the 10 h.p. motor, are all provided with welded end-ring construction in the rotor.

### Screen and Stacker Motors

These motors are of the slip ring, variable-speed type, provided with resistance for continuous operation at from 50 per cent to full speed and with reversible controllers. They operate at 600 r.p.m., the screen motor being 75-h.p. and the stacker motor 60-h.p. In most of the former gold dredges these motors were of the constant-speed squirrel-cage type. However, in the more recent large dredges, due to difficulties sometimes experienced with squirrel-cage motors on account of the heavy starting conditions and the desirability at times of running for short periods at reduced speeds, slip-ring motors with resistances for two-minute starting duty were used. In heavy work, however, these were found too light and for Yuba No. 14 resistances for continuous operation were installed and reversible controllers used.

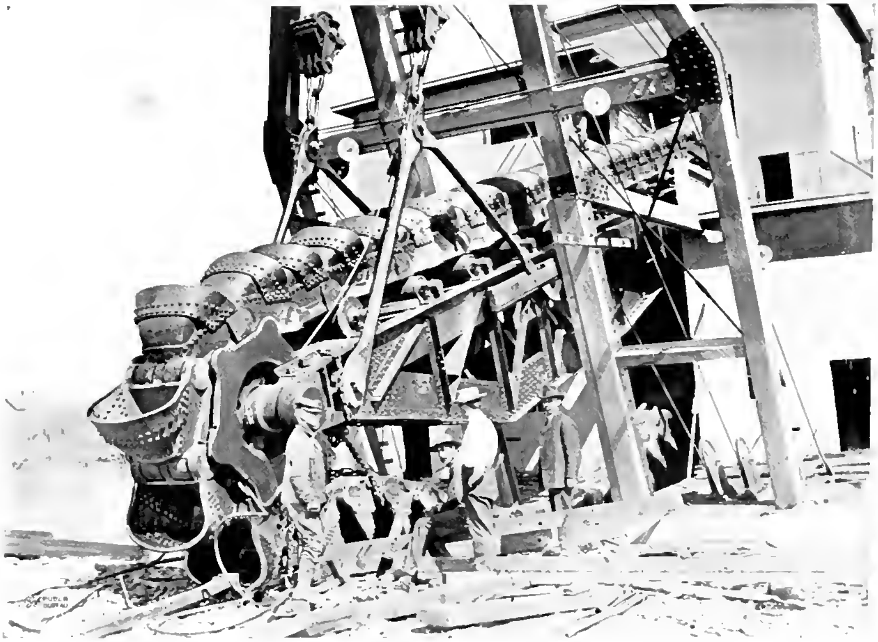
### Tool Motors

There is provided a 2-h.p., 1800-r.p.m. 3-phase motor with pulley and base for the repair shop on board the dredge.

### Power Consumption

The operating time of a gold dredge is between 85 and 88 per cent of the total time. The dredge operates night and day with three shifts. The load-factor varies from 62 per cent to 80 per cent, depending on the character of the ground, and as the dredge operates practically every day in the year throughout its life, except the Fourth of July and Christmas, it represents an excellent load for the power company.

Yuba No. 14 was built in four months and four days from the driving of the first rivet, a remarkable time considering the enormous total weight of the dredge. All material was transported 14 miles from the railroad over uncertain roads by means of power tractors and trailers, by no means a small job when it is noted that the completed dredge weighs very close to 1994 tons.



The Bucket Line of an Earlier Electrically Operated Gold Dredge

# PATENTS

By Chas. L. Clarke

Consulting Engineering Department, General Electric Company

## Part I

Mr. Clarke writes on patents from the standpoint of the technical and practical man in the field of engineering, to which has been added long experience as an expert in patent suits. Two articles on Patents, by Mr. Albert G. Davis, Head of the Patent Department of the General Electric Company, were published in 1908 in the June and July numbers of the Review, and represent the presentation of the subject by the patent lawyer. The engineer reader will do well to consider both series of articles together.—Editor.

### Introduction

It is our purpose broadly to consider the nature and effect of the exclusive right or monopoly, termed a Patent, as granted by the United States.

We shall endeavor to present the subject in its fundamental aspect, and in a manner directed to the understanding of engineers, rather than for the consideration of those versed in the law, whom we naturally disclaim qualification specially to interest and much less instruct. The subject is of particular interest to engineers because favoring opportunity in the practice of their profession frequently leads to invention, or to utilizing with premeditated understanding the inventions of others.*

### THE LAW

The power to grant patents was vested in the Congress by Article I Section VIII, of the Constitution, 1787, whereunder:

> The Congress shall have power—Clause 8. To promote the progress of science and useful arts, by securing for limited times to authors and inventors the exclusive right to their respective writings and discoveries.

The exclusive right of authors to their writings, referred to in the Constitution, and otherwise termed a copyright, has been, and is still secured under laws separate and apart from the laws relating to the granting of patents to inventors.

The first statute law on patents was enacted by the Congress in 1790, and entitled, "An act to promote the progress of useful Arts," which authorized the issue of "letters patent" to any person or persons that have:

> * * * * * invented or discovered any useful art, manufacture, engine, machine, or device, or any improvements therein not before known or used, * * * * * granting * * * * * for any term not exceeding fourteen years, the sole and exclusive right and liberty of making, constructing, using, and vending to others to be used, the said invention or discovery.

At that time there was no Patent Office with a Commissioner and staff, as now, to investigate the rights of applicants and issue patents, when justified.† Application was made to the Secretary of State, the Secretary of the Department of War, and the Attorney-General; and they, or any two of them, could cause letters-patent to be made out, which were examined by the Attorney-General, who certified thereon that they were conformable to law, if he found such to be the case, and the President then set his hand, and caused the seal of the United States to be affixed thereto.

The law now in force relating to the conditions controlling the granting of patents for inventions or discoveries, is embodied in Section 4886 of the Revised Statutes, March 3, 1897, as follows:

> Any person who has invented or discovered any new and useful art, machine, manufacture, or composition of matter, or any new and useful improvements thereof, not known or used by others in this country, before his invention or discovery thereof,

---

* In the preparation of this article, Walker on *The Patent Laws*, 1904, and Renwick on *Patentable Invention*, 1893, have freely been consulted. These works have mainly been relied upon because the former expounds the patent laws from the standpoint of an eminent, practicing lawyer, and writer of acknowledged reputation; while the latter, although now of somewhat early date, was written by one of the most talented experts in this country, who, after an experience of forty-three years, became so much in sympathy with the efforts of inventors, that he was inclined somewhat impatiently and controversially to view the patent situation, in regard to the question as to what should constitute patentable invention, more as he thought it ought to be answered, rather than as determined by the Courts in some very important respects, although his well-trained mind led him accurately to state in his book the actual condition of affairs from the legal point of view. We find expounded in these works, respectively, the legal side, and the inventor's side of the case. We purpose in this article to confine our attention to the patent situation as it exists by virtue of the statutes and decisions of the Courts.

† The first United States patent was issued, on July 31st, 1790, to Samuel Hopkins, of Philadelphia, for pot and pearl ash manufacture. Three patents were issued in that year. *Annual Report of the Commissioner of Patents*, 1891, page XX. By contrast, it is of interest to note that 33,941 patents for inventions and 1683 patents for designs were issued during the year 1913. The Patent Office was established by law in 1836, and a systematic examination into the novelty of inventions for which patent application was made was then begun for the first time. An interesting historical account of the Patent Office and earlier offices relating to patents, from 1790 to 1877, when the office was partially destroyed by fire, may be found in the *Official Gazette of the United States Patent Office*, Vol. XII, 1877, as a separately paged publication between pages 588 and 625 of the regular *Gazette* issue.

and not patented or described in any printed publication in this or any foreign country, before his invention or discovery thereof, or more than two years prior to his application, and not in public use or on sale in this country for more than two years prior to his application, unless the same is proved to have been abandoned, may, upon payment of the fees required by law, and other due processes had, obtain a patent therefor.

The monopoly granted by a patent is expressed in Section 4884, as "the exclusive right to make, use, and vend the invention or discovery throughout the United States, and the Territories thereof, referring to the specification for the particulars thereof." And the Courts have said that this monopoly likewise conveys the right of refusing to make, use, or sell the patented thing, or allowing others so to do; in other words, the owner may lock up his patent, so that the public can derive no benefit from the invention during its life.

In 1842, a law was enacted providing for the grant of patents of another sort, known as "design patents." The law in force from 1874 until 1902 was embodied in Section 4929 of the Revised Statutes, and read:

> Any person who, by his own industry, genius, efforts, and expense, has invented and produced any new and original design for a manufacture, bust, statue, alto-relievo, or bas-relief; any new and original design for the printing of woolen, silk, cotton, or other fabrics; any new and original impression, ornament, patent (obvious misprint for "pattern"), print, or picture to be printed, painted, cast, or otherwise placed on or worked into any article of manufacture; or any new, useful and original shape or configuration of any article of manufacture, the same not having been known or used by others before his invention or production thereof, or patented or described in any printed publication, may, upon payment of the fee prescribed, and other due proceedings had the same as in the cases of inventions or discoveries, obtain a patent therefor.

And in Section 4933:

> All the regulations and provisions which apply to obtaining or protecting patents for inventions or discoveries not inconsistent with the provisions of this title, shall apply to patents for designs.

Section 4929 was amended May 9, 1902, the law now in force relating to the grant of design patents reading as follows:

> Any person who has invented any new, original, and ornamental design for an article of manufacture, not known or used by others in this country before his invention thereof, and not patented or described in any printed publication in this or any foreign country before his invention thereof, or more than two years prior to his application, and not in public use or on sale in this country for more than two years prior to his application, unless the same is proved to have been abandoned, may, upon payment of the fees required by law and other due processes had, the same as in cases of invention or discoveries covered by Section forty-eight hundred and eighty-six, obtain a patent therefor.

## MEANING OF THE WORD "DISCOVERY"

### Laws of Nature not Invented

Under the Constitution, as we have seen, an exclusive right may be secured by law to an "inventor" for his "discoveries." By the law of 1790 this right, by letters-patent, was granted for an "invention or discovery." Today a patent is also granted for the same thing, and for designs.

The question naturally arises in the mind of the layman, say, the engineer who has not inquired into the subject and consulted the books: What is the difference between an "invention" and a "discovery"; the Constitution mentions the "discoveries" of "inventors," but says nothing about their "inventions"; the first patent law and the present law refer to an "invention or discovery" that has been "invented or discovered" by a "person" or "persons," but make no mention of an inventor, or of a discoverer?

The answer is that in the Constitution and in the law the word "discovery" means invention, and thus where the words "discovery" and "invention" are used, they are two names for the same thing. The "discoveries" of inventors are inventions.

According to amended Section 4929 and Section 4933, a design may not, however, be classed as an "invention," or as a "discovery," which are names of one meaning appropriated to arts, machines, manufactures, and compositions of matter. A design is simply a design (for an article of manufacture), and nothing else, although for patent purposes it must have been "invented."

It will be perceived that the word "discovery," in the Constitution and in the law, does not have the broad meaning in the dictionaries. A man may invent a machine (which may also be called a discovery, although this word should not be used in patent specifications in the sense of invention, but only in respect to a new fact ascertained), and he may also discover a comet, or a "law of nature" also spoken of as a "principle," a "scientific principle," a "scientific fact." For inventing the machine he may receive a patent, but no patent may be granted for discovering the comet or the law of nature because he did not invent either of them.

Patents for inventions or discoveries may be granted for four kinds of things, arts, machines, manufactures, and compositions of matter. Obviously none of these things are discoveries in the broad sense, but are the result of original thought and reasoning, whereby the thing is invented, and by which laws of nature are utilized. This is the thing and not the laws of nature, that may be patented. Ohm's law of the electric circuit is a law of nature, and would never have been patentable in this country, but a multitude of valid patents have been granted for electrical machines operating under Ohm's law.

The hope of reward through protection by patents has caused inventors to embody physical discoveries (laws of nature) in concrete material forms adapted to minister to the welfare of humanity. Except for this encouragement many such discoveries would have largely remained academic additions to our knowledge, exemplified at most in apparatus for merely demonstrating physical laws, and not of enough practical importance to be dignified as more than philosophical toys. Such was the apparatus ingeniously devised by Franklin in his electrical experiments and discoveries until he invented the lightning rod, which, however, he did not patent, although that could have been done by favor of the King even in those colonial days. The ground wire for protecting high potential transmission lines of today is a modified form of lightning rod, and utilizes the same electrical laws. Such also was the crude apparatus of Faraday with which he discovered the law of magneto-electric induction, or production of electricity by means of magnetism. But the efforts of inventors have so perfected the utilizing of this law in electrical machinery and appliances that the world is today receiving a marvelous benefit therefrom.

Laws of nature are ordinarily not referred to, as such, in patents, but manipulative steps, or the operation of a combination of devices or mechanisms by which the unexpressed laws of nature are utilized, and the results thereby obtained, are set forth in describing the invention. Occasionally, however, a law of nature is specifically mentioned in a patent, particularly if the inventor believes he discovered it, but this is unnecessary.

Furthermore, it is not necessary to give a theory of operation of the invention, or should a theory be propounded and subsequently be found wrong, no harm is done, so long as the patent does not mislead, and sets forth the invention sufficiently to enable those skilled in the art or calling to which it pertains, or to which it most nearly relates, to put the invention into practice and obtain substantially the result described.

## SUBJECTS OF PATENTS

Let us consider the general characteristics peculiar to the useful arts, machines, manufactures, compositions of matter, and improvements thereof, and to ornamental designs for articles of manufacture, for which patents may be granted.

### Useful Arts

A useful art, as distinguished from the liberal, polite, or fine arts, relates to a mode of treatment of, or a method or way of operating upon, an object by which a change in its form, condition, quality, or properties is produced. Such an art is usually termed a "method" or "process" (Renwick). Generically, a process is an operation performed by rule to produce a result. A patent for an art or process is a patent for the described *combined use* of the two or more laws of nature, as the case may be, that are utilized by the process. If a patent for the use of only one of the laws of nature utilized in a process were granted, it would be a patent for a "principle" and would be invalid (Walker).

Merely heating an iron article would, in the absence of any additional operation, utilize only one law of nature in respect to the iron, namely, conduction of heat thereto and therethrough; it would then involve the application of a principle, and not be patentable invention even if new. But if the article were an iron wheel, which after being expanded by heating, were slipped on a shaft so that when it shrunk on cooling, it became fixed to the shaft, this would be a process involving the combined use of several laws of nature resulting, respectively, in heating, expanding, cooling, shrinking, and cohesion, and, if new, would be invention. But the mere application of one of the laws utilized in the process, say, in the expanding, or in the cooling, or in the cohesion, would not be patentable.

Likewise heating an article of carbon steel would be the application of a principle. But hardening the article first by heating and then suddenly cooling it by plunging in water is a process involving two steps, and the utilizing of the laws of nature comprised in the heating, sudden cooling, and in the resulting molecular condition that produces the hardening. Tempering the article by reheating it to the requisite degree is an additional step bringing another law of nature into play.

Merely inducing magnetism in a soft iron armature by means of a steel magnet is a simple process involving one law of nature, but causing the armature to be attracted to the magnet involves a compound process utilizing two laws of nature, to wit, magnetization and magnetic attraction. Attracting the same armature by means of an electro-magnet calls for the operation of at least four laws, those pertaining to the electric current, electro-magnetism, magnetization and magnetic attraction.

Morse invented an electric telegraph in which the marking of intelligible signs upon paper was made by an electro-magnetically operated device energized by a current sent over a wire. The current represented one law of nature, while the electro-magnetic device was the concrete embodiment of another law discovered many years later, but before his invention was made, and magnetic attraction had been known for centuries. Morse might properly have claimed the method or process of marking intelligible signs at a distance, by causing an electric current to flow from the signalling point through a conductor to the distant point and there operate an electro-magnetic sign-marking device; this would have involved the combined use of at least two laws of nature. But the Court said in substance that he had not discovered that the electric current will always mark intelligible signs at a distance, no matter what the form of device operated thereby; that his broad eighth claim covered merely the use of the motive power of electro-magnetism, or magnetic attraction, for this purpose, and thus was for the application of a principle, and invalid. (O'Reilly v. Morse, 15 Howard, 412, 1853.)*

Processes consisting of operations partly or wholly employing heat, light, electricity, magnetism, chemistry, pneumatics, hydraulics, or some other non-mechanical science, are subjects of patents.

Processes made up of operations that are wholly mechanical, but which may be done either by hand or by any of several machines, are also subjects of patents; for example, the art of weaving, if it were new.

But all operations that are wholly mechanical, and are only the peculiar function of the respective machines constructed to accomplish them are not proper subjects of patents, although the machines themselves may be so (Walker). There cannot be a true patentable process worked out by machinery alone (Renwick). A claim for a method of forming cigarettes by drawing a paper ribbon through a tube-forming die and simultaneously feeding tobacco upon the ribbon, the same being previously gummed and finally pasted, was declared invalid on the ground that the process of making cigarettes by wrapping paper about tobacco was old, and the so-called method of the claim was only the operation of mechanical parts resulting in nothing new; the process was old, and only the mechanical means for performing it were new. In a patent for an envelope machine, a claim for feeding the envelope blanks under the table supporting the gum box, instead of over it, was declared invalid as a process because it covered merely that particular function or mode of operation of that machinery. A process claim for the operations performed upon a blank to form heel-stiffeners for shoes was pronounced invalid because these operations were wholly due to the machine devised for the purpose. The claim was merely a recitation of the peculiar functions performed by the machine, which itself was patentable. Such operations as sawing, grinding, planing, etc., which are merely the performance of, or results obtained by machines are not patentable processes.

A process is not a substance affecting the physical senses, but can only be comprehended by noting its constituent acts during their performance. So also, laws of nature are not substances, but when discovered become mental conceptions only. Thus processes and principles are alike in that they are intangible, which sometimes makes it difficult to distinguish them, or causes one to be mistaken for the other (Walker).

### Machines

A machine is a combination of heterogeneous mechanical parts adapted to *receive energy*, and apply it to the production of some *energetic result* or results. All the parts of a machine may be old, while the machine as a whole, and also the sub-combinations which are contained therein, are properly subjects of patents. An improvement of a machine may consist of additions thereto, or any subtractions therefrom, or in substituting for one or more of its parts something different, or in so rearranging its parts as to make it work better than before (Walker).

---

* Morse's eighth claim read: I do not propose to limit myself to the specific machinery or parts of machinery described in the foregoing specification and claims, the essence of my invention being the use of the motive power of the electric or galvanic current, which I call electro-magnetism, however developed, for marking or printing intelligible characters, signs, or letters, at any distance, being a new application of that power of which I claim to be the first inventor or discoverer.

From another standpoint, the term machine comprehends every device by means of which *force can be utilized or a useful operation can be performed.* Machines are simple or compound, the former consisting of a single member or device having but one function, and the latter of two or more members or parts; the class therefore includes tools, implements, etc., whose members are fixed relatively to one another, as well as mechanisms whose members are relatively movable (Renwick). Simple machines are comparatively rare; an example is a peck measure. Many machines seemingly simple are really compound; thus a chisel is generally regarded as a simple tool or machine, whereas it has two cooperating members, the cutting point to do the work for which it is designed, and the shank or handle by which the point is efficiently held to the work and force is applied to do the work.

### Combination and Aggregation of Parts in a Machine

A machine is patentable in respect to combinations of elements included therein, but:

> The combination, to be patentable, must produce a different force, effect, or result in the combined forces or processes from that given by their separate parts. There must be a new result produced by their union; otherwise it is only an aggregation of separate elements. (Reckendorfer v. Faber, 92 U. S. 357, 1875.)

The above opinion of the Court related to a lead pencil having a rubber eraser at one end. The decision practically was that the presence of the eraser made no difference in the mode of operation of the pencil, or the result obtained in writing, and vice versa, that the lead of the pencil had nothing to do with the erasing, and therefore the whole structure was not a *combination* of cooperating elements, producing by their joint action a unitary result, but a mere *aggregation* or collection of separate, non-related parts, as far as the lead and rubber were concerned, each producing its own result, and thus not patentable.

In the case of patents for certain self-feeding coal stoves, which were made of parts that were all individually old in other stoves, but so selected and assembled as to make a stove superior to its predecessors, it was decided that the parts assembled did not cooperate to perform any joint function, but each did only what it had done in former stoves, and that the whole was therefore only an aggregation of parts, and not a combination (Hailes v. Van Wormer, 20 Wallace, 353, 1873).

But it is not necessary for the performance of a joint function or unitary result that elements of a combination act simultaneously. The Court has said:

> To make a valid claim for a combination, it is not necessary that the several elementary parts of the combination should act simultaneously. If those elementary parts are so arranged that the successive action of each contributes to produce some practical result, which result, when attained, is the product of the simultaneous or successive action of all the elementary parts, viewed as one entire whole, a valid claim for thus combining those elementary parts may be made. (Forbush v. Cook, 2 Fisher, 669, 1857.)

This opinion was given years ago, but the same view has been held in more recent times. (San Francisco Bridge Co. v. Keating, 68 F. R. 353, 1895).

### Manufactures

The term manufacture or article of manufacture is generally applied to articles of utility made by hand or by machinery, that is, manufactured products or articles of merchandise, as cloths, pottery, nails, domestic utensils, and in general an almost innumerable number of made things. But the term "manufacture," as used in patent law in this country, has a very indefinite meaning. An article of manufacture, properly so called, should be distinguished by its peculiar properties, qualities, mode of operation, or structure. Thus the peculiarities which distinguish a rubber shoe from one of leather or cloth are readily apparent, chief among them being the waterproof character of the rubber shoe (Renwick). The word manufacture has a narrower significance in America than in England. In the latter country it includes everything made by the hand of man and also includes processes of manufacture. In America processes are patentable because they are "arts." While some of the things made by the hand of man are patentable as machines, others as composition of matter, and others as designs, whatever is made by the hand of man, *and is neither of these,* is a "manufacture" in American patent law (Walker).

In a suit relating to a patent for indexes to be used in connection with books, in which the defendant contended that the invention was not included among the things specified in the law as patentable, it was decided that the patent was for a manufacture. The Court said:

> The term "manufacture," as used in the patent law, has a very comprehensive sense, embracing whatever is made by the art or industry of man, not being a machine, a composition of matter, or a design. * * * * * I have no difficulty in holding that the subject matter of the patent in suit is patentable. (Johnson v. Johnston, 60 F. R. 620, 1894.)

### Compositions of Matter

A composition of matter may be defined as a compound of two or more substances which possesses a property or quality not possessed by the substances individually. The substances used constitute the ingredients of the composition. The composition may be chemical, as in nitro-glycerine, or mechanical, as in dynamite, which is a mixture of nitroglycerine and diatomaceous earth, or in black gun powder, which is a mixture of charcoal, saltpeter and sulphur (Renwick). The term covers all compositions of two or more substances, and includes composite articles, whether the result of chemical union, or of mechanical mixture, or whether they be gases, fluids, powders or solids. The composition must be new and useful to be an invention (Walker).

### Uncertainty Attending Classification

The distinction between a machine and a manufacture, and between a composition of matter and a manufacture, cannot be stated so that its application to every case would be clear to every mind, although in most cases it is obvious to which class a thing made by the hand of man should be assigned. If an inventor is certain the thing belongs to one of the three classes, no harm need result from not knowing, or stating, nor does it ever become vitally important to determine, to which class it really belongs; a seventeen-year patent may lawfully be granted for a thing that may come under either designation (Walker).

For example, if an art, or process, for extracting metals from their ores, and likewise a machine that may be employed in operating the process, be invented, the process must be distinguished from the machine, and each must be separately claimed, as a combination of operations in a process, and as a combination of elements in a machine, respectively, if both inventions are to be protected, although both may now be included in one patent. Incidentally, it may here be mentioned that both the process and the machine should be patented, for if the process alone be patented, some one might find a way to use the machine to advantage in a different process, or, if the machine alone be patented, the process might possibly be followed without using the particular machine.

But should an improved barber's chair be invented, the use of which involves no patentable process, it is not necessary in the patent to class it, either as a machine or as an article of manufacture. It may be referred to in the specifications and claims simply as a barber's chair.

Again, if the well-known process of making vulcanized rubber by heating a certain mixture of raw rubber and sulphur were a new invention, both the process and the resulting vulcanized rubber product night be patented, but whether the product be described and claimed as a manufacture, or as a composition of matter would be immaterial to the validity of the patent; the inventor might simply refer to it as a product, or merely call it vulcanized rubber. As a matter of fact, the product invented was claimed as a manufacture (Rubber Co. v. Goodyear, 9 Wallace, 795, 1869.)

While the law only specifies arts, machines, manufactures, compositions of matter and designs as subjects of patentable invention, these subjects have been subdivided by the Patent Office for convenience of closer designation, so that on January 1st, 1912, they included 243 classes of subjects of invention and about 14,000 sub-classes.

### Designs

The design of an article, whatever it may be, is the appearance of the thing as distinguished from its structure (Renwick). According to amended Section 4929 of the Revised Statutes now in force, the thing must be a "manufacture," and of new, original and *ornamental* design in order that such design—not the thing itself—may be protected by a patent. The single claim ordinarily granted in a design patent reads: "The ornamental design for [the thing, say, a watch case], as shown." Designs have been granted for freight cars, auto bodies, lamp shades, silver and china ware, oil cloth, ink stands, toys, and a great variety of other things, and even for machines. But there have been instances where the Courts have declared design patents invalid on the ground that the thing was not a proper subject for *ornamental* design.

(*To be Continued*)

# POWER-FACTORS OF ALTERNATING CURRENT CIRCUITS

By G. M. Brown and N. Shuttleworth

British Thomson-Houston Company

The authors have presented a very complete and interesting discussion of an important practical problem confronting the central station manager. Formerly, the question of power-factor was no problem because the loads were chiefly lighting or railway. However, the past ten years has seen a rapid industrial development. For all classes of this work, the induction motor has taken the lead until now we find on many systems that the induction motor load is larger than the lighting load. The authors have described English practice in particular. In America, both the synchronous condenser and phase advancer are in successful use. On this side we have been forced by our long high voltage lines to the general use of the synchronous condenser with its excitation under automatic control, this arrangement giving automatic voltage control as well as automatic phase or power-factor control. These machines are in operation in various sizes up to 15,000 kv-a. The phase advancer has only recently been developed in this country and reports on it are most encouraging. In early issues other articles will appear on these important subjects.—Editor.

The advantages to be gained by the use of electric motors driven by electric power from a central supply station are now fully recognized by the vast majority of power users. The results of this movement are evident in all directions, but more particularly so in the rapid extensions of municipal and other electricity generating plants and the great increase in the capacity of the generating units employed. The amounts of power distributed and the areas served by single generating stations have so increased as to make compulsory the adoption of polyphase alternating current systems of distribution even in cases where the continuous current system was originally contemplated and installed.

For the great majority of industrial purposes the alternating current induction motor is eminently suitable and its extended use has been due in no small measure to the rapid growth of alternating current supply systems and the natural desire to avoid the expense, complication and losses involved in the use of suitable transforming plant for the production of continuous current. The induction motor possesses, however, one great disadvantage from the point of view of the power supplier in that the current it draws from the mains includes a large wattless component which not only increases the losses in the generators and cables, but also makes the maintenance of a steady voltage at the consumer's terminals an expensive matter. As its name implies, this wattless component has no effect on the wattmeters by which the consumption of power is usually measured, and is not therefore in any way a disadvantage to the consumer who pays only for the power as measured by the wattmeter.

From the consumer's point of view the best motor is that which has the highest efficiency, an ample margin of power and a suitable speed for the purpose in view. An induction motor with such characteristics may have a comparatively low power-factor under normal conditions, and therefore the most undesirable from the power supplier's point of view; for high power-factors are generally only obtainable by sacrifices in efficiency and overload margin and at comparatively high speeds which may not be permissible or practicable for the applications in question. It is possible to improve the power-factor by reducing the clearance between the stationary and rotating parts, and therefore at the expense of reliability and durability, or by increasing the size and cost of the motor; so that unless some restriction is made by the power supplier it is not to the interest of the consumer to trouble about the amount of lagging or wattless current he may draw from the supply mains.

These points are well illustrated by the following figures for standard 400 volt three-phase slip ring induction motors.

| Size of Motor | Relative Amounts of Energy Recorded by Consumer's Wattmeter at | | |
|---|---|---|---|
| | 25 H.P. | 50 H.P. | 100 H.P. |
| 50 h.p., 725 r.p.m. | 30.7 | 60.4 | 118 |
| 100 h.p., 725 r.p.m. | | 59.8 | |
| 50 h.p., 360 r.p.m. | 31 | 61.2 | |
| 100 h.p., 360 r.p.m. | | 60.4 | 119.5 |

Apart from the prices of the motors, the consumer wishing to install an additional machine to deal with a load of 50 h.p. would find little in these figures to influence him one way or the other, and would probably decide on the motor with the most suitable speed and capacity to meet possible overloads. How his choice would affect the power supplier is shown by the following figures, indicating the relative losses in the supply main due to the lagging currents required by the various machines.

| Size of Motor | RELATIVE LOSSES DUE TO WATTLESS CURRENTS AT LOADS OF | | |
|---|---|---|---|
| | 25 H.P. | 50 H.P. | 100 H.P. |
| 50 h.p., 725 r.p.m. | 729 | 963 | |
| 100 h.p., 725 r.p.m. | | 2170 | 3250 |
| 50 h.p., 360 r.p.m. | 2210 | 2600 | |
| 100 h.p., 360 r.p.m. | | 4625 | 5820 |

The matter does not end here, for the power supplier has to provide plant to generate and transform these unprofitable lagging currents, which, were it possible to neutralize them, might be profitably employed in the further expansion of his business. Consider, for example, the case of a plant installed to deal with a load of 1000 kw., made up of motors, lamps, etc. Under normal conditions the power-factor of such a load would probably not exceed 0.7. From Fig. 1 it is clear that the generators, cables, transformers, etc., would have to be designed to deal with a load of 1430 kv-a., compounded of the useful load of 1000 kw. represented by $BC$ and 1020 kv-a. due to magnetizing and other lagging currents taken by the apparatus on the system and represented by $AB$.

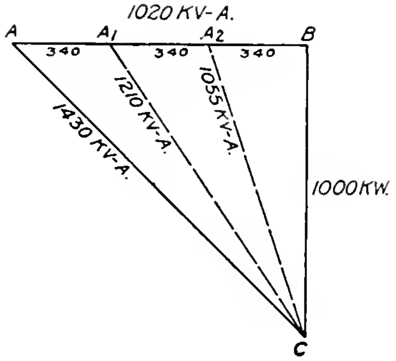


Fig. 1

If by suitable means one-third of the wattless load could be removed, leaving only the portion represented by $A_1B$, Fig. 1, that is 680 kv-a., the total load $A_1C$ would be reduced to 1210 kv-a. and the capacity of the plant might be reduced by not less than 15.3 per cent.

A further and similar reduction of the wattless load to 340 kv-a. ($A_2B$ Fig. 1) would result in a diminution of the resultant load to 1055 kv-a. ($A_2C$ Fig. 1), which would correspond to full load on a plant smaller by 26.2 per cent than that originally installed.

The total removal of the wattless component of the load of 1430 kv-a. at 0.7 power-factor would correspond to a reduction of 30 per cent in the capacity of cables, transformers, generators, etc.

The effect of the various reductions in the amounts of lagging current drawn from the mains may be summarized thus:

| | | | | |
|---|---|---|---|---|
| Useful load, kilowatts | 1000 | 1000 | 1000 | 1000 |
| Wattless load, kilovolt-amperes | 1020 | 680 | 340 | |
| Resultant load, kilovolt-amperes | 1430 | 1210 | 1055 | 1000 |
| Power-factor | 0.7 | 0.83 | 0.95 | 1.0 |
| Transmission losses | 1.00 | 0.71 | 0.55 | 0.49 |

It will be seen that there is no great object to be gained by the entire removal of the wattless component of the load. Assuming therefore that the removal of two-thirds of it is effected, the capacity rendered free for further expansion of business is 1403 − 1055 = 375 kv-a. and its capitalized value may be estimated as follows:

1. Extra generator capacity available 375 kv-a.

The capital cost may be taken from 15/- to £2 (approx. $3.75 to $10.00) per kilovolt-ampere according to capacity and speed.

2. Transformer capacity rendered available, 375 kv-a.

The capital cost per kv-a. may be taken at 10/- ($2.50) for transformers of large size and the value of extra capacity rendered available by improved power-factor will therefore be £187.10.0. ($910.00) if step-down transformers only are used, but will be £375 ($1820.00) if both step-up and step-down transformers are installed.

3. Transmission line capacity rendered available, 375 kv-a.

The saving effected in this direction is difficult to evaluate and at the least will be equal to the capital value of the copper required to transmit 375 kv.a. If by the improvement of the power-factor the necessity for laying an additional cable or an additional overhead line is obviated, the saving will be many times greater.

4. Switchgear capacity rendered available, 375 kv-a.

There will be a small advantage gained on this account which may be taken at, say £20 ($97.00).

The estimate therefore runs as follows:

| | | |
|---|---|---|
| By increased capacity of generators—high speed | £280 | |
| low speed | | £750 |
| By transformer capacity gained | 187 | 187 |
| By extra capacity of 1500 yd. of 3000 volt cable | 200 | 200 |
| By extra capacity of 200 yd. of 440 volt cable | 150 | 150 |
| By switchgear capacity gained | 20 | 20 |
| Total value of plant liberated for further expansion of business | £837 | £1307 |
| | $4050 | $6350 |

There will be further advantages gained through improving the power-factor in the improved regulation of the voltage and the higher efficiency of generators and transformers resulting from the elimination of the large wattless currents. Also, provided that the plant capacity thus made available can be utilized there will be an increased output without any increase in the standing charges for operating it, and consequently a reduction in the cost per unit generated. These gains will, however, be counterbalanced to some extent by the cost of running the apparatus required to produce the improvement in power-factor;—to what extent will depend largely on the nature and location of this apparatus, and therefore on the conditions under which power is supplied to the various consumers; but in any case it will be possible and advisable to offer a *substantial rebate* to those consumers who improve their power-factor to say 0.95 at full load.

Occasionally arrangements are made whereby the consumer pays, not for the true watts he uses, but for the apparent watts, that is, the product of volts and amperes. In cases of this kind it is evidently to the consumer's advantage to make every effort to reduce his current consumption to the lowest possible figure; a state of affairs which is realized when the collective power-factor of his equipment is unity, or at any rate not less than 0.95; but if, for instance, his average consumption of current corresponds to 100 kv-a. and the average power-factor is 0.7, by installing suitable apparatus to raise the power-factor to 0.95, he may reduce his average load to about 74 kv-a., including the small losses in the additional machinery. (Exactly how far it will be advisable to carry the rectification of the power-factor will depend on circumstances).

The various means of minimizing the cause of wattless current or producing wattless leading current to neutralize the wattless lagging currents required by induction motors, arc lamps, etc. are:

1. The installation of rotary converters for supplying those customers whose requirements are best satisfied with continuous current.
2. The installation of synchronous condensers.
3. The use of synchronous motors where possible.
4. The addition of phase advancers to large induction motors connected to the mains.
5. Static condensers.

The first method of improving the power-factor is not one that can be profitably adopted for several reasons, the principal one being that the alternating current induction motor complies quite satisfactorily with the requirements of the great majority of industrial applications, and so renders unnecessary the expense of installing and operating substations equipped with running machinery; and further, the amount of leading current that can be drawn from a rotary converter is strictly limited.

The British Thomson-Houston Company has installed in one of the substations of the Sheffield Corporation the large synchronous condenser illustrated in Fig. 2. This is a two-phase machine and is designed for an output of 600 kv-a. at 2200 volts and 50 cycles, the synchronous speed being 750 r.p.m. On one side there is coupled an induction motor capable of starting it with a comparatively small current and on the other side is a direct current exciter. In the immediate neighborhood of the substation there are consumers whose total day load averages 4000 kv-a. with a power-factor of 0.7. The actual load is thus 2800 kilowatts and the capacity of the synchronous condenser is 600 kilovolt-amperes, so that it is capable of reducing the apparent load to 3580 kilovolt-amperes and so releasing 420 kv-a. capacity in the generating plant and in the cables between the power station and the substation. The following table shows the improvement effected by this machine when the load is less than 1000 kv-a.

In this case the synchronous machine is designed to act purely as a generator of leading wattless current and the whole

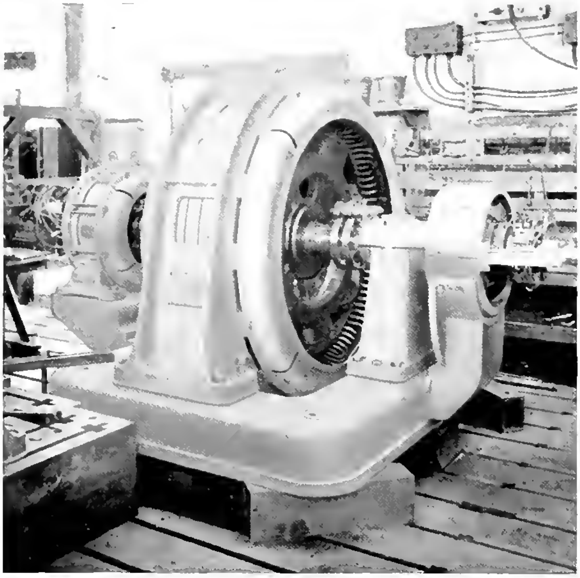

Fig. 2. 600 Kv-a., Two-phase, 2200 Volt Synchronous Converter Built by the British Thomson-Houston Co.

cost of installation and operation has been incurred on account of power-factor improvement; but in many industrial applications where a rebate could be granted to the consumer, advantage might be taken of this property of the synchronous motor at a comparatively small extra cost over and above that of a suitable induction motor. The question whether a consumer should in any given case install a synchronous motor and exciter in place of an induction motor depends entirely on his service requirements and the inducement offered him to incur the slight extra expenditure. The synchronous motor generally requires a large starting current, and is only capable of exerting a comparatively small starting torque; it is therefore only suitable when the starting conditions are *easy, or where it is possible to arrange to start light and apply the load by means of a suitable clutch after the motor has attained full speed; but it has the advantage that it can be constructed to draw leading currents of any desired magnitude no matter how small the mechanical load applied to it. Modern machines of this type are self-synchronizing and their control offers no special difficulties. They are generally started by means of a suitable auto-transformer, or compensator, and a switch for controlling the field excitation.

A group of three-phase motors of this type, built by the British Thomson-Houston Company, is shown in Fig. 3. These have each a capacity of 202 kv-a. at 500 r.p.m., with a working pressure of 400 volts and a periodicity 50 cycles per second. They are arranged for driving by belt, and as continuous current is available are not provided with exciters. When working under the best conditions each of these motors will give an output of 175 brake horse power and supply at the same time a leading current equivalent to 140 kv-a. which is sufficient to neutralize the lagging current required by induction motors having a total capacity of 450 h.p. To facilitate starting and reduce the starting current to a minimum, the rotors of these motors are provided with auxiliary squirrel cage windings similar to the rotor windings of ordinary induction motors. These special windings are shown in Fig. 4.

Where the conditions are such as to render a synchronous motor undesirable, or an induction motor is already installed, the phase advancer offers great advantages. By its use the power-factor may be raised to unity over a considerable range of load, and it may even be so proportioned as to cause the induction motor to draw a leading

| | Load in Kw. | Power-Factor | Load in Kv-a. | Kv-a. Supplied by Condenser | P-F. at Generator | Load on Generators Kv-a. |

---

*EDITOR'S NOTE: In American practice, certain applications of synchronous motors have arisen wherein difficult starting and running conditions have been successfully overcome. Among these cases may be mentioned the use of synchronous motors for driving line shafting, pulp grinders and pumps. In all of these cases the starting and pull in torque must be at least 40 per cent of the full load torque.

current from the supply mains and thus neutralize the effect of the lagging currents taken by other motors not provided with phase advancers.

Fig. 5 shows a British Thomson-Houston phase advancer with a capacity of 35 kv-a. at 750 r.p.m. It is a three-phase commutating machine designed for a full load current of 500 amperes and arranged for driving by belt from the shaft of the induction motor with which it is used or by a separate small motor, as may be more convenient. The power required is only that necessary to overcome windage and friction, and ranges from ½ to 2 h.p. according to the size of the phase advancer. In this particular case it is less than 1½ h.p.

The armature is similar to that of an ordinary continuous current machine and the stator is made with laminations after the manner of an ordinary induction motor, slots being provided for a suitable number of former-wound coils which ensure satisfactory commutation. The whole construction is even simpler than that of an ordinary continuous current motor.

This particular machine, when used in conjunction with an induction motor of 450 h.p., is capable of relieving the supply system of wattless current equivalent to 650 kv-a. and thus liberating plant capacity of a capital value of at least four or five times its own cost, which is approximately £250 ($1210).

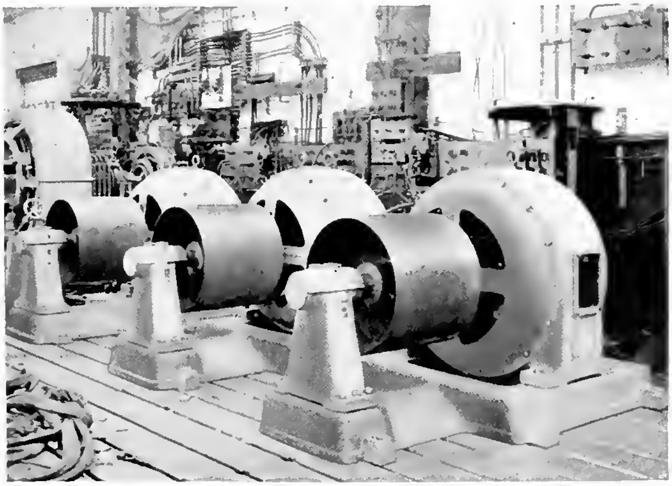

Fig. 3. Group of Three-phase Synchronous Motors Built by British Thomson-Houston Co.

The interaction between an induction motor and phase advancer is easily explained by a brief discussion of the principles involved. The principal cause of the comparatively low power-factor of an induction motor is the magnetizing current required to produce the working magnetic field of the machine. This current lags 90 deg. behind the working current, and were its neutralization possible the power-factor of the induction motor would at once be raised practically to unity, while over-compensation would result in the replacement of the lagging magnetizing current by a leading current which would be effective in neutralizing the lagging currents taken by other machines not provided with means for effecting such compensation. As far as the production of the working flux is concerned it is evidently immaterial whether the necessary magnetizing current passes through the stator or the rotor windings, and evidently it can be caused to pass through the rotor circuit if a suitable electromotive force is introduced in that circuit. On account of the much lower frequency in the rotor circuit a very much smaller electromotive force will be necessary to produce the magnetizing current in the rotor windings than is required to make it flow through the stator circuit at the full frequency, and the kilovolt-amperes it represents will be proportionally reduced. The function of the phase advancer is to provide a suitable electromotive force for this purpose, which it does in the following manner:

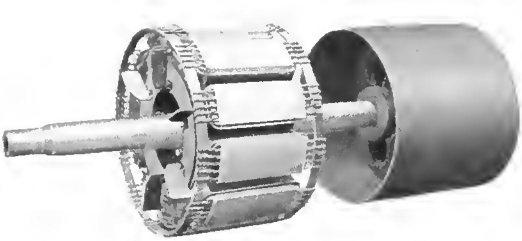

Fig 4. Revolving Field of Motors of Fig. 3, showing Amortisseur Winding

The rotor current flows through the phase advancer and the rotation of the armature in the flux so produced results in the generation of an electromotive force differing in phase from the current. This electromotive force is of the correct phase for producing the desired magnetizing current component in the rotor circuit of the induction motor; but its magnitude is evidently dependent on the design and capacity of the phase advancer and the load on the induction motor. If the electromotive force generated by the phase advancer is insufficient to force sufficient magnetizing current through the rotor windings, the deficiency must evidently be made good by lagging current flowing through the stator windings and drawn from the supply mains, but if on the other hand the electromotive force generated by the phase advancer is sufficient to force more than the necessary magnetizing current through the rotor windings the excess must be compensated by an opposing and therefore a leading component of current in the stator circuit. In other words the phase advancer may be designed to produce either lagging or leading currents in the stator circuit, and since it is excited by the rotor current it is evident that at light load when the rotor current is small its effect will be much less than at full load when the rotor current, and therefore the flux in the phase advancer, is large.

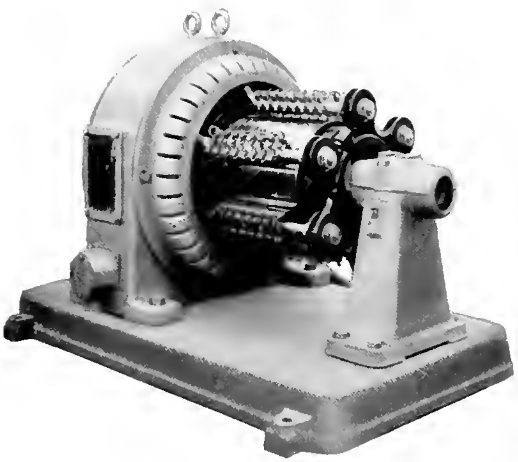

Fig. 5. Phase Advancer Manufactured by British Thomson-Houston Co.

In Fig. 6 are shown the results of tests with a phase advancer and a 10 pole, 450 h.p., 25 cycle induction motor. The normal power-factor without phase advancer is indicated by curve A, and the power-factor with the phase advancer in circuit and driven at a speed of 400 r.p.m. by curve B. Curve C shows the results obtained by introducing a higher electromotive force into the rotor circuit, the increased electromotive force being obtained by increasing the speed of the phase advancer to 600 r.p.m.

In the design of the British Thomson-Houston phase advancer special attention has been paid to commutation and provision made to ensure practically perfect operation. It is thus possible to use graphite brushes, which maintain a highly polished surface and reduce wear and tear of the commutator, and therefore attendance and maintenance, to a minimum. The low voltage at which the machine works and the simplicity of its construction are other factors in its favor. Further, as the electromotive force it generates differs in phase from the current by 90 deg. it exerts no torque either as a motor or a generator and the power required to drive it is simply that necessary to overcome friction and windage. Thus should the drive fail for any reason, there is no danger of the machine racing to destruction.

In addition to improving the power-factor, the phase advancer very greatly increases the maximum torque that can be exerted by an induction motor—a feature which is of great importance in a drive subject to large momentary overloads. The losses in the phase advancer, which are extremely small, are sometimes more than compensated for by the reduction of the losses in the induction motor, which can often be made considerably smaller than would be the case were it to be used without such an auxiliary.

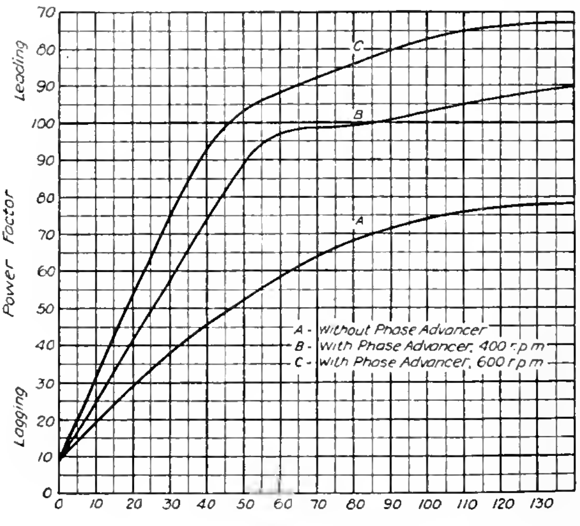

Fig. 6. Results of Tests on 450 H.P. Induction Motor with Phase Advancer

The method of starting an induction motor is not materially altered by the addition of a phase advancer. If the latter is driven from the shaft of the induction motor, the only addition necessary is a triple-pole change-over switch, the blades of which are connected to the slip rings as shown in Fig. 7. The contacts on one side are joined to the starting rheostat and on the other side to the phase advancer, and an interlock should be fitted to prevent any attempt to start unless the slip rings are connected to the rheostat. As soon as the induction motor has been brought up to full speed in the usual way the phase advancer should be thrown into circuit by means of the change-over switch. If the phase advancer is driven by a separate motor, the starting switch for the latter should be interlocked with the main motor switch and the change-over switch in such a manner that the main motor switches cannot be closed until the phase advancer has been started. This requirement offers no difficulty and does not involve any appreciable complication. The cable between the slip rings of the induction motor and its phase advancer should be liberally proportioned and kept as short as possible.

The rotor currents of induction motors of small and medium sizes are proportionally greater than those of motors of large power, and as the price of a phase advancer depends almost entirely on the rotor circuit it has to carry, it is evident that phase advancers for use with small motors will be relatively much more costly than those intended for use with machines of greater capacity. It is therefore not advisable to consider the addition of a phase advancer to each of a number of small motors, but rather to install a synchronous condenser or equivalent device capable in itself of supplying the leading current necessary to compensate the lagging currents drawn by the small machines. At constant excitation such a machine will supply a practically constant leading current, whereas the leading current component due to the use of a phase advancer is almost proportional to the load on the motor to which it is attached, and in this respect it differs from both synchronous machines used as rotary condensers and from static condensers.

The lagging currents required by small induction motors may conveniently be neutralized by leading currents supplied by static condensers connected across their terminals. If such a condenser is capable of supplying just sufficient leading current to produce unity power-factor at full load it will also maintain practically unity power-factor at all smaller loads; so that from this point of view there is nothing to choose between static and rotary condensers except as regards cost.

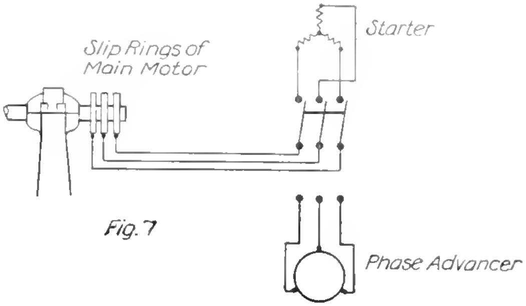

Fig. 7. Connection Diagram of Phase Advancer

The cost of such a machine as that installed in Sheffield may be taken as £2 ($10) per kilovolt-ampere, which is less than the cost of static condensers; but in an installation consisting of a few small induction motors it is possible that the positions would be reversed and the capital cost of suitable static condensers be less than that of a synchronous condenser of the same kilovolt-ampere capacity. As already pointed out, the cost of phase advancers for small induction motors is likely to be excessive, but where large machines are available the cost should not exceed 10 - ($2.50) per wattless leading kilovolt-ampere in the primary circuit. In fact, it has been seen that the phase-advancer described above costs rather less than 8 - ($2.00) per kilovolt-ampere. A synchronous motor working under the most favorable conditions, that is, at 0.7 leading power-factor and a reasonable speed, should not involve an expenditure of more than £1.5.0 ($6.00) per kilovolt-ampere of leading wattless output. In any case it is fairly evident that if a customer of electricity can obtain a rebate of 5 per cent by improving his power-factor to 0.95, the cost of the necessary apparatus will be saved in three or four years. The consumer who generates his own power will benefit to a larger extent by the improved conditions of operation, especially if his establishment contains a number of motors which are only called upon to exert their full powers for very short intervals during the working day.

# RECORDING DEVICES

By Charles P. Steinmetz

Chief Consulting Engineer, General Electric Company

Early in this article the author points out clearly the necessity for keeping a careful record of the details of operation in a power station. Human observations are faulty; and for the best results, therefore, it is necessary to install those types of recording devices which are most suited for the purpose. A description of the advantages and limitations of the disk, tape, photographic film, and multi-recording devices is then given. A very interesting set of analyses regarding the cause of a disturbance upon a transmission line, which has been assumed by way of example, shows the variance of the conclusions which may be arrived at without the assistance of automatic recording devices. This article was delivered as a paper before the Mid-winter Convention of the A.I.E.E., Feb. 27, 1914.—Editor.

While the keeping of records is essential in any business, it is especially important in the operation of electrical systems, and thus records have always been taken of voltage, current, power, of the time of starting or stopping generators, etc., in electrical systems.

Perfect reliability, however, can be secured only by automatic recording devices.

For instance, where it is the duty of the station operator to keep constant voltage, the voltage record made by noting down the voltmeter readings at constant periods of time would probably show uniformity, while an automatic recording device may show bad fluctuation between these times. A protection against neglect or carelessness of taking records, and a check on the operating force, is afforded only by automatic recording devices. But especially when things go wrong, when accidents happen, and the necessity of action interferes with careful observations, the human machine more or less breaks down and only automatic devices are reliable in recording the events.

Automatic recording devices are therefore extensively used: Revolving-disk recording voltmeters, ammeters, thermometers, steam flow meters, etc.; curve drawing instruments; the oscillograph.

In the revolving disk recording meter, a 24-hour, or 12-hour record is made on a circular chart. The shortest time interval which can, under industrial conditions, be accurately noted on these instruments is not much less than a quarter of an hour. Where the quantity changes slowly, as the temperature of a room, a clear chart is given. Where, however, more rapid fluctuations occur, as with current and often with voltage, the chart shows only a broad blur, and neither the individual variation nor the sequence of events can be seen, but merely the maximum and the minimum values estimated.

Curve drawing instruments, in which an endless tape moves with greater or less rapidity, in front of the recording pen, are used for records of more rapidly changing events, as current, voltage, speed, acceleration of a rapid transit train cycle, etc. But to take a continuous record of an interurban railway substation by a curve drawing instrument, moving sufficiently rapid to show all the fluctuations, would be feasible only in special investigations; but the enormous length of the record would exclude it in commercial operation.

One of the most rapid recording devices is the oscillograph and its use has been of material assistance in electrical development, for instance in giving information on momentary short circuit currents of alternators, on the performance of circuit breakers and other problems, upon which information could be derived in no other way. But the taking of a continuous record of station operation by oscillograph obviously is out of the question.

While automatic recording devices are necessary in the normal operation of electric systems, they are still much more essential under abnormal conditions, when things go wrong, and accidents happen. Usually no serious difficulty exists in designing apparatus to operate satisfactorily under normal conditions; also no serious difficulty exists in operating a system under normal conditions, but to meet the abnormal changes of accidental conditions is the serious problem of the electrical designer and of the station operator.

We really know relatively little of the abnormal conditions which are met in electrical operation, and most of our knowledge is rather theoretical, representing what might happen; but exact information of what actually happens is extremely limited. When some accident happens, whether it be the failure of a transformer, or the shut-down of a big system, usually an investigation is made, reports called for, and the witnesses cross examined. But the information gleaned from these examinations is practically always unsatisfactory and incomplete. Frequently no trained observer was present, or so many things happened almost simultaneously, that most of them could not be observed. The circumstances are very unfavorable for exact observation. The necessity of immediate action excludes close observation and almost always excludes immediate noting of the observations, so that the record must be based on the memory of the observer, which is not very reliable in times of excitement. The personal element also comes in, the natural tendency of avoiding personal responsibility for the accident. The sequence of the events, which is all important for the understanding of their cause, is rarely noted in the excitement, and thus such examination hardly ever definitely fixes the cause of the accident, without the necessity of very extensive guessing of more or less questionable reliability. It is, however, of the greatest importance to the operator as well as the manufacturer of the apparatus, to know exactly what happened, so as to guard against its recurrence, and to fix the responsibility.

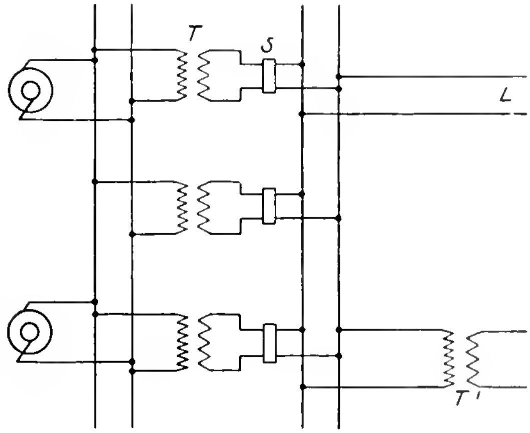

Fig. 1. A Diagram of a Transmission System in which Trouble is Assumed to have Taken Place at T, S, L and T'

For instance, in a large high voltage transmission system, partly illustrated diagrammatically in Fig. 1, a big transformer *T* in the generating station, a high-tension switch *S* in the generating station, and a transformer *T′* at the end of a branch line are destroyed. At the same time a flashover occurs on the transmission line *L*.

Postmortem examination of the transformer showed numerous arc burns on coils and on the tank, and the coils badly deformed and bent out of shape. Questioning of the operators elicited the information that lightning had been frequent during the period preceding the accident. One operator believes to have noticed static in the station for some time before the accident. It is suspected that numerous short circuits have occurred in the lines during the weeks preceding the accident.

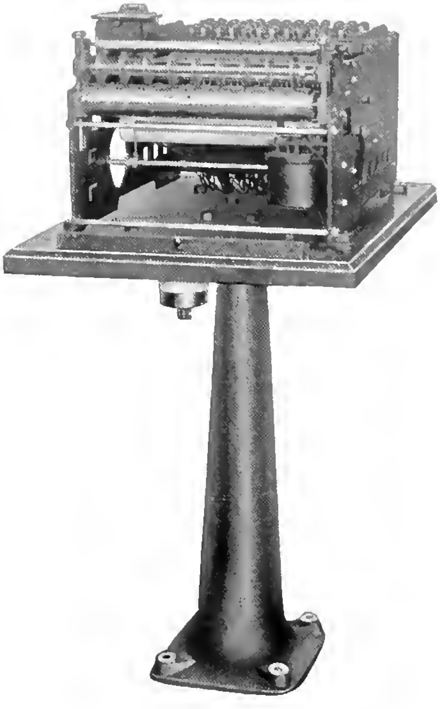

Fig. 2. A Fifty-Point Multi-Recorder

This information is altogether too meager to find out beyond doubt what actually happened. We can only theorize what may have happened, for instance:

1. An arcing ground occurred on the line *L*, producing moderately high frequency—a few thousand cycles. This lasted for some time, possibly hours, until the high frequency broke down somewhere, either by electrostatic heating of the insulation, or by the continual impact of the oscillation. It broke down to ground in the station transformer *T*, and thereby caused a short circuit through transformer *T* and line *L*. The high tension

switch $S$, in attempting to open this short circuit, failed due to the excessive current and the superposed high frequency oscillation, burned up and so created a dead short circuit at the transformer terminals. The mechanical magnetic forces, resulting therefrom in the transformer, moved the coils. The shock of the short circuit broke down the transformer $T'$ at the end of the branch line.

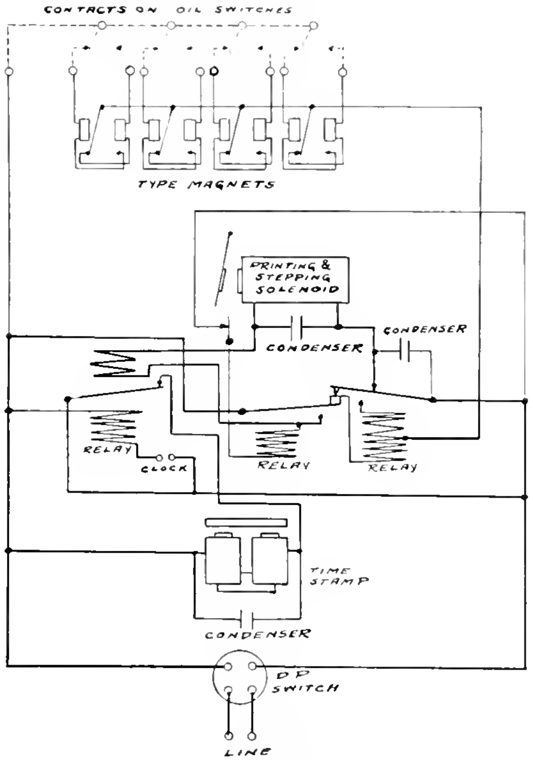

Fig. 3. Simplified Wiring Diagram of a Multi-Recorder

2. Numerous flash overs had occurred during the preceding weeks in the transmission lines, resulting in heavy short circuits. While the transformers were strong enough to stand occasional short circuits, the short circuit stresses were so enormous that continual short circuits gradually impaired and finally broke down a transformer $T$. This resulted in the destruction of the circuit breaker $S$, the failure of the second transformer $T'$ etc.

3. Lightning entering the line $L$ started a high frequency cumulative surge in the transformers, producing spark discharges between the coils. The same or another lightning stroke flashed between the lines, caused a short circuit, resulting in the destruction of the circuit breaker. The spark discharge in the transformers finally led to short circuit, which distorted the transformer coils.

4. An internal oscillation in the transformer, due to entrance of high frequency lightning, or resulting from an arcing ground on the line, caused spark discharges in the circuit breaker, leading to its destruction. The short circuit resulting therefrom moved the transformer coils and brought them sufficiently near to either end of the tank to cause arcing over, with the resulting destruction of the transformer.

Numerous other combinations of the phenomena could still be devised, to account for the accident, for instance, the transformer $T'$ at the end of the branch line may have broken down first, and the accidental arc may have produced the high frequency, which damaged the circuit breaker and main transformer, and flashed over the transmission line, etc. But whether the trouble started with a high frequency oscillation in the transformer, or resulted from a high power short circuit, or from lightning, or from an arcing ground on the line, or from a combination of two cases, as high frequency oscillation and short circuit cannot be obtained from the available sources of information. Neither can it be determined whether the transformer was mechanically too weak to stand a short circuit, or whether it was weakened by frequent short circuits combined with high frequency disturbances. It is, however, of importance to the manu-

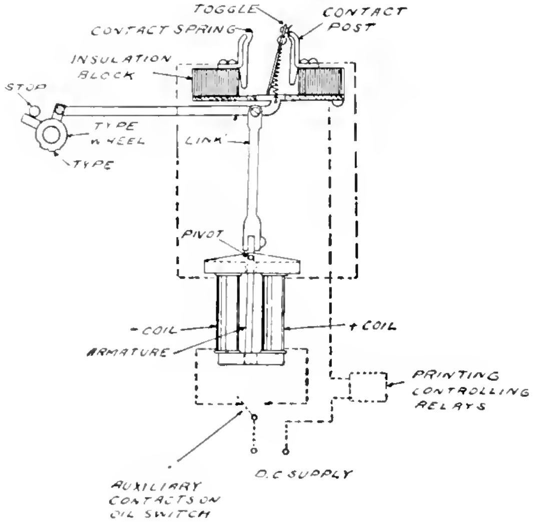

Fig. 4. Mechanism for Operating Type Wheels

facturer to fix the responsibility, and to know whether the transformers are mechanically too weak and should be made stronger, and correspondingly more expensive, or whether and what additional protective devices should be developed. And it is of still greater importance to the operating companies to take such steps as will insure reasonable reliability of operation.

If automatic recording devices would show what happened and the sequence of the happenings, whether the trouble started with lightning, or with an arcing on the line, or a line short circuit and how this originated, or a transformer surge in the generating station or the branch line, etc., then in most cases the phenomena could be exactly determined and with reasonable certainty precaution against their recurrence taken. Also, less difficulty would usually be experienced in fixing the responsibility on the manufacturer of the apparatus, or on the operating engineer, or on *vis major*. As it stands at present, the transformers are rebuilt with greater mechanical strength, and damping devices against transformer surges installed, and it is "hoped" that the phenomena against which these guard were the causes of the trouble, but we cannot possess the confidence that the same will not happen again, and if similar troubles do occur again, it merely means that some of the other various possibilities were the initial cause of the trouble, and that the remedy would lie in the installation of an arcing ground suppressor, or in grounding the neutral, or in disconnecting the grounding of the neutral, or in reducing the sag of long spans to eliminate the swinging together of the lines, or in adding another disk to the suspension insulators, or in better weeding out defective insulators by high frequency testing, etc.

Numerous such instances could be given. Thus, in underground cable systems, breakdowns occur frequently in groups, or practically simultaneously, and it is difficult to determine which cable started the trouble. For some time, often days, troubles with feeders may have preceded the break down, and if properly recorded, would explain its cause and so give a greater probability of guarding against its recurrence, etc.

The difficulty or impossibility of getting complete and exact records of what happens in electrical systems, and of the sequence of the events, is the most serious limitation, at present, to providing protection to such systems.

Automatic recording devices thus are of the greatest importance for the safety of operation of a system, especially where reliability is important. However, in case of trouble, the sequence of events commonly is so rapid, within seconds or less, that such devices must be capable of recording within fractions of seconds. The dial instruments, like the revolving disk recording meters, therefore, are out of the question, as they show everything within a few minutes as simultaneous. Curve drawing instruments would have to run the tape rather rapidly. If we assume that 50 records are needed, and allow between 1/8 and 1/4 in. per second as the minimum, about 15 miles of tape would be unrolled per day, and to look all this over to see the records obviously is impossible, especially when it is desirable to go back for weeks to see what has preceded. With phenomena like lightning, where several strokes may occur in one minute, and then no record for weeks or months, obviously any recording device with continuously moving tape is impracticable. Where records are made at more or less infrequent intervals—sometimes, as with circuit breakers, at fairly regular intervals, and sometimes, as with lightning discharges, at very irregular intervals—an instrument in which the tape does not continuously move, but, as in the typewriter, moves only when making a record, is essential.

To give reasonably complete information on the station performance under normal as well as abnormal conditions, records are required of the closing and opening of every circuit breaker, of the operation of the lightning arresters, of the appearance and duration of high frequency in the lines, of grounds and short circuits, possibly of excess currents, of overnormal and subnormal voltage, frequency, etc., etc. Considering then, that even a small station may connect two or three lines, and each line has three phases, and a separate record of each phase is necessary, it is obvious that a considerable number of records is needed. With a record sheet, moving only whenever a record is made, 50 records can easily be taken on the same sheet, and a 50 point multi-recorder thus appears as a convenient unit. In such a device, a sensitivity of at least 1/4 to 1/2 second is desirable, so that phenomena following each other at intervals of 1/4 second or more, are separately recording, while everything which occurs within 1/4 second appears as of the same time. Such high sensitivity is desirable to get the sequence of events which to the observer may appear simultaneous, as the break down of a number of feeders, etc. At the same time, such great rapidity of action requires a powerful mechanism and when considering that the operating mechanism must be capable of working very many thousand times without failure by wearing out, the problem in the development of such an automatic multi-recorder was rather a difficult one. Also, when a record comes in within less than $^1{}_4$ second from the preceding one, while the record sheet is still moving in receiving the previous record, the second record would blur, but this difficulty thus has to be overcome by retarding the second record until the taps have come to rest.

On such a multi-recorder print, one record point should be reserved for recording standard time at fixed intervals, thus giving the time correction of the clockwork which operates the recorder, so as to make it possible to record the sequence of events occurring almost simultaneously in distant stations and noted on different multi-recorders.

A description of this instrument is given by Prof. E. E. F. Creighton, in the A.I.E.E. Transactions, Vol. XXXI, 1912, p. 825.

# THE DEVELOPMENT OF ELECTRIC TRACTION

## By John R. Hewett

The urgent need for more rapid and better means of physical communication between nations and between sections of the same country has been responsible for the development of our modern transportation systems, to the extent where they have become absolutely indispensable to our present modes of living. Transportation requires energy, and there are only two suitable forms of energy that can be economically transported or transmitted to a distance from the source, electric energy and the chemical energy of coal. The flexibility and simplicity of the former and its ready and efficient conversion into mechanical energy render it greatly superior for almost all cases of energy transmission. The question of the electrification of steam railroads, however, is one of pure economics—whether it is cheaper to build a distribution system for the whole length of the line, or to carry the fuel and converting apparatus along with the train in the shape of a steam locomotive. A brief review is made of existing systems of electrification, and an argument is advanced to show that the so-called "Battle of the Systems," instead of hindering development as is contended by some, must of necessity work to its advantage, as only by attacking the problem from all sides can the best of which the art is capable be produced.—Editor.

The steam railroad is just about a century old and the electric railway about a quarter as old, and when we think of the astounding developments that have taken place in this comparatively short space of time, we can hardly refrain from asking ourselves why this development has come about. The answer to this question would seem to be that the civilization of the world is absolutely dependent upon rapid communication between man and man—the communication of thoughts and of material matter. The invention of the steam engine and locomotive pointed the way and then, with the introduction of the electric telegraph and the submarine cable, the different peoples of the world became so much more closely connected in thought that the general extension of a more rapid means of physical communication seemed imperative. The stage coach on land and the sailing ships on the seas had to be replaced by quicker methods of communication. It was about the beginning of the nineteenth century that people began to recognize that the country which developed the best means of rapid communication with other countries would be the leader in the commerce of the world—those that had most ships would control the seas and the markets of the world; and, similarly, that it was only those countries that developed an efficient system of land transportation that could develop their natural resources and consequently become manufacturing countries.

The recognition of these great economic truths came about just at a time when the whole world had been well nigh torn asunder and rent by a series of wasteful and disastrous wars. In looking back at the history of this period, the development seems miraculous. All sections of the civilized world would seem to have taken on a new form of life, and commerce became to be recognized as a better trade than war. The development of better means of communication aided the rapid spread of civilization and the spread of civilization stimulated industrial developments of all kinds. Thus was started an action and a reaction which has been continued up to the present time, with the result that today a man living in New York knows more about the capitals of China and Japan than his grandfather knew about many towns scarcely a hundred miles from his own door, and that each of us individually today are virtually in connection with the whole rest of the world. It is easier to make a trip around the entire globe today, in comfort and in luxury, than it was to travel from one end of New York State to the other, at the cost of hardships and dangers, a hundred years ago.

These developments have absolutely changed our modes of living and during the transition stage one thing of vital importance has happened, viz., we have let these means of communication become our masters as well as our servants. When we stop to consider the enormous populations congested into our large cities, and the distances from which their daily food supplies have to be transported, it is apparent that our means of communication are the masters of the situation. Should they for any reason fail to fulfill their functions in the community for even a brief time, it would spell death by starvation to hundreds and thousands of human beings.

So in this brief period of one century we have built up a set of conditions that has so complicated our modes of living and increased our dependence on the labors of others, living at a great distance from us, that now our transportation facilities have become just as much one of the necessities of life as are food and clothing. The character of our transportation systems has thus become a matter of national importance.

It was long after this civilizing movement had set in and become well established that the electric railway made its appearance. In fact, it is just about twenty-five years ago that Sprague, Van Depoele, Daft and Bentley-Knight, amongst other energetic pioneers in the industry in this country, began to show the possibilities of this new mode of traction. In this short space of time electric traction has not only become well established, but has grown to be one of the most important industries in the country. In the last twenty-five years electric traction has, practically speaking, superseded all modes of transportation for city, suburban and interurban service, including elevated railways and subways. A whole paper could be written with profit to show the advances that have been brought about in our social status by the electric railway. There are few who realize how much the public and especially those interested in real estate have benefited by the enterprise of those who have been responsible for the building of our electric railway systems, but we have not time to go into this phase of the subject here.

It seems today that the field for electric traction is as broad as the traction field—that is to say, that it has been developed to a stage where there are no longer any technical limitations to its adoption on every railroad in the country. The traffic could be handled electrically and the considerations which govern the choice between steam and electric traction are financial and economic, not technical. Within the last decade, we have seen many notable examples of the electrification of steam railroads, and judging by the general interest that has been awakened in railroad circles and the recognition of the splendid service being performed by those electric installations already made and the economies secured by their adoption, we shall see many more examples of steam railroads adopting electric traction during the next decade.

All modes of traction depend primarily upon energy, and whether steam or electric traction ultimately becomes universal depends upon the relative economic values of the form of energy used. It should be noted here that of all the forms of energy available, only two are generally considered for traction purposes, viz., the chemical energy stored in coal and electric energy. Dr. Steinmetz in a paper before the Franklin Institute has recently pointed out the reason for this, viz., because they are the only two forms of energy that can be economically transported or transmitted over long distances. The two following paragraphs are taken from Dr. Steinmetz's recent paper:

"Electrical energy can be transported or, as we usually call it, transmitted—economically over practically any distance. Mechanical energy can be transmitted over a limited distance only, by belt or rope drive, by compressed air, etc.; heat energy may be carried from a central steam heating plant for some hundred feet with moderate efficiency, but there are only two forms of energy which can be transmitted over practically any distance, that is, which in the distance of transmission are limited only by the economical consideration of a source of energy nearer at hand—electrical energy, and the chemical energy of fuel. These two forms of energy thus are the only competitors whenever energy is required at a place distant from any of Nature's stores of energy. Thus, when in the study of a problem of electric power transmission we consider whether it is more economical to transmit power electrically from the water power or the coal mine, or generate the power by a steam plant at the place of demand, both really are transmission problems, and the question is whether it is more economical to carry energy electrically over the transmission line, or to carry it chemically, as coal by the railroad train or boat, from the source of energy supply to the place of energy demand, where the energy is converted into the form required, as into mechanical energy by the electric motor or by steam boiler and engine or turbine.

"Electrical energy and chemical energy both share the simplicity and economy of transmission or transportation, but electric energy is vastly superior in the ease, simplicity, and efficiency of conversion into any other form of energy, while the conversion of the chemical energy of fuel into other forms of energy is difficult, requiring complicated plants and skilled attendants, and is so limited in efficiency as to make the chemical energy of fuel unavailable for all but very restricted uses: heating and the big, high-power steam plant. To appreciate the complexity of the conversion of the chemical energy of fuel, compared with the simplicity of electrical energy conversion, imagine the domestic fan motor with coal as source of energy: a small steam engine, with boiler and furnace, attached to the fan: to start the fan, we have to make a coal fire and raise steam to drive the engine. This illustrates how utterly unavailable the chemical energy of fuel is for general energy distribution. Generally energy distribution, therefore, may justly be said to date from the introduction of electric power."

From the foregoing it will be seen that electrical energy and the chemical energy stored in coal are the only two available sources of energy for traction purposes, and that in the case of coal we have to carry our fuel and generating apparatus adding enormously to the weight of the moving element and consequently to the cost of transportation, while in the case of electrical energy, there is no fuel or generating apparatus to be transported. This gives electric transportation a tremendous advantage, but at the same time it must be remembered that in the case of electric traction we have to provide the means for supplying the moving elements with a continual supply of energy, which means the construction of a trolley system or third rail for the whole length of the line.

The general extension of hydro-electric developments which is fast covering the country with a network of high tension transmission lines is making a source of cheap energy available in many localities. This development will prove quite an asset to many roads who would rather buy than manufacture their own power.

In the case of electric traction, the range of energy supply is very flexible—we have the whole resources of the power house available—while with steam traction, if we want excessive power for only a short distance we have to transport sufficient generating apparatus and fuel all the time we are working at light loads.

So the question of the electrification of steam railroads resolves itself to a question of whether it is cheaper to build a system for the distribution of energy for the whole length of the line than to carry the fuel and generating apparatus along with our freight and passenger trains.

This is absolutely a question of economies, and will be settled as such in each individual case after a careful analysis has been made of the individual requirements.

If the traffic was sufficiently dense, it would always pay to electrify a railroad, because the economies to be secured by electric operation would more than offset the interest to be paid on the initial expenditure, but where the traffic is scarce and the length of the line is long, that is to say, where the initial cost of electrification and the cost of operating and maintaining permanently an extensive system of energy distribution would be great, in comparison with the cost of hauling the fuel and generating apparatus along with the train, then steam traction is still the most economical.

We have many examples of steam railroads with dense traffic that have made or are contemplating the change from steam to electric traction to secure these economies, and also many special cases where electrification has come into being to secure some special economies or overcome some special conditions, such as the abatement of smoke in terminal stations, etc.

The analysis of operating conditions to determine whether it would be economical to electrify or to continue steam operation is becoming an important branch of the engineering profession. There are today many instances where electrification would pay, but where difficulty would be found in financing the undertaking. When some of the roads that are contemplating electrification have done so and have gained the experience from actual practice, it is likely that other roads will follow their example and that the electrification of our steam railroads will become one of the large electrical industries of the country.

When an analysis of the conditions in any particular instance has shown that electrification would be economical, we still have to determine which of the available systems of electrification is best suited to the requirements. This is purely a question of economics, and here again is the necessity for a careful analysis to determine the most economical way of distributing the expenditures to be made in the initial construction, the operation and the maintenance of the system.

For example, when the traffic is very dense, and where cars or trains of moderate size have to be run at very frequent intervals and the total energy used at any one instant is not very greatly in excess of the average load, then standard 600 volt apparatus has no equal. There is no objection to the heavy outlay in substation apparatus and feeder copper when such apparatus will be in operation at an efficient load factor for a good percentage of the twenty-four hours.

It is when the load is such that the cost of copper and of the machinery installed in the power house and substations is excessive, and the percentage of time that they will be working at anything like an efficient load factor is small, that we look about for ways and means of reducing the amount of machinery necessary and of increasing the time that it will be in actual use. As a matter of fact, these conditions are just what exist on most systems where electrification is contemplated, and it is to meet such conditions and make electrification an economic possibility that the high voltage systems, viz., the three-phase system, the single-phase alternating current system and the 1200 and 2400 volt direct current systems have been evolved; in other words, higher voltage is an economic necessity to avoid excessive expenditure in copper and in machinery which would only be working at part or no load for a great percentage of the working day.

The three-phase system has found but little favor up to the present in this country, while it has been very extensively adopted in Europe; but there is one case, viz., the electrification of the Cascade Division of the Great Northern Railway, where such a system has been in successful operation for some years in this country. It would seem in the light of our present knowledge that such a system, at least for conditions as they exist in this country, is likely to be confined to mountain grade work where the advantages of regeneration can be secured. On the other hand, as the high potential direct current system has been developed with these same features, there seems little to warrant the additional complication of the three-phase trolley.

During the last decade the relative merits of single-phase alternating current and high potential direct current systems have been freely discussed, and many examples of each system have been installed and have been operated for a sufficiently long period to enable a logical opinion to be formed as to their relative merits. It would be impossible to enter into a detailed discussion of this phase of the subject in a paper of this length, but judging from the results of operation, as published, and the number of single-phase interurban roads that have been changed from single-phase alternating current to direct current, and from the number of direct current roads now in successful operation, and the fact that no roads adopting higher direct current potential have changed, and the present ratio of alternating and direct current work now under construction and contemplated, it would seem safe to infer that at present, at least, the higher potential direct current road has a decided advantage over all other systems for heavy traction work.

What the future has in store no one can say. The alternating current system or some modification of it may be developed along lines that will enable advantage to be taken of its good features, and its inherent limitations to be overcome. And again, new modes of power transformation may come into use such as rectifying alternating current to direct current when the advantages of the alternating current secondary distribution could be combined with the excellent characteristics of the direct current railway motor. But if we start speculating on the future, there is no limit to the range of our imagination.

There has recently been said, both in the technical press and elsewhere, a great deal about what people are pleased to style "The Battle of the Systems." Some people have taken the attitude that electric railway developments have been hindered because all manufacturers of electrical apparatus are not agreed upon the best system for heavy traction purposes. Such people are prone to infer that such a condition of things is hindering development and that the manufacturers are responsible for this condition. As a matter of fact, such differences of engineering judgment, when there are several different methods of attacking a problem, must, in the long run, be beneficial to the railroads rather than harmful, as without such differences of judgment, the possibilities of the art can at best be but imperfectly developed. When any art has been developed to a reasonable state of perfection and the fundamentals have been well considered and thoroughly tried, and after the process of eliminating the less suitable factors and perfecting those which have shown themselves capable of meeting the necessary demands, under actual service conditions, has been carried to the point where our knowledge, based on experience, enables us to retain the good and reject the bad, then and not until then, is the time to talk of standardization. An attempt at standardization when an art is in a more or less embryo state is likely to work a permanent harm inasmuch as it limits our knowledge of the broader engineering possibilities that might be brought to bear upon the subject. This question is of such importance today that it is worthy of consideration from both sides.

This so-called "battle of the systems" today is, as we all know, applied to heavy traction between single-phase and high voltage direct current. Briefly, there are two courses open: to attempt to standardize one, or to try both. First, let us imagine that we are living under such conditions that an imperial edict has been issued that single-phase is par excellence and that henceforth every railroad in the country that wishes to be electrified must use this system. This is not very far from what has happened in Germany. The first fruits of such a condition might possibly be that a great amount of talent would be focussed upon one subject and that developments along certain limited lines might be stimulated. Also, the customers or railroads would be relieved of any worry concerning the selection of the correct system. There would be no choice in the matter: they must take what was presented or leave it. Under such conditions, the field of research and development would be limited to such an extent that any inherent limitations in this one system of electrification would literally form a stone wall across the paths of progress. If there are inherent limitations in any system and we insist on its adoption, we are hindering rather than helping the permanent sound progress of the art. On the other hand, when there are two or more systems that are recognized as competitors, and there are, as it were, opposing camps, one side championing one system and the other side championing the second system, we are building on broader foundations. As a matter of fact, the battle of the systems is merely a bogy—the selection of the best electrical apparatus to meet the service conditions in any particular case is the settlement of engineering details—not the adoption or rejection of a system.

There are some engineering firms that have thoroughly tried out all the apparatus which has been developed up to the present time, and their judgment in these matters is tempered by experience and costly tests, and the railroad companies are getting the benefit of this experience.

The development of the higher potential direct current railroad is of peculiar interest, as the apparatus used has gone through such a logical sequence of evolution. It is just about a decade ago that we began to recognize that 500 or 550 volts was no longer the standard potential for railway work. The voltage had gradually been raised from these figures to 600 volts until there were more roads operating on 600 volts than at any other potential. When this condition was recognized, 600 volts was talked of as the standard. The evolution from 500 to 600 volts was largely brought about by a gradual increase of the traffic on existing systems, the raising of the voltage being the simplest and cheapest method of meeting the severe demands. There have been isolated cases of roads operated at 700, 750 and 800 volts, and the step from these potentials to 1200 volts was a comparatively small one. It should be specially noted that the increase from 500 to 600 volts made no difference whatsoever in the design, construction and operation of the equipments. When the jump to 1200 volts was taken, it was made for purely economic reasons, and no radical changes were made in the equipment. To retain the good and well tried features of 600 volt control, a very simple piece of apparatus called the "dynamotor" was devised which enabled the control and auxiliary circuits to be operated at 600 volts and the main motors to use the higher potential. The only change in the motors to suit the higher voltage was that they were insulated for 1200 volts instead of 600 volts, the common arrangement being to operate two motors in series so that 600 volt windings were still used. The adoption of commutating poles on railway motors greatly facilitated the raising of the trolley potential without the introduction of complications. The marked success that attended the operation of 1200 volt apparatus under severe service conditions encouraged further steps along the same line with the result that some roads of 1500 volts were installed. The results were equally satisfactory. Most of the roads at present operating at higher direct current potentials are in the nature of interurban railways but some, however, approximated steam railroad conditions. In all cases the apparatus has proved itself as well suited to the severe conditions as the older 500 and 600 volt apparatus had. Under these circumstances it is not surprising that a still higher direct current potential should have been considered for a heavier class of service. In 1912, just five years after the first 1200 volt road was put into successful operation in this country, 2400 volt direct current was adopted as the most suitable system to meet the peculiarly severe conditions existing on the Butte, Anaconda & Pacific Railway—thus direct current apparatus has evolved from a small beginning until it has reached a stage where it meets the demands of the heaviest traction undertakings contemplated.

This is as far as we have gone at present in this direction, in actual practice, but there seem no logical reasons or limiting conditions, that we know of at present which would prohibit the use of still higher direct current potentials.

Since the initial adoption of 1200 volts, the extension of its use has been exceedingly rapid, and it may now be regarded as the standard for all new interurban railways. In some cases where marked economies can be secured 2400 volts may be used in interurban service. One example of this is already under construction, viz., the Michigan & Chicago Railway.

The first road to adopt 1200 volts in this country was the Pittsburgh, Harmony, Butler & New Castle Railway. This road started operation in 1907. Since this date, the extension of high potential direct current railways has been exceedingly rapid as shown in the following table.

| Date of Installation | No. of Roads | Total Road Mileage |
|---|---|---|
| 1907 | 1 | 41 |
| 1908 | 2 | 134 |
| 1909 | 0 | 0 |
| 1910 | 6 | 424.6 |
| 1911 | 2 | 201 |
| 1912 | 3 | 196.5 |
| 1913-14 | 17 | 1061 |
| Totals | 31 | 2058.1 |

Most of the roads are in the nature of interurban railways, but it should be noted that as far as we can see the vast majority of the heavy traction work now under construction or contemplation will employ direct current apparatus and this will, in most instances, be operated on "higher potentials."

We are apparently fast coming to recognize that there is such a thing as "a science of development" and that such a science among other factors must include the following fundamentals:

(1) An accurate determination of the actual operating conditions which will enable us to settle definitely what is wanted.

(2) The co-ordination of the work of a large number of differently trained men, so that the finished product may embrace the experience of each worker in his particular line, and thus become in every detail the product of experts.

(3) The confidence and cooperation of the users and makers of apparatus both before and after its manufacture, this cooperation to continue in some form or other during the useful life of the machine.

(4) The standardization of apparatus when such will be profitable to all concerned.

(1) There are, perhaps, many who do not realize the costliness of determining what is wanted to suit a particular set of service conditions. An accurate determination of the precise requirements will often necessitate months of exhaustive investigation, often including costly tests. This is particularly true in large undertakings. If we compare the work done in this direction today with the older haphazard methods of designing machinery first and seeing whether it would do the work afterwards, it is apparent that the art has benefited enormously by the work of the large corporation along these lines. Some phases of the research and development work undertaken today are so costly and require such a large staff of expert workers that no small engineering undertaking could shoulder the burden, as assumed by the large corporation.

(2) The proper co-ordination of the work of a host of men who are contributing to the design, manufacture and testing of electric railway apparatus is no small part of the Science of Development. The extent of this work is enormous, including as it does, preliminary proposition, final proposition, designing, drafting, actual manufacture and work incident to following apparatus through

the factory, assembling, testing, installing, and preliminary operation. The final cost of the apparatus depends largely upon whether this co-ordination of work is done in a scientific or unscientific manner.

(3) A whole paper might be read with profit on the subject of the confidence and cooperation between the user and the maker. Upon the encouragement and extension of what we might call "the modern business idea," the rapidity with which we are going to develop in the future must largely depend. The successful development of electric apparatus for traction purposes depends on "how it is made" and "how it is used." The manufacturer is dependent upon the user just as the user is dependent upon the manufacturer. An ounce of mutual confidence and cooperation will do more towards the development of the art than a ton of fault finding and mutual distrust. In the broadest sense, the aims and objects of both parties are identical. The user wants the best obtainable for his service and the maker wishes to produce the best and most efficient apparatus, as upon this his reputation and future business depends. The work of all parties concerned is in reality the part of one great plan.

(4) The correct time at which the standardization of electric apparatus should be attempted is a science in itself, e.g., it would undoubtedly be profitable to all concerned if all trolley systems would cooperate with the manufacturers in using standard apparatus, especially standard railway motors and standard control equipment, where such standards will fulfill the requirements. There will, however, always be special conditions arising that will demand special apparatus, and the things that dictate these special requirements are many and varied, e.g.: Who could have foreseen that the fashion of ladies' skirts could affect the design of railway motors? But such has been the case—the hobble skirt gave birth to the low step car—and the low step car required a new design of motor.

The standardization of all apparatus that is used in large quantities and has reached a high state of perfection would be a great asset to the industry.

On the other hand, until we have more experience with the different systems of electrification, it would seem unwise to lay down too definite standards for heavy traction work, although it might be profitable to standardize such things as trolley voltages that would vitally affect the future development of the art as much as the present.

In conclusion, it is well to emphasize one point, namely, that modern engineering involves, above all things, the study of economics. Yesterday we were finding out how to do things—today we are striving to find out how to do them more cheaply than yesterday. To combat the increased cost of living and of labor, etc., and the generally more complicated social and commercial conditions under which we are living, the work of the scientist and the engineer is to teach the world at large how to do for one dollar that which they could not do for two dollars yesterday.

# AUTO-TRANSFORMERS

By Lee Hagood

Lighting Department, General Electric Company

This article cites an instance of trouble which has been experienced in applying auto-transformers to an ungrounded system, and concludes with a statement of the factors which must be taken into consideration in such an installation.—Editor.

On account of cheapness an auto-transformer for power transmission makes an attractive proposition. Although some are in successful operation considerable care should be observed before adding an auto-transformer to a system.

The following example will serve to illustrate how serious some of the troubles may be which arise from the improper use of an auto-transformer.

A contract was made with Company "A" for the purchase of 60 cycle 22,000 volt power by Company "B." Available for supplying this power was a 16,000 volt 60 cycle system and a 25 cycle system. A frequency changer set was installed arranged for 2300 volts on the 60 cycle side. It was therefore necessary to furnish apparatus to step the voltage from 2300 to 22,000 volts and from 16,000 to 22,000 volts. To meet the two conditions of voltage transformation a transformer was installed having a delta connection from 2300 to 22,000 volts and the high tension winding connected as an auto-transformer for 16,000 to 22,000 volts. The connections are illustrated in the figure. In view of the fact that both systems were isolated the auto-transformer neutral was not grounded, since grounding would involve changing all the two-pole relays on the automatic oil switches to three-pole relays. This would have also involved the addition of another current transformer for each automatic switch. The transformer in question was 3600 kv-a. made up of three single-phase units.

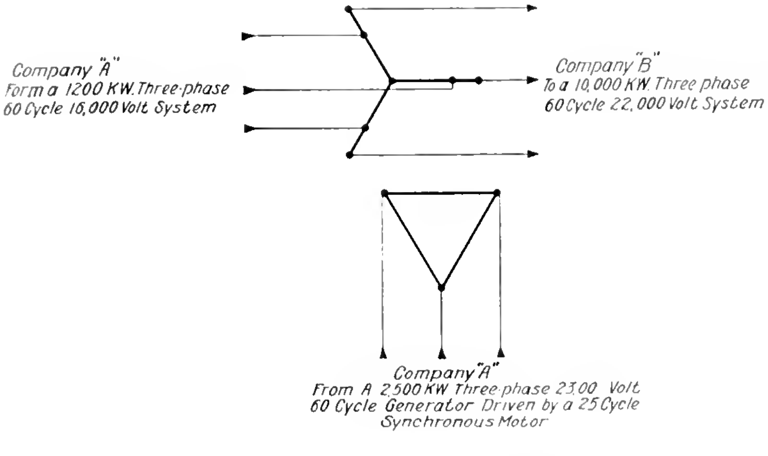

Fig. 1. Bank of Transformers consisting of three single-phase 1200 kv-a. transformers, connected delta on the low and Y on the high tension side. The high tension side is arranged for an auto-transformer connection from 16,000 volts to 22,000 volts

The first serious trouble arose as follows:

An attempt was made to supply power from the 16,000 volt system with the 2300 volt delta connection open. Immediately serious telephone disturbances arose. These troubles, it seemed, were so serious that some of the telephone lines were almost useless. One telephone company actually requested the manager of Company "B" to shut down his system until the trouble could be located. The best telephone men were sent out in search of the difficulty and its seat was finally located in the transformer bank in question. The remedy for the trouble was a simple one, since by closing up the 2300 volt delta winding the disturbance was brought to an end.

The next trouble arose some time later when Company "B" received a ground. This raised the dynamic voltage of the 16,000 system on Company "A" side to 19,000 volts. Simultaneously a high frequency was transmitted through the auto-transformer due to the arc at the ground on Company "B" side. This caused the horn gaps of the 16,000 volt lightning arresters to arc and thereupon the lightning arresters were destroyed. Lightning arresters are not suited for protection at a dynamic voltage exceeding fifteen to twenty per cent above normal. In the present case nothing can be accomplished by changing the lightning arresters. Adding cones will not help matters as the voltage at which protection is afforded depends upon the voltage at which the arresters are charged. Since the grounding of the auto-transformer is inadvisable due to the expense of changing to triple-pole relays on the oil switches the customer is led to face the proposition of purchasing an additional transformer for supplying power from the 16,000 volt system. As a matter of fact, if a transformer with two secondary windings had been selected in the first place it would have been only slightly more expensive than the present auto-transformer combination, and would not have been exposed to any of its troubles.

It might appear from the above that grounding an auto-transformer is a solution of all serious difficulties. Nevertheless the following should be borne in mind:

First. If a system is isolated and a grounded neutral established, all the automatic oil switches should be protected by triple-pole relays. It is customary on isolated systems to only use double-pole relays. The expense of such a change in most cases would be excessive.

Second. Having more than one ground on a system offers a path for harmonic currents and stray currents. These may cause serious telephonic interference. Furthermore, such currents may be of large enough magnitude to destroy apparatus. We are familiar with cases of both.

Third. It does not seem advisable in any event to tie two large systems together by means of auto-transformers, since disturbances due to lightning, arcing grounds, etc., have a free path from one system to the other. This, of course, does not exist to a serious extent where the transformation is by means of primary and secondary windings, since the electromagnetic coupling allows more flexibility.

# REPORT OF TEST OF ILLUMINATION ON PENNSYLVANIA AVENUE, WASHINGTON, D. C.

By Walter C. Allen

Electrical Engineer of the District of Columbia

The following article reports the results of the first illumination test of the luminous-arc lamps recently installed in Washington, D. C.—Editor.

Upon request of the Commissioners of the District of Columbia, the Bureau of Standards has made foot-candle measurements of a typical section of Pennsylvania Avenue, Washington, D. C. These show a remarkably uniform distribution of light obtained from the luminous arc lamp installation recently made on that thoroughfare, and fully described in the March, 1914, issue of the General Electric Review. The section of Pennsylvania Avenue chosen for this test lies between Fourteenth and Fifteenth streets where the lamps as actually installed follow as closely as possible the spacing of 100 feet, measured along the curb, which was chosen as necessary for proper illumination. The report states:

"The measurements were made by laying milk-glass test-plates on the pavement and determining the brightness of their surface by means of Sharp-Millar photometers. The test-plates were tested to determine their deviation from the cosine law of diffuse reflection, and the results as given (Fig. 1) are corrected for this deviation.

"At 35 of the stations, covering a representative rectangular portion of the block, entirely independent measurements were made at different times by two observers with different photometers, and the separate results are given under the headings photometer A and photometer B. The arcs flicker considerably, besides showing a more or less regular and continuous change as the arc stream grows longer between readjustments of the feeding device. Consequently considerable variations occur, especially at the stations near lamps where the light comes almost entirely from one lamp. It may be noted that the results obtained by the two photometers show a greater systematic difference than we usually have in measurements of this kind. For this difference we have no satisfactory explanation, although it may possibly arise in part from a difference in judgment of the proper mean value for flickering lights.

| 15 | 0.121 | 0.117 | 0.12 |
| 16 | 0.097 | 0.114 | 0.105 |

"These measurements were made between eleven and 1:30 o'clock on the night of March 23rd. Ammeters previously calibrated at the Bureau were placed in the circuits at the power plant and the currents were supposed to be kept as nearly as possible at 6.6 amperes."

# THE STORM DETECTOR AND ITS INFLUENCE UPON THE OPERATION OF LIGHTING CENTRAL STATIONS

By W. H. Lawrence

Superintendent Waterside Stations, New York Edison Company

Unexpected overloads have always been a source of danger to central station apparatus and are likely to be detrimental to the quality of the service furnished by the station. Sudden storms have embarrassed central station engineers to such an extent that some of the largest lighting stations keep a man posted on the roof to give warning of their approach. The author, after citing the load conditions in the New York Edison stations, describes a most ingenious storm detector which has been devised to supplant the above practice. The simplicity of construction and the effectiveness of operation are two notable features of this device which employs the principles of wireless telegraphy. Actual records of operation are given.—Editor.

## Introduction

Such public utilities as those supplying gas and water are fortunate in that the commodities they distribute are physical materials. During those parts of the day when the demand for their product is small, the excess delivered from the station can be economically stored in a reservoir for use at later periods in the day when the demand is greater than the capacity of the station.

The public utility that distributes electricity, however, cannot be modeled profitably after this plan on account of the properties of the commodity that it handles.

Electricity, like light and sound, is not a physical material and therefore can exist only as long as the influence of its generating source continues. This property renders it impossible to directly store or preserve electricity for future use. Although such an end may be indirectly accomplished by the use of storage cells, which convert the kinetic energy carried by the current into potential chemical energy and later carry out the reconversion, the efficiency of this method is very low. For this reason, the use of storage batteries in supplementing the generation of electricity has been restricted to such purposes as involve the furnishing of a reserve to safeguard the service against interruption when some accident temporarily affects the generating, transmission, or transforming systems.

Electrical stations, being unable to economically avail themselves of the use of a reservoir which may be charged with the excess energy of the station at light load periods and discharged to assist the station at the heavy load periods, have to be designed with a capacity equal to no less than the maximum demand upon them. This factor of an installed station capacity at least equal to the maximum peak load is the greatest financial handicap to which an electrical station is subjected. That this condition is unavoidable has long been recognized and accepted by our business men and engineers.

The variations in the load which are demanded of a lighting station during the day and the characteristic difference between the summer and winter loads are shown by Figs. 1 and 2, of which Fig. 1 is a typical load curve for a summer day and Fig. 2 one for a winter day. (A typical load curve for the month of March is shown in Fig. 3. It will be noted that the time at which the peak occurs lies between the hours of the winter and the summer peak.)

Since it is only during the peak load of the day that the whole equipment of the station is working, it is evident that the return on the entire investment during the remainder of the day must be earned by that portion of the equipment that is then operating.

This is a condition that makes it highly imperative that an electrical station be operated with maximum economy throughout the entire day. Given a certain station equipment, this is mainly accomplished by a strict adherence to a regular daily routine. Thus, at any period of the day only that number of machines is operated which is sufficient to economically carry the load then existing. At times of light load or average load, a steam-driven station will have a large share of its boilers "banked" and a number of its generating units idle. When under such a condition a large unexpected demand for an increased output may be made so suddenly that the number of machines which are operating will be insufficient to carry the abnormal demand, and it is probable that the standard of service will be lowered until such time as reserve boilers and generating units can be brought into service. For this reason it is imperative that the station receives preparatory warning of any abnormal demand.

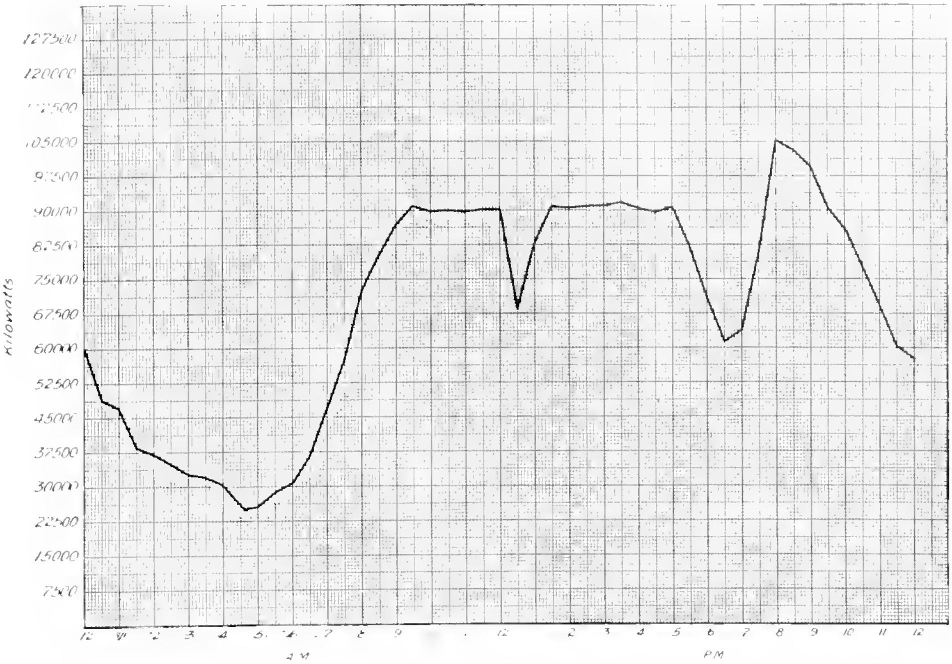

Fig. 1. A Typical Load Curve of a Lighting Central Station for a Normal Summer Day (1913)

Fig. 2. A Typical Load Curve of a Lighting Central Station for a Normal Winter Day (1913)

The rapidly moving clouds which accompany a storm constitute the principal cause for the sudden and unexpected increases in the demand for current from a lighting station. The effect which a sudden and heavy storm may have upon the station's output is shown by the sharp peak at the 3:35 p.m. point of the curve in Fig. 4. This is the record of an actual occurrence which took place during the month of March, 1911. It will be noted from this curve, and by a comparison with that of Fig. 3, that the demand at 3.35 p.m. is 73 per cent greater than it would have been had there been no storm. An increase of 49,500 kw., in this instance, was called for in about 5 minutes, which gives a good idea of the severe demands that may arise and which a lighting station must be prepared to meet.

Any device, therefore, that will provide a warning of the approach of a storm, at a time sufficiently far in advance to enable the station attendants to prepare for the exception to their daily routine in a deliberate and orderly manner, would be most welcome.

The storm detector is such a device.

### Storms and Their Effect on the Detector

All summer storms, or practically all of them, are accompanied by electrical disturbances in the ether. These cover a field far greater than that over which the storm clouds themselves are visible. By use of antennae, some of these radiations may be intercepted and by a suitable apparatus be made to give an indication of not only the presence but also the relative proximity of the storm.

The storms that occur during the winter months are usually snow storms and are of but a weak electrical nature. For this reason, they may perhaps not affect the device. At this season, that is a matter of but small moment. In winter, the load upon the stations during the daylight hours is uniformly greater than during the summer and the demand regardless of the severity of the storm will always be from 20 to 25 per cent less than the demand which occurs daily between 5 and 5:30 p.m., for which the station is always prepared.

This is evident when it is considered that winter storms have no effect on street lighting and other outside lighting, sign lighting, residence and apartment-house lighting, etc., all of which are on at the time of the daily peak at 5:00 p.m. For this reason, winter storms are of such minor importance that the service of the storm detector is dispensed with during that season.

### Description of Storm Detector

The various parts making up the detector are an aerial, a short-circuiting switch, a spark gap, a coherer, a relay and battery, a bell (which also acts as a decoherer) and battery, a condenser, and a ground connection. Fig. 5 shows the diagram of connection of these parts.

*Aerial:* Antennae, similar to the more simple ones used in connection with wireless telegraph outfits, have been found to serve the purpose admirably. It is this part of the equipment that receives the ether radiations resulting from the storm.

The oscillating current thus set up travels to and from the ground through the spark gap, coherer, and condenser.

*Short-Circuiting Switch:* This switch and its connections are shown in Fig. 5. Nominally, it is kept in the "open" position. After the alarm bell has begun to ring continuously, it is closed to protect the apparatus from heavy surges and to silence the bell.

*Spark Gap:* This consists of a simple gap with spherical terminals placed approximately $\frac{1}{64}$ in. apart. The purpose of this gap is to prevent those surges that are induced in the antennae by the radiations emanating from wireless telegraph stations, but which are very weak as compared to the lighting disturbances, from flowing through the remainder of the apparatus and thus causing a false alarm.

*Coherer:* This is also patterned after the type of the simple ones used in the early days of wireless telegraphy. In brief, it consists of a short section of glass tube of small bore loosely filled with nickel-silver filings. These are connected at each end to the outside circuit by german-silver plugs. The action of such a type of coherer is well known and needs no further explanation than to say that it acts as a high resistance to the low-voltage battery current impressed upon it until a high-frequency discharge current, between aerial and ground, has passed through it. This high-frequency current effectively lowers the coherer's resistance to the battery current, which consequently allows a greatly increased battery current to flow through the tube. The resistance of the tube then remains unchanged until it is violently jarred, at which time the high-resistance property returns.

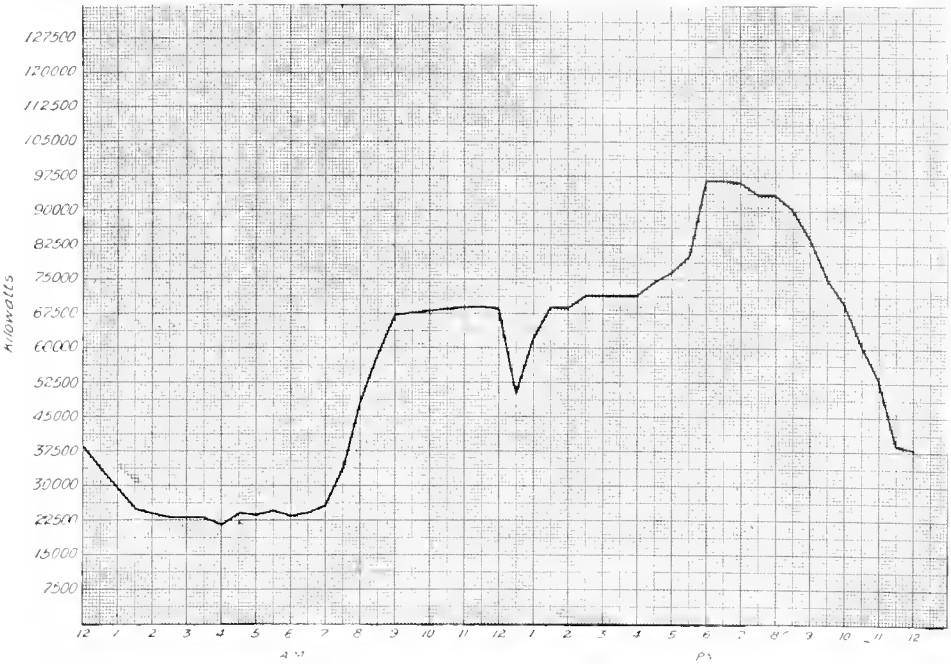

Fig. 3. A Typical Load Curve of a Lighting Central Station for a Normal March Day (1911)

Fig. 4. An Example of a Load Curve of a Lighting Central Station for a March Day (1911) during which a severe unexpected storm took place at 3.30 p.m. But for the abnormal peak occurring because of this storm, the curve would be similar to that of Fig. 3

*Relay and Battery:* The most effective type of alarm is an audible one, of which the simplest form is a bell. However, as a bell requires a greater amount of current for its operation than that increased amount of battery current which is caused to flow in the coherer by a high-frequency discharge, some magnifying or relay device must be used. The relay employed is one of the ordinary telegraph type and the battery $B_1$, Fig. 5, is of dry cells. The connections are given in Fig. 5.

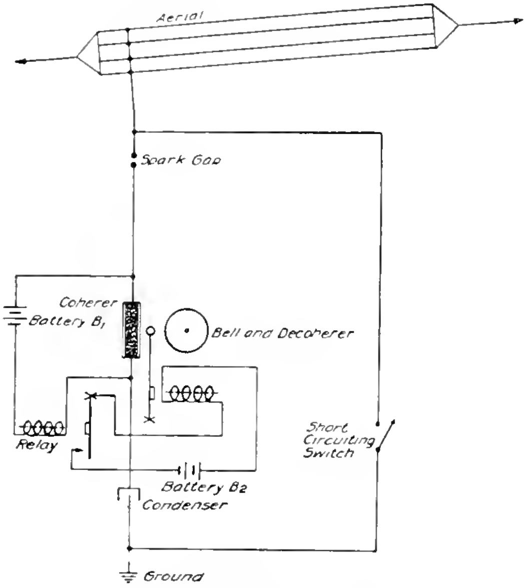

**Fig. 5, Complete Diagram of Connections of the Apparatus Comprising "The Storm Detector"**

*Bell and Battery:* The bell is one employing single-stroke connections and is of a size sufficient to be easily heard throughout the system operator's office. (The coherer, relay, condenser and bell are located in this office.) The bell has its own supply battery of dry cells, $B_2$, and is controlled by the secondary contacts of the relay, as shown in Fig. 5.

As the low-resistance condition into which the coherer is thrown by a high-frequency discharge is permanent until the tube is severely jarred, the bell is mounted so that its clapper will strike the tube and thus perform the two-fold function of bell and decoherer. (It is evident that the tube must be decohered, otherwise it would not show the effect of a later high-frequency discharge.)

*Condenser:* The condenser is an ordinary one and is inserted in the ground wire to prevent stray direct current from flowing in the apparatus.

*Ground Connection:* This connection completes the high-frequency circuit from aerial to ground.

### Operation

The operation of the apparatus comprising the storm detector leaves practically nothing to be desired. The manner in which it enters into the activities of a steam station will be described, as it is perhaps to such a station that it is of the most benefit.

It will be remembered that the bell or decoherer, together with the coherer and relay, are located in the system operator's office.

It is the duty of the system operator that he keep continuously posted on the demands that are or may be made upon the station for power and to so direct the disposal of all the generating machinery that the station will afford the highest quality of service and will operate with the maximum degree of economy. In detail, the latter function he performs by orders to the boiler room specifying how many boilers shall be maintained under load and how many shall be carried "banked," by instructions to the generating room as to which machines shall carry the load and which other units and auxiliaries shall be held idle or in readiness, and by orders to the various switchboard operators as to which feeders shall be used in the disposition of the output.

Under the usual daily conditions of operation the demand which will be made upon the station from hour to hour is accurately known, for the variations of the load curve constitute a daily cycle. These regular changes of load, being anticipated and taken care of by orders from the system operator, become a matter of station routine.

In order to secure smoothness of plant operation, the system operator is informed of the unusual departures from the regular load curve that are to be expected, e.g., exhibition lighting, etc., and also of the weather forecasts. All such is of great assistance in aiding good management. Those unusual irregularities of whose coming he is reliably warned present no difficulties. It has been found by operating experience, however, that the weather forecasts come far from providing a reliable and early warning. Further, the reports are not couched in such terms as furnish the system operator with the information that is of paramount importance to him, viz., the rapidity, in hours, of the approach of the storm.

It is true that the number of severe storms which come over a city with extreme rapidity is much less than that of the slower moving storms, but, on account of their tremendous capacity for suddenly deranging the orderly routine of the lighting station and perhaps even affecting the standard of its service, the fast moving storms make it requisite that all are to be guarded against.

Assume, for instance, such a storm to be approaching a city in which is located a lighting station that possesses a storm detector.

At a time varying from 2 hours to 7 hours before the actual storm clouds reach the city (depending upon whether the path of the storm is a direct or a round-about one), the alarm bell will begin to strike at intervals of from 5 to 15 minutes. The system operator regards this merely as the warning of the possible approach of a storm but gives it no further attention, for the storm may change its direction and pass off without molesting the quiet weather conditions of the city.

The disturbing conditions by their further approach cause the bell to ring oftener. With the storm but about two hours' travel away, the bell will strike about once every half-minute or every minute. When this occurs the system operator orders the reserve boilers into service, the auxiliaries of such generating units as he deems may be required started, and the generating units themselves run at low speed.

These conditions prevail until that later time when the bell gives an insistent warning by uniting its periodic strokes into a continuous ringing. This will ordinarily occur at about one-half hour to one hour before the storm reaches the city. It has been found quite often that even at this time the sky will remain clear and unclouded to the eye, which shows how much superior are the services of a storm detector to those of a watchman stationed upon the roof to observe the conditions prevailing in the sky. (This latter practice was the best one available prior to the development of the storm detector.) The switch short-circuiting the detector is closed when the bell begins to ring continuously to protect the receiving apparatus, for the storm will now be comparatively close, and to silence the bell for its warnings are no longer needed, since it is positively known by this time that the coming of the storm is a certainty. Simultaneous with this action goes the order to synchronize the incoming generating units with the bus. Everything is now in readiness to supply the increased load which will be demanded in but a matter of minutes.

The following are actual records of the frequency of the bell warnings and the loads existing at various times preceding two storms last year.

July 28.
  1:45 p.m. . . . . . . 1 bell.
  2:15–3:30 p.m. . . 1 bell every ½ to 1 minute.
  3:30 p.m. . . . . . . . bell began ringing continuously, load 96,000 kw.
  4:15 p.m. . . . . . . . (very dark, heavy rain storm), load 142,500 kw.

August 1
  8:25 a.m.–2.00 p.m. . . 1 bell every 3 to 5 minutes.
  2:02 p.m.–2:15 p.m. . . 1 bell every ½ minute, load at 2:00 p.m., 100,000 kw. (cloudy).
  2:15 p.m.–3:20 p.m. . . bell ringing continuously.
  3:45 p.m. . . . . . . . . . . . load 150,000 kw.

### Application of the Detector

The storm detector as described is in service and located in the office of the system operator in the Waterside stations of the New York Edison Company. These stations so far as it is known are the only ones possessing a device of the same nature.

The field for such a device among steam-driven lighting stations would seem to be in the larger cities, particularly in those which possess crowded office districts as it is the load derived from such a source that is most sensitive to changes in daylight.

A field in which it would also seem that the device would furnish valuable service is that of keeping the isolated hydro-electric station informed as to the weather conditions existing in the distant cities which it is supplying with lighting current. The places of generation and consumption being so far separated, a visual observance of the weather conditions at the power plant would be of no use. By means of storm detectors located in a few of the widely separated towns, which receive lighting current from the station, the attendants may keep forewarned by a bell in their station as to the irregular demands which may be made on them by storm clouds passing over those distant towns.

# SOME RECENT DESIGNS OF LARGE VERTICAL AND HORIZONTAL ALTERNATING CURRENT WATERWHEEL-DRIVEN GENERATORS

By M. C. Olson

A-C. Engineering Department, General Electric Company

The speed of waterwheel-driven generators varies over a very wide range, the head of water available being the chief factor in determining the speed and consequently the diameter of the machine for a given capacity. The author shows some interesting features in the design of both slow and high speed generators, e.g., one of the machines cited running at only 55.6 r.p.m. and having a larger diameter than any yet built. The mechanical design of some of the large units described are of special interest, and considerable attention is given to ventilation.—Editor.

On account of the wide variation in head of waterfalls throughout the country it is necessary to design large generators for speeds ranging from 50 to 600 r.p.m., and this fact has necessitated a number of different designs, in which the construction of the stator and rotor differs greatly, and in which special provision for ventilation must be made for the different speeds. This article is intended to show by means of sectional views and photographs some recent examples of these machines.

## VERTICAL MACHINES

Fig. 1 shows a 24-pole, 8000 kw. 0.6 power-factor, 13,333 kv-a., 250 r.p.m., 6600 volt generator. The temperature guarantee on this machine is 30 deg. C. rise for continuous operation at 8000 kw. with unity power-factor; 35 deg. C. for 8000 kw. at 0.8 power-factor or 10,000 kv-a.; and 40 deg. C. for 8000 kw., 0.6 power-factor, or 13,333 kv-a. At 25 per cent overload continuously the temperature rise is not to exceed 50 deg. C.; the temperature in each case being taken by thermometer or temperature coils.

This machine is arranged with shaft, two guide bearings, and base. As the thrust bearing is located beneath the generator no provision is made in the design of the generator for supporting the rotating element, thus simplifying the upper bearing bracket.

The armature spider is split in four parts, while the base and upper and lower bearing brackets are made in two parts on account of limiting dimensions and weights for transportation. The field spider, as will be noted, is made up in four sections of solid steel castings split at right angles to the shaft, thus making four wheels with rigid arms so designed as to take up their proper stresses. Making the field spider in sections in this way results in a more convenient structure for handling, and a more favorable shape for obtaining good castings. A steel reinforcing plate is arranged at the top and bottom of the field spider for supporting the ends of the field winding. The weight of the complete rotor is about 200,000 lb., and $WR^2$ is approximately 4,600,000.

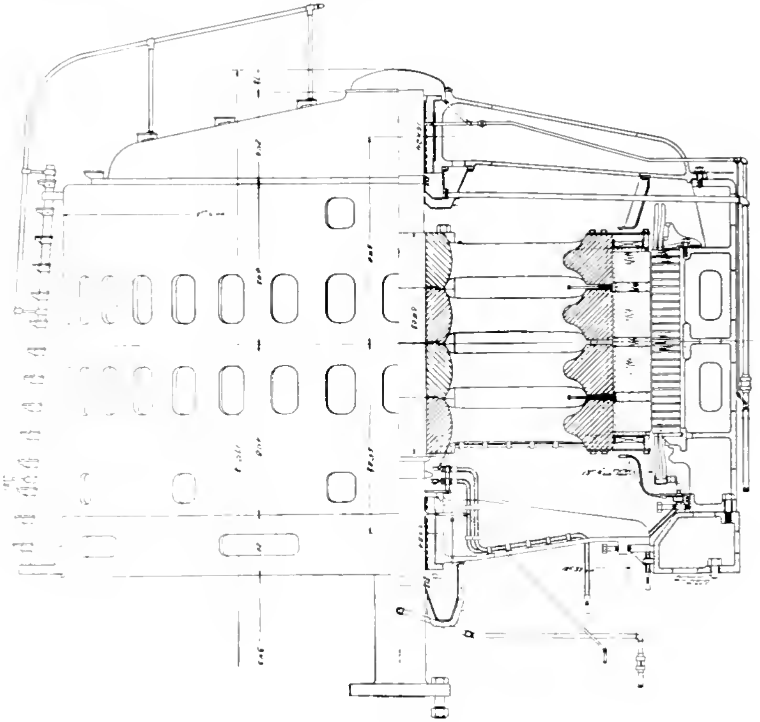

Fig. 1. 24-pole, 8000 kw., 0.6 p-f., 250 r.p.m., 6600 Volt Generator

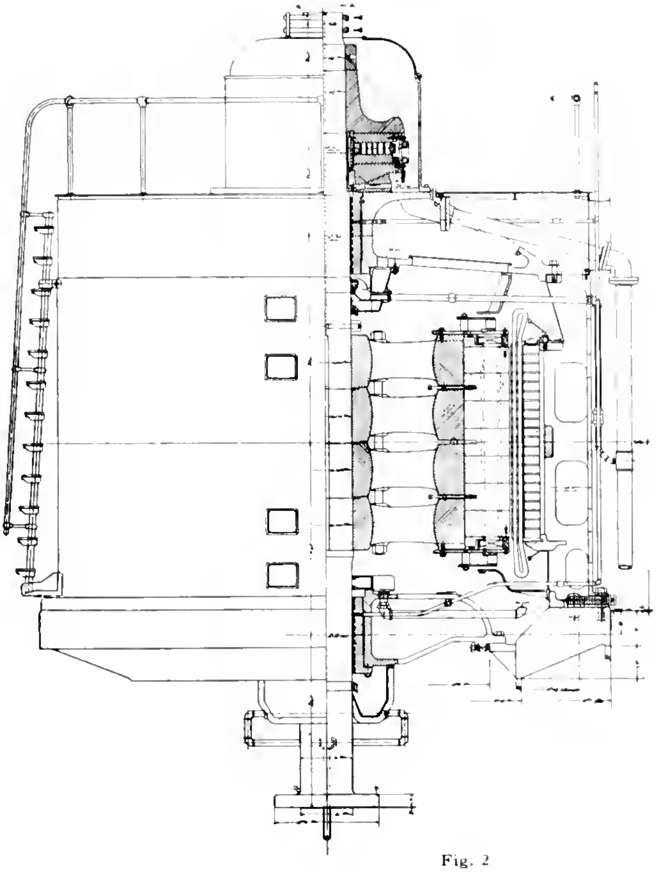

Fig. 2

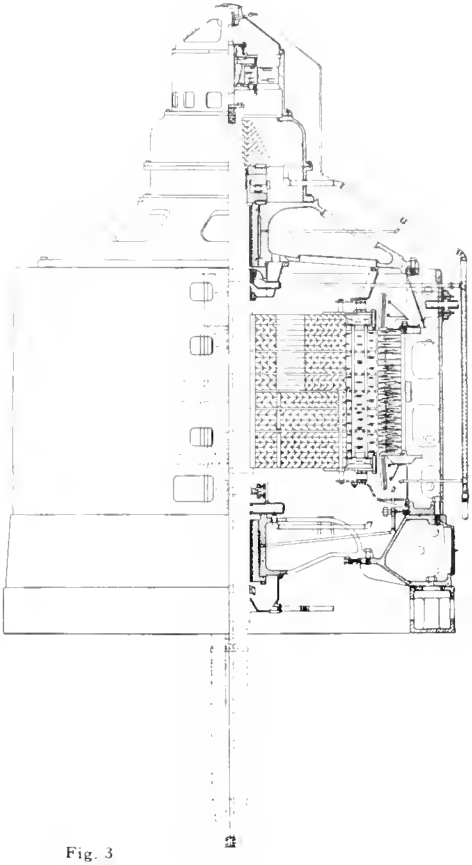

Fig. 3

Fig. 2. 18-pole, 10,000 kw., 0.8 p-f., 400 r.p.m., 11,500 Volt Generator

Fig. 3. 14-pole, 11,000 kw., 0.9 p-f., 514 r.p.m., 6600 Volt Generator

Fig. 4. 136-pole, 7500 kw., 0.75 p-f., 55.6 r.p.m. Generator with Single Runner Turbine.

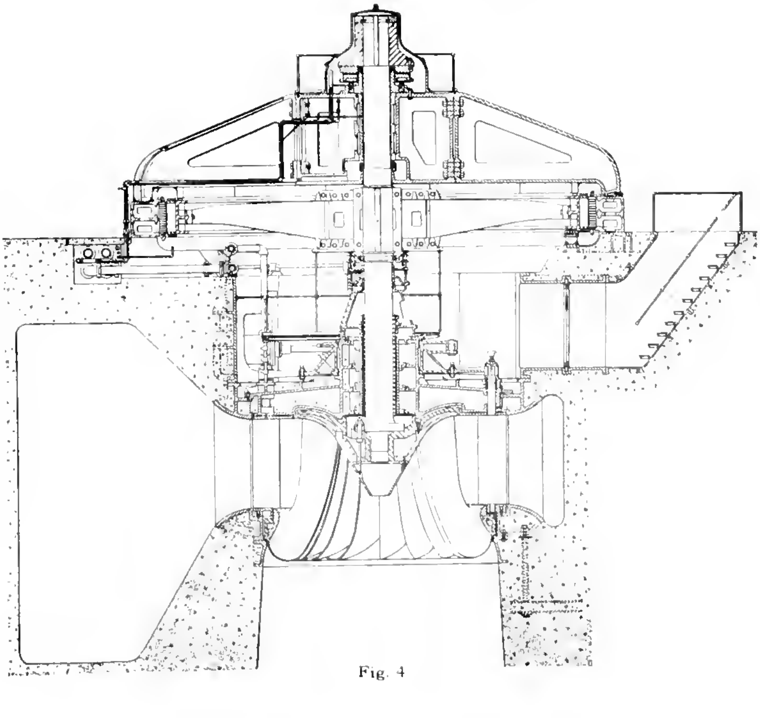

Fig. 4

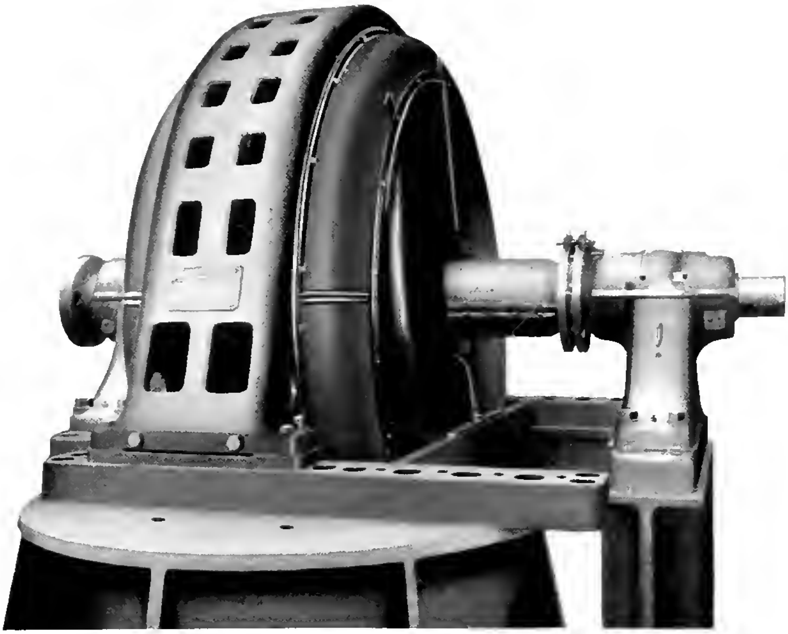

Fig. 5. 20-pole, 6250 kw., 0.8 p-f., 360 r.p.m., 4000 Volt Generator

Rotors for waterwheel-driven generators are designed to keep the stresses due to centrifugal force well within the elastic limit of all the material at the runaway speed of the waterwheels, which is usually from 80 to 100 per cent above normal.

Air for ventilation is supplied at the bottom of the machine and by means of bafflers is directed to all parts where heat is generated, and out through openings in the stator frame.

Fig. 2 shows an 18-pole, 10,000 kw., 0.80 power-factor, 12 500 kv-a., 60 cycle, 400 r.p.m., 11,500 volt generator. The heating guarantees are 50 deg. C. rise by thermometer or temperature coil. This machine has a combination roller and pressure bearing at the top for supporting the combined weight of the waterwheel and generator rotors, which is approximately 160,000 lb. and of which 25,000 lb. is the weight of the waterwheel. The hydraulic thrust in this case is nearly balanced, so that it may be neglected. The $WR^2$ of the generator rotor is 1,450,000.

Ventilation is provided for in a similar manner to that for the previous machine, except that the armature frame is entirely enclosed and the air, after passing through the stator, is expelled at the top.

Fig. 3 is a 14-pole, 11,000 kw., 0.9 power-factor, 12,222 kv-a., 60 cycle, 514 r.p.m. 6600 volt generator. The temperature guarantee is 50 deg. C. by thermometer. The machine is provided with a thrust bearing and direct-connected exciter at the top. The armature frame is entirely enclosed, and air for ventilation is admitted through large openings in the subbase, which is located between the stator frame and base.

On account of the peripheral speed of the rotor, the field spider is built up of a number of turbine plates approximately 2 in. thick, with large holes for ventilation. The total weight of waterwheel and generator rotors is approximately 147,000 lb., of which 12,000

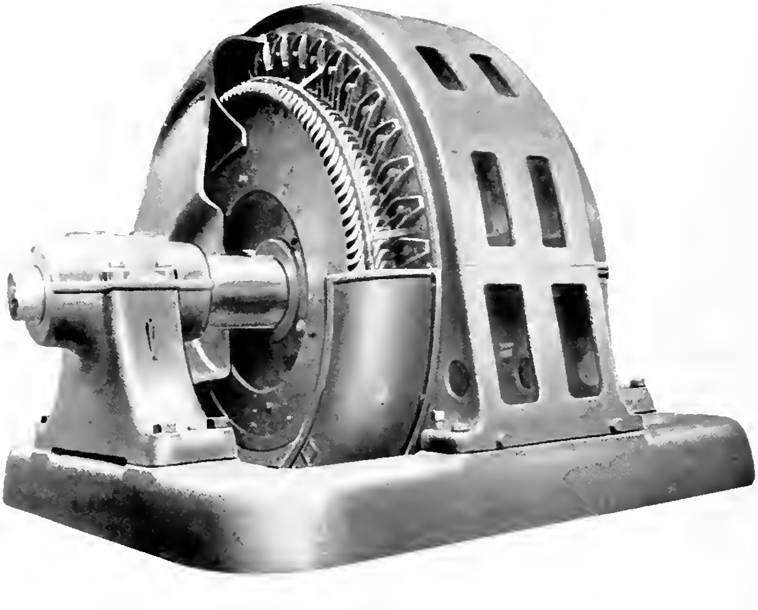

Fig. 6. 12-pole, 5600 kw., 0.8 p-f., 500 r.p.m., 11,000 Volt Generator

lb. is the weight and water thrust of the waterwheel. The $WR^2$ is 1,293,000. The maximum runaway speed of the waterwheel in this case is 975.

The lowest speed generator as well as the one of largest diameter ever built is shown in Fig. 4. This is a sectional view of a 136-pole, 7500 kw., 0.75 power-factor, 10,000 kv-a., 55.6 r.p.m. generator with single runner turbine.. Its temperature guarantee is 45 deg. C. for continuous operation, and 25 per cent overload for two hours without injury, the temperatures being taken by thermometer or temperature coil.

The weight of the waterwheel and generator rotors is carried by a roller bearing in the upper bearing bracket. The stator is made in four parts and is supported by foundation plates embedded in concrete.

The field spider consists of a cast iron field center made in two parts and a steel rim in four sections with bolted poles. The approximate weight of the generator rotor without shaft is 213,000 lb. and the total weight of the revolving elements including waterwheel is approximately 470,000 lb. The $WR^2$ of generator rotor is 31,000,000.

Ventilation is accomplished by fans at the top of the generator rotor and bafflers so arranged that the air, which is supplied to the bottom of machine, will not escape through the upper bearing bracket but will pass through the machine and out at the stator frame. Although these generators have large diameters, the peripheral speed is low and air for ventilation is supplied by blowers.

Most all large vertical generators are equipped with a brake to stop the revolving parts within a reasonable time. This brake is usually supplied by the waterwheel makers and works against the lower surface of the field spider rim.

Fig. 8. Field Spider of Generator shown in Fig. 7

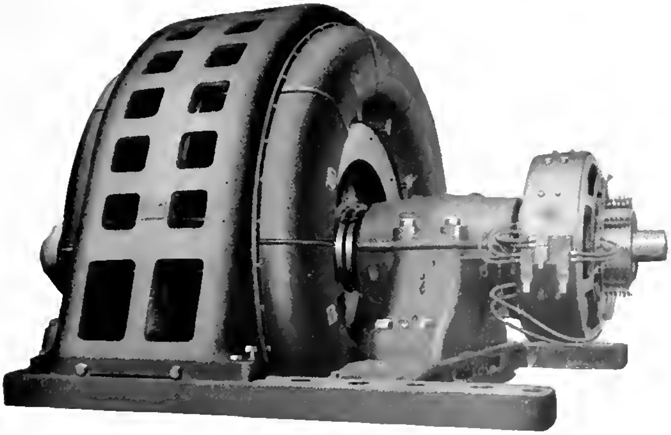

Fig. 7. 20 pole, 7500 kw., 0.8 p-f., 360 r.p.m., 6600 Volt Generator

### HORIZONTAL MACHINES

Illustrations of several horizontal machines are included, which show the general features of design and the means that have been adopted to secure proper ventilation.

On large units operating at certain speeds it is necessary to make special provision to prevent the warm air from passing through the machine again and again.

Fig. 5 shows a 20-pole, 6250 kw., 0.8 power-factor, 7800 kv-a., 60 cycle, 360 r.p.m. 4000 volt generator. Its guarantee for continuous operation is 40 deg. C. rise by thermometer. This machine has ventilating hoods to which air is carried by ducts in the station; the air after passing through the machine, being discharged into the room through large openings in the stator frame.

Instead of a regular base, this generator has foundation plates, and subbase for standards. Provision is made for movement along the shaft for convenience in repairing, It is, of course, necessary to remove the ventilating hoods before moving the stator.

Another type of construction is shown in Fig. 6. This is a 12-pole, 5600 kw., 0.8 power-factor, 7000 kv-a., 50 cycle, 500 r.p.m. 11,000 volt generator, with standard 25 per cent overload guarantee. In this case a base is provided and the bearings are equally spaced. Details of the ventilating hood are shown, as well as the method for clamping the armature laminations and anchoring the armature coils to an insulated steel ring by non-metallic lashing.

A very compact arrangement is shown in Fig. 7 which represents a 20-pole, 7500 kw., 0.8 power-factor, 6600 kv-a., 60 cycle, 360 r.p.m., 6600 volt generator with standard 25 per cent overload guarantee for 2 hours. Movement of armature frame for repairs is obtained in this case without the additional expense of heavier shaft and larger bearings, and without removing the exciter. The shaft at the exciter end is first blocked up, and the shields at the waterwheel end and the lower section of shields at exciter end are removed. The bridge under the bearing pedestal at exciter end is next removed and the stator then raised by means of adjusting bolts and rollers inserted in the track under the armature spider foot. The stator now can be moved along the shaft over the bearing and exciter.

The field spider for this generator is shown in Fig. 8. It is a steel casting made in two sections, with an opening at the center for ventilation.

# PUBLIC UTILITIES AND PUBLIC OPINION

By G. R. Parker

Turbine Department, General Electric Co.

This is an article dealing with the relationship between the public and public utilities. The author defines public utilities and notes specially that they are dependent upon the public. The author points out that some industries by their nature should be monopolies where competition in others is desirable. The regulation of public utilities by means of commissioners is dealt with, and it is pointed out that the regulation of such is for the benefit of all concerned. The public is protected against inefficient service and exorbitant rates, while the public utilities are guarded against the granting of franchises which would lead to the unnecessary duplication of service in one district. The author pays considerable attention to rate making.—Editor.

Public utilities may be broadly defined as those business enterprises which supply a community or a group of communities with a class of service not readily produced by individuals, and depending for its successful operation on the patronage of a large proportion of the population. In recent years the term has come to apply more generally to telephone and telegraph companies, electric railways, gas, electric light and power companies. However, steam railroads and steamship lines may properly be considered in the same category, since most of the general conditions governing them are similar.

In defining a public utility, attention has been called to its dependence upon the public. Yet in spite of the fact that its success, if not its very existence, is dependent upon the good will of the public, probably no other class of business enterprise has been the subject of greater antagonism, abuse and villification. Some manufacturers have grown rich by the exhorbitant profits on their products, some tradesmen have swindled and over-charged the public, many wild cat mining schemes have been successfully launched and their promoters enriched by a confiding populace; yet in no large number of such cases has the popular animosity and distrust been so generally aroused as against these corporations furnishing light, transportation and other modern necessities. Doubtless, in the past the public has had much justification, but it is probable that back of it all is the perfectly human dislike for paying for the intangible. It is human to like to have value in hand for money expended. A railroad ticket costs money. The bit of pasteboard doesn't look as if it were worth it. No matter what the amount, the resulting transportation does not seem like an adequate return. A gas or electric light bill is rendered the first of the month. No one likes to pay it. There is nothing to show for it. If it is larger than last month, probably the meter is wrong. At any rate it is too much. Many a crabbed customer of the lighting company would more cheerfully pay for a barrel of kerosene outright, and have something to show for his money than pay an equivalent amount for gas upon presentation of the bill.

In times past it is true that in many instances the Public Service Corporation was inclined to disregard public opinion; but in recent years, the more progressive companies have realized that even though they possessed a monopoly, no lasting success could be achieved without the good will of the community. Today we see everywhere evidence of the tendency to regard the interests of the public. Telephone and telegraph companies are constantly seeking to better their service. Street railways are endeavoring to provide better equipment. Electric light companies in particular have been active in establishing closer relations with the people whom they serve. It is not unusual to find the local electric light company the leader in arousing civic sentiment and in doing gratuitous advertising for the general betterment of the city. Evidently the company profits, along with other local enterprises, with an increase in the number of industries and the population. In addition they have done much to educate the public in the uses of electrical apparatus, both in its domestic and industrial application. Whether or not an altruistic motive should be attributed to the supply company, the net results are a benefit to the community.

Perhaps one of the principal causes of distrust is the fact that usually the public utility is a monopoly, and the individual is, therefore, obliged to accept its service or do without. The theory has often been advanced and occasionally put into practice that better results will accrue to the public through more than one competitive company supplying the same service. The fallacy of this is now generally recognized. A public utility is a natural monopoly. We cannot have two pairs of railway tracks through our streets. We cannot have our pavements torn up by several gas companies. We do not care to see the number of electric light and telephone poles doubled. Many similar examples could be cited. In addition, the cost to the consumer in such cases must inevitably be more in the end, due to the duplication of capital and consequent interest charges, the duplication of administrative charges, and of selling organizations and all those other items comprising overhead charges, which must be figured in the final cost of the product.

In other commercial enterprises a certain amount of healthy competition is no doubt of general benefit. Two merchants selling a community the same character of goods exercise a desirable influence over each other; and their product and method of doing business are necessarily kept at a high standard and both the public and they themselves are benefited. But the transaction of this competitive business does not involve the entire occupancy of the public thoroughfares, curbs and sidewalks.

Admitting, therefore, the necessarily monopolistic character of the public utility, the problem arises how to avoid the inevitable abuses which are bound to arise and how to encourage as good service and as low prices as would maintain were there open competition. This problem has been partly solved by the Public Service Commissions created in most states, and the supervision and regulation of rates by them.

While the scope and powers of the Public Service Commissions vary in the several states, in general they perform two broad functions. On the one hand they regulate the amount a corporation can charge the public for service and on the other they prevent the establishment or the granting of franchises to competing enterprises where service is being satisfactorily rendered by an existing company. In other words, the broad function of the Public Service Commission is to preserve the monopoly as such and at the same time prevent it from imposing on the public.

In some cases the Public Service Commission goes further than to merely pass on the rate for service based on the cost of the latter. It insists that the service shall be of a character consistent with the best modern practice, comparable with that obtainable in other similar communities, and that the cost shall be based on efficient methods of production.

A few examples of Commission regulations will be of interest. Recently a gas and electric light company applied to the Wisconsin Commission for permission to increase its rates. The Commission not only refused to grant the increase, but on the contrary ordered a reduction in rates. The decision notes that the interests controlling the property had actively extended the gas business, but had done little to develop the electric light and power business along modern lines. Commenting on this, the Commission states: "Companies holding indeterminate permits, whether for single or joint utilities, have assumed the responsibility for the highest reasonable development of their business, as well as for adequate distribution and sale." The decision further states that consumers should not be compelled to bear the high costs resulting from "what might be termed the neglect of the management to stimulate properly the sale of the utility product." In this case the corporation was penalized for failure to push its own business.

In another instance the Public Utilities Commission of the state of Oregon has denied application for the establishment of electric supply companies in districts already served. In rendering its decision, the Commission states: "One Company properly regulated and administered can generally give better and cheaper service than two.... Most utilities are natural monopolies, and the highest efficiency and lowest rates are possible only when each one has the entire business of a given city or territory."

Here we find the Commission protecting the established enterprises from competition. Similar decisions have been rendered by the Commission in Wisconsin, California and other states.

It is true that regulation has its disadvantages. A private undertaking in open competition with others of a similar character is privileged to charge whatever it can get for its product and retain its trade. The necessity for making competitive prices is a great stimulus to the most efficient methods of production and sale. On the other hand if a public utility is compelled to limit its profits to some pre-determined percentage, the incentive to strive for low production costs is largely eliminated. If a decrease in costs is immediately accompanied by an enforced reduction in selling price, it is evident that the tendency is to expend less effort on reducing costs. In other words, if the reward for originating new and better methods ceases, less brains and money are likely to be expended in perfecting such methods. It remains to be seen whether the state Commissions can devise satisfactory means for encouraging efficiency, and at the same time limit exhorbitant profits.

Another question which has taxed the genius of those interested is whether or not a corporation may add to the value of its physical property out of its earnings and then consider the increased valuation as a capital charge on which to base the percentage of subsequent net earnings. Assume for example, a corporation with a property valued at a million dollars. Assume also that the commission allows as a fair profit 6 per cent net, or sixty thousand dollars to be divided among the stock-holders. The corporation in due time decides that a larger or better plant is needed, and from time to time takes from its gross earnings enough to increase the real value of its physical property to a million and a half, at the same time maintaining rates which net the stockholders 6 per cent. It now appears that the total capital charge on which the rates are based is a million and a half instead of a million, and the public are therefore paying an interest charge on money which they themselves have contributed. The courts have generally held that the undertaking can set aside adequate funds to take care of depreciation and maintain the plant at high efficiency. But just where maintenance for depreciation stops and increase in plant value begins, is one of the vexing questions with which the courts and the commissions are constantly wrestling.

A phase of the situation as regards electric supply companies, which the lay public often fail to understand, is the reason for the wide difference in rates charged. A manufacturer pays the local electric concern say four cents per kilowatt-hour for power delivered at his factory. He goes to his residence and uses electricity supplied by the same company and his bill is based on ten cents per kilowatt-hour. If it is a steam plant, the same coal is being burned, the same boilers supply steam, the same turbines or engines generate electric current. A natural assumption is that the small consumer is paying more than his share. The fact is that a scientific study of the actual costs will often show that the reverse condition holds true; that the profit made on the ten cent rate is less than on the four cent rate. The causes of this are numerous, and some of them exceedingly complex. The general conditions governing wholesale and retail trade of any kind apply. It always costs less to sell a product in large lots than in small. The cost of selling to one customer is less than to several. The administrative and accounting charges and other general overload expenses are less. But this consideration is among the least in establishing the difference. It must be remembered that investment charges form a large part of the cost. To supply a single power customer with 100 kilowatts involves one set of transmission wires, one transformer, one meter. To supply twenty residences with a maximum demand of 5 kilowatts each, requires a perfect network of wires and poles, and practically as many transformers and meters as there are houses served. The total power sold is the same in both cases, while in the latter the investment required to supply service to the twenty small users is enormously greater. The cost of maintenance of service, repairs, renewals, etc., are similarly larger.

But another and more important condition exists, governed by the time of day and the time of year electric service is required. It is not generally appreciated that the average residence takes electric current for lighting for brief periods of the twenty-four hours. In winter the lights are turned on about five in the afternoon, and reach a maximum between six and seven, then gradually diminish toward midnight. In other words, the power house supplies current for lighting during about seven hours of the day, and the bulk of it is supplied during a period of two or three hours. This causes what is called the "peak load" on the power house. Its value depends on the amount of load carried by the station during the remainder of the twenty-four hours. In a majority of cases the peak load is more than double the average load for twenty-four hours, and occurs regularly each day. In addition, the lighting load causes an annual peak due to the fact that during winter, people turn on lights earlier, and since they spend more time in the house, a greater number of lamps are in service. This annual peak occurs the latter part of December, and is augmented by the increased lighting of residences and stores during the Christmas holidays.

Now let us see what these peaks have to do with costs. The manufacturer of electricity differs from nearly all other manufacturers in that he is unable to store his product. He must produce it at the very instant it is being consumed. In other lines of business production can be fairly well distributed by manufacturing the product during dull times and storing it in anticipation of a larger demand. Even the gas companies which have similar peaks can store up their product in tanks. In all these cases manufacturing equipment and labor need be only large enough to provide for the average output. The electric light plant, however, must provide generating apparatus and all the complex power house equipment, with necessary labor, to properly take care of the peak load, lasting but two or three hours a day. It must have large and expensive machinery standing idle nearly all day to light the city houses for a few hours each evening. All this means an investment bearing interest which must be figured in the rate.

The power load, however, consisting of electric motor service to various industrial customers can be counted on for all day, and sometimes at night. It is large and steady. The apparatus in the plant which produces this power would have to be there anyway, to take care of the lighting peak. If it can be used in the day time a low rate for power is justified, because the investment is in use for a longer period. The object of all electric company managers is to get as large a day load as possible. Evidently the larger the day load the more it is possible to reduce the rate for lighting. But even in the best managed companies, the day load seldom equals half the lighting peak. There is, therefore, no other just basis for figuring rates than to charge the lighting rate with the interest on the relatively large equipment necessary for supplying current during the two or three peak hours. Furthermore this investment must be based on the equipment necessary to carry the load during the holiday season in December, or at the time of the annual peak, since apparatus must be carried and maintained throughout the year for that one period.

Even this is not sufficient. Ample reserve apparatus must be installed to provide for breakdowns and repairs. Beside this the supply company must consider what is called its total connected load. By this is meant the number of lamps and motors which could be simultaneously thrown on the system. For example, in our houses there may be twice as many lamps as we ever use at one time. Yet the company must be ready to supply current if the unusual happened, and for one cause or another a large part of its customers decided to turn on all their lights at once.

In a word, a very much larger investment has to be carried to supply residence lighting than for an equivalent number of kilowatt-hours for motor power.

It has been suggested that an average rate for all classes of service should be established. A current writer* commenting on this, points out that the only conditions under which a schedule of charges based on average costs can succeed are those resulting from a natural or artificial monopoly, as for example, our postal system. This is an extreme case of average costs, since a letter may be sent across the street or across the continent for two cents. In the past, some local enterprises have undertaken to deliver mail within a given city at less than two cents. But the federal government has maintained its monopoly by making it a penal offense for anyone to compete against it in the carrying of letters.

Let us consider for a moment the somewhat analogous situation in reference to the steam railroads. Freight rates vary with the material handled and the character of the train. Goods going on a fast freight cost the shipper as high as five cents per ton mile. Coal on the other hand has a rate of about five mils per ton mile. Yet coal at that rate actually nets the railroad more than the high class merchandise of the fast freight. The reason is, that the latter usually runs with cars two-thirds empty. The "l.c.l." or less than car load lot is the bane of the traffic manager. It means that the dead loss of transporting the weight of the heavy trucks and the car above is not being compensated for by the maximum possible revenue producing load It costs almost as much to run a string of empty cars as one fully loaded. The train load of coal is run at maximum capacity, it moves right along without stop. Not only is coal cheaply handled at shipping points, but it has only to be handled twice—to be loaded and unloaded. Hence the statement which is truly made, that the railroads will transport a ton of coal three miles for a postage stamp. And that is more profitable than transporting a passenger weighing about a tenth of a ton, a third of the distance at the same price.

Railroad rates are older than electric light rates, and wide variation for different kinds of service rendered have stood the test of time. A farmer does not complain that it costs more to transport sheep than bailed hay, or that it costs more to transport his family than it does his sheep. And the farmer will, in time, come to realize that it may be quite as reasonable for him to pay the nearest electric transmission company one rate for power for his threshing machine, and another rate for lighting his house.

Indeed it is quite likely that before long various systems now in process of development will permit a housewife to iron and cook by electricity at a comparatively low rate, while electricity for illumination, although supplied from the same transformer and distribution lines, will be charged at a higher rate.

No criticism of charges is justifiable without due consideration to the value of the service rendered the consumer. Evidently, electric light service would not be worth much if it were available only in the day time, or if it were supplied only every other night, or if only two or three lamps could be lighted at once. It is the value of all the elements combined in the word "service" that the consumer pays for.

Obviously, there is nothing to compel an individual to avail himself of the service offered by an electric supply company. He is at liberty to burn kerosene if he prefers, and can operate his own engine for power. But a large percentage of present day consumers had decided that central station service was worth a definite value to them, before present comparatively low rates were in effect, and before modern high efficiency lamps had cut lighting costs in two, even based on the old rates.

Close study leads to the conclusion that most public utilities, even without the stimulus of competition, are making a constant effort to let the public share the benefits resulting from improvement in the art, and to give the community greater value for each dollar it expends.

As time goes on, the public will more and more come to realize that because a corporation is big it is not necessarily bad, and that because it has a monopoly does not means that it will resort to extortion. The interests of the public and the public service corporation are mutual, and will be best served by a common undertaking of each other's problems, and a proper tolerance for the occasional faults due to human weakness and human frailty.

# EDDY-CURRENT LOSSES IN SHEET STEEL AS A FUNCTION OF THE RESISTIVITY

By J. D. Ball and W. E. Ruder

Consulting Engineering Department and Research Laboratory, General Electric Company

It has been assumed for some time that the eddy-current losses in various magnetized materials vary inversely with the specific resistance. A number of observations have shown, however, that such is not always the case. For instance, certain silicon steels of five times the resistivity of common iron have been found to give only half as much eddy-current loss as the iron; and also certain heat treatments, which do not materially alter the resistivity, increase the eddy-current losses. It is also shown that the eddy currents increase rapidly with grain size up to a point where the grains can easily be seen with the naked eye. This article gives the results of several tests which have been made in an investigation of the factors influencing eddy-current loss. In addition it points out the unsatisfactory state of the knowledge on the subject at the present time.—Editor.

The present article gives the data of tests which have been made on sheet steel, and although the results herein recorded are insufficient to define a law, they may at least afford a step toward that end.

A few of the variables affecting eddy-current loss are generally accepted. For instance, its dependence upon the general kind, shape and geometrical construction of the sample tested, its variation with the square of the thickness of the laminations and with the square of the frequency and of the induction are acknowledged. For a given variety of steel this eddy-current loss has been found to be practically independent of the total loss except in that it is a part thereof, and, as is the resistivity, it is independent of the manner of cutting, so far as the grain or direction of rolling are concerned.

Eddy currents are induced currents and it would be expected that, other things being equal, they would vary as the induced voltage unless the thickness of the plates are sufficient that screening would appreciably affect the flux distribution. Following ohm's law, the resultant loss would therefore vary as the square of the amount and rate of flux change. We might also expect that, as these induced currents are flowing in the metal as a conductor or short-circuited secondaries of a transformer, the amount of current and loss would vary inversely with the electrical resistance of the material. The latter, however, has been found not to be the case. A few values that have been determined in the standardizing laboratory are here plotted to show the relation of eddy-current loss and resistivity, although the tests were not made with this purpose in view. Fig. 1 gives plotted results of a number of separation tests of Epstein samples. This method of testing consists in measuring the loss, at various frequencies, of a 10 kg. (22 lb.) sample of steel strips 50 cm. ($19\frac{11}{16}$ in.) by 3 cm. ($1\frac{3}{16}$ in.) built into a square magnetic circuit, details of which have been published elsewhere and need not be repeated here.* These results show that the eddy-current loss does not vary inversely as the first power of the resistivity. The average value of eddy-current loss for silicon steel is about one-third as much as that for standard iron, although five times the resistivity. Taking the standard iron alone, we find a variation as high as 400 per cent in eddy-current loss for the same resistivity and a variation of 45 per cent in resistivity for the same eddy-current loss. The tests were made assuming the specific gravity of standard steel as 7.7 and of silicon steel 7.5. Although some of the separation tests were made at two frequencies only, the errors of test are not large enough to appreciably alter the results. The plotted points in many cases are representative values of several samples.

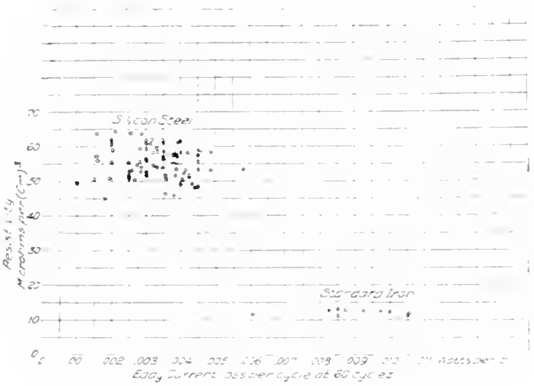

Fig. 1. Eddy-current Loss in Epstein Samples Having Different Values of Resistivity. B = 10,000

---

*ETZ—1900, pp. 303-307; 1905, pp. 403-411; 1911, pp. 334-339, pp. 363-368.

ASTM, Specifications for Magnetic Testing of Iron and Steel, 1912.

Trans. A I E E., Vol. XXX, 1911, pp. 747-755.

The eddy-current loss has been defined at "per cycle at 60 cycles." As the separation tests obtained gave practically straight lines, the per cent variations would be the same taking any ordinary frequency.

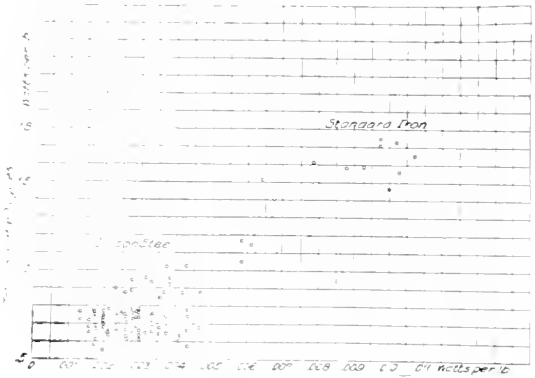

Fig. 2. Eddy-current and Total Loss in Epstein Samples. B = 10,000

Eddy-current loss is partly a function of the total loss as it is a component thereof; the hysteresis loss, however, being of the order of 80 per cent of the total loss at 60 cycles and at $B = 10{,}000$ is sufficient to overshadow this. Fig. 2 shows plotted values of eddy-current loss compared with total loss. Examination of the values for silicon steel shows eddy-current loss variations as high as 200 per cent for the same total loss, and total loss variations of 70 per cent for the same eddy-current loss.

These relationships may also be noted when the samples are tested as straight strips and the magnetic circuit is closed through air. In such a case the measured eddy-current loss, and consequently the total loss, is greater for the same weight of material than would be obtained in a closed ferro-magnetic circuit, and the measured eddy-current is not the same as would ordinarily be represented as the eddy-current in the iron. The unequal flux distribution alters the conditions somewhat; for example, if the test is made to give a hysteresis loss equivalent to a given uniform induction, the eddy-current will not be the representative value for the same induction, due to the difference of the loss exponents by which is determined the point where the induction is the same as that for which the properties are desired.

Figs. 3 and 4 show the results of tests made on 1 lb. (454 gr.) samples of straight strips 10 in. (25.4 cm.) by ½ in. (1.27 cm.) according to a separation method elsewhere described.* Fig. 3 represents the eddy-current loss derived from such tests on some 200 samples in which 19 cycles, 16 cycles, 13 cycles, and 10 cycles were the frequencies employed. The eddy-current loss is taken as the loss per cycle at 10 cycles and plotted as a function of the resistivity. In this case the silicon steel of five times the resistance of standard steel has about 4 7 as much average eddy-current loss. Here we find 200 per cent variation in eddy-current for standard steel of the same resistivity, and the same amount of variation in case of silicon steel. For constant eddy losses, the resistivity variation is 80 per cent for standard iron and 25 per cent for silicon steel, although, in amount, the variation for silicon steel is greater. While this variation in eddy-current loss is large, when it is remembered that this loss is a small per cent of the total loss at the testing frequency of 10 cycles, it will be seen that the average eddy-current loss, for any given kind and thickness of material, subtracted from the total loss will give sufficiently accurate hysteresis results. This is the method of procedure for which the outfit employed was designed. The adding of an average eddy-current loss to the hysteresis loss of a given material is also sufficiently accurate to determine the Epstein 60-cycle core loss

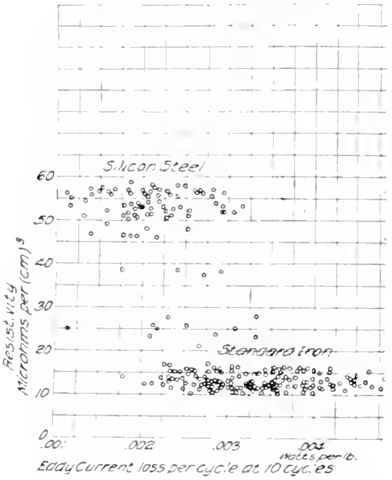

Fig. 3. Eddy-current Loss in 10 In. by ½ In. One Pound Samples. B = 10,000

required for ordinary commercial testing. For such a purpose, the eddy-current loss has been stated to be a function of the resistivity, if the variety of heat treatment

---

* Trans. A.I.E.E., Vol. XXX. 1912, pp. 743-747.

of the steel is known.* Plotting the eddy and total loss values obtained on the 1 lb. sample shows the independence of these functions. For constant total loss, the eddy-current variation for standard steel is 80 per cent and for the silicon steel 175 per cent.

An interesting phase of the matter lies in the results of investigations conducted to examine certain special annealing methods. A special heat treatment super-imposed upon a regular factory anneal was found to radically change the magnetic properties, and show a decided increase of eddy-current loss although the resistivity was practically unaltered. Table I gives some of the results obtained. The variation in average eddy-current loss of 20 samples is greater than the variation in average resistivity; whereas, analysis of Fig. 1 showed the contrary. The special heat treatment referred to alters the granular structure of the material by the formation of unusually large grains, which may account for the differences in general behavior,† although qualitative tests indicate that the resistance of a definite length of a strip is the same whether length be taken within a single grain or from grain to grain. Resistance measurements made on long wire, of 0.025 in. silicon steel, however, show that the large-grained material has a resistance 15 per cent lower than the same wire in the fine-grained state. By examining the structure of the sheet it was found that the eddy currents increased rapidly with the grain size up to a point where the grains could be easily seen with the naked eye. Above this size there was little change in the eddy-current loss, e.g., for steels of a certain composition, a value of about 0.0044 was obtained which remained practically constant for a wide range of grain size. It was also found that annealing in a reducing atmosphere would considerably increase the eddy currents independently of the change of grain size.

### TABLE I—RESISTIVITY AND EDDY-CURRENT LOSS OF EPSTEIN SAMPLES

| Sample No. | ANNEAL AT 800 DEG. C. | | SPECIAL ANNEAL AT 1300 DEG. C. | | SUPERIMPOSED ANNEAL | |

| Avg. 20 | 0.00295 | 58.0 | 0.00334 | 56.84 | | |
| Avg. 15 | 0.0031 | 54.8 | 0.0035 | 55.2 | 0.0042 | 53.1 |

Eddy-current loss values are given in watts per cycle at 60 cycles, $\beta = 10{,}000$.

Resistivity is given in microhms per cm³.

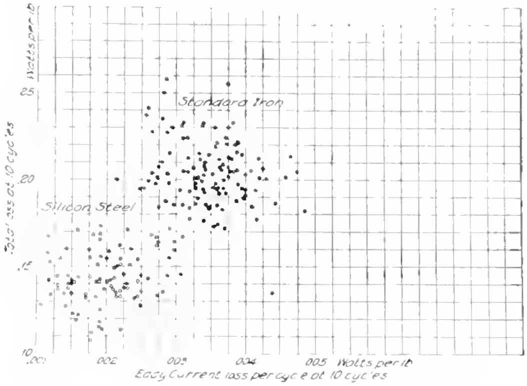

Fig. 4. Eddy-current and Total Loss in 10 In. by ½ In. One Pound Samples. B = 10,000

All samples referred to in this paper were cut from 0.014 in. sheets.

The conclusion from the foregoing data is that the eddy-current loss does not vary inversely as the first power of the resistivity and the effect of heat treatments and other considerations are so large that, except in a very general way, no definite value may be given for the power representing the variation. For a given variety of steel, therefore, no statement of a law seems warranted.

---

[*] From Electrotechnik und Maschinenbau, Vol. XXXI, 1913, pp. 737-742:

Eddy-current loss in watts per kilogram $= \frac{c\,(d\,n\,\beta)^2}{s\,\rho}$, where $c$ is a factor, $d$ thickness of plate in mm., $n$ the frequency, $\beta$ the induction, $s$ the specific weight, and $\rho$ the resistance in ohms $\frac{m}{mm^2}$.

# ECONOMIES IN THE OPERATION OF ELECTRIC CAR EQUIPMENTS

By J. C. Thirlwall

Railway and Traction Engineering Department, General Electric Company

The author, after having made a thorough investigation of the operating conditions at El Paso, records in this article the means adopted to greatly decrease the power consumption per car mile. The special physical conditions of the system are cited, which show that some of them are usually severe. Wattmeters were installed on the cars and a predetermined normal power consumption, called a bogey, was established for each run. Motormen kept records of the power used on each trip, and these, compared with the bogey, form a measure of the efficiency of operation. The spirit of competition that this system has developed between the men has led to very material savings, both in the power bills and in the cost of maintenance, as the maintenance charges are reduced by motormen immediately reporting defects in the equipment that would lead to inefficient operation. Actual service data are given.—Editor.

The writer was recently given the privilege of looking over some of the operating records of the El Paso Electric Street Railway Company at El Paso, Texas, and noted certain features in the operation of the system which are unusual in America. As the practices referred to have reduced the cost of power and the maintenance of electrical equipment, it is believed that they are of sufficient interest to record in the Review.

Operating conditions at El Paso are in many respects unusually difficult. The city is situated in the valley of the Rio Grande river, and surrounded on three sides by mountains and foothills, so that the majority of their lines have to climb long, steep grades. Some of these run up to 6 per cent or 8 per cent. This has necessitated the general use of four-motor equipments on double truck cars, with a heavy weight per passenger as compared with the two-motor maximum traction equipments so widely used in city service. Moreover, the town being situated in a desert country, where suburban property values are low, it has spread out over an unusually large area in proportion to its population, so that the average length of ride and the track mileage is high in proportion to the population served. These conditions have made overhead expenses and the cost of power more serious items than they are in the average city, and necessitated the closest analysis of every detail of operating expense to keep the road on a paying basis.

A study of power station records some two years ago showed a steadily rising cost per car mile, which was out of all proportion to the normal increase in traffic. In analyzing this it appeared to be largely due to the manner in which motormen were handling their equipment. To verify this, and as an aid to correcting the evil, wattmeters were installed on every car on the system. Tests were then made in the following manner to establish the standard figure for power consumption of each type of car on each line on which they operated. Experienced motormen made a number of runs on every line, under the personal supervision of an official, who watched and instructed each man in the rate of notching up the controller, particularly on grades; in the handling of his brakes, with especial reference to preventing starting up or running with brakes partially applied; and in coasting, with the object of securing as much coasting as possible, particularly at the lighter hours of the day, when the tendency is to overrun the schedule.

The average of a large number of such test runs, which were made in regular passenger service, established what they call a "bogie" on each line, for each of the four classes of cars owned; in other words, an average power figure for each trip. Conductors were then instructed to take readings of the wattmeter on their cars at the end of each trip, and to enter them on a card in the same manner that they record fare register readings. In this manner a daily record of each motorman's performance on power consumption was available, and at a negligible clerical expense for tabulation. Many motormen, usually those least experienced, were found to be far exceeding the standards. These men were at once given personal and individual instruction, and shown how the proper operation of the equipment resulted in lower power readings. On the other hand, those men making the best record in this respect had their names entered on an "Honor List," which was posted monthly. A spirit of competition speedily developed among the men, with most gratifying results.

In November, 1911, the month before this system was put into effect, power charges at the station averaged 2.75 kw-hrs. per car mile. By the end of January, it had dropped to 2.36 kw-hrs. and averaged for the whole of

1912, 2.39 kw-hrs. During the latter part of that year, a number of new four-motor equipments weighing approximately 41,000 lb. were put into service, replacing some single truck cars of about half this weight, which slightly raised the consumption per car mile for the system for 1913, the average for the year being 2.43 kw-hrs. The average reduction for 1912 and 1913 over the previous year was 200 watthours per car mile, and with an annual mileage of approximately 1,600,000 car miles, this totals 320,000 kw-hrs. per year or a monetary saving of approximately $6000.00 annually. This figure, while not large in itself, is a big item on a small road. It was made with an average of 40 cars in operation, so the saving per car was about $150.00 per year.

But even this did not represent the entire gain. Repeatedly, cars were noticed that showed high readings with a number of different men; on looking into the cause, some defect, either in the adjustment of brake rigging, in the rheostats, or in the motors, would be found and corrected, much sooner than would otherwise be the case. Indeed, motormen, impressed with the necessity of keeping within the "bogie," would report defects to the mechanical forces that otherwise would have been ignored, provided the car could be run to schedule. Partly from this, and partly from the reduced amount of abusing equipment by fast feeding, by running too much on resistance points, or by holding brakes partially on while running, a very appreciable reduction in equipment troubles resulted. Brake shoe consumption became much lower, resistance troubles dropped, and motor defects, in particular, reached a most gratifying figure. For instance, during July, August and September, 1913, out of 156 motors making a total of 850,000 motor miles, there were but 12 motor failures, or an average of 70,000 motor miles run per defect, a showing which is remarkable for motors of the classes operated, GE-54s, 57s, 80s and 81s. Cost figures on equipment maintenance were not available, but it is believed that the reduction there secured would amount to at least $2000.00 more, annually.

It is not believed by the writer that the chief credit for these savings should be given to the wattmeters. These were merely a means to an end. The psychological effect on motormen of any apparatus by which his handling of the equipment can be checked, whether it be a wattmeter, ammeter, or coasting clock, counts for more than the records themselves, provided they are even approximately accurate. But unless this feeling of carefulness on his part is reinforced by personal supervision and instruction on the part of some one who has a greater knowledge and appreciation of the effect of improper operation of equipment than the motorman, himself, any results secured will be but temporary. Even now, after two years operation of the system, any relaxing of the personal instruction and attention is followed by a marked rise in power consumption.

In riding upon the lines of this Company, the trained observer is immediately struck with a number of points of difference from what he is accustomed to see in most cities. The handling of brakes is unusually good, motormen releasing completely before applying power, except when ascending steep grades. This is especially marked on single truck cars, with hand-brakes. On such equipment, in most cities, motormen practically always run with brakes partially applied, with two purposes: One to be able to apply the brakes quicker for a stop, and the other with the idea that it holds the car body from swaying and lurching when running at full speed. That neither practice is necessary was demonstrated to the writer's satisfaction.

Another point, of even greater importance, is the usual methods of operation during the light traffic hours of the day. Schedules are usually laid out on the basis of the fastest time that can be made on a rush hour trip, when the load and number of stops are the greatest. Then during the lighter hours of the day, motormen will usually do one of two things; either they will push their cars to the limit, and reach the end of the line several minutes ahead of the next leaving time, and take an uncalled for "layover" to smoke or to sit down and talk with the conductor; or they will loaf along on series notches, running an excessive part of the time on resistance points, in order to keep on schedule. In either case, the power consumption and strain on the equipment is greater than necessary. In El Paso, neither practice was seen on any trip at any time of the day. Where schedules were light the motormen would notch up normally to full multiple, wherever possible, then throw off power and coast to the greatest possible extent. No unnecessary layovers were seen at any time. It is believed that the thorough instruction of the motormen in the importance of coasting accounts for the greater part of the reduction that has been made.

Individual wattmeters on cars are notoriously unreliable, in making an exact or accurate record of power; but when a very considerable number of such instruments are in service, and their readings averaged over a considerable length of time, it is believed that the resulting data can be regarded as substantially accurate. The figures shown below are the averages of 9 months operation, January to September, 1913, for two classes of cars. The first, known as their class B, are for double truck cars, weighing without load, approximately 41,000 lb., with a seating capacity of 44, and equipped with four GE-81 motors geared 67 14. There are 18 of these cars in service. The second, known as class D, comprise 36 single truck cars, weighing 24,000 lb., seating 26, and equipped with two GE-80 motors, geared 71 15.

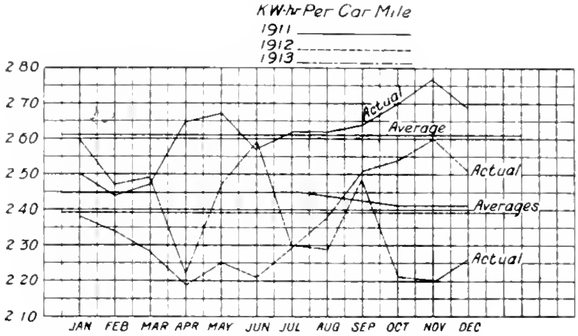

Fig. 1

The first four lines listed below are practically level. Sunset Heights line has about 4000 ft. of 3½ per cent grade; Fort Bliss line has 6500 ft. of 2½ per cent. These figures are averages, as grades for short stretches run up to considerably higher percentages.

The power figures show that on a level track, the factor affecting the power consumption of any type of car is primarily the number of stops made per mile. Where the difference in elevation of the two ends of the line is marked, as on Sunset Heights, the consumption will of course be high. This line, in spite of its schedule being less than that of the Second Ward line, takes more power per ton mile. The high readings on Fort Bliss are harder to explain. This line, however, extends further from the power station than any other, and it is believed that low voltage may have entered into the abnormal power consumption, together with the slight difference in elevation between the two ends of the line.

## POWER CONSUMPTION PER CAR-MILE AND PER TON-MILE.

| Line | KW-HRS. PER CAR MILE | | WATTHOURS PER TON MILE | |
|---|---|---|---|---|
| | Class B | Class D | Class B | Class D |
| Mexico | 2.20 | 1.64 | 100 | 126 |
| Washington Park | 2.02 | 1.51 | 92 | 116 |
| Government Hill | | 1.16 | | 89 |
| Fort Bliss | 2.82 | | 128 | |
| Second Ward | 2.13 | 1.55 | 97 | 119 |
| South Heights | | 1.73 | | 133 |
| Fort Bliss with trailers | 3.79 | | 95 | |

N.B.—In the figures per ton mile, an average load of 22 passengers is assumed for Class B and 15 passengers for Class D, these being actual records in service. The weight of a loaded trailer in Fort Bliss service is approximately 18 tons.

## SERVICE DATA

| Line | Distance Round Trip Miles | Schedule Speed M.p.h. | Average Stops per Mile | Average Duration of Stops Secs. | Average Passenger Load | Average Line Voltage |
|---|---|---|---|---|---|---|
| Mexico | 3.3 | 5.5 | 10.3 | 19 | 25 | 525 |
| Washington Park | 6.5 | 8.7 | 7.5 | 8 | 20 | 525 |
| Government Hill | 9.25 | 9.9 | 6.7 | 8 | 29 | 475 |
| Second Ward | 2.6 | 8.2 | 9.2 | 5 | 14 | 525 |
| Sunset Heights | 1.96 | 6.0 | 9.4 | 10 | 10 | 525 |
| Fort Bliss | 11.51 | 9.2 | 6.7 | 8 | 29 | 475 |

These figures are presented merely to show what are the actual readings at the car. As a basis for comparison with other roads, under different conditions of schedule, loads and voltage, they could hardly be applied.

What the writer has wished to bring out in this article is not the actual amount of power necessary to operate a car under any specified conditions, but simply the general idea that the education of motormen in the correct handling of car equipment can be made to yield very handsome returns upon the time or money invested in the effort. This is real economy and efficient management.

# NOTES ON METAL REFLECTOR DESIGN

By H. J. Tait and T. W. Rolph

It is erroneous to assume that a porcelain surface reflects light in exactly the same manner as a perfect mirror, and if such a false assumption is made in designing reflectors the results will not be satisfactory. It is essential to have accurate data on the reflecting properties of any material used in the manufacture of reflectors to obtain good results, and such data cannot be obtained from general laws without due deductions being made for the characteristics of specific material, i.e., rough surface materially alters the conditions. The author shows these differences in the reflection properties of smooth and rough surfaces by diagrams and discusses the differences between porcelain enamel and aluminum reflectors.—Editor.

Not long ago an advertisement appeared in the electrical trade papers in which a manufacturer of lighting specialties described his method of reflector design. The illustration of the advertisement was a diagram showing how the contour of a porcelain surface was calculated to produce a desired distribution of light. The basis of the design was the assumption, tacitly made, that a porcelain surface reflects light in *exactly* the same manner as a perfect mirror.

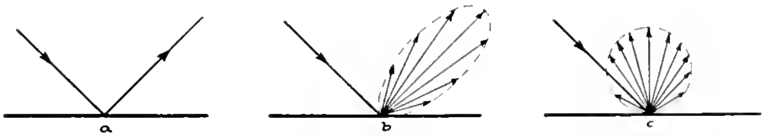

Fig. 1. Laws of Reflection:
(a) Regular Reflection
(b) Spread Reflection
(c) Diffuse Reflection

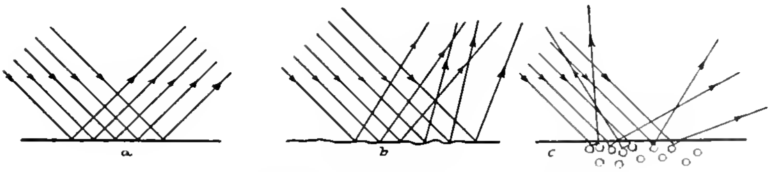

Fig. 2. Reflection of Pencils of Light Rays:
(a) Regular Reflection
(b) Irregular Reflection
(c) Sub-surface Reflection

That this assumption is in error, and that the error is greater than can be allowed in practical work, would have been proved if the design had been checked by a photometric test. The actual distribution of light would have been found to be so different from what was expected that the manufacturer could not have failed to recognize it.

Reflectors designed on such a basis are unfair. The purchaser is trying to buy, first of all, a lighting effect, and the manufacturer thinks that he is selling it. That both are fooled, illuminometer tests of installations in actual service have often proved.

Reflectors can be designed to produce the exact lighting result demanded, and, although practically all designs must finally be perfected by checking against actual photometric tests, the number of checks and changes in design can be made to a reasonable proportion of the design cost by a little investigation of the reflecting properties of the material used in the manufacture. An intelligent use of the knowledge of these reflecting properties will preclude the possibility of such absurdities in reflector design as occasionally appear in the technical press. The principles involved are not new but they are so seldom appreciated by designers that the repetition of them here is worth while.

The well-known law that the angle of light reflection is equal to the angle of incidence is illustrated in Fig. 1a. This is the law of regular reflection, which applies to every reflection of a single light ray from the infinitesimal surface which it strikes. But the law cannot be universally applied to the problem of reflector design in which a pencil of light rays must be considered. Practically the law can be applied to reflection from the surface only of a smooth reflecting medium. The action of such a surface on a pencil of rays is shown in Fig. 2a. Reflection from a rough surface or from particles lying beneath a smooth surface does not follow this law.

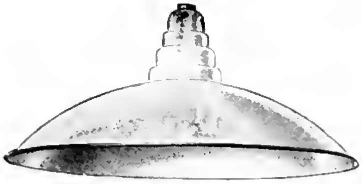

Fig 3. Shallow Dome Reflector

Of the metal reflectors now being sold for industrial lighting, the largest number have reflecting surfaces of porcelain enamel or of applied aluminum, the latter usually protected by a surface coat of lacquer to facilitate cleaning. With neither of these surfaces is a pencil of light rays reflected in accordance with the law of regular reflection.

Applied aluminum acts according to the law of spread reflection. Fig. 1b illustrates this law, showing the direction of rays emanating from a small portion of the surface with a given angle of incident light. Fig. 2b shows how spread reflection is produced by the action of infinitesimal portions of the surface on individual light rays. The major portion of the light deviates only slightly from the direction which it would take when regularly reflected.

Porcelain enamel acts by the law of diffuse reflection, illustrated in Fig. 1c. The maximum candle-power of the reflected light is normal to the surface, regardless of the angle of the incident light. This reflection is not produced by the surface itself but by the particles beneath the surface, as illustrated in Fig. 2c. In addition to the sub-surface reflection there is a small amount of reflection from the smooth surface itself, following, of course, the law of regular reflection. This amount is negligible in quantity as compared with the amount of diffusely reflected light.

The best control of light-rays can be obtained with surfaces giving regular reflection. Such surfaces are used for searchlights and projectors where it is important that every light-ray take a definite predetermined direction. With spread reflection, as shown in Fig. 1b, the major portion of the light deviates only slightly from the direction which would be taken by light regularly reflected. Consequently, reflectors with aluminum finish afford good light control and can be designed accurately to give pre-determined light distributions. With diffuse reflection (Fig. 1c), however, the reflected light is spread in all directions and the approximation of pre-determined results is difficult and often impossible. It follows that aluminum finished reflectors are preferable to porcelain enamelled reflectors from the standpoint of obtaining given distributions accurately. This is an important point for the user of reflectors who must have available a variety of distributions—focusing, intensive, extensive and widely distributing.

The difference between the action of porcelain enamel and aluminum is strikingly illustrated in the shallow dome shape of reflector. This reflector was designed as a porcelain enamel reflector to give the distributing photometric curve. When finished in aluminum, however, the reflector gives surprisingly different results. Fig. 3 shows the shape of the reflector. Fig. 4 shows the photometric curves in porcelain enamel finish and in aluminum finish. Porcelain enamel

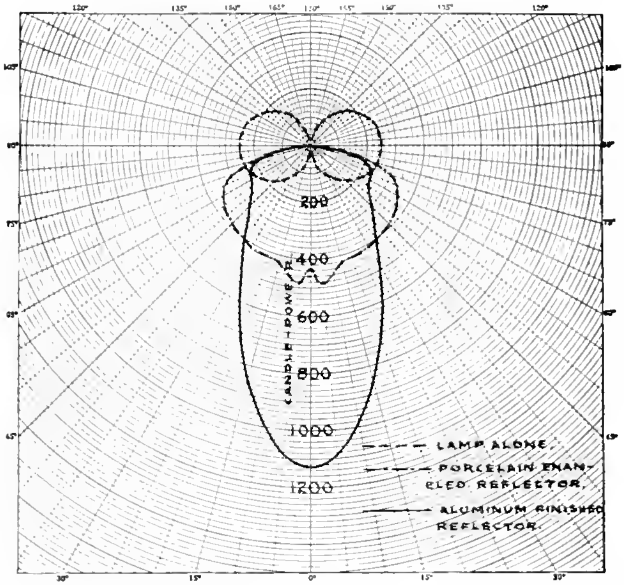

Fig. 4. Photometric Curve of Shallow Dome Reflector Porcelain Enameled and Aluminum Finished

gives the results desired, while aluminum gives a "freak" curve. The reflector approaches a shallow parabola in shape and the surface giving spread reflection naturally concentrates the light downward, though of course not as well as a reflector designed to do so would. The diffusely reflecting surface on the other hand spreads the light in many directions.

Fig. 5

To obtain the widely distributing curve with aluminum finish the shallow bowl shape is used as illustrated in Fig. 5.

To obtain extensive and intensive results in aluminum or porcelain enamel finish the deep bowl reflector is used. Fig. 6 shows a typical deep bowl. The focusing curve is also obtained with aluminum finished reflectors of the deep bowl type. With porcelain enamel, however, good focusing results cannot be obtained with any shape of reflector, owing to the diffuse nature of the reflection.

Fig. 6

Reflectors are being sold now in many instances on the basis of actual test in trial installation and those types are coming more into use which give a definite predetermined result, when installed according to rule.

# AIR COMPRESSORS FOR FOUNDRY USE

By B. L. Spain

Turbine Department, General Electric Company

In the introduction of this article the author defines the different types of air compressors in common use, viz., the fan blower, the positive pressure blower, the reciprocating or piston-type compressor, and the centrifugal compressor, and states what ranges of pressures are to be expected from each. The body of the article is given to a description of these various types, and their characteristics as influencing their selection for foundry use. In conclusion, data of combustion are furnished which will assist in computing the size of compressor to apply to a particular installation.—Editor.

The problem of compressing air should be of interest to every foundryman, not only from the standpoint of obtaining the best efficiency, but also from the standpoint of absolute reliability and ease of operation of the compressor, and above all the proper choice of a type of compressor that will assist in producing the increased output and best quality of castings.

There are now in existence four distinct types of air compressors and they may be classified as follows. The first is the fan blower, which is generally used where large volumes of air are required at low pressures, e.g., pressures ranging up to $\frac{1}{2}$ lb. per sq. in., and in some cases as high as 1 lb.; but this type has a rather low efficiency and should only be used for very low pressures. The second is the positive pressure blower, which compresses air to medium pressures, e.g., from 1 to 10 lb., but which has characteristics such that the higher the pressure the lower the efficiency, or the larger the volume the lower the efficiency. The third is the reciprocating or piston-type compressor, which is best adapted for compressing air to high pressures, e.g., from 30 lb. upwards. The fourth is the centrifugal compressor which is designed for any volume and pressure for which either the reciprocating or positive types have been used, viz., for volumes from 500 to 50,000 cu. ft. of air per minute, and pressures ranging from $\frac{3}{4}$ lb. per sq. in. upwards.

The fan blower as shown in Fig. 1 consists of an impeller mounted on a shaft, supported by bearings and enclosed in a sheet or cast-iron casing which provides the passage for the compressed air from the impeller to the discharge pipe. The impeller revolves at a comparatively low speed, and the pressure is produced almost entirely by centrifugal force because the fan blower is not provided with passages beyond the impeller for the efficient conversion of the velocity of the air, existing at the impeller exit, into pressure. Practically all of this velocity energy therefore is dissipated in eddy-currents and is lost in the form of heat. Blowers of this type are used for compressing large volumes of air to pressures of ½ lb. per sq. in. or less, and although the efficiency is not as high as that of other types, the first cost is of greater importance; consequently, as the powers involved are usually small, it does not pay to install a more efficient but costlier type. When, however, the power involved is considerable, or its cost is the main consideration, this type should not be used.

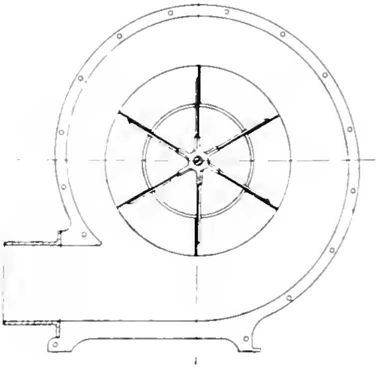

Fig. 1. Diagrammatic Section of an Ordinary Fan Blower

The principle and the characteristics of the positive pressure blower are different from those of the fan blower. This type consists of one or more drums with lobes arranged in such a manner as to provide pockets to receive air at the intake and convey it to the outlet as shown in Fig. 1a. If the outlet is not restricted, the air will be transferred from the intake to the discharge but without any rise in pressure. If a pressure above that of the atmosphere exists at the discharge, the air in the pockets will be raised to that pressure. If a positive pressure blower is run at full speed with the discharge pipe closed, the pressure will increase sufficiently to burst the casing, stall the driver, or produce a leakage between the drums and the casing equal to the amount of air entering. Usually, a by-pass valve is provided to compensate for changes in the load. This will pass air from the discharge side into the atmosphere when the pressure reaches a predetermined value. The power required to drive this blower against any given pressure is constant, even though the volume of air delivered varies greatly. This is shown by the curves in Fig. 2. The upper dotted line indicates the pressure that would be obtained from a positive pressure blower, provided with a by-pass valve and operated at constant speed, when delivering various volumes up

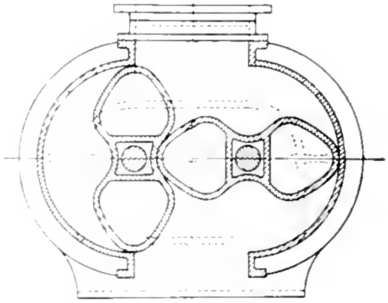

Fig. 1a. Diagrammatic Section of One Type of Positive Pressure Blower

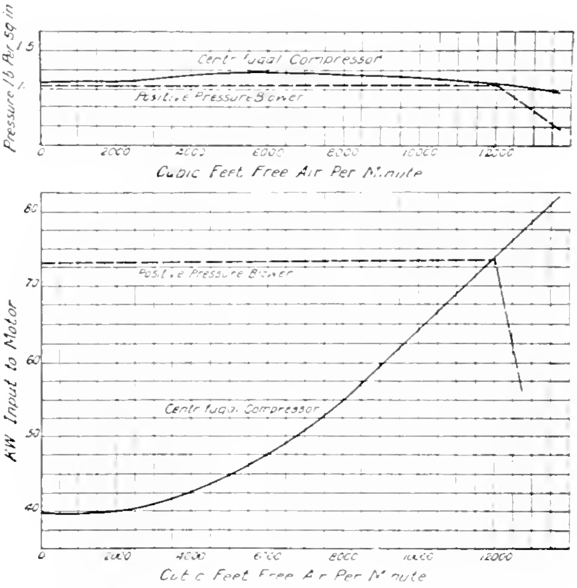

Fig. 2. Power Input and Delivered Pressure Curves for a Centrifugal Compressor and for a Positive Pressure Blower

to its normal free air rating of 12,000 cu. ft. per min. The lower dotted curve represents the power input of the motor corresponding to this pressure curve.

The power curve also shows that whereas the efficiency of a positive pressure blower in first class condition may be good at full load, for fractional loads it decreases rapidly, otherwise the curve of power required at fractional loads should be similar to that shown by the lower solid curve.

The efficiency of this type of blower at full load is good if the clearance between the rotating elements themselves and between them and the casing can be maintained small, but the unbalanced pressure on the two sides of the drums or impellers causes the bearings to wear rapidly, allowing the impellers to come in contact with the casing and to wear larger clearances. When these machines are designed for intermediate volumes and low speeds, the wear is not so great as in the case of larger units with their greater distances between the bearings, because the unequal pressures just referred to cause a greater deflection of the impellers and produce a greater loading on the bearings which results in more rapid wear of the parts named. This, of course, means an increased leakage of the high-pressure air back into the intake, which is accompanied with a corresponding decrease in efficiency.

A positive blower is usually connected to its driver by gears, the wear of which produces wear of the drums and hence lower efficiency. The wear of the various parts of this type of blower is also accelerated by the presence of dust and grit, which is always present in foundries. In order, therefore, to maintain good efficiency of the positive pressure blower, frequent repairs and replacement of parts are necessary.

Since the delivery of air to the discharge pipe intermittently, usually between one hundred and two hundred intervals per min., causes the pressure and flow of air through the tuyeres to fluctuate, and since the output of the cupola depends on the steady descent of the charge and the melting of the iron at a constant rate, it is easily seen that this fluctuation in the flow of air is not productive of the best results from the cupola.

Reciprocating compressors may be used to compress air to any desired pressure, but the application of this type of machine to low-pressure requirements is prohibitive on account of the cost. They are therefore used only where pressures from 30 lb. per sq. in. and upwards are required.

This type of compressor consists of a piston which moves forward and backward in a cylinder provided with ports and valves for the proper admission and discharge of air. The pressure in the clearance spaces between piston and cylinder head and in the ports leading to the discharge valves, is equal to the discharge pressure when the piston reaches the end of its compression stroke. When the piston returns the compressed air in the clearance space must expand to somewhat below atmospheric pressure, or the pressure of the air at the intake, before any air from the intake pipe can enter the cylinder. Consequently, air is admitted during only part of the piston stroke, and therefore the reciprocating compressor does not deliver a quantity of air equal to its piston displacement, but a considerably smaller quantity. The ratio of the actual air delivered to the displacement of the piston is called the volumetric efficiency. The volumetric efficiency is further affected by leakage of air through the valves which always wear with use and seldom remain tight. The usual rating of reciprocating compressors, as well as positive pressure blowers, is based on displacement of air and is therefore in excess of the actual free air delivered. The displacement in either case is between ten and fifteen per cent greater than the actual air delivered, and when wear occurs this percentage becomes very large. The term, *free air,* as usually applied to positive pressure and reciprocating blowers is used erroneously, because displacement of air is referred to and this differs greatly from the actual free air delivered. The necessity of frequent repairs to this type of apparatus, in order to maintain good efficiency, is self-evident.

The development of the steam turbine led to the introduction of the centrifugal pump. Since this type of pump could be direct connected to a high-speed driver and since its efficiency had been greatly increased over that of previous models, its success was well established.

The success of these two high-speed pieces of apparatus led to the development of the centrifugal compressor, and we can say today that the centrifugal compressor stands where the centrifugal pump stood five years ago. The initial development of this apparatus, which took place in Europe, was always of a type in which the air was admitted to only one side of the impeller and, just as in centrifugal pumps, in order to balance the end-thrust in multi-stage designs the impellers were placed back to back or some other equivalent means had to be employed.

The General Electric Company was the first to take up the design of the centrifugal compressor along lines entirely independent from those employed in Europe. The chief difference lay in the design of the impellers and in their arrangement in the compressor. Impellers of the double-inlet type are always used in both single and multi-stage machines for, as this type has inherently no end-thrust, their use prevents the necessity of a special arrangement of the stages or the use of the complicated devices which are necessary to counterbalance the end-thrust of single-sided impellers.

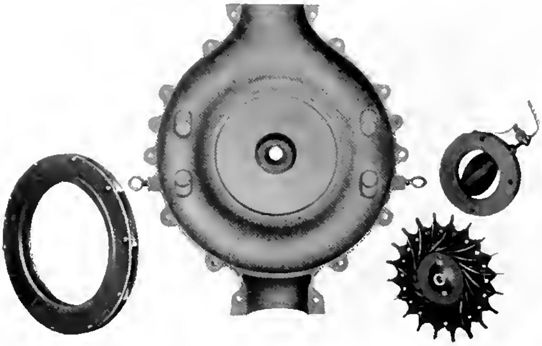

Fig. 3. The Parts of a Single-Stage Centrifugal Compressor

A centrifugal compressor consists of one or more rotating impellers supported on a shaft and surrounded by a stationary set of discharge vanes, the whole being enclosed in a casing. These parts are shown in Fig. 3. The driver may be a direct-current or alternating-current motor or a steam turbine. Figs. 4, 5, 6 and 7 show various types of compressors and drives.

When the impeller shown in Fig. 8 is made to revolve, it will entrain by centrifugal force a fluid, such as air, at its inner periphery and discharge it at its outer periphery. At this latter point the air contains by reason of its centrifugal pressure and its velocity two forms of energy, potential and kinetic. The function of the discharge vanes is to convert the velocity energy into pressure energy. These discharge vanes, Fig. 8, are designed in such a manner as to gradually reduce the speed of the air as it passes through them and thus recover the velocity energy in the form of an increased pressure. Fig. 9 illustrates the gain in pressure due to the discharge vanes; the lower curve represents pressure resulting from the centrifugal action of a perfect impeller with the small amount of velocity conversion obtained by the casing only, and the higher curve shows the increase of pressure due to the action of the discharge vanes. About 95 per cent of the energy supplied by the driver to the compressor appears in the two forms spoken of above. The five per cent loss is due to friction of the

Fig. 4. A Centrifugal Compressor Driven by a Direct-Connected 30 H.P., 230-Volt Direct-Current Motor

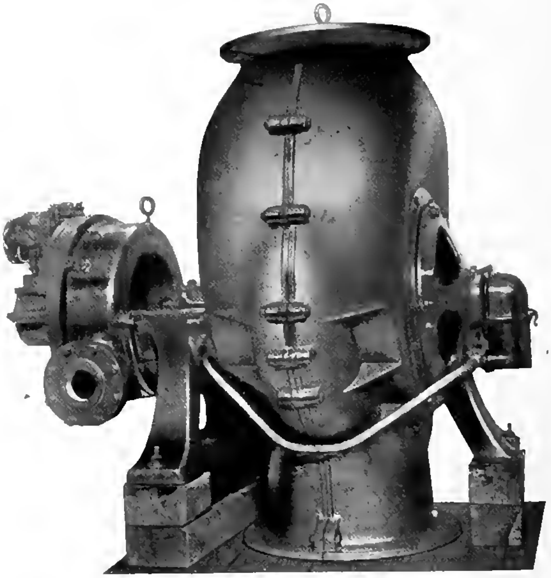

Fig. 5. A Centrifugal Compressor Driven by a Direct-Connected 75 H.P. Curtis Steam Turbine

air through the passages of the impeller. Of the 95 per cent energy existing at the discharge end of the impeller, or at the tips of the blades, approximately one-half exists in the form of centrifugal pressure and the other half exists in the form of velocity energy. The centrifugal pressure is directly available and is used without any additional losses. The velocity energy is transformed by the discharge vanes into pressure with an efficiency varying from 40 to 70 per cent depending upon the quantity and the pressure of fluid handled. It is this proportion of velocity energy recovered by the centrifugal compressor that is entirely lost in the fan blower. The centrifugal compressor is, therefore, much more efficient than the fan blower. Fig. 2 shows a pressure curve of a 12,000 cu. ft. centrifugal compressor, and also the power required at various loads. Note the decrease in power at light loads and the saving resulting therefrom.

The efficiency of this type of apparatus is but slightly affected by large clearances, and the clearance is therefore made ample to permit of satisfactory operation. When the rotating element is properly adjusted by means of shims in the bearing linings, it is impossible for it to come in contact with stationary parts. Consequently, we have in this type not only a blower of high efficiency but also one which will maintain that efficiency after long periods of service.

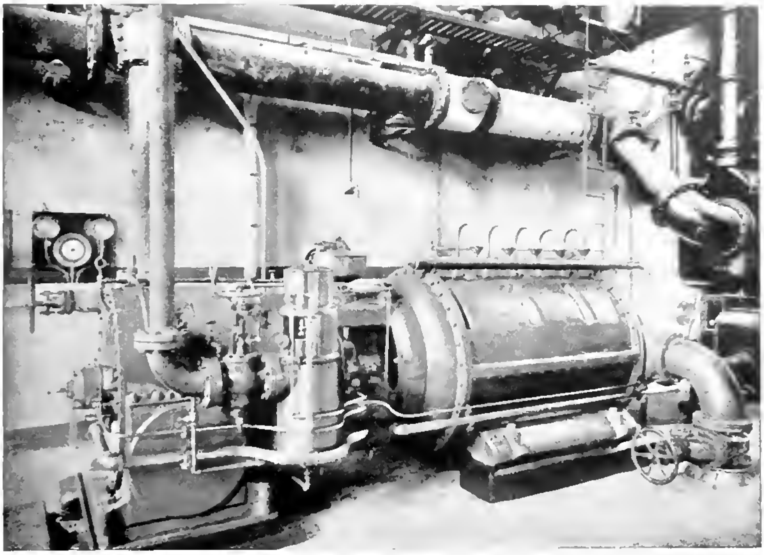

Fig. 6. Turbine-Driven Centrifugal Compressor for Bessemer Converter

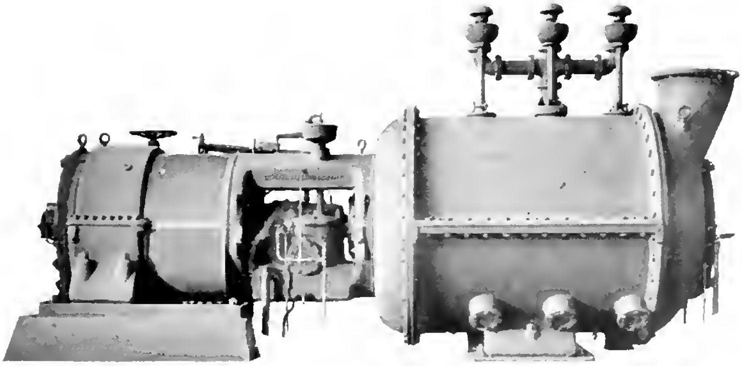

Fig. 7. A Large Centrifugal Compressor, Built Especially for Blast Furnace Work, Driven by a Direct-Connected Curtis Steam Turbine

The characteristics of the centrifugal compressor make it especially adapted to cupola blowing because the air is delivered from this apparatus at perfectly steady pressure, as shown in Fig. 9. The steady flow of air through the tuyeres, resulting from the steady pressure, produces a steady condition in the cupola and this causes not only the steady descent of the charge but also uniform melting. This in addition to being true for theoretical reasons has been borne out in practice.

Some of the other advantages which are possessed by this type of compressor are the small floor space occupied; the ability to use a direct connection to the driver without the use of belts or gears which involve additional losses and wear; the light weight which permits of the use of smaller foundations and lighter floors than are necessary for positive pressure types; the small number of bearings, never more than three;

and the elimination of repairs to the compressor end. For these reasons the centrifugal compressor is especially adapted for foundry use.

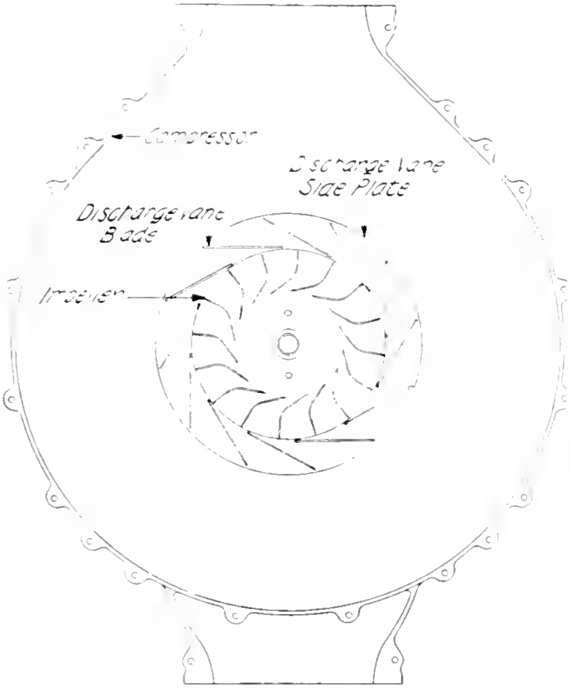

Fig. 8. A Diagrammatic Section of a Single-Stage Centrifugal Compressor

A large number of centrifugal compresssors have been manufactured and are in satisfactory operation. Without any doubt these machines will supplant all other types of air and gas compressors. There are several other manufacturers in this country which have begun to build the centrifugal compressor, but in all cases their designs are in accordance with European practice.

The established rule for the selection of positive pressure blowers for iron foundry cupolas has been the cause of the principal difficulty experienced with centrifugal compressor installations, in that the first machines supplied for this service were much too large. According to this rule, thirty thousand cubic feet of displaced air should be allowed for each ton of iron, and this has been interpreted to mean the actual free air delivered. In supporting this rule, computations have been made showing that 150 cu. ft. of air are required to burn 1 lb. of carbon to $CO_2$, and attention has been called to the results of experiments which show that 1 lb. of coke will melt 10 lbs. of iron. Assuming, for the moment, that coke is pure carbon and that all of it is burned to $CO_2$ it follows that 30,000 cu. ft. of free air should be provided for each ton of iron.

Since analyses of coke show a carbon content of from 85 to 92 per cent, only these percentages of air would be necessary to burn commercial coke to $CO_2$. As a matter of fact, however, all the carbon is not burned to $CO_2$, since some only reaches the CO stage. On account of this incomplete combustion of part of the carbon, it has been found that only about 90 per cent of the air necessary to produce complete combustion of all the carbon will be required. These two factors, impure coke and partial burning, are together responsible for reducing the demand for air by about 20 or 25 per cent. Eighty per cent of 30,000 cu. ft., or 24,000 cu. ft., of air would therefore be considered a liberal figure.

This theory has actually been proved by tests of positive pressure blowers and centrifugal compressors in conjunction with a cupola where it was found that 30,000 cu. ft. of displaced air from the former and 24,000 cu. ft. of free air from the latter are necessary to melt one ton of iron. It is of interest to know that this represents about the ratio of actual free air delivered to the displacement rating of a positive pressure blower.

The following conclusions may be drawn from the preceding description:

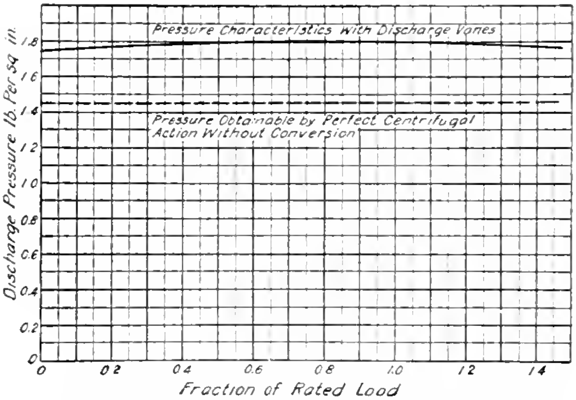

Fig. 9. Curve Showing the Discharge Pressure from a Centrifugal Compressor: Perfect Centrifugal Action, and Employment of Discharge Vanes

First, the principal difficulty with the fan blower when compressing air to sufficient pressure for cupola blowing is that its efficiency is lower than that of other types.

Second, the positive type of blower does not maintain its efficiency without excessive maintenance cost. It creates a fluctuating pressure which produces unsteady conditions in the cupola and results in irregular melting of the iron.

Third, the reciprocating compressor, although better adapted to higher pressures, is not applicable to cupola blowing.

Fourth, the centrifugal compressor has a high efficiency, maintains this efficiency, requires very little attention, the cost of maintenance is extremely low, and above all it produces a steady pressure which results in uniform operation of the cupola. It is therefore better adapted for foundry use than any of the other types in existence.

# MILITARY CAMP LIGHTING

By John Liston

General Electric Company, Schenectady, N. Y.

The following article describes an innovation in the use of electricity, viz., electric military camp lighting. In the introduction are named the primary requisites that must be possessed by the generating set to be used for this purpose, and the remainder of the article records the success of the first installation of this kind, which was at Camp Sulzer, August, 1913.—Editor.

In order adequately to supply electric illumination for temporary military camps, the lighting equipment must, of necessity, be portable and capable of meeting the following conditions:

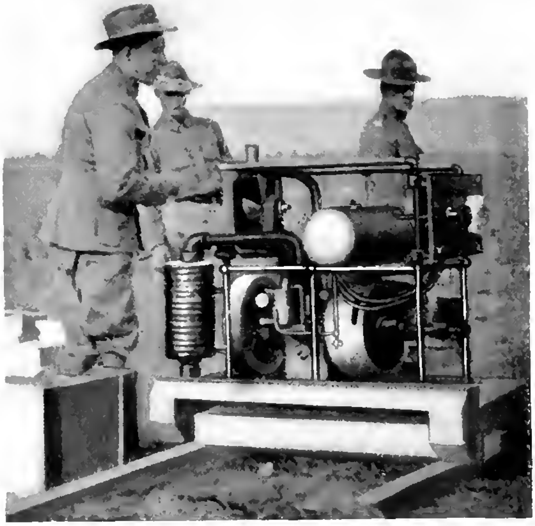

Fig. 1. Portable Gas-Electric Set in Service at Camp Sulzer, Glens Falls, N. Y., August, 1913

It must be compactly constructed, self-contained and of relatively light weight, so that it can be easily handled by a few men in loading and unloading the military transport wagons.

It must be sufficiently strong, mechanically, to successfully withstand the rough usage to which it may be subjected during its removal, transport, and installation at successive camp sites, and to minimize repair work which might be rendered exceedingly difficult or even impossible with the limited facilities ordinarily available under field service conditions.

It must be both simple and reliable in operation so that it may be safely entrusted to men lacking special electrical or mechanical training, and the fuel and other supplies required must be of such a nature as to be readily and generally procurable, or else easily and safely transported with the lighting equipment.

It must be so designed that the installing and assembling of the necessary wiring and lamps may be accomplished rapidly and also in a manner to insure freedom from accident during operation, by a comparatively few men and with a negligible effect on their purely military duties; and, lastly, its electrical characteristics must be such as to insure steady and efficient lighting.

The superiority of electric lighting over all other forms is so generally conceded that the relative values of the various forms of illumination available for temporary military camp lighting will not be here discussed, and the context will be devoted to an analysis of an electric lighting set which has already successfully undergone the "acid test" of actual service. This description will serve to indicate to what extent it meets the stipulated requirements.

The set consists of a single cylinder gasolene engine and a direct-current generator, the combined units having only two bearings and a common base, as is shown in Fig. 2. With the exception of the magneto, which is mounted on a bracket bolted to the end shield of the generator and directly coupled to the generator shaft, all the auxiliary equipment is compactly arranged above the generator on a metal pipe framework so that the radiator, gasolene tank, oiling system, rheostat, switch, etc., are readily accessible and require practically no addition to the ground space necessary for the generating unit alone.

The complete outfit is mounted on a small platform sledge, and has an overall length of 3 ft. 3 in., width 2 ft., and height 3 ft. 5½ in. Its net weight is about 465 pounds, and the necessary boxing for protection during transportation adds about 100 pounds to this figure. It is, therefore, evident that as far as bulk and weight are concerned, it is well adapted to meet the exigencies of temporary military camps and can be suitably housed, while in operation, in a standard "A" tent.

The fuel required is commercial motor gasolene, and approximately four hours running can be secured per gallon consumed. An efficient centrifugal governor, located within the flywheel, responds instantly to changes in load; and as the generator field is compound wound so as to compensate for any drop in engine speed between no-load and full-load, the maintenance of a practically constant voltage and, consequently, steady lighting is assured throughout the entire load range of the set. It is, therefore, obvious that the attention of a skilled attendant is not required for successful operation, as when once started the set is self-regulating and the proper initial adjustment of the hand-operated rheostat, which forms part of the equipment, can be readily made even by an inexperienced operator.

During the week ending August 9, 1913, a set of this type having an output of 1 kw. at 125 volts direct current was utilized at Camp Sulzer, near Glens Falls, N. Y., for lighting the tents of the officers of the 2nd Infantry, N.G., N.Y. Fifty 25-watt mazda lamps were used on three parallel circuits, approximately 700, 550 and 450 ft. in length.

The generating set was placed in an "A" tent about 100 ft. from the center of the three circuits, as shown in Fig. 3, and the feeder wires, which consisted of No. 14 rubber-covered twin-conductors enclosed in a weatherproof case, were embedded about six inches in the sand. In each tent a loop was made, extending a foot above the ground, and to this loop a 10-foot length of lamp cord provided with a porcelain key socket was connected and the lamp suspended from the ridge pole of the tent.

The entire work of installation was performed by six men in less than two hours, but as they had had no previous experience to guide them in the work it is reasonable to assume that the time required would be subject to a considerable reduction if this system of camp lighting were standardized for military use.

During the week the lights were in operation from 7 p.m. to 11:30 p.m. and on one occasion were kept going all night. In spite of the fact that high winds and two severe rain storms were experienced, there were no grounds or short circuits and the lighting service remained unaffected. The novelty of the equipment attracted a considerable number of visitors to the small power plant, and for this reason one man was stationed in

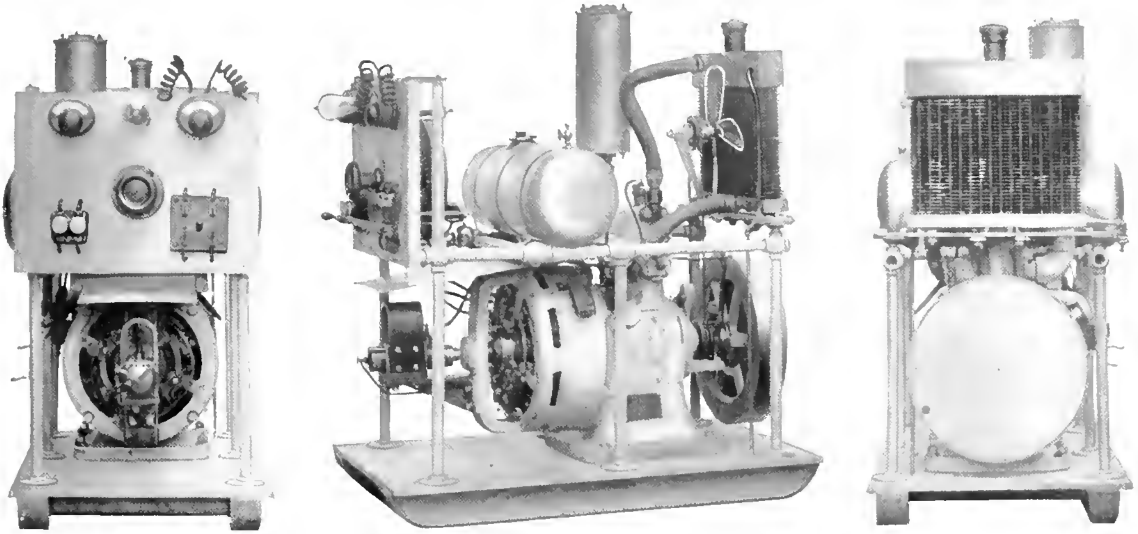

Fig. 2. Three Views of 1 Kw., 125 Volt Portable Gas-Electric Set

attendance throughout the operating period. His services as an operator, however, were almost purely nominal, and under ordinary circumstances only a very small amount of his time would be required.

An interesting auxiliary service rendered feasible by the generating set at the camp consisted in the use of a 10-inch incandescent hand-controlled searchlight projector at the guard house. The source of light in this equipment was a 6-volt, concentrated filament mazda lamp, and current was supplied by a compact 3-cell storage battery, which, in turn, was charged daily by the generating set. As the weight of the batteries was less than 20 pounds, the entire equipment could be readily manipulated or carried by one man, and any desired change in the location of the searchlight could be made easily and promptly.

While this particular service at Camp Sulzer was confined to the single unit, referred to above, the 1-kw. generating set was capable of supplying a considerable number of small independent searchlights in this way, or even of operating a limited number of more powerful arc-light projectors, although in the latter case it would have been necessary to connect the searchlight equipment to the generator feeder wires.

In addition to the general favor which the use of electric light gained thoughout the entire camp, it may perhaps be said that in no department was its use more appreciated than in the field hospital.

While the installation was originally regarded as an experiment and the generating set was not especially designed or constructed for the work actually performed, its successful operation under conditions paralleling those which might be expected to obtain in military field service clearly indicates the feasibility of providing a durable and convenient portable lighting outfit for military camps.

# FROM THE CONSULTING ENGINEERING DEPARTMENT OF THE GENERAL ELECTRIC COMPANY

## IRON CONDUCTOR AS A PROTECTION AGAINST HIGH FREQUENCY DISTURBANCES

Although skin effect and other high frequency phenomena in iron conductors is pretty thoroughly understood, there seems to be a general misconception as to the value of iron in affording protection to apparatus from line disturbances. A partial acquaintance with the phenomena that takes place in iron conductors at high frequencies, leads to the false conclusion that such a conductor affords considerable protection from line disturbances. After a careful perusal of all the available data, the question arises as to whether it affords appreciable protection or not.

A discussion of the relative merits of an ordinary copper coke coil and one using a soft iron conductor will perhaps throw some light on the subject.

It is assumed that the coil is to be placed in the high tension side of a transmission line, in series with the station apparatus, for the purpose of choking back high frequency disturbances and forcing them through the protective apparatus. There is a certain critical frequency between $10^4$ and $10^5$ cycles, which is destructive to station apparatus, and this article deals only with frequencies between these limits. Chapters VI, VII, VIII and XI of Dr. Steinmetz's "Transient Phenomena" cover the entire field thoroughly in a theoretical way, and if actual research data is desired a reference to Mr. E. F. W. Alexanderson's paper on "Magnetic Properties of Iron at Frequencies up to 200,000" in the Proceedings of the A.I.E.E. 1911, Part III, page 2433, would be of benefit.

It is well known that a copper choke coil does not give a sufficient degree of protection to station apparatus. Although it may choke back the greater part of the high frequency energy, enough seeps through before the protective apparatus is brought into play to start up destructive oscillations. To prevent this seeping an iron coil must have an appreciable increase in effective resistance and internal reactance at high frequencies over that of copper, and the high frequency hysteresis losses should be much more than at a commercial frequency. Even at low frequencies there is considerable skin effect in iron conductors; that is, the current flows only in the outer shell of the conductor and thus only a small volume of a solid conductor would have hysteresis loss. It must be remembered that, in most cases, the high frequency current is superimposed upon the commercial current in the form of a path in the outermost shell of the conductor, its depth of penetration being much less than that of the lower frequency. It would thus have a very small volume of iron to produce hysteresis loss, and for this reason the loss is not so pronounced as would be supposed. This is shown in Mr. Alexanderson's article.

There is, however, a considerable increase in effective resistance and internal reactance at high frequency. They vary as the square root of the frequency. But, the coil reactance varies directly as the frequency and thus at high frequencies is much greater than the internal resistance and reactance.

It seems then, that an ordinary copper coil, with an increased number of turns would be more effective in holding back disturbances than would one made of iron.

J.D.B.

## CLAUDE NEON VACUUM TUBE LAMP

Last year a Claude neon lamp was imported from France. However, owing to breakage in transit of an electrode connection within the tube, the lamp could not be operated with alternating current in the manner intended, but only in an incidental way, and at much lower than normal brilliancy by means of high-frequency current and the use of an external electrode, which was applied to the tube after it was received.

Two other lamps have lately been received which appear from preliminary tests to be in perfect condition. One of these lamps is now installed in the laboratory of Dr. C. P. Steinmetz, at his residence, and the other in the Light Research Laboratory, Building 28, Schenectady Works.

The lamp is nearly 20 feet long and made of a straight glass tube about 1¾ inches internal diameter, with enlarged cylindrical ends, which contain cylindrical sheet copper electrodes 13 inches long and 2⅜ inches in diameter. The tube contains pure neon gas at a pressure of about 1 mm. of mercury.

According to Claude, the lamp has a life of over 1000 hours, taking 800 volts. The current may be varied from 0.06 to 1.3 amperes, the light being redder with the lower current. At 1 ampere the lamp gives about 1000 candle-power, with a power-factor of about 0.8.

The light is of a decidedly rose-red tint; the spectroscope analyzes it into numerous lines lying in the red, orange, yellow and green regions, with an entire absence of blue and violet, which can be compensated for in practice by using mercury vapor lamps, which emit a large excess of blue and violet, in conjunction with neon lamps.

It is proposed to test the Claude lamp thoroughly and now that a supply of neon is at hand the use of this very rare gas in vacuum tubes for other electrical applications is under development.

# QUESTION AND ANSWER SECTION

The purpose of this department of the Review is two-fold.

First, it enables all subscribers to avail themselves of the consulting service of a highly specialized corps of engineering experts, or of such other authority as the problem may require. This service provides for answers by mail with as little delay as possible of such questions as come within the scope of the Review.

Second, it publishes for the benefit of all Review readers questions and answers of general interest and of educational value. When the original question deals with only one phase of an interesting subject, the editor may feel warranted in discussing allied questions so as to provide a more complete treatment of the whole subject.

*To avoid the possibility of an incorrect or incomplete answer, the querist should be particularly careful to include sufficient data to permit of an intelligent understanding of the situation. Address letters of inquiry to the Editor, Question and Answer Section, General Electric Review, Schenectady, New York.*

### EXCITER: AUTOMATIC VOLTAGE REGULATOR CONTROL

**(98) Difficulty has been experienced with the control of an exciter by an automatic voltage regulator. The exciter is a 40-kw. machine, over-compounded 10 volts, i.e., 125 volts no load, 135 volts full load. Its delivered voltage at full load, with the shunt field rheostat all cut in, is 75 volts. This we have found is not low enough for satisfactory operation. What steps should be taken to improve the control?**

The most prominent fault which seems to exist in the outfit is that the resistance in the shunt field rheostat is not sufficiently great. Initially, however, it would be better to readjust the exciter for a flat compounding, i.e., 125 volts no load, 125 volts full load; which can be readily accomplished by lowering the resistance of the shunt across the series field terminals. After this has been done, the maximum available resistance of the shunt field rheostat should be increased to at least three times the hot resistance of the shunt field winding, which amount has been found in practically every case sufficient to give the proper time element. This change can best be accomplished by replacing the present exciter field rheostat with one of higher resistance.

### WATTHOUR METERS: EFFECT OF CHANGE OF FREQUENCY

**(99) Is it a fact that a rise in frequency on a system, owing to the speeding up of the generator, will cause watthour meters to run slow? If so, please explain the cause and state how much they will slow down compared to the change in frequency.**

It is a fact that a rise in frequency on a system will cause some meters to run slow, although others will run fast under such a condition. Sometimes reducing the frequency will make a meter run fast for the first five or ten per cent of frequency reduction, while for a further reduction the frequency-speed curve bends over and the speed of the meter will be somewhat reduced. The change of the meter speed with an increase or decrease of frequency in either direction, however, is very small and, in a well designed meter, amounts to only a part of one per cent for as much as five per cent increase or decrease in frequency. An explanation of this changing action seems hardly feasible in the columns of this Section as the internal relations involved are very complex.

E.C.S.

### EARTH CURRENT: POSSIBILITY OF OBTAINING

**(100) Can an electric current be obtained directly from the earth? If so, by what means can this be done? Of what magnitude would the current be?**

If there is provided a place which is at a different potential from that of the earth and this point is connected to the earth an electric current will flow in the connector.

The current which does flow will then reduce this difference of potential to zero, unless a means is provided for constantly maintaining it at the desired value. This can best be done by an electric generator. The magnitude of the current flowing depends upon the potential difference between the earth and the place above mentioned and also upon the impedance of the connecting conductor.

S.T.

### INDUCTION MOTOR: OPERATION OF 25-CYCLE MOTOR ON 60-CYCLE SUPPLY

**(101) What would be the effect of operating a 25-cycle induction motor on a 60-cycle supply, for a period of not more than an hour?**

This depends largely upon the design and type of the motor. In general, for the same voltage the maximum output at 60 cycles will be roughly one-half that at 25 cycles. The speed will be increased in the ratio of 60 to 25, e.g., the synchronous speed of a 4-pole, 25-cycle motor will be 750 r.p.m. at 25 cycles, while at 60 cycles it will be 1800 r.p.m. It is doubtful, however, whether an ordinary 25-cycle rotor would be strong enough to run at the abnormal speed due to 60-cycle operation. The output being roughly one-half and the speed 2.4 times as great, the torque would be approximately one-fifth as great. The starting torque would be even slightly lower, in the neighborhood of only one-sixth as great. The resistance will, of course, remain unchanged for both frequencies, but the reactance will be proportional to the frequency. The maximum output and the starting torque are inverse functions of the impedance.

It would be impracticable in most cases to run a 25-cycle motor on a 60-cycle circuit of the same voltage. Since the output of any induction motor is roughly proportioned to the square of the voltage, a 25-cycle motor ought to be run at double the rated voltage to give its rated output on a 60-cycle circuit. Such an operation is not to be recommended generally, although it has been used with a considerable degree of success in some instances.

A.E.A.

### CHOKE COILS: REACTANCE FORMULA

**(102) There are four general types of reactance coils: the cylindrical helix, the hour-glass helix, the flat spiral, and the "triangular" spiral. What are the formulae to apply in calculating the reactance of these various types?**

The reactance of all these coils can be calculated with sufficient accuracy by the use of the "Universal Formula" of Prof. Morgan Brooks.

This is,

$$L = \frac{(2\pi\ an)^2 F' F''}{l + 1.5\ c + a} 10^{-6}$$

(Fig. 1 represents a cross-section of a coil wound with insulated wire.)

The symbols used in the formula are explained as follows:

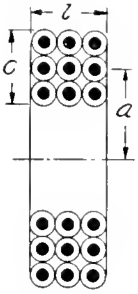

Fig. 1

$a$ = mean radius in centimeters. (See Fig. 1).

$l$ = total length of coil in centimeters. (See Fig. 1.)

$c$ = depth of winding in centimeters. (See Fig. 1.)

(Both $l$ and $c$ include the thickness of the insulation or, if the turns are air-insulated, are equal to the pitch of the winding times the number of turns. If there is only one turn, these equal the diameter of the wire.)

$n$ = total number of turns in the coil.

$L$ = inductance of coil in millihenrys.

$F'$ and $F''$ are correction factors.

$$F' = \frac{10\ l + 13\ c + 2a}{10l + 10.7\ c + 1.4\ a}$$

$$F'' = \tfrac{1}{2} \log_{10}\left( 100 + \frac{14a + 7c}{2l + 3\ c} \right)$$

1 inch = 2.54 centimeters.

Having determined the inductance ($L$), the reactance ($x$) may be calculated from the formula

$x = 2\pi\ f\ L\ 10^{-3}$.

Wherein,

$x$ = reactance in ohms.
$f$ = frequency in cycles per second.
$L$ = inductance in millihenrys.

The constants $a$, $l$, and $c$ are taken as follows in the four types of choke coils.

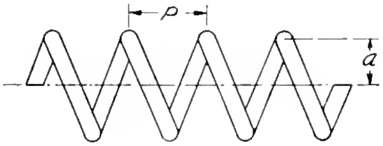

Fig. 2

*Cylindrical Helix:*

$a$ = mean radius of coil.
$c$ = diameter of conductor.
$p$ = pitch of turns.
$l = p\ n$.

Fig 3

*Hour-Glass Helix:*

$a$ = mean radius of coil.
$c$ = diameter of conductor.
$p$ = pitch of turns.
$l = p\ n$.

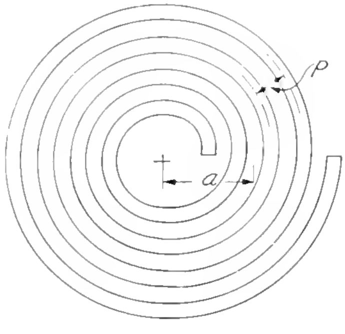

Fig. 4

*Spiral:*

$a$ = mean radius of coil.
$p$ = pitch of turns.
$c = p\ n$.
$l$ = diameter of conductor.

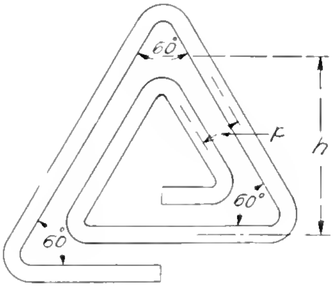

Fig 5

*"Triangular" Spiral:*

$p$ = pitch of turns.
$c = p\ n$.
$l$ = diameter of conductor.
$h$ = mean altitude of coil.

As a fair approximation, we may assume that this coil has the same inductance as has a flat spiral having a mean radius such that the area of the circle drawn with this radius equals the area of the equilateral triangle whose mean altitude is $h$.

Equivalent mean radius, $a = \frac{1}{\sqrt{\pi \sqrt{3}}} h. = 0.4287\ h.$

R. H. M.

### D-C. CIRCUITS: CHARGED DUST PARTICLES

**(103) It has been noticed that more dust particles collect on or around the positive than the negative wire of a d-c. circuit. What is the explanation of this phenomenon?**

It has long been known that when two dissimilar substances are rubbed together one will be found to have a positive charge imparted to it, while the other will assume an equal negative charge. In Faraday's Experimental Researches in Electricity may be found many experiments concerning this phenomenon. Among his experiments Faraday tried the effect of feeding fine powders of various substances into an air jet, which impinged upon some dissimilar substance. The following abstract is of interest:

"*Silica*, being either very finely powdered rock-crystal, or that precipitated from fluo-silicic acid by water, gave very constant and powerful results but both metal and wood were made strongly positive by it, and the silica when caught on a wet insulated board and examined was found to be negative."

Thus, it is probable that dust, which is the result of particles of matter being blown along the ground and then carried into the air, will have a charge imparted to it just as was artificially produced by Faraday in his experiments. If the dust were composed of fine particles of sand or silica which had been blown against trees or wooden houses, etc., it would be negative and the trees or houses would take the positive charge. If these negatively charged particles of dust were blown into a room where there were wires carrying a direct current, it is apparent that the positive wire would attract the negative dust particles, many of which would adhere to it, while the negative wire would repel the dust particles and would thus have less dust collected upon it. Thus, the phenomenon will depend upon whether the dust assumes a positive or negative charge as the result of the friction. For example, in a flour mill, the result might be just the reverse, that is, more dust (flour) might collect on the negative wire, for in this case friction between flour and metal or wood, etc. might result in a positively charged dust—the flour. As judged from the well-known tables of the arrangement of the various substances it is probable that in most instances the dust will have a negative charge, and therefore more will collect upon the positive than upon the negative wire.

C.W.R.

### INDUCTION MOTOR: GENERATOR ACTION

**(104) Is it possible for an induction motor to act as a generator under certain conditions?**

Yes, thoroughly possible.

When an induction motor is running under load it draws a current from the line. This current can be considered the combination of two currents, the first an exciting current which magnetizes the induction motor, and the second a load current whose energy carries the load.

The magnetizing current remains approximately unchanged with any change of load, provided all the qualities of the impressed electricity, such as voltage, frequency, etc., remain unchanged.

The load current varies directly with the power output (or input). An induction motor, as its name indicates, is ordinarily used to deliver mechanical power. It will, however, generate electrical power equally well, provided it is operating under suitable conditions.

Consider the motor under load, which for convenience we will consider a positive output. The motor has a certain input current of which the greater share by far is the load current. A reduction in the load lessens the load current drawn from the line and consequently the total input current. Assume all external load removed. The only load current drawn by the motor will then be that necessary to supply the mechanical losses, e.g., friction, windage, etc., of the motor. Now, maintaining the electrical connections to the motor unchanged, drive it by an engine or another motor at a slightly increased speed than that at which it would run unaided. It is evident that the load current part of the input current will soon fall to zero, for the externally applied power will take care of the mechanical losses. Without the aid of the engine these losses would be supplied by the running light load current.

It will be evident that a further increase in the power applied, which can be accomplished by driving the motor faster, will be more than that demanded by the motor to satisfy its losses. This power being in excess inside the motor must pass outward in some way. It does this in the form of electricity of the same properties as that applied to the motor and passes outward over the same circuits.

In other words, the motor acts as a generator. Under these conditions, it is called an induction generator. Comparable with other types of generators, it requires to be excited. This is done by the alternating current from other generators on the same system coming over the lines to the motor. Its output begins at a speed slightly above synchronous speed and is proportional to the increase of speed above synchronism at which it is driven. The voltage and frequency of its output are exactly the same as that of the alternating-current system to which it is connected.

E.C.S.

### TURBINE-GENERATOR: END-THRUST TROUBLE

**(105) Will you kindly furnish information as to whether such trouble as wear of the main bearing on one side only, and sparking at the commutator in a 25 kw., 4500 r.p.m., oil-lubricated Curtis turbine would be caused by the armature of the direct-connected generator not being in the longitudinal mechanical neutral, that is, midway between the sides of the poles?**

If the armature core of the generator is moved slightly from the longitudinal mechanical neutral with reference to the field cores, a certain sidewise magnetic pull will be exerted by the field on the armature tending to bring the neutral axis of the armature core into line with the neutral axis of the field cores. If the difference between the position of the axes is slight no trouble will be caused, but if the difference is greater the action of the field on the armature will be pronounced, thereby tending to wear the end of the bearing at the shoulder of the shaft, which results in the heating of the bearing and shaft and may possibly cause vibrations affecting the commutation.

F.A.H.

# GENERAL ELECTRIC REVIEW

## THE PATHS OF PROGRESS

The title to this issue, "Electric Power," is very broad, we recognize that "Electric Railways" and "Electric Lighting" could be included, but both of these subjects have been dealt with in special issues recently, so the present number in the main deals with some of the other aspects of "Electric Power" and its industrial applications.

In several previous issues of the REVIEW, we have drawn attention to the fact that we are becoming more and more dependent upon electric energy in our social and industrial life every day, and for this reason the future prosperity of the country must depend in a large measure upon how we provide for our future supply. A hundred years ago it was only those countries that had an abundant and easily accessible supply of coal that could become manufacturing countries. Coal is still the dominating factor in most localities, but the trend of modern engineering is placing our rivers and water-ways, where sites are available for the construction of hydro-electric generating stations, in the first rank of importance among our natural resources. A great many important hydro-electric sites have been developed and the wonderful improvements made during recent years in electrical apparatus has enabled voltages to be used that would have been impracticable only a few years ago with the result that greater quantities of power can now be transmitted economically for great distances, with a wonderful continuity of service, so that certain sections of the country are becoming well covered with a network of transmission lines which is leading to sound industrial developments of all kinds in those favored localities.

It is likely that in the future the fact of whether a place is to become a center of population and industry will depend less and less upon whether coal is really available, and more and more whether it is easily reached by transmission lines emanating from hydro-electric sites. It is then apparent that our hydro-electric generating stations must play an important part in the continuance of our industrial developments.

This being the case, it behoves us to carefully consider what provisions we are making for the future requirements of the country in this direction. There is quite a difference in opinion as to which is the best way to provide for the future, some are convinced that government ownership is the only safe and sane method of procedure and there are others equally insistent that the interests of the future can best be served by private ownership under due restrictions and regulations. From a purely theoretical standpoint, government ownership has much to recommend it, but in human affairs there are a vast number of theoretical possibilities that refuse to become accomplished facts. Politicians whose stock in trade is a multitude of platitudes, flavored according to the susceptibilities of the particular audience whose vote they are trying to catch, tell us that the government is the will of the people—and that the will of the people must prevail. But even the very best platitudes need examination and qualifications at times. As a matter of fact, by reason of our human frailty the government, especially in such matters as that under consideration, by no means represents the popular will, and further it is right to state that the will of the people is often lamentably at fault when judging of technical and economic matters which are entirely foreign to their daily life.

The two things which are of paramount importance are firstly, that a natural resource of such vital importance as hydro-electric power should be developed along rational and sane lines, so that it may be available where and when it is needed, and secondly, that the benefits of such developments should be permanently assured to the community at large at a reasonable cost.

It is by no means certain that a rational scheme of development would follow government ownership, judging by past experience from other things that have been thrown into the vortex of party politics it is likely rather that developments might be undertaken in localities where the chief benefits would be derived by special interests in payment of services rendered, but rendered not to the state, but rather to a political clique.

On the other hand, where a private or corporate interest is to undertake such developments they must be carried out both where and at a time when they are required or they will be financial failures and the loss will be borne by those who invested their money and had hoped to gain by their enterprise, while if a government development is not a paying proposition, the people as a whole must pay the bill one way or another, however ably the loss is covered by the juggling of accounts. The accounts of private interests in these days of commission must be kept in accordance with prescribed rules, while the government may keep its accounts as pleases it best, and the real loss can often be made to appear as a gain by neglecting to provide for such legitimate charges as depreciation which a private enterprise must provide for if they are to stay in business.

That the benefits of our natural resources should be assured future generations is apparent, but does government ownership provide for the future better than private ownership? There is one thing very certain that where private capital is expended in development work, those who are spending their money want to be reasonably sure that there is a market for their product, and if there is an extensive market it is reasonably sure there will be a commission already in power which will look after the interests of the public and also in a measure after the interests of the company or corporation.

The lesson to be learned, by those that take the trouble to study the subject, of what municipal ownership has done to retard electrical progress in some European countries should be carefully considered and the results, that have now been incorporated into the history of industrial development or lack of development, should be carefully weighed by those who advocate a measure the future results of which they are totally at a loss to foretell.

# ENGINEERING PROBLEMS OF ELECTRIC POWER COMPANIES

By David B. Rushmore

Chief Engineer, Power and Mining Department,
General Electric Company

The above subject is very broad and it has been therefore dealt with accordingly in the following article. Just enough supplementary detail has been included to illustrate the working out of the problems considered. In treating of systems in general, the advances which have been made in small generating station equipments, high-tension transmission lines, interchange-power propositions, and consolidations are briefly covered. The predominant factors which concern the location of both steam and hydraulic stations are named; and the most important considerations of plant operation, load-factor and diversity-factor are discussed. There is included in that discussion a very useful table listing the load-factors that are to be expected from different types of consumers. Remarks concerning the proper frequencies and voltages to be generated, and their transformation changes for distribution, conclude the article.—Editor.

D. B. Rushmore

In no other field has there been such a marvelous progress during the past twenty-five years as in the use of electricity for illumination and industrial power applications. In the beginning of this industry electricity was mainly used for lighting purposes and the communities served, as well as the power plants serving them, were comparatively small. The rapid increase in the size and population of these communities, and the progress of the electrical art, have, however, resulted in the gigantic installations which are now to be found in so many places.

## Systems

While it is true that the engineering problems incident to the larger installations have attracted the interest of our greatest and most able electrical engineers, a great deal of attention has also been paid to the smaller plants. Owing to the marked improvements in efficiency and design of electrical apparatus, together with an even more marked decrease in their cost, towns which ten years ago could not have supported electrical plants, can now advantageously consider such installations.

Modern improvements in high tension apparatus and appliances have furthermore made possible the construction of long-distance transmission lines which a few years ago would have been impracticable both from the standpoint of cost and reliability. As a result, small villages which formerly could not support any kind of independent central station, or which were inefficiently served, are now enjoying a high-class service from such transmission lines. It is furthermore safe to predict that in the near future all sections of the country with a substantial population will be served by a network of transmission lines, making it possible to convey energy into remote and rural districts for irrigation, farming, mining or other industrial work.

A marked advancement in the art has been brought about by the tying together of a number of systems under an "interchange" power contract. Such developments naturally are of very great importance, both from an economical and operating standpoint, as advantage may then be taken of the water flow from different water sheds, existing steam plants may be used for emergency conditions, and a most reliable service can be rendered to all sections served.

There is now also a very strong tendency towards central station consolidation with a view of concentrating the power supply for all uses for a large territory from one system. In some instances a company in a large city expands so as to embrace the whole district around it, and the class of service given originally within a small area is unified over hundreds of square miles. In other instances the properties in a given region are absorbed, merged and brought under one management. A striking illustration of this is the Central Illinois Public Service Company, one of the most recent organizations, where nearly one hundred communities were originally supplied by about fifty separate generating stations. These have now mostly been shut down and four modern stations will ultimately generate all the electric energy needed for this service. In still other instances, unrelated properties widely distributed may be brought together under one central control and management.

It is obvious that the advantages of such consolidations are many. The economy in having only one management is considerable. It is possible to obtain the best technical and expert advice. The cost of generating the power is less, and a reduction of the price to the consumer, as the natural result of the all-around improved situation, is generally possible. While these advantages are of very great value, the most important one is undoubtedly that of financing; in providing financial facilities for extensions to meet the growing demands of the public for electric service, the holding company performs its most important function.

**Steam Plants**

The energy supply for cities is, in most cases, furnished by steam generating stations, and the astonishing rate at which the size of some of these has increased is best illustrated by the growth of the Commonwealth Edison Company of Chicago. In the year 1903 this sytem had a total generator capacity of 38,350 kw. and in the year 1913 this had been increased to 302,500 kw.

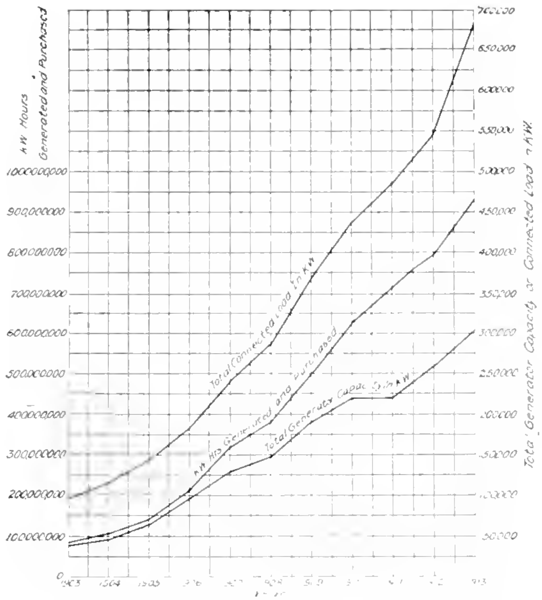

Fig 1. Curves showing Growth of the Commonwealth Edison Co., Chicago

The dominant factors determining the selection of a site for a modern generating station in a large city are usually the ones involving the economical handling of the coal. Unless the cost of fuel is to be increased very materially, the generating plant must be located so as to have the best railroad or wharf facilities. The avoidance of drawbridge tolls is an important factor and inland plants should, as far as possible, not be dependent upon a single railroad for their supply of coal.

The circulating water supply is, however, of greatest importance. The cost of fuel in large stations exceeds all other operating costs combined, and as the consumption of fuel is in the ratio of two to three, depending on whether the station is operating condensing or non-condensing, it follows that the station must be located near an abundant supply of condensing water. The cost of real estate must necessarily also be given consideration. Desirable power house sites are hard to find in large cities. They should be located near the load centers and when a satisfactory location is found it is advisable to provide for a large increase of plant.

The present trend in the design of steam turbines is in the direction of higher speeds and a greater number of stages. Various modifications in the arrangement of nozzles and buckets have also been made from time to time with the object of securing higher efficiencies. As to the size of these machines, the limit seems to be far from reached. The maximum rating has rapidly risen past the 10,000 kw. and 20,000 kw. sizes, and is now at the 35,000 kw. point, while there is every indication that even larger machines will be built in the near future. These enormous units naturally mean thermal economy, as well as economy in space and weight per unit of power developed. In this respect it is very interesting to compare the results obtained in the first 5000 kw. steam-turbo-generators built in 1903 and the 35,000 kw. unit which is being built at the present time. For example, the over-all efficiency has gone up about 25 per cent, while the weight per kilowatt has decreased to about one-third of what it was in the original machines. Obviously, however, these large turbines are only applicable in stations of large size where they can find an effective place on the daily load curve.

In connection with steam plants the problem sometimes arises nowadays, whether it will be more economical to transport the coal from the mines to the plant near the load center, or to generate the energy and transmit it electrically to the point of distribution. By generating the power directly at the mines one of the biggest items that enters into the cost of coal, viz., its handling and transportation, will be eliminated. Another saving is the utilization of the waste product, consisting of coal particles and dust, which otherwise is entirely unmarketable.

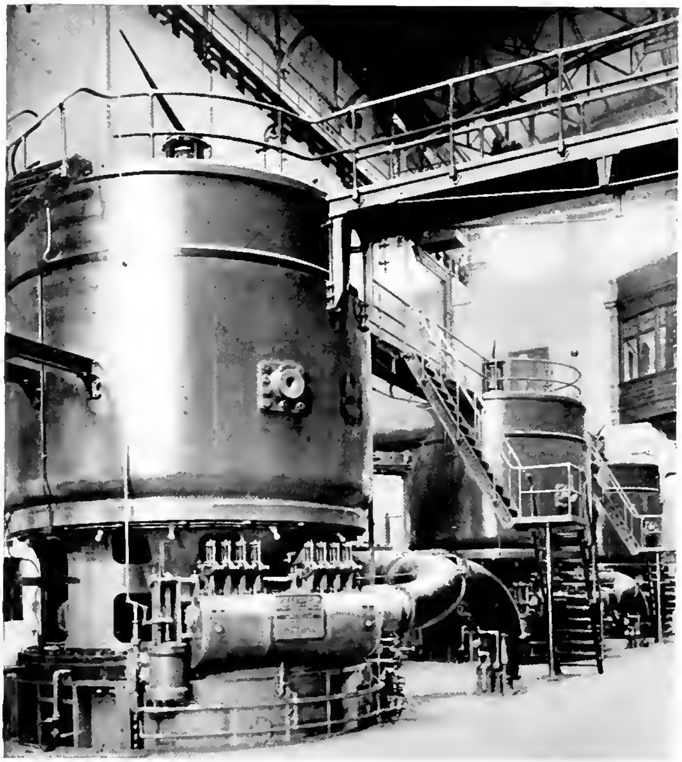

Fig. 2. Three 20,000 Kw. Curtis Turbo-generators, New York Edison Company, Waterside Station No. 1

In this country we have at least two important systems where it has proved to be economical to generate power at the coal mines and transmit it electrically for long distances over high tension transmission lines. In Europe several such systems are in operation and others of very large magnitude are being contemplated; while the South African transmission at the Rand is too well known to need any further comment.

**Water Power Plants**

The utilization of the water powers of the country has become a question of considerable importance to the public, and its success has mainly been due to the rapid development of high-tension apparatus and appliances which has made it possible to transmit the energy from obscure places to localities where a profitable market could be found for the same. It is also true that a general education of the public has had much to do to the conservation of these valuable natural resources, because the only true conservation of our water powers is by developing them. It was formerly generally believed that a hydro-electric plant was always a very profitable investment, that all that was necessary was to let the never failing water supply fall on the wheels, and that the cost of the generating station was the only investment needed. It is, however, now well understood that the cost of the hydraulic installation as well as the transmission lines in many cases reach very high values, so that the total cost of a water power plant is from two to five times that of a steam plant.

There is probably no other undertaking that requires a more careful preliminary engineering study than a hydro-electric power transmission system. The stream flow records for a long number of years must be investigated with a view of determining the minimum stream flow, and the question always comes up, for what stream flow shall the development be made, and to what extent shall an auxiliary steam plant be provided to convert the variable energy supply into a continuous supply.

Water power plants naturally divide themselves into low, medium and high head installations. For the two former, single-runner vertical shaft turbines are now being extensively used, where previously multi-runner turbines would have been used. This has been made possible by the progress in the design and development of high capacity runners, so that for a fixed head and capacity it is now possible to operate modern runners at a much higher rotational speed than was possible with runners of older design. While ten years ago it was considered a notable achievement to obtain a turbine efficiency of 82 per cent, during the past two years, efficiencies between 89 and 92 per cent have been quite common, while a maximum value of 93.7 per cent has been secured. This remarkable efficiency is by no means entirely due to superior runner design. As a matter of fact, the improvements in the design of wheel casings, wicket gates, draft chests and draft tubes have all increased the efficiency of the turbine as much as the more efficient runners.

That water powers may, in some instances, compete with very cheap steam power is best illustrated by the system of the Appalachian Power Company, which furnishes a considerable amount of power from its hydro-electric plants on the New River in Virginia to the Pocohontas coal fields, a distance of about fifty miles.

**Service Conditions**

The ideal condition of operation for an electric generating station is naturally that of supplying a uniform load during the twenty-four hours of the day equal to the full rated capacity of the plant. This ideal is, however, unattainable under practical conditions and even a close approach to it is possible only under very special conditions.

The load factor of a central station is therefore the proportion which the equivalent 24-hour load bears to the station peak, or, in other words, the ratio of the actual station output to the maximum possible output with continuous service. It is also a measure of the extent to which the necessary total investment is being used. A plant with a yearly load factor of 50 per cent is turning out just double the energy of another plant

of the same maximum load and with a load factor of 25 per cent. This means that while the fixed charges of both plants are the same, the gross income of the plant with 50 per cent load factor should be nearly twice as great as that of the other. The importance of a good load factor is thus apparent and everything that will improve this factor should be sought.

There is an enormous variety of uses to which electricity is applied, the yearly load factors of which also vary widely as shown in the following:

### SMALL AND MEDIUM LIGHTING CUSTOMERS

| | |
|---|---|
| Buildings, public | 17.6 per cent |
| Churches | 12.4 per cent |
| Clubs | 9.6 per cent |
| Flats | 6.9 per cent |
| Halls (public) | 6.9 per cent |
| Hotels | 24.4 per cent |
| Offices (business) | 9.2 per cent |
| Offices (professional) | 6.7 per cent |
| Residences | 7.8 per cent |
| Restaurants | 23.4 per cent |
| Shops (bakery) | 13.1 per cent |
| Shops (tailor) | 8.4 per cent |
| Schools | 7.2 per cent |
| Stores (dry goods) | 8.2 per cent |
| Stores (cigar) | 16.8 per cent |
| Stores (drug) | 19.3 per cent |
| Stores (grocery) | 10.3 per cent |

### LARGER POWER AND LIGHT CUSTOMERS

| | |
|---|---|
| Bakeries | 12 per cent |
| Blacksmith shops | 15 per cent |
| Breweries | 45 per cent |
| Boots and shoes | 25 per cent |
| Bottling works | 10 per cent |
| Candy manufacturing | 18 per cent |
| Clothing manufacturing | 15 per cent |
| Department stores | 30 per cent |
| Furniture manufacturing | 28 per cent |
| Foundries | 15 per cent |
| Ice cream manufacturing | 20 per cent |
| Ice making | 30 per cent |
| Laundries | 20 per cent |
| Machine shops | 20 per cent |
| Newspapers | 18 per cent |
| Packing houses | 30 per cent |
| Railroad depots | 50 per cent |
| Tanneries | 20 per cent |
| Textile mills | 20 per cent |

The yearly load factor for any class of service is determined largely by the seasons, the habits of the people, and other conditions which ordinarily do not change very materially. Improvement in the load factor must therefore be obtained largely by combining different classes of service, the maximum demands of which occur at different times of the day or of the year. Also, the larger the number of customers in any class the better will be the load factor.

A recognition of the importance of the diversity factor has undoubtedly the most marked effect in increasing the load factor and thereby the economy of production. This factor is the ratio between the sum of the maximum demands of various classes of service to the actual simultaneous maximum demand, and the more non-coincident these peak services are, the greater will be this factor.

The chief means of improving the load factor has been the addition of industrial load. In the early days of electric lighting companies, the load factors were very low due to the absence of day load. Today many central stations sell far more energy for power than for light and this is naturally distributed over a longer part of the twenty-four hours. The power load, also, not being simultaneous with the lighting load to any great extent, still further improves the load factor. Residence load has generally been characterized by a poor load factor, but by the use of day load devices such as flatirons, cooking devices, fans, heating apparatus, vacuum cleaners, etc., a much improved result is obtained.

The problem of combining electric railway loads and central station loads on one system has received increasing attention in recent years, and in some cities of this country great strides have been made toward effecting such combinations successfully. Chicago is an admirable example of what can be accomplished in this line. The Commonwealth Edison Company is today carrying a larger railway load than any other central station in the country, and the result is that this plant operates at the exceptionally high load factor of about 44 per cent, while from 30 to 34 per cent is the usual load factor of such systems. Furthermore if power should be furnished to the steam railroads in case of electrification, the load factor could still further be increased to about 50 per cent.

There are a number of other industries which offer ideal loads for large power companies, especially for hydro-electric companies; such as mining, electro-chemical work, irrigation and farming, while much is expected from the railroad field when the time has arrived for the economical electrification of our trunk lines.

The consolidation of central station interests creating a monopoly may, unless carefully regulated, result in increased prices to the consumer. In contra distinction to this we find, however, that the public generally has benefited greatly by the increased economies possible where public service corporations or properties have been merged and operated under one common management. The fear that public service commissions would be unduly influenced by political considerations, seems furthermore to have been largely imaginary, for as a rule, the opinions and rulings so far handed down have been free from partiality and prejudice.

One point which always enters into the electric power business and which naturally is very closely connected with the engineering problem is the question of quality of the service rendered. It is generally a very difficult matter to determine what, under given conditions, is good service and whether the quality of the service that has been specified is actually rendered. In general, the more reliable the service is, the more it costs, due to the increased investment in emergency apparatus, etc. Just what additional investment is justified for an increased reliability in operation is difficult to standardize. In other words, what is the value of reliability in the service? It obviously varies to a considerable extent for different classes of service. Take for example, the high pressure fire system in New York city, where an interruption of the service even for a short period would possibly prove disastrous; or a large steel mill where an hour's interruption in service may mean a loss of several thousand dollars. In other instances an interruption may not mean any serious loss, and it is therefore obvious that a fair return should take the comparative efficiency of the service rendered into consideration.

The frequencies most commonly used in this country are 25 and 60 cycles and depend chiefly on the character of the service. Where lighting load is predominating 60 cycles is generally selected, while if the load mainly consists of power, 25 cycles has been mostly adopted. It appears, however, that 60 cycles is being more and more used even for power installations since it gives a much larger number of possible speeds for induction motors.

In many of the large cities steam plants were laid out for 25 cycles and the a-c. power was converted to d-c. by synchronous converters and distributed by the Edison three-wire system. The choice of 25 cycles was in many such instances due to the less satisfactory operation of earlier types of converters for 60 cycles. With the present improvements in the design of such machines, their operation is, however, now just as satisfactory for the lower frequency. As these plants grew and service was required at greater distances from the power station, it became necessary to distribute at higher voltages to the remote districts, owing to the excessive loss in transmission over long feeders and mains at the direct current voltage. This is accomplished by frequency changers which furnish 60 cycle alternating current to customers too scattered to be supplied by the Edison three-wire system.

Many cities having a 60 cycle system and with power formerly supplied from steam plants have found it economical to buy power from hydro-electric developments. It is transmitted over long distance transmission lines at 25 cycles and converted to 60 cycles by frequency changers. The steam plant is shut down but maintained as a reserve in case of low water or transmission line trouble.

In many cases two systems of different frequencies can be tied together and many advantages derived therefrom. For instance, in many places in this country will be found a 60 cycle system which has expanded until it comes into close touch with a neighboring 25 cycle system, which may have its peak load at an entirely different time. In a case like this it would be to the mutual advantage of both systems to interchange power, and a reversible frequency changer set could be installed to tie the two systems together.

The effect of higher frequencies on the regulation of long distance transmission lines and on the capacity current in extensive underground cable systems should be given careful consideration when selecting the frequency of such systems.

The selection of the proper voltage for distribution and transmission is an important matter. The voltage must be high enough for economical transmission, and yet not so high that the amount of substation equipment, consisting of transformers and switching and protective apparatus, is so great as to make it impossible to render a fair return on the capital invested. The distribution of alternating current for general commercial purposes is accomplished almost universally by 2200 volt mains, supplying step-down transformers located near groups of consumers, whose premises are served by secondary mains at 110 to 220 volts. Single-phase circuits are quite generally used for lighting service, while power service is as a rule given from two-phase or three-phase mains. The former system is used chiefly where this method of distribution was established in the early period of the development, and where it is too extensive to warrant a change to the three-phase system, which is standard for all new installations where a polyphase supply is wanted for power service.

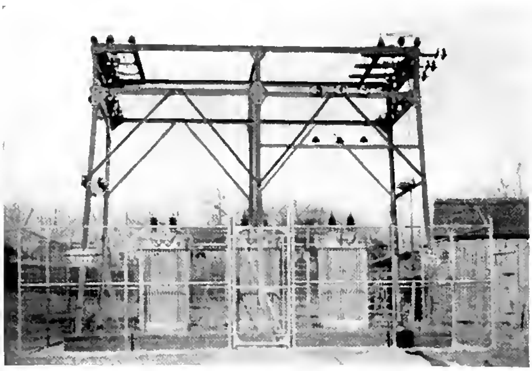

Fig. 5. 22,000 Volt Outdoor Substation

For small and medium sized cities a three-wire, "delta"-connected, 2200 volt system is very generally used for power distribution, while for larger cities there is a steady trend toward the four-wire, "Y"-connected system operating at 2300/4000 volts. There are numerous advantages with this system where feeders are extended more than two miles from the point of supply, and where adjacent towns within a radius of five miles may be served without step-up transformers or substations. It is possible to regulate the phases separately, and there is not so much of a necessity for maintaining a carefully balanced load. Even for secondary distribution the four-wire, three-phase system, operating at approximately 115/200 volts, is being generally used. With this system lighting and motor service may be given for all ordinary retail purposes from the same circuit, the principal disadvantages being that there are three phases to be kept balanced.

The selection of a voltage for a distribution system where there are a number of small demands to be supplied, is a very important matter, and has led to the development of small and inexpensive outdoor substations. The general practice seems to indicate that the most economical voltages for such systems are in the neighborhood of 22,000 to 33,000 volts. These voltages are high enough to carry power a considerable distance with small loss, so as to make the cost of the equipment not excessive.

A large majority of high voltage systems are really distributing rather than transmission systems, and with these the problem comes up as to the most economical way to take off small amounts of power. Even here the outdoor substation has come into extensive use, and numerous examples can be recited where outdoor substations have been built for voltages above 100,000 volts. The voltages of these systems are increasing from year to year, and in some cases it seems as if higher voltages have been used than would have been economically necessary. The highest transmission voltage in commercial use today is 150,000 volts. This is at the Big Creek Development of the Pacific Light & Power Corporation in California. That this is, however, not the limit is clearly indicated by the consideration of much higher voltages for new developments contemplated.

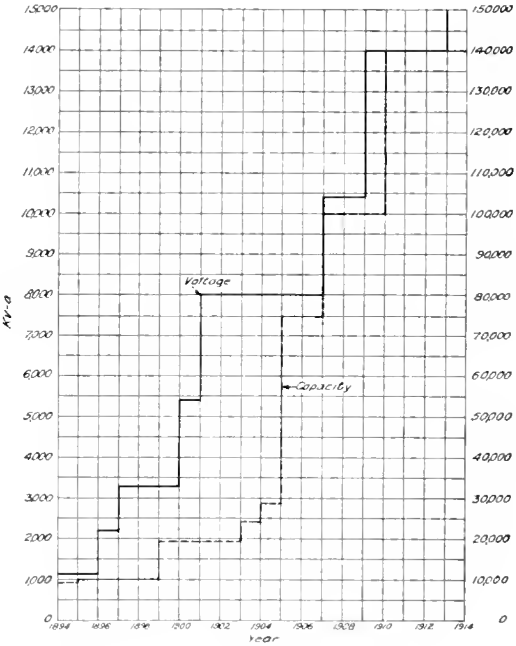

Fig. 6. Curves showing Transformer Development

## Operation

The problems of operation of power systems naturally divide themselves into, first: those of normal operation, and, second: those of emergency conditions. The method of operation and the layout of the system depend upon many factors, some of which are: the relative importance of the different stations, the number of power houses on the system and the relation of each to the whole system, the location and character of the load; the number, capacity and location of the reserve stations; and, with transmission systems, whether the high tension line is purely a transmission line, a high tension distributing circuit, or both. The normal problems of operation, such as starting up the system, paralleling the generators and the power stations and properly dividing the load among them, of putting units into service previous to the demands of the load conditions, of regulating the voltage for the proper distributing points, of connecting high tension lines, and, in general, of so manipulating the generating, transforming and switching apparatus as to deliver the desired load at the distributing centers with the desired characteristics. These problems can only be met after a careful study of the requirements.

Reliability of operation is one of the main problems in every power system, and consideration must be given to the cause of disturbances and the means for minimizing their effects. These are abnormal or so-called emergency conditions, and the possibility of all kinds of failure must be thoroughly analyzed and definite plans worked out for limiting the magnitude of such disturbances and confining them to the smallest possible area. For this reason the apparatus should be so arranged and the system so sub-divided that a disturbance in one part wull not affect the whole, and that such disturbance will be immediately localized within the lowest possible limits in such manner and time as not to cause interruption in the operation of the entire system. It should also be possible to remove the cause of such disturbance and, within the shortest possible time, to replace the disturbed apparatus in operation. This is in many cases, especially in high tension transmission systems, very difficult to accomplish. In such cases all high tension switching should be entirely abolished or confined to the absolute minimum. The reason for this is that high tension switching may set up high voltage surges, which may damage the insulation of the apparatus and cause a break-down of the system. By a careful study it is, however, as a rule possible to so lay out the system that while confining all the switches to the low tension side, a selective switching action may be obtained.

The efficiency and reliability of the operating force is without question one of the greatest assurances for a satisfactory operation, but this is also intimately connected with the means which are provided for communication between the different parts of the system.

The design and selection of the apparatus has necessarily also a most important bearing on the operation of a system, and a brief discussion of some of the important points connected therewith may be of interest.

### Apparatus

The rating and capacity of a generator must necessarily be considered in connection with the prime mover by which it is to be driven. This is fully emphasized by the fact that there are in operation in many stations in this country, units in which the output is unnecessarily limited by a discrepancy in the rating, in that the prime mover is either too small or too large for the generator. The latter may, for example, be designed for unity power-factor, while the actual operating power-factor may be eighty per cent, in which case the full capacity of the prime mover cannot be utilized. In the past every effort was made to adjust the ratings of generators to the station load curves, and the result was that they were designed for overload capacities of twenty-five or fifty per cent, usually for a period of two hours. With the growth of generating stations and improved load conditions, this practice is becoming more and more obsolete and the units are being rated on a maximum constant continuous rating which is not to be exceeded except during momentary peaks.

The generator should be well ventilated and a liberal supply of air should be supplied. While, as a rule, it has not been necessary to make any special provisions for forcing the air through the generators in water power plants, the introduction of very slow speed units seems, however, to indicate that it is highly desirable to provide such means.

Consideration of safety has led to the design of generators with a comparatively high inherent reactance. While this has been obtained by sacrificing a close inherent regulation of the machine, it does not, however, prevent a good regulation of the system, as the same may readily be accomplished by means of automatic voltage regulators.

The problem of excitation cannot be given too careful consideration in any system, and the capacity of the exciters should be very liberal. In certain plants each generator is provided with a direct-connected exciter, and in such cases it is a good practice to make the capacity of each exciter large enough so that it may furnish excitation for two of the main units, so that in case of a break-down of one exciter this will not cripple the entire unit, but excitation can be obtained from the other exciters. All exciters are nowadays, as a rule, provided with automatic voltage regulators for maintaining a constant bus voltage, and means are also being provided whereby, in case of short circuits on the system, etc., the generator voltage can be momentarily lowered by an automatic insertion of resistance in the exciter fields. This has in many cases proved to be quite effective in maintaining an uninterrupted operation, in that arcs, etc., may readily be extinguished through a lack of voltage.

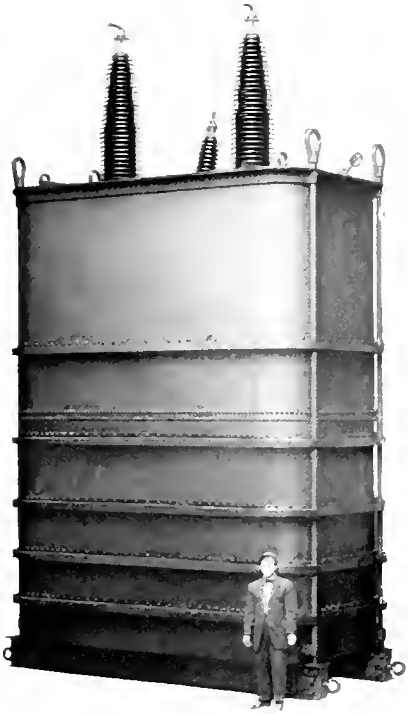

Fig. 7. A Water-cooled, 4500 Kv-a. Transformer, Primary Voltage, 150,000

Transformers also are now designed with a considerably higher reactance than was formerly the case—four to six per cent being now quite common. This will enable them to limit the current output at times of short circuits, and, besides this, to successfully withstand the tremendous mechanical strains to which the windings are subjected due to short circuits. It has been a common practice to provide step-down transformers with taps below the normal operating voltage, so that these taps could be used for compensating for the line drop as the load increased. It is obvious that the provision of these taps involves considerable difficulties, especially in very high-voltage transformers, and as very little use seems to be made of these taps in actual practice, they should be avoided as far as possible.

Considerable activity has of late taken place in the use of outdoor substations. This has been brought about with a view of reducing the investment cost although in many cases it seems as if just the opposite has been the result. In outdoor installations the transformers require the greatest consideration. Special precaution must be taken to protect them from heat in the summer and from cold in the winter. While the former can readily be obtained by providing sun shades, in certain instances very good results

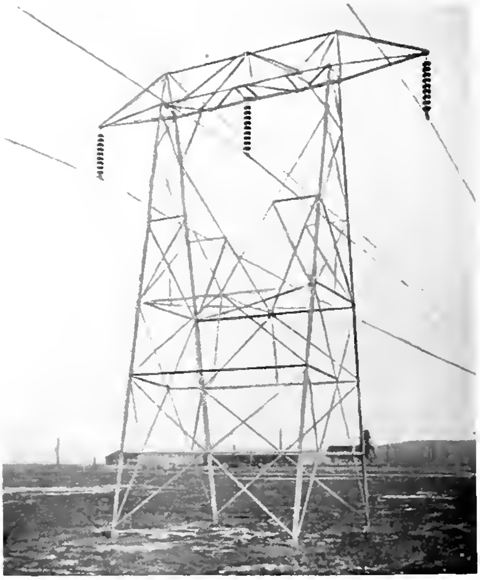

Fig. 8. A Tower of a 150,000 Volt Transmission Line

have been obtained by painting the tanks white. It is, however, more difficult to provide for the cold winter temperatures, especially with water-cooled transformers. With the transformers in service there seems to be no danger of freezing during cold weather, and the transformers should therefore always be connected to the system and thus energized. The main difficulty lies in the formation of moisture, which takes place when the temperature is allowed to fall below that of the surrounding air. This applies equally well to indoor transformers, and precautions must be taken therefore that this does not happen. Non-freezing oil may be used but its cost is comparatively high, and in many cases it is found more advantageous to provide heating grids in the bottom of the tanks.

On account of the increased size of our modern central stations and the concentration of large amounts of power in one place, it has been necessary to make provision for limiting the amount of current that may flow in case of a short circuit. This is, as previously mentioned, accomplished by designing the machinery for a higher inherent reactance and, where this is not sufficient, by inserting artificial reactances in the external circuits, such as the generator leads, the busses, or the outgoing feeders By so limiting the abnormal flow of current into a short circuit the generating system as a whole is relieved from the disastrous effects of such short circuits.

With the increased distances of power transmission lines and the higher voltages used for the same, the question of regulation has become one of utmost importance. The effect of the inductance and capacity of such line causes the voltage to vary within very wide limits from full-load to no-load. At no-load the large capacity current causes a rise of voltage from the generating station to the receiving end, while at full-load the lagging inductive current taken by the load in general more than off-sets the effect of the capacity current and causes a drop of voltage from the generating station to the receiving end. Many recent transmission systems have been made possible only by providing synchronous condensers for improving the regulation; so, for example, the latest 150,000 volt transmission system in California has required two 15,000 kv-a. synchronous condensers to take care of the regulation.

The electrolytic lightning arresters is generally used for protection against high voltage surges and has given very satisfactory results. It should not, however, be assumed that this device is a protection against all kinds of disturbances. Failures of lightning arresters can almost always be traced to some outside causes; as, for example, insufficient charging; poor regulation of the lines, causing higher voltages than for which the arrester is selected; high temperatures such as would be experienced from exposing the tanks to the sun, causing the electrolytic film on the cones to more rapidly dissolve, requiring a more frequent charging of the arrester.

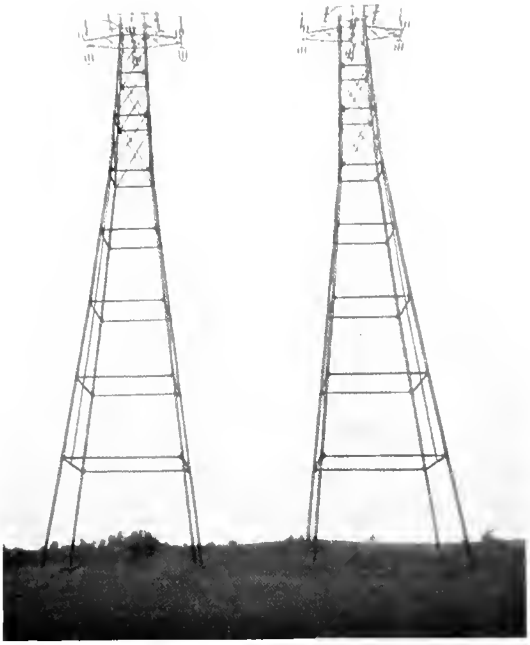

Fig. 9. Two 220-ft. Transmission Towers at River Crossing

The transmission line, on account of its position, is possibly the weakest link in a power system, and its design involves the highest class of engineering. Every precaution should be taken to avoid break-downs. The right of way should be of ample size, as far as commercial conditions will permit. Steel towers should be used as they insure an increased reliability as compared to wooden poles. For important plants it does not seem wise to depend entirely on a single transmission circuit, and double circuits are mostly provided. The same weight of copper divided into two circuits and supported by slightly modified towers will considerably reduce the chance of shut-down, with only a moderate addition of cost. The towers and line conductors should be designed with an ample factor of safety, and too much consideration can never be given to the effects of sleet and wind storms.

# RECENT ELECTRICAL PROGRESS IN THE INDUSTRIES

By A. R. Bush

Manager Power and Mining Department, General Electric Company

In spite of the enormous progress made in the use of electric energy by our industries during the last five years, the field for its useful application has not yet been half covered, and therefore the prospects for future business are very bright. Some of the older industries will have to adopt electric drive as an economic necessity when competition demands increased production at a decreased cost. The author shows that the electric motor has invaded almost every industrial field, and that results have been particularly gratifying in the mining, textile and agricultural industries. He concludes his article by referring to one or two notable accomplishments of the last year.—Editor.

A. R. Bush

During the past five years there has been a rapid increase in the volume of electrical apparatus distributed among the thirty or more industries in the domestic field, and as the number of plants equipped is a comparatively small proportion of the total number available for such installations, the same constant and healthful growth will undoubtedly continue for many years to come. With occasional peaks and valleys, the total amount of such business promises very shortly to far outrun in volume and variety, that of any other single class of manufacture. There is not an industry which can not profit very largely by the use of electricity in some form to enhance its economy, or increase its production with the resultant reduction in costs. There are, of course, many instances where the first cost of the necessary improvements in the way of electrical distribution of power may not be justified because of the previous expenditures made upon some other method of distribution, but there are probably very few, if any, instances where an original installation and distribution by electrical means will not, as a matter of economy, convenience, flexibility and cleanliness, prove its superiority in results over any other method now in use, and it has already been shown that there is a large field in all industries where it has been profitable to discard older methods and dispose of even comparatively new machinery to secure the benefits of electrical distribution, in spite of the added capital charges.

There are many amazing instances of inefficient and obsolete methods in the way of power distribution and power application still in use in some of the widely known industrial plants in this country. It is quite reasonable to suppose that the present profits in such plants are so satisfactory that there has not been that incentive to obtain lower costs in the matter of power and increased production, that is usually obtained. Unquestionably competitive conditions will ultimately make these changes necessary. In many industries, the cost of applied power to machinery is a very small proportion of the cost of the product of the same machinery, but of far greater importance is the increase of production to be obtained by the more flexible electrical methods. Progress in the development of special machinery to obtain the best results has naturally not kept pace with the increase in the volume, but a great deal has been accomplished in the last few years. There is a greater demand, on account of the benefits to be obtained, in the direct application of motors to machines of all types and capacities, and this requires the development of very considerable modifications of what have been called standard types of electrical apparatus, to secure the desired results. Progress in this direction will never cease if we are to judge by the progress in the past, and while the benefits of such development accrue in the largest measure to the user, the manufacturer also benefits in the constant increase of his output.

In the mining field, for instance, the results obtained from a properly designed and applied equipment are most gratifying. There has been a constant improvement in the type and character of mining locomotives with their more substantial steel side frames and electrical equipments, and a consequent lower cost of maintenance, and a promising field is developing in mining work for the storage battery locomotive, and possibly a little later we may see combinations of oil-electric trolley and storage battery locomotives for industrial, as well as mining work. It is not to be supposed that we have reached the ultimate type of locomotive for all such work. Increased economy is to be obtained in the operation of mine fans by the use of alternating current, varying speed motors of the Scherbius and brush shifting types, and the increasing promise of the introduction of electric hoists, as a measure of economy and increased production, will permit of complete operations by electrical means from a central source of power.

It is noteworthy that the two largest mining hoists in the world, thus far contracted for, are to be electrically driven in a territory where air and steam have been completely replaced by electricity. In the mining work, there is a large opportunity for the introduction of electrical or steam driven centrifugal compressors for furnaces and converters, and of electrolytic machines for the deposit of metals. Undoubtedly the process of leaching ores, now being introduced, will call for many machines of the latter type.

The introduction of central power stations, favorably located for the purpose of supplying power to widely scattered mines, has only just begun, and the possible available business in this line alone is enormous.

In the steel and iron industry, there is still a great work to be done in the volume of equipments of all kinds to be installed; but the engineering problems at present are largely those of refinement and improvement in details. The comparatively new varying speed, alternating current equipment of the Scherbius type for the operation of rolling mills introduces a new factor of value and importance in steel mill work. From results obtained, the turbine driven centrifugal compressors for blast furnace and converter work, on account of improvement in the operating conditions of furnace and increased production, will undoubtedly gradually replace other methods of furnishing air for the same purpose.

In the textile industry, new applications of a most interesting character are taking place with the special purpose of materially increasing the production of the mills with the same machinery and labor, and, in a measure, to get these results by automatic operations. This is very real progress and while textile mills were among the first to use the electric drive extensively, and some twenty years of steadily increasing installation work has ensued, there is still very satisfactory promise of new developments that will further enhance the value of the electrical drive. This can be attributed to the fact that our representatives and specialists in this particular line of endeavor have become so interested in their problems that they have spun yarns and woven cloth in order to become thoroughly familiar with the object they are striving to obtain—an idea which can undoubtedly be used to good advantage in various other lines of industrial work.

In practically all other industrial lines, there is the same tendency toward special applications to get better results.

It should be understood that the engineering problems of designing motors, in particular, to obtain the most desirable results, are not confined to any two or three industries. Specialization in this particular is necessary in nearly all the industries, and up to this time attention has been concentrated upon the larger industries, such as steel and iron, textile, cement and mining. This same study, in a measure, must be made in such industries as food products, oil, salt, rubber, sugar, tobacco, chemical works, etc., and while much has been done in such industries as shoe and leather, pulp and paper, lumber, woodworking and clay products, still further engineering investigations are desirable to improve the methods of applying power.

The irrigation field naturally increases with the distribution of transmission lines from central power stations and it is believed that this field for the use of motors will continually increase for many years to come. Naturally the extension of transmission lines through the oil fields brought about the use of motors for drilling and pumping oil wells, at a marked saving to the owner of the wells. In spite of the fact that this seems to be a simple application, standard motors were ineffective and specially designed motors for this particular duty were absolutely necessary to get desired results.

In the equipment of machine tools, specialization is the first principle, and the results obtained, as for instance in the reversing planer equipments, must certainly justify investigation and development. In so short an article, it is not possible to more than glance at the possibilities in the industrial field, but that can hardly be over-estimated.

The year just closed is somewhat remarkable for notable electrical accomplishments in our general work. The installation of the largest turbo-generator, electric locomotive, self-cooled transformers, highest operating voltage, largest d-c. generators and rotary converters is certainly an indication of progress, as well as the development of the Scherbius outfits, brush shifting, varying speed a-c. motors and phase advancers. The past year has been remarkable for the completion of some of the largest plants in existence and the placing of orders for others in the same general class—such as the hydroelectric plants of the Mississippi River Power Company at Keokuk, Iowa, of fifteen 10,000 kv-a. generators; Cedars Rapids Manufacturing and Power Company, near Montreal, of ten 10,000 kv-a. generators; Pacific Light & Power Company on Big Creek in Southern California of four 17,500 kv-a. generators; Southern Aluminum Company at Whitney, N. C., of eleven 5200 kw., 520 volt direct current generators, and the installation for the Aluminum Company of America at Massena, N. Y., of eighteen 2500 kw. rotary converters; together with the volume and variety of apparatus which has been installed on the Panama Canal, the New York State Barge Canal and the Catskill Aqueduct, the largest public improvements of their type in the world.

In general, these are only made practical and possible by the past twenty years of continued growth and progress in the development of electrical machinery.

A 110,000 Volt Outdoor Substation. Georgia Railway & Power Company

# ELECTRIC POWER: ITS SOURCES AND THEIR PERMANENCY

By Fred. M. Kimball

Manager, Small Motor Department, General Electric Company

The author points out that the prosperity of the country depends upon its industries and that its industries are dependent upon an ample supply of energy at a reasonable cost. The industrial progress already made has enabled the worker to live rather than exist, and future progress is likely to still better the conditions of life. While other sources of energy, such as coal and oil, may ultimately fail, the sun, from which they all originally derived their energy, will still remain and will at all times provide ample water power for future generations. —Editor.

**Fred. M. Kimball**

BROADLY speaking, all material progress in the development of a country, all important improvements in the conditions of life and living, are vitally dependent upon a reliable supply of power that can be readily augmented, as occasion requires, that can be easily and economically distributed, and that can be purchased at a moderate price.

In the United States particularly, where manufacturing dominates all other industries, and where success in every competitive business makes it more and more imperative to secure the greatest output in product or service per unit of labor employed, an ample supply of power at moderate price is a pre-eminently important essential.

The use of power and all the mechanical devices used to displace manual labor is by no means confined to manufacturing industries, but has been largely extended into the domains of mining, commerce and agriculture, as well as to those more commonplace, but not less important, domestic and personal services which contribute so much to the comfort of living in the 20th century. Because of the vast natural resources of our country, which modern transportation facilities have made so accessible to development, and which have yielded such generous and well distributed wealth to the inhabitants of the country, and by reason of the universality and excellence of the education which our magnificent public school system has made available to all, the people of the United States have come to exercise a nice discrimination between existence and living, and demand not only the necessities but a measurable share of the comforts and some, at least, of the luxuries of life. The constantly rising wage scale which permits the achievement of this standard of living has even now become so high that all employers must be indefatigable in providing every supplementary means that will insure the most efficient use of human labor. Power and machinery afford the best supplementary means to this end yet devised.

Nature has ever been wonderfully considerate and provident for the needs of her children. She has given lavishly for their necessities, and in no direction more generously than in her provision to supply heat, from which we derive our most important power supply.

While steam and gas engines or waterwheels fully realize the popular conception of primary sources of power, it must not be overlooked that the engine and the waterwheel are only devices for the transformation of other forms of energy into their mechanical equivalents of rotary torque, and in the last analysis and generally speaking, we shall find that that magnificent center of our universe, the sun, is the principal and perhaps the only source of all power which we at present utilize.

As a beam of sunshine of known dimensions has been made to give up its radiant energy to a weighed mass of water, scientists have calculated for us the amount of heat given off by the sun under varying conditions of time, distance and area. A brief reference at this point to generally accepted data concerning the intensity of solar heat may be pertinent and instructive. The sun's radiation in heat units has been calculated as exceeding 1,200,000 great calories per minute for each square meter of surface. Further calculations indicate that to produce this amount of heat by combustion would require the hourly burning of a layer of anthracite coal more than 19 feet thick over the entire surface of the sun—the sun's surface being 11,940 times that of our earth's. This is equivalent to a continuous radiation of about 12,000 h.p. from every square foot of the sun's entire area. Of this extraordinary outflow of heat, equal at the solar surface to 12,000 h.p. per square foot, the earth intercepts only about $\frac{1}{2,200,000,000}$ part. Even this minute fraction is equivalent to 1 h.p. for every 16 sq. ft. of the earth's surface.

The mighty power of this great luminary, 1,300,000 times larger than our own earth, has been appreciatively and eloquently expressed in the following fine passage from Tyndall:

> "I looked over this wondrous scene towards Mount Blanc and the thousand lesser peaks which seemed to join in the celebration of the risen day. I asked myself: How was this colossal work performed? Who chiselled these mighty and picturesque masses out of a mere protuberance of the earth? And the answer was at hand. Ever young, ever mighty—with the vigor of a thousand worlds still within him—the real sculptor was even then climbing up the eastern sky. It was he who raised aloft the waters which cut out these ravines; it was he who planted the glaciers on the mountain-slopes, thus giving gravity a plough to open up the valleys; and it is he who, acting through the ages, will finally lay low these mighty monuments, rolling them gradually seaward, sowing the seeds of continents to be; so that the people of an older earth may see mould spread, and corn wave over the hidden rocks which at this moment bear the weight of the Jungfrau."

The power obtained from falling water and in a large degree the power obtained through the combustion of coal and other fuels was primarily transmitted to the earth from the sun as heat. In case of the water, the transformation of solar heat into the potential energy contained in falling water is still going on. In case of the coal, the absorption of the sun's heat energy, transformed and stored up in the coal, took place thousands of years ago.

In addition to our stores of coal from which heat may be derived, but again essentially dependent on the sun for their contained latent energy, we have extraordinary stores of lignite, petroleum and peat, and an ever-perpetuated growth of wood and minor vegetation, from which latter alcohol may be easily and cheaply prepared, both wood and alcohol possessing high thermal values as fuel.

Finally, we have the direct heat radiated by the sun, and as additional but yet unutilized sources of power, the attractive or gravitational pull of the sun and moon, evidenced by the rising and falling tides and the ceaseless wave motion of our oceans and great lakes. Unfortunately, we have not yet been able to devise practicable means for utilizing the power of the tides and waves directly or with any mentionable degree of commercial efficiency, but both will undoubtedly be brought into the service of man.

The era of the formation of coal and oil deposits in the United States is past. It is hardly probable that any future era will witness conditions on this planet that will bring into operation the combination of forces which are necessary to form new supplies. When the existing coal and oil are consumed, the supply of heat and power derived from these sources will be at an end. Whatever equivalent of heat and power supply can be obtained from falling water is, however, so far as we now know, self-perpetuating as long as the phenomena of aqueous evaporation, condensation and precipitation survive, as long as the attraction of gravitation exists, in short, as long as the sun continues to shine, for the same source of energy which gave us our fuels makes possible our waterfalls.

The observed diminution in the radiation of heat and other forces projected from the sun has been so slight within the time covered by the records of man, that based on a priori reasoning, we feel quite sure that there will be no sensible diminution in the amount of energy which the sun will supply to this earth for thousands and perhaps for millions of years to come.

It is well known that heat and power, or, in its most useful form, rotary torque, are interconvertible, and the energy of falling water may be easily turned into the energy of heat through the intermediary of suitable mechanical and electrical devices.

With an adequate supply of water power available, we need not draw further on our supplies of coal, of oil or of wood for light, warmth or power, since through the agency of electricity we can transform the energy of falling water into the energy of heat, power or light, and in case of power and light particularly, this transformation can be accomplished with comparatively high efficiency. When we consider the average requirements of each individual for heat, light and power, and reduce them to a common unit of measurement, we find that, very roughly speaking, each inhabitant of the United States requires an average expenditure of the equivalent of something like 13 horse-power-hours per day to provide for his or her needs in heating, cooking, lighting, manufacturing, transportation and allied services. Of this amount, about three horse-power-hours is consumed in manufacturing, about 2.5 horse-power-hours is used in transportation; a somewhat smaller amount in lighting and general power purposes; and the balance, or five horse-power-hours, is consumed in heating and cooking. In other words, energy equivalent to about 5 horse-power-hours is consumed for maintaining suitable temperatures within doors and furnishing heat for all classes of domestic and other utilitarian uses.

As no means of distributing, transforming and utilizing power with a high degree of efficiency, wide applicability, thorough dependability and low cost, has yet been discovered that can compete with electricity, this wonderful agency has naturally become man's most popular, reliable and capable servant in doing the world's work. The public is already fairly well acquainted with the extraordinary growth of electric lighting, and the use of the incandescent lamp is quite general, even in small and remote villages. Although the advantages to be derived from the use of electric power are not so widely appreciated, and it is not quite as commonly used as is electric light, electric power is very generally employed in our large cities and towns. The electric motor is becoming ubiquitous; it is dependable, efficient and easily operated, it has been utilized in an extraordinary variety of services, and although now employed to a greater or less extent in almost every industry, the field for its application and use ever grows broader and more attractive as users gain additional familiarity with its advantages.

The present is truly the electrical age. The problems attendant upon the generation, transmission, transformation and utilization of electricity are well solved. We only need a larger supply at lower cost to make its use almost universal. A long step toward realizing this condition will have been taken when our law-makers come to appreciate that true conservation of our water powers really means their immediate development for enhanced supply of electric power, under just but liberal laws, and not the withholding or discouraging of such development for an indefinite time, with consequent irreparable waste of the enormous energies provided by Nature for the comfort and welfare of mankind.

# COOPERATIVE STANDARDIZATION

By J. W. Ham

Power and Mining Department, General Electric Company

This article, after pointing out the advantages that large manufacturers have gained by adopting individual standards for their own apparatus, proceeds to show that great economies could be secured to the industry as a whole if more universal standards were adopted. The author cites some of the advantages gained by international and national standards. He selects fifteen 3 h.p. constant-speed d-c. motors of different manufacturers and shows their physical differences, and after analyzing these suggests how standards might be adopted. The advantages of such standards to both the makers and users of machine tools, large pumps and compressors, and the motors to manufacturers themselves are enormous and the author thinks that these advantages should be secured by proper cooperation.—Editor

J. W. Ham

About 1,250,000* electric motors were purchased in the United States during the year 1913. Such is the demand, and it is ever increasing, for electric motors. To properly care for his share of the growing volume of business each manufacturer has found it necessary to standardize his product as far as possible and to put production on a quantity basis. Not only does this simplify factory methods, cut down overhead charges, and reduce the estimating force, but, what is of equal importance, it means better service at lower cost to purchasers—two vital considerations in business affairs.

The facilities for handling special, or modifications of standard apparatus of necessity extends through an entire organization as each case must be treated separately and on its merits; while in constructing and selling standard apparatus, the most direct course is adopted from producer to user. Herein lies the saving by standardization as it presupposes quantity production and the retailing of the article on the basis of wholesale cost.

If there is an advantage in individual standards how much more general and therefore greater are the benefits to be derived from what might be termed a universal standard,

---

*Estimated.

by which we mean one that falls within certain approved limits adopted by all manufacturers of a given product. But in the selection of individual standards has there not been an unintentional misdirection of effort, in that each manufacturer has worked out his own standards without due regard to those of others, so that after all we find as many standards as there are manufacturers of a given product. Due to the activities of the A.I.E.E. much has been accomplished along lines purely electrical. Only a few years ago we met with a great variety of temperature guarantees. Different engineers and different purchasers specified temperatures which were standard with one motor manufacturer but special with another. Out of that confusion the A.I.E.E. has brought uniformity by adopting standards now generally recognized. But there is as yet no mechanical uniformity nor are there any rules suggesting approved methods to serve as a guide to future development. That the minds of men who have to do with these things should be focused on this problem is obvious. One has but to compare the physical dimensions of the various makes of motors to appreciate the need of a concerted action toward a physical standard, within reasonable limits.

Selecting at random fifteen 3 h. p. constant d-c. motors of different manufacturers we find:

| | Min. for 15 Motors in In. | Max. for 15 Motors in In. | No. Alike | No. Different |
|---|---|---|---|---|
| Length over all | $17\frac{9}{16}$ | $28\frac{3}{16}$ | 2<br>2 | 13 |
| Width | 12 | $16\frac{3}{4}$ | 3<br>2 | 12 |
| Center line to bottom of feet | $6\frac{1}{4}$ | 9 | 2<br>2 | 13 |
| Distance between holding down bolts, end view | $9\frac{1}{4}$ | 13 | 3<br>2<br>2 | 11 |
| Distance between holding down bolts, side view | $5\frac{11}{16}$ | $13\frac{1}{4}$ | 2<br>2<br>2 | 12 |
| Shaft extension beyond housing | $2\frac{1}{8}$ | 5 | 3 | 13 |
| Diameter shaft extension | $\frac{7}{8}$ | $1\frac{1}{4}$ | 4<br>4<br>2<br>2 | 7 |

It will be seen that the nearest approach to a uniform standard is in the diameter of the shaft, but even that might be expressed as 46.6 per cent off standard while the greatest deviation is found in the length, which is 93.3 per cent off standard. Considering all the physical dimensions the variation from a universal standard is 100 per cent; i.e., no two are alike or sufficiently so to be easily interchangeable one for the other without more or less changes in the mounting.

Although the foregoing figures are for constant speed motors the comparison holds for those of the adjustable speed type as well, i.e., machine tool motors, because of the almost universal practice of obtaining adjustable speed motors from constant speed frames. It is, therefore, at once apparent that when the driven machine and its driving motor are to be assembled as a unit the problems of securing interchangeability are stupendous and often impossible without involving much additional expense, longer shipments and altogether poorer service to the purchaser. The shafts perhaps could be easily standardized, and there is no reason, except lack of cooperation, why shaft diameters, extensions and keyways for a given horse power and speed should not be alike for all motors of whatever manufacture when used for the same service. Suppose these fifteen motors to have identical shafts for the reception of pulleys, then one size pulley only would be used where now seven different ones are required. The pulley manufacturers cannot standardize all of these because of the limited demand for each size. They must therefore be built to order at necessarily higher cost to the user and delayed deliveries. This is equally true of pinions for geared machines, and for couplings when direct connection is desired so that savings which might be small per unit cost of production would in the aggregate be very great. It is doubtful if the actual savings could be determined in dollars and cents because interchangeability of spare parts is the best insurance against idle machines due to accidental breakage.

That no inflexible rule can be deduced fixing all the physical dimensions of motors is recognized because of differences in shop practices and the widely varying ideas of designing engineers, nor is such a thing to be desired; but there could be approved limits within which new designs should fall and which would not in the slightest degree interfere with each manufacturer's individuality of design or the successful operation of his machines. The art of designing small motors, after years of experience, is pretty well established and it is generally known about what output can be obtained from each pound of steel, iron and copper when properly distributed, so that it should not be difficult to reduce the housing of the different parts to a practical standard.

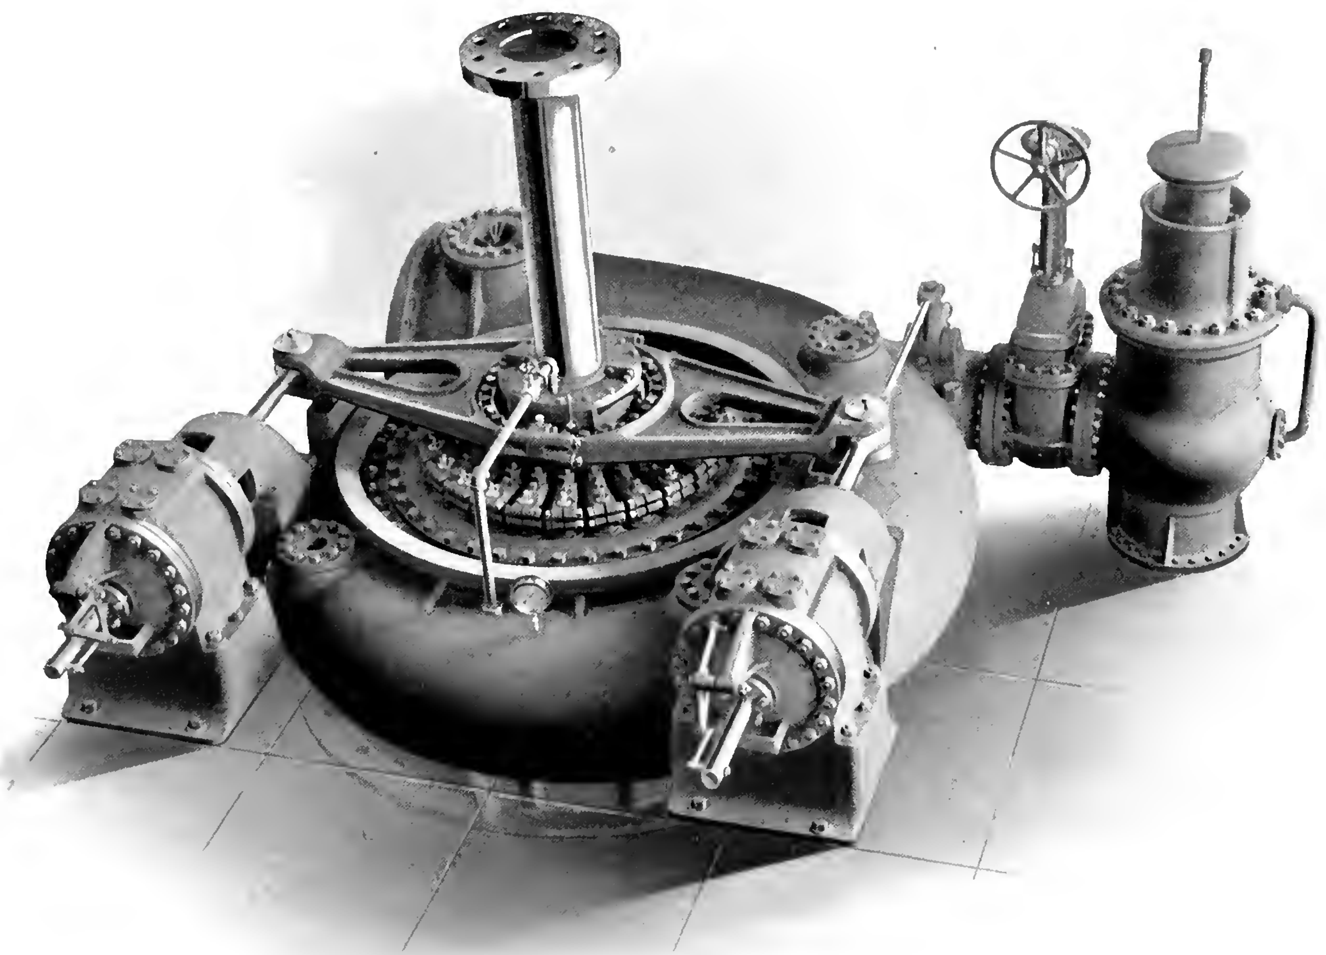
But the scope of a universal standard is much broader than its application to electric motors alone and the benefits to be derived through its realization would be restricted unless similar standards were adopted for the driven machines, such as machine tools, pumps, compressors and all those which in combination with the motor form a complete operating unit.

To construct machine tool motors of predetermined horse power capacities, speeds and physical dimensions would in a measure be like "chasing the rainbow" unless the tools were designed to receive motors capable of driving those tools at maximum duty, and with the proper gear ratios that would permit of standardization of pinions and gears. Reference is made to maximum duty because a given machine tool may be used for light, medium, or heavy duty, thus requiring three different horse power capacities for the same tool under different conditions of work. Here we have a condition where the tool is standard within its range but one for which the motor requirements may change in accordance with service conditions. It is then either necessary to standardize a motor capable of driving the tool under maximum cutting operations, and use it for lighter duties as well, or for the machine tool builders to provide a form of mounting that will take any one of three motors with the least possible inconvenience in the assembly. Obviously this is one of the problems for consideration by machine tool builders, none of which should offer insurmountable difficulties provided there is that cooperation which the results would justify.

That the tendency is steadily toward individual drive of machine tools is incontrovertible. The user first selects the make of tool which he considers best suited to his requirements, one of which is that it must remove so much metal in a specified time. To displace that metal a definite horse power is needed and just as there are reasons which cause the user to purchase a certain make of tool so are there considerations that often lead him to specify the make of motor, which he buys direct from the motor manufacturer or through the machine tool builder. In either event the machine tool builder must make provision for mounting the motor. He frequently has no choice in the matter nothwithstanding the fact he is prepared to furnish a standard outfit while special construction is necessary to meet the wishes of his customer. Were there standards for machine tools and standards for motors of various makes this difficulty would be eliminated.

In the case of large pumps and compressors the conditions are somewhat different from those of machine tool applications in that the physical dimensions are relatively less important, the variables being horse powers and speeds for direct current and induction motors with the added feature of power-factor and torque should the motor be of the synchronous type. Here the first step toward standardization clearly devolves upon the pump and compressor builders, because no scheme of standards for motors at present in use, or possible of adoption, could provide for the almost infinite variety of ratings required. Since electric motors are now generally employed to drive all classes of machinery the view that greater uniformity is needed in horse power and speed requirements of the driven machines seems warranted.

Perhaps this can best be illustrated by actual figures. The writer investigated the motor requirements of six manufacturers producing machines standard with them, and all for similar service. The driving motors required were three-phase, 60 cycle synchronous units and the capacities specified were from 44 h.p. to 1900 h.p., and the speeds were from 90 r.p.m. to 325 r.p.m. There were a total of 135 ratings needed to motor these machines, of which seven only could be used by more than one manufacturer. In other words, the list called for 128 different motors, not one of which could be used by any two manufacturers of the driven machines. As any one of four voltages, i.e., 220, 440, 550 and 2200 volts, is common throughout the country the actual number of motors to design was 512. With reasonably uniform speeds and capacities of the driven machines about 30 motors would fulfill the requirements of the 128, or considering all the voltages, the designs would number about 120 instead of 512. So we urge a greater and more comprehensive standardization, not only individually but collectively. Can it be done? Assuredly, since it is an urgent economic need and we have the faith to believe that that which is good for all will ultimately be achieved through cooperation.



17,000 H.P. Hydraulic Reaction Turbine of the Tallulah Falls Development, Georgia Railway & Power Co.
This turbine operates under a 600 ft. head, and is the highest head reaction turbine in service in this country
(This development is described in an article beginning on page 608)

# A REVIEW OF RECENT DEVELOPMENTS OF THE HYDRAULIC REACTION TURBINE

By H. Birchard Taylor

Hydraulic Engineer, I. P. Morris Company, Philadelphia, Pa.

Mr. H. B. Taylor's contribution to this special issue of the Review is a most comprehensive treatise on a subject which is of the utmost importance to the hydro-electric engineer. It would be impossible to give a brief digest of so full a discussion of this subject. The completeness can be judged by the following headlines, under which Mr. Taylor treats his subject: "The Design of Testing a Turbine in America; Mechanical Features of Turbine Construction; General Arrangement of Unit; Volute Casing; Draft Tubes; Supporting Rings and Face Plates; Pressure Thrust Bearing; Roller Bearing; Guide Bearing; Mechanical Details; and Speed Regulation.—Editor.

H. Birchard Taylor

## Design and Testing of Turbines in America

THIS article is limited to a discussion of the recent practice in the design and construction of reaction turbines in this country, with special reference to certain mechanical features of the modern turbine and the discussion of a number of points where practice has not yet become standardized. It is now well known that the early development of the hydraulic turbine in America was carried along empirical lines, and that the application of logical engineering methods has been of comparatively recent date. It is also known that many turbine manufacturers in this country still adhere to the older methods, and produce turbines of stock designs and standard sizes, relying to a great extent on the use of existing patterns.

It may not be as generally recognized as it should be that a considerable proportion of the current technical literature which has appeared upon this subject has dealt largely with the turbines included under this classification of stock apparatus. As little scientific engineering work has been involved in the development of this class of machinery, the value of such material as can be found in many of our technical papers is not great. When it is realized that many new problems of fundamental importance are being frequently met and solved in this field, and that much engineering effort is being called out in the present widespread development of water powers in this country, the need will be felt of the publication of information regarding recent practice in this field and for fuller discussion of the many important details of this subject.

The "stock turbine," so-called, has not for many years been representative of the best work produced in the United States. A number of American builders have successfully undertaken developments requiring the highest type of engineering skill and initiative, and much pioneer work in the extension of hydraulic turbines, to cover most severe conditions and a wide range of capacity and dimensions, has been undertaken.

A large part of the credit for present attainments in American turbine construction has been attributed to the systematic testing of waterwheels, which has always been a feature of American practice. Several thousand tests have been made at the Holyoke testing flume, and undoubtedly the results of these experiments have been of the greatest service to American engineers. Until these experimental results were supplemented by proper theoretical investigation progress was, however, comparatively slow, and recent progress has been possible only through a more scientific handling of the problems which have arisen.

While reviewing a discussion which took place at a meeting of one of the engineering societies held four years ago, the writer encountered a few statements which may be of interest at this point, such as the following:

"Many of the wheel manufacturers have gone to extreme pains to put their wheels into splendid condition for testing at Holyoke, and the wheels have shown correspondingly excellent results, but these conditions would not last long, so that in actual practice the wheels would doubtless show quite different results from those obtained at Holyoke . . . .

"The wheel manufacturers do not as a rule guarantee their wheels at over 80 per cent efficiency, and this would seem sufficient reason to believe that they themselves do not place too much reliance on the results obtained at Holyoke. There are times, however, when wheel manufacturers will guarantee considerable increases over 80 per cent. But I am strongly inclined to believe, partly from experience, that they will balk when the purchaser asks that this guarantee be placed on paper, that the wheels be tested and that a bonus and forfeiture clause be put into the contract. For these reasons, it seems to me decidedly advisable to test the wheels under conditions of installation . . . . . . . . ."

Quoting from another contribution to the same discussion:

"One of the greatest stumbling blocks in the path of turbine development in this country has been the lack of systematic testing after installation. Errors in design have been made and perpetuated year after year, simply because purchaser and manufacturer have been satisfied to believe that turbines showing splendid results at Holyoke, under a head of 18 feet or less, would give as creditable performances when used with heads five or ten times as great. That this was beyond the limits of reason we know now and should long since have known . . . . . . ."

The writer trusts that no one would at the present time repeat the foregoing strictures on the efficiencies of American turbines, because there have been many well authenticated tests of turbines after installation and, under actual conditions of operation, showing efficiencies ranging from 88 to 93.7 per cent. It is believed that the demand for high efficiency may now be said to have been satisfactorily met.

Before leaving the statements above quoted, attention may be called to a number of points which the writer believes are not clearly understood by some engineers. The following facts are in line with accepted principles, as well as with actual results:

First: If results of the Holyoke tests on a small model runner are properly interpreted and applied scientifically to the design of a large turbine of like characteristics, then the results with respect to efficiency and power obtained from the large turbine when tested in place will be found to check, within a very small percentage, the results forecasted by the Holyoke test.

Second: The variation of efficiency obtained in place from that shown at Holyoke may be calculated with a satisfactory degree of precision. If the setting of the large turbine is equivalent to that of the model when tested at the Holyoke flume, the shape of the efficiency-horse power curve of the large turbine will check the corresponding Holyoke curve very closely.

Third: If the setting of the large unit is superior to that in which the model runner was tested at Holyoke, as is almost always the case in larger modern developments, then the efficiencies of the large machine will exceed those obtained at Holyoke, and the effect of increased dimensions of the runner of the large turbine over the model runner, as well as the variation in head, can be definitely computed without any notable degree of uncertainty.

Fourth: The effect of increases in head and dimensions on turbines of exactly similar design is not to impair the efficiency, as might be inferred from the above quotations, but both changes have the same result, viz., an increase in efficiency if the character of the turbine setting remains the same. This is in accord both with a theoretical formula due to Dr. Camerer, of Munich, and with actual experience.

With reference to one of the statements just quoted, to the effect that it is unreasonable to expect that wheels tested in place under high heads should make as good a showing as the "splendid" results secured under a low head at Holyoke, it is worth noting that results are now secured in large wheels in place, under heads many times greater than the Holyoke head, which exceed the "splendid" results at Holyoke by an average of three or four per cent. In other words, the setting of the experimental model at Holyoke is, at best, by no means splendid when compared with the setting which may be secured in the case of large units.

The writer might also quote in this connection a few sentences from a technical journal regarding the recommendations read before the Boston Society of Civil Engineers, recently submitted in favor of a National Testing Flume:

"Waterwheels have increased so much in size in recent years, and are operated under so much higher heads, that there is no place in the United States where they can be adequately tested before their final installation.

"The Holyoke testing flume . . . . . . is no longer large enough, nor does it have sufficient head to meet all of the present day needs. . . . . . .

"The art of waterwheel design is still in rather a crude state and needs such authentic and reliable information as the proposed flume will furnish. . . . . . . . . ."

While not wishing to injure the movement mentioned in the slightest degree, the writer is of the opinion, in view of the character of arguments advanced, that the technical press in general as well as many engineers are not really familiar with the methods used by the builders of the higher class of apparatus, in respect to the application of the results of the Holyoke tests to the designs of large turbines.

It is not impossible, as may be inferred, to predict from tests at a low head on a small model runner of homologous design, the performance of a large turbine under a high head. The writer also does not consider that the art of waterwheel designing is in rather a crude state.

The efficiency guarantees covering the turbines for the Appalachian, Keokuk and Cedars Rapids developments were made under very severe bonus and penalty clauses. The guarantees made by the builders were based directly upon the Holyoke tests, and the results secured in the Appalachian and Keokuk units have clearly demonstrated to the satisfaction of all parties concerned that the methods used by the builders in interpreting and applying the Holyoke tests to the design of turbines of the largest sizes are correct.

It may be stated that in every instance where a large turbine has failed to produce results as good as those forecasted by the Holyoke tests, such failure may be attributed either to improper application of the tests or to the placing of too much reliance on the runner without proper regard to the effect upon the runner of defective wheel-casings and draft tubes. If engineers permit the runners of large turbines to be used in connection with defective settings, then the failure of the large turbines to come up to expectations should not reflect on the Holyoke flume.

Before leaving the question of the Holyoke tests, it may be pointed out that the builders of the better class of machinery have used and are now using the Holyoke flume only when they desire to secure experimental data beyond the range of the theoretical data previously substantiated, or in cases where it is desirable to insure the successful outcome of an important contract by checking the runner calculations previous to construction.

### Mechanical Features of Turbine Construction

Although the question of efficiency is of vital importance in many installations and is becoming increasingly important every day, there are other questions in connection with the construction and installation of the modern turbine which should be given even greater weight.

Many engineers have come to recognize the value of efficiency, but only those who have had actual experience in the operation of completed plants can realize the importance of questions of design and workmanship used in the structure of the unit and in the mechanical details of the machine. Such questions as continuity of operation; freedom from interruption for repairs; the rapidity with which accidental damage may be rectified; and absence of vibration, noise and rapid wear are vital considerations in any hydro-electric plant. The stability of the design of a turbine as affected by the amount and disposition of the material and the careful calculation of stresses under all possible conditions; the mechanical operation of the unit as affected by careful study of the design of each detail; the convenience of the arrangement of the parts and their accessibility for dismantling for repairs; and many other features of construction, have a much greater effect on the success of the turbine than is generally realized. Unfortunately, many of these points cannot be easily covered in specifications, and although the best solution of many of these problems involves considerable increases in the cost of the turbine, it is difficult to assign to them a monetary value, so that a decision regarding various questions of design is often one of the most difficult problems which the consulting engineer encounters.

Engineers who have been responsible for the operation of large stations over many years of service generally view these questions from a different standpoint from that held by the purchasing agents of new developments.

### General Arrangement of Unit

In the special number of this REVIEW for June, 1913, devoted to hydro-electric developments, the writer contributed an article on vertical shaft, single runner hydraulic turbines as applied to low heads. The advantages secured in this type of unit over the multi-runner horizontal wheels which had been popular until recently were discussed both from hydraulic and mechanical considerations, and it was predicted that in the future the single runner vertical wheel would be generally adopted for low head installations. During the past year, we find that the vertical unit has almost entirely superseded the multi-runner horizontal type and in the case of first class installations waterwheel builders now seldom receive inquiries for horizontal multi-runner units except as additions to existing installations.

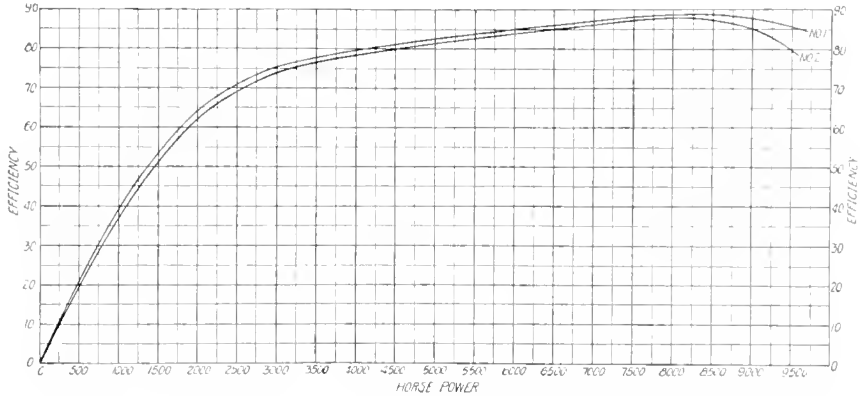


**Fig. 1**

Curve No. 1. Official efficiency test curve of the 9000 h.p. turbines designed and built by the I. P. Morris Company for the Washington Water Power Company. Head 66 ft.; speed 150 r.p.m.; rated runner diameter, 6 ft. 2 in. Test made January, 1911. The Washington wheels are of the horizontal shaft, two-runner, central discharge type, equipped with volute casings. Curve No. 2 is derived from test at Holyoke of the experimental runner, having a rated diameter of 2 ft. $8\frac{11}{16}$ in. Test made October, 1909. Experimental runner was tested in vertical setting.

The curves are almost identical in shape; the efficiency of the large units exceeding by a small margin that of the experimental runner. This illustrates the fact that in the case of large units, with properly designed water passages, even when the type of unit is entirely different from that of the experimental model, an accurate forecast of the performance of the large unit may be secured from the test of the model. Although there were losses in the draft chest of the large turbines which were not present in the experimental testing outfit, these losses were not sufficient to overcome the gain in efficiency in the other water passages.

Plans are now under consideration by a number of power companies contemplating the use in the case of additional units of the vertical single runner type even when the uniformity of the station is thereby destroyed, a fact which speaks strongly for the general appreciation of the advantages of this type of unit. In the plant of the Pennsylvania Water & Power Company at McCall Ferry there are now installed seven vertical shaft two-runner units. The substructure of the power house has been built for ten units of this type. Unit No. 8, however, which is now under construction, will be of the single runner type, and that part of the substructure which had previously been constructed will be remodeled so that the single draft tube required by the newer type of unit may be used, and the existing rectangular intake flume will be modified for the construction of a concrete volute casing. The fact that the company mentioned has found it an economical proposition to alter their existing substructure, at no little expense, to accommodate the single runner type of turbine is a strong argument for the adoption of this type in new installations.

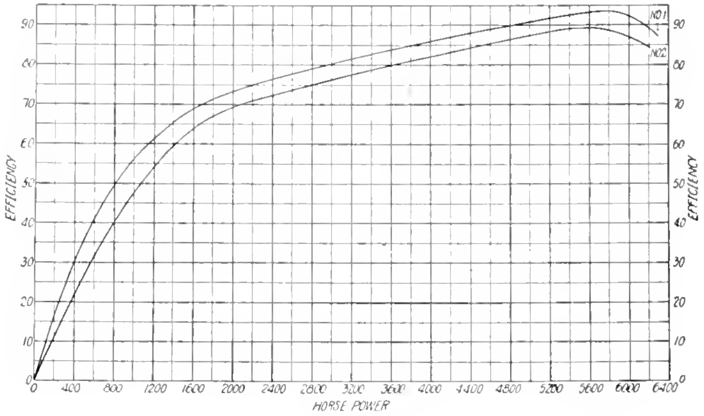

**Fig. 2**

Curve No. 1. Official test curve of the 6000 h.p. turbines designed by the I. P. Morris Company for the Appalachian Power Company. Head 49 ft.; speed 116 r.p.m.; rated runner diameter 7 ft. $6\frac{1}{4}$ in.; test made February, 1913. These turbines are of the single runner, vertical shaft type. Curve No. 2 is derived from the test of the small experimental runner at Holyoke; rated diameter $27\frac{3}{8}$ in.

Both curves are identical in shape, but owing to the superior arrangement of water passages in the Appalachian plant, the efficiencies of the large units exceed those of the experimental runner by a considerable margin.

It has also been noted during the past year or two that the vertical single runner type of unit has found increased application to moderate and high heads as well as in low head plants. While its advantages over the horizontal, multi-runner low head type of turbine are numerous, it also has a number of important advantages over the horizontal single runner or horizontal double runner turbine for high head installations.

The trend of present development in the field of the reaction turbine seems to be in the direction of a still wider application of the vertical single runner unit to all conditions of head and speed. There are, of course, a few cases where the horizontal shaft unit may still afford the best arrangement as, for instance, in plants where the layout of the power house requires an overhead intake to the turbines, and in cases where direct current generators are to be used.

### The Volute Casing

Present practice seems to favor the molding of the volute casing directly in the substructure of the power house, for all low head turbines. For heads exceeding 100 feet, the amount of reinforcement required in the concrete is almost always sufficiently great to call for the use of cast iron casings. As the pressures increase, the cast iron must be increased in thickness, and for heads exceeding about 250 feet the use of cast steel as the material for the casings may be said to be standard practice in the best class of turbine construction. The use of steel for such conditions is advisable upon many grounds, and most particularly from considerations of safety against the severe surges which may occur in most high head plants, since such plants almost invariably include long pipe lines or penstocks.

In this connection the use by some builders of a material designated as "semi steel" may be mentioned. This term may be understood to refer to material run from an ordinary iron cupola, in which a certain amount of steel scrap has been introduced. It may be safely stated, however, that castings made from such material, which is handled at temperatures much below that necessary for steel, are nothing more than cast iron, and when submitted to test will exhibit all the characteristics of cast iron, such as absence of ductility, poor resistance to shock, and rapid fatigue under repeated stresses. The term "semi steel" is, therefore, held to be meaningless, and the most that can be said for it is that it is sometimes used to indicate a good grade of cast iron as distinguished from a poor grade.

In connection with the question of the construction of the volute casing, an important point which is not always given proper consideration is the adherence in the design to principles which are in accord with the best foundry practice. Thus, care should be taken that the casting be of uniform thickness; that the attachments of brackets, lugs, feet or external projections of any kind to the shell be avoided; and, in fact, the recognized rules of good foundry practice be applied to this important part of the turbine. Any junction of an external web or projection with the shell of the casing, or any point where an increase of thickness of metal occurs, will result in unequal cooling in the mold, producing spongy metal in the interior of the casting where it is invisible but dangerous, and with an accompaniment of initial stresses of indeterminate amount. That these well-recognized rules are not followed in all cases is shown by the attachment by some builders of numerous pads and supporting brackets to the cast iron volute casing, and in some instances, the casting integrally with the casing of a heavy base ring or supporting flange; and still worse, of casting the speed ring vanes connecting the upper and lower sides of the casing in one piece with it. The speed ring vanes must be made very heavy in section, and it may be confidently stated that it is impossible to avoid the presence of defective metal at the juncture between these vanes and the casing, or at the juncture between supporting flanges and the casing. In addition to this, initial stress of indeterminate but certainly dangerous amounts must exist in such casings. The best modern practice seems to be in making the speed ring separate from the casing proper and, in the case of medium or high head turbines, to use a cast steel speed ring in connection with cast iron or cast steel casings.

In a number of notable recent developments involving high and moderate heads, the turbine casings have been embedded directly in the concrete substructure of the power house, and have been entirely surrounded by the concrete. This appears to be in line with the best recent practice, since it avoids the use of base rings or supporting flanges on the casings, and provides extremely stable and reliable support for the entire unit. All vibration during operation, or deflection of the casing due to water hammer is prevented, and if the concrete is extended above the turbine to form a foundation for the generator, the latter may be firmly tied to the structure of the power house in such a manner as to provide protection against a wrecking of the unit under the severest short circuits to which the generator may be subjected. The cast steel or iron casings are as well protected on their external surfaces against corrosion as is ordinary concrete reinforcement. Within the casing the water velocities are sufficiently low, and the pressure sufficiently high, to prevent the possibility of corrosion and, in fact, no such action has ever been observed in turbines which have operated over a long period of years.

Fig. 3. One of the Four 17,500 h.p. Turbines Designed and Built by the I. P. Morris Company for the Alabama Power Company

Head 68 ft.; speed 100 r.p.m.; rated runner diameter 9 ft. 11¼ in. This illustration shows the relation between the speed ring and movable guide vanes. At the time these turbines were built they were the highest powered vertical units ever attempted for low heads.

In low head plants where the head does not exceed 100 feet, the best present practice is believed to be the use of reinforced concrete as the material of the casing. Some builders urge the use of riveted plate steel casings embedded in the concrete and, although in some instances the local conditions may require the use of casings of this type, it is believed that progress in this branch of engineering, as in others, is in the direction of the extension of the use of reinforced concrete and its substitution in many cases where other materials were formerly used. In some recent instances a comparison of the cost of riveted steel as compared to the cost of the wooden forms required for concrete volute casings has shown that the cost of the steel exceeds that of forms alone in a ratio of approximately 3:1. The fact that the steel casing is surrounded by concrete does not remove the necessity for designing the steel to carry the entire pressure of the water without assistance from the concrete. In view of the poor resistance of plate steel to corrosion, coupled with the fact that the "breathing" of the casing may impair its bond with the concrete and permit the access of moisture to its outside surface, the advisability must be considered of reinforcing the surrounding concrete sufficiently to carry the pressure after the life of the casing has been exceeded. The writer therefore believes the use of riveted steel casings to be a retrogression rather than a forward step in turbine practice.

In the design of a concrete casing, a cross section of the volute may be given any desired shape, not subject to the limitations imposed by the fabrication of a plate steel casing; and by suitably modifying the form of the section the overall diameter of the casing may be reduced, with a consequent important reduction in the spacing of the units and the length of the power house.

The remarkably smooth surface and the well formed curves obtained in molding the concrete for some recent plants make this a most satisfactory material for the casing.

### Draft Tubes

Many of the points just brought out apply also to the question of the material for the draft tube. Draft tubes molded entirely in concrete with a short cast iron discharge ring below the runner, this ring being made long enough merely to provide a proper bond with the concrete, appears to be the economical and satisfactory solution. No examples are on record of hydraulic corrosion of smooth concrete, even by high velocities.

A prevalent fallacy may here be noted. It is thought by many that draft tube velocities in high head plants are such as to require metal linings to protect the concrete. It is a fact, however, that the proper velocity in the draft tube has no relation to the head on the turbine, and should have no higher values in high head than in low head plants.

### Supporting Rings and Base Plates

A number of years ago it was considered good practice in the construction of horizontal turbine units to provide a continuous cast iron base plate connecting all of the parts of the turbine, and sometimes including the generator, in a single foundation casting.

With the great increases of size of units which have taken place, it has been found that these base plates were serving no useful purpose, and they finally failed to survive in the larger developments, the turbine parts being supported directly by the heavy mass of concrete forming the foundation for the unit. The advantage of the base plate in the case of small units was the possibility of making the unit self-contained so that it could be aligned and completely erected in the shops of the manufacturer before shipment, erection in the field thus being simplified. In the case of large units, however, it was found impossible to make the iron base plate sufficiently heavy to hold the parts rigidly in line, so that it was necessary in all cases to align the unit at site during erection, whether base plates were used or not.

In a recent design of a vertical shaft turbine having a cast iron casing, the engineers required that a heavy cast iron supporting ring be provided below the casing, extending to a considerable depth, the idea being that this ring would facilitate the erection of the unit, in the same manner as a base plate would the erection of a horizontal unit.

Since the casing, when bolted together, is in one piece and embedded in the concrete, it is difficult to imagine what useful purpose this ring would possibly serve, and as it is just as easy a matter to align the casing itself as the base ring, it is very evident that such a supporting ring in the case of this unit cannot have any of the advantages claimed for the base plate of a horizontal unit, since it does not serve to align a number of different parts.

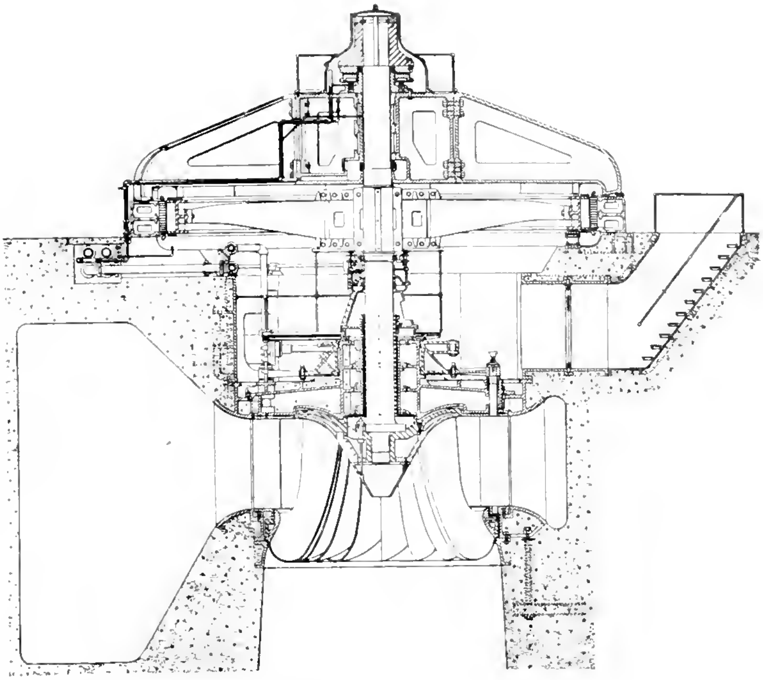

Fig. 4. Vertical Arrangement of the 10,800 h.p. Turbines Designed by the I. P. Morris Company for the Cedars Rapids Manufacturing & Power Company

Head 30 ft.; speed 55.6 r.p.m.; rated diameter 11 ft. 10½ in. These turbines are at present the largest in the world, and it may be noted that in the design there have been incorporated all of the latest features, viz.; volute casings and draft tubes moulded in the concrete; cast iron speed rings supporting the concrete, generator and thrust bearing loads from above; lignum vitae turbine guide bearing; thrust bearing support located above the generator; Kingsbury thrust bearing with roller auxiliary; and pneumatic brakes acting on the rotor of the generator.

The best method of supporting a vertical unit of the type having a volute casing molded in the concrete is now recognized to be the carrying of the load vertically downward through the concrete below the generator to the turbine speed ring, and through the speed ring vanes, acting as columns, to the base of the substructure which forms the foundation of the power house.

The method of support just described has been adopted for the turbines for the Appalachian, Georgia-Carolina, Laurentide, Cedars Rapids, Turners Falls, Northern Ontario, and Alabama developments, and for Unit No. 8 for the Pennsylvania Water & Power Company.

### Thrust Bearing

The thrust bearing of vertical wheels is now almost universally located above the generator on a cast iron supporting truss which forms at the same time the generator head cover. The location of the thrust bearing above the generator has two advantages: first, it places the thrust bearing in the most convenient and accessible location for dismantling and inspection; and second, it eliminates the requirement of a thrust deck in the substructure of the power house, thereby reducing the cost of the power house substructure.

Practice varies somewhat as to the detailed design of the thrust bearing truss, but the principal requirements, viz., that the truss shall be rigid and that the upper face upon which the thrust bearing is mounted shall be level, are adhered to in all cases. The upper guide bearing of the generator is incorporated in the truss directly below the thrust bearing and it is important that in the design of the truss it be made sufficiently rigid against local deflection to avoid binding of the guide bearing. It may be noted that in the design of this truss, time expended in endeavoring to reduce the weight of the truss to the lowest safe limits would not be well spent, since not only are strength and stiffness against deflection important considerations, but also it is desirable to have a considerable mass of metal present in this element in order to avoid the possibility of vibration of the thrust bearing. The thrust bearing support is sometimes included with the generator and in some instances it has been constructed by the turbine builders as a part of the turbine machinery.

The subject of the thrust bearing has been one of the most important considerations affecting the adoption of the vertical type of unit. The hesitation with which engineers formerly adopted the vertical type of unit and the preference which some engineers still express for horizontal shaft machines, have been due almost entirely to doubt concerning the reliability of the thrust bearing. The problem of properly taking care of the vertical load on the shaft due to the weight of the revolving parts of vertical units need no longer cause the apprehension which at one time existed. It may be stated that the difficulties which presented themselves until very recently in securing an economical and reliaable thrust bearing had much to do with the delay in the development and general adoption of the vertical turbine. Today there are, however, at least two types of bearings of demonstrated reliability which are giving satisfactory service in this application.

The old-fashioned pressure thrust bearing, in which oil under high pressure is pumped into an annular chamber between a revolving disk and a stationary disk, was used almost exclusively in large units until about five years ago, when it was generally superseded by the roller bearing or a combination of the roller and pressure bearings.

During the past two years the Kingsbury type of bearing has come into general use and has given eminently satisfactory results through a wide range of conditions. The roller type of bearing has also a number of important advantages and has given entire satisfaction in a number of notable installations.

### Pressure Thrust Bearing

In comparing the various types of bearings, it may be stated that the pressure thrust bearing when taken in connection with the necessary pumps and auxiliaries is the most expensive type both with respect to first cost and maintenance, and also in waste of power. An excessive dropping off of pressure or a momentary failure of the oil supply to the bearing will result in its immediate destruction.

When most successfully used, the oil pressure type of bearing has been operated on the principle of an oil supply of constant quantity. The portion of the thrust bearing load which is due to the hydraulic thrust of the turbine runner increases with the gate opening of the turbine, thus requiring an increase of pressure in the thrust bearing corresponding to the increase of load. As the pressure increases it is essential that the quantity of oil supplied to the bearing shall not be diminished, and this can be best accomplished by means of a positive displacement type of pump such as a triplex plunger pump geared directly to the turbine shaft. In starting up, a motor-driven pump supplies the oil until the unit has been brought up to speed, after which the geared pump is thrown in.

The interconnection of the thrust bearing and governor systems by the use of one set of pumps for both, is dangerous practice, as is also the supplying of the bearings of the various units in the station from a single pressure main. When the governor system is interconnected with the thrust bearings, since there is no connection between the demand on the pump by the governor and the amount of oil required by the thrust bearing, any increase in the load on the thrust bearing may result in a drop in the quantity of oil supplied to the bearing, oil being diverted to the governor system in the line of least resistance. This action need not be carried very far to cause the failure of the bearing.

Centrifugal pumps would be unfitted for use when applied to thrust bearing service, since it is characteristic of most centrifugal pumps that the discharge falls off as the pressure increases.

In some instances where the governor and thrust bearing systems have been interconnected, the attempted solution of the problem was by means of providing a pressure far in excess of that required for normal conditions in either systems, the idea being that even should the governor tend to rob the thrust bearing of its proper share of the oil, the resultant drop in pressure will still be insufficient to reduce the thrust bearing pressure to an unsafe value. This method has many objections, among which are the difficulty of calculating what the demand of the governor will be under abnormal conditions, and trouble with the oil due to its partial breaking down under the high pressure required. High oil pressures in governor systems have been definitely abandoned by engineers having experience in these lines.

The provision of an accumulator in the thrust bearing system in an attempt to create a steady supply to the bearing is not considered good practice, since the cushioning effect in the accumulator is opposed to the above principle of constant quantity supplied to the bearing. The inertia effect of the column of water in the draft tube of the turbine accompanying sudden changes of load on the unit may be such as to cause extremely sudden changes in the hydraulic thrust which must be safely carried by the thrust bearing. Augmenting surges of the water column in the draft tube, due to hunting of the turbine governor, have in some instances become so severe as to lift the thrust bearing disk off its seat, thus relieving the pressure and destroying all means of support. If the supply to the bearing can be cushioned by compressed air in an accumulator tank, there is danger of the thrust disks coming together and burning out under such conditions.

Most of the failures which have taken place in pressure bearings can be attributed to some condition in the pressure system which results in a variation in the rate of oil supply to the bearing. In brief, therefore, the pressure thrust bearing requires a separate pump for each unit and each pump of the positive displacement type, giving constant oil quantity with pressure varying automatically to suit the thrust.

In view of the great importance, in the present development of the vertical shaft hydraulic turbine, of the question of the life and satisfactory operation of the thrust bearing, some data have been collected relating to this subject which the writer believes will be of interest to engineers in charge of new developments.

The following discussion of two types of bearing, viz., the roller thrust bearing and the Kingsbury bearing, are not intended to constitute a comparison of the two bearings except in certain details, and the writer wishes to avoid giving the impression that either bearing can at this time be said to be superior to the other for all conditions of service. While it is felt that both bearings have been in operation sufficiently long and under sufficiently severe conditions to demonstrate that they will do the work satisfactorily, the point has not been reached, if it ever will be, where either bearing can be accepted under all conditions as superior to the other.

### Roller Bearing

The roller bearing was introduced somewhat in advance of the Kingsbury bearing, and the writer is able to give data on some of these bearings which have been in operation for periods as long as ten years. In the application of these bearings to large hydraulic units, the Standard Roller Bearing Company has accomplished excellent work, and the data stated below was furnished by the above company, and also by the engineers of developments in which the bearings have been used.

Table I gives some of the installations, particularly in the hydro-electric field, in which the roller bearing has been successfully employed.

There are a number of points of interest which may be mentioned in connection with this bearing. A distinct point in favor of the roller type of bearing is the fact, which is borne out by many experiences during operation, that even should the bearing be injured by defects in the rollers or tread plates, the bearing will still operate over long periods of time even in the defective condition without allowing the rotating parts to drop from their position of alignment.

One of the first installations in which the roller bearing was used for large hydroelectric units was their application at the McCall Ferry plant of the Pennsylvania Water & Power Company. The forgings required for the tread plates of these bearings were 53 inches in diameter, which exceeded the capacity of any crucible steel mill in the country at that time. The use of open hearth steel led to defective plates in several instances, these defects occurring chiefly in the hardened surfaces of the plates, which developed a spalling of the surface after several months of service. This action was believed to be due to fatigue of the carbonized layer on the surface of the plate under the stresses produced by the rollers. The valuable property of these bearings previously noted is well shown in this case. In one instance a roller bearing in which spalling had commenced was kept in continuous operation day and night without intermission for five weeks after the breakdown commenced without the necessity of removing the unit from service. The Standard Roller Bearing Company advises that they are now able to obtain crucible steel plates which make their bearing available for even the largest units.

It is believed that the minor difficulties which developed in first starting up these bearings in the Keokuk plant were due largely to the use of a combination of the roller and pressure bearings, which combination appeared to introduce complications in the operation of the roller bearing. The small clearances used in the internal seal of the pressure element were entirely closed up when the bearing was operating as a roller bearing, due to the rise in temperature, thus preventing proper circulation of the oil. The bottling up of the oil at the inner rollers evidently caused local heating, which resulted in an unequal distribution of the load carried by the rollers. The Standard Roller Bearing Company advises that these difficulties have been overcome by modifying the clearances in the internal seal of the pressure element.

The purpose of the combination bearing is, of course, to furnish an alternative method of carrying the load, as a provision against failure of either type. At the time the Keokuk bearings were installed, some doubt was felt as to the reliability of the roller bearings under such unusual and severe conditions, so that it was intended to operate the units normally with the pressure bearing in service, the rollers being intended to carry the load in the event of a failure of the supply of pressure oil. This solution, of course, involved all the objections accompanying the large amount of auxiliary machinery required, as well as the complication of the bearing itself.

Regarding the life of very large roller bearings, it may be said that in one of the early units installed in the McCall Ferry plant the bearing had been in continuous satisfactory service for over three years at the time the plates were reversed; and after a similar period the use may be continued by a slight regrinding of the plates. The bearings more recently installed, which are equipped with crucible steel plates, have not as yet been in operation sufficiently long to develop any definite data regarding wear, but are giving excellent satisfaction, and it is felt that with the crucible steel plates these bearings should give as satisfactory service as secured in the smaller bearings made of like materials.

Dismantling, complete examination and replacing of the roller bearing of a size similar to those at McCall Ferry requires from six to nine hours, the primary erection requiring ten hours. The Kingsbury bearing requires from twenty-four to forty-eight hours for initial erection and from nine to eleven hours for dismantling and replacement.

It is characteristic of the roller bearing that a bearing designed for a certain speed and load will run even more satisfactorily at lower speeds and is less suited to prolonged operation at higher speeds. The Kingsbury bearing on the other hand operates even better at high speeds than under normal conditions, but sometimes develops trouble if run too long at an extremely low speed. Thus, any trouble which may develop in these bearings is likely to appear in the roller bearings at runaway speed of the unit and in the Kingsbury bearing when starting or stopping the unit.

It may be of interest to note that the roller bearing plates used in some of the large hydroelectric units require nearly 100 crucibles to pour an ingot from which can be made only one bearing plate. The subsequent treatments are the cleaning of the ingot, forging under 1000 ton hydraulic press, annealing to relieve forging stresses, machining to proper dimensions, hardening, heat treating and grinding. The special steel now used is claimed to be of even finer quality than that used in the manufacture of the higher grade of cutlery.

### Kingsbury Bearing

Referring again to the McCall Ferry plant of the Pennsylvania Water & Power Company, which seems to furnish the best experience in actual service of large thrust bearings, the writer has been advised by Mr. J. A. Walls, Chief Engineer, that the plant now contains roller bearings on Units Nos. 3, 4 and 7 and exciter No. 1, and Kingsbury bearings on Units Nos. 1, 2, 5 and 6 and exciter No. 3. A satisfactory experience from the roller bearings has been noted above. Mr Walls states that the operation of all the Kingsbury bearings has been entirely satisfactory. The first Kingsbury bearing was put into service about two years ago, and frequent examina-

## TABLE I—STANDARD ROLLER BEARINGS

| Installation | Location | Number of Bearings in Service | Length of Service to Date | Total Load Pounds | Normal Speed R.P.M. |
|---|---|---|---|---|---|
| Niagara Falls Pwr. Co. | Niagara Falls, N. Y. | 11 | 1 to 10 yr. | 150,000 | 250 |
| Schenectady Pwr. Co. | Schaghticoke, N. Y. | 4 | 6 yr. | 45,000 | 300 |
| Edison Sault Ste. Marie Elect. Co. | Sault Ste. Marie, Mich | several | 8 yr. | 60,000 | 100 |
| Irrigation Project (Centrifugal Pumps) | Minidoka, Idaho | 15 | 8 yr. | 25,000 | 300 |
| Commonwealth-Edison Co. | Chicago, Ill., Substa. | several | 6 or 7 yr. | 67,000 | 300 |
| Commonwealth-Edison Co. | Quarry St. Substation | 1 | 6 or 7 yr. | 367,000 | 300 |
| North Carolina Elect'l Pwr. Co. | Asheville, N. C. | 2 | 2 yr. | 100,000 | 133 |
| Appalachian Pwr. Co. | New River, Va. | 7 | 1½ yr. | 100,000 | 97 and 116 |

| Utah Pwr. & Lt. Co. | Alexander, Idaho | 2 | | 29 | 155,000 | 370 | 514 |
| Calgary Pwr. Co. | Calgary, Alberta | 2 | | 29 | 130,000 | 310 | 150 |
| St. Lawrence River Pwr. Co. | Massena, New York | | 5 | 36 | 250,000 | 385 | 100 |
| Cedars Rapids Mfg. & Pwr. Co. | Cedars, Prov. of Que. | | 9 | 61 | 550,000 | 350 | 55.6 |
| Georgia-Carolina Pwr. Co. Stevens Creek Plant | Augusta, Ga. | 2 | 3 | 28 | 111,000 | 280 | 75 |
| Alabama Pwr. Co. | Birmingham, Ala. | | 4 | 42 | 324,000 | 370 | 100 |
| Idaho Rwy., Lt. & Pwr. Co. | Snake River, Idaho | 2 | | 21 | 66,000 | 300 | 90 |
| Laurentide Co., Ltd. | Grand Mere, Prov. of Que. | | 6 | 42 | 330,000 | 375 | 120 |
| Salt River Valley Water Users Association | Idaho | 6 | | 18 | 42,000 | 270 | 94 |

tions have indicated that the wear is so small as to be negligible and the life of the bearing, excluding accidents, is estimated by Mr. Walls at over 25 years without re-babbitting the bearing shoes.

In the Kingsbury bearings installed at Keokuk, trouble was experienced in some of the first bearings put into operation, due to a "wiping" of the babbitt at the instant of starting the unit from rest. In the few cases where wiping has developed, it has been due either to lack of proper finish of the rubbing faces of the collar or to the presence of air in the oil. It is important that the oil supply to the Kingsbury bearing is received from a lubricating system free from any disturbances which might otherwise result in the carrying of air to the bearing; also that the bearing itself should be submerged to such an extent that the rotating elements of the bearing will not force the oil away from the bearing shoes sufficiently to allow air to reach the babbitted faces, and it is equally important that the rotating element presents a smooth surface to the oil, as otherwise any churning of the oil would result in an admixture of air and oil. It is appreciated that the presence of air in the film of oil on the babbitted faces prevents proper lubrication and results in the wiping of the babbitt. Such troubles as were experienced during the early operation of the Kingsbury bearings at Keokuk have disappeared so that all of the bearings have now been in operation for eight months or more without giving trouble.

Table II is a list of the important installations of the Kingsbury bearing in connection with hydro-electric plants.

It should be mentioned that both the roller and Kingsbury bearings have had many applications in other fields of service which are not covered here. The roller bearing has been used in many electrical applications, such as in rotary converters and synchronous condensers involving heavy loads, and the Kingsbury bearing has been operated under severe conditions on steam turbines.

Mr. Kingsbury states that the first bearing installed at the McCall Ferry plant was inspected after fourteen months service, during which period it had been stopped and started about two hundred times, and it was found that the wear of the babbitt had not been sufficient to remove the scraper marks made in fitting. The procedure at McCall Ferry in starting a unit equipped with Kingsbury bearings is to allow fifteen minutes for the cooling of the bearing after a shutdown before re-starting the unit, except in case of emergency; and in stopping the unit it must be quickly shut down by the use of the brakes assisted by the generator field. Slight improvements in the details of the Kingsbury bearing which have been made recently would indicate that even these precautions are no longer necessary.

As indicating the high mechanical efficiency of both the above types of bearings, tests show that the total friction loss in one of the Kingsbury bearings at McCall Ferry amounts to from 7½ to 10 kilowatts, with approximately the same low loss in the case of the roller bearings, so that either type of bearing involves a loss well below one-tenth of one per cent of the power of the unit. When it is considered that the guide bearings of the vertical units have a very light lateral load to carry, it will be realized that the mechanical efficiency of large hydraulic units installed in place approaches closely to 100 per cent.

Some tests on the temperature rise in Kingsbury bearings at McCall Ferry result in the following data: Temperature rise for normal or higher speeds with initial temperature of 30 to 35 deg. C., amounted to about 2.3 deg. C. for a twenty-minute run with no supply of fresh oil. At 20 r.p.m. (normal speed 116 r.p.m.) with an oil supply of the normal amount of fifteen gallons per minute, the oil temperature rise was about 1.5 deg. C. for a test of one hour's duration. On tests in which the speed was slowly raised from an initial speed of 3 to 5 revolutions per minute to a final speed of 18 r.p.m., during a run of two minutes duration, no trouble was experienced in a number of repetitions of this test. Either the roller or Kingsbury bearing will operate for a long period of time even when the oil supply is cut off.

An interesting combination of the two types of bearing will be installed in the plant now under construction at Cedars Rapids, Canada, in which the thrust of each unit is carried normally by a Kingsbury bearing. A roller bearing of reduced dimensions is placed within the Kingsbury bearing, but is allowed normally to remain out of action by the provision of a slight clearance. Should any wiping action take place in the Kingsbury bearing, the rotating parts would then settle a slight distance and the load be transferred to the roller bearing. While the roller bearing is not sufficiently large to carry the load indefinitely, it is designed to be of sufficient capacity to operate long enough for the station operators to prepare for a shutdown of the unit, thus providing a safeguard against any injury to the turbine.

**Guide Bearing**

During the past two years, the lignum vitae guide bearing has come into general use with vertical turbines for both low and high head installations. The bearing now used must be distinguished from the old-fashioned lignum vitae guide bearing commonly employed years ago. The older bearing consisted of three large lignum vitae blocks evenly spaced around the circumference of the shaft, each block being equipped with adjusting screws for taking up the wear. This design presented a small amount of bearing area to the shaft, a portion of each block immediately in line with the adjusting screw taking most of the load. The load on the bearing was, therefore, concentrated at the centers of the blocks, resulting in rapid wear and making frequent adjustment and renewal necessary.

The bearing now used is so designed as to present a somewhat greater amount of projected area to the shaft than first class practice would call for in the case of a babbitted bearing. The lignum vitae is dovetailed into the bearing boxes in the form of strips running parallel to the axis of the shaft and with the end grain of the wood placed normally to the surface of the shaft. Twenty or more of these strips, evenly spaced in a liberal length and separated by spaces for the circulation of cooling water, are so proportioned as to present sufficient area to the shaft to insure very satisfactory performance. The resulting bearing pressure per square inch may be made so light as to eliminate the provision of any adjustment for taking up the slight amount of wear which may take place. Bearings of this design have been uniformly applied to the stern tubes of propeller shafts in marine practice, and have been frequently used for turbines of the open flume or submerged type. They have not until recently been generally applied to cases where the bearings are not submerged. Present practice, however, is to use this type of bearing in connection with all vertical turbines, and provision is made to pipe clear water to the bearings in the same manner as oil is brought to the babbitt type. An examination of bearings of the lignum vitae type in connection with large vertical open flume turbines, after continuous operation for a year without shutdown, has shown that practically no wear has taken place and it is quite possible that for a considerable period of time the wood will swell rapidly enough to compensate for the very slight wear which takes place.

In the case of turbines operated in clear water, the supply for the bearing may be taken through a pipe directly from the wheel-casing. A duplex strainer is connected in the line to remove any foreign substances which might otherwise reach the bearing and damage it. In installations in which the water carries large quantities of foreign matter in suspension, the power companies arrange a suitable central filtering system from which the filtered water is piped to the bearings of each turbine.

A bronze sleeve is provided on the turbine shaft where it passes through the bearing and stuffing box. This sleeve prevents the trouble which would be caused by the rusting of an unprotected shaft and also prevents injury to the shaft by the accidental presence of foreign bodies in the water. It has the further advantage of being renewable after a long period of service has produced wear either in the portion within the bearing or where it passes through the stuffing box. In some very old units, a considerable reduction of effective area of shaft has been produced by prolonged wear.

The bronze sleeve is usually, and preferably, cast in one piece and forced over the end of the shaft; but in cases where the turbine shaft is provided with a coupling flange at the lower end for the attachment of the runner, the sleeve is made in halves.

The chief advantages secured by the use of the lignum vitae bearing as compared with the ordinary babbitt type of oil bearing which has often been used for a turbine guide bearing, are as follows:

First: The possibility of locating the bearing much closer to the runner, thus avoiding a considerable space by which the runner must be overhung below the bearing when the babbitt bearing is used in order to accommodate an oil shedder, an oil catcher and seal ring.

Second: No pump is required to remove the lubricant from below the bearing, as in the case of an oil bearing, and to pump the oil back into the lubricating system at a higher elevation.

In connection with the first point, the importance of placing the bearing close to the runner, while perhaps not as great as in a horizontal shaft unit, is still considerable. While a runner may be put in almost perfect static balance, there still remains the possibility of a considerable side thrust developing during operation, due to variations in hydraulic conditions around the circumference resulting from inequalities in the areas and angles of the vanes secured in casting the runner. A runner overhung at too great a distance from the bearing is in danger of developing vibrations under some conditions of loading.

The chamber below the lignum vitae bearing is vented through cored passages in the runner hub into the draft tube, and it is into the draft tube that the circulating water from the lignum vitae bearing escapes. Difficulties have been experienced in the operation of babbitted oil bearings located at this point, on account of the difficulty of providing a seal below the oil catcher which will satisfactorily prevent escape of oil into the draft tube and the leakage of water into the oil catcher, both of which actions involve loss or inconvenience. It should also be considered that the necessity for an oil circulating pump required by the babbitt type of bearing and the dependence which must be placed on this pump is an element of weakness, since any interruption to the lubricating system endangers the burning out of the bearing and the shutdown of the unit.

### Mechanical Details

A number of features of the turbine structure and mechanism deserve to be considered, but lack of space prevents their being thoroughly covered. Present practice in the construction of the large single runner vertical turbine with volute casings molded in the concrete, has endorsed the use of a speed ring for supporting the top of the volute casing and the weight of the parts above. The form of speed ring which has been given preference in the best practice is one consisting of an upper and lower ring, or crown, shaped to conform to the volute, connected by heavy vanes cast integrally with the upper and lower crowns. These vanes are shaped to suit the free path of the water entering the guide vanes. This use of the speed ring vanes seems preferable in every way to round staybolts. The large projected area and the poor form of the circular section causes hydraulic losses, and there appears to be a mechanical advantage in the use of a rigid cast iron connection between the upper and lower speed ring crowns without the possibility of deflection involved in the use of separate parts.

The guide vanes of turbines are now almost invariably made of cast steel, with the stems or fulcrum pins cast in one piece with the vanes. In the case of exceptionally high heads where the water carries sand in suspension, bronze guide vanes are sometimes advisable to resist erosion. The vane stem can be cast integrally with the vane in this case also. In exceptionally large units, such as those at Cedars Rapids and Keokuk, the vanes are of cast steel with separate forged steel stems passing through them and keyed to them, in order to permit the removal of separate guide vanes without requiring the dismantling of the remainder of the unit.

Suggestions have been made at various times, and have in a few instances been put into practice, of using forged guide vanes rather than castings. The question is mainly one of expense, and it is believed that vanes conforming closely to the design and shape and having necessary strength can be much more cheaply obtained by casting than by forging.

It has been claimed by some of the builders who have used forged steel guide vanes that these vanes can be made smaller than steel castings, owing to the greater strength of the forging over the casting. If, however, the vane is reduced in size to compensate for the increased strength, then wherein lies the advantage of the forged vane over the cast vane?

The iron runner cast in a single piece is now standard practice for all turbines for low and moderate heads under ordinary conditions. All of the turbines now under construction for Cedars Rapids, and eight of the fifteen installed at Keokuk, have been built in sections rather than in a single casting. This construction has been adopted at Cedars Rapids on account of the additional ease of handling in shipment and erection, and also to provide greater assurance of sound castings being obtained. The possibility of shrinkage stresses existing in very large runners when cast in a single piece, is an important consideration which is met by the division of the runner into four parts.

This construction of runner has, of course, no connection with what is known as the "built-up" runner. The latter term is used to denote a runner containing steel plate vanes held in a separate cast hub and band. In the large runners referred to above, each section containes hub, vanes and band cast in one piece, so that no local weaknesses at the joints between vane and band or vane and hub may develop, and the runner as a whole possesses great strength and rigidity. The sections are held together by a heavy cast steel crown at the top which encloses the sections, and a cast steel ring in one piece which surrounds the band and is joined to the band by a light forcing fit.

### Speed Regulation

Next in importance to efficiency and mechanical reliability, the regulation of the turbine is a factor which requires much consideration. While it is felt that engineers sometimes desire guarantees of unnecessarily close regulation when considering such extreme conditions as full load thrown suddenly on or off a unit, conditions which seldom occur in a plant, and when they do occur it is usually due to a short circuit or a dropping of load under circumstances in which regulation ceases to be a consideration, still it must be granted that proper speed control is of the utmost importance in modern hydro-electric developments.

The problem of speed regulation may be considered in relation to two considerations which may exist in a plant. First, the control of speed during sudden changes in load which occur during normal operation; and second, the control of speed during a period of constant load on the units.

As is now well known, the control of the speed of a turbine during sudden change of load is dependent to a great extent, in fact chiefly, upon the inertia of the rotating parts and the length of and velocities in the closed water conduit supplying the turbine, and including the draft tube taking the water from the turbine. Given a certain length and velocity of water column, and a certain flywheel effect in the revolving parts, a certain necessary speed variation results, which cannot be reduced beyond a certain minimum even by a perfect or ideal governor. The necessary actions which the governor must provide are few and simple, consisting of a movement of the turbine gates in such a manner as to suit any particular change in load which is encountered, and to restore the unit speed only after sufficient time has been allowed for the acceleration or retardation of the water in the water passages.

There has been a tendency on the part of the builders of stock governing apparatus in this country to throw a veil of mystery over the action of the governor, the idea being suggested that the governor follows some complicated mode of action, and in fact it has been said to show "almost human intelligence." As a fact, the governor mechanism consists of a few distinct parts, and may be built to give perfect action without the use of any partitioned devices or any mysterious mechanisms. The failure to explain clearly to engineers who have encountered these problems the theoretical and actual conditions which the problem of regulation involves, has been a feature of the methods of stock governor builders in this country. Insistent demand on the part of engineers in charge of the older power developments, as well as those projected, has forced some stock governor builders to develop a machine embodying a type of construction more in harmony with the large units to be controlled than the governors which were built a number of years ago. It is felt, however, that in the attempt to meet the demanded reliability, as well as the higher capacities required in modern units, the stock governor designers have failed to appreciate the great importance of a simple, substantial, stable machine which will not be subject to accidental derangement during service and which will operate over long periods of time without being continually shut down for repairs or adjustments due to wear.

The second condition enumerated above, viz., the action of the governor during the normal condition of steady load on a plant, is nearly as important as its action during load changes. The defective action of many governors, and this may be seen in many small plants where stock governors are installed as well as in some larger stations, consists not in their failure to move the gates of a turbine when a change in load occurs, but in their failure to hold the gates steady during constant load conditions. The ever-continuing oscillation of the turbine gates which is seen in some units, even though small in amount, is a sign of an unstable governor, and its result is rapid wear of the turbine gate mechanism with resulting looseness of joints and a consequent augmentation of the unnecessary motion.

Another frequent cause of failure to conform to the second requirement is the susceptibility of the stock governor, which is almost invariably of extremely light and delicate construction, to accidental conditions such as the presence of grit or waste carried by the oil entering the governor valve, or slight changes in the friction of the parts. The writer believes that the best practice demands the installation in connection with large and important units, of governors specially constructed by the maker of the turbine to suit the exact conditions of the installation; that these governors should be of a capacity corresponding to the size of the unit to be controlled, and that all of the governor parts should have strength and rigidity in harmony with the turbine itself.

It may be particularly noticed that some stock governors have been installed with a number of very large units where the centrifugal governor head, which is the element on which all other actions of the governor depend, has been made of the lightest and most delicate construction, sufficient power to move the turbine gates being obtained through a series of pilot and relay valves. The writer believes this construction to be inconsistent with reliability and continuity of service, and contends that the centrifugal governor head should be designed to have an amount of power consistent with the unit which it must control. In the effort to make the governor conform to the character of the turbine design, some governor makers have completely enclosed the governor in a box or casing. This design provides an apparent simplicity to external view, but does not affect the delicacy and complication of the mechanism contained within, and in fact greatly hinders the accessibility of the parts and prevents proper attention being given to the operation of the apparatus.

### Conclusion

Summing up the points brought out in the foregoing discussion, it will be seen that the trend of recent development has been, in almost every particular, in the direction of increased simplicity of the turbine itself and of the accompanying accessories.

Efficiencies have been increased to a high figure even with the high specific speeds used in American practice, and the high efficiencies obtained at Holyoke have been exceeded in large units under operating conditions after installation. The increase of efficiency due to an increased size of unit and increased power under high heads which was expected from theoretical considerations has been verified in actual tests, where the efficiencies obtained at Holyoke in small wheels under low heads have been exceeded in large wheels of homologous design, tested in place.

In the design of the turbines themselves, unnecessary parts have been eliminated and improvements in the arrangement and details of the apparatus have been developed. The large amount of auxiliary machinery installed in some of the older plants has been greatly reduced in recent installations, this change permitting great economies in plant operation and in the cost of maintenance and repairs. In some of the older plants, the equipping of each unit with a separate thrust bearing pump, separate governor pump and individual system of piping, together with the interconnection of the necessary spare pumps, caused a great complication in the apparatus which is now overcome by the use of Kingsbury or roller bearings supplied by the common gravity lubricating system connected to all units, and a central pumping system to supply the governors of all units.

All of the above factors are contributing to the success of a number of notable installations which have been made in the last few years, a success which the writer believes reflects much credit on American engineers.

# MODERN TANGENTIAL WATERWHEEL PRACTICE

By Heinrich Homberger

The Pelton Waterwheel Company

Although there have been may improvements and great changes in the design of tangential waterwheels, the basic principles are the same as those of the old hurdy-gurdy of the California miner. The electric generator has given the waterwheel its present characteristics. The author gives a great deal of interesting detail on the construction and improvement in the tangential waterwheel, such as the number and type of wheels and nozzles, the manner of fastening the buckets to the disks, the construction of the housing, speed regulating devices, and the means of securing good water economy.—Editor.

**Heinrich Homberger**

IN recent years the development of the high head hydraulic prime mover, known as the tangential or impulse waterwheel, has manifested itself primarily in two directions:

(1) Increase in the size or output of the individual unit.

(2) Economy in water consumption.

The Pacific Coast, which has been the cradle of this type of machine, still maintains its position as principal user of high head waterwheels, since the precipitous mountain chains of the Sierra Nevada and Cascades afford more opportunities for economical high head power plants than any other region of the United States.

From the simple wooden hurdy-gurdy of the early California miner, the tangential waterwheel has developed into a powerful and rather complex machine, although still maintaining its original elements and also its simplicity in operation.

The basic principle of a disk shaped wheel, upon the periphery of which are mounted a number of individual buckets or cups upon which a free jet of water issuing from a nozzle impinges, has not been changed. There have been a number of modifications to suit special conditions, such as double or multiple nozzles applied on one wheel and also more than one wheel mounted upon the shaft of one single waterwheel unit.

Electric power transmission has made it possible and profitable to develop water power hundreds of miles from the point of power consumption and the requirements of the electric generator have given the characteristics to the modern tangential waterwheel. The electric generator and waterwheel are direct connected almost always, the methods used for the connection of the two being dependent largely upon the ratio of head, horse power and speed. The three principal types of construction most favored in modern hydraulic practice are the single overhung type, double overhung type and the complete iron-mounted type; and these with their various modifications practically meet all requirements.

Where conditions are such that all the power required can be developed on a single wheel, the single overhung type of construction is generally used. In this type, the generator shaft is carried on two main bearings only, and the waterwheel mounted on the overhung extension of the generator shaft. Two methods of fastening the waterwheel to the generator shaft are used. If the conditions are such that the centrifugal stresses are not too great, the waterwheel is bolted to a coupling which is forged on the generator shaft. For conditions in which this construction is not permissible, the generator shaft is made parallel, key-seated, and the waterwheel pressed on. The objection to this second method is the difficulty of pressing the waterwheel on the generator shaft in the field, although in certain instances this is unavoidable.

In some cases, where all the power required cannot be developed on a single wheel with one stream, the single overhung type wheel is used and equipped with a duplex, or double nozzle, by which means the power output of the one waterwheel runner is practically doubled. This results in a very compact unit with only two bearings and short, reliable governor connections. The general popularity of this type of installation has led the electrical manufacturers to develop a standard line of generators which are specially adapted to the single overhung construction of waterwheel units and which are known as the "waterwheel" type.

Where sufficient power cannot be developed on one wheel, the double overhung type of construction is adaptable. This is exactly like the single overhung type in principle, excepting that both ends of the generator shaft extend beyond the bearings and a waterwheel is mounted on each end. This is the ideal type of construction for large units and there are in operation in California individual units of this type continuously developing as much as 20,000 horse power. In the installation of large double overhung units, where the waterwheel runners are necessarily very massive, weighing frequently 12 tons or more, the duty of the bearings often makes special construction necessary; and owing to the waterwheel engineering problems involved, in many cases it is advisable that the waterwheel manufacturers furnish the generator shaft and bearings as a part of their contract.

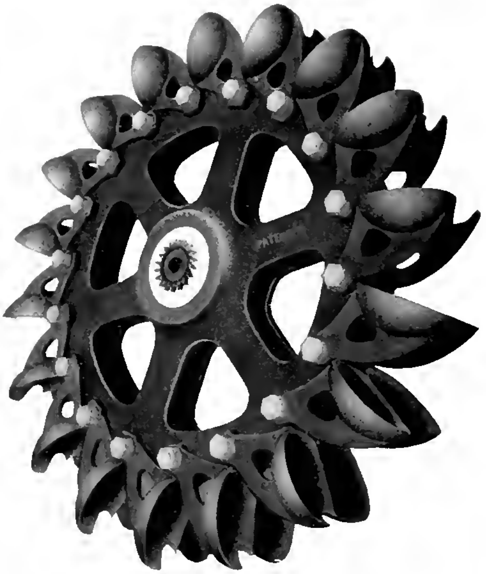

Fig. 1. Pelton-Doble Tangential Waterwheel Runner, equipped with patent interlocking chain type buckets. Diameter 152 in.; weight, 14 tons

The duplex nozzle is also used in conjunction with the double overhung type unit, thus permitting the capacity under a given set of conditions to be practically doubled.

The complete or self-contained type of waterwheel, with its own shaft, bearings, bedplate and housing, independent of the generator, is extensively used and meets many conditions not suitable for either the single or double overhung types. With this type two or more wheels can be mounted upon the same shaft and in the same housing. Water can be supplied to the wheels through nozzles of either the single or duplex type, thus permitting the development of large power outputs at medium heads and speeds suitable for direct connection to the electrical generators. For example, single units of this type are in operation developing as much as 10,500 horse power at 390 feet head.

As many of the most marked improvements in modern waterwheel practice concern the individual parts which go to make up the complete unit, a few of the most important will no doubt be of interest to the reader.

In the past, considerable difficulty was encountered in the fastening of the buckets to the wheel disk, particularly when a large bucket had to be used on a comparatively small diameter wheel. The room available for the fastening lugs in such cases is very scant and it is impossible to place in it two bolts of sufficient size to take care of the stresses with adequate safety. This fact often limited the diameter and in consequence the speed for which an impulse wheel could be designed for satisfactory operation under given conditions.

A great step forward was made by the invention of the "interlocking chain type" buckets, wherein the number of fastening bolts is equal to the number of buckets. As shown in the illustration, Fig. 1, this type of bucket fastening is made by building the runner of two separate disks, the hubs of these abutting each other and in this manner maintaining the correct

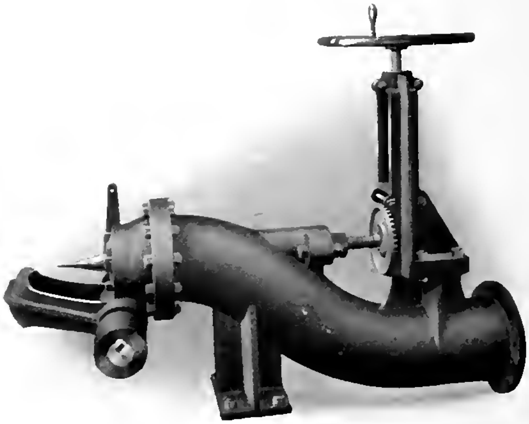

Fig. 2. Pelton-Doble Hand-Operated Needle Nozzle of the Reverse Vertical Curve Type, with balanced stream deflector for speed control

distance between the wheel rims when the wheels are pressed to place upon the shaft. Each bucket is fastened by one central and two outside lugs; the outside lugs being at the rear when the wheel is viewed in the direction of the issuing water jet and the central lug being in front, extending somewhat beyond the face of the bucket. The front lugs of the buckets are placed between the rims of the two wheel disks, while the rear lugs straddle the outside of the two rims; so that when completely assembled, the front lug of each bucket is exactly in line with the rear lugs of the preceding bucket, thus causing each fastening bolt to pass through both rear lugs of one bucket, the two wheel rims and the central or forward lug of the bucket next following it. In other words, the buckets themselves if detached from the wheel and bolted together would form a continuous chain, from which the name "interlocking chain type" has been derived. The particular advantage of this type of construction lies in the fact that larger bolts may be used than with the ordinary type of bucket fastening and the distance between two bolts is much greater than would be permissible if independent buckets, each provided with two fastening bolts, were used, as is the case with the familiar design of bucket fastening. With the arrangement of the interlocking chain type buckets, the stress resulting from centrifugal force is applied approximately midway between the two bolts and is distributed equally on the two bolts when the jet is full off the buckets; and when the jet is full on, the stress will be nearly uniform on the two bolts on account of the greater bolt spacing. With this form of construction, the nuts of the holding bolts are readily accessible for wrenches, and what is more important, this particular type of design admits of a higher speed for a given power output than is possible with other methods of bucket fastening.

Fig. 3. Excellent example showing application and method of governor and hand control connection for double overhung type Pelton-Doble auxiliary relief needle regulating nozzles

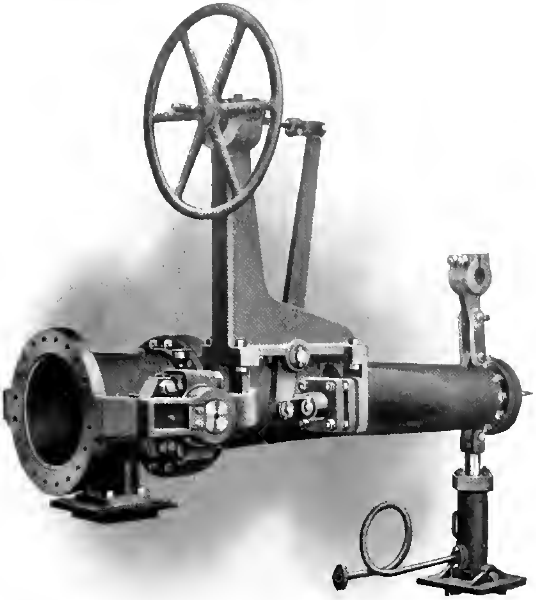

Fig. 4. Pelton-Doble Deflecting Nozzle with Hydraulic Counterbalance and Hand-Operated Needle

It may be of interest to state that on large wheels the fastening bolts securing the buckets to the wheel disks are very simply placed in position or removed with a special portable hydraulic press.

But few material changes have been made in the design of waterwheel housings during the past few years, excepting in some special types of installations. The standard construction of housings for single nozzle wheels still embodies the riveted sheet steel upper part and cast iron lower. The sheet steel upper housing is heavily re-inforced and is riveted to a cast flange which is in turn fastened to the lower housing with cap screws.

The lower housing in many instances also acts as a baseplate, being suitably constructed for this purpose and having a wide base and cast ribs for imbedding in the concrete foundation. The base of the lower housing contains a drip trough which is connected directly to the tail race for the purpose of carrying off condensation water. In many cases the requirements of the waterwheel design are such that the cast lower section of the housing is carried up to the center line of shaft.

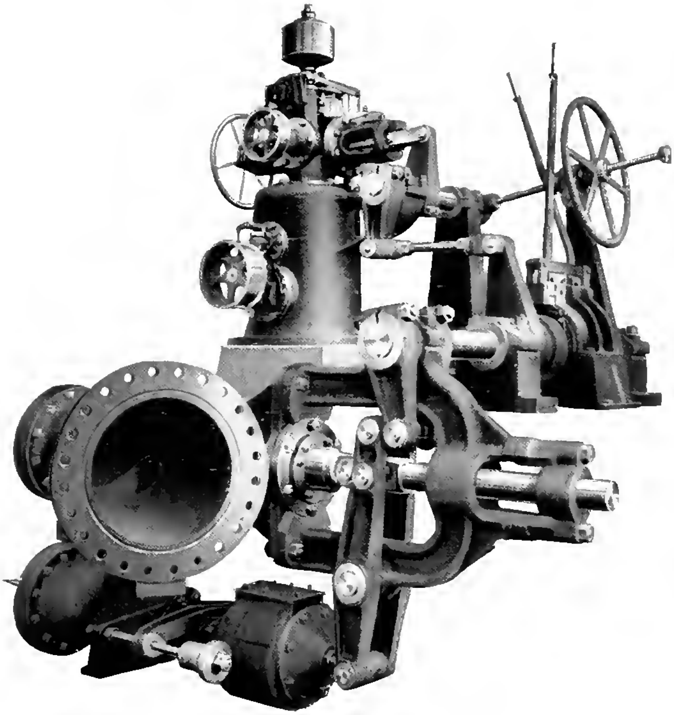

Fig. 5. View showing Pelton-Doble auxiliary relief needle regulating nozzle, with governor and auxiliary hand controls, as applied to a single overhung wheel unit

For wheels equipped with duplex nozzles, the entire housing is usually made of cast iron in order to provide a rigid support for the upper nozzles. Such housings are usually made in three parts to facilitate the removal of one part for inspection and repairs.

Marked improvements have been made in the methods of preventing water leakage where the shaft enters the housing, the present types accomplishing this without any metal to metal contact between rotating and stationary parts and without the use of any packing, thus making the device frictionless.

Excellent speed regulation of waterwheels is an accomplished fact today, as the waterwheel manufacturers have made rapid strides in governor design, which makes it possible to satisfactorily meet the strictest requirements. Good speed regulation requires a means of quickly and efficiently changing the quantity of water impinging upon the waterwheel buckets to conform with sudden load changes. This is accomplished in a number of ways. The oldest form of nozzle is of the deflecting type, consisting of a swinging pipe, pivoted upon a stationary spherical or ball shaped surface known as a ball joint. The swinging part of the device is connected to the power cylinder of the speed governor, by means of which it is lowered in order to have the jet of water miss the buckets and pass out freely into the tailrace in undiminished quantity, until an increase in load causes the governor to raise the nozzle again to a position where the jet partially or completely is received by the buckets.

Other devices for regulation are cut-off hood and jet deflector. Both are placed in front of a fixed nozzle and swing on fulcrums, in order to intercept the jet of water. The cut-off hood is made in such a way that it fits the tip of the nozzle with a spherical surface and is supposed to close it entirely in case of full load going off. The high velocity of

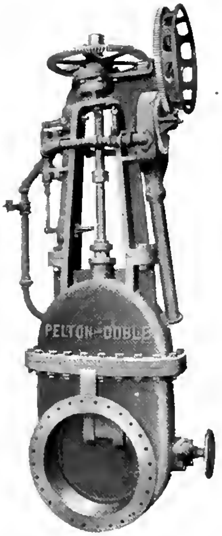

Fig. 6. Modern construction of reversible water motor operated high pressure gate valve with auxiliary hand control

the issuing water, however, causes the cut-off hood surfaces to wear rather rapidly and the desired feature of complete closure does not last long. The jet deflector, of which there are a number of different forms, is placed freely in front of the nozzle tip and regulates the speed by intercepting or deflecting the stream. Economy in water consumption is not expected with the deflector and not obtainable with the cut-off hood for any length of time, on account of the above mentioned rapid wear and water leakage. Of the two devices, the jet deflector is the better and in its improved form is still largely used in modern installations where economy of water consumption is not desired.

The Pelton-Doble deflector is a further development, consisting of a circular ring with renewable liner which is swung in front of the fixed nozzle with the stream continuously passing through it. This has the advantage of only deflecting the stream sufficiently to miss the buckets and discharging it directly into the tailrace in the line of water flow. Moreover, the removable liner may be easily replaced when worn out.

The first device which permitted any economy in water consumption was the needle regulating nozzle, perfected and patented by Wm. A. Doble, now chief engineer of the Pelton Water Wheel Company. This nozzle was equipped with a conical co-axial core-piece, movable in the axis of the jet. It issued an annular jet which, owing to the form of the needle point protruding outside the nozzle tip, closed itself into a solid cylindrical stream immediately in front of the nozzle. A screw spindle, with or without gearing or similar device, was provided to change the position of the needle. This spindle was usually either operated by hand or by an electric motor.

The combination of the needle with the deflecting nozzle or the fixed nozzle with the deflector permits considerable saving of water, but the degree of economy is entirely dependent upon the power plant operator.

The necessity of making the water economy automatic and the water consumption absolutely proportional to the load carried by the wheel became more and more desirable as the number and capacity of the plants increased. Consequently, seasonal storage of water was found necessary. To operate the needle nozzle directly by the governor seemed natural and simple enough; but high head power plants with necessarily long pipe lines and large quantities of water moving at high velocities now possess characteristics making it impossible to quickly stop the flow of water in the pipe, since this would increase the water pressure to such a point as to endanger the pipe material; and, even where such danger does not exist, pressure fluctuations would be set up in the pipe line which would make satisfactory regulation absolutely impossible. It was therefore necessary to provide a means by which, in case of a drop of load, the water could be cut off from the wheel instantly, but the rate of flow in the pipe line reduced at a lesser speed, permitting the moving column of water to adjust itself to the changed condition of velocity of flow without undue pressure rise.

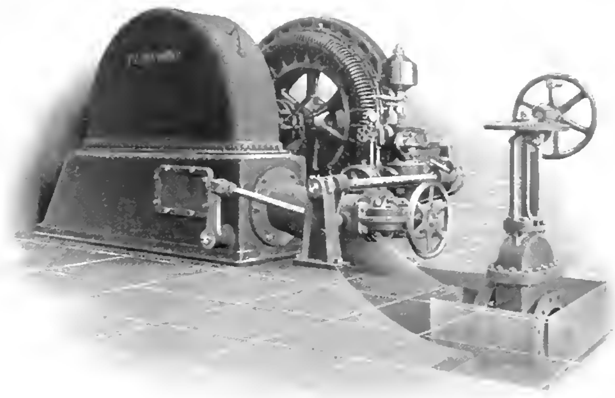

Fig. 7 Example of Single Overhung Type Construction, direct connected to an engine type alternator with belt-driven exciter. The hand-operated needle nozzle and connections for stream deflector speed control by oil pressure governor are clearly shown

This was successfully accomplished by the introduction of the synchronous by-pass or auxiliary relief nozzle in conjunction with the needle nozzle. This was first brought out by the Abner Doble Company and covered by a number of patents which have since become the property of the Pelton Water Wheel Company. The basic feature of this device is the combination of a main or power needle nozzle which furnishes water to the wheel and a branch or auxiliary relief needle nozzle discharging into the tailrace. Both nozzles are operated by the power mechanism of the speed governor simultaneously, but in opposite directions. The auxiliary nozzle opens when the power nozzle closes and vice versa, the volumetric relationship between the two being adjustable, according to the conditions at the plant. This in itself would prevent any pressure rise in the pipe conduit, but would not afford any economy in water consumption. In order to save water, it is necessary to keep the auxiliary relief nozzle closed during a partial and slow motion of the main needle and also to have it close at a safe rate of speed after it has been opened. This result is accomplished by a cataract cylinder which is inserted in the operating gear of the auxiliary relief needle. A description of this device may prove of interest.

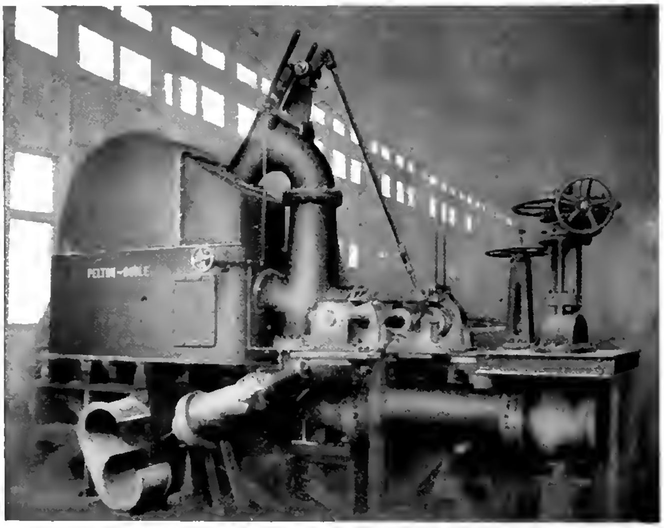

Fig. 8. Pelton-Doble Single Overhung Type Tangential Waterwheel Unit of the auxiliary relief needle regulating type, with duplex power nozzles. The Ensign Patent vortex baffle is also shown in position to receive the stream discharge from the auxiliary relief nozzle

The auxiliary needle is designed in such a way that the hydraulic pressure has the tendency to keep it closed. A cataract cylinder is connected to the auxiliary needle by means of a pin, in which cylinder moves a piston. This piston is connected to the lower arm of a lever, the upper arm of which is connected to the main needle. The cataract cylinder communicates with an oil chamber through a port and adjustable valves. The piston is provided with valve openings which permit the oil to pass from one side to the other in one direction only. When the power needle is opening, the lower end of the lever moves forward in the direction of the issuing jet, pushing the piston forward in the cylinder. The pressure of the oil in front of the piston opens the valve and the oil passes through the piston to the rear. Thus the forward movement of the piston is not impeded.

When the power needle closes, the lower end of the lever pulls the pistons back, forcing oil through the valves and into the oil chamber. The valves are adjustable to permit the oil to pass freely until the piston itself covers the valve openings. In this way, during partial closing of the power needle, the auxiliary relief needle does not come into action. If, however, the main needle continues closing, oil can escape from behind the piston only through a small adjustable pin valve. The rate of oil flow through this pin valve is too slow to permit the piston to continue moving within the cylinder, the oil forming a practically rigid and incompressible connection between the two, causing them to move together to open the auxiliary relief needle. There is now a stream of water running to waste from the auxiliary relief nozzle but, as mentioned above, the hydraulic pressure tends to close the auxiliary relief needle at a rate of speed which is adjustable by means of a small valve. If the rate of speed with which the power needle closes is sufficiently slow to permit all the oil in back of the piston to pass through the small valve, the auxiliary needle will remain closed. On the other hand, should the rate of closing of the power needle be very rapid, the auxiliary relief needle will be caused to open.

This device has proven eminently satisfactory, even when the most difficult combinations of high heads with long pipe lines and heavy load fluctuations were encountered. The adjustable feature of the cataract cylinder makes it possible to try out the apparatus after installation, setting it first for a very slow rate of closing of the auxiliary relief needle and then adjusting it until the point of maximum permissible pressure rise in the supply pipe is reached and the maximum economy of water consumption is obtained. Naturally, where one single wheel receives two streams of water from a duplex nozzle, or where a waterwheel unit is equipped with two wheels, a single auxiliary relief nozzle may be designed of sufficient capacity to serve the requirements of the entire unit.

With the perfection of the auxiliary relief needle regulating nozzle, it became necessary to provide some means for effectively absorbing the energy of the jet momentarily issuing from the relief needle nozzle. The Ensign vortex baffle plate, patented by Mr. O. H. Ensign, Chief Electrical Engineer, U. S. Reclamation Service, has proved to be an eminently satisfactory device for this purpose. It consists of a casting formed like the figure three, with a sharp, renewable, central splitter, much like the central splitter of a waterwheel bucket. The jet impinges upon the splitter and is turned back upon itself and absorbs its own energy in a whirlpool. One of the accompanying illustrations shows an Ensign vortex baffle plate in place opposite the auxiliary nozzle.

In order to insure the safety and continuous operation of the large hydro-electric units used in modern engineering practice, too much importance cannot be attached to the design of the main stop gate valves, which directly control the flow of water from the pipe lines to the waterwheel units. The so-called standard or commercial types of gate valves have so often failed to be satisfactory in operation that their use cannot be considered a justifiable economy. There is such a number of requirements and special conditions connected with the operation of gate valves in high head plants, which do not prevail elsewhere even though the capacity and pressure should be the same, that a special power plant type of gate valve is always desirable. The essential requirements for successful power plan. gate valves are that they must be easily operated by one attendant and also at the maximum safe speed. Therefore, when the load on the operating gear becomes too great and multiple gearing would make the closing time too long, power-operated gate valves have to be used. Of these, electric motor-driven valves have many points in their favor, but the possibility that they might have to be operated when there is no current available gives hydraulically-operated valves the preference. The well known type, operated by a hydraulic cylinder placed on top of the valve, has recently been supplanted by the more modern reversible water motor operated gate, such as shown in the accompanying illustration. This has the great

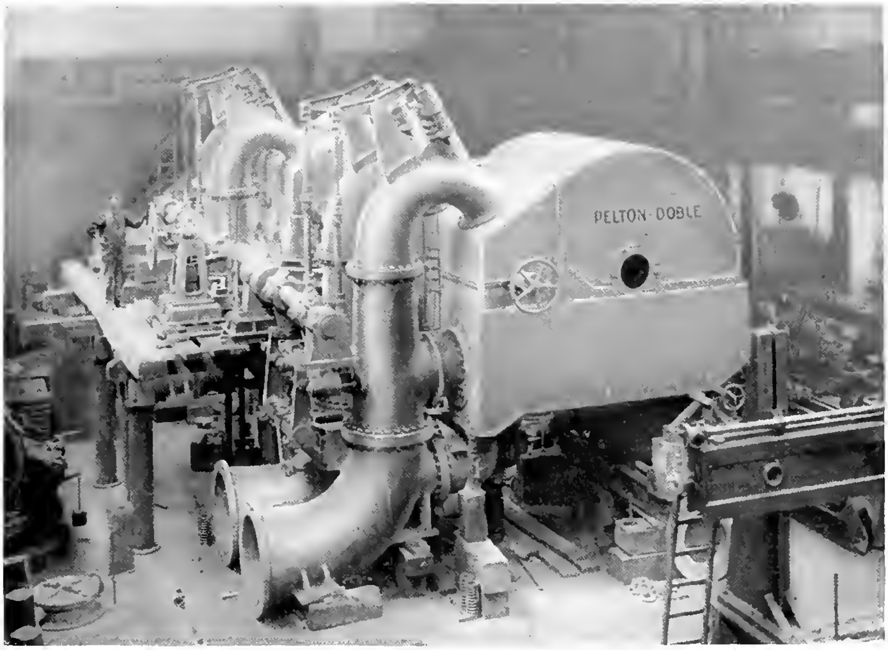

Fig. 9. Shop Erection View of Pelton-Doble Multiple Runner, Duplex Nozzle Type of Construction, four waterwheel runners being provided for each unit

advantage that the operating speed can be definitely fixed, so that the valve will not take too much time for opening or closing and still can never be shut too rapidly. Furthermore, an emergency hand gear can be easily provided, which is rather difficult with the hydraulic cylinder operated gate The waterwheel operated with water taken from the main pipe line, is of the reversible type equipped with two nozzles, one for closing and one for opening the valve. Automatic stops shut off the water, so that it is impossible for the gate disk to travel too far in either direction. The water motors used to operate the gates are constructed so that their torque increases as their operating speed decreases; for it is known that the greatest torque is required when first opening or finally closing, and of course these are the times when the speed of operation is naturally the slowest.

Fig. 10. Interior View Lake Buntzen No. 1 Power House, B. C. Electric Railway Company, Ltd., of Vancouver, B. C., showing a number of high capacity Pelton-Doble Tangential Waterwheel Units of modern design

For handling large water quantities under high heads, the needle type valve, hydraulically or oil pressure controlled, is one of the most marked strides in modern construction. The discharge co-efficient is very high. Since this type of gate is balanced in all positions and losses from eddy currents at partly closed positions are practically nil, the wear is reduced to a minimum.

In modern hydro-electric plants, it has become standard practice to drive exciters with small independent waterwheels, direct connected. In the most modern installations, it is desirable that the exciter set be controlled by a governor where the voltage at the plant is regulated by a Tirrill regulator, as in this case the load on the exciter unit is continually changing and it is essential to maintain constant speed.

Among the most interesting as well as useful modern devices which help much to simplify hydro-electric plant operation, are the tailrace ventilator and the vacuum cleaner attachment. The tailrace ventilators are installed in the walls of the concrete foundation, between the waterwheel and generator pits, and provide a free circulation of cool air for the generator. The vacuum cleaning device is designed to take advantage of the natural vacuum which tends to form at the center of waterwheel runner rotation and by means of suitable attachments it is possible to remove all dust from the power house and direct its discharge into the tailrace, without in any way disturbing the power house atmosphere. Needless to say this means much in the freedom of grit in bearings, collector rings, commutators, etc.

Before closing this article upon modern practice in high head hydro-electric plants, which it is hoped will be of interest to the readers of the REVIEW, one very important point should not be neglected. While it is true that the modern tangential waterwheel still remains the simplest form of hydraulic prime mover, there are many features in the consideration of its proper selection in which only the close cooperation of the consulting engineer and the waterwheel manufacturer, for the determination of such characteristics as size, type and speed, will be productive of best results; for the experience and viewpoint of one must be complemented by that of the other, if the future development of the art is to progress satisfactorily.

# THE SPEED REGULATION OF WATER TURBINES

By Allan V. Garratt

General Manager, The Lombard Governor Company

The author urges a more intimate cooperation between electrical manufacturing companies, water turbine and turbine governor companies in order that matters concerning speed regulation may be more intelligently dealt with in specifications and inquiries. Following this are given very interesting and valuable discussions (illustrated by plotted or instantaneous curves where needed) of the customary speed regulation formula and its factors, relief valves, surge tanks, positive and negative pressure calculations, flywheel effects, and quickness of governor action. A brief description of the method of control employed in the type of governor used in the Keokuk plant of the Mississippi Power Company, and of the types of governor pumps included in the equipments for various size plants, pictures the apparatus which has been developed to fulfill the requirements mentioned earlier in the article. The conclusion names the facts that should be kept in mind by all who are concerned with the speed regulation of water turbines.—Editor.

**Allan V. Garratt**

THE literature pertaining to the speed regulation of water turbines is meager and consists mostly of either purely theoretical treatments of the subject or of popular articles; neither of which aspects is as helpful as it might be to the busy engineer. This article will follow a middle course in presenting briefly some matters which may possibly be useful to the man who is neither interested in designing governors nor in an attempt to treat the question of speed regulation as a purely mathematical subject. It is addressed rather to the engineer who comes in contact with the regulation of water turbines as only one of the many subjects with which he must have an easy familiarity.

Perhaps what bothers the average engineer most in writing the governor part of his specifications for a hydro-electric plant is to know just what he wants the governor maker to guarantee, and what it is reasonable to expect him to guarantee.

It seems to be customary to do one of two things: either to ask the governor builder what regulation he will guarantee, and this frequently without giving sufficient data to enable such a predetermination to be made: or, to specify arbitrarily a certain degree of regulation, which sometimes is impossible under the physical conditions which obtain.

In the first case the governor builder does not know what the engineer wants. In the second case he sometimes knows that the engineer wants something which cannot be obtained. In the first case the governor maker may be destroyed by the Scylla of offering to do something which is not wanted. In the second case he may be tempted into wrecking himself on the Charybdis of offering to do something which he has grave doubts of being possible.

It would seem as though it were a better plan for the engineer to satisfy himself first as to the limits of speed variation, under different conditions of load change, which may be permitted in the plant under consideration, and then to enquire into the feasibility of obtaining the desired regulation. The permissible speed variation in a hydro-electric plant is purely an electrical question and should be treated as such and may not be elaborated here, as it is a somewhat complex matter which warrants careful treatment.

Not only the required speed behavior of an electric generator when the unit is tied into a large electrical system which is more or less self-regulating should be thought of; but also, consideration should be given to its behavior under those large and sudden load changes, which occur with more or less frequency under accidental or intentional conditions, as well as its speed behavior under friction load prior to synchronizing it with the rest of the system.

The limits of speed variation which can be realized depend only partly on the design of the governor. They depend largely on the entire design of the water column from open forebay to tail race and upon the inertia effects in the rotating masses. So far as the present writer knows, that matter was first treated in a paper by him before the American Institute of Electrical Engineers in 1899 (*Trans. A.I.E.E.*, Vol. XVI, p. 361). The experimental data then were very few and the deductions were somewhat crude. Since then the very large amount of data which has become available through the observed regulation of several thousand turbines, operating under a great variety of hydraulic conditions, permits at the present time of approaching such problems with some degree of confidence.

Unfortunately, it is usually unwise to rely wholly upon a purely mathematical treatment of the question on account of the impossibility of getting an accurate knowledge of all the inertia and dynamic forces at work. Some matters pertaining to that subject will be presented later, but for the moment let us return to the customary regulation specifications.

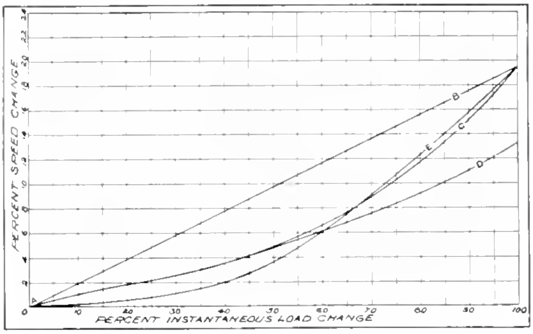

Fig. 1. Curves showing the relationship between the per cent instantaneous load change on a water turbine and resulting per cent speed change for various specified and actual conditions

They are apt to read something like this: "The speed must not vary (let us say) more than 20 per cent upon an instantaneous load change of the maximum horse power of the turbine, 15 per cent upon 75 per cent load change, 10 per cent upon 50 per cent load change, 5 per cent upon 25 per cent load change, and 2 per cent upon 10 per cent load change." Now the above values, if plotted, will result in a straight line curve as *B*, Fig. 1. The waterwheel governor has not yet been built which will give a straight line curve, neither would such a curve be desirable, yet that is what is frequently specified. The curve which obtains is ordinarily concave. The line *C*, Fig. 1, shows a characteristic curve made with one well-known design of governor when the inertia of the rotating masses, hydraulic conditions and time action of servomotor were such that the maximum speed change was 20 per cent upon the whole load of the turbine being thrown off instantly. If the whole load were thrown on instantly the curve would be like *D*, Fig. 1. Just why the load thrown on results in less speed change than a corresponding load thrown off is a rather involved matter which will not be discussed here as it would lead us a long way from the subject in hand.

It is evident that the larger the load variation and the slower the governor action, the greater will be the speed variation; and the greater the inertia of the rotating masses and the higher their rotation, the smaller the speed variation will be. These four quantities, combined with a proper constant, should give a somewhat accurate measure of maximum speed changes in those cases where the inertia of the moving water column is a negligible quantity. Note that there cannot be any predetermination of speed regulation without knowing the four quantities above named. Those who are in the thick of this matter receive many letters every day, which omit one or more of the above four quantities, but which ask for predeterminations of speed regulation which are, of course, impossible. The writing of several thousand letters each year would be obviated if the above matter were kept in mind.

It has become customary to write

$$\frac{K \times h.p. \times T}{I \times S^2} = \delta$$

for the determination of speed regulation of water turbines, where

$\delta$ = percentage temporary change in speed for load thrown off.
$K$ = 81,000,000.
$h.p.$ = the maximum horse power of the turbine.
$T$ = the time in seconds occupied by the governor in moving the turbine gates through their range.
$I$ = the moment of inertia of the rotating parts expressed in $WR^2$.
$S$ = the normal r.p.m. of the rotating parts.

So far as the writer knows, the constant 81,000,000 was first used by Mr. H. E. Warren in a paper written in 1907 and published in the *Technology Quarterly*, Vol. XX, No. 2, which see for the mathematical derivation.

The above formula, which is the best available, applies in practice through only a comparatively small range of values of *T*, *I* and *S*, for it should be remembered that a water turbine is a prime mover, the runaway speed of which is not greatly in excess of its normal speed; and with small values of *I* or *S*, or a large value of *T*, the formula may easily solve for a greater maximum speed than the turbine would acquire if uncontrolled by any governor action. The permissible limits of *I* and *S* will be briefly alluded to later.

The time in seconds occupied by the governor, *T*, is the time for moving the turbine gates through their range, as for example, upon the maximum load of the turbine being instantly thrown off. If the governor moved the gates through the proper range for a half load change in the same interval of time as occupied for a full load change, the speed variation would be one-half and the regulation curve would be a straight line curve, as *B*, Fig. 1. The governor never does this. If the governor occupied only half as much time in moving the gates to the correct position for a half load change as for a whole load change, the speed variation would be only one-quarter of that which obtains under whole load change, and would be curve *E*, Fig. 1. No governor yet built behaves in this exemplary manner, though good governors approach somewhat closely to it, as curve *C*, Fig. 1.

It is interesting to note that in curve *C* the governor actually moved the gates to the correct position for a 75 per cent load change in less than 75 per cent of the time for full load change but at about 67 per cent load change the governor fell behind the theoretical speed of action; the falling behind the theoretical time of action on small load changes is true of all governors, but they vary greatly in this respect. The less they fall behind the better the governor.

Different designs of governor show in practice different approximations of time action to load change; hence each has its characteristic curve or curves. For each design of governor, the curves are more or less homologous for workable values of *I*, *T* and *S*, so that one skilled in the art, looking at such a curve, would know something of the design of the governor that produced it.

The value of *I* is difficult to arrive at accurately in practice, for it is composed of a number of elements, some of which are hard to determine. Generator manufacturers usually know the $WR^2$ of their rotors with considerable accuracy and show perfect willingness to state it, and even to increase it within limits, to conform to the wishes of the engineer. The waterwheel builders seem to have difficulty in stating the $WR^2$ of their runners, and that, therefore, remains an unknown part of the flywheel effect. The water within the turbine runner has also some flywheel effect, but this information is seldom available for purposes of calculating regulation, and hence it has become a general custom to call the value of *I* simply the $WR^2$ of the electrical rotor, which is, of course, only part of it. Also it should be remembered that motors and motor-generators on the line act as flywheel effect and often greatly improve the regulation: so that the regulation under commercial conditions is frequently much better than on a rheostatic test. It is for this reason that the calculated speed regulation of an hydro-electric unit is usually not so good as the results which are actually obtained in practice, where the steadying effect of unknown, and hence unassumed, inertia forces are in operation to assist the governor in its work.

The assumption last made applies chiefly to turbines which are set in open water or under practically open water conditions, for if the water coming to the turbine is enclosed in a lengthy feed pipe, its inertia must be reckoned with, for the water is an exceedingly heavy mass, the velocity of which must be changed with every load change on the turbine; and it cannot change its velocity without either absorbing or liberating kinetic energy which is entirely independent of its potential energy which is the prime moving force of the turbine. This liberation, or absorption, of kinetic energy by the moving water column is frequently the most difficult matter to contend with in holding the speed of a turbine within close limits under large instantaneous load changes. Suppose, for example, that a one thousand horse power turbine is set at the end of a feed pipe of such length and diameter that the enclosed water, when the turbine is developing full power, contains 500 h.p.-seconds of kinetic energy; and that when the turbine is developing only 100 h.p. the velocity of the water is reduced so that it contains only 10 h.p.-seconds of kinetic energy. It is evident that upon throwing off 900 h.p. from the turbine, there are in addition 490 h.p.-seconds of kinetic energy lost, which will re-appear as force, and which will be applied to speeding up the turbine. A very small part of this kinetic energy will be converted into potential energy by compressing the water and in enlarging the steel pipe, but it is so small as to be in most cases of only academic interest.

Relief valves, at the turbine case, are sometimes employed to obviate the difficulties of long feed pipes, but it is evident that they can be of use only upon the load going off. They can be of no use upon the load going on, for they cannot supply to the moving water column kinetic energy which it has lost and which it must regain before it can flow at the higher velocity required by an increase of load.

Surge tanks are better; in fact, they are often imperative. If of improper design, they frequently add to the difficulty of obtaining regulation. If of proper design, they simply result in shortening the closed water column; that is, they bring the turbine nearer to being set under open water conditions which are the most favorable conditions. Where they may be advantageously employed, they offer a complete solution to the difficulties of obtaining regulation. Their design is an intricate subject, which, if presented in only an elementary way, would extend this article far beyond its proper limits.

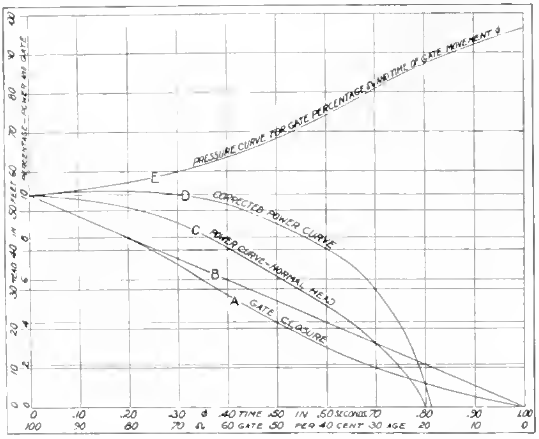

Fig. 2. Curves showing the relationship between the various factors expressed as functions of time action of governor, amount of gate travel, effective head, percentage gate opening and power

Unfortunately the conformation of the country is often such that a surge tank is unfeasible, and reliance must be placed on relief valves to prevent dangerous water pressures being developed and upon flywheels to liberate or absorb kinetic energy as the closed water column absorbs or liberates it. But for the moment, let us defer the flywheel question and inquire further into the kinetic energy in the closed water column and its effect upon the speed of the turbine while the governor is performing its function of altering the turbine gate upon a load change taking place.

Fig. 2 shows some of the phenomena which take place upon a governor closing the gates of a turbine. The time action of the governor and the amount of gate travel are plotted on the abscissa and the effective head upon the turbine and the percentage of gate opening and power are plotted on the ordinates. The curve *B* (a straight line) shows the closure of gates in one second if the governor acted with a uniform rate of motion. The curve *A* shows the actual motion of the governor. The curve *C* shows the power developed by the turbine while the governor is closing the gates on the assumption that the head on the turbine remained constant all the time. The curve *E* shows the pressure rise in the closed penstock due to the gate closure slowing up the moving water; thus causing the turbine to develop more power than that due to normal head. The curve *D* shows the actual power developed by the turbine due to the abnormal head *E*. The area between the curves *C* and *D* shows the amount of power the governor has to correct for in excess of the actual load thrown off the turbine. This area of power must be taken account of in arriving at anything like an accurate predetermination of speed regulation.

The pressure developed in penstocks by governors should be regarded from other considerations also than their effect on speed regulation.

Fig. 3 is a photograph of a model (by courtesy of Mr. George F. Hardy, C.E.) of the entire water column of one of the 20,000 h.p. turbine units in the power house now being built by The Laurentide Company of Grand Mere, P.Q. Of course, the same unit number of cubic feet of water per second is passing through each longitudinal foot of the water way, but as the cross section is constantly varying all the way from open forebay to tail water, the water velocity, and hence its kinetic energy is constantly varying.

Fig. 3. Photograph of the Model of Water Column of a 20,000 h.p. Water Turbine

To get at a close approximation of the abnormal pressure or head, as well as its component parts, it is customary to cut up the entire length of the water way above the turbine, around the scroll and down the draft tube into sections as indicated on the model and calculate the abnormal pressure developed in each of them. From these calculations, the pressure anywhere in the water way may readily be determined.

It is not usually necessary to calculate this force with great accuracy, and the complicated formulae which give very accurate results need not be employed. Merriman's approximate formula

$$P = \frac{.027 \times L \times V}{T}$$

is sufficiently close, or a simpler way is to consult the writer's Table of Time Averaging-Pressures. To convert Time-Average-Pressure into actual maximum pressure, multiply by two, which will give results within a few per cent of being accurate.

## TIME AVERAGE PRESSURE

The following table shows the constant pressure in pounds per square inch which, exerted for one second, will bring to a rest a moving water column. Note that as the pressure is directly as the length and velocity of the water column, and inversely as the time in which it is stopped, the pressure for any length, velocity and time may be readily calculated from this table:

| VELOCITY OF WATER IN FT. PER SEC. | LENGTH OF PIPE IN FEET | | | | | | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | 50 | 75 | 100 | 125 | 150 | 175 | 200 | 250 | 300 | 350 | 400 | 450 | 500 | 600 | 700 | 800 | 900 | 1000 |
| 1 | .662 | .993 | 1.324 | 1.655 | 1.986 | 2.317 | 2.648 | 3.310 | 3.972 | 4.634 | 5.296 | 5.958 | 6.620 | 7.944 | 9.268 | 10.59 | 11.92 | 13.24 |
| 2 | 1.324 | 1.986 | 2.648 | 3.310 | 3.972 | 4.634 | 5.296 | 6.620 | 7.944 | 9.268 | 10.59 | 11.92 | 13.24 | 15.89 | 18.54 | 21.18 | 23.84 | 26.48 |
| 3 | 1.986 | 2.979 | 3.972 | 4.965 | 5.958 | 6.951 | 7.944 | 9.930 | 11.92 | 13.90 | 15.89 | 17.87 | 19.86 | 23.84 | 27.80 | 31.78 | 35.74 | 39.72 |
| 4 | 2.648 | 3.972 | 5.296 | 6.620 | 7.944 | 9.268 | 10.59 | 13.24 | 15.89 | 18.54 | 21.18 | 23.93 | 26.48 | 31.78 | 37.08 | 42.36 | 47.86 | 52.86 |
| 5 | 3.310 | 4.965 | 6.620 | 8.275 | 9.930 | 11.58 | 13.24 | 16.55 | 19.86 | 23.16 | 26.48 | 29.79 | 33.10 | 39.72 | 46.32 | 52.96 | 59.58 | 66.20 |
| 6 | 3.972 | 5.960 | 7.944 | 9.930 | 11.92 | 13.90 | 15.89 | 19.86 | 23.84 | 27.80 | 31.78 | 35.76 | 39.72 | 47.68 | 55.60 | 63.56 | 71.52 | 79.44 |
| 7 | 4.634 | 6.950 | 9.268 | 11.58 | 13.90 | 16.22 | 18.54 | 23.16 | 27.80 | 32.44 | 37.08 | 41.70 | 46.34 | 55.60 | 64.88 | 74.16 | 83.40 | 92.68 |
| 8 | 5.290 | 7.940 | 10.59 | 13.24 | 15.88 | 18.53 | 21.18 | 26.48 | 31.76 | 37.66 | 42.36 | 47.64 | 52.96 | 63.52 | 74.12 | 84.72 | 95.28 | 105.9 |
| 9 | 5.960 | 8.940 | 11.92 | 14.90 | 17.88 | 20.86 | 23.84 | 29.80 | 35.76 | 41.72 | 47.68 | 53.64 | 59.60 | 71.52 | 83.44 | 95.36 | 107.3 | 119.2 |
| 10 | 6.620 | 9.930 | 13.24 | 16.55 | 19.86 | 23.17 | 26.48 | 33.10 | 39.72 | 46.34 | 52.96 | 59.58 | 66.20 | 79.44 | 92.68 | 105.9 | 119.2 | 132.4 |

A careful study of the abnormal pressures which may be developed by governor action in penstocks is advisable for the following reason. Frequently from considerations of advantageous design of power house and proper economy of material, the concrete is not very thick over the penstock where it passes under the generator room floor, and in designing its thickness and reinforcement thought should be given to what the governors are likely to do to the penstock pressures.

It sometimes comes about that the strength of the concrete is limited to a value which leads the thoughtful engineer to [illegible] slower governor action than he would like and compensate for the slower generator action by additional flywheel effect. Governors can be obtained which will give a complete range of gate movement in one second or even less, but it is sometimes unwise to develop the water pressures which such quick action entails.

The negative pressure which may be developed in the draft tube should also be calculated in the same way as the pressure above the turbine. In some cases where the draft tube curves into a more or less horizontal and long extension the negative pressure developed in the draft tube by a very quick governor action may be greater than atmospheric pressure and may cause the water in the draft tube to part company with the turbine and to return with a rush which may be disastrous. This consideration may lead to modifying the design of power house and tail race contemplated.

The proper flywheel effect to give an hydro-electric unit should be given consideration, and in the present state of the art, it is perhaps wiser to lean somewhat upon empirical data rather than to be guided solely by mathematical deductions.

A great amount of empirical data has accumulated. Turbines set under heads varying from a very few feet to several hundred feet and set at the ends of closed penstocks varying from a few feet to six thousand feet, or more, have been observed under governor control and flywheel values through a ratio of from 1 : 50 have been employed. A study of such data is a valuable guide in determining what can be done in the way of regulation under a great variety of conditions.

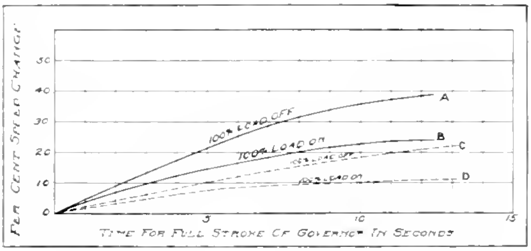

Fig. 4. Curves showing the relationship between the per cent speed change of a turbine and the time required to complete the gate motion

The flywheel effect in the electrical rotor is a very large part of the whole and as stated previously it is customary to consider it only, ignoring the small flywheel effect of the other rotating masses. It is usual to state it as the $WR^2$ or as the weight that will give a corresponding effect at one foot from the center of rotation, symbolized as $I$. Its value in steadying the speed of the unit depends, of course, upon the power of the unit and upon the square of its r.p.m. For purposes of comparison it has become customary to reduce all values of $WR^2$ to corresponding values for units developing one h.p. at one r.p.m. This new value is symbolized by $I_1$, and is obtained by multiplying the known $WR^2$ by the square of the r.p.m. and dividing by the h.p. of the unit. We may write

$$I_1 = \frac{I.\ S^2}{h.p.}$$

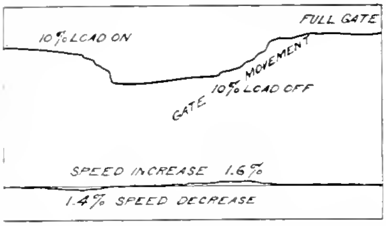

Fig. 6. Curves of the Same Nature as those of Figs. 5 but employing different load changes

Somewhat careful speed regulation experiments have been made with turbine units having values of $I_1$ ranging from 1,000,000 to 47,000,000.

The useful range seems to be from 3,000,000 to about 30,000,000, according to the difficulty of the hydraulic conditions and the severity of the instantaneous load changes.

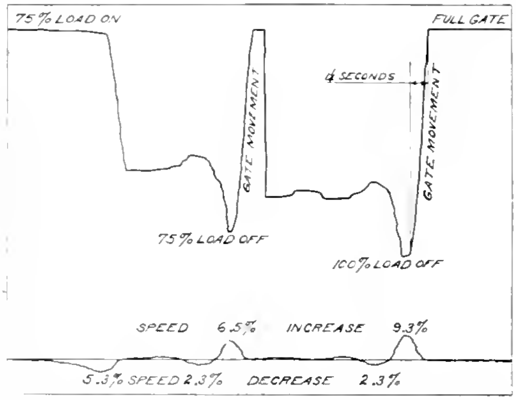

Fig. 5. Curves from Actual Test made to determine the gate movement and the speed change for various sudden changes of load

Above 30,000,000 the gain does not seem to be worth the cost. Commercial electric rotors have a range of $I_1$ from about 2,240,000 to about 14,000,000, and with such values of $I_1$ satisfactory regulation can be obtained under comparatively simple hydraulic conditions unless the regulation requirements are exceedingly exacting, when some additional flywheel effect may be required. Manufacturers of electric generators are usually willing to increase the $WR^2$ of their rotors somewhat upon request. If the hydraulic conditions are very unfavorable, it is often necessary to install an independent flywheel upon the generator shaft.

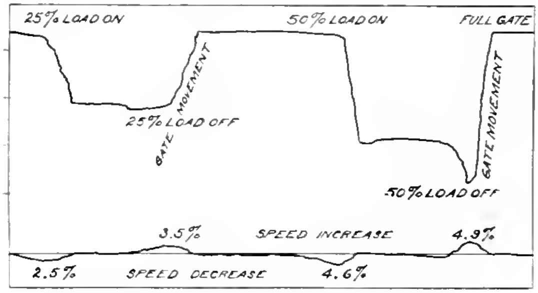

Fig. 7. Curves of the Same Nature as those of Fig. 5, and 6, but employing different load changes

In one plant in New York State, for example, where the turbines are set at the ends of closed feed pipes 2300 ft. long, additional flywheels were installed, bringing the total value of $I_1$ per unit up to 20,000,000. The satisfactory regulation which obtained was due to a careful study of the inertia forces at work, and checking up calculated values of the proposed flywheels with much experimental data already at hand.

The mere statement that a certain governor is a one-second governor, or a two-second governor, or so on, does not mean much unless it is known how long it takes the governor to get into action, and if it starts off at full speed. Governors vary greatly in this respect.

Some modern governors are of such design that they make most of their motion in a very short time and slow up near the point of complete gate closure. It is evident that such governors may safely move much quicker than though they lacked the above adjustment.

The effect of the quickness of a governor upon the regulation it will give, aside from theoretical considerations, and as a matter of experiment is a natural subject of inquiry. Fig. 4 shows an actual experiment made to illustrate this matter. A governor of good design was connected to a hydro-electric unit set under open water conditions and was successively adjusted to give a complete range of gate motion in from one to 13.5 seconds. That is, the governor was first made to perform its function in one second, then in two seconds, and so on. It did not seem desirable to continue the experiment more than 13.5 seconds as the curves had become practically flat. Curves *A* and *C* were made with a value of $I_1 = 13{,}000{,}000$. With curves *B* and *D*, $I_1 = 29{,}000{,}000$. It will be observed with curve *A* that the regulation between one second and six seconds is almost directly proportional to the quickness of the governor; above six seconds, the quickness of the governor did not count for so much, though that is not of much importance, for above six seconds the regulation is so bad that it would be intolerable in most plants. With the larger flywheel effect, curve *B*, quickness of governor action does not count for so much for the curve is more convex its entire length. It will be noted that with the larger flywheel effect the same regulation is obtained with eight seconds governor action that was obtained with the smaller flywheel effect in 4.5 seconds, which illustrates the value of large flywheel effects with long penstocks, previously alluded to. The curves on Fig. 4 indicate plainly that governors should be as quick as the physical properties of the plant will permit if the best regulation is expected.

The reader will naturally inquire as to what may be regarded as first-class practice. Figs. 5, 6 and 7 show the regulation obtained with a governor of very recent design. These curves were made on a chronographic instrument of precision. The upper curves were made by connecting the pen with the gate stem of the turbine by means of a fine wire and a suitable lever. The speed lines were drawn by a sensitive recording tachometer of the mercury, vacuum type. The load consisted of a rheostat. The load changes were as nearly instantaneous as possible for they consisted of opening and closing the rheostat switch. The governor was adjusted for 1.25 seconds time of operation for complete load change. Note that this interval of time is from the moment of the load change to the moment when the governor has moved the gates to the proper position. A governor

**Fig. 8.** **The Type of Turbine Governor used in the Mississippi River Power Company's station at Keokuk**

may move very quickly when it once gets started but is so slow in getting started as to give poor results, for the speed begins to change the instant the load begins to change and does not wait for the governor to work.

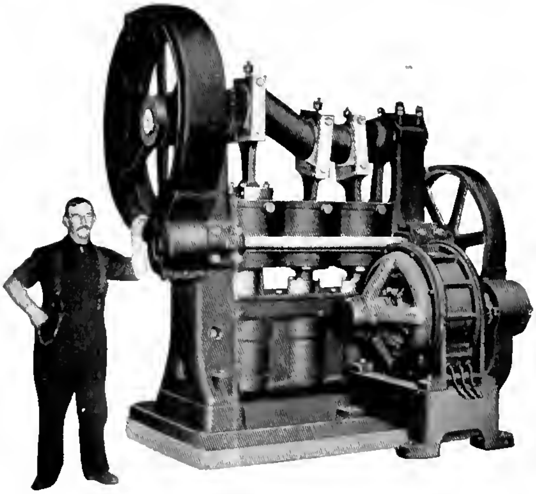

Fig. 9. An Electrically-Driven Pump which furnishes oil under pressure to the governor

Neither the limits nor the purpose of this article will allow much reference to governor design but a brief allusion to a few recent governors may be permitted. Fig. 8 shows one of the governors in the Keokuk installation of the Mississippi River Power Company and several other large plants. The principal idea in this machine, aside, of course, from the technique of the valve motions, centrifugal elements, anti-racing mechanisms, etc., which it would take much space to describe, was to give perfect accessibility to all working parts and at the same time absolute protection from unauthorized meddling. The cast iron case, which is about seven feet high, is provided on the back with plate glass doors, under lock and key, which when opened permit of every part of the governor mechanism to be reached and all adjustments to be readily made. An electric lamp in the interior illuminates all parts which are, of course, visible through the glass doors. The face of the governor carries ten-inch dials indicating tank pressure, back pressure, if any, on the receiving tank, speed of the unit expressed in cycles, and actual gate opening (not gate position). There are also rotary handles controlling the primary and relay valves and near the top and at the center a synchronizing switch which duplicated the function of the synchronizing switch in the switchboard gallery. The central hand wheel on the face of the actuator is of interest, as it consists of an hydraulic hand control for use when it is desired to cut the governor out. By rotating this wheel, the turbine gates will move to any desired position and stay there until the hand wheel is again moved, or until the governor is again cut in. The servomotors or power cylinders, which are under control of the governor, are located on the floor below and are connected to the turbine gate ring by means of tangent rods. Fig. 9 shows one of the pumps which maintains pressure on the oil circulating system of the governor which is the force actuating the servomotors. There is a pump and tank set for each governor. The pumps are intermittently motor-driven. That is, they are automatically started and stopped

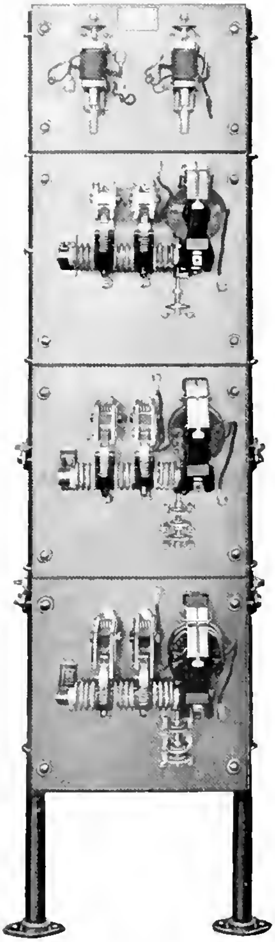

Fig. 10. Contactor Panel for automatically starting and stopping the motor driving the oil pump in accordance with the demands on the governor

according to the governor requirements by means of the pressure controlled motor starting sets shown in Fig. 10.

In some other large plants the motors are allowed to run continuously; magnetic clutches under pressure control being interposed between them and the pumps. Either of these methods is preferable to running the pumps continuously as it relieves the pumps of at least three-quarters of the wear and tear, for the governors ordinarily require that the pumps run only one quarter, or less, of the time.

In the Keokuk plant the various pumping units are not interconnected; in some other large plants they are. Each method has its advantages and disadvantages which make it advisable in one installation and not advisable in another. It is too broad a question to be satisfactorily treated briefly.

Fig. 11 shows a horizontal, direct connected governor built in various sizes up to 60,000 ft-lb. which may be found in many modern plants. In this design the entire governor mechanism except the pump and tanks is self-contained on one bed. Attention is called to the powerful mechanical hand control which may be instantly thrown in or out of action by the lever shown. The connection to the gate shaft is through the link shown to the extreme right. The arrangement permits of direct connection to either vertical or horizontal gate shafts.

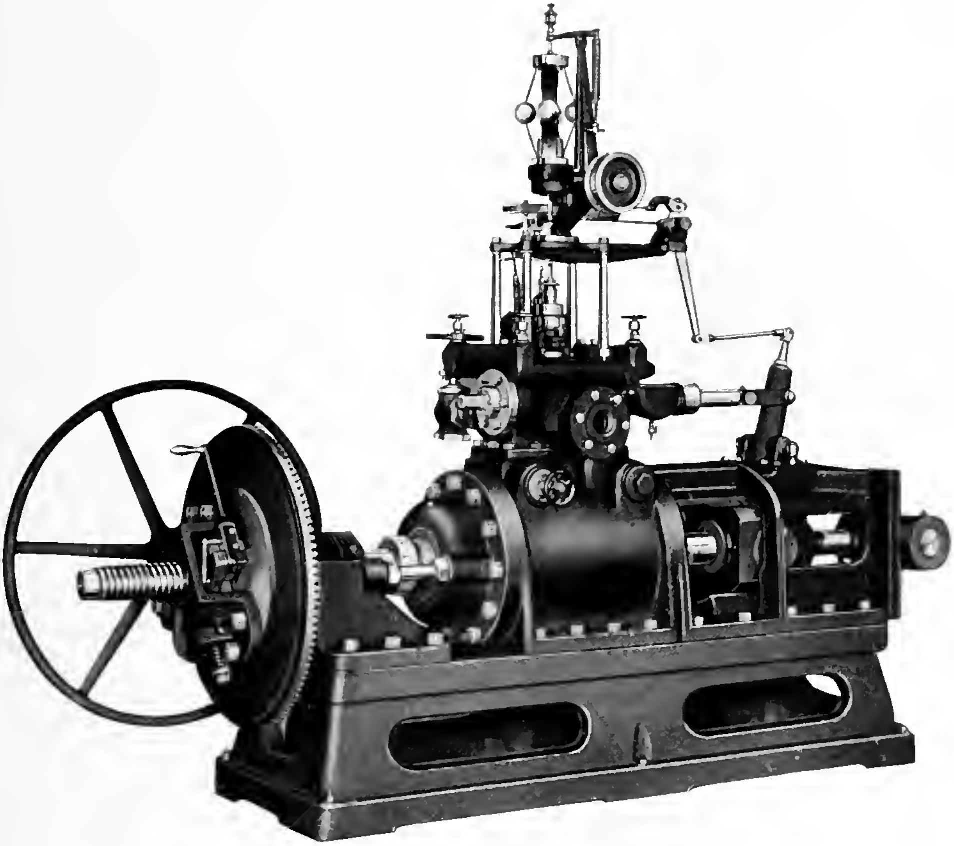

Fig. 11. A Horizontal Direct-Connected Governor

Fig. 12 shows a motor-driven governor pump for governors of moderate and small size. The convenience of this particular design is indicated by the fact that more than fifty of them may be found in various hydro-electric installations on the locks of the barge canals of New York.

In conclusion, a few words may be permitted on writing governor specifications. No general form will be suggested for every engineer should impress his own individuality upon his specifications: but there are some matters of such general importance that they may appropriately be insisted upon.

Every waterwheel governor should be substantial in construction for no other machine of delicate function is subjected to greater shocks or more continuous service. This does not mean simply weight of cast iron but where the strains and wear come ample provisions should be made.

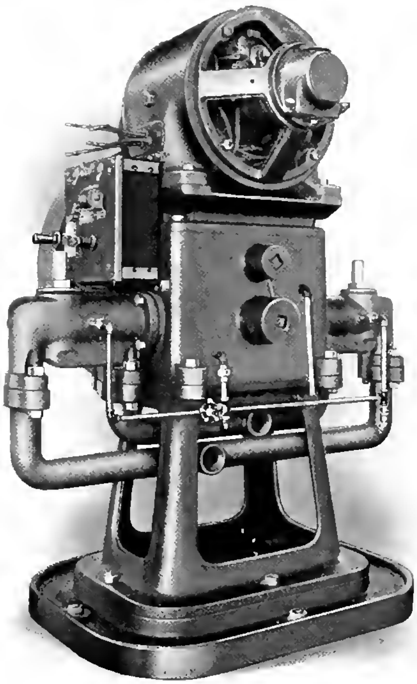

Fig. 12. **An Electrically-driven Pump for small and medium size governors**

They should be built with accurately interchangeable parts so that repair parts that will fit may be readily obtained.

The design should be such that they may be adjusted for any degree of sensitiveness and any degree of quickness (two distinct functions), while they and the waterwheels they are governing are in commercial operation, and the engineer has a right to be convinced that these adjustments can be made and how they are made.

The ratio of pumping capacity and tank capacity to servomotor capacity should be plainly stated by the manufacturer, and if the pumps are motor-driven, the method of driving whether continuous or intermittent, and if the latter, in what manner, should be insisted upon and clearly described.

If the pumping system is to be interconnected, the manufacturer should give very complete details of the piping system.

The requirements as to the degree of regulation under various load conditions should be very fully stated by the engineer and the necessary data for predetermining regulation should be given. This data is: 1st, maximum horse power of unit; 2nd, r.p.m.; 3rd, $WR^2$; 4th, time operation of governor, suggested, or required, or optional; 5th, a very complete statement of the hydraulic conditions.

# EXCITATION OF HYDRO-ELECTRIC POWER PLANTS

By R. E. Argersinger

Power and Mining Engineering Department, General Electric Company

The author gives the result of an analysis of the exciter arrangement of some seventy-five hydro-electric plants, which indicates a general preference for waterwheel-driven exciters. A comparison is made of the waterwheel-driven exciter plant with exciters direct-connected to the main generating units, bringing out the difference in exciter plant capacity and the advantages of the latter arrangement in first cost and operating cost. Some disadvantages are also pointed out, with possible remedies.—Editor.

R. E. Argersinger

THERE seems to be a tendency in laying out hydro-electric plants to give too little attention to the arrangement of the exciter plant, and to assume that since there is running water available it follows necessarily that waterwheels should be used to drive the exciters directly. A study of some seventy-five plants, made by the writer, showed a total of thirty-one using waterwheel-driven exciters only, and thirteen more using waterwheel exciters with motor-generator sets in conjunction therewith. Eight additional plants use exciters having waterwheels and motors attached to the same exciter. Two additional plants use waterwheel exciters with some additional exciters direct connected to the shafts of the alternating current generators. In other words, out of seventy-five plants, a total of fifty-four use separate waterwheel units for exciter drive. Fourteen plants use only direct connected exciters on the alternator shafts. Three additional plants use a combination of direct connected exciters and motor-generator sets. Two plants use motor-generator exciters only, and two have special arrangements which would not fall in any of these groups.

The analysis shows that waterwheel exciters have been much more extensively used than direct connected exciters. The plants using waterwheel exciters embrace a wide variety of types. They cover heads ranging from 20 ft. to 2350 ft., total kilowatt capacities from 1600 kw. to 40,000 kw. and range from plants having a minimum of three generating units to a maximum of twelve. The smallest exciter is of 45 kw. and the largest of 600 kw. capacity. The plants having direct connected exciters cover heads from 20 ft. to 1800 ft., the kilowatt capacities range from 3600 to 54,000 kw. and the number of units vary from two to six, and the exciter capacities from 30 to 150 kw. The main difference in plant characteristics lies in the number of generating units, that is, although the minimum limit is practically the same in either class, the maximum limit is twelve units for waterwheel exciter plants and six units for direct connected exciter plants. This bears out the more or less prevalent feeling that direct connected exciters find their greatest usefulness in plants having a small number of units. There are factors, however, affecting the two types of exciter plants, including both first cost and operating cost, which are usually considered of no great importance and often overlooked. A brief study of these may be of interest.

In laying out a waterwheel-driven exciter plant, it is usually customary to put in two units, either one of which will take care of the excitation of the entire plant. Occasionally three units are used, two of which will take care of the entire plant, but the arrangement is unusual. Out of the thirty-one plants mentioned above, twenty-seven have two exciters and four have three. The two-unit arrangement, laid out as above, gives us 100 per cent reserve exciter capacity and one complete spare unit. This arrangement necessitates the provision for operating both machines in parallel on the exciter bus, with a more or less extensive installation of copper and switching connections for supplying power to any or all of the generator fields from either exciter. Provision is often made, in addition, for auxiliary busses from which station power circuits can be taken, and in many cases this provision for station power and the possible operation of auxiliaries from direct current supplied by this spare exciter is considered as an important item in deciding the type of excitation plant to be used. The exciters are usually made compound wound and often arranged for control by voltage regulators. The installation of 100 per cent reserve exciter capacity usually carries with it the installation of 100 per cent reserve regulator capacity.

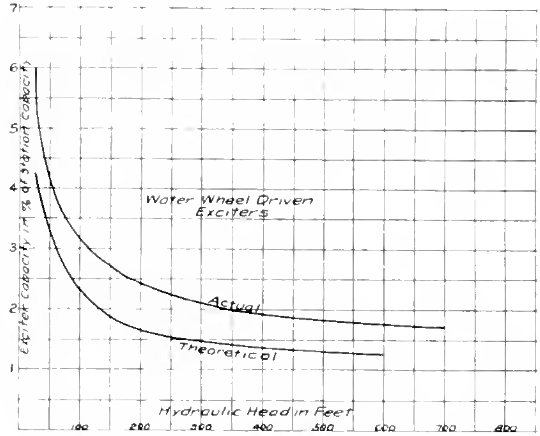

Fig. 1 Curves showing Capacity of Waterwheel-driven Exciter Plant in per cent of station capacity

The practice as regards the layout of a direct connected exciter plant has not been so well established. Where only two generating units are installed each exciter should be, and usually is, large enough to excite both generators. If there are three generating units, it may still be advisable to make each exciter large enough to excite two generators, but with four or more units there seems to be no reason for making each exciter larger than is sufficient to take care of the excitation of its own generator. In order to obtain reserve capacity, motor-generator sets can be installed. It is difficult to imagine a condition which would result in damaging two direct connected exciters without, at the same time, injuring either the waterwheels or the generator units to which the exciters in question are connected. As far as trouble with the main generating unit is concerned, it is usually considered sufficient to have one spare generating unit in the station. At the same time minor troubles with commutating apparatus are more likely to arise than with alternating current generators, and a larger factor of safety in this respect would, therefore, appear reasonable, although exciter service at the worst is not to be compared in severity with the treatment to which other classes of commutating apparatus, such as railway equipment, etc., is subjected, and even in stations containing the latter class of apparatus one spare unit is considered sufficient. It will, however, not be a very severe charge against the station if we provide a total reserve exciter capacity equivalent to the capacity of two direct connected exciters, and it appears that this amount of reserve capacity is sufficient to maintain a high factor of safety in the operation of the exciter plant. We may even go so far as to divide this reserve capacity in two units, say in two motor-generator sets, each equal to the capacity of one exciter, placing them in different parts of the station to avoid any communication of trouble between them.

Some comparisons of waterwheel-driven and direct connected exciter arrangements on this basis may be of interest. Curves have been plotted from a considerable quantity of data, showing variation in the total exciter capacity in per cent of the total kilowatt capacity of the station, with the hydraulic head, for both exciter arrangements.

Fig. 1 shows two curves. The one marked "actual" is plotted from actual data of a large number of stations having waterwheel-driven exciters. The curve marked "theoretical" is plotted taking the actual excitation of a large number of generators actually installed and calculating the total excitation required by the station, assuming that there will be two waterwheel exciters each of a capacity to excite all of the generators. It should be noticed that there is a considerable gap between the curve plotted from actual installations and the curve made up from what might be called the calculated possi-

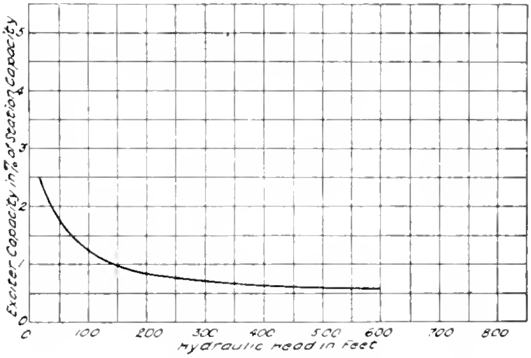

Fig. 2. Theoretical Curve showing Total Capacity of Direct-connected Exciters required for stations of 12 generators in per cent of station capacity

bilities of actual machines. It should be noted in connection with this curve that the percentage of the total station capacity represented by the exciters does not vary no matter how many generating units are installed. For instance, suppose the station contains four 5000 kw. units each requiring 50 kw. excitation, the excitation plant will have a total capacity of 400 kw., or 2 per cent of the total station capacity. If the station contains eight of the same units the exciter plant will be of 800 kw. capacity and the percentage remains unchanged.

Fig. 2, on the other hand, shows a similar curve for direct connected exciters, which is marked "theoretical," that is, it has been made by taking the excitation of actually installed generators, assuming that there are twelve generators installed in each plant, that each exciter is sufficient for exciting one machine and that there is a total reserve capacity equivalent to two exciters. It has been impossible to draw an "actual" curve such as shown in Fig. 1 for the direct connected exciter arrangement, since the percentage varies with the number of units installed in the plant.

Fig. 3 shows a theoretical waterwheel exciter curve and a theoretical direct connected exciter curve based on the use of twelve generators. The difference in the ordinates between the two curves will increase with the number of generators, so that for plants having less than twelve units, the difference in exciter capacities demanded by the two arrangements will be less than that shown on the curve. The theoretical ratio of the capacity between the two arrangements can easily be expressed by assuming that the exciter capacity required by a given generator is equal to $A$. Then, for a waterwheel exciter arrangement the total exciter capacity will be $2NA$, where $N$ is the number of generators. The total exciter capacity of the direct connected exciter arrangement, however, will be $A(N+2)$. By assigning numerical values to these, the percentage difference in the excitation required for any given number of machines can easily be calculated, and the curve in Fig. 4 shows the percentage excess of waterwheel-driven exciter capacity over the direct connected exciter capacity for any number of generators up to twelve. For instance, if there are six generators, the total waterwheel exciter capacity is 50 per cent more than the direct connected exciter capacity, assuming that each waterwheel exciter is large enough for the entire station, and that the direct connected arrangement provides for a total spare capacity equivalent to the excitation required by two generators. In the same way, with twelve generators, the waterwheel exciter capacity will be 71½ per cent in excess of the capacity required by the direct connected exciter arrangement.

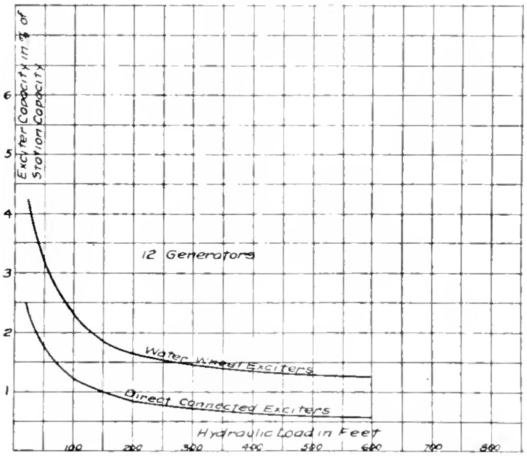

Fig. 3. Comparison of Theoretical Curves shown in Figs. 1 and 2

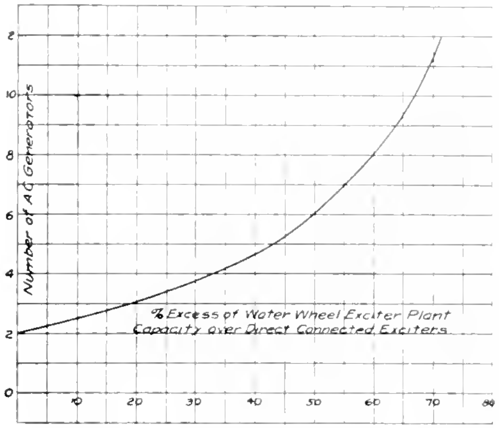

Fig. 4. Curve showing Percentage Difference in total exciter capacities for waterwheel-driven and direct connected exciter arrangements

Referring to Fig. 3, curves of which are based on twelve generators, we should expect the ordinates of the waterwheel curve to be 71½ per cent more than those of the direct connected exciter curve. While they are fairly close to this figure, they do not check exactly. This is due to the fact that they are plotted from actual excitation of various machines at different heads, and are more or less an average of all of these various machines, which of course, vary in operating characteristics. In other words two machines, although designed for the same head and capacity, even though they have the same speed, may vary in excitation through a considerable range. It is rather remarkable that the agreement is so close to the calculated figure. The direct connected exciters will presumably operate at a slower speed, and consequently will be more expensive per kilowatt than the waterwheel-driven units. With a low head and small number of units the direct connected arrangement will doubtless show a higher exciter cost; but as the head and number of units increases the difference in the cost of the electrical machines will decrease, so that the important factor, as far as the saving in first cost is concerned, which should be considered in deciding upon either of the two arrangements, is the saving made possible by the omission of the hydraulic equipment, including the waterwheels, governors, gates, penstocks, possibly forebay gates, etc., necessary to drive exciter units, and the further saving in building cost by the reduction in space required for their installation, and the decreased amount of foundation work.

There is a further factor which is usually neglected; that is, the difference in operating efficiency of the two methods. Assume, for instance, that the full load efficiency of the alternating current generator wheel is 90 per cent, the efficiency of the alternating current generator 95 per cent, the exciter wheel 87 per cent, and the waterwheel-driven exciter 90 per cent, and of the direct con-connected exciter 89 per cent. These figures are probably representative of good modern practice at ordinary heads. The full load efficiency, then, of the excitation at the generator fields with the waterwheel arrangement will be 78.3 per cent, or with the direct connected exciter 80 per cent. It should be borne in mind that exciters are usually given a normal full load rating equal to the total generator excitation at the most severe guaranteed condition of load and power-factor. Under ordinary full load operation, then, of the a-c. generator with average power-factor, and allowing for the fact that for a considerable portion of time at least one of the a-c. generators will not operate, it is probably safe to assume that the exciter will not be operating much above two-thirds of its normal rating. The normal full load operating point of the exciter wheel will probably be at about seven-eighths or nine-tenths gate opening, at which point it will have maximum efficiency. At smaller gate openings the efficiency will drop off quite rapidly, and at the operating load the wheel efficiency will probably be at least 4 per cent less than normal, and the generator will probably drop off 1 per cent, so that the combined efficiency at the generator field will be about 74 per cent. With the direct connected exciter the difference in exciter output, whether it operates at its normal rating or even at one-half load, will not materially affect the efficiency of the main a-c. generator wheel by which it is driven, so that the only reduction in efficiency will come from the exciter itself and will amount to say 1 per cent, giving an efficiency at the generator field of say 79 per cent as against 74 per cent with the waterwheel-driven exciters. Further, when the station is operating at a low load, a number of generators will be shut down, and consequently the waterwheel-driven exciter will be operated at a proportionally reduced output. The number of generators kept in operation will, however, be adjusted so that each will run at as nearly full load as possible, and consequently the direct connected exciters which remain in operation will be run at their maximum efficiency point. This means a still greater difference in operating efficiency over long periods between the two systems. It is probably safe to say that this difference in operating efficiency throughout the year will amount to at least 10 or 15 per cent in favor of the direct connected arrangement.

Suppose that a 30,000 kw. plant is installed with 2 per cent of its rating in waterwheel-driven exciter capacity; that is, assume that the rated excitation required for the machines will be 300 kw., but that the average excitation required is say 150 kw. On the basis of a 10 per cent difference in efficiency, we shall have, then, a constant loss of 15 kw. to be charged against the waterwheel exciter plant. This represents 130,250 kw-hr. per year. The latest figures from the United States census report indicate that the average gross income per kw-hr. from the central stations in this country is approximately 2.6 cents, and, at that figure, the difference in efficiency of the two systems means an annual income loss to the assumed station of $3412.50, a sum not to be despised. From the data cited at the beginning of this article it appears that in many plants having waterwheel-driven exciters, motor-generator sets are also used for the excitation of the station through a considerable period of time. A little consideration shows that with motor-generator sets in use the efficiency of excitation at the alternator field will be from 8 to 10 per cent less than the efficiency of the waterwheel-driven exciter, so that under such circumstances the direct connected arrangement shows up still more favorably.

These figures make the direct connected exciter arrangement attractive. There are however, some objectionable features. For instance, with such an arrangement the exciter system is directly involved with the generating system, and troubles with the generating units, or troubles with generators or generator wheels, directly affect the exciter. Repairs to one cannot be made without shutting down the other. This objection, however, is not so serious as it at first appears, since if the generator is shut down either by internal trouble or by trouble in the wheel there is no occasion for running its exciter.

An objection is also sometimes raised to the effect that in case of low water with some generating units shut down, if it becomes necessary to make repairs on an operating exciter, it is then necessary to start up a large generator wheel in order to run another exciter. This objection is, of course, answered by having available spare motor-generator capacity to provide emergency excitation. Complaints have been made that, with direct connected exciters, the exciter is over speeded as well as the generator, if for any reason the generator wheel runs away, and the generator voltage is consequently increased much more rapidly than would be the case with entirely separate exciters. The writer recently saw data from an actual waterwheel-driven generator runaway where the exciter speed increased synchronously. The normal high tension voltage at the transmission line was 66,000, while under the overspeed conditions it reached approximately 200,000 volts, subjecting all of the apparatus in the circuit to more than three times its normal voltage. This is a very real danger and if direct connected exciters are considered it should be provided against. Two things can be done. First, emergency devices can be provided on the turbine shaft which will admit high pressure oil from emergency storage tanks to the gate operating cylinders, the device being entirely separate from the mechanism operated from the governor. In addition to this, an over-voltage relay can be provided which will cut into the exciter field a large amount of resistance when the a-c. voltage rises above a predetermined amount. In order to accomplish this result, however, the exciter should be shunt wound, since a compound wound exciter might, at high speed, build up its voltage to normal or even higher with only the series field active. Some plants, where hydraulic conditions are severe, have even gone so far as to install water rheostats which can be cut into circuit on overspeed, thus throwing an artificial load on the generators and reducing the speed of the unit. Such devices have been used irrespective of the exciter arrangement.

One of the strong arguments for an isolated waterwheel-driven exciter plant has been that it offers a separate source of direct current for operating station auxiliaries, lights, cranes, pumps, fans, etc. The development of a-c. equipment, however, has made this feature unimportant. Some of the largest stations in the country, such, for instance, as that of the Mississippi River Power Company at Keokuk, are equipped throughout with a-c. auxiliaries, including the cranes. Further, we believe there are objections to operating any such service from the exciter system since troubles are always likely to occur in these circuits that may damage the exciters at times when such damage would cause considerable inconvenience in the operation of the station. The supply of direct current for control circuits can be easily taken care of by the use of a small motor-generator set combined with a storage battery, which gives a reliable source of power at constant voltage, and no complications are introduced by voltage variations, such as those caused by regulators when control circuits are operated from exciter busses.

With the waterwheel-driven exciter arrangement, one, or at most two, regulators are usually installed, while with the direct connected exciters if there are any considerable number of units it becomes advisable to install a regulator with each exciter, otherwise the number of contacts per regulator becomes excessive, and further by installing the separate regulator with each exciter the system is made more flexible and there is no necessity for paralleling. Under such conditions it becomes convenient to wire each direct connected exciter straight to its own generator, providing a tap connection, however, to a transfer bus so that any exciter may be connected to any generator. This connection should be made so that it will not be necessary to connect the exciter to the bus in order to excite its own generator, and normally, the exciters will not be parallelled. Each will be shunt wound and provided with its own regulator and overvoltage relay.

In some localities difficulties have arisen from waterwheel-driven exciters due to bad ice conditions. The exciter wheel passages are, of course, much smaller than those of the main a-c. units, and in a number of instances anchor ice has stopped the passages in the exciter wheels and shut down the station thereby, when the large passages in the main a-c. generator wheels have passed the ice freely without causing any particular trouble. Remedy for this is, of course, the installation of motor-generator sets which can be used for operation at such periods.

The great advantage in the waterwheel-driven exciter arrangement lies in the fact that it is entirely separate in every way from the main generator system, and it will undoubtedly always be used for this reason. The possibility, however, of protecting the direct connected exciter system from its apparent disadvantages and the gain in efficiency to be made in the operation of stations by its use warrants its careful consideration in every important plant.

# VENTILATION OF HYDRO-ELECTRIC POWER STATIONS

By R. C. Muir

Power and Mining Engineering Department, General Electric Company

The tendency of present practice in hydro-electric power station design is to use individual generating units of large capacity, the economical design of which depends upon a definite circulation of air to dissipate the losses incident to operation. This article does not enter into the design of the generator itself, but treats of the provisions that must be made by the designer of the power station in order to meet the ventilation requirements of the various types of generators. The author points out the fact that this feature in power station design has been badly neglected in the past and shows the necessity of cooperation between manufacturer and architect. —Editor.

R. C. Muir

The ventilation of hydro-electric power stations should be carefully worked out by the designer of the station in conjunction with the manufacturer of the electrical apparatus. In the past this feature has seldom received the attention it deserves, in fact in most cases where any special provisions for ventilation exist it is quite plain to see that such arrangements are the result of an afterthought. It is hoped that the few brief comments following will assist in the correction of this common fault.

The ventilation scheme of the power house is dependent upon the ventilation scheme of the generators; therefore, before completing his design the architect should first ascertain from the manufacturer the size and location of air inlets and outlets and the quantity of air required by each generator. In order to dissipate the losses most effectively provisions must be made for the passage of a definite quantity of cool, clean air through the generators, and the design of the generator room should be such that all of the heated air can pass on readily to the outside. Generally speaking, hydro-electric stations require no special provisions for cleaning the air other than a coarse screen over the air intake to keep out large objects. Air intakes can usually be located over the tail race where the air is most likely to be free from dust and dirt. An arrangement whereby part or all of the heated air can be made to re-enter the generator and heat the station in cold weather should also be made.

No one arrangement is suitable for all types of machines; therefore the following examples are given.

### Slow Speed Vertical Machines

The principal difficulties encountered in the ventilation of large slow speed, vertical type, alternating current, revolving field generators are:

1st. To design a rotor with sufficient fan effect to draw the required amount of air from the pit and force it through the stator.

2nd. To make arrangements whereby air ducts of sufficient cross section can be introduced into the wheel pit.

These difficulties are overcome either by providing forced ventilation, or by using generators having more material (iron and copper) than is customary. The dividing line where forced or natural ventilation should be used is not at all definite; therefore, with all slow speed generator installations comparative costs and efficiencies of installations suitable for each scheme should be carefully investigated before a decision is made.

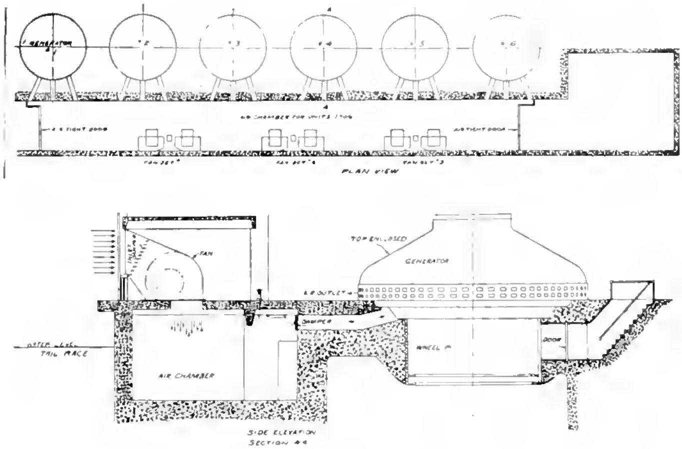

Fig. 1. Plan and Sectional Elevation of Ventilating System for large horizontal slow-speed generators

The following rather complete description of the arrangement being provided by the Cedars Rapids Manufacturing & Power Company for the ventilation of eighteen 10,000 kv-a., 53 r.p.m. generators will serve as a suitable example for machines of this type. Fig. 1 shows a sectional and plan view of the installation. It will be noted that the limited distance between the concrete scroll case of the water turbine and the floor level affords very little space for air ducts into the wheel pit.

The layout is so arranged that every six units have a separate ventilating system. Each system is provided with three blowers which take air through the tail race wall of the power house and discharge it downwards into a large air chamber. The air passes through ducts which lead through the concrete substructure of the power house from the air chamber to the wheel pits and then on through the generator out into the room. A screen of about ⅛ in. square mesh is placed in the blower inlets, and as the air will be free from dust and dirt no further provision for cleaning is made.

Each generator requires a maximum of 35,000 cu. ft. of air per minute. Two of the blower sets have sufficient capacity to supply the required amount of air for six generators, the extra blower acting as a spare. Each fan inlet is equipped with a damper which controls the admission of air, and an automatic shut-off damper is provided on the discharge so that when one fan is shut down no leakage can occur through the fan from the air chamber. The amount of air supplied to each generator is regulated by dampers in the ducts leading from the air chamber to the wheel pits, and these dampers are operated from the generator floor. The air velocity through the ducts is 1875 ft. per minute maximum; 2000 ft. per minute is not considered excessive for forced ventilation. The entrances to the wheel pits are provided with air-tight doors and the pressure in the wheel pits will be approximately 1 in. water, just enough to insure a positive air passage through the generator.

The fans are driven by slow speed induction motors, the power required being approximately 50 h.p. per fan, or 100 h.p. for a generator capacity of 60,000 kv-a. In cold weather the temperature of the station can be controlled by opening the doors to the wheel pits and shutting down one or both fans.

The generators are equipped with temperature exploring coils located in the hottest places and connected to temperature indicators on the switchboard so that any danger of overheating the machines can be avoided.

### High Speed and Moderate Speed Vertical Machines

Vertical alternating current revolving field generators, having sufficient fan effect to draw the required amount of air from the wheel pit and force it out through the stator, afford a very convenient arrangement for ventilation. Fresh air is drawn from the outside through ducts into the wheel pit. The velocity of the air in the ducts depends upon the speed of the generator and upon the length and number of bends in the ducts. The ducts should be made as straight and large as the station will permit in all cases, and where bends or changes in cross section are necessary, they should be made as gradual as possible. With ducts of average length and straightness, air velocities of 1000 ft. per minute for the moderate speed machines and 1500 ft. per minute for the higher speed machines are not excessive.

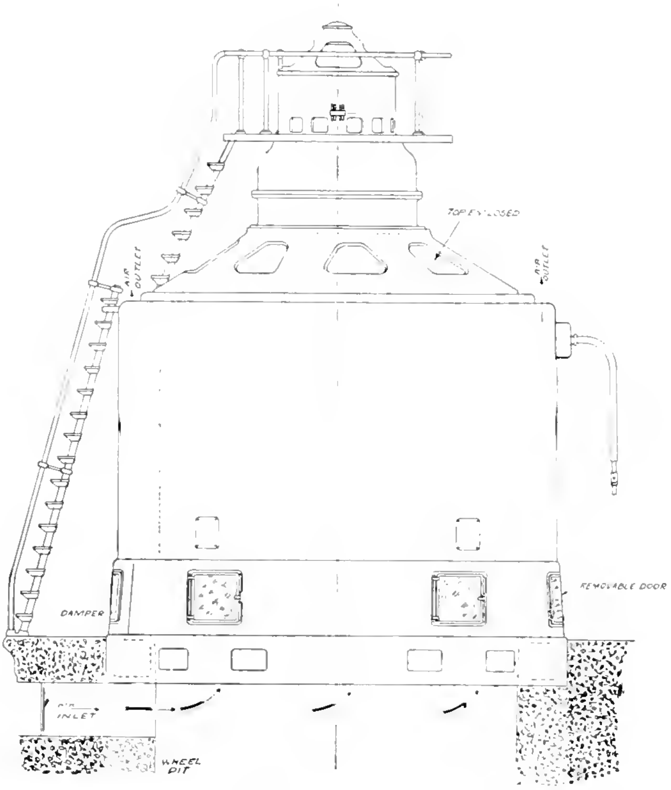

Fig. 2. Elevation of a Moderate or High Speed Vertical Generator showing the path of the ventilating air

Fig. 2 shows the arrangement adopted by the Utah Power & Light Company for ventilating two 12,222 kv-a., 514 r.p.m. generators; the arrangement will serve as a suitable example for machines of this type. It will be noted that in this case removable doors are provided on the base of the generator so that in cold weather the temperature of the generator room can be controlled by adjusting the damper on the inlet ducts and removing part, or all, of the doors in the base as desired. The generators are provided with temperature indicators to prevent overheating.

### High Speed and Moderate Speed Horizontal Machines

Fig. 3 shows the most convenient and effective scheme for ventilating high and moderate speed horizontal alternating current revolving field generators. The ends of the stator are enclosed by a housing so designed that air can be taken only from the pit below the machine. In this case air enters both ends of the generator and is forced out through the stator by the revolving field. Fans are usually provided on the ends of the field to insure a more positive and definite circulation. The bottom of the stator is enclosed so that heated air from the generator cannot re-enter the pit and be used over again.

The ducts should be arranged so that air can be taken from the outside or from the generator room, or from both, as desired. In general, the same principles involved in the ventilation of vertical machines apply to horizontal machines of this type.

### Other Machines

Many of the smaller and slow speed horizontal alternating current generators do not lend themselves to the convenient arrangement of ventilation described above. This remark also applies to direct current machines. With these machines the ventilation is not positive and the generator room should be so designed that there will not be a tendency for the machines to use the same air over and over again.

The most effective method of preventing this is by introducing cool air through ducts in the floor or basement of the power station, preferably into the pits of the machines, and allowing the heated air to escape through openings in the roof. The size of the inlets and outlets depends upon the losses to be dissipated, the allowable difference in temperature between the inside and outside air and the height of the building, but a good plan to follow is that they cannot be too large.

The maximum difference between inside or room temperature and outdoor temperature should not exceed 20 deg. F. (11.1 deg. C.) during hot weather, since the air entering the machine is taken from the room and the air leaving the machine is considerably warmer than the room temperature. The ventilation scheme should be laid out for most severe or hot weather conditions. It is very important to make the difference in height between inlet and outlet openings as great as the station will permit, as is shown from the following table.

**Quantity of Air in Cu. Ft. Discharged Per Minute through a Ventilating Duct of 1 Sq. Ft. in Cross-Sectional Area. Difference in Temperature of Air in Duct and Outside—20 Deg. F.**

| Height of Vent. Duct in Ft. | Cu. Ft. Per Minute |
|---|---|
| 10 | 153 |
| 20 | 217 |
| 30 | 265 |
| 40 | 306 |
| 50 | 342 |
| 60 | 375 |

The amount of air required for the generating room can be easily calculated, as follows:

One kw.-hour will raise the temperature of 10,000 cu. ft. of air from 80 deg. F. to 100 deg. F., a rise of 20 deg. F. (11.1 deg. C.).

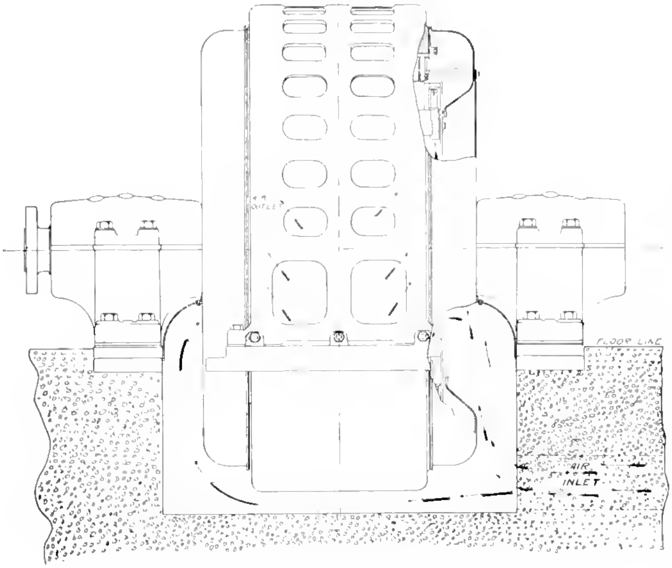

Fig. 3. Elevation of a Moderate or High Speed Horizontal Generator showing a convenient means of ventilation
