FOREWORD

The 19th century writer/journalist Ambrose Bierce once dismissed an entire book in one nine-word review, stating: "The covers of this book are too far apart." This 9th edition of the *NAB Engineering Handbook* could perhaps also be so criticized, but only on the basis of the substantial shelf space it occupies. Inside, the material between the covers includes a tremendous amount of useful reference information, covering all aspects of broadcast engineering technology and practices. This Handbook is the definitive reference source on the subject of broadcast engineering, and well deserves and utilizes these widely displaced covers.

It has been six years since a new edition of the *NAB Engineering Handbook* was produced. In the current environment, complete product introduction cycles from research to production lines can span less than a year. In a perfect world, a new edition of the *NAB Engineering Handbook* might be produced on an annual basis, or even semi-annually, to attempt to truly keep pace with the rate of technology changes. But we don't live in a perfect world, do we? The compilation of this Handbook is a gargantuan task, requiring significant work effort from literally hundreds of people and thousands of hours of writing, editing and preparatory work. It is a multi-year effort of large proportion and it is no exaggeration to say that work on the 9th edition began not long after the 8th edition was published. All those who worked so tirelessly to bring this publication to life have our deepest appreciation and hearty congratulations.

The *NAB Engineering Handbook* is a snapshot in time of broadcast and broadcast-related technology. In that sense it is not perfect, because it is a snapshot, while the blistering pace of broadcast and telecommunications technology development and deployment continues. However, as our industry now finds itself in the initial stages of the digital broadcasting age, it is truly a perfect time to introduce this new edition of the *Handbook*. Many subjects related to the "digital revolution" that were not covered in the 8th edition, because they were at an early stage of development or only theorized about at that time, are dealt with in great detail in this edition.

NAB Science and Technology remains committed to being responsive to the dynamic, time-sensitive needs of the ever-evolving broadcast industry. Please feel free to let us know your views on this edition of the *Handbook* and your suggestions for future editions.

Lynn D. Claudy
Senior Vice President, Science and Technology
National Association of Broadcasters

ACKNOWLEDGEMENTS

"Its technical future is as limitless as space, its service potential is bounded only by the ingenuity of man, and its economic progress will keep step with that of the country itself." These words taken from the 5th edition of the *NAB Engineering Handbook* are as true today about the broadcasting industry as they were in 1960.

To prepare engineers for the technical future of broadcasting, we called upon the ingenuity of many to produce this 9th edition of the *NAB's Engineering Handbook*. First among those is Jerry Whitaker, the editor-in-chief of this edition. Jerry, who is the president of Technical Press and the former editor and publisher of *Broadcast Engineering Magazine,* has lent his talents to numerous technical broadcast publications. Jerry brought a truly fresh perspective and limitless enthusiasm to this publication.

It would be difficult for anyone to imagine that a publication like the *NAB Engineering Handbook* could be produced without the assistance of numerous individuals. We would like to express our appreciation to the members of the NAB Handbook Board of Advisors:

Andy Butler, PBS, Alexandria, VA
Randall Hoffner, ABC, New York, NY
Louis Libin, Broadcast Comm Inc., Woodmere, NY
Alfred Resnick, ABC, New York, NY
Milford Smith, Greater Media, East Brunswick, NJ
Donald Wilkinson, Fisher Broadcasting, Seattle, WA

Recognition is also due to the engineering staff of NAB's Science and Technology department for reviewing all of the manuscripts: John Marino, Art Allison, David Layer, David Wilson, and Kelly Williams.

Technical editing was handled by Courtenay Smith Brown. Text processing and author communications was led by Sharon Devine with Cheryl Coleridge providing additional text processing support. Finally, a special thanks to Lynn Claudy, Senior Vice President of NAB Science and Technology for supporting and encouraging this project, John Battison for lending his expertise to review manuscripts, Dos Schuette for contributing her design expertise, and Ann Carper for adding her editing skills to this publication.

Janet H. Elliott
Managing Editor

SECTION 8. ANCILLARY BROADCAST SYSTEMS

SECTION 9. TECHNICAL MANAGEMENT AND SAFETY

Section 1: Broadcast Standards and Practices

Introduction by Al Resnick, ABC, New York, NY

By its very nature, broadcasting requires coordination and cooperation among stations and end-users. The fundamental basis of radio and television broadcasting is the application of mutually-agreeable standards and practices that permit stations to meet their charter—namely, serving the public interest, convenience and necessity. To accomplish this goal, the Federal Communications Commission (FCC) has established a body of standards and rules upon which broadcast services in the U.S. are based. Building upon this foundation, a number of organizations have developed additional policies that guide the broadcast industry, the most recent being the Advanced Television Systems Committee (ATSC), which built upon a rich history of standards work by the Society of Motion Picture and Television Engineers (SMPTE) and related organizations around the world to produce the new digital television (DTV) standard. It is the examination of these important issues that this section of the *NAB Engineering Handbook* is devoted.

John Norgard provides a comprehensive overview of the lifeline of the broadcast industry, in his chapter, *Electromagnetic Spectrum.*

William R. Meintel's *Frequency Allocations For Broadcasting and the Broadcast Auxiliary Services* chapter provides an overview of terrestrial frequency allocations and a listing of the frequencies available for AM, FM and TV broadcast stations as well as for the auxiliary broadcast services that support broadcasting operations.

If you are new to the broadcast industry, the Office of Public Affairs of the FCC contribution is an invaluable chapter. It is full of information on the Commission's organization and administrative practices.

In his chapter, *FCC Compliance and Information Bureau,* NAB staffer David E. Wilson explains the intricacies of the FCC bureau that is responsible for providing information to the general public, resolving telecommunications interference problems and, most importantly, enforcing the FCC's technical rules.

How broadcasters co-exist in the increasingly crowded spectrum is the focus of Robert Van Buhler's and Richard Rudman's *Frequency Coordination* chapter. Frequency coordination is necessary to facilitate the allocation of limited spectrum for a growing number of uses among a growing number of users.

Do you know the difference between the *flat-earth and spherical-earth* distance calculation methods? In his chapter, *Distance and Bearing Calculations,* Dane E. Ericksen provides an in-depth analysis of both methods.

NAB staffer Courtenay Smith Brown's *Broadcast Related Organizations and Information* chapter provides a general overview of entities whose activities affect the work of broadcast engineers.

As the broadcast industry enters the digital era, Chip Morgan and Randall Hoffner team up to provide the latest information on digital audio technology in their *Digital Audio Standards and Practices* chapter.

As we look forward to the digital age, it behooves us to consider our analog past. The definitive chapter on NTSC is presented here in a chapter titled *NTSC Standard.*

If film can be exchanged internationally, why can't we accomplish the same exchange with television programming? D.H. Pritchard and J.J. Gibson explore this lack of compatibility in their *Worldwide Television Standards for Conventional Television* chapter.

NAB staffers contribute to this opening section once again, in a chapter prepared by Arthur Allison and David H. Layer, entitled *Digital Television*

Terrestrial Transmission Standards. Their joint effort provides background information on the various aspects of DTV technology and introduces the reader to the standards that define DTV technology.

David E. Wilson's second offering to this section is the *EAS Standard* chapter. Wilson's chapter analyzes EAS from four different perspectives—the modulation method, the coding structure, how each party that participates in EAS relates to each of the other parties and the EAS responsibilities of individual broadcasters.

1.1
ELECTROMAGNETIC SPECTRUM

JOHN NORGARD
UNIVERSITY OF COLORADO, COLORADO SPRINGS, CO

INTRODUCTION

The electromagnetic (EM) spectrum consists of all forms of EM radiation [EM waves (radiant energy) propagating through space, from DC to light to gamma rays]. The EM spectrum can be arranged in order of frequency and/or wavelength into a number of regions,[1] usually wide in extent, within which the EM waves have some specified common characteristics, (*e.g.*, those characteristics relating to the production or detection of the radiation). A common example is the spectrum of the radiant energy in white light, as dispersed by a prism, to produce a "rainbow" of its constituent colors.

The EM spectrum is typically displayed as a function of frequency (or wavelength), as shown schematically in Figure 1.1-1. In air, frequency (f) and wavelength (λ) are inversely proportional ($f = c/\lambda$, where $c \approx 3 \times 10^8$ m/s is the speed of light in vacuum). The Meter Kilogram Second (MKS) unit of frequency is the Hertz (1 Hz = 1 cps); the MKS unit of wavelength is the meter. Frequency is also measured in the following sub-units:

Kilohertz, 1 kHz = 10^3 Hz
Megahertz, 1 MHz = 10^6 Hz
Gigahertz, 1 GHz = 10^9 Hz
Terahertz, 1 THz = 10^{12} Hz
Petahertz, 1 PHz = 10^{15} Hz
Exahertz, 1 EHz = 10^{18} Hz

or, for very high frequencies:

electron volts[2], 1 ev ~ 2.41×10^{14} Hz

Wavelength is also measured in the following sub-units:

Centimeters, 1 cm = 10^{-2} m
Millimeters, 1 mm = 10^{-3} m
Micrometers, 1 μm = 10^{-6} m (microns)
Nanometers, 1 nm = 10^{-9} m
Ångstroms, 1 Å = 10^{-10} m
Picometers, 1 pm = 10^{-12} m
Femtometers, 1 fm = 10^{-15} m
Attometers, 1 am = 10^{-18} m

SPECTRAL SUB-REGIONS

In this chapter, for convenience, the overall EM spectrum is divided into three main sub-regions:

Optical spectrum
DC to light spectrum
Light to gamma ray spectrum

This section focuses on the main sub-regions of the EM spectrum. Note that the boundaries between some of the spectral regions are somewhat arbitrary. Some spectral bands have no sharp edges and merge into each other and some spectral segments overlap each other slightly.

Optical Spectrum

The optical spectrum is the "middle" frequency/wavelength region of the EM spectrum. It is defined here as the visible and near-visible regions of the EM spectrum and includes:

- The infrared (IR) band, circa 300 μm–0.7 μm (circa 1 THz–429 THz)
- The visible light band, 0.7 μm–0.4 μm (429 THz–750 THz)
- The ultraviolet (UV) band, 0.4 μm–circa 10 nm (750 THz–circa 30 PHz, approximately 100 ev)

These regions of the EM spectrum are usually described in terms of their wavelengths.

Atomic and molecular radiation produce radiant light energy. Molecular radiation and radiation from hot bodies produce EM waves in the IR band. Atomic radiation (outer shell electrons) and radiation from arcs and sparks produce EM waves in the UV band.

Visible Light Band

In the "middle" of the optical spectrum is the visible light band, extending *approximately* from 0.4 μm (violet) up to 0.7 μm (red), (from 750 THz (violet)–429 THz (red)). EM radiation in this region of the EM spectrum, when entering the eye, gives rise to visual sensations (colors), according to the spectral response of the eye, which responds only to radiant energy in the visible light band extending from the extreme long wavelength edge of red to the extreme short wavelength edge of violet.[3] This visible light band is further subdivided into the various colors of the rainbow (in decreasing wavelength/increasing frequency):

- Red, a primary color, peak intensity at 700.0 nm (429 THz)
- orange
- yellow
- green, a primary color, peak intensity at 546.1 nm (549 THz)

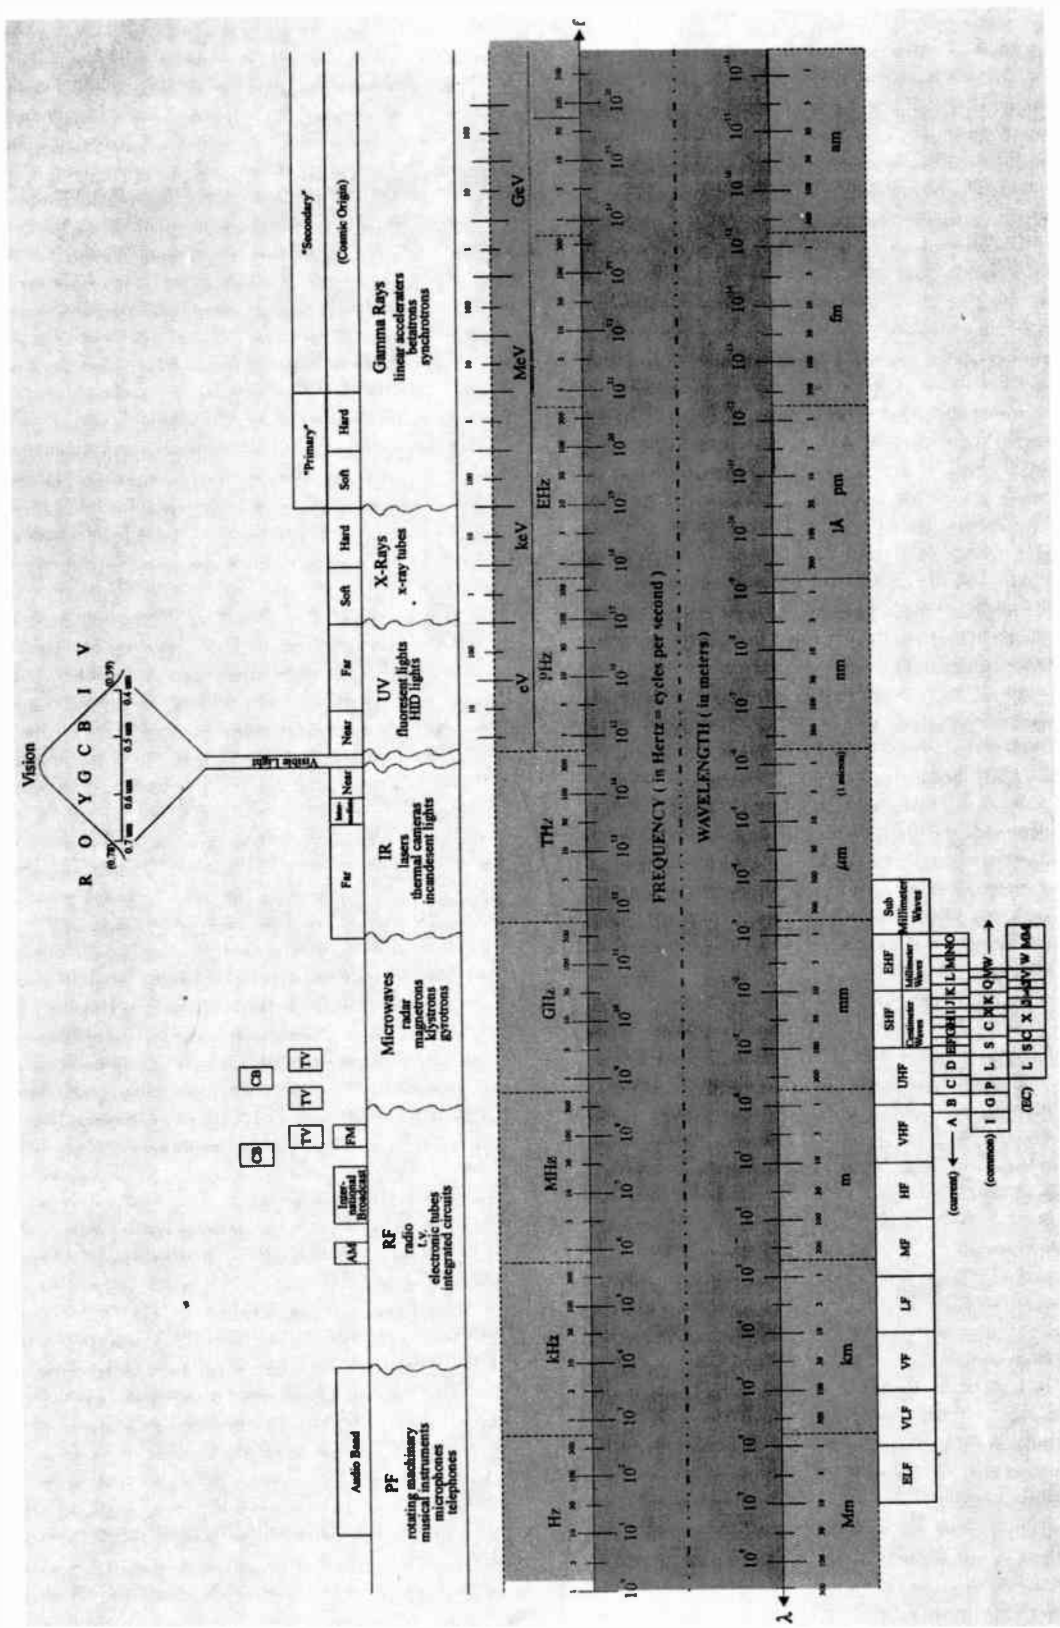

Figure 1.1-1. Simplified chart of the electromagnetic spectrum. (From, Whitaker, J. C., The Electronics Handbook, CRC Press, Boca Raton, FL, 1996. Used with permission.)

- cyan
- blue, a primary color, peak intensity at 435.8 nm (688 THz)
- indigo
- violet

IR Band

The IR band is the region of the EM spectrum lying immediately below the visible light band. The IR band consists of EM radiation with wavelengths extending between the longest visible red (circa 0.7 μm) and the shortest microwaves (300 μm–1 mm), (circa 429 THz to 1 THz–300 GHz).

The IR band is further subdivided into the "near" (shortwave), "intermediate" (midwave), and "far" (longwave) IR segments as follows: [4]

Near IR segment, 0.7 μm–3 μm (429 THz–100 THz)

Intermediate IR segment, 3 μm–7 μm (100 THz–42.9 THz)

Far IR segment, 7 μm–300 μm (42.9 THz–1 THz)

Note that the sub-millimeter region of wavelengths is sometimes included in the very far region of the IR band.

Sub-millimeter band, 100 μm up to 1 mm (3 THz–300 GHz)

EM radiation is produced by oscillating and rotating molecules and atoms. Therefore, all objects at temperatures above absolute zero emit EM radiation by virtue of their thermal motion (warmth) alone. Objects near room temperature emit most of their radiation in the IR band. However, even relatively cool objects emit some IR radiation; hot objects, such as incandescent filaments, emit strong IR radiation.

IR radiation is sometimes incorrectly called "radiant heat," because warm bodies emit IR radiation and bodies that absorb IR radiation are warmed. However, IR radiation is not itself "heat." This radiant energy is called "black body" radiation. Such waves are emitted by all material objects. For example, the background cosmic radiation (2.7K) emits microwaves, room temperature objects (293K) emit IR rays, the Sun (6000K) emits yellow light, the Solar Corona (1 Million K) emits X-rays.

IR astronomy uses the 1 μm to 1 mm part of the IR band to study celestial objects by their IR emissions. IR detectors are used in night vision systems, intruder alarm systems, weather forecasting and missile guidance systems. IR photography uses multilayered color film, with an IR sensitive emulsion in the wavelengths between 700–900 nm, for medical and forensic applications and for aerial surveying.

UV Band

The UV band is the region of the EM spectrum lying immediately above the visible light band. The UV band consists of EM radiation with wavelengths extending between the shortest visible violet (circa 0.4 μm) and the longest X-rays (circa 10 nm)[5], from 750 THz (approximately 3 ev) up to circa 30 PHz (approximately 100 ev).

The UV band is further subdivided into the "near" and the "far"[6] UV segments as follows:

Near UV segment, circa 0.4 μm down to 100 nm (circa 750 THz–3 PHz), approximately 3 ev up to 10 ev

Far UV segment, 100 nm down to circa 10 nm, (3 PHz–circa 30 PHz), approximately 10 ev up to 100 ev

UV radiation is produced by electron transitions in atoms and molecules, as in a mercury discharge lamp. Radiation in the UV range is easily detected and can cause florescence in some substances and can produce photographic and ionizing effects.

In UV astronomy, the emissions of celestial bodies in the wavelength band between 50–320 nm are detected and analyzed to study the heavens. The hottest stars emit most of their radiation in the UV band.

DC to Light

Below the IR band are the lower frequency (longer wavelength) regions of the EM spectrum, subdivided generally into the following spectral bands (by frequency/wavelength):

Microwave band, 300 GHz–300 MHz[7] (1 mm–1 m)

Radio frequency (RF) band, 300 MHz–10 kHz (1 m–30 Km)

Power(PF)/telephony band, 10 kHz–DC (30 Km–∞)

These regions of the EM spectrum are usually described in terms of their frequencies.

EM radiation whose wavelengths are of the order of millimeters and centimeters are called *microwaves*, and those still longer are called radio frequency (RF) waves (or *Hertzian waves*).

Radiation from electronic devices produces EM waves in both the microwave and RF bands. Power frequency energy is generated by rotating machinery. Direct current (dc) is produced by batteries or rectified alternating current (ac).

Microwave Band

The microwave band is the region of wavelengths between the far IR/sub-millimeter region and the conventional RF region. The boundaries of the microwave band have not been definitely fixed, but it is commonly regarded as the region of the EM spectrum extending from about 1 mm–1 m in wavelengths (300 GHz–300 MHz). The microwave band is further sub-divided into the following segments:

Millimeter waves,[8] 300 GHz–30 GHz (1 mm–1 cm), "EHF" band

Centimeter waves, 30 GHz–3 GHz (1 cm–10 cm), "SHF" band

The microwave band usually includes the "UHF" band from 3 GHz–300 MHz (10 cm–1 m). Microwaves are used in radar, in communication links spanning moderate distances, as radio carrier waves in radio broadcasting, for mechanical heating and cooking in microwave ovens.

Radio Frequency (RF) Band

The RF range of the EM spectrum is the wavelength band suitable for utilization in radio communications extending from 10 kHz–300 MHz,[9] (30 Km–1 m). Some of the radio waves serve as the carriers of low-frequency audio signals; other radio waves are modulated by video and digital information. The *amplitude modulated* (AM) broadcasting band uses waves with frequencies between 550–1640 kHz; the *frequency modulated* (FM) broadcasting band uses waves with frequencies between 88–108 MHz.

In the U.S., the Federal Communications Commission (FCC) is responsible for assigning a range of frequencies (*e.g.*, a frequency band in the RF spectrum) to a broadcasting station or service. The International Telecommunications Union (ITU) coordinates frequency band allocation and coordination on a worldwide basis.

Radio astronomy uses a radio telescope to receive and study radio waves naturally emitted by objects in space. Radio waves are emitted from hot gases ("thermal" radiation), from charged particles spiraling in magnetic fields (synchrotron radiation), and from excited atoms and molecules in space (spectral lines), such as the 21 cm line emitted by hydrogen gas.

Power Frequency (PF)/Telephone Band

The PF range of the EM spectrum is the wavelength band suitable for generating, transmitting, and consuming low frequency power, extending from 10 kHz down to DC (30 km to ∞). In the U.S., most power is generated at 60 Hz (some military and computer applications use 400 Hz); in Europe, power is generated at 50 Hz.

FREQUENCY BAND DESIGNATIONS

The combined microwave, RF and power/telephone spectra are subdivided into the specific bands shown below in Table 1.1-1. The radar band often is considered to extend from the middle of the HF (7) band to the end of the EHF (11) band. Note that the band designated (12) has no commonly used name or abbreviation.

The U.S. military Tri-Service designations for radio communications bands are as shown in Table 1.1-2.

Another set of designations that pre-date the U.S. Tri-Service designations are in Table 1.1-3. Sometimes, the prior S band extended from 1.5 GHz to 5.85 GHz, and the prior X band extended from 5.85 GHz to 10.9 GHz, eliminating the C band.

The "EC" radar band designations in prior use are contained in Table 1.1-4. The prior K band sometimes included the Ka band and extended from 18 to 40 GHz.

An alternate and more detailed sub-division of the UHF (9), SHF (10), and EHF (11) bands is shown in Table 1.1-5.

Table 1.1-1

International Radio Frequency Band Designations and the Numerical Designations

Band Name	Designation	Frequency Range	Wavelength Range
Extremely Low Frequency	ELF (1) Band	3 Hz–30 Hz	100,000 km–10,000 km
Super Low Frequency	SLF (2) Band	30 Hz–300 Hz	10,000 km–1,000 km
Ultra Low Frequency	ULF (3) Band	300 Hz–3 kHz	1,000 km–100 km
Very Low Frequency	VLF (4) Band	3 kHz–30 kHz	100 km–10 km
Low Frequency	LF (5) Band	30 kHz–300 kHz	10 km–1 km
Medium Frequency	MF (6) Band	300 kHz–3 MHz	1 km–100 m
High Frequency	HF (7) Band	3 MHz–30 MHz	100 m–10 m
Very High Frequency	VHF (8) Band	30 MHz–300 MHz	10 m–1 m
Ultra High Frequency	UHF (9) Band	300 MHz–3 GHz	1 m–10 cm
Super High Frequency	SHF (10) Band	3 GHz–30 GHz	10 cm–1 cm
Extremely High Frequency	EHF (11) Band	30 GHz–300 GHz	1 cm–1 mm
	(12) Band	300 GHz–3 THz	1 mm–100 μm

Table 1.1-2

Current U.S. Tri-Service Radar Band Designations

Band Designation	Frequency Range	Wavelength Range
A Band	0 Hz–250 MHz	(∞–1.2 m)
B Band	250 MHz–500 MHz	(1.2 m–60 cm)
C Band	500 MHz–1 GHz	(60 cm–30 cm)
D Band	1 GHz–2 GHz	(30 cm–15 cm)
E Band	2 GHz–3 GHz	(15 cm–10 cm)
F Band	3 GHz–4 GHz	(10 cm–7.5 cm)
G Band	4 GHz–6 GHz	(7.5 cm–5 cm)
H Band	6 GHz–8 GHz	(5 cm–3.75 cm)

Several other frequency bands of interest (not exclusive) are shown in Tables 1.1-6, 1.1-7, and 1.1-8.

Light to Gamma Rays

Above the UV spectrum are the higher frequency (shorter wavelength) regions of the EM spectrum, subdivided generally into the following spectral bands (by frequency/wavelength):[10]

X-ray band, approximately 10 ev–1 Mev (circa 10 nm–circa 1 pm), circa 3 PHz–circa 300 EHz

Gamma ray band, approximately 1 Kev–∞ (circa 300 pm–0 m), circa 1 EHz–∞

These regions of the EM spectrum are usually described in terms of their photon energies in electron volts. Notice that the bottom of the gamma ray band overlaps the top of the X-ray band.

Radiation from atomic inner shell excitations produces EM waves in the X-ray band. Radiation from naturally radioactive nuclei produces EM waves in the gamma ray band.

X-Ray Band

The x-ray band is further sub-divided into the following segments:

Soft X-rays, approximately 10 ev–10 Kev (circa 10 nm–100 pm), circa 3 PHz–3 EHz
Hard X-rays, approximately 10 Kev–1 Mev (100 pm–circa 1 pm), 3 EHz–circa 300 EHz

Because the physical nature of these rays was first unknown, this radiation was called X-rays. The more powerful X-rays are called hard X-rays and are of high frequencies and, therefore, are more energetic; less powerful X-rays are called soft X-rays and have lower energies.

X-rays are produced by transitions of electrons in the inner levels of excited atoms or by rapid deceleration of charged particles (Brehmsstrahlung "breaking radiation"). An important source of X-rays is synchrotron radiation. X-rays can also be produced when high energy electrons from a heated filament cathode strike the surface of a target anode (usually tungsten) between which a high alternating voltage (approximately 100 kV) is applied.

X-rays are a highly penetrating form of EM radiation and applications of X-rays are based on their short wavelengths and their ability to easily pass through matter. X-rays are very useful in crystallography for determining crystalline structure and in medicine for photographing the body. Since different parts of the body absorb X-rays to a different extent, X-rays passing through the body provide a visual image of its interior structure when striking a photographic plate. X-rays are dangerous and can destroy living tissue. They can also cause severe skin burns. X-rays are useful in the diagnosis and non-destructive testing of products for defects.

Gamma Ray Band

The Gamma Ray band is sub-divided into the following segments:

Primary gamma rays, approximately 1 Kev–1 Mev (circa 300 pm–300 fm), circa 1 EHz–1000 EHz

The primary Gamma Rays are further sub-divided into the following segments:

Soft gamma rays, approximately 1 Kev–circa 300 Kev (circa 300 pm–circa 3 pm), circa 1 EHz–circa 100 EHz
Hard gamma rays, approximately 300 Kev–1 Mev (circa 3 pm–300 fm), circa 100 EHz–1000 EHz
Secondary gamma rays, approximately 1 Mev–∞ (300 fm–0 m), 1000 EHz–∞

Secondary gamma rays are created from collisions of high energy cosmic rays with particles in the Earth's upper atmosphere.

Gamma rays are essentially very energetic X-rays. The distinction between the two is based on their origin. X-rays are emitted during atomic processes involving energetic electrons; gamma rays are emitted by excited nuclei or other processes involving subatomic particles.

Gamma rays are emitted by the nucleus of radioactive material during the process of natural radioactive decay as a result of transitions from high energy excited states to low energy states in atomic nuclei. Cobalt 90 is a common gamma ray source (with a half-life of 5.26 years). Gamma rays are also produced by the interaction of high energy electrons with matter. "Cosmic" gamma rays cannot penetrate the Earth"s atmosphere.

Applications of gamma rays are found both in medicine and in industry. In medicine, gamma rays are used for cancer treatment, diagnoses, and prevention. Gamma ray emitting radioisotopes are used as tracers. In industry, gamma rays are used in the inspection of castings, seams and welds.

Defining Key Terms

Cosmic "rays"—Highly penetrating particle "rays" from outer space. Primary cosmic "rays" which enter the Earth's upper atmosphere consist of mainly protons. Cosmic "rays" of low energy have their origin in the sun, those of high energy in galactic or extragalactic space, possibly as a result of supernova explosions. Collisions with atmospheric particles result in secondary cosmic "rays" (particles) and secondary gamma rays (EM waves).

Electromagnetic spectrum—EM radiant energy arranged in order of frequency and/or wavelength and divided into regions within which the waves have some common specified characteristics (*e.g.*, the waves are generated, received, detected, or recorded in a similar way).

Gamma rays—Electromagnetic radiation of very high energy (> 30 Kev) emitted after nuclear reactions or by a radioactive atom when its nucleus is left in an excited state after emission of alpha or beta particles.

Infrared (IR) radiation—Electromagnetic radiation whose wavelengths lie in the range from 0.7 nm (the long-wavelength limit of visible red light) to 1 mm (the shortest microwaves). A convenient sub-division is as follows: Near: 0.7 μm to 2–5 μm; intermediate: 2–5 μm to 10 μm; far: 10 μm to 1 mm.

Light—White light, when split into a spectrum of colors, is composed of a continuous range of merging colors: red, orange, yellow, green, cyan, blue, indigo, violet.

Microwaves—An electromagnetic wave which has a wavelength between approximately 0.3 cm (or 1 mm) and 30 (or 10) cm, corresponding to frequencies between 1 GHz (or 300 MHz) and 100 (or 300) GHz. Note that there are no well defined boundaries distinguishing microwaves from infrared and radio waves.

Radio waves—Electromagnetic radiation suitable for radio transmission in the range of frequencies from about 10 kHz to about 300 MHz.

Ultraviolet (UV) radiation—Electromagnetic radiation whose wavelengths lie in the range from 0.4 nm (the shortest-wavelength limit of visible violet light) to 3 nm (the longest X-rays). A convenient sub-division is as follows: Near: 0.4 μm to 100 nm; far: 100 nm to 3 nm.

X-rays—Electromagnetic radiation of short wavelengths (circa 3 nm to 30 pm) produced when cathode rays impinge on matter.

REFERENCES

1. Note that specific frequency ranges are often called "bands;" several contiguous frequency bands are usually called "spectrums;" and sub-frequency ranges within a band are sometimes called "segments."
2. Note that $\varepsilon = hf = eV$ where $h = 6.63(10^{-34}$ Js (Planck's Constant) and $e = 1.602 \times 10^{-19}$ C.
3. The spectral response of the eye is sometimes described as extending from 0.38 μm (violet) up to 0.75 or 0.78 μm (red), i.e. from 789 THz down to 400 or 385 THz).
4. Some reference texts use 2.5 μm (120 THz) as the breakpoint between the near and the intermediate IR bands and 10 μm (30 THz) as the breakpoint between the intermediate and the far IR bands. Also, 15 μm (20 Thz) is sometimes considered as the long wavelength end of the far IR band.
5. Some reference texts use 4, 5, or 6 nm as the upper edge of the UV band.
6. The far UV band is also referred to as the *vacuum UV band*, since air is opaque to all UV radiation in this region.
7. Some reference works define the lower edge of the microwave spectrum at 1 GHz.
8. Some reference articles consider the top edge of the millimeter region to stop at 100 GHz.
9. Some authors consider the RF band as extending from 10 kHz to 300 GHz, with the microwave band as a subset of the RF band from 300 MHz to 300 GHz.
10. Note that *cosmic "rays"* (from astronomical sources) are not EM waves (rays) and, therefore, are not part of the EM spectrum. Cosmic "rays" are high energy charged particles (electrons, protons, and ions) of extraterrestrial origin moving through space, which may have energies as high as 10^{20} ev. Cosmic "rays" have been traced to cataclysmic astrophysical/cosmological events, such as exploding stars and black holes. Cosmic "rays" are emitted by supernova remnants, pulsars, quasars, and radio galaxies. Cosmic "rays" which collide with molecules in the Earth's upper atmosphere produce secondary cosmic "rays" and gamma rays of high energy which also contribute to the natural background radiation. These gamma rays are sometimes called "cosmic" or *secondary* gamma rays. Cosmic rays are a useful source of high-energy particles for experiments.

1.2
FREQUENCY ALLOCATIONS FOR BROADCASTING AND THE BROADCAST AUXILIARY SERVICES

WILLIAM R. MEINTEL
TECHWARE, INC., CHANTILLY, VIRGINIA

INTRODUCTION

This chapter provides an overview of terrestrial frequency allocations and a listing of the frequencies available for AM, FM, and TV broadcast stations as well as for the "auxiliary" broadcast services that support broadcasting operations.[1] Necessarily, such an overview needs to include a description of the decision-making process that is involved in allocating a frequency band for a specific purpose.

This complex subject of allocations involves more than just the location of the service in the frequency spectrum; it includes decisions as to the number and width of channels, power and antenna limitations, as well as decisions concerning the technical standards that define how the spectrum will be shared with other users. Because each broadcast service presents unique service and interference objectives, the allocation process has been and will continue to be different for each of these services.

Here it is possible to provide only a brief description of the allocation process before turning to the current situation for each of the services. Where appropriate, the discussion will touch on changes expected in the foreseeable future.

HOW SPECTRUM IS ALLOCATED

It is a fundamental characteristic of radio wave propagation that these waves follow the laws of physics and thus ignore political or geographic boundaries. As a result, decisions concerning radio frequency allocations cannot be made solely at the local level but must take into account their anticipated impact outside the station's coverage area. Recognizing that coordination in the allocation and use of spectrum is essential, an international mechanism has been established to perform this function, and in the United States, a parallel coordination system has been established at the federal level.

[1] Technically the term "allocation" refers to the process by which a frequency band is made available for a specific purpose. However, it is used here in a broader sense that includes the "allotment" of frequencies within a band, and the "assignment" of individual stations.

International Allocation

At the international level, frequency allocation decisions are made by the International Telecommunication Union (ITU), a specialized agency of the United Nations, headquartered in Geneva, Switzerland. Like the United Nations, the ITU is a consortium of more than 180 governments, whose purposes are to propose, develop, revise and administer world-wide frequency allocation plans. In the terminology of the ITU, participating governments are referred to as "states," "members" or "administrations." Such international cooperation serves to minimize interference and maximize use of the spectrum.

Although the ITU maintains a permanent staff, the power of the organization, as indicated by the structure shown in Figure 1.2-1, resides with the member nations who direct its activities through periodic meetings. At the highest level of this structure is the Plenipotentiary Conference that adopts the fundamental policies of the organization and decides on the organization and activities of the Union through a treaty known as the *International Telecommunication Constitution and Convention*. Plenipotentiary Conferences are held at four year intervals and are open to ITU member countries, the United Nations and its specialized agencies, the International Atomic Energy Agency, regional telecommunications organizations and intergovernmental satellite operators.

Proceeding down the structure, the ITU Council consists of a representative group of Members elected by the Plenipotentiary Conference. The task of the Council is to insure that in the period between Plenipotentiary conferences, that the ITU's policies and strategy are adequately responding to the constantly changing telecommunication environment. The Council is also responsible for insuring efficient coordination of work, effective financial management and assisting Members in the implementation of the provisions and regulations of the Union.

The day-to-day work of the ITU is performed in the three sectors of which the Radiocommunications Sector is relevant to this discussion. The other sectors, as their names imply, deal with standardization and development of telecommunications.

World-wide allocations for radio services are made through decisions made at international conferences of the Radiocommunications Sector called World Radio

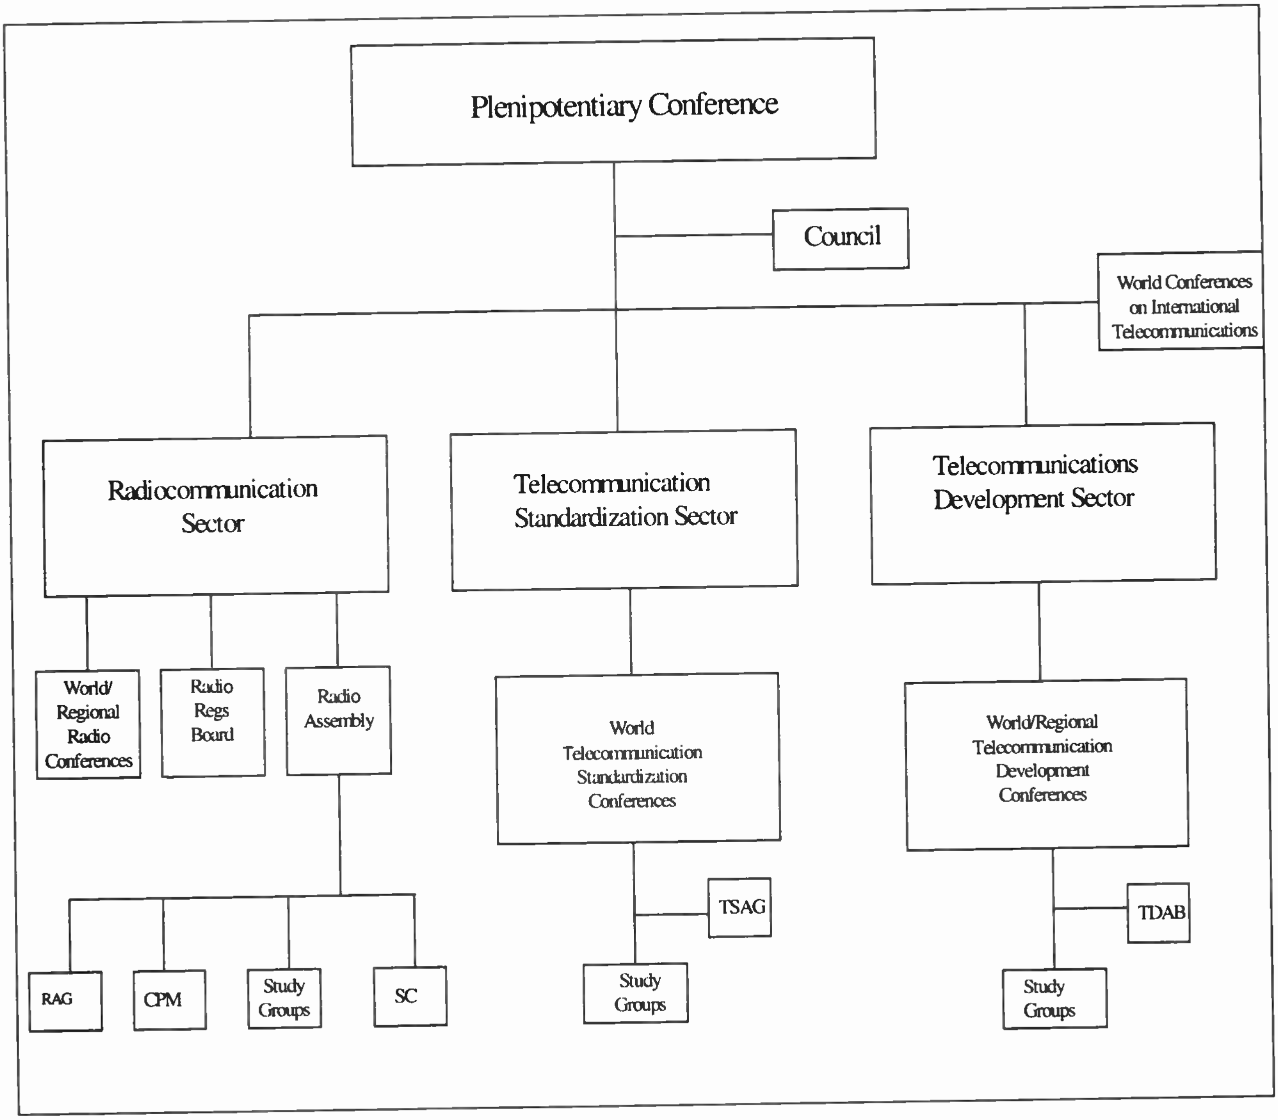

Figure 1.2-1. Organizational structure of the ITU.

Conferences (WRCs). These WRCs deal with frequency allocations and related matters of concern on a world-wide basis through review and revision of the international Radio Regulations. Through a process of give and take, decisions, are made for the allocation of spectrum. WRCs are held at two year intervals and deal with a limited agenda that is generally established four years in advance with a final agenda established by the ITU Council two years prior to the WRC. The early establishment of the agenda is intended to allow for proper preparation so that the work of the conference can be concluded in a timely manner; however, due to the rapid changes occurring in telecommunications, last minute requests for agenda changes are not uncommon.

Because of the geographic separation of certain parts of the world it was determined to be practical to divide the world into three regions. Region 1 consists of Europe and Africa; Region 2 consists of North and South America, Greenland and the Caribbean, and Region 3 consists of Asia and Oceania. In view of this, the ITU sometimes convenes Regional Radio Conferences (RRCs) to consider questions that are unique to a specific ITU Region. Often these RRCs consider implementation of decisions made at an earlier WRC.

Technical Submissions

Radiocommunications Assemblies are held in conjunction with and prior to the World Radio Conferences and provide the technical basis for the work of the WRC.[2] The Assemblies also approve and set

[2] In a reorganization of the ITU, the work of developing recommendations and providing reports dealing with technical issues formerly performed by the International Radio Consultative Committee (CCIR), that some readers may be familiar with, is now performed by the Radiocommunications Assemblies.

priorities for the work of the study groups that operate under the Assemblies' supervision. In addition, the Assemblies also setup or abolish study groups as deemed appropriate. This work is carried out by eight study groups, each of which is devoted to a particular radio communication service or specific technical issue.[3]

The work of two study groups is relevant to Broadcasting: Study Group 10 (Broadcasting Service—Sound) and study group 11 (Broadcasting Service—Television).[4] Under both of these Study Groups, there are sub-groups to deal with specific areas of interest. There also are joint study groups that deal with questions that are of relevance to more than one study group. Each study group has an international chairperson and one or more vice-chairmen who are provided by interested participating administrations.

ITU study group work is carried out by the members of the ITU as well as recognized users and standard setting groups such as the European Broadcasting Union and the U.S. broadcasting networks. Within individual administrations, organized structures often are created to provide input for the administration to submit to the Radio Assembly through its Study Groups. In the United States, this activity is chartered by and operates under the Department of State (DOS). There is a U.S. National Chairperson appointed by DOS, and two National Vice Chairpersons one from the Federal Communications Commission (FCC) and one from the National Telecommunications and Information Administration (NTIA). The DOS also appoints a U.S. National Chairperson for each of the individual study groups. Each is responsible for the work of the group and heads the U.S. delegation to international meetings of the study group. In the United States, study group activities are open to participation by the public. Contributions to study group work in the United States come mainly from the private sector. Elsewhere in the world, such work is performed primarily by government employees.

In general, the work of the study groups is timed to coincide with scheduled WRCs and RRCs with an international meeting of each study group usually occurring about once a year. In the interim, work is carried out by correspondence. Administrations may suggest any matter of interest for study that is within the purview of the Radiocommunications Sector, but priority is given to issues that are relevant to a scheduled WRC or RRC.

The cumulative recommendations and reports of the various study groups are updated and published periodically in hard copy books commonly referred to as the "Green Books." However, in recent years the ITU has begun providing material in electronic format and in a more timely manner by making individual recommendations available as they are approved. Interested parties may obtain information on obtaining these as well as numerous other ITU publications, in both hard copy and electronic form, from the ITU website (http://www.itu.int). The study group reports and recommendations contain a wealth of information relating not only to spectrum allocation but also related information concerning measurement procedures and standards for audio and video recording equipment used for the exchange of broadcast programming.

The Allocation Process

The allocation of radio frequency spectrum occurs as a result of a series of interrelated decisions. On the first, most basic level, blocks of frequencies are allocated on a worldwide basis by the ITU WRC process. Exactly which blocks of frequencies are allocated to particular services is determined by evaluating the many specific proposals submitted to the WRC for each frequency band. Technical input is obtained from propagation studies and other engineering analyses undertaken as part of the study group process and from the submissions of individual administrations. Frequently, blocks of spectrum are allocated for the same purpose on a worldwide basis, but may also be allocated for different purposes on a regional basis.

Member nations theoretically retain the sovereign right to domestic use of the spectrum so long as such use is not in contravention of the international Radio Regulations or the international agreements to which that administration is a party. However, as a practical matter, the flexibility of administrations to use the spectrum is limited by the worldwide allocation system and the need to avoid harmful interference.

Unlike the FCC, the ITU does not license users of the spectrum. Instead, it operates only as a coordinator, maintaining a Master International Frequency Register (MIFR or Master Register) of radio stations worldwide maintained by the Radiocommunications Bureau within the Radiocommunications Sector. Member administrations have agreed to provide notifications of new stations or modifications in existing stations operating within their respective countries. The Radiocommunications Bureau studies these notifications for compliance with the existing world or regional agreements and provides the results of its studies to the member nations. Only those notifications that comply with the existing agreements are placed in the Master Register of stations. Once a station has been placed in the Master Register, the member nations are obliged to provide it with the internationally agreed level of interference protection.

Because the WRC and RRC agreement texts provide only a general framework, many specific matters are left to individual nations to resolve and implement. In the U.S., the FCC and NTIA share the responsibility for implementing agreements to which the U.S. has assented, including the bilateral or multilateral agreements negotiated with our neighbors to deal with concerns that are unique to the countries involved.

[3] A complete list of the Radiocommunications Study Groups is contained in Appendix A.

[4] The numbering of the study groups is a carry over from the old CCIR structure.

There are differences in the treatment of the various broadcast services. Because lower frequency signals, such as those used by AM broadcasting, propagate over great distances, international decisions have a much greater impact on AM broadcasting than FM and television, whose VHF or UHF propagation is much more limited. This means that the restrictions on FM and TV allocations imposed by international agreements are usually applied only to areas near the borders. However, international agreement on technical transmission standards often is desired in order to foster the absence of interference and the world-wide free flow of communication.

Domestic Allocation Process

Regulation of spectrum began with the U.S. Department of Commerce in the early 1920s, when the Secretary of Commerce granted the first AM broadcasting licenses. By 1927, the number of AM stations had increased to 733, and over 6,000,000 radio receivers had been manufactured. However, because of an unfortunate court decision that precluded the Secretary of Commerce from dealing with the specific choice of location, power, and operating frequency, these matters were left largely to the discretion of the broadcaster. This led to a chaotic use of the spectrum, with widespread interference, a situation that led to the creation of the Federal Radio Commission in 1927. Seven years later the Federal Radio Commission was replaced by the FCC, formed pursuant to the Communications Act of 1934. Ever since, anyone desiring to operate a broadcast station, or most any kind of radio transmitting device, must apply to the FCC and be granted a license before commencing operation. Today, a broadcast license sets forth all essential technical parameters of station operation. The NTIA performs a similar function and coordinates the spectrum used by government agencies. The FCC works with the NTIA where there is a need for coordination between government and private uses of the spectrum.

Spectrum for use domestically, must be allocated by FCC rule making proceedings. Domestic allocation rule making proceedings can be initiated by the FCC on its own motion or in response to requests from the public, but in so doing it must not act in contravention of international agreements to which the United States is a party. Rule making proceedings are based on a public record developed through responses to the issuance of a *Notice of Proposed Rule Making* that are filed by interested parties. In addition to filing comments on the FCC's proposal, the public may reply to the comments of other parties. After the Commission evaluates the responses to its *Notice*, it may decide to either adopt the proposal as originally set forth, or modify it, based on the comments received, or possibly reject the proposal.[5]

Many FCC proceedings are controversial in nature. Allocations proceedings may be especially controversial, since a particular communications industry's livelihood may depend in part on how much spectrum is allocated. Thus, FCC allocation decision making is not simply a matter of technical evaluation but must be seen as part of the political process as well, as happens when entire industries may compete for a limited amount of spectrum. Where the number of users in a particular frequency band is expected to be relatively small or their use is sporadic, the FCC may propose sharing of this spectrum with other users. Such proposals may also be controversial, since sharing spectrum with a dissimilar service invites the possibility of interference and difficulties in coordinating the use of the frequencies. Because of these and other factors, FCC allocations proceedings consume a great deal of its time and energy and can impose burdens on the organizations that participate in them.

From time to time, alternative methods have been proposed for allocating spectrum. These ideas usually envision the removal of the FCC as the arbiter of mutually exclusive requests for spectrum and, instead substituting marketplace forces. Under a market allocation system, frequencies would become used by entities who would pay the most for them; social, or public policy aspects would not be considered. In recent years such a system has been employed for some frequency allocations in the form of spectrum auctions. In these cases the Commission's role is reduced to that of a technical "traffic cop" of the airwaves.

UNITED STATES AM BROADCASTING FREQUENCY ALLOCATION

In the United States, amplitude-modulated (AM) stations operate with carrier frequencies spaced 10 kHz apart. For many years the AM broadcast band in the United States included 107 channels, spaced 10 kHz apart, in the band from 535–1605 kHz. However, the frequency band allocated to AM broadcasting now includes a total of 117 channels in the band 535–1705 kHz, as shown in Figure 1.2-2.

Currently, there are over 4,700 commercial and noncommercial AM stations operating in the United States. These stations operate with various power levels, up to a maximum of 50 kW. About half of these stations use multi-tower directional antennas to restrict radiation in certain directions, for the purpose of controlling interference or maximizing radio service in particular directions.

Allocation decisions for the AM broadcast band are probably the most complex of the broadcast services. Since propagation varies with time of day, geographic latitude, soil conductivity and frequency, the engi-

535 kHz	-	1705 kHz
AM BROADCASTING		

Figure 1.2-2. The limits of the AM broadcast band.

[5] The nature of the Commission's rule making process is described in greater detail in Chapter 1.3.

neering analyses necessary to establish interference protection for other stations can be quite complicated. Engineers, the FCC and the ITU have sophisticated computer programs that analyze the input of a new or modified AM station proposal. Before going into the details of the AM broadcast allotment system currently in place in the United States, it is necessary to provide a brief history of AM broadcasting allocations.

Over the years, there have been many changes in the nature of AM broadcasting in the United States. In early years, clear channel stations provided the only service available in many areas of the U.S., but with the end of World War II, demand increased greatly and many AM stations were established in all areas of the country. Because of its early development of AM radio service, the U.S. experience has been used as a model for regional and bilateral agreements.

Early in the history of AM broadcasting, the countries in the North American area recognized the need to cooperate in the use of AM frequencies, and in 1937 they reached agreement on how to proceed. Soon, however, this agreement was found to be inadequate and negotiations began on a new agreement. Although the North American Regional Broadcasting Agreement (NARBA) was signed on November 15, 1950, it did not go into effect until 10 years later, on April 16, 1960. Signatories to NARBA include the United States, Canada, Cuba, the Dominican Republic and the United Kingdom on behalf of Jamaica and the Bahama Islands. Mexico, an earlier participant, removed itself from these negotiations, and a bilateral agreement between the U.S. and Mexico was reached in 1957.

These international agreements became necessary principally because nighttime AM propagation has the potential for causing widespread interference to neighboring countries unless mutual allocations criteria and related technical standards could be agreed upon and implemented by the parties to the agreement. To this end, NARBA provided for a partitioning of AM broadcast channels into three basic classes. The first of these are the so called "clear" channels, whose high-powered stations would have primary access to the frequency and other stations could use the channel subject to providing full protection to the dominant station(s). Clear channel dominant stations were designed to provide service over extensive areas by means of skywave as well as ground wave signals. NARBA set aside 60 of the 107 channels then available for clear channel use. Each NARBA country, except Jamaica, received a "priority" on one or more clear channels, with the U.S. receiving a major portion of available priorities. NARBA countries without a priority on a given clear channel could still assign stations on that channel, provided that these stations protected the wide-area service of the dominant station in the country with the NARBA priority.

The second class of channels were called "regional" channels and these occupied an additional 41 channels. Unlike clear channels, these channels were shared on an equal basis by all the NARBA countries. Stations operating on these channels were intended to provide service to a considerable area, but, unlike the clear channel stations that received protection for their skywave as well as groundwave service, only the groundwave service provided by the "regional" stations was protected.

The remaining six frequencies were the "local" channels that provide an even more limited type of groundwave service. Only limited interference protection was provided to these relatively low power operations.

Recognizing the need for updating these agreements and for developing more efficient coordination throughout Region 2 (North and South America), the 1979 General WRC called for a conference to be held in Region 2 to address AM broadcasting and sharing criteria. That conference was held in two sessions in 1980 and 1981 and resulted in the adoption of an agreement among most of the countries of the hemisphere. Included as part of that agreement, referred to as the 1981 Rio Agreement (for Rio de Janeiro, the location of the second conference session), was a list of all of the operating stations in the hemisphere along with information indicating whether or not the stations were receiving or causing harmful interference according to the technical criteria set forth in the agreement. Stations not causing interference were placed in the ITU Master Register and accorded protection from interference as defined by the agreement. In situations where interference already existed, the countries involved were asked to meet and work out mutually satisfactory solutions.

Because the general framework of the Rio Agreement did not deal with the particular needs and desires of the United States, Canada and Mexico, separate new bilateral agreements have been negotiated which incorporate the required additional items concerning coordination and technical parameters. Although the Rio Agreement applies throughout most of Region 2, as of this writing, relations with the Bahamas and the Dominican Republic continue to be governed by NARBA, as neither country has taken the necessary steps to replace the NARBA provisions with the Rio 1981 Agreement. Relations with Cuba regarding the 535–1605 kHz band are governed solely by the international Radio Regulations rather than by agreement.

The AM broadcasting system in the United States has continued to evolve as the demand for more stations has grown. One result of the demand for facilities is the increased use of directional antennas to provide required interference protection while enhancing coverage in other directions. With the spectrum becoming crowded, another development was a large increase in the number of daytime-only stations. These are stations that were authorized to operate only during daylight hours. Since propagation conditions during these daylight hours do not normally support significant skywave transmission, there are many locations where a station can be operated during the daytime without causing harmful interference to other stations. Based on this concept, the FCC over the years licensed approximately 1200 stations for daytime-only operation.

Recognizing that daytime-only stations (and even some full-time stations that operate with restrictive directional antenna patterns during the night) are unable to provide effective service during early morning hours, the FCC originally allowed these stations to operate during this period so long as no interference complaint had been received. Ultimately, this proved to be unworkable, and a more formalized approach was adopted. The FCC began granting Pre-Sunrise Authorizations (PSRAs), permitting many of these stations to operate with their daytime facilities with powers up to 500 W during the pre-sunrise period between 6:00 AM and local sunrise. While some interference occurred, the FCC believed the interference was balanced by the public's need for local informational services during this very important morning time period.

While pre-sunrise operation did provide some relief, it did not end the economic problems many stations faced in effectively competing with full-time stations. The FCC was pressed to provide relief in the form of post-sunset operation for daytime-only stations. With the removal of international impediments, the FCC did provide such relief. Once again, taking into consideration the need for more service of a local nature, and recognizing the changing nature of propagation conditions in which full nighttime conditions do not exist until several hours after sunset, the FCC granted Post Sunset Authorizations (PSSA) for most of the daytime only stations. These authorizations permit operation for periods of up to two hours past sunset with power reduced to prevent interference. The FCC also changed its rules concerning the minimum power at which a station is permitted to operate. This, in turn, led to a subsequent decision allowing many PSSA stations to operate throughout the night, albeit with reduced power.[6]

Still another change that has occurred pertained to the use of the Class I-A clear channels. At one time, only a single station was permitted to operate on these channels at night, but in two FCC decisions, first some and now all of these channels have been "broken down" to permit the authorization of additional nighttime operations. Clear channel stations that at one time provided service for a major portion of the country during nighttime hours now are protected only out to a distance averaging 750 miles.

Use of the Expanded Band

At an ITU Regional Radio Conference that concluded in 1988, participating administrations reached an agreement on the criteria for expanding the AM band in Region 2 by adding 10 new channels between 1605 to 1705 kHz. Although the regional agreement established specific technical criteria for the implementation of the new channels, (including the granting of priority usage of certain channels) the United States still retains considerable latitude in its domestic implementation. In a large country like the U.S., the use of the channels is unrestricted except in the relatively few areas near the borders with our neighbors.

The basic criteria set forth in the Regional Agreement are as follows: stations may operate with 1 kW of power with a non-directional antenna height of 90°, or stations may operate with a power not in excess of 10 kW by employing a directional antenna to provide equivalent protection to stations in other countries. The channels allotted to the United States in the border areas vary from location to location, but, as noted, over a large portion of the U.S. all ten of the channels may be used. Non-allotted channels are not precluded from use, but the allotted channels in the other countries must remain fully protected.

After a lengthy proceeding, the FCC developed a system whereby the channels in the expanded band would be used to improve the current interference situation by giving selected stations the opportunity to move to the new band. In view of this, applications for new stations are not currently being accepted for operation in the band 1605–1705 kHz.

Persons seeking an authorization for a new AM broadcast station on frequencies below 1605 kHz may do so by filing an application with the FCC. Applications must provide documentation that the proposed operation will comply with all applicable FCC rules as well as the appropriate international regulations. The details and methodology for allocating AM radio stations along with basic design specifications for AM directional antennas can be found in FCC Rules at Sections 73.14 to 73.190.

The 1981 Rio Agreement changed the NARBA station classifications. No longer are the channels themselves classified. Stations are now classified without regard to the channel on which they operate. Stations providing wide area service, both groundwave and skywave, are now designated Class A stations, while stations providing the equivalent of the regional and local services are designated as Class B and C respectively. The new agreement permits any class of station to operate on any channel so long as it provides protection to other stations based on their classification. Figures 1.2-3, 1.2-4 and 1.2-5 show the relationship

International classes of M stations	Corresponding U.S. classes prior to 1990	Classes of Channels available in U.S. for each class
Class A	I-A	Clear Channels
	I-B	Clear Channels
	I-N	Clear Channels
Class B	II	Clear Channels
	II-A	Clear Channels
	II-B	Clear Channels
	II-C	Clear Channels
	II-D	Clear Channels
	II-S	Clear Channels
	III	Regional channels
	III-S	Regional channels
Class C	IV	Local channels

Figure 1.2-3. International and domestic classifications of stations and channels prior to 1990.

[6] The rules pertaining to PSSA and PSRA are contained in FCC Rules and Regulations Section 73.99.

Frequency	Class of Station*	Frequency	Class of Station*	Frequency	Class of Station*
640 kHz	I-A	650 kHz	I-A	660 kHz	I-A
670 kHz	I-A	680 kHz	I-B	700 kHz	I-A
710 kHz	I-B	720 kHz	I-A	750 kHz	I-A
760 kHz	I-A	770 kHz	I-A	780 kHz	I-A
810 kHz	I-B	820 kHz	I-A	830 kHz	I-A
840 kHz	I-A	850 kHz	I-B	870 kHz	I-A
880 kHz	I-A	890 kHz	I-A	940 kHz	II
000 kHz	I-B	1020 kHz	I-A	1030 kHz	I-A
1040 kHz	I-A	1060 kHz	I-B	1070 kHz	I-B
1080 kHz	I-B	1090 kHz	I-B	1100 kHz	I-A
1110 kHz	I-B	1120 kHz	I-A	1130 kHz	I-B

1180 kHz	I-A	1190 kHz	I-B	1200 kHz	I-A
1210 kHz	I-A	1500 kHz	I-B	1510 kHz	I-B
1520 kHz	I-B	1530 kHz	I-B	1540 kHz	I-B
1550 kHz	II	1560 kHz	I-B		

* In addition to the Class I-A or Class I-B stations that could be assigned to the above channels, various Class II stations could also be assigned.

REGIONAL CHANNELS

(Class III or III-S stations were assigned to these channels)
550, 560, 570, 580, 590, 600, 610, 620, 630, 790, 910, 920, 930, 950, 960, 970, 980, 1150, 1250, 1260, 1270, 1280, 1290, 1300, 1310, 1320, 1330, 1350, 1360, 1370, 1380, 1390, 1410, 1420, 1430, 1440, 1460, 1470, 1480, 1590, and 1600 kHz

LOCAL CHANNELS

(Class IV stations were assigned to these channels)
1230, 1240, 1340, 1400, 1450, and 1490 kHz

Figure 1.2-4. Channel utilization in the United States prior to 1990 clear channels.

between these international classifications and those that existed in the United States prior to 1990. In 1990, the FCC proposed to align the U.S. domestic classification system for AM stations with the 1981 Rio Agreement system. In addition to the three international classes of stations the FCC has added a fourth, Class D. Class D stations are those stations that operate nighttime with a power of less than 250 W and an equivalent RMS antenna field of less than 141 mV/m at 1 km. Such stations are usually former daytime only stations that have been granted some limited amount of nighttime operation. The current status of AM station classification is contained in Section 73.21 of the FCC Rules and Regulations. In that the allocation system

Class of Station	Power in kW Daytime hours Minimum	Maximum	Power in kW Nighttime hours Minimum	Maximum
IA	10.0	50.0	10.0	50.0
I-B	10.0	50.0	10.0	50.0
I-N	10.0	50.0	10.0	50.0
II	10.0	50.0	10.0	50.0
II-A	10.0	50.0	10.0	50.0
II-B	0.25	50.0	0.25	50.0
II-C	0.25	50.0	0.25	1.0
II-D	0.25	50.0	*	*
II-S	0.25	50.0	Less than 0.25	
III	0.25	5.0	0.25	5.0
III-S	0.25	5.0	Less than 0.25	1.0
IV	0.10	1.0	0.10	1.0

Figure 1.2-5. Power limitations by class of station.

Class A, B and D stations may be assigned to these channels
540, 640*, 650*, 660*, 670*, 680, 690, 700*, 710, 720*, 730, 740, 750*, 760*, 770*, 780*, 800, 810, 820*, 830*, 840*, 850, 860, 870*, 880*, 890*, 900, 990, 940, 1000, 1010, 1020*, 1030*, 1040*, 1050, 1060, 1070, 1080, 1090, 1100*, 1110, 1120*, 1130, 1140, 1160*, 1170, 1180*, 1190, 1200*, 1210*, 1220, 1500, 1510, 1520, 1530, 1540, 1550, 1560, 1570, 1580 kHz

* Only one Class A station will be assigned on this channel.

REGIONAL CHANNELS

Class B and D stations may be assigned to these channels
550, 560, 570, 580, 590, 600, 610, 620, 630, 790, 910, 920, 930, 950, 960, 970, 980, 1150, 1250, 1260, 1270, 1280, 1290, 1300, 1310, 1320, 1330, 1350, 1360, 1370, 1380, 1390, 1410, 1420, 1430, 1440, 1460, 1470, 1480, 1590, 1600, 1610, 1620, 1630, 1640, 1650, 1660, 1670, 1680, 1690 and 1700 kHz

LOCAL CHANNELS

Only class C stations will be assigned to these channels
1230, 1240, 1340, 1400, 1450, and 1490 kHz

Figure 1.2-6. Current channel utilization in the United States (Clear, Regional, Local channels).

in the United States had been long established, the station classifications still are primarily related to frequency. The current scheme is shown in Figures 1.2-6 and 1.2-7.

FM BROADCASTING FREQUENCY ALLOCATION

The frequency band 88–108 MHz is allocated for FM broadcasting in Region 2 and, with some exceptions, the same is true in Regions 1 and 3 as well. However, unlike AM, FM broadcast allotments are largely a domestic matter, (especially in large countries such as the United States) due to the limited nature of signal propagation at these frequencies. Although there are some international regulations regarding FM broadcasting, there is no region-wide FM agreement in Region 2. Instead, there are bilateral agreements between the U.S. and Canada and the U.S. and Mexico. Both regulate the use of FM channels in the border areas and specify technical standards in order to insure system compatibility.

The basic plan of the FM broadcast band is shown in Figure 1.2-8. The band is divided into 100 channels, each 200 kHz wide. In the United States, the lower 20 channels, located between 88 and 92 MHz, have been reserved for non-commercial broadcasting, how-

Class of Station	Power in kW Daytime hrs. Minimum	Maximum	Power in kW Nighttime hrs. Minimum	Maximum
A	10.0	50.0	10.00	50.0
B	0.25	50.0	0.25	50.0 (below 1605 kHz)
B	0.25	10.0	0.25	10.0 (1605–1705 kHz)
C	0.25	1.0	0.25	1.0
D	0.25	50.0	–	Less than 0.25

Figure 1.2-7. Power limitations by class of station.

Figure 1.2-8. Limits of the FM broadcast band.

ever such stations are not restricted to these channels. In addition, although it is part of television channel 6, the frequency 87.9 MHz can be used for low power non-commercial FM stations, but its use is severely restricted.

As with AM broadcasting, there are different classes of FM stations designed to provide different types of service. As the demand for more stations has increased so has the number of different classes of stations. In response, the FCC has significantly modified the criteria concerning the use of the frequencies. In June 1983, the FCC concluded a lengthy rule making proceeding and modified the domestic allotment criteria for FM broadcasting. Prior to this action, there were three classes of stations in the 80 channel commercial band. Twenty of these channels were used for lower power Class A stations having a maximum effective radiated power (ERP) of 3 kW and a maximum antenna height-above-average-terrain (HAAT) of 300 ft. Class A stations had a 1 mV/m service radius of about 15 miles. Higher power Class B or C stations operated on the remaining 60 channels. Whether a station was designated Class B or C depended on where it was located.[7] Class B stations were located in Zone I or I-A. Zone I is the northeast U.S., extending south to the Virginia-North Carolina border and west to the Mississippi River. Zone I-A is all of California but its northernmost portion, plus Puerto Rico and the U.S. Virgin Islands. Class C stations operated elsewhere in the country, which is referred to as Zone II.

Class B stations operate with a maximum ERP of 50 kW at 500 ft. (152 m) HAAT and have a service radius of about 32 miles. Class C stations operate with a maximum power of 100 kW at 2000 ft. (610 m) HAAT, for a service radius of approximately 57 miles. FM stations in each of these classes may elect to operate at a HAAT above the maximum, but in such cases they are required to make a compensatory reduction in ERP as noted in FCC Rules and Regulations Section 73.211.

This system was changed drastically by the above noted 1983 proceeding. The FCC:

1. Permitted Class A stations to operate on channels previously reserved for Class B or C stations.
2. Created three new classes of FM stations. Class B1 stations are permitted to operate in Zones I and I-A with a maximum ERP of 25 kW at 100 m (328 ft. HAAT); Class C1 and Class C2 stations are permitted to operate in Zone II. Class C1 stations are permitted a maximum ERP of 100 kW at 299 m (981 ft.) HAAT and Class C2 stations are permitted a maximum ERP of 50 kW at 150 m (492 ft.) HAAT.
3. Required stations that were previously licensed as a Class B or C, and were not operating at the minimum level specified for their class under the new rules, to upgrade their facilities within 3 years. Otherwise, the under-minimum facilities would be reclassified to the appropriate lower class based on the facilities they used.
4. Increased the maximum antenna HAAT for Class A stations to 100 m (328 ft.).

[7] The concept of allowing different classes of stations in different areas or "zones" is based on the population density of the areas. The Commission has assumed that there is less need for wide areas of service in areas of dense poplation.

Station Class	Maximum ERP	Maximum HAAT in meters (ft.)	Expected Service Radius
A	6 kW	100 (328)	28 km
B1	25 kW	100 (328)	39 km
B	50 kW	150 (492)	52 km
C3	25 kW	100 (328)	39 km
C2	50 kW	150 (492)	52 km
C1	100 kW	299 (981)	72 km
C	100 kW	600 (1968)	92 km

Puerto Rico and the Virgin Islands

Station Class	Maximum ERP	Maximum HAAT in meters (ft.)	Expected Service Radius
A	6 kW	240 (787)	42 km
B1	25 kW	150 (492)	46 km
B	50 kW	472 (1549)	78 km

Figure 1.2-9. Standards for FM allotments (a) for locations other than Puerto Rico and the Virgin Islands (b).

In 1989, the FCC further modified the rules to permit Class A stations to operate with an ERP of 6 kW and a HAAT of 100 m, (328 ft.) and added an additional classification C3 that permits operation in Zone II with a maximum of 25 kW at 100 m (328 ft.) HAAT.

In addition to the above, there also are Class D stations that operate as non-commercial educational stations with power not in excess of 10 W. However, applications for this class of station are no longer being accepted.[8] A complete list of the station classes and a summary of FM allotment standards can be found in Figure 1.2-9.

Unlike AM broadcasting, where a new station may be applied for at any location where it can meet applicable criteria, the use of commercial FM channels (channels 221–300) is governed by the FM "Table of Allotments" found in Section 73.202 of the FCC's rules. This table lists all FM channel allotments that have been made available for use. Most already are in use. If the Table does not list a vacant channel in the desired community, the prospective applicant must file a rule making petition with the FCC seeking to add such a channel for the community. The rule making petition proposing such addition must provide a show-

D–D	18(11)	10(6)	5(3)	3(2)

Note: For purposes of the Mexican Agreement, U.S. Class A allotments with more than 3 kW ERP and an antenna HAAT above 91 m (299 ft.), or with equivalent lower ERP and higher HAAT, are considered to be Class B allotments. Also, U.S. Class B1, C2 and C3 allotments are considered to be Class B, and U.S. Class C1 allotments are considered to be Class C.

Figure 1.2-12. Minimum distance separation requirements in kilometers (miles)—Mexican Agreement.

Assignment of stations on the non-commercial educational channels (201–220) is accomplished more in the manner that is followed in AM, where an application includes a showing that interference will not be caused to other stations. In addition, for proposals to use Channels 218, 219 and 220, compliance with applicable separation requirements to any allotments on higher, adjacent commercial channels is required.

In addition to the regular FM broadcast stations, there are two other types of stations that are permitted to operate in the FM band on a secondary basis. These are FM translator stations and FM booster stations. An FM booster station retransmits the signal of a primary station on the primary station's channel in order to serve areas where the primary station's signal is inadequate. An FM translator station is similar to an FM booster station, except that the signal is not retransmitted on the same channel but instead is translated to a different channel. These stations are authorized under Part 74, Subpart L of the FCC Rules, which among other things, requires that such stations provide protection from interference to all full service FM broadcast stations.

TELEVISION BROADCASTING FREQUENCY ALLOCATION

The frequency bands used for television broadcasting in the United States are illustrated in Figure 1.2-14. They include the low-VHF band channels 2 to 4 (54 MHz to 72 MHz) and 5 and 6 (76 MHz to 88 MHz),

FM Class	TV Zone I	TV Zone II and III
A	17	22
B1	19	23
B	22	26
C3	19	23
C2	22	26
C1	29	33
C	36	41

Figure 1.2-13. Minimum distance separation requirements in kilometers to TV channel 6 from FM stations on channel 253 (98.5 MHz) kilometers.

54–72 MHz	76–88 MHz	174–216 MHz	470–806 MHz
TV Channels 2–4	TV Channels 5–6	TV Channels 7–13	TV Channels 14–69

FM CLASS	TV ZONE I	TV ZONE II and III
A	17	22
B1	19	23
B	22	26
C3	19	23
C2	22	26
C1	29	33
C	36	41

Figure 1.2-16. Minimum distance separation requirements in kilometers to TV channel 6 from FM stations on channel 253 (98.5 MHz).

the high-VHF band channels 7 through 13 (174 MHz to 216 MHz), and the UHF band channels 14 through 69 (470 MHz through 806 MHz). The greater portion of all of these bands is allocated for broadcasting throughout the world; but this allocation is not uniform and in many areas other uses such as land mobile are permitted on a secondary basis. This is also the case in the U.S., where certain UHF television channels are now used for land mobile in some major cities. In general, due to the limited extent of radio wave propagation in the television band, TV allocations, like FM, are basically a domestic matter, with few international regulations. Although no regional agreement exists, the United States does have agreements with both Canada and Mexico concerning television allocation.

Like FM broadcasting, TV allocations in the United States are governed by a "Table of Frequency Allotments." The current FCC Rules (fall 1997) contain two allotment tables one for analog stations in Section 73.606 and one for digital stations in Section 73.622. These tables contain all commercial as well as non-commercial allotments (the latter are identified by an asterisk). Although the FCC is no longer accepting petitions to modify the analog table, a description of how it was constructed is given below for historical purposes. The analog table is based on the co-channel adjacent channel, and FM channel 253 separation criteria contained in Section 73.610 (see Figures 1.2-15 and 1.2-16), and on the UHF channel separation criteria listed in Table II of Section 73.698 of the FCC Rules. As can be seen in Figures 1.2-15 and 1.2-16, there are different requirements for different zones or areas of the country. Zone I is the northeast U.S. extending south to the Virginia-North Carolina border and west to the Mississippi River. Zone II consists of that portion of the United States that is not in Zone I or Zone III, along with Puerto Rico, Alaska, the Hawaiian Islands and the Virgin Islands. Zone III is that portion of the southeast United States extending from the east coast of Georgia westward to the Mexican border. An exact description of the zones is contained in Section 73.609 of the FCC Rules. As with FM, the zones reflect the differing population densities in various parts of the country. In addition, differences in propagation conditions were also considered. The closer spacings in Zone I recognize the fact that in the northeast portion of the United States there are many large population centers needing stations of their own, which are close enough to one another to lessen the need for wide area service. Zone II is characterized by fewer population centers, usually smaller and further apart. For them, wide area service is a necessity. Finally, because the area of the country along the Gulf Coast (Zone III) is susceptible to high levels of tropospheric propagation, stations in that area need to be spaced further apart to minimize interference. Although there are differences in the powers authorized for low-VHF, high-VHF, and UHF stations, unlike AM and FM broadcasting, there are no class designations as such in television. The differing power limitations reflect the differences in signal propagation for low VHF, high VHF and UHF.

The Digital Television (DTV) "Table of Allotments was developed through a complex analysis that took into consideration actual computations of coverage and interference. The DTV Table contains an entry for each analog station that was in operation or for which an application had been filed prior to a cutoff date specified by the FCC.

A petition for rule making may be filed with the FCC seeking to modify the Table to include a new allotment. Such petitions must provide a showing that the proposal complies with applicable separation criteria that serve to prevent mutual interference (see Figure 1.2-17). Furthermore, applications to construct a station on a new allotment must demonstrate that the proposed facility would provide applicable coverage to the city of license and that no new interference would be caused to existing stations either analog or digital.

In addition to the regular television broadcast stations, there are three other types of analog stations that are permitted to operate in the television bands. However, these other stations operate with low power,

ZONE	CHANNELS 2–13	CHANNELS 14–69
I	272.7 (169.5 mi.)	248.6 (154.5 mi.)
II	304.9 (189.5 mi.)	280.8 (174.5 mi.)
III	353.2 (219.5 mi.)	329.0 (204.5 mi.)

MINIMUM ADJACENT CHANNEL SEPARATION DISTANCES IN KILOMETERS (MILES)

Channels 2–13	95.7 km (59.5 mi.)
Channels 14–69	87.7 km (54.5 mi.)

In addition to the above there are other constraints on UHF channels due to various types of problems caused by the mixing of the signals of stations operating on different channels. A complete table of these restrictions, referred to as the "UHF Taboos", is contained in Section 73.698 of the FCC Rules.

Figure 1.2-15. Minimum co-channel television separation distances in kilometers (miles).

VHF Channels 2–13	DTV to DTV	DTV to Analog TV
Co-channel—Zone I	244.6 (152.0)	244.6 (152.0)
Co-channel—Zone II & III	273.6 (170.0)	273.6 (170.0)
Adjacent Channel—Zone I	<20.0 (12.4) or >110.0 (68.4)	<9.0 (5.6) or >125.0 (77.7)
Adjacent Channel—Zone II & III	<23.0 (14.3) or >110.0 (68.4)	<11.0 (6.8) or >125.0 (77.7)
UHF Channels	**DTV to DTV**	**DTV to Analog TV**
Co-channel—Zone I	196.3 (122.0)	217.3 (135.2)
Co-channel—Zone II & III	223.7 (139.0)	244.6 (152.0)
Adjacent Channel—Zone I	<24.0 (14.9) or >110.0 (68.4)	<12.0 (7.5) or >106.0 (65.9)
Adjacent Channel—Zone II & III	<24.0 (14.9) or >110.0 (68.4)	<12.0 (7.5) or >106.0 (65.9)
[9]Taboo Channels—Zone I		<24.1 (15.0) or > 80.5 (50.0)
[10]Taboo Channels—Zone II & III		<24.1 (15.0) or > 96.6 (60.0)

[9] Values are only specified for DTV to analog TV and are for DTV channels ±2, ±3, ±4, ±7, ±8, +14 and +15 channels away from the analog TV channel.
[10] Ibid.

Figure 1.2-17. Required television separation distances in kilometers (miles)—DTV to analog TV and DTV to DTV.

on a secondary basis. These are Low Power Television Stations (LPTV), TV Translator Stations and TV Booster Stations. A TV Booster Station retransmits the signal of a primary station on the primary station's channel in order to serve areas where the primary station's signal is inadequate. A TV Translator Station is similar to a TV Booster Station, except that the signal is not retransmitted on the same channel but instead is translated to a different channel. Low Power Television Stations may retransmit the signals of another station or they may originate programming. All of these stations are authorized in accordance with Part 74, Subpart G of the FCC Rules, which requires full protection from interference to all regular television broadcast stations. In addition, these stations are not accorded any protection from the operation of regular television broadcast stations either analog or digital. As of this writing, the future of LPTV, TV Translator and TV Booster Stations is unclear since the advent of DTV will displace many of these stations since they were not protected in the DTV planning process.

AUXILIARY BROADCAST SERVICES FREQUENCY ALLOCATION

Although all auxiliary broadcast services share a common role in support of AM, FM or TV broadcast operations, there are important differences between them. The nature of the service they provide varies as does the frequency band in which they operate. For these reasons, the allotments available for each auxiliary service need to be discussed separately. However, before turning to a specific discussion of each service, some general comments are necessary.

The steady growth in the number of AM, FM and TV stations including DTV, as well as their desire to use more advanced technology in every aspect of their operation, has greatly increased demand for spectrum in all auxiliary services. Because of the continuing demand for spectrum from a multitude of other broadcast and non-broadcast activities, it has been difficult for the FCC to allocate more spectrum to alleviate the congestion faced by the auxiliary services. At the same time, some relief has come through changes in the FCC rules to facilitate the use of newer, more spectrum-efficient, technology. In using this material, the reader should be aware that additional changes may take place. Accordingly, the careful reader should check the current regulations governing each particular radio service.

Recognizing that available spectrum is limited, it is imperative for broadcasters to use it efficiently. To do this, it is first necessary to understand what spectrum is allocated, how it may be used and what advantages or disadvantages, if any, may be involved in the use of a particular band for each of the auxiliary services discussed below.

Remote Pickup Broadcast Stations (RPUs)

RPUs are mobile or portable facilities used to transmit live on-the-air programming from a temporary remote location, such as a shopping center or football game, to the station's studio facilities. This material can be taped for later rebroadcast, or it can be incorporated into actual on-going live broadcasts. Radio stations typically have several RPUs that may be licensed to one or more frequencies.

In November 1984, the FCC significantly revised its radio broadcast auxiliary frequency allocations to permit operational use of narrow band technologies in the broadcast remote pickup service. The Commission's goal was to foster spectrum efficiency in a flexible manner. Broadcasters and equipment manufacturers who wanted to operate narrow band equipment, the Commission believed, should not be precluded from doing so by rigid FCC rules. However, these changes have not yet been formally implemented by the FCC due to delays in setting up the mechanism to handle the expected applications, but formal implementation is expected in the near future. In the meantime, the FCC will accept applications based on this revised allocation.

The following are the frequency allocations for radio broadcast remote pickup stations.

1. 25.85–26.48 MHz: There are a total of 25 frequencies available in this band for use by remote pickup broadcast stations. Bandwidth is limited to 20 kHz except between 25.87 and 26.03 MHz where 40 kHz is permitted. Please note that the use of the frequencies between 25.87 and 26.09 are subject to the condition that no harmful interference is caused to broadcast stations sharing this band. It is also noted that the frequencies between 26.100 and 26.175 have been allocated on a worldwide basis

to the Maritime Mobile Services. Although this service has not yet been implemented, at such time as the maritime service is implemented, these frequencies may no longer be available for use by remote pickup stations. It is further noted that the frequencies between 26.175 and 26.47 are allocated on a worldwide basis for use by various types of fixed and mobile operations. Hence, in selecting a frequency in this band for remote pickup use, the implications of the above should be taken into consideration.

2. 152.855–153.3645 MHz: There are a total of 54 frequencies available in this band for use by remote pickup broadcast stations. Each channel is 5 kHz wide, and they may be stacked to form a single channel with a maximum bandwidth of 30 kHz. This band is shared with the Private Land Mobile Radio Service and the Maritime Service, and operation of remote pickup stations is subject to the condition that no harmful interference is caused to these other services. Please note that these frequencies are not available to network entities or for use on board aircraft unless they were previously licensed for such purpose.
3. 160.86–161.4 MHz: There are a total of 108 frequencies available in this band for use by remote pickup broadcast—but they are available *only* to stations in Puerto Rico or the Virgin Islands where they are shared with the Public Safety and Land Transportation Radio Services. Each channel is 5 kHz wide and they may be stacked to form a single channel width a maximum bandwidth of 30 kHz.
4. 161.625–161.775 MHz: There are a total of 30 frequencies available in this band for use by remote pickup broadcast stations. Each channel is 5 kHz wide and they may be stacked to form a single channel width a maximum bandwidth of 30 kHz. These frequencies are *not* available to network entities and are *not* available for use in Puerto Rico or the Virgin Islands. Also, Public Safety and Land Transportation Radio Service stations may continue to operate on these frequencies on a non-interference basis.
5. 166.25 and 170.15 MHz: These frequencies may be used by remote pickup stations with a maximum bandwidth of 25 kHz; however, the area in which they may be used is restricted. A description of the area in which they may be used is found in FCC Rule Section 74.402.
6. 450.005–450.025 MHz, 450.975–450.995 MHz, 455.005–455.025 MHz and 455.975–455.995 MHz: These frequencies may be used by remote pickup stations only for the transmission of operational communications, including tones for signaling and for remote control and automatic transmission system control and telemetry. Bandwidth is limited to a maximum of 10 kHz.
7. 450.025–450.625 MHz and 455.025–455.625 MHz: There are a total of 240 frequencies available in these bands for use by remote pickup broadcast stations. Each channel is 5 kHz wide, and they may be stacked to form a single channel with a maximum bandwidth of 50 kHz.
8. 450.625–450.875 MHz and 455.625–455.875 MHz: There are a total of 20 frequencies available in these bands for use by remote pickup broadcast stations. Each channel is 25 kHz wide, and they may be stacked to form a single channel with a maximum bandwidth of 50 kHz. Users who commit to 50 kHz bandwidths and are transmitting program material have primary use of these channels.
9. 450.875–450.975 MHz and 455.875–455.975 MHz: There are four frequencies available in these bands for use by remote pickup broadcast stations. Each channel is 50 kHz wide, and they may be stacked to form a single channel with a maximum bandwidth of 100 kHz. Users committed to 100 kHz bandwidths to transmit program material will have primary use of these channels.

Aural Broadcast Auxiliary Stations

Aural Broadcast Auxiliary Stations include studio transmitter link (STL), intercity relay (ICR) and Microwave Booster Stations used by radio broadcast stations. STL stations are fixed stations used for transmitting program material between the studio and the transmitter of a broadcasting station. ICR stations are fixed stations used for the transmission of program material between broadcasting stations, except international stations, for simultaneous or delayed broadcast. ICRs may also be used on a secondary basis to transmit program material from FM stations to co-owned FM translator or booster stations. Microwave Booster Stations are used to relay the signals of a STL or ICR station over a path that cannot be covered with a single station. They receive and transmit on the same frequency. One or more Microwave Booster Stations may be authorized to licensees of STLs or ICRs. It should be noted that stations in the Aural Broadcast Auxiliary service may be authorized on a secondary non-interference basis to licensees of TV broadcast stations to transmit aural material.

The following frequencies are available for assignment to STL, ICR and Microwave Booster Stations:

1. 942–944 MHz: These frequencies are available for assignment *only* in Puerto Rico. Stations licensed on these frequencies in other parts of the United States prior to November 21, 1984, may continue to operate on a co-equal primary basis in this band.
2. 944–952 MHz: There are 320 channels (25 kHz wide) available in this band. The channels may be stacked to form a single channel up to 300 kHz wide. Separately, stations also may be authorized additional 25 kHz wide channels up to a grand total of 20 channels. The use of these frequencies by ICR stations is subject to the condition that no harmful interference is caused to other classes of stations.
3. 18760–18820 MHz and 19100–19160 MHz: There are 24 channels (5 MHz wide) available in these bands. These frequencies are shared on a co-pri-

mary basis with other fixed services and their use is subject to the rigorous coordination requirements of FCC Rule Section 21.100(d).

4. 31000–31300 MHz: Frequencies in this band are shared on a co-equal basis with stations in the fixed and mobile services operating under parts 21, 78, and 95 of the FCC rules. No interference protection is afforded to fixed or mobile stations operating in this band.

Television Broadcast Auxiliary Stations

The demand for the spectrum allocated for television auxiliary services is significantly greater than for spectrum allocated for radio broadcasting services. In addition to the extensive local demand, network remote units travel extensively and compete with local broadcasters for available frequencies, resulting in increased spectrum congestion. Finally, it is also important to recognize that the variety of activities undertaken by television broadcasters usually requires more complex auxiliary systems than is the case in the radio industry.

The following are the types of Television Broadcast Auxiliary Stations: TV Pickup Stations, TV STL stations (studio transmitter link), TV Relay Stations, TV Translator Relay Stations and TV Microwave Booster Stations.

TV Pickup Stations are land mobile stations used for the transmission of TV program material and related communications from the scenes of events to TV broadcast or Low Power TV (LPTV) stations.

TV STL Stations are fixed stations used for the transmission of program material and related communications from the studio to the transmitter of a TV broadcast or LPTV station.

TV Relay Stations are fixed stations used for transmitting visual program material between TV broadcast or LPTV stations or for the relay of transmissions from a remote pickup station to a single TV station.

TV Translator Relay Stations are fixed stations used for relaying programs and signals of TV broadcast stations to LPTV stations or TV translator stations.

TV Microwave Booster Stations are fixed stations used to receive and amplify signals of TV Pickup, TV STL, TV Relay or TV Translator Relay Stations and retransmit them on the same frequency. These stations are used to transmit signals over a path that cannot be covered by a single transmitter.

The following bands are available for assignment to TV Pickup Stations:

1. 1990–2110 MHz: Seven channels are available in this band which is also available for assignment to all the other types of Television Broadcast Auxiliary Stations. (*Note:* As this *Handbook* goes to press the FCC is considering reallocating some of this band in one of its open rule making proceedings.)
2. 2450–2483.5 MHz: Two channels are available in this band which is also available for assignment to all the other types of Television Broadcast Auxiliary Stations. This band is shared with industrial, scientific and medical (ISM) devices and is not afforded any protection from these ISM devices.
3. 6425–6525 MHz: The channels available in this band are for mobile use only and are co-equally shared with mobile stations licensed under Parts 21, 78 and 94 of the FCC Rules. The available channel bandwidth varies from 1 MHz to 25 MHz and Section 74.602(j) of the FCC Rules contains further explanation concerning the usage of this band.
4. 6875–7125 MHz: Ten channels 25 MHz wide, are available in this band which is also available for assignment to all the other types of Television Broadcast Auxiliary Stations.
5. 12700–13250 MHz: This band contains 43 channels; however, the channels overlap and therefore if use of this band is contemplated Section 74.602 of the FCC Rules should be consulted for a more complete understanding of their usage. This band is also available for assignment to all other types of Television Broadcast Auxiliary Station.
6. 38.6–40 GHz: This band is available without channel bandwidth limitation on a secondary basis to fixed stations.

The following are available for assignment to TV STL, TV Relay or TV Translator Relay Stations.

1. 1990–2110 MHz: Seven channels are available in this band which is also available for assignment to TV Pickup Stations.
2. 2450–2483.5 MHz: Two channels are available in this band which is also available for assignment to TV Pickup Stations.
3. 6875–7125 MHz: Ten channels 25 MHz wide, are available in this band which is also available for assignment to TV Pickup Stations.
4. 12700–13250 MHz: This band contains 43 channels; however, the channels overlap and therefore if use of this band is contemplated Section 74.602 of the FCC Rules should be consulted for a more complete understanding of their usage. This band is also available for assignment to TV Pickup Stations. In addition, the channels between 13150 and 13200 MHz are not available within 50 km of the top 100 markets.
5. 17700–18580 MHz and 19260–19700 MHz: Frequencies in these bands are shared on a co-equal basis with stations in the fixed service authorized by Parts 21, 78 and 94 of the FCC Rules. The available channel bandwidth varies from 2 MHz to 80 MHz. Complete details concerning the use of this band are contained in Section 74.602 of the FCC Rules.

In addition to the above frequencies, TV STL and TV Relay Stations also may be authorized to use UHF-TV channels 14–69 on a secondary basis provided no interference is caused to TV and LPTV stations operating in this band.

Furthermore, the aural portion of television broadcast program material may be transmitted over an aural broadcast STL or ICR station on a secondary, non-interference basis. Likewise, remote pickup stations may be used to transmit the aural portion of television program material.

CONCLUSION

As can be seen from the material contained in this chapter, frequency allocation is a very complex matter and is subject to frequent changes. Therefore, the reader is advised to consult the FCC Rules and Regulations for a complete description of the current allocation situation, including the procedures and policies currently being applied by the FCC concerning a particular band.

APPENDIX A

ITU Study Groups

Study Group	Subject
1.	Spectrum management
3.	Radiowave propagation
4.	Fixed-satellite service
7.	Science services
8.	Mobile, radio determination, amateur & related satellite services
9.	Fixed service
10.	Broadcasting service (sound)
11.	Broadcasting service (television)

Currently there are no study groups 2, 5 or 6. The numbering scheme reflects that which was in existence before the ITU reorganization.

1.3 FCC ORGANIZATION AND ADMINISTRATIVE PRACTICES

BY THE OFFICE OF PUBLIC AFFAIRS, FEDERAL COMMUNICATIONS COMMISSION, WASHINGTON, DC

STATUTORY AUTHORITY

Congress, through adoption of the Communications Act of 1934 created the Federal Communications Commission (FCC) as an independent regulatory agency. Section I of the Act specifies that the FCC was created: "For the purpose of regulation of interstate and foreign commerce in communication by wire and radio so as to make available, so far as possible, to all the people of the United States a rapid, efficient, nationwide, and worldwide wire and radio communication service with adequate facilities at reasonable charges, for the purpose of the national defense, for the purpose of promoting the safety of life and property through the use of wire and radio communication, and for the purpose of securing a more effective execution of this policy by centralizing authority heretofore granted by law to several agencies and by granting additional authority with respect to interstate and foreign commerce in wire and radio communication. . .".

The Commission

The FCC is directed by five Commissioners appointed by the President, by and with the advice and consent of the Senate for staggered five-year terms. No more than three can be members of the same political party. The President designates one Commissioner as Chairman. The Commissioners make their decisions collectively by formal vote although authority to act on routine matters is normally delegated to the staff.

FCC Organization

The staff of the FCC performs the day-to-day functions of the agency, including: 1) license and application processing, 2) drafting of rulemaking items, 3) enforcing rules and regulations, and 4) formulating policy. Normally, broadcasters deal with the Mass Media Bureau (MMB); however, actions by other elements of the agency may directly affect broadcasters. The Commission reorganized itself in 1995 to establish two new bureaus—Wireless Telecommunications and International—to reflect the changes in the industries it regulates. The organizational units of the FCC are shown in Figure 1.3-1. The staff is divided along functional lines into six operating bureaus and ten offices, which provide support services.

Office of the Managing Director (OMD)

The Managing Director serves as the Chief Operations and Executive official, as supervised and directed by the Chairman. The OMD recommends, to the Chairman, program priorities, resources and position allocations, management and administrative policies. The OMD operates the agency's personnel office and has responsibility for emergency communication policies.

Office of Public Affairs (OPA)

The OPA is responsible for informing the press and public of the FCC's actions, facilitating public participation in the FCC's decision-making processes, and operating many of the FCC's public reference rooms and the library. The OPA issues daily news releases, Public Notices and other informational material; prepares the Annual Report and other publications; and handles telephone, written and walk-in requests for information. The OPA maintains the FCC's Internet homepage at http://www.fcc.gov.

The FCC is expanding its Internet communications pipeline to meet increased use by the public. The OPA also operates a phone fax-on-demand system (202) 418-2830 to allow quick access to forms, press releases, public notices, and other information.

Office of Inspector General (OIG)

The OIG was created by the Inspector General Amendments Act of 1988. The Inspector General conducts and supervises audits and investigations relating to the programs and operations of the agency. The Inspector General recommends policies for activities designed to promote economy, efficiency, and effectiveness, as well as to prevent and detect fraud and abuse in agency programs. The OIG also provides a means for keeping the Chairman, Commissioners and the Congress fully informed about problems and deficiencies at the agency.

Office of Administrative Law Judges (OALG)

Administrative Law Judges preside over hearings and issue initial decisions. Review of initial decisions is done by the full Commission.

Office of General Counsel (OGC)

The General Counsel serves as the chief legal advisor to the Commission and the various bureaus and offices. The General Counsel also represents the Commission before the federal courts of appeals, recommends decisions in adjudicatory matters before the Commission, assists the Commission in its decision making capacity, performs a variety of legal functions

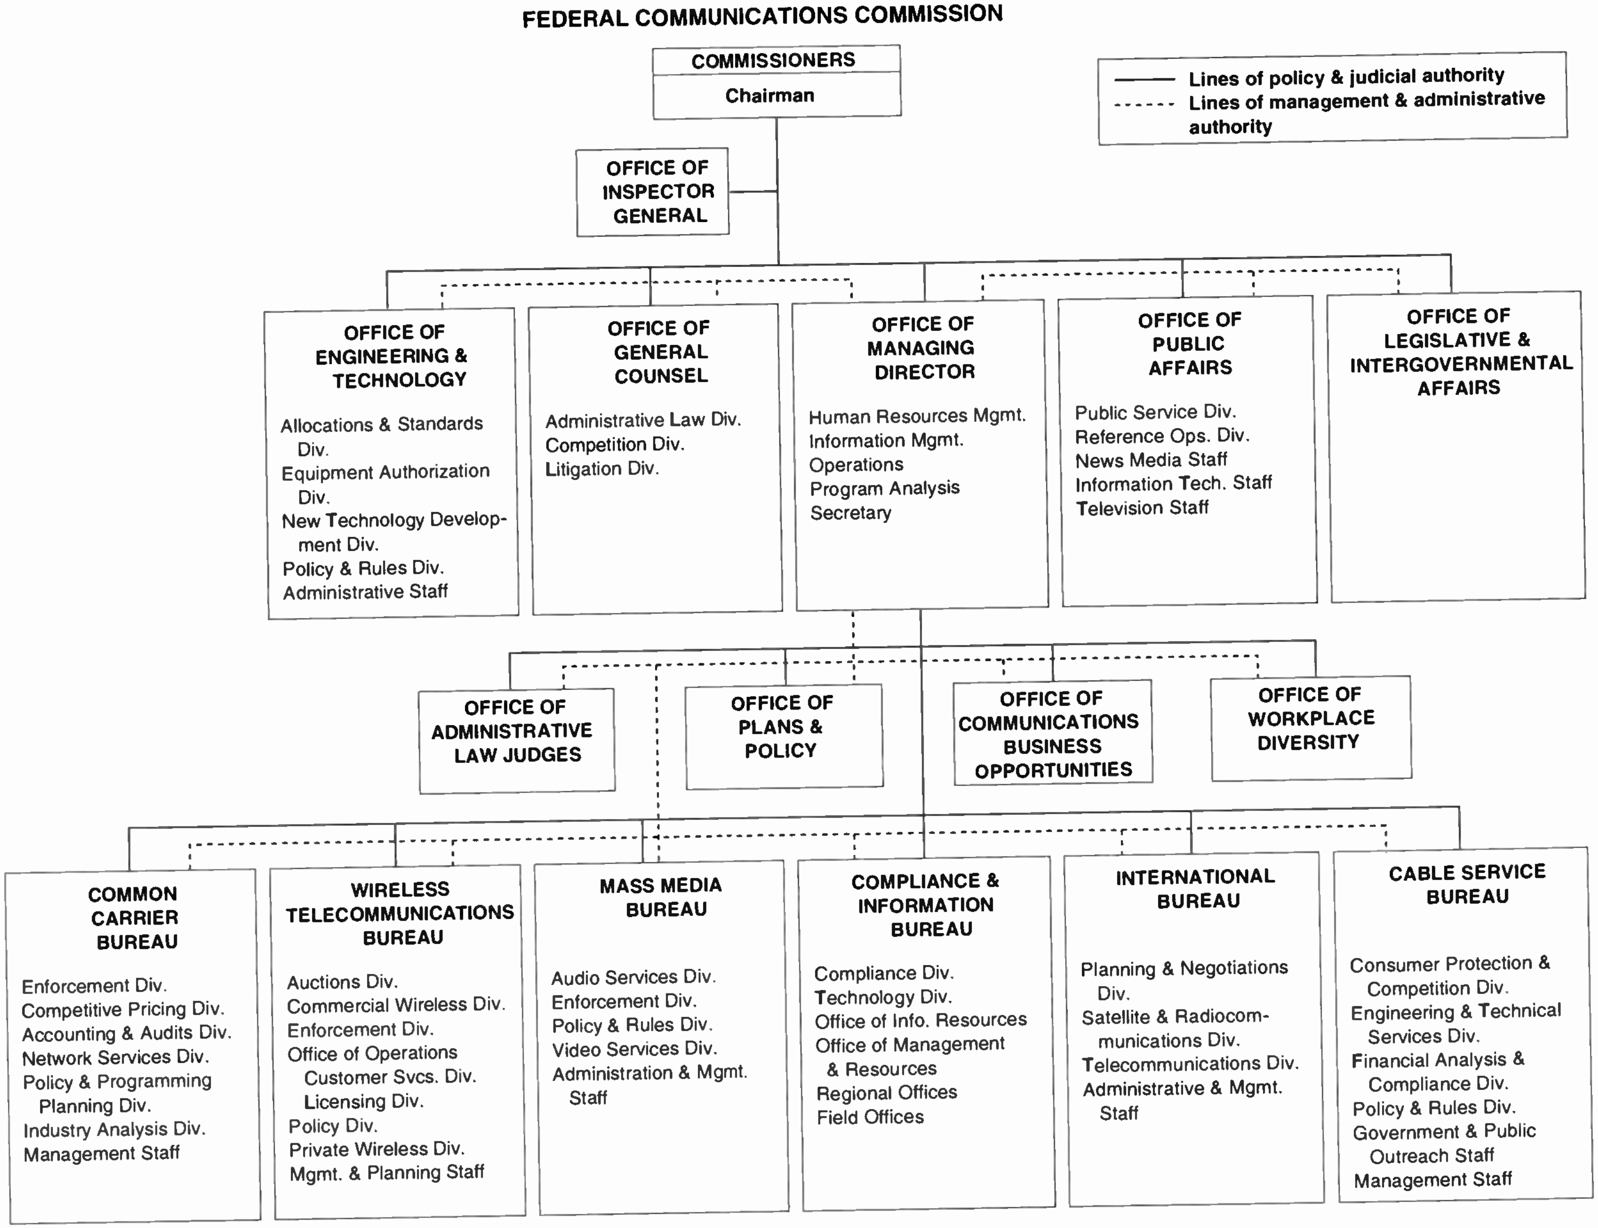

Figure 1.3-1. Operational/organizational chart for the Federal Communications Commission.

regarding internal administrative matters and advises the Commission on fostering competition and promoting deregulation in a competitive environment.

Office of Workplace Diversity (OWD)

The OWD, established in 1995, serves as the principal advisor to the Chairman and Commission on all aspects of workforce diversity, affirmative recruitment, equal employment opportunity, and civil rights within the Commission. The office develops, coordinates, evaluates, and recommends to the Commission internal policies, practices, and programs designed to foster a diverse workforce and to promote equal opportunity for all employees and applicants for employment.

Office of Communication Business Opportunities (OCBO)

The OCBO, established in 1995, is responsible for providing advice to the Commission on issues and policies concerning opportunities for ownership and contracting by small, minority and women-owned communications businesses. The office also advises the Commission on policies to foster equal employment opportunity in the communications industries for minorities, women, and people with disabilities. The office works with entrepreneurs, industry and public interest organizations and individuals to provide information about policies to promote ownership and employment opportunities in the communications industry.

Office of Plans and Policy (OPP)

The OPP serves as the principal economic, technical, and policy adviser to the Commission, analyzing agenda items and developing long term policy on issues that cut across traditional industry and institutional boundaries. The OPP also produces working papers on major policy issues. The continuing focus of OPP's work is to encourage economic growth; enhance access to telecommunications service offerings for consumers, producers, and new entrants, encourage the creation of new services; and promote market-oriented approaches to spectrum management.

Office of Legislative and Intergovernmental Affairs (OLIA)

The OLIA serves as the Commission's principle point of contact with Congress and other governmental entities. Among its functions, the OLIA informs the Congress of the Commission's regulatory decisions, facilitates responses to congressional inquiries, drafts Commission legislative proposals and bill comments, and helps the Commission prepare for congressional hearings. In addition, the OLIA acts on FCC policies and acts as liaison to other federal, state and local government agencies.

Office of Engineering and Technology (OET)

The OET is responsible for managing the non-government use of the spectrum. The OET makes recommendations to the Commission on how the radio spectrum should be allocated and establishes the technical standards to be followed by users. The OET provides technical leadership to create new opportunities for competitive technologies and services for the American public. The OET has four divisions.

Allocations and Standards Division: conducts engineering, economic, legal, social, and statistical studies related to spectrum management. It supports the implementation of new services and technologies by developing technical rules and standards.

Equipment Authorizations Division: authorizes radio transmitters and certain electronic equipment to ensure compliance with the FCC technical standards and to prevent radio interference.

New Technology Development Division: issues licenses for radio experiments, conducts laboratory analyses, and special tests to evaluate performance and spectrum efficiency of new services and technologies.

Policy and Rules Division: prepares rulemaking items on spectrum allocations, radio frequency devices, and industrial, scientific, and medical equipment. It also advises on technical, policy, and standards issues for the various radio services.

BUREAUS

The FCC is organized into six operating bureaus—Common Carrier, Wireless Telecommunications, Compliance and Information, Cable Services, International and Mass Media.

Common Carrier Bureau (CCB)

The CCB is responsible for FCC policies concerning telephone companies that provide interstate telecommunications services to the public through the use of wire-based transmission facilities. These companies provide voice, data, and other transmission services. Under the Communications Act of 1934, as amended by the Telecommunications Act of 1996, the FCC is charged with ensuring that common carriers provide services at just, reasonable, and affordable prices and in a nondiscriminatory manner. The CCB implements FCC regulations and programs designed to meet these objectives. The CCB also recommends and implements proposals designed to encourage the introduction and advancement of competition in telecommunications markets.

Wireless Telecommunications Bureau (WTB)

The WTB oversees the use of radio spectrum to fulfill the communications needs of businesses, local and state governments, public safety service providers, aircraft and ship operators, and individuals. In addition to licensing commercial providers of wireless services, the WTB monitors the more than 2,500,000 licensees that use private wireless radio for personal convenience, to promote safety of life and property, to increase commercial productivity, and to advance the science of telecommunications. The principal functions of the WTB include evaluating new technologies (with the OET); assessing utilization levels of the spectrum and the competitiveness of markets; identifying and allocating spectrum appropriate for licensing; developing through rulemaking the operating rules for radio-based services; assigning licenses through competitive bidding (auctions) and other methods; developing methodologies for conducting complex auctions of radio spectrum; maintaining an antenna structure registration program; licensing commercial radio operators; and enforcing the Commission's rules.

Compliance and Information Bureau (CIB)

The CIB is one of the FCC's primary points of contact with the public. Through its headquarters, staff and various field offices, the CIB informs the public about FCC regulations, policies, practices, and procedures. The CIB also informs the Commissioners and other Bureaus about telecommunications problems and the needs of users; ensures compliance with FCC rules; and uses its technical expertise to solve problems in the communications environment. The Bureau carries out its programs to serve the public and the Commission through 16 district offices, 9 resident agent offices, and 14 remotely-controlled monitoring and radio direction-finding sites located throughout the United States.

Field office activities are directed by three regional offices. The Bureau's radio direction-finding network is controlled from its Columbia, MD, Operations Center. The CIB also maintains a Communications and Crisis Management Center at its Washington, DC, headquarters. The Bureau's field offices are the vital link with the public, licensees, and other users of the radio spectrum. Program and policy development for the Bureau is the responsibility of the Bureau's Divisions and other Offices located at the FCC's headquarters in Washington, DC. In furtherance of the regulatory reform goals of the Telecommunications Act of 1996, the CIB undertook rulemaking proceedings to reduce economic burdens on ship owners and the Commission by privatizing ship inspections previously performed by the Commission on large cargo and small passenger ships and Great Lakes vessels.

Cable Services Bureau (CSB)

The CSB administers and enforces cable television rules and licenses private microwave radio facilities used by cable systems. The Bureau is charged with implementing the 1992 Cable Television and Consumer Protection and Competition Act, which directed the Commission to ensure good service and reasonable rates for cable television subscribers nationwide. The 1996 Telecommunications Act revised many provisions of the 1992 Cable Act and significantly altered the workload for the Bureau. The 1996 Act continues the Bureau's—and the Commission's—process of moving towards competition and away from regulation. The 1996 Act changed the rules of this lane of the information highway for the industry and for consumers. For example, the 1996 Act changed the way cable television subscribers can complain about rates. Prior to the signing of the 1996 Act by President Clinton on February 8, 1996, cable subscribers who had a complaint about rates on the cable programming service tier could file a complaint directly with the Commission. Now, under the 1996 Telecommunications Act, a subscriber must first file with the local franchise authority in the area in which the cable system is located. The Bureau provides a single point of contact for consumers, community officials and the industry for cable related issues pending before the Commission.

International Bureau (IB)

The mission of the IB to promote innovative, efficient, reasonably priced, widely available, reliable, timely, and high-quality domestic and global communications services. The Bureau develops, recommends and administers policies, standards, procedures, and programs for the authorization and regulation of international telecommunications facilities and services and the licensing of domestic and international satellite systems. The Bureau advises and recommends to the Commission, or acts for the Commission under delegated authority, in the development and administration of international telecommunications policies and programs.

Mass Media Bureau (MMB)

The MMB advises the Commission on policy pertaining to broadcasting—television and radio—as well as Multipoint Distribution Service (MDS) (sometimes called *wireless cable*) and Instructional Television Fixed Service (ITFS), a service used mainly by educational entities to provide classroom instruction to multiple locations. The Bureau issues licenses (authorization of service), performs policy and rulemaking functions, and administers the enforcement program for all mass media services. The Bureau has four divisions:

Audio Services Division (ASD): reviews and takes action on all applications filed by the nation's 12,000 FM and AM stations and 2,500 FM translator and booster stations. In March 1996, ASD launched its homepage on the Internet, providing broadcasters with direct access to application status reports, engineering databases, and staff letter decisions of general interest. The Division also has a customer service team and renewal information line, which provide broadcasters and the public with a ready source of information on the status of applications, filing procedures and radio rules.

Enforcement Division: responds to complaints, conducts investigations concerning broadcast stations, handles matters concerning political broadcasting, enforces the broadcast and cable television equal employment opportunity laws and rules, and participates in formal adjudicative proceedings involving broadcast stations. During FY96 the Enforcement Division fully implemented improvements effected in FY95 to streamline its organization and improve speed of service. As a direct result, it was able to expedite enforcement clearances for grant of the increased number of stations changing hands because of the 1996 Telecom Act's liberalization of the multiple ownership rules.

Policy and Rules Division (PRD): conducts rulemaking proceedings which affect the mass media services and provides legal and technical analyses of these rules. The PRD also conducts economic studies to formulate and evaluate Commission policies in terms of their economic effects on the mass media or on other industries or society, as appropriate, and evaluates economic and other studies submitted to the Commission in connection with various proceedings.

Video Services Division (VSD): reviews and takes action on all applications filed by the nation's 1,550 commercial and non-commercial educational television and the nearly 6,850 TV translator and low power television broadcast stations. The VSD is also responsible for the disposition of applications and other requests regarding the development and licensing of facilities in the Multipoint and/or Multichannel Distribution Service (MDS) and the Instructional Television Fixed Service (ITFS).

THE LICENSING PROCESS

Any qualified citizen, company, or group may apply to the FCC for authority to construct a standard (AM), frequency modulation (FM), or television (TV) broadcast station. Licensing of these facilities is prescribed by the Communications Act of 1934, as amended, which sets up certain basic requirements. In general, applicants must satisfy the Commission that they are legally, technically, and financially qualified, and that operation of the proposed station would be in the public interest. Full details of the licensing procedure and station operation are in Part 1 of the Commission's Rules, "Practice and Procedure," and Part 73, "Radio Broadcast Services."

Part 73 includes technical standards for AM, FM, and TV stations, and TV and FM channels (frequency) assignments by states and communities. Copies of the complete rules may be purchased from the Superintendent of Documents, Government Printing Office, Washington, D.C. 20402; (202) 512-1800.

Most applicants retain engineering and legal services in preparing their applications. The Commission does not perform technical or other special studies for prospective applicants nor does it recommend individual lawyers or engineers. Names of firms and individuals practicing before the Commission are listed in various trade publications. (*Broadcasting & Cable Yearbook* and the *Television and Cable Factbook* are two such publications.) These publications can be found in most public libraries or may be obtained by writing: Reed Reference Publishing Company, Attention: Customer Service, 121 Chanlon Road, New Providence, NJ 07974; (1-800-521-8110 and Warren Publishing, Inc., 2115 Ward Court, NW, Washington, D.C. 20037; (202) 872-9200).

The following is a summary of the consecutive steps to be followed in applying for the authorization to build and operate a broadcast station. The application procedure is substantially the same whether the facility sought is AM, FM, or TV.

AM Stations

An applicant must make their own search for an AM frequency on which to operate without causing or receiving interference from existing stations and stations proposed in pending applications. AM stations operate on frequencies from 540 kHz to 1700 kHz—though the frequencies from 1610–1700 are not at present available to new applicants. In the United States and in Region 2, the channels are spaced at 10 kHz intervals. Stations are designated channel by channel to serve various size areas and operate on *clear, regional,* and *local* channels. Dominant clear channel stations (Class A) operate at a maximum power of 50,000 watts; secondary clear channel stations (Class B) operate at a power between 250 watts and 50,000 watts. Many stations operate as daytime-only stations (Class D). (Applications are no longer being accepted for daytime-only stations). Class B stations operating on regional channels may now operate at power levels between 250 watts and 50,000 watts. Class C stations operate on local channels serving limited areas and operating with no more than 1,000 watts day and night. Submission of an application for an AM station requires the payment of an application filing fee.

FM Stations

The FM service includes the frequencies from 88.1 MHz through 107.9 MHz. These frequencies are also known as *FM broadcast channels* (See 47 CFR Section 73.201). The FM channels run from Channel 201 (88.1 MHz) through Channel 300 (107.9 MHz). Channels 221 through 300 (92.1 MHz through 107.9 MHz) are generally used for commercial FM stations. Any applicant wishing to apply for a commercial FM station (or a noncommercial educational station on Channels 221 to 300) must first determine if there are any unused frequencies ("allotments") assigned to the community to be served. The FCC maintains a Table of Allotments (47 CFR Section 73.202) that is helpful in identifying any available channels.

These tables are available from the FCC's Copy Contractor, ITS at 1231 20th Street, NW, Washington, D.C. 20036; (202) 857-3800. (Information on Table of Allotments is also available on the Commission's Internet site at http://www.fcc.gov/mmb/prd/allocate. html.) If an applicant identifies an unused channel that is listed as a first come, first served allotment, then the applicant may file an application (FCC Form 301) for the vacant allotment. If the applicant identifies an unused channel that has a window filing period for the allotment, the applicant may file an application for that channel before the end of the window filing period. If the current FM Table of Allotments indicates that there are no unused channels allotted to the community, the applicant may have a private consulting engineer, of the applicant's choice, perform an engineering study to identify a channel that may be allotted to the desired community.

If the applicant identifies a channel that could be allotted to serve the community, the applicant may submit a petition for rulemaking to the FCC's Allocations Branch (Policy and Rules Division, Mass Media Bureau) requesting allotment of the channel to serve the desired community. If the FCC approves the petition, the channel will be added to the FM Table of Allotments and applications may be filed during a "window" filing period (usually a 30 day period) specified by the FCC. (See *FM Commercial Application Filing Windows* for additional information.)

Applicants filing for a commercial FM station during a window filing period, or filing for a first come, first served vacant allotment, must include the application filing fee with the construction permit application. Channels 201–220 (88.1 MHz to 91.9 MHz) are reserved for noncommercial educational operation. Applicants for noncommercial FM radio stations must first conduct an engineering study for a suitable channel within the reserved band to serve the desired community.

Once the engineering study has been completed and a suitable channel within the reserved band is identified to serve the desired community, an application (FCC Form 340) may be filed for that channel. The application is then placed on an *A* cutoff list, which defines a date by which any competing applications or petition to deny must be filed. If no competing applications are filed, a legal review and further technical review is performed on the application, with that application being granted if it is acceptable. Channels in the unreserved portion of the FM band (Channel 221 through Channel 300 or 92.1 MHz–107.9 MHz) may be used for noncommercial programming. However, procedures governing commercial FM channels will apply (i.e., window filing periods, technical requirements). No application filing fee is required for applicants seeking authorization for a noncommercial educational station. The Commission authorizes seven classes of FM stations: A, B1, B, C3, C2, C1, and C.

The maximum power for a Class A station is 6,000 watts, Class B1 is 25,000 watts, Class B 50,000 watts, Class C3 is 25,000 watts, Class C2 is 50,000 watts, Class C1 is 100,000 watts, and Class C is 100,000 watts but at a higher (300 to 600 meter) antenna height above average terrain (AHAAT). The minimum power authorized for any FM station is 100 watts. (*See Low Power Broadcast Radio Stations.*)

FM Translator Stations

FM translators comprise a low-power service on the FM broadcast band (88 to 108 MHz) which complements the primary FM service. This service was created in 1970 to allow FM stations to provide supplementary service to areas in which direct reception of radio service is unsatisfactory due to distance or intervening terrain barriers. Translators may not originate programming, except for very limited fund raising efforts. Translator stations rebroadcasting commercial FM stations may be authorized on Channel 221 through 300 (92.1 MHz to 107.9 MHz), while translators rebroadcasting a noncommercial educational FM station may be authorized on any FM channel (201 to 300). The maximum effective radiated power permitted for any translator station is 250 watts. The maximum power permitted for a particular transmitter station may be further limited by the location of that station. Applications for a construction permit for an FM translator station must be filed on FCC Form 349. Once construction is completed in accordance with the construction permit granted by the FCC, a license application on FCC Form 350 is then necessary. An application filing fee is required for FM translator stations which rebroadcast a commercial FM primary station. Further information about FM translator stations is available in the Fact Sheet, *FM Translator and Booster Stations,* available from the Commission's Public Service Division.

TV Stations

As is the case in applying for a commercial FM station, an applicant for a TV station must request an unused channel listed in the Commission's Table of Allotments. Television channels are designated commercial or noncommercial. If there are no channels assigned to the city where an applicant proposes to construct the new station, the applicant may have a private engineer do a channel search. Once a channel is identified, a petition for rulemaking to add the channel to the Table of Allotments may be filed with the Allocations Branch. If the FCC approves the petition, the channel will be added to the Table of Allotments and will become available for application. Television stations currently operate on VHF Channels 2 through 13, or UHF Channels 14 through 69, with power depending on the channels used (VHF or UHF), and station separations determined by three zones. However, after the conversion to digital television (DTV) is complete, television stations will operate only on channels 2 through 51. Channels 52 through 69 will be used for other purposes(though the possibility remains that some of this spectrum may be used for broadcasting by licensees who bid for it at auction. All new applications for television stations must be for DTV facilities.

TV Translators/Low Power TV (LPTV) Stations

There are two types of secondary television stations—*television translators* and *Low Power Television* (LPTV) stations. A TV translator is a station that rebroadcasts signals from full-service television stations. LPTV stations may rebroadcast a full-service station television signal and may also originate their own programming. LPTV stations may also operate as a subscription service. These two secondary television services may operate on any available VHF or UHF channel, provided they do not cause objectionable interference to full-service stations or other authorized translator or LPTV stations.

How to Apply for an AM, FM or TV Broadcast Station

To apply for a new AM station, or a commercial FM station or a commercial TV broadcast station for which a vacant allotment is available, the applicant must submit FCC Form 301 (Application for Construction Permit for Commercial Broadcast Station), with the appropriate application filing fee. Noncommercial educational television applicants, and noncommercial educational FM station applicants filing for operation on Channels 201 through 220, must submit FCC Form 340 (Application for Construction Permit for Noncommercial Educational Broadcast Station). No application filing fee is required for noncommercial educational applicants.

These forms are also used to make modifications in an existing facility. FM translator, TV translator, and LPTV applicants must submit FCC Form 346 (Application for Authority to Construct or Make Changes in an LPTV, TV Translator, or FM Translator Station). These forms require information about the citizenship, legal, and financial qualifications of the applicant, as well as engineering and technical specifications of the proposed or modified transmitter site.

Another way to obtain a broadcast station is to purchase an existing station that the owner is willing to sell. The FCC does not maintain a list of stations for sale and does not participate in the negotiations of the sales contract.

Station brokers and communications attorneys can assist in identifying stations that are for sale. You may also contact individual station owners directly to see if they are interested in selling their station. After you have found a station for sale, and have signed a contract to purchase the station, FCC Form 314 (Application for Consent to Assignment of Broadcast Construction Permit or License) must be submitted within 30 days accompanied by appropriate filing fees. Applicants who apply to purchase a station may not take over operation until the FCC approves the application to purchase the station.

Once the application is approved, the buyer must submit a letter of consummation within 90 days of the grant. FCC Form 323 (Ownership Report for Commercial Stations) or FCC Form 323-E (Ownership Report for Noncommercial Educational Stations) must also be submitted within 90 days of the grant. FCC Form 315 (Application for Consent to Transfer of Control of Corporation Holding Broadcast Station Construction Permit or License) must be submitted when a controlling block of shares of a broadcasting company is transferred to a new entity or an individual. There is also a FCC Form 316 (Application for Consent to Assignment or Transfer of Control) which is used when a station is involuntarily transferred, such as to a trustee in bankruptcy. FCC Form 316 is also used for Pro Forma (changes in form, not substance) assignments and transfers, such as a sale from a person to a corporation controlled by that person.

Broadcast applications must be submitted in triplicate, with the appropriate application filing fee attached. (See *Mass Media Fee Filing Guide* for fee information, fees, and filing forms. These are available from the Public Service Division or the FCC Call Center at 1-888-CALL-FCC.) Applications for noncommercial educational stations do not require a filing fee.

Applicants Must Give Local Notice

All applicants must give local notice in a newspaper of general circulation in the community in which the station is licensed or proposed to be licensed. They must also afford an opportunity for the public to file comments on these applications with the Commission. Copies of the application must be maintained in the station's public files or at a location accessible to the public in the community where the station is proposed, (i.e. public library or post office). Licensees who submit a license renewal application must give local public notice of the filing by broadcasting announcements over their stations. Any application that is designated for hearing must again give local public notice indicating such action by the Commission. (See 47 CFR Section 73.3580).

What Happens Once an Application is Filed With The FCC?

Applicants for new and major modifications in existing facilities of commercial and noncommercial AM, FM, and TV broadcast stations are tendered for filing and then placed on a cutoff list once the application is accepted for filing. The cut-off Public Notice of Acceptance triggers a 30 day filing period for any competing applicants interested in filing an opposition or petition to deny any of the applications listed on the public notice.

For the AM expanded band, the Commission issued a public notice in 1992 establishing a filing window for existing AM stations to file a petition to migrate. The Commission ranked all the petitions to migrate in accordance with the station's priority group and the interference improvement factor. Based on the overall ranking of the petitions, the Commission produced an Allotment Plan, and issued a public notice (which was later revised twice) identifying the stations receiving an allotment authorization. The Commission gave these stations until June 15, 1997, to file applications for construction permits to build facilities in the expanded band.

Applications generally are processed in the order in which they are filed. They are reviewed for engineering, legal, and financial data by the Mass Media Bureau, which under delegated authority acts on routine applications. If an application is defective, the applicant will be afforded one opportunity to amend their application. Thereafter, if all defects have not been corrected, the application will be returned. In most instances all filing fees are retained by the Commission regardless of final disposition of the application. If an application is complete and has no defects, petitions to deny, or competing applications, the application may be granted without hearing and a Construction Permit will be issued. All dispositions of applications are announced by the Commission.

Petitions for Reconsideration of grants made without hearing can be filed within 30 days of the release date of the public notice of such grant. However, when an objection is filed, the petitioner must show good cause why the objection was not raised before the grant.

Hearing Procedure

In instances where it appears that an application does not conform to Commission Rules and Regulations, and petitions to deny or competing applications are filed, the Commission may designate the application for hearing. The Commission will issue a Public Notice listing the applications that are designated for hearing. The hearing fee must be paid within 60 days of the release of that Public Notice. The hearing notice generally allows the applicant 20 days to file a "Notice of Appearance." The Administrative Law Judge (ALJ) hearing the case is also assigned at this time. Amendments to the application may be filed as a matter of right within 30 days, with a showing of good cause, if the amendment relates to issues first raised in the Hearing Designation Order. After the hearing procedure and review of evidence and statements, the ALJ issues an Initial Decision. Initial Decisions may be contested within specified time limits. In all cases heard by an ALJ, the Commission or a review board it establishes may hear oral arguments and may adopt, modify or reverse the ALJ's Initial Decision. Any action taken by the Commission may be appealed to the District of Columbia Appellate Courts.

Construction Permits

When an application is granted, either by Bureau staff or as a result of a comparative hearing, there is a specified period of time given the grantee for completing the construction of the station. Construction permits for radio are issued for 18 months, 24 months for television. Grantees must request call sign assignment when the construction permit has been granted. If no request is received from the grantee for a specific call sign, the Commission will automatically assign one. If for whatever reason a grantee of a construction permit cannot complete the construction of the station within the specified months, the grantee may request an extension of time on FCC Form 307 (Application for Extension of Broadcast Construction Permit or to Replace Expired Construction Permit) provided the grantee justifies the request showing the amount of completion and estimated amount of time needed to complete construction. Upon completion of construction, the grantee may begin program tests. However the appropriate form must be on file within 10 days of commencement of program tests. This procedure for program tests applies only to nondirectional stations. Directional stations must receive approval from the Commission prior to commencing program tests. For AM, FCC Form 302-AM (Application for New Broadcast Station License); for FM, FCC Form 302-FM (Application for FM Broadcast Station License); or for TV, FCC Form 302-TV (Application for TV Broadcast Station License).

Comparative Hearings

In April 1996, the Commission adopted an order implementing Section 204(a) of the Telecommunications Act of 1996 ("Telecom Act"). The Telecom Act adopts new Section 309(k) of the Communications Act, which eliminates comparative renewal hearings and directs the Commission to grant a broadcaster's renewal application if statutory renewal standards are met. This new procedure effects a major change in the way the Commission processes renewals. With respect to broadcast renewal applications filed after May 1, 1995, the statute eliminates comparative renewals and establishes, instead, a new twostep renewal procedure. It also codifies specific standards for the Commission to apply in considering broadcasters' renewal applications. Additionally, Section 204(a)(2) of the Telecom Act amends Section 309(d) of the Communications Act to make the standard for filing petitions to deny conform to the new statutory renewal standards. The Commission's rules will be modified to conform to the renewal procedures and standards adopted in the Telecom Act.

The Telecom Act does not define the terms contained in the renewal standards embodied in Section 309(k), and the Commission likewise does not define those terms in this order. It is the Commission's present intent to continue to apply existing policy statements and case law, refining these as appropriate on a case-by-case basis in interpreting the statutory terms that govern the new renewal process. If the Commission determines at some future time that further clarification of the renewal standards is appropriate, it will conduct such proceedings as may be warranted.

Pending comparative renewal proceedings and mutual exclusivities involving applications filed on or before May 1, 1995, will be concluded pursuant to the current rules, and accordingly, the Commission will leave intact procedural provisions of the current rules that refer to comparative renewal proceedings until those pending proceedings and exclusivities are finally resolved. The Commission also terminated BC Docket No. 81-742 in which the Commission had been considering reform of the comparative renewal process.

Licenses and Ownership

All radio and television stations are licensed for eight years. With regard to ownership, on March 8, 1996, the Commission released an order implementing Sections 202(a) and 202(b)(1) of the Telecommunications Act of 1996. These provisions direct the Commission to eliminate the national multiple radio ownership rule and modify the local radio ownership ("radio contour overlap") rule. With the order, the Commission conformed its rules to these provisions of the Telecom Act. The new rules became effective upon their publication in the *Federal Register*, which occurred on March 15, 1996.

Previously the Commission's rules limited commercial radio ownership on a nationwide basis to 20 AM stations and 20 FM stations, except that minority owners were permitted to own up to 25 AM and 25 FM stations. Nonminority owners, in addition to being permitted to own up to 20 AM and 20 FM stations, were permitted to hold an attributable interest in 5 additional stations per service, provided that those additional 5 stations were small business-controlled or minority-controlled. Section 202(a) of the Telecom Act directs the Commission to eliminate its rules limiting the number of AM or FM broadcast stations that may be commonly owned nationally and the order implemented this provision.

Previously, with regard to local ownership, the Commission's rules permitted ownership of up to three commercial radio stations, no more than two of which may have been in the same service, in radio markets with 14 or fewer stations, provided that the owned stations, if other than a single AM and FM station combination, represented less than 50 percent of the stations in the market; in markets with 15 or more commercial radio stations, ownership of up to two AM and two FM commercial radio stations was generally permitted if the combined audience share of the commonly owned stations did not exceed 25 percent in the market. Section 202(b)(1) of the Telecom Act requires the Commission to revise its rules to provide that:

- In a radio market with 45 or more commercial radio stations, a party may own, operate, or control up to 8 commercial radio stations, not more than 5 of which are in the same service (AM or FM).
- In a radio market with between 30 and 44 (inclusive) commercial radio stations, a party may own, operate, or control up to 7 commercial radio stations, not more than 4 of which are in the same service (AM or FM).
- In a radio market with between 15 and 29 (inclusive) commercial radio stations, a party may own, operate, or control up to 6 commercial radio stations, not more than 4 of which are in the same service (AM or FM).
- In a radio market with 14 or fewer commercial radio stations, a party may own, operate, or control up to 5 commercial radio stations, not more than 3 of which are in the same service (AM or FM), except that a party may not own, operate, or control more than 50 percent of the stations in such market.

Accordingly, the Commission implemented these changes. In so doing, it noted that it was not altering any of its other rules regarding the local ownership of radio stations.

On November 7, 1996, the Commission released a Notice of Proposed Rule Making in MM Dockets No. 96-222, 91-221, and 87-8, reviewing the Commission's national broadcast television ownership rules. Pursuant to the Telecommunications Act of 1996, an entity may generally not have an attributable interest in commercial television stations with an aggregate national audience reach exceeding 35 percent. A station's audience reach is determined by the number of television households in that station's Area of Dominant Influence (ADI), as determined by the commercial ratings service Arbitron. The *Notice* first addressed the "UHF discount," by which a UHF station is attributed with only 50 percent of the television households in the market, and postponed further consideration of whether to modify or repeal the rule until 1998 (at which time all ownership rules will undergo a statutorily-mandated biennial review. Second, the *Notice* proposed to eliminate the satellite exemption to the rule for satellite stations that operate in separate markets from their parent stations. However, for same-market satellites, the Commission proposed not to double count the audience in that market when calculating the parent station's national audience reach. Similarly, where one station has a local marketing agreement (LMA) with another, the *Notice* proposed not to double count that market. Finally, the Commission proposed to define a station's market for the purposes of calculating audience reach by using Designated Market Areas (as determined by Nielsen) instead of ADIs, because Arbitron no longer updates its county by county determinations of each station's ADI.

Auctions for Certain Mutually Exclusive Initial License Applications

The Balanced Budget Act of 1997 provides, with respect to certain Mutually Exclusive (MX) applications for an initial license or construction permit filed on or after July 1, 1997, that the Commission *must* grant the license or permit to a qualified applicant through a system of competitive bidding. The Balanced Budget Act specifies, however, that the Commission's competitive bidding authority does not extend to licenses or construction permits for certain public safety radio services, for noncommercial educational broadcast and public broadcast stations, or for digital television service given to existing terrestrial broadcast licensees to replace their analog television service licenses.

With respect to such applications that were filed before July 1, 1997, the Balanced Budget Act (1) *authorizes* the Commission to resolve mutually exclusive applications for an initial construction permit for a commercial radio or television broadcast station through competitive bidding, rather than through the comparative hearing process; (2) specifies that the persons filing such applications shall be treated as the only persons eligible to be qualified bidders; and (3) directs the Commission to waive any FCC rules necessary to permit such persons to enter into an agreement to procure the removal of a conflict between their applications during the 180-day period beginning on the day of the Balanced Budget Act's enactment.

RULES AND REGULATIONS

FCC Rules may be obtained by writing or calling the Government Printing Office, Washington, DC 20402; (202) 512-1800. The Rules on FCC Practice and Procedures are contained in the Code of Federal Regulations (CFR), Title 47, Parts 0–19. Broadcast rules are found in Title 47 of the CFR Parts 70–79. An on-line version of the CFR rules is available at the U.S. House of Representatives Internet Law Library Home Page. To search in the CFR, (e.g. find rule section 47 CFR Section 73.1226), enter the search item as 47:cite w/ 3 73.1226. To search for a whole part, (e.g. Part 73), enter the search item as 47:cite w/3 73. To use wildcard, (e.g. to find all 73.500 rule sections), enter the search item as 47:cite w/3 73.5*. Note that if a whole part is to be retrieved, the maximum number of records retrieved will need to be increased (e.g., to 400 for Part 73). Items will not be retrieved in order by CFR section number. Please be aware that FCC rules received from this site may not incorporate recent revisions.

Application Forms

Application forms may be obtained by calling the automated forms request line at 1-800-418-3676 or 1-202-418-3676 (recording machine available 24 hours a day, seven days a week), writing to Federal Communications Commission, Forms Distribution Center, 9300 E. Hampton Drive, Capital Heights, MD 20743, or using the FCC's Internet on-line Forms Request link at http://www.fcc.gov/formpage.html. Questions concerning filing procedures should be directed to the Public Service Division, Consumer Assistance Branch, 1919 M Street, N.W., Washington, DC 20554; telephone: (202) 418-0200. Alternatively, questions may be referred to the Audio Services Division for the radio services [(202) 418-2720 for technical questions, (202) 418-2710 for legal questions] or the Video Services Division at (202) 418-1600.

THE RULE MAKING PROCESS

The FCC, like all other federal government agencies, enacts new rules and regulations through the terms of the Administrative Procedures Act (APA). The APA specifies how rules may be proposed, adopted, and appealed. The APA assures that the public has input into the rule making process. Part I of the FCC Rules and Regulations provides detailed information on the FCC's general rules of practice and procedure.

Initiation of Actions

Rule making actions can be proposed by anyone through a *Petition for Rule Making*. Such petitions bring the desires of individuals or groups to the attention of the Commission. The FCC will evaluate the petitions and either dismiss them for one of the reasons in Section 1.401 of the Rules or accept them for action. If accepted, a *Public Notice* will be released giving a brief description of the details of the petition. Other rulemakings may begin by direction of Congress, the President, or the courts. The FCC may also initiate rule makings on its own motion.

Early Options

Initiation actions are handled in one of four ways. A petition can be dismissed directly through a *Memorandum Opinion and Order* (MO&O). Minor rule changes of an administrative nature can be made effective directly through a *Report and Order* (R&O). Generally, however, either a *Notice of Inquiry* (NOI) or a *Notice of Proposed Rule Making* (NPRM) will be drafted by the staff. If enough information is at hand to draft the proposed rule changes, an NPRM will be issued without first gathering background material in an NOI. After adoption of an NPRM by vote of the Commissioners, the *ex parte* rules become effective. Because this inhibits direct contact between FCC staff and concerned parties, the NOI may be considered an essential first step in many matters. *Ex parte* does not apply at the NOI stage. Comment periods are provided to allow interested parties to express their views. If, based on a review of the comments received, the Commission finds that an NOI should be terminated without further action, it will issue an MO&O stating the reasons for the termination. Otherwise, the matter will be considered for specific rule making in an NPRM. The MO&O is subject to a 30 day period in which parties may file petitions for reconsideration if they have good reason to believe the Commission acted incorrectly.

Notice of Proposed Rule Making (NPRM)

Most rule making items begin as an NPRM. The staff prepares the NPRM for consideration by the five Commissioners. An NPRM normally presents the issues and alternatives, may ask specific questions to help finalize the matter, and sets forth proposed rules or rule amendments. An NPRM may address one or multiple topics. Comments must be filed by the close of the commend period, usually 30 days. Reply comments may then be filed in response to comments, usually for a 15 day period. These two comment periods provide the Commission with a "written debate" of the issues. The comments and reply comments received are reviewed and enter heavily into the Commission's final actions. However, a comment does not represent a vote for the proposed rules. The Commission must decide on each issue based on the public"s interest, convenience, and necessity. Even if the majority of the comments oppose an item, the FCC can nevertheless adopt the proposal. The FCC can also schedule items for oral argument among the interested parties.

Filings should be clear, concise, and address the issues in the NPRM. Emotional responses or uninformed responses are of little value. Copies of the actual texts of the NPRM need to be studied before making comments. All NPRMs are published in the *Federal Register* and are available at most larger libraries or law libraries.

The comments are reviewed by Commission staff at the Branch or Division levels. Recommendations are then passed to the Bureau level and ultimately to the Commissioners. The Commissioners will then approve, disapprove, or direct the staff to modify the recommendations. The staff or the Commissioners may also decide that the record still does not support a decision, and a *Further Notice of Proposed Rule Making* (FNPRM) will be released. Like an NPRM, the comment periods apply. Once the record supports a final decision, the FCC will act by the adoption of a *Report and Order.*

Report and Order (R&O)

An R&O may be used to dismiss the proposals in the NPRM, adopt some of the proposals (possibly modified based on the comments), or adopt the rules as proposed. Rules will normally not become effective until 30 days after publication of the R&O in the *Federal Register.* The R&O constitutes the Commission's final action unless a petition for reconsideration is filed.

Petition for Reconsideration

Any interested person may petition for reconsideration of a final action. The petitions for reconsideration must be filled within 30 days of the date the R&O was published in the *Federal Register.* The Commission will act on a petition for reconsideration by *Memorandum Opinion and Order.* The initial decision may be modified or the petition may be denied in the MO&O.

Ex Parte Considerations

The FCC revised its *ex parte* rules June 2, 1997. The *ex parte* rules govern the manner in which persons may communicate with the Commission concerning the issues in a proceeding. The rules play an important role in protecting the fairness of the FCC's proceedings by assuring that FCC decisions are not influenced by impermissible off-the-record-communications between decision-makers and others. At the same time, the rules are designed to ensure that the FCC has sufficient flexibility to obtain the information that is necessary for it to make reasonable decisions. The *ex parte* rules apply to anyone who engages in the kind of communications covered by the rules whether or not they are a party to the proceeding. The rules govern *ex parte* presentations to FCC decision makers. The rules are found in sections 1.1200 to 1.1216 of Title 47 of the Code of Federal Regulations, as amended by FCC 97-92, released March 19, 1997.

In some types of proceedings (*restricted proceedings*), the rules prohibit *ex parte* presentations to decision makers concerning the issues in its proceedings. In other types of proceedings (*permit-but-disclose proceedings*), the rules require that summaries of such presentations be placed in the record. In some types of proceedings (*exempt proceedings*), there are no restrictions on *ex parte* presentations. The rules describe which types of restrictions or requirements, if any, apply to *ex parte* presentations in the various types of Commission proceedings.

A presentation is a communication directed to the merits or outcome of a proceeding, including any procedural or other issues raised in the proceeding—there are some exceptions, however. Communications which are inadvertently or casually made are not presentations. Neither are routine inquiries about compliance with the Commission's procedural rules, such as when a pleading must be filed, so long as the question has not become the subject of dispute in the proceeding.

Inquiries relating solely to the status of a proceeding are not presentations. However, a status inquiry is deemed a presentation if it states or implies a view as to the merits or outcome of the proceeding or a preference for a particular party, states why timing is important to a particular party (other than the need to avoid administrative delay), or indicates a view as to the date by which a proceeding should be resolved.

An *ex parte* presentation is any presentation which, if written (including electronic mail), is not served on the parties to the proceeding, or, if oral, is made without advance notice to the parties and without opportunity for them to be present.

Decision-making personnel are those people at the Commission who are or who may reasonably be expected to be involved in formulating a decision, rule, or order in a proceeding. All FCC Bureau or Office staff are considered decision-making personnel with respect to decisions, rules, and orders in which their Bureau or Office participates unless they have been designated as part of a separate trial staff or otherwise formally excluded from the decisional process in the proceeding.

Certain kinds of *ex parte* presentations are considered "exempt" and may be freely made even if a proceeding is permit-but-disclose or restricted. Participants in Commission proceedings should be aware that these include:

- Presentations authorized by statute or by the Commission's rules to be made without service, as well as the filing of required forms
- Presentations to the General Counsel's office concerning judicial review of a proceeding
- Presentations directly relating to emergency situations
- Situations where confidentiality is necessary to protect persons making *ex parte* presentations from possible reprisals

Participants in Commission proceedings are also permitted to make presentations requested by (or made with the advance approval of) the Commission or staff for the clarification or presentation of evidence, or for resolution of issues, including possible settlement, subject to certain disclosure requirements. Parties to restricted Commission proceedings are permitted to orally request that the Commission act by a particular date or give reasons for expediting the case other than the need to avoid administrative delay. If they do so, however, they must promptly file a detailed summary of the presentation in the record and serve it on the other parties to the proceeding. Other parties may respond similarly in support or opposition to the request. The rules contain other exemptions and should also be consulted to determine if a particular exemption contains a disclosure requirement.

Ex parte presentations are permissible in "exempt" proceedings. There are six kinds of exempt proceedings:

- Notice of Inquiry proceedings.
- Petitions for Rulemaking (except for petitions requesting the allotment of a broadcast channel) and other requests for rule changes and policy statements.
- Tariff proceedings (including directly-associated waiver requests or requests for special permission) prior to being set for investigation.
- Proceedings relating to prescription of common carrier depreciation rates under section 220(b) of the Communications Act prior to release of a public notice of specific proposed depreciation rates.
- Informal complaint proceedings under section 208 of the Communications Act.
- Complaints against a cable operator regarding its rates that are not filed on FCC Form 329.

Ex parte presentations are permitted in "permit-but-disclose" proceedings provided that the presentations are disclosed in the manner specified in the rules. There are 11 kinds of permit-but-disclose proceedings:

- Informal notice and comment rulemaking proceedings other than a proceeding for the allotment of a broadcast channel, upon release of a Notice of Proposed Rulemaking.
- Proceedings involving a rule change, policy statement, or interpretive rule adopted without a Notice of Proposed Rule Making upon release of the order adopting the rule change, policy statement, or interpretive rule.
- Declaratory ruling proceedings.
- Tariff proceedings which have been set for investigation under section 204 or 205 of the Communications Act (including directly-associated waiver requests or requests for special permission).
- Unless designated for hearing, proceedings under section 214(a) of the Communications Act that do not also involve applications for authorizations for radio communications services.
- Unless designated for hearing, proceedings involving applications for Cable Landing Act licenses that do not also involve applications for authorizations for radio communications services.
- Proceedings involving a request for information filed pursuant to the Freedom of Information Act.
- Proceedings before a Joint Board or proceedings before the Commission involving a recommendation from a Joint Board.
- Proceedings conducted pursuant to section 220(b) of the Communications Act for prescription of common carrier depreciation rates upon release of a public notice of specific proposed depreciation rates.
- Proceedings to prescribe a rate of return for common carriers under section 205 of the Communications Act.
- Cable rate complaint proceedings pursuant to section 623(c) of the Communications Act where the complaint is filed on FCC Form 329.

If there is only one party involved in a permit-but-disclose proceeding, that party may communicate with the Commission without disclosure. If, however, a presentation is made by a non-party or by one of multiple parties in such a proceeding, the presentation is deemed *ex parte* and must be disclosed.

There are specific procedures for ensuring that the presentations are reflected in the record of a permit-but-disclose proceeding. *Ex parte* presentations by members of Congress or their staffs and other federal agencies or their staffs need be disclosed only if they are of substantial significance and clearly intended to affect the ultimate decision in the proceeding. Disclosure of *ex parte* presentations by members of Congress or their staffs and other federal agencies or their staffs will generally be made by the Commission's staff.

In other circumstances, persons making written *ex parte* presentations must, no later than the next business day after the presentation, submit two copies of the presentation to the Commission's secretary under separate cover for inclusion in the public record. The presentation (and cover letter) must clearly identify the proceeding to which it relates, (including the docket number, if any) indicate that two copies have been submitted to the Secretary; and be labeled as an *ex parte* presentation. If the presentation relates to more than one proceeding, two copies must be filed for each proceeding.

Persons making oral *ex parte* presentations must disclose them if they present data or arguments not already reflected in that person's written comments, memoranda or other filings in that proceeding. In that case, the person must, no later than the next business day after the presentation, submit to the Commission's Secretary, with copies to the Commissioners or Commission employees involved in the oral presentation, an original and one copy of a memorandum which summarizes the new data or arguments. The subject matter of the presentation must be fully disclosed; a mere listing of the subjects discussed is not sufficient, and more than a one or two sentence description of the views and arguments presented is required.

The memorandum (and cover letter) must clearly identify the proceeding to which it relates (including the docket number, if any), indicate that an original and one copy have been submitted to the Secretary, and be labeled as an *ex parte* presentation. If the presentation relates to more than one proceeding, two copies of the memorandum (or an original and one copy) must be filed for each proceeding. There is an exception to these requirements where, for example, presentations occur in the form of discussion at a widely attended meeting, and preparation of a memorandum as specified in the rule might be cumbersome. Under these circumstances, the rule may be satisfied by submitting a transcript or tape recording of the discussion as an alternative to a memorandum.

The Commission's Secretary issues a Public Notice at least twice a week listing any written *ex parte* presentations or written summaries of oral *ex parte* presentations in permit-but-disclose proceedings. It is possible that some presentations might inadvertently be omitted from this list, so interested persons should review the public file or record in proceedings about which they are concerned, where the copies of written presentations and memoranda of oral presentations can be found.

In all proceedings other than those specifically listed as "exempt proceedings" or "permit-but-disclose proceedings," *ex parte* presentations are prohibited. In such proceedings, called "restricted proceedings," any written presentations to FCC decision-makers must be served on all the parties and oral presentations may not be made unless all parties are given advance notice and an opportunity to be present. If there is only one party involved in a restricted proceeding, that party may freely communicate with the Commission, because there are no other parties entitled to advance notice or service.

However, presentations by a non-party or by one of multiple parties in a proceeding are prohibited unless all parties are served or given an opportunity to be present. Restricted proceedings include all proceedings that have been designated for hearing, proceedings involving amendments to the broadcast table of allotments, applications for authorizations for radio communications services, and all waiver proceedings (except for those directly associated with tariff filings).

Certain circumstances make you a party with a right mto service of written presentations and advance notice of oral presentations in restricted proceedings and to disclosure of presentations in permit-but-disclose proceedings. Being a party for purposes of the ex parte rules does not necessarily mean that you will be considered a party for other purposes. Parties include people who file applications, petitions, or other requests for relief and those making responsive filings. To make someone a party, such an application or petition must be directed to the Secretary, the relevant Bureau or Office, or the Commission as a whole—not just to the Chairman or individual Commissioners. In addition, to make someone a party, responsive filings must reference the original filing and be served on the filer. For example, persons who file petitions to deny license applications are parties. In addition, persons who file "informal objections" under rule section 73.3587 are parties if their objections are served. (However, the rules contain a special exception for individual listeners or viewers who file informal comments about pending broadcast applications. Such persons are not made parties even if their informal comments are served, and they do not have to serve their comments on the applicant.)

When a Freedom of Information Act request is filed, the person who filed the request is a party and, where the requested information is the subject of a request for confidentiality, the person filing the request for confidentiality is also a party. Applicants and people filing mutually-exclusive applications are parties with respect to each others' applications except in services that the Commission has announced will be subject to competitive bidding or lotteries.

People who file complaints and the subject of the complaint are parties if the complaint is a formal complaint under § 208 of the Communications Act or the complaint shows that it was served on the subject of the complaint. (Earlier, it was noted certain kinds of complaints are treated as exempt.) A person who files a petition to revoke a license or other authorization or who files a petition for an order to show cause and the subject of the petition are parties. The subject of an order to show cause, hearing designation order, notice of apparent liability, or similar notice or order, or petition for such notice or order is a party.

In informal notice and comment rulemaking proceedings (except for those involving the allotment of a broadcast channel), and proceedings before a Joint Board or before the Commission to consider the recommendation of a Joint Board, members of the general public after the issuance of a notice of proposed rulemaking or other order are parties. In rulemakings for the allotment of a broadcast channel, the petitioners and those making responsive filings are parties.

The sunshine period prohibition imposes a restriction on presentations to Commission decision-makers in addition to the limitations otherwise applicable under the *ex parte* rules. It applies to proceedings in which the Commission has issued a Public Notice that a matter will be considered at a Commission meeting—that is, the matter has been placed on the "Sunshine Agenda." While the sunshine period prohibition is in effect, all presentations to decision-makers concerning matters listed on a Sunshine Agenda, whether *ex parte* or not, are prohibited unless they fall within certain exceptions. In particular, presentations are permitted if they occur in the course of a widely attended speech or panel discussion and concern a Commission action in an exempt or a permit-but-disclose proceeding that has been adopted. Members of Congress or their staffs and other federal agencies or their staffs may make presentations in exempt or permit-but-disclose proceedings, but presentations that are of substantial significance and clearly intended to affect the ultimate decision in the proceeding must be disclosed, either by the presenter or the Commission's staff.

The sunshine period prohibition applies from the release of a Public Notice that a matter has been placed on the Sunshine Agenda until the Commission releases the text of a decision or order relating to the matter, issues a Public Notice stating that the matter has been deleted from the Sunshine Agenda, or issues a Public Notice stating that the matter has been returned to the staff for further consideration, whichever occurs first.

Appeal to the Courts

After the Commission has considered and reconsidered a matter, interested parties may appeal the decision to the federal courts. Ultimately, the Supreme Court could hear the case. Under current law, however, the Commission need not wait for the court decision before enacting the new rules and regulations. As long as the matter has been given full consideration under the Administrative Procedures Act, the FCC may place the new rule in effect until a court rules to the contrary or orders a "stay."

1.4
FCC COMPLIANCE AND INFORMATION BUREAU

BY DAVID E. WILSON
NATIONAL ASSOCIATION OF BROADCASTERS, WASHINGTON, DC

OVERVIEW

The Compliance and Information Bureau (CIB) of the Federal Communications Commission (FCC) is responsible for providing information to the general public, resolving telecommunications interference problems and enforcing the FCC's technical rules. It also operates the network of FCC field offices throughout the United States.

Since the eighth edition of this handbook, many changes have occurred to the FCC's field office structure.

The most significant of these are:

The closing of numerous field offices across the country and their replacement with resident agents.

The elimination of individual public contact points at each field office and their replacement with a centralized National Call Center in Gettysburg, Pennsylvania.

The bureau name changed from Field Operations Bureau to the Compliance and Information Bureau.

In the course of this restructuring the number of CIB employees nationwide was reduced from nearly 400 to approximately 250.

As a result of these changes, the country is now divided into three regions of CIB responsibility—the Western Region, the South Central Region, and the Northeast Region. The Western Regional Director is responsible for the field offices in Denver, Los Angeles, San Diego, San Francisco, and Seattle, in addition to the resident agents in Anchorage, Honolulu, and Portland. The South Central Regional Director is responsible for the offices in Atlanta, Dallas, Kansas City, New Orleans, and Tampa, as well as the resident agents in Houston, Miami, Norfolk, and San Juan. The Northeast Regional Director is responsible for the offices in Boston, Chicago, Columbia (Maryland), Detroit, New York, and Philadelphia, and for the resident agents in Buffalo and St. Paul. Each of the cities covered by resident agents has two agents located there. There are no FCC offices in these cities, instead, all work is conducted out of the agents' homes.

Geographic Area Covered by Each Field Office

Table 1.4-1 provides an alphabetical listing of all states and territories under FCC jurisdiction. The table shows which FCC field office is responsible for each of the counties in every state and territory.

The mailing addresses for each of these offices are listed below. All telephone calls to the CIB should be directed to the FCC's National Call Center in Gettysburg (1-888-CALL-FCC).

Atlanta Office
Federal Communications Commission
3575 Koger Boulevard, Suite 320
Duluth, GA 30096-4958

Boston Office
Federal Communications Commission
1 Batterymarch Park
Quincy, MA 02169-7495

Chicago Office
Federal Communications Commission
Park Ridge Office Center, Room 306
1550 Northwest Highway
Park Ridge, IL 60068-1460

Columbia Office
Federal Communications Commission
9200 Farm House Lane
Columbia, MD 21046

Dallas Office
Federal Communications Commission
9330 LBJ Freeway, Room 1170
Dallas, TX 75243-3429

Denver Office
Federal Communications Commission
165 South Union Boulevard, Room 860
Lakewood, CO 80228-2213

Detroit Office
Federal Communications Commission
24897 Hathaway Street
Farmington Hills, MI 48335-1552

Kansas City Office
Federal Communications Commission
8800 East 63rd Street, Room 320
Kansas City, MO 64133-4895

Los Angeles Office
Federal Communications Commission
Cerritos Corporate Tower
18000 Studebaker Road, Room 660
Cerritos, CA 90701-3684

New Orleans Office
Federal Communications Commission
2424 Edenborn Avenue, Suite 460
Metarie, LA 70001

New York Office
Federal Communications Commission
201 Varick Street, Suite 1151
New York, NY 10014-4870

Philadelphia Office
Federal Communications Commission
One Oxford Valley Office Building, Room 404
2300 East Lincoln Highway
Langhorne, PA 19047-1859

San Diego Office
Federal Communications Commission
Interstate Office Park
4542 Ruffner Street, Room 370
San Diego, CA 92111-2216

San Francisco Office
Federal Communications Commission
3777 Depot Road, Room 420
Hayward, CA 94545-2756

Seattle Office
Federal Communications Commission
11410 NE 122nd Way, Room 312
Kirkland, WA 98034-6927

Tampa Office
Federal Communications Commission
2203 North Lois Avenue, Room 1215
Tampa, FL 33607-2356

Table 1.4-1
FCC Field Office Responsible for Each State/Territory

State	Area Served
Alabama	All counties are served by the Atlanta field office.
Alaska	All counties are served by the Seattle field office.
American Samoa	All counties are served by the San Francisco field office.
Arizona	All counties are served by the San Diego field office.
Arkansas	All counties are served by the New Orleans field office.
California	Kern, Los Angeles, Orange, San Bernardino San Luis Obispo, Santa Barbara, and Ventura counties are served by the Los Angeles field office.
	Imperial, Riverside, and San Diego counties are served by the San Diego field office.
	Alameda, Alpine, Amador, Butte, Calaveras, Colusa, Contra Costa, Del Norte, El Dorado, Fresno, Glenn, Humboldt, Inyo, Kings, Lake, Lassen, Madera, Marin, Mariposa, Mendocino, Merced, Modoc, Mono, Monterey, Napa, Nevada, Placer, Plumas, Sacramento, San Benito, San Francisco, San Joaquin, San Mateo, Santa Clara, Santa Cruz, Shasta, Sierra, Siskiyou, Solano, Sonoma, Stanislaus, Sutter, Tehama, Trinity, Tulare, Tuolumne, Yolo, and Yuba counties are served by the San Francisco field office.

Table 1.4-1 (*Continued*)
FCC Field Office Responsible for Each State/Territory

State	Area Served
Colorado	All counties are served by the Denver field office.
Connecticut	All counties are served by the Boston field office.
Delaware	Kent, Sussex, and New Castle (below C&D Canal) counties are served by the Columbia, Maryland, field office.
	New Castle (above C&D Canal) county is served by the Philadelphia field office.
District Of Columbia	All of the District is served by the Columbia, Maryland, field office.
Florida	Escambia and Santa Rosa counties are served by the Atlanta field office.
	All other counties are served by the Tampa field office.
Georgia	All counties are served by the Atlanta field office.
Guam	All counties are served by the San Francisco field office.
Hawaii	All counties are served by the San Francisco field office.
Idaho	All counties are served by the Seattle field office.
Illinois	All counties are served by the Chicago field office.
Indiana	Allen, De Kalb, Elkhart, Fulton, Kosciusko, La Grange, Marshall, Noble, St. Joseph, Steuben, and Whitley counties are served by the Detroit field office.
	All other counties are served by the Chicago field office.
Iowa	All counties are served by the Kansas City field office.
Kansas	All counties are served by the Kansas City field office.
Kentucky	Bath, Bell, Boone, Bourbon, Boyd, Bracken, Breathitt, Campbell, Carter, Clark, Clay, Elliott, Estill, Fayette, Fleming, Floyd, Franklin, Gallatin, Garrard, Grant, Greenup, Harlan, Harrison, Jackson, Jessamine, Johnson, Kenton, Knox, Knott, Larel, Lawrence, Lee, Leslie, Letcher, Lewis, Lincoln, Madison, Magoffim, Martin, Mason, McCreary, Menifee, Montgomery, Morgan, Nicholas, Owen, Ownsley, Pendleton, Perry, Pike, Powell, Pulaski, Roberston, Rockcastle, Rowan, Scott, Wayne, Whitley, Wolfe, and Woodford counties are served by the Detroit field office.
	All other counties are served by the Chicago field office.
Louisiana	All counties are served by the New Orleans field office.
Maine	All counties are served by the Boston field office.
Mariana Islands	All counties are served by the San Francisco field office.
Maryland	All counties are served by the Columbia, Maryland, field office.
Massachusetts	All counties are served by the Boston field office.
Michigan	Alger, Baraga, Delta, Dickinson, Gogebic, Houghton, Iron, Keweenaw, Marquette, Menominee, Ontonagon, and Schoolcraft counties are served by the Chicago field office.
	All other counties are served by the Detroit field office.
Midway Islands	All counties are served by the San Francisco field office.
Minnesota	All counties are served by the Chicago field office.
Mississippi	All counties are served by the New Orleans field office.
Missouri	All counties are served by the Kansas City field office.

Table 1.4-1 (*Continued*)
FCC Field Office Responsible for Each State/Territory

State	Area Served
Montana	All counties are served by the Seattle field office.
Nebraska	All counties are served by the Kansas City field office.
Nevada	All counties are served by the San Francisco field office.
New Hampshire	All counties are served by the Boston field office.
New Jersey	Bergen, Essex, Hudson, Hunterdon, Mercer, Middlesex, Monmouth, Morris, Passaic, Somerset, Sussex, Union, and Warren counties are served by the New York field office. Atlantic, Burlington, Camden, Cape May, Cumberland, Gloucester, Ocean, and Salem counties are served by the Philadelphia field office.
New Mexico	All counties are served by the Denver field office.
New York	All counties are served by the New York field office.
North Carolina	All counties are served by the Kansas City field office.
North Dakota	All counties are served by the Chicago field office.
Oklahoma	All counties are served by the Dallas field office.
Ohio	All counties are served by the Detroit field office.
Oregon	All counties are served by the Seattle field office.
Pacific Trust Territories & Commonwealth	All counties are served by the San Francisco field office.
Pennsylvania	All counties are served by the Philadelphia field office.
Puerto Rico	All counties are served by the Tampa field office.
Rhode Island	All counties are served by the Boston field office.
South Carolina	All counties are served by the Atlanta field office.
South Dakota	All counties are served by the Denver field office.
Swains Island	All counties are served by the San Francisco field office.
Tennessee	All counties are served by the Atlanta field office.
Texas	All counties are served by the Dallas field office.
Utah	Emery, Garfield, Grand, Kane, Piute, San Juan, Sevier, and Wayne counties are served by the San Diego field office. All other counties are served by the San Francisco field office.
Vermont	All counties are served by the Boston field office.
Virgin Islands	All counties are served by the Tampa field office.
Virginia	Arlington, Fairfax, Loudoun, and Prince William counties are served by the Columbia, Maryland, field office. All other counties are served by the Kansas City field office.
Wake Island	All counties are served by the San Francisco field office.
Washington	All counties are served by the Seattle field office.
West Virginia	All counties are served by the Columbia, Maryland field office.
Wisconsin	All counties are served by the Chicago field office.
Wyoming	All counties are served by the Denver field office.

FCC National Call Center

All telephone inquiries to the CIB field offices are now handled through the FCC's toll-free National Call Center in Gettysburg, Pennsylvania. The number for the call center is: 1-888-CALL-FCC (1-888-225-5322). Broadcasters may call this number to check the status of pending license applications. They may also use it to report interference problems and request FCC enforcement action. For example, recently the CIB received complaints from many broadcasters about pirate radio operations. These complaints led to FCC enforcement actions across the country.

COMMON TECHNICAL COMPLAINTS ABOUT BROADCASTERS

The complaint-resolution aspect of the CIB's function has a flip side to it—CIB also handles complaints received from the public about broadcasters. Usually the complaints that come from the public regarding broadcasters deal with non-technical issues such as program content. However, some public complaints are related to the technical side of broadcasting. For example, complaints about broadcast signals causing telephone interference and blanketing interference are very common. To maintain good public relations, and avoid FCC penalties for non-compliance, broadcasters should be particularly aware of their responsibilities in these two common complaint areas.

Blanketing interference is a phenomenon that occurs when a strong signal from a nearby transmitter overloads the front end of a receiver and thus prevents the receiver from receiving other signals. The FCC rules clearly define the extent of the area around a radio broadcast antenna that is considered to be blanketed. For AM stations, this area is the region encompassed by the 1 V/m contour (see Section 73.88). For FM stations, it is the 562 mV/m contour (see Section 73.318). No specific contour has been defined as the *blanketing contour* for TV stations, although TV broadcasters are required to correct reasonable complaints of blanketing interference within the immediate vicinity of new or recently modified transmission facilities (see Section 73.685(d)). Broadcasters who build new or modified facilities that require an FCC construction permit are required to correct all blanketing interference problems for which complaints are received within one year after program tests begin.

Broadcasters are not required to correct interference to telephones unless it is the rare case of a receiver in a cordless telephone being "blanketed" by a nearby broadcast transmitter. Neither standard wired telephones nor cellular telephones are covered by the FCC's blanketing rules. Nevertheless, in order to maintain a good relationship with their community, many broadcasters do provide assistance to consumers who experience interference to their home phones.

As this *Handbook* goes to press, the FCC is considering changes to its blanketing rules in MM Docket 96-62. Broadcasters frequently should consult a current version of the FCC's rules and regulations to determine if their blanketing responsibilities have changed.

The *Interference to Home Electronic Entertainment Equipment Handbook*, Bulletin CIB-2 is a publication that helps explain interference issues to the general public. The booklet describes various types of interference to consumer electronic devices and recommends various corrective actions. It also provides information about suppliers of RF filtering devices. It is available from the FCC's website at www.fcc.gov and the U.S. Government Printing Office.

SELF-INSPECTION CHECKLISTS

The CIB role that is probably of most concern for many broadcasters is its program of inspecting broadcast facilities. Most CIB inspections are conducted without prior notice to the licensee. Most times these inspections will involve a visit to the station's studios, transmitter and/or transmitter control points. However, on some occasions, the FCC may simply monitor the station's signal off the air for compliance with modulation and spurious emission limits.

The CIB has prepared self-inspection checklists for AM, FM and TV stations. These checklists provide descriptions of the most frequently-violated broadcast regulations, references to the rule sections where these regulations can be found, and check-boxes that station personnel may use to keep track of their compliance status for each item. Copies of these checklists can be obtained from any CIB field office or from the FCC's website.

FCC FINES

In 1997, the FCC revised its guidelines for assessing forfeitures in cases of non-compliance with its rules. A base forfeiture amount is assigned for various types of violations. However, the forfeiture amount can be adjusted upward for one or more of the following reasons:

Egregious misconduct
Ability to pay/relative disincentive
Intentional violation
Substantial harm
Prior violations of any FCC requirements
Substantial economic gain
Repeated or continuous violation

The fine can also be adjusted downward for these reasons:

Minor violation
Good faith or voluntary disclosure
History of overall compliance
Inability to pay

The types of violations most likely to concern broadcasters, and their associated base forfeiture amounts, are listed in Table 1.4-2. These amounts are for each violation. The reader should note, however, that in cases where a particular violation continues for multiple days the FCC considers each day of the continuing violation to be a separate violation. Also, the FCC has the option of applying alternative or additional sanctions as permitted by law.

Table 1.4-2
Base Fine Amounts for Various FCC Violations

Violation	Fine
Misrepresentation/lack of candor	$25,000
Construction and/or operation without an instrument of authorization for the service	$10,000
Failure to comply with prescribed lighting and/or marking	$10,000
Violation of public file rules	$10,000
Violation of political rules: reasonable access, lowest unit charge, equal opportunity, and discrimination	$9,000
Unauthorized substantial transfer of control	$8,000
Violation of children's television commercialization or programming requirements	$8,000
EAS equipment not installed or operational	$8,000
Failure to maintain directional pattern within prescribed parameters	$7,000
Violation of main studio rule	$7,000
Violation of broadcast hoax rule	$7,000
AM tower fencing	$7,000
Failure to permit inspection	$7,000
Transmission of indecent/obscene materials	$7,000
Interference	$7,000
Exceeding of authorized antenna height	$5,000
Fraud by wire, radio or television	$5,000
Unauthorized discontinuance of service	$5,000
Use of unauthorized equipment	$5,000
Broadcasting telephone conversations without authorization	$4,000
Exceeding power limits	$4,000
Failure to respond to Commission communications	$4,000
Violation of sponsorship ID requirements	$4,000
Unauthorized emissions	$4,000
Using unauthorized frequency	$4,000
Failure to engage in required frequency coordination	$4,000
Construction or operation at unauthorized location	$4,000
Violation of requirements pertaining to broadcasting of lotteries or contests	$4,000
Violation of transmitter control and metering requirements	$3,000
Failure to file required forms or information	$3,000
Failure to make required measurements or conduct required monitoring	$2,000
Violation of enhanced underwriting requirements	$2,000
Failure to provide station ID	$1,000
Unauthorized pro forma transfer of control	$1,000
Failure to maintain required records	$1,000

ALTERNATIVE INSPECTION PROGRAM

The FCC has teamed up with some state broadcaster associations to implement a self-inspection program that enables broadcasters to avoid surprise FCC inspections. The Alternative Inspection Program (AIP) is a voluntary program that provides broadcasters with an opportunity to demonstrate compliance with the FCC rules without an actual FCC inspection and the accompanying threat of citations and fines. Under the AIP, a state broadcaster association-designated person, who is not an FCC employee, will inspect a station at the station's request. There is usually a nominal fee associated with the inspection. If the broadcaster is found to be in compliance with the FCC rules, a Certificate of Compliance will be issued and the FCC will be notified. If the station is found not to be in compliance it will be notified of the reason(s) for its failure but the FCC will not be notified of the inspection. The FCC field offices have agreed not to conduct a surprise inspection of any station that has received a Certificate of Compliance under the AIP for two or three years after the certificate is received. The exact duration of this "no surprise inspection" period depends on the particular field office involved. A field office might still inspect a station that has received a certificate, however, if it has a reason to believe that the station is not operating in compliance, such as when the FCC receives a complaint about the station's operation.

Broadcasters who wish to participate in an AIP should contact their state broadcaster association to find out if the program is available in their state.

1.5
FREQUENCY COORDINATION

ROBERT VAN BUHLER
KNIX-FM/TEMPE, ARIZONA

RICHARD RUDMAN
RADIO STATION KFWB, LOS ANGELES, CALIFORNIA

WHAT IS FREQUENCY COORDINATION?

The push to leave the studio to originate programs has been a part of broadcasting from the beginning. Now with over 12,000 radio and 1,500 TV stations on the air, the demand for reliable ways to get news, sports, public affairs, and entertainment programming from the field back to the studio has naturally increased. Part 74 of the FCC's Rules deals with segments of the spectrum that have been assigned to the Broadcast Auxiliary Service (BAS) to accommodate this demand. Part 74 also covers other services outside the scope of this discussion, such as FM and TV translators, Low Power TV, ITFS, and experimental broadcast stations.

While the number of stations requiring support spectrum has grown tremendously since 1970, the amount of spectrum allocated for this support has decreased. Broadcasters using Part 74 spectrum began to experience competition for the limited number of channels allocated not only among broadcasters, but also among the other users who share some of the Part 74 spectrum such as cable operators. Interference from other broadcasters has gradually become a critical problem in many markets and there are no provisions for exclusive licensing in Part 74. Consequently, frequency coordination is necessary to facilitate the allocation of limited spectrum for a growing number of uses among a growing number of users.

The coming age of personal communication brings new pressures. The FCC has already designated a portion of broadcast auxiliary 2 GHz spectrum for other users. While there may be some hope for replacement spectrum, there are no longer any certainties. We must face the fact that we may not have sufficient spectrum to meet our own growing needs. The reality of digital television as well as the prospect of digital AM and FM mean that our needs for auxiliary spectrum for high quality transmission will certainly grow. The need to keep our coordination efforts alive and active will be greater than ever ass pressures from both sides increase. We should also look carefully at the very technologies that are driving spectrum refarming for solutions to our needs.

Some History of Broadcast Coordination

Formal coordination has existed for some time for major events such as the Olympics, political conventions and space launches. In the case of the political conventions, the major national television networks have rotated the chairmanship of an ad hoc group, known as the National Political Conventions Frequency Coordinating Committee. Washington, D.C. has had unique coordination problems along with a history of cooperative effort for pool feeds to cover events of national interest. Such committee activity has traditionally arisen out of a need, mutually felt by broadcast engineers, to discuss concerns before they become problems. Among the oldest groups formed to deal with mutual operational problems, including coordination, were the Washington Executive Broadcast Engineers (WEBE) and the TV Broadcasters All-Industry Committee in New York.

The first major region to form a committee to deal exclusively with Part 74 coordination was Southern California. In 1976, the FCC revised Part 74, Subpart D, of its Rules, which deals with the Remote Pickup Service used by radio and television stations for dispatch, on-air remote pickup, cues and orders, communications and transmitter telemetry. Recognizing the use of narrowband FM telemetry. Recognizing the use of narrowband FM technology, the Commission reallocated the UHF (450 and 455 MHz) frequencies from wideband 100 kHz channels to smaller bandwidth 50 kHz, 25 kHz and 10 kHz channels. Under the FCC's 1976 changes, R and S channels were intended for program material, and cues and orders necessary to implement that programming. N1 and N2 channels were to be used for broadcast program material, cues and orders necessary to that material, and operational communications. Microwave path setup and dispatch functions fall under this last category. P channels may be used only for Operational Communications and telemetry. In 1980 the FCC granted the Southern California Frequency Coordinating Committee (SCFCC) a waiver which further split the S and N1 channel as shown in Table 1.5-1.

Note that since the SCFCC plan allows for center

Table 1.5-1
1976 FCC 450 Channel Plan Showing SCFCC Waiver Changes

Channel Waiver Designation	Channel Bandwidth	Peak FM Deviation	Total # of CHS.	Total # of SCFCC Channels
N1	50 kHZ	10 kHz	12	0
N2	25	5	24	60
R	50	10	10	14
S	100	35	2	0
P	10	1.5	8	8

channel use of the split N1 50 kHz channels, the maximum number of 25 kHz channels can jump from 24 to 60 since the center channel can be used when geographic separation and or terrain shielding permit.

The FCC will now accept license applications based on channel segments of 5 kHz. These 5 kHz segments can be stacked for the Part 74 VHF high band and for UHF band to form channels of the required bandwidth for a given use. Users should consult either their local coordination group or the FCC's Auxiliary Branch in Washington about a local band plan if questions arise. Regions considering formation of a coordination group can study existing band plans based on segmented channels before implementing new plans. No examples of band plans are given. Plans must be custom tailored for each region.

Coordination activity spans many aspects of broadcasting. Some regions have not experienced congestion and interference with their own licensees, but have organized committees to deal with problems associated with broadcasters who enter their regions for temporary operation. After conducting a survey at the chapter level on how this problem is viewed locally, the Society of Broadcast Engineers (SBE) has for many years identified frequency coordination as a chapter project. The SBE National Frequency Coordinating Committee (NFCC) was formed to assist any chapters interested in this project. In addition, the SBE NFCC publishes quarterly a list of volunteer coordinators who are responsible for over 100 regions in 50 states, plus Puerto Rico.

If there is one adjective that can be used to describe the nature of effective frequency broadcast coordination that word is local. Electronic news gathering (ENG) for both radio and television introduces many unknowns. Mobile paths cannot be predicted from day to day, or even hour to hour. Large scale news, public affairs, or sporting events may mean interference for everyone involved unless technical personnel familiar with a number of factors are consulted. Since many of these factors are dependent on local propagation anomalies, terrain considerations, and user patterns, experience has proven that engineers who work with these factors at the local level on a day-to-day basis are the best people to consult with and to ask for advice for successful operations.

Propagation Characteristics

A number of factors can modify the expected line-of-sight characteristics of VHF and UHF aural and visual transmission. Many of these can be understood best if the radio waves as affected are compared to light travelling through the reflective surfaces of a periscope so the viewer can see around corners.

The three most common propagation anomalies are: (1) ducting effects, (2) reflection due to thermal inversion layers and (3) obstacle gain (sometimes referred to as knife edge refraction).

These anomalies can occur for seconds at a time, or may exist in a predictable manner for much longer periods. For instance, obstacle gain can be used in some cases to provide permanent and quite dependable links. In the Part 74 environment, these anomalies have to be recognized and taken into account to assure co-channel and adjacent channel users of adequate protection for both fixed and mobile links. Known anomalies in a region must be factored into any coordinated environment. As in the case of terrain, licensees should seek out engineers who have longtime experience in the region to coordinated so anomalies that have been identified, and the paths they affect, can be taken into consideration.

THE BROADCAST COORDINATION PROCESS

Successful coordination efforts are all founded on licensee-to-licensee contact. The coordination effort, however it is structured, acts to facilitate this contact. As of this writing, Part 74 of the FCC's Rules places the burden of preventing interference squarely on the licensee. Since broadcasting is highly competitive, no local committee should place itself in a position where it assigns spectrum. Eligible radio, TV, cable and other selected entities have an equal right to use shared frequencies specified under Part 74 or part 78 of FCC Rules and Regulations, subject only to the service and classifications contained therein. No action taken by a coordination committee should restrain these privileges in any way.

Unless otherwise determined by future FCC actions, committees are voluntary facilitators of the coordination process. The committee has no authority to force adoption of its recommendations. Successful committees never act as policemen. This role is left to the FCC if all other means of settling disputes fails. However, committees can and do use neutral mediators to try to solve the inevitable problems and disputes that arise in a competitive world. The committee exists to facilitate coordination, not to enforce it.

A chaotic situation would already exist in most markets if the engineering community had not developed fundamental coordination techniques and practices. Many cable and network entities, production originally users, and others who now have access to spectrum intended to serve only the needs of local broadcasters would not be able to operate reliably otherwise.

The broadcast or cable engineer does not operate in a purely technical environment when it comes to frequency coordination. It is an art and technical discipline that extends beyond the skills normally found in the engineering department. There are other key players whose cooperation and participation is essential to efficient frequency coordination.

A news director can create a climate of efficient spectrum management in a radio or TV operation by stressing the importance of adhering to good operating practice and home channel plans.

Both news and engineering managers must realize that frequency (or channel) information must be shared by users for coordination to succeed. The ultimate goal is interference-free operation for all users. This goal must be kept in mind whenever Broadcast Auxiliary Spectrum/Cable TV Relay Service (BAS/CARS) frequencies are employed. Cooperation from all parties, and an active and supportive leadership example from engineering and news managers in charge, is essential. Radio/TV station and cable general managers can make frequency coordination possible by allowing engineers the time and financial support needed to get the job done. Many progressive local broadcast associations have seen value in underwriting the costs of frequency coordination by providing computer equipment, postage, stationery, duplication expenses and other support to make frequency coordination a success.

General managers are vital to the process in another way. In a growing number of stations, engineering is provided by a contractor whose services are limited to maintenance and repair. By nature of their contract, these providers have very little input on the design of mobile systems or fixed links. In such cases, it is important that the manager insist that his BAS/CARS equipment applications and operation be handled harmoniously with the needs of the local coordinating committee and the broadcast and cable community it serves.

Station or system managers should know if their engineers are involved in frequency coordination. The best approach is to meet with the engineer and discuss the importance of coordination to the well being of the broadcast and cable community.

Simply requiring chief engineers to attend regular coordination meetings is helpful to the coordination process. By attending the meetings, the engineer is familiarized with the process and becomes acquainted with license changes and coordination problems occurring in the market.

In addition to the reasons mentioned that might lead broadcasters to start coordination activity, one more must be added. Many broadcasters now travel outside their markets to cover news, sports, or public affairs events. In 1983 the FCC revised Section 74.24 of the Rules to make it easier for broadcasters to cover such events. A footnote to this Rule change asked that regional coordinators make themselves known to the Commission. The SBE NFCC was first formed to compile a list of coordinators to go beyond the Commission's request.

COORDINATOR CONSIDERATIONS FOR VARIOUS BROADCAST USES OF PART 74 SPECTRUM

Dispatch and Aural Remote Pickup

Channels for this purpose are currently available in a range from 26 MHz to and including 455 MHz.

In major markets experiencing congestion, and in other markets where older equipment is still in service, 26 MHz operation for dispatch and even some types of remote pickup are still being done. Lower power cueing systems for TV field operations sometimes appear in this band. Since it is near to present Citizen's Band channels, it is subject to interference from this service. Propagation conditions at 26 MHz include skip so it is common to experience interference in this band from hundreds, or thousands, or miles away at certain times of the year.

VHF dispatch and aural remote pickup are more common throughout the country. With the advent of excellent commercial narrowband FM mobile transceivers and remotely operated base stations on hills and mountains, many radio and TV stations have used Part 74 VHF channels reliably for years.

Committees will be confronted with a number of seemingly conflicting uses and users as they sort through the years of accumulated problems in VHF and UHF bands. One guiding principle that has helped many committees is the order of priorities outlined by the FCC in Section 74.403(b). The transmission of remote pickup program material for broadcast, either live or delayed, takes precedence over other permissible uses.

VHF and UHF remote pickup with usable audio frequency response to 15 kHz is available with a variety of equipment. In many regions, interference from adjacent channels licensed to other services makes such operation difficult. A strong adjacent channel signal can capture a FM receiver, pulling the discriminator away from the desired signal. As channel use builds in a region, broadband white noise rises, making life difficult for wideband receivers.

Some equipment marketed for broadcast use was not designed for today's levels of channel congestion and sometimes makes the problem appear worse than it really is.

Transmitters should always be connected to antennas through ferrite isolation devices and harmonic filters to minimize generation of mixing products in solid state finals. This applies to repeaters, base stations, and mobile transmitters. This was not as important in the days of tube finals, but is critical in today's nonlinear solid state world. Ferrite isolators are used for simplex transmitters. Ferrite circulators are used for repeaters.

Receivers can use combinations of attenuators, helical tuned circuits and cavity filter to protect against first stage overload from out of channel emissions. This is especially important since the 450 MHz Part 74 allocations are within 1 MHz of Land Mobile dispatch and paging bands. Paging transmitters operating at 250 W commonly employ two-way sites also used by broadcasters and can easily overload an unprotected receiver.

Broadband white noise at common sites is now being viewed as much of a culprit to degraded receiver performance as spurious emissions. As the number of transmitters at a site increases, the noise level at the site increases. This noise desensitizes all receivers at the site. If a user is operating a receiver at a common site used for high power paging transmitters that are on the air most of the time, the receiver may be trying to listen in a channel less than 1 MHz away from a 250 W transmitter with a high gain antenna. The resultant 1000 W (ERP) can cause problems for even the best equipment. Committees can educate members on this subject as well.

At quiet sites, receivers with GAsFET preamplifiers working with preselector/filter network receivers have been used successfully to increase receiver sensitivity or regain insertion losses from various filter elements. Careful design can prevent overloading the receiver with the add-on preamplifer.

Remotely located (satellite) receivers will give users better coverage and better immunity to various types of interference. It is desirable to locate satellite receivers at receive-only locations. Such locations can be selected after spectrum analysis shows that adjacent channel and out-of-band emissions are well within the receiver's ability to function at an optimal performance level. Receive-only locations are also good places to utilize high gain GAsFET preamplifiers. Local coordination groups may be of service in locating such sites, and maintaining their RF integrity. Getting the receiver closer to the transmitter is always preferable to increasing transmitter power as a technique to improve reliability. Leased program circuits can deliver audio back to the studio.

Committees can educate members on the pitfalls of common sites, and work with site managers to let them know of licensee concerns. There is a trend in many markets toward re-engineering common sites using transmitter and receiver combiners, and physical separation of transmit and receive antennas. These changes can improve the transmit and receive performance at most sites. Changes like this are expensive. A committee can educate users on the benefits of such projects, and help generate support to make them happen.

Committees can also make members aware of non-Part 74 licensing options for broadcasters who require two-way communications which are not related to Part 74 priorities such as the business band spectrum or cellular telephones. Cellular telephones have been used by many stations for some years now for coverage of news and even program length material. The FCC makes no distinction between cellular and wired telephones for the purpose of broadcast transmissions as of this writing. Stations should check, however, to see how and if broadcast use of cellular phones conforms with state telephone tariffs. Extended cellular transmissions from any site that can lock up a number of cells may be an abuse of the cellular system.

The two blocks of UHF channels available to broadcast licensees are separated by 5 MHz. This is adequate for repeater operations, and many licensees in markets with hilly or mountainous terrain have employed this type of system to allow field units to communicate with the base no matter where they are. The convention of repeater pair frequencies is that the 455 group be used for the repeater output. Many markets have taken great pains to correct reversed situations for mutual benefit. Simplex channels have to treated on a case-by-case basis. Repeater operation has the benefit of being truly wireless, since remote base systems usually depend on telephone company local channels for control and audio. Unfortunately, repeater operation requires two channels.

Spectrum efficiency in the UHF bands by splitting channels is an accepted mode of operation in some markets. Since it is possible to drive audio response beyond 5 kHz from a 25 kHz narrowband FM channel, many radio stations which want better audio quality for news reports can get it without using a 50 kHz R channel, provided the receiver used is well into full quieting. Committees can work with their members to make sure everyone is using the least amount of bandwidth consistent with needs.

Similarly, a station engaged in voice dispatch does not need a 50 kHz N1 channel. A 25 kHz N2 channel is more than adequate for this use. Responsible committees can help assure that use is matched to bandwidth.

Narrow band radio systems that exhibit better that 5 kHz audio response with 5 kHz FM deviation made possible use of splinter or offset channels where distance separations and relative transmitter power levels would permit. High performance receiver IF filters have been in use for this purpose since the early '80s, usually as a part of audio processing modifications to FCC type accepted transmitters that required an FCC modified type acceptance. Built on a firm base of existing rugged mobile equipment, such systems proved that further channel splitting was practical. Receivers designed to take advantage of the spectrum efficiencies of low FM modulation indexes are now coming to market. These receivers promise even greater quality improvements along with greater spectrum efficiency.

High Band VHF and UHF Coordination

Committees can sometimes arrange sharing of channels between users. This can even involve several licensees operating a community repeater system. This choice not only helps enhance spectrum efficiency, but may mean small stations can become part of a larger system they could not otherwise afford. The following are guidelines for new users of Part 74 communications:

1. The potential user should understand that he must be a part 73 licensee, or a network (as defined in Part 74) to qualify for Part 74 channels.
2. Know that the committee really exists to help accommodate new users in bands already crowded—not to keep new users out.
3. The potential user should explain his needs during an open committee meeting, and publish what is said in the newsletter so everyone concerned can be aware of what is going on. It may be that someone at the meeting might make a suggestion to the potential user that could improve his system, or even accommodate his needs by some other means. For instance, cellular mobile telephone might be all someone needs to do ENG microwave setup if there are no dispatch channels left in the market.

4. The committee may recommend certain frequencies. At this point, it is up to the potential licensee to contact each co-channel and adjacent channel occupant and complete the transaction. It is NOT the responsibility of the committee to do this.
5. In the event the parties reach an impasse regarding an issue, the committee can and should act as a mediating force. Usually a compromise can be arranged.

In a congested RF environment, there is always the possibility of adjacent channel interference. Mobiles operating in the field can find themselves next to other mobiles transmitting on an adjacent channel. If this channel happens to be on the repeater output of the first station, the person in the mobile cannot communicate with its base while the other mobile has its transmitter on. If this is a chronic problem, one station may find it desirable to change frequencies. No amount of after the fact coordination can ever solve all of these problems.

There is at least one operating practice a committee can promote that will help: make it a standard in the market for each licensee to use the appropriate station identification and unit designator call sign. Not only is this in compliance with FCC Rules, but call signs make it easier to track down interference problems that will inevitably arise.

Wireless Microphones

Wireless microphone are becoming more common and should not be overlooked in the coordination process. Coordinators are often asked to act as a clearinghouse for major events where a large number of such mikes are in use. Wireless microphone operation is a permitted use in the band specified in Part 74.802.

Non-RF Alternatives

There are non-RF alternatives available for STL systems. Laser links are feasible for very short distances where there is little likelihood of any interruption of the line-of-sight path.

Many stations still rely on program channels leased from their local telephone company. For short distances that do not involve very many telephone exchanges, this may still represent the best solution for some stations. This may be true especially in markets that have reached STL saturation.

TV MICROWAVE CONSIDERATIONS

Television has come to rely on their own or common carrier microwave links to interconnect their studios with their transmitters and to facilitate live remote broadcasts. Rules governing links operated by broadcasters are found in Part 74 of the FCC Regulations and cover frequencies from 2, 2.5, 5, 6, 4, 7, 13, 18, 21, 23 and 40 GHz bands.

Microwave transmissions can accommodate one or more subcarriers imbedded in the video signal to carry mono or stereo television sound, aural service for a coo-owned AM or FM station, program cueing, telemetry, or a combination of these elements. In congested markets one should use the lowest possible subcarrier frequency combinations to keep occupied bandwidth as low as possible.

In major markets the number of stations engaged in field operations exceeds the number of available channels. While spectrum is available in the 2, 2.5, 6.4, 7, 13, 18, 23, and 40 GHz bands at this time, many stations and coordinating committees in these major markets have opted to make 2 GHz the primary band for ENG. However, this band will have some level of STL and Inter-City Relay (ICR) activity for the foreseeable future due to its long haul propagation characteristics.

The use of 2 GHz for ENG with its better propagation characteristics means stations have to install fewer ENG receive locations in their service area. Path lengths up to 50 miles can be operated reliably and under optimum conditions, including low humidity, path lengths up to 100 miles may be possible.

In many markets, there is intense competition for the seven primary 2 GHz channels (1.9 through 2.1 GHz) and for the 2 (+1 grandfathered) channels at 2.5 GHz. The 2.5 GHz band is shared with other user such as the industrial, scientific, and medical (ISM), service and the private operational fixed microwave service.

Stations having 2 GHz STLs have been, for the most part, relocating to 7 or 13 GHz for several reasons. First, they may themselves be involved in 2 GHz ENG. Second, a fixed link in this band has a high potential risk of interference from mobile operations. Since modern TV ENG portable equipment is frequency agile, and non-technical personnel are more involved in field operations, this is a very real risk.

Coordination for ENG is being done more and more on a real time basis. Coverage of breaking news cannot be planned. Coupled with the limited number of 2 GHz channels, coordination will only be more difficult in the future.

Suggested Operational Guidelines for TV ENG Operations—The Home Channel Plan

1. Form a Microwave Subcommittee. Compile a list of persons responsible for ENG technical and operational decisions at each station. This list should contain telephone numbers providing access 24 hours a day. This list should be circulated to all stations involved in ENG operations and be updated as needed.
2. The Microwave Subcommittee should be a forum to devise a Home Channel Plan for the region. The purpose of this plan is to give each user a primary channel for his operation. Alternate polarization is assigned to each channel. Split channel operation should be the long range goal for the market. Every user is furnished with a copy of this plan for reference.

3. As part of this plan, each user should set a goal to become frequency, polarization and power agile.
4. Once the Home Channel Plan has been developed a method of coordinating this plan in real time is needed. This can be accomplished by a hard wired ring down network between ENG control points, by using a two-way radio system with base stations located at the control point of each ENG license or by establishing and maintaining a list of phone numbers for ENG control points of all participating stations.
5. Each licensee should equip the ENG operation at the following level:
   - Mobile transmitters should be frequency agile.
   - Each transmitter shall have continuously variable control of output power.
   - Each mobile truck should ideally be equipped with an antenna with excellent sidelobe suppression of the silhouette type.
   - Each mobile truck should be capable of changing the polarity of their feed.
   - Each truck should have a means of identifying its test bars, and ideally be able to identify its transmission in the vertical interval. If this latter type of equipment is employed, the ID is viewed by unlocking the vertical hold control of a video monitor.
   - Use frequency agile ENG receive sites with remote steerable antennas.
   - Employ multiple receive sites.
   - Use steep-skirted channel filters ahead of receivers.
6. Truck crews are instructed never to light up until they receive permission from their control point, even on their home channel.
7. Truck crews should receive careful instruction on polarity settings; using only enough power for the path involved, and in the overall operational agreements with other stations engaged in ENG activity.
8. Stations normally stay on their home channel. They use the ENG control point communication system to request different channels for extra activity, to eliminate inevitable adjacent channel interference during some operations, or for paths that conflict on their home with ICR links, or STLs. The request is made of the station which is assigned the desired channel as its Home Channel.
9. Remember, no one really owns a channel. Anyone might be called upon to share his or her channel on a real time coordination basis.

The plan must enjoy unequivocal support from all levels of management. It is imperative that this support be articulated and understood throughout the entire ENG operation, both in technical and non-technical areas, verbally and in writing.

All reasonable requests for temporary sharing of channels must be accommodated.

Spectrum use for all major events should be preplanned. When advance notice of a major event is given, a coordinator is assigned. Requests for channel assignment are solicited, operating channel assignments are made, and contingencies considered and addressed.

Examples of this would include community celebrations of a regional or national interest, a papal visit to a particular market or the opening of the United Nations General Assembly. On a larger scale, examples would include Olympic coverage or political conventions. The foregoing are documented examples of successful coordination.

Temporary Operation for TV Microwave RPU

As in the aural services, temporary operation away from a station"s service area without a special license is permitted for up to 720 hours or 30 days per year under Section 74.24 of the rules. As mentioned earlier in this chapter, the Coordinator Listing compiled and maintained by the SBE can make coordination for this type of operation less painful. The coordination burden is still on the licensee who is visiting not to cause interference to the local stations.

During this type of operation, visitors should use their broadcast on-air call sign, not their Part 74 call sign. They should work closely with the local coordination group. Confirm all communications in writing.

A visiting broadcaster should also obtain an accurate database to determine existing co-channel and adjacent channel users. If such a database is not available through a local coordinator, it is incumbent on the temporary user to accurately ascertain who would be affected.

It is important to notify existing co-channel and adjacent channel users of the intended link giving transmitter power output, dates and times of operation, and antenna type and gain information. Exchange names, addresses and 24-hour telephone numbers.

An engineering study of the path should be performed. This should include detailed path calculations. Several computer programs using accepted path consideration algorithms are available from a number of sources, including the SBE NFCC.

A field spectrum analysis is a valuable tool for engineering any link, fixed or temporary. It may uncover licensees who have not been entered in the database, newly authorized construction that may interfere with the path, temporary users who have not notified affected licensees or the local coordination group, Section 74.24 users, or multipath from co-channel links on different paths.

This rule is primarily designed to cover special events and should not be substituted for filing licenses.

Major Event Frequency Coordination for RF Equipment

The FCC has traditionally recognized ad-hoc coordination groups for many years for events such as the national political conventions, major sporting events such as the Olympic Games and the America's Cup races, and news events like NASA shuttle launches and landings.

Such events require a great deal of planning and hard work. Preparation for the national conventions typically begin 24 to 18 months in advance, although no substantive work can commence until the city sites are announced.

The FCC's normal course of action for such events is to suspend Section 74.24 of the Rules for a period before and during the event. This has the effect of requiring all Part 73 licensees wanting to use RF equipment of any type at the event to contact and coordinate with other users via the ad-hoc coordination group.

SBE, through its Washington, D.C. attorney will assist local groups with making the proper request and showing to the FCC for such a waiver to be issued for an event.

If an event takes place in an enclosed venue, it may be possible to use channel in use by local broadcasters outside the venue. Using very low power transmitters is an excellent way to allow a number of users to coexist inside such a venue. A large number of hand-held transceivers can often be used in adjacent channels by simple expedient of removing the rubber duck antenna and substituting a 50 Ω termination resistor. TV microwave transmitters should be cut back or attenuated to 50-11 mW. If all users cooperate, receivers in the various bands being used will be quite happy, and the needs of all users will be met with little or no interference.

Weekend events may make it possible to use TV and radio ENG channels only used during weekdays. Compatible sharing should take place in the spirit of good cooperation between engineers.

Assuring all equipment used for such events is working properly is an important consideration. While this is the responsibility of the licensee, the coordinating body can sometimes help them deal with this burden. Various techniques have proven to be effective. For example, the FCC usually sends one of its sophisticated trucks to the major political conventions to look for spurious and unauthorized emissions. NASA and the United States Air Force usually check all equipment as it comes into Edwards Air Force Base for Shuttle landings. NASA requires everyone to participate in a full light up test two hours before each landing. For smaller events, local groups commonly borrow or rent a spectrum analyzer as a service to guest broadcasters.

If it is not possible to accommodate all users within the existing Part 74 bands for major events, the FCC has granted waivers in the past for one or more unused TV UHF channels, usually for two-way dispatch. This is not possible in all markets. When this spectrum is finally allocated, this option will no longer be available.

Whatever the event, the primary goals of special event coordination are:

1. Protect the existing base of local users.
2. Accommodate itinerant users to the greatest extent possible.
3. Be present at the event to help unsnarl the inevitable glitches that will happen.
4. Report to the industry and FCC after the event so all can learn for the future.

The Benefits of Coordination for Microwave Licensees

As in the case of all Part 74 coordination, committees exist to help new and existing licensees share very limited amounts of spectrum. The move to frequency agility has made real time coordination possible for mobile operations. It mandates cooperation and sharing. In return, it allows licensees to operate their field ENG equipment and STLs with reduced risk of interference.

The Risks and Penalties of Not Coordinating

Failure to coordinate can be an expensive proposition for those who do not participate in this voluntary process. Uncoordinated mobile and fixed links have been taken off the air and re-engineered when they interfered with licensees operating under rules and procedures they agreed to abide by along with other broadcasters in the market. Precedent has been set for FCC support of local agreements where consensus is evident.

Expensive recrystalling, reprogramming, and retuning, antenna and site changes may be the only way to correct interference problems, most of which could have been avoided by communication with the coordinating committee and other users prior to the installation.

Because the broadcasting and cable industries are not monolithically structured, frequency coordination techniques cannot be identical in each market. Only general suggestions can be given as to what each manager or news director can do to participate in and support the coordination process. However, it is clear that coordination cannot succeed without the active support of general managers and news directors at whatever level is practical in a given situation.

INTERFERENCE AND THE PART 74 LICENSEE

Interference to a Part 74 licensee's operations may come from almost any source of RF one cares to mention. Radiation from unshielded computer cables has interfered with wireless microphone operation, for instance. Channel interference from other broadcasters can be thought of as a problem that can be solved by additional attempts at coordination, followed, if necessary, by mediation by a neutral party.

Locating the source of spurious emissions can be a real challenge. The committee can offer some advice and support when a suspected case of interference from an out-of-channel source is reported. Quite often, other stations in the market can make spectrum analyzers available to eliminate the possibility of a mixing product that is actually generated in the front end of the receiver due to an overload condition. This type of problem is common for both voice and video equipment.

Older solid state receivers are sometimes quite prone to front end overload. When an overload prone receiver is operating at a common site with an appreciable amount of adjacent channel activity, the receiver may be rendered useless. Filtering and attenuator pads can sometimes be suggested as cures. Video microwave receivers operating with preamplifiers can overload easily as a result of proper adjacent channel operation. In such cases, a suggestion to provide a bypass switch is in order.

Committees should encourage licensees to use call letters and unit identifiers for all voice transmissions. All video ENG trucks should be able to transmit bars with ID, and ideally should be able to place ID in the vertical interval as well as for identification during program transmission.

Tracking unidentified interference is not unlike detective work. For video, tuning through the on-air signals may provide a clue. If bars with no ID are seen at an ENG receive location, triagulation may be possible if the interference can be seen by two other locations equipped with steerable dishes. Trucks have been identified by reading street signs that appear in shots. Talent on other stations can sometimes be a good means of identification.

Interference to aural links can be challenging to trace. If call letters are not being used, anything heard then becomes a clue. If a street address is mentioned a newsroom criss-cross telephone directory can be used to find a telephone number at or near the address. A call to the number identifying yourself, your reason for calling, and if a taxicab or delivery truck has been there (or will be there) often works wonders.

Land mobile transmitters are sometimes designed so the final has power applied to it at all times. Any instability in the final can start it oscillating. These transmitters can sometimes migrate through many megahertz of spectrum, almost at random. When their exciters are keyed, they return to their proper channel. Sometimes only a spectrum analyzer and a lot of patience can trace this type of problem.

Inexpensive direction finding equipment is available for VHF and UHF tracking. Some units work with any hand-held portable. For unmodulated carriers and other types of interference that are present for long periods of time, direction finding can be a very effective (though time consuming and expensive) process.

If the licensee(s) involved, even with committee guidance, are unable to locate the interference, a call to the FCC may be in order. You will be asked for all pertinent information, such as time the interference occurs, its nature, duration, and any other details you might have learned. The FCC generally will not take interference complaints unless you can supply this information. Remember that coordinating committees and their members are never to act as police in such matters.

Local FCC offices have suffered deep staffing cutbacks that have further restricted their ability to help us find sources of willful and accidental interference. There is hope that passive tracking technology will be available in the near future. Passive tracking uses receivers located at multiple remote sites. These receivers are monitored at one location. Their signals are processed real time by computer. A source of interference can be located rapidly and accurately. The offender's RF envelope can be recorded and positively identified by its unique RF signature.

Curing Interference

Dealing with the broad topic of interference cures is beyond the scope of this chapter. When committees are working to solve such problems, creativity is definitely an asset. For instance, in a case where an aural STL on an adjacent channel on a parallel path was causing interference, the cure that was tried and worked involved installing a large dish at the transmitter. The dish was aimed slightly off azimuth from its receiver so that the receiver site being interfered with appeared in a deep null of the interfering transmit antenna.

MORE INFORMATION

For more information on frequency coordination, including a subscription to the SBE National Frequency Coordinators' Listing, or information on starting a local coordinating committee, contact the Society of Broadcast Engineers, 8445 Keystone Crossing, Suite 140, Indianapolis, IN 46240, (317) 253-1640. 1.6
DISTANCE AND BEARING CALCULATIONS

DANE E. ERICKSEN, P.E., CSTRE
HAMMETT & EDISON, INC., CONSULTING ENGINEERS, SAN FRANCISCO, CALIFORNIA

INTRODUCTION

The current FCC Rules for distance calculations use two methods: *flat-earth* and *spherical-earth*. The flat-earth method assumes the distance between two points to be the hypotenuse of a right triangle whose sides are determined by the difference in latitude and longitude of the starting and ending points, multiplied by the length per degree of latitude and longitude at the mid-latitude of the two points, as shown in Figure 1.6-1. The *flat-earth* term is not meant to be disparaging, and merely refers to the use of a right triangle to calculate the distance. Because the lengths of a degree of longitude and a degree of latitude used in the flat-earth method are derived from an ellipsoid rather than a spheroid model of the earth, the flat-earth method is actually more accurate than the spherical-earth method for short to moderate distances.

The spherical-earth method uses conventional spherical trigonometry to determine the distance. Section 73.208 of the FCC Rules now requires that the flat-earth method be used for distances up to and including 475 km. Distances greater than 475 km must be calculated using the spherical-earth method, which becomes more accurate than the flat-earth method for large distances. Section 73.208 is silent on how azimuths are to be calculated, it does not specify the earth radius to be used for spherical-earth calculations.

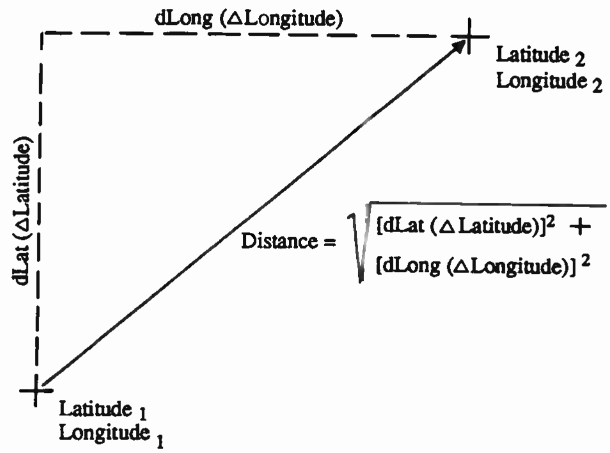

Figure 1.6-1. Flat-earth method.

FCC FLAT-EARTH METHOD

In FCC Docket 80-90,[1] formulas were substituted for the tables previously used for determining the length of a degree of latitude or of longitude as a function of latitude. However, the coefficients adopted in Docket 80-90 truncated to only two terms the trigonometric series used to generate the tables and "adjusted" the coefficients by a factor of (1.609/1.609347) because of the Docket 80-90 decision to define the conversion factor from U.S. statute miles to kilometers as 1.609,[2] rather than the value of (5,280 ft/mile) × (1200/3937 m/ft) × (1/1000 km/m), or 1.609347219 km/mile (approximately[3]).

In the *Second Report and Order* to Docket 86-144,[4] the FCC corrected these problems by adopting the full-precision, non-truncated trigonometric series for the arc length formulas given in the 1966 edition of U.S. Naval Hydrographic Office Publication Number 9 (H.O. 9) or the *American Practical Navigator* or simply *Bowditch* after Nathaniel Bowditch (1773–1838), its original author. These trigonometric series are based upon a binomial theorem expansion[5] of an ellipsoid model of the earth corresponding to the Clarke spheroid of 1866, upon which topographic maps in the United States are currently based.[6]

The trigonometric series defining the length of one degree of latitude and one degree of longitude for the Clarke spheroid of 1866 are:

$$\text{dLat} = 111.13209 - 0.56605\cos(2L) + 0.00120\cos(4L)\ldots \quad [1.6.1]$$

$$\text{dLong} = 111.41513\cos(L) - 0.09455\cos(3L) + 0.00012\cos(5L)\ldots \quad [1.6.2]$$

where dLat is the length in kilometers of one degree of latitude at latitude L and dLong is the length in kilometers of one degree of longitude, again at latitude L.

The latitude, L, is taken as the mid-latitude of the two points between which the distance is to be calculated, as follows:

$$L = (\text{Latitude}_1 + \text{Latitude}_2)/2 \quad [1.6.3]$$

where Latitude_1 and Latitude_2 are the latitudes of the starting and ending points. Similarly, Longitude_1 and Longitude_2 are the longitudes of the starting and ending points. In all cases, north latitudes are treated as positive and south latitudes as negative, and west longitudes are treated as positive and east longitudes as negative.

The distance between two points is then given by the Pythagorean theorem:

$$D = \sqrt{[(dLat)(Lat_1 - Lat_2)]^2 + [(dLong)(Long_1 - Long_2)]^2} \quad [1.6.4]$$

Plots showing how the lengths of one degree of latitude and longitude vary with latitude are given in Figures 1.6-2 and 1.6-3.

Canadian Method

In August 1987,[7] the Canadian government adopted the truncated and adjusted arc-length formulas which had been implemented by the FCC in Docket 80-90. Namely,

$$dLat = 111.108 - 0.566\cos(2L) \quad [1.6.5]$$

$$dLong = 111.391\cos(L) - 0.095\cos(3L) \quad [1.6.6]$$

Unfortunately, the Canadian Government has not yet adopted the corrected, more accurate formulas that were implemented by the FCC in Docket 86-144. Nor was the flat-earth versus spherical-earth break point changed from 350 km to 475 km. This is the source of current discrepancies between the U.S. and Canadian distance calculation methods. Although the differences between the two methods will usually not be significant when the calculated distance is rounded to the nearest kilometer (for FM) or to the nearest one-tenth kilometer (for TV), one should always check to see whether there is a difference between roundings. For calculations involving Canadian stations, the Canadian (Docket 80-90) version of the Clarke spheroid formulas is controlling.

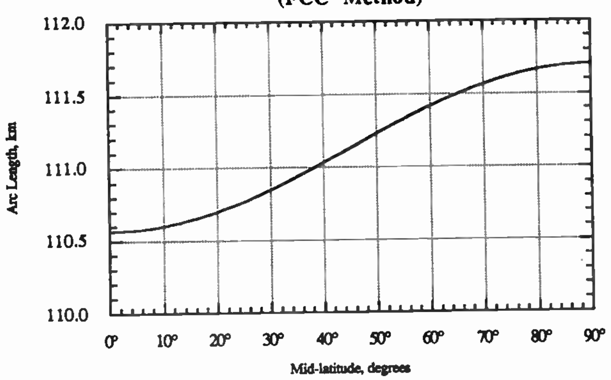

Figure 1.6-2. Length of 1° arc at latitude (FCC method).

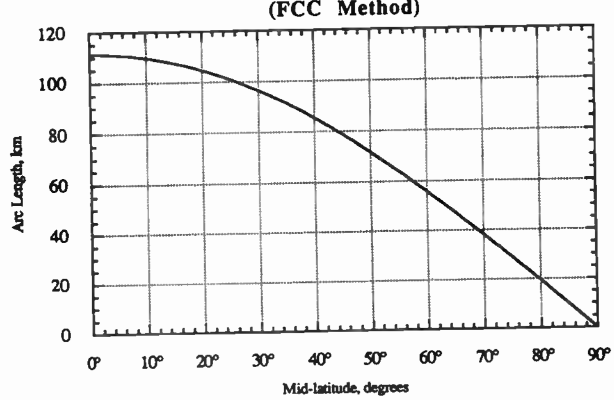

Figure 1.6-3. Length of 1° arc of longitude (FCC method).

Mexican Method

The August 11, 1992, U.S.-Mexican FM Agreement specifies the spherical-earth method exclusively; there is no provision for using the FCC flat-earth method for short to moderate distances. However, the Mexican Agreement specifies a spherical earth arc of 111.18 kilometers per degree, corresponding to an earth radius of 6,370.14 kilometers. The Mexican Agreement further specifies that azimuths are to be calculated on a spherical-earth basis. Finally, the Mexican Agreement specifies the rounding of distances to the nearest kilometer, so in that respect it matches the FCC rounding practice for FM station distances.

Spherical-Earth Method

The formula for the spherical-earth distance, or great-circle distance, is:

$$D = K\cos^{-1}[(\sin Lat_1)(\sin Lat_2) + (\cos Lat_1)(\cos Lat_2)\cos(Long_2 - Long_1)] \quad [1.6.7]$$

The constant K is in km/degree and is determined by the radius of the sphere being modeled. The FCC has never defined the earth radius to be used for spherical-earth calculations. The example given in Section 73.185(d) of the FCC Rules suggests an earth radius of 6,365 km (K = 111.090 km/degree). A 6,373 km radius (K = 111.230 km/degree) is implied by the 5,280-mile 4/3-earth radius given in Section 73.684(c)(1) of the FCC Rules. This 4/3-earth radius was also used in FCC Report No. R-6410, "Elevation and Depression Angle Tables," September 15, 1964. An earth radius of 6,367 km (K = 111.125 km/degree) can be deduced from the 1,852-meter definition of a nautical mile.[8] Finally, an earth radius of 6,371 km (K = 111.195 km/degree) corresponds to the mean radius of the Clarke spheroid of 1866.

Until such time as the FCC so specifies, the author suggests using the mean Clarke spheroid value of 6,371 km (K = 111.195 km/degree).[9]

AZIMUTH CALCULATIONS

Because the FCC Rules are silent on how azimuth, or bearing, calculations are to be performed, both the flat-earth and spherical-earth methods are commonly used. The flat-earth method determines azimuth using the arctangent of the right triangle defined in the FCC method. The spherical-earth method uses standard

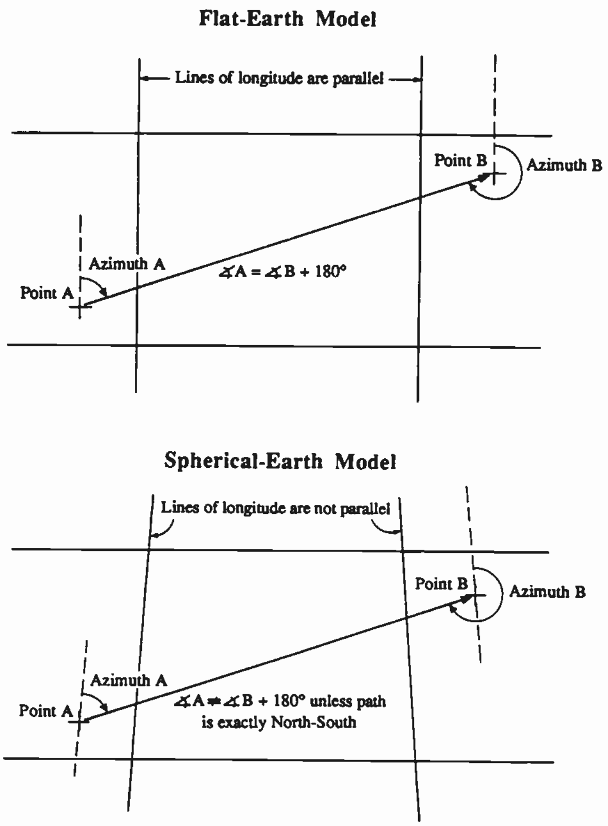

Figure 1.6-4. Azimuth calculations.

spherical trigonometry. It is the author's recommendation that azimuth always be determined using the spherical-earth method, even when the FCC flat-earth method is used to determine distance. The flat-earth method will be in error by up to two degrees at distances approaching 500 km, whereas the spherical-earth azimuth will be correct within about 0.1 degrees at such distances.[10] Figure 1.6-4 shows why this is true. Azimuths determined using the arctangent of the right triangle defined by the FCC flat-earth method assume that lines of longitude are parallel, whereas they are not. This is why the forward and back (reciprocal) azimuths using the spherical-earth method will generally not be exactly 180° apart, whereas the forward and back azimuths using the flat-earth method are always 180° apart.

The formula for determining azimuth by the spherical-earth method is:

$$C = \cos^{-1}\frac{\sin \text{Lat}_2 - \sin \text{Lat}_1 \cos(D/K)}{\sin(D/K)\cos \text{Lat}_1} \quad [1.6.8]$$

$$\text{if } \sin(\text{Long}_2 - \text{Long}_1) < 0, \text{ Azimuth} = C \quad [1.6.9]$$

$$\text{if } \sin(\text{Long}_2 - \text{Long}_1) = 0, \text{ Azimuth} = 360 - C \quad [1.6.10]$$

The ratio (D/K) is the great circle arc length *in degrees,* and is obtained from equation [1.6.7]. It should be noted that the Canadian Department of Communications Rules and the U.S.-Mexico FM Agreement *do* specify that azimuth is to be calculated using the spherical-earth method and, further, that for Canadian azimuth calculations, the bearing is to be rounded to the nearest degree.[11] It should also be noted that the radius of the sphere is irrelevant for azimuth calculations.

Clarke Spheroid Versus WGS Ellipsoid

The original FCC distance tables were based upon the Clarke spheroid (or ellipsoid) of 1866, with a major-axis radius of 6,378.2064 km and ellipticity of 1/294.98.[12] The current edition[13] of the *American Practical Navigator* now bases Table 7, "Length of a Degree of Latitude and Longitude," on the World Geodetic System (WGS) ellipsoid of 1972. The coefficients for dLat and dLong for this ellipsoid are:

$$\text{dLat} = 111.13292 - 0.55982\cos(2L) + 0.001175\cos(4L)\ldots \quad [1.6.11]$$

$$\text{dLong} = 111.41282\cos(L) - 0.0935\cos(3L) + 0.000118\cos(5L)\ldots \quad [1.6.12]$$

The difference between the Clarke 1866 and WGS 1972 trigonometric series is inconsequential when coordinate data bases are maintained only to the nearest second and distances are rounded to the nearest kilometer or one-tenth kilometer. Over a zero to 90 degree arc of latitude, at one-degree increments, the RMS difference between the two arc length formulas is only 0.0041% for latitude and 0.0033% for longitude. For this reason the FCC decided not to amend the formulas given in Section 73.208(c) of its Rules from the Clarke 1866 coefficients to WGS 1972 coefficients.

Rounding Practices

There continues to be an inconsistency in rounding practices between the FCC FM and TV Rules. For FM distance calculations, Section 73.208(c)(8) specifies rounding to the nearest kilometer. For TV distance calculations, Section 73.611(d) specifies rounding to the nearest one-tenth kilometer. Persons performing distance calculations must, therefore, be mindful of the different rounding criteria between the FM and TV Rules. The AM Rules and the Broadcast Auxiliary Rules are silent on distance rounding practices. The Broadcast Auxiliary Rules also do not prescribe how distances are to be calculated, even though portions of those Rules include minimum distance requirements (for example, Subpart G, *Low Power TV, TV Translator, and TV Booster Stations,* specifies certain minimum distances between LPTV/TV Translator stations and land mobile stations; and Subpart I, *Instructional Television Fixed Service,* specifies certain search distances for interference studies). The FCC was urged to make its distance calculation rules applicable to all Part 73 and Part 74 services in the Docket 86-144 comments, but again did not do so. Calculations regarding distances between TV Translator and LPTV stations should, presumably, use the flat-earth method specified in the FCC's FM Rules.

NAD27/NAD83 Datums

The Federal Geodetic Committee is in the process of converting all maps in the United States from the 1927 North American Datum (NAD27), which is based upon the Clarke spheroid of 1866, to the 1983 North American Datum (NAD83). NAD83 differs from NAD27 in that it is referred to the earth's center of mass, making it fully compatible with satellite systems for position determination. The FCC has indicated it will eventually convert to NAD83 to maintain accuracy and consistency with other government agencies. NAD83 is based upon the Geodetic Reference System ellipsoid of 1980 (GRS 1980), with a major axis of 6,378.135 km and an ellipticity of 1/298.26. These are the same parameters as for the WGS 1972 ellipsoid, and the trigonometric series for the one-degree arc length formulas are identical to those for WGS 1972.[14]

Current 7.5 minute topographic quadrangle maps published by the U.S. Geological Survey specify NAD27 as the reference datum, in the lower left corner of the map. At some point in the future, the U.S. Geological Survey will begin issuing maps based on the NAD83 datum. Initial attempts at printing dual-sided (NAD27/NAD83) maps proved impractical.[15]

In order to prevent intermixing of numerical information using two different map datums, the FCC has stated that the following procedures will be in effect until further notice:[16] Applicants must continue to furnish coordinates based on NAD27.

- Applicants who have filed applications with coordinates based on the NAD83 datum must provide NAD27 coordinates.
- Until further notice, the FCC will continue to specify NAD27 coordinates in its databases, authorizations, notifications, forms, and rules.
- The FCC will issue further guidance on the conversion to NAD83 as more informationbecomes available.

An exception to the above policy is FCC Form 854, *Application for Antenna Structure Registration*, which allows reporting tower coordinates in either the NAD27 or the NAD83 datums.

Conversion Between Datums

The National Geodetic Survey (NGS) has developed an algorithm known as the North American Datum Conversion program (NADCON). The program is bi-directional, meaning that it will convert NAD83 coordinates to NAD27 coordinates, as well as NAD27 coordinates to NAD83 coordinates. It also applies in Alaska, Hawaii and Puerto Rico. But, most importantly, it is the conversion algorithm recommended by statute. The *Federal Register* dated August 10, 1990, Volume 55, Number 155, Page 32681 stated:

The intent of this notice is to standardize a horizontal datum transformation method when a mathematical transformation is desired. FGCC [Federal Geodetic Control Committee] selected the method incorporated in the software identified as NADCON. It is not the intent of the notice to declare when to use a datum transformation or by what method but only to declare that when a mathematical transformation is appropriate, NADCON is recommended.

Thus, while use of NADCON is not mandatory, use of conversion algorithms other than NADCON may result in a rounding error that will cause the results to be inconsistent with those obtained by the FCC or by the Federal Aviation Administration (FAA), which do use NADCON.

NADCON uses a minimum-curvature approach to transforming between the two datums, and comes with four reference files: a large file for the contiguous United States, and smaller files for Alaska, Hawaii and Puerto Rico. By having a separate set of polynomial coefficients for each 7.5 minute topographic map, NADCON achieves an improved conversion accuracy of approximately ±0003 seconds in latitude and ±0.0005 seconds in longitude. Because of the size of these data files, programmable calculators are unable to implement the program, but today's personal computers are certainly capable of loading the NADCON data files.[17]

The NADCON software (Version 2.1) and data files are provided on two 3.5-inch disks for IBM-compatible personal computers with a math co-processor chip. The source code can be re-complied for use with other computers. A hard drive with at least 1.5 Mb of RAM is recommended.

For a more detailed discussion of the NAD27/NAD83 DATUMS, see *NAD83: What It Is and Why You Should Care*, by the author, published in the Proceedings of the 1994 SBE Engineering Conference.

USE OF GPS TO DETERMINE COORDINATES

With the widespread availability of low-cost Global Positioning System (GPS) receivers, there is a temptation to use such devices to determine latitude and longitude. Unless a considerably more expensive differential GPS receiver is used, the reported coordinates may not meet FCC accuracy requirements, which require coordinates to be reported to the nearest second of latitude and longitude. Non-differential GPS receivers will provide coordinates only accurate to ±100 meters, or approximately ±3 seconds, whereas differential GPS receivers provide coordinates accurate to ±1 meter, or approximately ±0.05 seconds.[18]

A further potential source of error exists because most GPS receivers have user-driven menus allowing display of coordinates in either the NAD27 or NAD83 datum. However, consumer grade GPS receivers are unlikely to use the NADCON conversion, and there is always the possibility that the user does not realize which datum the GPS receiver has been set to display. On more than one occasion the author has discovered parties reporting GPS-derived coordinates as NAD27 when in fact the GPS receiver had been programmed to display NAD83 coordinates. If NADCON is then used to convert the coordinates from NAD27 to NAD83, in the mistaken belief that the reported coordinates were NAD27, a bogus set of coordinates, corresponding to neither datum, are then created. Therefore, persons using GPS receivers to determine coordinates should ensure they are aware of which datum their receiver is displaying, and they should only use a GPS receiver capable of differential corrections.

BROADCAST RELATED ORGANIZATIONS AND INFORMATION

COURTENAY SMITH BROWN
NATIONAL ASSOCIATION OF BROADCASTERS, WASHINGTON, DC

INTRODUCTION

This chapter provides a general overview of entities whose activities affect the work of broadcast engineers. It is divided into five categories:

- Federal government
- State and local government
- Trade associations
- Professional associations
- Related broadcast-oriented organizations

Web site references are included to direct broadcast engineers to more information on the listed entity, including publications, conferences, committees, and other resources. The chapter concludes with a list of broadcast engineering and related periodicals.

Federal Government

U.S. Department of Agriculture, Forest Service
14th and Independence Avenue, SW
Washington, DC 20250
(202) 205-1760, Website: http://www.fs.fed.us

The U.S. Department of Agriculture (USDA) Forest Service oversees 190 million acres of public land under the domain of the National Forest System. Often, the use of a mountaintop transmitter site is administered by the Forest Service. Leases authorizing communications facilities are issued by the Forest Supervisor for the particular forest of interest. The Forest Supervisor has policy directives for permissible activities and fee schedules for communication uses utilizing the National Forests.

U.S. Department of Commerce, National Institute of Standards and Technology(NIST) Headquarters
Quince Orchard and Clopper Rds
Gaithersburg, MD 20899
(301) 975-2000, Website: http://www.nist.gov

The National Institute of Standards and Technology (NIST) is a non-regulatory agency within the U.S. Department of Commerce Technology Administration. NIST"s primary mission is to promote U.S. economic growth by working with industry to develop and apply technology, measurements, and standards.

U.S. Department of Commerce, Time and Frequency Division, Boulder Laboratories
325 Broadway
Boulder, CO 80303
(303) 497-3000, Website: http://www.boulder.nist.gov/timefreq/

The Time and Frequency Division, part of the Physics Laboratory of NIST, is located in Boulder, Colorado. Its functions include:

- Maintaining the primary frequency standard for the United States.
- Developing and operating standards of time and frequency.
- Coordinating U.S. time and frequency standards with other world standards.
- Providing time and frequency services for United States clientele.
- Performing basic and applied research in support of improved standards and services.

Precise time and frequency information is needed by radio and television stations, electric power companies, telephone companies, air traffic control systems, participants in space exploration, computer networks, scientists monitoring data of all kinds, and navigators of ships and planes. These users need to compare their own timing equipment to a reliable, legally traceable, internationally recognized standard. NIST provides this standard for civilian users in the United States.

Broadcast services include shortwave radio signals from NIST radio stations WWV and WWVH; 60 kHz signals from WWVB; and time signals carried by satellites. Precise frequency references are available from WWV, WWVH, WWVB, and Loran-C. Time signals are also available using telephone voice and data lines and the Internet. Time synchronization can also be accomplished via Global Positioning Satellites (GPS).

The division offers a fee-supported Frequency Measurement Service (FMS) that allows users to make accurate, NIST-certified frequency calibrations at their site, rather than sending their oscillators to NIST or elsewhere for calibration. Broadcast engineers requiring more information on this service can contact:

John A. Wessels
Time and Frequency Division
Mailcode 847.00
325 Broadway, Boulder, CO 80303

voice: (303) 497-5634, fax: (303) 497-6461
email: wessels@boulder.nist.gov

National Telecommunications and Information Administration
14th Street and Constitution Avenue N.W.
Washington, D.C. 20230
Phone: (202) 482-1835, Website: http://www.ntia.doc.gov

The National Telecommunications and Information Administration (NTIA) of the Department of Commerce is the Executive Branch agency principally responsible for domestic and international telecommunications and information technology issues. With roughly $65 million available, NTIA works to spur innovation, encourage competition, help create more jobs, and provide consumers with more choices and better quality telecommunications products and services at lower prices.

NTIA's mission is to promote the development of an advanced telecommunications and information infrastructure that efficiently serves the needs of all Americans, creates job opportunities for American workers, and enhances the competitiveness of U.S. industry in the global marketplace.

NTIA addresses a broad range of telecommunications issues and concerns. Many efforts cross-cut across the agency, drawing on telecommunications policy expertise, radio wave propagation knowledge, spectrum engineering, and lessons learned from actual applications.

U.S. Department of the Interior, Bureau of Land Management
1849 C Street, N.W.
Washington, D.C. 20240
(202) 452-5125, Website: http://www.blm.gov

The Bureau of Land Management oversees the use of 360 million acres of "public domain" lands that are not under the domain of the USDA Forest Service. Broadcaster use of these lands for transmitter sites is coordinated by the State Director of the Bureau of Land Management.

U.S. Department of the Interior, U.S. Geological Survey National Center
12201 Sunrise Valley Drive
Reston, VA 20192
Phone: (703) 648-4000, Website: http://www.usgs.gov

The U.S. Geological Survey provides the nation with information to describe and understand the Earth. This information is used to:

- Minimize loss of life and property from natural disasters
- Manage water, biological, energy, and mineral resources
- Enhance and protect the quality of life
- Contribute to wise economic and physical development

In support of the U.S. Geological Survey's mission to provide information about the Earth and its physical resources, the National Mapping Program (NMP) provides geographic, cartographic, and remote sensing information, maps, and technical assistance, and conducts related research responsive to national needs.

The NMP also makes available maps, images, spatial data, remote sensing data, and related information; provides assistance in selecting, acquiring, and using geographic and cartographic products; and designs, prints, and distributes maps of the National Atlas. It coordinates Federal topographic mapping and digital cartographic activities and provides leadership in the development and advancement of surveying and mapping technology. The NMP is administered through the USGS National Mapping Division (NMD).

Topographic maps usually used in the prediction of coverage and other engineering studies, which require accurate information about the position and elevation of terrain features may be obtained from the U.S. Geological Survey. Refer to your local phone book's yellow pages for the nearest commercial dealers that sell USGS maps and contact them directly for pricing and ordering information. For more information or ordering assistance, call 1-800-HELP-MAP, or write:

USGS Information Services
Box 25286
Denver, CO 80225

Department of Labor, Occupational Safety and Health Administration
200 Constitution Ave., N.W.
Washington, DC 20210
(202) 219-8151 (OSHA), Website: http://www.osha.gov

Broadcast engineers should be aware that two federal laws—the Federal Labor Standards Act and Occupational Safety and Health Act—empower the Department of Labor (DOL) to regulate work place safety standards and the wages and hours of employment for broadcast employees. Occupational safety standards are enforced by the Occupational Safety and Health Administration (OSHA) of the Department of Labor (DOL), while the minimum wage and hours of employment are enforced by DOL's Wage and Hour Division.

Applicability of OSHA regulations depend upon hazards, while Wage and Hour Division regulations encompass many factors, such as the station's geographic location, the number of station employees, and the type of work they perform. Broadcast engineers should consult their station's attorney to determine what regulations apply to them and how to abide by them.

Department of Transportation, Federal Aviation Administration
400 7th Street, S.W.
Washington, D.C. 20590
(202) 426-4000, Website: http://www.faa.gov

When construction or alteration of a broadcast tower is proposed, the Federal Aviation Administration (FAA) conducts an aeronautical study to determine the potential impact that the proposal may have on the navigable airspace.

Broadcasters are required to notify the FAA of new proposals or alterations to existing towers. The obstructions standards in Title 14 of the Code of Federal Aviation Regulations (Part 77) are applied to determine the effect the proposal would have on aeronautical operations. It may be necessary for broadcasters to amend their proposal by modifying the tower height or location in order to eliminate a *determination of hazard to air navigation.* When an aeronautical study results in a *determination of no hazard to air navigation,* the FAA will recommend the marking and/or lighting for that structure, if appropriate. The Federal Communication Commission's license will contain the marking and/or lighting recommended by the FAA.

Conspicuity is achieved only when all recommended lights are working. Therefore, it is important that any outage be corrected as soon as possible. However, the FAA must receive notice immediately of any failure or malfunction that lasts more than 30 minutes and affects a top light or flashing obstruction light regardless of its position.

Environmental Protection Agency
401 M Street, S.W.
Washington, DC 20460
(202) 260-2090, Website: http://www.epa.gov

The Environmental Protection Agency protects public health and safeguards and improves the natural environment—air, water, and land—upon which human life depends. EPA's purpose is to ensure that:

- Federal environmental laws are implemented and enforced fairly and effectively.
- Environmental protection is an integral consideration in U.S. policies concerning economic growth, energy, transportation, agriculture, industry, international trade, and natural resources.
- National efforts to reduce environmental risk are based on the best available scientific information.
- All parts of society—business, state and local governments, communities, and citizens—have full access to information so that they can become full participants in preventing pollution and protecting human health and the environment.

When broadcasters construct station facilities such as antenna towers or large satellite earth stations they should be aware that these activities may fall under the scope of the National Environmental Protection Act (NEPA). NEPA grants the Environmental Protection Agency (EPA) authority to regulate activities that may affect the "quality of the human environment." The FCC cooperates with EPA in enforcing provisions of NEPA that relate to telecommunication licensees.

Federal Communications Commission
1919 M Street N.W.
Washington, D.C. 20554
(202) 418-0200, Website: http//www.fcc.gov

For detailed information on the Federal Communications Commission, see Chapters 1.3, "FCC Organization and Administrative Procedures," and 1.4, "FCC Compliance and Information Bureau." Every station should have a current copy of the FCC's broadcast rules. There are two ways to obtain them:

- Order a set of the Code of Federal Regulations (CFR)—*47 CFR Parts 0–19* for the tower regulations in Part 17 and the Emergency Alert System (EAS) regulations in Part 11, and *47 CFR Parts 70–79* for the broadcast rules Part 73 and broadcast auxiliary rules Part 74—issued annually by the U.S. Government Printing Office (GPO). For payment by credit card, call (202) 512-1800, Monday–Friday, 8 a.m.–4 p.m. EST. Or fax your order to (202) 512-2233, 24 hours a day. For payment by check, write to the Superintendent of Documents, Attn: New Orders, P.O. Box 371954, Pittsburgh, PA 15250-7954. For GPO Customer Service call (202) 512-1803.
- For a continuously updated subscription (in loose-leaf form or on diskette), call the Rules Service Company at (301) 4249402 or fax your subscription request at (301) 762-7853, Monday–Friday, 8 a.m.–3:30 p.m. EST. Send written requests to: 7615 Standish Place, Rockville, MD 20855. To view the list of available Parts/Titles, visit their Web site at http://www.ruleserv.com.

National Labor Relations Board
1099 14th Street, N.W.
Washington, D.C. 20570
(202) 208-3000, Website: http://www.nlrb.gov

Broadcast engineers should be aware that the National Labor Relations Act (NRLA) protects the right of station employees to bargain collectively with management over the "terms and condition of employment." The National Labor Relations Board (NLRB), an independent federal agency, was established to enforce the right of workers to organize and engage in "concerted activity." As with the Department of Labor regulations, the extent of these rights depends upon many factors such as the type and the number of employees involved.

State and Local Governments

A number of aspects of a broadcast engineer's job are affected or controlled by state or local government agencies. It is important for engineers to have some familiarity with the laws, codes, and zoning ordinances governing such matters as building construction, electrical wiring, and fire safety. Regulations may vary from one community to another, even within the same state or county.

While there are model national codes, these codes may or may not be adopted by a state or local government. If adopted, there may be some changes from the national model. The only way to determine this is to check with the local agency or agencies having jurisdiction over the matter in question. For more information on state or local regulations, see the following:

- The broadcast station's local lawyer
- The county or city business licensing office
- The county or city building inspector or fire marshal
- A licensed local contractor who performs the type of work in question

Trade Associations

Association of Federal Communications Consulting Engineers (AFCCE)
Website: http://www.afcce.org

AFCCE was founded in 1948 as a professional association of communications engineers practicing before the Federal Communications Commission. Engineering for broadcast stations in the AM, FM, and TV services, for microwave, cellular radio, PCS, paging systems, cable systems, and for satellite facilities are some of the areas in which AFCCE members offer their professional services. Associate membership is offered to technical personnel and to other professionals sharing an interest in the technical aspects of communications.

The purpose of the Association is to aid and promote the proper federal administration and regulation of those engineering and technical phases of communications which are regulated by the Federal Communications Commission.

Association for Maximum Service Television (MSTV)
1776 Massachusetts Avenue, N.W.
Suite 310
Washington, DC 20036
Phone: (202) 861-0344, Fax: (202) 861-0342, Website: http://www.mstv.org

The Association for Maximum Service Television, Inc. (MSTV) is a national association of local television stations dedicated to preserving and improving the technical quality of free, universal, community-based television service to the American public.

In the spring of 1996, MSTV and the Consumer Electronics Manufacturers Association (CEMA) created the Model HDTV Station Project to provide hands-on education and experience for broadcasters and equipment manufacturers in the implementation of DTV. The project's station, licensed by the FCC as WHD-TV in Washington, DC, is supported by more than 260 funding television stations and by major equipment manufacturers.

Cable Television Laboratories Inc. (CableLabs)
400 Centennial Parkway
Louisville, Colorado 80027-1266
Phone: (303) 661-9100, Fax: (303) 661-9199, Website: http://www.cablelabs.com

CableLabs is a research and development consortium of cable television system operators representing more than 85 percent of the cable subscribers in the United States.

Electronic Industries Alliance (EIA)
Consumer Sector, Consumer Electronics Manufacturers Association (CEMA)
Telecommunications Sector, Telecommunications Industry
Association (TIA)
2500 Wilson Boulevard
Arlington, VA 22201-3834
Phone: (703) 907-7500, Fax: (703) 907-7501, Website: http://www.eia.org

For more than 75 years, the Electronic Industries Alliance has been the national trade organization representing U.S. electronics manufacturers. Committed to the competitiveness of the American producer, EIA represents the entire spectrum of companies involved in the design and manufacture of electronic components, parts, systems, and equipment for communications, industrial, government, and consumer uses.

Engineering activity includes the publication of voluntary standards. Those of interest to broadcasters are standards covering transmitters, towers, microwave transmission systems, and tape cartridges. The standards work is primarily done in the National Radio Systems Committee (NRSC) and standing EIA Engineering Department Committees. The NRSC is a joint engineering committees with the National Association of Broadcasters (NAB). The EIA, Joint Electron Device Engineering Council (JEDEC, a cooperative effort of EIA and the National Electrical Manufacturers Association), and TIA Standards and Engineering Publications catalog of standards and engineering publications may be obtained from Global Engineering Documents (1-800-854-7179).

A selection of EIA voluntary standards of interest to broadcast engineers is given next, along with the date of acceptance or reaffirmation. Interested readers should contact Global for a current listing and prices, or visit EIA's Website.

- EIA-189-A, Encoded Color Bar Signal, 1976.
- EIA-200-A, Circular Waveguides, 1975.
- EIA-211-D, Processed Analog Disc Records and Reproducing Equipment, 1981.
- EIA-215, Basic Requirements for Broadcast Microphone Cables, 1958.
- EIA-219, Audio Facilities for Radio Broadcasting, 1959.
- EIA-221-A, Polarity or Phase of Microphones for Broadcasting, Recording, and Sound Reinforcement, 1979.
- EIA-222-D, Structural Standards for Steel Antenna Towers and Antenna Supporting Structures, 1987.
- EIA-225, Rigid Coaxial Transmission Lines, 1975.
- EIA-232-D, Interface Between Data Terminal

Equipment and Data Circuit Terminating Equipment Employing Serial Binary Data Interchange, 1986.
- EIA-238-B, Standards for Stylus Tips Used for Disc Phonograph Record Reproducing, 1981.
- EIA-250-C, Electrical Performance Standards for Television Relay Facilities, 1977.
- EIA-258, Semi-flexible Air Dielectric Coaxial Cables and Connectors, 1962.
- EIA-261-B, Rectangular Waveguides, 1979.
- EIA-264, Magnetic Recording Tape Cartridge Dimensions, 1962.
- EIA-288, Audio Magnetic Playback Characteristic at 7 1/2 IPS, 1963.
- EIA-295, Disc Recording Characteristic, 1982.
- EIA-297-A, Cable Connectors for Audio Facilities for RadioBroadcasting, 1970.
- EIA-355, Standard Dimension for Unrecorded Magnetic Sound Recording Tape, 1974.
- EIA-462, Electrical Performance Standards for Television Broadcast Demodulators, 1979.
- EIA-508, Electrical Performance Standards for Television Broadcast Transmitters, 1987.
- EIA-549, NRSC AM Preemphasis/Deemphasis and Broadcast Audio Transmission Bandwidth Specifications, 1990.
- EIA-560, Standard Method of Measurement for Compact Disc Players, 1989.
- TR-107, Electrical Performance Standards for FM Broadcast Transmitters, 1949.
- TR-117, Antennas and Combination of Antennas for FM Broadcasting Stations, 1949.

National Association of Broadcasters (NAB)
1771 N Street, N.W.
Washington, D.C. 200362891
Phone: (202) 429-5346, Fax: (202) 775-4981
Website: http://www.nab.org

The NAB represents the broadcasting industry before Congress, the courts, regulatory agencies, the White House, and before the general public. The NAB Science and Technology Department represents the industry before the FCC and other agencies on issues affecting spectrum management and technical regulations. The Department's mission is to preserve and improve the ability of radio and television stations to distribute services to consumers and businesses.

The Department conducts a series of technical conferences—NAB Broadcast Engineering Conference, NAB MultiMedia World, and NAB Communications & Connectivity—at the annual NAB spring convention. The department also provides timely, useful, and accurate technical information in *Radio & TV Tech-Check*, a weekly technical news fax and through numerous other NAB technical publications including, the *Broadcast Engineering Conference Proceedings.*

For a listing of NAB technical publications visit the technical publications web site at http://www.nab.org/scitech/files/techpub.asp. NAB publications may be ordered by calling 1-800-368-5644. The Science & Technology Department also maintains a *Broadcast Sites of Interest* web site at http://www.nab.org/scitech/files/broadsts.htm.

National Cable Television Association (NCTA)
1724 Massachusetts Avenue N.W.
Washington, D.C. 20036
(202) 775-3550, Website: http://www.ncta.com

The National Cable Television Association (NCTA) is the major trade association for the cable industry. The organization represents the cable television industry before Congress and Federal Agencies, in the courts, and before state regulatory agencies. NCTA represents cable systems serving more than 80 percent of the nation's approximately 64 million cable subscribers. It also represents over 100 cable program networks such as CNN, HBO, and MTV. In addition, NCTA represents the hardware suppliers and providers of other services to the industry.

Professional Associations

Broadcast Education Association (BEA)
1771 N Street, N.W.
Washington, D.C. 20036
(202) 429-5354, Website: http://www.beaweb.drg

The Broadcast Education Association (BEA) provides professional development for people who teach and research electronic media and multimedia. Academics, media professionals, and students participate in this organization, which has served the industry for more than 43 years. The BEA publishes the *Journal of Electronic Media, Feedback,* and the *Journal of Radio Studies.* It also administers 14 scholarships ranging from $1,250–$5,000, awarded to juniors, seniors and those pursuing graduate studies at BEA member schools.

IEEE Broadcast Technology Society
Institute of Electrical and Electronics Engineers (IEEE)
345 East 47th Street
New York, New York 10017
(212) 705-7900, Website: http://www.ieee.org

The IEEE's 311,000 members in 150 countries, includes engineers and scientists in electrical engineering, electronics, computers, and allied fields as well as over 40,000 students. The IEEE Broadcast Technology Society is one of the Institute's 36 societies addressing member interests.

The IEEE holds numerous meetings and special technical conferences, conducts lecture courses at the local level on topics of current engineering and scientific interest, assists student groups, and awards medals, prizes, and scholarships for outstanding technical achievement. Publications of the IEEE include the *Proceedings* (monthly), *IEEE Spectrum* (monthly), and *Directory* (annually) and more than 700 industry standards. The societies and councils publish journals, magazines, and conference proceedings.

Society of Broadcast Engineers (SBE)
8445 Keystone Crossing, Suite 140
Indianapolis, Indiana 46240
Phone: (317) 253-1640, Fax: (317) 253-0418, Website: http://www.sbe.org

With more than 5,300 members, the Society of Broadcast Engineers is the largest national organization for broadcast engineers. SBE is devoted to the professional development of its members and the field of broadcast engineering. SBE promotes communication between SBE members and provides national representation for those members before federal and state regulatory agencies, manufacturers, and the general public. SBE, through its 100 plus local chapters, holds monthly meetings and technical conferences. There are eight levels of membership in the society:

- Honorary Member
- Fellow
- Senior Member
- Member
- Associate
- Student
- Life Member
- Sustaining Member

SBE administers a certification program, recognizing four levels of engineering achievement:

- Certified Broadcast Technologist, CBT
- Certified Broadcast Engineer: Television or Radio, CBTE or CBRE
- Certified Senior Broadcast Engineer: Television or Radio, CSTE or CSRE
- Certified Professional Broadcast Engineer, CPBE

SBE offers certification in two non-RF categories:

- Certified Engineer/Audio, CEA
- Certified Engineer/Video, CEV

SBE also offers certification for the operator level:

- Certified Radio Operator, CRO
- Certified Television Operator, CTO

The SBE National Frequency Coordinating Committee was established in 1982 when the FCC asked the broadcast industry to identify local contacts for Part 74 frequency coordination. The SBE formed a national network of volunteers to develop local databases of frequencies and users to assist the FCC and Part 74 users. Voluntary frequency coordination is handled on a local basis by SBE coordinators.

The Ennes Educational Foundation Trust was founded in 1981. Each year the Trust awards scholarships to qualified individuals pursuing an education in broadcast engineering or to those pursuing continuing education in broadcast technology. The Trust presents workshops around the country, providing in-depth instruction to members, and underwrites educational publications of a technical broadcast nature.

Society of Cable Telecommunications Engineers (SCTE)
140 Phillips Road
Exton, PA 19341-1318
Phone: (610) 363-6888, Fax: (310) 363-5898, Website: http://www.scte.org

The Society of Cable Telecommunications Engineers Inc. (SCTE), is a non-profit professional organization formed in 1969 to promote the sharing of operational and technical knowledge in the field of cable TV and broadband communications. Through the efforts of both the national and local chapter levels of the organization, SCTE provides training opportunities, standards development, and certification at the technician and engineer levels. Additional information and exchange opportunities are provided through the Society's national conferences, Board of Directors, committees, newsletter, and associated trade journals. Based in Exton, Pennsylvania, SCTE has 15,000 members and over 70 national and international Chapters and Meeting Groups.

Society of Motion Picture and Television Engineers (SMPTE)
595 West Hartsdale Avenue
White Plains, New York 10607
(914) 761-1100, Website: http://www.smpte.org

The membership of SMPTE is comprised of professional engineers and technicians in motion pictures, television, and allied arts and sciences. The Society advances engineering technology, disseminates scientific information, and sponsors lectures, exhibitions, and conferences to advance the theory and practice of motion-picture and television engineering. As an accredited standards developer under the American National Standards Institute, SMPTE develops national standards for motion pictures, television, and sound associated with motion picture and television images. The Society also develops Recommended Practices and Engineering Guidelines. For copies of SMPTE engineering documents, contact their Standards Department.

SMPTE also makes available picture and sound test films and video tapes for use as standardized measuring tools, serves as administrator of the Secretariat of International Organization for Standardization (ISO) Technical Committee 36 on Cinematography, and of the U.S. Technical Advisory Groups for ISO/TC 36 and Insternational Electrotechnical Commission Subcommittee (IEC/SC) 100B on Recording.

The Society sponsors technical courses at universities on such subjects as digital television, sound techniques, laboratory processing, special effects, and lighting for technicians and students. The Society presents nine annual awards for outstanding contributions to motion-picture and television engineering.

SMPTE engineering committees include:

- Audio Recording and Reproduction Technology
- Film Technology

- Laboratory Services Technology
- Projection Technology
- Video Recording and Reproduction Technology
- Television Production Technology
- Television Signal Technology
- Multimedia Technology and Packetized Television Technology

Publications of the Society include the monthly *Journal,* books of papers presented at the Society's Conferences, and other books on motion-picture and television technology.

RELATED ORGANIZATIONS

Advanced Television Systems Committee (ATSC)
1750 K Street, N.W.
Suite 800
Washington, DC, 20006
Phone: (202) 828-3130, Fax: (202) 828-3131, Website: http:\\www.atsc.org

The ATSC, comprised of over one hundred member corporations, associations, and research and educational institutions around the world, was established in 1983. ATSC is developing voluntary standards for the entire range of advanced television systems, and is also developing digital television implementation strategies and creating a certification program for television sets, computers, and other consumer video devices.

On December 24, 1996, the U.S. Federal Communications Commission mandated use of the ATSC DTV Standard for digital terrestrial television broadcasting in the United States, except for the specific video formats spelled out in the Standard, which are being implemented as a voluntary industry standard.

American National Standards Institute (ANSI)
11 West 42nd Street
New York, New York 10036
Phone: (212) 642-4900, Fax: (212) 398-0023, Website: http://www.ansi.org

The Institute represents the interests of its nearly 1,400 company, organization, government agency, institutional and international members through its headquarters in New York City, and its satellite office in Washington, D.C. ANSI serves as the clearinghouse for nationally-coordinated voluntary safety, engineering, and industrial standards. The institute gives status as American National Standards to standards developed by agreement from all groups concerned, in such areas as:

- Definitions, terminology, symbols, and abbreviations
- Materials and performance characteristics
- Procedures and methods of rating
- Methods of testing and analysis
- Size, weight, volume, and rating
- Practices, safety, health, and building construction

The organization also provides information on foreign standards, and represents United States" interests in international standardization work.

American Radio Relay League (ARRL)
225 Main Street
Newington, CT 06111
Phone: (860) 594-0200, Fax: (860) 594-0259, Website: http://www.arrl.org

The American Radio Relay League's (ARRL) membership is comprised of licensed amateur radio operators in the U.S. and Canada, and others interested in amateur radio, communication, and experimentation. The league operates the National Traffic System—a nationwide message-handling network Its members serve as official relay stations, observers, phone stations, emergency coordinators, experimental stations, and bulletin stations. They operate an experimental equipment laboratory and maintain the Museum of Amateur Radio. They also sponsor contests and present awards for operating proficiency. ARRL serves as secretariat for International Amateur Radio Union. Publications include *QST* (monthly) and *Radio Amateur's Handbook* (annually).

Audio Engineering Society (AES)
60 East 42nd Street
Room 2520
New York, NY 10165
(212) 661-8528, Website: http://www.aes.org

The Audio Engineering Society (AES) is devoted exclusively to audio technology. Its membership includes engineers, scientists and other authorities throughout the world. The AES serves its members, the industry, and the public by stimulating and facilitating advances in the constantly changing field of audio. It encourages and disseminates new developments through annual technical meetings and exhibitions of professional equipment, and through the *Journal of the Audio Engineering Society,* the professional archival publication in the audio industry.

Illuminating Engineering Society of North America (IESNA)
120 Wall Street, 17th Floor
New York, NY 10005
(212) 248-5000, Website: http://www.iesna.org

IESNA is the recognized technical authority for the illumination field. For over 90 years its objective has been to communicate information on all aspects of good lighting practice to its members, to the lighting community, and to consumers through a variety of programs, publications, and services. The strength of IESNA is its diversified membership: engineers, architects, designers, educators, students, contractors, distributors, utility personnel, manufacturers, and scientists, all contributing to and benefiting from the Society.

IESNA is a forum for exchange of ideas and information and a vehicle for its members" professional development and recognition. Through its technical committees, with hundreds of qualified members from the lighting community, the IESNA correlates vast amounts of research, investigations, and discussions to guide lighting experts and laymen on research- and consensus-based lighting recommendations. Complete lists of current and available recommendations may be obtained by writing to the IESNA Publication Office.

In addition to the *IESNA Lighting Handbook,* the IESNA publishes *Lighting Design + Application* (LD+A) and the *Journal of the Illuminating Engineering Society* (JIES) as the official magazines of the Society.

The National Radio Systems Committee (NRSC)
1771 N Street, N.W.
Washington, DC 20036
voice: (202) 429-5346, fax: (202) 775-4981, Website: http://www.nab.org

The NRSC is jointly sponsored by the NAB and the Consumer Electronics Manufacturers Association (CEMA). Its purpose is to study and make recommendations for technical standards that relate to radio broadcasting and the reception of radio broadcast signals. The NRSC is a vehicle by which broadcasters and receiver manufacturers can work together towards solutions to common problems in radio broadcast systems.

Anyone who has a business interest in the technology being investigated by the NRSC is welcome to join the Committee and participate in its activities. Members of the NRSC are generally engineers, scientists, or technicians with in-depth knowledge of the subject being studied. In order to promote the free exchange of ideas during Committee work, members of the press are not allowed to attend NRSC meetings. However, members of the press are free to contact Committee chairpersons, NAB, or CEMA with general questions about meetings. NRSC meetings are held on an as-needed basis, and NRSC members must participate at their own expense.

Underwriters Laboratories (UL)
333 Pfingsten Road
Northbrook, Illinois 60062
(847) 272-8800, Website: http://web138.bbnplanet.com/

UL is the leading third-party certification organization in the United States and the largest in North America. As a not-for-profit product safety testing and certification organization, UL has been evaluating products in the interest of public safety since 1894. Additional UL testing laboratories are located in Melville, New York; Santa Clara, California; and Tampa, Florida. UL seeks "by scientific investigation, study, experiments, and tests to determine the relation of various materials, devices, products, equipment, constructions, methods, and systems to hazards appurtenant thereto or to the use thereof affecting life and property, and to ascertain, define, and publish standards, classifications, and specifications for materials, devices, products, equipment, construction, methods, and systems affecting such hazards, and other information tending to reduce loss of life and property from such hazards."

1.8 DIGITAL AUDIO STANDARDS AND PRACTICES

CHIP MORGAN
CMBE, EL DORADO HILLS, CA AND

RANDALL HOFFNER
ABC, INC. NEW YORK, NY

INTRODUCTION

Digital audio technology is quickly supplanting analog audio technology in United States television and radio production and broadcast facilities. Like digital video, digital audio offers many advantages in production, editing, distribution and routing. Digital audio is remarkably robust and far less susceptible to degradation from hum, noise, level anomalies and stereo phase errors than analog audio. Each analog audio recording generation and processing step adds its own measure of noise to the signal, but in the digital domain audio is not subject to such noise build-up. Once audio is converted to the digital domain, there are a number of storage options beyond magnetic tape. Digital audio may be stored on magnetic, optical, or magnetooptical discs and in solid state memories. When audio samples have been reduced to a series of numbers, processing and manipulation become largely mathematical operations, and a whole new world of possibilities opens. Non-linear editing is an example of a process that cannot be done in the analog domain. Ultimately, the breakthrough technology of digital compression creates new economies in the storage and transport of digital audio and permits the broadcast of digital audio within a reasonable segment of spectral bandwidth.

The distribution and routing of audio in the digital domain present the broadcaster with new options as well, such as the capability to embed digital audio within a serial digital video signal, facilitating the carriage of video and multiple audio channels on a single coaxial cable. Although digital audio presents its own unique set of challenges, its advantages far outweigh its disadvantages.

Digital audio systems are inherently free of the hum and noise problems that can invade analog audio systems. The nature of the digital domain gives rise to a new set of considerations for the facility planner and designer. Digital audio signals operate in the multiple megahertz frequency domain that video engineers are well acquainted with, raising such considerations as signal reflections and impedance discontinuities. System synchronization is another new concept for the audio engineer. In digital audio system engineering, just as in analog audio system engineering, cognizance of the potential pitfalls to be avoided, and the application of good engineering practices, will result in facilities that function well.

DIGITAL AUDIO STANDARDS

The fundamental signal interface for digital audio systems is AES3, the standard digital audio interface jointly developed by the Audio Engineering Society (AES) and the European Broadcast Union (EBU). AES3 is accompanied by a number of ancillary standards addressing such aspects of digital audio as sample rates, system synchronization and equipment testing, and by application notes that provide guidance in the implementation of digital audio systems.

In addition to the AES/EBU interface, several other digital audio interfaces have been and continue to be used in certain applications. These include such interfaces as the Sony/Philips digital audio interface (S/PDIF), which, although it is the consumer version of the IEC 958 interface, has found its way into professional applications and the Sony developed digital audio interface SDIF-2, which is frequently used in CD mastering and multi-track recording applications.[1]

S/PDIF and SDIF are used in some confined subsystems within many digital audio plants. The requirement for multichannel interconnections between multitrack audio recorders and multitrack audio consoles resulted in the expansion of the AES/EBU interface into the Multichannel Audio Digital Interface (MADI).

AES3—AES Recommended Practice for Digital Audio Engineering—Serial Transmission Format for Two-Channel Linearly Represented Digital Audio Data

The interface defined in AES3 is commonly known as the AES/EBU digital audio interface. European

[1] Since 1997, the IEC document numbering system has added 60000 to the old IEC standard number, so the official number of this standard is now IEC 60958. Because the three-digit number is more widely known, this number will be used descriptively within the chapter.

broadcasters were about a decade ahead of United States broadcasters in their initial implementation of digital audio, and the requirement for a standard professional interface led the EBU and the AES to collaborate on the development of such an interface. The result of that collaboration is AES3 (ANSI S4.40), first standardized in 1985, revised in 1992, and revised again in 1997.

The first sentence of the abstract of AES3 is quite descriptive of its scope: "The format provides for the serial digital transmission of two channels of periodically sampled and uniformly quantized audio signals on a single shielded twisted wire pair."[2] AES3 defines a digital protocol and physical and electrical interfaces for the carriage of two discrete audio channels, accompanied by various housekeeping, status and user information in a single serial digital bitstream. As its title indicates, AES3 was designed to carry linearly quantized (uncompressed) digital audio. Compressed digital audio may be carried on the IEC 958 digital audio interface. IEC 958 is identical to AES3 in protocol and electrical characteristics, but it addresses a professional implementation (AES/EBU) and a consumer implementation (S/PDIF). The AES3 interface has the capacity to carry linearly sampled digital audio at bit depths from 16 to 24, data descriptive of such factors as channel status and sample validity, along with parity checking data and user data. Total bit count per sample, including audio and housekeeping, is 32 bits. An ancillary standard, AES5, recommends use of the professional audio sample rate of 48 kHz on AES3, while recognizing the use of sample rates of 44.1 kHz, 32 kHz and 96 kHz. AES3 carries audio samples using time-division multiplexing, in which samples from each of the two represented audio channels alternate.

The data carried on the AES/EBU interface is divided into blocks, frames and subframes. An AES block is constructed of 192 frames, each frame being composed of two subframes, each subframe containing a single audio sample. A subframe begins with a preamble that provides sync information and describes what type of subframe it is, and ends with a validity bit, a user bit, a channel status bit and a parity bit.

The subframe is divided into 32 *time slots*, each time slot being one sample bit in duration. The first four time slots are filled with a 4 bit preamble. The 24 time slots following the preamble may be filled in one of two ways. As shown in Figure 1.8-1 (a), an audio sample word of up to 24 bits may fill all the time slots. Figure 1.8-1(b) illustrates that the first four time slots of the audio sample word space may be filled with auxiliary bits, which can represent user data or low-quality audio for informational or cueing purposes, for example. In all cases, the audio word is represented least significant bit (LSB) first, most significant bit (MSB) last. If digital audio words of bit depth less than the maximum are represented, the unused bits are set to logic 0. Time slots 28, 29, 30 and 31 are filled with a validity bit (V), a user bit (U), a channel status bit (C), and a parity bit (P), respectively. The subframes are assembled into frames and blocks as shown in Figure 1.8-2.

Figure 1.8-1(a). Subframe format—16–20 Bit Audio Word[3]

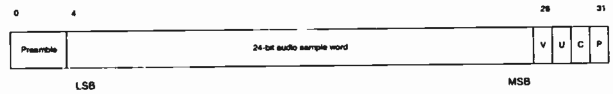

Figure 1.8-1(b). Subframe format—16–24 Bit Audio Word[4]

Each subframe begins with one of three preambles. The first subframe in the 192 frame block, a Channel 1 subframe, starts with Preamble Z. All other Channel 1 subframes in the block start with Preamble X. All Channel 2 subframes start with Preamble Y. Figure 1.8-2 represents the last frame of a block, and the first two frames of the following block. Subframe 1 of Frame 0, the first subframe of the block, begins with Preamble Z, uniquely identifying the beginning of the block. After the first subframe, the successive subframes are marked by Preamble Y and Preamble X, to identify Channel 2 and Channel 1 subframes respectively.

A frame, consisting of two 32 bit subframes, is made up of 64 bits, and the data rate of the interface signal may be readily calculated by multiplying the sampling rate times 64. In the case of the 48 kHz sample rate, the total data rate of the signal is 64 times 48,000 or 3.072 Mbps. As will be explained later, the interface employs an embedded clock signal that is twice the sample rate, making the actual frequency of this signal about 6.1 MHz.

All time slots except the preambles are encoded using biphase-mark coding to prevent the transmission of long strings of logic 0's or logic 1's on the interface, and thereby minimize the dc component on the transmission line; facilitate rapid clock recovery from the serial data stream; and to make the interface insensitive to the polarity of connections. The preambles intentionally violate the rules of biphase-mark coding by differing in at least two states from any valid biphase code to avoid the possibility of other data being mistaken for a preamble. Biphase-mark coding requires a

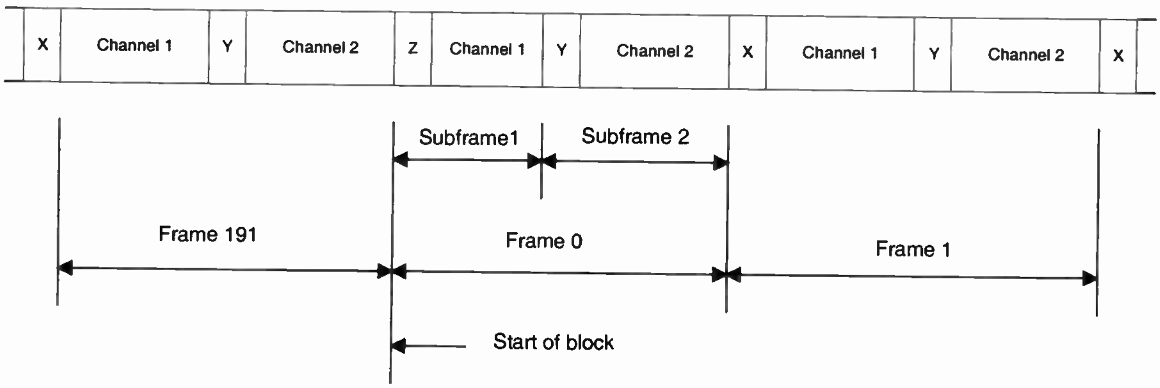

Figure 1.8-2. AES-3 Block and Frame Structure[5]

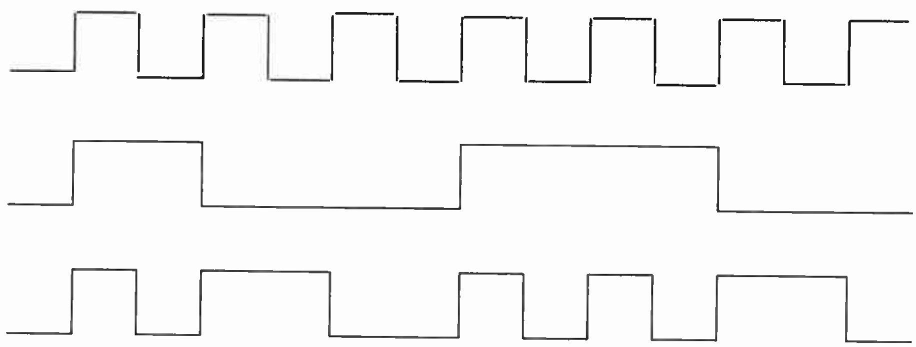

Figure 1.8-3. AES Channel Coding[6]

clock that runs at twice the sample rate of the data being transmitted, and each bit that is transmitted is represented by a symbol that is composed of two binary states. Figure 1.8-3 illustrates these relationships.

The top sequence of Figure 1.8-3 illustrates the interface clock pulses, running at a speed twice the source-coded sample rate. The middle sequence shows the source coding, which is the series of pulse code modulated (PCM) digital audio samples. The bottom sequence shows how the source coded data is represented in biphase-mark coding. In biphase-mark coding, each source coded bit is represented by a symbol that is composed of two consecutive binary states. The first binary state of a biphase-mark symbol is always different from the second state of the symbol preceding it. A logic 0 is represented in biphase-mark coding by a symbol containing two identical binary states. A logical 1 is represented in biphase-mark coding by a symbol containing two different binary states. This relationship may be seen by examining in the first full source coding bit at the left in the figure, which is a logic 1. Note that the duration of this bit is two clock pulses. Because the symbol immediately before it ended with a logic 0, the biphase-mark symbol representing it begins with a logic 1. As the bit to be transmitted is a logic 1, the second state of the biphase-mark symbol representing it is different from the first, a logic 0. The second source coded bit to be transmitted is a logic 0. Its first biphase-mark binary state is a logic 1, because the immediately previous state was a logic 0, and the second state is also a logic 1. The fact that the first binary state of a biphase-mark signal is always different from the last binary state of the previous symbol ensures that the signal on the interface does not dwell at either logic 0 or logic 1 for a period longer than two clock pulses. Because biphase-mark coding does not depend on the absolute logic state of the symbols representing the source coded data, but rather on their relative states, the absolute polarity of a biphase-mark coded signal has no effect on the information transmitted, and the interface is insensitive to the polarity of connections.

---

[5] AES3-1992 (r1997), *AES Recommended Practice for Digital Audio Engineering—Serial Transmission Format for Two-Channel Linearly Represented Digital Audio Data,* Figure 1.8-2.

[6] AES3—1992 (r1997), *AES Recommended Practice for Digital Audio Engineering—Serial Transmission Format for Two-Channel Linearly Represented Digital Audio Data,* Figure 1.8-3.

The last four time slots in a subframe are occupied by various housekeeping and user data. The validity bit (V) indicates whether the audio sample word is suitable for conversion to an analog audio signal. The channel status bit (C) from each subframe is assembled into a sequence spanning the duration of an entire AES3 block, and these 192 bit blocks of channel status data describe a number of aspects of the signal. Examples of channel status data include the length of audio sample words, sampling frequency, number of audio channels in use, emphasis information, consumer or professional interface implemented, audio or data being transmitted on the interface and a host of other possible information.

The 192 bit channel status bits (per block) are subdivided into 24 byte units. There is a separate channel status block for each audio channel, so channel status may be different for each of the audio channels. User data, or U-bits, may be used in any way desired. The parity bit (P) facilitates the detection of data errors in the subframe by applying even parity, ensuring that time slots 4–31 carry an even number of logic 1's and logic 0's.

The electrical interface specified by AES3 is a two-wire balanced signal. The AES interface was devised by audio engineers, with the intent to create a digital audio signal that could be carried on the same balanced, shielded, twisted pair cables and XLR-3 type connectors that are used for analog audio signals. The specified source impedance for AES3 line drivers and the specified input impedance for AES3 line receivers is 110 Ω, which is the approximate characteristic impedance of shielded twisted pair cable as used for analog audio. The permitted signal level on the interface ranges from 2–7 V peak-to-peak.

The balanced, twisted pair electrical interface can give rise to some problems in implementation. XLR-type connectors and audio patch panels, for example, are not impedance matched devices. This is of no import when the highest frequency of interest is 20 kHz, but it can cause serious problems when a 6 MHz signal must be passed. These considerations, plus the familiarity of television engineers with unbalanced coaxial transmission of 5 MHz analog video, generated the requirement for standardization of an unbalanced, coaxial electrical interface for the AES3 signal. Such an electrical interface is standardized in SMPTE 276M, which describes carriage of the AES/EBU interface on standard 75 Ω video cable using BNC connectors, at a signal level of 1 V peak-to-peak. The fact that the 110 Ω balanced and 75 Ω unbalanced signal formats coexist in many systems frequently presents the requirement to translate between these two signals. Devices to perform such translations are available for purchase, and SMPTE 276M has an informative annex explaining how to build them.

AES2–id is an information document containing guidelines for the use of the AES3 interface. *AES3–id* is an information document containing descriptive information about the unbalanced coaxial interface for AES3 audio.

AES5—AES Recommended Practice for Professional Digital Audio—Preferred Sampling Frequencies for Applications Employing Pulse-Code Modulation

This companion document to AES–3 contains the recommended digital audio sample rate for signals to be carried on the interface. The professional digital audio sample rate of 48 kHz is recommended, with recognition given to the use of the compact disc sample rate of 44.1 kHz, a low bandwidth sample rate of 32 kHz, and, new for the 1998 review, the use of a 96 kHz sampling frequency for applications requiring a higher bandwidth or more relaxed anti-alias filtering. SMPTE EG 32, engineering guideline on AES/EBU audio emphasis and sample rates for use in television systems, also recommends that the 48 kHz sample rate be used.

Variations on these sample rates are encountered. Varispeed operation requires the ability to adjust these sample rates by about ±12%, and of course accommodation to 59.94 Hz video requires operation at 48 kHz/1.001.

AES10—AES Recommended Practice for Digital Audio Engineering—Serial Multichannel Digital Audio Interface (MADI)

MADI is a multichannel digital audio interface that is based on AES3. It is designed for the carriage of up to 56 audio channels on a single coaxial cable or optical fiber. MADI preserves the AES3 subframe protocol except for the preamble. A MADI frame is composed of 56 channels, which are analogous to AES3 subframes. Each MADI channel contains 32 time slots, as does an AES3 subframe. The first four time slots contain synchronization data, channel activity status (channel on/off), and other such information. The following 28 time slots are filled in the same way as in an AES3 subframe—24 audio bits, followed by a V bit, a U bit, a P bit and a C bit.

The MADI coaxial cable interface is based on the on the fiber distributed digital interface (FDDI) standardized in ISO 9314, for which chip sets are available. Data is transmitted using non-return-to-zero inverted (NRZI), polarity-free coding and a 4–5 bit encoding format, in which each channel's 32 bits are grouped into 8 words of 4 bits each, and each 4 bit word is then encoded into a 5 bit word. The data rate on the interface is a constant 125 Mbps, with the payload data rate running between approximately 50 and 100 Mbps, depending on the sample rate in use. Sample rates may vary from 32 to 48 kHz ±12.5%. The specified coaxial cable length for the MADI signal is up to 50 m. A standard for carriage on optical fiber is under consideration.

MADI finds frequent use in multitrack audio facilities, for example, as an interface between multitrack audio recorders and consoles. It is conceivable that the MADI interface could be transmitted over very long distances, using, for example, a synchronous optical network (SONET) circuit.

AES10–id is an information document containing engineering guidelines for the implementation and use of the MADI interface.

AES11—AES Recommended Practice for Digital Audio Engineering—Synchronization of Digital Audio Equipment in Studio Operations

This document describes a systematic approach to the synchronization of AES3 digital audio signals. Synchronism between two digital audio signals is defined as that state in which the signals have identical frame frequencies, and the timing difference between them is maintained within a recommended tolerance on a sample-by-sample basis.

AES11 recommends that each piece of digital audio equipment have an input connector that is dedicated to the reference signal. Two methods of synchronization are proposed: (a) the use of a master digital audio reference signal, insuring that all input/output equipment sample clocks are locked to a single reference; and (b) the use of the sample rate clock embedded within the digital audio program signal that is input to the equipment. Method (a) is preferred for normal studio practice, as method (b) may increase the timing error between pieces of equipment in a cascaded implementation.

The digital audio reference signal is to have the format and electrical configuration of the two-channel AES3 interface, but implementation of only the basic structure of the interface format, where only the preamble is active, is acceptable as a reference signal. A digital audio reference signal may be categorized in one of two grades. A grade 1 reference signal must maintain a long-term frequency accuracy within ±1 ppm, while a grade 2 reference signal has a tolerance of less than ±10 ppm.

AES17—AES Standard Method for Digital Audio Engineering—Measurement of Digital Audio Equipment

This standard defines a number of tests and test conditions for specifying digital audio equipment. Many of these tests are substantially the same as those used for testing analog audio equipment, but the unique nature of digital audio dictates that additional tests are necessary beyond those used for analog audio equipment.

AES18—AES Recommended Practice for Digital Audio Engineering—Format for the User Data Channel of the AES Digital Audio Interface

This standard describes a method of formatting the user data channels within the AES3 digital audio interface using a packet based transmission format.

ATSC A/52—Digital Audio Compression (AC-3) Standard, Annex B, "AC-3 Data Stream in IEC 958 Interface"

Annex B of the ATSC AC-3 Digital Audio Standard for digital television broadcast describes the carriage of compressed AC-3 elementary streams on the IEC 958 digital audio interface. The advent of digital television broadcasting will necessitate the carriage of AC-3 compressed digital audio streams between pieces of DTV equipment. An example is the interface between an AC-3 encoder and the program data stream multiplexer of a DTV transmission system.

IEC 60958 Digital Audio Interface

IEC 60958 (IEC 958) is logically identical to the AES3 digital audio interface. Electrically, it provides for both the 110 Ω balanced and the 75 Ω unbalanced interfaces. Two versions are described, a consumer version, the S/PDIF interface, in which bit 0 of the channel status word is set at logic 0; and a professional version, the AES/EBU interface, in which bit 0 of the channel status word is set at logic 1. Provision is made in the location of time slots 12–27, which are normally used to carry linear 16 bit PCM audio words, to permit some recording equipment to record and play back either linear 16 bit PCM audio or encoded data streams (compressed digital audio). The consumer implementation permits only the 32 bit mode, in which channel 1 and channel 2 subframes are simultaneously employed to carry 32 bit words. The professional implementation permits either the 32 bit mode or the 16 bit mode, in which each subframe carries a 16 bit digital audio word. The consumer implementation may carry either two channels of linear PCM digital audio, or one or more compressed audio bitstreams accompanied by time stamps. The professional implementation may carry two channels of linear PCM digital audio, two sets of compressed audio bitstreams with time stamps, or one channel of linear PCM digital audio and one set of compressed audio bitstreams with time stamps.

SMPTE STANDARDS AND RECOMMENDED PRACTICES CONCERNING THE USE OF AES DIGITAL AUDIO IN TELEVISION SYSTEMS

SMPTE 272M—Formatting AES/EBU Audio and Auxiliary Data Into Digital Video Ancillary Data Space

This standard defines the embedding of AES/EBU digital audio into the standard definition serial digital interface specified in SMPTE 259M, *10-Bit 4:2:2 Component and 4f_{sc} NTSC Composite Digital Signals—Serial Digital Interface*. With such embedding, up to eight channels of digital audio in the AES3 format may be carried on the serial digital video interface signal that travels on a single coaxial cable.

SMPTE 276M—Transmission of AES/EBU Digital Audio Signals over Coaxial Cable

This SMPTE standard defines the unbalanced 75 Ω coaxial cable electrical interface for the AES3 bitstream.

SMPTE 299M—24-Bit Digital Audio Format for HDTV Bit-Serial Interface

This standard defines the embedding of AES/EBU digital audio data into the high definition serial digital video interface specified in SMPTE 292M, *Bit Serial Digital Interface for High-Definition Television Systems.* This is the high definition counterpart to SMPTE 272M.

SMPTE RP 155—Audio Levels for Digital Audio Records on Digital Television Tape Recorders

This recommended practice describes a reference level lineup signal for use in digital audio recording on digital television tape recorders, and recommends the proper setting for the lineup signal on the recorder's digital audio level meters. The reference signal is the digital representation of a 1000 Hz sine wave, the level of which is 20 dB below the system maximum (full scale digital). Meters are to be calibrated with this signal to indicate −20 dBFS (20 dB below full scale digital).

SMPTE EG 32—Emphasis of AES/EBU Audio in Television Systems and Preferred Audio Sampling Rate

This engineering guideline recommends that no emphasis be used on digital audio recordings for television applications, and that the professional digital audio sample frequency of 48 kHz be used.

IMPLEMENTATION ISSUES

Interconnection & Cabling

The key to realizing the benefits of digital audio on a system-wide scale is a thorough understanding of the principles underlying digital signal distribution, routing and switching. There are, as explained, two electrical interfaces available for AES3 signals, and both require good engineering practices for successful implementation. Digital audio's data rate dictates that uncompressed digital audio signals occupy a bandwidth similar to that of analog video. Regardless of the electrical interface, a well-engineered interconnect requires proper match of source, destination and characteristic cable impedances. Prior to the 1992 revision of AES3, any equipment manufactured to AES3–1985 violated this principle, as that standard specified a 250 Ω load impedance for receivers and a 110 Ω source impedance for transmitters. Beginning in 1992, AES3 specifies impedance matching among transmitter, receiver and cable.

Choice of Cable

The use of the unbalanced coaxial cable interface for AES3 data transmission is often preferred by video engineers. SMPTE 276M and *AES3–id* provide guidance for using the 75 Ω unbalanced AES3 interface. Any high quality video cable will be found quite acceptable for unbalanced AES3 signals. Those engineers designing facilities dealing only with audio may prefer the use of balanced, shielded, twisted pair cables with XLR-type connectors to carry AES3 signals, but should be aware of the cable length restrictions of this implementation, and of the possibility that problems will arise from impedance mismatches at connectors and patch panels. For balanced transmission of AES3 signals, special low capacitance twisted pair cable intended especially for digital audio use is recommended over the standard twisted pair cables used for analog audio, as the higher capacitance of analog audio cable tends to distort square wave signals by rolling off the higher frequency components.

Digital Audio Distribution

The use of analog video distribution and routing equipment is not recommended for AES3 signals, as such equipment may distort AES signal shapes and risetimes, adversely affecting the decoding of the signal at receiving equipment. The spurious high frequency signal energy that may be generated by such distortions of signal shape can cause crosstalk related bit errors that are difficult to dissect and analyze. Distribution of the AES3 signal using high quality digital audio distribution amplifiers maintains the proper frequency and phase relationships, as well as signal shapes and risetimes.

System Synchronization

When possible all digital audio signals should be synchronous in order to avoid objectionable digital artifacts. In a large plant, it is necessary to provide a single master reference signal to which all interconnected systems are synchronized. The master reference, fed to all pieces of equipment, allows audio data to be re-timed and synchronized within specified tolerances.

Larger facilities, in particular, will benefit from the conversion of digital audio signals from sources without external sync capability to a standard, synchronized audio sample rate. Broadcast digital audio plants typically contain consumer and other non-synchronizable equipment which requires sample rate conversion. Audio sample rate converters perform a function similar to video standards converters, in that a dynamic low pass filter continually adjusts the offending signal's phase at the output of the converter. In some cases, the output and input sample rates can be locked together via an integer relationship in a process known as *synchronous sample rate conversion*. For example, 48 kHz and 44.1 kHz are related by the integer ratio of 160 to 147.

MADI Synchronization

It is necessary for the equipment transmitting MADI data to include timing information that the receiving equipment can extract and use for synchronization. At least one sync code must be sent per frame; a sync code consists of two consecutive 5 bit words not used in the 4 bit to 5 bit encoding scheme. The total MADI interface data rate is higher than the payload data rate required, the difference between these two rates being sufficient to include sync codes within each frame. The fiber distributed digital interface (FDDI) chip set used for MADI implementation automatically handles the required synchronizing and coding operations.

Word Clock Synchronization

SDIF-2 word clock, commonly referred to as simply *word clock*, is a square wave signal at the digital audio sample rate. Word clock is commonly used as a reference signal in small, audio-only facilities. In facilities that handle both video and audio, black burst is commonly used as the reference for both video and AES audio signal synchronization.

AES3 Synchronization

AES3 is inherently synchronous, the clock signal being readily recovered from the AES3 bitstream. However, the use of a master digital audio reference insures that all digital audio equipment in a system will be frequency and phase locked and free of cascaded timing errors, and is highly recommended by AES11. The master reference signal may come from the digital audio console in a facility on the scale of a single room, or from an external reference generator in larger facilities. The master sync signal should be sent to all equipment capable of accepting external sync signals.

Digital audio phase integrity must remain intact during the conversion of multiple audio channels between the digital and analog domains. Perfect phase synchronization requires use of an SDIF-2 word clock or an AES3 signal as the common master clock. Digital audio recording and processing equipment forces any AES3 input signal into a common AES3 frame phase. When such an AES3 frame alignment is performed, a phase error will result if there are any deviations in the frame phase of A/D converters.

When digital audio signals are transferred to a piece of equipment that is not synchronized using a master sync signal, sample rate converters must be used at the inputs to the receiving equipment to prevent clicks and pops.

Signal Routing

Asynchronous routing is the simplest and most cost-efficient method of routing digital audio. It passes digital audio signals at any sample rate, a degree of flexibility that is ideal in situations where a number of different audio sample rates are encountered. However, the lack of synchronization to a master reference makes it a poor choice for on-air applications or any other situation where frame accurate switching or editing is required.

An asynchronous router may be thought of as an electronic patching system, functioning as though simple wires were used to connect inputs to outputs. In an asynchronous system, it is imperative that the destination equipment be capable of locking to the sample rate of the signal routed to it, otherwise muting usually takes place.

The disadvantage of asynchronous routers is that their output signal is almost always corrupted when a switch is made between input signals. A switch typically results in one or more AES frames being damaged, and this may cause destination equipment to momentarily lose lock, causing muting or the generation of pops and clicks.

Synchronous routing ensures precise timing and no corruption of the data stream during switches. It is considerably more complex and costly than asynchronous routing, as it requires that a transition between two inputs be made at an AES frame boundary. All inputs to a synchronous router must be locked to a common digital audio reference. A digital audio console is essentially a synchronous router with a lot of controls.

Jitter

Jitter is short-term frequency variation in the input data stream to a digital audio device. It can result from a number of causes, including such things as the coupling of excessive noise into a transmission link. Some jitter build-up is inevitable in a system, as certain components of the system inherently generate some amount of jitter. For example, noise in the phase-locked loops that control clock frequencies in the components of the system unavoidably generates some jitter. The presence of out-of-specification jitter on a digital audio signal or clock can result in bit errors that generate clicking and popping sounds. High levels of jitter may cause a receiving device to lose lock, while a relatively small amount may have no negative effect unless present in devices performing A/D or D/A conversions. Excessive jitter is seldom a problem when only two pieces of equipment are involved, but typically builds up when three or more pieces are interconnected. Jitter may be eliminated through the use of synchronizing D/As or a common synchronization signal. Jitter on the synchronization signal itself can cause degradation of digital audio in devices locked to it.

Levels and Metering

When an analog audio signal is converted to digital, the greatest analog voltage level that may be represented digitally is called full scale digital (FSD). When quantized, this voltage level causes all digital audio bits to be set to logic 1, and this level is called 0 dBFS (full scale). This is an inflexible limit, and any excursion of the analog signal above this level will be clipped off, as the digital audio word does not have the capacity to faithfully represent it. In practice, the FSD level is often set about 1 dB above the analog clip level in an effort to assure that digital clipping never occurs.

When signals are converted between the analog and digital domains, the analog reference levels of A/D and D/A converters may be set to any number of values. If the analog reference level is improperly calibrated in any of the converters in the path, A/D and D/A conversions may result in an increase or a decrease in the level of the recovered analog signal.

Consistency in the type of digital audio metering device used, good operator training and the establishment of strict house standard reference levels and alignment practices are the best defenses when it comes to accurate audio level control.

There is no United States standard for a specific digital audio level meter. Digital audiometers are often of the instantaneous response type, with no integration time, permitting them to respond with full excursion to a peak as brief as a single digital audio sample. Contrast this with the standard volume indicator (vu meter) which is an average-responding device, and the typical peak-program meter, which does not respond with full excursion to peaks with durations less than 10 ms. Typically, digital audio metering devices display a maximum value of 0 dBFS, and reference level lineup tone is set to a designated point below 0 dBFS to accommodate peaks without digital clipping.

Figure 1.8-4 shows a representative digital audiometer, the display device of which is usually an array of light emitting diodes or other such devices. This representative meter displays a range of −40 dB to 0 dBFS, with lineup tone being calibrated at −20 dBFS.

For television applications, SMPTE RP 155 recommends adjusting the level of lineup tone to read −20 dBFS on digital audiometers used on digital videotape recorders. Other industry segments have variously used lineup tone levels of −15, −18 and −20 dBFS. These varying reference levels may cause inconsistent results when digital audio recordings are interchanged. It is therefore important to establish common digital audio reference and operating levels when exchanging digital audio recordings.

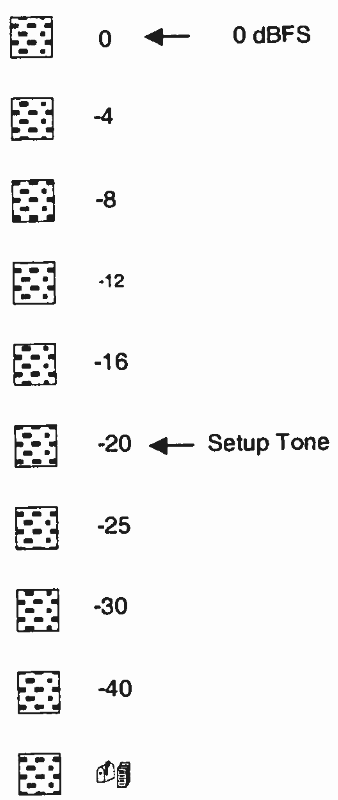

Figure 1.8-4. Representative digital audio level meter

Digital audio, with its many advantages, is not inherently susceptible to many of the problems that are encountered in analog audio systems. It does harbor some potential hazards of its own, however. With care and attention to good engineering practices in the design and maintenance of digital audio facilities, outstanding results will be realized.

NTSC STANDARD[1]

STAFF

INTRODUCTION

Nearly every branch of science, including chemistry and psychology, contributes in some way to the reality of color television. Through chemistry, improved phosphors are continually being found for use in color picture tubes.[2] Psychology enters into the selection of lighting arrangements and picture composition to obtain desirable interpretations by the viewer. But physics plays the leading role with intense application in optics and illumination as well as in the design of electronic circuitry and components for the complete television system.

Two specialized branches of physics, namely radio and television engineering, are responsible for the electronic techniques which make color television compatible with black and white (monochrome) television.

Compatibility

When introduced in 1953, the compatible color system offered tremendous economic advantages to the home viewer and the television broadcaster. Because of compatibility, color telecasts could be seen (in monochrome) on black and white television receivers without any changes or added devices. Also, color receivers could receive monochrome as well as color telecasts. Since compatible color is transmitted over the same channels as monochrome and within the same framework of standards, the television broadcaster could utilize the monochrome system as the transmitting nucleus when installing equipment to broadcast color.

Another important advantage of the compatible color system was the part it played in the conservation of the radio frequency spectrum. Compatible color required no additional space in the spectrum. However, it employed techniques which made much more efficient use of the standards originally set up for monochrome television.

A brief review of the fundamentals of monochrome television, particularly the areas wherein specialized color methods are employed, is presented in the next few paragraphs as an aid in describing the basic color concepts.

Television: A System of Communications

Very simply, the function of the television system is to divide and subdivide the optical image into over 200,000 picture elements, each of different light intensity; convert these light elements to electrical equivalents; and transmit them in orderly sequence over a radio-frequency carrier to the television receiver.

Reversing the process at the receiver, these electrical signals are each converted to light of corresponding brightness and reassembled to produce the transmitted image on the fact of the picture tube.

Scanning

Picture elements to be transmitted in sequence are selected by a process of image scanning, which takes place in the television camera focused on the studio scene at the station. Within the camera, an electron beam in a pickup tube scans a sensitive surface containing an electrical image of the scene of action, as illustrated in Figure 1.9-1. The electron beam successively scans the image at great velocity, beginning at the upper left corner and continuing left to right in a series of parallel lines to scan the image completely. Movement of the electron beam, which can be controlled magnetically by vertical-and horizontal-deflection coils surrounding the tube, is analogous to that of the eye in reading a printed page. The speed of movement is such, however, that 30 complete image frames of approximately 500 lines each are scanned every second. Of course, at the receiver, an electron beam in the picture tube, moves with the same speed and in synchronism with the camera tube beam so that the corresponding picture elements appear in the proper relative position on the television screen (see Figure

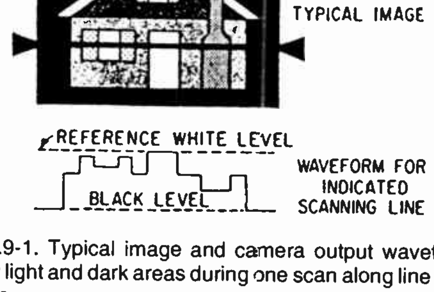

Figure 1.9-1. Typical image and camera output waveform produced by light and dark areas during one scan along line indicated by arrows.

[1] This section adapted from *Color Television, Manual for Technical Training,* RCA Corp. used with permission.

[2] In this chapter the terms CRT, kinescope and picture tube are used interchangeably.

1.9-2). Modern cameras use CCD devices in place of pickup tubes, however, the tube based explanation is the more straightforward approach.

Owing to persistence of vision and the speed of scanning, these elements appear to be seen all at once as a complete image rather than individually. Thus, the impression is one of continuous illumination of the screen and direct vision.

Scanning standards have been established in this country to assure that all television receivers are capable of receiving programs broadcast by any television station within range. The scanning pattern adhered to by manufacturers in the design of television receivers and broadcast equipment consists of 525 lines with odd-line interlaced scanning. Interlaced scanning, effective in eliminating perceptible flicker, is a method whereby the electron beam scans alternate rather than successive lines. For example, the beam begins by scanning odd-numbered lines (1, 3, 5, 7) until it reaches the bottom of the image, whereupon it returns to the top of the image to scan the even-numbered lines (2, 4, 6, 8). Thus, each scan, or field, comprises only half of the total number of scanning lines, and two fields are required to produce the 525-line frame. Each field is completed in one-half the frame time. The vertical scanning frequency is 2 × 30 or 60 Hz, and horizontal scanning frequency is 30 × 525 or 15,750 Hz. This process is illustrated in Figure 1.9-3.

Resolution and Bandwidth

The degree of resolution, or fine detail, that can be seen in a televised image depends upon the number of scanning lines used and the bandwidth of the transmitting and receiving system (see Figure 1.9-4).

The relationship between resolution and bandwidth can be seen by considering the number of picture elements that can be transmitted each second.

The standard 6 MHz broadcast channel provides a video bandwidth of approximately 4.1 MHz (the remaining bandwidth being required for a vestigial sideband plus the sound signal). Since each cycle of a sine wave is capable of conveying two picture elements (one black and one white), the maximum rate at which picture elements can be transmitted is 4,100,000 × 2, or 8,200,000 per second. Since 30 complete frames are transmitted per second, the number of picture elements per frame would be 8,200,000 ÷ 30, or 273,333 (if it were not for the retrace blanking problem, which requires interruption of the picture signal periodically by blanking pulses). Since the combination of horizontal and vertical blanking pulses requires nominally 25% of the total time, the maximum number of picture elements per frame is reduced in practice to 0.75 × 273,333, or approximately 205,000.

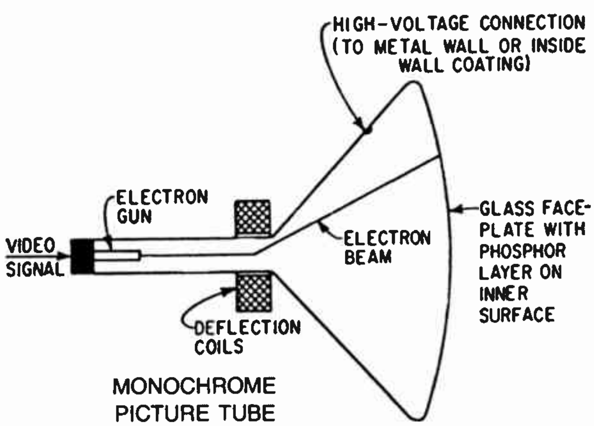

Figure 1.9-2. Diagram showing principal elements of the monochrome picture tube.

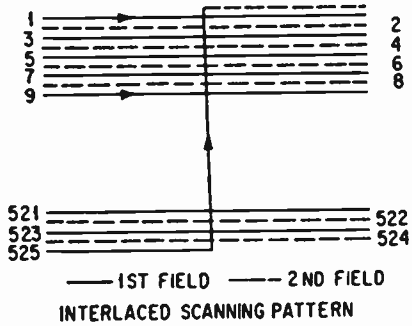

Figure 1.9-3. Diagram showing paths of the electron beam in both the pickup tube and CRT to produce the interlaced scanning pattern.

Synchronizing

In addition to the picture information, or video signals, blanking and synchronizing signals are transmitted by the television station to control the intensity and movement of the scanning beam in the CRT of the television receiver. Both these signals are in the form of rectangular pulses. Moreover, their polarity and amplitude are such that they are received as black signals and therefore do not appear on the receiver screen.

Blanking pulses eliminate the *retrace* lines which would otherwise appear between scanning lines and at the end of each field from the bottom of the picture to the top. Horizontal blanking pulses, transmitted at the end of each line, or at intervals of 1/15,750 sec,

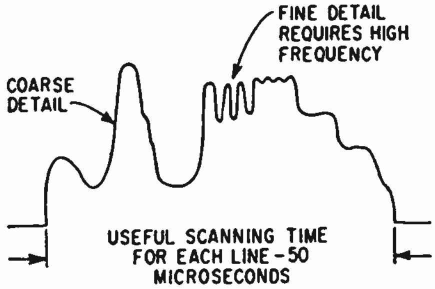

Figure 1.9-4. Diagram illustrating the relationship between picture detail and signal bandwidth.

blank the beam during retrace periods between lines. Vertical blanking pulses, transmitted at the end of each field, or at intervals of 1/60 sec, blank the beam during the time required for its return to the top of the picture. Because the vertical retrace is much slower than the horizontal, the vertical blanking periods are longer than the horizontal blanking periods. Vertical blanking pulses are about 20 lines duration, while horizontal blanking pulses have a duration of only a small fraction of a line.

Synchronizing signals keep the scanning beam of the picture tube in step with that of the camera tube. These signals consist of horizontal and vertical pulses which are transmitted within the respective blanking periods. Although the sync pulses are of the same polarity as the blanking pulses, they are of greater amplitude (blacker than black) and thus easily separated in the receiver and fed to the deflection circuits of the picture tube.

Since the vertical sync pulses are quite long compared with the horizontal sync pulses and the two are of the same amplitude, separation at the receiver is accomplished through frequency discrimination. Serrations, or slots in the vertical pulses, prevent loss of horizontal sync during the vertical blanking period.

The Monochrome Television System

The major equipment in a typical television station consists of the aural and visual units illustrated in the block diagram of Figure 1.9-5. In the visual channel, the video signal leaving the camera is passed through processing equipment which inserts the blanking and synchronizing signals and performs other functions (such as aperture compensation and gamma correction). From the processing chain, the video signal is fed to a switching system which provides for selection

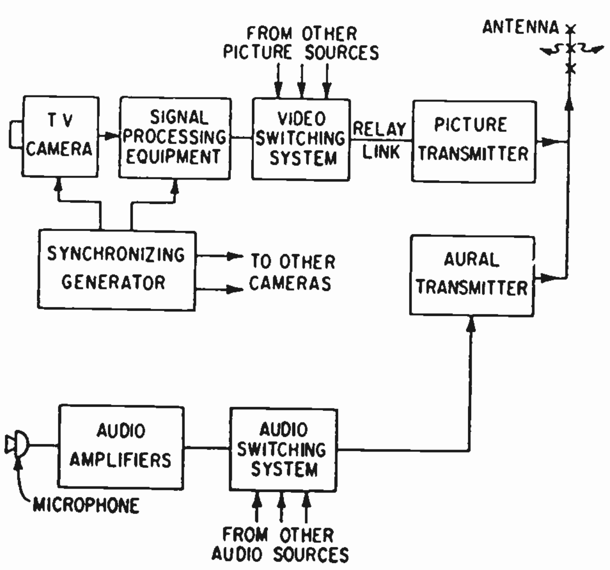

Figure 1.9-5. Simplified block diagram of the monochrome television station.

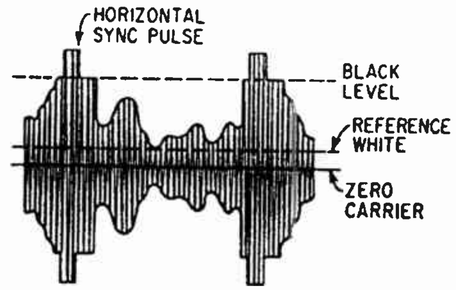

Figure 1.9-6. Waveform and radiated picture signal.

from a number of video sources. The selected signal is then sent to the visual transmitter through coaxial cable or over a microwave relay link, depending upon the distance between the television studio and transmitter. In the transmitter, the composite video signal amplitude modulates a carrier in the VHF or UHF range, which is radiated by the television antenna.

In the aural channel, the audio signal is fed from the sound sources through the switching system and to the aural transmitter. Frequency modulated output from the aural transmitter is combined with the visual output and radiated from the same antenna.

The Radiated Picture Signal

Amplitude relationships between the synchronizing pulses and the tonal gradations from white to black in the picture are represented in the waveform of the radiated picture signal. From Figure 1.9-6, it can be seen that modulation takes place in such a way that an increase in the brightness of the picture causes a decrease in carrier output power. Note that the reference white line indicated on the sketch is relatively close to zero carrier level. Also, the synchronizing pulses are in the *blacker than black* region, representing maximum carrier power. Use of a widely different range of amplitude for the sync pulses makes it possible for home receivers to separate them by a simple clipping technique.

Receiver

The basic elements of the television receiving system are illustrated in Figure 1.9-7. The radiated television signal is picked up by an antenna and fed to a tuner, which selects the desired channel for viewing. Output from the tuner is passed through an intermediate-frequency amplifier, which provides the major selectivity and voltage gain for the receiver. A second detector then recovers a video signal which is essentially the same as that fed to the visual transmitter.

The sound signal is usually taken off at the picture second detector in the form of a frequency-modulated beat between the picture and sound carriers. The sound signal is further amplified in an intermediate frequency IF stage, detected by a discriminator or ratio detector, and applied to the speaker through an audio amplifier.

Picture output from the second detector is fed to two independent channels. One of these is the video

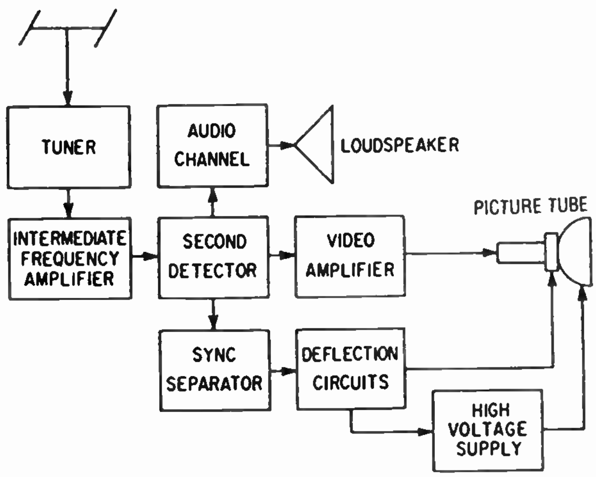

Figure 1.9-7. Block diagram of monochrome television receiver.

amplifier, which drives the electron beam in the picture tube, and the other is the sync separator, or clipper, which separates the sync pulses from the picture information. The separated pulses are then used to control the timing of the horizontal and vertical deflection circuits. The high-voltage supply, which is closely associated with the horizontal deflection circuit, provides accelerating potential for the electron beam.

The Three Variables of Color

Color is the combination of those properties of light which control the visual sensations known as *brightness, hue* and *saturation*. Brightness is that characteristic of color which enables it to be placed in a scale ranging from black to white or from dark to light. Hue, the second variable of a color, is the characteristic which enables a color to be described as red, yellow, blue or green. Saturation refers to the extent to which a color departs from white, or the neutral condition. Pale colors, or pastels, are low in saturation, while strong or vivid colors are high in saturation.

The monochrome system is limited to the transmission of images that vary with respect to brightness alone. Thus, brightness is the only attribute of a color which is transmitted over a monochrome television system. To produce a color image, therefore, provisions must be made for the transmission of additional information pertaining to all three of the variables of color. However, since the primary color process can be employed, it is not necessary to transmit information in exactly the form expressed by the three variables.

Primary Colors in Television

Experiments have proved conclusively that virtually any color can be matched by the proper combination of no more than three primary colors. While other colors could be used as primaries, red, green and blue have been selected as the most practical for color television use. Red and green combined produces yellow, red plus blue produces purple and green plus blue produces cyan or blue-green. The proper combination of all three of the primary colors produce white, or neutral, as shown at the center of the illustration. By relatively simple optical means, it is possible to separate any color image into red, green and blue, or RGB components.

Generating RGB Signals

Major components of a color television camera may have the block diagram form shown in Figure 1.9-8. Whereas the monochrome camera contains only one pickup tube, or solid-state sensor, the color camera usually contains three separate pickup devices. An

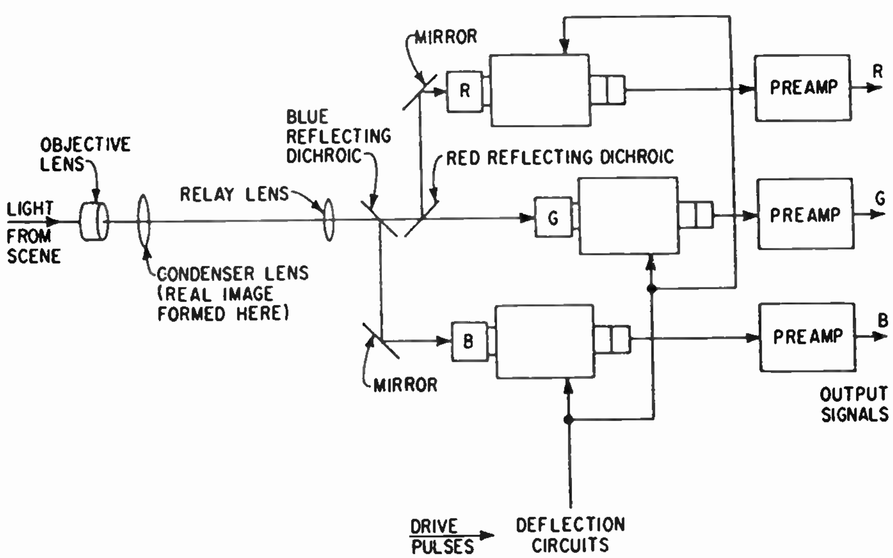

Figure 1.9-8. Simplified block diagram of the optical and electrical components of the color camera.

objective lens at the front of the camera forms a real image within a condenser lens which is located where the pickup device is usually mounted in a monochrome camera. A relay lens transfers this real image to a system of dichronic (color separating) mirrors or prisms which shunt the red and blue light to the red and blue pickup devices and permit the green to pass straight through to the green tube or sensor. In this manner, the three pickup devices produce three separate images corresponding to the RGB components of the original scene. These images are scanned in the conventional manner by common deflection circuits.

A single scanning line through the typical color image at a given point produces three separate waveforms (see Figure 1.9-9). It is important to note the correlation between these waveforms and the image at the top. The yellow shutters in the image, for example, must be produced by a mixture of red and green, and the blue signal is not required. Thus, at this interval of scanning the red and green signals are both at full value and the blue signal is at zero. The white door utilizes all three color signals. Of course, similar correlations can be seen for other parts of the image along the scanning line.

Displaying RGB Signals

RGB signals are displayed in color by the tricolor picture tube, the basic components of which are shown in Figure 1.9-10. Three electron guns produce three beams, which are independently controlled in intensity by the red, green and blue signals. These three beams are all made to scan in unison by deflection coils around the neck of the tube. The three beams converge at the screen owing to the magnetic field produced by a convergence yoke.

The phosphor screen of the color picture tube consists of an array of very small primary color dots. Approximately 1/2 in. behind the phosphor screen is an aperture mask which has one very small opening for each group of red, green and blue phosphors. Alignment of this aperture mask and screen is such that each beam is permitted to strike phosphor dots of only one color. For example, all the electrons emitted by the red gun must strike red phosphor dots on the aperture mask; they cannot strike either the green or blue dots because of the shadow effect of the mask. Likewise, the beams emanating from the other two guns strike only green or blue dots.

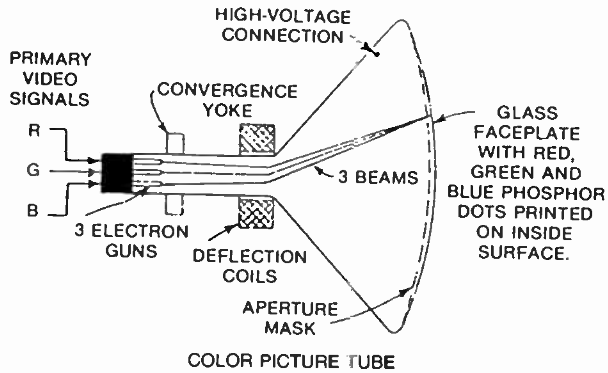

Figure 1.9-10. Diagram showing components of the three-gun picture tube.

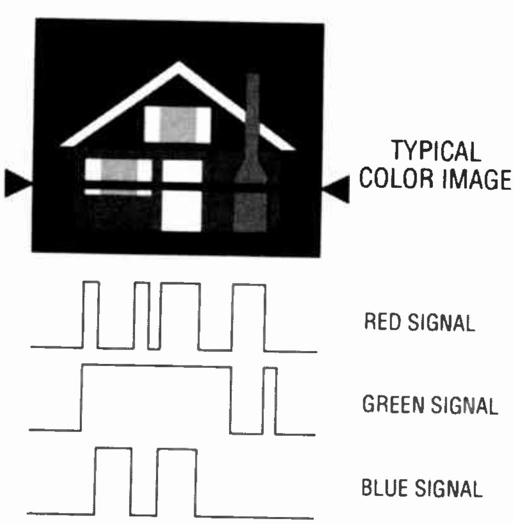

Figure 1.9-9. Typical color image and RGB waveforms.

In this way, three separate primary color images are produced on the screen of the tricolor tube. But since these images are formed by closely intermingled dots too small to be resolved at the normal viewing distance, the observer sees a full color image of the scene being televised.

ELECTRONIC ASPECTS OF COMPATIBLE COLOR TELEVISION

To achieve compatibility with monochrome television, color television signals must be processed so that they can be transmitted through the same channels used for monochrome signals, and they must also be capable of producing good monochrome pictures on monochrome receivers. Since color television involves three variables instead of the single variable (brightness) of monochrome television, an encoding process is required to permit all three to be transmitted over the one available channel. Likewise, a decoding process is required in the color receiver to recover the independent RGB signals for control of the electron guns in the color picture tube. Moreover, the process used must enable existing monochrome receivers to produce a monochrome picture from the color information (see Figure 1.9-11.)

Encoding and decoding processes used in compatible color television are based on four electronic techniques known as *matrixing, band shaping, two-phase modulation* and *frequency interlace.* It is these processes which make the color system compatible with monochrome and enable the color system to occupy the existing 6 MHz channel.

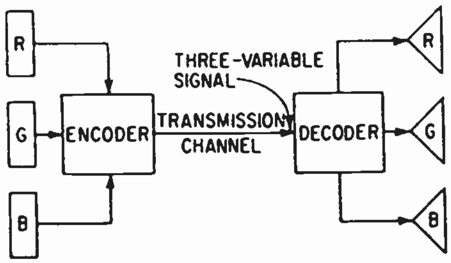

Figure 1.9-11. Encoding of the RGB signals provides a three-variable signal which can be transmitted over existing monochrome channels.

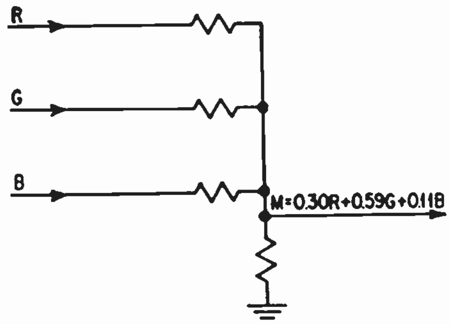

Figure 1.9-13. Diagram of resistance matrix circuit used to produce the M luminance signal.

Matrixing

Matrixing is a process for repackaging the information contained in the red, green and blue output signals from a color camera to permit more efficient use of the transmission channel. The matrix circuits which perform this function consist of simple linear cross-mixing circuits. They produce these signals, commonly designated M, I, and Q, each of which is a different linear combination of the original red, green and blue signals (see Figure 1.9-12). Specific values for these signals have been established by FCC standards.

The M-signal component, or *luminance* signal, corresponds very closely to the signal produced by a monochrome camera, and therefore is capable of rendering excellent service to monochrome receivers. The M component is obtained by combining red, green and blue signals in a simple resistor network (see Figure 1.9-13) designed to produce a signal consisting of 30% red, 59% green, and 11% blue.

The I and Q signals are *chrominance* signals which convey information as to how the colors in the scene differ from the monochrome, or neutral condition. The component I is defined as a signal consisting of 60% red −28% green and −32% blue. Minus values are easily achieved in the matrix circuits by use of phase inverters to reverse the signal polarity (see Figures 1.9-14 and 15). The Q signal is defined as 21% red −52% green and 31% blue.

It can be seen that the quantities are related so that when red, green and blue are equal, corresponding to the neutral condition, both I and Q go to zero. Thus, when the color camera is focused on an object having no color information, such as a monochrome test chart, the I-signal and Q-signal components are absent, leaving only the M component, or monochrome signal.

The matrix circuits, therefore, produce a new set of waveforms corresponding to the M, I, and Q components of the image. A comparison of the MIQ and RGB waveforms obtained from the image illustrates the correlation among the types of signals (see Figures 1.9-9 and 16). It will be seen that the M signal remains in the region between black level and reference white. The I and Q signals, on the other hand, swing positive and negative around a zero axis.

Band Shaping

The eye has substantially less acuity in detecting variations in chrominance than it has for resolving differences in brightness. This important characteristic of human vision was considered in setting up the I and Q equations because it permitted a significant reduction in the bandwidth of these signals through use of low pass filters. A bandwidth of approximately 1.5 MHz was found to be satisfactory for the I signal, which corresponds to color transitions in the range extending from orange to blue-green. For color transitions in the range from green to purple, as represented by the Q signal, the eye has even less acuity and the bandwidth was restricted to only 0.5 MHz. The M-

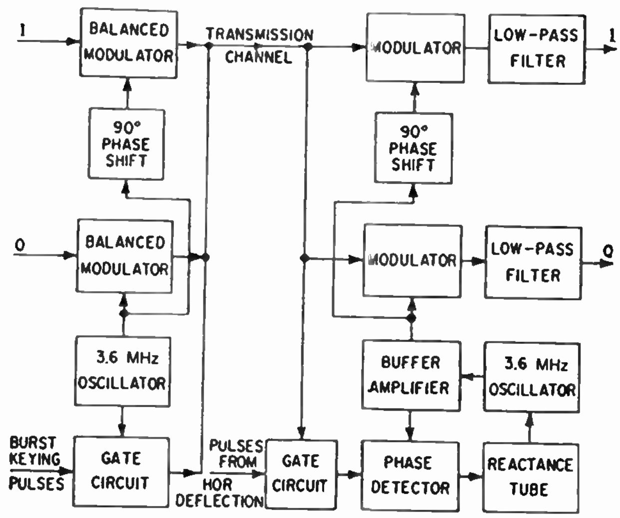

Figure 1.9-17. Simplified block diagram showing elements for transmitting and receiving the I, Q, and burst signals.

signal component, which conveys the fine details, must be transmitted with the standard 4 MHz bandwidth.

Two-Phase Modulation: Generation of Color Subcarrier

Two-phase modulation is a technique by which the I and Q signals can be combined into a two-variable signal for transmission over a single channel. This is accomplished by adding the sidebands obtained through modulation of two 3.6 MHz carriers separated in phase by 90°. The resultant waveform is the vector sum of the components. Elements of the transmitting and receiving system are shown in Figure 1.9-17. The two carriers, which are derived from the same oscillator, are suppressed by the balanced modulators. Thus, only the two amplitude modulated sidebands, 90° out-of-phase, are transmitted. At the receiving end of the system, the I and Q signals are recovered by heterodyning the two-phase wave against two locally generated carriers of the same frequency but with a 90° phase separation and applying the resultant signals through low pass filters to the matrix circuits. Typical signal waveforms are illustrated in Figure 1.9-18.

The 3.6 MHz oscillator at the receiver must be accurately synchronized in frequency and in phase with the master oscillator at the transmitter. The synchronizing information consists of 3.6 MHz bursts of at least 8 Hz duration transmitted during the back porch interval following each horizontal sync pulse as shown in Figure 1.9-19. The bursts are generated at the transmitter by a gating circuit which is turned on by burst keying pulses derived from the synchronizing generator. At the receiver, the two-phase modulated signal is applied to another gating circuit, known as a *burst separator*, which is keyed on by pulses derived from the horizontal deflection circuit. The separated bursts are compared in a phase detector with the output of the local 3.6 MHz oscillator. Any error voltage developed is applied through a smoothing filter to a varactor which corrects the phase of the local oscillator.

FCC Standard phase relationships between the I and Q signals and the color synchronizing burst are shown

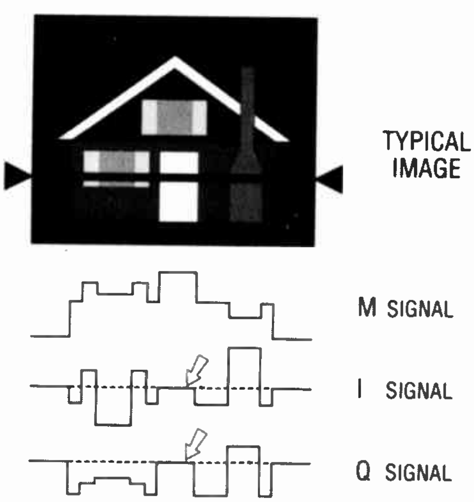

Figure 1.9-16. Typical color image and MIQ waveforms.

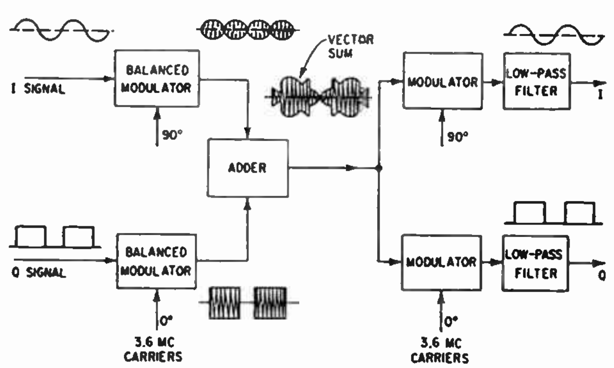

Figure 1.9-18. Representative waveforms of the separate I, Q signals and the vector sum of the suppressed carrier sidebands at the modulator output. Original I and Q signals are recovered by heterodyning in balanced modulators at receiver.

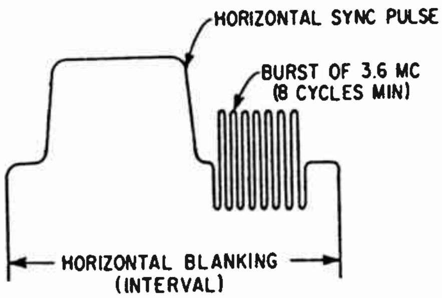

Figure 1.9-19. Diagram showing position of subcarrier burst during horizontal blanking interval.

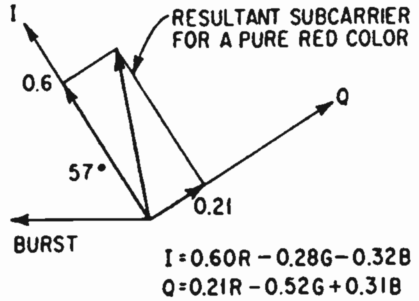

Figure 1.9-21. Vector diagram showing phase and amplitude of subcarrier for a pure red signal.

in the vector diagram of Figure 1.9-20. The I and Q signals are transmitted in phase quadrature, and the color burst is transmitted with an arbitrary 57° phase lead over the I signal.

Several interesting properties of the two-phase modulated signal are illustrated by the vector diagrams which represent the resultant signal under known transmission conditions. For example, when a pure red color of maximum amplitude is being transmitted, the green and blue components are at zero and the I and Q signals have levels of 60 and 21%, respectively. When modulated upon their respective carrier, these signals produce the resultant shown in Figure 1.9-21. The phase and amplitude shown are characteristic of pure red of maximum relative luminance. Figure 1.9-22 is a composite vector diagram showing the phase and amplitude characteristics of the three primaries and their complementary colors. This composite diagram indicates that there is a direct relationship between the *phase* of the resultant two-phase modulated signal and the *hue* of the color being transmitted. There is also a relationship (although indirect) between the *amplitude* of the resultant signal and the saturation of the color being transmitted. If the phase of the resultant subcarrier and the level of the monochrome signal both remain constant, then a reduction in the amplitude of the subcarrier indicates a decrease in color saturation. The composite vector diagram also shows an interesting symmetry between complementary colors (colors are complementary if they produce a neutral when added together); the resultants for any two complementary colors are equal in amplitude but opposite in phase.

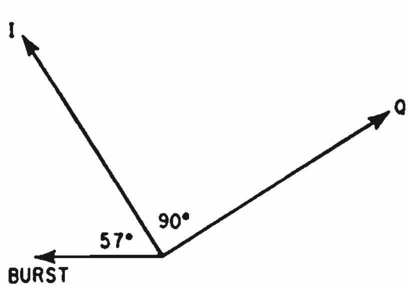

Figure 1.9-20. Diagram showing phase relationship of I, Q, and burst signals.

Frequency Interlace

Since the 3.6 MHz carriers, consisting of the I and Q sidebands, fall within the video passband as shown in the diagram of the television channel (Figure 1.9-23), they become subcarriers and can be handled in many respects like unmodulated video signals. By use of frequency interlace it is possible to add the several components of the chrominance and monochrome signals together without causing objectionable mutual interference.

The significance of the straightforward addition of signal components made possible by frequency interlace may be brought out by a study of waveforms derived from a simple color image. Figure 1.9-24 shows M, I, and Q signals after the latter two have been modulated upon 3.6 MHz subcarriers. Note that both the I-and Q-signal components are at zero during the scanning of the white door, a neutral area. Figure 1.9-25 shows the vector sum of the I and Q signals and also the complete compatible color signal formed by adding together all the components, including synchronizing pulses and color synchronizing bursts. The most significant fact about this signal is that it is still capable of providing good service to monochrome receivers, even though a modulated wave has been added to the monochrome signal component. Although the modulated wave is clearly a spurious signal with respect to the operation of the kinescope in a mono-

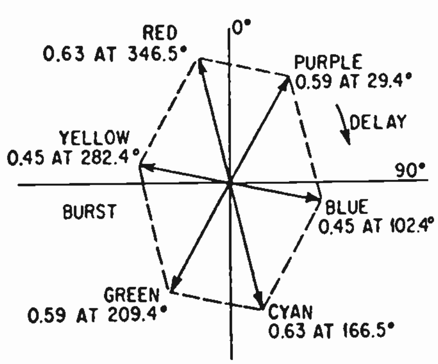

Figure 1.9-22. Composite vector diagram showing subcarrier phase and amplitude for each of six colors.

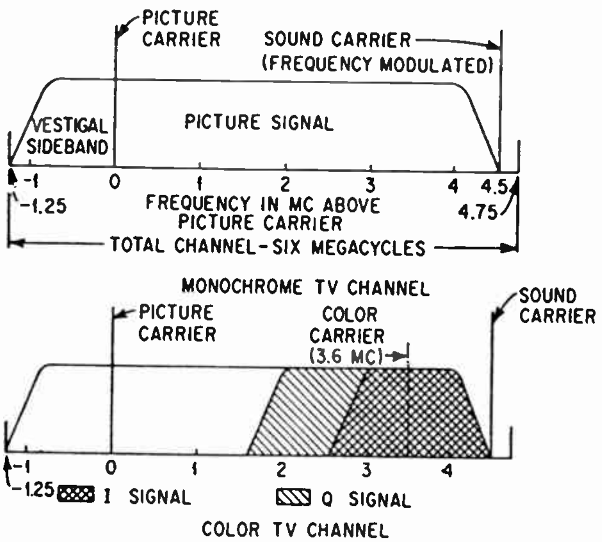

Figure 1.9-23. Diagram of television channel sing portions occupied by color and monochrome signal components.

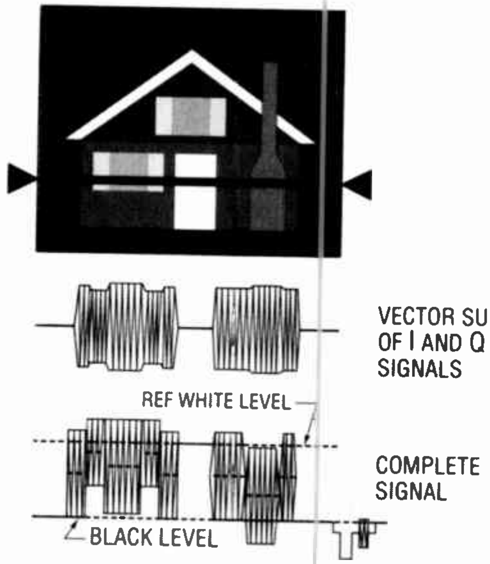

Figure 1.9-25. Typical color image.

chrome receiver, its interference effects are not objectionable because of the application of the frequency interlace principle.

The frequency interlace technique is based on two factors: a precise choice of the color subcarrier frequency and the familiar persistence-of-vision effect. If the color subcarrier is made an *odd multiple of one-half the line frequency*, its apparent polarity can be made to reverse between successive scans of the same area in the picture. Since the eye responds to the average stimulation after two or more scans, the interference effect of the color subcarrier tends to be self-canceling, owing to the periodic polarity reversals (see Figure 1.9-26).

Color Frequency Standards

The relationships among the various frequencies used in a compatible color system are illustrated in the block diagram of Figure 1.9-27. The actual frequency of the color subcarrier, which has been referred to as 3.6 MHz is specified by FCC Rules as 3.579545 MHz or exactly 455 multiplied by 1/2 the line frequency.

In broadcast practice, the frequency of the color subcarrier provides a frequency standard for operation of the entire system. A crystal oscillator at the specified frequency provides the basic control information for all other frequencies. Counter stages and multipliers derive the basic frequencies needed in the color studio.

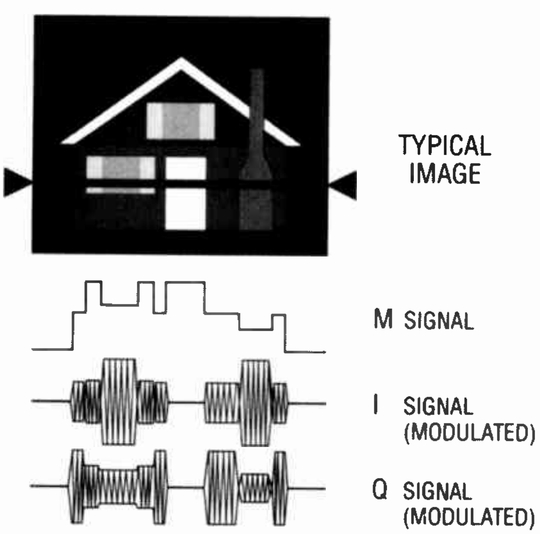

Figure 1.9-24. Typical color image and waveforms of the M signal and modulated I and Q signals.

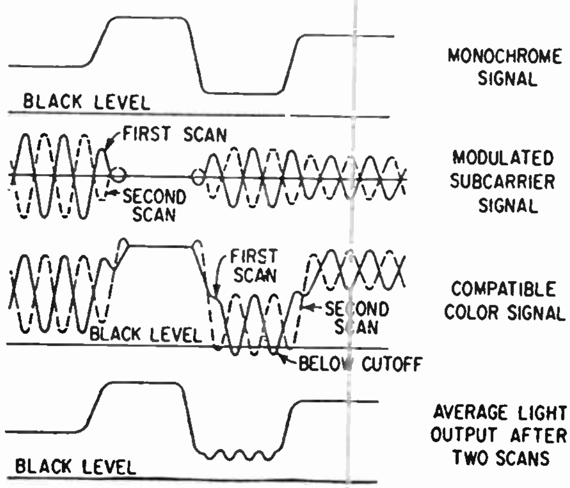

Figure 1.9-26. Waveforms showing superposition of modulated subcarrier on scanning signals, compatible color signal and effect of subcarrier on average light output.

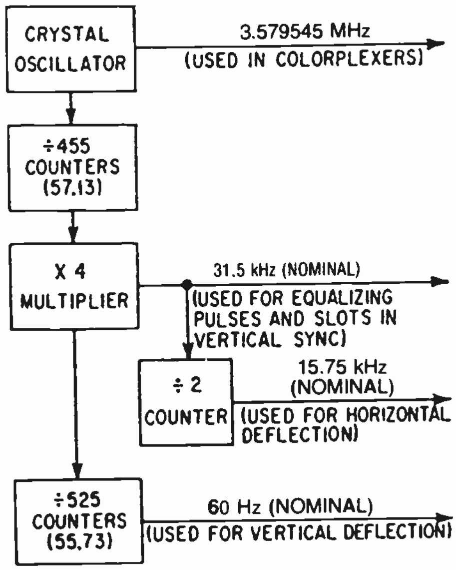

Figure 1.9-27. Block diagram showing relationship between various frequencies used in color television station.

A frequency of nominally 31.5 kHz is required for the equalizing pulses, which precede and follow each vertical sync pulse and for the serrations in the vertical sync pulse. A divide-by-2 counter controlled by the 31.5 kHz signal provides the line frequency pulses at nominally 15.75 kHz needed to control the horizontal blanking and synchronizing waveforms. Another counter chain provides the 60 Hz pulses needed for control of the vertical blanking and synchronizing circuits.

The Overall Color System

The major functions performed in transmitting and receiving color are shown in the overall block diagrams of the transmitting and receiving systems (see Figures 1.9-28 and 29).

At the transmitting end, camera output signals corresponding to the red, green and blue components of the scene being televised are passed through nonlinear amplifiers (the gamma correctors) which compensate for the nonlinearity of the picture tube elements at the receiving end. Gamma corrected signals are then matrixed to produce the luminance signal M and two chrominance signals I and Q. The filter section establishes the bandwidth of these signals. The 4.1 MHz filter for the luminance channel is shown in dotted lines because in practice this band shaping is usually achieved by the attenuation characteristics of the transmitter and the filter is not required.

The bandwidths of 1.5 and 0.5 MHz known for the I and Q channels, respectively, are nominal only; the required frequency response characteristics are described in more detail in the complete FCC signal specifications. Delay compensation is needed in the filter section in order to permit all signal components to be transmitted in time coincidence. In general, the delay time for relatively simple filter circuits varies inversely with the bandwidth. The narrower the bandwidth, the greater the delay. Consequently, a delay network or a length of delay cable must be inserted in the I channel to provide the same delay introduced by the narrower band filter in the Q channel, and still more delay must be inserted in the M channel.

In the modulator section, the I and Q signals are modulated upon two subcarriers of the same frequency but 90° apart in phase. The modulators employed are the double balanced type, allowing both the carriers and the original I and Q signals to be suppressed, leaving only the sidebands. Some sort of keying circuit must be provided to produce the color synchronizing bursts during the horizontal blanking intervals. To comply with the FCC signal specifications, the phase of the burst should be 57° ahead of the I component (which leads the Q component by 90°). This phase position was chosen mainly because it permits certain simplifications in receiver designs. Timing information for keying in the burst can be obtained from a *burst flag generator*, which in early systems was a simple arrangement of multivibrators controlled by horizontal and vertical drive pulses.

In the mixer section, the M signal, the two subcarriers modulated by I and Q chrominance signals, and the color synchronizing bursts are all added together. Provision is also made for the addition of standard synchronizing pulses, so that the output of the mixer section is a complete color television signal containing both picture and synchronizing information. This signal can then be put on-the-air by means of a standard television transmitter, which must be modified only to the extent necessary to assure performance within the reduced tolerance limits required by the color signal. (Since the color signal places more information in the channel than a black-and-white signal, the requirements for frequency response, amplitude linearity and uniformity of delay time are stricter).

The Color Receiving System

In a compatible color receiver, the antenna, RF tuner, IF strip and second detector serve the same functions as the corresponding components of a black-and-white receiver except that the tolerance limits on performance are somewhat tighter.

The signal from the second detector is utilized in four circuit branches. One circuit branch directs the complete signal toward the color picture tube, where it is used to control luminance by being applied to all kinescope guns in equal proportions. In the second circuit branch, a band-pass filter separates the high-frequency components of the signal (roughly 2.0 to 4.1 MHz) consisting mainly of the two-phase modulated subcarrier signal. This signal is applied to a pair of modulators which operate as synchronous detectors to recover the original I and Q signals. It should be noted that those frequency components of the luminance signal falling between about 2 and 4.1 MHz are also applied to the modulators and are heterodyned down

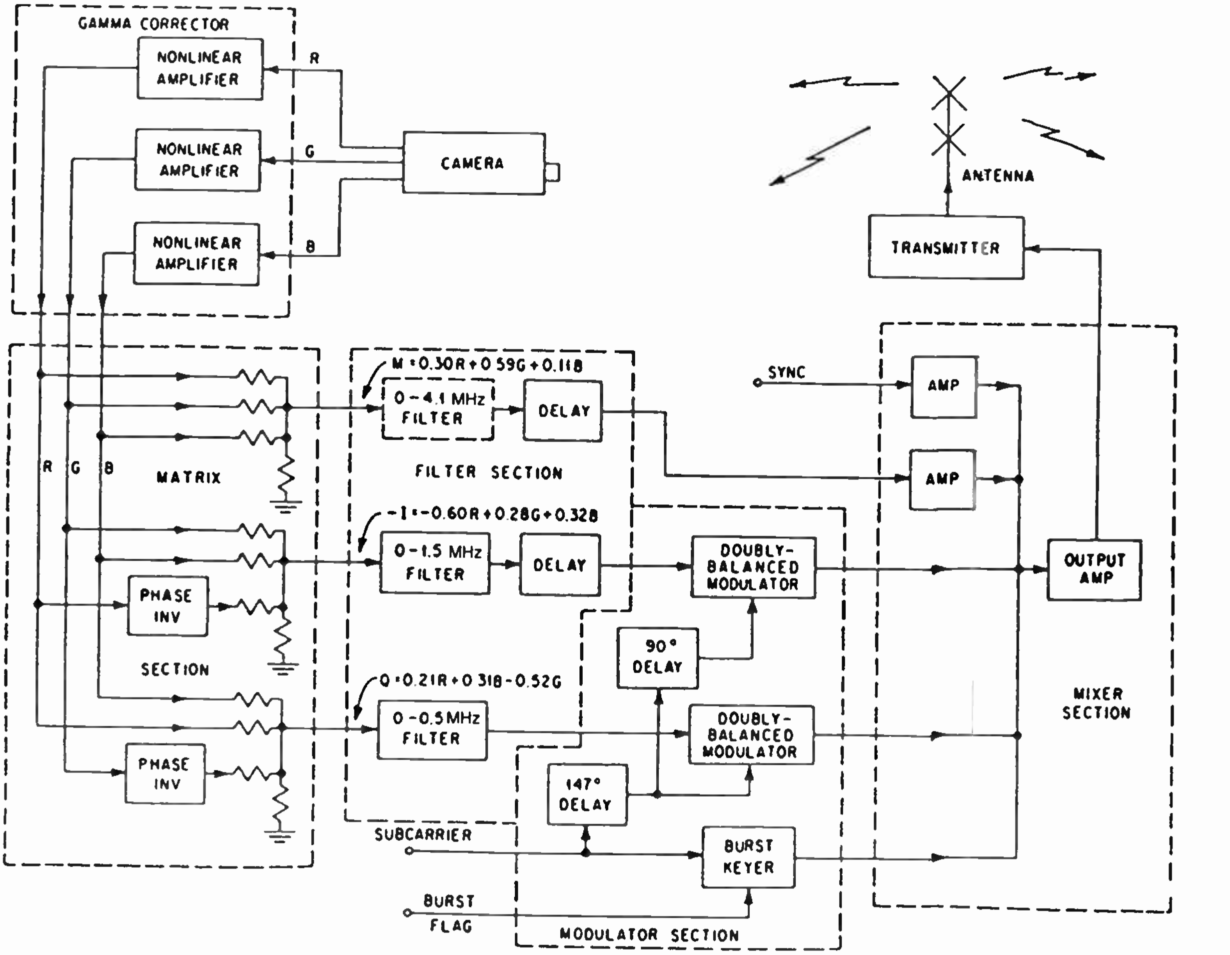

Figure 1.9-28. Block diagram showing major functions of color-transmitting system.

to lower frequencies. These frequency components do not cause objectionable interference, however, because they are frequency interlaced and tend to cancel out through persistence of vision.

The remaining two circuit branches at the output of the second detector make use of the timing or synchronizing information in the signal. A conventional sync separator is used to produce the pulses needed to control the horizontal- and vertical-deflection circuits which are also conventional. The high-voltage supply for the kinescope can be obtained either from a flyback supply associated with the horizontal deflection circuit or from an independent RF power supply. Many color CRTs require convergence signals to enable the scanning beams to coincide at the screen in all parts of the picture area; the waveforms required for this purpose are readily derived from the deflection circuits.

The final branch at the output of the second detector is the burst gate, which is turned on only for a brief interval following each horizontal sync pulse by means of a keying pulse. This pulse may be derived from a multivibrator controlled by sync pulses, as illustrated in Figure 1.9-29, or it may be derived from the flyback pulse produced by the horizontal output stage. The separated bursts are amplified and compared with the output of a local oscillator in a phase detector. If there is a phase difference between the local signal and the bursts, an error voltage is developed by the phase detector. This error voltage restores the oscillator to the correct phase by means of a varactor connected in parallel with the tuned circuit of the oscillator. This automatic frequency control circuit keeps the receiver oscillator in synchronism with the master subcarrier oscillator at the transmitter. The output of the oscillator provides the reference carriers for the two synchronous detectors; a 90° phase shifter is necessary to delay the phase of the Q modulator by 90° relative to the I modulator.

There is a *filter section* in a color receiver that is rather similar to the filter section of the transmitting equipment. The M, I and Q signals must all be passed through filters in order to separate the desired signals from other frequency components which, if unimpeded, might cause spurious effects. The I and Q signals are passed through filters of nominally 1.5 and 0.5 MHz bandwidth, respectively, just as at the trans-

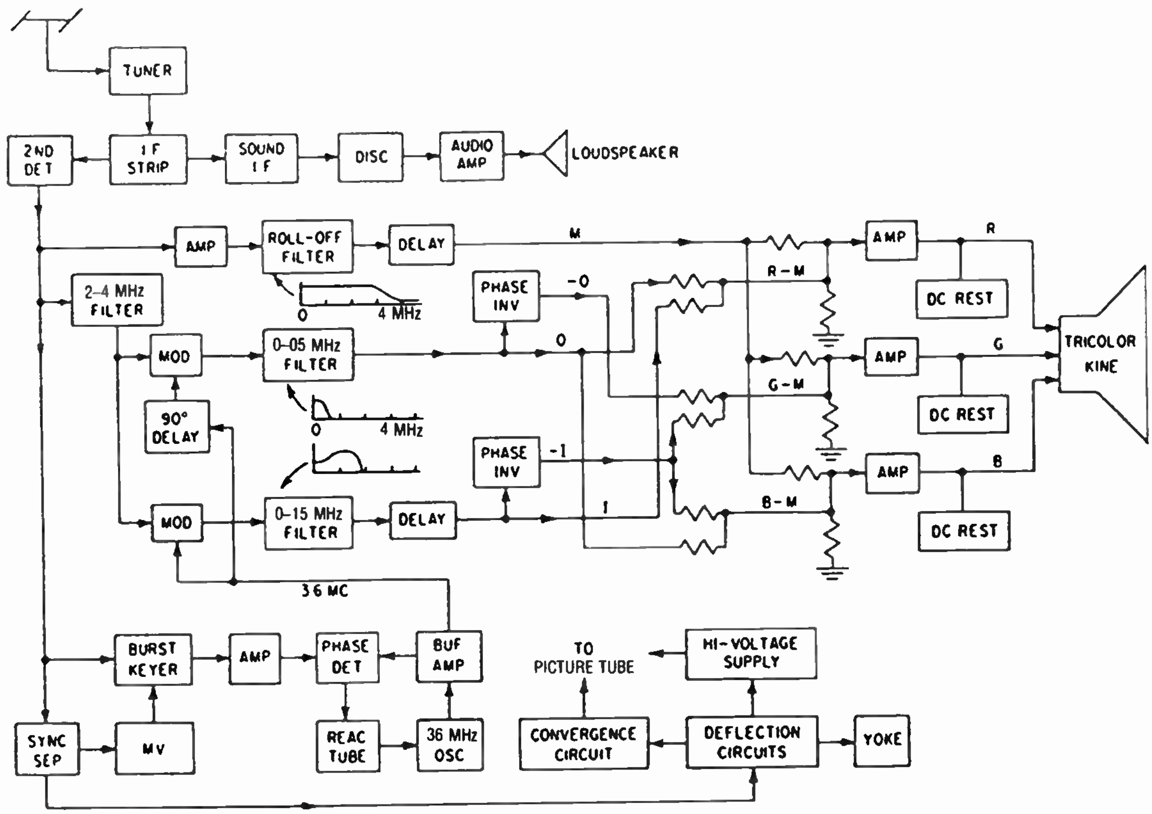

Figure 1.9-29. Block diagram showing major functions of color-receiving systems.

mitting end. A step type characteristic is theoretically required for the I filter, as indicated in Figure 1.9-23, to compensate for the loss of one sideband for all frequency components above about 0.5 MHz. Actually, this requirement is ignored in many practical receiver designs, resulting in only a slight loss in sharpness in the I channel. A roll-off filter is desirable in the M channel to attenuate the subcarrier signal before it reaches the CRT. The subcarrier would tend to dilute the colors on the screen if it were permitted to appear on the CRT grids at full amplitude. Delay networks are needed to compensate for the different inherent delays of the three filters, as explained previously.

Following the filter section in the receiver there is a matrix section in which the M, I and Q signals are cross-mixed to recreate the original R, G and B signals. The R, G and B signals at the receiver are not identical with those at the transmitter because the higher frequency components are mixed and are common to all three channels. This mixing is justifiable because the eye cannot perceive the fine detail (conveyed by the high-frequency components) in color. There are many possible types of matrixing circuits. The resistance mixers shown provide one simple and reliable approach. For ease of analysis, the matrix operations at the receiver can be considered in two stages. The I and Q signals are first cross-mixed to produce R-M, G-M and B-M signals (note that *negative* I and Q signals are required in some cases), which are, in turn, added to M to produce R, G and B.

In the output section of the receiver, the signals are amplified to the level necessary to drive the kinescope and the dc component is restored. The image which appears on the color CRT screen is a high quality full color image of the scene before the color camera.

It should be made clear that the block diagram of Figure 1.9-29 is intended only to illustrate the principles used in color receivers and does not represent any specific model now on the market. Design engineers of color receivers have shown great ingenuity in simplifying circuits, in combining functions, and in devising subtle variations in the basic process which have made possible significant cost reductions while maintaining excellent picture fidelity.

COLOR FIDELITY

Color fidelity as used herein, is the property of a color television system to reproduce colors, which are realistic and pleasing to the average viewer.

Although perhaps not apparent at first, color fidelity is analogous to high fidelity as applied to sound reproduction. Just as a high fidelity audio system faithfully reproduces sounds reaching the microphone, the color television system is capable of faithfully reproducing colors as seen by the television camera. In fact, the color television system is capable of reproducing colors more accurately than techniques presently used in color printing and color photography.

Tests have shown, however, that color television pictures are generally more pleasing to viewers when deliberate modifications are made in the reproduced colors to compensate for the surroundings in which they are reproduced. The situation is similar to that experienced in the art of sound reproduction in the case of a symphony orchestra recorded at high sound levels in a large hall and reproduced at lower sound levels in a small room. In this case, a more pleasing effect is obtained if the ear's new environment is taken into consideration and the reproduction modified accordingly. Similarly, in color television, the changed environment of the eye must be considered and the reproduced colors modified accordingly.

Color fidelity, therefore, is a term used to indicate a color reproduction, which pleases viewers aesthetically and persuades them that they are viewing a faithful reproduction of the original colors in the scene being televised.[1]

The following describes possible distortions in the color system and their effect on the picture and prescribes amounts or degrees of distortion that can be tolerated without adverse effects on picture quality.

Color System Analysis

Individual elements or areas of the complete color system are discussed in the following paragraphs with the aid of the diagrams shown in Figures 1.9-30 through 34.

Figure 1.9-30 is a theoretical color system in that it assumes linear camera pickup devices and a linear picture tube interconnected by a distortionless wire system. The only distortion that can result from this system is a flaw in colorimetry.

Figure 1.9-31 introduces linearity correctors to compensate for color errors produced by nonlinearities in the transducers.

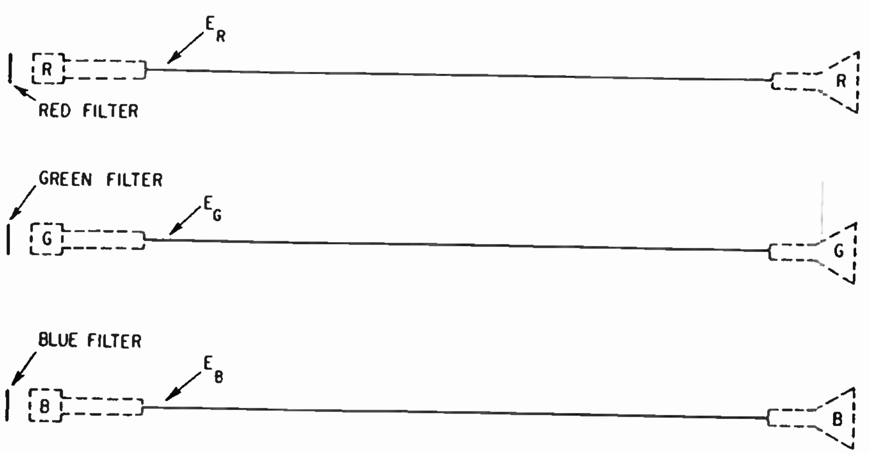

Figure 1.9-30. Diagram of theoretical color system showing linear RGB pickup elements and picture tubes interconnected by wire.

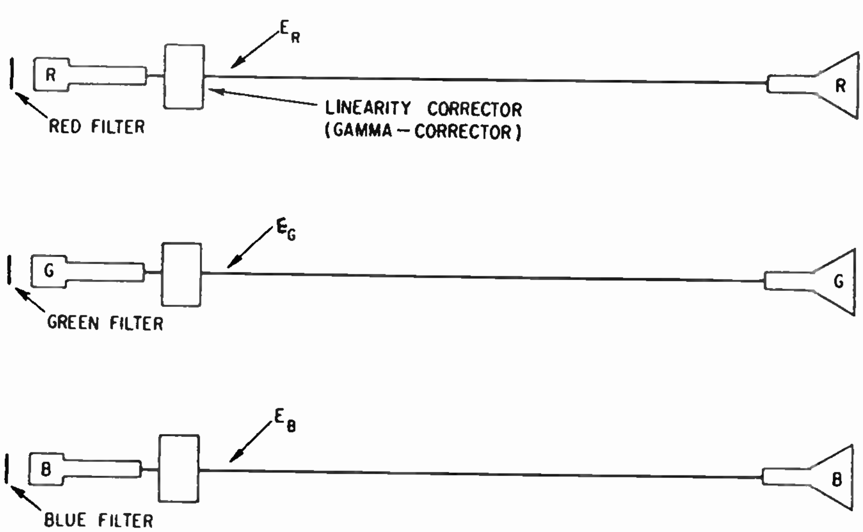

Figure 1.9-31. The basic color system shown with necessary linearity correctors to compensate for color errors introduced by the nonlinear transducers.

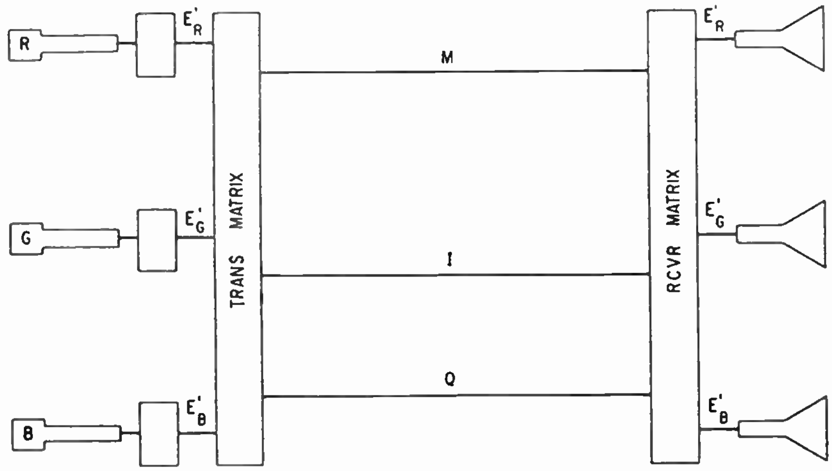

Figure 1.9-32. Diagram showing transmitter and receiver matrix functions in the color system.

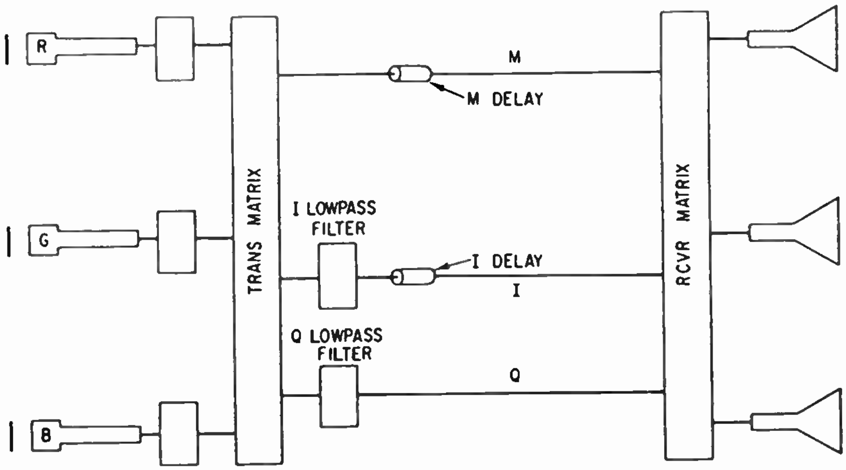

Figure 1.9-33. Basic color system with band limiting and delay compensation.

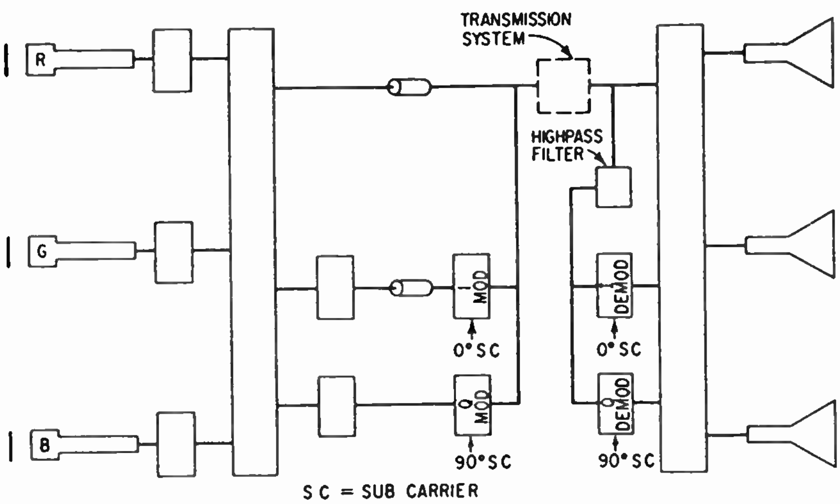

Figure 1.9-34. Basic color system showing all major elements, including the transmission system.

Figure 1.9-32, 33, and 34 successively introduce the complexities of matrixing, band limiting, delay compensation and the transmission system (shown dotted in Figure 1.9-34). These diagrams, each representing a possible color system, introduce techniques used in compatible color television and permit the study of color distortions peculiar to each technique.

The systems diagrammed in Figures 1.9-30 and 31 are described under *Possible Distortions in Transducers*, and those in Figures 1.9-32, 33 and 34 under *Possible Distortions in Encoding and Decoding Processes*. The system shown in Figure 1.9-34 is discussed under *Distortions in the Transmission System*.

Characteristics of the Eye

To appreciate fully the significance of color fidelity, it is helpful to consider some of the characteristics of the eye that are associated with color perception and to analyze such terms as color adaptation, reference white and primary colors and determine their relationship to a color television system.

Color Adaptation

One amazing characteristic of the eye is the phenomenon known as *color adaptation*. It is this adaptation which enables one to describe accurately the color of an object under white light while viewing in nonwhite light. That is to say, recognition of color is surprisingly independent of the illumination under which an object is viewed. For example, if sunlight at high noon on a cloudless day is taken as white light, then, by comparison, the illumination from a typical 100 W incandescent bulb is very yellow light. Yet it is known that an object viewed under sunlight looks very little if any different when viewed under incandescent light. Moreover, it is obvious to the observer, after a very few minutes in a room illuminated with incandescent lights, that the light is not yellow at all; it is really white.

It is apparent, then, that the color seen by an observer is dependent upon the illumination to which that observer has been exposed for the past several minutes. This ambient illumination will have a marked effect on the choice of color to be called white.

This phenomenon can cause a loss of color fidelity under certain conditions. Consider, for example, a theoretically perfect color system with the camera viewing an outdoor scene under a midday sun while the reproduced picture is being viewed in a semidarkened room, with what little light is in the room also being derived from the midday sun. Under these conditions, the ambient illuminations at both camera and receiver are identical, so a person standing alongside the camera and one viewing the receiver would both see the same colors. Now, if a change in the weather at the camera location should cause a cloud to cover the sun, the ambient illumination at the camera location would shift toward a bluer color. This shift would not disturb the viewer standing alongside the camera, because the observer's eyes, bathed in the new ambient light, would rapidly adapt to the new viewing conditions and they would perceive the scene as being unchanged.

The person viewing the receiver would not be so fortunate. Assuming that they are far enough away that this same cloud would not affect their ambient, they would observe that everything on the screen had suddenly and inexplicably taken on a bluish cast, which would certainly be most disturbing.

Such errors in color fidelity can be corrected by making the camera imitate the human eye in adaptation. The eye adapts to changes in ambient illumination by changing its sensitivity to a certain color. For example, if a light source changes from white to blue-white (as in the example), the eye reduces its blue sensitivity until the light again appears to be white to the observer. Likewise, a camera operator can correct for the same situation by decreasing the gain of the blue channel of the camera or by attenuating the light reaching the blue camera tube. In this way, the camera is made to color adapt, and the reproduced picture on a receiver loses its bluish cast.

Reference White

Although color adaptation can generate a problem such as the one just described, it also simplifies certain requirements. Specifically, it eases the requirement that white be transmitted as a definite, absolute color, for there clearly can be no absolute white when almost any color can be made to appear subjectively white by making it the color of the ambient illumination to which an observer's eye has adapted.

In color television, this characteristic is taken advantage of in the following manner: A surface in the studio which is known by common experience to be white, for example, the Electronic Industries Alliance (EIA) Gray-Scale Chart of a piece of Neutracor white paper, is selected to be reproduced as white on a home receiver. The relative sensitivities of the three-color channels of the camera are then adjusted so that the camera adapts to this white regardless of the studio illumination. The home receiver can then be adjusted to reproduce the surface as any white which the home viewer prefers, depending upon his surroundings.

It has already been mentioned that the eye adapts readily to the illumination that surrounds conditions of an overcast day. This representative standard illumination has been adopted internationally as a base for the specification of the color of objects when they are viewed outdoors. This standard (Illuminant C) has been chosen to be the "standard-viewing-white" of the receiver.

The change in reference white between studio and home will inevitably produce errors in all reproduced colors, but the errors are small and, more important, tend to be subjectively self-correcting, so that any given object will produce the same color sensation whether viewed in relation to the studio reference white or the home reference white.

Consequently, a viewer may become familiar with an object such as a sponsor's packaged product and will recognize it on the television screen, under the fluorescent lighting of the supermarket, or under the incandescent lighting of the home and, furthermore, will note little difference in the colorimetric values of the package under the three conditions, even though the absolute colorimetric values would be appreciably different in the three situations.

Primary Colors

Of all the characteristics of the eye, there is perhaps none more fundamental to practical color television than that characteristic which allows viewers to choose certain colors called primary colors, and from these synthesize almost any other desired color by adding together the proper proportions of the primary colors. If it were noted for this characteristic, each hue in a color system would have to be transmitted over a separate channel; such a system would be too awkward to be practical. Because of the eye's acceptance of synthesized colors, it is possible to provide excellent color rendition by transmitting only the three primary colors in their proper proportions.

Possible Errors in Transducers

The block diagram of Figure 1.9-30 shows a fundamental color television system using red, green and blue primaries and three independent transmission channels. The camera tubes and kinescopes are shown dotted to indicate that any inherent nonlinearities in these devices are to be disregarded, for the moment, in order to simplify the discussion of the colorimetry of the system.

The general plan is a system, such as Figure 1.9-30, to provide the three picture tubes with red, green and blue phosphors, respectively, and to allow the corresponding camera tubes to view the scene through an appropriate set of red, green and blue filters. If a phosphor and a filter have the same dominant wavelength, that is, if they appear to the eye to be the same color, it might be mistakenly supposed that they would be colorimetrically suited to be used as a filter and phosphor set for the channel handling that color. Actually, the basis for choosing filters and phosphors is much more complex and is based on the shape of the response curve of the filter, plotted against wavelength, and the shape of the light output curve of the phosphor, also plotted against wavelength. The following paragraphs will discuss briefly a technique which might be used to determine the required relationship between the phosphor curves and the filter curves.

The color characteristics of the phosphor are generally less easily changed than are filter characteristics; for this reason characteristics of phosphors are taken as the starting point, and characteristics of the filters are determined from them. A laboratory setup which could be used to determine these characteristics is shown in Figure 1.9-35. In this figure, an observer (who must have normal vision) is simultaneously viewing two adjacent areas, one of which is illuminated by a source of single-wavelength light which can select any wavelength in the visible spectrum, the other of which is illuminated by a red picture tube, a green picture tube and a blue picture tube. The phosphors of these CRTs are the phosphors which are to be used in the color system. Starting at the red end of the spectrum, a single-wavelength red is selected to illuminate the left-hand area, and the light from each of the three phosphors is varied until a color match is obtained between the left-hand and right-hand areas. The respective amounts of red, green and blue lights needed to accomplish this match are recorded. Then another wavelength is chosen, the kinescope outputs varied to produce a match, and the new amounts of red, green and blue needed for a match are recorded. Similarly, points are obtained throughout the entire spectrum, and a graph is plotted showing the various required outputs versus wavelength. The shapes of these three curves (one for red, one for green and one for blue) are the required shapes for the three camera-filter response curves. The resulting curves would in general resemble Figure 1.9-36.

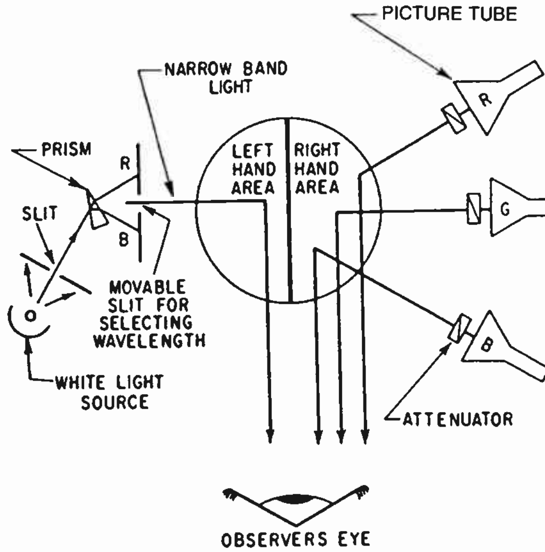

Figure 1.9-35. Diagram showing laboratory setup arranged to compare narrow-band light source and R, G and B light produced by picture tubes to determine proper camera-filter color characteristics.

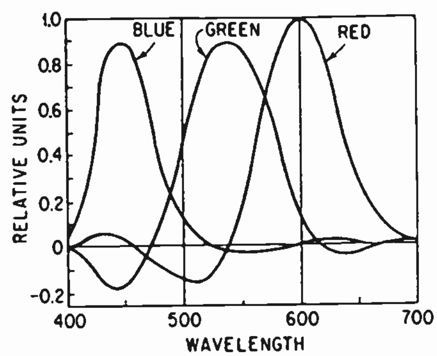

Figure 1.9-36. Curves showing relative quantities in camera output required to produce correct picture tube colors over the visible spectrum.

(To simplify the above discussion it was assumed that the camera pickup devices responded equally well to all wavelengths. In practice, tubes show higher output at certain wavelengths than at others. The filter-response curves derived by the technique would have to be modified so that the combined response of filter and camera would be correct.)

Certain practical difficulties could result in errors in the previous procedure. For example, if the observer had any deviations from normality in color vision characteristics (as most people do), these deviations would result in nonstandard matches and, hence, improper camera filter characteristics. Also, if the phosphors were contaminated in any way during their manufacturing process (as most phosphors are, at least to some small degree), the resulting phosphor characteristics would not be the proper ones and hence would give rise to improper camera filter characteristics. The observer errors can be normalized out by standard colorimetric procedures, but phosphor errors represent a basic error which may possibly be present not only in the previous experiment but also in varying degrees in a large number of receivers. Quality control of phosphor manufacture is sufficiently good, however, to make the net effect unnoticeable in home receivers.

A striking practical difficulty would also arise regardless of observer or phosphor errors. For most wavelengths, no combination of red, green and blue picture tube outputs could be found which would produce a match. In order to obtain a match at these wavelengths, it would be necessary to move one or two of the CRTs over to the other side so that they could add their light to the single-wavelength light being matched. This procedure can be described mathematically, for graphing purposes, by saying that adding light to the left-hand area is the same as subtracting light from the right-hand area. Therefore, the amount of light added on the left would be considered as a negative quantity and would result in a point below the axis on the graph. Since this condition would be found to exist for several successive wavelengths, the resulting graph would show one or more minor lobes below the axis. These are called *negative lobes*.

These negative lobes represent a need for filters with negative light transmission characteristics at certain wavelengths. Simple attenuating filters cannot yield such a characteristic, much more elaborate means would be required.

It is theoretically possible to achieve these negative lobes with added camera complexity but it has been shown that excellent color fidelity can be obtained by ignoring the negative lobes and using filters, which yield the positive lobes only. Positive lobe processes such as color photography have gained wide acceptance for years. Masking techniques which employ electrical matrixing have been introduced which can modify the spectrum characteristics of a color camera. These techniques can be used to help compensate for deficiencies in the color fidelity such as the lack of negative lobes.

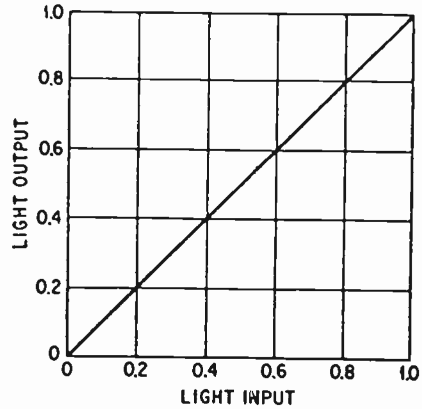

Figure 1.9-37. Curve showing light transfer characteristics of a perfectly transparent piece of window glass.

Transfer Characteristics

A piece of window glass is perhaps the nearest approach to a perfect video system. For a piece of glass, the light output (to the viewer) is essentially identical with the light output (from the scene). This fact is shown graphically in Figure 1.9-37. This plot could be called the *transfer characteristic* of a piece of glass, since it describes the way that light is transferred through the system.

If the window glass is replaced by a neutral density filter, which attenuates light 3-to-1, the transfer characteristic will then be given by Figure 1.9-37. The difference between Figure 1.9-37 and 38 can be described by these simple relationships:

For the glass:

$$\text{Light output} = \text{light input}$$

For the neutral density filter:

$$\text{Light output} = k \times \text{light input}$$

where: $k = 1/3$ in this case.

Both systems are linear—doubling the light input of either will double its light output, tripling input will triple output, etc. A nonlinear system does not exhibit this simple proportionality. For example, consider a system described by

$$\text{Light output} = k \times (\text{light input})^2$$

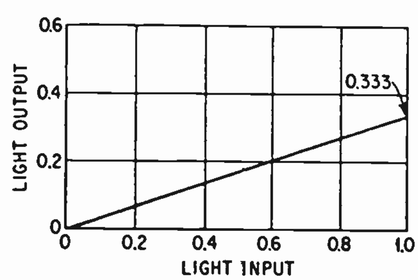

Figure 1.9-38. Curve showing transfer characteristic of a neutral density filter with 3-to-1 light attenuation.

Doubling the input to this system will quadruple its output, a threefold increase in input will result in a ninefold increase in output, etc. The transfer characteristic for this type of system is shown in Figure 1.9-39. Note that the characteristic is definitely nonlinear; that is, it is not a straight line as were Figures 1.9-37 and 38.

In television and photography, nonlinearity is more common than linearity. For example, an ordinary picture tube is a nonlinear device, having a transfer characteristic which can be approximated by the expression:

$$\text{Light output} = k(\text{voltage input})^{2.2}$$

Camera tubes can be linear or nonlinear devices. For example, the characteristic of a vidicon is approximately

$$\text{Current input} = k(\text{light input})^{0.65}$$

The general expression for nonlinear transfer characteristic can be given approximately as

$$\text{Output} = k(\text{input})^{\gamma}$$

where the exponent is the Greek letter gamma.

Graphical Displays of Transfer Characteristics

The first reaction of any person asked to display two variables (like light input and light output) on a set of XY coordinates is to divide X and Y coordinates into equal increments and plots the variables in this manner. A typical result of such a plot has already been described (see Figures 1.9-37 and 38). Such a plot has the advantage of showing at a glance the linearity of the device described by the variables. If the plot is a straight line, the device is linear; if curved, the device is nonlinear. Moreover, the slope of the line describes the attenuation (or gain) of the device. If the slope is unity (which occurs when the plot makes a 45° angle with the X axis), there is no attenuation. It is a very good piece of glass. For the neutral density filter previously described, which has the equation

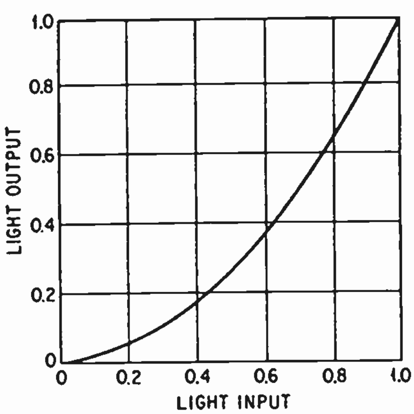

Figure 1.9-39. Curve showing a nonlinear transfer characteristic.

(light output) = 1/3 (light input), the line has a slope of one-third (see Figure 1.9-38).

Such are the advantages of plotting transfer characteristics with equal increment divisions of the X and Y axis. However, other advantages (very important ones) can be obtained by dividing up the X and Y coordinates logarithmically. Such a plot is called a *log-log* plot.

Consider a system which has a transfer characteristic given by $L_0 = (L_{in})^{2.2}$. If this equation is plotted on axes which are divided logarithmically, the resulting plot is the same as though the logarithm of both sides of the equation were plotted on equal increment axes. Taking the logarithm of both sides, we obtain

$$\log L_0 = \log (L_{in})^{2.2}$$

Since $\log (L_{in})^{2.2}$ is the same as $2.2 \log (L_{in})$, then

$$\log L_0 = 2.2 \log L_{in}$$

Comparing the form of this equation with an earlier equation, light output = 1/3 light input, the attenuation, 1/3, was the slope of the earlier equation, so 2.2, the exponent, is the slope of the latter equation. The use of logarithmically divided coordinates yields a plot in which the exponent is given by the slope of the line. Therefore, this plot will show at a glance the magnitude of the exponent and will also show whether or not the exponent of the system is constant for all light levels. It also is advantageous in showing the effects of stray light.

Figures 1.9-40(a) and 40(b) compare the two types of plotting for three types of transfer characteristics.

The Effect of a Nonlinear Transfer Characteristic on Color Signals

In monochrome television, some degree of nonlinearity can be tolerated, but such is not the case for a color television system. It can be shown that a system exponent different from unity must inevitably cause a loss of color fidelity. For an example, consider a situation in which signals are being applied through linear amplifiers to the red and green guns of a perfectly linear (theoretical) picture tube. The green amplifier is receiving 1.0 V; the red amplifier, 0.5 V. If everything is perfectly linear, the proportions of the light output should be 1.0G + 0.5R = greenish yellow. However, if the CRT has an exponent of 2.0, the light output will be $(1.0)^2G + (0.5)^2R = 1.0G + 0.25R$ = greenish yellow with an excess of green.

From the previous specific case, it may be correctly inferred that in general, a system exponent greater than 1 will cause all hues made of the combination of two or more primaries to shift toward the larger or largest primary of the combination. Conversely, a system exponent less than 1 will shift all hues away from the largest primary of the combination.

In the previous example, an exponent of 0.5 would yield $(1.0)^{0.5}G + (0.5)^{0.5}R = 1.0G + 0.70^{7}R$ = a greenish yellow which is a shade off a pure yellow.

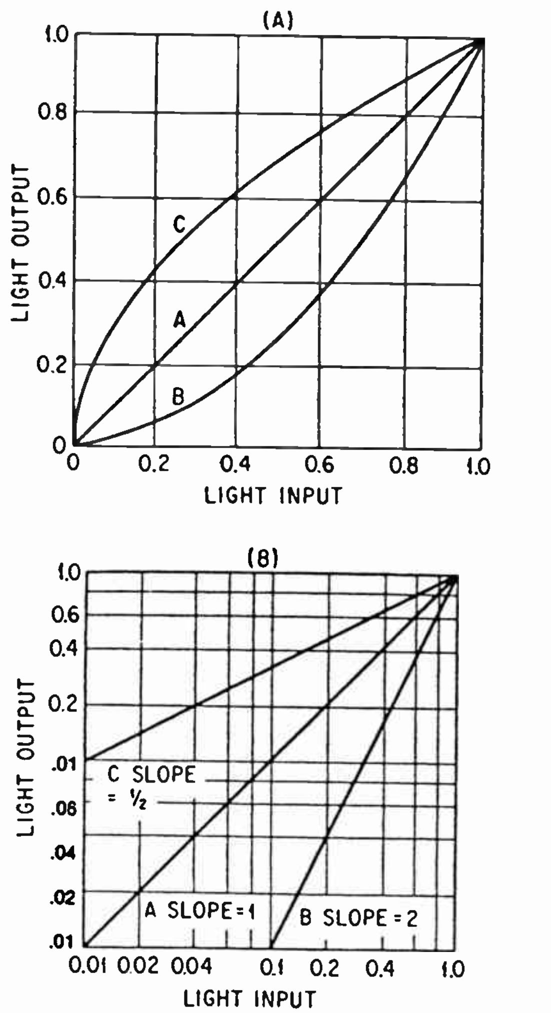

Figure 1.9-40. Graphs showing the curves obtained by plotting A, B and C types of transfer characteristics on linear coordinated (a) and on log-log coordinates (b).

In addition, the reader can correctly conclude that white or gray areas, in which all the primaries are equal, will not be shifted in hue by a nonunity exponent.

Effect of Differing Exponents in Each Channel

The preceding discussion assumed that all three channels (in Figure 1.9-30) have the same exponent, whether in unity or not. In practical systems, however, there is always the possibility that the exponents of the channels may differ from one another. This situation will produce intolerable color errors if the differences become even moderately large. In general, the requirements for tracking among the light transfer characteristics of the individual channels are even more stringent than the requirement for unity exponent.

Figures 1.9-41(a), 41(b), 41(c) and 41(d) show the effects of unequal exponents in the three channels. In all four figures, the red and blue exponents are taken as unity; in Figures 1.9-41(a) and 41(b) the green exponent is taken as less than 1, and in Figures 1.9-41(c) and 41(d), as greater than 1. In Figure 1.9-41(a), the transfer characteristics are shown for the system adjusted to produce peak white properly. It can be seen that the bowed characteristic of the green channel will cause all whites of less than peak value to have too much green. A gray-scale step tablet before the camera would be reproduced properly only at peak white; the gray steps would all have a greenish tinge. Relative channel gains could be readjusted to reproduce one of the gray steps properly (Figure 1.9-40(b)), but then all highlight steps would be purplish while lowlight steps would still be greenish.

A green-channel exponent greater than unity would reverse those results (Figure 1.9-41(c) and 41(d)). With gains adjusted to reproduce peak white properly (Figure 1.9-41(c)) lowlights would be purplish; with gains readjusted to provide proper reproduction for one of the lower steps (Figure 1.9-41(d)) highlights would be green and lowlights purple.

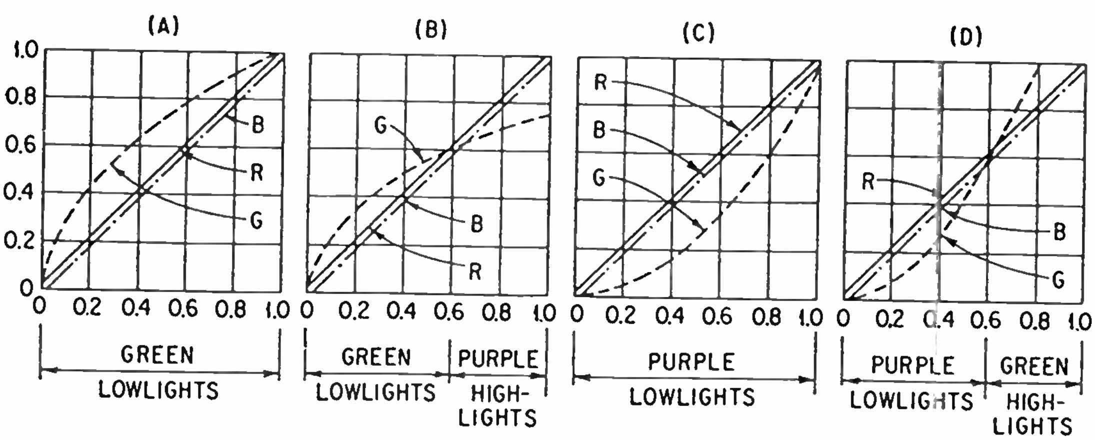

Figure 1.9-41. Linear plots showing graphically the effect of unequal exponents in the R, G and B channels. In all four graphs the R and B exponents are taken as unity. In (a) and (b) the green exponent is taken as less than 1, and in (c) and (d), as greater than 1.

The Effect of Stray Light

If a picture tube is viewed in a lighted room, there will always be some illumination on the faceplate. Therefore, the eye will always receive some *light output* from the picture tube, regardless of the magnitude of the signal input voltage. Under this condition, a true black is impossible to obtain.

This condition is reflected in the transfer characteristic of the system. If, for example, the stray light were 5% of the peak highlight brightness of the picture, a linear plot of light output versus light input would have the entire transfer characteristic shifted upward by 5%. However, the most interesting change is found in the log-log plot, where, as seen in Figure 1.9-42, the stray light causes a change in the slope in the lowlight regions. Since the slope is equal to the exponent, this change shows that stray light causes an effective exponent error in the lowlight regions of the picture and hence will cause color fidelity errors, which will be most marked in lowlight regions.

These errors will be noted by an observer as improper hues and saturations, with the saturation errors (a washing out of the more saturated lowlight areas) being the more objectionable to a viewer.

Stray light is not the only cause of errors of this type. Similar effects will be noted whenever the CRT bias (brightness) is set too high, if the camera pedestal is set too high, or if stray light enters the camera (whether through lens flare or any other source). In general, any condition which prevents the light output of the system from becoming zero when the light input is zero will cause errors similar to those caused by stray light.

Linearizing a System

It can be shown that a system using a vidicon with an exponent of 0.675 to drive a CRT with an exponent of 2.2 will have an overall exponent given by the product $0.65 \times 2.2 = 1.43$, assuming that all devices in the system are linear. In general, the overall exponent of a system is the product of the exponents of the cascaded elements.

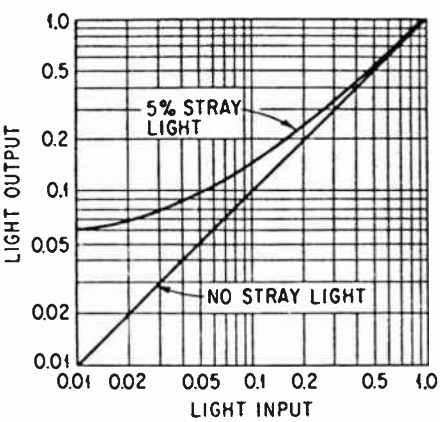

Figure 1.9-42. Log-log plot of system with stray light, illustrating change of slope in the low-light regions.

This knowledge provides an excellent tool for linearizing a system. For example, a system with an overall exponent of 1.43 could be linearized by inserting somewhere (in a video path) an amplifier having an exponent of 1/1.43 (= 0.7) so that the product becomes unity: $1.43 \times 1/1/43 = 1$.

In Figure 1.9-31, a nonlinear amplifier, or gamma corrector, is shown inserted in each of the three paths.

Possible Encoding and Decoding Distortions

The second of the two systems discussed in the preceding section bordered on being a practical system but still required three independent 4 MHz channels. A fortunate characteristic of the human eye (the inability to see colored fine detail) allows us to modify this requirement to one 4 MHz channel for monochrome fine detail and two much narrower channels for color information. Before this modification can be made, the red, green and blue signals must be combined to form three other signals, usually called M, I and Q, such that the M signal alone requires a 4 MHz channel, and the I and Q channels, which contain the color information, are confined to narrower channels. This rearrangement of red, green and blue to form M, I and Q is called matrixing and was described in the previous section. A system which uses a matrix is block diagramed in Figure 1.9-32. The illustration also shows that to recover the original red, green and blue signals at the receiving end, a rearranging device is needed. This device is usually called the *receiver matrix.*

Matrixing alone offers no advantage unless steps are taken actually to limit the I-signal and Q-signal channels to the narrow bandwidths allowed. Figure 1.9-33 shows a system employing such band shaping. The band shaping filters themselves always introduce delay, which must be compensated for by placing delay lines in the wider band channels, as shown in the diagram.

To put both color and monochrome information in the spectrum space normally occupied by monochrome only requires that the color information overlap the monochrome. This overlap can be allowed for both I and Q signals, without incurring visible crosstalk, if frequency interlace and two-phase modulation are employed. A system using these techniques, which were described, in the section on *Electronic Aspects of Compatible Color Television,* is block diagramed in Figure 1.9-34.

Possible Errors in the Matrixing Process

The entire matrixing process can be summed up in two sets of equations, the first describing how the transmitter matrix takes in red, green and blue and turns out M, I and Q:

$$M = 0.30R + 0.59G + 0.11B$$
$$I = 0.60R - 0.28G - 0.32B$$
$$Q = 0.21R - 0.52G + 0.31B$$

and the second describing how the receiver matrix takes in M, I and Q and recreates red, green and blue:

$$R = 0.94I + 0.62Q + M$$
$$G = 0.27I + 0.67Q + M$$
$$B = 1.11I + 1.7Q + M$$

Both matrices continuously compute the desired output from the given input. The coefficients in the previous six equations are usually determined by precision resistors or, in the case of negative numbers, by precision resistors and signal-inverting amplifiers. The basic error that can occur, therefore, is a change in a resistor value or an amplifier gain, resulting in a change in one or more coefficients. In general, the resulting picture error resembles cross talk among the primary colors.

More specifically, the transmitter matrix can have two distinct types of errors. The first involves the coefficients of the equation for M, the second, the coefficients for I and Q. An error in an M coefficient will brighten or darken certain areas. In a monochrome reproduction of a color signal, such an error, if small, would not be noticed; if large, it would still probably be tolerated by the average viewer. In a color reproduction, however, even a small error would be objectionable. For example, a reduction of the red coefficient from 0.3 to 0.2 would cause a human face to be reproduced with an unnatural ruddy complexion and dark red lips.

Note that the sum of the M coefficients is 1. An error in one coefficient would change this sum, so that peak white would no longer occur as 1 V. An operator could mistake this condition for a gain error and adjust either M gain or overall gain in an effort to obtain the correct peak white voltage. Changing M gain would cause errors to occur in all M coefficients; changing overall gain would put errors in all coefficients. Although such an error is rare in well engineered equipment, it is a possible source of color error, which can be compounded by misdirected attempts at correction.

Note that the sums of the Q and I coefficients are each zero, which means that when R = G = B (the condition for white or gray), Q and I both equal zero. An error in a Q or I coefficient would cause color to appear in white or gray areas and, in addition, would cause general errors in colored areas resembling cross talk among the primaries. Controls are usually provided in the Q and I matrices, called *Q white balance* and *I white balance,* respectively, which allow the operator to adjust the sum of the Q or I coefficients by changing the value of one of the coefficients. If the coefficient controlled is the one in error, then adjusting white balance restores the condition that the sum of the coefficients is zero, that is, it removes the color from white and gray objects, but it does so by giving the controlled coefficient an error which just counteracts the error of a nonadjustable coefficient, so that two coefficients are wrong instead of one. Again, such an error is rare in well engineered equipment, for the adjustable coefficient is usually the one in error. However, the possibility of an error compounded by adjustment should be kept in mind.

A far more likely cause of white balance error is an error in input level, that is, a discrepancy between the peak white levels of input red, green or blue. In such a case, an operator can still achieve white balance (Q and I = 0 for white input) but the entire system will be in error. The starting point for all investigations of the cause of white balance errors should be the levels of the red, green and blue inputs.

In the receiver matrix, only one general type of error can occur instead of two as in the case of the transmitter matrix. This type of error, a *general coefficient error,* results in cross talk among the primary colors. For example, a change in the I coefficient for the red equation from 0.94 to 0.84 would yield about a 7% reduction in the peak red output available and would also result in unwanted red light output in green or blue areas at about 3-1/2% of the green or blue level.

Gain Stability of M, I and Q Transmission Path

In the system of Figure 1.9-32, every gain device or attenuating device in the three transmission paths must maintain a constant ratio between its input and output in order to maintain the proper ratios among the levels of M, I and Q at the input to the receiver matrix. A variation in the gain of one of these paths will result in a loss of color fidelity.

For example, a reduction in M gain must obviously cause a reduction in the viewer's sensation of brightness. Not quite so obvious are the effects of I and Q gain. Since these are color signals, their amplitude would be expected to influence the sensation of saturation, but the manner of this influence is not intuitively obvious until the factors which influenced the selection of I and Q compositions are recalled. It previously was pointed out that the eye has the greatest need for color detail in the color range from orange to blue-green (cyan) and the least in the range from green to purple. Hence I, the wider band signal, conveys mainly orange and cyan information, and Q, the narrower band signal, conveys principally the greens and purples. Therefore, a reduction in I gain could be expected to reduce the saturation sensation for colors in the orange and cyan gamut, leaving the greens and purples virtually unaffected. Conversely, Q gain will influence the greens and purples without causing much change in the appearance of orange and cyan objects.

Modulation and Demodulation

The system depicted in Figure 1.9-32, which introduced bandwidth limiting of the I and Q signals in accordance with the capabilities of the eye to see colored fine detail, is a fairly practical and economical system, except for the fact that three individual transmission channels are employed. To have a compatible system, however, these three channels must be reduced to one through some multiplexing technique. The technique used has already been described, and a system employing this technique is block diagrammed in Figure 1.9-34.

Possible Errors in Modulation

Burst Phase Error

Perhaps the most fundamental error in the multiplexing process would be an error in the phase of the main timing reference, burst. Since the entire system is based on burst phase, an error in burst phase will appear as an opposite error in every phase except burst, because the circuits will insist that burst phase cannot be wrong. The general result will be an overall hue error in the reproduced picture. This effect can be better visualized by referring to Figure 1.9-43.

A phase error in burst produces the same result as holding burst phase stationary and allowing all other phases to slip around the circle an equal amount (but in a direction opposite to the burst phase error). Each color vector then represents a hue other than the one intended.

Burst Amplitude Error

In theory, the receiver circuits which extract timing information from the burst are insensitive to variations in burst amplitude as long as the burst is large enough to maintain a respectable signal-to-noise ratio and not so large that some type of clipping or rectification upsets the burst circuitry. But practical receivers always exhibit some degree of sensitivity depending mainly upon the error in the subcarrier oscillator in the receiver. If the free-running frequency of the receiver oscillator is very different from burst frequency—particularly if the difference is so great that the burst is in danger of losing control of the oscillator—then a fairly appreciable amplitude sensitivity will be noted. This sensitivity will take the form of a phase error, and the net result will be indistinguishable from a burst phase error, as previously discussed.

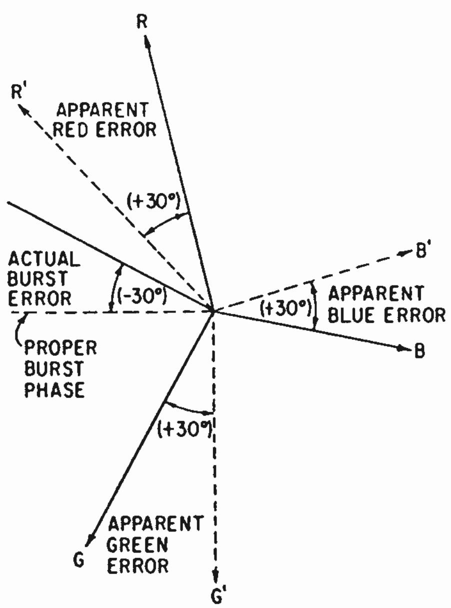

Figure 1.9-43. Vector diagram showing how error in subcarrier phase becomes an opposite error in all other phases.

Some receivers have a circuit which automatically adjusts the gain of the color information channels so that the viewer always sees the proper saturations, regardless of errors, which might tend either to wash out or oversaturate the picture. Such a circuit, called an *automatic chroma control* (ACC), derives its control information from the amplitude of burst, which is presumed to bear a constant ratio to the amplitude of chroma. Transmission distortions, for example, might decrease the amplitude of both burst and chroma, but since the ratios of their amplitudes would be preserved, an ACC receiver could automatically modify its chromachannel gain to compensate for the decreased chroma amplitude. However, if a color encoder error should cause burst alone to decrease in amplitude, the ACC circuits would increase chroma gain just as in the previous case, with the result that a viewer would receive an oversaturated picture.

Two-Phase Modulation Errors

The fidelity of color reproduction can be seriously affected if the phase separation of the Q and I subcarriers is not maintained at 90°. It can be shown that a slip in the angular position of the Q axis, for example, will result in cross talk of Q and I. The final result will be the same as cross talk among the primary colors.

Likewise, in a receiver, the phase relationship between the reference subcarriers must be maintained to avoid a similar error. Any deviation from the proper phase relationship will have a similar result, that is, cross talk of I into Q or Q into I, with the net picture result resembling cross talk among all the primary colors.

Carrier Unbalance

In a properly operating doubly balanced modulator, the carrier component of the signal is suppressed in the modulator circuit. If some error in components or operation causes this suppression to be imperfect, the carrier will appear in the output. This condition is known as *carrier unbalance*.

The effect of carrier unbalance can be evaluated by considering the unwanted carrier as a vector of constant amplitude which adds itself vectorially to every vector present in the colorplexer output. In general, such a vector will shift all vectors and hence all hues seen in the picture toward one end of the other of the color axis represented by the unbalanced modulator. For example, a positive unbalance in the I modulator would shift all colors toward the color represented by the positive I axis, that is, toward orange. A negative I unbalance would shift all colors toward cyan.

To visualize this effect, refer to Figure 1.9-44, in which has been added to each color vector a small positive vector which is parallel to the I axis. This small vector represents the amount of carrier unbalance. The resultant vectors will all be rotated toward the positive I axis and changed in amplitude as well. Such changes represent errors in both hue and saturation.

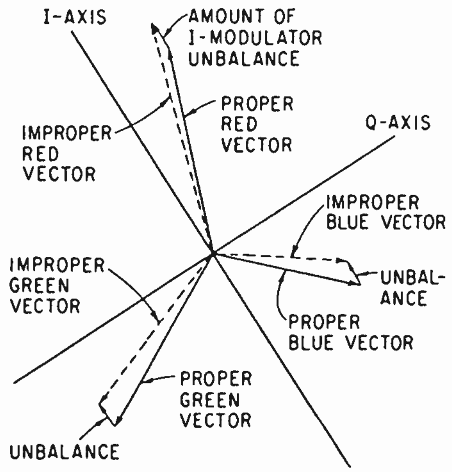

Figure 1.9-44. Vector diagram of subcarrier phase and amplitude with positive vectors added to represent carrier unbalance in the I modulator.

Another error from carrier unbalance occurs in white and gray areas of the picture. In a normally operating colorplexer, a white (or gray) area in the scene causes the Q and I signals to become zero and thereby causes the modulator outputs to become zero. Hence, a white or gray area will normally appear in the signal as an interval of zero subcarrier amplitude. If one of the modulators begins to produce a carrier unbalance vector, however, a white or gray area will become colored because of the subcarrier which will be added in this interval. Moreover, certain areas, which are normally colored, may have their subcarrier canceled by the carrier unbalance vector and become white. Such white-to-color and color-to-white errors are very objectionable.

Video Unbalance

A doubly balanced modulator derives its name from the fact that it balances out or suppresses both the carrier and the modulating video (Q or I). If, for any reason, the video suppression becomes less than perfect, the resulting condition is called *video unbalance*.

Video unbalance will cause unwanted Q or I video to appear in the modulator output, in addition to the desired sideband outputs. This unwanted video signal will be added to the luminance signal, thereby distorting the gray scale of the picture. For example, a slight positive unbalance in the Q modulator would slightly brighten reds and blues and slightly darken greens. A negative unbalance would have the opposite effect.

Subcarrier Frequency Error

The color subcarrier frequency is specified by the FCC to be 3.579545 MHz ± 10 Hz. Deviations within this specified limit are of no consequence (provided they are slow deviations). Large deviations, however, can affect color fidelity. The effect does not usually become serious within the possible frequency range of a good crystal-controlled subcarrier source driving a properly designed receiver.

In receivers, the subcarrier timing information is extracted from the burst on the back porch and used to control the frequency of a subcarrier-frequency oscillator in the receiver. As long as the unlocked frequencies of the burst and the receiver oscillator remain the same, the locked phase relationship between the two will remain the same. But if either the burst frequency or the receiver-oscillator frequency becomes different (and the difference between them is not so large that lockup is impossible), then the locked error, which obviously cannot be a frequency error, manifests itself as a phase error. This error can become as large as ±90° before the AFC circuit can no longer hold the receiver oscillator on frequency. The frequency range over which this phase shift occurs depends upon the receiver design.

Possible Distortions in the Transmission System

Preceding sections have described the processes involved in the generation and display of a color television signal. Errors in these processes are not the only possible source of distortion; when the signal is transmitted over great distances, the transmission system itself may contribute errors. This section discusses parameters which specify the behavior of a transmission system and describes the effects that errors in these parameters can have on the reproduced picture.

This section is divided into two parts. The first relates to the parameters of a perfectly linear transmission system, while the second part discusses the additional parameters required to describe the nonlinearities that are inevitable in any practical system.

The Perfectly Linear Transmission System

A perfectly linear and noise free transmission system can be described by its gain and phase characteristics plotted against frequency as the independent variable.[2] Typical plots are shown in Figures 1.9-45 and 46, respectively. These two characteristics known, it is possible to predict accurately what effect the transmission system will have on a given signal.

Gain Characteristic

Figure 1.9-45 is usually known as the frequency response or gain characteristic of the system. Ideally,

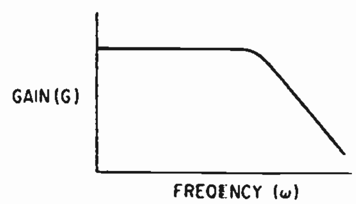

Figure 1.9-45. Typical curve showing a gain of a system plotted against frequency to determine its gain characteristic.

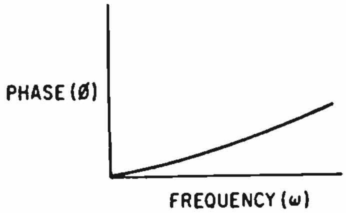

Figure 1.9-46. Curve showing phase characteristic of a system plotted versus frequency.

it should be perfectly flat from zero to infinite frequency, but this, of course, is impossible to attain. An amplifier has a definite gain bandwidth product, depending upon the transconductance of its active elements (transistors, ICs, etc), the distributed capacity shunting these elements, and the types of compensation (peaking) employed. The bandwidth of a given combination of transistors, stray capacitances, and peaking networks can be increased only by decreasing its gain, or conversely, its gain can be increased only by decreasing its bandwidth. There is a limitation, therefore, to the actual bandwidth that can be obtained. For a given scanning standard, the bandwidth required in a monochrome television system is determined by the desired ratio between the horizontal resolution and the vertical resolution. Although nominally a 4.0 MHz bandwidth is required for the monochrome standards, the requirement can be relaxed to the detriment of only the horizontal resolution. The subjective result is a softening of the picture in proportion to the narrowing of the bandwidth (neglecting the influence of the phase characteristic in the vicinity of the cutoff frequency). As pointed out in preceding sections, the entire chrominance information of the color system is located in the upper 1.5 MHz of the prescribed 4.0 MHz channel; hence, any loss of response in this part of the spectrum can have a marked effect on the color fidelity of the reproduced picture.

One of the most serious forms of distortion inflicted on a color picture by bandwidth limiting is loss of saturation. Consider a case in which the bandwidth is so narrow as to result in no gain at the color subcarrier frequency. The output signal then contains no color subcarrier and hence reaches the color receiver as a monochrome signal, producing zero saturation. Nearly as poor results can be expected from an amplifier with response such that the gain at 3.58 MHz is one-half the low-frequency gain. Since the saturation depends chiefly on the amplitude of the subcarrier, the saturation will be correspondingly reduced. The resultant color picture will have a washed out look.

Loss of high-frequency response, which can be expected to contribute to loss of fidelity, is usually accompanied by phase disturbance, depending on the type of networks employed in the system. The intent in this section, however, is to treat each variable separately. Therefore, discussions are based on the effects of varying only one parameter of a system. It is suggested that the reader can determine the combined effect of two or more variables by comparing the results shown for the individual variables.

Phase Characteristic

An ideal system has a *linear* phase characteristic, as shown in Figure 1.9-47(a). Such a characteristic implies that all frequencies of a signal have exactly the same *time delay* in passing through this system, since the time delay is given by the phase angle divided by the (radian) frequency. It can be seen in Figure 1.9-47 that if three frequencies are chose arbitrarily, then the corresponding phase angles must have values proportional to their corresponding frequencies (because of the geometric properties of a right triangle). To state it another way, if $\varphi_1/\omega_1 = 0.2$ μsec, then $\varphi_2/\omega_2 = 0.2$ μsec and φ_3/ω_3 also equals 0.2 μsec. Plotting these three values and drawing a straight line through them as in Figure 1.9-47(b) will show that the time delay for all frequencies is 0.2 μsec.

A signal is not distorted by delay as long as all parts of it are delayed by the same amount. However, when the phase characteristic is nonlinear (as in Figure 1.9-48(a)), the time delays for all parts of the signal are no longer equal (see Figure 1.9-48(b)). For example, if a complex waveform is made up of a 1 MHz sine wave and its third harmonic, these two components will suffer unequal delays in passing through a system having the characteristics of Figure 1.9-47. The resultant distortion can be seen by comparing Figures 49(a), 49(b) and 49(c).

Such distortion is detrimental to both the luminance and chrominance of a composite signal. The luminance signal will have its edges and other important details *scattered,* or *dispersed,* in the final image. Such a transmission system is said to introduce *dispersion.* (Conversely, if a system does not scatter the edges and other high-frequency information, it is said to be

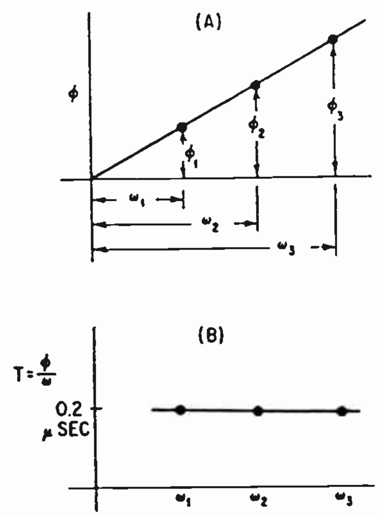

Figure 1.9-47. Curves illustrating a system with linear phase characteristics, which will give the same time delay for signals of all frequencies.

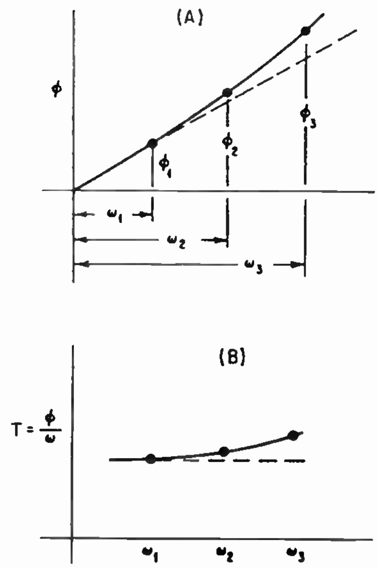

Figure 1.9-48. Curves showing the effect of nonlinear phase characteristic on time delay characteristic.

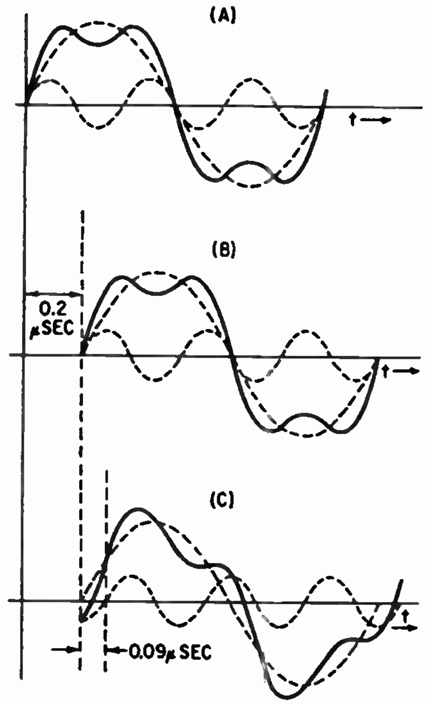

Figure 1.9-49. Curves showing that a complex wave (a) is not distorted by time delay (b) when both components (shown dotted) are delayed by the same amount. Unequal delays (c), however, cause distortion.

dispersionless.) The effect of phase distortion on the chrominance information is of a rather special nature and can best be explained by introducing the concept of *envelope delay.*

Envelope Delay

In the preceding discussion, the time delays φ_1/ω_1, φ_2/ω_2 and φ_3/ω_3 were always determined by measuring the frequencies and the phases from $\varphi = 0$ and $\omega = 0$. It might be said that the delay at zero frequency is commonly taken as the reference point for all other delays. This method is usually adequate for determining the performance of systems that do not carry any signals which have been modulated onto a carrier. But a carrier, with its family of associated sidebands (Figure 1.9-50(b)), can be thought of as a method of transmitting signals in which the zero frequency reference is translated to a carrier frequency reference. This translation can be understood by referring to Figures 1.9-50(a) and 50(b). To calculate the delay of the carrier borne signals *after* they have been demodulated, measurements of φ and ω must be referenced, not from zero frequency, but from *carrier* frequency.

In Figure 1.9-51(a), an impossible phase characteristic has been drawn to aid in further discussion of this subject. Such a characteristic, consisting of two perfectly straight lines, is never met in practice but makes a very simple system for developing the subject of envelope delay.

First, pass two frequencies ω_1 and ω_2 through this system. Let ω_1 be a carrier and ω_2 a sideband which might be, for example, 1,000 Hz higher. If ω_1 and ω_2 fall on the characteristic as shown in Figure 1.9-51(a), the delay which the 1,000 Hz will show after demodulation can be found by putting new reference axes (shown dotted) with ω_1, the carrier, at zero on these new axes. Now, when ω_s and φ_s are measured as shown, the time delay after demodulation is φ_s/ω_s. In this case, the delay of the 1,000 Hz after demodulation is the same as it would have been had it been passed through the system directly.

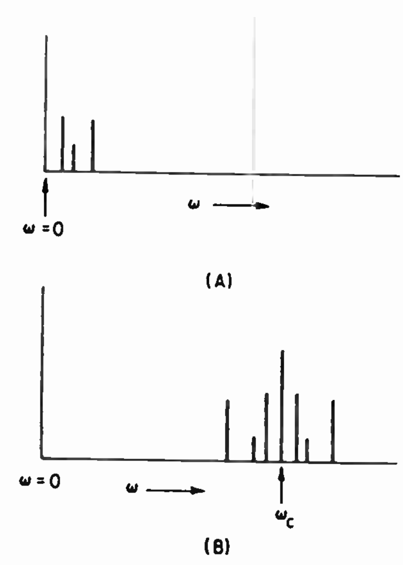

Figure 1.9-50. Sketch showing how a group of frequencies near $\omega = 0$ [sec. (a)] can be translated by modulation onto a carrier to a group of sidebands near ω_c – a carrier frequency (b).

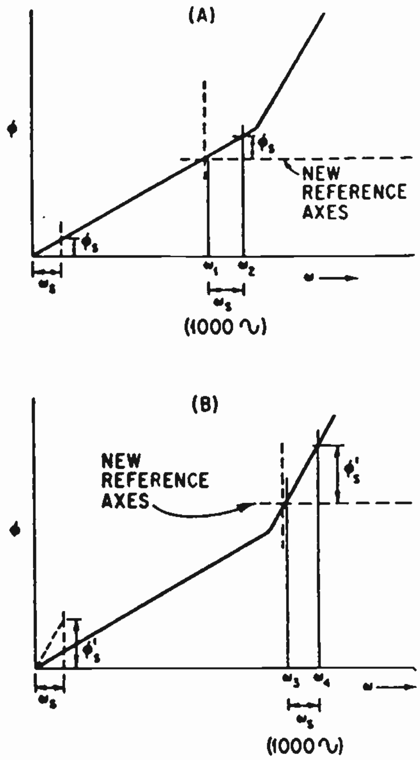

Figure 1.9-51. Idealized straight-line phase characteristics showing how a carrierborne 1,000 Hz signal can be delayed excessively when the carrier and sideband fall on a steeper portion of the phase characteristic.

Second, pass two other frequencies ω_3 and ω_4 through this system as redrawn in Figure 1.9-51(b). This time drawing in the new axes at ν_3, it can be seen that although ω_s is still 1,000 Hz, φ_s is larger than φ_s. Therefore, it can be concluded that the time delay φ_s/ω_s for this second case is greater than for the first case. The 1,000 Hz, when demodulated, will show a considerable error in timing.

Stressing the phrase *delay in a demodulated wave* should not be taken to mean that the demodulation process produces this delay or even make it apparent where it was previously not detectable. Any delay that a demodulated wave shows was also present when the wave existed as a carrier having an envelope. In short, the delay of the demodulated wave appears first as a delay of the envelope, hence the term *envelope delay.*

Envelope delay does not constitute a distortion. If a system such as the one shown in Figure 1.9-51(a) introduces a delay of 0.2 μsec to the 1,000 Hz wave (measured after demodulation), then the envelope delay of the system is 0.2 μsec. However, it was shown that a 1,000 Hz signal passed directly through the system (without first being modulated into a carrier) would also suffer a delay of 0.2 μsec. As long as the envelope delay φ_s/ω_s is the same as the time delay φ_1/ω_1 the envelope delay introduces no timing errors. But in the second system (Figure 1.9-51(b)) the demodulated 1,000 Hz wave suffered a *larger* delay, say 0.29 μsec. A 1,000 Hz signal passed directly through this system, however, would still be delayed only 0.2 μsec. Therefore, the second system has an envelope delay of 0.29 μsec and an *envelope delay distortion* of 0.09 μsec.

It is probably wise to point out that the time delay φ_3/ω_3 in Figure 1.9-51(b) is considerably less than the 0.29 μsec estimated for the value of envelope delay. Although φ_3/ω_3 would be greater than 0.2 μsec (say, for example, that φ_3/ω_3 is 0.22 μsec), the value would be optimistic about the amount of timing error that would be shown by the demodulated 1,000 Hz signal. The need for knowledge of the envelope delay φ_s/ω_s of the system is therefore obvious.

Effect of Envelope Delay Distortion on a Color Picture

A transmission system which exhibits envelope delay distortion will destroy the time coincidence between the chrominance and luminance portions of the signal. This will result in misregistration between the color and luminance components of the reproduced picture. The following paragraph explains briefly how envelope delay distortion causes this error.

Any colored area in a reproduced picture is derived from two signals: a chrominance signal and a luminance signal. Since these two signals describe the same area in the scene, they begin and end at the same time. The chrominance signal arrives at the receiver as a modulated subcarrier; the luminance signal does not. Therefore, as previously shown, the delay of the chrominance signal is determined principally by the envelope delay of the system and the delay of the luminance signal is determined principally by the ordinary time delay φ/ω. If the two delays are not identical (that is, if there is envelope delay *distortion*), then the chrominance signal does not coincide with the luminance signal and the resultant picture suffers *color luminance misregistration* in a horizontal direction.

For example, in a system having the characteristic of Figure 1.9-51(b), the luminance signal is delayed by 0.2 μsec but the chrominance signal is delayed by 0.29 μsec. The error in registration then amounts to 0.09 μsec, or about 0.2% of the horizontal dimension of the picture, which is about 0.3 in. on a 21-in. (diagonal) picture.

Although the subject of compatibility is outside the scope of this chapter, it is worth noting in passing that envelope delay distortion adversely affects compatibility, since it causes wideband monochrome receivers to display a misregistered dot-crawl image in addition to the proper luminance image.

General Method for Envelope Delay

The specific cases described (Figures 1.9-51(a) and 51(b)) made use of simple, idealized straight line approximations to develop the concept of envelope delay. Practical circuits are not so simple. For example, a simple *RC* network has a φ versus ω plot as in Figure 1.9-52. Finding the envelope delay of this curved line plot will clarify what is meant by envelope delay.

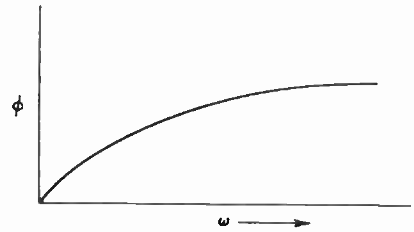

Figure 1.9-52. Phase characteristic of an RC network.

Referring back to the plots of Figure 1.9-50(a) and 50(b), it can be seen that the characteristic of the plot that determines the value of envelope delay is its *slope*. The larger envelope delay, which was suffered by the ω_3-ω_4 pair (Figure 1.9-51(b)), was a result of their lying on the steeper slope. The envelope delay of *any* system is equal to the slope of the phase versus frequency characteristic. If this characteristic is a curved line (as for the *RC* network, Fig. 1.9-52), then the slope is different at every frequency.

The slope of a curved line can be found by the methods of the differential calculus or to a good approximation by breaking up the line into a number of straight-line segments, as in Figure 1.9-53. If the slope of each of these straight lines is plotted against its corresponding frequency (that corresponding to the center of the line), the resulting curve will be approximately the envelope delay characteristic.

Nonlinearities of a Practical Transmission System

It is important to emphasize that the effect of nonlinearities in a color television system depends upon whether these nonlinearities precede or follow the matrixing and modulation sections of the system. Nonlinearities in transfer characteristics detract from color fidelity; the same degree of nonlinearity after matrixing and modulation also affects color fidelity although in a different way. The purpose of the following paragraphs is to discuss how a nonlinear transmission system affects a *composite* color signal. It is assumed that all other nonlinearities in the entire system either are negligible or have been canceled by use of nonlinear amplifiers such as gamma correctors.

The major sources of nonlinearity in a transmission system are its amplifying devices. These devices have a limited dynamic range. For example, if too much signal is supplied to them, an *overload* results. The transfer characteristic of such a system can be sketched as in Figure 1.9-54(a).

Such a nonlinearity is one of three types commonly encountered in video transmission systems. These three types are:

- Incremental gain distortion
- Differential gain
- Differential phase

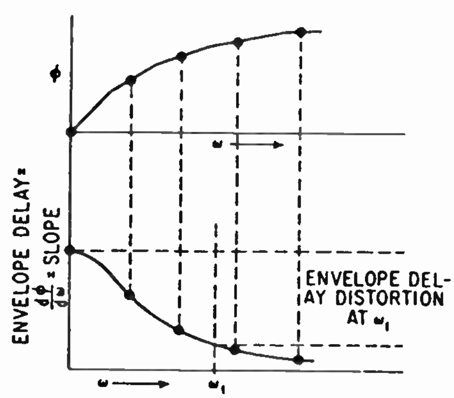

Figure 1.9-53. Graphs showing how a series of straight-line segments can be used to approximate the envelope delay characteristics (bottom).

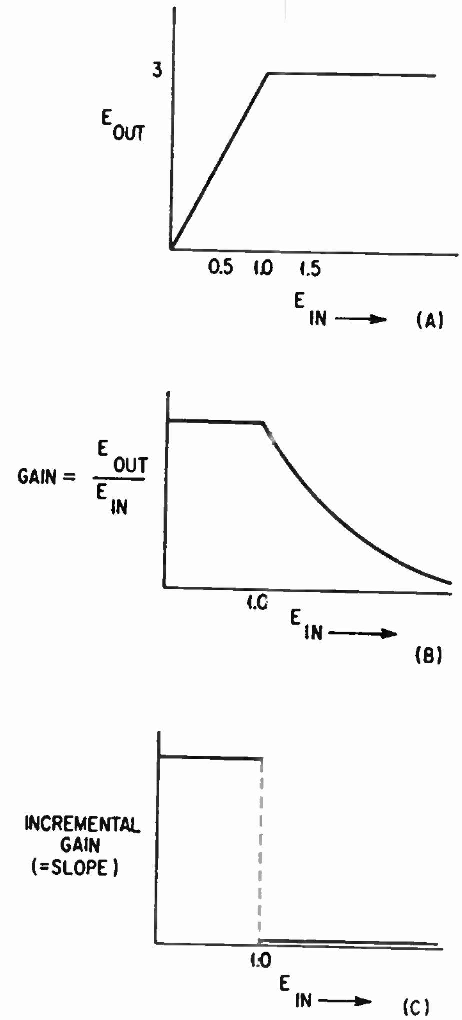

Figure 1.9-54. Idealized straight-line plots showing (a) output voltage of an amplifier versus input voltage (b) gain of the amplifier versus input voltage and (c) incremental gain of the amplifier versus input voltage. Curve (c) is the slope of curve (a).

Incremental Gain

The concept of the slope of a plot, developed in the discussion of envelope delay, will be useful here as well. Consider a plot as in Figure 1.9-54(a) which shows output voltage of an amplifier plotted against input voltage. Idealized straight-line plots are shown for simplicity. It can be seen that the amplifier has a maximum output of 3 V for 1 V input. Larger input voltages result in no more output; the amplifier *clips* or *compresses* when inputs larger than 1 V are applied.

The gain of the amplifier is

$$\text{Gain} = \frac{E_0}{E_{in}} = \frac{3\text{ volts}}{1\text{ volt}} = 3$$

The gain is obviously constant below the clip point. For example, *k* an input voltage of 0.5 V gives

$$\text{Gain} = \frac{1.5\text{ volts}}{0.5\text{ volts}} = 3$$

But at an input of 1.5 V, the output is still 3 V, so the gain is only 2. (The word "gain" is of doubtful use here because of the clipping involved.) The gain, defined as E_0/E_{in}, is plotted against E_{in} in Figure 1.9-54(b). It can be seen in this figure that the gain is constant only as long as the *slope* of Figure 1.9-54(a) is constant.

It is useful, then, to establish a new term, *incremental gain*, which will be defined as the *slope* of a plot such as Figure 1.9-54(a). For the particular plot of Figure 1.9-54(a), the slope is constant up to E_{in} = 1 V and then suddenly becomes zero. The corresponding plot of slope versus E_{in} is shown in Figure 1.9-54(c).

The importance of incremental gain in color television can be assessed by applying the input signal shown in Figure 1.9-55 to the distorting system of Figure 1.9-54(a). Before being applied to the distorting system, such a signal could be reproduced on a monochrome receiver as a vertical white bar and on a color receiver as a pastel colored bar, say, for example, a pale green. After passing through the distorting system, the signal would still be reproduced as a white bar on the monochrome receiver with the only apparent error being a luminance distortion, that is, a slight reduction in brightness, which, for the magnitudes shown here, would probably pass unnoticed. The color receiver, however, would receive a signal completely devoid of any color information and would reproduce a white bar in place of the former pale green one.

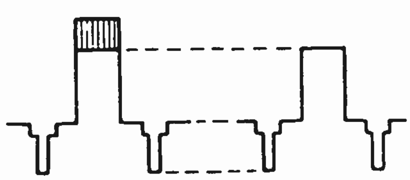

Figure 1.9-55. Extreme case of distortion resulting from passing signal at left (a) through the amplifier represented by Figure 1.9-54. The output (b) has no color information remaining.

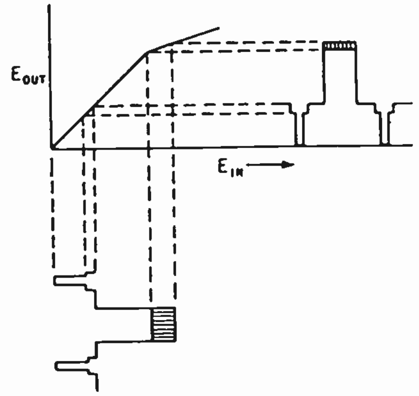

Figure 1.9-56. Diagram showing effect of incremental gain distortion of reducing amplitude of color portion of signal.

The less extreme case is shown in Figure 1.9-56. For the system represented by this characteristic, the slope (incremental gain) does not become zero for inputs above 1 V but instead falls to one-half its below-1 V value. The color signal of Figure 1.9-56 would not lose all color in passing through this system, but the amplitude of the subcarrier would become only one-half of its proper value. Since saturation is a function of subcarrier amplitude, the pale green of the undistorted reproduction would, in this case, become a paler green. The luminance distortion would also be less than in the extreme (clipping) case.

It can be seen, then, that unless the incremental gain of a system is constant, that system will introduce compression which will distort the saturation and brightness of reproduced colors. Usually, the error is in the direction of *decreased* luminance and saturation. For certain systems, however, exceptions can be found. For example, the effect that the system represented by Figure 1.9-56 will have on a signal depends on the polarity of the signal. For the signal as shown, the usual decrease in luminance and saturation is exhibited. For an inverted signal, however, the subcarrier amplitude would not be reduced, but the luminance signal would still be diminished. The subjective result of this distortion would be an *increase* in saturation. The unusual behavior of this particular system is attributable to its peculiar transfer characteristic, which was drawn with curvature at one end only to simplify the discussion. Most practical system transfer characteristics exhibit curvature at both ends and therefore have an effect on the signal, which is essentially independent of polarity.

Incremental gain can be measured in two ways, the first of which stems from its contribution to luminance distortion and the second, from its contribution to chrominance distortion.

In the first method, an equal-step staircase waveform such as shown in Figure 1.9-57(a) is applied to the system to simulate a signal having equal luminance increments. If the system has constant incremental gain, the output will, of course, also have equal-step increments. But if the system does not have constant

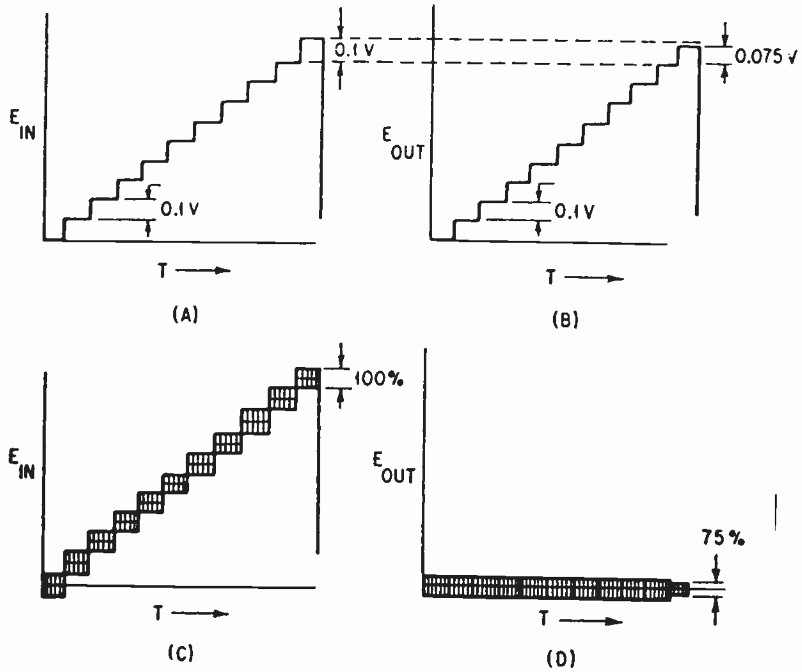

Figure 1.9-57. Diagrams showing two methods of measuring incremental gain distortion, namely, in (a) and (b) by its contribution to luminance distortion and in (c) and (d) chrominance distortion.

incremental gain, certain of the steps will be compressed, as in Figure 1.9-57(b). If the compression is as in the Figure, the *incremental gain distortion* (IGD) is indicated by the distorted amplitude of the last step. Numerically, it can be stated as a percentage:

$$\text{IGD} = 1 - \frac{S_{distorted}}{S_{undistorted}} \times 100\%$$

where S is a step amplitude.

For example, if an undistorted step is 0.1 V and the distorted one is 0.075 V, then the incremental gain distortion would be 25%.

Using the chrominance distortion technique, an input signal consisting of the step wave plus a small, high-frequency sine wave, as shown in Figure 1.9-57(c), is applied to the system. After the signal has passed through the system, it is fed through a high pass filter, which removes the low-frequency staircase. The incremental gain distortion then is indicated by the differences in the amplitude of the high-frequency sine waves (see Figure 1.9-57(d)). In this case, the high-frequency sine wave associated with the top step is shown as having 75% of the amplitude of the sine waves associated with the lower steps, which are assumed to be undistorted. Again, the incremental gain distortion is 25%.

A most important point must be made regarding the equivalence of these two techniques. Certain systems which show incremental gain distortion when tested by the luminance-step technique may or may not show the same distortion when tested by the high-frequency and high pass filter technique. Moreover, a system which shows distortion by the second technique may or may not show distortion by the first. In other words, the incremental gain distortion may be different for different frequencies. Such differences are frequently found in staggered amplifiers, feedback amplifiers or amplifiers having separate parallel paths for high and low frequencies, such as might be found in stabilizing amplifiers.

A thorough test of a system, therefore, should include a test of its incremental gain by both techniques. The staircase-plus-high-frequency waveform can be used to provide *both* tests by observing the system output (for this test waveform input) first through a low pass filter and then through a high pass filter. The first test will show low-frequency distortions; the second, high-frequency distortions.

Differential Gain

On the basis of the previous discussion of incremental gain distortion, the extremely important concept of *differential gain* can be presented merely as a simple definition. Differential gain is identical with incremental gain distortion when the latter is measured by observing ". . . the difference in the gain of the system for a small high-frequency sine-wave signal at two stated levels of a low-frequency signal upon which it is superimposed."[4] In other words, differential gain is a special form of incremental gain distortion, which describes the IGD of a system for the superimposed high-frequency case only.

One of the reasons for selecting the high-frequency aspect of incremental gain distortion for the Institute of Radio Engineers (IRE) definition of differential gain was applied in Figure 1.9-55, when the "... high-frequency sine wave ..." of the definition was made equal to color subcarrier. This special case of differential gain explores the system gain linearity in the vicinity of this particularly important frequency. The definition of differential gain was purposely made in the broad terms of a "... high frequency sine wave ..." to allow the greatest possible versatility in devising methods of measurement. In present color television practice, however, the "... high frequency sine wave ..." is always color subcarrier and the low-frequency signal mentioned in the definition is a 15,750 Hz staircase, sine wave, or sawtooth.

Another reason for emphasizing high-frequency IGD was implied previously by the sentence "... the signal ... would ... be reproduced ... with the only apparent error being a luminance distortion ... which, for the magnitudes shown here, would probably pass unnoticed." The magnitude shown was a 25% IGD, which is passing unnoticed, indicating that large incremental gain distortions usually cause no detectable luminance errors. Incremental gain distortion is almost too sensitive a tool to measure luminance distortions. For this purpose, simple gain distortion (compression) is more useful. Therefore, the luminance/distortion aspect of IGD was deliberately omitted from the definition of differential gain.

Incremental Phase and Differential Phase

The phase characteristic sketched in Figure 1.9-46 indicates that the system described by this plot will introduce a certain amount of phase shift for any given frequency. For example, it might be found that a certain system would introduce a phase shift of 60° at 2 MHz. If the system in question were perfectly linear, this 60° phase shift would be produced regardless of how the 2 MHz signal might be applied to the system.

It can be shown, however, that some systems, when presented with a signal of the type shown in Figure 1.9-58, will introduce a delay different from 60°, depending on where the zero axis of the sine wave falls on the transfer characteristic of the system. For the case sketched in the figure a phase shift of 70° is drawn for the largest zero-axis displacement.

By analogy with the incremental gain and differential gain arguments, it is possible to define three quantities which pertain to this type of distortion. These quantities are *incremental phase, incremental phase distortion,* and *differential phase.* It can also be shown that of the three, differential phase is the most important quantity.

Incremental phase is the least exact analogue, since it is not very similar in form to incremental gain. Incremental *gain* is a *slope*; incremental phase is simply the absolute value of phase shift. In the previous system, the incremental phase was 60° or 70° (or somewhere in between), depending upon the location of the zero axis.

Incremental phase distortion, like its analogue (*incremental gain distortion*), depends upon the magnitude of the error. It should be zero for a perfect system. In the system of Figure 1.9-58 the 2 MHz signal with 70° incremental phase would be said to have 10° incremental phase distortion, so it is clear that the difference between two phases (one of which is assumed to be correct) gives the incremental phase distortion.

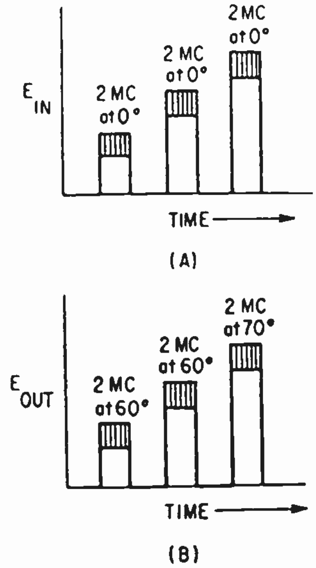

Figure 1.9-58. Graphs illustrating how a signal (a) may undergo different phase shifts (b) depending upon where the zero axis at the sine wave falls on the system transfer characteristic. This distortion is called differential phase.

As previously stated, *differential gain* is identical with incremental gain distortion for the superimposed high-frequency case only. Similarly, differential phase is identical with incremental phase distortion, but there is no need to limit the definition to the superimposed high-frequency case, since there is no other case which is meaningful for phase distortion. Without the superimposed sine wave, no phase measurement is possible. Therefore, differential phase is identical with incremental phase distortion. In practical work, the first two terms are seldom used, for the last, differential phase, has been found completely adequate to describe this aspect of a system.

In summary, the differential phase of a system is "the difference in phase shift through the system for a small high-frequency sine wave signal at two stated levels of a low-frequency signal on which it is superimposed."[5]

Effect of Differential Phase on Color Picture

The phase of a subcarrier in a composite signal carries information about the *hue* of the signal at that instant. If the signal passes through a system which introduces differential phase, the subcarrier phase (and hence, the hue) at the output will become dependent upon the amplitude of the luminance associated with the hue, since it is the luminance signal which determines the location of the zero axis of the subcarrier.

For example, a system introducing 10° of differential phase might be adjusted to reproduce properly a low-luminance hue such as saturated blue or a high-luminance hue such as saturated yellow, but *not both*. One or the other would have to be in error.

Conclusion

This discussion of color errors indicates possible degradations in color fidelity and their probable sources. However, in a properly adjusted color TV system the picture quality is excellent. The various techniques now in use within the framework of the NTSC system have assured a long future for color TV, even in the DTV era now upon us.

THE COLOR ENCODER

The color encoder in the color television system performs the required encoding of the R, G, B signals from three-tube cameras or the R, G, B and Y (luminance) signals from four-tube cameras into a single color video signal conforming to FCC specifications. It is the heart of the modern color television system and represents a most ingenious application of many elements of communication circuit theory. Figure 1.9-59 shows a block schematic of a basic color television system indicating the functions and major components of the color encoder.

A more detailed block diagram of the color encoder showing the matrixing, bandwidth limiting and quadrature modulation functions is shown in Figures 1.9-33 and 34.

Basic Functions

The principal operations and functions performed by the color encoder are:

- Matrixing of R, G, B video signals to produce luminance and chrominance signals
- Filtering of the chrominance signals to obtain the required bandwidth
- Delay compensation to correct for band-limiting time delay
- Modulation of 3.58 MHz carriers by chrominance signals
- Insertion of color sync burst
- Addition of luminance and chrominance signal to form a complete color signal
- Optional addition of sync.

Color encoders of modern design are inherently stable and require only routine verification or adjustment. Set-up of a color encoder involves the use of color bars which are electrically generated waveforms of high precision. A color bar generator is capable of producing on a color monitor all of the signal bars illustrated in Figure 1.9-60.

Colors at the top of this display pattern are arranged from left to right as white, yellow, cyan, green, magenta, red and blue in their decreasing order of luminance. The lower portion of the pattern contains I, 100% white, Q, and black signal areas. The I and Q signals simplify subcarrier phase adjustments in the color encoder and the 100% white bar facilities white balance adjustments. The specifications of the standard encoder color bar signal are given in EIA Standard RS-189.

Waveforms

Figure 1.9-61 shows the oscilloscope waveforms at a horizontal sweep rate of the color bar signals displayed on the television raster. Note that this is a composite representation of waveforms of the top and

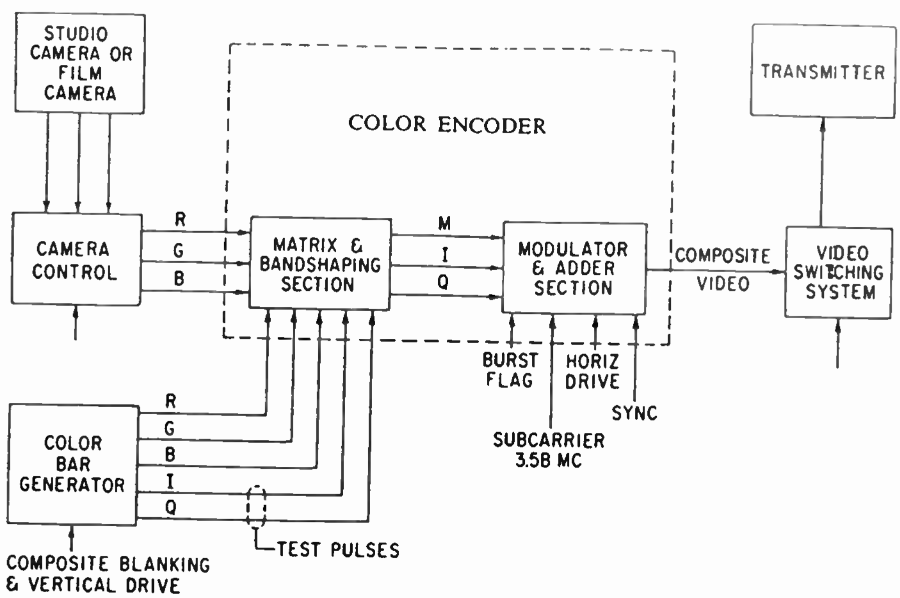

Figure 1.9-59. Basic color television system showing functions and major components of the color encoder.

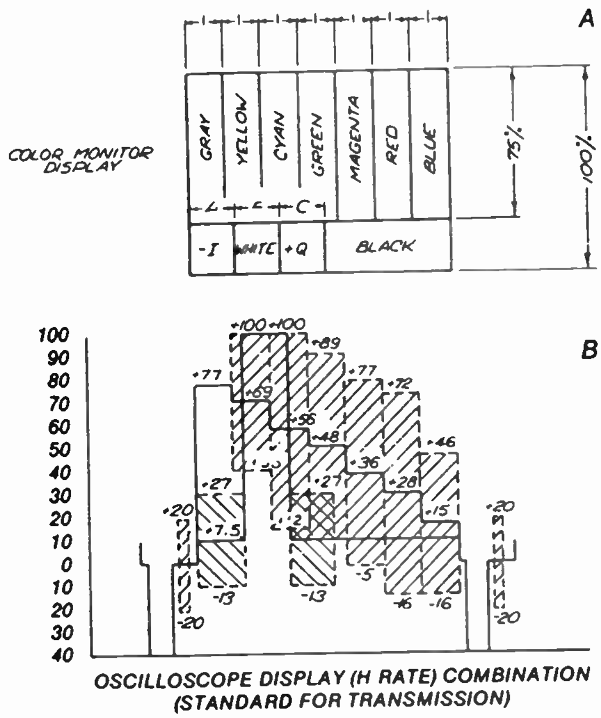

Figure 1.9-61. (a) Color monitor display and (b) Oscilloscope display (H rate).

bottom areas of the raster. The color sync precedes the color bar pulse information.

Figure 1.9-62 shows the various band-pass response characteristics of the luminance channel and of the I and Q channels of the color encoder.

A color encoder is set up and adjusted by using the calibrated color bars just described. The color encoder luminance gain is adjusted by using the 75% white bar as a reference. By switching off the luminance channel the appropriate I and Q waveforms are available to set the proper peak amplitudes and the 90° phase separation. Either a wide-band oscilloscope or a vectorscope can be used for display in a variety of specialized setup procedures. The vector relationship of chrominance components is shown in Figure 1.9-63.

COLOR TEST EQUIPMENT

The color television broadcast station relies heavily on specialized test and monitoring facilities in order to maintain adequate standards of performance and to ensure compliance with FCC regulations. Test signals have become quite sophisticated and yield much useful information on the performance of the systems.

A stable high performance color monitor is an essential element of color test equipment. This, together with a vectorscope and a standard color bar generator for setup and calibration serves as a means of evaluating performance.

The color monitor, vectorscope and color bar generator find utilization in a rapid routine day-to-day check of the television system adjustments.

Additional test equipment needed for color TV performance evaluation falls into two categories: equipment to evaluate studio performance and equipment to evaluate microwave relay and transmitter performance.

The important electrical characteristics to be measured in either category are:

- Linearity or differential gain
- Frequency response and differential phase performance
- Group delay characteristic
- Low frequency square-wave response.

Evolutionary developments have followed the requirement that specific test waveforms be made available which are compatible with normal television sig-

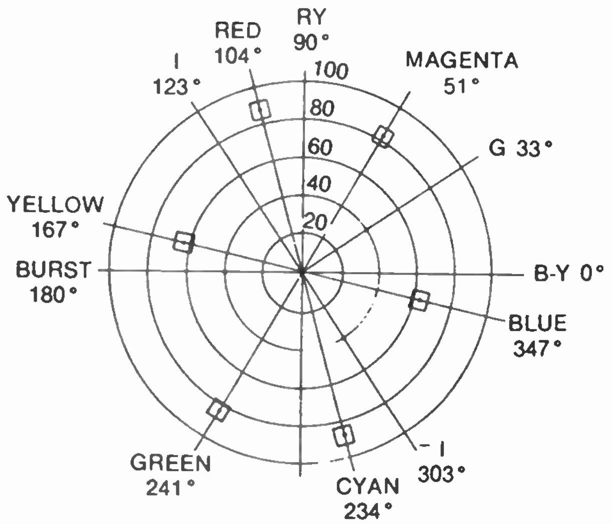

Figure 1.9-63. Vector relationship among chrominance components.

nal systems and can be introduced easily without disabling or upsetting normal operating conditions. Measurements of such test waveforms, after passing through selected portions of the equipment or the complete system under evaluation, will give the required differential gain, phase and group delay information.

Stair-Step Generator

A modulated stair-step generator waveform is shown in Figure 1.9-64. It consists of five 20-IRE-unit risers with subcarrier modulation on each transition. The amplitude-linearity or differential gain response of an amplifier can be determined directly from oscilloscope measurements of the output wave display. By the use of a high pass filter the differential gain characteristic can be displayed more graphically (Figure 1.9-65, input), (Figure 1.9-66, output) showing appre-

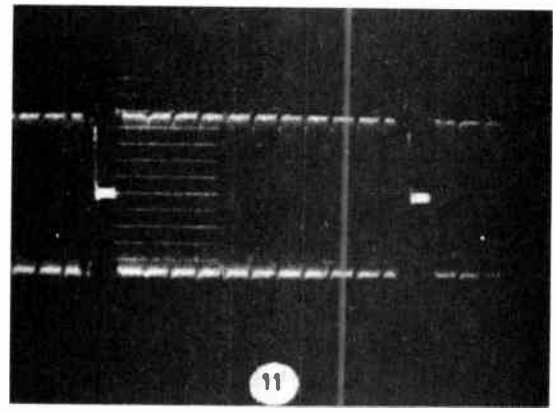

Figure 1.9-65. High pass filter output with modulated stair-step waveform input. (Picture courtesy of Marconi Instruments.)

ciable distortion. Differential phase measurements can be obtained by comparison of the subcarrier phase at each discrete level with phase of the color burst. Various oscillographic display techniques for precision phase measurements are available.

Sine-Squared Pulse and Bar

A second specialized waveform is the sine-squared pulse and bar with chrominance subcarrier modulation as shown in Figure 1.9-67. It evolved from the monochrome sine-squared pulse and bar shown in Figure 1.9-68. Use of this color test signal shows the presence of differential gain distortions as in Figure 1.9-69 and delay distortions as shown in Figure 1.9-70. Operationally the elegance of the method is in the direct display presentation where distortion limits may be checked by reticle overlay techniques.

Another frequently used waveform is the multiburst signal, Figure 1.9-71 and 72, which provides a series of selected frequency, constant-amplitude sine wave electrical bursts of 0.5 MHz, 1, 2, 3 and 4 sweep signals which sequentially sample all frequencies in

the video pass band. However, it is more convenient to use and to interpret in routine frequency response tests of broadcast equipment.

Vectorscope

The *vectorscope* is a measurement instrument developed especially for color TV system tests and monitoring. Its essential feature is the polar or vectorial display of chrominance information in which the radial deflection is proportional to saturation of a color, and the angular position is equal to the phase angle of that color subcarrier with respect to the color burst. The 360° polar coordinate display corresponds to a complete cycle of color subcarrier or 280 nsec in a time display. By convention, the color burst is normalized at 180°. If the color bar signal described in Figures 1.9-61 and 63 is applied to the input to the vectorscope and the burst is normalized at 180°, the display shown in Figure 1.9-73 is obtained on the graticule.

It is noted that for standard signal levels each color vector in the color bar sequence falls within its approximately marked box on the graticule. The outer boxes define the FCC maximum permissible errors of ±10° in phase and ±20% in amplitude. The inner boxes correspond to ±2.5 phase error and 2.5% amplitude error.

A feature of the vectorscope color bar technique is that it gives immediate reassurance on system performance with a color bar test signal display.

By alternating two signal sources at the input, one can obtain direct readings on differential phase and amplitude behavior of any selected picture sources.

Vertical Interval Reference and Test Signals

The *vertical interval reference* (VIR) signal, consists of a chrominance bar having the same phase as color burst, together with an appropriate luminance pulse and a black level interval. The VIR signal is added to the main video signal and is in fact a certification that at the time it is added all conditions are normal. If various distortions occur to this VIR, it can

be corrected, with the expectation that the main signal will also be corrected. Thus, more rigorous control and compensation of system errors is possible. A *vertical interval test* (VIT) signal is used to verify transmission conditions using multiburst, sine-squared or stair-step

test signals. Such signals can be used for continuous monitoring of TV system performance.

A detailed discussion of video signal analysis and measurement can be found in Chapter 7.2, *Video Signal Analysis.*

1.10
WORLDWIDE STANDARDS FOR CONVENTIONAL TELEVISION

D. H. PRITCHARD AND J. J. GIBSON

INTRODUCTION

The performance of a motion picture system in one location in the world is generally the same as in any other location. Thus, international exchange of film programming is relatively straightforward. This is not the case, however, with the conventional broadcast color television systems. The lack of compatibility has its origins in many factors, such as constraints in communications channel allocations and techniques, differences in local power source characteristics, network requirements, pickup and display technology, and political considerations relating to international telecommunications agreements.

Background

The most outstanding effort—as well as the most controversial effort—of the Eleventh Plenary Assembly of the International Radio Consultative Committee (CCIR), held in Oslo in 1966, was an attempt at standardization of color television systems by the participating countries of the world. The discussions pertaining to the possibility of a universal system proved inconclusive. Therefore, the International radio Consultative Committee, instead of issuing a unanimous recommendation for a single system CCIR, was forced to issue only a report describing the characteristics and recommendations for a variety of proposed systems. It was left to the controlling organizations of the individual countries to make their own choice as to which standard to adopt.

This outcome was not totally surprising because one of the primary requirements for any color television system is compatibility with a coexisting monochrome system. In many cases, the monochrome standards already existed and were dictated by such factors as local power line frequencies (relevant to field and frame rates) as well as radio frequency channel allocations and pertinent telecommunications agreements.

Thus, such technical factors as line number, field rate, video bandwidth, modulation technique, and sound carrier frequencies were predetermined and varied in many regions of the world. The ease with which international exchange of program material may be accomplished is thereby hampered, and has been accommodated over the years by means of standards conversion techniques, or *transcoders*, with varying degrees of loss in quality. While invariably introducing some compromises, standards conversion techniques have provided surprisingly good service in recent years with the growing use of satellite relays coupled with the advances in digital signal processing in both the video and audio domains.

MONOCHROME COMPATIBLE COLOR TV SYSTEMS

In order to achieve success in the introduction of a color television system, it is essential that the color system be fully compatible with the existing black-and-white system. That is, monochrome receivers must be able to produce high-quality black-and-white images from a color broadcast, and color receivers must produce high-quality black-and-white images from monochrome broadcasts. The first such color television system to be placed into commercial broadcast service was developed in the United States. On 17, December 1953, the Federal Communications Commission (FCC) approved transmission standards and authorized broadcasters, as of January 23, 1954, to provide regular service to the public under these standards. This decision was the culmination of the work of the National Television System Committee (NTSC) upon whose recommendation the FCC action was based[1]. Subsequently, this system, commonly referred to as the NTSC system, was adopted by Canada, Japan, Mexico, and others.

That more than 40 years ago, these standards are still providing color television service of good quality testifies to the validity and applicability of the fundamental principles underlying the choice of specific techniques and numerical standards.

The previous existence of a monochrome television standard was two-edged in that it provided a foundation upon which to build the necessary innovative techniques while simultaneously imposing the requirement of compatibility. Within this framework, an underlying theme—that which the eye does not see does not need to be transmitted nor reproduced—set the stage for a variety of fascinating developments in what has been characterized as an "economy of representation"[1].

The countries of Europe delayed the adoption of a color television system, and in the years between 1953 and 1967, a number of alternative systems that were compatible with the 625-line, 50-field existing monochrome systems were devised. The development of these systems was to some extent influenced by the fact that the technology necessary to implement some of the NTSC requirements was still in its infancy. Thus, many of the differences between NTSC and the other systems are the result of technological rather than fundamental theoretical considerations.

Most of the basic techniques of NTSC are incorporated into the other system approaches. For example, the use of wideband luminance and relatively narrowband chrominance, following the teachings of the principle of *mixed highs*, is involved in all systems. Similarly, the concept of providing horizontal interlace for reducing the visibility of the color subcarrier(s) is followed in all approaches. This feature is required to reduce the visibility of signals carrying color information that are contained within the same frequency range as the coexisting monochrome signal, thus maintaining a high order of compatibility.

An early system that received approval was one proposed by Henri de France of the Compagnie de Television of Paris. It was argued that if color could be relatively band-limited in the horizontal direction, it could also be band-limited in the vertical direction. Thus, the two pieces of coloring information (hue and saturation) that need to be added to the one piece of monochrome information (brightness) could be transmitted as subcarrier modulation that is sequentially transmitted on alternate lines—thereby avoiding the possibility of unwanted crosstalk between color signal components. Thus, at the receiver, a one-line memory, commonly referred to as a 1-*H* delay element, must be employed to store one line to then be concurrent with the following line. Then a linear matrix of the red and blue signal components (R and B) is used to produce the third green component (G). Of course, this necessitates the addition of a line-switching identification technique. Such an approach, designated as *S*equential *C*ouleur *A*vec *M*emoire, for sequential color with memory (SECAM) was developed and officially adopted by France and the USSR, and broadcast service began in France in 1967.

The implementation technique of a 1-*H* delay element led to the development, largely through the efforts of Walter Bruch of Telefunken Company, of the *Phase Alternation Line* (PAL) system. This approach was aimed at overcoming an implementation problem of NTSC that requires a high order of phase and amplitude integrity (skew-symmetry) of the transmission path characteristics about the color subcarrier to prevent color quadrature distortion. The line-by-line alternation of the phase of one of the color signal components averages any colorimetric distortions to the observer's eye to that of the correct value. The system in its simplest form (simple PAL), however, results in line flicker (Hanover bars). The use of a 1-*H* delay device in the receiver greatly alleviates this problem (standard PAL). PAL systems also require a line identification technique.

The standard PAL system was adopted by numerous countries in continental Europe, as well as in the United Kingdom. Public broadcasting began in 1967 in Germany and the United Kingdom using two slightly different variants of the PAL system.

NTSC, PAL, AND SECAM SYSTEMS OVERVIEW

In order to properly understand the similarities and differences of the conventional television systems, a familiarization with the basic principles of NTSC, PAL, and SECAM is required. As previously stated, because many basic techniques of NTSC are involved in PAL and SECAM, a thorough knowledge of NTSC is necessary in order to understand PAL and SECAM.

The same R, G, and B pickup devices and three primary color display devices are used in all systems. The basic camera function is to analyze the spectral distribution of the light from the scene in terms of its red, green, and blue components on a point-by-point basis as determined by the scanning rates. The three resulting electrical signals must then be transmitted over a band-limited communications channel to control the three-color display device to make the *perceived* color at the receiver appear essentially the same as the *perceived* color at the scene.

It is useful to define color as a psycho-physical property of light—specifically, as the combination of those characteristics of light that produce the sensations of brightness, hue, and saturation. Brightness refers to the relative intensity; hue refers to that attribute of color that allows separation into spectral groups perceived as red, green, yellow, and so on (in scientific terms, the *dominant wavelength*); and saturation is the degree to which a color deviates from a neutral gray of the same brightness—the degree to which it is "pure," or "pastel," or "vivid." These three characteristics represent the total information necessary to define and/or recreate a specific color stimulus.

This concept is useful to communication engineers in developing encoding and decoding techniques to efficiently compress the required information within a given channel bandwidth and to subsequently recombine the specific color signal values in the proper proportions at the reproducer. The NTSC color standards define the first commercially broadcast process for achieving this result.

A preferred signal arrangement was developed that resulted in reciprocal compatibility with monochrome pictures and was transmitted within the existing monochrome channel, as shown in Figure 1.10-1. Thus, one signal (luminance) is chosen in all approaches to occupy the wide-band portion of the channel and to convey the *brightness* as well as the detail information content. A second signal (chrominance), representative of the chromatic attributes of *hue* and *saturation*, is assigned less channel width in accordance with the principle that, in human vision, full three-color reproduction is not required over the entire range of resolution—commonly referred to as the *mixed-highs principle*.

Another fundamental principle employed in all systems involves arranging the chrominance and luminance signals within the same frequency band without excessive mutual interference. Recognition that the

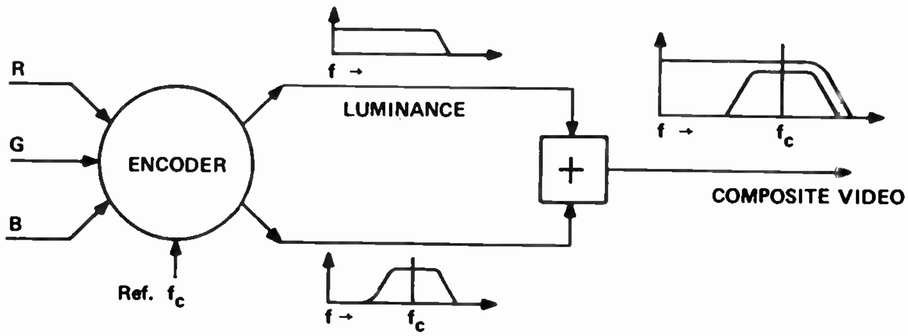
  - WIDEBAND LUMINANCE (BRIGHTNESS)
  - NARROW-BAND MODULATION OF A COLOR SUBCARRIER (Hue and Saturation)



- SUBCARRIER FREQUENCY INTERLACE
  - ODD MULTIPLE OF ½H TO REDUCE VISIBILITY OF CHROMINANCE INFORMATION SUBCARRIER.

Figure 1.10-1. Basic communications channel principles applied to color television.

scanning process, being equivalent to sampled-data techniques, produces signal components largely concentrated in uniformly spaced groups across the channel width, led to introduction of the concept of horizontal frequency interlace (dot interlace). The color subcarrier frequency is so chosen as to be an odd multiple of one-half the line rate (in the case of NTSC) such that the phase of the subcarrier is exactly opposite on successive scanning lines. This substantially reduces the subjective visibility of the color signal "dot" pattern components.

Thus, the major differences among the three main systems of NTSC, PAL, and SECAM are in the specific modulating processes used for encoding and transmitting the chrominance information. The similarities and differences are briefly summarized in Table 1.10-1.

- ALL SYSTEMS:
  - THREE-PRIMARY ADDITIVE COLORIMETRIC PRINCIPLES
  - SIMILAR CAMERA PICK-UP AND RECEIVER DISPLAY TECHNOLOGY
  - WIDEBAND LUMINANCE AND NARROW-BAND COLOR
- COMPATIBILITY WITH CO-EXISTING MONOCHROME SYSTEM:

  INTRODUCES FIRST ORDER DIFFERENCES
  - LINE NUMBER
  - FIELD/FRAME RATES
  - BANDWIDTH
  - FREQUENCY ALLOCATION
- MAJOR DIFFERENCES IN COLOR TECHNIQUES
  - NTSC – PHASE AND AMPLITUDE QUADRATURE MODULATION OF INTERLACED SUBCARRIER
  - PAL – SIMILAR TO NTSC BUT WITH LINE ALTERNATION OF "V" COMPONENT
  - SECAM – FREQUENCY MODULATION OF LINE SEQUENTIAL COLOR SUBCARRIERS

Table 1.10-1. General comparison of worldwide television systems.

The NTSC Color System

The importance of the colorimetric concepts of brightness, hue, and saturation comprising the three pieces of information necessary to analyze or recreate a specific color value becomes evident in the formation of the composite color television NTSC format.

The luminance, or monochrome, signal is formed by addition of specific proportions of the red, green, and blue signals and occupies the total available video bandwidth of 0–4.2 MHz. The NTSC, PAL, and SECAM systems all use the same luminance (Y) signal formation, differing only in the available bandwidths.

The Y signal components have relative voltage values representative of the brightness sensation in the human eye. Therefore, the red, green, and blue voltage components are tailored in proportion to the standard luminosity curve at the particular values of the dominant wavelengths of the three color primaries chosen for color television. Thus, the luminance signal makeup for all systems, as normalized to white, is described by:

$$E'_Y = 0.299E'_R + 0.587E'_G + 0.114E'_B \qquad (1)$$

The signal of Equation (1) would be exactly equal to the output of a linear monochrome sensor with ideal spectral sensitivity if the red, green, and blue elements were also linear devices with theoretically correct spectral-sensitivity curves. In actual practice, the red, green, and primary signals are deliberately made nonlinear to accomplish *gamma correction* (adjustment of the slope of the input/output transfer characteristic). The prime mark (′) is used to denote a gamma-corrected signal.

Table 1.10-2 gives the equations for the chrominance signal components. Signals representative of the chromaticity information (hue and saturation) that relate to the differences between the luminance signal and the basic red, green, and blue signals are generated in a linear matrix. This new set of signals is termed *color-difference* signals and is designated as R − Y, G − Y, and B − Y. These signals modulate a subcarrier that is combined with the luminance component and passed through a common communications channel. At the receiver, the color difference signals are detected, separated and individually added to the luminance signal in three separate paths to recreate the original R, G and B signals according to the equations:

$$E'_Y + E'_{(R-Y)} = E'_Y + E'_R - E'_Y = E'_R \qquad (2a)$$

$$E'_Y + E'_{(G-Y)} = E'_Y + E'_G - E'_Y = E'_G \qquad (2b)$$

$$E'_Y + E'_{(B-Y)} = E'_Y + E'_B - E'_Y = E'_B \qquad (3c)$$

In the specific case of NTSC two other color-difference signals, designated as *I* and *Q*, are formed at the encoder and are used to modulate the color subcarrier.

Another reason for the choice of signal values in the NTSC system is that the eye is more responsive to spatial and temporal variations in luminance than it is to variations in chrominance. Therefore, the visibility of luminosity changes resulting from random noise and interference effects may be reduced by properly proportioning the relative chrominance gain and encoding angle values with respect to the luminance values. Thus, the *principle of constant luminance* is incorporated into the system standard.[1,2]

LUMINANCE:

$$E'_Y = 0.299\ E'_R + 0.587\ E'_G + 0.114\ E'_B$$

(Common for all systems)

CHROMINANCE:

$$D'_B = 1.5\ (E'_B - E'_Y)$$

Table 1.10-2. Electronic color signal values for NTSC, PAL, and SECAM.

The voltage outputs from the three camera sensors are adjusted to be equal when a scene reference white or neutral gray object is being scanned for the color temperature of the scene ambient. Under this condition, the color subcarrier also automatically becomes zero. The colormetric values have been formulated by assuming that the reproducer will be adjusted for *illuminant C*, representing the color of average daylight.

Figure 1.10-2 is a CIE chromaticity diagram indicating the primary color coordinates for NTSC, PAL, and SECAM. It is interesting to compare the available color gamut relative to that of all color paint, pigment, film, and dye processes.

In the NTSC color standard, the chrominance information is carried as simultaneous amplitude and phase modulation of a subcarrier chosen to be in the high frequency portion of the 0–4.2 MHz video band and specifically related to the scanning rates as an odd multiple of one-half the horizontal line rate, as shown by the vector diagram in Figure 1.10-3. The hue information is assigned to the instantaneous phase of the subcarrier. Saturation is determined by the *ratio* of the

		x	y

Figure 1.10-2. CIE chromacity diagram-system comparison.

instantaneous amplitude of the subcarrier to that of the corresponding luminance signal amplitude value.

The choice of the *I* and *Q* color modulation components relates to the variation of color acuity characteristics of human color vision as a function of the field of view and spatial dimensions of objects in the scene. The color acuity of the eye decreases as the size of the viewed object is decreased and thereby occupies a small part of the field of view. Small objects, represented by frequencies above about 1.5–2.0 MHz, produce no color sensation (*mixed-highs*). Intermediate spatial dimensions (approximately in the 0.5–1.5 MHz range) are viewed satisfactorily if reproduced along a preferred orange-cyan axis. Large objects (0–0.5 MHz) require full three-color reproduction for subjectively-pleasing results. Thus, the *I* and *Q* bandwidths are chosen accordingly, and the preferred colorimetric reproduction axis is obtained when only the *I* signal exists by rotating the subcarrier modulation vectors by 33. In this way, the principles of mixed-highs and *I*, *Q color-acuity axis* operation are exploited.

At the encoder, the *Q* signal component is band-limited to about 0.6 MHz and is representative of the green-purple color-axis information. The *I* signal component has a bandwidth of about 1.5 MHz and contains the orange-cyan color axis information. These two signals are then used to individually modulate the color subcarrier in two balanced modulators operated in phase quadrature. The *sum products* are selected and added to form the composite chromaticity subcarrier. This signal—in turn—is added to the luminance signal along with the appropriate horizontal and vertical synchronizing and blanking waveforms to include the color-synchronization burst. The result is the total composite color video signal.

Quadrature synchronous detection is used at the receiver to identify the individual color signal components. When individually recombined with the luminance signal, the desired R, G and B signals are recreated. The receiver designer is free to demodulate either at *I* or *Q* and matrix to form B − Y, R − Y and G − Y, or as in nearly all modern receivers, at B − Y and R − Y and maintain 500 kHz equiband color signals.

The chrominance information can be carried without loss of identity provided that the proper phase relationship is maintained between the encoding and decoding processes. This is accomplished by transmitting a reference burst signal consisting of eight or nine cycles of the subcarrier frequency at a specific phase [−(B − Y)] following each horizontal synchronizing pulse as shown in Figure 1.10-4.

The specific choice of color subcarrier frequency in NTSC was dictated by at least two major factors. First, the necessity for providing horizontal interlace in order to reduce the visibility of the subcarrier requires that the frequency of the subcarrier be precisely an odd multiple of one-half the horizontal line rate. Figure 1.10-5 shows the energy spectrum of the composite NTSC signal for a typical stationary scene. This interlace provides line-to-line phase reversal of the color subcarrier, thereby reducing its visibility (and thus improving compatibility with monochrome reception). Second, it is advantageous to also provide interlace of the beat-frequency (about 920 kHz) occurring between the color subcarrier and the average value of the sound carrier. For total compatibility reasons, the sound carrier was left unchanged at 4.5 MHz and the line number remained at 525. Thus, the resulting line scanning rate and field rate varied slightly from that of the monochrome values, but stayed within the previously existing tolerances. The difference is exactly one part in one thousand. Specifically, the line rate is 15.734 kHz, the field rate is 59.94 Hz, and the color subcarrier is 3.578545 MHz.

PAL Color System

Except for some minor details, the color encoding principles for PAL are the same as those for NTSC. However, the phase of the color signal, $E_V = R - Y$, is reversed by 180° from line-to-line. This is done for the purpose of averaging, or canceling, certain color errors resulting from amplitude and phase distortion of the color modulation sidebands. Such distortions

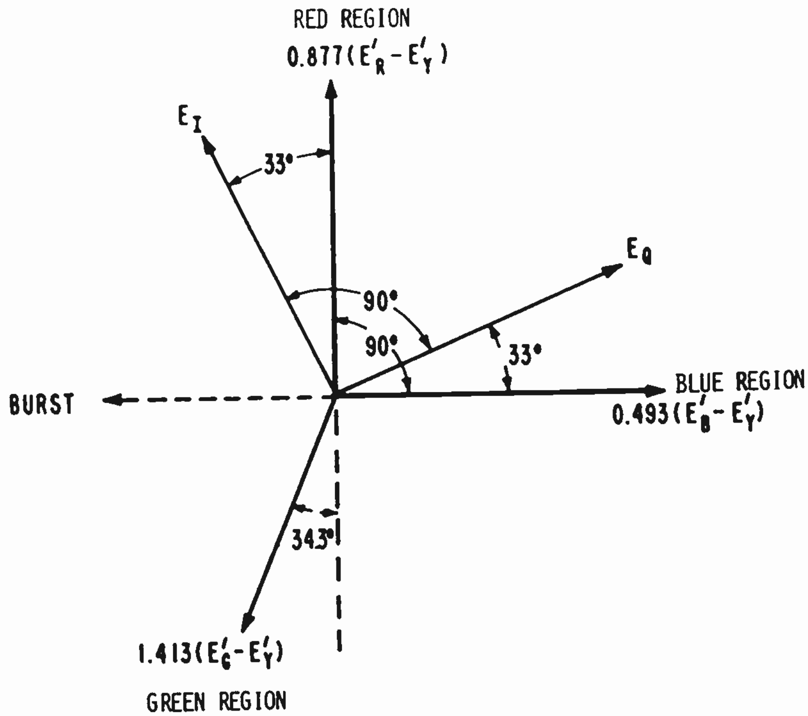

Figure 1.10-3. NTSC color modulation phase diagram.

might occur as a result of equipment or transmission path problems.

The NTSC chroma signal expression within the frequency band common to both I and Q is given by:

$$C_{NTSC} = \frac{B - Y}{2.03} \sin \omega_{SC}t + \frac{R - Y}{1.14} \cos \omega_{SC}t \quad (3)$$

The PAL chroma signal expression is given by:

$$C_{PAL} = \frac{U}{2.03} \sin \omega_{SC}t \pm \frac{C}{1.14} \cos \omega_{SC}t \quad (4)$$

where U and $\pm V$ have been substituted for $B - Y$ and $R - Y$ signal values, respectively.

The PAL format employs equal bandwidths for the U and V color-difference signal components that are about the same as the NTSC I signal bandwidth (1.3 MHz at 3 dB). There are slight differences in the U and V bandwidth in different PAL systems because of the differences in luminance bandwidth and sound carrier frequencies. (See the applicable ITU-R documents for specific details.)

The V component was chosen for the line-by-line reversal process because it has a lower gain factor than U and, therefore, is less susceptible to switching rate ($\frac{1}{2} f_H$) imbalance. Figure 1.10-6 indicates the vector diagram for the PAL quadrature modulated and line-alternating color modulation approach.

The result of the switching of the V signal phase at the line rate is that any phase errors produce complementary errors from V into the U channel. In addition, a corresponding switch of the decoder V channel results in a constant V component with complementary errors from the U channel. Thus, any line-to-line averaging process at the decoder, such as the retentivity of the eye (simple PAL) or an electronic averaging technique such as the use of a 1-H delay element (standard PAL), produces cancellation of the phase (hue) error and provides the correct hue but with somewhat reduced saturation—this error being subjectively much less visible.

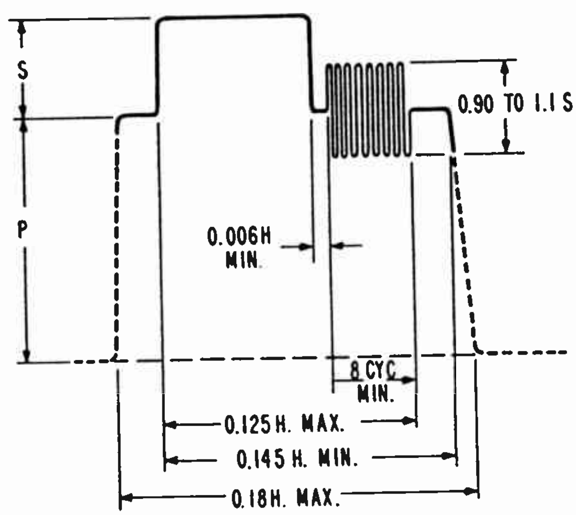

Figure 1.10-4. NTSC color burst synchronizing signal.

Obviously, the PAL receiver must be provided with some means by which the V signal switching sequence

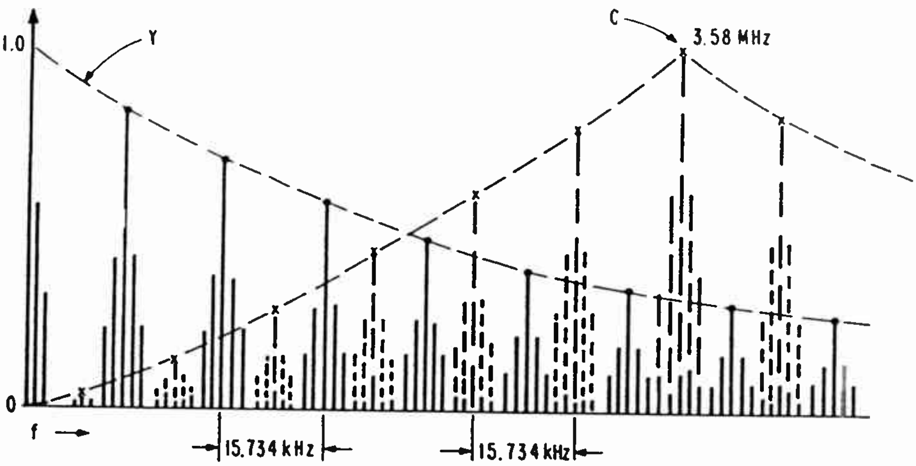

Figure 1.10-5. Luminance/chrominance horizontal frequency interface principle.

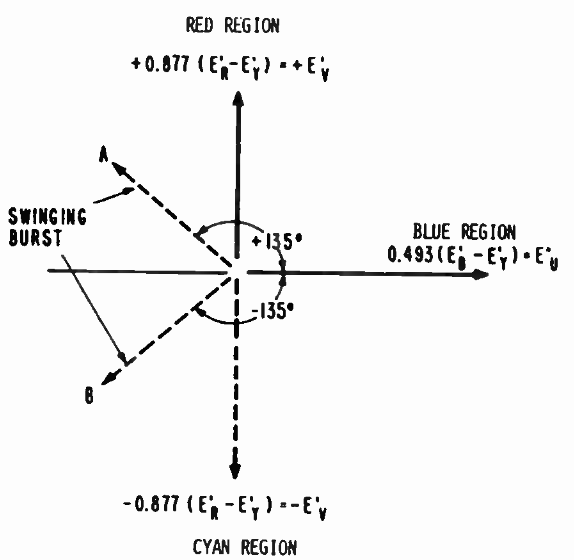

Figure 1.10-6. PAL color modulation phase diagram.

may be identified. The technique employed is known as *A B* sync, PAL sync, or *swinging burst* and consists of alternating the phase of the reference burst by ±45° at a line rate as shown in Figure 1.10-6. The burst is constituted from a fixed value of *U* phase and a switched value of *V* phase. Because the sign of the *V* burst component is the same sign as the *V* picture content, the necessary switching "sense" or identification information is available. At the same time, the fixed-*U* component is used for reference carrier synchronization.

Figure 1.10-7 explains the degree to which horizontal frequency (dot) interlace of the color subcarrier components with the luminance components is achieved in PAL and may be summarized as follows: in NTSC, the *Y* components are spaced at f_H intervals as a result of the horizontal sampling (blanking) process. Thus, the choice of a color subcarrier whose harmonics are also separated from each other by f_H (as they are odd multiples of $\frac{1}{2} f_H$) provides a half-line offset and results in a perfect dot interlace pattern that moves upward. Four complete field scans are required to repeat a specific picture element dot position.

In PAL, the luminance components are also spaced at f_H intervals. Because the *V* components are switched symmetrically at half the line rate, only odd harmonics exist, with the result that the *V* components are spaced at intervals of f_H. They are spaced at half-line intervals from the *U* components which, in turn have f_H spacing intervals due to blanking. If half-line offset were used,

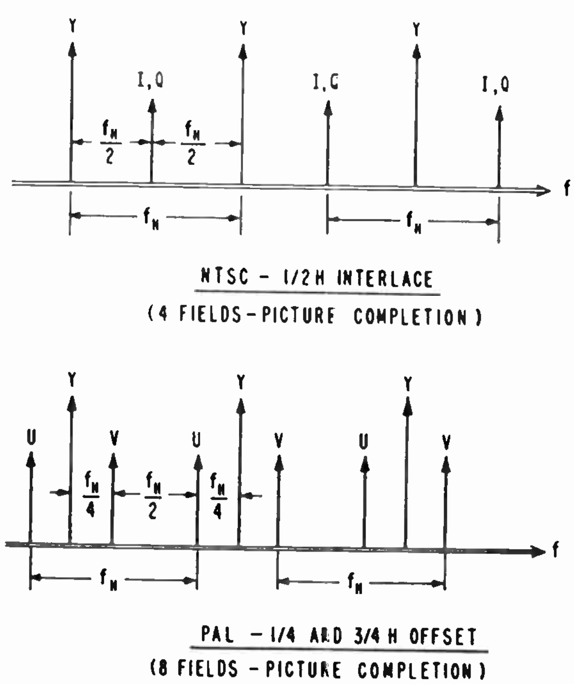

Figure 1.10-7. NTSC and PAL frequency interface relationship.

the U components would be perfectly interlaced but the V components would coincide with Y and, thus, not be interlaced, creating vertical, stationary dot patterns.

For this reason, in PAL, a $\frac{1}{4}$-line offset for the subcarrier frequency is used as shown in Figure 1.10-7. The expression for determining the PAL subcarrier specific frequency for 625-line/50-field systems is given by

$$F_{SC} = \frac{1135}{4} f_H + \frac{1}{2} f_V \qquad (5)$$

The additional factor $\frac{1}{2} f_V = 25$ Hz is introduced to provide motion to the color dot pattern, thereby reducing its visibility. The degree to which interlace is achieved is, therefore, not perfect, but is acceptable, and eight complete field scans must occur before a specific picture element dot position is repeated.

One additional function must be accomplished in relation to PAL color synchronization. In all systems, the burst signal is eliminated during the vertical synchronization pulse period. Because, in the case of PAL, the swinging burst phase is alternating line-by-line, some means must be provided for ensuring that the phase is the same for the first burst following vertical sync on a field-by-field basis. Therefore, the burst reinsertion time is shifted by one line at the vertical field rate by a pulse referred to as the *meander* gate. The timing of this pulse relative to the A versus B burst phase is shown in Figure 1.10-8.

The transmitted signal specifications for PAL systems include the basic features discussed previously. Although a description of a great variety of receiver decoding techniques is outside the scope and intent of this chapter, it is appropriate to review—at least briefly—the following major features: "Simple" PAL relies upon the eye to average the line-by-line color switching process and can be plagued with line beats known as *Hanover bars* caused by the system nonlinearities introducing visible luminance changes at the line rate. "Standard" PAL employs a 1-H delay line element to separate U color signal components from V color signal components in an averaging technique, coupled with summation and subtraction functions. Hanover bars can also occur in this approach if an imbalance of amplitude or phase occurs between the delayed and direct paths.

In a PAL system, vertical resolution in chrominance is reduced as a result of the line averaging processes. The visibility of the reduced vertical color resolution as well as the vertical time coincidence of luminance and chrominance transitions differs depending upon whether the total system, transmitter through receiver, includes one or more averaging (comb filter) processes.

Thus, PAL provides a similar system to NTSC and has gained favor in many areas of the world, particularly for 625-line/50-field systems.

SECAM Color System

The optimized SECAM system, known as SECAM III, is the system adopted by France and the USSR in 1967. The SECAM method has several features in common with NTSC such as the same E'_Y signal and the same $E'_B - E'_Y$ and $E'_R - E'_Y$ color-difference signals. However, this approach differs considerably from NTSC and PAL in the manner in which the color information is modulated onto the subcarrier(s).

First, the $R - Y$ and $B - Y$ color difference signals are transmitted alternately in time sequence from one successive line to the next, the luminance signal being

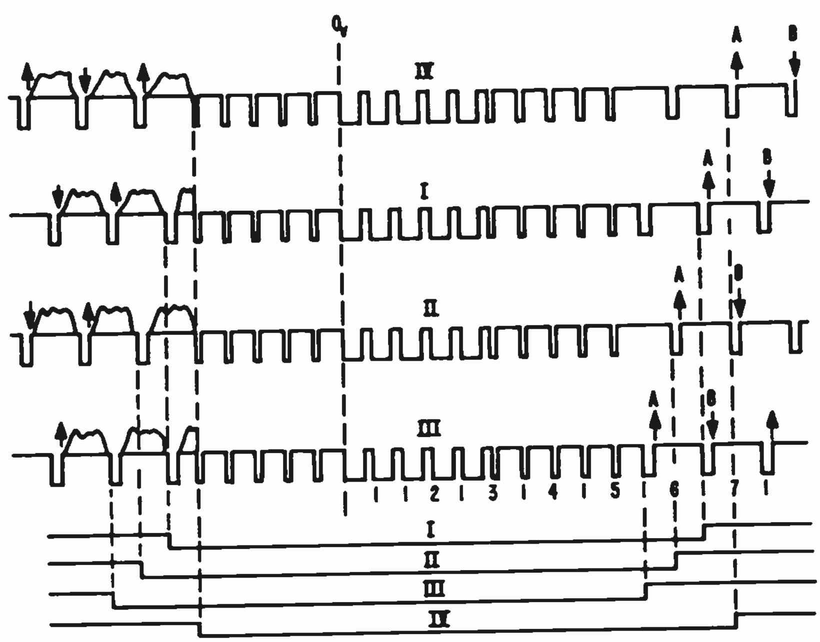

Figure 1.10-8. PAL "meander" burst blanking gate timing diagram for B, G, H, and I Pal.

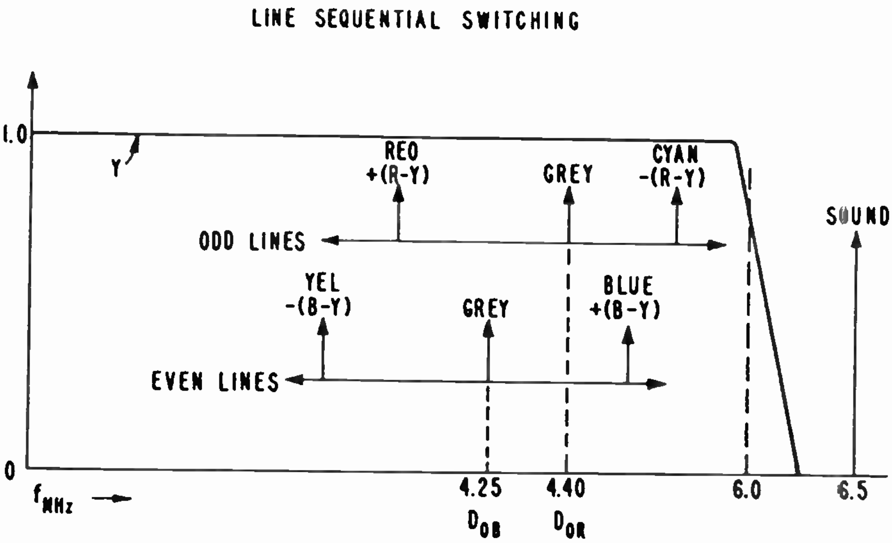

Figure 1.10-9. SECAM FM color modulation system.

common to every line. Because there is an odd number of lines, any given line carries $R - Y$ information on one field and $B - Y$ information on the next field. Second, the $R - Y$ and $B - Y$ color information is conveyed by frequency modulation of different subcarriers. Thus, at the decoder, a 1-H delay element, switched in time synchronization with the line switching process at the encoder, is required in order to have simultaneous existence of the $B - Y$ and $R - Y$ signals in a linear matrix to form the $G - Y$ component.

The $R - Y$ signal is designated as D'_R and the $B - Y$ signal as D'_B. The undeviated frequency for the two subcarriers, respectively, is determined by

$$\begin{aligned} F_{OB} &= 272\, f_H = 4.250000 \text{ MHz} \\ F_{OR} &= 282\, f_H = 4.406250 \text{ MHz} \end{aligned} \qquad (6)$$

These frequencies represent zero color difference information (zero output from the FM discriminator), or a neutral gray object in the televised scene.

As shown in Figure 1.10-9, the accepted convention for direction of frequency change with respect to the polarity of the color difference signal is opposite for the D_{OB} and D_{OR} signals. A positive value of D_{OR} means a decrease in frequency, whereas a positive value of D_{OB} indicates an increase in frequency. This choice relates to the idea of keeping the frequencies representative of the most critical color away from the upper edge of the available bandwidth to minimize the instrumentation distortions.

The deviation for D'_R is 280 kHz and D'_B is 230 kHz. The maximum allowable deviation, including preemphasis, for $D'_R = -506$ kHz and $+350$ kHz, while the values for $D'_B = -350$ kHz and $+506$ kHz.

Two types of preemphasis are employed simultaneously in SECAM. First, as shown in Figure 1.10-10, a conventional type of preemphasis of the low-frequency color difference signals is introduced. The characteristic is specified to have a reference level break-point at 85 kHz (f_1) and a maximum emphasis of 2.56 dB. The expression for the characteristic is given as

$$A = \frac{1 + j(f/f_1)}{1 + J(f/3f_1)} \qquad (7)$$

A second form of preemphasis (Figure 1.10-10) is introduced at the subcarrier level where the amplitude

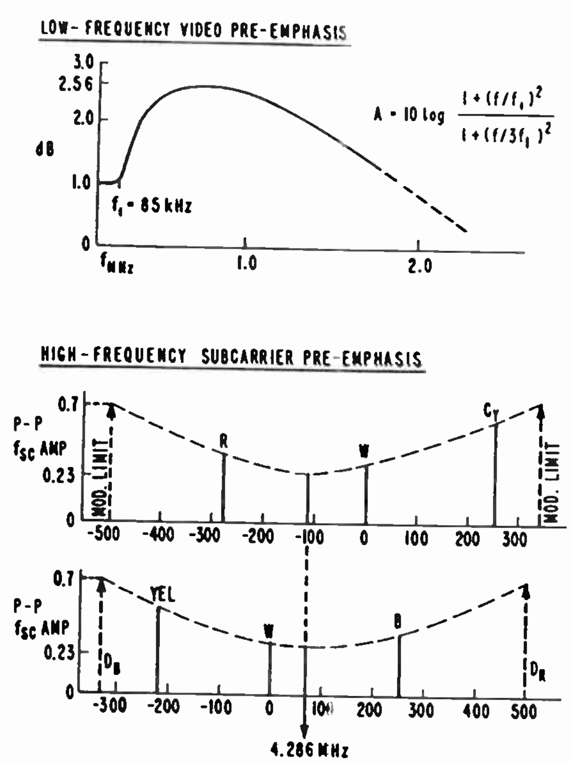

Figure 1.10-10. SECAM color signal pre-emphasis.

FIELD	LINE #	COLOR	SUBCARRIER Ø
ODD (1)	n	f_{OR}	0°
EVEN (2)	n + 313	f_{OB}	180°
ODD (3)	n + 1	f_{OB}	0°

EVEN (12)	n + 318	f_{OR}	180°

Note:
- 2 frames (4 fields) for picture completion.
- Subcarrier interlace is field-to-field and line-to-line of same color.

Figure 1.10-11. Color vs. line and field timing relationship for SECAM.

of the subcarrier is changed as a function of the frequency deviation. The expression for this inverted bell shaped characteristic is given as

$$G = M_O \frac{1 \times j16\left(\frac{f}{f_c} - \frac{f_c}{f}\right)}{1 + j1.26\left(\frac{f}{f_c} - \frac{f_c}{f}\right)} \qquad (8)$$

where: f = 4.286 MHz and 2M = 23 percent of the luminance amplitude (100 IRE).

This type of preemphasis is intended to further reduce the visibility of the frequency modulated subcarriers in low luminance level color values and to improve the signal-to-noise ratio (SNR) in high luminance and highly saturated colors. Thus, monochrome compatibility is better for pastel average picture level objects but sacrificed somewhat in favor of SNR in saturated color areas.

Of course, precise interlace of frequency modulated subcarriers for all values of color modulation cannot occur. Nevertheless, the visibility of the interference represented by the existence of the subcarriers may be reduced somewhat by the use of two separate carriers, as is done in SECAM. Figure 1.10-11 indicates the line-switching sequence in that at the undeviated "resting" frequency situation, the two-to-one vertical interlace in relation to the continuous color difference line-switching sequence produces adjacent line pairs of f_{OB} and f_{OR} signals. In order to further reduce the subcarrier dot visibility, the phase of the subcarriers (phase carries no picture information in this case) is reversed 180 degrees on every third line and between each field. This, coupled with the bell preemphasis, produces a degree of monochrome compatibility considered subjectively adequate.

As in PAL, the SECAM system must provide some means for identifying the line-switching sequence between the encoding and decoding processes. This is accomplished by introducing alternate D_R and D_B color identifying signals for nine lines during the vertical blanking interval following the equalizing pulses after vertical sync (see Figure 1.10-12). These bottle shaped signals occupy a full line each and represent the frequency deviation in each time sequence of D_B and D_R at zero luminance value. These signals can be thought of as fictitious green color that is used at the decoder to determine the line-switching sequence.

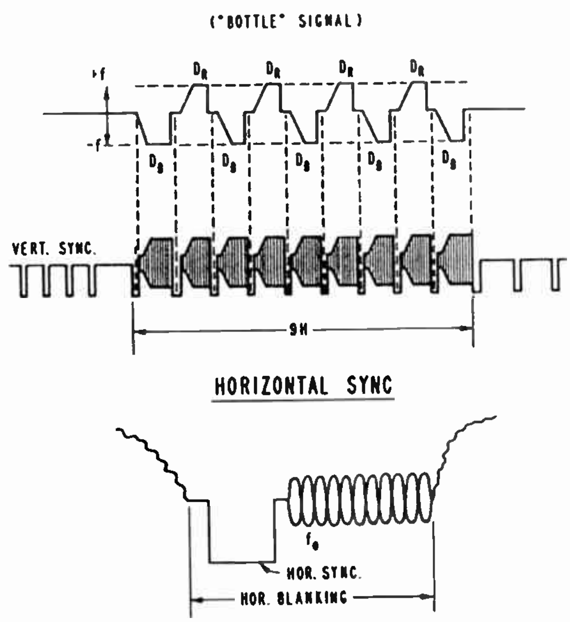

Figure 1.10-12. SECAM line identification signal.

During horizontal blanking, the subcarriers are blanked and a burst of f_{OB}/f_{OR} is inserted and used as a gray level reference for the FM discriminators, to establish their proper operation at the beginning of each line.

Thus, the SECAM system is a line sequential color approach using frequency modulated subcarriers. A special identification signal is provided to identify the line-switch sequence and is especially adapted to the 625-line/50-field wideband systems available in France and the USSR.

It should be noted that SECAM, as practiced, employs amplitude modulation of the sound carrier as opposed to the FM sound modulation in other systems.

Additional Systems of Historical Interest

Of the numerous system variations proposed over the intervening years since the development of the NTSC system, at least two others, in addition to PAL and SECAM, should be mentioned briefly. The first of these was additional reference transmission (ART), which involved the transmission of a continuous reference pilot carrier in conjunction with a conventional NTSC color subcarrier quadrature modulation signal. A modification of this scheme involved a *multiburst* approach that utilized three color bursts, one at black level, one at intermediate gray level, and one at white level, to be used for correcting differential phase distortion.

Another system, perhaps better known, was referred to as NIR or SECAM IV. Developed in the USSR Nauchni Issledovatelskaia Rabota or scientific discriminating work (NIR), this system consists of alternating lines of (1) an NTSC-like signal using an amplitude and phase modulated subcarrier and (2) a reference signal having U phase to demodulate the NTSC-like signal. In the linear version, the reference is unmodulated, and in the nonlinear version, the amplitude of the reference signal is modulated with chrominance information.

SUMMARY AND COMPARISONS OF SYSTEMS STANDARDS

History has shown that it is exceedingly difficult to obtain total international agreement on "universal" television broadcasting standards. Even with the first scheduled broadcasting of monochrome television in 1936 in England, the actual telecasting started using two different systems on alternate days from the same transmitter. The Baird system was 250 lines (noninterlaced) with a 50 Hz frame rate while the Electric and Musical Industries (EMI) system was 405 lines (interlaced) with a 25 Hz frame rate.

These efforts were followed in 1939 in the United States by broadcasting a 441 line interlaced system at 60 fields per second (the Radio Manufacturers Association (RMA) system). In 1941, the NTSC initiated the present basic monochrome standards in the U.S. of 525 lines (interlaced) at 60 fields per second, designated as system M by the CCIR. In those early days, the differences in power line frequency were considered as important factors and were largely responsible for the proliferation of different line rates versus field rates as well as the wide variety of video bandwidths. However, the existence and extensive use of monochrome standards over a period of years soon made it a top-priority matter to assume reciprocal compatibility of any developing color system.

The CCIR documents define recommended standards for worldwide color television systems in terms of the three basic color approaches—NTSC, EPAL, and SECAM.[4] The variations—at least 13 of them—are given alphabetical letter designations; some represent major differences while others signify only very minor frequency allocation differences in channel spacings or the differences between the VHF and UHF bands. The key to understanding the CCIR designations lies in recognizing that the letters refer primarily to *local monochrome standards* for line and field rates, video channel bandwidth, and audio carrier relative frequency. Further classification in terms of the particular color system then adds to NTSC, PAL, or SECAM as appropriate. For example, the letter "M" designates a 525-line/60-field, 4.2 MHz bandwidth, 4.5 MHz sound carrier monochrome system. Thus, M(NTSC) describes a color system employing the NTSC technique for introducing the chrominance information within the constraints of the basic monochrome signal values. Likewise, M(PAL) would indicate the same line/field rates and bandwidths but employing the PAL color subcarrier modulation approach.

In another example, the letters "I" and "G" relate to specific 625-line/50-field, 5.0 or 5.5 MHz bandwidth, 5.5 or 6.0 MHz sound carrier monochrome standards. Thus, G(PAL) would describe a 625-line/50-field, 5.5 MHz bandwidth, color system utilizing the PAL color subcarrier modulation approach. The letter "L" refers to a 625-line/50-field, 6.0 MHz bandwidth system to which the SECAM color modulation method has been added (often referred to as SECAM III). System E is an 819-line/50-field, 10 MHz bandwidth, monochrome system. This channel was used in France for early SECAM tests and for system E transmissions.

Some general comparison statements can be made about the underlying monochrome systems and existing color standards:

- There are three different scanning standards: 525-lines/60-fields, 625-lines/50-fields, and 819-lines/50-fields.
- There are six different spacings of video-to-sound carriers, namely 3.5, 4.5, 5.5, 6.0, 6.5, and 11.15 MHz.
- Some systems use FM and others use AM for the sound modulation.
- Some systems use positive polarity (luminance proportional to voltage) modulation of the video carrier while others, such as the U.S. (M)NTSC system, use negative modulation.
- There are differences in the techniques of color sub-

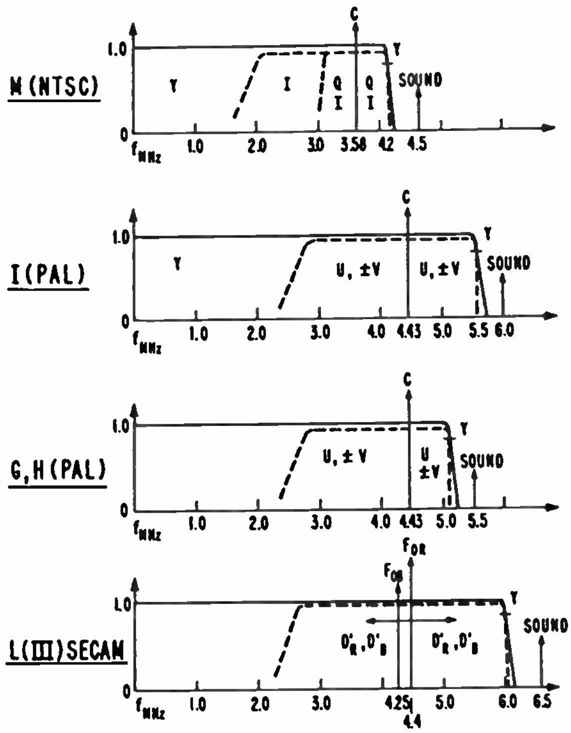

Figure 1.10-13. Bandwidth comparison between NTSC, PAL, and SECAM.

carrier encoding represented by NTSC, PAL, and SECAM, and of course, in each case there are many differences in the details of various pulse widths, timing and tolerance standards.

It is evident that one must refer to the ITU documents for accurate information on the combined monochrome/color standards. Figure 1.10-13 presents a comparison of the relative bandwidths, color subcarrier frequencies, and sound carrier spacing for the major color systems used in the world today.

The signal in the M(NTSC) system occupies the least total channel width, which when the vestigial sideband plus guard bands are included, requires a minimum radio frequency channel spacing of 6 MHz. The L(III) SECAM system signal occupies the greatest channel space with a full 6 MHz luminance bandwidth. Signals from the two versions of PAL lie in between and vary in vestigial sideband width as well as color and luminance bandwidths. NTSC is the only system to incorporate the *I*, *Q* color acuity bandwidth variation. PAL minimizes the color quadrature phase distortion effects by line-to-line averaging, and SECAM avoids this problem by only transmitting the color components sequentially at a line-by-line rate.

Figures 1.10-14–16 summarize, in organization chart form, the CCIR designations for NTSC, PAL, and SECAM basic system identifications and characteristics. In Figure 1.10-14, M(NTSC) identifies the system used in the United States, Canada, Japan, Mexico, the Philippines and several other Central American and Caribbean area countries. The N system may be implemented in color either in the NTSC or the PAL format.[3] Figure 1.10-15 provides a Pritchard summary of the PAL systems. PAL systems in one or another of the 625-line formats are predominately used in Continental Europe, the United Kingdom, some African countries and China. An "M" (525-line) version of PAL has been in use in Brazil.

Figure 1.10-16 summarizes the SECAM III system, which is in use primarily in France and the USSR. The SECAM IV system, as a proposal almost gained favor in 1966 as a universal European approach but was never implemented.[1] The E system, mentioned in connection with early SECAM tests in France, is limited to monochrome broadcasts.

Table 1.10-3 provides a summary of the major color television system general characteristics. Table 1.10-4 characterizes the fundamental features relating to the differences between NTSC, PAL, and SECAM in the critical areas of color encoding techniques. Similarly,

1.11
DIGITAL TELEVISION TERRESTRIAL TRANSMISSION STANDARDS

COMPILED FROM ATSC DOCUMENTS
INTRODUCTION BY ARTHUR ALLISON
NAB, WASHINGTON, DC
EDITED BY DAVID H. LAYER
NAB, WASHINGTON, DC

INTRODUCTION

The Federal Communications Commission (FCC), with its December 27, 1996 release of the *Fourth Report & Order* in MM docket 87-268, officially established a new standard for television broadcast service in the United States. This new standard is a digital system, based on that established by the broadcast industry through the Advanced Television Systems Committee (ATSC), and promises to fundamentally change not only the technology but the business of TV broadcasting.[1]

This new digital television (DTV) system is described in a series of standards documents adopted by the ATSC. The purpose of this chapter is to provide some background information on the various aspects of DTV technology and to introduce the reader to those standards that define this technology.

Development of the DTV system has its roots in what was originally the desire to increase the resolution of television by developing high definition television (HDTV) systems, which began to gain momentum in the late 1980"s. By 1987, this desire, along with spectrum pressures, led to broadcasters petitioning the FCC to consider the public policy and technical issues related to a significant resolution upgrade of the NTSC system. The FCC began a proceeding by establishing MM Docket 87-268 in July 1987. Later that year the Advisory Committee on Advanced Television Service (ACATS) was formed by the FCC to consider the issues and advise them on how to proceed with a new TV service. The formal objective for the ACATS was:

> *The Committee will advise the Federal Communications Commission on the facts and circumstances regarding advanced television systems for Commission consideration of technical and public policy issues. In the event that the Commission decides that adoption of some form of advanced broadcast television is in the public interest, the Committee would also recommend policies, standards and regulations that would facilitate the orderly and timely introduction of advanced television services in the United States.*

The ACATS established a Planning Subcommittee, a Systems Subcommittee and an Implementation Subcommittee to meet this objective. Each subcommittee then established subgroups to focus investigations into specific areas.

Back in 1987, digital television systems were only gleams in the eyes of those who would invent them. Over the next two years, proposals for delivery of high definition television were offered to the ACATS. A total of 21 systems were proposed with technologies including simulcast, NTSC augmentation, satellite delivery and current NTSC receiver compatibility-but no digital proposals. The candidates were evaluated, with the best proposals withstanding scrutiny and the others falling by the wayside. Then, just before the final cutoff date for submitting proposals in June 1990, General Instrument Corporation submitted an all-digital system.

The digital revolution would change the world forever. In short order, three more all-digital proposals were submitted. The formal testing process began in 1992 with two analog and four digital systems. Although one analog system remained in the competition through the completion of the test process, the digital systems proved far superior. The four digital contenders were found to have different areas of best performance. These four finalist proponents were about to be authorized to implement improvements when another historic milestone was created. The Chairman of ACATS, Richard Wiley, was able to cause the formation of a consortium of the proponents, which became the Grand Alliance on May 24, 1993. The Grand Alliance was to create a single system that would deliver the "best of the best."

In June 1992, the ACATS offered to document the standard for the new television system. This organization had been established in 1983 by the Joint Committee on Inter-Society Coordination (JCIC) to coordinate

---

[1] The Advanced Television Systems Committee (ATSC) is an international cross industry group consisting of over 120 members (companies and organizations) with significant business interest in standardization of various aspects of advanced television systems.

and develop voluntary national standards for advanced television systems.[2]

Testing of the system resulting from the merged designs was completed by 1994. This Grand Alliance system did deliver the "best of the best" of the competing systems. Meanwhile, multiple technical committees were busy writing a standard that described how to provide each element in the HDTV delivery chain. This work was combined into a set of standards, generally referred to as the ATSC Digital Standard, which were voted upon by the ATSC membership in March 1995 and overwhelmingly passed.

During this finalization period, standardization work continued and expanded the scope of the standard to address digital television more generally by adding the capability to encode and transmit standard definition television (SDTV) scanning formats that were compatible with the already standardized HDTV formats. The enhanced standard included formats that exactly matched computer scanning formats as well as those that were directly backward compatible with digitized NTSC video. The updated standard was again overwhelmingly approved by the membership of the ATSC, in September 1995. In November 1995, the ACATS met for the last time and recommended that the FCC adopt the digital TV standard that had been developed and documented by the ATSC, and had been proven practical by the HDTV prototype built by the Grand Alliance.

Meanwhile, the FCC had been requesting input and proposing direction through the rule making process. Each of the last three of six major *Notices of Proposed Rule Making* (NPRM) addresses one of three major areas for rules. One addresses the policy issues, another the technical standard and the last the channel assignments. The key enabling decision was made in December 1996, with the FCC mandating the use of all but one section of the ATSC DTV Standard for the new broadcast service. This was followed in April 1997 with orders on service rules and DTV channel assignments.

The one exception to the FCC mandate of the ATSC Standard is the definition of a subset of the possible scanning formats. By not mandating the entire standard, the particular choices of picture formats made in the ATSC and FCC ACATS processes were made optional. Thus, it will be legal for a broadcaster to send information in any picture format that he chooses to implement within the overall constraints of the transmission technology. However, the broadcast, consumer electronics and other affected industries have agreed on a set of scanning formats; that agreement is embodied in the ATSC DTV Standard which remains a voluntary industry standard.

[2] The members of the JCIC are the National Association of Broadcasters (NAB), the National Cable Television Association (NCTA), The Electronics Industries Association (EIA), the Society of Motion Picture and Television Engineers (SMPTE) and the Institute of Electrical and Electronic Engineers (IEEE).

Receiver manufacturers understand that it is beneficial to all for receivers to have the capability to decode and display all of the picture formats in the ATSC DTV Standard, and are expected to build sets that will do just that. Many standards that the broadcast industry uses are voluntary, that is, no regulatory authority mandates their use. The set of picture formats in the ATSC DTV Standard provide no less a foundation for successful market development than, for example, the industry standards that enable a D1 tape to be recorded and interchanged from machine to machine, or component video signals to be connected among different vendors' equipment. Voluntary standards form the basis of the interoperation of television equipment today and the picture formats standardized by the industry for DTV broadcasting will now join them for the future.

Organization of DTV Standards

The ATSC DTV Standards are organized to define how to get the information from the broadcaster to the receiver, and to select from (or constrain) the options provided by other applicable standards. ATSC's document numbering system uses "A/nn" for the full committee endorsed documents. The ATSC DTV standards are listed in Table 1.11-1.

Although no one document explicitly defines the relationships of the ATSC Standards, the controlling standard is, in effect, Document A/53. This document, along with Document A/52, has the force of regulation since they were both adopted into the FCC rules (in all but one small part). A/53 defines specific requirements, or references other standards with specific constraints, when the entire referenced standard is not included. The referenced standards typically define extensions or alternatives to the MPEG-2 standard to deliver specific functions.

Since A/53 has not been updated since it was adopted, some of the references therein are to document number(s) of work which later became adopted standards, and some relevant documents are not mentioned at all, if they came into existence after A/53 was

A/65	Program and System Information Protocol for Terrestrial Broadcast and Cable

approved. There is an *Informative Guide*, Document A/54, which served as the source for much of this chapter. There are two optional Standards (A/55 and A/56) which have been superceded by Document A/65. Document A/65 is the mandatory standard for the Program and System Information Protocol (PSIP) that defines how to locate television programs and other services. Document A/57 defines a mandatory numbering process for programs. Document A/58 is a *Recommended Practice* (as opposed to a standard), written so as to reduce the possibility that devices and systems designed to the ATSC standard will conflict with those that meet the European set of DTV standards known as DVB. Document A/63 defines 25/50 Hz video formats, for use by those countries that prefer to use that hierarchy of formats. Document A/64 is the *Transmission Measurement and Compliance Document.*

The ATSC standards define how the signal is structured for transmission, while the ISO-1818 (MPEG-2) standards define what the receiver expects as well as the decoding model. While the structure has to be the same from both views of the system, not being aware of the point of view can introduce confusion to one reading both in order to understand the entire system. These standards state the degree of compliance that is expected from implementations, and are typically divided into two sections—*normative* and *informative.*

Those system aspects or specifics contained in the normative section of the standard contain precise technical definitions or requirements. The informative section, on the other hand, is intended to facilitate understanding and/or show one possible way to implement the standard. It is important to note that no requirements can be deduced from the informative section; they only exist in the normative section.

Within the normative section, there are both required and optional specifications. System features that are *required* must be done (system designers *must* implement these system aspects and/or specifics to be considered in compliance with the standard). Things that are *optional* must be done per the standard, if done at all.

There are two basic types of information which exist in an ATSC DTV-standard system—payloads and labels. *Payloads* are audio (A/52), data (no standard as of yet), and video (A/53, Annex A). *Labels* control and describe how to find the payloads. The main label standard is A/53, Annex C, which defines how the payloads are to be combined in the multiplex. The Standards A/53 Annex B, A/57 and A/65 provide the information describing how to find and associate the data streams into programs or services. The RF transmission standards are found in Annex D of A/53. Figure 1.11-1 shows the inter-relationships of these standards from an origination to transmission perspective.

Another perspective which may help in understanding the material contained in this chapter is that the ATSC DTV system, and therefore to a degree the standards which describe it, are organized like a freight train switchyard with a lot of very small cars. Various payloads are defined, divided into standard size containers and assembled into the train with rules about spacing between the containers and their contents.

There are other standards that describe aspects of digital television transmission. One of the more im-

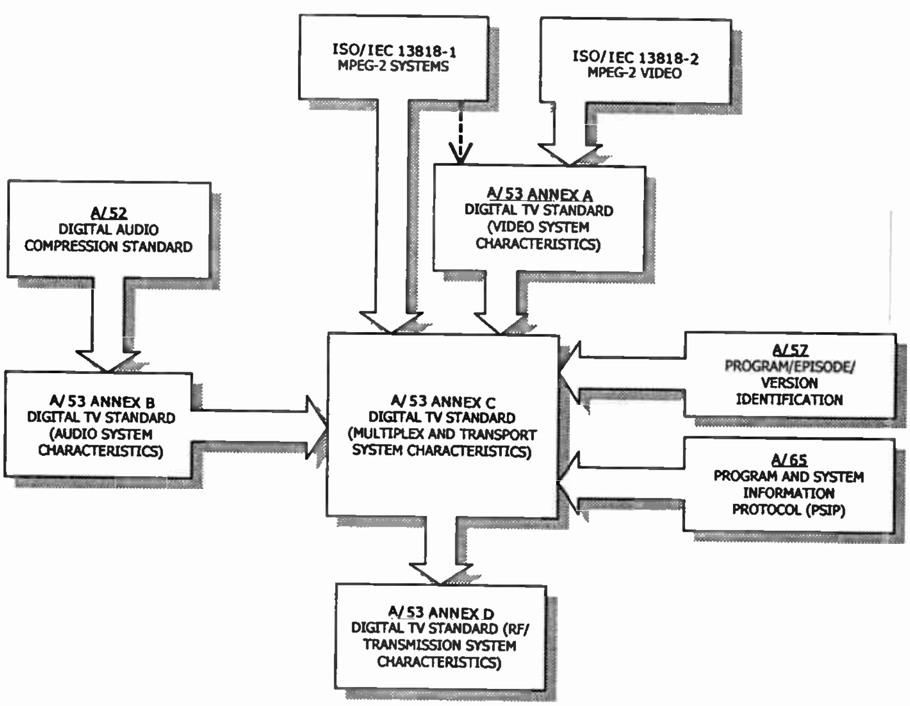

Figure 1.11-1. ATSC DTV Standards—Inter-relationships.

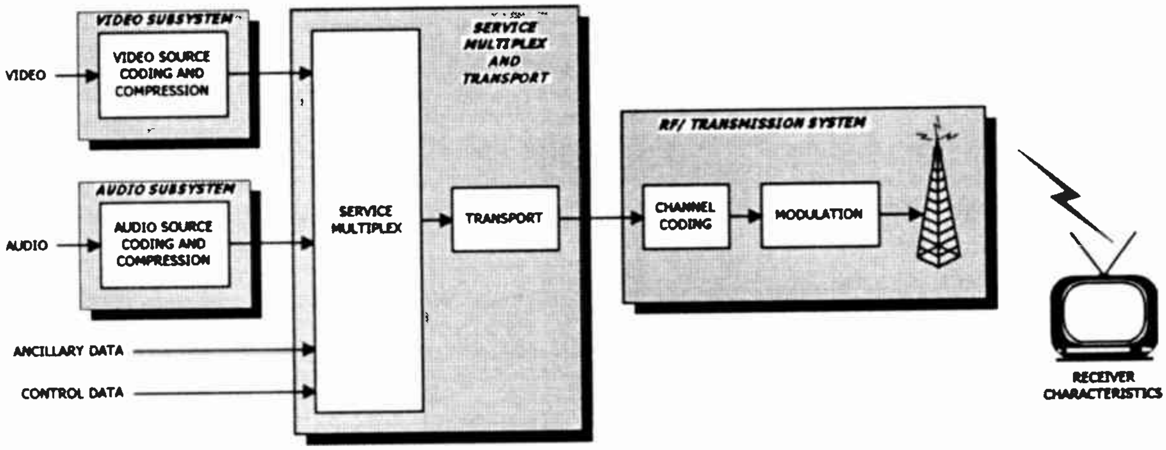

Figure 1.11-2. ITU-R Digital terrestrial television broadcasting model.

portant of these is EIA-708—*Advanced Television Closed Captioning*. EIA-708 describes the contents of the closed captioning container defined by the ATSC standards. This document also references ATSC draft working documents whose contents were incorporated into A/65.

The Society of Cable Telecommunications Engineers (SCTE) adopted standards intended for the cable industry for use in the re-transmission of broadcast DTV signals. These cable standards are different in some aspects with respect to the corresponding broadcast standards. Efforts to reconcile conflicts between differing standards for the same functions are ongoing, and this dynamic situation is not covered in this chapter as a result.

DTV TECHNOLOGY

The following material was excerpted from the various standards and recommended practices documents prepared and adopted by the ATSC, along with the Advanced Television Test Center (ATTC) test reports and FCC determinations as relevant. This material is provided both as an introduction to the technology which forms the basis for DTV as well as for an introduction to the standards themselves. Space limitations prevent complete inclusion of every aspect of these standards. Interested readers are encouraged to consult the actual standards documents for the most complete information, available in original form from the ATSC both in hard-copy and electronic forms.

System Overview

The ATSC DTV Standard describes a system designed to transmit high quality video, audio and ancillary data over a single 6 MHz channel. The system can deliver reliably about 19.4 Mbps of throughput in a 6 MHz terrestrial broadcasting channel. This means that encoding a video source whose resolution can be as high as 5 times that of conventional television (NTSC) resolution requires a bit rate reduction by a factor of 50 or higher. To achieve this bit rate reduction, the system is designed to be efficient in utilizing available channel capacity by exploiting complex video and audio compression technology.

The objective is to maximize the information passed through the data channel by minimizing the amount of data required to represent the video image sequence and its associated audio. This requires representing the video, audio and data sources with as few bits as possible while preserving the level of quality required for the given application.

A basic block diagram representation of the system is shown in Figure 1.11-2, based on a diagram adopted by the International Telecommunication Union, Radiocommunication Sector (ITU-R), Task Group 11/3 (Digital Terrestrial Television Broadcasting). According to this model, the digital television system can be seen to consist of three subsystems.[3]

1. Source coding and compression;
2. Service multiplex and transport; and
3. RF/Transmission.

Source coding and compression refers to the bit rate reduction methods, also known as data compression, appropriate for application to the video, audio and ancillary digital data streams. The term *ancillary data* includes control data, conditional access control data, and data associated with the program audio and video services, such as closed captioning. Ancillary data can also refer to independent program services. The purpose of the coder is to minimize the number of bits needed to represent the audio and video information. The digital television system employs the MPEG-2 video stream syntax for the coding of video and the Digital Audio Compression (AC-3) Standard for the coding of audio.

Service multiplex and transport refers to the means

[3] ITU-R Document TG11/3-2, *Outline of Work for Task Group 11/3, Digital Terrestrial Television Broadcasting*, June 30, 1992.

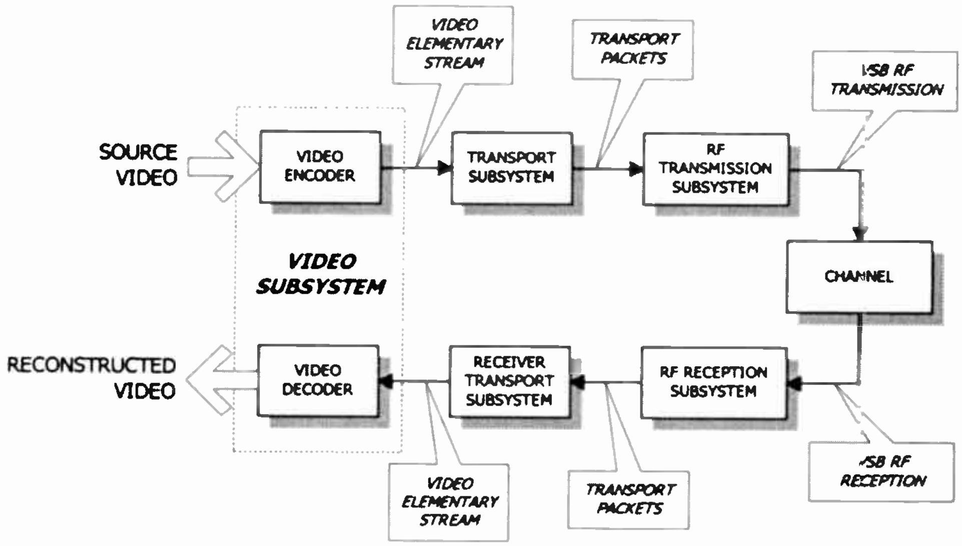

Figure 1.11-3. Video coding in relation to the ATSC DTV system *(Source: ATSC Doc A/54).*

of dividing the digital data stream into packets of information, the means of uniquely identifying each packet or packet type, and the appropriate methods of multiplexing video data stream packets, audio data stream packets, and ancillary data stream packets into a single data stream. The digital television system employs the MPEG-2 transport stream syntax for the packetization and multiplexing of video, audio, and data signals for digital broadcasting systems.[4]

RF/Transmission refers to channel coding and modulation. The channel coder takes the data bit stream and adds additional information that can be used by the receiver to reconstruct the data from the received signal which, due to transmission impairments, may not accurately represent the transmitted signal. The modulation (or physical layer) uses the digital data stream information to modulate the transmitted signal. The modulation subsystem offers two modes: a terrestrial broadcast mode (8 VSB) and a high data rate mode (16 VSB).

VIDEO COMPRESSION

The need for compression of the video information in a digital HDTV system is apparent from the fact that an HDTV studio signal can have 1080 active lines, 1920 samples per line, 10 bits per sample, and 30 frames per second producing a new bit rate of $3 \times 1080 \times 1920 \times 10 \times 30$ or 3 Gbps, but the data capacity of a standard 6 MHz TV channel is approximately 19 Mbps. Consequently, a compression ratio is required. This full data rate is normally converted to 4:2:0 at 8 bits per pixel before compression.

The DTV Standard specifies video compression using a combination of compression techniques, and for reasons of compatibility these compression algorithms have been selected to conform to the specifications of MPEG-2, which is a flexible, internationally accepted collection of compression algorithms. The MPEG-2 specification is organized into a system of profiles and levels, so that applications can ensure interoperability by using equipment and processing that adhere to a common set of coding tools and parameters.[5] The DTV Standard is based on the MPEG-2 Main Profile, which includes three types of video frames (intracoded or I-frames, predicted or P-frames, and bi-directional or B-frames) and an organization of luminance and chrominance samples (designated 4:2:0) within the frame.

The video compression system takes in an analog video source signal and outputs a compressed digital signal that contains information that can be decoded to produce an approximate version of the original image sequence. The goal is for the reconstructed approximation to be imperceptibly different from the original for most viewers, for most images, for most of the time. In order to approach such fidelity, the algorithms are flexible, allowing for frequent adaptive changes in the algorithm depending on scene content, history of the processing, estimates of image complexity and perceptibility of distortions introduced by the compression.

Figure 1.11-3 shows the overall flow of video signals in the ATSC DTV system. A video program source is encoded by a digital television video encoder. The output of the video encoder is a string of bits that represent the video source, and is referred to as a *video elementary stream.* The transport subsystem packetizes the video data into *packetized elementary stream* (PES) packets that are then further packetized into transport packets. The transmission subsystem converts the

[4] Chairman, ITU-R Task Group 11/3, *Report of the Second Meeting of ITU-R Task Group 11/3, Geneva, October 13–19, 1993,* January 5, 1994, p. 40.

[5] For more information about profiles and levels see ISO/IEC 13818-2, Section 8.

Table 1.11-2
Compression Formats (Table 3 of ATSC A/53)

Vertical lines	Pixels	Aspect ratio	Picture rate
1080	1920	16:9	60I, 30P, 24P
720	1280	16:9	60P, 30P, 24P
480	704	16:9	60P, 60I, 30P, 24P
480	704	4:3	60P, 60I, 30P, 24P
480	640	4:3	60P, 60I, 30P, 24P

transport packets into a modulated RF signal for transmission to the receiver. At the receiver, the received signal is demodulated by the receiver transmission subsystem. The receiver transport subsystem converts the received video packets back into a video elementary stream that is decoded by the digital television video decoder. The partitioning shown is conceptual, and practical implementations may differ.

Table 1.11-2 lists the compression formats allowed in the DTV Standard. This table contains the same information as Table 3 in A/53, which has the precise syntax and parameters.

In Table 1.11-2, *vertical lines* refers to the number of active lines in the picture. *Pixels* refers to the number of pixels contained in the active line. *Aspect ratio* refers to the picture aspect ratio *Picture rate* refers to the number of frames or fields per second. In the values for picture rate, "P" refers to progressive scanning; "I" refers to interlaced scanning. Note that each picture rate shown has a dual rate which is 1000/1001 times the rate given in the table (only the base rates are shown in the table for simplicity). It is expected that all frame rates will be at the dual rate as long as NTSC is broadcast due to the complexities of maintaining two timing references in a studio. Document A/63 defines additional video formats for countries which have historically used 50 Hz systems.

Samples are typically obtained using analog-to-digital converter circuits with 8-bit precision. After preprocessing, the various luminance and chrominance samples will typically be represented using 8 bits per sample of each component.

The input video source to the ATSC DTV video compression system is typically in the form of RGB components matrixed into luminance (Y) and chrominance (Cb and Cr) components using a linear transformation (3-by-3 matrix, specified in the standard). The luminance component represents the intensity, or black-and-white picture, while the chrominance components contain color information. The original RGB components are highly correlated with each other. The resulting Y, Cb, and Cr signals have less correlation and are thus easier to code efficiently. The luminance and chrominance components correspond to functioning of the biological vision system; that is, the human visual system responds differently to the luminance and chrominance components.

The coding process may take advantage also of the differences in the ways that humans perceive luminance and chrominance. In the Y, Cb, Cr color space, most of the high frequencies are concentrated in the Y component; the human visual system is less sensitive to high frequencies in the chrominance components than to high frequencies in the luminance component. To exploit these characteristics the chrominance components are low-passed filtered in the ATSC DTV video compression system and sub-sampled by a factor of two along both the horizontal and vertical dimensions, producing chrominance components that are one-fourth the spatial resolution of the luminance component.

Figure 1.11-4 illustrates the spatial relationship between chrominance and luminance samples. For every four luminance samples, there are one each of the Cb and Cr chroma samples. The Cb and Cr chroma samples are located in the same place.

Note that the vertical spatial location of chrominance samples does not correspond to an original sample point, but lies halfway between samples on two successive lines. The 4:2:0 sampling structure thus requires the Cb and Cr samples to be interpolated. For progressively scanned source pictures the processor may simply average the two adjacent (upper and lower) values to compute the sub-sampled values. In the case of interlaced pictures, it can be seen from Figure 1.11-4 that the vertical positions of the chrominance samples in a field are not halfway between the luminance samples of the same field. This is done so that the spatial locations of the chrominance samples in the frame are the same for both interlaced and progressive sources.

The pixels are organized into blocks for the purpose

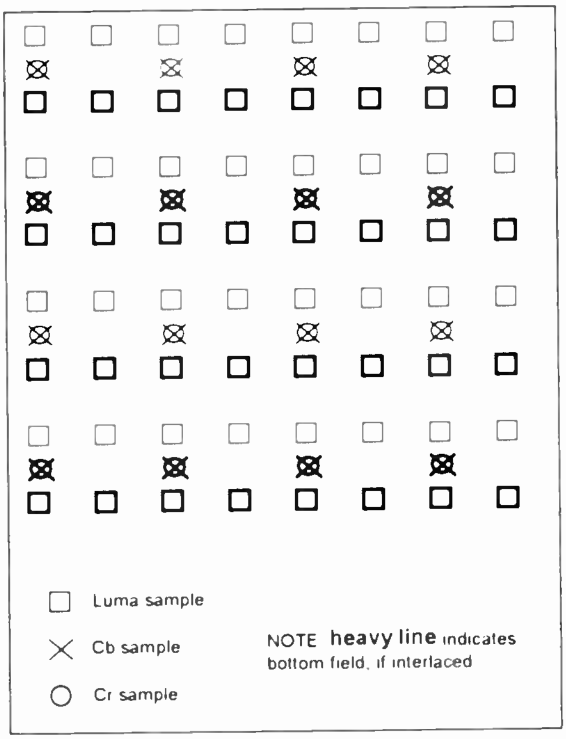

Figure 1.11-4. Placement of luma/chroma samples for 4:2:0 *(Source: ATSC Doc A/54).*

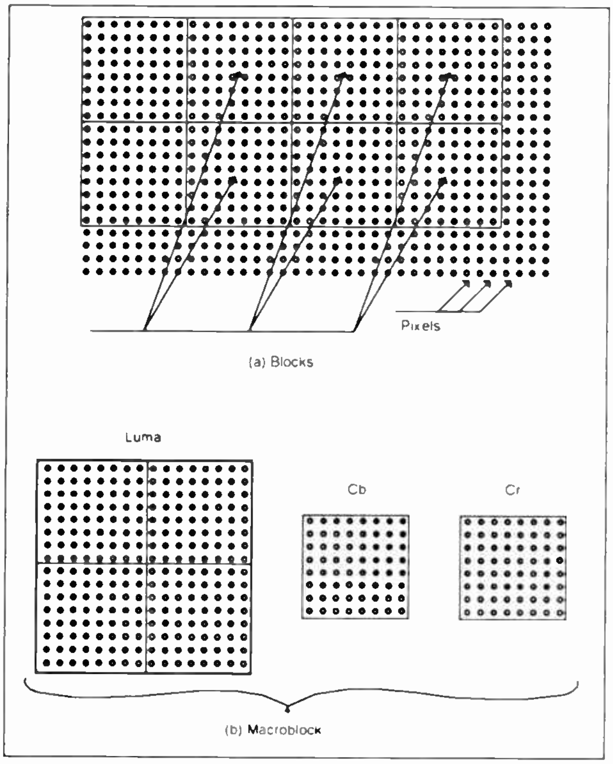

Figure 1.11-5. Blocks and macroblocks *(Source: ATSC Doc A/54).*

of further processing. A block consists of an array of pixel values or an array that is some transform of pixel values. A block for the ATSC DTV system is defined as an array of 8-by-8 values representing either luminance or chrominance information (see Figure 1.11-5a).

Blocks of information are organized into *macroblocks.* A macroblock consists of four blocks of luminance (or a 16 pixel by 16 line region of values) and two chroma (Cb and Cr) blocks. The term macroblock may be used to refer directly to picture element (pel) data or to the transformed and coded representation of pel data. As shown in Figure 1.11-5b, this yields 256 luminance samples and 64 Cb samples and 64 Cr samples (total of 384) per macroblock.

For the 1080 line format (with 1920 samples per line), there are 68 rows of macroblocks (including the row that adds eight dummy lines to create the 1088 lines for coding), with 120 macroblocks per row. For the 720 line format (with 1280 samples per line), there are therefore 45 rows of macroblocks, with 80 macroblocks per row. For the 480 line format with 704 samples per line, there are 30 rows of macroblocks, with 44 macroblocks per row. For the 480 line format with 640 samples per line, there are 30 rows of macroblocks, with 40 macroblocks per row. Horizontal alignment with systems using 720 horizontal samples was in dispute when this chapter was written.

The video coding system requires that the coded picture area has a number of lines that is a multiple of 32 for an interlaced format, and a multiple of 16 for a non-interlaced format. This means that for encoding the 1080 line format, a coder must actually deal with 1088 lines ($1088 = 32 \times 34$). The extra eight lines are in effect dummy lines having no content, and the coder designers will choose dummy data that simplifies the implementation. The extra eight lines are always the last eight lines of the encoded image. Note that the normative standard does not specify top or bottom justified pictures, but the informative states top alignment should be used.

One or more contiguous macroblocks within the same row are grouped together to form *slices.* The order of the macroblocks within a slice is the same as the conventional television *raster* scan, being from left to right. Slices provide a convenient mechanism for limiting the propagation of errors. Since the coded bit stream consists mostly of variable-length codewords, any uncorrected transmission errors will cause a decoder to lose its sense of codeword alignment. Each slice begins with a *slice start* code. Since the MPEG codeword assignment guarantees that no legal combination of codewords can emulate a start code, the slice start code can be used to regain the sense of codeword alignment after an error. When an error occurs in the data stream, the decoder can thus skip to the start of the next slice and resume correct decoding.

The number of slices affects the compression efficiency, partitioning the data stream to have more slices provides for better error recovery but uses bits that could otherwise be used to improve picture quality. The slice is the minimum unit for resynchronization after an error. In the ATSC DTV system, the initial macroblock of every horizontal row of macroblocks is also the beginning of a slice, with possibly several slices across the row.

The primary coding unit of a video sequence is the individual video frame or picture. A video picture consists of the collection of slices that constitute the active picture area. Figure 1.11-6 illustrates a time sequence of video frames consisting of intracoded pictures (I-frames), predictive coded pictures (P-frames) and bi-directionally predictive coded, pictures (B-frames).

Some elements of the compression process exploit only the spatial redundancy within a single picture (frame or field). These processes are called *intraframe coding,* and do not take advantage of the temporal correlation addressed by temporal prediction, which is referred to as *interframe coding.* Frames that do not use any interframe coding are referred to as I-frames (where "I" denotes *intraframe* coded). The ATSC DTV video compression system utilizes both intraframe coding and interframe coding.

The use of periodic I-frames facilitates receiver initializations and channel acquisition (when the receiver is turned on or the receiver channel is changed). The decoder can take advantage of the intraframe coding mode when non-correctable channel errors occur. With motion compensated prediction, an initial frame must be available at the decoder to start the prediction loop. Therefore, a mechanism must be built into the system

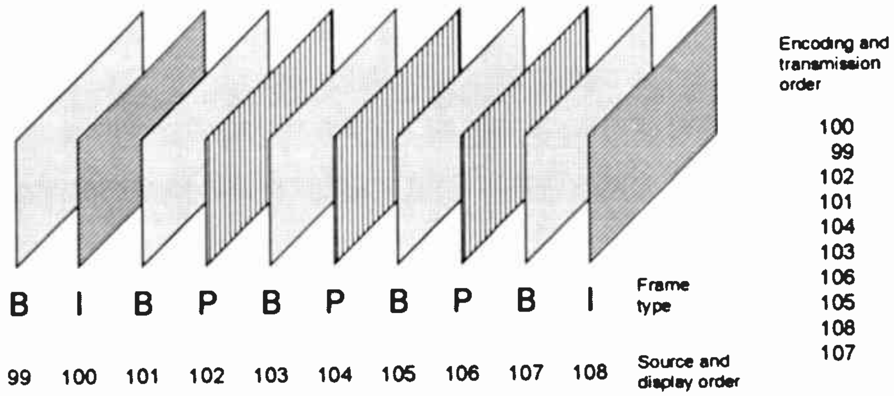

Figure 1.11-6. Illustration of I-frames, P-frames, and B-frames *(Source: ATSC Doc A/54).*

so that if the decoder loses synchronization for any reason, it can rapidly reacquire tracking. The frequency of occurrence of I-pictures may vary and is selected at the encoder. This allows consideration to be given to the need for random access and the location of scene cuts in the video sequence.

P-frames (where "P" denotes *predicted)* are frames where the temporal prediction is in the forward direction only (predictions for the P-frame are formed only from pixels in the most recently decoded I or P-frame). These forward predicted frames allow the exploitation of interframe coding techniques to improve the overall compression efficiency and picture quality. P-frames may include portions that are only intraframe coded. Each macroblock within a P-frame can be either forward-predicted or intraframe coded.

The B-frame (where "B" denotes *bi-directionally* predicted) is a picture type within the coded video sequence that includes prediction from a future frame as well as from a previous frame. The referenced future or previous frames, sometimes called *anchor* frames, are in all cases either I or P-frames.

The basis of the B-frame prediction is that a video frame is correlated both with frames that occur in the past and frames that occur in the future. Consequently, if a future frame is available to the decoder, a superior prediction can be formed, thus saving bits and improving performance. Some of the consequences of using future frames in the prediction are: the B-frame cannot be used for predicting future frames, the transmission order of frames is different from the displayed order of frames and the encoder and decoder must reorder the video frames thereby increasing the total latency. In the example illustrated in Figure 1.11-6, there is one B-frame between each pair of I/P-frames. Each frame is labeled with both its display order and transmission order. The I and P frames are transmitted out of sequence so the video decoder has both anchor frames decoded and available for prediction.

B-frames are used for increasing the compression efficiency and perceived picture quality when encoding latency is not an important factor. The use of B-frames increases coding efficiency for both interlaced and progressively scanned material. The choice of number of bi-directional pictures between any pair of reference (I or P) frames can be determined at the encoder.

Video Encoder Image Prediction and Transform Coding

The DTV compression algorithm depends on creating an estimate of the image being compressed, and subtracting from the image to be compressed the pixel values of the estimate or prediction. If the estimate is good, the subtraction will leave a very small residue to be transmitted; in fact, if the estimate or prediction were perfect, the difference would be zero for all the pixels in the frame of differences, and no new information would need to be sent (that condition can be approached for still images).

If the estimate is not close to zero for some pixels or many pixels, those differences represent information that needs to be transmitted so the decoder can reconstruct a correct image. The kinds of image sequences that cause large prediction differences include severe motion and/or sharp details.

The video coding system uses *motion compensated* prediction as part of the data compression process. Thus macroblocks in the current frame of interest are predicted by macroblock-sized regions in previously transmitted frames. Motion compensation refers to the fact that the locations of the macroblock-sized regions in the reference frame can be offset to account for local motions. The macroblock offsets are known as *motion vectors,* which are *not* specified by the standard. One possible approach might be to perform an exhaustive search to determine the vertical and horizontal offsets that minimize the total difference between the offset region in the reference frame and the macroblock in the frame to be coded.

The estimation of interframe displacement is calculated with half pel precision, in both vertical and horizontal dimensions. That means the displaced macroblock from the previous frame can be displaced by non-integer displacements, and will require interpolation to compute the values of displaced picture elements at locations not in the original array of samples. Estimates for half-pel locations are computed by averages of adjacent sample values.

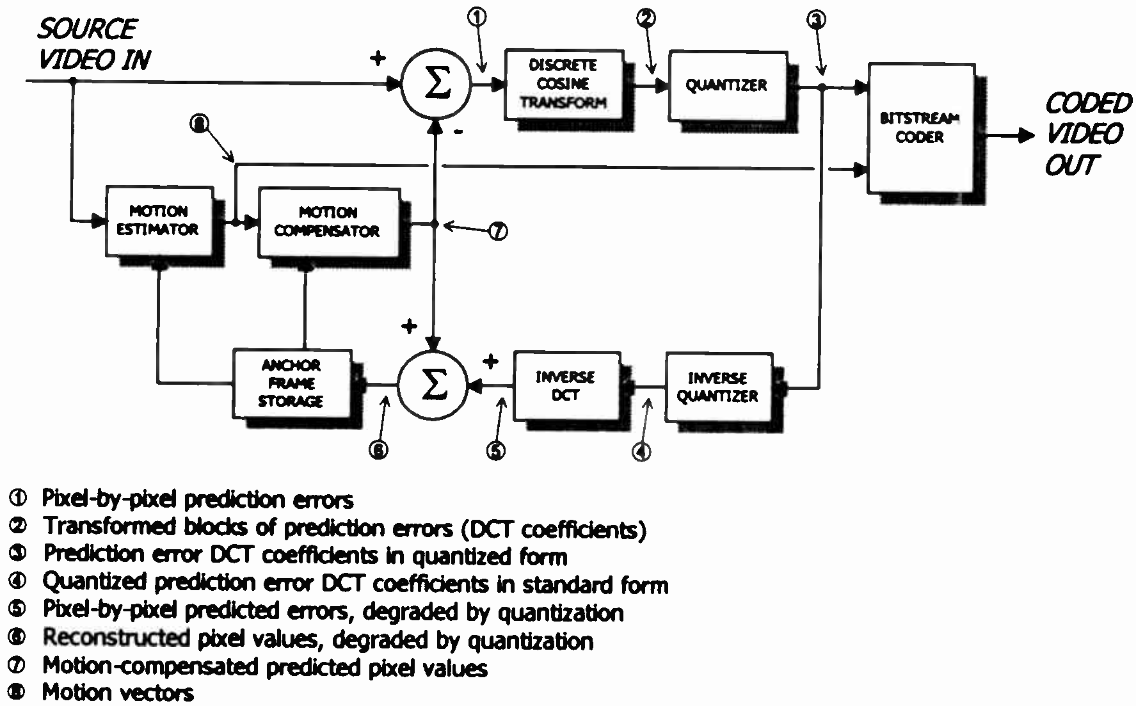

Figure 1.11-7. Encoder prediction loop.

Examination of the encoder prediction loop, shown in Figure 1.11-7, provides insight into the way the different algorithmic elements combine to achieve video compression. This closed feedback loop is the heart of the video compression for the ATSC DTV system.

The prediction loop contains a prediction function that estimates, or predicts, the picture values of the next picture to be encoded in the sequence of successive pictures that constitute the TV program. This prediction is based on previous information that is available within the loop, derived from earlier pictures. The transmission of the predicted compressed information works because the very same information used to make the prediction is available also at the receiving decoder (barring transmission errors, which are expected to be infrequent within the coverage area).

The subtraction of the predicted picture values from the new picture to be coded is at the core of predictive coding. The goal is to do such a good job of predicting the new values that the result of the subtraction function at the beginning of the prediction loop is zero or close to zero for most of the time. The prediction differences are computed separately for the luminance and two chrominance components before further processing. As discussed under I-frames, there are times when prediction is not used, for part of a frame or for an entire frame. Those portions are said to be intraframe coded, while the portions that use the prediction from previous or future pictures are said to be interframe coded.

The prediction differences (sometimes referred to as prediction errors) are grouped into 8-by-8 blocks and a spatial transform is applied to the blocks of difference values. In the intraframe case, the spatial transform is applied to the raw, undifferenced picture data. The luminance and two chrominance components are separately transformed. Since the chrominance data is sub-sampled vertically and horizontally, each 8-by-8 block of chrominance (Cb or Cb) data corresponds to a 16-by-16 macroblock of luminance data, which is not sub-sampled.

The spatial transform used is the *discrete cosine transform* (DCT). The formula for transforming the data is given by:

$$F(u, v) = \frac{1}{4} C(u)C(v)\sum_{x=0}^{7}\sum_{y=0}^{7} f(x, y) \cos\left[\frac{(2x + 1)u\pi}{16}\right] \times \cos\left[\frac{(2y + 1)v\pi}{16}\right]$$

where x and y are pixel indices within an 8-by-8 block, u and v are DCT coefficient indices within an 8-by-8 block, and:

$$C(w) = \frac{1}{\sqrt{2}} \quad \text{for } w = 0$$

$$C(w) = 1 \quad \text{for } w = 1, 2, \ldots, 7$$

Thus an 8-by-8 array of numbers $f(x, y)$ is the input to a mathematical formula, and the output is an 8-

by-8 array of different numbers, $F(u, v)$. The inverse transform[6] is given by:

$$f(x, y) = \frac{1}{4} \sum_{u=0}^{7} \sum_{v=0}^{7} C(u)C(v)F(u, v) \cos\left[\frac{(2x + 1)u\pi}{16}\right] \times \cos\left[\frac{(2y + 1)v\pi}{16}\right]$$

In principle, applying the inverse discrete cosine transform (IDCT) transform to the transformed array would yield exactly the same array as the original. In that sense, transforming the data does not modify the data but merely represents the data in a different form.

The decoder uses the inverse transformation to approximately reconstruct the arrays that were transformed at the encoder, as part of the process of decoding the received compressed data. The approximation in that reconstruction is controlled in advance during the encoding process so as to minimize the effects of coefficient inaccuracies as perceived by the viewer, while simultaneously reducing the quantity of data that needs to be transmitted.

The process of transforming the original data organizes the information in a way that exposes the spatial frequency components of the images or image differences. Using knowledge about the response of the human visual system to different spatial frequencies, the encoder can selectively adjust the precision of transform coefficient representation. The goal is to include as much information about a particular spatial frequency as needed (and possible, given constraints on data transmission), but not to use more precision than is needed, based on visual perception criteria.

Coefficient Quantization and Entropy Coding

The DCT of each 8-by-8 block of pixel values produces an 8-by-8 array of DCT coefficients. The relative precision accorded to each of the 64 DCT coefficients can be selected according to its relative importance in human visual perception. A quantizer matrix represents the relative coefficient precision information, which is an 8-by-8 array of values. Each value in the quantizer matrix represents the coarseness of quantization of the related DCT coefficient.

Two types of quantizer matrices are supported—one which is used for macroblocks which are intraframe coded, and the other for non-intraframe coded macroblocks. The video coding system defines default values for both the intra-quantizer and the *non-intra-quantizer* matrices. Either or both of the quantizer matrices can be overridden at the picture level by transmitting the appropriate arrays of 64 values. Any quantizer matrix overrides stay in effect until the following sequence start code.

The transform coefficients, which represent the bulk of the actual coded video information, are quantized to various degrees of coarseness. As previously indicated the appearance of some portions of the picture will be more affected than others to the loss of precision through coefficient quantization. This phenomenon is exploited by the availability of the quantizer scale factor (used in addition to the coefficient scaling done with the quantizer matrices), allowing the overall level of quantization to vary for each macroblock. Thus entire macroblocks which are deemed to be visually less important can be quantized more coarsely, which results in decreasing the number of bits needed to represent the picture.

For each coefficient other than the DC coefficient of intraframe coded blocks, the quantizer scale factor is multiplied by the corresponding value in the appropriate quantizer matrix to form the quantizer step size. Quantization of the DC coefficients of intra-coded blocks is unaffected by the quantizer scale factor, and is only governed by the (0, 0) element of the intra-quantizer matrix, which is always set to be 8 by ISO/IEC 13818-2.

An important effect of the quantization of transform coefficients is that many coefficients will be rounded to zero after quantization. In fact, a primary method of controlling the encoded data rate is the control of quantization coarseness, since a coarser quantization leads to an increase in the number of zero-value quantized coefficients.

Quantization creates an efficient discrete representation for the data to be transmitted. Codeword assignment takes the quantized values and produces a digital bit stream for transmission. Hypothetically, the quantized values could be simply represented using uniform or fixed-length codewords. Under this approach, every quantized value would be represented with the same number of bits. Greater efficiency, in terms of bit rate, can be achieved by employing entropy coding. Entropy coding attempts to exploit the statistical properties of the signal to be encoded. A signal, whether it contains a pixel value or a transform coefficient, has a certain amount of information, or entropy, based on the probability of the different possible values or events occurring. For example, an event that occurs infrequently conveys much more new information than one that occurs often. By realizing that some events occur more frequently than others, the average bit rate may be reduced.

Huffman coding, which is utilized in the DTV video compression system, is one of the most common entropy coding schemes. In Huffman coding, a codebook is generated which can approach the minimum average description length (in bits) of events, given the probability distribution of all the events. Events that are more likely to occur will be assigned shorter length codewords while those that are less likely to occur will be assigned longer length codewords.

In video compression, most of the transform coefficients are frequently quantized to zero. There may be a few non-zero low frequency coefficients and a sparse scattering of non-zero high frequency coefficients, but

[6] The IDCT is required to conform to *IEEE Standard Specifications for the Implementation of 8×8 Inverse Discrete Cosine Transform*, Std 1180-1990, December 6, 1990.

the great majority of coefficients may have been quantized to zero. To exploit this phenomenon the two-dimensional array of transform coefficients is reformatted and prioritized into a one-dimensional sequence through either a zigzag or alternate scanning process. This results in most of the important non-zero coefficients (in terms of energy and visual perception) being grouped together early in the sequence. They will be followed by long runs of coefficients that are quantized to zero. These zero valued coefficients can be efficiently represented through run-length encoding.

In run-length encoding, the number (run) of consecutive zero coefficients before a non-zero coefficient is encoded, followed by the non-zero coefficient value. The run-length and the coefficient value can be entropy coded, either separately or jointly. The scanning separates most of the zero and the non-zero coefficients into groups, thereby enhancing the efficiency of the run-length encoding process. Also, a special end-of-block (EOB) marker is used to signify when all of the remaining coefficients in the sequence are equal to zero. This approach can be extremely efficient, yielding a significant degree of compression.

As previously indicated above, the array of 64 DCT coefficients is arranged in a one-dimensional vector before run-length/amplitude codeword assignment. Two different one-dimensional arrangements, or *scan types,* are allowed, which are generally referred to as zigzag scan (shown in Figure 1.11-8a) and alternate scan (shown in Figure 1.11-8b). The scan type is specified before coding each picture, and is permitted to vary from picture-to-picture.

Whenever entropy coding is employed, the bit rate produced by the encoder is variable and is a function of the video statistics. Since the bit rate permitted by the transmission system is less than the peak bit rate produced by the variable length coder, a *channel buffer* is necessary at the decoder. The buffering must be carefully designed. Some form of buffer control is necessary to allow efficient allocation of bits to encode the video while ensuring that no overflow or underflow occurs.

The buffer control typically involves a feedback mechanism to the compression algorithm whereby the amplitude resolution (quantization) and/or spatial, temporal and color resolution may be varied in accordance with the instantaneous bit rate requirements. If the bit rate decreases significantly, a finer quantization can be performed to increase it.

As previously indicated the peak bit rate produced by variable length coding will typically fluctuate dramatically and frequently exceed the desired peak channel bandwidth allocation.[7] This situation is handled by the presence of a channel buffer at each decoder for temporary storage of the coded bit stream. The DTV Standard specifies a channel buffer size of 8 Mbits.

A model buffer is defined in the video coding system

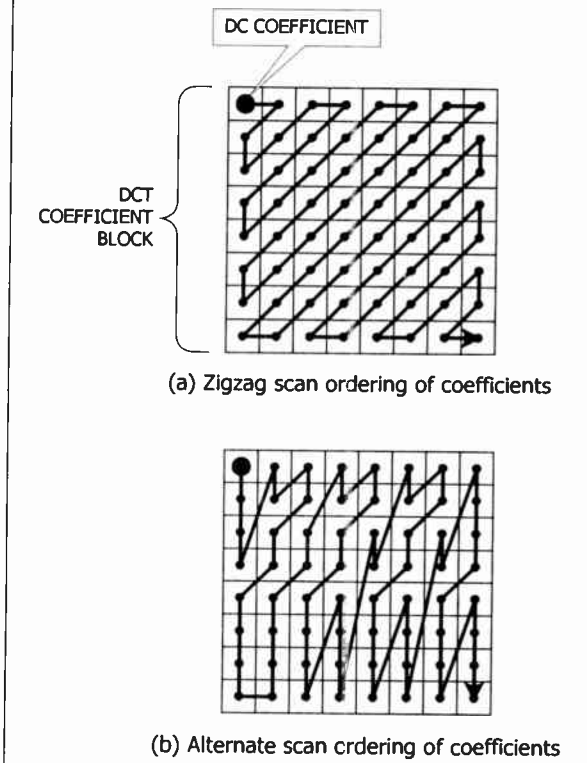

Figure 1.11-8. Scanning of coefficient blocks.

as a reference for manufacturers of both encoders and decoders to ensure interoperability. An encoder will control its production of bits so that the model buffer does not overflow or underflow.[8] In order to avoid overflow or underflow of the model buffer, an encoder may maintain measures of buffer occupancy and scene complexity. When the encoder needs to reduce the number of bits produced, it may do so by increasing the general value of the quantizer scale, which will increase picture degradation. When it is able to produce more bits, it may decrease the quantizer scale thus decreasing picture degradation.

At the decoder the coded coefficients are decoded and an 8-by-8 block of quantized coefficients is reconstructed. Each of these 64 coefficients is *inverse quantized* according to the prevailing quantizer matrix, quantizer scale and frame type. The result of inverse quantization is a block of 64 DCT coefficients.

The decoded and inverse quantized coefficients are organized as 8-by-8 blocks of DCT coefficients and the IDCT is applied to each block. This results in a

[7] Note that the average bit rate, by definition, cannot be permitted to exceed the peak allocated channel bandwidth.

[8] Buffer underflow is actually permitted in the case of low delay bit streams which do not contain B-frames. In such cases underflow might occur due to an unusually difficult picture which requires a particularly large number of bits. The result of underflow is the repeat of one or more pictures, which are presented in lieu of pictures that were skipped in the encoder.

new array of pixel values, or pixel difference values that correspond to the output of the subtraction at the beginning of the prediction loop. If the prediction loop was in the interframe mode, the values will be pixel differences. If the mode was in the intraframe mode, then the inverse transform will produce pixel values directly.

If a portion of the image has not moved, then it is easy to see that a subtraction of the old portion from the new portion of the image will produce zero or nearly zero pixel differences, which is the goal of the prediction. If there has been movement in the portion of the image under consideration, the direct pixel-by-pixel differences will in general not be zero, and might be statistically very large. However, the motion in most natural scenes is organized, and can in most cases be approximately represented locally as a translation. For this reason the video coding system allows for motion compensated prediction, whereby macroblock sized regions in the reference frame may be translated vertically and horizontally with respect to the macroblock being predicted, to compensate for local motion.

The pixel-by-pixel differences between the current macroblock and the motion compensated prediction are transformed by the DCT and quantized using the composition of the *non-intra-quantizer* matrix and the quantizer scale factor. The quantized coefficients are then coded. In the case of I-frames, the entire frame is encoded without reference to any other coded frames. P-frames are referenced to the most recently decoded I or P-frame. B-frames, however, permit the use of two frames as prediction references. One of the reference frames occurs earlier than the coded frame in display order (which can be used for forward prediction), and the other occurs later in display order (which can be used for backward prediction).

For a given macroblock within a B-frame, the encoder has four options-forward prediction, backward prediction, bi-directional prediction, and intraframe coding. When bi-directional prediction is used, the forward and backward predictors are averaged and then subtracted from the target macroblock to form the prediction error. The prediction error is then transformed, quantized and transmitted in the usual manner. Note that both of the frames used as references in coding a B-frame are coded and transmitted prior to the coding of the actual B-frame. This results in the need for frame reordering within the decoder to produce the proper display order. A given picture may be sent by describing the differences between it and one or two previously transmitted pictures. In order for this scheme to work, there must be some way for decoders to become initialized with a valid picture upon tuning into a new channel, or to become re-initialized with a valid picture after experiencing transmission errors.

The process whereby a decoder becomes initialized or re-initialized with valid picture data without reference to previously transmitted picture information is termed *image refresh.* Image refresh is accomplished by the use of intraframe coded macroblocks. There are two general classes of image refresh that can be used either independently or jointly, periodic transmission of I-frames and progressive refresh.

An alternative method for accomplishing image refresh is to encode only a portion of each picture using the intraframe mode. In this case the intraframe coded regions of each picture should be chosen such that, over the course of a reasonable number of frames, all macroblocks are coded intraframe at least once. In addition constraints might be placed on motion vector values in order to avoid possible contamination of refreshed regions through predictions using unrefreshed regions in an uninitialized decoder.

AUDIO COMPRESSION

The audio compression system conforms to the Digital Audio Compression (AC-3) Standard specified in ATSC Document A/52. The audio compression system is considered a constrained subset of the AC-3 Standard. The constraints are specified in Annex B of the DTV Standard.

As illustrated in Figure 1.11-9, the audio subsystem comprises the audio encoding/decoding function and resides between the audio inputs/outputs and the transport subsystem. The audio encoders are responsible for generating the audio elementary streams which are encoded representations of the baseband audio input signals. The flexibility of the transport system allows multiple audio elementary streams to be delivered to the receiver. At the receiver, the transport subsystem is responsible for selecting which audio streams to deliver to the audio subsystem. The audio subsystem is responsible for decoding the audio elementary streams back into baseband audio.

An audio program source is encoded by a digital television audio encoder. The output of the audio encoder is a string of bits that represent the audio source, and is referred to as an *audio elementary stream.* The transport subsystem packetizes the audio data into PES packets that are then further packetized into transport packets. The transmission subsystem converts the transport packets into a modulated RF signal for transmission to the receiver. At the receiver, the received signal is demodulated by the receiver transmission subsystem. The receiver transport subsystem converts the received audio packets back into an audio elementary stream that is decoded by the digital television audio decoder. The partitioning shown is conceptual, and practical implementations may differ. For example, the transport processing may be broken into two blocks; one to perform PES packetization, and the second to perform transport packetization. Or, some of the transport functionality may be included in either the audio coder or the transmission subsystem.

The audio system accepts baseband audio inputs with up to six audio channels per audio program bit stream. The channelization is consistent with ITU-R Recommendation BS-775, *Multi-channel Stereophonic Sound System With and Without Accompanying Picture.* The six audio channels are: Left, Center,

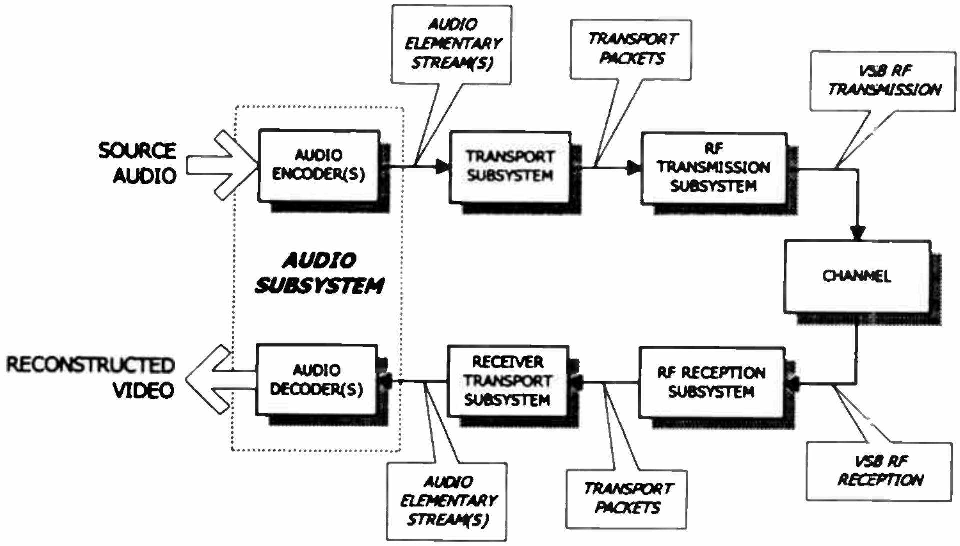

Figure 1.11-9. Audio subsystem within the digital television system.

Right, Left Surround, Right Surround, and Low Frequency Enhancement (LFE). Multiple audio elementary bit streams may be conveyed by the transport system. The bandwidth of the LFE channel is limited to 120 Hz. The bandwidth of the other (main) channels is limited to 20 kHz (this bandwidth difference led to the designation of the 6 channels as 5.1 channels in most documents). Low frequency response may extend to DC, but is more typically limited to approximately 3 Hz (-3 dB) by a DC blocking high-pass filter. Audio coding efficiency (and thus audio quality) is improved by removing DC offset from audio signals before they are encoded.

The system conveys digital audio sampled at a frequency of 48 kHz, locked to the 27 MHz system clock. If analog signal inputs are employed, the A/D converters should sample at 48 kHz. If digital inputs are employed, the input sampling rate shall be 48 kHz, or the audio encoder shall contain sampling rate converters which convert the sampling rate to 48 kHz. The sampling rate at the input to the audio encoder must be locked to the video clock for proper operation of the audio subsystem. In general, input signals should be quantized to at least 16-bit resolution. The audio compression system can convey audio signals with up to 24 bit resolution.

The audio compression system relies upon three basic operations, as shown in Figure 1.11-10. In the first stage, the representation of the audio signal is changed from the time domain to the frequency domain, which is a more efficient domain in which to perform psychoacoustically-based audio compression. The resulting frequency domain coefficients are then encoded. The frequency domain coefficients may be

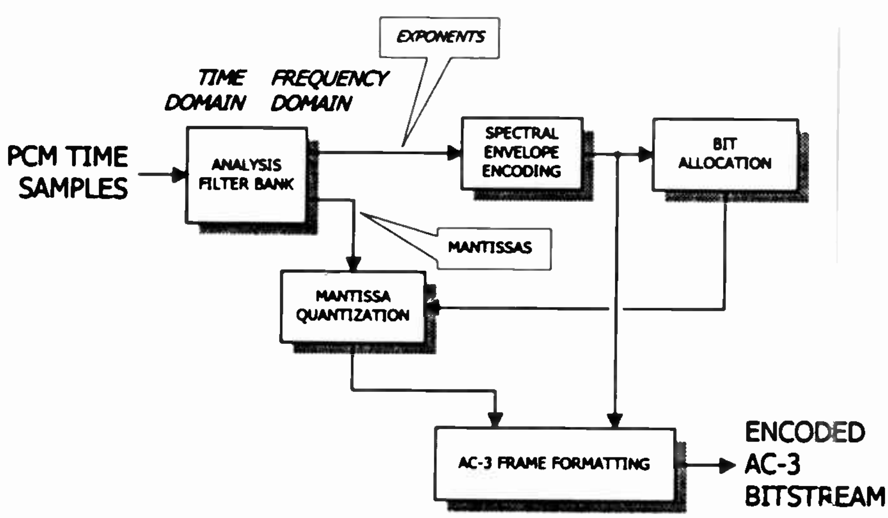

Figure 1.11-10. Overview of audio compression system.

coarsely quantized because the resulting quantizing noise will be at the same frequency as the audio signal, and relatively low signal to noise ratios are acceptable due to the phenomena of psychoacoustic masking. The bit allocation operation determines, based on a psychoacoustic model of human hearing, what actual signal to noise ratio *(SNR)* is acceptable for each individual frequency coefficient.

Finally, the frequency coefficients are coarsely quantized to the necessary precision and formatted into the audio elementary stream. The basic unit of encoded audio is the AC-3 sync frame, which represents 1536 audio samples. Each sync frame of audio is a completely independent encoded entity. The elementary bit stream contains the information necessary to allow the audio decoder to perform the identical (to the encoder) bit allocation. This allows the decoder to unpack and *de-quantize* the elementary bit stream frequency coefficients, resulting in the reconstructed frequency coefficients. The synthesis filterbank is the inverse of the analysis filterbank, and converts the reconstructed frequency coefficients back into a time domain signal.

The process of converting the audio from the time domain to the frequency domain requires that the audio be blocked into overlapping blocks of 512 samples. For every 256 new audio samples, a 512 sample block is formed from the 256 new samples, and the 256 previous samples. Each audio sample is represented in two audio blocks, and thus the number of samples to be processed initially is doubled. The overlapping of blocks is necessary in order to prevent audible blocking artifacts. New audio blocks are formed every 5.33 ms. A group of 6 blocks are coded into one AC-3 sync frame.

Prior to being transformed into the frequency domain, the block of 512 time samples is windowed. The windowing operation involves a vector multiplication of the 512 point block with a 512 point window function. The window function has a value of 1.0 in its center, and tapers down to almost zero at its ends. The shape of the window function is such that the overlap/add processing at the decoder will result in a reconstruction free of blocking artifacts. The window function shape also determines the shape of each individual filterbank filter.

The analysis filterbank is based on the *fast Fourier transform (FFT)*. The particular transformation employed is the oddly stacked *time domain aliasing cancellation (TDAC)* transform. This particular transformation is advantageous because it allows the 100% redundancy that was introduced in the blocking process to be removed. The input to the TDAC transform is 512 windowed time domain points, and the output is 256 frequency domain coefficients.

The frequency coefficients that result from the transformation are converted to a binary floating point notation. The scaling of the transform is such that all values are smaller than 1.0, with 1/65536 resolution. An example value in binary notation (base 2) with 16-bit precision would be:

$$0.0000\ 0000\ 1010\ 1100_2$$

The number of leading zeroes in the coefficient, 8 in this example, becomes the raw exponent. The value is left shifted by the exponent, and the value to the right of the decimal point (1010 1100) becomes the normalized *mantissa* to be coarsely quantized. The exponents and the coarsely quantized mantissas are encoded into the bit stream.

Some processing is applied to the raw exponents in order to reduce the amount of data required to encode them. First, the raw exponents of the six blocks to be included in a single AC-3 sync frame are examined for block-to-block differences. If the differences are small, a single exponent set is generated which is useable by all six blocks, thus reducing the amount of data to be encoded by a factor of six. If the exponents undergo significant changes within the frame, then exponent sets are formed over blocks where the changes are not significant. Due to the frequency response of the individual filters in the analysis filter bank, exponents for adjacent frequencies rarely differ by more than ±2. To take advantage of this fact, exponents are encoded differentially in frequency. The first exponent is encoded as an absolute, and the difference between the current exponent and the following exponent is then encoded. This reduces the exponent data rate by a factor of two. Finally, where the spectrum is relatively flat, or an exponent set only covers 1-2 blocks, differential exponents may be shared across two or four frequency coefficients, for an additional savings of a factor of two or four.

The final coding efficiency for exponents is typically 0.39 bits/exponent (or equivalently, 0.39 bits/sample since there is an exponent for each audio sample). Exponents are only coded up to the frequency needed for the perception of full frequency response. Typically, the highest audio frequency component in the signal that is audible is at a frequency lower than 20 kHz. In the case that signal components above 15 kHz are inaudible, only the first 75% of the exponent values are encoded, reducing the exponent data rate to <0.3 bits/sample.

The exponent processing changes the exponent values from their original values. The encoder generates a local representation of the exponents which is identical to the decoded representation that will be used by the decoder. The decoded representation is then used to shift the original frequency coefficients to generate the normalized mantissas that are quantized.

The precision of the frequency coefficients produced by the analysis filterbank depends on the word length of the input pulse coded modulation (PCM) audio samples and the precision of the transform computation. Typically this precision is on the order of 16-18 bits, but may be as high as 24 bits. Each normalized mantissa is quantized to a precision between 0 and 16 bits. The goal of audio compression is to maximize the audio quality at a given bit rate. This requires an optimum (or near optimum) allocation of the available bits to the individual mantissas.

The number of bits allocated to each individual mantissa value is determined by the bit allocation routine. The identical core routine is run in both the encoder and the decoder, so that each generates the identical bit allocation.

Compressed Audio Bit Stream

The audio bit stream consists of a repetition of audio frames which are referred to as *AC-3 sync frames*. Each AC-3 sync frame is a self contained entity consisting of synchronization information (SI), bit stream information (BSI), 32 ms of encoded audio, and a CRC error check code. Every sync frame is the same size (number of bits) and contains six encoded audio blocks. Within SI is a 16-bit sync word, an indication of audio sample rate (48 kHz for the digital television system) and an indication of the size of the audio frame (which indicates bit rate).

The ideal place to splice encoded audio bit streams is at the boundary of a sync frame. If a bit stream splice is performed at the sync frame boundary, the audio decoding will proceed without interruption. If a bit stream splice is performed randomly, there will be an audio interruption. The frame which is incomplete will not pass the decoder''s error detection test and this will cause the decoder to mute. The decoder will not find sync in its proper place in the next frame, and will enter a sync search mode. Once the sync code of the new bit stream is found, synchronization will be achieved, and audio reproduction may begin once again. The outage will be on the order of two frames, or about 64 ms. Due to the windowing process of the filterbank, when the audio goes to mute there will be a gentle fade down over a period of 2.6 ms. When the audio is recovered, it will fade up over a period of 2.6 ms. Except for the approximately 64 ms of time during which the audio is muted, the effect of a random splice of an AC-3 elementary stream is theoretically relatively benign.

Loudness and Dynamic Range

The digital television system was designed to provide uniform subjective loudness for all audio programs. Audio levels fluctuate between broadcast channels (observed when channel hopping), or between program segments on a particular channel (commercials much louder than the entertainment) in the NTSC system, which consumers find to be very annoying. One element that is found in most audio programming is the human voice. Achieving an approximate level match for dialogue (spoken in a normal voice, not shouting or whispering) amongst all audio programming was a design goal. The AC-3 audio system provides syntactical elements that are expected to make this goal achievable.

Since the digital audio coding system can provide more than 100 dB of dynamic range, there is no technical reason for dialogue to be encoded anywhere near 100% as is commonly done in NTSC television. However, there is no assurance that all program channels, or all programs or program segments on a given channel, will have dialogue encoded at the same (or even similar) level. Lacking a uniform coding level for dialogue (which would imply a uniform headroom available for all programs) there would be inevitable audio level fluctuations between program channels and even between program segments.

Encoded AC-3 elementary bit streams are tagged with an indication of the subjective level at which dialogue has been encoded. Different audio programs may be encoded with differing amounts of headroom above the level of dialogue in order to allow for dynamic music and sound effects. The digital television receiver (and all AC-3 decoders) are able to use this information on dialog level to adjust the reproduced level of audio programs, so that different received programs have their spoken dialogue reproduced at a uniform level. Some receiver designs may even offer the listener an audio volume control calibrated in absolute sound pressure level. The listener could dial up the desired sound pressure level (SPL) for dialogue, and the receiver would scale the level of every decoded audio program so that the dialogue is always reproduced at the desired level.

It is common practice for high quality programming to be produced with wide dynamic range audio, suitable for the highest quality audio reproduction environment. Broadcasters, serving a wide audience, typically process audio in order to reduce its dynamic range. The processed audio is more suitable for the majority of the audience that does not have an audio reproduction environment that matches that of the original audio production studio. In the case of NTSC, all viewers receive the same audio with the same dynamic range, and it is impossible for any viewer to enjoy the original wide dynamic range audio production.

The DTV audio coding system provides an embedded dynamic range control system that allows a common encoded bit stream to deliver programming with a dynamic range appropriate for each individual listener. A dynamic range control value is provided in each audio block (every 5 ms). The audio decoder uses these values in order to alter the level of the reproduced audio for each audio block. Level variations of up to ±24 dB may be indicated. The dynamic range values are generated in order to provide a subjectively pleasing but restricted dynamic range.

Some receivers may offer the viewer the option to scale the dynamic range values in order to reduce the effect of the dynamic range compression that was introduced by the broadcaster. Thus the viewer may be given independent control of the amount of compression applied to loud and quiet sounds. Therefore, while the broadcaster may introduce dynamic range compression to suit the needs of most of the audience, individual listeners may have the option to choose to enjoy the audio program with more or all of its original dynamic range intact.

Service Types

An AC-3 elementary stream contains the encoded representation of a single audio service. Multiple elementary streams provide multiple audio services. Each elementary stream is conveyed by the transport multiplex with a unique *packet identifier* (PID). There are a number of audio service types that may be (individually) coded into each elementary stream. Each elementary stream is tagged as to its service type. There are two types of main service and six types of associated service. Each associated service may be tagged (in the AC-3 audio descriptor in the transport PSI data) as being associated with one or more main audio services. Each AC-3 elementary stream may also be tagged with a language code.

Associated services may contain complete program mixes, or may contain only a single program element. Associated services that are complete mixes may be decoded and used in its present state. Associated services that contain only a single program element are intended to be combined with the program elements from a main audio service.

The service types available are defined in the Digital Audio Compression (AC-3) Standard and in Annex B of the DTV Standard. This information is reproduced in Table 1.11-3 and the following paragraphs briefly describe the meaning of these service types:

Complete main audio service (CM) This is the normal mode of operation. All elements of a complete audio program are present. The audio program may be any number of channels from 1 to 5.1.

Main audio service, music and effects (ME) All elements of an audio program are present except for dialogue. This audio program may contain from 1 to 5.1 channels. Dialogue may be provided by a D associated service (that may be simultaneously decoded and added to form a complete program).

Associated service: visually impaired (VI) This is typically a single-channel service, intended to convey a narrative description of the picture content for use by the visually impaired, and intended to be decoded along with the main audio service. The VI service also may be provided as a complete mix of all program elements, in which case it may use any number of channels (up to 5.1).

Associated service: hearing impaired (HI) This is typically a single-channel service, intended to convey dialogue which has been processed for increased intelligibility for the hearing impaired, and intended to be decoded along with the main audio service. The HI service also may be provided as a complete mix of all program elements, in which case it may use any number of channels (up to 5.1).

Associated service: dialogue (D) This service conveys dialogue intended to be mixed into a main audio service (ME) which does not contain dialogue.

Associated service: commentary (C) This service typically conveys a single-channel of commentary intended to be optionally decoded along with the main audio service. This commentary channel differs from a dialogue service, in that it contains optional instead of necessary program content. The C service also may be provided as a complete mix of all program elements, in which case it may use any number of channels (up to 5.1).

Associated service: emergency message (E) This is a single-channel service, which is given priority in reproduction. If this service type appears in the transport multiplex, it is routed to the audio decoder. If the audio decoder receives this service type, it will decode and reproduce the E channel while muting the main service - this is a mandatory requirement.

Associated service: voice-over (VO) This is a single-channel service intended to be decoded and added into the center loudspeaker channel.

Each audio bit stream may be in any language. In order to provide audio services in multiple languages a number of main audio services may be provided, each in a different language. This is the (artistically) preferred method, because it allows unrestricted placement of dialogue along with the dialogue reverberation. The disadvantage is as much as 384 kbps is needed to provide a full 5.1 channel service for each language. One way to reduce the required bit rate is to reduce the number of audio channels provided for languages with a limited audience. For instance, alternate language versions could be provided in 2 channel stereo with a bit rate of 128 kbps. Or, a mono version can be supplied at a bit-rate of approximately 64-96 kbps.

Formation of a complete audio program requires that the appropriate language D service be simultaneously decoded and mixed into the ME service. This method allows a large number of languages to be efficiently provided, but at the expense of artistic limitations. The single channel of dialogue would be mixed into the center reproduction channel and could not be panned. Also, reverberation would be confined to the center channel, which is not optimum. Nevertheless, for some types of programming (sports, etc.) this method is very attractive due to the savings in bit rate it offers. Another way to offer service in multiple languages is to provide a main multi-channel audio service (ME) which does not contain dialogue. Multiple single channel dialogue associated services (D) can then be provided, each at a bit-rate of approximately 64-96 kbps.

Some receivers may not have the capability to simultaneously decode two audio services.

Table 1.11-3

Table of Service Types

Bsmo d	Type of service
000 (0)	Main audio service: complete main (CM)
001 (1)	Main audio service: music and effects (ME)
010 (2)	Associated service: visually impaired (VI)
011 (3)	Associated service: hearing impaired (HI)
100 (4)	Associated service: dialogue (D)
101 (5)	Associated service: commentary (C)
110 (6)	Associated service: emergency (E)
111 (7)	Associated service: voice-over (VO)

ANCILLARY DATA SERVICES

The digital television system affords the opportunity to augment the basic television video and audio service with ancillary digital data services. The flexibility of the MPEG-2 transport layer employed in the system allows new digital services to be easily introduced at any time in a completely backward compatible manner. Two basic ancillary services were specified as a part of the DTV Standard from the outset. These services were to provide for the transmission of Closed Captioning (mislabeled as Program Subtitles in A/54), ancillary services, and program selection information.

Program Subtitles are completely analogous to the Closed Caption service transmitted on line 21 of the analog NTSC signal. Emergency Messages are mixed into the baseband video signal in the case of NTSC signals. The ancillary services envisioned are a mix of associated audio services and textual services.

The original standards adopted in 1995 provided multiple methods for locating a program. In 1997, a new structured method for tuning to programs was created and documented as an ATSC standard. This mandatory standard provides a way for the broadcaster to announce and the receiver to select a program. It contains time and control information to facilitate navigation and as such it allows suitably equipped receivers to build an interactive on-screen grid of program information. The information about the planned programs is carried in three major tables-a master guide table, a virtual channel table and an event information table. In addition, tables to provide system time, programs ratings and extended text messages about events are also defined. More information about this standard is in the Program and System Information Protocol (PSIP) section of this chapter and in Document A/65, which was approved by the ATSC on December 22, 1997.

When new data services are defined, the rules in Section 5.6.2 of Annex C of the DTV Standard specify that the ancillary services be specified in terms of a verification model by defining the characteristics of the transmitted syntax and an idealized decoder.

In MPEG-2 parlance, these ancillary services are referred to as *private data.* Private data provides a means to add new ancillary services to the basic digital television service specified in this Standard. Private data is supported in two bit stream locations:

1. Private data can be transmitted within the adaptation header of transport packets (Sections 2.4.3.4 and 2.4.3.5 of ISO/IEC 13818-1);
2. Private data can be transmitted as a separate transport stream with its own PID.

In either case, it is necessary that the standards that specify the characteristics of such data be consistent with A/53.

This mechanism is being used by ATSC to define how to provide both one-way and two-way interactive data services.

Transport Mechanism

The precise transport system standard for DTV is based on MPEG-2 and is given in ISO/IEC 13818-1 as constrained and extended for the DTV Standard. The constraints and extensions to the MPEG-2 standard that apply are given in Annex C of the DTV Standard.

The transport system employs the fixed length transport stream packetization approach defined by MPEG. This approach to the transport layer is well suited to the needs of terrestrial broadcast and cable television transmission of digital television. The use of moderately long, fixed length packets matches well with the needs and techniques for error protection in both terrestrial broadcast and cable television distribution environments. At the same time it provides great flexibility to accommodate the initial needs of the service to multiplex video, audio and data while providing a well-defined path to add additional services in the future in a fully backward compatible manner. By basing the transport layer on MPEG-2, maximum interoperability with other media and standards is maintained.

While the transport format conforms to the MPEG-2 Systems Standard, it will not exercise all the capabilities defined in the MPEG-2 Standard. Therefore, a digital television decoder need not be fully MPEG-2 Systems compliant, in that it will not need to decode any arbitrary MPEG-2 Systems bit stream. However, all MPEG-2 decoders should be able to decode the digital television bit stream syntax at the transport system level.

Figure 1.11-11 illustrates the organization of a digital television transmitter-receiver pair and the location of the transport subsystem in the overall system. The transport resides between the application (audio or video) encoding/decoding function and the transmission subsystem. At its lowest layer, the encoder transport subsystem is responsible for formatting the encoded bits and multiplexing the different components of the program for transmission. At the receiver, it is responsible for recovering the bit streams for the individual application decoders and for the corresponding error signaling. (At a higher layer, multiplexing and demultiplexing of multiple programs within a single bit stream can be achieved with an additional system level multiplexing or demultiplexing stage before the modem in the transmitter and after the modem in the receiver.) The transport subsystem also incorporates other higher level functionality related to identification of applications and, as illustrated, synchronization of the receiver.

As described earlier, the data transport mechanism is based on the use of fixed length packets that are identified by headers. Each header identifies a particular application bit stream (also called an elementary bit stream) which forms the payload of the packet. Applications supported include video, audio, data, program and system control information, etc. The elementary bit streams for video and audio are wrapped in a variable length packet structure called the packetized elementary stream (PES) before transport processing. The PES layer provides functionality for identification,

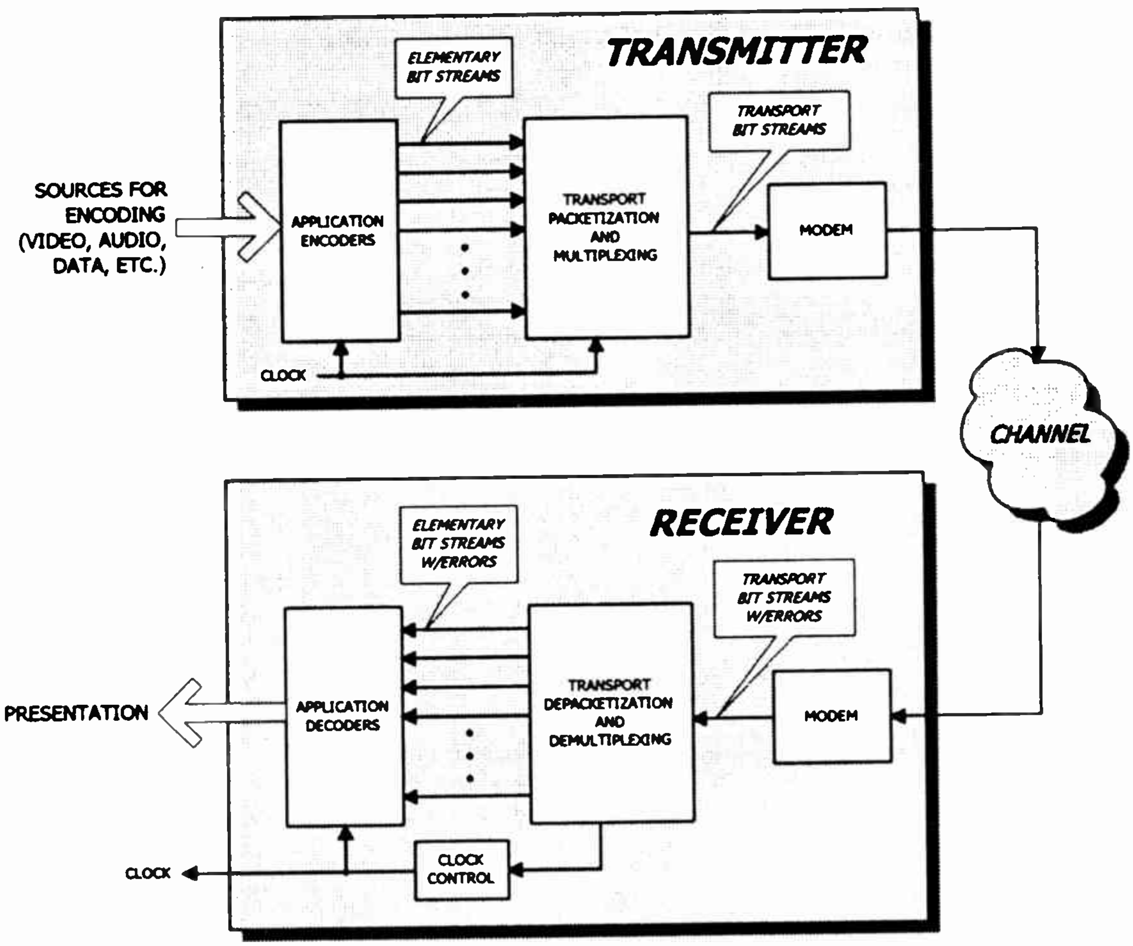

Figure 1.11-11. Sample organization of functionality in a transmitter-receiver pair for a single digital television program.

and synchronization of decoding and presentation of the individual application.

Moving up one level in the description of the general organization of the bit streams, elementary bit streams sharing a common time base are multiplexed, along with a control data stream, into *programs*. Note that a program in the digital television system is somewhat analogous to a channel in the NTSC system in that it contains all of the video, audio, and other information required to make up a complete television program.[9] These programs and an overall system control data stream are then asynchronously multiplexed to form a multiplexed *system*.

At this level, the transport is flexible in two aspects:

- It permits programs to be defined as any combination of elementary bit streams; specifically, the same elementary bit stream can be present in more than one program (two different video bit streams with the same audio bit stream); a program can be formed by combining a basic elementary bit stream and a supplementary elementary bit stream (bit streams for scaleable decoders); programs can be tailored for specific needs (regional selection of language for broadcast of secondary audio); etc;
- Flexibility at the systems layer allows different programs to be multiplexed into the system as desired, and allows the system to be reconfigured when required. The procedure for extraction of separate programs from within a system is also well defined. A/65 defines both required methods as well as optional methods.

The transport system provides other features that are useful for both normal decoder operation and for the special features required in broadcast and cable applications. These include:

- Decoder synchronization
- Conditional access
- Local program insertion

The transport bit stream definition directly addresses issues relating to the storage and playback of programs. Although this is not directly related to the transmission of digital television programs, it is a fundamental re-

[9] If one ignores the data which can reside in the NTSC analog multiplex.

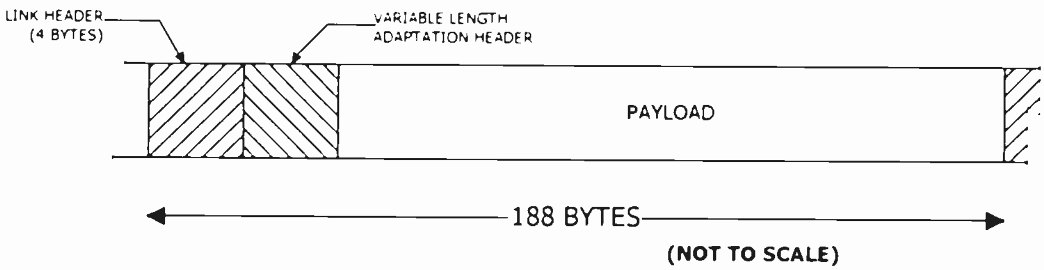

Figure 1.11-12. Transport packet format.

quirement for creating programs in advance, storing them and playing them back at the desired time. The programs are stored in the same format in which they are transmitted, as transport bit streams. The bit stream format also contains the hooks needed to support the design of consumer digital products based on recording and playback of these bit streams, including the use of the trick modes that one is familiar with for current analog VCRs (but no standard methods are defined). It should be noted that the issues related to storage and playback of digitally compressed video bit streams are quite different from those that apply to analog systems such as NTSC.

The transport bit stream consists of fixed length packets with a fixed and a variable component to the header field as illustrated in Figure 1.11-12.

Each packet consists of 188 bytes and is constructed in accordance with the MPEG-2 transport syntax and semantics. The choice of this packet size was motivated by a few factors. The packets need to be large enough so that the overhead due to the transport headers does not become a significant portion of the total data carried. However, they should not be so large that the probability of packet error becomes significant under standard operating conditions (due to inefficient error correction). It is also desirable to have packet lengths consistent with the block sizes of typical, block oriented, error correction methods, so that packets may be synchronized to error correction blocks, and the physical layer of the system can aid the packet level synchronization process in the decoder. Another reason for the particular packet length selection is interoperability with the ATM format. It has been shown that one can transmit a single MPEG-2 transport packet in four ATM cells.

The packet headers identify the contents of each packet. The packet header structure is layered and may be described as a combination of a fixed length link layer and a variable length adaptation layer. Each layer serves a different function similar to the link and transport layer functions in the OSI layered model of a communications system. In the digital television system, this link and adaptation level functionality is used directly for the terrestrial broadcast link on which the MPEG-2 transport bit stream is transmitted. However, in a different communications system (ATM), the MPEG-2 headers would not play a role in implementing a protocol layer in the overall transmission system. The MPEG-2 headers would be carried as part of the payload in such a case and would continue to serve as identifiers for the contents of the data stream.

Random entry into the application bit streams such as video and audio is necessary to support functions such as program acquisition and program switching. Random entry into an application is possible only if the coding for the elementary bit stream for the application supports this functionality directly. For example, the video bit stream supports random entry through the concept of intraframes (or I-frames) that are coded without any prediction, and can therefore be decoded without any prior information. The beginning of the video sequence header information preceding data for an I-frame could serve as a random entry point into a video elementary bit stream. In general, random entry points should also coincide with the start of PES packets where they are used (for video and audio).

The support for random entry at the transport layer comes from a flag in the adaptation header of the packet that indicates whether the packet contains a random access point for the elementary bit stream. In addition, the data payload of packets that are random access points starts with the data that forms the random access point of entry into the elementary bit stream itself. This approach allows packets to be discarded directly at the transport layer when switching channels and searching for a resynchronization point in the transport bit stream, and also simplifies the search for the random access point in the elementary bit stream once transport level resynchronization is achieved.

The transport system supports insertion of local programs and commercials by use of flags and features dedicated to this purpose in the transport packet Adaptation Header. This important issue was discussed at great length within MPEG. The syntax allows local program insertion to be supported and its performance to improve as techniques and equipment are developed around these syntax tools. The use of these syntax elements will need to be within imposed constraints to ensure proper operation of the video decoders. There may also need to be constraints on some current common broadcast practices, imposed not by the transport, but rather by virtue of the compressed digital data format. Significant effort by industry to develop improved switching techniques, to provide broadcasters with at least the same functionality as NTSC switching, are currently underway.

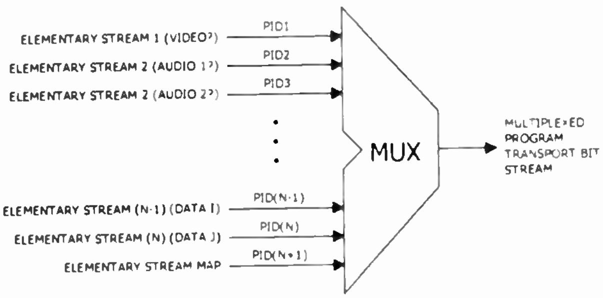

Figure 1.11-13. Illustration of the multiplex function to form a program transport stream.

Multiplexing

A program transport stream is formed by multiplexing individual elementary bit streams (with or without PES packetization) that share a common time base.[10] As the elementary streams are multiplexed, they are formed into transport packets and a control bit stream that describes the program (also formed into transport packets) is added. The organization of this multiplex function is illustrated in Figure 1.11-13. The elementary bit streams, and the control bit stream (also called the elementary stream map in Figure 1.11-13), are identified by their unique PIDs in the link header field. The control bit stream contains the information that describes the elementary stream map, including information about the PIDs of the transport streams that make up the program, the identification of the applications (audio, video, etc.) that are being transmitted on these bit streams, the relationship between these bit streams, etc.

The transport syntax allows a program to be comprised of a large number of elementary bit streams, with no restriction on the types of applications required within a program. For example, a program transport stream does not need to contain a single video or audio bit stream; it could be a data program. On the other hand, a program transport stream could contain multiple related video and audio bit streams, as long as they share a common time base. The data applications that can be carried are flexible; the only constraint is that there should be an appropriate ID assignment to enable recognition of the application corresponding to the bit stream by a decoder.

Note that, for the different elementary bit streams that make up a program, the link level functions are carried out independently without program level coordination. This includes functions such as PID manipulation, bit stream filtering, scrambling and descrambling, definition of random entry packets, etc. The coordination between the elements of a program is primarily controlled at the presentation (display) stage based on the use of the common time base. This common time base is imposed by having all elementary bit streams in a program derive timing information from a single clock, and then by transmitting this timing information via the program clock reference (PCR) on one of the elementary bit streams that constitute the program. The data for timing of presentation is present in the elementary bit stream for each individual application.

The system multiplex is created by assembling different program transport streams in a proscribed manner. In addition to the transport bit streams (with the corresponding PIDs) that define the individual programs, a system level control bit stream with PID = 0 is also defined and included in the multiplex. Although this bit stream carries the information that maps program identities to their program transport streams, the PSIP standard enables determination of the contents of the multiplex before the channel change is attempted, facilitating faster program acquisition (what we used to know as channel change). Again, in this context, a program corresponds to what has traditionally been called a channel (PBS, C-SPAN, etc.).

The system layer of multiplexing is illustrated in Figure 1.11-14. Note that during the process of system level multiplexing, there is the possibility of PIDs on different program streams being identical at the input. This poses a problem because PIDs for different bit streams need to be unique. A solution to this problem lies at the multiplexing stage, where some of the PIDs are modified just before the multiplex operation. Hardware implementation of the PID reassignment function in real time is helped by the fact that this process is synchronous at the packet clock rate. The other approach, of course, is to make sure up front that the PIDs being used in the programs that make up the system are unique. This is not always possible with stored bit streams.

Note that the architecture of the bit stream is scalable. Multiple system level bit streams can be multiplexed together on a higher bandwidth channel by extracting the appropriate information from each system multiplexed bit stream and reconstructing a new PID = 0 bit stream. Note again that PIDs may have to be reassigned in this case.

Note also that in all descriptions of the higher level

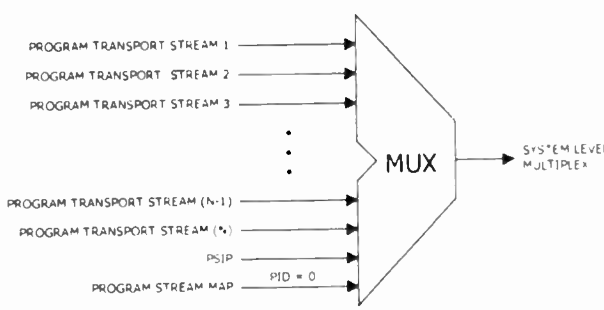

Figure 1.11-14. Illustration of the multiplex function to form the system level bit stream.

[10] The terminology can be confusing. The term **program** is analogous to a channel in NTSC; the term **program stream** refers to a particular bit stream format defined by MPEG but not used in the ATSC Digital Television Standard. **Program transport stream** is the term used to describe a transport bit stream that has been generated for a program.

multiplexing functionality, no mention is made of the functioning of the multiplexer and multiplexing policy that should be used. This function is not a part of the Standard and is up to individual designers. Because its basic function is one of filtering, the transport de-multiplexer will function on any digital television bit stream regardless of the multiplexing algorithm used.

RF/TRANSMISSION SYSTEMS

The RF/transmission subsystem portion of the DTV system is referred to as the VSB (for vestigial sideband) system. The VSB system offers two modes: a terrestrial broadcast mode, and a high data rate mode. The two modes share the same pilot, symbol rate, data frame structure, interleaving, Reed-Solomon (RS) coding and synchronization pulses. The terrestrial broadcast mode is optimized for maximum service area, and supports one ATSC DTV signal in a 6 MHz channel, with a payload data rate of 19.28... Mbps.

Both modes of the VSB transmission subsystem take advantage of a pilot, a segment sync and a training sequence for robust acquisition and operation. The two system modes also share identical carrier, sync, and clock recovery circuits, as well as phase correctors and equalizers. Additionally, both modes use the same RS code for forward error correction (FEC).

In order to maximize service area, the terrestrial broadcast mode incorporates both an NTSC rejection filter (in the receiver) and trellis coding. Pre-coding at the transmitter is incorporated in the trellis code. When the NTSC rejection filter is activated in the receiver, the trellis decoder is switched to a trellis code corresponding to the encoder trellis code concatenated with the filter.

The high data rate mode, on the other hand, does not have as severe an environment to work in as that of the terrestrial system (a cable environment is assumed). Therefore, a higher data rate is transmitted in the form of more data levels (bits/symbol). No trellis coding or NTSC interference rejection filters are employed.

VSB transmission inherently requires only processing the in-phase (I) channel signal, sampled at the symbol rate, thus optimizing the receiver for low cost implementation. The decoder only requires one A/D converter and a real (not complex) equalizer operating at the symbol rate of 10.76 Msamples/s.

The parameters for the two VSB transmission modes are shown in Table 1.11-4.

A functional block diagram of a representative 8 VSB terrestrial broadcast transmitter is shown in Figure 1.11-15. The input to the transmission subsystem from the transport subsystem is a 19.39.. Mbps serial data stream comprised of 188-byte MPEG-compatible data packets (including a sync byte and 187 bytes of data that represent a payload data rate of 19.28... Mbps).

The incoming data is randomized and then processed for FEC in the form of RS coding (20 RS parity bytes are added to each packet), 1/6 data field interleaving and 2/3-rate trellis coding. The randonization and FEC

Table 1.11-4
Parameters for VSB Transmission Modes

Parameter	Terrestrial mode	High data rate mode
Channel bandwidth	6 MHz	6 MHz
Excess bandwidth	11.5%	11.5%
Symbol rate	10.76 Msymbols/s	10.76 Msymbols/s
Bits per symbol	3	4
Trellis FEC	2/3 rate	None
Reed-Solomon FEC	T = 10 (207,187)	T = 10 (207,187)
Segment length	832 symbols	832 symbols
Segment sync	4 symbols per segment	4 symbols per segment
Frame sync	1 per 313 segments	1 per 313 segments
Payload data rate	19.28 Mbps	38.57 Mbps
NTSC co-channel rejection	NTSC rejection filter in receiver	N/A
Pilot power contribution	0.3 dB	0.3 dB
C/N threshold	14.9 dB[11]	28.3 dB

(Source: ATSC Doc A/54)

processes are not applied to the sync byte of the transport packet, which is represented in transmission by a *Data Segment Sync* signal. Following randomization and forward error correction processing, the data packets are formatted into Data Frames for transmission and Data Segment Sync and *Data Field Sync* are added.

Figure 1.11-16 shows how the data are organized for transmission. Each *Data Frame* consists of two *Data Fields*, each containing 313 *Data Segments*. The first Data Segment of each Data Field is a unique synchronizing signal (Data Field Sync) and includes the training sequence used by the equalizer in the receiver. The remaining 312 Data Segments each carry the equivalent of the data from one 188 byte transport packet plus its associated FEC overhead. The actual data in each Data Segment comes from several transport packets because of data interleaving. Each Data Segment consists of 832 symbols. The first four symbols are transmitted in binary form and provide segment synchronization. This Data Segment Sync signal also represents the sync byte of the 188 byte MPEG compatible transport packet. The remaining 828 symbols of each Data Segment carry data equivalent to the remaining 187 bytes of a transport packet and its associated FEC overhead. These 828 symbols are transmitted as 8-level signals and therefore carry three bits per symbol. Thus, 828 x 3 = 2484 bits of data are carried in each Data Segment, which exactly matches the requirement to send a protected transport packet:

187 data bytes + 20 RS parity bytes = 207 bytes
207 bytes $\times$ 8 bits/byte = 1656 bits
2/3 rate trellis coding requires 3/2 $\times$ 1656 bits = 2484 bits.

[11] Note that this published value was not confirmed during testing. The value used for noise limited service by the FCC was 15.19 dB, which was the test result selected by ACATS under one of many different test conditions measured by the ATTC.

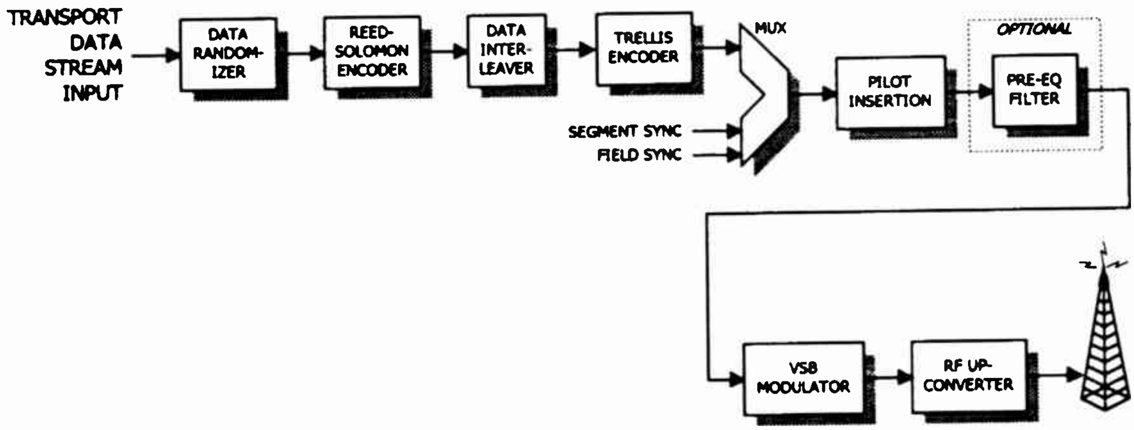

Figure 1.11-15. VSB transmitter.

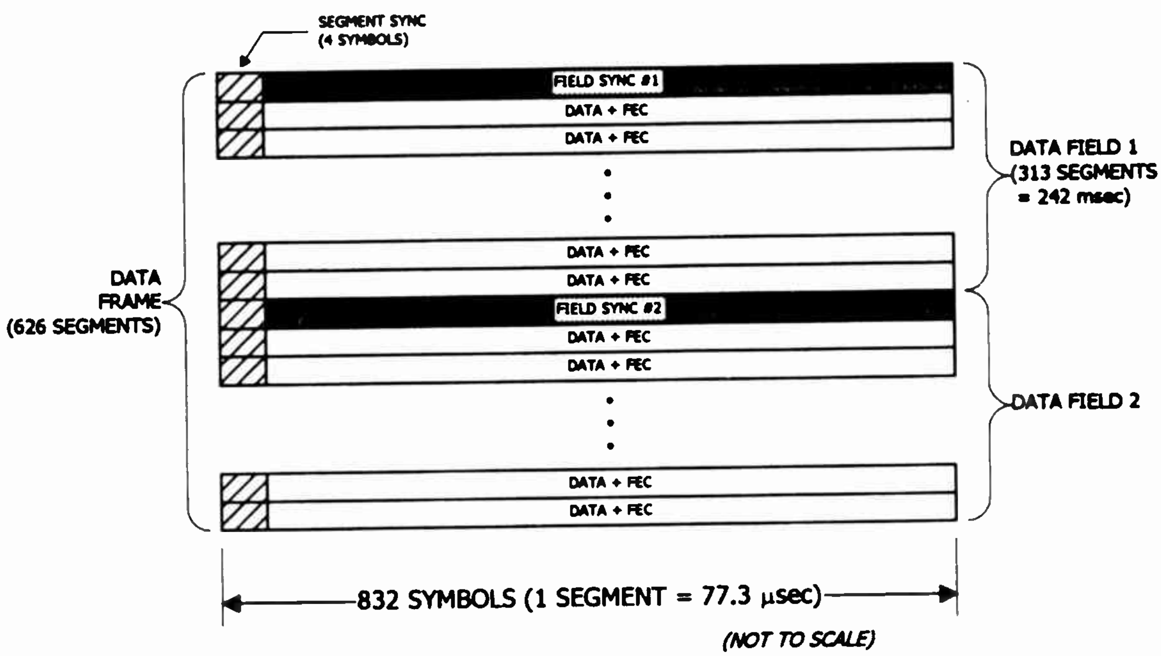

Figure 1.11-16. VSB data frame.

The exact symbol rate is given by:

$$S_r \text{ (MHz)} = 4.5/286 \times 684 = 10.76 \ldots \text{ MHz} \quad (1)$$

The frequency of a Data Segment is given by:

$$f_{seg} = S_r/832 = 12.94 \ldots \times 10^3 \text{ Data Segments/s} \quad (2)$$

The Data Frame rate is given by:

$$f_{frame} = f_{seg}/626 = 20.66 \ldots \text{ frames/s} \quad (3)$$

The symbol rate S_r and the transport rate T_r shall be locked to each other in frequency, where:

$$T_r = 2 \times \left(\frac{188}{208}\right)\left(\frac{312}{313}\right)\left(\frac{684}{286}\right) \times 4.5 = 19.39 \ldots \text{ Mbps}$$

and

$$S_r = \left(\frac{684}{286}\right) \times 4.5 = 10.76 \ldots \text{ Msps}$$

is the symbol rate S_r in Msymbols per second for the transmission subsystem.

The symbol rate must be locked in frequency to the transport rate. The transmission subsystem carries 2 information bits per trellis-coded symbol (fundamentally, 8 VSB modulation is 3 bits per transmitted symbol, however, in this context a trellis-coded symbol means *without* the trellis overhead, resulting in the 2 bits-per-symbol figure just stated), so the gross payload is:

$$10.76 \ldots \times 2 = 21.52 \ldots \text{Mbps} \qquad (4)$$

To find the net payload delivered to a decoder it is necessary to adjust (4) for the overhead of the Data Segment Sync, Data Field Sync, and RS FEC. Upon doing this the net payload bit rate of the 8 VSB terrestrial transmission subsystem becomes:

$$21.52 \ldots \text{Mbps} \times 312/313 \times 828/832 \times 187/207 = 19.28 \ldots \text{Mbps} \qquad (5)$$

The factor of 312/313 accounts for the Data Field Sync overhead of one Data Segment per field. The factor of 828/832 accounts for the Data Segment Sync overhead of four symbol intervals per Data Segment, and the factor of 187/207 accounts for the RS FEC overhead of 20 bytes per Data Segment.

The calculation of the net payload bit rate of the high data rate mode is identical except that 16 VSB carries 4 bits per symbol. Therefore, the net bit rate is twice that of the 8 VSB terrestrial mode:

$$19.28 \ldots \text{Mbps} \times 2 = 38.57 \ldots \text{Mbps} \qquad (6)$$

To get the net bit rate seen by a transport decoder, however, it is necessary to account for the fact that the MPEG sync bytes are removed from the data stream input to the 8 VSB transmitter. This amounts to the removal of one byte per data segment. These MPEG sync bytes are then reconstituted at the output of the 8 VSB receiver. The net bit rate seen by the transport decoder is:

$$19.28 \ldots \text{Mbps} \times 188/187 = 19.39 \ldots \text{Mbps} \qquad (7)$$

The net bit rate seen by the transport decoder for the high data rate mode is:

$$19.39 \ldots \text{Mbps} \times 2 = 38.78 \ldots \text{Mbps} \qquad (8)$$

The 8-level symbols combined with the binary Data Segment Sync and Data Field Sync signals are used to suppressed-carrier modulate a single carrier. Before transmission, however, most of the lower sideband is removed. The resulting spectrum is flat, except for the band edges where a nominal square root raised cosine response results in 620 kHz-wide transition regions.

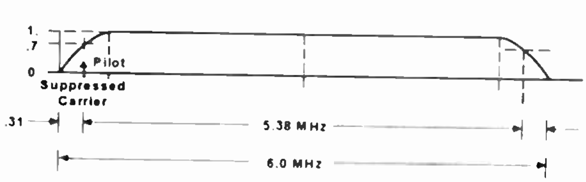

Figure 1.11-17. VSB channel occupancy (nominal) *(Source: ATSC Doc A/54).*

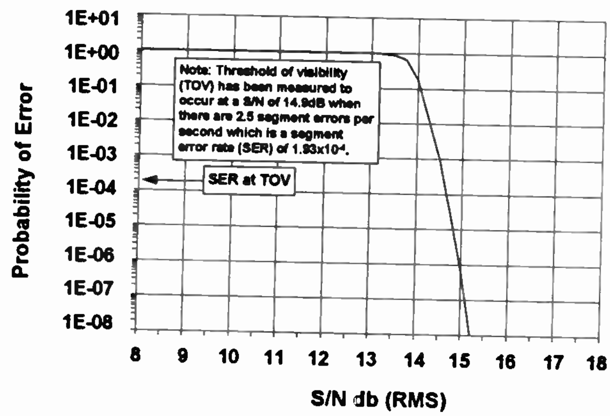

Figure 1.11-18. Segment error probability, 8 VSB with 4-state Trellis, RS (207,187) *(Source: ATSC Doc A/54).*

The nominal VSB transmission spectrum is shown in Figure 1.11-17. At the suppressed-carrier frequency, 309.441 kHz from the lower band edge, a small pilot is added to the signal.

The theoretical analysis of the terrestrial VSB system predicts that it can operate in a signal-to-additive-white-Gaussian-noise (S/N) environment of 14.9 dB. The 8 VSB, 4-state segment error probability curve in Figure 1.11-18 shows a segment error probability of $1.93 \times 10_{-4}$. This is equivalent to 2.5 segment errors/second which has been established by measurement as the threshold of visibility (TOV) of errors. Tests at ATTC showed a S/N of 15.19 dB with a BER of $\sim 1 \times 10_{-6}$ for the TOV in the strong signal, random noise test. Subsequently, the FCC elected to use 15.19 dB as the planning factor for the noise-limited service contour.

The cumulative distribution function (CDF) of the peak-to-average power ratio, as measured on a low power transmitted signal with no non-linearities, is plotted in Figure 1.11-19. This theoretical plot shows

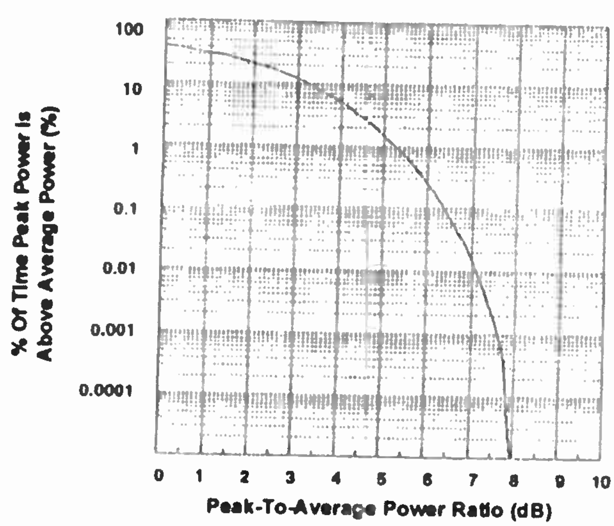

Figure 1.11-19. Theoretical cumulative distribution function of 8 VSB peak-to-average power ratio *(Source: ATSC Doc A/54).*

that 99.9% of the time the transient peak power should be within 6.3 dB of the average power. Tests of the Grand Alliance implementation showed the same shape curve, this result being further confirmed by the fact that two different measurement approaches yielded only slightly differing results. The 99.9% ratio was either 5.9 dB or 6.17 dB. The 99.99% of the time ratios were 6.6 and 6.89 dB. This is an important parameter because if the peak-to-average ratio of the transmitter is exceeded, clipping will occur as the signal transitions from one state to another. The effect of this clipping is generally expected to be negligible as long as the clipping is small, but this remains an area where long-term experience is needed to fully understand any impact. Although precise ratios appear in the test reports and standards documents, practical implementations of the DTV system cannot be expected to produce these exact performance levels.

A pre-equalizer filter is recommended for over-the-air broadcasts where the high power transmitter used may have significant in-band ripple or roll-off at band edges. This linear distortion can be detected by an equalizer in a reference demodulator (ideal receiver) located at the transmitter site that is receiving a small sample of the antenna signal feed provided by a directional coupler, recommended to be located at the sending end of the antenna feed transmission line. The resulting equalizer tap weights are then transferred into the transmitter pre-equalizer for pre-correction of transmitter"s linear distortion.

The VSB transmitter applies a two-step modulation process. In the first step, the baseband 8 VSB signal is modulated onto an IF carrier which will typically be the same for each transmission site regardless of the final RF frequency. Then, an RF upconverter translates the filtered, flat IF data signal spectrum to the desired RF channel. For the same approximate coverage as an NTSC transmitter (at the same frequency), the average power required of the ATSC DTV signal is approximately 12 dB less than the corresponding NTSC peak sync power for the same reception assumption.

The frequency of the RF upconverter oscillator in ATSC DTV terrestrial broadcasts will typically be the same as that used for an NTSC signal at the same channel (except for NTSC offsets). However, in extreme co-channel interference situations, the ATSC DTV system is designed to take advantage of precise RF carrier frequency offsets with respect to an NTSC co-channel carrier. As the VSB data signal sends repetitive synchronizing information (segment syncs), precise offset causes NTSC co-channel carrier interference into the VSB receiver to phase alternate from sync to sync. The VSB receiver circuits average successive syncs to cancel the interference and make data segment sync detection more reliable.

For ATSC DTV co-channel interference into NTSC, the interference is noise-like and does not change with precise offset. Even the ATSC DTV pilot interference into NTSC does not benefit from precise frequency offset because it is so small (11.3 dB below the data power) and falls far down the Nyquist slope (20 dB or more) of NTSC receivers.

Interference to an NTSC signal from an upper adjacent DTV channel is minimized by requiring (as part of the FCC rules) that the pilot carrier of DTV transmitters located within 88 kilometers of a lower-adjacent NTSC transmitter must be maintained at a precision frequency offset of 5.082138 MHz (±3 Hz with respect to that NTSC video carrier.

For DTV-into-DTV co-channel interference, precise carrier offset prevents possible misconvergence of the adaptive equalizer. If perchance the two ATSC DTV Data Field Sync signals should fall within the same data segment time, the adaptive equalizer could misinterpret the interference as a ghost. Although the FCC did not specify this parameter, testing for DTV to DTV co-channel interference thresholds was done with a frequency offset of 19,403 Hz ±5Hz separation and the FCC's planning factors used were the ones from this test.

DTV RECEIVER

The DTV system design partitioned responsibility for overall performance between the transmitter and the receiver. All testing of the system was based on the Grand Alliance implementation of a receiver. However the DTV receiver is not covered by any specific standard. The information in this section is provided to provide an overview of how receivers may work.

The following descriptions were based upon the Grand Alliance HDTV System Specification and are specific to the hardware implementation of the Grand Alliance. Figure 1.11-20 shows the receiver block diagram of the VSB terrestrial broadcast transmission system. Descriptions of each block follow.

The tuner receives the 6 MHz signal (UHF or VHF) from the antenna, and is a high-side injection double-conversion type with a first IF frequency of 920 MHz. This selection of first IF frequency is high enough so that the input band-pass filter selectivity prevents the local oscillator (978-1723 MHz) from leaking out the tuner front end and interfering with other UHF channels, yet it is low enough for second harmonics of UHF channels (470-806 MHz) to fall above the first IF band-pass.

The tuner input has a band-pass filter that limits the frequency range to 50-810 MHz, rejecting all other non-television signals that may fall within the tuner"s image frequency range (beyond 920 MHz). In addition, a broadband tracking filter rejects other television signals, especially those much larger in signal power than the desired signal power.

A 10 dB gain, wideband RF amplifier increases the signal level into the first mixer, and is the dominant determining factor of receiver noise figure (7-9 dB over entire VHF, UHF, and cable bands). The FCC planning factors assumed 7 dB Nf for UHF. The system Nf for LVHF and HVHF was assumed to be 10 dB. It is clear that, for LVHF, the FCC assumed the environmental noise component of this total to be 5 dB.

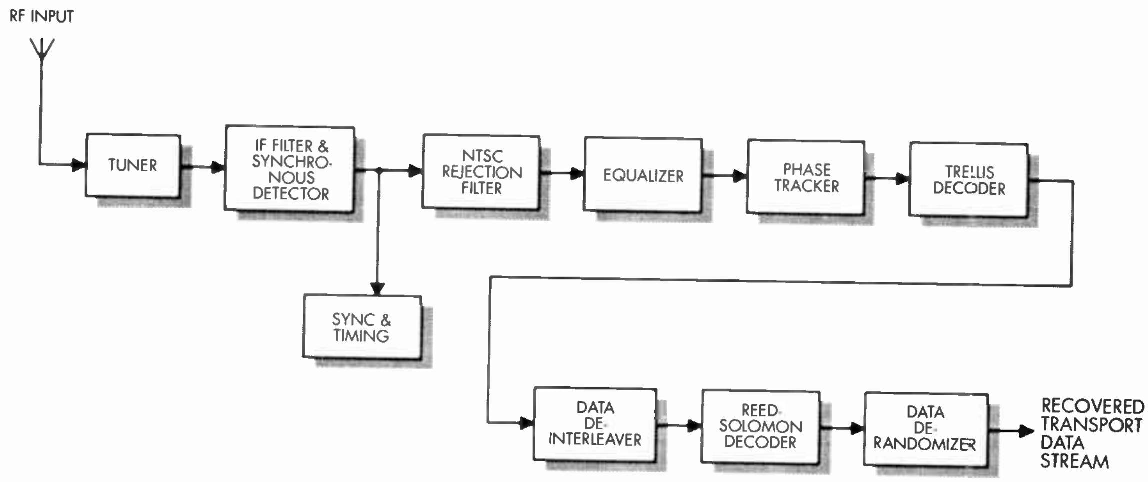

Figure 1.11-20. VSB receiver.

The assumptions about partitioning the system noise figure for HVHF were not disclosed. Interpolation of the receiver Nf from the two known values yields 5, 6, and 7 dB for LVHF, HVHF and UHF respectively. As of this writing no voluntary industry standards or requirements for receiver performance to match these values exist.

The first mixer is a linear double-balanced design to minimize even harmonic generation, is driven by a synthesized low phase noise local oscillator (LO) above the first IF frequency (high-side injection). This mixer is followed by an LC filter in tandem with a narrow 920 MHz band-pass ceramic resonator filter. A 920 MHz IF amplifier is placed between the two filters. Delayed AGC of the first IF signal is applied immediately following the first LC filter. The AGC circuit is intended to protect the remaining active stages from large signal overload.

The second mixer is driven by the second LO, which is an 876 MHz voltage-controlled SAW oscillator. It is controlled by the frequency and phase locked loop (FPLL) synchronous detector. The second mixer, whose output is at the desired 44 MHz second IF frequency, drives a constant gain 44 MHz amplifier. The output of the tuner feeds the IF SAW filter and synchronous detection circuitry.

Carrier recovery is performed on the small pilot carrier by an FPLL circuit. The first LO is synthesized by a PLL. The third LO is a fixed reference oscillator. Control for the second LO comes from the FPLL synchronous detector, which contains both a frequency loop and a phase locked loop in one circuit. The frequency loop provides a wide frequency pull-in range of ± 100 kHz while the phase locked loop has a narrow bandwidth (less than 2 kHz).

During frequency acquisition, the frequency loop uses both the in-phase (I) and quadrature-phase (Q) pilot signals. All other data processing circuits in the receiver use only the I channel signal. Prior to phase-lock, as is the condition after a channel change, the automatic frequency control (AFC) low-pass filter acts on the beat signal created by the frequency difference between the VCO and the incoming pilot.

When the frequency difference comes close to zero, the APC loop takes over and phase-locks the incoming IF signal to the third LO. The correct phase-lock polarity is determined by forcing the polarity of the pilot to positive. Once locked, only the phase-locked loop is active. The APC low-pass filter is wide enough to allow ± 100 kHz frequency pull-in, yet narrow enough to consistently reject all strong white noise (including other DTV signals) and NTSC co-channel interference signals. The PLL has a bandwidth that is narrow enough to reject most of the AM and PM generated by the data, yet is wide enough to track out any phase noise on the signal (and, hence, on the pilot) out to about 2 kHz.

The repetitive data segment syncs are detected from among the synchronously detected random data by a narrow bandwidth filter. From the data segment syncs, a properly phased 10.76 MHz symbol clock is created along with a coherent AGC control signal.

The 10.76 Msymbols/s ($684 \div 286 \times 4{,}500{,}000$ Hz) I channel composite baseband data signal (syncs and data) from the synchronous detector is converted by an A/D converter for digital processing. A PLL is used to derive a 10.76 MHz symbol clock for the receiver.

With the PLL free-running, the data segment sync detector containing a 4-symbol sync correlator looks for the two level syncs occurring at the specified repetition rate. The repetitive segment sync is detected while the random data is not, enabling the PLL to lock on the sampled sync from the A/D converter, and achieve data symbol clock synchronization. Upon reaching a predefined level of confidence (using a confidence counter) that the segment sync has been found, subsequent receiver loops are enabled.

Data Field Sync detection is achieved by comparing each received data segment from the A/D converter (after interference rejection filtering to minimize co-channel interference) with ideal field #1 and field #2

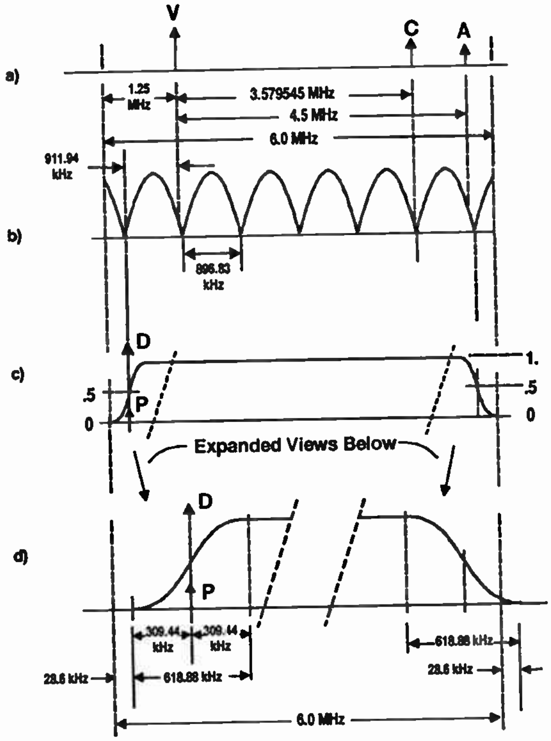

Figure 1.11-21. Location of NTSC carriers—comb filtering *(Source: ATSC Doc A/54).*

reference signals in the receiver. The field sync recovery circuit knows exactly where a valid field sync correlation should occur within each data segment, and only needs to perform a symbol-by-symbol difference.

NTSC Signal Rejection

The interference rejection properties of the VSB transmission system are based on the frequency location of the principal components of the NTSC co-channel interfering signal within the 6 MHz television channel and the periodic nulls of a VSB receiver baseband comb filter. Figure 1.11-21a shows the location and approximate magnitude of the three principal NTSC components: (1) the visual carrier (V) located 1.25 MHz from the lower band edge, (2) the chrominance subcarrier (C) located 3.58 MHz higher than the visual carrier frequency, and (3) the aural carrier (A) located 4.5 MHz higher than the visual carrier frequency.

The NTSC interference rejection filter (comb) is a one tap linear feed-forward filter, as shown in Figure 1.11-22. Figure 1.11-21b shows the frequency response of the comb filter, which provides periodic spectral nulls spaced 57 * f_H (10.762 MHz/12, or 896.85 kHz) apart. There are 7 nulls within the 6 MHz channel. The NTSC visual carrier frequency falls close to the second null from the lower band edge. The 6th null from the lower band edge is close to the NTSC chrominance subcarrier frequency, and the 7th null from the lower band edge is near the NTSC aural carrier.

Although the comb filter reduces the NTSC interference, the DTV datastream is also modified. The 7 data eyes (8 levels) are converted to 14 data eyes (15 levels). This conversion is caused by the partial response process which is a special case of intersymbol interference that does not close the data eye but creates double the number of eyes of the same magnitude. The trellis decoder can properly decode the modified DTV signal. Note that, because of sampling process, only the maximum data eye value is seen after A/D conversion.

NTSC interference can be detected by a circuit in which the signal-to-interference plus noise ratio of the binary Data Field Sync is measured at the input and the output of the comb filter, and then these values are compared. The comb filter is switched in and out of the system automatically, to achieve the lower interference energy.

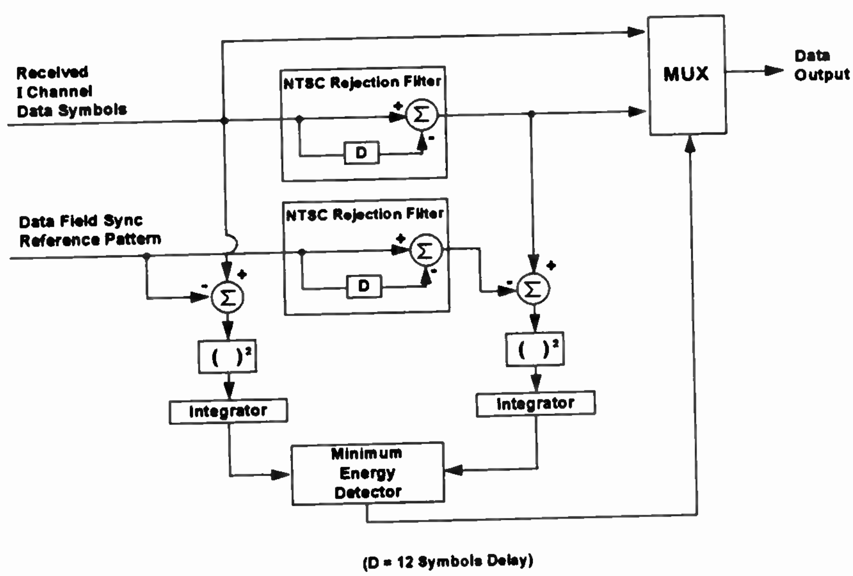

Figure 1.11-22. NTSC interference rejection filter *(Source: ATSC Doc A/54).*

There is a good reason to not leave the rejection comb filter switched in all the time. The comb filter, while providing needed co-channel interference benefits, degrades white noise performance by 3 dB. This is due to the fact that the filter output is the subtraction of two full-gain paths, and as white noise is uncorrelated from symbol to symbol, the noise power doubles. In addition, there is a further 0.5 dB of degradation due to the 12 symbol differential coding. When the NTSC service has been phased out, the comb filter can be omitted from the design.

The 8 VSB channel spectrum was illustrated in Figure 1.11- 17. This spectrum is fixed in frequency relative to the pilot carrier, but it may be slightly offset from the assigned 6 MHz channel, depending upon interference criteria. The FCC requires an offset with respect to a lower adjacent 6 MHz NTSC signal, such that the DTV pilot is 5.082138 MHz ± 3 Hz from the NTSC video carrier. This shifts the whole DTV spectrum up by 22.697 kHz. If the upper-adjacent signal is another DTV channel, its spectrum is expected to be shifted upward so that no spectral overlapping occurs. (Note that the FCC does not require this second shift). If the upper-adjacent signal is an NTSC signal, the shift of the DTV signal pushes part of the DTV spectrum out of its channel, but it is below the (RF equivalent of the) Nyquist slope of an NTSC receiver where there is high attenuation.

There are also offsets that have been determined to minimize interference to the DTV signal from a co-channel NTSC or DTV signal. The FCC does not require these offsets. The DTV pilot should be 911.944 kHz ± 1 kHz below a co-channel NTSC video carrier. This shifts the DTV spectrum up by 28.615 kHz. Finally, the DTV pilot should be 19.403 kHz ± 10 Hz from a co-channel DTV pilot carrier. Since there are three different interference minimizing offsets, there may be situations where they conflict. No guidance is available for that case.

When there is an NTSC neighbor, and the NTSC signal is currently assigned either a plus or minus 10 kHz offset, the absolute frequency of the DTV pilot would shift to maintain the offsets indicated above.

Equalizer

The equalizer/ghost canceller compensates for linear channel distortions, such as tilt and ghosts. These distortions can come from the transmission channel or from imperfect components within the receiver.

The equalizer uses a Least-Mean-Square (LMS) algorithm and can adapt on the transmitted binary Training Sequence as well as on the random data. The LMS algorithm computes how to adjust the filter taps in order to reduce the error present at the output of the equalizer. This algorithm can achieve equalization through three means: it can adapt on the binary training sequence, the data symbols throughout the frame when the eyes are open; or on data when the eyes are closed (blind equalization). The principal difference among these three methods is how the error estimate is generated.

For adapting on the training sequence, the training signal presents a fixed data pattern in the data stream. Because the data pattern is known, the exact error is generated by subtracting the training sequence from the output. The training sequence alone, however, may not be enough to track dynamic ghosts as these require tap adjustments more often than the training sequence is transmitted. Therefore, once equalization is achieved, the equalizer can switch to adapting on data symbols throughout the frame, and produce an accurate error estimate by slicing the data with an eight-level slicer and subtracting it from the output signal.

For fast dynamic ghosts (airplane flutter) it is necessary to use a blind equalization mode to aid in acquisition of the signal. Blind equalization models the multilevel signal as binary data signal plus noise, and the equalizer produces the error estimate by detecting the sign of the output signal and subtracting a (scaled) binary signal from the output to generate the error estimate.

To perform the LMS algorithm, the error estimate is multiplied by delayed copies of the signal. The delay depends upon which tap of the filter is being updated. This multiplication produces a cross-correction between the error signal and the data signal. The size of the correlation corresponds to the amplitude of the residual ghost present at the output of the equalizer and indicates how to adjust the tap to reduce the error at the output.

A block diagram of the equalizer is shown in Figure 1.11-23. The DC bias of the input signal is first removed by subtraction. The DC may be caused by circuit offsets, non-linearities or shifts in the pilot caused by ghosts. The DC offset is tracked by measuring the DC value of the training signal.

The equalizer filter consists of two parts, a 64 tap feed-forward transversal filter followed by a 192 tap decision feedback filter. The equalizer operates at the 10.762 MHz symbol rate (T-sampled equalizer).

The output of the forward filter and feedback filter are summed to produce the output. This output is sliced by either an eight level slicer (15 level slicer when the comb filter is used) or a binary slicer depending upon whether the data eyes are open or not. This sliced signal has the training signal and segment syncs reinserted as

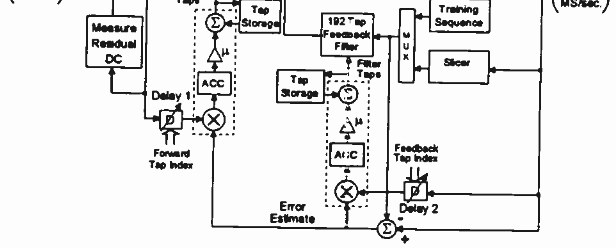

Figure 1.11-23. VSB receiver equalizer *(Source: ATSC Doc A/54)*.

these are fixed patterns of the signal. The resultant signal is fed into the feedback filter, and subtracted from the output signal to produce the error estimate. The error estimate is correlated with the input signal (for the forward filter), or by the output signal (for the feedback filter). This correlation is used to adjust the value of the tap. The delay setting of the adjustable delays is controlled according to the index of the filter tap that is being adjusted.

Phase Tracking Loop

The phase tracking loop is an additional decision feedback loop which further tracks out phase noise which has not been removed by the IF PLL operating on the pilot. Thus, phase noise is tracked out by not just one loop, but two concatenated loops. Because the system is already frequency locked to the pilot by the IF PLL (independent of the data), the phase tracking loop bandwidth is maximized for phase tracking by using a first order loop. As the phase tracker is operating on the 10.76 Msymbol/s data, the bandwidth of the phase tracking loop is fairly large, approximately 60 kHz.

Trellis Decoder

To help protect the trellis decoder against short burst interference, such as impulse noise or NTSC co-channel interference, 12 symbol code intrasegment interleaving is employed in the transmitter. As shown in Figure 1.11-24, the receiver uses 12 trellis decoders in parallel, where each trellis decoder sees every 12th symbol. This code interleaving has all the same burst noise benefits of a 12 symbol interleaver, but also minimizes the resulting code expansion (and hardware) when the NTSC rejection comb filter is active.

Before the 8 VSB signal can be processed by the trellis decoder it is necessary to suspend the Segment Sync. The Segment Sync is not trellis encoded at the transmitter.

The trellis decoder performs the task of slicing and convolutional decoding. It has two modes; one when the NTSC rejection filter is used to minimize NTSC co-channel, and the other when it is not used. The insertion of the NTSC rejection filter is determined automatically (before the equalizer), with this information passed to the trellis decoder. When there is little or no NTSC co-channel interference, the NTSC rejection filter is not used, and an optimal trellis decoder is used to decode the four state trellis encoded data. Serial bits are re-created in the same order in which they were created in the encoder.

When the NTSC rejection filter is employed, a trellis decoder optimized for this partial response channel is used. This optimal code requires eight states. In order to minimize the expansion of trellis states, two measures are taken: (1) special design of the trellis code, and (2) twelve-to-one interleaving of the trellis encoding. The interleaving, which corresponds exactly to the 12 symbol delay in the NTSC rejection filter, makes it so that each trellis decoder only sees a one-symbol delay NTSC rejection filter. By minimizing the delay stages seen by each trellis decoder, the expansion of states is also minimized.

Data De-interleaver

The convolutional de-interleaver performs the exact inverse function of the transmitter convolutional interleaver. Its 1/6 data field depth, and intersegment dispersion properties allow noise bursts lasting about 193 σs to be handled. The de-interleaver uses Data Field Sync for synchronizing to the first data byte of the data field. The convolutional de-interleaver is shown in Figure 1.11-25.

Reed-Solomon Decoder

The trellis decoded byte data is sent to the (207,187) t = 10 RS decoder, where it uses the 20 parity bytes to perform the byte-error correction on a segment-by-segment basis. Up to 10-byte errors per data segment are corrected by the RS decoder. Any burst errors created by impulse noise, NTSC co-channel interference, or trellis decoding errors, are greatly reduced by the combination of the interleaving and RS error correction.

Data Derandomizer

A Pseudo Random Sequence (PRS) randomizes the data at the transmitter. The derandomizer accepts the error-corrected data bytes from the RS decoder, and applies the same PRS randomizing code to the data.

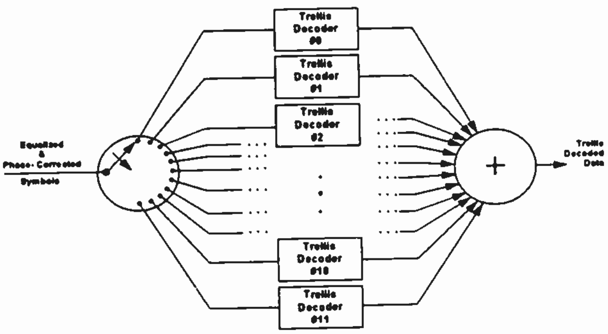

Figure 1.11-24. Trellis code de-interleaver *(Source: ATSC Doc A/54).*

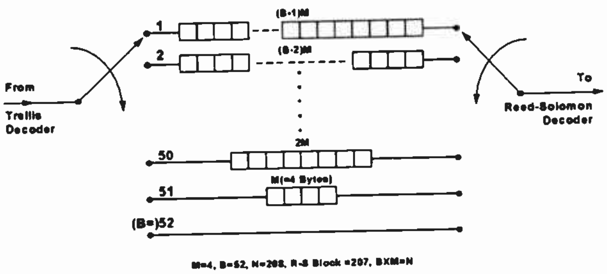

Figure 1.11-25. Convolutional de-interleaver *(Source: ATSC Doc A/54).*

The PRS code is generated identically as in the transmitter. Since the PRS is locked to the recovered Data Field Sync, it is exactly synchronized with the data.

PROGRAM AND SYSTEM INFORMATION PROTOCOL (PSIP)

The heart of the method to select one of the services in the DTV multiplex is a global assignment of a major_channel_number for each broadcaster and another number for each service which is locally controlled (minor_channel_number). The standard calls for the major channel to be the NTSC channel number of the station. The RF channel used for the (officially) minor facility change to add DTV broadcast capability is hidden from the consumers. The programs in the DTV multiplex are selected through a virtual channel mechanism, which the consumer sees as a second channel number (minor_channel_number). The DTV multiplex will carry program/service information about both the DTV programs (and data) and the current NTSC channel in a construct known as Program and System Information Protocol (PSIP) for terrestrial broadcast and cable.

The PSIP industry standard (ATSC document A/65) is a small collection of tables designed to operate within every transport stream for terrestrial broadcast of digital TV. It also contains tables for use by cable TV for the same purposes. It is needed so that consumers can select a TV program. PSIP is the result of combining and compacting the original two optional ATSC protocols: A/55 and A/56, whose implementation was difficult due to their structural differences and their overlapping definitions. PSIP solves this problem and establishes a channel tuning method that is uniform across terrestrial broadcast and cable. The tables defined in PSIP use packet identifiers (PIDs) that are different from those specified by the optional A/55 and A/56 standards that have in effect been superseded. The program paradigm is also superseded, and though its continued use is not precluded, its use does consume a significant portion of the PID number space.

An important feature of terrestrial broadcasting is that sources follow a distributed information model rather than a centralized one. Unlike cable or satellite, service providers are geographically distributed and have no interaction with respect to data unification or even synchronization. It was necessary to develop a protocol for describing system information and event descriptions that could be followed by every organization in charge of a physical transmission channel. System information allows navigation and access to each of the channels within the transport stream, whereas event descriptions give the user content information for browsing and selection. Meeting the needs of cable systems was a significant consideration, and both distribution systems requirements appear to be met. Work on extension of PSIP for satellite distribution has begun.

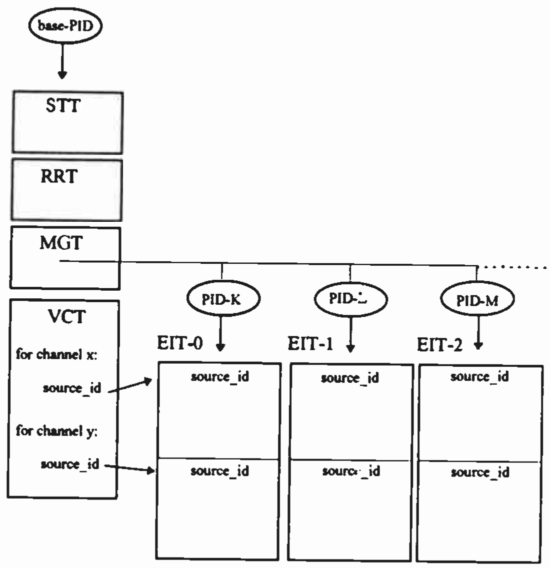

Figure 1.11-26. Main structure for the PSIP tables *(Source: ATSC Doc A/65).*

Elements of PSIP

PSIP is a collection of hierarchically-associated tables each of which describes particular elements of typical digital TV services. Figure 1.11-26 and Figure 1.11-27 show the different components and the notation used to describe them. The base tables are: the System Time Table (STT), the Rating Region Table (RRT), the Master Guide Table (MGT) and the Virtual Channel Table (VCT). A second set of tables includes the Event Information Tables (EIT) whose PIDs are defined in the MGT. A third set of tables includes the Extended Text Tables (ETT), and similarly, their PIDs are defined in the MGT.

The System Time Table (STT) is a small data structure that fits in one packet and serves as a reference for time of day. Receivers can use this table as a timing reference for start times of advertised events. System time for DTV is based on GPS and is a count of seconds since 12:00 a.m., January 6, 1980. The standard requires accuracy of ±4 seconds at the receiver, implying higher, but undefined, accuracy at the station.

The Rating Region Table (RRT) has been designed to communicate the definition of the selected

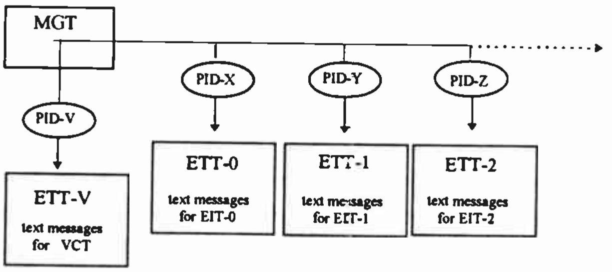

Figure 1.11-27. Extended text tables in the PSIP hierarchy. *(Source: ATSC Doc A/65)*

rating standard(s), such as the MPAA or the recently introduced television rating system. It has enough free space to include future developments, and it can also incorporate multiple multi-country aggregates definitions (to serve multiple countries or groups of countries simultaneously).

The Master Guide Table (MGT) provides general information about all of the other tables that comprise the PSIP standard. It defines table sizes necessary for memory allocation during decoding and version numbers to identify those tables that need to be updated. It also gives the PIDs which label the tables.

The Virtual Channel Table (VCT), also referred to as the Terrestrial VCT (TVCT), contains a list of all the channels that are or will be on-line, plus their attributes. Among the attributes are the channel name, navigation identifiers, stream components and types, etc.

As part of PSIP there are several EITs, each of which describes the events or TV programs associated with each of the virtual channels listed in the VCT. Each EIT is valid for a time interval of three hours. Since the total number of EITs is 128, up to 16 days of programming may be advertised in advance. EIT-0 always denotes the current three hours of programming, EIT-1 the next three hours, and so on. As a minimum, the first four EITs must always be present in every transport stream.

Start times for EITs are constrained to be one of the following Universal Coordinated Time (UTC) times: 0:00 (midnight), 3:00, 6:00, 9:00, 12:00 (noon), 15:00, 18:00, and 21:00. Imposing constraints on the start times as well as the interval duration is necessary for the purpose of re-multiplexing. During re-multiplexing, EIT tables coming from several distinct transport streams may end up grouped together or vice versa. If no constraints were imposed, re-multiplexing equipment would have to parse EITs by content in real time, which is a difficult task.

For example, consider a broadcast corporation operating in the Eastern time Zone of the U.S. This corporation decides to carry 6 EITs (18 hours of TV program information). If at present, the Eastern Time is 15:30 EDT (19:30 UTC), then the coverage times for the EIT tables are given in Table 1.11-5.

The abbreviation "nd" denotes next day. Before 17:00 EDT, the MGT will list the currently valid PIDs as: 123, 190, 237, 177, 295, and 221. At 17:00 EDT,

Table 1.11-5

An Example of EIT Coverage TimesTable

EIT number	Version Num.	Assigned PID	Coverage (UTC)	Coverage (EDT)
0	6	123	18:00–21:00	14:00–17:00
1	4	190	21:00–24:00	17:00–20:00
2	2	237	0:00–3:00	20:00–23:00
3	7	177	3:00–6:00	23:00–2:00 (nd)
4	8	295	6:00–9:00	2:00 (nd)–5:00 (nd)
5	15	221	9:00–12:00	5:00 (nd)–8:00 (nd)

(Source: ATSC Doc A/65)

table EIT-0 will become obsolete while the other ones will remain valid. At that time, the PID list can be changed to 190, 237, 177, 295, 221, maintaining the version number list as 4, 2, 7, 8, 15. Therefore, by simply shifting the listed PID values in the MGT, table EIT-1 can become EIT-0, table EIT-2 can become EIT-1, and so on.

However, it is also possible to regenerate one or several EITs at any time for correcting and/or updating the content (in cases where to be assigned events become known). Regeneration of EITs is flagged by updating version fields in the MGT. For example, if table EIT-2 needs to be updated at 16:17 EDT, then the new table must be transmitted with a version number equal to 3. Whenever the decoder monitoring the MGT detects a change in the version number of a table, it assumes that the table has changed and needs to be reloaded.

As illustrated in Figure 1.11-27, there can be several Extended Text Tables (ETTs), each of them having its PID defined in the MGT. Each EIT can have one ETT. Similarly, the VCT can have one ETT. As its name indicates, the purpose of an Extended Text Table (ETT) is to carry text messages. For example, for channels in the VCT, the messages can describe channel information, cost, coming attractions, etc. Similarly, for an event such as a movie listed in the EIT, the typical message is a short paragraph that describes the movie itself. ETTs are optional.

The minimum amount of information required in an ATSC terrestrial digital transport stream is the VCT, the MGT, the RRT, the STT, and the first four EITs. All of the other elements are optional.

PSIP Application Example

For the purpose of this example, assume that a broadcast station, here denominated NBZ, manages the frequency bands for RF channels 12 and 39. The first one is its analog channel whereas the second one will be used for digital broadcast. According to the premises established in A/65, NBZ must carry the PSIP tables in the digital transport stream of RF channel 39. The tables must describe TV programs and other services provided on RF channel 39 but can also describe information for the analog RF channel 12.

Assume that NBZ operates in the Eastern time zone of the U.S., and that the current time is 15:30 EDT (19:30 UTC). NBZ decides to operate in minimal configuration, therefore only the first four EITs need to be transmitted. As explained previously, EIT-0 must carry event information for the time window between 14:00 and 17:00 EDT, whereas EIT-1 to EIT-3 will cover the subsequent nine hours. For the first six hours, the scenarios presented in Table 1.11-6 and in Table 1.11-7 apply.

Similar tables can be built for the next six hours (for EIT-2 and EIT-3). According to this scenario, NBZ broadcasts four regular digital channels (also called virtual channels and denoted as VC), one matching the analog transmission (simulcast), another for sports, and a third one for movies. The fourth one

The Master Guide Table (MGT)

The purpose of the MGT is to describe everything about the other tables, listing features such as version numbers, table sizes and PIDs. Figure 1.11-28 shows a typical MGT indicating, in this case, the existence in the transport stream of a VCT, the RRT, four EITs, one ETT for channels, and two ETTs for events.

The first entry of the MGT describes the version number and size of the VCT. The second entry corresponds to an instance of the RRT. If some region"s policy makers decided to use more than one instance of an RRT, the MGT would list each PID, version number, and size.

The next entries in the MGT correspond to the first four EITs that must be supplied in the transport stream. The user is free to choose their PIDs as long as they are unique in the MGT list of PIDs. After the EITs, the MGT indicates the existence of an ETT for channels carried using PID 0x1AA0. Similarly, the last two entries in the MGT signal the existence of two ETTs, one for EIT-0 and the other for EIT-1.

Descriptors can be added for each entry as well as for the entire MGT. By using descriptors, future improvements can be incorporated without modifying the basic structure of the MGT. The MGT is like a flag table that continuously informs the decoder about the status of all the other tables (except the STT which has an independent function). The MGT is continuously monitored at the receiver to prepare and anticipate changes in the channel/event structure. When tables are changed at the broadcast side, their version numbers are incremented and the new numbers are listed in the MGT. Based on the version updates and on the memory requirements, the decoder can reload the newly defined tables for proper operation.

MGT

table_type	PID	version num.	table size
VCT	0x1FFB (base_PID)	4	485 bytes

ETT-1	0x1BA1	2	42734 bytes

Figure 1.11-28. Content of the master guide table. *(Source: ATSC Doc A/65)*

The Virtual Channel Table (VCT)

Figure 1.11-29 shows the structure of the VCT that essentially contains the list of channels available in the transport stream. For convenience, it is possible to include analog channels and even other digital channels found in different transport streams.

The field number_channels_in_section indicates the number of channels described in one section of the VCT. In normal applications, as in the example being considered here, all channel information will fit into one section. However, there may be rare times when most of the physical channel is used to convey dozens of low-bandwidth services such as audio only and data channels in addition to one video program. In those cases, the channel information may be larger than the VCT section limit of 1 kB and therefore VCT segmentation will be required.

VCT

current_next_indicator = 1
number_channels_in_section = 5

major num.	minor num	short name	carrier freq. (MHz)	channel TS ID	progr. num	flags	service type	source id	descriptors
12	0	NBZ	205.25	0x0AA0	0x0AA0	--	analog	20	ch_name
12	1	NBZD	620.31	0x0AA1	0x00F1	--	digital	21	ch_name serv_locat.
12	5	NBZ-S	620.31	0x0AA1	0x00F2	--	digital	2	ch_name serv_locat.
12	12	NBZ-M	620.31	0x0AA1	0x00F3	--	digital	23	ch_name serv_locat.
12	31	NBZ-H	620.31	0x0AA1	0x00F8	--	digital	24	ch_name serv_locat.

Figure 1.11-29. Content of the virtual channel table. *(Source: ATSC Doc A/65)*

For example, assuming that a physical channel conveys 20 low-bandwidth services in addition to a TV program, and assuming that their VCT information exceeds 1 kB, then two or more sections may be defined. The first section may describe 12 virtual channels and the second 9 if such a partition leads to VCT sections with less than 1 kB.

A new VCT containing updated information can be transmitted at any time with the version_number increased by one. However, since a VCT describes only those channels from a particular transport stream, virtual channels added to the VCT at arbitrary times will not be detected by the receiver until it is tuned to that particular transport stream. For this reason, it is highly recommended that channel addition be made in advance to give the receivers the opportunity to scan the frequencies and detect the channel presence.

The fields major_channel_number and minor_channel_number are used for identification. The first one, the major channel number, is used to group all channels that are to be identified as belonging to a particular broadcast corporation (or particular identifying number such as 12 in this case). The minor channel number specifies a particular channel within the group.

The field short_name is a seven character name for the channel and may allow text-based access and navigation. The fields transport_stream_id and program number are included to link the VCT with the PAT and PMT. A sequence of flags follows these fields. The flags indicate: (1) if the channel is hidden (for NVOD applications), (2) if the channel has a long text message in the VCT-ETT and (3) if the channel is visible in general or has some conditional access constraints.

After the flags, a description of the type of service offered is included, followed by the source_id. The source_id is simply an internal index for representing the particular logical channel. EITs and ETTs use this number to provide a list of associated events or text messages respectively.

Two descriptors are associated with the logical channels in the example. The first one is extended_channel_name and, as its name indicates, it gives the full name of the channel. An example for channel NBZ-S could be: "NBZ Sports and Fitness." The other one, the service_location descriptor, is used to list the available bit streams and their PIDs necessary to decode packets at the receiver. Assuming that NBZ-M offers bilingual transmission, then the following attributes are tabulated within its service_location descriptor:

PID_audio_1	AC-3 audio	English
PID_audio_2	AC-3 audio	Spanish
PID_video	MPEG-2 video	No lang

Another method would be to provide a separate minor channel and bit entry to advertise availability of the second language as a separate program. A maximum of two VCTs may exist simultaneously in a transport stream: the current and the next VCT. The current VCT is recognized by having the flag current_next_indicator set to 1, while the next one has this flag set to 0. Although carrying the next VCT is optional, its

EIT- 0
source_id = 22 (NBZ-S instance)

num_events_in_section = 3

event ID	start time	length (seconds)	ETM location	title	descriptors

52	14:30	3600	00	Golf Report	closed_caption
53	15:30	9000	01	Car Racing	content_advisory

Figure 1.11-30. Content of EIT-0 for NBZ-S. *(Source: ATSC Doc A/65)*

use is recommended to give receivers advance notification of the new parameters that become operational during a VCT update.

Assume for example that a transport stream contains a VCT with a version number of 6 which has been operational for 20 hours. At 10:00 p.m., a football game using much more bandwidth will be broadcast, and for this reason, the number of available channels and PIDs will be redefined. A few minutes before the change (10:00 p.m. in this example) simultaneous transmission of the next VCT can start with a version number of 7. By continuously monitoring the MGT, a receiver can be informed that a next VCT is available. The receiver may want to cache the new VCT for future use. The receiver continues monitoring the MGT and when this table signals a version change for the current VCT (from 6 to 7), then the cached information can be used.

When the VCT refers to an analog service type, the channel_TSID TSID cannot refer to the identifier of a transport stream in the MPEG-2 sense. Analog NTSC broadcast signals can, however, carry a 16 bit unique identifier called a *Transmission Signal Identifier.*[12] For the example VCT in Figure D.4, the Transmission Signal Identifier for channel 12.0 is 0x0AA0. A receiver can use the Transmission Signal ID given in the analog channel's channel_TSID field to verify that the NTSC signal received at the frequency given in the VCT is actually the desired signal. In the case that the Transmission Signal ID is not known or not available, the channel_TSID field may contain 0xFFFF to indicate "unknown."

The Event Information Tables (EITs)

The purpose of an EIT is to list all events for those channels that appear in the VCT for a given time window. As mentioned before, EIT-0 describes the events for the first 3 hours, EIT-1 for the next 3 hours, and so on. EIT-i and EIT-j have different PIDs as defined in the MGT. In PSIP, tables can have a multitude of instances. The different instances of a table share the same table_id value and PID but use different table_id_extension values.

In PSIP, an instance of EIT-k contains the list of events for a single virtual channel with a unique source_id. For this reason, the table_id_extension has been renamed as source_id in the EIT syntax. Figure 1.11-30 shows, for example, the NBZ-S instance for EIT-0. Following similar procedures, the NBZD, NBZ-M, and NBZ-H instances of EIT-0 can be constructed. The process can be extended and repeated to obtain all of the instances for the other tables in the time sequence: EIT-1, EIT-2, etc.

The three events programmed for the 3-hour period for NBZ-S are listed in Figure 1.11-30. The field event_id is a number used to identify each event. If an event time period extends over more than one EIT, the same event_id has to be used. The event_id is used to link events with their messages defined in the ETT, and therefore it has to be unique only within a virtual channel and a 3-hour interval defined by EITs. The

[12] EIA has standardized the Transmission Signal Identifier in EIA-752 *Transport of Transmission Signal Identifier (TSID) Using Extended Data Service (XDS).* This standard defines how to carry the analog TSID in a new XDS packet, within the Channel Information class.

event_id is followed by the start_time and then the length_in_seconds. Notice that events can have start times before the activation time of the table. The ETM_location specifies the existence and the location of an Extended Text Message (ETM) for this event. ETMs are simply long textual descriptions. The collection of ETMs constitutes an ETT.

An example of an ETM for the car racing event may be:

> Live coverage from Indianapolis. This car race has become the largest single-day sporting event in the world. Two hundred laps of full action and speed.

Several descriptors can be associated with each event. One of these is the content advisory descriptor that assigns a rating value according to one or more systems. Recall that the actual rating system definitions are tabulated within the RRT. When a closed caption descriptor is included, it signals the existence of closed captioning and lists the necessary parameters for decoding.

The details of the information carried in the closed captioning field are specified in EIA-708, *Advanced Television Closed Captioning*. EIA-708 also defines how to carry the current EIA-608 closed captions. It also defines a new set of captions which are based on a window concept with color, shading, backgrounds and positioning information to take advantage of the ten-fold increase in data rate allocated to closed captioning in DTV.

EIA-708 is intended primarily for receiver and captioning encoder manufacturers. It describes a layered protocol stack starting from the transport layer and moving up to an interpretation layer which generally corresponds to the application layer in the OSI stack. It contains a description of the transport method, the new data packets and their structures, specification of how the captioning data is to be processed, minimum implementation requirements for receivers, and a set of recommended practices for encoder and decoder manufacturers.

Note that EIA-708 was completed before A/65 was completed, so it referenced T3/S8-145, which was incorporated into A/65. The location of the caption service descriptor in the DTV multiplex changed after EIA-708 was approved, obsoleting some descriptive references, but not the functionality. From a broadcaster perspective, one should expect that program material may have either 608 style closed captions or 708 style captions, or both. It is expected that if 708 style captions are present then 608 style captions will typically also be present. Standards for how to transport/store this data in pre-encoded material have not been completed.

1.12

EAS STANDARD

DAVID E. WILSON
NATIONAL ASSOCIATION OF BROADCASTERS, WASHINGTON, DC

INTRODUCTION

The primary purpose of the Emergency Alert System (EAS) is to provide a means for the President to communicate quickly with all citizens of the United States in the event of a national emergency. However, like its predecessor the Emergency Broadcast System (EBS), the EAS is most often activated for state, local and regional emergencies. Over-the-air broadcast stations provide the most important link in this system—the link that enables the emergency message to be simultaneously received by a large, yet locally targeted audience of both stationary and mobile individuals.

The FCC required EAS equipment to be installed and operational in all over-the-air broadcast stations beginning January 1, 1997. Cable systems that serve 10,000 or more subscribers must have EAS equipment installed and operational by December 31, 1998, and all others by October 1, 2002.

This chapter will analyze the EAS from four different perspectives. First, the modulation method used to generate the EAS signal will be discussed, including the four different tones and audio information that make up the EAS signal. Next, the coding structure used to create the digital message will be described. It is this digital coding that is the primary improvement of the EAS over the old EBS. Third, a description of how each party that participates in the EAS relates to each of the other parties participating in the system will be provided. Finally, the EAS responsibilities of individual broadcasters will be explained.

Modulation method

An EAS message consists of four elements in the following order: digital header code, two-tone attention signal, audio message describing the actual alert and digital end-of-message code. The components of an EAS message are illustrated in Figure 1.12-1. There are four different tones used to create an EAS message. Their frequencies are 853 Hz, 960 Hz, 1562.5 Hz and 2083.3 Hz, respectively. The first two tones are the same ones that were used to produce the well-known two-tone attention signal in the old EBS. They are used to produce the same two-tone signal in the EAS, although their duration is not as long as it was under the EBS—and they are used less frequently. The second two tones are used to produce the digital header and end-of-message codes, which are the principal improvements of the new EAS over the old EBS.

In the digital header and end-of-message codes the 2083.3 Hz tone represents a mark (or "1") and the 1562.5 Hz tone represents a space (or "0"). When a digital bit is transmitted, its associated tone is transmitted for precisely 1.92 msec, which is the amount of time it takes to transmit exactly three cycles of the 1562.5 Hz tone, and four cycles of the 2083.3 Hz tone. Figure 1.12-2 illustrates, in the time domain, how these tones can be merged together to create an 8-bit digital byte—or one ASCII character. The character depicted in Figure 1.12-2, for example, is the capital letter "U," as defined in ANSI X3.4-1977, which is the ASCII character set standard referenced in the FCC's EAS rules. In this form of ASCII text transmission, the least significant bit is transmitted first and the most significant (seventh) bit is transmitted last followed by an eighth null bit (either 0 or 1) to create an 8-bit byte. Thus, in Figure 1.12-2, the character being transmitted is "X1010101" which corresponds to the decimal ASCII character value of 85, and the capital letter "U."

The two-tone attention signal is produced by simultaneously transmitting an 853 Hz tone and a 960 Hz tone. Figure 1.12-3 is an illustration of the composite two-tone signal.

When the digital components of an EAS message are transmitted FCC rules require that they modulate the transmitter at no less than 80% of full channel modulation. When the two-tone attention signal is transmitted FCC rules require that each individual tone modulate the transmitter at no less than 40% of full

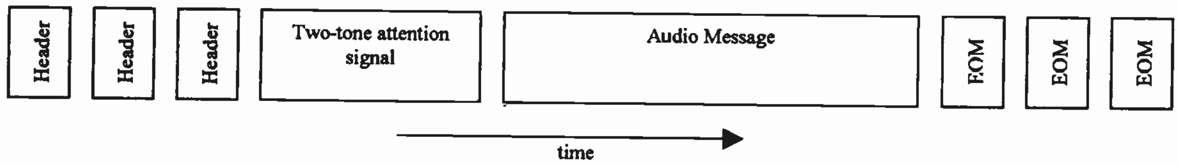

Figure 1.12-1. The primary elements of an EAS message.

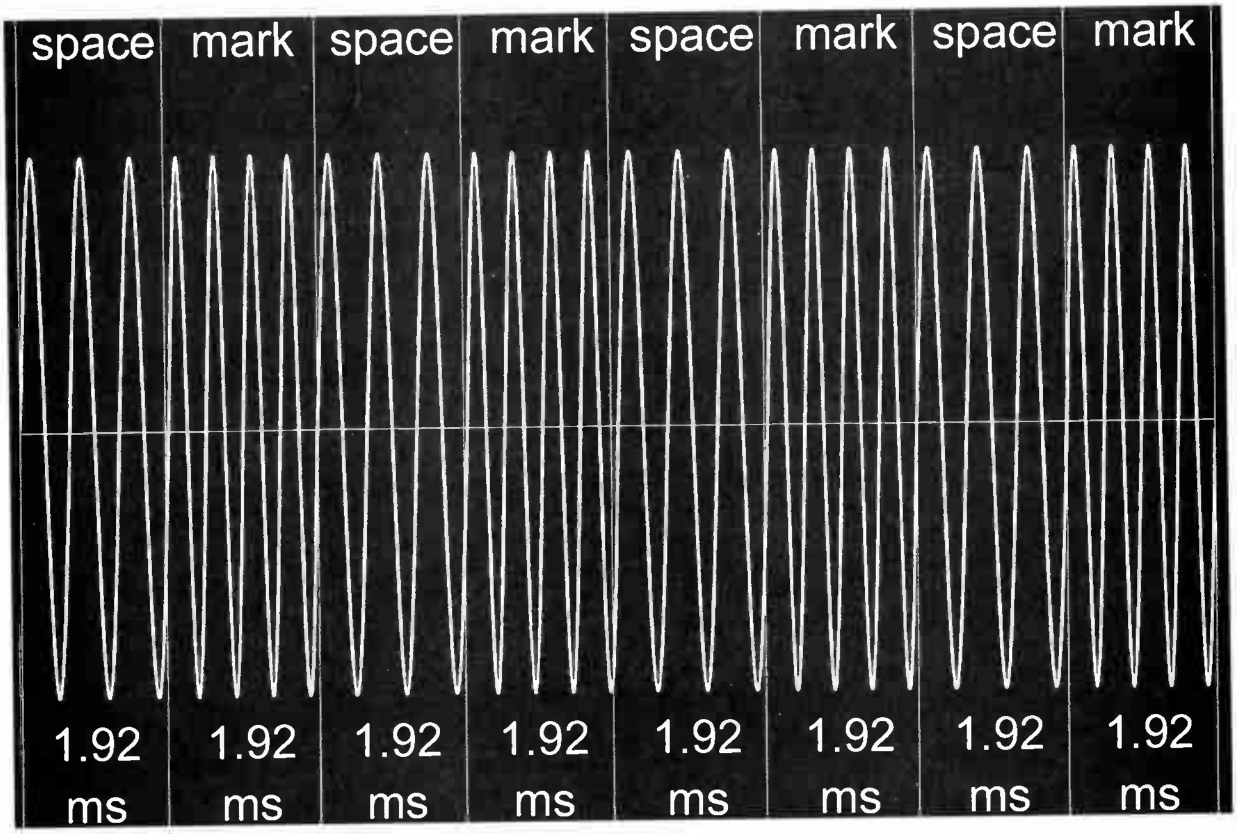

Figure 1.12-2. Time domain illustration of an EAS digital byte.

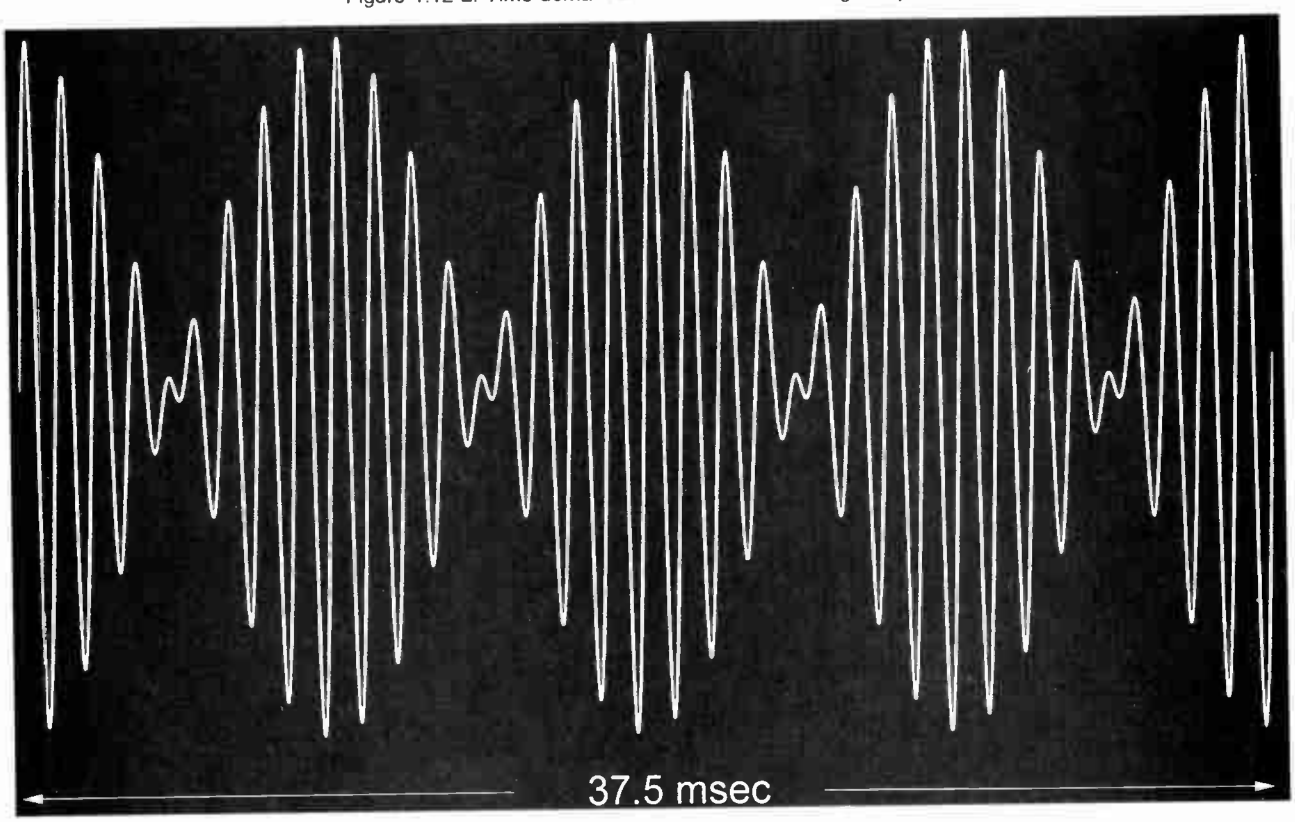

Figure 1.12-3. Time domain illustration of two-tone EAS attention signal.

channel modulation—and that the modulation levels of the two tones be within one dB of one another. When the audio portion of an EAS message is transmitted, it is subject to the same modulation requirements as the station's normal audio programming. This means that, for AM, FM and TV stations, the modulation level of the audio portion of an EAS message should be no less than 85% on peaks of frequent recurrence.

None of the components of an EAS message should exceed the maximum modulation limits specified for the relevant service. For AM stations, the maximum modulation level is 100% on negative peaks of frequent recurrence and 125% on positive peaks of frequent recurrence. For FM and TV stations the maximum modulation level is 100% on peaks of frequent recurrence—except that FM stations may increase their total modulation 0.5% for every 1% of subcarrier injections, up to a maximum level of 110% total modulation.

Coding Method

The header codes and the end-of-message codes in an EAS message are composed of a series of digital bytes and are transmitted using the 1562.5 Hz and 2083.3 Hz tones. The header and end-of-message codes are each repeated three times to ensure that they are received correctly. (For all EAS transmissions *except* the weekly test, television stations must transmit the header code data both aurally *and* visually. If they use a video crawl to do this, the crawl must be displayed at the top of the television screen or at another location where it will not interfere with other visual messages such as closed captioning.) The two-tone attention signal is created by simultaneously transmitting the 853 Hz and 960 Hz tones, and it is the same two-tone signal that was used in the old EBS. The actual audio message is simply an audio signal. The possibility exists that video and/or text messages may be transmitted in place of the audio message in the future, and television stations may, if they wish, transmit related video to accompany the audio message.

Except for the actual audio message itself the header is the portion of the EAS message that contains the most information. The two-tone attention signal is not intended to serve any other purpose than to audibly alert the audience that an EAS message is about to be broadcast, and the end-of-message code is simply a series a four ASCII "N" characters used to indicate that the alert is over and that the EAS equipment should reset itself to its normal, non-alert state. Both the header and end-of-message codes are each preceded by a preamble which is a string of 16 bytes (128 bits) consisting of ASCII character 171 ("$\frac{1}{2}$") repeated 16 times. The purpose of this preamble is to prepare EAS receivers to accept data by setting their automatic gain control (AGC) circuits and asynchronous clocking cycles.

Table 1.12-1
EAS Originator Codes

Originator	Originator Code
Broadcast station or cable system	EAS
Civil authorities	CIV
Emergency Action Notification Network	EAN
National Weather Service	WXR
Primary Entry Point System	PEP

The header code contains 42 bytes of information, which are illustrated in Figure 1.12-4. The first code segment in the header code consists of the characters "ZCZC" which indicates that an ASCII code sequence is about to begin. The next code segment is the Originator Code, which indicates who initiated activation of the EAS for the particular alert in question. The list of acceptable Originator Codes is provided in Table 1.12-1. The Event Code, which follows the Originator Code, indicates the type of emergency that is the subject of the alert. The Event Codes used in the EAS are the same ones defined in the Specific Area Message Encoder (SAME) standard used by the National Weather Service (see Table 1.12-2). Following the Event Code is the Location Code which indicates the state, county, and county subdivision (northwest, south central, etc.) that is affected by an EAS alert. The valid values for the three segments of the Location Code are described in Tables 1.12-3a, 3b and 3c. The FCC expects most alerts to have a Location Code that shows the alert to be effective over an entire county. It only expects the county subdivision feature to indicate something other than the entire county in cases involving oddly shaped or unusually large counties. The Valid Time Period of the alert, in HHMM format follows the Location Code. It indicates the length of time after the origination of the alert during which it is effective. The Valid Time Period of an EAS alert must be in 15 minute increments for periods that are no longer than an hour, and 30 minute increments for periods that are longer than an hour. The Origination Time of the alert follows the valid time period. It is in JJJHHMM format where JJJ represents the day of the year in Julian Calendar days (July 4 would be 185 in a non-leap year), and HHMM is in 24-hour format

(10:00 PM is 22:00). Following the Origination Time is the Transmitting Station Identifier. This is the identification of the station transmitting the alert-not the station that originated the alert-but the station that is actually transmitting, or retransmitting it. When the EAS is activated, and an alert is making its way through the web network of stations, the Transmitting Station Identifier will be the only part of the header that gets changed as the message is relayed from one station to the next. All other components of the header will remain unchanged.

ASCII character 45, the dash/hyphen character (-), is used at the end of all but one of the code segments within the header code as a separator. The Location Code ends with ASCII character 43, the plus character (+).

Clearly, the EAS header code contains enough information to enable the receiving broadcast station to generate its own audible emergency message. Many stations choose to do this simply because they prefer to have their own announcers provide the emergency information to their audiences. During national level alerts and the required monthly test, however, stations are required to rebroadcast the audio that they receive without modification. One of the advantages of using the received audio for state and local emergencies is that, in some cases, the audio portion of the EAS message received by a station may contain more information than the header alone. For example, the header might indicate that there is a tornado watch for a particular county, but the audio portion of the received alert might indicate that a tornado has actually touched down at a particular location in the county.

SYSTEM ORGANIZATION

One of the primary improvements of the EAS over the old EBS is that it is generally more reliable since it utilizes a web structure instead of a daisy chain structure to connect all of the system's participants. In the EBS, each broadcast station was assigned one other station to monitor. In the EAS each station is

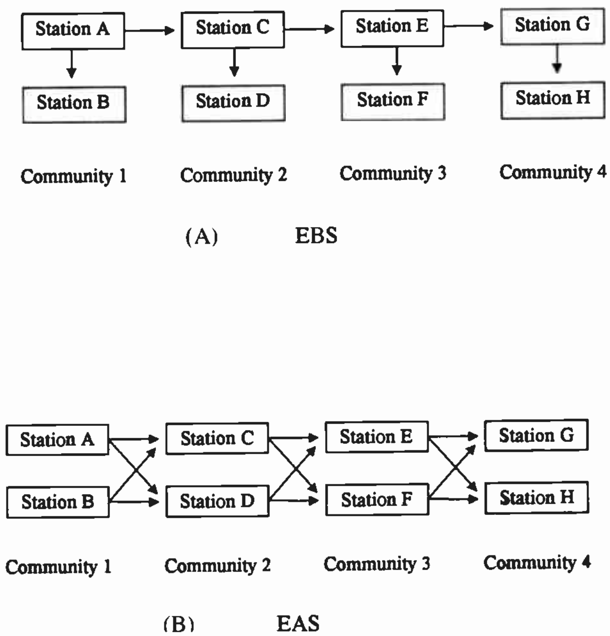

Figure 1.12-5. Comparison of emergency networks: (A) EBS system, (B) EAS system.

assigned two other stations to monitor. An example of how this design change can impact the effectiveness of the emergency network is illustrated in Figure 1.12-5.

As shown in the Figure 1.12-5 example, under the EBS there was only one path that an emergency message would take to get to Station H:

$$A \rightarrow C \rightarrow E \rightarrow G \rightarrow H$$

However, under the EAS there are eight different paths that a message takes to get to Station H:

$$A \rightarrow C \rightarrow E \rightarrow H$$
$$A \rightarrow C \rightarrow F \rightarrow H$$
$$A \rightarrow D \rightarrow E \rightarrow H$$
$$A \rightarrow D \rightarrow F \rightarrow H$$
$$B \rightarrow C \rightarrow E \rightarrow H$$
$$B \rightarrow C \rightarrow F \rightarrow H$$
$$B \rightarrow D \rightarrow E \rightarrow H$$
$$B \rightarrow D \rightarrow F \rightarrow H$$

The actual improvement in network dependability for any particular station depends on how far down the chain it was under the old EBS, and what stations it has been assigned to monitor under the new EAS. However, Figure 1.12-5, provides a general explanation of why the web structure of the new EAS is an improvement over the old system.

In the EAS, all broadcast stations fall into one of six basic categories: National Primary (NP) source, State Primary (SP) source, State Relay (SR) source, Local Primary (LP) source, Participating National (PN) source or Non-participating National (NN) source. The decisions regarding what type of source an individual station will be and what stations it must monitor are made by its State Emergency Communications Committee (SECC). Some localities may also have a Local Emergency Communications Committee (LECC) that specifies procedures for local emergencies. SECCs and LECCs are made up mostly of broadcasters who serve on a voluntary basis. These committees develop the state and local emergency communications plans for their regions. Their plans must first be approved by the FCC before they can go into effect. Once approved by the FCC a state plan, or a state plan amendment, is incorporated into the FCC's EAS mapbook for that state. The FCC mapbook for a state lists all of the broadcast stations in the state organized by their EAS local area and any special designations needed to identify each station's role in the EAS. Broadcasters who would like a copy of the FCC EAS mapbook for their state should contact the FCC's EAS Office.

The FCC Rules do give stations the option to decline to participate in the EAS. Non-participating national stations however, are still required to have EAS encoders/decoders, and they are still required to monitor two EAS sources and perform weekly and monthly tests. They must also transmit both the digital EAS codes and the two-tone attention signal during a national level alert. The only difference between a PN station and a NN station is that, during a national alert, and immediately following broadcast of the two-tone attention signal, the NN station must turn its transmitter off instead of broadcasting the actual audible alert. The NN station may only turn its transmitter back on again after the national alert is over. NN stations are not required to go off the air at all during state or local alerts-and they may participate in state or local alerts if they wish. Stations that opt to become NN sources must provide written notification of their decision to the FCC's EAS Office.

The EAS network from the perspective of a local community is illustrated in Figure 1.12-6. There are three possible entry points where an EAS alert can begin:

1. The federal government can initiate a message by feeding it to a NP source. Presently, all NP sources are broadcast stations.
2. State governments can initiate EAS messages by feeding them into SP sources. Typically, an SP source will be located in the state capital—though it can be located anywhere within the state. Most states are large enough that a single broadcaster's

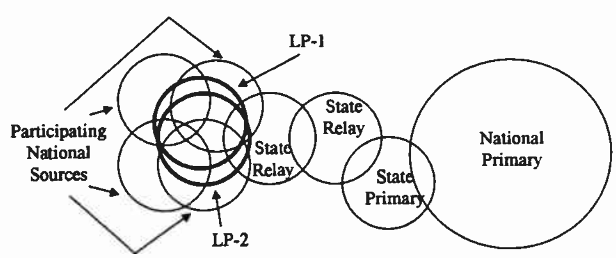

Figure 1.12-6. Typical geographic relationship of stations in the EAS network.

signal cannot cover the entire state. In these situations, it is necessary to have relay stations that pick up state level alerts and relay them out to distant counties. These relay stations are called, not surprisingly, SR sources.

3. Local governments, local emergency management offices and the National Weather Service can initiate EAS messages by feeding them into LP sources. LP sources are assigned numbers (LP-1, LP-2, etc.) to indicate the sequence in which they are to be monitored by other broadcast stations in the local area.

Individual Station Operating Requirements

The EAS responsibilities for individual stations are very simple. There are six things every station must do:

1. Own, install and keep in good working order an EAS encoder/decoder.
2. Have in its posession a copy of the *EAS Handbook* and current authentication list. (Note: at this writing the FCC and FEMA are considering eliminating the authentication list but have made no final decision).
3. Send a test message once every week, and log the fact that it was sent. The weekly test must be sent on random days within the week and at random times throughout the day or night. No weekly test is required during any week that a monthly test occurs, nor is a weekly test required during any week when a state or local emergency causes the station to transmit an EAS message. If, however, during the week the station receives one or more EAS messages concerning state or local emergencies and the station elects not to retransmit any of these messages, then the station must still broadcast the weekly EAS test message sometime during the week.
4. Log the date and time that weekly test messages, and state or local alert messages, are received from both assigned monitoring sources. If a test is not received from either one of these sources, then the reason for the failure to receive the test must be determined. This can be done by checking the station's EAS equipment, and by calling each monitoring source from which no EAS messages were received during the week. The station log must reflect the findings of any investigation into why EAS messages were not received. Also, any necessary corrective action must be taken to ensure that EAS tests, and EAS alerts, will be received properly as soon as possible.
5. Transmit the monthly test message within 15 minutes of receiving it every month, and log both the receipt and transmission of this message. The monthly test must be conducted between 8:30 am and sunset, local time, in odd-numbered months, and between sunset and 8:30 am, local time, in even-numbered months. During the week that the monthly test occurs, no weekly test is required. Monthly test messages must be rebroadcast in their entirety, except for the Transmitting Station Identifier code. Each station that rebroadcasts a monthly test message must insert its own Transmitting Station ID code. SP and LP sources originate these monthly tests. If, during a particular month, a station transmits an actual EAS emergency message that is of the same format as the monthly test, then the station does not have to transmit the monthly test.
6. Immediately broadcast any national level alerts that are received. NN stations must immediately rebroadcast the digital header and two-tone attention signal for national level alerts, followed by an announcement that indicates there is a national level alert about to be broadcast by other stations, and that this station is about to go off the air. The NN station must then go off the air for the duration of the national level alert and wait for the Emergency Action Termination message.

While not required by the FCC rules, many stations choose to voluntarily rebroadcast certain EAS messages regarding state and local emergencies. Whenever a state or local EAS message is rebroadcast, no weekly test need be transmitted that week.

Broadcasters may operate their EAS equipment in either an *automatic* or a *manual* mode. In the automatic mode the broadcaster programs the EAS unit to automatically relay certain selected EAS messages that are received by its decoder, but to only log all other received EAS messages. Stations that are operating without a transmitter duty operator will typically operate their EAS equipment in automatic mode. When EAS equipment is operated in manual mode the broadcaster must assign a person to monitor the EAS equipment and make decisions about which alerts to relay. Stations that operate their EAS equipment in manual mode are allowed to control their EAS equipment from a remote location, provided their remote control system enables them to put national level alerts on the air immediately and required monthly tests on the air within 15 minutes.

Although broadcasters can choose to air, or not to air, any state or local alert, they have no discretion when a national level alert is received. Both automatically operated and manually operated stations must interrupt their programming immediately when a national level alert is received. Stations that are participating in the EAS must put the national alert on the air. Stations that have opted not to participate in the EAS (by providing written notification to the FCC's EAS Office) must broadcast the digital EAS header codes and a short announcement then shut their transmitters off for the duration of the alert.

Every EAS message that is received by a broadcaster must be logged, regardless of whether the broadcaster decides to relay the message to its audience, and regardless of whether the station is operating in automatic or manual mode.

EAS Transmissions Via RDS

EAS information may be transmitted via an FM station's Radio Data System (RDS) subcarrier—

though transmitting EAS information via RDS does not relieve a station of its responsibility to transmit EAS information in its main audio channel. One of the advantages of using the RDS subcarrier for EAS transmissions is that it enables *silent* emergency warning networks to be developed that can provide very locally specific alerts to audiences that have RDS EAS decoding equipment. For example, using RDS a broadcaster could send out an alert about a chemical spill at a factory that would only be heard by people who are living and working in the immediate vicinity of the factory. This would be done by coding the RDS EAS message with an access code that would prevent receivers that are not programmed with the same access code from decoding the alert message.

RDS uses a 1,187.5 baud data stream that is transmitted on an FM station's 57 kHz subcarrier. The format of RDS transmissions in the United States is specified in the *United States Radio Broadcast Data System (RBDS)* Standard, which was adopted by the National Radio Systems Committee. (See Chapter 4.6, *Radio Broadcast Data System (RBDS)*, for a more complete discussion of the format of the RDS signal). The following is a description of a typical sequence of events that occurs when an EAS message is transmitted via RDS:

1. The Warning Activation bit in Group 3A of the RDS signal is set to 1 to tell sleeping battery operated receivers to wake up.
2. The Program Type code (ROCK, COUNTRY, JAZZ, etc.) is set to "ALERT!" to tell consumer RDS equipment to interrupt current activity (CD/cassette playback, radio off state, etc.) and switch to FM reception.
3. The actual audio alert message is transmitted in the FM station's main audio channel, and a text version of the alert message is transmitted to radiotext equipped RDS receivers using Groups 2A or 2B.
4. The SAME codes are transmitted using Group 9A. These codes may be useful to specialized RDS receivers equipped to decode SAME data. However, consumer RDS radios generally do not make use of this data because of the additional signal processing circuitry that would have to be included to decode the information. Consumer radios rely on the actual audio alert message, and any radiotext information that is transmitted.
5. At the end of the EAS alert, the Program Type code is set back to its appropriate state (ROCK, COUNTRY, JAZZ, etc.), and the Warning Activation bit is set back to zero to tell battery operated receivers that they may return to their *sleep* state.

CONCLUSION

For most broadcasters, the EAS is an improvement over the EBS because it enables them to automate the emergency warning function at their stations, thus making it easier for them to operate unattended transmitters and thereby reduce their operating expenses. Broadcasters that make use of RDS technology to enhance their EAS alerts can provide added services to their audiences by enabling RDS equipped radios to do such things as automatically turn on in the middle of the night to warn of approaching danger.

Section 2: Broadcast Towers and Systems

Introduction by Louis Libin, Broad Comm, Inc. Woodmere, New York

In this section, readers will be given an overview of the broadcast signal, as it begins to travel through the coaxial transmission line and takes on propagational characteristics. This section also discusses all aspects of the physical towers, design, erection and maintenance, as well as the required lightening protection for the tower structure. This section is of vital importance to the broadcast engineer because the transmission path is critical to the transmission and reception of a high quality broadcast signal. As broadcasters begin the transition from analog to digital, the highest quality of the broadcast signal will be needed from the beginning of the transmission path.

The many changes that are taking place in the broadcast industry do not mean that we can put aside the physical transmission. The physics of radio frequency propagation remain the same for digital broadcasting. The techniques relating to the transmission and reception, as well as the frequency bands will be different. The *Radio Wave Propagation* chapter begins with a valuable tutorial. For those engineers without an engineering background, the chapter will provide the framework for a real understanding of the physical concepts that play a role in wave propagation. Basic mathematical equations are included for educational purposes, and the variations in propagation, through a description of the electromagnetic spectrum are described in detail. The chapter will then explain propagation in free space and apply it to real broadcasting—just in time to usher in a better understanding of the transmission of digital technology. Broadcast engineers need more than just a cursory knowledge of the science of propagation, because many stations are now switching to the UHF band. Broadcast engineers will find that this chapter will assist them in responding to their newest audiences, the digital audiences, whose signals are now taking different routes, over the same terrain to reach the home antenna.

The transition to digital is now beginning. For many stations, the tower issues are now more of a focus than ever before. Every station needs to either replace a tower or add an antenna. The *Design, Erection and Maintenance of Antenna Structures* chapter by Thomas Hoenninger is extremely timely to broadcast engineers. This chapter provides necessary overview to familiarize the broadcast engineer with the various types of physical tower configurations, and various materials used in their construction. There are also regulatory requirements imposed on the owners of towers. This chapter focuses the broadcast engineer on the various requirements for lighting, modification, maintenance, inspections and reporting. In today's world, where the bottom line is cost, this overview is of great importance to the engineer and owner.

Broadcasters are investing more and more into their transmission facilities, including towers, waveguide and antennas. The *Lightening Protection For Tower Structures* chapter by Ed Lobnitz provides a very practical look at lightening and how the broadcaster can prepare best for this natural phenomena. Broadcasters need to protect their most valuable assets, their tower, transmission line and of course, the antenna itself from damage. The smartest design dictates that the best strategy would prevent damage from occurring; on the flip side, few crews are available, the process is expensive and towers are becoming more crowded and complex systems. The chapter is written in tutorial form, and is most significant to broadcasters. The reader will learn everything from thunderstorm cell development, and associated lightening discharge, to the best structural protection strategies available today.

In its simplest form, the transmission line guides the energy along, from one point to another. The transmission line is one of the most significant pieces of hardware in the broadcast transmission plant. It must operate with extremely high efficiencies and losses must be kept to an absolute minimum. The *Coaxial Transmission Lines* chapter by Kerry Cozad discusses the major selection criteria used for transmission line, both electrical and physical. The broadcasters who are now mandated by the Federal Communications Commission to begin to broadcast the digital signal will find this chapter extremely helpful. The chapter provides an overview on design considerations including, but not limited to, power handling and attenuation and VSWR. Physical connections, installation and testing are also described.

2.1
RADIO WAVE PROPAGATION

MARTIN H. BARRINGER
ADDITIONAL MATERIAL PROVIDED BY
KENNETH D. SPRINGER

INTRODUCTION

Radio wave propagation is the study of the transfer of energy at radio frequencies from one point, a transmitter, to another, a receiver. Radio waves are part of the broad electromagnetic spectrum that extends from the very low frequencies which are produced by electric power facilities up to the extremely high frequencies of cosmic rays. Between these two extremes are bands of frequencies that are found in every day uses: audio frequencies used in systems for the reproduction of audible sounds, radio frequencies, infrared light and ultraviolet light and x-rays.

All electromagnetic waves propagate at the same velocity, regardless of the frequency. Light is an electromagnetic wave, and thus the propagation velocity is often referred to as "the speed of light" (c), which for a vacuum is approximately 3×10^8 m/sec. The velocity of any wave is dependent upon the medium in which it is travelling, but for simplicity is usually considered with respect to a vacuum. The frequency of a wave is defined in terms of the number of cycles per second or hertz (Hz) and is related to the wavelength (λ) by the expression $f = c/\lambda$. Figure 2.1-1 shows the ranges of various bands within the electromagnetic spectrum in terms of frequency and wavelength.

Radio frequencies are generally considered to be that portion of the electromagnetic spectrum below the infrared frequencies. At present, the practical upper limit of radio frequencies is roughly 100 GHz.[1] Within the radio frequency spectrum are bands of frequencies that have been allocated to the broadcast service. The following discussions and methods will apply particularly to these bands of the radio frequency spectrum.

The AM band frequency allotments are contained in what is referred to as medium frequencies (MF), 300 kHz to 3 MHz. The FM band frequencies and a portion of the TV band are contained in the VHF band which extends from 30 MHz to 300 MHz. The remaining TV allocations are contained in the UHF band of 300 MHz to 3 GHz. Allocations for broadcast auxiliary services such as remote pickup, studio/transmitter links, intercity relays, MDS, and ITFS are interspersed within the MF, VHF, UHF and SHF (super high frequency) bands. Table 2.1-1 illustrates some of the allotments assigned to the broadcast service. The allocations for auxiliary services may change from time to time as the needs of various services for radio frequencies change and as technology for equipment improves.

QUANTIFYING PROPAGATION

The energy that is emitted from a transmitter may take many different paths before it is received. The path that the radio wave will take depends on many factors, some of which include: frequency, antenna type and height, atmospheric conditions and terrain. Radio waves that propagate along the surface of the earth are commonly referred to as ground waves. All radio waves have some ground wave component, however, because the earth is a lossy medium, it severely attenu-

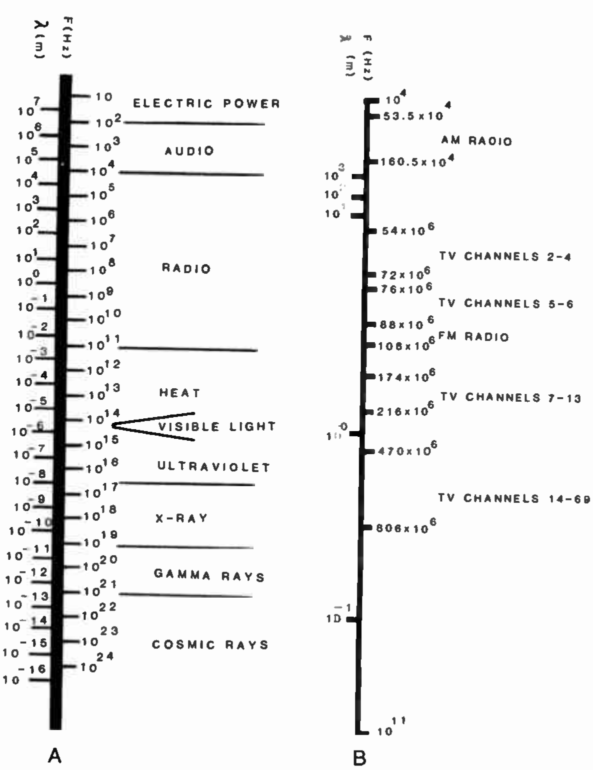

Figure 2.1-1. Electromagnetic spectrum and broadcast radio spectrum.

Table 2.1-1

Broadcast Frequency Allocations

MW 300 kHz–3 MHz	
AM:	525 kHz–1705 kHz
VHF 30 MHz–300 MHz	
FM:	88 MHz–108 MHz
TV:	54 MHz–72 MHz Channels 2–4
	76 MHz–88 MHz Channels 5–6
	174 MHz–216 MHz Channels 7–13
UHF 300 MHz–3 GHz	
TV:	470 MHz–806 MHz Channels 14–69
AM-FM STL:	947 MHz–952 MHz
MDS:	2150 MHz–2162 MHz
ITFS:	2500 MHz–2686 MHz
Auxiliary Services:	2000 MHz–3000 MHz
SHF 3 GHz–30 GHz	
Auxiliary Services:	6.425 GHz–7.125 GHz
CARS:	12.700 GHz–13.250 GHz
TV STL:	17.700 GHz–19.700 GHz

ates the radio wave. This attenuation increases with frequency, so this mode of propagation is useful only for frequencies below 30 MHz. To achieve significant distances, the atmosphere is preferred over the ground as a transmission medium. The atmosphere is comprised of several different layers, as depicted in Figure 2.1-2. The troposphere is the layer that extends from the earth's surface up to about 16 km. This layer is the chief mode of propagation for frequencies above about 30 MHz, and propagation through this layer is dependent upon weather conditions. The next layer is the stratosphere which extends to about 40 km above the earth. This layer has no major effect on the propagation of radio waves. The ionosphere extends upwards of 400 km above the surface of the earth. This region is a charged environment where the air is sufficiently ionized, mainly by the sun's ultraviolet radiation, to reflect or absorb radio waves below about 30 MHz. The ionosphere is constantly changing and is usually considered as consisting of the following sublayers.[2]

- D layer—This layer exists at heights from about 50 km to 90 km and is present only during daylight hours. The electron density is directly related to the elevation angle of the sun. This layer absorbs medium and high frequency waves.
- E layer—This layer exists at a height of about 110 km and is important in the nighttime propagation of medium frequency waves. The ionization of this layer is closely related to the elevation angle of the sun. At certain times irregular cloud-like areas of high ionization may occur. These areas are known as sporadic E and occasionally prevent frequencies that normally penetrate the E layer from reaching higher layers. The sporadic E layer is prevalent during the summer and winter months. The sporadic E layer formed during the summer is the longest lasting from May to August, and the winter layer lasts about half as long beginning in December. During the midsummer months when the electron density is at its greatest levels, TV signals in the lower VHF band can be transmitted over distances of hundred or thousands of kilometers.[4]
- F1 layer—This layer exists at heights of about 175 to 200 km and is present only during the day. Waves that usually penetrate the E layer (3 to 30 MHz) will penetrate this layer and be reflected by the F2 layer. This layer introduces additional absorption of these waves.
- F2 layer—This layer exists at the upper boundaries of the atmosphere, 250 km to 400 km, and is present at all times; though the height and electron density will vary from day to night, with the seasons, and over sunspot cycles. During the night the F1 layer merges with the F2 layer at about 300 km. This, in addition to the reduction of the D and E layers, causes nighttime field intensities and noise to be generally higher than during the day.

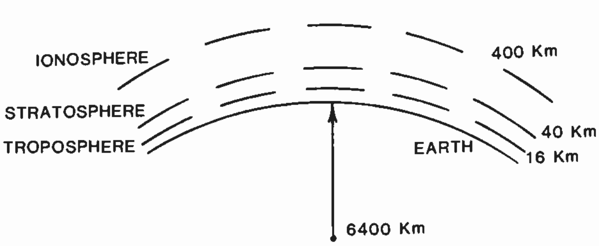

Figure 2.1-2. Atmosphere layers.

Free Space Propagation

To evaluate and compare radio wave propagation under various conditions, it is convenient to establish a reference standard. It is customary to consider as a standard the theoretically calculated loss for waves propagated in free space between two idealized antennas. The simplest case to investigate is the radiation emitted from an isotropic source: an ideal antenna which radiates energy with uniform intensity in all directions. An analogy to an isotropic antenna is a point source of light, such as a candle. The intensity of the energy varies proportionally to the inverse of the distance squared from the source, the *inverse square law*. The power of flux per unit area P_a(W/m^2) at a distance d(m) from a loss free isotropic antenna radiating a power P_1(W) is given by:

$$P_a = P_t/4\pi d^2 \qquad [1]$$

where $4\pi d^2$ is the surface area of a sphere at a distance d(m) from the source. The power available from a loss free antenna P_r is the product of the power flux per unit area (P_a), and the effective aperture area of the receiving antenna (A_e). This area is related to the gain of the antenna by the expression:

$$A_e = G\lambda^2/4\pi \qquad [2]$$

Aperture areas and gains for a specific antenna can be found in the sixth edition of the NAB *Engineering Handbook*, page 121.[3] For a loss free isotropic antenna, $G = 1$, the basic free space transmission loss is defined as:

$$L_{bf} = P_t/P_r = (4\pi d/\lambda)^2 \qquad [3]$$

where d and λ have the same units. This equation can be rewritten in its more common form, expressing the loss in dB, as:

$$L_{bf} = 32.44 + 20\log(F) + 20\log(d) \qquad [4]$$

where F is the frequency in megahertz (MHz) and d is the distance between the antennas in kilometers. In the above equation is should be remembered that ideal loss-free isotropic antennas are considered. In real world systems, antenna gain is a significant factor. The transmission loss, L, incorporates the antenna gains and is defined as:

$$L = L_{bf} - (G_t + G_r + L_d) \qquad [5]$$

Where G_t and G_r are the free space antenna gains with respect to isotropic for the transmitting and receiving antenna respectively. The term L_d is the aperture-to-medium coupling loss or polarization coupling loss between the antennas. The term L_d will have a value of 0 dB when the transmitting and receiving antenna have the same polarization.

In considering the potential service area coverage for a broadcast station, it is usually more desirable to express measurements in terms of field strength rather than transmission loss as previously presented. The root mean square (RMS) field strength, E(V/m), at a point where the power density of a plane wave is P_a(W/m^2) is given by:

$$E = \sqrt{120\pi P_a} \qquad [6]$$

where the term 120π is the impedance of free space. The field strength is related to the power available from a loss free isotropic antenna by combining Equations [1], [3] and [6] above as:

$$E = \sqrt{480\pi^2 P_r/\lambda^2} \qquad [7]$$

A more useful form of the free-space field can be expressed in logarithmic terms above 1 microvolt per meter (dBu) when F is in megahertz and P_r is expressed in decibels above 1 kW (dBK):

$$E(\text{dBu}) = 107.2 + P_r + 20\log(F)\text{dBu} \qquad [8]$$

The electric field produced by a transmitter radiating a power P_t(W) at a distance d(m) in free space can be derived from Equations [1], [3] and [6] and is given by:

$$E = \sqrt{30 P_t/d^2} \qquad [9]$$

or, in logarithmic terms, where P_t is expressed in decibels above 1 kW (dBK), d is in kilometers, and a transmitting antenna has a gain G_t in decibels above isotropic:

$$E(\text{dBu}) = 105 + P_t + G_t - 20\log(d) \qquad [10]$$

Using the same units, the field strength E(dBu) for nonfree-space environments can be related to the basic transmission loss by:

$$L_b(\text{dB}) = 137 + 20\log(F) + P_t + G_t - E \qquad [11]$$

These equations form the basis for characterizing propagation. They do not, however take into account such real world factors as the presence of the earth, atmosphere or obstructions. To adequately describe an actual radio system, additional losses will need to be added to the free-space equations derived above.

Presence of Earth

When the transmitting and receiving antennas are placed over ground, the propagation of radio waves is modified from the free-space models presented above. Radio waves that strike the earth are partially absorbed and partially reflected. Waves that are reflected by the earth experience changes in the phase of the wave, which affects the distribution of available energy. The extent to which the waves are reflected or absorbed is dependent upon frequency and the ground constants: conductivity and permittivity.

Propagation Over Plane Earth

The geometry of the idealized situation of propagation between two antennas placed above a plane earth is shown in Figure 2.1-3. This geometry is valid for antennas that are sufficiently closely located so that the curvature of the earth is not a factor, yet far enough apart from each other so that the energy may be described as a plane wave, and ray theory can be applied. The resultant received electric field can be represented as the sum of the direct and reflected rays:

$$E = E_d[1 + |R|e^{j(\phi_\Delta + \phi_r)}] \qquad [12]$$

This equation is valid for small angels of θ and deserves some additional explanation. The term E_d is the free-space electric field that is produced at a distance d(m) by the direct ray. The terms $[R]$ and ϕ_r are the magnitude and phase of the complex reflection coefficient. This term is dependent upon the nature of the surface (conductivity (δ) and permittivity (E_r)), the angle between the surface and incident wave, the wavelength of the radio wave, the polarization of the wave and the curvature of the earth. The magnitude of the reflection coefficient varies between -1 and $+1$. Several sources have derived equations for the reflection coefficient and plotted the effects of changing variables, and the reader is referred to these for further study.[4,5] The term ϕ_Δ is the phase delay due

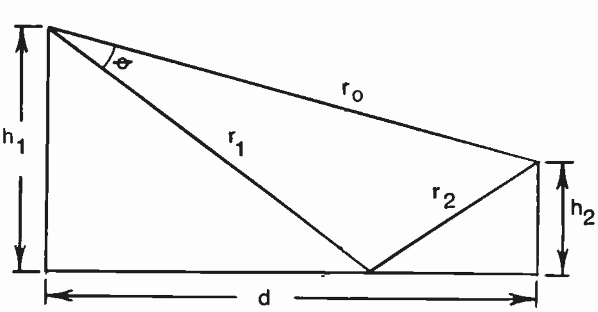

Figure 2.1-3. Path rays for plane earth.

to the longer path that must be taken by the reflected wave, and has the form of:

$$\phi_\Delta = 4\pi h_1 h_2/\lambda d \qquad [13]$$

It is often sufficient to assume the ground approximates a large flat surface. In such a case, a sufficiently accurate expression is given by:[4]

$$E = 2E_d \sin(2\pi h_1 h_2/\lambda d) \qquad [14]$$

Some cases of special merit that can be derived from Equation [14] are:

Case I	$h_1h_2 = d\lambda/2$	$E = 0$
Case II	$h_1h_2 = d\lambda/4$	$E = 2E_d$
Case III	$h_1h_2 = d\lambda/12$	$E = E_d$

Therefore, depending on the antenna heights, distances, and wavelength, it is possible to totally cancel out the field at the receiver or magnify the wave to a field strength double that which could be achieved from a free-space field. The variation of signal strength due to multipath effects can be minimized in point-to-point applications through the use of antennas with narrow beamwidths.

When considering the case of VHF antennas that are close to the ground, the effective antenna heights h_t(m) and h_r(m) will need to be substituted for h_1 and h_2 respectively for Equation (14). The new antenna heights *ht* and *hr* allow for the effects caused by the relative permittivity (ϵ_r), and conductivity (δ) of the ground. The effective antenna heights are related to the physical antenna heights above ground level by:[4]

$$h_t = \sqrt{h_1^2 + h_0^2} \qquad [15.1]$$

$$h_r = \sqrt{h_2^2 + h_0^2} \qquad [15.2]$$

the term h_0 is dependent upon the type of polarization being considered.

Vertical Polarization

$$h_0 = (\lambda/2\pi)[(\epsilon_r + 1)^2 + (60\lambda\sigma^2)]^{1/4} \qquad [16.1]$$

Horizontal Polarization

$$h_0 = (\lambda/2\pi)[(\epsilon_r - 1)^2 + (60\lambda\sigma^2)]^{-1} \qquad [16.2]$$

Table 2.1-2 lists values for conductivity and permittivity for various soil conditions. As a way of example, assume that an antenna is placed 3 m (9.8 ft) above dry, sandy, flat coastal land ($\delta = 8 \times 10^{-3}$ S/m, $\epsilon_r = 10$) and operates at a frequency of 100 MHz ($\lambda = 3$ m). Then h_0 in [16.1] and [16.2] will be 1.59 m and 0.16 m respectively. The effective height of the antenna will then be increased to 3.4 m (11.1 ft) for vertical polarization and will remain unchanged at 3 m (9.8 ft) for horizontal polarization. As the frequency increases above VHF, the wavelength becomes increasingly small and the distinction between true antenna height and effective height is immaterial.

Medium Frequency Propagation

As stated earlier, medium frequency waves lie in the frequency range of 300 kHz to 3 MHz and are characterized by their long wavelengths (1,000 to 100 meters). The standard AM broadcasting band frequencies are within this range. For the AM service, the transmitting antenna is located right at the surface of the earth, and the receiving antenna is very close to the earth's surface with respect to a wavelength. In this case the direct and ground reflected waves cancel, and the transmission is by means of the ground wave (also known as the surface wave) and the sky wave.

Table 2.1-2
Ground Conductivity and Dielectric Constants

Terrain	Conductivity, δ (S/m)	Relative Dielectric Constant, ϵ_r (esu)
Sea Water	5	80
Fresh Water	8×10^{-3}	80
Dry Sandy, flat coastal land	8×10^{-3}	10
Marshy, forested flat land	8×10^{-3}	12
Rich agricultural land, low hills	1×10^{-2}	15
Pasture land, medium hills and forest	5×10^{-3}	13
Rocky land, steep hills	2×10^{-3}	10
Mountainous	1×10^{-3}	5
Residential Area	2×10^{-3}	5
Industrial Area	1×10^{-4}	3

Ground Waves

These waves are characterized by the fact that they are guided along the earth's surface, similar to a transmission line. The field is attenuated in this propagation mode by losses in the ground. Therefore the composition of the soil, ϵ_r and δ, have a direct bearing on the amount of attenuation the wave will experience, and subsequently how far reliable communications can be established. The attenuation is also dependent upon the frequency and polarization type. The attenuation factor, A, is a measure of the amount of attenuation present and can be determined for a ground wave using the chart of Figure 2.1-4. The term ρ is known as the numerical distance and b is the phase constant. Values for these terms can be calculated from the following equations:[5]

$$\rho = (\pi d/\lambda x)\cos(b) \qquad [17.1]$$

$$b = \arctan[(\epsilon_r + 1)/x] \qquad [17.2]$$

$$x = 18 \times 10^3\sigma/F \qquad [17.3]$$

To determine the electric field strength, the attenuation factor must be added to Equation [12].

$$E = E_d[1 + re^{j(\phi_\Delta + \phi_\Delta)} + (1 - R)Ae^{j(\phi_\Delta + \phi_\Delta)}] \qquad [18]$$

It is interesting to note that the same earth which acts as a conductor at very low frequencies will act as a small-loss dielectric at very high frequencies. It is also noteworthy to observe that the losses for horizontally polarized waves are much greater than for vertically polarized waves. Thus, for practical applications only, vertically polarized waves should be considered. For more detailed and accurate representations of the ef-

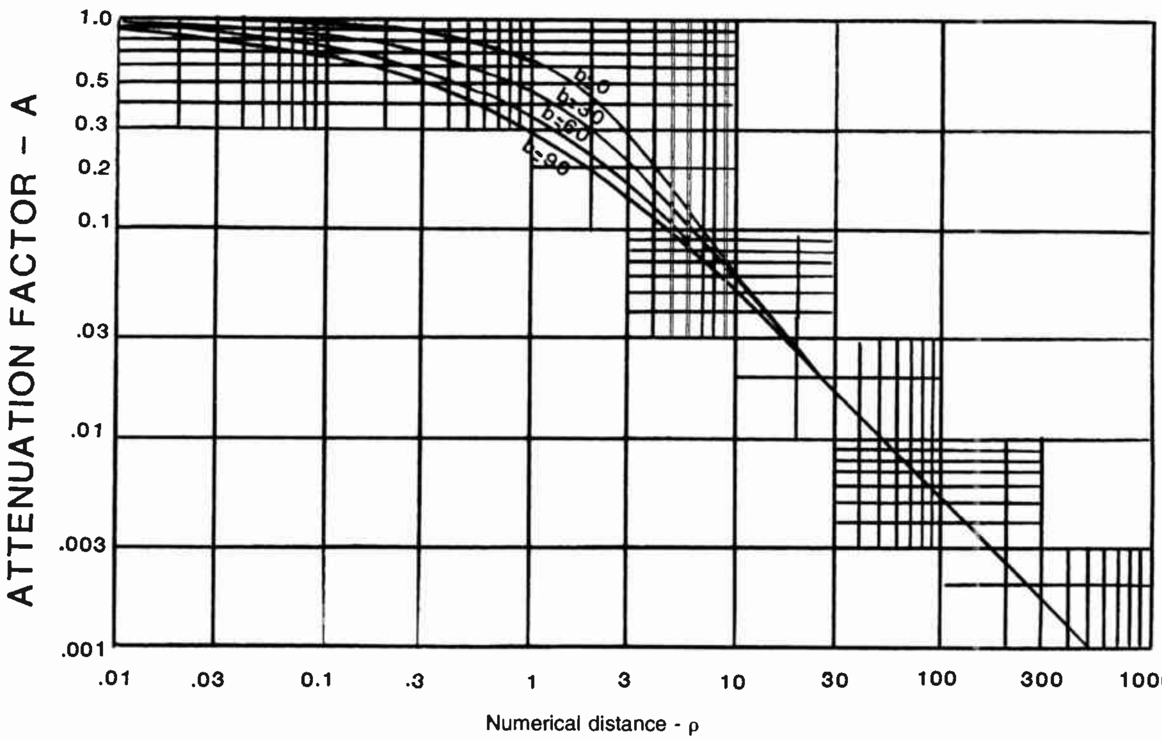

Figure 2.1-4. Attenuation factor of ground waves.

fects of ground wave, the works of Norton and as expanded upon by Jordan should be consulted.[6,5]

Sky Waves

While the ground wave provides the major path for medium frequency propagation, the wave attenuates relatively quickly with distance and is reliable for distances of only a few hundred kilometers. To achieve greater distances, the waves propagate via the ionosphere and are known as sky waves, and can provide sufficient signal strength at distances up to a few thousand kilometers.

The ionosphere is a constantly changing environment that begins approximately 65 km (40 miles) above the earth and extends to about 400 km (250 miles). This region of the atmosphere is composed of three major sublayers, D, E, and F. These layers are not present at all times. For example, the D layer is present only during the day and is a major absorber of medium-frequency waves. The E layer is a principal reflector of medium-frequency waves. Thus during the day the majority of the medium-frequency waves are absorbed by the D layer, but at night the D layer is not present, allowing the medium-frequency waves to be reflected by the E layer.

Interference Between Ground Waves and Sky Waves

Interference to a receiver may occur from co-channel stations located many kilometers from the desired station. Because of the sky wave, sufficient signal strength may be received to interfere with the local station. This effect has been minimized by the FCC by limiting two factors in the operation of some AM stations: the operating power and time of operation.

Multipath interference occurs when the waves from a transmitting antenna reach a receiver from different paths in such a manner as to cancel or severely interfere with each other. This can happen at distances where both the ground wave and sky wave are sufficiently strong to interact. The geometry of this is similar to that shown in Figure 2.1-3, except the direct ray will be a result of the ground wave and the reflected wave will be from the ionosphere. At distances relatively close to the transmitter, the ionosphere will not reflect waves back to the earth, so the ground wave is predominant. At distances beyond a few hundred kilometers, the sky wave will dominate and the ground wave will be too weak to interfere. Multipath interference can also occur where the sky wave follows more than one path to the receiver.

Effects of Solar Activity

Interference to medium-frequency waves can also be caused by solar activity such as sunspots and flares which manifest an increased or reduced emission of radiation from the sun. The changes in solar radiation levels can cause changes in the ionospheric layers that may result in unusual sky wave propagation conditions called *skip*, which, in turn, can cause inter-station interference. The effects of such solar activity will have their strongest effect on propagation in the AM band during the first 5 to 10 days after the start of a storm. This has the effect of reducing sky-wave field strengths. The effect has been observed to increase with frequency.[13]

Propagation Above 3 MHz

At frequencies above about 30 MHz the principal propagation mode is tropospheric. The surface wave is attenuated too severely to be of any practical long distance use and, though attenuated, the sky wave is usually passed through the ionosphere to space.

For waves that propagate close to the earth's surface the curvature of the earth will introduce additional effects that must be included in the plane earth model that was considered earlier Figure 2.1-5 shows the geometry of a smooth earth model. First the reflection coefficient R of the reflected wave has different characteristics that for a plane surface. Since the wave is reflected against a curved earth the energy diverges more than is predicted by the inverse square law and the reflection coefficient R, in Equation [12], must be multiplied by the divergence factor D, given by:[4]

$$D = \sqrt{1 + 2d_1d_2/2a_e(h_t' + h_r')} \qquad [19]$$

It should be noted that for smooth earth conditions, the heights h_t' and h_r', for the transmitting and receiving antennas above the plane tangent to the earth at the point of reflection are less than the antenna heights h_t and h_r above the surface of the earth.

Under normal propagation conditions, the refractive index of the atmosphere decreases with height so that radio waves near the surface of the earth travel more slowly than at high altitudes. This variation in velocity as a function of height results in a bending of the radio waves. This may be represented as a modified earth radius commonly known as the effective earth radius, a_e, which allows the radio waves to be represented as straight lines. The ratio of the effective earth radius to true earth radius is commonly known as the k factor. Values of k can vary between from 0.6 to 5.0 depending

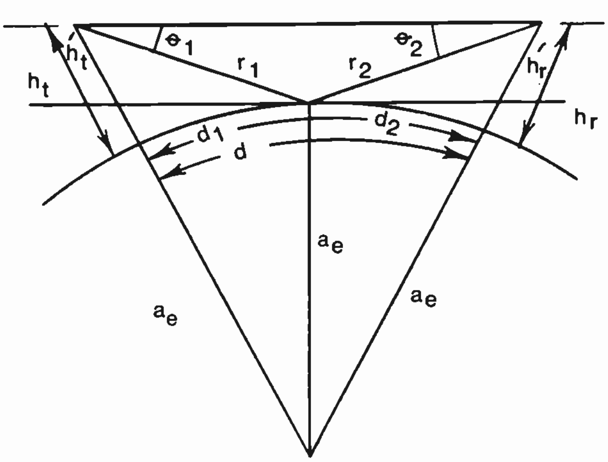

Figure 2.1-5. Reflection from smooth earth on line-of-sight path.

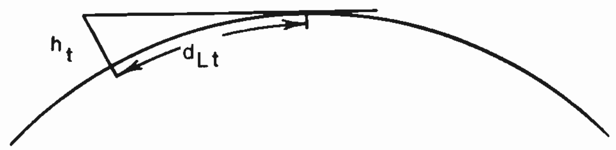

Figure 2.1-6. Distance to radio horizon.

on the climate being considered. For temperate climates the average value of k is 1.33, and most works refer to this as the 4/3 earth model when used in calculation.[2]

Beyond Line of Sight Conditions

In order to determine when conditions exist where propagation is considered to be beyond line of sight, the respective distances from the transmitter and receiver to the radio horizon must be calculated. The radio horizon is the distance the horizon appears from an antenna, as defined by a plane from the antenna to the tangent of the earth's surface and is depicted in Figure 2.1-6. The equation for the radio horizon in terms of d_{lt} (km) and h_t (m) and the k factor is of the form:

$$d_{lt} = 3.57\sqrt{h_t k} \qquad [20]$$

When the sum of the distances to the radio horizon for the transmitter and receiver is less than the total distance of the path under consideration, then a beyond line of sight condition exists. Diffraction makes it possible for radio waves to travel beyond that possible for line of sight transmission, though an additional loss term must be added to the free-space loss. The amount of attenuation can be determined by diffraction methods. The geometry of beyond line of sight propagation is shown in Figure 2.1-7.

The exact calculation of the field strength at any point beyond the line of sight for a smooth earth is rather complex and the presentation of such a method is beyond the scope of this text. However, nomograms have been developed that apply to a large number of cases. For the reader interested in the actual prediction of the losses to be expected for smooth earth diffraction, the National Bureau of Standards publication may be consulted.[9]

Figure 2.1-8 is a nomogram that can be used to determine the loss that must be added to the free-space loss. In order to use the nomogram, the distance d_{lt} must be less than d_{lr}. The total loss (L) is the sum of the three losses L1, L2, and L3. By way of example, assume a system that has the following parameters:

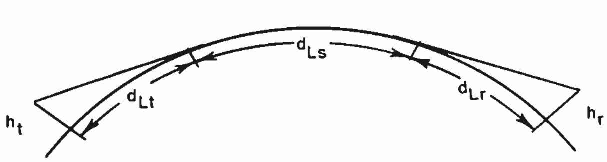

Figure 2.1-7. Beyond line of sight.

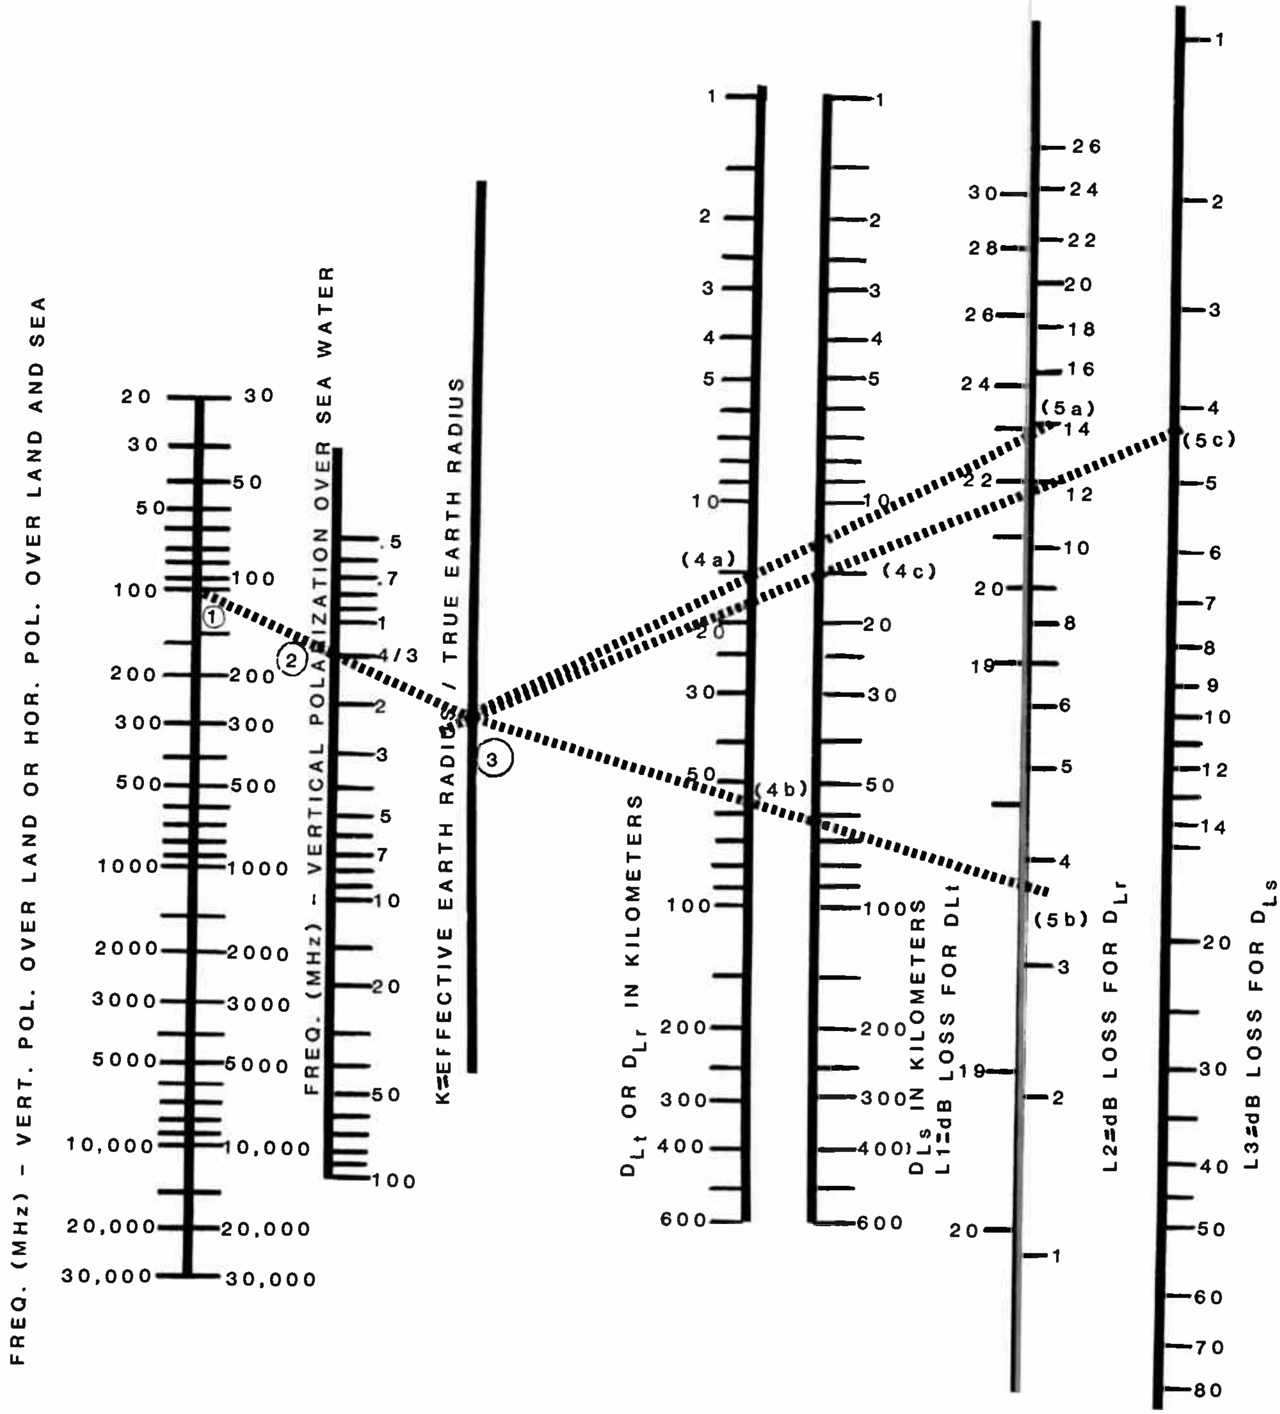

Figure 2.1-8. Diffraction loss over smooth earth.

h_{lt} = 14 m (14.9 ft); h_{lr} = 178 m (583.8 ft); F = 100 MHz; k = 4/3; total path length of 85 km; and the wave is vertically polarized over land. The distances are calculated to be: d_{lt} = 15 km (9.3 miles), d_{lr} = 55 km (34.2 miles), and d_{ls} = 15 km (9.3 miles). The total loss relative to free space is this L = L1 + L2 + L3 = 22.9 + 3.8 + 4.3 = 31.0 dB.[7]

Effects of Obstacles on Propagation

In the previous sections, a perfectly smooth sphere was assumed for earth. Only the effects of the atmosphere were accounted for in the k factor. The assumption of a perfectly smooth earth allowed for a relatively simple calculation of the expected field strengths and transmission losses at various points within the line of sight and regions beyond the line of sight. However, the real world is much less than ideal, and the presence of hills, buildings, foliage, as well as the atmosphere all have a bearing on the computation of field strengths. These obstacles have a complex effect on the propagation of radio waves which makes it virtually impossible to predict the field strength or transmission losses at discrete points close to these obstacles. However, the path being considered may be quantized by use of earth profiles, and through the use of some simplifying assumptions, predictions of the field strength which are more accurate than smooth earth approximations can be performed.

Hills

Perhaps the most common obstructions that will appear in the path of a radio wave are hills. The amount of attenuation the hill will introduce into a path is a function of the distance from the antenna terminals to the hill, and the height of the hill above or below the line-of-sight ray between the transmitting and receiving antennas. The hill's height and distance from the antenna can be determined by constructing a path profile and plotting the terrain features on special graph paper that includes the effect of refraction. The most common charts are defined for a factor of k of 4/3. A typical path is shown in Figure 2.1-9. Terrain elevations necessary to construct a path profile can be obtained from topographical maps of the area, or from computer databases. To obtain the best accuracy in using topographical maps the smallest scale available should be used, 1:24,000. These maps can be obtained from the United Stated Geological Survey (USGS) in Denver, Colorado or from any of its branch offices. Computer models exist that can map the terrain along a propagation path and are available from many sources.

In order to determine when a hill is sufficiently removed from a path to allow free-space conditions to exist, the Fresnel zone clearance equation can be used. This equation was initially developed to explain the diffraction of light around knife edged obstacles, and has since been applied to radio theory. This equation describes a radio path as an ellipsoid with the transmitting and receiving antenna located at the focal points of the ellipse. As Figure 2.1-10 depicts, the curves for various reflection coefficients intersect at 0 dB from free space when the clearance is equal to six-tenths of the distance to the first Fresnel zone clearance. Thus free space conditions exist when obstacles are outside the 0.6 F_1 zone radius. This distance can be calculated by:

$$h = 0.6\,F_1 = 328.6\sqrt{d_1 d_2 / Fd} \qquad [21]$$

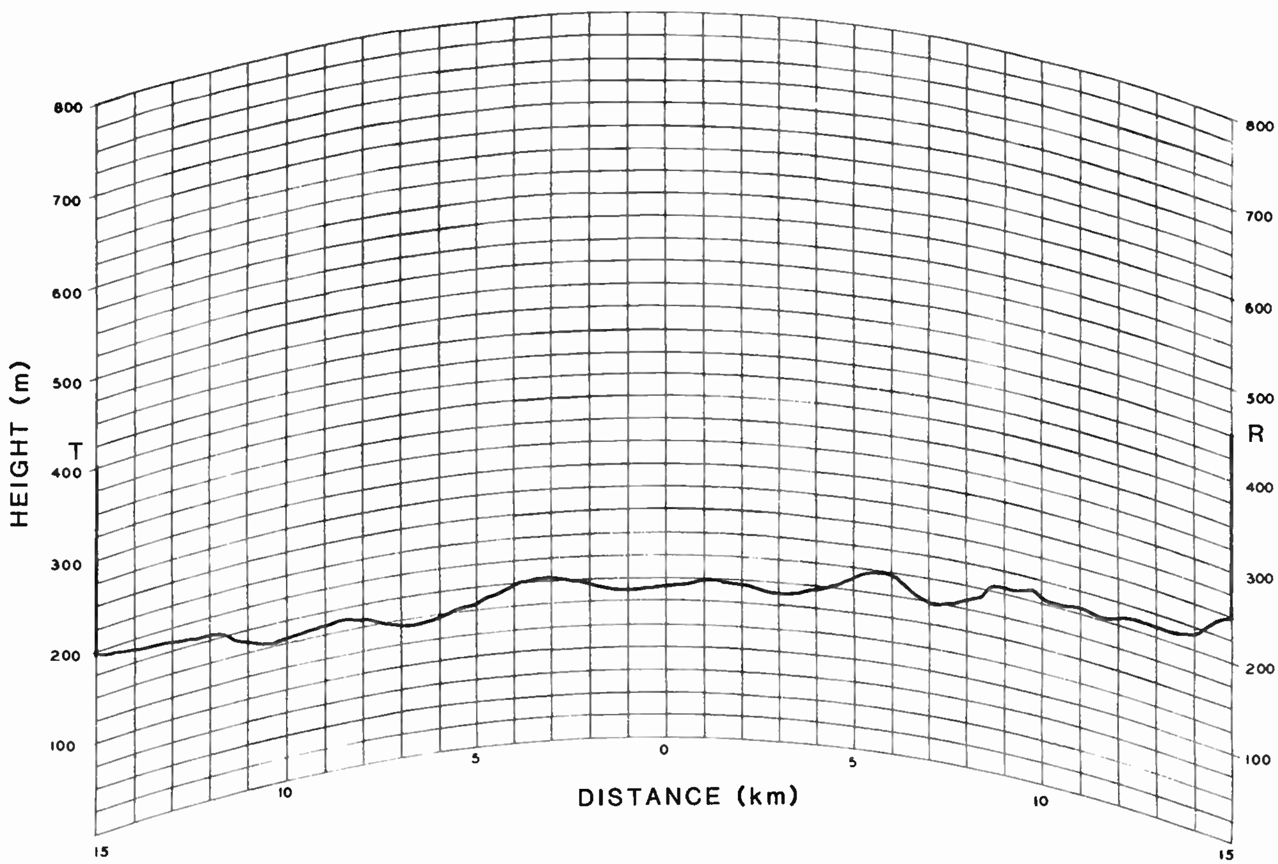

Figure 2.1-9. Typical 4/3 earth path profile.

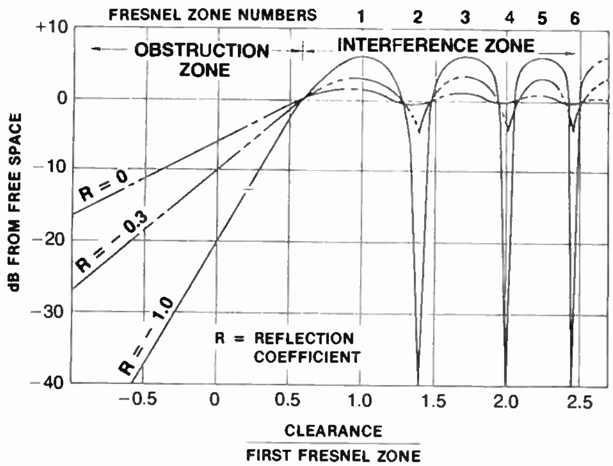

Figure 2.1-10. Effect of path clearance on radio propagation.

where the height of the 0.6 F_1 zone is in meters; d is the distance from one antenna to the obstacle in kilometers; d_2 is the distance from the second antenna to the obstacle in kilometers; d is the total path distance in kilometers; and F is the frequency in megahertz. When determining whether a path clears a hill, an additional height typically 15 meters, should be added to the height of the hill to account for any trees that may be present.

If the hill lies within the calculated Fresnel zone radium then nonfree-space conditions exist and additional losses will be present. When the frequency is high enough for the hill to be considered as a sharp ridge, and the transmitter and receiver are far enough away from the hill, then the loss may be calculated using diffraction from a knife edge, as shown in Figure 2.1-11. The height of the hill H(m) is measured from the line joining the centers of the two antenna to the top of the ridge. The amount of attenuation or shadow loss with respect to free space may be read from the graph shown in Figure 2.1-12. The value of v, the diffraction parameter, can be calculated, with respect to the distances measured in kilometers and the frequency F(MHz) from:[4]

$$v = 0.00258H\sqrt{dF/d_1d_2} \qquad [22]$$

When considering paths that are obstructed by hills that appear rounded rather than knife edged, the attenuation can be calculated using diffraction around a cylindrical surface, as depicted in Figure 2.1-13. This condition

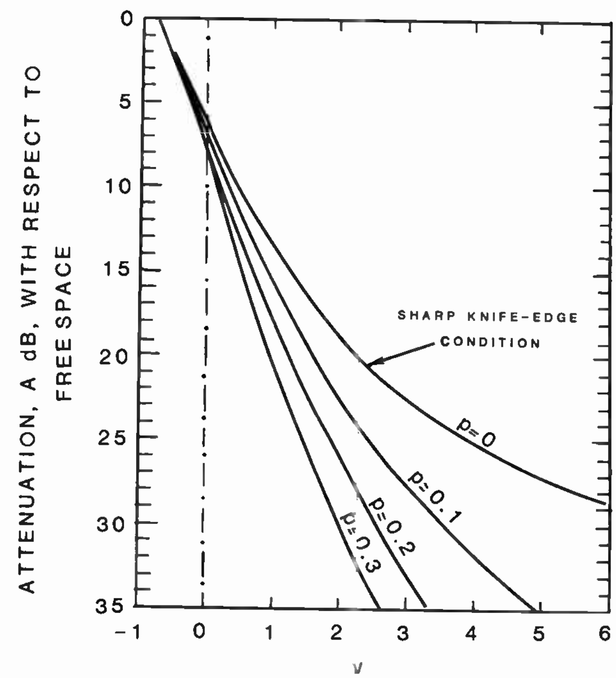

Figure 2.1-12. Attenuation due to various diffraction conditions.

predominates when the elevation of the hill changes drastically within a wavelength. This can occur when considering paths at the lower end of the VHF spectrum that pass over older mountain ranges, (Appalachian, Blue Ridge, Catskill).

The amount of attenuation can be found from the chart of Figure 2.1-12. The term p from the chart is a dimensionless quantity known as the index of curvature of the cylinder's radius $\boldsymbol{R}$ and is calculated from:[4]

$$\rho = 0.83\boldsymbol{R}^{1/3}\lambda^{1/4}\sqrt{d/d_1d_2} \qquad [23]$$

where all distances are in the same units. For those interested in incorporating the calculation of losses due to diffraction over knife edge and rounded obstacles into computers more exact equations can be found in Rice, et al.[9]

While the method for calculating the loss due to a single obstacle is relatively straightforward, there are times when successive obstacles are present in a radio path as shown in Figure 2.1-14. In order to determine the loss associated with multiple diffraction regions, an approximation method has been developed based on

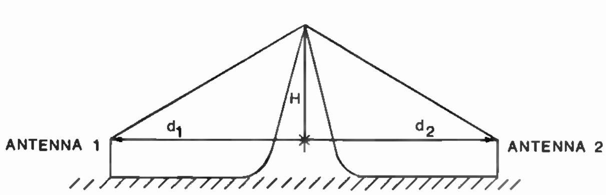

Figure 2.1-11. Ray path for knife edge diffraction.

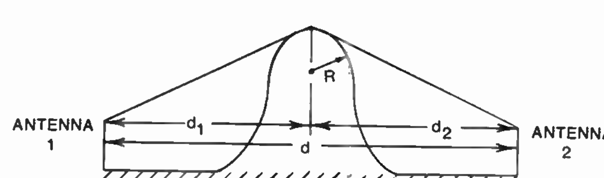

Figure 2.1-13. Diffraction due to cylinder.

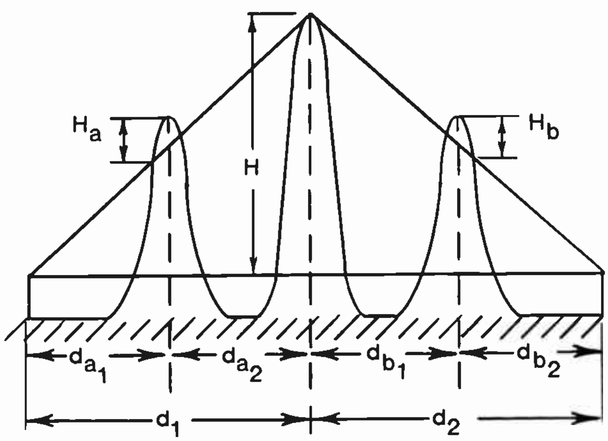

Figure 2.1-14. Multiple knife edge diffraction.

an extension of single-edge diffraction. The obstacles which would singly produce the greatest diffraction loss is determined using the methods discussed above. Lines are drawn joining the summit of this obstacle to the transmitter and receiver antenna locations. The additional attenuation caused by the remaining obstacles should be calculated using their heights, H_a and H_b, above these lines. These additional losses are then added to the loss due to the main obstacle in calculating the nonfree-space loss. It is important to note that even if H_a and H_b are slightly negative (below the lines) they may still produce a small amount of attenuation due to the Fresnel zone clearance requirements.[4]

Buildings

When planning for transmitting locations within built-up areas of cities or residential areas, buildings will have an effect on radio propagation. For radio relay stations, such as studio-to-transmitter links it is the normal practice to select sites that will be clear of buildings. However, where this is not feasible and the path geometry is known, (height and location of buildings) then the diffraction methods discussed for hills may be applied. In planning for broadcast systems it is not practical to relate attenuation measurements made in built-up areas to the particular geometry of buildings. Therefore it is more conventional to treat the losses in statistical manner, dividing the general classifications of building types into loss groups, so that a loss can be derived for a particular type of building (multi-story made of concrete and steel versus single story residential made of wood).

Within built-up areas there is much more back scatter than in open country. Additionally, due to the fact that buildings are more transparent to radio waves than the earth, there tends to be less shadow loss caused by buildings. However, the angles of diffraction due to buildings are usually much greater than in open country for natural terrain and thus the loss resulting from the presence of buildings tends to increase. Measurements indicate that at 100 MHz the median field strengths are 4 dB to 6 dB below that expected for a plane earth and drop off to about 10 dB for 200 MHz.[3] These measurements were made in areas containing some large buildings and open areas, but mainly consisting of residential areas. Measurements conducted in the 850 MHz band indicate field strengths 20 dB to 34 dB below that expected for free space for path distances of 1 km to 25 km.[10]

Vegetation

Among the many factors that have an effect on the determination of the losses present in a propagation path, vegetation is sometimes the most overlooked. Depending on the type of terrain in consideration, (open or forest) the effect of vegetation can add a several dB loss to the system. The amount of attenuation present is dependent upon the frequency and polarization of the wave (see Figure 2.1-15). As can be seen, the attenuation for a horizontally polarized wave for frequencies below about 1000 MHz is much less than for a vertically polarized wave. At around 1000 MHz, trees that are thick enough to block the field of vision can be modeled as an almost solid obstruction and the attenuation over or around these obstructions can be predicted from knife edge diffraction methods.[3]

The effect of vegetation on a radio path varies seasonally in the case of deciduous trees. During the winter months the losses due to shadowing and absorption are less than those during the spring and summer. It is interesting to note that the greatest losses will occur during the spring since new growth has more sap and moisture content which adds to the absorption losses. When the antenna is raised above trees and other vegetation, the prediction of field strengths depends upon the estimation of the height of the antenna above areas of reflection and the reflection coefficients.

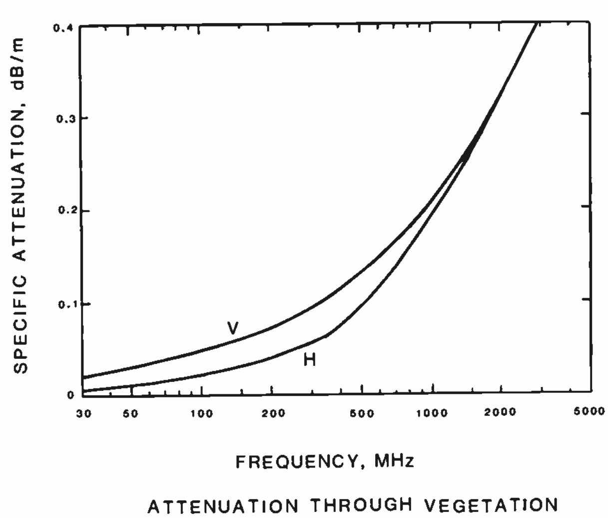

Figure 2.1-15. Attenuation through vegetation.

For areas of fairly uniform growth and for angles of incidence approaching grazing, the reflection coefficient will approach −1 at about 30 MHz. Even low growth that is uniform, (a wheat field) may yield a value of −0.3 for the reflection coefficient.

Atmosphere

As was discussed earlier, the troposphere is the major medium for propagation at VHF frequencies. The refractive index (n) of air has a value near unity (typically 1.00035). The index is dependent upon the dielectric constant, and can vary depending on the pressure and temperature of the air and on the amount of water vapor present. Therefore the refractive index changes with weather conditions and with the height above the earth. The velocity of radio waves is dependent on the refractive index of the atmosphere. As a general rule the velocity of a wave is slower at the earth's surface than at higher altitudes. So a horizontally polarized wave will be refracted back towards the earth, though unusual atmospheric conditions may change this, some simplifying assumptions are generally needed to obtain a solution under known meteorological conditions.

Ducting

Changes in the index of refraction of only a few parts per million can have dramatic effects on radio waves. Therefore it is usually more convenient to refer to the refractive index in terms of the refractivity, N:

$$N = (n - 1) \times 10^6 \qquad [24]$$

Under meteorological conditions where the refractive index decreases rapidly with height over a large horizontal distance, radio waves can become trapped and experience low propagation loss over long distances. This phenomenon is known as ducting. Although ducting is frequent with some locations and meteorological conditions, due to its randomness and long range unpredictability it is not a reliable mode for communications. However, due to the strong fields over the horizon caused by ducting, inter-station interference can result. In addition, line of sight paths may be affected by severe fading.

In order for atmospheric ducts to occur, two conditions must exist. First the refractive index gradient must be equal to or more negative than −157 N/km. The refractive index gradient is a measure of the change of the refractivity across a vertical height h, dN/dh. When this condition is present, the radio waves will remain close to the earth's surface beyond the normal horizon. Secondly, the refractive index gradient must be maintained over a height of many wavelengths. The duct may be thought of in the same manner as a transmission line waveguide. However unlike metallic waveguides, natural ducts do not have sharp boundaries, although there is a wavelength cut-off above which waves will not propagate. Since the duct does not have sharp boundaries, the thickness (t) will not be rigid. Therefore the cut-off wavelength (λ) will not be fixed but an estimate can be obtained from:[4]

$$\lambda = 2.5 \times 10^{-3} t^{2/3} \sqrt{\frac{\delta N}{t} - 0.157} \qquad [25]$$

where the wavelength and thickness are in meters. The term δN represents change in refractive index across the duct. As an example, a duct near the ground that is 25 meters thick and has a refractive index change of 10 N, (400 N/km) will have a cut-off wavelength of 0.15 m (2 GHz). However, a duct with the same refractive index gradient will have to be about 87 meters thick to propagate a wavelength of 1 meter (300 MHz).

A duct spreads the energy within it in the horizontal direction, but is contained in the vertical direction as the distance from the transmitter is increased. Thus, in principle it is possible for the field strength within a duct to be greater than the free-space field at the same distance. However, a duct will leak, or allow energy to escape at the boundary, adding to the transmission losses so that field strengths are seldom greater than free-space values.[4]

There are typically two types of ducts: ground based and elevated. A ground-based duct forms close to the earth's surface. Energy is propagated in this duct by being refracted back to the earth, reflected off the earth, then refracted again, see Figure 2.1-16(a). An elevated duct forms above the earth's surface and is generally very short lived. Energy in an elevated duct is refracted back and forth between boundaries without coming in contact with the earth, similar to the way coherent light propagates in a graded index optical fiber. (See Figure 2.1-16(b).) Shadow regions are formed along the area outside of a duct where, due to the nature of the duct, radio waves are not present. Receiving antennas placed in such a region will experience a loss

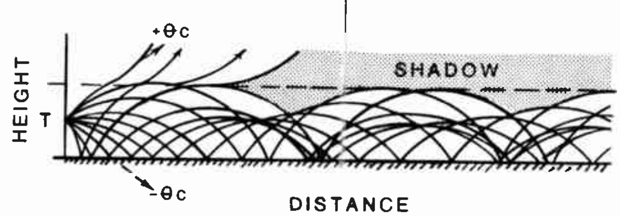

Figure 2.1-16a. Ray propagation in a ground based duct.

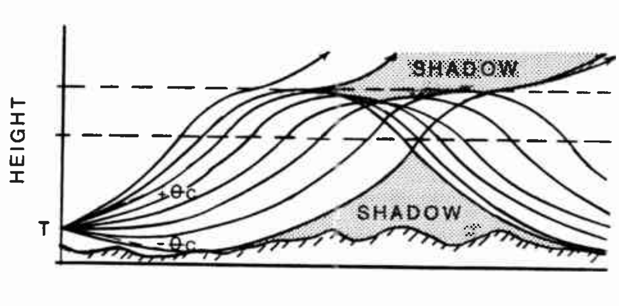

Figure 2.1-16b. Ray propagation in an elevated duct.

of signal. As can be seen from Figures 2.1-16(a) and 2.1-16(b) these regions can form not only above the earth's surface from a ground-based duct, but can also form along the earth's surface in the case of an elevated duct. Therefore a shadow region, that can result in loss of communications, can form at a receiver that is located relatively close to the transmitter.

Radio waves that leave the transmitting antenna at an angle greater than a certain angle, the critical angle, will not become trapped in a duct. These radio waves will propagate through the boundary of the duct, though they will experience some bending due to the change in the index of refraction at the duct's boundary.

Atmospheric Absorption

Radio systems using frequencies above 1 GHz experience another loss that must be accounted for when planning the system: atmospheric absorption. Relay links and STLs that are inadequately engineered may experience outages during periods of heavy rainfall due to this loss. The amount of attenuation due to rain is dependent upon three factors: (1) the rate the rain is falling; (2) frequency of the wave and (3) length of the rain cell a wave must propagate through. If the path length is only several kilometers long, it is usually adequate to approximate the length of the rain cell by the total path length. The average rainfall rate varies from one section of the country to another, however typical rainfall rates are given in Table 2.1-3. The specific attenuation

$$\gamma_r = KR_r^\alpha dB/Km \qquad [26]$$

where R_r is the rainfall rate in millimeters per hours, and the terms K and α are found[9] as:

$$K = [3(F-2)^2 - 2(F-2)] \times 10^{-4} \qquad [27.1]$$

$$\alpha = [1.14 - 0.07(F-2)^{1/3}] \times [1 + 0.085(F-3.5)e^{(-0.0066F^2)}] \qquad [27.2]$$

where F is the frequency in GHz. These equations give a good approximation to attenuation curves published by the ITU-R for frequencies below 50 GHz.[14]

In addition to rain, attenuation can also be caused by water vapor and oxygen that is present in the air. The attenuation due to water vapor and oxygen is less than that for rain and usually can be neglected. However, as radio systems employ higher microwave frequencies, attenuation due to these losses will become significant.

Table 2.1-3
Rainfall Amounts

Characteristics	Rate
Drizzle	0.25 mm/hr
Light Rain	1.00 mm/hr
Moderate Rain	4.00 mm/hr
Heavy Rain	16.00 mm/hr
Very Heavy Rain	100.00 mm/hr

Coverage Areas

Engineering a radio or television broadcast station using the methods presented previously are too cumbersome to be of any practical use in determining the service area of the station. While radio waves actually behave in the manner described in the previous sections, it would be too involved to use these methods at every point surrounding a station. Therefore other quantitative methods are needed to determine field strengths quickly and reliably. Considerable work has been conducted in this area and is still being carried out.

As can be seen from previous sections, the received field strengths are subject to natural and manmade phenomena. These can cause the field strengths to vary over periods of time and from one location to another. These changes can be long term such as seasonal change (weather, temperature and foliage) or short-term changes such as weather disturbances (storms and fronts, and vehicles passing in front of the receiver). These variations have an effect on radio systems that is difficult to account for when determining service areas. Thus it is appropriate to describe the field strength statistically, by what percentage of locations will receive a particular field strength for what percentage of time. By describing field variations in this manner, it is possible to determine the service area of a station. However, the terrain still needs to be defined. In preparing propagation curves, this is accomplished by incorporating a terrain roughness factor h. The terrain roughness factor is a generalization of the local terrain and is defined as the difference in elevation between the levels exceeded for 10% and 90% of the terrain along a path. The average value of h for the United States is 50 meters.[11] In using the propagation curves found in the FCC Rules and Regulations for FM and television stations, the local terrain is accounted for by determining the height of the antenna above average terrain along a radial.[12]

Field Strength Prediction

To simplify field strength prediction, curves have been developed to determine the service area of a station. These curves are generally developed using measured values taken from different geographical areas over certain periods of time. The median values are incorporated into a family of curves that describe the field strengths for various antenna heights, frequencies, and distances. The curves used by the FCC for FM and NTSC TV describe the field strengths for service at 50% of the locations for 50% of the time. These curves are referred to as F(50,50) and are based on an effective power of 1 kW radiated from a half-wave dipole in free space. The F(50,10) curves used by the FCC describe the field strength for 50% of the locations for 10% of the time. These curves can be used in conjunction with the method described by Allen to estimate the service provided by FM and television stations.[3]

Computer Databases

Through the use of personal computers, field strength estimates can be made quickly, allowing designers to try more options and see the effect on the service area. The designer can change transmitter locations, power levels and tower heights to optimize the station. There are typically four modules which comprise a computer simulation package: 1) the environmental data base, 2) the equipment data base, 3) the propagation loss module, and 4) the graphical output module.

The environmental data base defines the conditions in which the radio station must operate. For stations operating in the AM broadcast band this database is a digitized version of ground conductivity constants for an area. Programs are available which allow a user to search an area to determine appropriate ground conductivity values. For stations operating in the frequency range above 30 MHz this is a topographical database. The USGS and National Geophysical Data Center (NGDC) provide digitized terrain elevation data. The most common resolutions provided for terrain elevation provides data spaced at 3 or 30 arc-second intervals. The 30 arc-second database still provides acceptable results for area of coverage predictions but should be used with caution for STL or microwave planning as it may underestimate significant terrain features. For detailed point-to-point profiling, the 3 arc-second database is recommended.

The equipment database defines variables relating to equipment used in the radio system. This includes transmitter output, receiver sensitivity (or field strength), and feed line losses. More sophisticated packages will allow the user to define additional losses such as foliage and buildings to be accounted by the propagation loss program. In addition, these packages may allow a user to define additional standard deviation values to Rayleigh fading losses. Many packages account for transmitter antennas in varying degrees of sophistication. The simplest accounts for only omnidirectional patterns. More in-depth packages allow the user to define directional antenna patterns.

The propagation-loss module uses the information contained in the environmental and equipment databases to calculate the propagation loss for the area. There are two typical methods for calculating the propagation losses, theoretical and empirical. Theoretical methods are based on well understood physical equations as presented earlier in the chapter. These methods typically do not account for such clutter factors as foliage and buildings. These losses must be accounted for by the user. Empirical methods are based on measured observances of actual propagation characteristics for a particular frequency band and geography. These methods typically employ measurements taken throughout a range of environments, and hence account for such factors as foliage and buildings.

The graphical output module presents the data derived from the propagation loss module in a form easily understood by the user.

INTRODUCTION

The purpose of this chapter is to provide broadcast engineers and managers information concerning the design, erection, and maintenance of antenna structures. While fundamental principles of the design and behavior of these structures will be discussed, this chapter is not intended to enable readers to design and build their own tower, but provides instead a basic understanding of these unique structures to facilitate planning, modifying, and maintaining broadcast facilities.

TOWER CHARACTERISTICS

All towers may be classified in one of the two basic groups, guyed or self-supporting. As their names imply, guyed towers depend on cables extending from the tower to anchors located some distances from the tower base for their structural integrity, while self-supporting towers rely solely on their own construction as a cantilevered space truss.

With only a few exceptions, the cost of the actual tower structure and foundations is considerably less for a guyed tower than for one that is self-supporting. The advantage of the self-supporting tower is relatively small land area required. Therefore, the choice between guyed or self-supporting depends to a large degree on the availability and cost of real estate.

A self-supporting tower requires a nearly square plot of land with equal sides that are 8% to 20% of the tower's height, provided local zoning rules do not require tower height radius of land.

The amount of land required for a guyed tower depends on the distance between the tower base and the guy anchors. This distance is preferably between 70% and 80% of the height, which would require a rectangular plot having sides equal to 125% and 145% of the height.

Because of the great flexibility in guyed tower design, it is possible to reduce the anchor distance to as little as 35% of height, thereby requiring a much smaller land area. However, the cost of the tower increases as the anchor distance decreases. The approximate relationship of cost to anchor distance for a representative 1,200 ft television broadcast tower is shown in Figure 2.2-1.

It is often possible to position a guyed tower on an irregularly shaped plot or to obtain long term lease agreements or easements for guy paths and anchor locations in order to minimize the tower cost without obtaining large, rectangular land areas.

Self-Supporting Towers

Self-supporting towers may be either square or triangular in cross section. While it is usually more economical to use a triangular cross section, there are situations

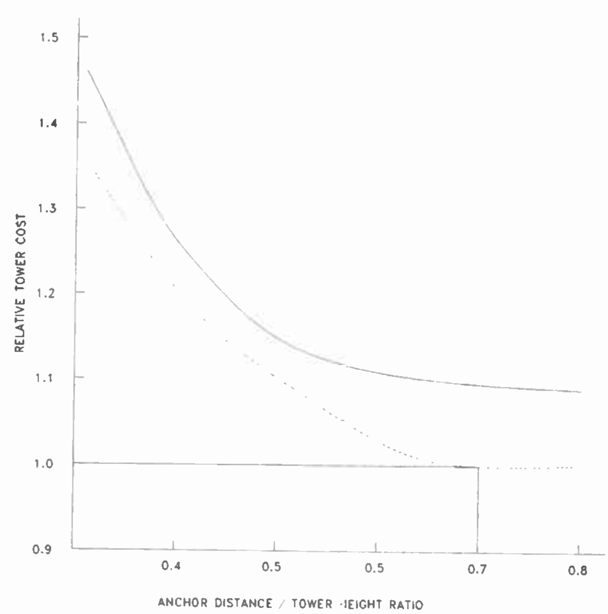

Figure 2.2-1. Effects of anchor distance on cost of a 1,200 foot guyed TV broadcast tower using ANSI/TIA/EIA Standard 222-F-1996.

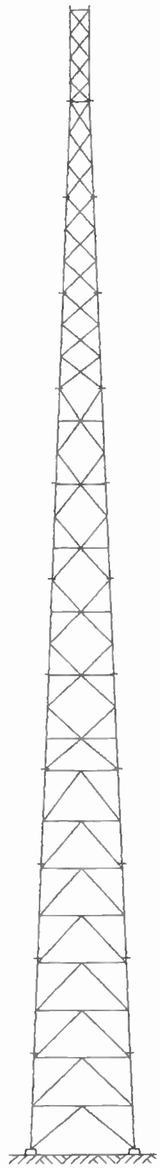

Figure 2.2-2. Elevation view typical self supporting tower.

where a square cross section is a better choice. The principle structural elements are the legs, the web bracing in each face, and if required for stability, horizontal diaphragm bracing. The legs are usually sloped (tapered) to provide adequate strength and stability as the height increases. The degree of slope is an option of the designer to suit the equipment supported, the required rigidity, and the available land area. The slope is sometimes varied within a tower to maintain a desirable balance between the costs of leg members and bracing, or to reduce the foundation loads. Frequently, the legs in the top section of the tower will be parallel to simplify the mounting of equipment (see Figure 2.2-2).

There are several different configurations of bracing members for the individual truss panels. The choice is influenced by the width of the panel, the magnitude of the wind and ice loads imposed, the location of equipment and required stability. Continuity in transferring the applied loads through the structure without significant eccentricity is essential regardless of the configuration used.

Guyed Towers

Guyed towers are almost always of triangular cross section although there are a few unique conditions for microwave and panel type FM and TV antenna supports where a square cross section is advantageous. The principle structural elements are the legs, the web bracing in each face, and the guy support systems (see Figure 2.2-3). Except for sections at the tower base and locations where the width changes, the legs are parallel. The width of the tower is usually constant throughout the height of the tower with the exception of sections supporting antennas requiring a specific width of support structure. The base section is often tapered to a single point to provide a pivot support to eliminate large bending and torsional moments.

Theoretically, there are an infinite number of arrangements of guy cables to support a tower. The most common arrangement is three cables spaced at 120° with one attached to each leg, as shown in Figure 2.2-4(a). This is the minimum number of cables that can be used. When the tower supports equipment, which imposes large twisting moments (torque), it is necessary to provide six cables at a level to maintain torsional stability. If the torque is localized, the guys at this location may be attached to triangular frames as shown in Figure 2.2-4(b). If the torque occurs throughout the height, it may be desirable to double-guy the tower at every level as shown in Figure 2.2-4(c).

The number of guy cable levels required to support the tower is dependent on a number of factors including the height of the tower, width, location of equipment and the environmental loading conditions. Because the tower is an axially compressed column, its strength is a function of its slenderness. While design codes permit

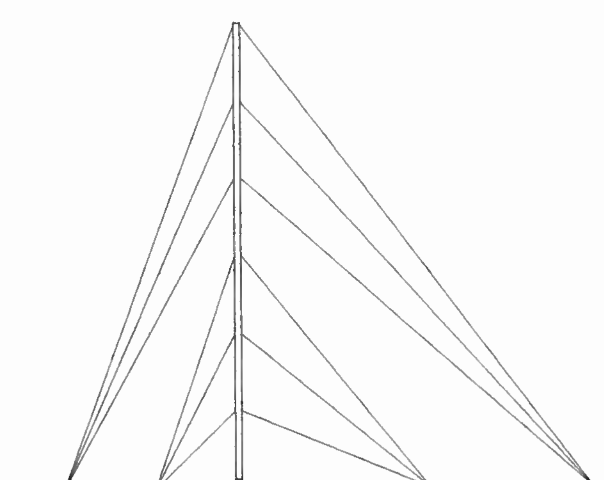

Figure 2.2-3. Elevation view typical guyed tower.

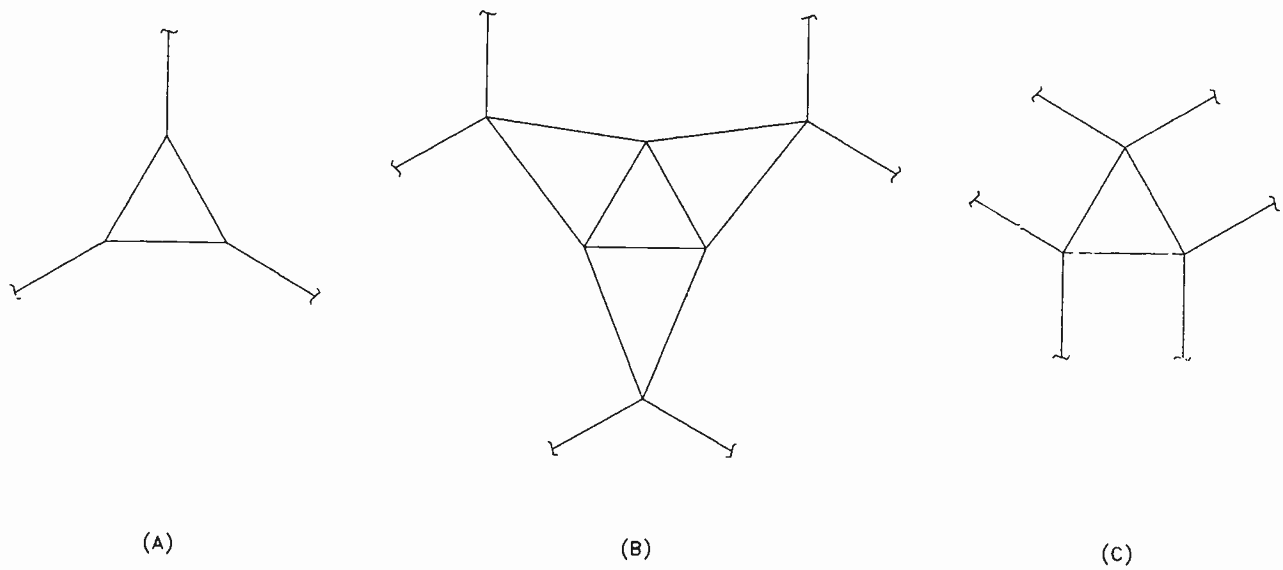

Figure 2.2-4. Typical guy arrangements.

slenderness ratios resulting in triangular towers having a span-to-width ratio as great as 49, it is usually economical to limit the ratio to a maximum of 30. While there is no upper limit to the number of guy levels imposed by any code, a practical limit for economical design is ten.

The position of equipment on the tower is an important factor in determining the location of guy levels. Preferably, guy attachments should not be located within the apertures of side mounted TV and FM broadcast antennas. Equipment producing large localized wind loads, such as microwave antennas or clusters of two-way radio cabinets and antennas, should not be positioned near the center of a span between guys.

If the tower will be subjected to ice loading, it is desirable to reduce the number of guy levels to minimize loads imposed on the tower by ice accumulation on the guy cables.

The number of anchors in each guy direction is dependent on several factors including the number of guy levels, the soil conditions, topography, and obstacles. As a general guideline, it is desirable to limit the number of guy levels attached to a single anchor to five. However, there is nothing absolute about this number, and other conditions may dictate using an anchor for a greater number. There are some soil conditions where it may be economical to provide two or more smaller anchors, while another instance the use of one large anchor might be desirable. If minimizing the area within which the tower would fall in the event of collapse is a consideration, a minimum of two anchors should be used in each direction. Where the elevations of the anchors differ from the tower base, it is desirable to vary the distance of the anchors from the tower base to maintain nearly equal initial tensions in the guy cables. Anchors higher than the tower base should be moved toward the tower; and anchors that are lower, away from the tower. The designer should specify the amount of movement.

Materials

Nearly all broadcast towers are made from steel because it provides the most economical structure. The selection of the grade and shape of steel is obviously an important design consideration.

Steel used for towers commonly has low carbon content with yield strengths in the range of 36,000 to 60,000 psi. These materials have good ductility and are suitable for welding. Some towers have been built using higher grade materials with yield strengths up to 100,000 psi, but the savings in weight are more than offset by higher base prices and increased fabrication costs. Regardless of the grade of material, the steel's mechanical and chemical properties should be certified by the producing mill to ensure that it conforms to the design requirements.

The shape of the material as well as its size and strength affects the tower's load carrying capacity. The shape also has a significant effect on the magnitude of loads produced by wind. Design standards permit a reduced wind load on round members as little as 57% of the wind load for flat or angular members of the same width. For this reason, solid round bars, round structural tubes and pipe are often used. This advantage in wind load is offset somewhat by increased fabrication costs, due to the necessity of welding plates to connect the various members.

There is no one grade or shape of materials that is best. The choice depends to a large degree on the preference of the designer and the type of fabricating facilities available.

A factor equally as important as the selection of the grade and shape of the structural steel is the design of the connections. For shop welded connections, the compatibility of the base and filler metals and required preheat temperatures must be considered. The procedures used must be qualified and the welders certified to use them. Inspection procedures should be compatible with the weld design.

Bolts for field assembly may be of various types. Usually those for the main load carrying members are high strength. If positive resistance to slippage of the connections is required, they should be designed as friction connections.

Guys

The most common material for tower guys is galvanized strand. This material has excellent strength and durability. Its structural elongation due to seating of the individual wires in the strand is small and can be almost entirely eliminated by pre-stressing the strand to 50% of its breaking strength at the factory. This should be performed for guys on tall towers with factory connected end fittings.

For guys on AM towers, and those close to FM and TV antenna apertures, a nonconductive material is sometimes desirable. Two such materials that have been used are Kevlar rope and fiberglass rods. When using these materials, careful attention must be given to protection against corona effects, fatigue, and deterioration due to exposure to ultraviolet light. Also, their elongation characteristics under load must be evaluated. They require delicate handling at all times.

Just as for the tower structure, the connections for the guys are as important as the guy material itself. Some of the most common connections are as follows:

- *Sockets* of forged or cast steel attached with molten zinc or epoxy resins develop the full strength of the guy. They are normally installed at the factory and proof loaded to 50% of the guy breaking strength. This type of fitting is most common for the larger guys used on tall towers.
- *Dead end grips* are preformed spiral wire loops in the shape of large hairpins. The two legs of the hairpin are wrapped around the guy with its closed end forming an eye. These grips are used for guys up to 1 in. in diameter and usually develop their full strength. They are easily installed in the field, but the ends must be completely snapped into place and a protective device installed to prevent ice from sliding down the guy and loosening the grip.
- *Clips* used to clamp the ends of guys (when properly applied and tightened) develop 90% of the guy's strength for sizes up to and including 7/8 in. and 80% for larger sizes. To install them it is necessary to bend the strand back on itself to form a loop; thus, the use of clips on large cables is difficult. The saddle of U-bolt type clips must be installed on the load side and not the dead end side, which provides another potential error in their installation.
- *Swaged sleeves* develop between 85% to 100% of a guy's strength depending on the size of the guy and equipment used to squeeze the sleeve. These fittings are usually installed at the factory and can be proof loaded. They are advantageous for connecting closely spaced insulators where the length of dead end grips is unacceptable.
- *Wedge Type Sockets* are available for guys up to 1-1/4 in. diameter and develop 100% of their strength. They are most advantageous for guys larger than those for which dead end grips are available.
- A *serving* is a connection made by rolling the individual wires of a strand back on the strand itself. This method has for the most part been replaced with dead end grips, but it is advantageous for small guys with closely spaced insulators.

Insulators

Insulators in radio frequency applications must withstand mechanical and electrical stress in a varied, changing exterior environment. Selection of insulators should be made with these factors in mind. Insulators primarily designed for 60 Hz applications are unsuitable, particularly at high RF powers.

The most common insulating material is a wet process porcelain, which has excellent compressive strength and good insulating capabilities for frequencies up to 2 MHz. Synthetic materials are also used. Some other types of insulators are as follows:

- *Base insulators* for AM towers are made from porcelain with appropriate steel end plates or ferrous/nonferrous castings. For guyed towers, a rocking arrangement is provided in the form of a convex plate and pin at the top, or a pivot pin at the bottom of the assembly to hold the tower in place and relieve the porcelain from bending loads which could cause cracking. For self-supporting towers, the insulators are bolted between the tower leg and base pier, and are designed to sustain both uplift and download while keeping the porcelain in compression.
- *Sectionalizing insulators* are sometimes required to isolate sections of a guyed tower. Where a compression load only is applied, a guyed tower base with minor modifications can be used. If a tension load is anticipated, a push-pull insulator similar to the type used for self-supporting towers is required. Under no circumstances should the porcelain be put in tension.
- *Guy insulators* are available for primary insulation and for break-up purposes. Primary insulation (insulators next to the tower) should be selected to withstand the full voltage appearing at the guy attachment point. This is to ensure that sufficient insulation remains if all the break-up insulators in the guy line flash over. Break-up insulators, used to reduce reradiation, are selected to withstand the transmitter induced voltage and static voltage. Break-up insulators are usually low voltage types, sometimes protected from flashover and subsequent power arc by a static dissipation device. Guy insulators are available in many styles classified as either compression or tension types.

Finishes

Steel is susceptible to deterioration from atmospheric corrosion. To prevent deterioration, the tower members and hardware must be given a protective coating. This coating is usually zinc, which has excellent resistance to corrosion, and, because it is higher in the electrochemical series of the periodic table of elements, it provides cathodic protection to exposed steel surfaces adjacent to it. Even though the zinc coating may be scraped or otherwise damaged, it continues to inhibit corrosion of these exposed areas, and rust will not develop beneath adjacent zinc coats.

There are several methods for applying the zinc including hot dip galvanizing, flame spraying, electroplating and painting. All must be applied to clean surfaces.

- *Hot dip galvanizing* consists of dipping the steel into a bath of molten zinc. A metallurgical bond develops between the steel and the zinc, which adheres to it. When galvanizing tubular members, it is necessary to provide holes in both ends to ensure that the inside surfaces are coated. Careful attention must be given to the type of base and weld metals used, as well as to the welding and forming procedures used in fabrication, to safeguard against possible embrittlement of the steel when galvanized. When properly applied, this process provides the most durable coating.
- *Flame spraying* consists of spraying molten zinc at high pressure onto the steel surfaces. The bond in this process is mechanical rather than metallurgical. The coating produced is more porous and has less resistance to abrasion than the hotdip galvanized coating. It cannot be used for the inside of hollow sections or other cavities where access is difficult.
- *Electroplating*, while suitable for small objects, does not produce a coating thick enough to withstand a hostile environment. This method is not recommended for tower parts or hardware.
- *Zinc rich paint* consists of extremely finely divided zinc in an inorganic or organic vehicle. It is not a metal coating method, but rather a painting procedure. Its resistance to abrasion and durability are less than hotdip galvanizing. This procedure is, however, useful for maintenance.

Ice Prevention

Coatings are available to reduce the adherence of water to surfaces and subsequently the formation of ice on them. However, no reliable means exists to completely remove the risk of severe ice accretion.

Access Facilities

A tower must have some access facilities in order to maintain it and the equipment the tower supports. For small towers, the bracing members of the tower itself often serve as steps, or step bolts are attached to one leg or face.

Ladders

For taller broadcast towers, a fixed ladder inside the tower is desirable. The Occupational Safety and Health Administration (OSHA) standards for these ladders require a minimum clear width between side rails of 16 in. and a maximum rung spacing of 12 in. OSHA also requires that any continuous ladder more than 20 ft in height be equipped with a safety device. This device consists of a continuous rail, either rigid or cable, running up the center of the ladder. A clamping device attached to the climber's safety belt rides along this rail. As long as the climber is in a normal position, the clamp slides freely; if the person begins to fall, a cam actuated mechanism freezes the clamp to the rail and prevents the person from falling.

Elevators

For tall towers supporting multiple antennas, it is often desirable to install an elevator. Most tower elevators are of the power, cable driven type with a capacity of 500 to 750 lbs. and a speed between 80 and 100 ft per minute. They consist of a drive mechanism, car, guide rails, hoist cable with supporting sheaves, tension weights, electronic controls and a two-way communications system.

Considerable attention must be given to elevator safety features. These should include limit switches to prevent travel beyond the upper and lower landings on the tower, an automatic brake on the driving mechanism that is activated by an interruption in power, a mechanism to automatically clamp the car to the rails in the event of a broken hoist cable and interlocks to prevent operation with the car gate open. It is advisable to determine the applicable state or municipal government regulations that may apply and whether permits, tests and inspections are required before the tower and elevator system are designed.

The added wind and dead loads from an elevator system are substantial and must be considered in the tower design. Also, careful attention must be given to the positioning of the ladder. RF transmission lines and electrical conduits in relationship to the elevator. The ladder must be positioned so it is accessible from the elevator car and can be used for an emergency descent. While the elevator hoist cables can be restrained in guides on the return side, they are free to move about under wind load on the lifting side. Therefore, the conduits and transmission lines must be protected from hoist cables striking and damaging them. If a side mounted TV or FM antenna produces a high RF field within the hoistway, protection must be provided to prevent arcing between the hoist cables, the tower structure, and other appurtenances.

Transmission Line Bridges

To allow for the different thermal expansion and contraction characteristics of broadcast towers and transmitter buildings, it is necessary to keep the tower separated from the transmitter building. Unless the transmission line is placed underground, it is necessary to provide a structural support for it at a height compatible with the transmitter location in the building. The top of the support can be covered with steel grating or plate to protect the line from falling ice. The details of this structure can become quite involved for sites with multiple antennas, uneven terrain and roadways, or obstacles between the tower and building.

Stairways

The lower landing for a tall, guyed broadcast tower with an elevator is often 30 ft or more above ground level. A stairway may be desirable to permit easier access to the landing. This structure can be combined with the transmission line support bridge, or it may be completely separate. It may also be desirable to install a small capacity boom above the lower landing to lift radio cabinets or other equipment onto the landing.

ANTENNA STRUCTURE REGISTRATION REQUIREMENTS

On November 30, 1995, the FCC adopted rules to streamline the Commission's antenna structure clearance process by requiring owners to register their antenna structures with the Commission by June 1998. The registration generally applies to structures more than 60.96 m (200 ft) above ground or located near an airport. Detailed information concerning registration is available from the FCC's Forms Distribution Center at 1-800-418-FORM or through the Internet at http://www.fcc.gov/wtb/antstruc.html.

Upon registering an antenna structure with the Commission, an owner will receive a Registration (FCC Form 854R) containing a Registration Number which uniquely identifies the structure. The owner must provide each tenant licensee and permittee with a copy of the Registration. In turn, licensees and permittees must reference this registration number on all subsequent Commission filings.

Marking and Lighting Antenna Structures to Meet FAA/FCC Requirements

Unless otherwise specified by the Commission, each new or altered antenna structure to be registered on or after July 1, 1996, must conform to the FAA's marking and lighting recommendations set forth on the structure's FAA determination of "No Hazard," as referenced in the following FAA Advisory Circulars: AC 70/7460-1H, *Obstruction Marking and Lighting* and AC 150/5345-43D, *Specification for Obstruction Lighting Equipment*. These documents contain FAA recommendations for marking and lighting structures which pose a potential hazard to air navigation. The Commission considers these specifications, standards and general requirements stated in these documents to be mandatory. The Advisory Circulars listed above may be obtained from the U.S. Department of Transportation, Subsequent Distribution Office, Ardmore East Business Center, 3341 Q 75th Avenue, Landover, Maryland 20785. Fax requests for these publications may be sent to (301) 386-5394.

CERTIFICATION PROCEDURE FOR FAA APPROVED LIGHTING EQUIPMENT

To assure that all lighting equipment manufactured to meet the specifications in the FAA Advisory Circulars, a certification program was established. On January 1, 1990, ETL Testing Laboratories, Inc., began administering the certification program for airport and obstruction lighting equipment. Lighting equipment approved by the FAA prior to January 1, 1990, continued its approved status without additional product qualification testing for a period of five years through a grandfather clause, provided sufficient documentation exists to support the certified status.

The FAA's Advisory Circular 150/5345-53, *Approved Airport Equipment* lists the certified lighting equipment that ETL has verified as meeting the applicable FAA specifications. When building or modifying an antenna structure that involves the use of obstruction lighting equipment, it would be wise to check the FAA approved lighting equipment list or require a certificate of compliance from the manufacturer.

FCC Lighting Requirements

During construction of an antenna structure for which obstruction lighting is required, a temporary light must be installed at the uppermost point of the structure. This light shall be similar in type and intensity to the permanent light that is required for that level. In addition, as the height of the structure exceeds each level at which permanent obstruction lights will be required, another level of temporary lighting must be installed. If practical, the permanent obstruction lights may be installed and operated at each required level as construction progresses.

Inspection of Antenna Structure Lights and Associated Control Equipment

The owner of any antenna structure which is registered with the Commission and has been assigned lighting specifications:

(a) (1) Shall make an observation of the antenna structure's lights at least once each 24 hours either visually or by observing an automatic properly maintained indicator designed to register any failure of such lights, to insure that all such lights are functioning properly as required: or alternatively. (2) Shall provide and properly maintain an automatic alarm system designed to detect any failure of such lights and to provide indication of such failure to the owner.

(b) Shall inspect at intervals not to exceed three months all automatic or mechanical control devices, indicators, and alarm systems associated with the antenna structure lighting to insure that such apparatus is functioning properly.

Notification of Extinguishment or Improper Functioning of Lights

The owner of each antenna structure which is registered with the Commission and has been assigned lighting specifications:

(a) Shall report immediately by telephone or fax to the nearest Flight Service Station or office of the

FAA any observed or otherwise known extinguishment or improper functioning of any top steady burning light or any flashing obstruction light, regardless of its position on the antenna structure, not corrected within 30 minutes. Such reports shall set forth the condition of the light or lights, the circumstances which caused the failure, the probable date for restoration of service, the FCC Antenna Structure Registration Number, the height of the structure (AGL and AMSL), and the name, title, address, and telephone number of the person making the report. Further notification by telephone or fax shall be given immediately upon resumption of normal operation of the light or lights.

(b) An extinguishment or improper functioning of a steady burning side intermediate light or lights, shall be corrected as soon as possible, but notification to the FAA of such extinguishment or improper functioning is not required.

Recording of Structure Light Inspections in the Owner Record

The owner of each antenna structure which is registered with the Commission and has been assigned lighting specifications must maintain a record of any observed or otherwise known extinguishment or improper functioning of a structure light and include the following information for each such event:

(a) The nature of such extinguishment or improper functioning.
(b) The date and time the extinguishment or improper operation was observed or otherwise noted.
(c) The date and time of FAA notification, if applicable.
(d) The date, time and nature of adjustments, repairs or replacements made.

Time When Lights Should be Exhibited

Red obstruction lights may be operated by a control device adjusted so the lights will be turned on when the northern sky illuminance reaching a vertical surface falls below a level of 60 footcandles (645.8 lux) but before reaching a level of 35 footcandles (376.7 lux). The control device should not turn the lights off until the northern sky illuminance rises to a level of at least 60 footcandles (645.8 lux). The lights may also remain on continuously.

Medium intensity white and dual obstruction lights should be operated by a control devise so the lights will switch from their day/twilight to night mode of operation when the northern sky illuminance reaching a vertical surface falls below a level of 5 footcandles (53.8 lux) but before reaching a level of 2 footcandles lux). The control device should reverse intensity changes when going from night to day/twilight mode.

High intensity white and dual obstruction lights should be operated by a control device so the lights will switch from their day to twilight mode of operation when the northern sky illuminance reaching a vertical surface falls below a level of 60 footcandles (645.8 lux) but should occur before it drops below 35 footcandles (376.7 lux). These lights should switch from their twilight to night mode of operation when the level falls below 5 footcandles (53.8 lux) but should occur before reaching a level of 2 footcandles (21.5 lux). The control device should reverse intensity changes when going from night to twilight to day within these same levels.

Options for Marking and Lighting Antenna Structures

Red obstruction lights are used to increase conspicuity during nighttime. Painting is required for daytime and twilight marking. The red obstruction lighting system is composed of flashing omnidirectional beacons (L-864) and steady burning lights (L-810). When the system is comprised of more than one level of flashing beacons, the beacons should flash simultaneously.

Medium Intensity Flashing White Lighting System

Medium intensity flashing white (L-865) obstruction lights provide conspicuity both day and night and eliminates the need to paint the structure. The medium intensity flashing white light system is composed of flashing omnidirectional lights. These systems are used on structures up to 500 ft (153 m).

Dual Red and White Flashing Medium Intensity Lighting System

The dual lighting system includes red flashing beacon or beacons (L-864) and steady burning red lights (L-810) for nighttime and medium intensity flashing white lights (L-865) for daytime and twilight use.

These systems may be comprised of a red flashing beacon (L-864) and a medium intensity flashing beacon (L-865) or a single beacon which incorporates both the red and white flashing beacons (L-864/L-865). These systems are used on structures up to 500 ft (153 m) and eliminate the need to paint the structure.

High Intensity Flashing White Lighting System

Lighting with high intensity flashing white obstruction lights (L-856) provides the highest degree of conspicuity both day and night. When this system is operated 24 hours a day, other methods of marking and lighting may be omitted. These systems are used on structures from 500 ft. (153 m) to the maximum height allowed by the FAA.

Dual Red and White Flashing High Intensity Lighting System

The dual lighting system includes flashing red lights (L-864) and steady burning red lights (L-810) for nighttime and high intensity flashing white lights (L-856) for daytime and twilight use. When using this system, marking the structure with paint is eliminated. These systems are used on structures from 500 ft (153 m) to the maximum height allowed by the FAA.

Other Electrical Circuits to Consider in Antenna Structure Planning

During the planning and design stages for an antenna structure, there are other electrical circuits that are necessary or should be considered to make its operation more efficient and provide a source for future income. Most tall antenna structures require deicing circuits with their associated control devices. An ac utility circuit can provide access to 120 volt power at selected elevations on the structure and will reduce costly maintenance time. If the structure's height justifies an elevator, control circuits for the elevator are necessary.

Circuits to provide power and multi-pair cables to various platforms are needed for rental communication system customers.

DESIGN STANDARDS

The vast majority of towers in the United States have been designed in accordance with the EIA-222, *Structural Standards for Steel Antenna Towers and Antenna Supporting Structures.* This standard has been used since 1959 when it replaced the Radio Electronic Television Manufacturers Association (RETMA) Standard TR-116. The current revision "F" of EIA-222 was issued in 1996. The standard has been approved by the American National Standards Institute and carries the designation ANSI/TIA/EIA-222-F-1996.

This standard is intended to provide minimum criteria for specifying and designing steel antenna towers and antenna supporting structures. Unlike general specifications and building codes, it is applicable only to antenna tower and supporting structures. As such it contains criteria specific to these structures that are not readily available elsewhere. Therefore, it is always advisable to specify that your tower must conform to this standard.

Appendix A: Purchase Checklist of this standard is provided to alert the purchaser to the most common area where site-specific data may be required to supplement the minimum criteria of the standard.

Statutory

Most municipal and state governments have statutory codes regulating the design of structures. Many of these are patterned after or include one of several model codes. The most common of these are:

- Building Officials and Code Administrator International (BOCA) Basic *Building Code.*
- International Conference of Building Officials (ICBO) *Uniform Building Code.*
- Southern Building Code Congress (SBC) *Standard Building Code.*

These codes cover all types of structures and are directed primarily toward conventional types of buildings. As such, they do not contain all the criteria necessary to design broadcast towers. For example, none of them includes a recommended safety factor for guy cables.

The industry standard ANSI/TIA/EIA-222-F-1996 is compatible with these codes. In fact, its use for calculating and applying wind loads is required by the BOCA Basic Building Code and, as an approved American National Standard, is permitted by the ICBO Uniform Building Code.

Since it is necessary to comply with the applicable statutory requirements, it is important to determine what these requirements are and include them in the purchase specifications for the tower.

Loads, Analysis & Safety Factors

In addition to a tower's own dead weight and the dead weight of the appurtenances and equipment it supports, the tower must withstand the forces of nature, wind, ice, temperature changes, and earthquakes.

Wind Load

Wind produces a principal load on tower structures. For design purposes it is represented as a horizontal static force.

Wind load is specified in terms of a basic wind speed at 10 m (33 ft) above ground level. The ANSI/TIA/EIA-222-F-1996 standard provides a tabulation of recommended minimum values for this speed for each county in the United States. This standard also gives specific procedures and factors for calculating wind loads considers the following:

- Wind pressure is proportional to the square of wind speed.
- Wind speed and, consequently, wind pressure vary with respect to the height above ground.
- The effects of gusts of brief duration, which exceed the fastest mile basic wind, speed.
- The effects of the configuration, size, proportions, shape and orientation with respect to the wind direction of the structural components of the tower and its appurtenances.

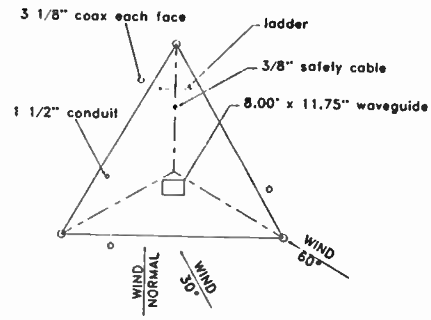
An example of wind load calculation for a typical broadcast tower is given in Figure 2.2-5.

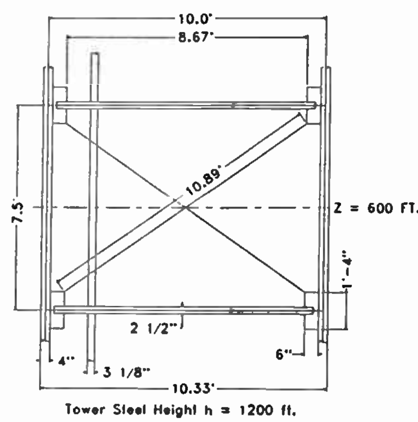
Since the wind may act from any direction it is necessary to apply the calculated wind loads in any horizontal direction to determine the maximum stresses produced in the structure. For a triangular tower, three directions must be considered; while for a square tower, two are sufficient (see Figure 2.2-6).

In addition to this direct load in the direction of the wind (drag), there may also be a component of load perpendicular to the wind direction (lift). These lift components are calculated in a manner similar to that for drag forces using different shape coefficients that vary with respect to the angle of attack between the member's geometric axis and the wind direction. They are most significant for wind acting on guy cables, microwave antennas and rectangular waveguides.

Ice Loads

Ice accumulations have two effects on a tower. The weight of the ice acts directly on the structure in the same manner as the dead weight. The ice accumulation





PROCEDURE

1. Determine basic wind speed V (mph). Minimum recommended values in Section 16
2. Calculate exposure coefficient $K_z = (Z/33)^{2/7}$ where Z is the height (ft) above ground level to midpoint of section. $1.0 \le K_z \le 2.58$.
3. Calculate velocity pressure. $Q_z = 0.00256 K_z V^2$ (lbs/sq.ft).
4. Calculate gust response factor. $G_h = .65 + 0.6/(h/33)^{1/7}$ $1.0 \le G_h \le 1.25$ where h is the height (ft) of the main tower structure.
5. Calculate the projected areas A_f and A_r (sq. ft.) of the flat and round structural components in one face including any linear appurtenances attached to a face and considered as structural appurtenances. Include the thickness of any ice load.
6. Calculate the solidity ratio $e = (A_f + A_r)/A_g$ where A_g is the gross area (sq. ft) of one tower face as if the face were solid.
7. Calculate the structure force coefficient. $C_f = 3.4e^2 - 4.7e + 3.4$ (Triangular cross section) $C_f = 4.0e^2 - 5.9e + 4.0$ (Square cross section)
8. Calculate reduction factor for round structural components $Rr = 0.51e^2 + 0.57 \le 1.0$.
9. Determine direction factors D_f and D_r from Table 2 for the wind direction considered.
10. Calculate the projected area A_e (sq. ft) of the structural components. $A_e = D_f \times A_f + D_r \times A_r$
11. Calculate the projected area A_a (sq. ft) of each individual appurtenance not considered as a structural component.
12. Determine the appropriate force coefficient C_a from Table 3 for each individual appurtenance and sum the products $C_a \times A_a$ (sq. ft).
13. Calculate total wind force. $F = q_z \times G_h (C_f \times A_e + \Sigma C_a \times A_a)$

EXAMPLE

1. V = 80 mph.
2. $K_z = (600/33)^{2/7} = 2.29$
3. $q_z = 0.00256(2.29)(80)^2 = 37.52$ lbs/sq. ft
4. $G_h = 0.65 + 0.60/(1200/33)^{1/7} = 1.009$
5.

	Structural Component	Af	Ar
Legs	2 x 4/12 x 7.5	-	5.00
Gusset PL	4 x (6 x 8)/144	1.33	-
Horizontal	2.5/12 x 8.67	1.81	-
Diagonals	2 x 0.75/12 x 10.84	-	1.36
3-1/8"coaxes	3.125/12 x 7.5	-	1.95
	Σ	3.14	8.31

6. $e = (3.14 + 8.31)/(10.33 \times 7.5) = 0.148$
7. $C_f = 3.4(0.148)^2 - 4.7(0.148) + 3.4 = 2.78$
8. $R_r = 0.51(0.148)^2 + 0.57 = 0.58$
9. For wind normal $D_f = 1.0$, $D_r = 1.0$.
10. $A_e = (1.0)(3.14) + (1.0)(0.58)(8.31) = 7.96$
11.

Appurtenance	A_a	C_a	$C_a \times A_a$
Ladder rails(2 x 0.75)/12 x 7.5	0.94	1.2	1.13
Lad. rungs(7.5 x 0.75)/12 x 1.33	0.63	1.2	0.76
Safety cable 0.375/12 x 7.5	0.23	1.2	0.28
1-½" Conduit 1.9/12 x 7.5	1.19	1.2	1.43
Waveguide 11.75/12 x 7.5	7.34	2.0	14.68

12. $\Sigma C_a \times A_a = 18.28$ sq.ft
13. $F = (37.52)(1.009)((2.78)(7.96) + 18.28) = 1531$ lbs.
$F = 1531/7.5 = 204.2$ lbs/ft.

Figure 2.2-5. Wind force calculations for latticed towers using ANSI/TIA/EIA-222-F-1996.

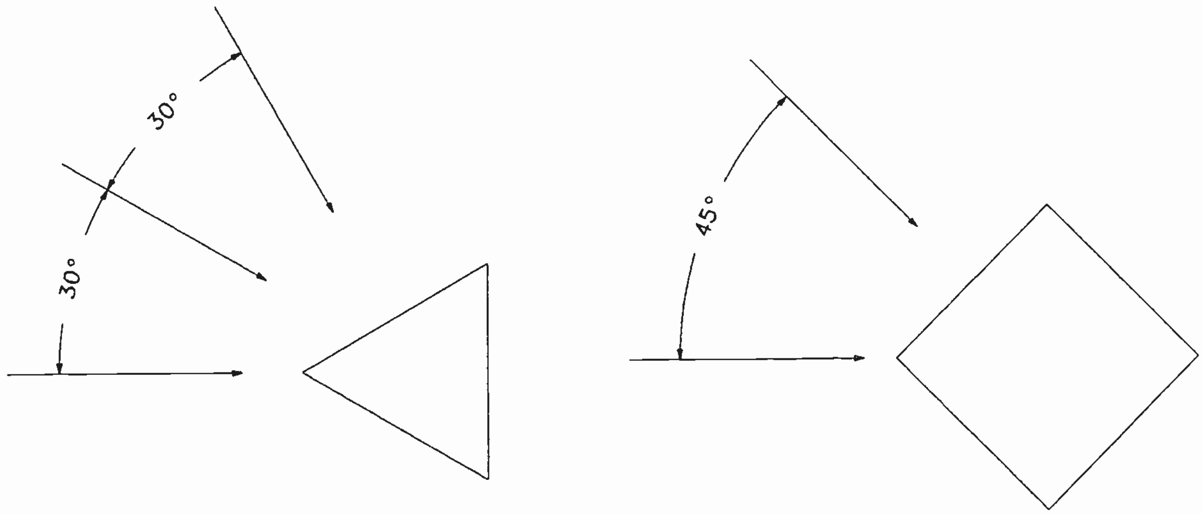


Figure 2.2-6. Wind directions to be considered.

also increases the area exposed to the wind and consequently the load produced by the wind. This increase is substantial on small components such as guy cables, tension rods, ladders, small diameter transmission lines and reflector screens for antennas. It is also possible for the ice accumulation to alter the aerodynamic shape of members, thereby requiring the use of a different coefficient in calculating the wind load. An example is a set of closely spaced parallel coaxial lines. Without ice each would be considered a round cylindrical member. With accumulated ice, they would present a large flat area to the wind requiring a different coefficient.

Ice produces an entirely different stress distribution in a tower than wind, so it is not reasonable to merely increase the design wind load to provide for ice accumulation. It is also a misconception that ice will break up and blow off the tower, and therefore, ice and wind need not be considered simultaneously. The ANSI/TIA/EIA-222-F-1996 Standard states that unless otherwise specified by the purchaser, 75% of the wind load shall be applied in combination with the ice load. This is equivalent to reducing the basic wind speed by a factor of 0.866. In areas where ice is likely to form, it is advisable to specify a basic wind speed to act concurrently with the ice load as well as the basic wind speed without ice), (70 mph with ice and 80 mph without ice).

While the ANSI/TIA/EIA-222-F-1996 Standard emphasizes the need to consider ice loads, it does not provide specific recommendations for the magnitude of the accumulation. This responsibility is left with the purchaser.

Temperature Changes

Changes in temperature have no significant load producing effects on self-supporting towers, but they can on guyed towers. Because of their differences in length, the guy cables expand and contract different amounts than the tower itself and thereby require elastic deformations from stress changes. The effects are greatest for those cables having the flattest angle with the ground. While the stresses produced are considerably less than those produced by wind and ice loads, they should be considered in the design of guyed tower.

Seismic Loads

Loads due to earthquakes are considered to act horizontally and are dependent on the mass and stiffness of the tower. They are usually less than those produced by wind but are distributed in a different manner. Procedures for calculating these loads are given in some of the design standards including ASCE 7, but not in ANSI/TIA/EIA-222-F-1996. While a tower properly designed for wind loads is usually adequate for seismic forces, they cannot be neglected in areas with frequent and intense earthquake occurrences.

Structural Models & Analysis

A self-supporting tower may be described structurally as a cantilevered space frame or truss. Although it may have many different members, it is a relatively simple structure, and the determination of the forces in the individual members due to the applied static loads is easily done using fundamental principles of structural mechanics. The potential modes of failure are buckling of individual leg or bracing members under compressive loads, and shear or tension failures of the connections.

A guyed tower is a much more complex structure than a self-supporting tower. Whereas there is only one basic path through a self-supporting tower for the loads to be transferred to the ground, there are several for a guyed tower. The distribution of the loads among these paths is dependent upon the relative stiffness of guy systems and the tower shaft.

Each span of the tower has a stiffness with respect to relative deflections from axial and shear forces and bending and torsional moments. This stiffness is a function of several variables, including the geometric configuration, the mechanical properties and the sizes of the individual members.

Each guy cable also has a stiffness with respect to movement of its attachment point to the tower that is a function of the amount of initial tension, the magnitude of ice load, and the magnitude and direction of wind load on the cables. By evaluating all of these, it is possible to simulate all the guys at a given level as a spring having a specific stiffness. Because of the nonlinearity of some of the relationships involved, the spring constant derived is only valid for a specific set of conditions and for a finite range of translation. Similarly, a torsional spring constant can be derived. It is interdependent with the translation stiffness and is also valid for only a finite range of translation.

Another difference between a guyed and self-supporting tower is the magnitude and significance of the axial load. For a self-supporting tower this is composed only of the gravity loads from the tower, its appurtenances and any ice load. It is independent of wind load, and its effects on individual member loads are relatively small. The axial load for a guyed tower includes in addition to the gravity loads, the vertical components of the tensions in the various guys. Since these tensions are directly affected by the wind load, the axial load is now dependent upon wind load and its effects on the individual leg members are relatively large. Tension in the guy wires also produces an additional bending moment on the tower equal to the product of the axial load and the deflection of the tower.

Despite the complexity of the relationships involved, the availability and widespread use of computer systems permits accurate structural analysis of guyed towers. There are several different structural models that may be used.

One of the most commonly used idealizes the tower shaft as a continuous beam-column on nonlinear elastic supports (the guys) subjected to simultaneous transverse (wind and or seismic) and axial (dead, ice and vertical components of guy tensions) loads.

The modes of failure are buckling of individual leg or bracing members under compressive loads; rupture of bracing members, guys, or guy anchor arms under tensile loading; and shear or tension failures of the connections.

Dynamic Considerations

As previously mentioned, even though wind and earthquakes involve kinetic energy, their effects are simulated by equivalent static loads determined in accordance with the design standards. In recent years there have been more sophisticated efforts to investigate the actual response of tower structures to the dynamic aspects of wind gusts. A conclusion drawn from these studies is that the bending moments in the upper portions of tall, guyed towers are considerably higher than those determined by the usual static analysis. Consequently, the loads imposed on the vertical legs and their splice connections would be amplified beyond safe limits indicating a potential failure condition. Considering the usual fundamental periods of tall guyed towers, it appears that towers taller than 1,200 to 1,300 ft. should be investigated dynamically as well as statically.

There are two other phenomena related to the dynamics of wind that are important in guyed tower design. These are aeolian vibrations and *galloping*, both of which involve periodic loading.

Aeolian vibrations are low amplitude, high frequency movements, which occur in the tower guy cables due to a phenomenon known as vortex shedding. If they are not suppressed through the use of dampers, they can result in destruction of the filaments in the tower lights at the least, or fatigue failure of guy cable and collapse of the tower at the worst. Dampers attached at one or both ends of the guy cables have proven effective in controlling these vibrations and should be considered for all tall, guyed towers.

Galloping is a condition of instability involving large amplitude, low frequency movements. It is caused by the perpetual amplifications of periodic loads due to the motion of the body itself. The most dramatic and well-known example of galloping is the collapse of the Tacoma Narrows suspension bridge in 1940.

For tower structures, galloping is usually associated with the guy cables on tall towers, but in at least one instance it was related to a large rectangular waveguide. There have been several different methods involving detuning and energy dissipation used for preventing galloping in guy cables that appear to be successful. In the case of the rectangular waveguide, galloping was controlled by moving the waveguide inside the tower along the centroidal axis from its original position on the outside of one face. This reduced the torsional rotation of the structure, which was the source of the perpetuating force. Based on this experience, it would appear prudent to always install this type of waveguide inside the tower unless adequate torsional rigidity is provided throughout the height of the tower.

Allowable Stresses & Safety Factors

Towers, like all other structures, are designed so that the maximum anticipated stresses are less than those which would cause failure. This ratio of failure stress to maximum allowable stress is known as the safety factor. It is intended to provide for several variations from the ideal conditions assumed for design including loads greater than anticipated, imperfections in materials and tolerances in fabrication and construction.

The ANSI/TIA/EIA-222-F-1996 Standard refers to the American Institute of Steel Construction (AISC) *Specification for the Design, Fabrication and Erection of Structural Steel for Buildings* for the design of the structure's members and to the American Concrete Institute (ACI) *Building Code Requirement for Reinforced Concrete Structures* for the design of the reinforced concrete foundations and guy anchors.

For towers under 700 ft in height the allowable stresses given in the AISC specification may be increased by one third. For towers 1,200 ft or taller, no increase is permitted. For towers between 700 and 1,200 ft, the amount of increase permitted is determined by linear interpolation.

In a similar manner, the required reinforced concrete strength for towers under 700 ft in height must equal 1.3 times the calculated reactions and for towers 1,200 ft and taller, 1.7 times the calculated reactions. Linear interpolation between these two values is used for towers between 700 and 1,200 ft to determine the required strength.

The minimum safety factor for guy cables is 2 for towers under 700 ft in height and 2.5 for towers 1,200 ft and taller with linear interpolation applied between these two heights.

EFFECTS OF ANTENNAS AND TRANSMISSION LINES

Except for AM radiators, the tower is the necessary evil to support the broadcast antennas and transmission lines at a suitable height above ground. Thus the effects of this equipment are of paramount importance.

Loads

Every antenna imposes a wind load and a dead load on the tower. If the antenna is mounted atop the tower, it also imposes an overturning moment. If it is mounted on a side of the tower, the antenna imposes a torsional moment. For TV and FM broadcast and microwave antennas, these loads are relatively large, and their location has a significant effect on the placement of guy cables.

Transmission lines feeding the various antennas also impose wind and dead loads on the tower. These loads are distributed uniformly between the antenna and their entry point near the base of the tower. The total produced by a coaxial line or waveguide is frequently greater than that produced by the antenna itself. The shape of the transmission line influences the magnitude of the wind load, with circular or elliptical lines having loads that are 60% of those for rectangular lines with the same projected area.

It is important not to overlook the support system required for transmission lines. Some large waveguides have support systems that require nearly continuous vertical structural members that add substantial wind and dead loads. Small, flexible lines require supports at a maximum interval of 3 to 4 ft, which is often less than the vertical spacing of horizontal members in the tower. Thus, it may be necessary to provide an additional support structure for these lines, again adding to the total load.

An important consideration when locating transmission lines is that the ANSI/TIA/EIA-222-F-1996 Standard permits linear appurtenances that are attached to the tower face, and do not extend in width beyond the normal projected area of the face, to be treated as structural components rather than individual appurtenances for purposes for purposes of calculating wind load. The effect of this is to substantially reduce the magnitude of the calculated wind load on these appurtenances (see Figure 2.2-7). When this procedure is used, it is mandatory that the transmission lines be installed as specified in the design. This may not be

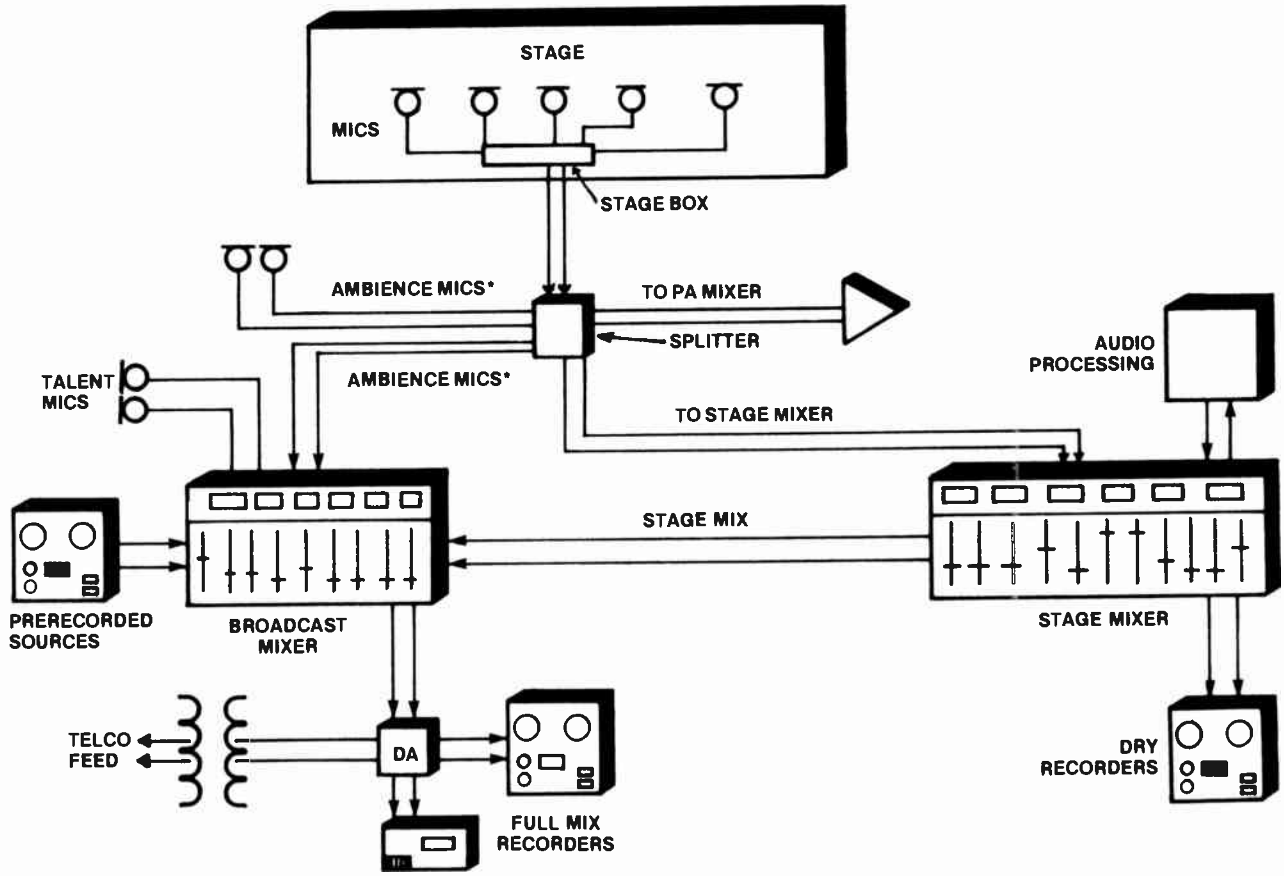

Figure 3.9-14. Typical setup for a large scale remote, using two separate mixing positions. This arrangement is ideal for events such as festivals or conventions, where several separate performances with set-changes in between will be broadcast in a long, continuous program from the site.

remote setup, in which two separate mix positions are used.

When multiple mixers (such as the PA and separate radio truck just mentioned) each require access to the same microphones, a number of options are available. The most primitive would be to put separate microphones up for all mixers, but this becomes extremely impractical and unsightly, especially in the case of handheld vocal or announce microphones. For this reason, a shared arrangement is best, using proper *microphone splitting* techniques. Good transformer isolated microphone splitters are recommended for this. One mixer remains directly connected to the microphones, while the others are fed by the secondary of a bridging input transformer. The microphones see only one load, and the consoles remain electrically isolated from one another. Typical microphone splitters also provide separate ground lift switches for each channel (or in some cases, a single, ganged switch), by which ground loops between consoles can also be eliminated. If condenser microphones are used, their phantom power can only come from the console receiving the direct feed, since dc supply voltage from the transformer fed consoles will not pass back across the transformers.

A cassette or DAT recorder is often useful at a remote broadcast because it gives added flexibility to the remote crew. The recorder input signal can be taken from an auxiliary output on the audio mixer, allowing interviews or material from the PA system to be mixed and recorded for later use on the air. This is always preferred over relying on a recorder at the station end, because the backhaul system may degrade the audio quality, especially when a POTS line is used, but also because the line may fail during the broadcast. In either case, an on site deck provides a good quality recording for later production and broadcast.

In cases where a separate stage mixer or truck is used for the stage premix, it is this *dry* premix that is usually recorded on site. These production recordings therefore include only the mix of the actual event, and do not contain any continuity or other local production elements added at the broadcast mixer. The full broadcast mix can be recorded for archival purposes either at the remote site or at the station.

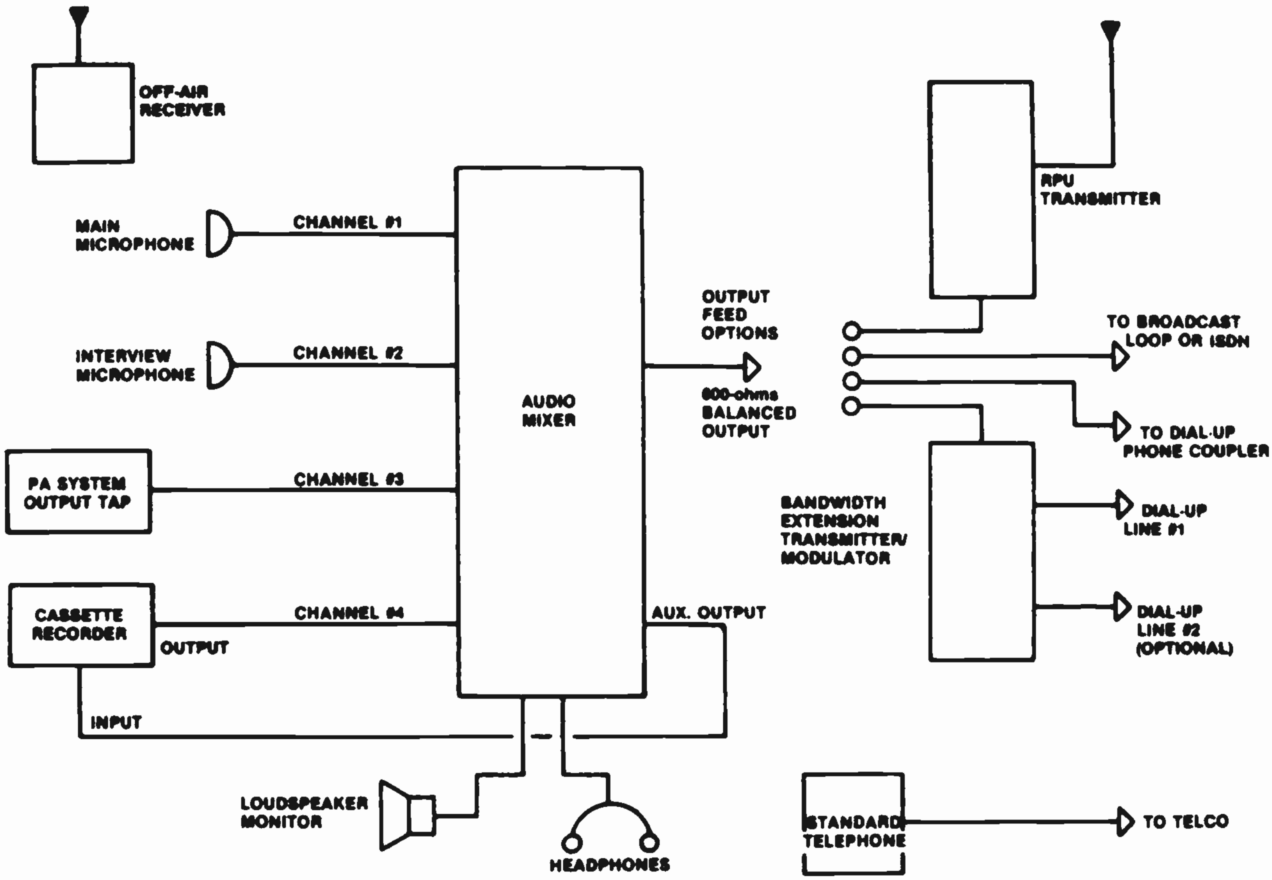

Figure 3.9-13. A typical equipment configuration for a medium scale RENG broadcast.

components below about 60 Hz. At the studio, the receiver audio output would run through another high pass filter to remove any control tone signals from the automation system program channel feed.

A more recent solution available in most cases is the use of the cellular telephone system for this purpose. A portable or transportable cellular phone has become a common part of most RENG systems today. When more than just simple voice communication is required—such as *interruptible foldback* (IFB) or other audio signals to talent headphone or monitor speakers—an audio interface to and from the cellular phone may be used, on both ends of the link. Unlike the standard dial-up system, the cellular phone system is 4-wire end-to-end (it uses a *pair* of RF channels, one for transmit and one for receive), so that no hybrid or gating circuitry is required. The same type of hardware may be used for feeding RENG program audio from the field when no other method is possible. Audio performance will typically be somewhat degraded from what is expected from the standard dial-up phone feed.

REMOTE PRODUCTION EQUIPMENT

The audio equipment used at the site of the remote will vary as widely as the types of programs broadcast. Figure 3.9-13 illustrates a typical production setup used with either a wired or wireless backhaul system.

In this example, a 4-channel audio mixer is used to mix the sources and drive the telco service or RPU transmitter. Careful attention should be given to the connection of the mixer output to a POTS line. A phone coupler should be used between the mixer and the telephone unless the mixer is specifically designed to work directly into a hot dial-up line (one with dc voltage across it). This caution applies to a connection made either to the phone-line tip and ring wire or to the telephone set through the handset terminals.

As shown in Figure 3.9-13, two microphones are used—one for the announcer and another for interview guests. An output is taken from the local PA system to pick up audio from meetings, speeches, music or whatever. For more complex and high budget music remotes, a separate mixer or audio truck is used to *premix* the stage microphones down to a stereo feed, which is then fed to the mixer in Figure 3.9-13. Sound reinforcement (PA) feeds of musical acts are not always inclusive of all the elements required—or are improperly balanced—for the radio mix. For this reason, a separate radio mix is often required if proper radiophonic balance and control of the stage event's mix is critical. Figure 3.9-14 shows a more complex

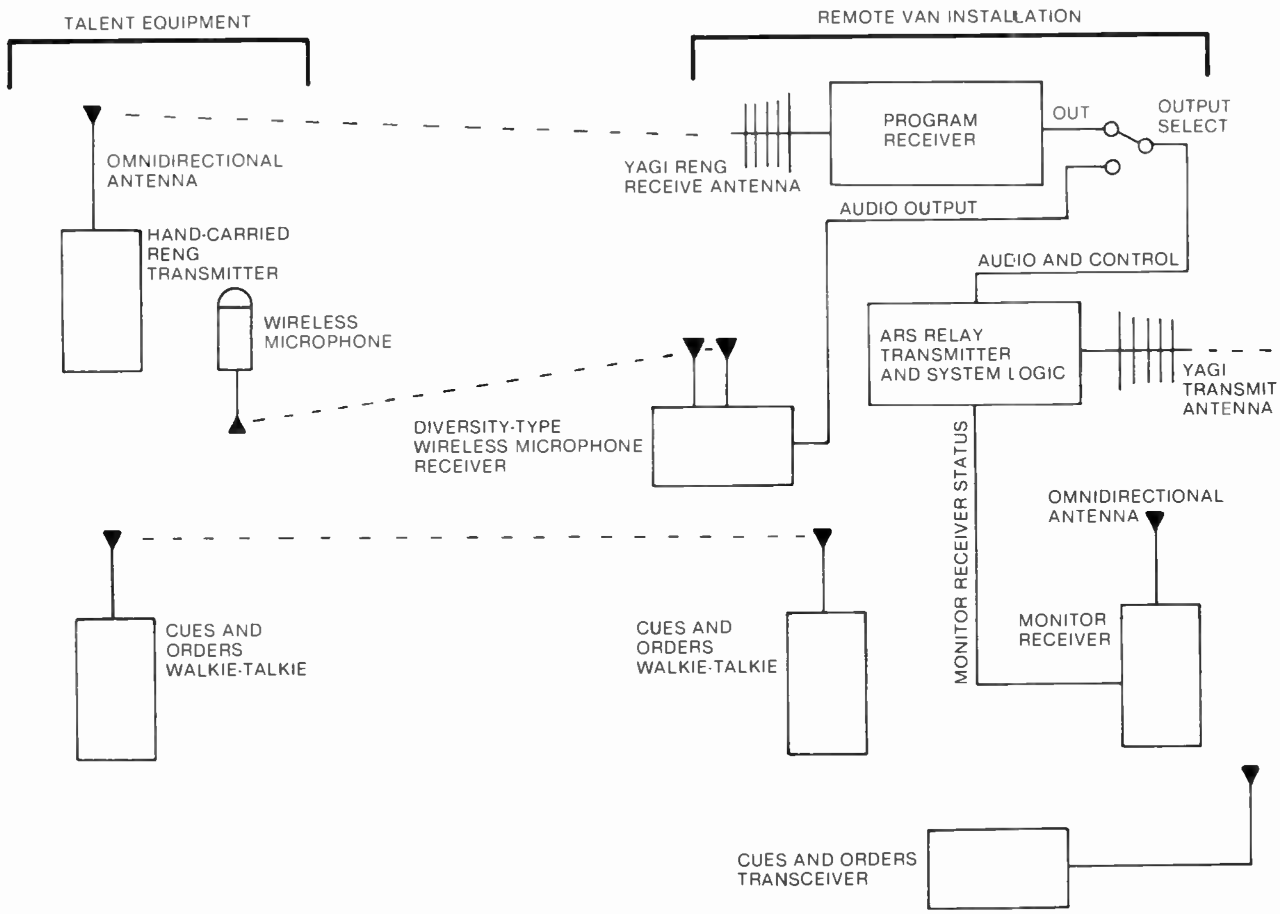

Figure 3.9-12. The use of an ARS system at the event site for added range and talent flexibility.

plest method is an over-the-air cue in which the talent simply listens to the station's air signal and takes cues from the studio announcer or a pre-recorded introduction. Other methods include use of an FM station's subcarrier signal for cueing information or a separate, dedicated, radio link specifically used for cueing instructions, either from the remote truck (as shown in Figure 3.9-12) or from the main studio.

If a station needs a more sophisticated intercommunication system, a trunked 800 MHz radio system can be considered. A 5- or 10-channel trunked repeater acts like a small telephone exchange in which the number of users (telephones) exceeds the number of channels (trunk lines). Telephone system theory is used to predict the busy level that can be expected during periods of heavy radio traffic. Three minute time out timers are usually included in mobile transmitters to enforce time limits.

These trunked systems can tie into the regular telephone system at hilltop repeater sites or at trunked base stations. Broadcasters interested in 800 MHz trunked radio should contact their local area land mobile operator to see if such a system is available.

In certain situations, a station may be able to design and license a UHF business radio system for dispatch and coordination of RENG crews. These systems offer the user the luxury of not encountering a busy signal, as may occasionally happen in a trunked system. As with the trunked network, no programming is allowed on a UHF business radio system.

One of the problems often encountered when carrying remote broadcasts on an automated station is the need to have an operator standby during the broadcast to trip the automation system to the next event when the talent at the remote site gives the proper cue. The simplest way around this problem is through the use of a sub-audible tone that is high enough in frequency to not interfere with the ARS sub-audible tone that may be used for repeater equipment, and low enough in frequency so that it does not interfere with normal program audio. For example, in a system where the ARS access sub-audible tone is 25 Hz, an *advance system* control tone of 45 Hz could be used. In order to prevent premature automation system trip commands, the program audio input to the remote location transmitter would be passed through a high pass filter to remove any audio

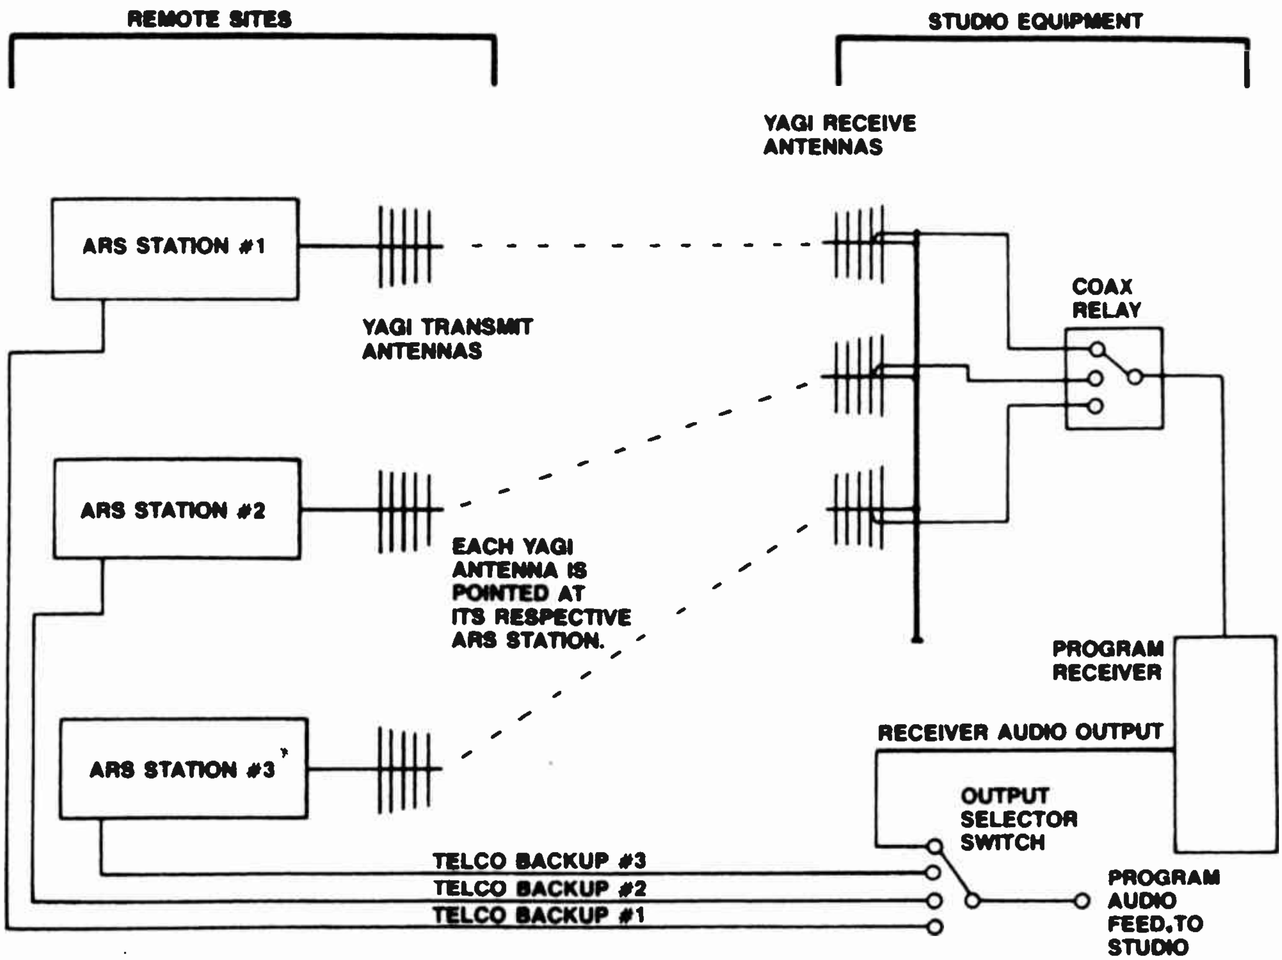

Figure 3.9-11. A multiple site ARS network feeding a central studio control point. Note each ARS station is also connected to the studio via a land line for backup protection.

allows the receiver to squelch and generate a loss-of-carrier command to the ARS system logic. In order to maintain positive control over the system, a means should be provided to override the ARS logic by remote control from the studio.

Figure 3.9-12 shows some of the ways the remote location program audio can be transmitted. As mentioned previously, the communications transceiver is used for cues and orders from the studio location. The program channel signal can consist of a hand- or pack-carried transmitter, which directly feeds the studio receiver or one or more ARS systems. Figure 3.9-12 also shows a repeater station configuration that can be used when a high power transmitter is required to reach either the studio or the ARS relay point. The use of a repeater—configured as a standard ARS station—in a car or van outside the remote location also gives the talent at the event greater flexibility, because a small hand-carried transmitter can be used there, rather than a larger unit with antenna and power cables attached. This arrangement is also ideally suited for use with a wireless microphone, which gives the talent an even greater degree of flexibility. The receive antenna at the remote van can be either an omnidirectional unit or a Yagi. The system shown in Figure 3.9-12 includes a monitor receiver to prevent ARS transmission over traffic already in progress.

There is a limit, of course, to the number of times a signal can be repeated and still maintain good audio specifications. Moreover, each added hop in the path between the remote site and the studio increases the chances of a spurious signal interrupting the remote feed. Each additional hop also increases the complexity of the system and the vulnerability of the link to equipment failure. The design goal for any RENG system should be to keep the arrangement as simple and direct as possible, while still providing talent flexibility, backup protection and high performance.

Remote Cues and Orders

Communications with a remote crew from the studio can be accomplished in one of several ways. The sim-

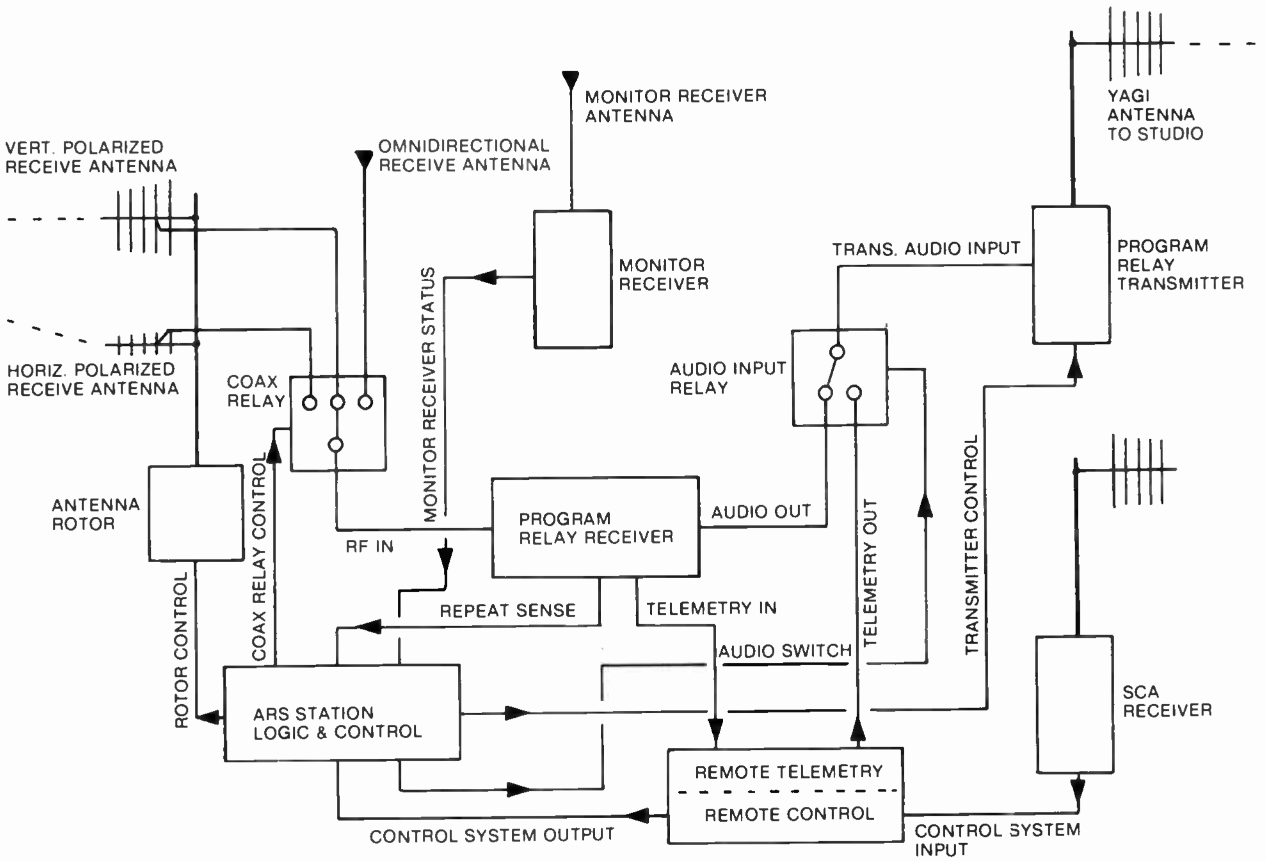

Figure 3.9-10. A high performance secure channel ARS station with remote control of system functions.

necessary switching and positioning work at the ARS site. For stations with multiple site capability on the main transmitter remote control system, the ARS remote points can be simply treated as other *transmitter sites* and controlled as such from the master unit.

A monitor receiver is included at each ARS installation to inhibit activation of the ARS transmitter if a transmission is already in progress on that frequency. As shown in Figure 3.9-10, the control commands are received over a subcarrier receiver from the main station transmitter. The relay station logic interfaces the remote control unit with the receive antenna coaxial switch and the antenna rotor control box. During set up, the telemetry section of the remote control unit provides an audio FSK signal that is sent back to the studio control unit via a telco line or the ARS transmitter, as shown.

The SCA, omnidirectional program, monitor and relay transmit antennas are all fixed in position. Only the directional receive antennas, one set for horizontal polarization and the other for vertical polarization, are movable. An arrangement such as that shown in Figure 10, will provide maximum flexibility and minimum risk of program audio disruption.

In a system where two or more of the ARS stations shown in Figure 3.9-10 are used, an arrangement such as that shown in Figure 3.9-11 may be implemented. The studio remote control unit is used to determine which of the ARS stations is allowed to repeat the program traffic. Those stations that will not be used to repeat the program material would be instructed by the studio operator to remain inactive. For multiple site ARS operation, as shown in Figure 3.9-11, individual directional receive antennas, or a single directional receive antenna mounted on an antenna rotor, may be used to receive the ARS traffic at the studio.

For protection against system failure, an equalized telco loop can be installed between each ARS point and the main studio. With this backup provision, an equipment failure in the relay gear would not interrupt a remote broadcast.

One of the problems sometimes experienced with ARS equipment is the possibility of a desired signal opening the system, and an undesired signal keeping it open after the desired traffic has ended. This can occur if the tone burst method of repeater keying is used. For example, a valid tone burst signal unlocks the ARS system and then undesired noise or traffic holds the channel open after the desired traffic has ended by prohibiting a loss-of-carrier indication from the receiver. The ARS will thus be stuck open until the level of the interfering signal drops to a point that

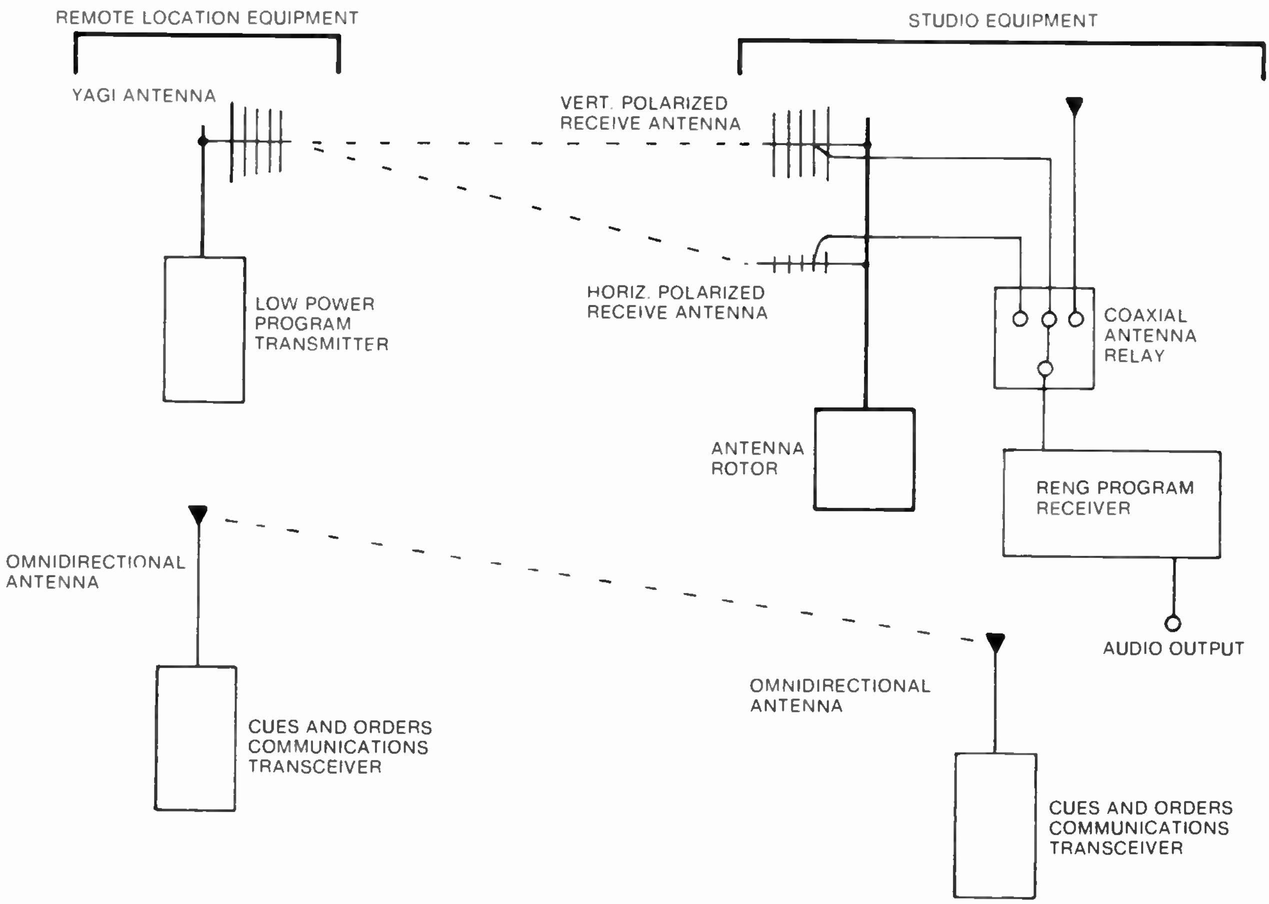

Figure 3.9-9. A high performance 2-point RPU system designed for operation in frequency-congested areas.

requiring wide frequency response and a high signal-to-noise ratio. The lower power program relay transmitter and directional receive and transmit antennas provide a secure and quiet channel, without causing interference to other RPU band users in the area.

Between remote broadcasts and when beginning the initial set up procedure for a remote, the omnidirectional antenna is patched into the broadcast quality RPU band receiver at the studio through the coaxial antenna relay. Once contact has been established with the remote crew, one of the directional antennas—which are mounted on a common mast driven by a remote-controlled antenna rotor—is switched into the studio receiver. The polarization of the transmission from the remote site is planned before the remote crew leaves the studio. Selection of either horizontal or vertical polarization is made during the frequency coordination process, or at the discretion of the user. Engineers may find that a particular polarization may yield better results from certain geographical areas, and in such cases, that polarization would be chosen. Once the proper antenna has been selected, the antenna rotor is adjusted for maximum received signal strength. The studio operator then talks the remote crew into the best position for its Yagi transmit antenna. At this point, the antennas are locked down and the link is ready for the remote broadcast.

If a variable power transmitter is used at the remote site, or transmitters of various power levels are available, the transmitter power would next be adjusted to the point necessary to achieve the required S/N performance at the receiver. After power output adjustment, the antennas on both the receive and transmit ends should be checked again for correct positioning.

While this process may be time consuming and require the purchase of additional equipment, it will assure a high quality, secure RF link from the field to the studio. This system will also result in a minimum of unwanted radiation to other RPU band users.

Figure 3.9-10 shows a high performance, secure channel ARS. The same antenna selection and positioning procedure is used in the ARS installation as was used in the 2-point system of Figure 9, except that the antenna switching and positioning work is done by remote control. The link for this remote control system can be a subcarrier on the main station broadcast signal, a separate dedicated radio link, a dial-up telephone patch or a leased telco data or voice loop. A standard broadcast transmitter remote control system is used, with the common channel on-off/up-down functions performing the is side mounted on the station's broadcast tower, and the RPU receiver system is housed in the shack or transmitter building with the station's broadcast transmission equipment. RPU audio is routed from the receiver output back to the studio via a high quality transmitter-to-studio link (TSL). Simple control of the RPU receiver (power on/off, frequency selection) can be broken out on spare relays or closures from the broadcast transmitter's remote control system.

A more sophisticated approach may be called for in rougher terrains. The system configuration shown in Figure 3.9-8 overcomes the geographical coverage area problem through the use of an automatic relay station (ARS). The range of a RENG system can be greatly extended through the use of an ARS. Such systems also make it possible to use lower power transmitters in the field, since the transmitter at the program origination point need only be powerful enough to reach the ARS site. This often allows the use of smaller and lighter remote transmitters, usually hand-carried or pack-carried units. The arrangement shown in Figure 3.9-8 will satisfy the requirements for wide area coverage and is sufficient for radio markets where spectrum congestion is not a problem. Because all antennas in the system are omnidirectional, however, the configuration is not suitable for use in larger urban areas which are experiencing frequency allocation problems. For such applications, a more sophisticated approach is needed to RENG activity.

Figure 3.9-9 shows a high performance 2-point RENG system designed for operation in spectrum congested areas. At the remote site, two transmitters and two antennas are used. The communications transceiver is used for conveying setup information between technical personnel at either end, and to relay cues and coordinating information. The low power transmitter and its associated directional transmit antenna are used to relay the program audio signal to the studio. At the studio site, a communications transceiver, feeding an omnidirectional antenna, is used for the setup information, cues and coordination work. The multi-antenna receive system is used for program audio pickup.

The *cues and orders* radio system shown in Figure 3.9-9 is used for general purpose communications not

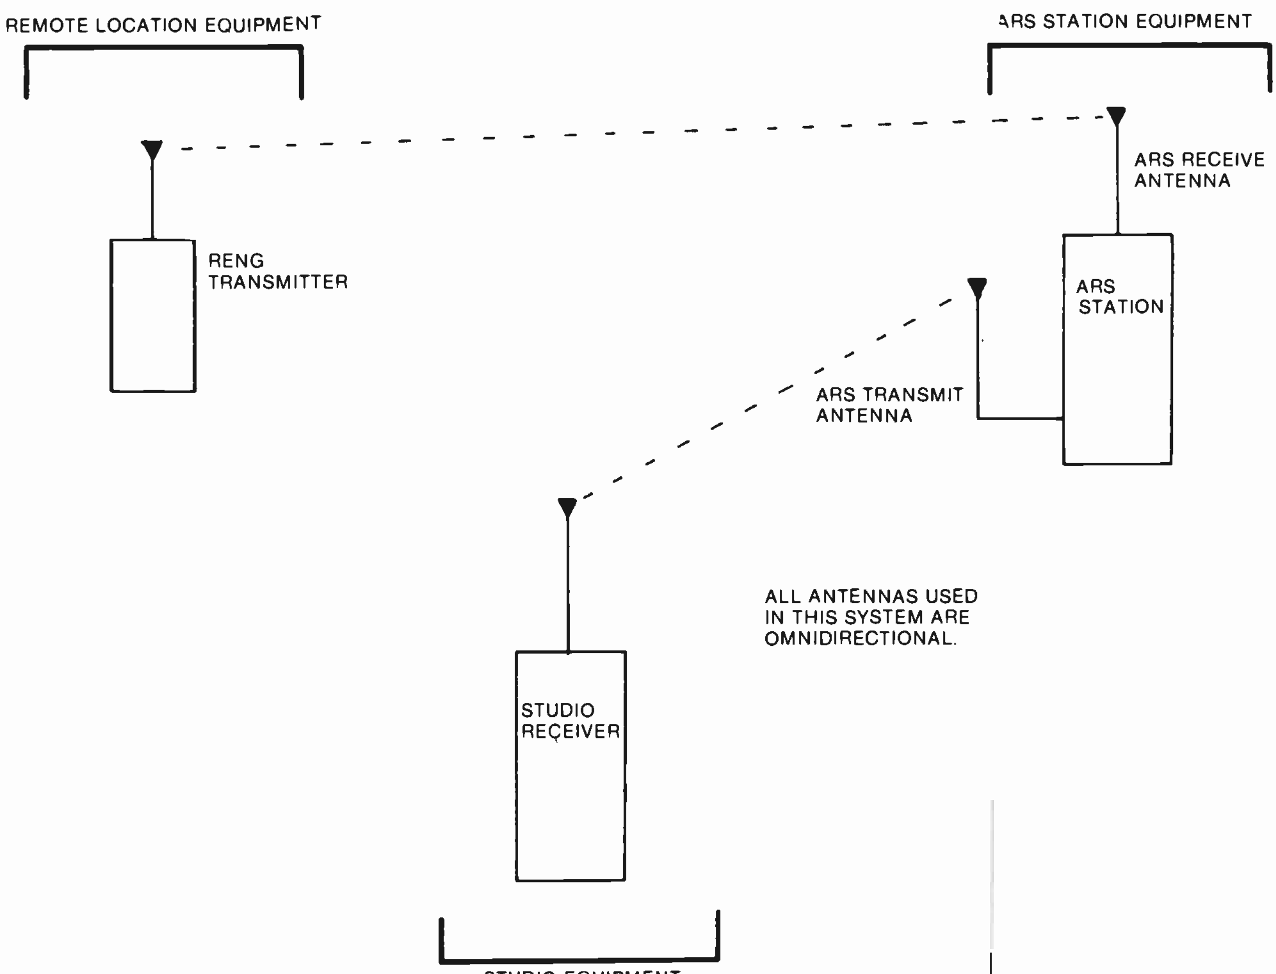

Figure 3.9-8. The basic RENG program relay configuration using an ARS station between the remote location and the studio.

of medium level co-channel signals. Preselectors are often necessary at mountaintop or antenna farm locations because of the high level RF signals present at such sites. It is not uncommon to have a 1 kW land mobile paging transmitter operating in the 454–455 MHz range located near an RPU band receiver that is working in the 455–456 MHz frequencies. High power FM or TV transmitters can also cause desensitizing of the receiver front end, unless adequate bandpass filtering has been included in the receiver design.

The locations commonly used for relay sites are seldom ideal from an environmental standpoint. They are often inaccessible during portions of the year, very hot in the summer and very cold in the winter. For these reasons, rugged equipment should be selected, in order to minimize downtime. Temperature extremes can also cause problems for frequency determining elements, as well as accessories such as cavity filters, preselectors and preamplifiers. Since relay sites are often difficult to reach, equipment should be designed for easy maintenance, preferably through module replacement. A spare stock of modules should be kept at the site so that the system can be quickly returned to operation. The defective module can then be serviced at the studio, or returned to the factory for repair.

Regular performance tests should be made of the RENG system, just as an engineer would do with any other important chain of equipment at the station. Regular checks and measurement often allow the engineer to spot problems that could cause a total system failure if left unattended. If trouble is experienced with a piece of receiving equipment, the possibility of interference from other services should not be overlooked. A spectrum analyzer is invaluable for such work.

System Configuration

The requirements of users will vary greatly from one station to the next and from one market to the next. There are, however, several standard system configurations that can be modified to fit the requirements of most users. These range from the simple point-to-point program relay system common on many small-scale operations, to complicated multi-point relay installations with automatic signal-quality voting circuits.

Figure 3.9-7 shows the basic RENG program relay system in which one (or more) transmitters on a particular frequency are used in the field, and a signal receiver is located at the studio. All antennas used in the system are omnidirectional. While there is much to be said for system simplicity, such an arrangement is not practical in an increasing number of urban areas because of spectrum congestion problems and the need to cover large geographical areas.

A simple alternative approach for a station with a good yet conveniently located transmitter site (not co-located with the studio) is as follows. The RPU antenna

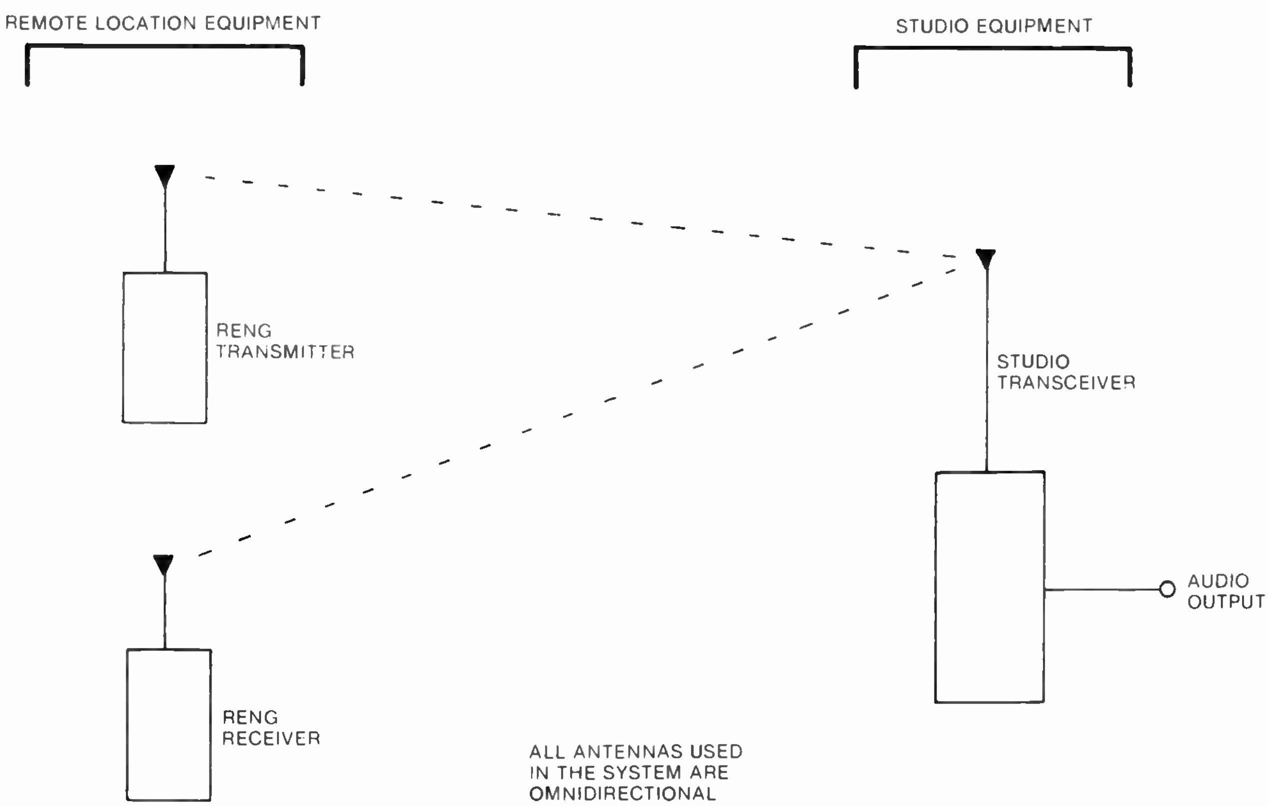

Figure 3.9-7. The basic RENG program relay system using a single hop from the remote location to the studio.

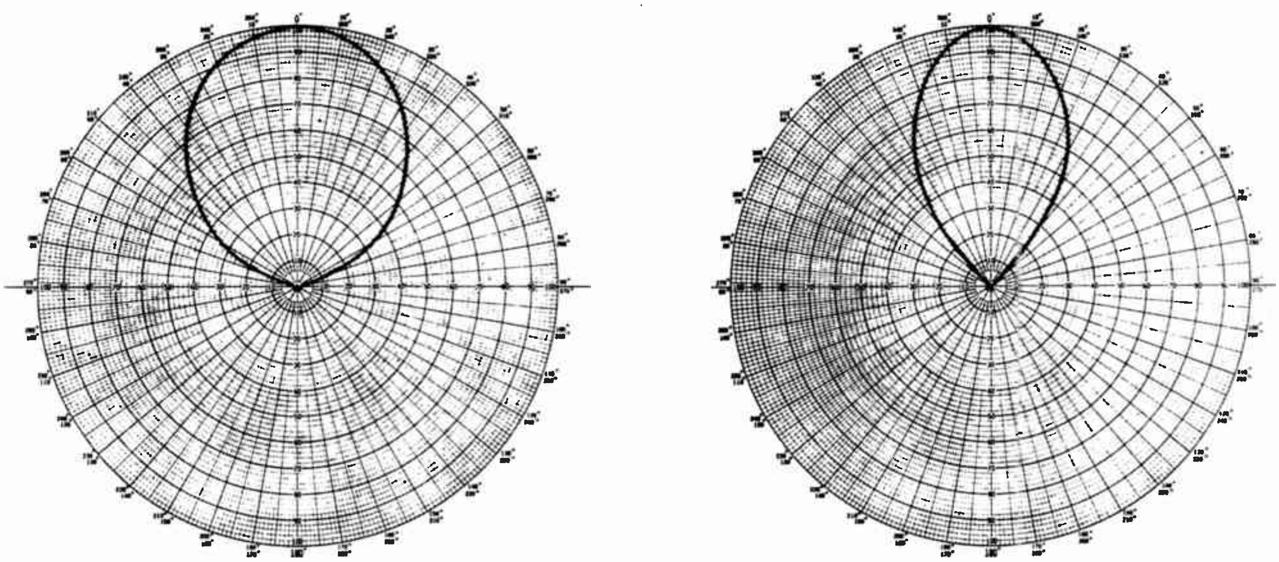

Figure 3.9-6. The radiation patterns for the Scala CL-400 broadband log periodic antenna, designed for use in the 450 MHz RPU frequency band. (Courtesy of Scala Electronics.)

back ratio of approximately 14 to 18 dB. Figure 3.9-5 shows the radiation pattern for a commonly used 5 element 150 MHz Yagi. This particular antenna measures 40″ × 40″ × 4″ and weighs 8 lbs. Thus it is small and light enough to be used on remote broadcasts. It is also suitable for permanent installations using either horizontal or vertical polarization. These antennas may be stacked in 2 and 4 bay arrays (with suitable phasing harnesses) for additional gain and directivity.

Most Yagi antennas are made to match the specific frequency requirements of the user. Multiple frequency operation using a single antenna is possible, however, with reasonable VSWR numbers, as long as the operating frequencies are not removed from the cut center frequency by more than 1 to 2%.

A more recent addition to the RENG user's bag of electronic tricks is the broadband log periodic antenna, which can be used on any channel within a wide band of frequencies. Such antennas provide a smooth pattern with minimal sidelobe radiation and a high front-to-back ratio (typically 25 dB in the 150 MHz band). Nominal gain for 150 MHz operation is 7 dB. Units can also be stacked to provide additional gain and directivity. Such antennas are usually larger and heavier than the familiar Yagi; however, they allow use of the antenna for virtually any frequency within the specified band at low VSWR levels (a maximum of 1.5-to-1 is typical). Figure 3.9-6 shows the radiation pattern of a log periodic antenna designed for use in the 450 MHz band. Horizontal or vertical polarization is available. The antenna shown in Figure 3.9-6 has a gain of 8 dB and a front-to-back ratio of 35 dB. Such a unit is therefore well-suited for operation in areas with high spectrum congestion.

Just as a TV or FM broadcast antenna must be protected against icing problems, so should antennas used in RENG applications. Although antenna deicers are not used in RENG installations, a radome is often available for an antenna to protect it from damage or degradation in performance due to snow, ice or salt spray.

Transmitter-receiver Considerations

Whatever the configuration of the planned RENG system, there are several important points that should be considered. Most of these items apply to receiving equipment, which usually present the greatest problems to a system designer. Transmitting equipment must also be selected with care, but the receiving links in a RENG system are the ones most often subjected to conditions that may make good performance difficult.

A receiver that has sufficient dynamic range and headroom should be selected to allow the system to deal with strong adjacent-channel signals, as well as very weak and very strong co-channel signals from transmitters in the network. A receiver with inadequate headroom will clip and yield distortion. Wide dynamic range active devices should be used in the receiver front-end, such as *gallium arsenide field effect transistors* (GAsFETs).

The need for a preamplifier or cavity preselector network ahead of the first RF stage should also be considered. RF preamplifiers can add sensitivity, but they can also cause overload conditions in the presence

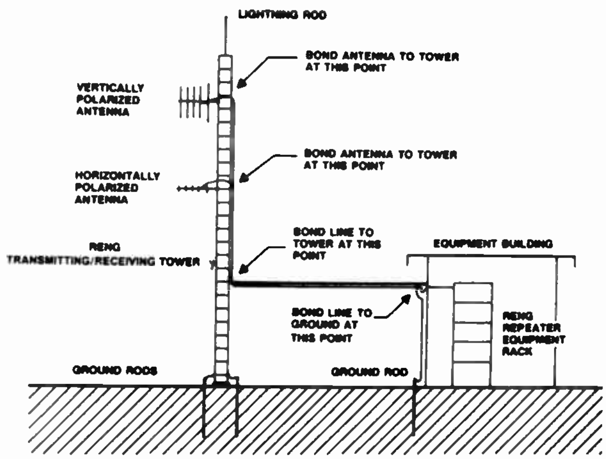

Figure 3.9-4. The recommended installation practices for RENG antennas and transmission lines.

wrapped with good quality tape. Unless this is done, rain may eventually work its way into the connector and cause signal loss or VSWR problems. The line should be grounded (using a recommended grounding kit) at the point where it leaves (or enters) the equipment building and where it starts its climb up the tower (unless the vertical distance to the antenna is less than 10 ft.). This will prevent any high voltage transients caused by lightning from entering the equipment building, and thus the RENG equipment. The advantages of using a low loss line are illustrated in Table 3.9-1. The two ends of the transmission line (at the receiver and transmitter) are probably the easiest parts of the hardwired system in which loss can be introduced, and so care should be taken to install the lines and connectors according to good engineering practice.

A short length of flexible coax is generally used on each end of the two transmission lines for connection to the equipment and antennas (when 1/2 in. or larger coax is used). This *pigtail* is normally no more than 18 in. long (see Figure 3.9-4).

Antenna Considerations

The selection of an antenna for use in a RENG system is an important decision because of the effect the antenna has on system performance and spectrum usage. The usual RENG antenna has, until recently, been the omnidirectional vertical whip with a small amount of gain. Many system planners, however, are now being forced by interference concerns to use directional antennas with moderate amounts of gain. The low power levels commonly used with RENG equipment and the RPU band frequencies make it possible economically to achieve increased ERP through the use of high gain transmit antennas. The use of high gain antennas also concentrates the radiated signal where it will do the most good, and minimizes radiation in directions that may adversely affect the RENG activities of other stations in the same, or nearby, communities.

The omnidirectional base station antennas commonly used in the 150 MHz and 450 MHz bands are vertically polarized units with 4 to 6 dB gain. Electrical beam tilt is sometimes available. Depending upon the manufacturer, up to 20° downtilt can be provided on 150 MHz antennas, and up to 11° is common for 450 MHz omnidirectional units. Large amounts of beam tilt are normally used when the antenna is to be mounted on a structure that is substantially above the surrounding terrain, thereby improving the antenna's close in coverage.

The typical directional RENG antenna is a medium gain 5 element Yagi. Such a unit provides about 9 to 10 dB gain over a reference dipole, with a front-to-

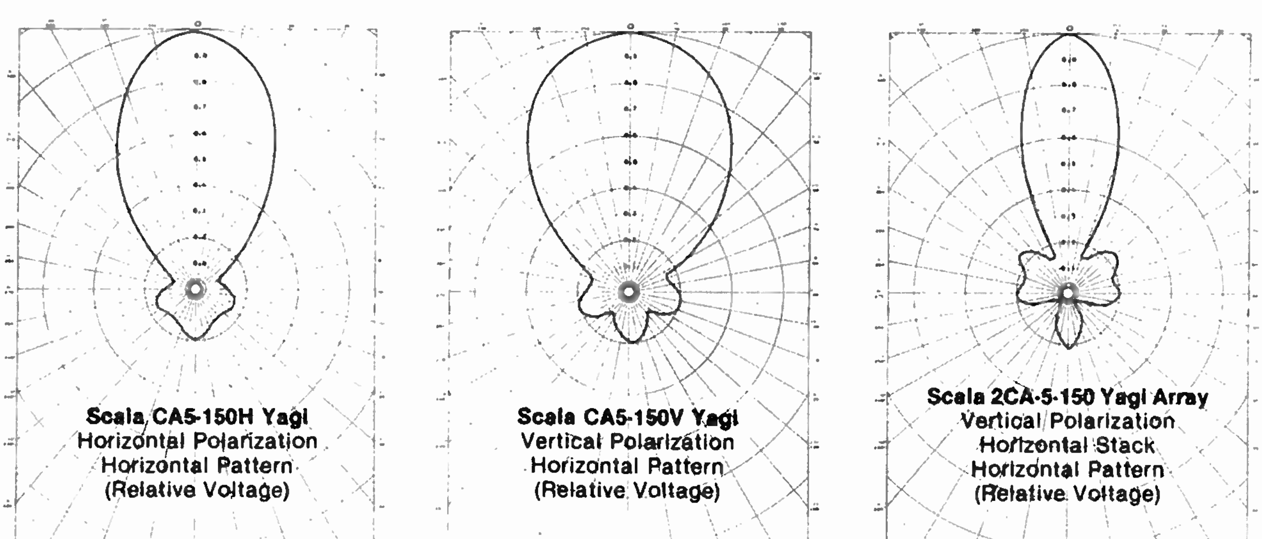

Figure 3.9-5. Radiation patterns for the CA5-150 5-element Yagi antenna made by Scala Electronics for use in the 150 MHz frequency band.

Now, the fade margin can be calculated:

Fade Margin (dB) = $G_s - L_s - R_m$

Where: G_s = total system gain (dB)
L_s = total system losses (dB)
R_m = minimum signal strength required for target S/N (dBm, a negative number)

G_s and L_s are determined by the equations previously shown. R_m (receiver sensitivity) is determined from the receiver manufacturer's specifications. If the manufacturer gives a receiver sensitivity figure in microvolts, the following formula can be used to convert to dBm:

$$R_m = 20 \log \times (V_r \times 10^{-6}/.7746)$$

Where: R_m = minimum required signal strength (dBm)
V_r = receiver sensitivity (microvolts)

R_m can also be found by using a communications receiver test set, available at most commercial and industrial communications radio service shops.

In order to predict accurately the performance of a RENG radio link, the value of R_m must be determined carefully. Many receiver manufacturers specify V_r for 20 dB of receiver quieting. This level is a convenient reference point; however, it should not be used for fade margin calculations. For maximum system performance and reliability, the fade margin determination should be made based upon the signal level required to provide the minimum acceptable receiver signal-to-noise performance.

The recommended fade margin for a 150 MHz band RPU system is at least 10 dB plus 2 dB for each 10 miles of line-of-sight path distance greater than 10 miles. At 450 MHz, the fade margin should be increased to a minimum of 15 dB plus 3 dB for each 10 miles of path distance greater than 10 miles. These fade margins are designed to limit periods of performance degradation of the radio link to 1% or less during worst case environmental conditions. The fade margin assumes transmit and receive antenna clearance above the ground and all obstructions of 50 to 100 ft.

While it is important to provide an adequate fade margin, needlessly high fade margins should be avoided because of the spectrum congestion problems that may result.

Other Planning Considerations

Path engineering for remote location broadcasts is seldom done for RENG activities because of the transient nature of such events. Rough estimates should be made, however, of the geographical areas of interest before attempting remote feeds. It is well worth the time spent to conduct a coverage survey of the primary areas of interest for RENG activity when planning an overall system to determine which locations provide good or marginal performance. A little planning and work ahead of time will save many problems (and probably dead air) once the system is put into operation.

For base or relay installations that, for one reason or another, cannot use frequencies in the RPU bands for program or control data interconnection, there is often an alternative to the telephone company audio loop back to the studio. Private common carriers in many markets are installing competitive audio circuits, which can be leased. If the RENG installation is co-located with a television relay station, it may also be possible to backhaul the RENG audio on one of the TV microwave system's subcarrier channels. The selection of receiving sites must be made with care, keeping in mind the area of coverage required of the receiver. The best location for a RENG system is not always the highest building in town. Placing a receive antenna at a high elevation in a metropolitan area can result in poor performance of the system in the downtown area, since the gain of many omnidirectional vertically polarized antennas decreases as the antenna is raised above the transmitting point. Tall buildings are excellent for point-to-point relay transmissions, but are generally unsatisfactory for wide area coverage in a metropolitan region.

An inexpensive installation option is available to AM broadcast stations that do not want to erect a separate RENG transmitting tower at the main transmitting site. An isocoupler can be installed at the AM tower base that will pass the RPU transmitter frequency with good efficiency (90% is typical), while at the same time presenting a high impedance to the AM band energy. Isocouplers are available in various frequency and power ranges. Installation of these devices may change the base impedance of the AM tower slightly thus an engineering consultant should be contacted before installation work begins.

Every effort should be made to locate the receiving antennas of a RENG system as far away from high power transmitting antennas as possible. This should be attempted regardless of the frequency separation between the receive unit and the suspect high power transmitting antenna. Failure to achieve adequate physical separation may require the installation of filters of various types on the receiver front-end.

In order to keep system losses to a minimum, a low loss transmission line should be used, such as the 1/2-in. foam filled coax shown in Figure 3.9-3. The transmission line and connectors must be made watertight if exposed to the elements. Each connector should be sealed with a silicone dielectric compound and then

Table 3.9-1
Typical Cable Loss for Popular Types of Transmission Line

	Transmission Line Comparisons					
	150 MHz		450 MHz		950 MHz	
	L	E	L	E	L	E
RG-58/U	6.0dB	25%	12.0dB	6.3%	20.0dB	1%
RG-8/U	2.5dB	55%	5.0dB	31%	9.0dB	13%
LDF4-50A	0.85dB	83%	1.7dB	67%	2.5dB	55%
LDF5-50A	0.48dB	90%	0.9dB	85%	1.55dB	71%
LDF7-50	0.28dB	94%	0.56dB	88%	0.88dB	84%

L = Loss in dB per 100 feet.
E = Approximate power transmission efficiency of 100-ft. length.
Note the poor performance figures for RG-58/U. LDF4-50 is 1/2-in. foam filled line, LDF5-50 is 7/8-in. line and LDF7-50 is 1-5/8-in. line. (Courtesy of Scala Electronics.)

change either the transmitting or receiving antenna height or to employ a diversity reception system, if a long term solution is needed.

Determining the Fade Margin

A gain and loss balance sheet should be computed to determine the fade margin of the proposed system. An adequate fade margin is vital to reliable performance of the system, because a link that is operating on the edge of the minimum acceptable receiver quieting will encounter problems later down the road. Normal component aging in the receiver or transmitter can cause a loss in received signal level and thus degrade the system performance. Likewise, new construction near the transmitting or receiving site can degrade the path, resulting in poor performance. Atmospheric conditions—such as severe weather in the area or ice on the transmitting or receiving antennas—can also cause sharp fading, and even a complete loss of signal, if an adequate fade margin above minimum receiver quieting is not provided. The RENG system fade margin can be computed by using the following equations:

$$G_s = G_t + G_{ta} + G_{ra}$$

Where: G_s = total system gain (dB)
G_t = transmitter power output (dBm)
G_{ta} = transmit antenna gain (dBi)
G_{ra} = receive antenna gain (dBi)

The values for G_{ta} and G_{ra} are gathered from the antenna manufacturer's literature.

(Note: dBi = dBd + 1.1 dB, approximately.) The value for G_t is given by the following formula:

$$G_t = 30 + 10 \log P_o$$

Where: G_t = transmitter power output in dBm
P_o = transmitter power output in watts.

Next, the system losses are computed:

$$L_s = L_p + L_l + L_c + L_m$$

Where: L_s« = total system losses (dB)
L_p = path loss (dB)
L_l = transmission line loss (dB)
L_c = connector losses (dB)
L_m = misc. losses (dB)

The values for L_t and L_c can be determined from the manufacturer's literature. Figure 3.9-3 shows typical loss values for 1/2-in. foam filled transmission line. A reasonable value for connector loss with components normally used in 1/2-in. transmission line installations is 0.5 dB. The value for L_p can be found by using the following formula:

$$L_p = 36.6 + 20 \log F + 20 \log D,$$

Where: L_p = free space attenuation loss between two isotropic radiators (dB)
F = Frequency of operation in MHz
D = the distance between the antennas in statute miles

possible, but in the majority of cases, continuously variable power output transmitters are not available. User modification of existing equipment is not an acceptable solution, since such work would most likely invalidate the transmitter's FCC type acceptance.

A more practical solution, therefore, is to purchase RENG transmitters of several different power levels operating on the same frequency (or frequencies). All of the popular RENG broadcast equipment manufacturers offer units with different power output levels. With some equipment, a low power transmitter is used and an optional power amplifier module is added between the transmitter and the antenna to give the needed RF output.

Directional receive and transmit antennas are a good idea from both an efficiency and coordination standpoint. The use of a pair of high gain antennas make it possible to achieve a much greater ERP for the same transmitter power. Of equal benefit in a crowded urban area is the elimination of any non-essential radiation. Through the use of directional transmit and receive antennas, stations can establish more secure channels by placing the radiated energy where it will do the most good (from the transmit end), and rejecting unwanted signals from other directions (at the receive end).

A simple and sometimes effective coordination tool is cross polarization. Two stations on adjacent frequencies may achieve as much as 25 dB RF isolation through the use of different polarizations of transmit antennas, matched by like polarization at their respective receive antennas. Cross polarization results in varying degrees of success, depending upon the frequency of operation and the surrounding terrain. Line-of-sight paths usually will provide good results, but urban centers with their highly reflective buildings, generally cause polarity shifts in the transmitted signal that may significantly reduce the benefits of cross polarization.

Path Engineering for Fixed Stations

Careful path engineering should be performed prior to any licensing work to determine if the proposed locations of base station and ARS installations will be able to achieve the desired results without using excessive amounts of transmitter power. There is much more to path engineering for a RENG system than simply pointing the transmitting and receiving antennas at each other (when directional antennas are used) and turning the equipment on. Base station and ARS systems are fixed position installations that cannot always be located in the best possible geographic locations because of space availability problems, excessive construction or site rental costs, or local or federal licensing difficulties. In such cases, the required path is not the ideal path, and the link will have to be engineered around these fixed points.

The site selection process for repeaters and receivers should also take into consideration the RF environment in which the equipment will be working. Multi-user locations, such as the World Trade Center in New York City or Mount Wilson near Los Angeles, are very good transmit sites, but terrible receive sites. For such situations, a remotely located receiver (in the case of a repeater system) should be considered. The two sections of the ARS station would then be tied together with telco facilities.

The use of a telco loop to feed a remotely located transmitter introduces several familiar problems, such as noise, crosstalk, distortion (if repeated several times), limited frequency response and installation and service delays. In some arrangements, the use of a telco loop to the transmitter (or receiver) is the only economical way to complete the link. Although such a hybrid system is not the ideal configuration, it will get the job done. Here again, the newer digital telco services can be helpful, because of their higher audio fidelity and freedom from crosstalk, and their ease in bidirectional, multi-line applications.

Planning for any RENG system should begin with an accurate, detailed U.S. Geological Survey (USGS) map covering the proposed path. Note should be made of any natural obstructions or Fresnel clearance obstructions (such as mountains, hills or vegetation) or manmade obstructions (such as buildings, water tanks or transmitting towers) in the proposed path. The transmitting and receiving antennas should be plotted so that a minimum of .6 Fresnel Zone clearance is obtained over 4/3 earth radius. Information on obtaining USGS maps may be found in Chapter 1.7, *Broadcast Standards and Recommended Practices*; Fresnel Zone clearance is covered in more detail in Chapter 6.2, *Microwave and STL Systems*.

When planning a RENG path, a profile drawing of the transmitting and receiving antenna site, the terrain and any obstructions in between, should be made on graph paper set to 4/3 earth radius. The use of such graph paper will compensate for the curvature of the earth and the normal refraction of VHF and UHF frequency signals when determining Fresnel Zone and obstruction clearance. Simple height above sea level is insufficient to determine whether a natural or manmade obstruction will interfere with the RENG signal on a long distance path. Once a proposed path has been drawn, a visual inspection must be made of the area for any problems that could degrade the performance of the system. Particular attention should be paid to items not documented on the USGS maps, such as buildings and towers.

The terrain from the transmitting antenna to the receiving antenna must be examined not only for obstructions but for reflection possibilities as well. A large body of water will usually cause problems for a RENG system operating in the UHF frequencies. If the water is an even number of Fresnel Zones from the direct path, signal attenuation will likely occur at the receiver. Temperature changes and tidal conditions will also have an effect. Likewise, thick vegetation or forested areas can be reflective to RF signals when wet, creating a similar (but not so troublesome) problem. Generally, the solution to reflection problems is to size of a briefcase and weighed 35 lbs. Today's gear is small, lightweight and can deliver excellent audio quality. Stations can now go into the field for news and special event programs and maintain studio-like sound. The audio quality of remote broadcasts is more important now than ever before because radio station transmission systems and consumer receivers are constantly improving. Further, the listening audience is becoming more discriminating and demanding of news operations. Today's competitive marketplace requires more than just sound from the field. It demands clean, quiet audio with good frequency response and low distortion. TV news has shown the public that this is possible and has conditioned consumers to expect it.

Radio channels used for RENG work are typically shared by multiple broadcasters within a market, and so receipt of a license is no guarantee of unlimited interference free operation. Indeed, an unused channel is the exception, not the rule, in most urban areas of the United States. The frequency coordination process is a complicated procedure that requires careful thought and planning, and generally a great deal of lead time. Broadcasters in a given geographical area rarely have to decide whether they wish to become involved in frequency coordination efforts. Usually the need for coordination is painfully obvious to all persons involved in RENG activity in the region.

The main driving force behind coordination efforts has been the Society of Broadcast Engineers (SBE), which has set up a National Frequency Coordinating Committee (NFCC) to encourage and support local coordination efforts, and to provide whatever support might be needed in this regard. The subject is discussed in detail in Chapter 1.5, *Frequency Coordination*. Spectrum congestion is a sad fact of life to many stations engaged in RENG today. Users must recognize that coordination is vital to the reliable operation of remote broadcast systems, since spectrum congestion will no doubt become worse in the future, rather than better.

Licensing Procedures

RENG work is done on two primary bands of frequencies set aside by the FCC for RPU operation. A number of frequency groups are allocated near 150 MHz and 450 MHz. Some assignments are also made on frequencies in the 25 MHz region. A particular broadcast station is not restricted to a maximum number of RPU systems that it may put into operation. The needs of the station and the budget available for equipment purchase are, instead, the major controlling factors.

Most RENG activity is currently centered in the 150 MHz and 450 MHz bands. In these slices of spectrum, three major license classifications exist: *Automatic Relay Station* (ARS), *Base Station* and *Remote Pickup Mobile Station*.

ARS systems are designed to receive program material on one frequency and retransmit on another. In this way, the average area of the RENG system can be extended considerably.

Base stations are, as might be expected, fixed position transmitters used for communication between the central point and one or more remote points. Base stations may, in the event of emergency conditions, be used as a program relay channel for Emergency Alert System information.

Remote Pickup Mobile Stations consist of vehicle-mounted and portable (hand carried) transmitters. They are usually licensed as a system in conjunction with a principal base station, or stations. Remote Pickup Mobile Station licenses generally specify a minimum and maximum number of mobile transmitters allowed in the RPU system. Standard divisions include from 1 to 4 stations, 4 to 12 stations, 10 to 20 stations and 20 to 50 stations.

The Commission's Rules require that the transmitter power for a RPU station be limited to a level necessary for satisfactory coverage of the service area. In any event, not more than 100 W of transmitter power output will be licensed. RPU transmitting equipment operating onboard an aircraft is normally limited to a maximum transmitter power of 15 W. A Mobile Station consisting of a hand carried or pack carried transmitter is restricted to not more than 2.5 W power output.

All RPU transmitting equipment must be type accepted by the Commission and checked each year (for units with more than 3 W output) for frequency accuracy, deviation and RF power output. FCC Rules also require that RPU transmitters rated for 3 W or greater must be equipped with a circuit that will automatically prevent modulation in excess of the authorized limits.

There are virtually no operator requirements for the use of a unit in the RPU service. Any person designated by and under the control of the licensee of the station may operate the equipment. An operator's license, as detailed in Part 13 of the Commission's Rules, is not required.

Building an RPU System

In view of the serious spectrum congestion problems that exist today in many areas of the country, any RPU/RENG system should be designed to be as spectrum efficient as possible and—equally important—to be as immune to undesired transmissions as possible. Even if the system will be operated in an area that currently does not have a spectrum congestion problem, there is no guarantee that such a problem will not surface in the near future. In any event, a well engineered system is also a spectrum efficient system.

The first rule of spectrum efficiency is to use only the effective radiated power (ERP) necessary to do the job. There is no justification for putting 15 W into the air when 5 W will provide the desired (or acceptable) signal-to-noise figure from the receiver. Ideally, all transmitters in a RENG system would therefore be equipped with continuously variable power output stages. The operator at the remote site would then run the transmitter with only enough power output to reach the required S/N figure at the receive (studio) point. With some types of units, this method of operation is

A program transmitted back to the studio via a standard POTS line—without any bandwidth extension—will usually be brief in duration, if for no other reason than the poor audio quality typical of such an arrangement. Spot news reports are common examples of this method of program return.

Small, battery powered mic-to-line amplifiers are available to drive dial-up telephones through direct connection to the tip and ring wires of the phone company cable or through clip leads at the handset microphone pins. The direct connection method of coupling is preferred over the handset connection because the former bypasses the telephone hybrid coil assembly with its associated level loss and possible distortion. But for this direct connection method, the device feeding the phone line—known as a *coupler*—should have the ability to seize the line (meaning to hold it open, in an off-hook condition), which the telephone instrument itself does when using the handset type connection. With such a *seizing coupler*, a call can be established with the telephone instrument, then the coupler can be switched on, and the handset of the telephone hung up, with the coupler holding the line open by itself. Many couplers (based on the original Western Electric *QKT* style) will *not* seize without another phone instrument off-hook on the same line. The advantage of the seizing coupler is twofold. First, the handset microphone will not contribute its output to the phone feed, so the signal transmitted will be only what comes from the amplifier or mixer plugged into the coupler's input. Second, the transmitted level of the audio signal will be higher without the instrument off-hook. This will maximize the signal-to-noise ratio of the feed.

Output level of the device feeding a phone line (whether by coupler or handset) should be carefully controlled, since the dynamic range of the dial-up network is somewhat limited. Transmit level should not exceed +8 dBm for program material, or 0 dBm for test tones. Be aware that the received end noise floor may be only 25–30 dB below this on local calls, and considerably less on some international long distance calls.

A program sent to the studio over dial-up telco lines using bandwidth extension equipment can provide impressive audio quality. Reasonably flat frequency response from 50 Hz to 5 kHz is possible in real-time using a 2-line system, or at half speed with a single-line system; 3-line systems can pass 7.5 kHz audio in real-time. The multi-band compandor systems used by the latter are required to reduce the dial-up network noise, which exhibits a rising characteristic with frequency and also becomes more subjectively noticeable as the high frequency cutoff of the system is raised.

These multi-line frequency shifting systems are falling into disfavor as POTS codecs become more popular. It is expected that frequency shifting on POTS lines will become obsolete as the cost effectiveness, audio quality and reliability of POTS codecs exceed the earlier technology.

Two- and 3-line frequency shifting systems or POTS codecs can also be operated at half-speed, with the expected effective doubling of their high frequency passband (one octave added), and a commensurate loss of an octave on the low end—usually a worthwhile tradeoff in terms of resulting audio quality. Thus the dial-up network can actually pass 15 kHz audio, with a 3-line frequency shifter or a POTS codec (on one line), at half-speed.

Note that none of these systems (with the possible exception of the single-line frequency extender) can operate reliably via cellular phone. This is due to a cellular phone line's bandwidth limitations and the potential change in level and frequency response that can occur at cell-boundary switches. Such cell switches can occur even when the remote site is a fixed location, due to moving obstructions in the path (such as a passing truck or bus), or atmospheric disturbances. (For more information on use of the POTS network, see Chapter 3.10, *Telephone Network Interfacing*.)

The other option for dial-up remotes is ISDN, which is becoming widely available. Many permanent remote sites (concert halls, convention centers, sports venues, etc.) are already wired with ISDN circuits ordered by broadcasters. In some areas, lead time for ordering new ISDN service is substantially longer than for POTS, and installation and service fees are also somewhat higher for ISDN. Nevertheless, ISDN is becoming the service of choice for on-demand, high-quality dial-up audio backhaul from frequently used remote sites. (For more information on use of the ISDN network, see Chapter 3.11, *Common Carrier Audio Program Services*.)

Setting Up Leased-line Remotes

The most critical element in using dedicated, leased line telco service for remote backhaul is getting the order placed properly and with sufficient advance notice. Today, T-1 service is the most often used of leased line service for broadcast backhaul, rapidly replacing the earlier analog *equalized broadcast loop* or *program circuit*. (ISDN service is also increasingly used in applications that previously required broadcast loops, particularly for longer backhauls and local events of short duration or infrequent recurrence.)

Changing tariffs continue to alter the comparative costs of these services (analog loops, ISDN and T-1). The comparison is further complicated by the inequality of service structure. For example, program loops are one-way paths while T-1 and ISDN are bidirectional; ISDN is pay-by-the-minute service while analog loops and T-1 are charged on a flat fee per month basis. Installation fees and space requirements for terminal equipment will also vary among these services.

For critical live remotes, installation of more than one service may be advisable for purposes of redundancy. (For more on digital services, see *Emerging Technologies* in this chapter, and Chapter 3.11, *Common Carrier Audio Program Services*.)

WIRELESS SYSTEMS

RENG has come a long way since the narrow-band walkie-talkie days, when a 5 W portable unit was the

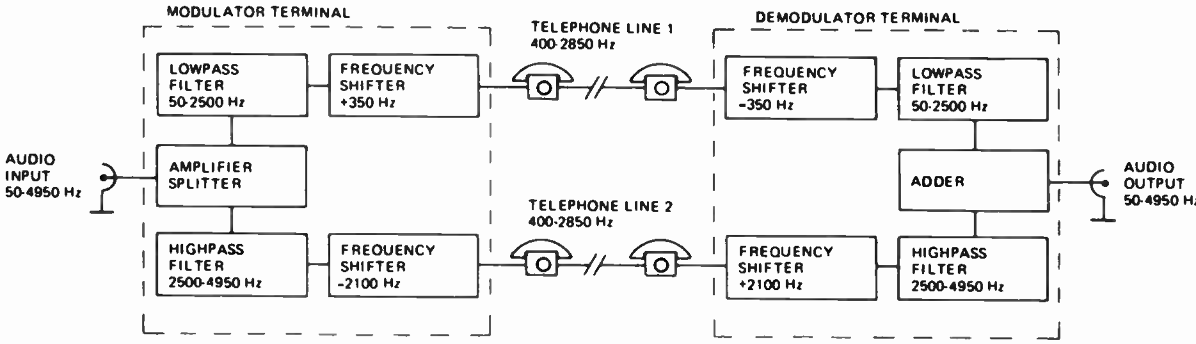

Figure 3.9-1. The basic 2-line frequency extension process for dial-up telephone links. (Courtesy of C. N. Rood.)

frequency-shifted back to their original values, filtered and recombined to form the output of the system. These multi-line systems may also include a multi-band compandor circuit for reducing phone line noise.

A useful variant of the single-line frequency extender employs *half-speed transmission*, as shown in Figure 3.9-2. Audio is recorded at the remote site on a two-speed analog tape recorder, using its higher recording speed. When the material is fed to the phone line, the deck's *lower* speed is used for playback and the audio is frequency-extension encoded by a single-line bandwidth extension system as it is played. At the receive end, the feed is decoded by the frequency extender and recorded using the low speed of another two-speed tape machine. When this program material is played back on high speed at the studio, an effective doubling of frequency response (a one octave increase) at the high end is achieved with a concurrent loss of one octave on the low end. The low end loss is usually of little consequence, since the frequency extension adds over two octaves, which is more than enough. This arrangement makes it possible to squeeze a signal bandwidth of 100 Hz-5 kHz through a single dial-up telco line. Phone feeding time takes twice as long, of course, and the process cannot be monitored for audio quality as the feed comes in. (For long feeds, it is therefore a good idea to make a short test recording and check its playback at the higher speed before proceeding with the entire program transmission.)

A more recent improvement to POTS audio transmission combines the technologies of computer modems with the perceptual coding (or *data compression* algorithms of the digital audio world. This class of devices, generically called *POTS codecs,* provides approximately 7 kHz audio transmission in real time on a single POTS line. The POTS codec turns a monaural analog audio input into a digital signal, applies a relatively heavy (around 30:1) data compression process—resulting in a datastream of about 24 kb/s—and feeds it to the POTS line via a standard 28.8 kb/s modem. At the receive end the process is reversed for a real-time audio output. (Actually, the term real-time in this context is inexact, since the throughput delay on a POTS codec path can be one second or more.) Some POTS codecs can adapt to variable phone line conditions and reduce their transmitted data rates to accommodate degraded line conditions—with corresponding reductions in audio bandwidth. In some cases (particularly for international calls), line quality is so poor that POTS codecs cannot operate reliably or at all. Some POTS codecs also include capacity to handle auxiliary control data or closures.

Setting Up a Dial-up Remote

If the dial-up (switched) option is chosen for a particular broadcast's backhaul, the broadcaster will have some, if not all, of the previously described service options available from the telco involved. The decision will depend upon the requirements of the particular broadcast and the costs of various services. Some generalizations can be made about these options, however, which will apply to most broadcast remote events.

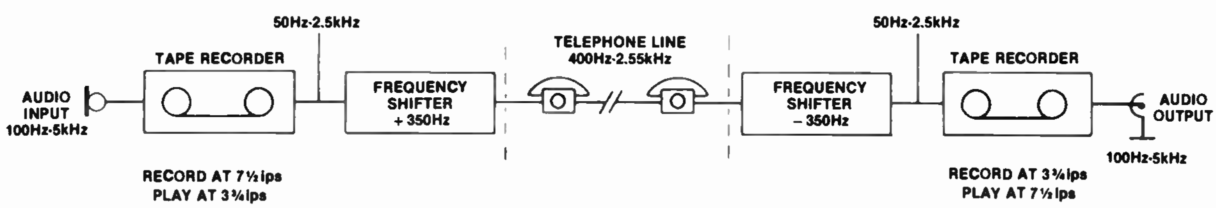

Figure 3.9-2. A frequency doubling technique using 2-speed tape recorders and a single-line bandwidth extension system. (Courtesy of C. N. Rood.)

company (telco) service. Spot news events, on the other hand, do not lend themselves to much advance planning. For these, an RF system is extremely useful.

The cost of telco facilities must also be considered. Unless the service is to be left in place for a long period of time, installation costs can become prohibitive, especially if high performance lines are needed. Many stations are able to justify the cost of a RENG RF system based solely on the telco savings that can be anticipated.

The best approach, therefore, implements both wired links and a wireless system. Large scale systems are often built using both interconnection methods, either as various links in the chain or as redundant services for recovery from a partial system failure.

While earlier dial-up (*switched*) and dedicated (leased line) telco services were exclusively analog, newer digital systems are becoming commonplace in most areas. For dedicated paths, the *T-1* service (also referred to as *DS1*) may be appropriate for broadcast use, particularly when multiple and/or bidirectional circuits are required between remote site and station. The T-1 format is a bidirectional digital service with a data transmission rate of 1.544 megabits per second (Mb/s) in each direction. It is primarily used by telcos to carry 24 voice-grade channels of 3.5 kHz bandwidth each, but can be easily reconfigured to carry a smaller number of wider-bandwidth signals by means of changing plug-in cards in terminal racks at each end of a dedicated T-1 path.

Program audio can be carried on T-1 in uncompressed or compressed digital form. A T-1 circuit can carry one uncompressed CD-quality stereo audio signal in each direction (occupying most of the path's 1.5 Mb/s bandwidth), while it may handle six or more such signals in compressed form. Alternatively, a mix-and-match configuration can be established with a variety of different bandwidths—a typical broadcast configuration between a studio and a permanent remote site (such as a news bureau or sports arena). For example, a T-1 link could be configured to carry several 15 kHz stereo program circuits bidirectionally (for transmission from, and monitoring returns back to, the remote site), bidirectional 5 kHz communication paths, bidirectional fax lines, voice circuits, and data control lines.

In some cases, a half-DS1 circuit or some other partial-carrier arrangement may be obtained, when capacity needs are not so great. Not available in all areas, this service is called *Fractional T-1*. In most cases, the T-1 digital service will be significantly more cost-effective than its analog program circuit equivalents (particularly when considering that the latter are not inherently bidirectional).

A more recent entrant to digital telco service is the *Integrated Switched Digital Network* (ISDN). ISDN is a dial-up digital service intended to replace the existing public switched telephone network. It uses telcos existing network of copper lines, and widespread, if not universal, ISDN deployment is expected by the end of the 1990s. The most common form of ISDN service, *basic rate interface* (BRI), provides two 64 kb/s channels for program audio. Using a technique called *inverse multiplexing* (IMUX), these two channels can be combined to provide a 128 kb/s path, which allows good stereo or excellent mono audio fidelity in a compressed digital form. ISDN therefore puts real time, high quality audio backhaul only a (digital) phone call away. Like POTS, either local or long-distance ISDN paths can be routed via dialing. ISDN fee schedules are also similar to or slightly higher than POTS service costs.

Note that broadcasters using T-1 or ISDN services for high quality audio transport must purchase or lease specialized terminal equipment (including codecs, when compressed audio is used), however. This can amount to several thousand dollars for each circuit, in addition to the one-time installation and ongoing monthly interconnection fees for digital service paid to telcos. (For more information on T-1 and ISDN, see Chapter 3.11, *Common Carrier Audio Program Services*.)

POTS Systems

For most remote backhaul needs, the conventional analog dial-up telephone network still gives today's broadcaster the greatest degree of flexibility in terms of when and where, including bidirectional ability. Of course, POTS audio quality leaves a great deal to be desired. For this reason, a number of encode-decode systems have been developed that improve the fidelity of audio signals that pass through a POTS line.

One such system that became quite popular during the 1980s is *frequency extension*. A variety of extension methods exist, each with a different way of accomplishing the task. Generally speaking, however, audio from the remote source is heterodyned up or down to frequencies that will pass through POTS circuits (which typically exhibit an approximate 300 Hz-3 kHz bandwidth), then detuned back to the original frequencies at the receive end. The one-decade response of the phone line can thereby be made to pass not *more*, but *a different set* of frequencies than it would normally carry.

The simplest of these systems shifts the effective passband of a phone line down by 250 Hz, making it approximately 50–2750 Hz. The process adds over two octaves to the low-end cutoff of the typical phone line, while only sacrificing a small portion (about 1/6) of an octave on the high end. This is a result of the heterodyne-shift's frequency-linear action, versus the logarithmic (octave-based) spectral perception of human hearing.

More sophisticated shifting systems add a second or even a third phone line to the process, using them to extend the *upper* frequency limit of the feed (see Figure 3.9-1). For example, in a 2-line unit, remote audio is split into two frequency bands by a filtering network. The lower frequency components are shifted upward by one conversion circuit (as in the basic system) and fed into one phone line, while the higher frequency components are shifted downward by a second conversion circuit, and applied to a second telephone line. At the receive end, the two signals are

INTRODUCTION

Radio stations have used the remote location broadcast for decades to bring the listener an added sense of realism and excitement. Although the concept of the remote, as it is better known, has not changed substantially over the years, the means to accomplish the task has moved quantum leaps in terms of performance, ease of operation and reliability.

This chapter addresses the two most critical technical areas in remote broadcasting: 1) the portable production systems used to create the program (field production); and 2) the method of *backhaul* (the means of delivering the signal from the remote site to the broadcast studio location). The latter, often referred to as *radio electronic news gathering* (RENG), utilizes either telephone lines or RF links in the broadcast auxiliary or other spectrum.

Today's RENG systems can be configured to provide virtually any degree of sophistication required by the broadcaster. As with any other area of telecommunications, the key to a successful RENG system is thoughtful planning.

PLANNING THE RENG NETWORK

The importance of careful planning of a RENG system cannot be overemphasized. The network should be configured based on the precise needs of the broadcaster. Everyone involved in the use of the system should be consulted to determine what will be needed. Whether a broadcaster's format is *all news* or *all hits*, everyone in the news, production and engineering departments should sit down and define the requirements of the network. At such gatherings, engineers should resist the urge to be negative when someone asks for a level of performance that is not practical. Even though the engineers may know that it is impossible to provide every reporter on the staff with a separate frequency that can be received at the studio from anywhere in town, at least listen to what the users would like the system to do. The realities of station economics and the laws of physics can be explained after the desires of the participants have been outlined.

Many—perhaps most—RENG systems have been built on a piecemeal basis, as needs dictated and economics allowed. The lack of a unified plan has often led to RENG systems that are cumbersome to operate and, in the long run, more expensive to build than necessary for a given level of performance.

The size and layout of the broadcaster's market will have a substantial effect on how the RENG network is designed. A system intended to cover a sprawling urban area of 10,000 square miles will be configured much differently than a tightly clustered urban center covering 2,000 square miles. The number of broadcasters in the market that are involved in RENG activity may also affect how a system is designed, and what types of equipment are used. Broadcasters in major metropolitan areas may find that few, if any, frequencies are available for RENG activity.

Program material can be returned from the field to the studio through either of two common routes—wired telephone lines or wireless transmission systems of various types. The route back to the studio will depend upon a number of factors, including the location of the event, availability and type of telephone service in the area, amount of setup time provided and duration of the broadcast.

Wired vs. Wireless

Until the 1960s, the word *remote* was rarely spoken without reference in the same sentence to the telephone company. Wired systems, either using the dial-up *plain old telephone service* (POTS) network or leased broadcast loops, provided the vast majority of interconnections from remote broadcast sites to a station's studio facilities. Since that time, however, RF systems have assumed an important role in remote activities because they inherently offer greater flexibility and in many cases provide a higher quality audio link. Given sufficient use over time, they may also be more cost effective than leased program circuits from the telephone company.

Radio systems are ideally suited for broadcasts of relatively short duration and from several different locations during a short span of time. Longer lasting remotes, such as meetings, speeches and sporting events, are probably best handled by a wired arrangement. The amount of frequency congestion in the origination area will also have an effect on which method a station will choose for the greatest reliability. Urban areas in which secure *remote pickup unit* (RPU) channels are difficult to find are also good candidates for wired links.

The amount of lead time provided before a remote is scheduled to occur will also have a significant effect on the backhaul method chosen. Remotes scheduled weeks in advance are well suited for use of a telephone market stations, some degradation of the program (as perceived on a high-quality monitor) is often accepted for the sake of maximizing punch and loudness. Moderate quality compromises are usually masked on smaller and lower cost radios and are noticeable only on higher-quality radios by critical listeners.

In all cases: It is not appropriate to attempt to extrapolate the results of tone tests to program material, because superposition does not hold.

6. A phase-linear filter has constant delay with frequency.
7. A minimum phase filter has no zeros in the right half of the s-plane. As its name implies, there is no filter with the same magnitude response that can have less phase shift. Given the magnitude response of a minimum-phase filter, its phase shift can be computed (with the Hilbert Transform). This means that if a minimum-phase filter has constant group delay in its passband, this is associated with a certain type of magnitude response which rolls off gently around the filter's cutoff frequency: a minimum-phase filter with constant group delay in the passband cannot simultaneously have a highly selective magnitude response. Many textbooks provide the well-known mathematical details. See, for example, H.J. Blinchikoff & A.I. Zverev, *Filtering in the Time and Frequency Domains*, New York, Wiley, 1976, pp. 89-94.
8. Simply stated, almost all feedback systems contain a filter that forces the open loop characteristic to be either low-pass (all-pole, *lag compensation*) or low-pass shelving, with poles *and* zeros (*lead-lag compensation*). Feedback forces the amplifier before this filter to present a pre-emphasized signal to the filter's input such that the total response of the system is flat. If the filter rolls off at 6 dB/octave starting at 15 Hz (a typical situation in an opamp like the TL072 or the LF353), this pre-emphasis *rises* at 6 dB/octave 15 Hz. High frequencies applied to this system will obviously challenge the headroom of the amplifier prior to the filter. For example, 20 kHz will be up 62.4 dB! If high frequencies drive the amplifier prior to the filter into clipping or substantially nonlinear operation, transient intermodulation distortion occurs. Because a filter with a low-pass characteristic follows the clipping process, harmonics generated by clipping will be de-emphasized, so difference-frequency IM tests are more sensitive than THD tests to this mechanism.
9. For a maximum audio bandwidth f, the required slew rate in percent modulation per microsecond is $0.0002\pi f\%/\mu s$. For 4.5 kHz, this is 2.827%/μs.

channels are left, center, right, left surround, right surround, and a limited-bandwidth subwoofer channel (the 0.1) for effects. The audio is digitally data-compressed using the Dolby AC-3 system. This system specifies two auxiliary data channels. The first, *dialog normalization*, provides information to the receiver about the nominal level of the dialog so that the receiver can hold this constant. This lets the broadcaster trade off headroom (for loud sound effects, for example) against noise floor without changing the loudness of dialog at the receiver.

The second auxiliary data channel is a dynamic range control channel that provides a wideband gain reduction signal that can be used by the receiver, under the viewer's control, to selectively compress the dynamic range of the broadcast. Unfortunately, at the time of this writing it is unclear how these signals will be provided operationally in a typical television broadcast environment, particularly with regard to older material mixed without these signals, and live news.

TECHNICAL EVALUATION OF AUDIO PROCESSING

Common swept frequency response, harmonic distortion, and intermodulation distortion tests are often used to evaluate audio processors. Therefore, it is useful to discuss why these tests may at times produce misleading results.

Definition of Linearity

A system can be tested for linearity as follows. Apply an input signal A to the system and measure its output. Let X be the output signal caused by input A. Then, remove A from the input and apply another signal B. Let Y be the output signal caused by the input B.

The system is linear if the following things happen: (1) If the input waveform is multiplied by a factor k to scale it, the output waveform also becomes scaled by a factor of k, but its shape is not distorted by the process of scaling. (2) If inputs A and B are applied to the system simultaneously, the system's output is X + Y (*superposition*).

It is clear that expanders, compressors and limiters are strongly nonlinear systems. The output of such a device is not scaled proportionally to its input; it is expanded or compressed. Similarly, when two signals are applied to such a device, its output is not the same as the sum of its response to either signal individually; superposition does not hold. Clippers are similarly nonlinear.

Sinewave Measurements and Non-Linearity

When predicting a system's response to program material by measuring its response to individual sinewaves, certain assumptions are made. The first assumption is that can be adequately represented program material as a sum of sinewaves (Fourier analysis). The second assumption is that superposition holds, so that the response of the system to single sinewaves also applies when several sinewaves are added together at the system's input. Thus, the sinewave results can be extrapolated to program material.

Because dynamic audio processing (compression, limiting, clipping, expansion, gating) is strongly nonlinear, the usual assumptions of superposition and scaling, which permit sinewave measurements to be extrapolated to complex program material through Fourier analysis, do not hold. Conventional harmonic and intermodulation distortion measurements, historically designed to measure slight departures from linearity in weakly nonlinear systems, are of very limited usefulness. Swept or spot frequency response measurements are not useful.

When making distortion measurements with tones, their relevance must be assessed psychoacoustically. Does the system output *sound* distorted when listening to the tones? For example, when measuring harmonic distortion using fundamentals in the 50–1000 Hz region, the higher harmonics are more significant than the lower harmonics because the higher harmonics are less readily masked by the desired fundamental. However, as the fundamental frequency is increased, the harmonics become less troublesome because the ear becomes less and less sensitive to them. Eventually, their frequency exceeds the passband of the system and they become irrelevant.

Similarly, SMPTE intermodulation distortion methods measures the level of 50 or 60Hz sidebands around a high-frequency tone induced by system nonlinearity. Because these sidebands are within a single critical band (approximately 1/3 octave) of the high-frequency tone, they are maximally masked by it. Therefore rather high amounts of measured SMPTE IM distortion are not necessarily cause for concern. On the other hand, ITU-R difference-frequency intermodulation distortion measurements measure the low-frequency difference tone caused by two high-frequency tones. Because the difference tone is far removed in frequency from the desired tones, it is not well masked by them, and high amounts of ITU-R IM are of some concern. See Chapter 7.1, "Audio Signal Analysis," for more information on distortion and measurements.

Subjective Listening Tests

There are few, if any, measurement techniques that can adequately predict whether the subjective effect of an audio processor will be satisfactory. The only effective way to evaluate nonlinear broadcast audio processing is by *subjective listening tests*. These must be done over a long time period, using many different types of program material, because a processor that sounds good on a certain type of program material may sound unsatisfactory on other program material having markedly dissimilar spectral balance or dynamics.

Usually, the subjective goal of broadcast processing is to have its action undetectable to the audience. In the case of processing in highly competitive major

AUDIO PROCESSING REQUIREMENTS FOR DIGITAL AUDIO RADIO (DAR) TRANSMISSION

At this writing, the question of which system the United States will adopt for DAR broadcasting is unsettled. Most of the rest of the world has already standardized on the Eureka 147 system. To encode the audio, all systems use lossy data reduction with no pre-emphasis. The specific system of lossy data reduction that is used depends on the DAR system, with Eureka 147 using the MPEG-1 Layer 2 algorithm, and some other proposed systems using the Lucent/AT&T PAC algorithm or the MPEG AAC algorithm.

The Eureka 147 system provides an auxiliary data channel that can be used as a gain reduction signal to provide dynamic range compression at the receiver under the listener's control. Because this provides wideband compression, it cannot provide a processed sound without overt spectral gain intermodulation. Indeed, it is intended only to provide gentle AGC to make the signal comfortably listenable when the radio is turned down to background levels or when it is located in an acoustically noisy environment.

As of this writing, there is no history of commercial engineering practice in DAR broadcasting, as the pioneer broadcasters have principally been government and public radio services. Nevertheless, based on the experience of FM, the author expects that some stations will want to apply substantial multiband audio processing at the transmitter. Such processing will perform no high frequency limiting (because there is no pre-emphasis). Peak limiting can be similar to the technology used for compact disc mastering, which often uses delay-line limiters.

One important consideration in processing for DAR is the possibility of the lossy data reduction decoder's clipping at the receiver because of overshoots added by the data reduction. An aggressively peak-limited signal will spend considerable time close to digital full-scale, and, due to the addition of quantization noise, the lossy algorithms will introduce considerable overshoots above this level. At this writing, most of the decoder algorithms have no headroom built-in to accommodate such overshoots, instead clipping them. The author hopes that this oversight will be corrected before DAR receivers hit the mass market.

AUDIO PROCESSING REQUIREMENTS FOR TELEVISION BROADCAST TRANSMISSION

The processor should provide a comfortably listenable dynamic range in domestic listening environments by applying subtle compression to the signal. Such compression should be undetectable to the ear unless the original source is available for comparison. Usually an available gain reduction range of 25 dB is adequate to handle the level variations encountered in typical operations.

The processor must provide high frequency limiting to complement the pre-emphasis employed (50 μsec or 75 μsec, depending upon the region in which the transmission occurs). The processor should provide accurate peak control (as measured by a modulation monitor meeting the standards of the governing authority) in both the positive and negative directions. In general, the comments on FM (given previously) apply here as well.

The processor should control subjective loudness to prevent unpleasant inconsistencies when transitions occur between various program elements. This is most accurately achieved using technology similar to that developed for loudness measurement (discussed earlier). In essence, the processor uses a loudness meter in a servo loop to control loudness and ensure consistency of loudness between one program source and the next.

The processor should handle voice cleanly. The Hilbert-Transform clipper and delay-line limiter are effective for this, because neither creates audible clipping distortion on voice, even when the source is narrowband (such as optical film or telephone). Such narrowband sources are extremely difficult for a conventional audio-frequency clipper to process without introducing some audible harmonic distortion on voice.

Audio Processing for Stereo Television

The general requirements for stereo television processing are not very different from the general requirements enumerated previously. As discussed in the *Processing for Stereo* section earlier in this chapter, the processing elements with slow release time constants must be coupled to preserve the stability of the stereo image. In the North American BTSC system, the peak modulation criteria are complex. However, it can be shown that FM stereo-style processing will always prevent over-modulation in BTSC stereo, although it will not necessarily allow the most L + R modulation theoretically possible in this system. This style of processing is also appropriate for the other international stereo systems,[10] since it will always prevent over-modulation.

Because of the close proximity between the edge of the audio passband (approximately 15 kHz) and the stereo pilot tone (15.734 kHz), the BTSC system requires sharp low-pass filters to prevent aliasing. It is impractical at the current state of the art to apply nonlinear overshoot compensation to these filters. Such overshoots do not cause interference or problems in television receivers. Thus these overshoots must be accepted as inherent to the BTSC system, and must be ignored by modulation monitors designed as a reference for setting modulation levels. If these overshoots are not ignored, average modulation will be set too low and the viewer will experience annoying increases in loudness when switching from stereophonic to monophonic channels.

The new advanced digital television system specified by the Grand Alliance and approved by the FCC for use in the U.S. specifies 5.1 channel audio. The

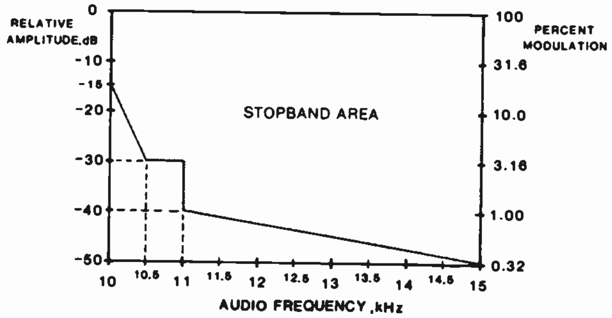

Figure 3.8-5. NRS low-pass filter curve.

audio bandwidth to 5 kHz at night. This will cause little or no audible change in frequency balance as heard on the average AM radio (whose audio bandwidth at −3 dB continues to be approximately 3 kHz, despite the push by broadcasters for AMAX radios), but it will completely prevent any interference from being applied to first-adjacent channels. (At night, skywave propagation can convey such interference to stations hundreds of miles from the interferer.) In addition, the station is likely to find that it can process its audio harder for a given amount of processor-induced distortion, increasing on-air loudness and coverage. This is particularly important at night because interference increases (see Figure 3.8-5).

On April 27, 1989, The FCC released a *Report and Order* that amended section 73.44 of the FCC Rules by requiring all U.S. AM stations to comply with the occupied bandwidth specifications of the NRSC-2 standard by June 30, 1990. The NRSC-2 standard is an *RF mask* which was derived from the NRSC-1 audio standard by the NRSC. The purpose of the NRSC-2 RF mask is to provide a transmitted RF occupied bandwidth standard that any station with a properly-operating transmitter will meet, *provided that NRSC-1 audio processing is used prior to the transmitter*, and *provided that the station is not overmodulating.*

AUDIO PROCESSING FOR AM STEREO

In all AM stereo systems, the envelope modulation is forced to a close approximation of the sum of the left and right channels to ensure compatibility with mono radios equipped with envelope detectors. To ensure minimum loudness loss compared to monophonic transmission, it is necessary to process stereo audio in the *sum and difference* format. This means that the left and right channels are passed through matrix circuits to create L + R (sum) and L − R (difference) signals. These signals are then passed separately through those parts of the processing that control modulation.

To prevent clipping and distortion in the C-Quam decoder in the receiver, the negative-going modulation in the left and right channels must be no greater than −75% modulation (where 100% modulation is carrier pinch-off). Therefore, an audio processor for C-Quam must have both a sum and difference processor (which does the main processing) and a safety limiter to protect the left and right channels. This safety limiter is usually inactive, and typically only comes into play when the input program has sections which are momentarily single-channel, such as ping-pong stereo.

AUDIO PROCESSING REQUIREMENTS FOR FM (VHF) BROADCAST TRANSMISSION

The processor should provide a comfortably listenable dynamic range in domestic and automotive listening environments by applying subtle compression to the signal. Unless the program director requests otherwise for competitive reasons, such compression should be undetectable to the ear unless the original source is available for comparison.

The processor must provide high frequency limiting to complement the pre-emphasis employed (50 μsec or 75 μsec, depending upon the region in which the transmission occurs).

The processor must provide accurate peak control (as measured by a modulation monitor meeting the standards of the governing authority) in both the positive and negative directions. To ensure that absolute peak control will be retained at the system output, any system elements following the processor must have flat frequency response (±0.1 dB) and constant group delay (deviation from linear phase <±10°). Because the pre-emphasis networks and low-pass filters ordinarily found in stereo encoders do not meet these requirements, they should be bypassed. Thus, the processor should provide pre-emphasis and band limiting for the transmission system. Its output must contain negligible energy above the bandwidth limit of the transmission system. In FM stereo broadcasting by the world-standard pilot-tone method, this bandwidth is limited to less than 19 kHz to prevent aliasing from the stereo subchannel into the main channel, and vice-versa. To protect the pilot tone itself (ensuring correct operation of the phase-locked loop subcarrier regeneration circuitry in the receiver's stereo decoder), the bandwidth must be further limited to no greater than 17 kHz. In practice, it is customary to begin the HF rolloff at slightly above 15 kHz to minimize group delay distortion in the low-pass filters used to effect the bandwidth limit. Nonlinear low-pass filters are usually used to prevent overshoot, enabling the processor to control peak deviation absolutely.

The processing system must be readily adjustable to achieve the subjective effect desired by the broadcasting authority operating it. To achieve a competitive sound in markets where many stations compete for listeners, it may be necessary to add additional multiband limiting to the basic audio processing system (which usually consists of compressor, HF limiter, and peak limiter/clipper). Adding additional multiband limiting can create greater program density than the basic processing system alone without introducing spectral gain intermodulation.

amplification stage prior to the frequency compensation stage) probable.[8] To minimize the probability that TIM will be bothersome, any amplification stage before the frequency compensation stage should be designed to be very linear to its clipping point, and to have sufficiently high headroom to accommodate the maximum rate of change to be expected at the transmitter's audio input.[9]

A transmitter can be qualified for TIM by one of the various difference-frequency intermodulation distortion tests. If the tests indicate that the transmitter has a low slew rate, it will not respond well to pre-emphasized audio and pre-emphasis will have to be reduced until the first derivative of the processed audio waveform seldom, if ever, exceeds the slew rate limit of the transmitter. Because of the benefits of pre-emphasis at the receiver, it is desirable to modify such transmitters to increase their slew rate, even if this means somewhat compromising harmonic distortion performance at low frequencies.

The NRSC-1 Audio Standard

As the North American AM band became more crowded, interference from first and second adjacent stations became more of a problem. Receiver manufacturers responded by producing receivers with decreased audio bandwidth, so that the encroachment of an adjacent station's modulation extremes would not be audible as interference.

This truncating of the bandwidth had the effect of diminishing the receiver's high-frequency response, but it was felt that lower fidelity would be less annoying than interference. To address these problems, the National Radio Systems Committee (NRSC) in 1987 formalized a standard for pre-emphasis and low-pass filtering for AM broadcast to provide brighter sound at the receiver while minimizing interference. See Chapter 4.3, "AM Transmitters," for more information on NRSC work.

AM Stereo Introduces a Pre-emphasis Dilemma

Certain AM receivers manufactured since 1984 for sale in North America, particularly those designed for domestic AM stereo reception, have a frequency response that is substantially wider than that of the typical mono AM receiver. The frequency response was widened largely to enhance the sales potential of AM stereo by presenting a dramatic, audible improvement in fidelity in the showroom. As these new receivers became more prevalent, broadcasters had to choose whether the station's pre-emphasis would be optimized for the new AM stereo receivers or for the existing conventional receivers that form the vast majority of the market.

If the choice was for conventional receivers (which implies a relatively extreme pre-emphasis), the newer receivers might sound strident or exceptionally bright. If the choice favored the newer receivers (less pre-emphasis and probably less processing), the majority of receivers would be deprived of much high-end energy and would sound *duller* and have less loudness.

NRSC Standard Pre-emphasis and Low-pass Filtering

In response to this dilemma, the NRSC undertook the difficult task of defining a voluntary recommended pre-emphasis curve for AM radio that would be acceptable to broadcasters (who want the highest quality sound on the majority of their listeners' radios) and to receiver manufacturers (who are primarily concerned with interference from first- and second-adjacent stations).

A modified 75-microsecond pre-emphasis/de-emphasis standard was approved (see Figure 3.8-4). That provides a moderate amount of improvement for existing narrowband radios, while optimizing the sound of wideband radios. Most importantly, it generates substantially less first-adjacent interference than do steeper pre-emphasis curves.

The second part of the NRSC standard calls for a sharp upper limit of 10 kHz for the audio presented to the transmitter (see Figure 3.8-5). This essentially eliminates interference to second and higher adjacencies. While some broadcasters believe that this is inadequate and that 15 kHz audio should be permitted, it is not likely that interference-free 15 kHz audio could be achieved except by a reallocation of the AM band. The practical effect of widespread implementation of the 10 kHz standard is that 10 kHz radios are feasible, and the bandwidth perceived by the average consumer (now typically limited by the receiver to 3 kHz) can be dramatically improved. The difference between AM and FM reception will then become less pronounced.

The NRSC and the EIA worked together to define a standard for wideband, NRSC-compliant AM stereo radios, which was trademarked as AMAX. Several manufacturers (most notably Delco) have introduced AMAX radios into the marketplace.

Although the NRSC standard calls for a 10 kHz audio bandwidth at all times, one can seriously argue that any North American AM station whose programming is primarily talk should voluntarily reduce its

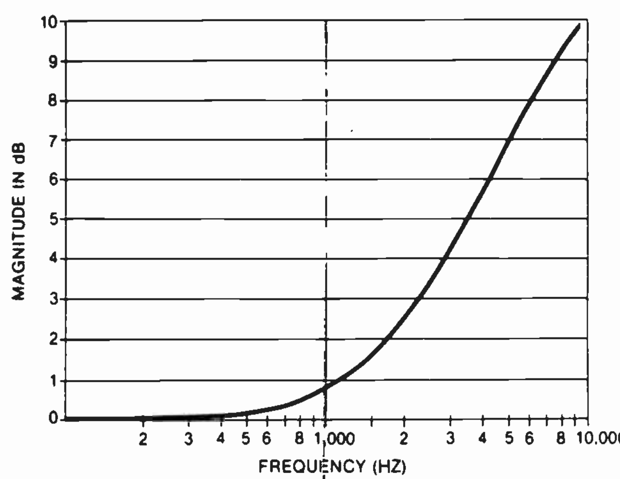

Figure 3.8-4. NRSC pre-emphasis curve.

cessor must compensate for noise (electrical and acoustic) and interference by reducing dynamic range. This is most readily done by multiband compression and limiting to achieve lowest peak-to-average ratio without significant processing-induced side effects.

The processor must provide absolute negative peak control to prevent AM carrier pinch-off, which would otherwise cause out-of-band emissions. Additionally, the processor must incorporate overshoot-free filtering to control the audio input spectrum to the transmitter, thus preventing out-of-band emissions and interference. National (FCC) or international broadcast authorities (most notably ITU-R) usually specify the permissible occupied bandwidth to make most efficient use of available radio frequency spectrum.

The processor may also be equipped with a receiver equalizer that compensates for the poor frequency response of the typical MW or SW radio due to narrowband RF and intermediate frequency (IF) stages.

Transmitter Equalization

The processor may provide a transmitter equalizer to eliminate tilt, overshoot, and ringing in the transmitter and antenna. Accurate reproduction of the shape of the processed waveform requires that the transfer function between the audio input and the modulated RF envelope represent a constant delay (which may be any positive number or 0) at all frequencies contained within the audio input signal. Failure to meet this criterion can result in tilt, overshoot, and *ringing* in the modulated RF envelope. The cause of overshoot and ringing as spectrum truncation and time dispersion at the high-frequency end of the system bandpass were discussed earlier. Tilt, on the other hand, is caused by problems at low frequencies.

Figure 3.8-3 shows the response of a 10 kW plate-modulated transmitter to a 50 Hz square wave. The transmitter causes the waveform to tilt, which increases peak modulation in both positive and negative directions. The magnitude of the transmitter's frequency response is essentially flat to 50 Hz; the problem is caused by infrasonic rolloff. This rolloff is equivalent to that of a high-pass filter and is minimum-phase, which introduces time dispersion, causing the shape of the waveform to change and further increasing the peak level.

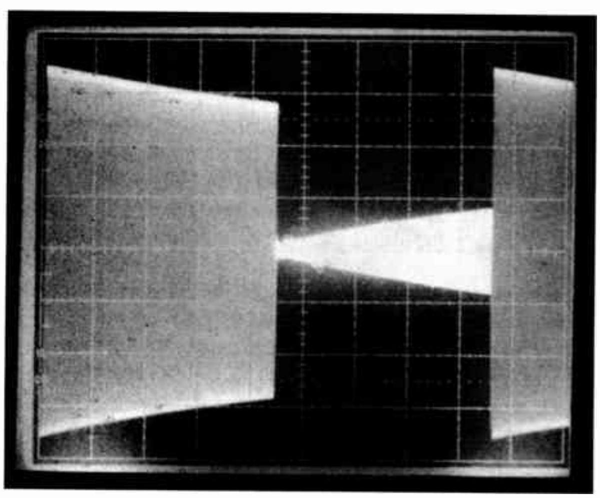

Figure 3.8-3. Tilt in plate modulated transmitter.

Some transmitters contain high-pass filters at their audio inputs to protect high-power stages. *This location is absolutely inappropriate;* these filters can easily increase the peak-to-average ratio of the input audio by 3-4 dB. The correct location for a protection high-pass filter is in the audio processor where measures can be taken to prevent the high-pass filter from increasing the peak-to-average ratio at the audio processor's output.

Bounce

Predistorting the waveform in the audio processor can equalize linear errors. However, one major nonlinear error, commonly called *power supply bounce* is caused by resonances in the LC filter elements of the transmitter's high voltage power supply. These resonances superimpose a sub-audible modulation onto the power supply voltage, resulting in a form of very fast carrier shift that is too quick to be seen on a conventional carrier shift meter. The net result is to compromise the control of modulation peaks, particularly on strong bass transients which cause momentarily large current demands on the power supply, and which excite the resonance.

In some older transmitters, bounce has been known to compromise achievable modulation by up to 3 dB. Because bounce is not linearly related to the modulation, small-signal equalization cannot cure it. The most successful cure has been the use of a 12-phase power supply in the transmitter. The AC ripple from such a supply is down about 40 dB without filtering; a simple filter capacitor is all that is necessary to achieve adequate smoothing. Because there are no chokes in the power supply filter, resonance cannot occur. In all cases, bounce can be minimized by preventing excessive bass energy from being applied to the transmitter.

Slew Rate Limiting (Transient Intermodulation Distortion)

Transmitters using pulse-duration modulation (PDM) schemes are prone to problems with slew rate limiting. Because the PDM low-pass filter is located within the audio feedback loop of the transmitter, and because this filter is typically a multi-pole elliptic function filter with a cutoff frequency below 70 kHz, it will introduce substantial delay into the feedback loop. This has two consequences: stability requires the amount of feedback applied around the transmitter to be limited, and it also requires that the open-loop gain of the modulator be rolled-off at a very low frequency. The first issue makes it difficult to design PDM transmitters with THD below 1%–2% at midrange frequencies, while the second renders *transient intermodulation distortion* (TIM non-linear behavior of the can cause noise that would otherwise be masked to become unmasked because the psychoacoustic masking conditions under which the masking thresholds were originally computed have changed. Second, the frequency response of the radio receiver (particularly in AM) can remove frequencies that were used to make the psychoacoustic masking calculations and that would otherwise have masked the added quantization noise.

Accordingly, if you use lossy data reduction in the studio you should use the highest data rate possible. This maximizes the headroom between the added noise and the threshold where it will be heard. Also, you should minimize the number of encode/decode cycles, because each cycle moves the added noise closer to the threshold where it will be heard.

Transmission Levels and Metering

Engineers at the transmitter and the studio consider transmission levels and their measurements differently. Transmission engineers need to know the peak level of a transmission commonly measured by an oscilloscope. Studio engineers need to know the line-up (or reference) level of a transmission commonly measured by a VU meter (as the approximate RMS level) or by a peak program meter (as the PPM level). For details, see the standard established by the Institute of Electrical and Electronic Engineers, *Recommended Practice for Audio Program Level Measurement* (Doc G-2.1.2/13, 1988).

Metering

The VU meter is an average-responding meter (measuring the approximate RMS level) with a 300 ms rise time and decay time; the VU indication usually lags the true peak level by 8 to 14 dB. PPM indicates a level between RMS and the actual peak. The PPM reading has an attack time of 10 ms, slow enough to cause the meter to ignore narrow peaks and lag the true peak level by 5 dB or more.

Transmission Levels

The transmission engineer is primarily concerned with the peak overload level of a transmission to prevent overloading. This peak overload level is defined differently, system to system. In tape, it is defined as the level producing the amount of harmonic distortion considered *tolerable*—often 3% THD at 400 Hz. In FM, microwave, or satellite links, it is the maximum-permitted RF carrier deviation. In AM, it is negative carrier pinch-off. In analog telephone transmission, it is the level above which serious crosstalk into other channels occurs, or the level at which the amplifiers in the channel overload. In digital, it is the largest possible digital word.

Studio Levels

The studio engineer is primarily concerned with what is commonly called the reference level, operating level, or line-up level. This line-up level aids studio engineers in providing adequate headroom between line-up level and the overload level of equipment to allow for the peaks that the meter does not indicate. In facilities that use VU meters, line-up level is usually at 0 VU, which corresponds to the studio standard level, typically +4 or +8 dBm. In systems that use PPM, line-up level may be at PPM 4 (for the BBC standard) or at the studio standard level (often +6 dBm).

Transmission-Link Limiting

Transmission-link limiting devices are sometimes used ahead of the transmission link to protect it from overload. (These links might be STLs, satellite uplinks, inter-studio digital links etc.) These devices are usually used below-threshold (that is, with no gain reduction) as protection limiters to control peak levels. They only produce gain reduction when abnormally high levels are applied to their input due to operator error or unforeseen level variations at the source. This is useful to transmission engineers concerned with overload, and as useful to studio engineers concerned with headroom. For the needs of both engineers, such a limiter's output must be adjusted to be at or slightly below the peak overload level of the transmission channel.

To properly match the studio line-up level to the transmission protection limiter, the desired headroom must be known. For example, assume that the transmission protection limiter produces 0 dBm at its output at 100% modulation of the transmission link. Further, assume that the line-up level in a production facility is designed to allow 8 dB of headroom. The input attenuator of the transmission protection limiter would then be adjusted so that studio line-up tone produces −8 dBm at the output of the transmission protection limiter.

This assumes that the amplifier or other link between the studio and the input of the transmission protection limiter has enough headroom to drive the transmission protection limiter into gain reduction without clipping this link. The transmission protection limiter only protects a link connected to its output. In the previous example, if the transmission protection limiter provides 15 dB of maximum protection, the system prior to the transmission protection limiter requires 8 + 15 = 23 dB of headroom above studio line-up level. If the link is simply an amplifier, this should be achievable without difficulty if the absolute level of the studio line-up tone is chosen carefully. In our example, if the amplifiers in the system clip at +21 dBm, the level of the studio line-up tone can be no greater than −2 dBm (i.e., 23 dB below +21 dBm).

AUDIO PROCESSING REQUIREMENTS FOR MW AND HF BROADCAST TRANSMISSION

In amplitude-modulated services, reception is usually compromised by noise and interference and may be further compromised by acoustic noise in the listening environment (such as the automobile). Thus the pro-

Where only an audio link is available, feed the audio output of the processing system directly into the link. If possible, transmitter protection limiters should be adjusted for minimum possible action as the processing system does most of that work. Transmitter protection limiters should respond only to signals caused by faults or by spurious peaks introduced by imperfections in the link.

Where maximum quality is desired, it is important that all equipment in the signal path after the studio be carefully aligned and qualified to meet the appropriate standards for bandwidth, distortion, group delay, and gain stability, and that such equipment is requalified at reasonable intervals.

Requirements for STLs

If the STL is prior to the audio processor, the STL's signal-to-noise ratio (SNR) must be sufficient to pass unprocessed audio. This means that the SNR of the link must be better than the sum of the desired SNR of the transmitted signal plus the maximum gain of the audio processor plus about 6 dB (a useful rule-of-thumb). If the STL follows the audio processor, its SNR must be 6 dB better than the desired SNR of the transmitted signal. To ensure that the STL does not distort the shape of the audio waveform (preventing introduction of overshoot into peak-limited waveforms applied to the STL input), the frequency response must be flat (±0.1 dB) throughout the operating frequency range, typically 20–15,000 Hz. The group delay must be essentially constant throughout this range (deviation from linear phase <±10°). Phase correction can be applied to meet the requirement at high frequencies.

At low frequencies, by far the best way to achieve the specification is to extend the −3 dB frequency of the STL to 0.15 Hz or lower and to eliminate any peaking in the infrasonic frequency response prior to the rolloff. It is not unusual for a microwave STL to bounce because of a large infrasonic peak in its frequency response caused by an under-damped automatic frequency control (AFC) phase-locked loop. This bounce can increase the STL's peak carrier deviation by as much as 2 dB, reducing average modulation. Many commercial STLs have this problem. Such problems can be corrected by modifying the STL's AFC loop, or by applying equalization prior to the STL transmitter that is complementary to existing low-frequency rolloff, such that the overall system frequency response rolls off smoothly at 0.15 Hz or below. This solution is far better than clipping the tilt-induced overshoots after the STL receiver because the clipping will introduce nonlinear distortion, while the equalizer is distortion-free.

For highest quality, the nonlinear distortion of the STL system should be less than 0.1% total harmonic distortion (THD) throughout the operating frequency range.

Digital links may pass audio as straightforward Pulse Code Modulation (PCM) encoding, or they may apply data-rate-reduction processing to the signal to reduce the number of bps required for transmission through the digital link. Such processing will almost invariably distort peak levels, and such links must therefore be carefully qualified before you use them to carry the peak-controlled output of the audio processor to the transmitter or stereo encoder. For example, the MPEG-1 Layer 2 algorithm can increase peak levels up to 4 dB at 160 kB/sec by adding large amounts of quantization noise to the signal. While the desired program material may psychoacoustically mask this noise, it is nevertheless large enough to affect peak levels severely. For any lossy compression system, the higher the data rate, the less the peak levels will be corrupted by added noise, so use the highest data rate practical in the system. Even with the maximum available data rate, overshoot will probably be large enough to require use of an overshoot compensator at the STL receiver (or in the equipment being driven by it). Some modern FM exciters and stand-alone stereo encoders are now equipped with such compensators.

Other links may use straightforward PCM without lossy data rate reduction. These can be very transparent and can exhibit accurate pulse response provided that their input anti-aliasing filters and output reconstruction filters are rigorously designed to achieve constant group delay over the frequency range that contains significant program energy. This is not particularly difficult to do with modern over-sampled converter technology.

NICAM is essentially a hybrid between PCM and data-rate-reduced systems. It uses a block-companded floating-point representation of the signal with J.17 pre-emphasis. NICAM links can exhibit low overshoot if designed for good low-frequency response and equipped with phase-linear anti-aliasing and reconstruction filters.

Because the output spectrum of most modern audio processing systems is already tightly band-limited, you may bypass any anti-aliasing filters in digital links driven by such systems. This ensures the most accurate possible transient response.

Using Lossy Data Reduction in the Studio

Many stations are now using lossy data reduction systems to increase storage time of digital playback media. In addition, source material is often supplied through a lossy data reduction system, whether from satellite or over landlines. Sometimes, several encode/decode cycles will be cascaded before the material is finally presented to the audio processor's input.

All such algorithms operate by increasing the quantization noise in discrete frequency bands. If not psychoacoustically masked by the program material, this noise may be perceived as distortion, *gurgling*, or other interference. Psychoacoustic calculations are used to ensure that the added noise is masked by the program material and cannot be heard. In addition, there are at least two other mechanisms in broadcasting that can cause the noise to become audible at the radio. First, a modern multiband transmission audio processor performs an *automatic equalization* function that can radically change the frequency balance of the program. This frequency bands have slower time constants than the high-frequency bands. This multiband compressor usually does most of the work in increasing program density.

The amount of *gain reduction* determines how much the loudness of soft passages will be increased (and, therefore, how consistent overall loudness will be). Our hypothetical system reduces gain with the broadband AGC and the multiband compressor. The broadband AGC is designed to control average levels, and to compensate for a reasonable amount of operator error. It is *not* designed to substantially increase the short-term program density; the multiband compressor and peak limiters handle that function.

Modern audio processing systems usually add other elements to the basic system described here. For example, it is not unusual to incorporate an equalizer to color the audio for artistic effect. The equalizer may be any of the types described earlier and is usually found between the slow AGC and the multiband compressor. The multiband compressor itself can also be used as an equalizer by adjusting the gains of its various bands.

Various low-pass filters are often included in the system to limit the bandwidth of the output signal to 15 kHz (for FM), 10 kHz (AM in NRSC countries), 4.5 kHz (AM in EBU countries, and shortwave worldwide) or other bandwidths as required by the local regulatory authority. The final low-pass filter in the system is almost always overshoot-compensated to prevent introducing spurious modulation peaks into the output waveform. High-pass filters may be incorporated to protect the transmitter. This is particularly important in high-power AM and shortwave installations exceeding 100 kW carrier power.

A transmitter equalizer that corrects the pulse response of the transmitter is found on high-end AM processors.

Location of System Components

The best location for the processing system is as close as possible to the transmitter, so that the processing system's output can be connected to the transmitter through a circuit path that introduces the least possible change in the shape of the carefully peak-limited waveform at the processing system's output. Sometimes, it is impractical to locate the processing system at the transmitter, and it must instead be located on the studio side of the link connecting the audio plant to the transmitter. (The studio/transmitter link (STL) might be telephone or post lines, analog microwave radio, or various types of digital paths.) This situation is not ideal because artifacts that cannot be controlled by the audio processor can be introduced in the link to the transmitter or by additional peak limiters placed at the transmitter. (Such additional peak limiters are common in countries where the transmitter is operated by a different authority than that providing the broadcast program.)

In this case, the audio output of the processing system should be fed directly to the transmitter through a link that is as flat and phase-linear as possible. Deviation from flatness and phase-linearity will cause spurious modulation peaks because the shape of the peak-limited waveform is changed. Such peaks add nothing to average modulation. Thus the average modulation must be lowered to accommodate those peaks within the carrier deviation limits dictated by government authorities.

This implies that if the transmitter has built-in high-pass or low-pass filters (as some do), these filters *must* be bypassed to achieve accurate waveform fidelity. Modern processing systems contain filters that are fully able to protect the transmitter, but which are located in the processing system where they do not degrade control of peak modulation.

Where Access To The Transmitter Is Available

The audio received at the transmitter site should be of as good quality as possible. Because the audio processor controls peaks, it is not important that the audio link (STL) feeding the processing system's input terminals be phase-linear. However, the link should have low noise, flattest possible frequency response from 30–15,000 Hz, and low nonlinear distortion.

If the audio link between the studio and the transmitter is noisy, performing the compression function at the studio site can minimize the audibility of this noise. Compression applied before the audio link improves the signal-to-noise ratio because the average level on the link will be greater. If the STL has limited dynamic range, it may be desirable to compress the signal at the *studio* end of the STL. To apply such compression, split the processing system, placing the AGC and multiband compressor sections at the studio, and the peak limiter at the transmitter.

Where Access To The Transmitter Plant Is Not Available

In some situations, the organization originating the program does not have access to the transmitter, which is operated by a separate entity. In this case, all audio processing must be done at the studio, and any damage that occurs later must be tolerated. A peak limiter would, however, be used at the transmitter to provide protection against overmodulation.

If it is possible to obtain a broadband phase-linear link to the transmitter, the processing system at the studio location can feed the STL. The output of the STL receiver is then fed directly into the transmitter with no intervening processing. A *composite* STL (ordinarily used for FM stereo baseband) has the requisite characteristics, and can be used to carry the output of the processing system to the transmitter. However, the output of a typical composite STL receiver is at the wrong level and impedance to directly drive a typical transmitter (most of which require +10 dBm into 600 Ω). Therefore, the transmitter must almost certainly be modified to make it compatible with the composite STL. Use of a composite STL has many ramifications, and the installation of the processing system at the transmitter may be less complicated.

changing—a characteristic side-effect of wideband compressors and limiters when driven heavily), *breathing* (audible pulling up of background noise, cured by a compressor gate), and *hole-punching* (a sudden drop in loudness after a program transient, caused by the transient's inducing a large amount of gain reduction which then does not decay quickly, and cured by multiple time-constant release time circuitry).

The processor must be packaged so that it is easy to operate and maintain, and can work in high RF fields without compromise.

The processor should have setup controls with enough versatility to enable the subjective effect to be readily tuned to the requirements of the broadcasting authority operating it. For mixed-format applications the processor may have several presets, selectable by remote control, that permit the operator to set the amount of compression, limiting, clipping and other parameters to complement the program material being transmitted.

Ordinarily, the processor should be equipped with sufficient remote control facilities to enable it to be interfaced efficiently with modern, automated plants. Most of the required facilities are specific to the application: for example, medium wave (MW), shortwave (HF), FM (VHF), or television.

The processor should have sufficient metering to permit it to be easily set up with tones or program material. The metering should also provide operations and diagnostic capabilities. Metering usually includes input level, output level, and gain reduction (the amount of limiting or compression) occurring in each variable-gain stage.

Processing for Stereo

Processing for stereophonic transmission is similar to processing for monophonic transmission, except that two audio processing chains are used. To preserve stereo imaging, the gains of the left and right automatic gain control and compression circuitry must be identical. Conversely, experience has shown that fast peak limiting and high-frequency limiting circuits sound best when operated independently (without stereo coupling), because the ear does not perceive channel-imbalance-induced spatial shifts with these fast time constants. However, the ear can perceive the loudness of one channel's being modulated unnaturally by a dominant element in the other channel when the channels are coupled.

The gain of the coupled elements is determined by the requirements of the transmission service. In FM, the channel requiring the greatest amount of limiting determines the gain of both channels. The processor operates by sensing the higher of the left and right channels and determining the gain of *both* channels such that the higher channel does not exceed a given level at the processor's output.

In AM, the gain of both channels is controlled by sensing and controlling the level of their sum (L + R), because the envelope modulation represents the sum of the channels.

SYSTEM CONSIDERATIONS

Reducing the peak-to-average ratio of the audio increases *loudness*. If peaks are reduced, the average level can be increased within the permitted modulation limits. The level with which this can be accomplished without introducing objectionable side effects (like clipping distortion) is the single best measure of audio processing effectiveness. *Density* is the extent to which the amplitudes of audio signal peaks are made uniform (at the expense of dynamic range). Programs with large amounts of short-term dynamic range have low density and highly compressed programs have high density.

Compression reduces the difference in level between the soft and loud sounds to make more efficient use of permitted peak level limits, resulting in a subjective increase in the loudness of soft sounds. It *cannot* make loud sounds seem louder. Compression reduces dynamic range relatively slowly in a manner similar to "riding the gain." Limiting and clipping, on the other hand, reduce the short-term peak-to-average ratio of the audio.

Limiting increases audio density. Increasing density can make loud sounds seem louder, but can also result in an unattractive, busier, flatter and denser sound. It is important to be aware of the many negative subjective side effects of excessive density when setting controls that affect the density of the processed sound.

Clipping sharp peaks does not produce any audible side effects when done moderately. Excessive clipping will be perceived as audible distortion.

Building a System

Combining several audio processors into a good sounding system is tricky because of headroom and time constant considerations. The device driving a given processor must be able to drive that processor into full compression or limiting. If the driving device (for example, distribution amplifier) runs out of headroom before full limiting occurs in the driven device, then that device cannot achieve its full capability. This consideration is particularly critical when setting up the input A/D converter of a digital audio processor. The analog drive level to the A/D converter must be set so that the A/D converter does not clip when receiving levels sufficient to cause full gain reduction in the following audio processor.

Beware of interactions between the attack times and release times when cascading several processors. It is wise to start the system with the slowest device. This is usually a compressor or automatic gain controller (AGC) with slow attack and release times and a compressor gate to prevent noise breathing. Such a processor does not significantly increase the *density* of the audio; it simply does gentle gain riding to ensure that following stages are driven at the correct level.

A multiband compressor with moderate attack and release times often follows the slow AGC. Correctly designed multiband processors have these time constants optimized for each frequency band. The low-well to perceived loudness. A meter that purports to measure loudness must agree with a panel of human listeners.

There are three important factors that correlate to subjective loudness:

- The spectral distribution of the sound energy. The ear's sensitivity depends strongly on frequency. It is most sensitive to frequencies between 2 and 8 kHz. Sensitivity falls off fastest below 200 Hz.
- Whether the sound energy is concentrated in a wide or narrow bandwidth. For a given total sound power, the sound becomes louder as the power is spread over a larger number of *critical bands* (about 1/3 octave). This is called *loudness summation*.
- The duration of the sound. A given amount of sound power appears progressively louder until its duration exceeds about 200 nsec, at which point no further loudness increase will occur.

Torick and Jones have published a paper describing a meter for measuring the loudness of broadcast signals.[3] The FCC did an informal validation of the results of this meter, and concluded that it was effective in assessing whether commercials in television were noticeably louder than the surrounding entertainment programming.[4]

Additionally, the independently developed loudness measuring methods of Stevens and of Zwicker have both become international standards. At the time of this writing there is at least one commercially available loudness meter using the Jones & Torick method. This can be used as an approximate measure of subjective loudness. Bear in mind that members of Jones & Torick's listening panel disagreed on the loudness of certain sounds by over 3 dB, so any metering represents an average and many not agree exactly with loudness as perceived by any one individual.

GENERAL PERFORMANCE REQUIREMENTS FOR TRANSMISSION AUDIO PROCESSORS

The audio processor must control the peak modulation of the RF carrier to the standards required by the governing authority, such as the FCC in the United States. In AM, this usually means that negative carrier pinch-off must not occur at any time because this would cause splatter interference into adjacent channels. In FM and television (NTSC and PAL), the peak deviation of the carrier must be controlled so that the modulation monitor specified by the governing authority does not indicate overmodulation.[5] Because the rules often permit the modulation monitor to ignore very brief overshoots, the instantaneous peak deviation might exceed the peak modulation as indicated on the modulation monitor.

The requirements for peak control and spectrum control tend to conflict, which is why sophisticated nonlinear filters are required to achieve highest performance. Applying a peak-controlled signal to a linear filter almost always causes the filter to overshoot and ring because of two mechanisms: *spectral truncation* and *time dispersion*. One can build a square wave by summing its Fourier components together with correct amplitude and phase. Analysis shows that the fundamental of the square wave is approximately 2.1 dB higher than the amplitude of the square wave itself. As each harmonic is added in turn to the fundamental, a given harmonic's phase is such that the peak amplitude of the resulting waveform *decreases* by the largest possible amount. Simultaneously, the RMS value *increases* because of the addition of the power in each harmonic. This is the fundamental theoretical reason why simple clipping is such a powerful tool for improving the peak-to-average ratio of broadcast audio: clipping adds to the audio waveform spectral components whose phase and amplitude are precisely correct to minimize the waveform's peak level while simultaneously increasing the power in the waveform.

If a square wave (or clipped waveform) is applied to a low-pass filter with constant time delay at all frequencies, the higher harmonics that reduce the peak level will be removed, increasing the peak level and with it the peak-to-average ratio. Thus even a perfectly phase-linear low-pass filter will cause overshoot.[6] *There is no sharp-cutoff linear low-pass filter that is overshoot-free:* overshoot-free spectral control to FCC or ITU-R standards must be achieved with filters that are embedded within the processing, such that the nonlinear peak controlling elements in the processor can also control the overshoot.

If the sharp-cutoff filter is now allowed to be minimum-phase, it will exhibit a sharp peak in group delay around its cutoff frequency.[7] Because the filter is no longer phase-linear, it will not only remove the higher harmonics required to minimize peak levels, but will also change the time relationship between the lower harmonics and the fundamental. They become delayed by different amounts of time, causing the shape of the waveform to change. This *time dispersion* will therefore further increase the peak level.

When a square wave is applied to a linear-phase filter, overshoot and ringing will appear symmetrically on the leading and trailing edge of the waveform. If the filter is minimum phase, the overshoot will appear on the trailing edge and will be about twice as large. In the first case, the overshoot and ringing are in fact caused by spectrum truncation which eliminates harmonics necessary to minimize the peak level of the wave at all times; in the second case, the overshoot and ringing are caused by spectrum truncation *and* by distortion of the time relationship between the remaining Fourier components in the wave.

Application Considerations

Except as required to achieve very specific artistic goals (most notably in some major-market high-energy hit-music formats), the processed audio should be free from unnatural subjective side-effects, such as *pumping* (a sense that the gain is constantly and unnaturally

The *noise gate* is an expander with a high expansion ratio. Its purpose is to reduce noise. Because it causes gain reduction when the input level drops below a given threshold, the ear is likely to hear the accompanying gain reduction as a fluctuation in the noise level, sometimes called *breathing*. This can sound unnatural. Therefore, the noise gate is most useful when applied to a single microphone in a multi-microphone recording. Usually, the other microphones will mask any breathing, yet the noise reduction provided by the noise gate will still be appreciated during quiet program material.

Multiband Compression and Frequency-Selective Limiting

These techniques divide the audio spectrum into several frequency bands and compress or limit each band separately (although some interband coupling may be used to prevent excessive disparity between the gains of adjacent bands). This is the most powerful and popular contemporary audio processing technique, because, when done correctly, it eliminates spectral gain intermodulation. This occurs in a wideband compressor or limiter when a voice or instrument in one frequency range dominates the spectral energy, thus determining the amount of gain reduction. If other, weaker, elements are also present, their loudness may be audibly and disturbingly modulated by the dominant element. Particularly unpleasant effects may occur if the dominant energy is in the bass region, because the ear is relatively insensitive to bass energy, so the loudness of the midrange is pushed down by the dominant bass energy seemingly inexplicably.

Another type of frequency-selective limiting uses a program-controlled filter. The filter's cutoff frequency, its depth of shelving, or a combination of these parameters, is varied to dynamically change the frequency response of the transmission channel. Such program-controlled filters are most often used as *high-frequency limiters* to control potential overload due to pre-emphasis in pre-emphasized systems like FM (VHF), and television audio (NTSC and PAL), and in FM modulated transmission channels such as microwave links and satellite circuits.

Equalization

Equalization is changing the spectral balance of an audio signal, and is achieved by use of an *equalizer*. In broadest terms, an equalizer is any frequency-selective network (filter) placed in the signal path. In audio processing, an equalizer is usually a device that can apply a *shelving* or *peaking* curve to the audio.

A shelving curve starts off at a certain gain. As frequency changes, the gain increases (boost) or decreases (cut) asymptotically. Finally, the gain shelves off and does not change with further changes in frequency.

A peaking curve is bell-shaped on the frequency axis. As opposed to a shelving curve, it has a well-defined peak frequency. The shape of the curve can be uniquely defined by three *parameters: the amount of equalization* (in dB), *the frequency of maximum equalization* (in Hz) and the *Q*, which is a dimensionless number that describes whether the curve is broad or sharp.

A *parametric equalizer* provides several peaking equalizers, in which the user has control of all three parameters. This type of equalizer is generally considered to be the most flexible and musical-sounding equalizer. Some parametric equalizers can also be used as notch filters.

A *graphic equalizer* provides a number of peaking equalizers (usually 8 to 31) distributed on octave or fractions of octave (1/4 or 1/3) spaced frequency centers throughout the audible range. The controls for the amount of equalization are linear-throw faders, and are arranged on the panel in order of frequency. The positions of the controls, when considered together, thus provide a very rough graphic display of the amount of equalization provided by the entire equalizer. The advantage of a graphic equalizer is that it is easy to understand and quick to adjust. Its primary disadvantage is lack of flexibility. Usually, only the amount of equalization is adjustable, the Q and center frequency being fixed. However, a few manufacturers make parametric equalizers with graphic-style controls. These provide the advantages of both types.

Low-pass and high-pass filters remove spectrum at the top and bottom of the audible range, respectively. They are usually used to remove unwanted high- or low frequency noise, and can also produce special effects (like telephone simulation).

These filters come with their rate of cutoff fixed in multiples of 6 dB/octave. 12 dB/octave and 18 dB/octave are popular. In addition, the shape of the region around the cutoff frequency has a considerable effect on the listening quality of such filters. Bessel (constant-delay) filters have a gentle transition into cutoff, and sound pleasant and musically neutral. Butterworth (maximally-flat magnitude) filters have a sharper transition into cutoff. They are more effective at removing noise than Bessel filters, but have a more colored listening quality.

Equalizers are sometimes used on-line in transmission to create a certain sonic signature for a broadcast. Any of the types above may be used. Commercial audio processors may include equalizers for program coloration, or for correcting the frequency response of previous or subsequent transmission links. Sometimes the various bands of a multiband compressor or limiter are used as an equalizer by adjusting the gains of the various bands to achieve the desired equalized frequency response.

Loudness

One of the main uses of audio processing is to increase perceived loudness within the peak modulation constraints of a transmission channel. Assessing the effectiveness of audio processing thus requires a means of measuring loudness. *Loudness is subjective: it is the intensity of sound as perceived by the ear/brain system*. No simple meter, whether peak program meter (PPM) or VU, provides a reading that correlates

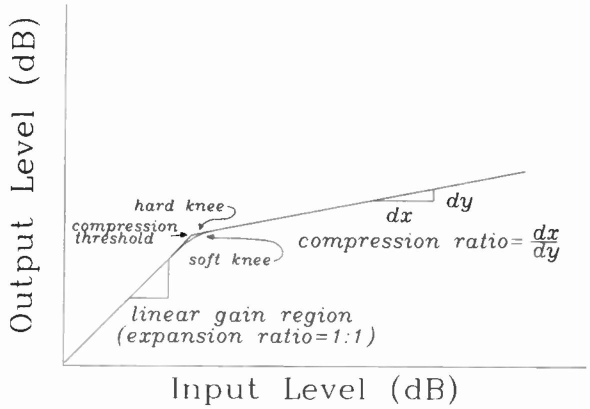

Figure 3.8-1 Input versus output levels for compressors.

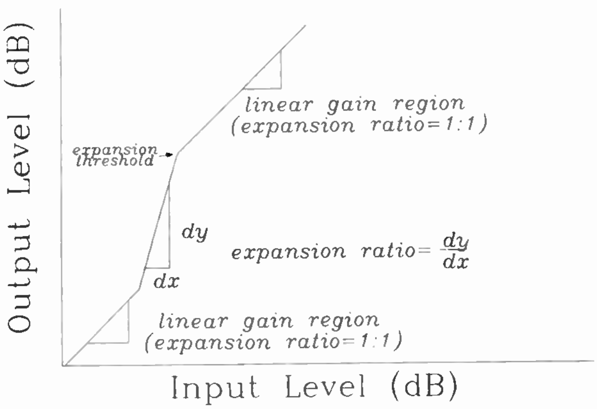

Figure 3.8-2. Input versus output levels for expanders.

attack time (typically less than 2 μsec), and fast release time (typically less than 200 μsec). In modern audio processing, a peak limiter, by itself, usually limits the peaks of the *envelope* of the waveform, as opposed to individual instantaneous peaks *in the waveform*. These are usually controlled by *clipping*. As a matter of good engineering practice, peak limiters are usually adjusted to produce no more than 6 dB of gain reduction to prevent offensive audible side effects.

The main purpose of limiting is to protect a subsequent channel from overload, as opposed to compression, the main purpose of which is to reduce the dynamic range of the program.

Peak clipping is a process that instantaneously chops off any part of the waveform that exceeds the *threshold of clipping*. This threshold can be either symmetrical or asymmetrical around 0 volts. While peak clipping can be very effective, it causes audible distortion when over used. It also increases the bandwidth of the signal by introducing both harmonic and intermodulation distortion into its output signal. Manufacturers of modern audio processors have therefore developed various forms of *overshoot compensation*, which is essentially peak clipping that does not introduce significant out-of-band spectral energy into its output.

Radio frequency clipping (RF clipping) is peak clipping applied to a single-sideband RF signal. (A typical carrier frequency is 1 MHz). All clipping-induced harmonics fall around harmonics of the carrier (2 MHz, . . .). Upon demodulation, these harmonics remain at high frequencies and are removed by a low-pass filter. Thus RF clipping produces only intermodulation distortion, and no harmonic distortion. Ordinary or audio-frequency (AF) clipping produces both. RF clipping is substantially more effective than AF clipping on voice because intermodulation distortion is considered less objectionable than harmonic distortion in this application. On the other hand, RF clipping is considered much more objectionable than AF clipping on music.

The *Hilbert Transform clipper* combines the features of RF and AF clippers.[1] It acts as an RF clipper below 4 kHz (the region in which most voice energy is located), and acts as an AF clipper above 4 kHz to prevent excessive intermodulation distortion with music.

Unless a limiter has an attack time of less than about 10 μsec, it will exhibit *overshoots* at its output. If the goal of the processing is to precisely constrain the instantaneous values of the waveform to a given threshold, it usually sounds best to control these overshoots by a limiter with 2 nsec attack time followed by a clipper. Attempting to provide all peak control with the limiter does not sound as good, because the clipper affects only the offending overshoot and does not apply gain reduction to the surrounding signal.

When used in this way, clippers can cause audible distortion on certain program material. However, fast-attack limiters will cause audible clipping of the first half-cycle of certain program material, such as solo piano, harp, and nylon string acoustic guitar. Such distortion can be eliminated by a *delay line limiter*.[2] This device consists of two audio paths. The audio is applied to a pilot limiter, which has a very fast attack time. The gain control voltage generated by the pilot limiter is applied to a low-pass filter to smooth its sharp edges, and then to the gain control port of the variable gain amplifier that passes the actual program signal. To compensate for the group delay in the control voltage low-pass filter (which delays application of gain control to the audio), the audio is delayed equally by a delay line prior to the variable gain amplifier's input.

Gating

There are two fundamental types of gates, the *compressor gate* and the *noise gate*. The *compressor gate* prevents any change in background noise during pauses or low-level program material by freezing the compressor gain when the input level drops below the *threshold of gating*. Because it produces natural sound, it is very popular in broadcasting.

Instead of freezing, many compressor gates will cause the gain to move very slowly to a nominal value (typically 10 dB of gain reduction) if the gating period is long enough. This prevents the compressor from getting stuck with an unusually high or low gain.

3.8
TRANSMISSION AUDIO PROCESSING

ROBERT ORBAN
ORBAN, INC., A HARMAN INTERNATIONAL COMPANY, SAN LEANDRO, CA

INTRODUCTION

Transmission audio processing is both an engineering and artistic discipline. The engineering goal is to make most efficient use of the signal-to-noise ratio and audio bandwidth available from the transmission channel while preventing its overmodulation. The artistic goal is set by the organization using audio processing. It may be to avoid audibly modifying the original program material at all. Or it may be to create a distinct *sonic signature* for the broadcast by radically changing the sound of the original. Most broadcasters operate somewhere in between these two extremes.

Provided that the transmitted signal meets regulatory requirements for modulation control and RF bandwidth, there is no well defined right or wrong way to process audio. Like most areas requiring subjective, artistic judgement, processing is highly controversial and likely to provoke exceedingly opinionated arguments between its practitioners. Ultimately, the success of a broadcast's audio processing must be judged by its results—if the broadcast gets the desired audience, then the processing must be deemed satisfactory regardless of the opinions of audiophiles, purists, or others who consider processing an unnecessary evil.

One mark of the professionalism of a broadcast engineer is their mastery of the techniques of audio processing. The canny practitioner has a bag of tricks that can be used to achieve the processing goal specified by the station's management, whether it is purist or "squashed against the wall."

FUNDAMENTALS OF AUDIO PROCESSING

Compression reduces the dynamic range of program material by reducing the gain of material whose average or root mean square (RMS) level exceeds the *threshold of compression.* The amount by which the gain is reduced is called the *gain reduction* (G/R).

Above threshold, the slope of the input/output curve is the *compression ratio.* Low ratios provide loose control over levels, but generally sound more natural than high ratios, which provide tight control.

The *knee* of the input/output level graph can show an abrupt transition (*hard-knee*) into compression, or a gradual transition (*soft-knee*), in which the ratio becomes progressively larger as the amount of gain reduction increases.

The *attack time* is, generally, the time that it takes the compressor to settle to a new gain following a step increase in level. There is no generally agreed upon precise definition on how to measure attack time. Some measure it as the *time constant*—the time necessary for the gain to achieve 67% of its new value. Others measure it as the time for the gain to reach 90% of its new value for a given amplitude step (often 10 dB).

The *release time* is the time necessary for the gain to recover to within a certain percent of its final value after the level of the input signal to the compressor has been reduced below the compression threshold. It is sometimes convenient to specify the release time in dB per second if the shape of the release time is a straight line on a dB versus time graph. However, this shape often is not linear. *Multiple time constant* (sometimes called automatic) release time circuits change the release rate (in dB/second) according to the history of the program, and according to how much gain reduction is in use. For example, the release time will temporarily speed up after an abrupt transient, to prevent a hole from being punched in the program by the gain reduction. The release time may slow down as 0 dB gain reduction is approached to make compression of wide-dynamic-range program material less obvious to the ear.

Delayed release holds the gain constant for a short time (typically less than 20) after gain reduction has occurred. This prevents fast release times from causing modulation of individual cycles in the program waveform, thus reducing the tendency of the compressor to introduce harmonic or intermodulation distortion when operated with fast attack and release. The foregoing compression parameters are illustrated in Figure 3.8-1.

Expansion

Expansion increases the dynamic range of program material by reducing gain when the program level is lower than the *threshold of expansion* (see Figure 3.8-2). The primary purpose of expansion is to reduce noise, either electronic or acoustic. Expanders are often coupled to compressors so that low-level program material is not amplified, thus reducing the noise that would otherwise be exaggerated by the compression. Expanders have attack times, release times and expansion ratios that are analogous to those for compressors.

Peak Limiting and Clipping

Peak limiting is an extreme form of compression characterized by a very high compression ratio, fast

to assessing the overall performance of an audio broadcasting system.

The problem with subjective evaluations is that, while accurate, they are time consuming and expensive to undertake. Traditional objective benchmarks of audio performance, such as signal-to-noise ratio or total harmonic distortion, are not reliable measures of perceived audio quality, especially when perceptually coded signals are being considered.

To remedy this situation, ITU-R established Task Group 10-4 to develop a method of objectively assessing perceived audio quality. Conceptually, the result of this effort would be a device having two inputs—a reference and the audio signal to be evaluated—and would generate an audio quality estimate based on these sources.

Six organizations proposed models for accomplishing this objective, and over the course of several years these models were evaluated for effectiveness, in part by using source material from previously documented subjective evaluations. Ultimately, the task group decided that none of the models by themselves fully met the stated requirements. The group decided, instead, to use the best parts of the different models to create another model that would meet the sought after requirements.

This approach resulted in an objective measurement method known as *perceptual evaluation of audio quality* (PEAO). The method contains two versions—a basic version designed to support real-time implementations, and an advanced version optimized for the highest accuracy but not necessarily implementable in real-time. The primary applications for PEAQ are summarized in Table 3.7-2.

PERSPECTIVE ON AUDIO COMPRESSION

A balance must be struck between the degree of compression available and the level of distortion that can be tolerated, whether the result of a single coding pass or the result of a number of passes, as would be experienced in a complex audio chain or network. There have been many outstanding successes for digital audio data compression in communications and storage, and as long as the limitations of the various compression systems are fully understood, successful implementations will continue to grow in number.

Compression is a trade off and in the end you get what you pay for. Quality must be measured against the coding algorithm being used, the compression ratio, bit rate and coding delay resulting from the process.

There is continued progress in expanding the arithmetical capabilities of digital signal processors, and the supporting hardware developments would seem to be following a parallel course. It is possible to obtain a single chip containing both encoder and decoder elements, including stereo capabilities. In every five year period, it is not unreasonable to expect a ten fold increase in the processing capabilities of a single DSP chip, thus, increasing flexibility and processing power. Speculation could point to an eventual position when a completely lossless algorithm with an extremely high compression ratio would become available. In any event, the art of compressing audio data streams into narrower and narrower digital pipes will undoubtedly continue.

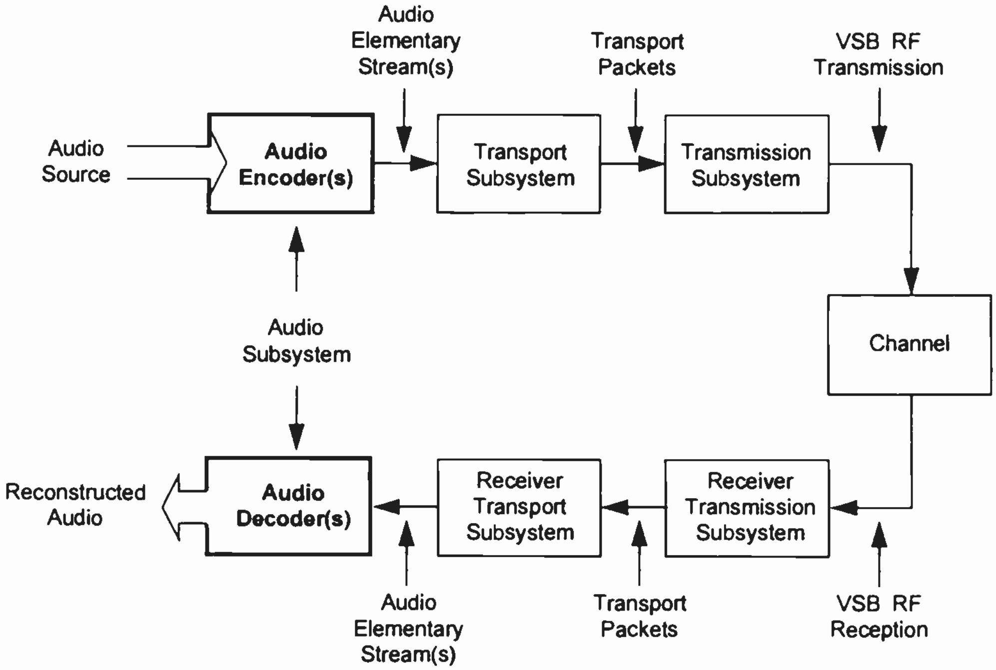

Figure 3.7-11. The audio subsystem in the DTV standard.[2]

An audio program source is encoded by a *digital television audio encoder*. The output of the audio encoder is a string of bits that represent the audio source (the audio elementary stream). The transport subsystem packetizes the audio data into *packetized elementary system* (PES) packets, which are then further packetized into transport packets. The transmission subsystem converts the transport packets into a modulated RF signal for transmission to the receiver. At the receiver, the signal is demodulated by the receiver transmission subsystem. The receiver transport subsystem converts the received audio packets back into an audio elementary stream, which is decoded by the digital television audio decoder.

The partitioning shown in Figure 3.7-11 is conceptual and practical implementations may differ. For example, the transport processing may be broken into two blocks; the first would perform PES packetization and the second would perform transport packetization. Or, some of the transport functionality may be included in either the audio coder or the transmission subsystem.

Sampling Parameters

The AC-3 system conveys digital audio sampled at a frequency of 48 kHz, locked to the 27 MHz system clock.[2] If analog signal inputs are employed, the A/D converters should sample at 48 kHz. If digital inputs are employed, the input sampling rate should be 48 kHz, or the audio encoder should contain sampling rate converters that translate the sampling rate to 48 kHz. The sampling rate at the input to the audio encoder must be locked to the video clock for proper operation of the audio subsystem.

In general, input signals should be quantized to at least 16 bit resolution. The audio compression system can convey audio signals with up to 24 bit resolution.

Objective Quality Measurements

Perceptual audio coding has revolutionized the processing and distribution of digital audio signals. One aspect of this technology, not often emphasized, is the difficulty of determining, objectively, the quality of perceptually coded signals. Audio professionals could greatly benefit from an objective approach to signal characterization because it would offer a simple but accurate approach for verification of good audio quality within a given facility.

Most of the discussions regarding this topic involve reference to the results of subjective evaluations of audio quality, where for example, groups of listeners compare reference audio material to coded audio material and then judge the level of impairment caused by the coding process. A procedure for this process has been standardized in ITU-R Rec. BS.1116, and makes use of the ITU-R five grade impairment scale:

- 5.0—Imperceptible
- 4.0—Perceptible but not annoying
- 3.0—Slightly annoying
- 2.0—Annoying
- 1.0—Very annoying

Quality measurements made with properly executed subjective evaluations are widely accepted and have been used for a variety of purposes, from determining which of a group of perceptual coders performs best, by the core bit allocation routine, which determines how many bits should be used to encode each individual mantissa. The spectral envelope and the coarsely quantized mantissas for six audio blocks (1536 audio samples) are formatted into an AC-3 frame. The AC-3 bit stream is a sequence of AC-3 frames.

The actual AC-3 encoder is more complex than shown in the simplified system of Figure 3.7-9. The following functions also are included:

- A frame header is attached, containing information (bit rate, sample rate, number of encoded channels and other data) required to synchronize to and decode the encoded bit stream
- Error-detection codes are inserted to allow the decoder to verify that a received frame of data is error-free
- The analysis filterbank spectral resolution may be dynamically altered to better match the time/frequency characteristic of each audio block
- The spectral envelope may be encoded with variable time/frequency resolution
- A more complex bit allocation may be performed, and parameters of the core bit allocation routine may be modified to produce a more optimum bit allocation
- The channels may be coupled at high frequencies to achieve higher coding gain for operation at lower bit rates
- In the 2-channel mode, a rematrixing process may be selectively performed to provide additional coding gain, and to allow improved results to be obtained in the event that the 2-channel signal is decoded with a matrix surround decoder.

Decoding

The decoding process is, essentially, the inverse of the encoding process.[1] The basic decoder, shown in Figure 3.7-10, must synchronize to the encoded bit stream, check for errors and deformat the various types of data (the encoded spectral envelope and the quantized mantissas). The bit allocation routine is run, and the results are used to unpack and dequantize the mantissas. The spectral envelope is decoded to produce the exponents. The exponents and mantissas are transformed back into the time domain to produce the decoded PCM time samples. Additional steps in the audio decoding process include the following:

- Error concealment or muting may be applied in the event a data error is detected
- Channels that have had their high frequency content coupled must be decoupled
- Dematrixing must be applied (in the 2-channel mode) whenever the channels have been rematrixed
- The synthesis filterbank resolution must be dynamically altered in the same manner as the encoder analysis filterbank was altered during the encoding process

Implementation of the AC-3 System

As illustrated in Figure 3.7-11, the audio subsystem of the ATSC DTV Standard comprises the audio encoding/decoding function and resides between the audio inputs/outputs and the transport subsystem.[2] The audio encoder is responsible for generating the *audio elementary stream*, which is an encoded representation of the baseband audio input signals. (Note that more than one audio encoder may be used in a system.) The flexibility of the transport system allows multiple audio elementary streams to be delivered to the receiver. At the receiver, the transport subsystem is responsible for selecting which audio streams to deliver to the audio subsystem. The audio subsystem is then responsible for decoding the audio elementary stream back into baseband audio.

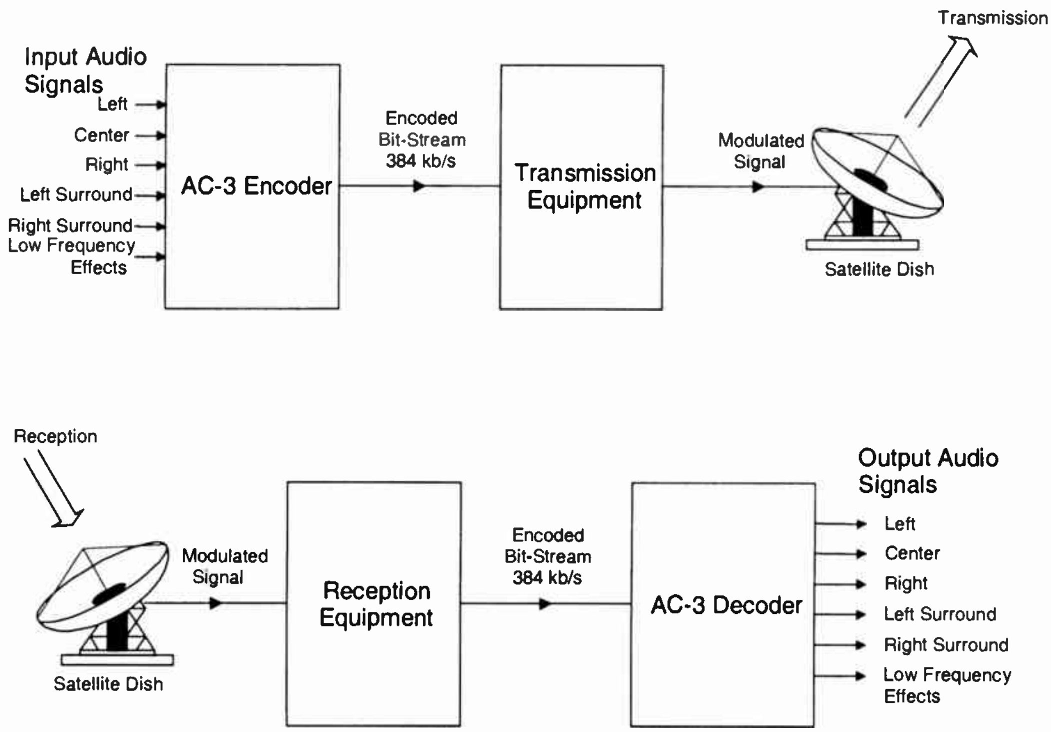

Figure 3.7-8. Example application of the AC-3 audio subsystem for satellite audio transmission.[1]

filterbank. Overlapping blocks of 512 time samples are multiplied by a time window and transformed into the frequency domain. Because of the overlapping blocks, each PCM input sample is represented in two sequential transformed blocks. The frequency domain representation then may be decimated by a factor of 2, so that each block contains 256 frequency coefficients. The individual frequency coefficients are represented in binary exponential notation as a binary exponent and a mantissa. The set of exponents is encoded into a coarse representation of the signal spectrum, referred to as the *spectral envelope*. This spectral envelope is used

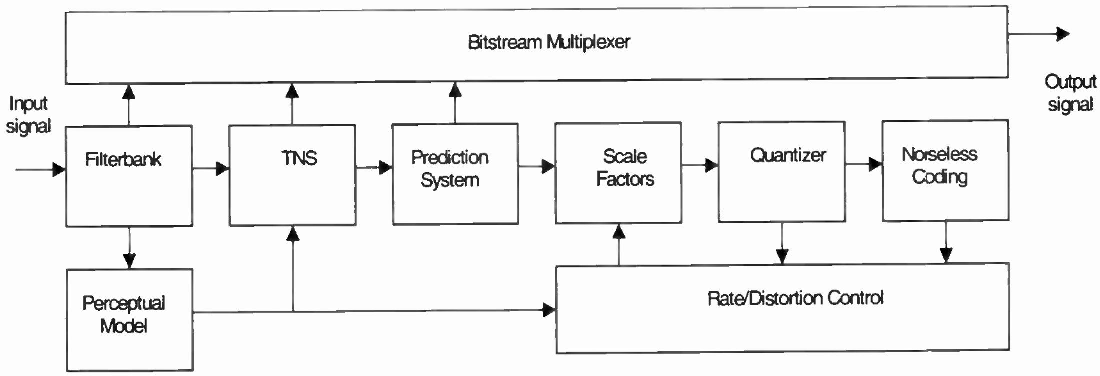

Figure 3.7-7. Functional block diagram of the MPEG-2 AAC coding system.

(maximum). AAC is not backward compatible with the Layer 1 and Layer 2 codes.

MPEG-4

MPEG-4, as with the MPEG-1 and MPEG-2 efforts, is not concerned solely with the development of audio coding standards, but also encompasses video coding and data transmission elements. In addition to building upon the audio coding standards developed for MPEG-2, MPEG-4 includes a revolutionary new element—*synthesized sound.* Tools are provided within MPEG-4 for coding of both natural sounds (speech and music) and for synthesizing sounds based on structured descriptions. The representations used for synthesizing sounds can be formed by text or by instrument descriptions, and by coding other parameters to provide for effects, such as reverberation and spatialization.

Natural audio coding is supported within MPEG-4 at bit rates ranging from 2–64 kbps and includes the MPEG-2 AAC Standard (among others) to provide for general compression of audio in the upper bit rate range (8–64 kbps), the range of most interest to broadcasters. Other types of coders, primarily voice coders (or *vocoders*) are used to support coding down to the 2 kbps rate.

For synthesized sounds, decoders are available that operate based on so-called structured inputs, that is, input signals based on descriptions of sounds and not the sounds themselves. Text files are one example of a structured input. In MPEG-4, text can be converted to speech in a text-to-speech (TTS) decoder. Synthetic music is another example, and may be delivered at extremely low bit rates while still describing an exact sound signal. The standard's structured audio decoder uses a language to define an orchestra made up of instruments, which can be downloaded in the bit stream, not fixed in the decoder.

TTS support is provided in MPEG-4 for unembellished text, or text with prosodic (pitch contour, phoneme duration, etc.) parameters, as an input to generate intelligible synthetic speech. It includes the following functionalities:

- Speech synthesis using the prosody of the original speech
- Facial animation control with phoneme information (important for multimedia applications)
- Trick mode functionality: pause, resume, jump forward, jump backward
- International language support for text
- International symbol support for phonemes
- Support for specifying the age, gender, language and dialect of the speaker.

MPEG-4 does not standardize a method of synthesis, but rather a method of describing synthesis.

AC-3 Audio System for DTV

The AC-3 digital compression algorithm specified in the ATSC DTV system can encode from 1–5.1 channels of source audio from a PCM representation into a serial bit stream at data rates ranging from 32–640 kbps.

A typical application of the bit-reduction algorithm is shown in Figure 3.7-8. In this example, a 5.1 channel audio program is converted from a PCM representation requiring more than 5 Mbps (6 channels $\times$ 48 kHz $\times$ 18 bits = 5.184 Mbps) into a 384 kbps serial bit stream by the AC-3 encoder. Radio frequency (RF) transmission equipment converts this bit stream into a modulated waveform that is applied to a satellite transponder. The amount of bandwidth and power thus required by the transmission has been reduced by more than a factor of 13 by the AC-3 digital compression system. The received signal is demodulated back into the 384 kbps serial bit stream, and decoded by the AC-3 decoder. The result is the original 5.1 channel audio program.

Encoding

The AC-3 encoder accepts PCM audio and produces the encoded bit stream for the ATSC DTV Standard.[1] The AC-3 algorithm achieves high *coding gain* (the ratio of the input bit rate to the output bit rate) by coarsely quantizing a frequency domain representation of the audio signal. A block diagram of this process is given in Figure 3.7-9. The first step in the encoding chain is to transform the representation of audio from a sequence of PCM time samples into a sequence of blocks of frequency coefficients. This is done in the *analysis*

After the number of side information bits required for scale factors, bit allocation codes, cyclic redundancy check (CRC) and other functions have been determined, the remaining bits left in the pool are used in the recoding of the audio subband samples. The allocation of bits for the audio is determined by calculating the SMR, via the FFT, for each of the 12 subband sample blocks. The bit allocation algorithm then selects one of 15 available quantizers with a range such that the overall bit rate limitations are met and the quantization noise is masked as far as possible. If the composition of the audio signal is such that there are not enough bits in the pool to adequately code the subband samples, then the quantizers are adjusted down to a best-fit solution with (hopefully) minimum damage to the decoded audio at the output.

If the signal block being processed lies in the lower one third of the 32 frequency subbands, a 4 bit code word is simultaneously generated to identify the selected quantizer; this word is, again, carried as side information in the main data frame. A 3 bit word would be generated for processing in the mid frequency subbands and a 2 bit word for the higher frequency subbands. When the audio analysis demands it, this allows for at least 15, 7 and 3 quantization levels, respectively, in each of the three spectrum groupings. However, each quantizer can, if required, cover from 3 to 65,535 levels and additionally, if no signal is detected then no quantization takes place.

As with the scale factor data, some further redundancy can be exploited, which increases the efficiency of the quantizing process. For the lowest quantizer ranges (3, 5 and 9 levels), three successive subband sample blocks are grouped into a *granule* and this—in turn—is defined by only one code word. This is particularly effective in the higher frequency subbands where the quantizer ranges are invariably set at the lower end of the scale.

Error detection information can be relayed to the decoder by inserting a 16 bit CRC word in each data frame. This parity check word allows for the detection of up to three single bit errors or a group of errors up to 16 bits in length. A codec incorporating an error concealment regime can either mute the signal in the presence of errors or replace the impaired data with a previous, error free, data frame. The typical data frame structure for ISO/MPEG-1 Layer 2 audio is given in Figure 3.7-6.

MPEG-2 AAC

Also of note is MPEG-2 advanced audio coding (AAC), a highly advanced perceptual code, used initially for digital radio applications. The AAC code improves on previous techniques to increase coding efficiency. For example, an AAC system operating at 96 kbps produces the same sound quality as ISO/MPEG-1 Layer 2 operating at 192 kbps—a 2:1 reduction in bit rate. There are three modes (profiles) in the AAC standard:

- **Main.** Used when processing power, and especially memory, are readily available
- **Low complexity.** (LC) used when processing cycles and memory use are constrained
- **Scaleable sampling rate (SSR).** Appropriate when a *scalable decoder* is required. A scalable decoder can be designed to support different levels of audio quality from a common bit stream; for example, having both high and low cost implementations to support higher and lower audio qualities, respectively

Different profiles trade off encoding complexity for audio quality at a given bit rate. For example, at 128 kbps, the main profile AAC code has a more complex encoder structure than the LC AAC code at the same bit rate, but provides better audio quality as a result.

A block diagram of the AAC system general structure is given in Figure 3.7-7. The blocks in the drawing are referred to as *tools* that the coding algorithm uses to compress the digital audio signal. While many of these tools exist in most audio perceptual codes, two are unique to AAC—the *temporal noise shaper* (TNS) and the *prediction system* tool. The TNS uses a backward adaptive prediction process to remove redundancy between the frequency channels that are created by the prediction system tool.

MPEG-2 AAC provides the capability of up to 48 main audio channels, 16 low frequency effects channels, 16 overdub/multilingual channels, and 10 data streams. By comparison, ISO/MPEG-1 Layer 1 provides two channels and Layer 2 provides 5.1 channels

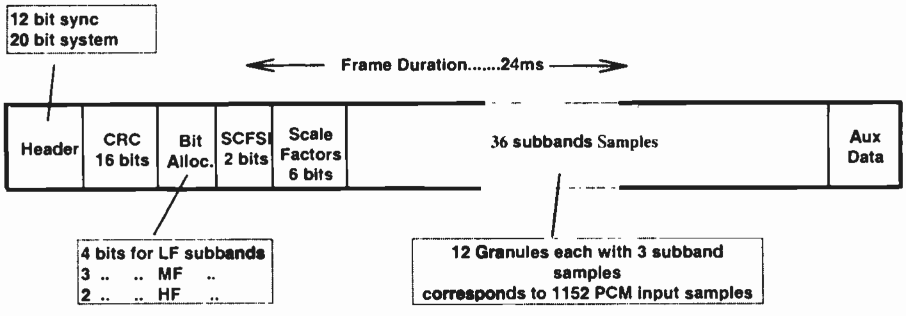

Figure 3.7-6. ISO/MPEG-1 Layer 2 data frame structure.

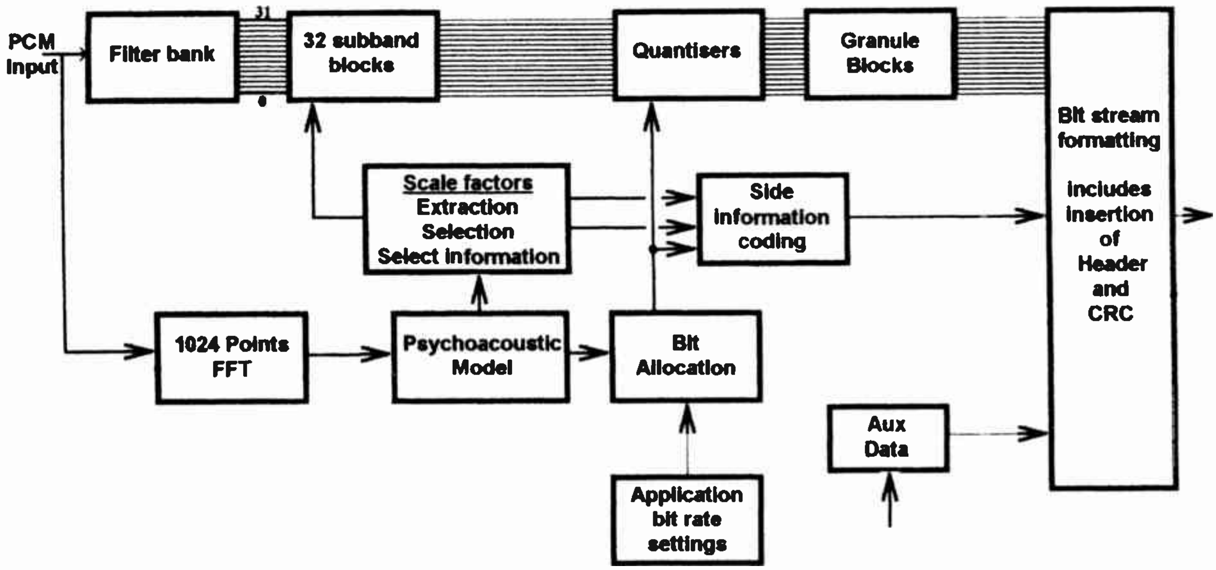

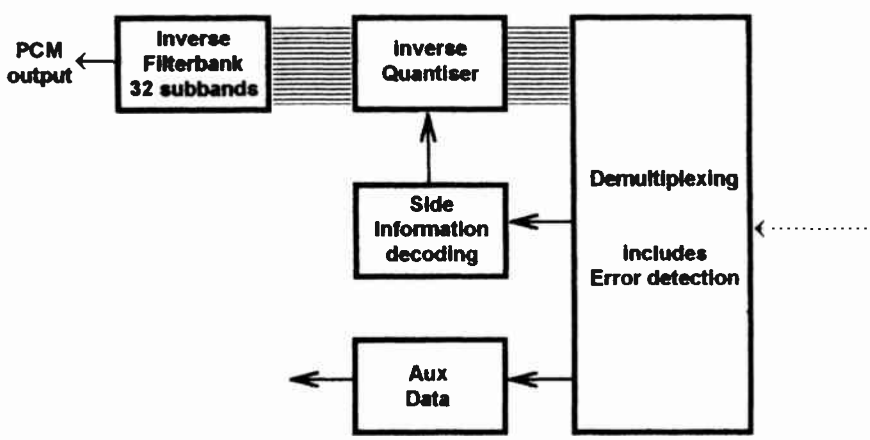

Figure 3.7-5. ISO/MPEG-1 Layer 2 system: (a) encoder block diagram, (b) decoder block diagram.

data rate for these scale factors can be reduced by exploiting some redundancy in the data. Three successive subband scale factors are analyzed and a pattern is determined. This pattern, which is obviously related to the nature of the audio signal, will decide whether one, two or all three scale factors are required. The decision will be communicated by the insertion of an additional *scale factor select information* (SCFSI) data word of 2 bits.

In the case of a fairly stationary tonal-type sound, there will be very little change in the scale factors and only the largest one of the three is transmitted; the corresponding data rate will be (6 + 2) or 8 scale factor bits per frame. However, in a complex sound with rapid changes in content, the transmission of two or even three scale factors may be required, producing a maximum scale factor bit rate demand of (6 + 6 + 6 + 2) or 20 bits per frame. Compared with Layer 1, this method of coding the scale factors reduces the allocation of data bits required for them by half.

The number of data bits allocated to the overall bit pool is limited or fixed by the data rate parameters. These parameters are set out by a combination of sampling frequency, compression ratio, and—where applicable—the transmission medium. In the case of 20 kHz stereo being transmitted over ISDN, for example, the maximum data rate is 384 kbps, sampling at 48kHz, with a compression ratio of 4:1.

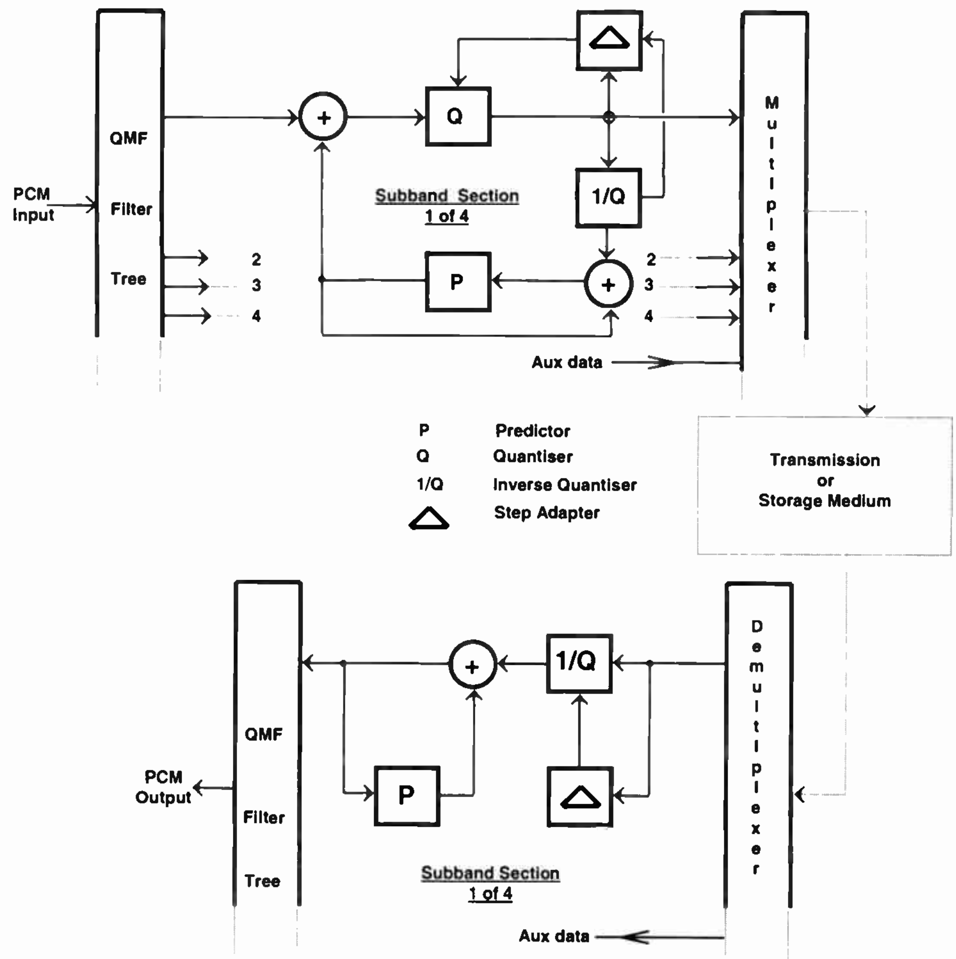

Figure 3.7-4. apt-X100 audio coding system: (a) encoder block diagram, (b) decoder block diagram.

The incoming linear PCM signal block is divided into 32 equally spaced subbands using a polyphase analysis filter bank (see Figure 3.7-5(a)). At 48 kHz sampling, this equates to the bandwidth of each subband being 750 Hz. The bit allocation for the requantizing of these subband samples is then dynamically controlled by information derived from analyzing the audio signal, measured against a preset psychoacoustic model.

The filter bank, which displays manageable delay and minimal complexity, optimally adapts each block of audio to balance between the effects of temporal masking and inaudible pre-echoes.

The PCM signal is also fed to a *fast Fourier transform* (FFT) running in parallel with the filter bank. The aural sensitivities of the human auditory system are exploited by using this FFT process to detect the differences between the wanted and unwanted sounds and the quantization noise already present in the signal, and then to adjust the signal-to-mask thresholds, conforming to a preset perceptual model.

This psychoacoustic model is only found in the coder, thus making the decoder less complex and permitting the freedom to exploit future improvements in coder design. The actual number of levels for each quantizer is determined by the bit allocation. This is arrived at by setting the *signal-to-mask ratio* (SMR) parameter, defined as the difference between the minimum masking threshold and the maximum signal level. This minimum masking threshold is calculated using the psychoacoustic model and provides a reference noise level of *just noticeable* noise for each subband.

In the decoder, after demultiplexing and deciphering of the audio and side information data, a dual synthesis filter bank reconstructs the linear PCM signal in blocks of 32 output samples (see Figure 3.7-5(b)).

A scale factor is determined for each 12 subband sample block. The maximum of the absolute values of these 12 samples generates a scale factor word consisting of 6 bits, a range of 63 different levels. Because each frame of audio data in Layer 2 corresponds to 36 subband samples, this process will generate 3 scale factors per frame. However, the transmitted

- **The ATSC DTV system.** Uses the subband APCM algorithm in Dolby AC-3 for the audio surround system associated with the ATSC DTV Standard. AC-3 delivers five audio channels plus a bass-only effects channel in less bandwidth than that required for one stereo CD channel. This configuration is referred to as 5.1 channels.

For the purposes of illustration, two commonly used audio compression systems will be examined in some detail:

- apt-X100
- ISO/MPEG-1 Layer 2

apt-X100

apt-X100 is a four subband prediction (ADPCM) algorithm. Differential coding reduces the bit rate by coding and transmitting or storing only the difference between a predicted level for a PCM audio sample and the absolute level of that sample, thus exploiting the redundancy contained in the PCM signal.

Audio exhibits relatively slowly varying energy fluctuations with respect to time. Adaptive differential coding, which is dependent on the energy of the input signal, dynamically alters the step size for each quantizing interval to reflect these fluctuations. In apt-X100, this equates to a backward adaptation process and involves the analysis of 122 previous samples. Being a continuous process, this provides an almost constant and optimal signal-to-quantization noise ratio across the operating range of the quantizer.

Time domain subband algorithms implicitly model the hearing process and indirectly exploit a degree of irrelevancy by accepting that the human ear is more sensitive at lower frequencies. This is achieved in the four subband derivative by allocating more bits to the lower frequency bands. This is the only application of psychoacoustics exercised in apt-X100. All the information contained in the PCM signal is processed, audible or not (no attempt is made to remove irrelevant information). It is the unique fixed allocation of bits to each of the four subbands, coupled with the filtering characteristics of each individual listener's hearing system, that achieves the satisfactory audible end result.

The user-defined output bit rate ranges from 56–384 kbps, achieved by using various sampling frequencies from 16–48 kHz, which produce audio bandwidths from 7.5 kHz mono to 22 kHz stereo.

Auxiliary data up to 9.6 kbps can also be embedded into the data stream without incurring a bit overhead penalty. When this function is enabled, an audio bit in one of the higher frequency subbands is replaced by an auxiliary data bit, again with no audible effect.

An important feature of this algorithm is its inherent robustness to random bit errors. No audible distortion is apparent for normal program material at a bit error rate (BER) of 1:10,000 (1×10^{-4}), while speech is still intelligible down to a BER of 1:10 (1×10^{-1}).

Distortions introduced by bit errors are constrained within each subband and their impact on the decoder subband predictors and quantizers is proportional to the magnitude of the differential signal being decoded at that instant. Thus, if the signal is small—which will be the case for a low level input signal or for a resonant, highly predictable input signal—any bit error will have minimal effect on either the predictor or quantizer.

The 16 bit linear PCM signal is processed in time blocks of four samples at a time. The 64 bits are filtered into four equal width frequency subbands—for 20 kHz, this would be 0–5 kHz, 5–10 kHz and so on. The four outputs from the quadrature mirror filter (QMF) tree are still in the 16 bit linear PCM format, but are now frequency limited.

As shown in Figure 3.7-4, the compression process can be mapped by taking, for example, the first and lowest frequency subband. The first step is to create the difference signal. After the system has settled down on initiation, there will be a reconstructed 16 bit difference signal at the output of the inverse quantizer. This passes into a prediction loop that, having analyzed 122 previous samples, will make a prediction for the level of the next full level sample arriving from the filter tree. This prediction is then compared with the actual level.

The output of the comparator is the resulting 16 bit difference signal. This is requantized to a new 7 bit format, which in turn is inverse quantized back to 16 bits again to enable the prediction loop.

The output from the inverse quantizer is also analyzed for energy content, again for the same 122 previous samples. This information is compared with onboard look up tables and a decision is made to dynamically adjust, up or down as required, the level of each step of the 1024 intervals in the 7 bit quantizer. This ensures that the quantizer will always have adequate range to deal with the varying energy levels of the audio signal. Therefore, the input to the multiplexer will be a 7 bit word but the range of those bits will be varying in relation to the signal energy.

The three other subbands will go through the same process, but the number of bits allocated to the quantizers are much less than for the first subband.

The output of the multiplexer or bit stream formatter is a new 16 bit word that represents four input PCM samples and is, therefore, one quarter of the input rate—a reduction of 4:1.

The decoding process is the complete opposite of the coding procedure. The incoming 16 bit compressed data word is demultiplexed and used to control the operation of four subband decoder sections, each with similar predictor and quantizer step adjusters. A QMF filter tree finally reconstructs a linear PCM signal and separates any auxiliary data that may be present.

ISO/MPEG-1 Layer 2

This algorithm differs from MPEG Layer 1 by adopting more accurate quantizing procedures and removing any apparent redundancy from the generated scale factors. The ISO/MPEG-1 Layer 2 scheme operates on a block of 1152 PCM samples, which at 48 kHz sampling represents a 24 ms time block of the input audio signal. Simplified block diagrams of the encoding/decoding systems are given in Figure 3.7-5.

several factors tend to limit the number of subbands employed. The primary considerations include:

- The level variation of normal audio signals leading to an averaging of the energy across bands and a subsequent reduction in the coding gain
- The coding or processing delay introduced by additional subbands
- The overall computational complexity of the system

The two key issues in the analysis of a subband framework are:

- Determining the likely improvement associated with additional subbands
- Determining the relationships between subband gain, the number of subbands, and the response of the filter bank used to create those subbands

APCM Coding

The APCM processor acts in a similar fashion to an automatic gain control system, continually making adjustments in response to the dynamics—at all frequencies—of the incoming audio signal. Transform coding takes a time block of signal, analyzes it for frequency and energy and identifies irrelevant content. Again, to exploit the spectral response of the ear, the frequency spectrum of the signal is divided into a number of subbands, and the most important criteria are coded with a bias toward the more sensitive low frequencies. At the same time, through the use of psychoacoustic masking techniques, those frequencies which it is assumed will be masked by the ear are also identified and removed. The data generated, therefore, describes the frequency content and the energy level at those frequencies, with more bits being allocated to the higher energy frequencies than those with lower energy.

The larger the time block of signal being analyzed, the better the frequency resolution and the greater the amount of irrelevancy identified. The penalty, however, is an increase in coding delay and a decrease in temporal resolution. A balance has been struck with advances in perceptual coding techniques and psychoacoustic modeling leading to increased efficiency. It is reported that, with this approach to compression, some 80% of the input audio can be removed with acceptable results.

This hybrid arrangement of working with time domain subbands and simultaneously carrying out a spectral analysis can be achieved by using a dynamic bit allocation process for each subband. This subband APCM approach is found in the popular range of software-based MUSICAM, Dolby AC-2 and ISO/MPEG-1 Layers 1 and 2 algorithms. Layer 3—a more complex method of coding and operating at much lower bit rates—is, in essence, a combination of the best functions of MUSICAM and ASPEC, another adaptive transform algorithm. Table 3.7-1 lists the primary operational parameters for these systems.

Additionally, some of these systems exploit the significant redundancy between stereo channels by using a technique known as joint stereo coding. After the common information between left and right channels of a stereo signal has been identified, it is coded only once, thus reducing the bit rate demands yet again.

Each of the subbands has its own defined masking threshold. The output data from each of the filtered subbands is requantized with just enough bit resolution to maintain adequate headroom between the quantization noise and the masking threshold for each band. In more complex coders (ISO/MPEG-1 Layer 3), any spare bit capacity is utilized by those subbands with the greater need for increased masking threshold separation. The maintenance of these signal-to-masking threshold ratios is crucial if further compression is contemplated for any postproduction or transmission process.

Common Compression Techniques

Subband APCM coding has found numerous applications in the professional audio industry, including:

- **The DCC.** Uses the simplest implementation of subband APCM with the PASC/ISO/MPEG-1 Layer 1 algorithm incorporating 32 subbands offering 4:1 compression and producing a bit rate of 384 kbps
- **The MiniDisc with the proprietary ATRAC algorithm.** Produces 5:1 compression and 292 kbps bit rate. This algorithm uses a modified discrete cosine transform (MDCT) technique ensuring greater signal analysis by processing time blocks of the signal in non uniform frequency divisions, with fewer divisions being allocated to the least sensitive higher frequencies
- **ISO/MPEG-1 Layer 2 (MUSICAM).** A software-based algorithm that can be implemented to produce a range of bit rates and compression ratios commencing at 4:1

Table 3.7-1
Operational parameters of subband APCM algorithm.

Coding System	Compression Ratio	Subbands	Bit Rate, kbits/s	A to A Delay, ms[1]	Audio Bandwidth, kHz
Dolby AC-2	6:1	256	256	45	20
ISO Layer 1	4:1	32	384	19	20
ISO Layer 2	Variable	32	192–256	>40	20
ISO Layer 3	12:1	576	128	>80	20
MUSICAM	Variable	32	128–384	>35	20

[1] The total system delay (encoder to decoder) of the coding system.

both the noise floor and the audio bandwidth will be set by the stage operating at the lowest bit rate. It is, therefore, worth emphasizing that after these platforms have been set by a low bit rate stage, they cannot be subsequently improved by using a following stage operating at a higher bit rate.

A stage of compression may well be followed in the audio chain by another digital stage, either of compression or linear, but—more importantly—operating at a different sampling frequency. If a D/A conversion is to be avoided, a sample rate converter must be used. This can be a stand-alone unit or it may already be installed as a module in existing equipment. Where a following stage of compression is operating at the same sampling frequency but a different compression ratio, the bit resolution will change by default.

If the stages have the same sampling frequencies, a direct PCM or AES/EBU digital link can be made, thus avoiding the need for sample rate or D/A conversion.

Editing Compressed Data

The resolution of the compressed data may or may not be adequate to allow direct editing of the audio signal. The minimum audio sample that can be removed or edited from a transform-coded signal will be determined by the size of the time block of the PCM signal being analyzed. The larger the time block the more difficult the editing of the compressed data becomes.

Prediction and Transform Algorithms

Most audio compression systems are based upon one of two basic technologies:

- Predictive or adaptive differential PCM (ADPCM) time domain coding
- Transform or adaptive PCM (APCM) frequency domain coding

It is in their approaches to dealing with the redundancy and irrelevancy of the PCM signal that these techniques differ.

The time domain or prediction approach includes G.722, which has been a universal standard since the mid 70s, and was joined in 1989 by a proprietary algorithm, apt-X100. Both these algorithms deal mainly with redundancy.

The frequency domain or transform method adopted by a number of algorithms deal in irrelevancy, adopting psychoacoustic masking techniques to identify and remove those unwanted sounds. This range of algorithms includes the industry standards ISO/MPEG-1 and 2; Layers 1, 2, and 3; MPEG AAC; MUSICAM; Dolby AC-2 and AC3, apt-Q and others.

Subband Coding

Without exception all of the algorithms just mentioned process the PCM signal by splitting it into a number of frequency subbands, in one case as few as two (G.722) or as many as 1024 (apt-Q). MPEG-1 Layer 1, with 4:1 compression, has 32 frequency subbands and is the system found in the Digital Compact Cassette (DCC). The MiniDisc ATRAC proprietary algorithm at 5:1 has a more flexible multisubband approach, which is dependent on the complexity of the audio signal.

Subband coding enables the frequency domain redundancies within the audio signals to be exploited. This permits a reduction in the coded bit rate, compared to PCM, for a given signal fidelity. Spectral redundancies are also present as a result of the signal energies in the various frequency bands being unequal at any instant in time. By altering the bit allocation for each subband, either by dynamically adapting it according to the energy of the contained signal or by fixing it for each subband, the quantization noise can be reduced across all bands. This process compares favorably with the noise characteristics of a PCM coder performing at the same overall bit rate.

On its own, subband coding, incorporating PCM in each band, is capable of providing a performance improvement or gain compared with that of full band PCM coding, both being fed with the same complex, constant level input signal. The improvement is defined as subband gain and is the ratio of the variations in quantization errors generated in each case while both are operating at the same transmission rate. The gain increases as the number of subbands increase, and with the complexity of the input signal. However, the implementation of the algorithm also becomes more difficult and complex.

Quantization noise generated during the coding process is constrained within each subband and cannot interfere with any other band. The advantage of this approach is that the masking by each subbands dominant signals is much more effective because of the reduction in the noise bandwidth. Figure 3.7-3 charts subband gain as a function of the number of subbands for four essentially stationary, but differing, complex audio signals.

In practical implementations of compression codecs,

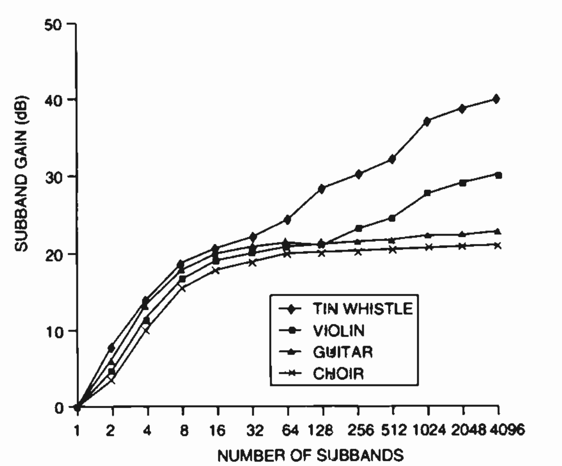

Figure 3.7-3. Variation of subband gain as a function of the number of subbands.

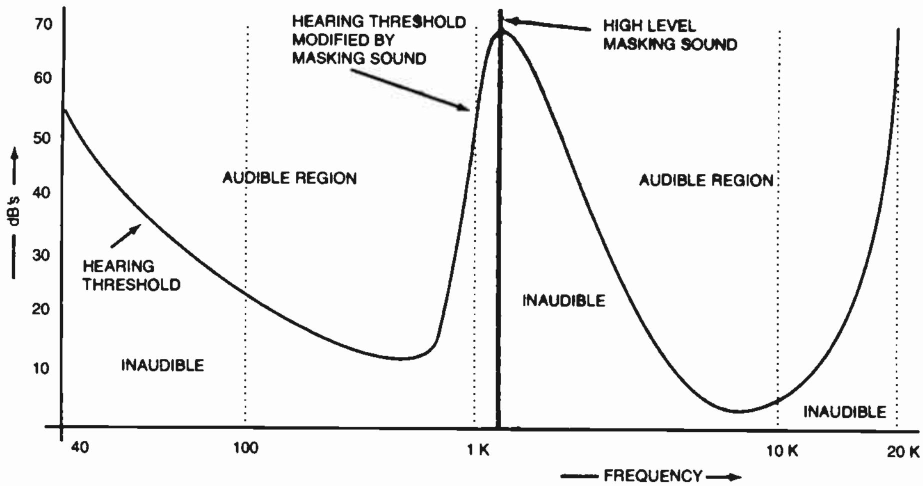

Figure 3.7-2. Example of the masking effect of a high-level sound.

Compression or bit rate reduction of the PCM signal leads to the requantizing of an already quantized signal, which will unavoidably inject further quantization noise. It always has been good operating practice to restrict the number of A/D and D/A conversions in an audio chain. Nothing has changed in this regard, and now the number of compression stages also should be kept to a minimum. Additionally, the bit rates of these stages should be set as high as practical or, the compression ratio should be as low as possible.

Sooner or later—after a finite number of A/D, D/A conversions and passes of compression coding, of whatever type—the accumulation of quantization noise and other unpredictable signal degradations eventually will break through the noise/signal threshold, be interpreted and processed as part of the audio signal and heard by the listener.

Sampling Frequency and Bit Rate

The bit rate of a digital signal is defined by:

sampling frequency × *bit resolution* × *number of audio channels*

The rules regarding the selection of a sampling frequency are based on *Nyquist's theorem.* This ensures that, in particular, the lower sideband *alias,* with its dc component located at the sampling frequency, does not encroach into the baseband audio. Objectionable and audible aliasing effects would occur if the two bands were to overlap. In practice, the sampling rate is set slightly above twice the highest audible frequency, which makes the necessary filter designs less complex and less expensive.

In the case of a stereo CD with the audio signal having been sampled at 44.1 kHz, this sampling rate produces audio bandwidths of approximately 20 kHz for each channel. The resulting audio bit rate = 44.1 kHz × 16 × 2 = 1.411 Mbps, as discussed previously.

Processing and Propagation Delay

As noted previously, the current range of popular compression algorithms operate—for all intents and purposes—in real-time. However, this process does of necessity introduce some measurable delay into the audio chain. All algorithms take a finite time to analyze the incoming signal, which can range from a few milliseconds to tens and even hundreds of milliseconds. The amount of processing delay will be crucial if the equipment is to be used in any interactive or two-way application. As a rule of thumb, any more than 20 ms of delay in a two way audio exchange is problematic. Propagation delay in satellite and long terrestrial circuits is a fact of life. A two-way hook up over a 1000 km, full duplex, telecom digital link has a propagation delay of 3 ms in each direction. This is comparable to having a conversation with someone standing 1 m away. It is obvious that even over a very short distance, the use of a codec with a long processing delay characteristic will have a dramatic effect on operation.

Bit Rate and Compression Ratio

The ITU has recommend the following bit rates when incorporating data compression in an audio chain:

- 128 kbps per mono channel (256 kbps for stereo) as the minimum bit rate for any stage if further compression is anticipated or required
- 192 kbps per mono channel (384 kbps for stereo) as the minimum bit rate for the first stage of compression in a complex audio chain.

These markers place a 4:1 compression ratio at the safe end in the scale. However, more aggressive compression ratios, currently up to a nominal 20:1, are available. Keep in mind, though, that low bit rate, high level compression can lead to problems if any further stages of compression are required or anticipated.

With successive stages of compression, either or that is highly predictable and, therefore, can be considered redundant.

Redundancy, measurable and quantifiable, can be removed in the coder and replaced in the decoder; this process often is referred to as statistical compression. *Irrelevancy,* on the other hand, referred to as perceptual coding, once removed from the signal cannot be replaced and is lost, irretrievably. This is entirely a subjective process, with each proprietary algorithm using a different psychoacoustic model.

Critically perceived signals, such as pure tones, are high in redundancy and low in irrelevancy. They compress quite easily, almost totally a statistical compression process. Conversely, noncritically perceived signals, such as complex audio or noisy signals, are low in redundancy and high in irrelevancy. These compress easily in the perceptual coder, but with the total loss of all the irrelevant content.

Human Auditory System

The sensitivity of the human ear is biased toward the lower end of the audible frequency spectrum, around 3 kHz. At 50 Hz, the bottom end of the spectrum, and 17 kHz at the top end, the sensitivity of the ear is down by approximately 50 dB relative to its sensitivity at 3 kHz (see Figure 3.7-1). Additionally, very few audio signals—music or speech based—carry fundamental frequencies above 4 kHz. Taking advantage of these characteristics of the ear, the structure of audible sounds, and the redundancy content of the PCM signal is the basis used by the designers of the *predictive* range of compression algorithms.

Another well-known feature of the hearing process is that loud sounds mask out quieter sounds at a similar or nearby frequency. This compares with the action of an automatic gain control, turning the gain down when subjected to loud sounds, thus making quieter sounds less likely to be heard. For example, as illustrated in Figure 3.7-2, if we assume a 1 kHz tone at a level of 70 dBu, levels of greater than 40 dBu at 750 Hz and 2 kHz would be required for those frequencies to be heard. The ear also exercises a degree of temporal masking, where a strong sound will mask a weaker sound which is close by, before or after, in time proximity.

It is by mimicking these additional psychoacoustic features of the human ear and identifying the irrelevancy content of the input signal that the *transform* range of low bit rate algorithms operate, adopting the principle that if the ear is unable to hear the sound then there is no point in transmitting it in the first place.

Quantization

Quantization is the process of converting an analog signal to its representative digital format or, as in the case with compression, the requantizing of an already converted signal. This process is the limiting of a finite level measurement of a signal sample to a specific preset integer value. This means that the *actual* level of the sample may be greater or smaller than the preset *reference* level it is being compared with. The difference between these two levels, called the *quantization error,* is compounded in the decoded signal as *quantization noise.*

Quantization noise, therefore, will be injected into the audio signal after each analog-to-digital (A/D) and digital-to-analog (D/A) conversion, the level of that noise being governed by the bit allocation associated with the coding process (the number of bits allocated to represent the level of each sample taken of the analog signal). For linear PCM, the bit allocation is commonly 16. The level of each audio sample, therefore, will be compared with one of 2^{16}, or 65,536 discrete levels or steps.

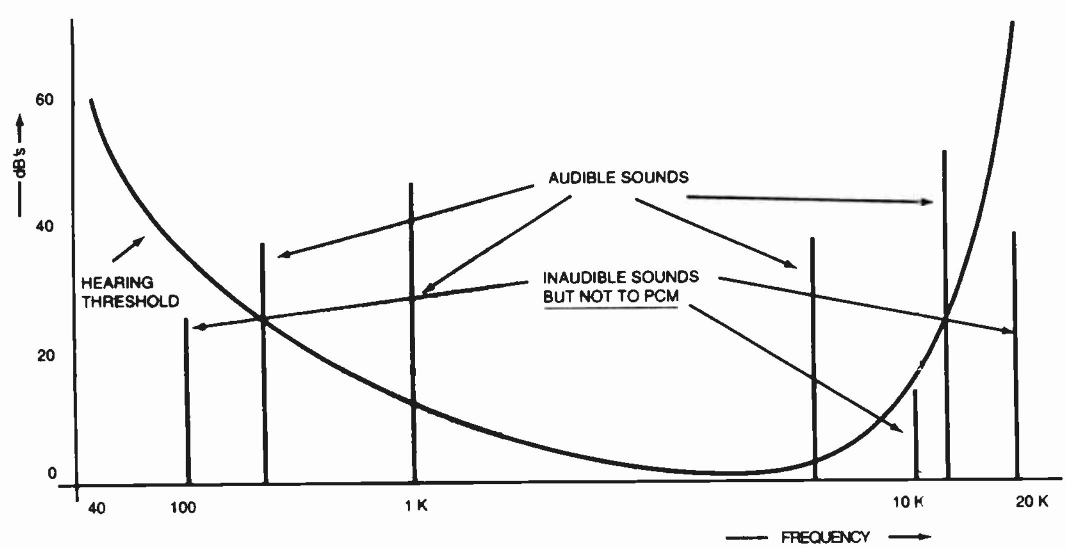

Figure 3.7-1. Generalized frequency response of the human ear. Note how the PCM process captures signals that the ear cannot distinguish.

3.7 DIGITAL AUDIO COMPRESSION TECHNOLOGIES

FRED WYLIE
AUDIO PROCESSING TECHNOLOGY, LTD.
BELFAST, NORTHERN IRELAND

INTRODUCTION

Virtually all applications of digital audio deal with an enormous amount of data. Because of this, compression is an integral part of most modern digital audio systems. In fact, compression is essential to the ATSC DTV and digital audio broadcasting (DAB) systems.

A number of existing and proposed audio-compression systems employ a combination of processing techniques. Any scheme that becomes widely adopted can enjoy economies of scale and reduced market confusion. Timing, however, is critical to market acceptance of any standard. If a standard is selected well ahead of market demand, more cost-effective or higher-performance approaches may become available before the market takes off. On the other hand, a standard may be merely academic if it is established after alternative schemes already have become well entrenched in the marketplace.

These forces are shaping audio technology of the future. Any number of scenarios have been postulated as to the hardware and software that will drive the digital audio facility of the year 2000 and beyond. One thing is certain, however: It will revolve around compressed signals.

As with video, high on the list of priorities for the professional audio industry is to refine and extend the range of digital equipment capable of the capture, storage, post production, exchange, distribution and transmission of high quality audio, be it mono, stereo, or multichannel surround sound. This demand is being driven by end-users, broadcasters, film makers and the recording industry alike, who are moving rapidly towards a tapeless environment. Over the last two decades, there have been continuing advances in *digital signal processing* (DSP) technology, which have supported research engineers in their endeavors to produce the necessary hardware, particularly in the field of digital audio data compression or—as it is often referred to—*bit rate reduction.* There exist a number of real-time or—in reality—near instantaneous compression coding algorithms. These can significantly lower the circuit bandwidth and storage requirements for the transmission, distribution and exchange of high-quality audio.

The introduction in 1983 of the compact disc (CD) digital audio format set a quality benchmark that the manufacturers of subsequent professional audio equipment strive to match or improve. The discerning consumer now expects the same quality from radio and television receivers. This leaves the broadcaster with an enormous challenge.

It can be an expensive and complex technical exercise to fully implement a linear *pulse code modulation* (PCM) infrastructure, except over very short distances and within studio areas. To demonstrate the advantages of distributing compressed digital audio over wireless or wired systems and networks, consider again the CD format as a reference. The CD is a 16 bit linear PCM process, but it has one major handicap: the amount of circuit bandwidth the digital signal occupies in a transmission system. A stereo CD transfers data at 1.411 Mbps, which would require a circuit with a bandwidth of approximately 700 kHz to avoid distortion of the digital signal. In practice, additional bits are added to the signal for channel coding, synchronization, and error correction; this increases the bandwidth demands yet again. 1.5 MHz is the commonly quoted bandwidth figure for a circuit capable of carrying a CD or similarly coded linear PCM digital stereo signal. This can be compared with the 20 kHz needed for each of two circuits to distribute the same stereo audio in the analog format, a 75 fold increase in bandwidth requirements.

AUDIO BIT RATE REDUCTION

In general, analog audio transmission requires fixed input and output bandwidths. This condition implies that in a real-time compression system, the quality, bandwidth and distortion/noise level of both the original and the decoded output sound should not be subjectively different, thus giving the appearance of a lossless and real-time process.

In a technical sense, all real-time bit rate reduction systems can be referred to as *lossy.* In other words, the digital audio signal at the output is not identical to the input signal data stream. However, some compression algorithms are, for all intents and purposes, lossless—they lose as little as 2% of the original signal. Others remove approximately 80% of the original signal.

Redundancy and Irrelevancy

A complex audio signal contains a great deal of information, some of which, because the human ear cannot hear it, is deemed irrelevant. The same signal, depending on its complexity, also contains information

RAID 4 or 5 but lacked the control features required to fine tune the RAID for demanding multi-media applications. However, the current generation of these devices provides outstanding performance and includes a complete set of sophisticated control and maintenance features. Functions such as multiple RAID Level support, choice of cache write policy and battery backup options, on-line spare drive support, dynamically adjustable rebuild rates, and drive enclosure monitoring and alarm support are common. And since the controller is a part of the server PC, the interface to monitor detailed operational statistics and access the administration utilities runs directly from the server console—no other PC is required. In addition, some of these controllers include software that will send the user a page, e-mail or a fax with an error code if the system encounters a failure, and will allow a system administrator to monitor and perform RAID maintenance from a remote PC. And best of all, these devices are becoming more affordable due to the economy of scale associated with the PCI bus and the chipsets involved.

It is very important that the data stored on a centralized server be secure and a redundant disk sub system is the best way to ensure this. Whether you decide to use standard duplexing or RAID technology depends mostly on your comfort level with the setup and maintenance of the technology.

SUMMARY

Station automation is a continuously evolving entity, especially now that a larger portion of it emanates from software running on generic data processing "bit boxes." No matter when you decide to join the digital age, advancements are occurring so quickly that what is rocket science today will surely be obsolete before it wears out. It is therefore wise to use the most stable, reliable advanced technology available today and use a platform that is off the shelf so that it can be continuously upgraded with emerging technology.

Level Number	Name	Description	Minimum No. Drives	Fault Tolerance
0	Striping (see Spanning in table above)	Block striping is available. Level 0 yields higher performance than is possible with individual drives. I/O transfer speed is increased. No data redundancy: loss of a single component can lead to unrecoverable data loss.	2	No
1	Disk Mirroring	Drives are paired and mirrored, resulting in twice the cost per megabyte (MB). All data is 100 percent duplicated on the mirrored drive.	2	Yes
0+1	Striping and Mirroring	Combination of RAID levels 0 and 1. Data is striped across several physical drives. Each drive has a mirror drive. This level provides redundancy through mirroring.	3	Yes
2	Disk Array	Hamming code error checks across the disks. Data can be recovered without complete duplication of all data, although several check disks are needed. All disks in a group must be accessed, even for transfers, and the slowest must finish before the transfer is complete.		Yes
3	Disk Array	A single parity drive accomplishes redundancy. Parity information is interleaved at the byte level. Drive spindles are typically synchronized; all disks must be accessed and the slowest must complete the process before a transfer is complete.	9	Yes
4	Disk Array (Striping with Fixed Parity)	Interleaving parity at the sector or transfer level results in faster individual disk reads for small transfers. The parity check disk becomes a throughput bottleneck.	3	Yes
5	Disk Array (Striping with Floating Parity)	Parity information is spiraled across all data drives, which combats the throughput bottleneck problem in Level 4. Distributed parity increases write performance but introduces high overhead to track the location of parity addresses.	3	Yes
JBOD	Just a Bunch of Drives	Each drive is operated independently like a normal disk controller, or multiple drives can be spanned and seen as a single large drive. No data redundancy.	1	No

Figure 3.6-15. RAID (Redundant Array of Independent Disks) features.

extensive write back caching and provide battery backup options to protect unflushed data. Most of these devices include extensive control/setup programs that allow the user to fine tune critical parameters such as the level of resources devoted to rebuild a failed/replaced drive. Additional features, like audible alarms to indicate trouble and on-line spare drives that are automatically rebuilt in the event of failure, make these units fairly easy to keep up and running. However, only a few of the more expensive units provide a standard monitor and keyboard interface to their control utilities. Most of these units must be monitored and controlled through a serial port using a serial communications program running on a separate PC or via a limited built-in keypad and cryptic LCD display panel.

A controller based RAID uses a specialized multi-channel disk controller card that plugs into an expansion slot on the host PC (server). These controllers typically contain on-board processing power and memory that is used to administer the RAID functions. Early versions of these RAID controllers often had enough horsepower and memory to run an effective

Disk Configuration	Description, advantages, and disadvantages
Non-Redundant Disks with Tape backup	Backup software is used to save data to a data tape, which is then safely stored. *Advantages* • Good for recovering from catastrophic failure *Disadvantages* • Data transfer is relatively slow compared to a disk drive. You must exit applications and spend time on the backup process • Snapshot of data at time of backup-backup data is only as current as the most recent backup • Data must be accessed linearly and sequentially, so restoring data can also be time-consuming
Disk Mirroring	Identical disk drive is used as backup device. Data on first drive is automatically replicated onto second drive, either by an operating system (like Novell NetWare) or by a special controller (as with RAID technology). *Advantages* • Network operation is unaffected by the failure of one drive-the network just uses the other drive • You can use more than two disks in order to increase redundancy even further • System performance during disk reads may be enhanced, because the system or controller can retrieve the data from whichever disk is better-positioned to provide the data *Disadvantages* • Disk size requirements for data are doubled
Disk Duplexing	Similar to Disk Mirroring above, only the primary and backup drives use separate controllers and cables. This provides another level of hardware fault tolerance. *Advantages* • In most cases, the system will be unaffected by a failure of any component of the subsystem, including drive, controller, and cable • Additional read performance benefit over Disk Mirroring, because additional data buses are now available to transmit data • Write performance advantage over Disk Mirroring, because multiple controllers are available to cache and write data to drives simultaneously *Disadvantages* • Same as Disk Mirroring
Spanning (Striping)	Data is divided between two or more drives. Operating system or controller divides data between drives. Total capacity equals the sum of all drives. *Advantages* • Disk I/O throughput is increased by a factor equal to the number of drives *Disadvantages* • If one of the drives fails, *all data on all drives is lost*–and since total number of components is increased, probability of failure is increased • Offers no redundancy
Mirroring/ Duplexing + Spanning (Striping)	Uses a set of spanned drives; each drive has a mirrored drive. *Advantages* • Increased performance and additive capacity of spanning (striping) • Redundancy and performance advantages of mirroring/duplexing • Failure of single component often undetectable with respect to overall system performance *Disadvantages* • Must routinely monitor components, since failure is sometimes difficult to detect with respect to system performance
RAID Technology	Highly flexible disk subsystem that offers several levels of redundancy and performance. Uses a specialized software and/or hardware RAID controller. *Advantages* • Increased performance and additive capacity of spanning (striping) • Redundancy and performance advantages of mirroring/duplexing • Failure of single component often undetectable with respect to overall system performance • Increased efficiency with advanced RAID controllers (can provide redundancy with fewer drives than mirroring/duplexing) *Disadvantages* • Advanced calculations in higher RAID levels carry high computational overhead, which can affect I/O applications

Figure 3.6-14. Disk configurations-advantages and disadvantages.

There is also a slight performance advantage associated with using separate logical drives and manually distributing your data files between them. Audio inventory can often be distributed in such a way that normal system use does not hit just a single drive but creates balanced activity between all the drives so more heads are utilized simultaneously.

It is possible to combine mirroring/duplexing with spanning/striping. In this configuration, you span a set of drives, each of which has its own associated mirror drive. This gives you the increased performance and the additive capacity of spanning/striping as well as the redundancy and performance advantages of mirroring/duplexing. In fact, this arrangement performs so well that it is possible for such a system to experience multiple drive failures without significantly affecting system performance. This makes it very important to diligently monitor the status of your drive sub-system and correct any failures as soon as possible. This configuration offers the best of both the performance and redundancy worlds, but with a one drive for the price of two price tag.

Figure 3.6-14 summarizes the relative merits of various disk storage configurations.

Raid

Another disk arrangement, known as *Redundant Array of Inexpensive Disks* (RAID), has been around for a number of years but has recently become very popular. These disk sub-systems are usually comprised of a specialized multi-channel disk controller combined with three or more disk drives. The reason for their popularity is that they are capable of providing high capacity, excellent performance and data redundancy with fewer disks than other configurations mentioned previously.

RAID units can function in several modes referred to as RAID Levels. The various levels offer different combinations of capacity, performance and redundancy. *RAID Level 0* also known as disk striping, provides scalable capacity and high performance but offers no redundancy. *RAID Level 1* also known as disk mirroring, provides redundancy but doubles the number of disks required for a given capacity. RAID controllers can also provide a combination of RAID 0 + 1, which provides scalable capacity, excellent performance and redundancy, but still gives away one half of the capacity to accomplish the redundancy. *RAID Level 2* uses multiple check disks to allow error correction without having to completely duplicate all data. This can provide fully redundant storage with less than double the number of disks, but since higher RAID levels are even more efficient, Level 2 is rarely used. *RAID Level 3* provides redundancy by using nine synchronized drives with a bit of each byte written to the first eight along with a parity bit that gets written to a ninth dedicated parity drive. Level 3 can provide excellent performance, but storing parity at the byte level requires a large number of synchronized drives, which add considerable expense of the system.

The real efficiency comes with *RAID Levels 4* and *5*. In both of these modes, the data stream is sub-divided into smaller blocks (which can be many bytes) with each block being written to a separate disk just as in disk striping (Level 0). But in addition, the blocks written to each drive are compared by an algorithm that generates parity data that is written to another drive. If any drive in the stripe fails, this parity information is combined with the other good drives to recreate the data from the missing drive. When the failed drive is replaced, a similar process is used to rebuild the new disk to the original data structure.

The main difference between the two levels is that Level 4 always stores the parity information for every stripe on a single drive, while Level 5 stores parity information for each stripe on a different drive. RAID Level 4 can only access one stripe at a time limiting its effective I/O for random transfers; however, its parity calculations are somewhat simpler, making it effective for long sustained sequential operations as in single user multimedia applications. RAID Level 5 is able to process multiple stripes simultaneously, making it better suited for random scattered disk requests as in multi user centralized storage environments. The parity structure of RAID Level 5 is a bit more complicated than other levels, but given the proper horsepower and caching to offset this overhead, it is the best choice for a wide variety of file I/O operations. Figure 3.6-15 summarizes the features of the various RAID Levels.

With all of the administration associated with striping along with parity calculations and tracking, these higher RAID levels carry a significant computational overhead. Where these computations take place and how these functions are implemented has a direct bearing on a specific system's suitability for demanding I/O applications.

RAID systems are available in three basic implementations—software RAID, independent hardware RAID and disk controller based RAID.

A software RAID does not use any special hardware but instead utilizes special software running on the server's CPU to manage the striping and parity requirements of the disk array. Simple disk spanning and mirroring functions such as those integrated into the NetWare and Windows NT operating systems are quite effective since they don't add much of a load to the host. However, with higher RAID levels like 4 and 5, this overhead can be quite hefty and unless the server operating system employs some scalable resources to handle the extra load (like the ability to use multiple processors), this implementation will most often consume a significant portion of the server's horsepower and ultimately degrade the overall system performance.

An independent hardware RAID is a self contained unit external to the host PC that communicates with the server through a standard disk controller as if it were a single large disk drive. These external units are very powerful and usually include their own Pentium or RISC processor to handle the RAID management. They can be loaded with large amounts of RAM for drives wear so badly that they would rumble loudly then come to a horrible grinding halt.

While this sort of problem has largely disappeared through improved design and manufacturing processes, mechanical problems associated with handling remain.

Disk drives are extremely sensitive to shock and vibration. A short fall to a workbench or floor is often enough to destroy a drive. The manufacturers have addressed these kinds of problems through improved packaging and handling procedures, but what shipping companies and stock room personnel do with the drive before it gets to you is another story. The best advice for purchasing disk drives is *caveat emptor*—buyers beware—there is probably a good reason for those super deals.

Once the drive has made it to the final destination and is up and running, the biggest environmental factor is heat. Disk drive cabinets must have adequate cooling fans and the fan filters must be kept clean. Air flow through the enclosure should be free flowing and unimpeded by doors or covers. Some cabinets offer temperature sensitive fans that will increase flow as the temperature rises. Others provide temperature monitoring devices and alarms to alert maintenance personnel of a problem. Even though most drives are rated to operate in temperatures up to 50°C (122°F), the cooler they are, the longer they will run.

In an expected lifetime of 100 years, failures within 6 months to a year could be considered infant mortality—certainly within the hardware warranty. But a radio or TV station can become very dependent on such a system in that time frame and will trust it with a considerable amount of irreplaceable data. It is therefore imperative that anyone planning to invest in a station automation system be aware of these issues and be prepared for such an occurrence.

There are several ways to protect data from drive failure. The most basic approach is to use a tape backup device. These are available in a number of different formats, the most popular currently being the 4 mm DAT drives.

Backup software is used to stream the hard disk data onto the tape, which can then be removed and stored safely in another location until needed. The biggest problem with these devices is that the data transfer rate is very slow compared to a disk drive, so backup sessions can take long periods of time. If the system is a single stand-alone computer, you might be required to exit the automation application to run the backup, producing considerable down time.

The data stored on tape is a snapshot of the files at the time of the backup, so it is only as current as the last backup. While many backup software packages allow you to schedule periodic backup sessions, they will usually lag behind the rapid changes made daily in a broadcast automation system.

Also, because the data on the tape must be accessed linearly and sequentially, restoring even a single file can be very time consuming. With these facts in mind, tape based backups should be not be considered "on-line" backup but only for recovering from catastrophic failure.

A much more transparent way to achieve disk redundancy is through *disk mirroring*. With this configuration, the backup device is an identical disk drive. The data on the first drive is automatically replicated onto the second drive, either by the operating system (as in the case of Novell NetWare) or via a special disk controller (as in RAID technology). Either disk can fail and the operation will be unaffected because the system will just use the other drive. It is also possible to mirror more than two disks for additional redundancy; however, this is usually not very cost effective.

Disk mirroring can also enhance system performance during disk reads. Because two (or more) copies of the data are available on independent drives, the controller can pull from both, using whichever drive is better positioned to service a particular request. This increases the number of heads available to gather data. The downside of disk mirroring is that the disk requirements for a given capacity are doubled. For systems requiring large capacity, this can be very costly.

An extension of disk mirroring is known as *disk duplexing*. This is the same as mirroring except that each mirror drive also has its own controller and cable. Disk duplexing adds another level of hardware fault tolerance, allowing the system to be unaffected by a failure of any part of the disk sub-system including the drive, controller, or cable.

Disk duplexing achieves a slightly higher read performance benefit over disk mirroring, since in addition to the multiple heads available to gather data, there are now multiple data buses to carry the data to the host. In addition, this configuration will also provide a write performance boost over mirroring, since the multiple controllers are able to cache and write data to both drives simultaneously.

To increase disk performance even further, a disk configuration called *spanning* or *striping* is often employed. The idea behind this scheme is to sub-divide the data between two or more drives. The operating system or a specialized disk controller takes the data stream and divides it into smaller units then writes one unit to each drive. Because each drive is able to write (or read) simultaneously with the other drives, the disk I/O throughput is increased by a factor equal to the number of drives. This also means the total capacity is equal to the sum of all the drives.

However, there is no redundancy with this configuration. It actually puts a facility at greater risk of overall failure. If any of the drives in the span fail, all of the data on all of the drives is lost. Since more drives increases the total parts count, the probability of failure due to one of the components increases.

In a situation with only a tape backup device or possibly no backup at all, it would be wise to configure each physical disk as a separate logical drive. That way, if one disk drive fails, only the contents of that drive are lost. And, if restoring from a tape drive a single disk's contents will take far less time to restore than the entire disk collection.

	Sampling Rate kHz	KBit Rate	Compression Ratio	MB per sterec minute Divide by 2 for Mono	Stereo hours per GB Multiply by 2 for Stereo

$$= \frac{\text{SAMPLE RATE}}{\text{COMPRESSION}} \times 2.28881835 \times 10^{-4}\ \text{MB/min}$$

Megabytes per stereo minute

Sample rates are not abbreviated: use 32000, 44100, or 48000.
Use compression=1 for linear audio files.
Dolby compression is always 6.
MPEG compression is variable; consult the "Approximate Storage Requirements" chart from Figure 3.6.13 for the compression ratio that corresponds to the bit rate used.

Figure 3.6-12. Digital audio data rate calculation.

resolution or accuracy of the sample. This determines the quantization (digital) noise floor which relates directly to the overall dynamic range, signal to noise (signal to error) ratio and distortion components of the digitized signal. Sixteen bit quantization provides a theoretical signal to error ratio of 98 dB, which is very near the limit of human perception. The mono/stereo issue is simple—stereo produces twice as much data as mono.

Putting these numbers together, we arrive at the two equations shown in Figure 3.6-12. The first allows us to calculate the number of hours of stereo audio that can be stored per gigabyte of disk capacity. The second gives us the number of megabytes required to store a minute of stereo audio. As you can calculate, digital audio requires a considerable amount of hard disk capacity.

Which brings us to the issue of data compression. The equations of Figure 3.6-12 include a possible compression factor which will reduce the overall disk capacity requirements. The data compression issue is quite complex and is beyond the scope of this discussion. It is, however, discussed in detail in Section 3.7. For the purpose of this discussion, we will indicate that most networked digital audio automation systems use data compression to keep network bandwidth and hard disk storage requirements down. Among the several good compression algorithms available, MPEG and Dolby AC-2 are two of the most popular. Figure 3.6-13 compares Linear PCM, Dolby AC-2 and MPEG compressed digital audio in terms of effective compression ratios and required storage capacity for the sample rates and data rates commonly used by automation systems.

Disk Drive Systems

Now that we have a handle on the capacity we require, we must decide where to store it and what components to use to store it. As described earlier, we can choose to provide hard disk storage in each workstation, in a centralized server, or in both. For reasons stated earlier, a network employing a centralized dedicated file server provides the most complete set of features for a multi-station automation system. We will therefore focus on the disk requirements of such a system. In particular, we will mention some hard disk performance issues then describe several disk configurations, including *disk spanning*, *disk mirroring*, *disk duplexing* and *RAID Technology*, and outline their advantages, shortcomings and levels of redundancy.

The greatest point of failure in any computer based system is the hard disk drive. The issue is not *if* a disk drive will fail, but *when* it will fail. Current premium quality high performance drives are quoting figures of 1 million hours *mean time between failure* (MTBF), which is over 100 years. However, a large percentage of the high capacity drives being used for multimedia systems are falling far short of this mark—many failing within the first 6 months of operation. There appear to be several reasons for this. A few stem from manufacturing problems while most are related to environmental conditions such as heat, shock and vibration.

Although the drive manufacturers are continuously improving the reliability of disk drives by reducing the internal parts count and using higher levels of integration in the on board electronics, the ultimate storage mechanism is mechanical, and therefore subject to mechanical failure.

In the early releases of high capacity drives, primarily the 4 and 9 GB sizes, several manufacturers had problems with the bearings used to support the spindle and its associated media platters. The bearings would wear prematurely causing the spindle and platters to shift and wobble, thereby degrading track alignment and causing loss of data. It was not uncommon to see for two nodes to end up transmitting at the same time. Packets take a finite amount of time to move down the wire, even when traveling near the speed of light. It is therefore possible that a workstation on one end of the wire might start transmitting and before the signal reaches a workstation at the other end of the wire, this workstation checks the network and believing it is free, also begins transmitting. When these packets collide, the communication becomes garbled and useless. This is what *collision detection* is designed to detect and correct. During transmission, a node continues to listen. If at any time during a transmission a node detects another node's signal, it stops transmitting and sends a jamming packet to alert all workstations that a *collision* has occurred. Each transmitting node then waits for a short random period then tries the transmission again. If there is another collision, the node waits an even longer period then tries again. This continues until the back-off-time reaches some maximum limit. As crude as the process sounds, this contention access method is very effective, due to the available bandwidth of the network and the small packet size of Ethernet (1518 bytes).

CSMA/CD is not deterministic. Access to the network is not guaranteed, only statistically assured. For multimedia networks, this might not be good enough. As traffic increases on an Ethernet network, so do collisions. Collisions cause extra *latency* or time delay between the request for data and the receipt of data. Real time processes like digital audio and video require that data packets arrive at very regular intervals and thus are very sensitive to latency. Even with large amounts of available bandwidth (such as with 100BaseTX), it is possible that a workstation requesting audio data from the server might encounter enough sustained collisions on a busy network to delay the packets to the point of causing dropouts in the audio playback. If loaded even further, the number of collisions can increase to the point that packets cannot successfully be exchanged and are lost, resulting in major problems.

Token passing schemes as used in Token Ring can provide determinism since every node is guaranteed regular access to the network. But as described earlier, a node must have possession of the token in order to transmit, and is then only allowed to send one packet before passing the token to the next node. To send another packet, the workstation must wait for the token to be passed all the way around the network even if the other workstations have nothing to transmit. If the network is large, the latency associated with this mechanism might also be unacceptable.

This is where 100BaseVG-AnyLAN excels. 100VG uses a new access control mechanism known as demand priority protocol (DPP) which places the hub in the role of traffic cop. When a workstation has data for transmission, it registers a request with the hub that places the request in a queue. The hub grants access to the network according to the queue and thus provides guaranteed access in an orderly, first come first served basis. And the latency associated with this mechanism is low because no time is wasted passing control through every node on the network whether they need access or not. If only one workstation is requesting the right to transmit, the hub will continue to give it clearance to transmit as long as no other requests are received. This provides a much more efficient use of the network since only workstations that need to move packets use any resources.

Another important feature of DPP is the ability to prioritize network access. One hundred VG hubs support connections at two separate priority levels, normal and high. Each has its own associated queue. Requests in the high priority queue are acknowledged first, providing minimum latency to connections running time sensitive applications. Requests from the normal queue. can be interrupted by high priority requests, but are ultimately protected by an internal mechanism that guarantees they will receive timely servicing even in the presence of large numbers of high priority requests. This feature allows a single 100 VG segment to service time sensitive applications like automation workstations as well as less critical applications like scheduling and billing systems without the fear of affecting the audio performance.

CENTRALIZED STORAGE REQUIREMENTS

Now that we have a better idea of what a station automation system is and how individual units can be networked to enhance efficiency, we should turn our attention to the storage requirements of a networked digital audio automation system.

Analog audio is encoded for digital storage through a modulation technique known as *sampling*. This is sort of like taking a snapshot of the audio waveform at regular intervals. Sampling a continuous waveform produces a stream of pulses, and is thus a form of pulse modulation. The amplitude of each pulse is then converted into a digital number that can be stored as data, which is known as *coding*. Therefore, the overall process of sampling an analog signal into a stream of digital data is known as *pulse coded modulation* (PCM) and is often referred to as *linear PCM* to emphasize that no data compression or reduction schemes have been applied. The amount of data generated by this process depends on how fast we sample, how many bits are devoted to each sample and how many signals we sample simultaneously (mono or stereo).

In order to completely describe the incoming audio waveform, the *Nyquist sampling theory* states that the sampling must occur at a rate at least twice as fast as the highest frequency in the incoming audio. Due to the limitations of real world filtering required to keep samples from being contaminated (known as anti-aliasing filters), the sample rate must actually be slightly higher than twice the highest input frequency expected. Thirty-two kHz sampling has a reasonable frequency response up to 15 kHz, 44.1 kHz sampling is good to about 20 kHz and 48 kHz sampling can produce frequencies up to 22 kHz or so.

The number of bits used to describe each sample is known as the level of quantization and determines the

100Mbps networks	Description, advantages, and disadvantages
100BaseTX	Fast Ethernet uses Carrier Sense Multiple Access with Collision Detection (CSMA/CD) contention-based media access control. *Advantages* • Helps bandwidth issue (but performance in multimedia applications is not bandwidth issue–real-time processes are more affected by latency) *Disadvantages* • Network slows down when loaded • Packets can be lost from "aborts due to excessive collisions" • Hub-to-node connections are limited to 100 meters (328 feet) with CAT5 wiring • Hub-to-hub connections are limited to five meters (16 feet) • Total network span is limited to 250 meters
100BaseVG-AnyLAN	Best of Ethernet combined with the determinism of Token Ring. No collision mechanism; uses centrally controlled round-robin polling network access method called Demand Priority Protocol (DPP). Each node's request is queued at the hub. The hub responds to the requests in order of priority and time received. When access is granted, node gets use of wire's full bandwidth. *Advantages* • Perfect for feeding the sustained data streams encountered in multimedia applications • Loading has minimal effect on interface speed • Supports high/low priority so that workstations can be assigned priority • Hub-to-node connections can be up to 150 meters (492 feet) with CAT5 wiring • Hub-to-hub connections can also be up to 150 meters (492 feet) • Three hub-to-hub uplinks are possible–network diameter of over 2000 feet possible with standard equipment *Disadvantages* • Not as popular as 100BaseTX–fewer suppliers

Figure 3.6-11. Comparison of 100 megabit network technologies.

particularly for multimedia networks such as station automation systems. This network can support both Ethernet and Token Ring frame types and cabling schemes and is therefore a logical upgrade from either environment. It is, however, different enough from both that it is covered by its own standard, IEEE 802.12. 100VG (as it is often abbreviated) is a physical star network that utilizes 4 pair of voice grade wires or better to connect a workstation or server to the hub. This allows a simple upgrade to the 100 Mbps world for nearly any existing installation. Using voice grade or Category 3 cable, this connection can be up to 100 m. If using Category 5 wiring, this connection can be extended to 150 m. Also, up to 3 hubs can be interconnected with the hub-to-hub distance following the same rules. This provides for networks to span as much as 750 m without any special equipment. The most interesting feature of this network is the use of intelligent hubs that manage how the workstations are able to access the network. To understand the benefits of this new media access control mechanism, we must first see how Ethernet manages transmissions.

No matter what the physical topology or speed, all IEEE 802.3 Ethernet networks operate as bus networks. This is obvious with the coax based networks, but is also true of the star wired twisted pair variations. These networks employ hubs that give all the benefits of point-to-point node-to-hub connections but internally provide a shared bus for network communications. And as discussed earlier, for a bus network to function, it must include a control mechanism to ensure only a single transmitter accesses the network at a time. In Ethernet, this mechanism is known as *carrier sense multiple access with collision detection* or CSMA/CD. What this means is that multiple workstations have equal access to the same media but must first sense that the network is free (has no carrier) before they begin to transmit. But it is still possible

Network Topology	Ethernet Class Supported	Description, Advantages, and Disadvantages
Bus	10Base2 10Base5	Simple workstation/server connections; best for small installations. *Advantages* • No hub is required • Good RF shielding (can be improved with grounding and ferrite cores) *Disadvantages* • Sensitive to proper termination • Single point failure can kill entire segment • Load balancing across multiple segments can get messy
Star	10BaseT 100BaseTX 100BaseVG-AnyLAN	Requires a hub/router per segment, so best for medium-large installations. *Advantages* • Single point failure only kills single client • Easy to cable and terminate if quality cable and connectors are used • UTP cable has reasonable RF/noise immunity due to twisted pair, can be improved with STP • Easy to load balance by repatching at hubs *Disadvantages* • Hubs can be costly for small installations

Figure 3.6-10. Features of common network topologies.

from 10 Mbps based on a 200 m (approximate) segment. The specification defines the maximum supported length as 185 m with a maximum of 30 nodes spaced a minimum of 0.5 m apart. Workstations are attached directly to the backbone by a BNC "T" connector placed on the BNC port of their NIC and then inserted into the backbone. To make these connections, the backbone must be routed past the back of every networked PC. Due to the number of connectors involved, the potential for cable failure is sizeable. In a bus network, a single point failure will kill the entire network. However, the advantage of the less expensive, more flexible and easier to work with RG-58 style cable can often outweigh this concern and makes Thinnet a viable cabling scheme for small to moderate sized networks.

10BaseT, stands for 10 Mbps based on twisted pair wiring. 10BaseT is physically a star network which utilizes UTP to make point-to-point connections between each workstation or server and a centrally located hub. The UTP cable, typically used, includes 4 separate pairs in a single sheath and is rated by category. 10BaseT requires UTP cable rated as *Category 3* or higher. 10BaseT connections require only 2 of the pairs (one transmit, one receive), and use standard easy to apply RJ-45 connectors. Cable runs are limited to 100 m, making the effective distance from workstation to hub to server up to 200 m. The use of active hubs provides isolation of each connection, reducing the sensitivity to single point failure, and provides convenient patch points, which can ease expansion and load balancing. The low cost of the cabling and the ease of installing, connecting and maintaining these networks has made 10BaseT the most popular cabling arrangement for mid to large size networks. Figure 3.6-10 presents a quick comparison of these common 10 Mbps Ethernet configurations.

In addition to the 10 Mbps offerings, Ethernet has recently advanced to the 100 Mbps arena. 100BaseT, dubbed *Fast Ethernet*, includes three different cabling standards: 100BaseFX, 100BaseTX, and 100BaseT4 (see Figure 3.6-11). All use a star physical topology, with each node having a point-to-point connection with the hub. With 100BaseFX, these connections are made with two strands of fiber-optic cable. 100BaseTX uses two twisted pairs of Category 5 UTP or STP. 100BaseT4 uses four twisted pairs of Category 3, 4 or 5. For new installations where no existing cable needs to be integrated, either the FX and TX options make good sense since all new cabling must be installed anyway. For existing 10BaseT installations that utilize Category 3 wiring, 100BaseT4 allows a simple upgrade path to 100 Mb without having to replace the wiring. In practice, 100BaseTX using Category 5 wiring has become the standard of choice and there has been relatively little application of the others. 100BaseTX links are limited to 100 m with an overall segment length limit of 250 m.

Another 100 Mbps standard called 100BaseVG-AnyLAN has emerged with some excellent features, point to point transfers such as workstation to server communications.

A star network offers some distinct advantages over other topologies. Point-to-point communications between the workstation (or server) and hub can provide more efficient full duplex communications. The connection ports on a hub provide a central patch point for easy expansion and reorganization of the network. Most all hubs in use today are active devices that include signal conditioning electronics to clean and reshape waveforms, which improves the performance, reliability and range of the network. The conditioning electronics also buffer the ports making the network less sensitive to a single point cable failure. The hub can just ignore the disconnected (or shorted) port without affecting the rest of the connections. And most hubs also include traffic monitoring and management functions, which allow system administrators to analyze and *fine tune* their networks. The one disadvantage of this topology is the cost of the hub itself, which for small networks may not be warranted.

Network Cabling and Hardware

So what does all this mean to the station engineer who needs to install and connect the station automation system? To get to the real world nuts and bolts of networking, we must discuss cabling standards.

There are three popular local area network (LAN) cabling standards: Ethernet, Token Ring and ARCnet. Two of these, Ethernet and Token Ring, are defined as international standards by the Institute of Electrical and Electronics Engineers (IEEE). ARCnet is not an IEEE standard but has a substantial installed base and therefore deserves some mention.

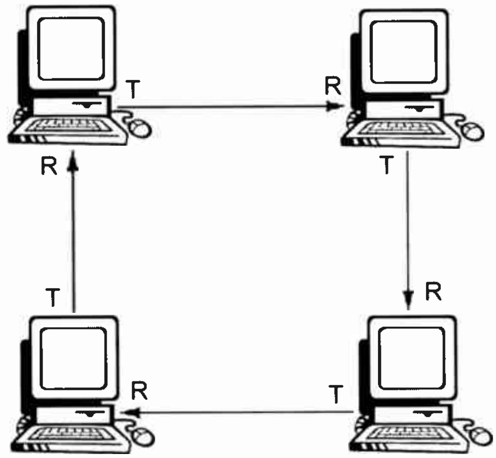
ARCnet utilizes a star physical topology with 93 Ω coaxial cable (RG-62 style) connecting workstations and servers to a mixture of passive and active hubs. The use of passive hubs makes the network inexpensive and simple to wire, however, the network logically functions as a bus and is therefore sensitive to proper termination and cable failure. Active hubs isolate connections to protect the network from single point cable failures and extend the span of the network (up to 20,000 ft. overall). This network was the first supported by Novell NetWare and still retains a respectable presence, mostly from early NetWare networks. ARCnet originally provided a data rate of only 2.5 Mbps as compared to Ethernet's 10 Mbps, but at lower cost, making it a reasonable trade off for many installations. It has since been upgraded to provide 20 Mbps, but ARCnet has never been able to overcome the growing popularity of Ethernet and is rarely seen in new LAN installations.

Token Ring networks can provide data rates of either 4 Mbps or 16 Mbps over either *shielded twisted pair* (STP) or more recently *unshielded twisted pair* (UTP) cabling. The network is physically wired in a star topology with hubs, also know as *multi-station access units* (MSAU), providing a logical ring connection between *nodes*. Access to transmit on the ring is controlled by a special data frame called a *token*, which is circulated around the ring from the transmitter of one node to the receiver of the next and so on. If a workstation has data to transmit, it must wait until it receives possession of the token. When the workstation has transmitted its data frame, it must then release the token to the next workstation in the ring. This is a very effective access control mechanism because it is deterministic, meaning every node is given equal opportunity to access the network on a regular basis. Token access control is, however, a complicated mechanism to implement because it must include provisions for detecting and dealing with lost tokens and undelivered packets that could circulate the ring for ever. IBM is the originator of Token Ring and still holds the patents for the most common chipset used for Token Ring NICs. This has caused Token Ring to be viewed as more proprietary than other technologies. And while Token Ring has enjoyed widespread popularity particularly in large corporate and educational environments, it is more expensive than Ethernet for a similar level of performance, and is therefore less likely to be used in new systems. Token Ring is defined in the IEEE 802.5 Standard.

Ethernet was the first and is by far the most favored network cabling standard in use. It has a number of different physical implementations including 10Base5, 10Base2 and 10BaseT which are 10 Mbps technologies, and 100BaseTX, 100BaseT4 and 100BaseFX which are 100 Mbps technologies. Another standard known as 100BaseVG-AnyLAN is a special 100 Mbps technology that is somewhat of a cross between Ethernet and Token Ring and offers some very interesting features.

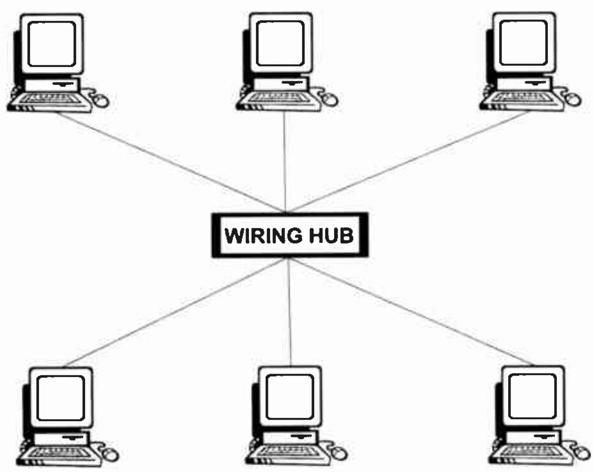
10Base5 is physically a bus topology that utilizes a 0.5 inch diameter 50 Ω coaxial cable (RG-8 style) as a trunk or backbone. The size of this cable has led to 10Base5 being dubbed *thick wire Ethernet* or *thicknet*. The coaxial backbone acts as a transmission line, and therefore must be terminated in its characteristic impedance (a 50 Ω load) at each end to minimize the reflection of signals that may be traveling on it. Workstations are attached to the network through NICs with *attachment unit interface* (AUI) ports that connect through 15 conductor cable to transceivers called *media attachment units* (MAU) that are either inserted into or tapped onto the trunk cable. The trunk can be up to 500 m long, hence the IEEE designation 10Base5—meaning 10 Mbps based on a 500 m segment. A single segment can support up to 100 nodes which must be spaced a minimum of 2.5 m apart. The connectors, cable and attachment units required for 10Base5 are expensive and difficult to work with while offering few advantages over other connection schemes. Thicknet is therefore rarely seen in new installations.

10Base2 is also physically a bus network that uses a 0.2 in. 50 Ω coaxial cable (RG-58 style) as the main trunk. Due to the thinner cable, this configuration is often called *thin wire Ethernet* or *thinnet*, and due to the lower cost of the cable, it is often referred to as *cheapernet*. The 10Base2 IEEE designation comes



T=TRANSMIT R=RECEIVE

(d)



(e)

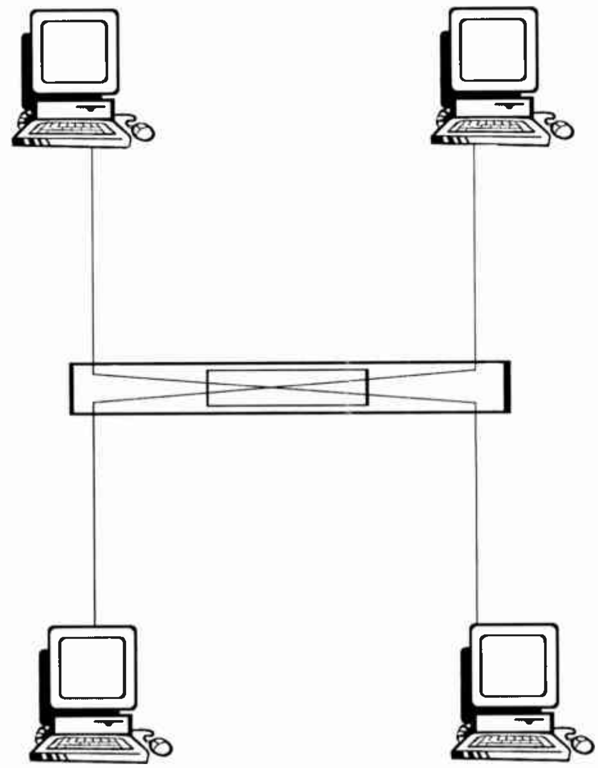

Figure 3.6-9. Logical topologies: a) star as bus, b) star as ring.

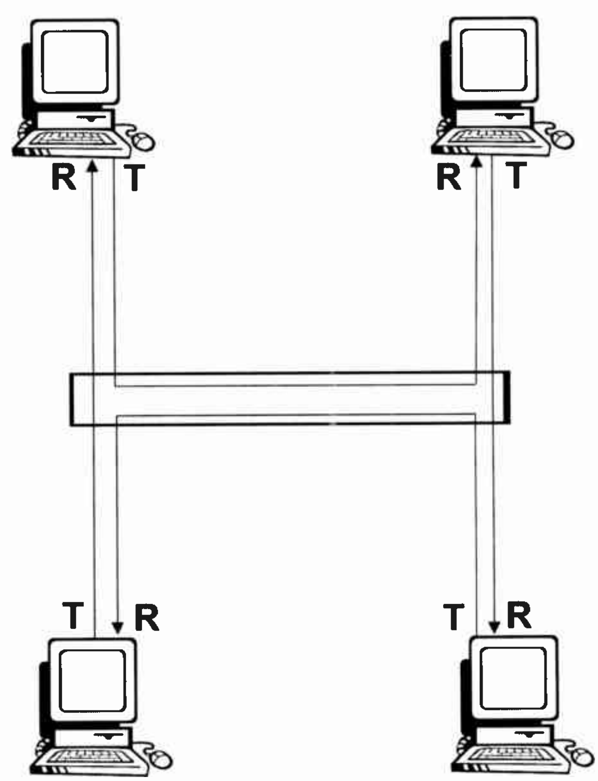

(b)

can be situations where a packet must travel the entire circumference of the ring to reach the workstation immediately adjacent to it. If the network is very large, this can add a considerable delay to the exchange of data, resulting in a sluggish network.

By far, the most popular implementation of the point-to-point link network is the *star* topology (see Figure 3.6-8 (e)). In this arrangement, all workstations/ servers have a point-to-point connection with a centrally located wiring cabinet called a hub, which provides the signal routing between the nodes. How the hub internally connects the nodes determines the *logical topology* of the network, or, how the network works. While the network might physically be a star topology using point-to-point connections, the hub might logically connect the workstations as a ring or bus as shown in Figures 3.6-9 (a) and (b). Advanced switching hubs can provide a form of mesh logical topology which can greatly increase the efficiency of

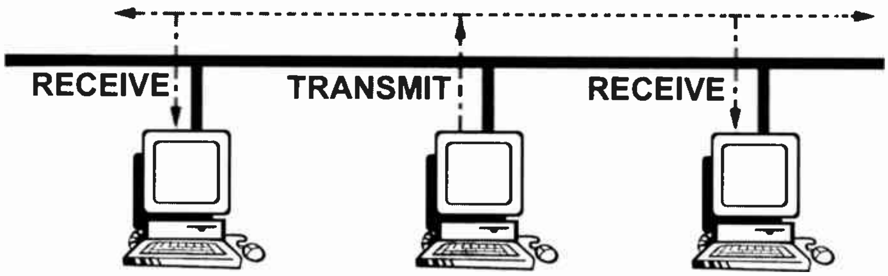

Figure 3.6-8. Physical topologies: a) bus, b) point to point, c) mesh.

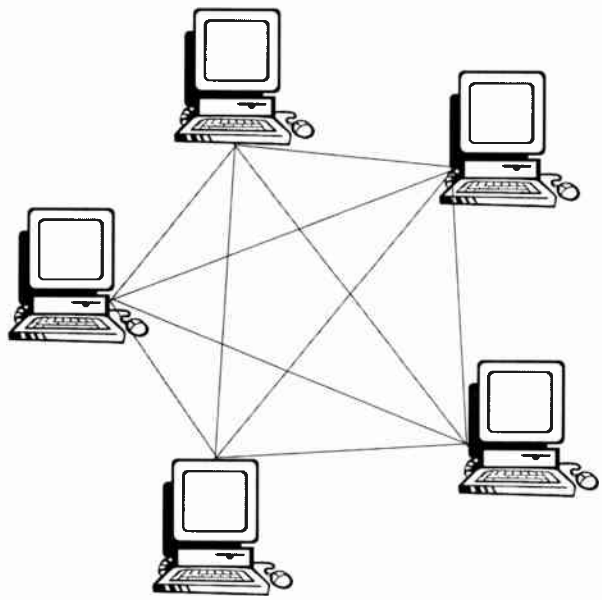
(b)



(c)

Each of these network architectures provides useful connectivity between workstations and has its place in station automation. But, all things considered, the dedicated server based network offers the best collection of features from which to build a multi-station automation system.

Network Topologies

With a basic understanding of some of the operational benefits that PC networking can bring to our overall station automation picture, it makes sense to discuss how this networking is physically accomplished. The way cables are arranged to provide interconnection in a network is known as its *shape* or *physical topology*. The way the signals are actually routed throughout the network is known as its *logical topology*. The physical topology and logical topology may not necessarily be the same, as we will see shortly.

There are two building blocks for all physical topologies: the *bus* and the *point-to-point* link.

The bus topology uses a single cable that each workstation and server attaches to and shares. When any *node* (connected devices are often referred to nodes) transmits, it broadcasts over this transmission line with every node hearing every transmission. Communications would become hopelessly confused if multiple workstations tried to transmit on this shared line simultaneously; therefore, bus networks must employ a control mechanism to make sure only one transmitter is active at a time. The bus topology can be easily expanded by making the bus cable longer and attaching more workstations up to the electrical limitations of the cable. It is also possible to expand beyond this limit through the use of repeater electronics and multiple cable segments. Figure 3.6-8 (a) represents the basic concept of the bus topology.

Point-to-point networks, on the other hand, do not broadcast on a shared cable, but as the name implies, transmit to exactly one receiver and receive from exactly one transmitter. As Figure 3.6-8 (b) illustrates, the transmitter of one workstation is connected directly to the receiver of another with the transmitter of that workstation connected back to the receiver of the first. Because transmission and reception occur over separate wires, this topology has the advantage of supporting *duplex operation* (simultaneous transmit and receive), which doubles the communication speed. However, point-to point networks are somewhat more complicated to expand. One way to add workstations is to provide a point-to-point connection between every pair of workstations in the network as shown in Figure 3.6-8 (c). It is obvious that this would become overly complex for even a small group of computers. Another way to expand a point-to-point link network is to connect the workstations in a *ring* arrangement as shown in Figure 3.6-8 (d). The transmitter of one workstation is connected to the receive port of the next workstation in the ring. Data, transmitted in individually addressed units called *packets*, travels from point-to-point-to-point around the ring until it reaches its destination address. With full duplex communications, this can be an effective arrangement, however, since packets are transferred around the ring in a single direction, there tion can suffer during a transfer. In a peer-to-peer network, each unit typically runs from its own database, requiring considerable file maintenance to keep the multiple separate inventories organized.

An audio server based network usually consists of one or more workstations communicating with a dedicated and often proprietary computer that houses both the audio processing hardware (DSP boards) and audio file hard disk storage (see Figure 3.6-6). The workstations act as control interfaces that command the central audio server to perform all record and play functions. A nice feature of the arrangement is that all the audio data is stored centrally, making it instantly accessible by any workstation. Audio recorded by a production workstation can be immediately played by an on-air workstation without requiring any file copying to the local hard drive. A serious disadvantage to this network configuration is that all audio processing is performed by the audio server, which has a physical limit to the number of audio channels it can contain (typically 8 or less). This limits the number of workstations that can be supported by the system and makes it difficult and expensive to expand. Also, because all audio inputs and outputs occur at the audio server, audio interconnect wiring is required to and from each studio adding to the installation complexity and potential points of failure. And since the workstations contain no audio hardware themselves, they have no functionality in the event of an audio server or network failure.

A dedicated file server based network combines the good points of these first two architectures. The network generally consists of one or more workstations linked to a central high performance, non-proprietary computer that runs a standard high performance NOS like Novell NetWare, Unix NFS, or Windows NT Server. The server presents itself to the rest of the system as a large shared disk drive and manages the digital storage of all audio and system data. As with the audio server concept, the audio is stored centrally and is therefore instantly accessible by any of the workstations. The major advantage this configuration has over the audio server configuration is that the audio processing hardware (DSP boards) are located in each of the individual workstations as illustrated in Figure 3.6-7. This places the audio inputs and outputs at the workstation with the network used to transfer packets of digitized audio data between the workstation and server. Not only does this allow all workstations to share the centrally stored audio, but it also provides

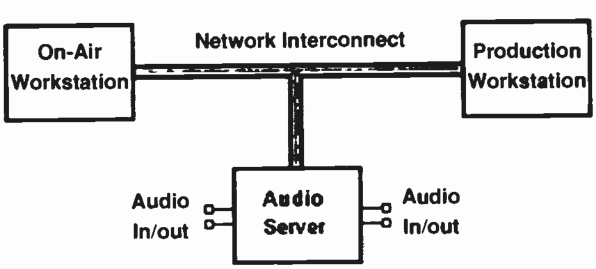


Figure 3.6-6. Audio server network.

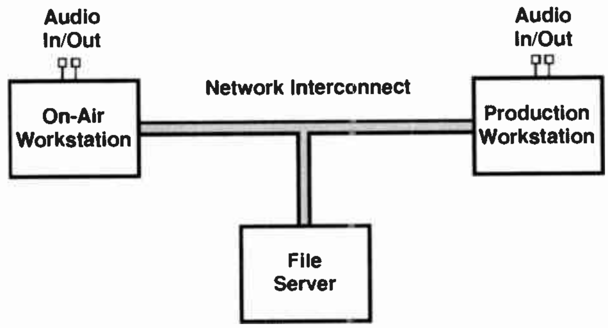

Figure 3.6-7. Dedicated file server network.

audio distribution via the data network. An audio source local to a workstation at one end of a facility can be recorded and then immediately played by a workstation at the other end of the facility. A practical example of this is a workstation installed in an equipment room with the station's satellite receivers and programmed to automatically record multiple news feeds throughout the day. Workstations anywhere within the facility can access, edit, and play portions of these feeds without having any direct audio feed from the receivers themselves. The interesting thing is that the complete interconnect for distributing the normal system data and audio is a single piece of coax or twisted pair cable!

The fact that the file server contains no audio hardware is also very significant to server functionality, because this means it is not bound by any physical number of channels. The server is designed to service large numbers of data streams bound only by performance and capacity of its disk (input/output) subsystem and the speed of the network. With proper server design, any number of workstations/audio channels can be supported, making this type of network scalable.

Another excellent benefit of the dedicated file server based network is the various data redundancy (backup) options available. With a number of workstations relying on the file server to store all of their work, it is important that this storage remains online at all times and is protected in the event of catastrophic hardware failure such as a hard disk failure. NOS software for dedicated file servers is quite sophisticated and generally contains special fault tolerant features to protect the integrity of the data being stored. Features like disk mirroring, server mirroring and Redundant Array of Inexpensive Disks (RAID) are available, along with support for a considerable range of industry standard hardware components designed to provide performance and redundancy. Also, the dedicated file server architecture is able to provide a level of redundancy via the workstation. The primary mode of operation is for each workstation to record and play directly to and from the server; however, because each workstation contains its own audio processing hardware, local hard disk storage can be included for emergency use in the event of file server or network maintenance or failure.

Figure 3.6-4. Touchscreen controlled audio playback buttons integrated with text.

as PC networking. A single stand-alone PC with the features described thus far can do an excellent job providing the basic production, live-assist and automation features required for a single station. If you need to automate multiple stations, you have two choices: try to *squeeze* the additional resources from a single workstation or add additional workstations to handle the additional stations. Using a single workstation simplifies inventory management and allows the production and scheduling to be shared; however, as you try to do more and more within a single box, the unit's capabilities will be spread thinner and thinner until the overall performance is no longer satisfactory. If you add more independent units, you maintain each system's performance level but add the burden of managing multiple inventories, multiple production facilities and multiple scheduling systems. To achieve the best of these two scenarios we would need to interconnect the workstations so they could share audio inventory, share production elements and share scheduling resources while they each provided high performance live-assist and/or automation features to their individual stations. This kind of interconnection is exactly what PC networks are designed to provide.

Networking the individual workstations together enables them to move audio, automation schedules, as-play logs, scripts and wire copy text, configuration and control data and software updates from unit to unit without having to physically transport the data via removable media (floppy disk, Bernoulli cartridge, writable CD, magnetooptical disk or data tape). Eliminating the time and effort associated with such a *sneaker net* is usually by itself enough to justify the expense of the network hardware and software. But in addition to providing a conduit to expedite the exchange of information between one unit and another, networking can actually increase the overall efficiency of a group of workstations by eliminating unnecessary replication of resources and by allowing individual workstations to be specialized for particular functions. For instance, it is usually more efficient in both equipment and manpower, to equip a single workstation with the production facilities to create spots for all of the stations than it is to perform production at each of the on-air workstations. This also makes the on-air workstations more efficient by allowing them to devote their resources to their primary on-air functions. The same is true of other group wide functions such as wire service integration, news feed collection, scheduling and overall inventory management.

Network Architectures

A number of computer network architectures are presently being utilized for broadcast applications. Each has certain advantages and disadvantages. The three most common configurations are the *peer-to-peer* network, the audio (video) server based network, and *dedicated file server* based network.

A peer-to-peer network is simple and inexpensive way to link two or more workstations at the file system level, permitting file transfer between them. This arrangement has achieved reasonable popularity since it only requires the addition of *network interface cards* (NIC) to each workstation and the loading of some relatively simple *network operating system* (NOS) software. The basic concept of a two workstation network is illustrated in Figure 3.6-5. Peer-to-peer networks allow each workstation to access the contents of another workstation's drive; however, the performance of this connection is such that audio files cannot be shared directly. To play or record audio files, the files must reside on that workstation's local hard drive. If an audio file required for playback exists on another workstation's drive, it must be copied across the network to the local hard drive before it can be used. This can add a considerable delay between the production and use of an audio cut if it must be transferred since audio files can be quite large. Also, a workstation's capabilities can be taxed by the overhead required to service the network, and normal on-air opera-

Figure 3.6-5. Peer-to-peer network.

sion of custom serial protocols, be capable of storing and running *control macros* that execute specific command sequences and provide these features through a user programmable mechanism so that each station's unique compliment of equipment can be administered and maintained.

Even if an automation system possesses all of the key features described thus far, it MUST have a clear, well organized, intuitive operator interface or much of its power will go unused. Many of the early automation systems were quite powerful but displayed busy text based screens and required multiple key keyboard commands to operate. The *computer-phobic* shied away from these units, making them useful to only the more computer literate station personnel. Graphic user interfaces (GUI) like Mac O/S, IBM O/S2, Unix X-Windows and various versions of Microsoft's Windows have made it possible to display screens that provide more visual clues as to function and use. The necessary text-based data remains, but it is surrounded with buttons and scroll boxes that allow the operator to navigate the screen and operate the system with a simple pointing device like a mouse or trackball (see Figure 3.6-1).

Some of the more advanced automation systems have taken this a step further by allowing the pointing device to be the operator's finger. This touch screen technology coordinates a touch sensitive x-y matrix placed over the display screen with the graphics displayed through it by the program. The operator can *press* a button on the screen and get the illusion that they are operating a physical button due to the program's resultant visual clues like color change and shadow reversal. This type of interface has engendered PC based automation systems into common use by even the most computer-phobic staff members, and has enhanced the role of the automation system as an on-air live assist device. Screens that present lists of cuts to be played sequentially along with their *hit times*, transition information, a count down clock, a time of day clock and audition functions work well for tightly formatted live assist periods (see Figure 3.6-2). Screens that present panels of programmable playback buttons provide the instantaneous playback capabilities needed for spontaneous live shows (see Figure 3.6-3). And script based programs like newscasts can benefit from systems that allow the integration of text and audio to provide sound bite playback from buttons that are embedded in and scroll with the script (see Figure 3.6-4). Examples such as these illustrate how a well designed human-machine interface can broaden an automation system's usability and enhance its effectiveness.

NETWORKED AUTOMATION SYSTEMS

Of all of the contributions the personal computer has made to advance the state of the art of station automation perhaps none has had as pronounced an effect gramming and thus represent the station's daily program schedule or log. In addition to the actual audio elements, these playlists need to include automation information that instructs the system how to sequence from one to the next automatically. The ability to program lists to cover multiple days or the ability for one list to sequence to another list is also very important.

Because these playlists might typically hold hundreds or possibly thousands of elements, scheduling each and every event and programming the automation manually would be very tedious. Again, the power of the PC comes to the rescue. There are many PC based programs in existence that use database functions combined with user defined sets of rules to manage and schedule commercials/promos (traffic) and music. Each category is handled somewhat differently. Programs that schedule commercials generally take sales department information (orders) and apply rules based on air time rates, time of day, time of year and adjacent programming to generate a daily schedule or log. These programs are usually also tied to the billing department and are often able to accept *as-played* logs from the automation system and reconcile them with the original schedule to generate the appropriate billing invoices. Music scheduling programs on the other hand must choose cuts based on the station's format, time of day, music category and artist, and may apply rules like not allowing two artists from the same music category to play back-to-back or like limiting specific cuts from playing more than once per hour or once per day.

While some automation systems provide these scheduling features as part of an overall comprehensive automation package, it is not necessarily a great advantage to obtain everything from a single vendor. With all the excellent scheduling software that is already available from a multitude of vendors, often the most flexible approach is to choose each package separately based on its individual merits (possibly already familiar or in use). Then select an automation system that can interface with these systems to import and merge the traffic and music schedules and provide seamless integration of scheduling and playback. The automation system then exports an as-played log representing what actually aired to the traffic system which uses the data to expedite the billing process. In short, to be a good automation system, it is not necessary to possess scheduling features, but a good system must be able to use the schedules generated by other applications and then report back to them the on-air as-played results.

A good automation system will include several options for controlling when and how the system automates from event to event. Features to preset and/or execute transitions at a specific time of day are important for cueing up *stopsets* and starting programs. Transitions that tie the end of one event to the beginning of the next are useful for connecting multiple spots in a single stopset. Advanced systems often provide the ability to overlap events to provide segues between audio elements and to add voiceover announcements over background audio. The ability to perform these overlaps with dynamic level control (crossfades, ducking) all within a single stereo playback channel is highly desirable.

Another desirable automation system feature is the ability to record into the device while simultaneously playing audio. This allows production personnel to create new inventory without having to wait for specific breaks in the normal on-air programming. Most systems provide this function by offering multiple record and/or play audio channels. Some systems are scalable, allowing the channels to be added as needed by inserting additional DSP boards.

An important extension of this function is the ability to play a file while it is still being recorded. One excellent use of this feature is to perform short interval time shifts.

Once you begin recording a program, you can start playback of the same cut at any time, even before the program (and recording) is completed. This allows hour long programs to be delayed by as little as a few minutes. Another powerful use is to be able to play excerpts of a news feed while it is still being recorded. Sound bites can be used on air before the feed is over without having to make multiple progressive length recordings. Most automation systems require that a recording be in progress for a specified amount of time before the cut may be accessed for playback, but this interval is typically only a few seconds making this feature very handy.

An automation system rarely contains everything necessary for complete walk-away operation. For it to be truly effective, a system needs to be able to interface with various other broadcast devices, like—audio switchers, audio consoles, satellite receivers, CD players, DAT players, station clocks and more. These interfaces are created in two parts: the hardware interface, which provides proper electronic interconnection, and the software interface which communicates specific commands to/from the peripheral.

Systems based on personal computers can take advantage of a multitude of *off the shelf* hardware (plug-in I/O boards) that can provide any mix of RS-232, RS-422, RS-485 and large numbers of opto-isolated contact closure inputs and dry contact outputs. Systems that are able to address these *generic* I/O products are generally more flexible than those that offer their own custom I/O hardware that may offer a mix of these features.

But the greatest strength of an automation system is in its software interface—how it uses the hardware to communicate with the various devices external to the PC. A wide variation of command syntax and order exists among the various peripheral devices an automation system might connect to. Command strings, string lengths and the use of carriage return and/or line feed varies from device to device. Even simple contact closure controlled devices can often require specific closure sequences to perform a given function. It is therefore very important that the automation system software support the creation and transmisthat a more sophisticated "CD quality" version of the cart machine was needed to play spots, IDs, jingles etc.

As *digital cart* machines began appearing as direct hardware replacements for the existing analog units, some clever computer people were realizing that everything needed for a digital cart machine was already in a PC except the analog to digital and digital to analog conversion electronics. And this could easily be added by building a custom signal processing circuit board designed to plug into one of the existing PC expansion slots. Since PCs were already driving the development of the hard disk storage technology, they had access to the capacity required to store many hours of digital audio. This could be divided into any number of any size pieces, allowing an extensive inventory; and unlike tape or floppy disk based systems, PC based systems could provide *random* access to any and all of the material they contained.

Adding these powerful audio capabilities to the automation strengths of the PC has created the perfect platform for the continued evolution of station automation.

Key Features of an Automation System

The personal computer is capable of providing all of the key functions required for a powerful station automation system in a single box: random access CD quality audio, database operations, communications capabilities, programmability, and user-friendly operator interface. But to be an effective automation system, the hardware and software must be designed to provide certain key features.

Let's start with *CD quality* audio. Once the audio is digitized, it is manipulated as data, which the PC handles nicely. Therefore, the primary factor that determines the audio quality of a PC based digital audio system is the quality of the electronics used to convert between the analog and digital worlds. In a PC based system, this usually means the quality of the plug in digital signal processing (DSP) board. These boards include the analog input stage, the input low-pass filter, the analog to digital (A/D) and digital to analog (D/A) converter devices, the output reconstruction filter, and the analog output stage for each audio channel. It is very important that the analog stages have very low noise, wide dynamic range and be very linear. The input low-pass filter must have a steep enough response to preserve the maximum high frequency information for a given sample rate, should have minimal passband ripple, minimal ringing, and have a linear phase response. The analog to digital converter must have very accurate quantization levels (high linearity) and must complete each conversion very quickly (short conversion time). The digital to analog converter and reconstruction filter should use higher resolution (more bits) than the A/D to keep from raising the noise floor and limiting the headroom of the output signal.

It is often difficult to obtain many of these parameters directly without extensive technical documentation, which makes comparisons challenging. To complicate things further, many manufacturers will measure these parameters and report the resulting specifications using differing terminology and references. Without going too far into the specification jungle, we can state that most *professional* PC based digital audio systems use premium quality electronics with at least 16 bit quantization and therefore have similar excellent audio quality specifications:

Frequency response @ 48 kHz sampling 20 Hz – 20 kHz = ±0.5 dB

Dynamic Range (measured from digital clip) >90 dB

Signal to Noise (measured from digital clip) >90 dB

THD + N (measured at max level) <0.05%

Phase error between L–R channels <1 degree @ kHz

There are also systems available that utilize consumer grade multimedia audio cards. Consumer units typically have more high frequency roll-off for a given sample rate, more passband ripple, more interchannel phase error and higher distortion due to less expensive A/D and D/A converters. Generally speaking, products intended for the professional market (radio, TV, recording studio) use high quality components and provide noticeably better audio quality than consumer grade multimedia units. Pro units also usually provide balanced audio connections and direct digital audio connections where consumer units do not. And most pro units provide onboard DSP *horsepower* to perform real-time data compression and audio effects where consumer units do not. The bottom line is when it comes to audio quality, you get what you pay for.

With the ability to record and play high quality audio established, the next most important feature an automation system must possess is a way to organize its inventory. This is where the PC's database capabilities are utilized. The system should be able to hold numerous fields of information for each piece of audio recorded into the system. Things like the title, length, out cue, record date, start date and kill date should be stored along with a unique cut identifier (numeric or alpha-numeric) for every recording. The system should be able to sort the database by any of these fields, and should offer search functions able to find a string from any of the fields. It should be easy to change, update or remove data as well as to generate electronic or hard copy reports of the contents. More advanced systems might also include features like storing segue points, auxiliary cue points, back timer points, number of plays counters and the date and time of each cut's last use. Most importantly, the information and tools to manipulate it must be presented clearly and logically to the user.

From this overall database of the complete system inventory, an automation system must be able to create (or import from an external source) sub-databases that include the elements that will be used (played) in secession. These *playlists* might contain elements for a single stop set or might contain an entire day's pro-

3.6 STATION AUTOMATION AND NETWORKING

DAVID T. TURNER
ENCO SYSTEMS, INC., FARMINGTON HILLS, MI

INTRODUCTION

The term *station automation* is a very broad concept. It generally refers to the use of devices, processes and system interconnections designed to make a broadcast station (radio or TV) run a series of scheduled events automatically—without operator intervention. This includes every scheme ever devised from massive reel-to-reel tapes and interconnected cart machines to all encompassing control systems that steer the directional array, turn on the transmitter, play the audio, control the console crossfades and generate transmitter logs and billing information.

While the individual pieces of hardware involved in broadcasting have evolved to include powerful automatic functions and interconnect capabilities, nothing has advanced the station automation state of the art more than the personal computer.

SYSTEM OVERVIEW

It wasn't too long ago that station automation referred to a 15 in. reel of tape playing at 1 and 7/8 in. per second on an auto-reversing tape deck. This automation arrangement could provide most of a day's programming with minimal operator intervention, but the audio quality was mediocre due to the slow tape speed, and it required production personnel to invest a great deal of time assembling the contents of the tapes. Once the tapes were assembled, it was very difficult to make any changes, especially if the tape was playing on-air.

A more flexible arrangement used a stack of cart machines with the secondary cue (SEC) output of one wired to the start input of the next, and so on with the last machine connected back to the first. This allowed the operator to load several songs and commercials to play automatically in sequence, freeing up short amounts of time for other important operations. This crude form of automation was followed by numerous variations of mechanical beasts designed to hold and cycle dozens and sometimes hundreds of carts through multiple playback decks. These electro-mechanical marvels were capable of automatically sequencing days worth of programming.

These machines were incredible achievements in station automation and have faithfully served the broadcast industry for many years. However, their dependency on extensive mechanical transports made them high maintenance devices and limited their flexibility. Even the audio quality was hard to maintain due to the number of capstans and tape heads involved. Broadcasters needed newer, higher quality, easier to maintain, more versatile automation systems.

As CD players and DAT tape machines became common place in the home and in the studio, the audience demand for *CD Quality* broadcast audio also grew. Along with the improved audio this new generation of equipment brought improved control features that allowed broadcasters to elevate automation to a new level. In addition to the standard START and STOP functions, a much more complete set of instructions including shuttling and indexing were now available, usually through a serial data protocol. This enabled a single electronic controller to *talk* to multiple devices, directing them to queue up then play individual tracks from CDs and tapes containing multiple tracks. With *CD jukebox* devices available that could hold and play tracks from over 300 CDs and DAT tape machines that could queue and play hours worth of programming, a station could now automate for days at a time, if the controller was programmed properly.

While several manufacturers developed automation systems for their own equipment, these were mostly proprietary hardware and not able to communicate with devices from other manufacturers. These units often employed special keypads for data entry and ran ROM based programs that were difficult to upgrade or modify. This is where the Personal Computer made its biggest mark on station automation. PCs were already being used in business and at home to run database applications, perfect for storing a *log* of scheduled events. PCs had excellent serial (and parallel) communications capability and could be configured/programmed to *speak* any protocol required. PCs used a standard user interface (keyboard and monitor). PC based programs were stored on disk and ran from RAM and were therefore relatively simple to modify and reload. The personal computer was an excellent platform for station automation controllers.

A number of manufacturers created custom software packages using standard PC hardware to automate CD jukeboxes, DAT players, and fire relays to play standard cart machines. These were quite effective and could provide a good level of *walk away* automation, but some of the stations most important material, (commercials, IDs, and promos) were left to the weakest link—the cart machine. It became increasingly obvious names emerge and some industry leaders fade from vogue as they fall behind the pace of changing technology. Pressure is on broadcast engineers also to educate themselves in order to provide a competitive product to their listeners and viewers.

Special thanks to Elaine Jones of Comrex Corporation, Dave Burns of Harris Corporation's Broadcast Division and Daniel Queen of the Audio Engineering Society for their contributions, clarifications and assistance in preparation of this chapter.

equalizer with slider controls creates a visual picture of the frequency response curve that is being produced. Non-technical people find it easy to use because of this design.

The *parametric equalizer* provides more versatility in the hands of a trained operator. A specific frequency can be dialed in with a parametric equalizer for elimination or boosting. A graphic equalizer does not allow this frequency specific accuracy. The parametric equalizer also allows the adjustment of filter bandwidth or selectivity. A narrow bandwidth can notch out a hum or buzz. A wide bandwidth produces broad curve to boost or cut an entire band of frequencies. The typical parametric equalizer offers three or four sections covering the entire audio spectrum. Parametrics are prized as valuable tools in the production studio.

Microphone Processors

Stations spend thousands of dollars for processing equipment to compress and equalize their music program material. The studio microphone often suffers from processing neglect although it deserves major attention. Compression, equalization and de-essing of the studio microphone give the on-air talent a fighting chance of competing with the professionally produced program material played on the air. A good microphone processor elevates the local disk jockey closer to the voice quality level of professional voice talent.

Compression reduces the dynamic range of the natural voice providing more power and punch by raising its average energy; it becomes louder. The added power prevents the voice from being buried by song introductions and music beds. The equalizer provides a means of boosting regions of the voice spectrum that lack natural presence. Male jocks always want a generous boost of low-frequency energy. A muddy voice benefits from a boost in brightness from the equalizer's upper mid-range (around 2.5 kHz).

Sibilance problems show up at frequencies between 6 and 7 kHz. The de-esser monitors the energy level in this range and kicks in additional compression to reduce sibilance problems. When adjusted properly, the de-esser will take the edge off a sibilance problem without punishment to the high-end frequency response. A de-esser circuit requires fast attack and release timing and a narrow (less than 0.5 octave) bandwidth.

Without voice processing on the studio microphone, the station may find itself over-processing its music while stretching to achieve a suitable amount of processing for the on-air voices. The addition of a microphone processor provides a more balanced processing mix from on-air voices and produced program material.

Noise Reduction Systems

Noise reduction systems minimize source noise from analog audio tape, vinyl records and remote pickup (RPU) radio links. Dolby and dual-ended systems record encoded audio on tape and decode it to reproduce the original audio with a lower level of system noise.

Audio *companding* (compression/expanding) systems provide another option. During the recording process the dynamic range of the program material is severely compressed keeping it further above the noise floor of the recording medium. The process reverses during playback when the recorded audio is expanded restoring the normal dynamic range. These dual-ended systems provide benefit in audio tape recording but require identical equipment on each end of the record/reproduce process.

Dolby and companding noise reduction systems paint over the noise. Single-ended systems provide freedom from the encode/decode process by sweeping noise under the rug. These frequency sensitive gating devices eliminate all audio in certain bands when the signal falls below a fixed threshold. The theory of operation assumes that anything below the threshold must be noise and should be eliminated.

Single-ended systems offer a better solution than cutting the frequencies associated with tape hiss with an equalizer. The equalizer also eliminates desirable program material in that spectrum. The noise reduction unit attenuates a part of the audio spectrum only when no significant program material appears in that band.

Effects Generators

Digital effects generators enable production directors to produce the special effects of *phasing, flanging* and *echo* for creative production. Several effects devices allow easy pitch changes of voice and music for special effects and to compensate for speed adjustments made to time tapes perfectly to 30 or 60 seconds. When tape speed varies more than 2 or 3%, pitch correction restores normal tone to the voice.

When using reverberation in program material, the amount mixed in should be 20 dB down from normal program level. Otherwise the effect will be too distracting. When used with compression or limiting, it should be mixed back into the audio chain at the limiter output. This prevents the percentage of the mix from varying with the operation of the compressor/limiter.

SUMMARY

The standards that have served us well since the infancy of broadcasting are now falling to new technology. The digital AES/EBU (AES-3) interface is superseding the standard 600 Ω, +4 dB connection between audio equipment. Our long familiar hardware friends, punch blocks, screw barrier strips and XLR connectors make way for DB25s, fiber optic cable and ISDN.

The broadcast engineer can now build a studio using source material from digital audio storage devices mixed on a totally digital console. The console can even be a touch-screen controlled computer. The all-digital processing system has arrived. Some stations have already replaced their 950 MHz STLs with T1 carrier systems. Digital stereo generators arrived several years ago as did digital FM exciters.

Retooling to produce digital studio equipment is challenging the equipment industry. We have seen new is less apparent as the compressor begins to act on the rising audio signal. This describes a *soft-knee compressor.* The old tube-type compressors, the UREI LA-2 for example, remain popular because of the smooth transition through their soft-knee.

The combination of input level, threshold, and ratio set the amount of compression applied to the audio. The compressor's attack time and release time also factor into the proper setup of a compressor. The attack time specifies how quickly the compressor responds to a rising audio voltage as it crosses the threshold. A slow attack time, one measured in milliseconds, lets a few overshoots through. Aggressive compression utilizes a fast attack time, one measured in microseconds.

Release time determines how quickly the compressor releases the compression when a falling voltage drops below the threshold. A slow release time may measure 2.5 seconds or longer. A fast release time, measured in milliseconds, will release as each low frequency waveform decays. A high compression ratio coupled with fast release time may result in too much of a good thing.

When more aggressive compression hammers the dynamic range the resulting audio product becomes grunge music or punk rock. Gone are the normal soft passages in music, and normal voice migrates to a stream of shouted commands. Over-compressed audio becomes irritating over a period of time. Some musical notes can actually be lost. If guitar notes and the beats of a kick drum arrive at the input of a compressor at the same time, the compression required to tame the kick drum will drop the level of the guitar so much that some notes will not be heard.

Limiters

Take everything that you just learned about compressors and apply a 20:1 compression ratio; now you have a peak limiter. The limiter fits in the program chain just ahead of the transmitter (the stereo generator for FM). The limiter provides a brick wall for any overshoots which the compressor misses. Its sole purpose is to prevent overmodulation of the transmitter.

Limiters used for FM broadcast in the United States include the 75 msec preemphasis curve that boosts the high frequencies. Some countries outside the United States use other preemphasis curves; check the local standards. FM limiters operate symmetrically; positive and negative peaks receive equal limiting. AM limiters operate asymmetrically. They clamp their negative peaks at 100% modulation while allowing positive peaks to shoot upward to 125%. This maximizes the modulation and output power of the AM transmitter. AM limiters also include the NRSC preemphasis curve and 10 kHz low-pass filter. C-QUAM, AM stereo processing, usually requires an optional circuit board.

Most engineers locate the peak limiter at the transmitter site, feeding its input from the STL output. Leaving the compressor at the studio end maximizes the modulation capabilities of a 950 MHz STL.

AGC/Levelers

A novice may confuse an automatic gain control (AGC) amplifier with a compressor. The AGC/leveler is not an audio processing device. It will not reduce the dynamic range or limit loud audio peaks. The AGC amplifier insures that the compressor and limiter receive constant input levels.

The AGC operates like a compressor when a signal above its target output range appears at the input. In this case the AGC amplifier gently pulls the signal level down to the target output level. It is operating like a compressor set with a 2:1 ratio and a slow, two minute release time.

The AGC amplifier reacts differently when the input signal falls below the target output level. Now it turns up the gain of the low-level signal bringing it slowly up to the target output range.

AGC/levelers provide a safety net for sloppy board operation, the times when the meters remain buried in the red for minutes at a time. Stations employing walk-away operations, where no one sits at the console correcting levels as the automation system switches between sources, benefit greatly from the processing consistency created by an AGC amplifier.

Equalization

Engineers work nights in anguish maintaining audio frequency response as flat or linear as possible. Program directors toil overtime in anguish producing a signature sound for the station. The two professionals collide at the equalizer. In the audio processing chain, creative use of an equalizer gives character to the station's audio. In production, an equalizer routinely cleans hum and hiss from noisy tapes. The production director also creates special effects and unique voice tracks with the help of an equalizer.

Low frequencies can be boosted to produce a heavy thumping bass and the upper mid-range can be boosted to add brightness. Enhancement of the highs and lows with an equalizer satisfies the desire to make your station sound better to the average non-technical listener than the station across town. Table 3.5-2 matches the audio ranges and qualities with the knobs on your equalizer.

Equalizers come in two types. The best known, the *graphic equalizer,* divides the audio spectrum into a series of bands represented by rotary or slider controls on the front panel. The operator adjusts the controls to affect gain in each particular band. The graphic

Table 3.5-2
Common Audio Frequency Classifications

Range	Audio Frequencies
Sub-Bass	15 Hz–65 Hz
Bass	65 Hz–256 Hz
Voice	256 Hz–2048 Hz
Upper-Vocal	2048 Hz–3750 Hz
Presence	3750 Hz–5000 Hz
Sibilance	6000 Hz–7000 Hz
Brilliance	6500 Hz–15 kHz

to-reel recorders. One large system offers simultaneous access to program audio by seven studios. Digital audio storage systems remove the classification cart librarian from the on-air talent's job description.

Digital Editing and Work Stations

The digital audio workstation benefits the broadcast station with faster and more creative production, using a process quite similar to the way word processors edit written text. Digital workstation systems store multiple audio tracks on hard disk and allow editing in random access memory (RAM). Two or more analog input channels (through A/D converters) and direct digital inputs receive the incoming audio. Options allow analog or digital outputs. They allow editing tracks individually and produce a finished product by using keyboard and scrub wheel rather than grease pencil and razor blade. The audio waveform of each track crawls across a screen allowing visual as well as audible cueing and editing.

To produce a spot with a digital audio workstation, the operator records the audio tracks and music beds in the system memory, commands the workstation to move component sounds, adjusts timing, edits tracks and finally completes a stereo mix. Unlike razor blade editing with analog tape, the software process preserves the original material. Correcting mistakes and editing experiments become child's play with the undo key found on most editors.

Workstation editors most closely emulating the operation of a reel-to-reel recorder get production work flowing quickly with minimal training time. An accurate scrub wheel operation speeds the work of a producer tightening loose voice tracks and other tricky edits. Look for scrub audio that sounds exactly like that heard when manually rocking tape back and forth across the playback head of an analog tape deck.

A good display shows the audio waveform of all tracks on the screen simultaneously. Most editors show a vertical cursor line that moves across a stationary audio waveform as the editor reproduces the audio. This display mode consumes less computer resources than a system that shows the audio waveform crawling across a stationary cursor because the screen is not continually refreshed. Some audio producers favor a display that depicts the waveform moving across a stationary cursor as the screen more accurately represents the operation of a reel-to-reel machine where the tape travels left to right across the stationary playback head.

Creative engineers can assemble a two-track audio workstation with a Pentium PC, a good sound card and editing software. The system should include as large a hard drive as possible; the source material plus overhead consumes about 12 mB per minute for stereo audio. Some audio clips will certainly be archived on the hard disk so it is very important to get the largest one possible. More elaborate systems include mixing capabilities providing an all-in-one approach for production work.

AUDIO PROCESSING EQUIPMENT

The difference between the loudest sound and the quietest equals the dynamic range. Audio compressors take large, rapidly rising audio voltages and make medium-sized, slowly rising audio voltages. The goal remains simple; reduce the dynamic range and increase the average modulation level of the transmitter.

If the output of a CD player was directly connected to the audio inputs of a transmitter the wide dynamic range would prevent the average modulation from reaching more than 50 to 60%. The station would disappear from the band among those processing their audio by today's aggressive standards. An AM station operating in this manner would sacrifice a part of its coverage area. An audio compressor reduces the dynamic range to a more practical spread and holds the modulation level at a much higher value.

Here's how it works. A threshold control defines the point where the compressor starts to attack a rising audio voltage. If the compressor's threshold control instructs it to attack a voltage at −20 dB, the compressor will attempt to hold down a rising audio signal after it rises above the −20 dB level. A signal below −20 dB will pass through the compressor unscathed.

Once the audio passes the threshold (−20 dB), the ratio control instructs the compressor how serious it is about restricting the level of the audio voltage. A ratio of five to one (5:1), limits an audio signal which has risen five decibels to an increase of only one decibel at the compressor output. Using this example an input signal of −20 dB would appear at the compressor output at −20 dB; no compression would take place. An input signal of −15 dB (5 dB higher), would show up at the output at a level of −19 dB. (1 dB higher).

Low ratios induce less compression for any given input above the threshold. When the user increases the ratio, the compressor aggressively attacks the dynamic range of the source material. The threshold presents more of a "brick wall" to the incoming audio as the operator dials in ratios of 10:1 and higher. Premium quality compressors offer two thresholds with an independent ratio control attached to each threshold.

This type of compressor moderately squeezes a rising signal of low level as it crosses the first threshold level. Should the signal continue to rise above the second threshold, more aggressive compression attacks the signal. A compression ratio of 20:1 used above the second threshold provides the peak-limiting required to properly modulate a transmitter.

The compressor's *knee* is the point where the incoming audio signal rises above the threshold and the compression action begins. A *hard-knee compressor* engages the compression precisely at the exact threshold value with the exact ratio. A good ear hears the full amount of processing kick in as the signal rises above the threshold. If the compressor smoothes the transition with a gradual, rounded transition point at the threshold, the processing action engages slowly over about a 6 dB range. The transition into processing

System designers greatly increase the storage capacity of hard disks by using the bit rate reduction techniques of ISO/MPEG, Audio Processing Technology's apt-X, Musicam, the international telephone ITU G.722 Standard, Dolby's AC-2 or AC-3. Bit rate reduction, or audio data compression, allows six gallons of audio to be stored in a one gallon audio bucket. Without bit rate reduction one minute of stereo audio consumes about 10 mB of hard drive space. With a 4:1 bit rate reduction the same 10 mB could store four minutes of audio.

Early algorithms accomplished bit rate reduction by transmitting only the difference between samples. These systems gained a 2:1 reduction in digital data, but were non-destructive. The algorithm restored the original audio signal when decoded.

Lossy bit rate reduction discards bits not needed because the human ear would not hear the sound reproduced by the bit when played back. The sound would either be too low in volume to be heard, or covered up by a louder sound. Digital audio compressed in this manner, when converted back to analog, produces an audio signal almost indistinguishable from the original to the critical ear. This destructive process changes the source audio forever. Once compressed, the exact original audio can never be recovered. Huge gains in storage space and transmission bandwidth requirements justify the use of these algorithms.

The Moving Pictures Experts Group (MPEG) compression algorithm is the audio portion of a video compression system standardized by the International Standards Organization (ISO). The fact that it is accepted worldwide and is attached to a video compression scheme ensure that it will be with us for a long time. MPEG offers three levels of signal quality identified as Audio Layers I, II, and III. The complexity of the system, including hardware, and quality of the audio improves with each advancing layer. Audio Layer I provides transparent 20 kHz audio quality at a compression ratio of 4:1. Audio Layer II achieves the same results but at a ratio of 6:1. Audio Layer III operates as high as 24:1.

Musicam USA's compression system is compatible with MPEG Audio Layer II. Musicam chops the 20 kHz audio spectrum into bands of 750 kHz. It then discards any unnecessary bits in each band. The Musicam system represents a compromise between transparent recreation of compressed audio and complexity of the processing algorithm. Processing delays increase with complexity of any system's algorithm.

Bit rate reduction serves to allow digitized audio transmission over limited bandwidth mediums. Early digital STL systems used bit rate reduction to squeeze two channels of 15 kHz audio and remote control data into the 500 kHz bandwidths of the 950 MHz spectrum. Remember that bit rate reduction algorithms throw away part of the digitized audio, preventing further audio processing. All audio compression and limiting must happen before the program audio passes through a digital STL that uses bit rate reduction. There are, however, some digital STL systems that do not use audio compression algorithms. Such systems do permit audio processing to occur at the transmitter site, if desired.

T1 digital telephone systems offer enough bandwidth to allow uncompressed audio to reach the transmitter. A T1 STL system offers flexibility in the location of audio processors. Multi-band compression may be applied at the studio and final limiting accomplished at the transmitter site. T1 systems also solve the problem of the congested 950 MHz spectrum.

Digital Audio Storage Systems

Digital audio storage is the most rapidly developing technology in the broadcast audio field. Its acceptance by the industry became apparent in December 1995 when Ampex and 3M announced their exit from the magnetic tape business. The magnitude of this development becomes evident after considering that Ampex pioneered magnetic tape recording in the United States. Digital recording mediums now include: magnetic tape, hard-drives, high density floppy disks and magnetooptical disks.

Designed for the consumer market, the rotating head digital audio tape (DAT) machine became widely accepted by broadcasters. This format uses a rotating head much like a video cassette recorder (VCR), and records on a cartridge tape. DAT cartridges offer recording times of 60, 90, and 120 minutes. Professional models feature fast cueing, instant starts, remote control and time-code compatibility. DAT machines offer broadcasters the ability to record live events, concerts, and network feeds in the digital domain without increasing noise and sacrificing dynamic range.

Stations using multi-track consoles for production work may take advantage of eight-track DAT recorders. Like their smaller cousins, the eight-track models use a rotating head but they record on VHS video tape cartridges. These DAT recorders excel in recording live concerts and storing multi-track production work.

Smaller facilities may opt for the digital cart machines coming on the market. These record to super high-density floppy disks, mini-disks or magnetooptical disks. They offer the advantages of low-noise digital audio reproduction, elimination of head alignment woes and maintenance associated with analog cart machines. However, the disk jockey still has to sort and slam plastic devices into slots and pushing start buttons.

If you plan a transition to digital, why require talent to handle the storage medium at all? Digital audio storage systems using hard drives as the storage medium threaten to oust cart machines and carts, of all types from the control room. Hard drive systems now offer the capability to store and play all of the station's commercial library plus its program material. Mirrored hard drives, (multiple hard drives containing the same information) provide the necessary crash protection. The systems can automatically record network feeds for delayed broadcast, eliminating the need for reel-

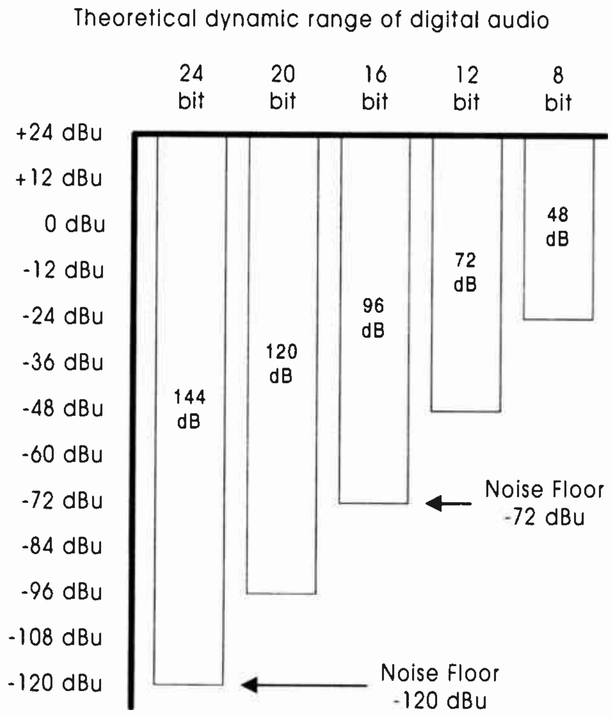

Figure 3.5-7. Higher quantization rates (bit rates) result in a wider dynamic range for digital audio. 24 bit audio provides a theoretical dynamic range of 144 dB for a 48 dB improvement over 16 bit audio. This also means a 48 dB lower noise floor.

An increase in dynamic range means a lower noise floor. Note the 48 dB reduction in the noise floor when comparing 16 bit digital audio with a 24 bit signal. Assuming a clip level of +24 dBu, 16 bit digital audio equipment can theoretically reproduce a minimum signal level of −72 dB. 20 bit digital audio has the potential of reproducing a minimum signal of −120 dBu. Figure 3.5-7 illustrates the difference in possible dynamic range between 24 bit, 20 bit and 16 bit digital audio.

AES3 standardizes sample rates of 32.0, 44.1 and 48.0 kHz. The digital recording process limits the maximum recordable audio frequency to one-half of the sample rate. Why? Each cycle of a sine wave must be sampled at least twice during a cycle. If not sampled once during its positive peak and once on its negative peak, the sound cannot be accurately sampled and converted to digital audio.

A sample rate of 44.1 kHz permits audio bandwidth up to 22 kHz. The sample rate of 48.0 kHz pushes the upper limit to 24 kHz. Equipment using a 32.0 kHz sample rate chokes off the audio at 16 kHz, but consumes less bandwidth and/or hard disk space.

Today, the existence of three sample rates hinders digital broadcasting. Compact discs came out of the gate with the sample rate of 44.1 kHz. This single standard sample rate crossed all brand names and entrenched itself as *the* sample rate for CD work. Recording studios adopted the sample rate of 48.0 kHz in an effort to achieve better fidelity. Digital audio workstation and digital audio storage equipment manufacturers shifted downward to 32.0 kHz to conserve disk space since FM radio only passes 15 kHz of audio bandwidth.

As digital audio consoles become more common in the control room, the engineer wishing to go completely digital in the studio has a problem. It is not possible to combine digital audio of different sample rates even though all of the sources adhere to the AES/EBU Standard. Somewhere in the studio system sample rate conversion must take place. The 44.1 kHz sample rate of the CD must switch to the 48.0 kHz sample rate of the console which must convert to the 32.0 kHz sample rate of the digital STL.

One console manufacturer offers input modules that match the sample rate of input audio to that of the console. Their solution to the problem is sample rate conversion on each input. A standard sample rate for all broadcast applications offers a better solution; but we are not there yet. Careful planning during equipment selection remains the best defense for minimizing potential problems.

Even after the sample rate issues are worked out, one more problem surfaces when a digital console arrives in the on-air studio. When mixing two digital audio sources of the same sample rate, their clocks must be synchronized. Suppose one digital audio source runs at 48,000.00 Hz and you mix it with a second signal running at 48,000.02 Hz. If the internal clocks run separately, digital train wrecks occur.

The results pollute the combined audio with clicks and pops. A digital master clock provides a workable solution. A single timing signal connected to all digital audio equipment in the station synchronizes everything in frequency as well as phase.

This plan works when all digital equipment in the studio offers clock input connections. Be aware, however, that not all digital equipment is designed with this feature. Older digital equipment featured a *word clock* that ran at the sample rate. Newer equipment locks internal clocks together with the AES Standard *Digital Audio Reference Signal* (DARS) which is an AES3 digital signal without audio. Check your digital equipment manuals to verify which systems will operate in your facility.

Three more pieces of the AES/EBU puzzle remain. The first bit of the digital signal indicates whether the output signal originates from *consumer equipment* or *professional gear*. If the first bit of the first 8 bit word is a 0, the source audio is from consumer equipment. Professional equipment is identified with a 1. Many professional recorders will not accept a signal from semi-pro equipment.

Digital audio may also include a consumer copyright protection bit. The Serial Copy Management System (SCMS) prevents illegal digital copying. Digital audio also includes a parity check-sum for the channel status data. The cyclic redundancy check (CRC) error light on your recorder may indicate a problem with your recording configuration.

POTS Codecs

The compression algorithms discussed previously were designed for use on Switched 56 or ISDN lines, which have a guaranteed data rate of 56 or 64/128 kbps. Standard analog Plain Old Telephone Service (POTS) provide varying data rates depending on line quality. Telephone modems are designed to scale the transmitted and received data rate accordingly. This sliding data rate makes it very difficult to use compression algorithms that were designed for specific transmission speeds.

In the last couple of years new technologies have emerged that permit the transmission of compressed audio over POTS, thus delivering a bandwidth much higher than the 3 kHz signal normally available. POTS codecs use high speed modems (33.6 kbps as of this writing) and compression rates in the 12:1 range to deliver audio bandwidths varying from 5–10 kHz, depending on the connection speed of the modems.

There is an important difference between audio sent by POTS codecs and audio sent via computer or the Internet. Computers use asynchronous modems, which means they send a packet of information, wait for confirmation that the packet was received, then go on to the next packet. For one-way delivery of audio that has been stored at a site, this method of transmission is not a problem. However, asynchronous modems must use a buffer to reconstruct the audio. This creates a delay large enough that two-way communication with the studio is simply not possible over the single telephone line used for the remote. For real time bi-directional remotes, most POTS codecs use synchronous modems. With a synchronous modem, a bit is transmitted, and without waiting for verification of receipt, the modem goes on to the next bit. This constant data stream in both directions results in audio that is delayed only by the compression algorithm used. The modems go through a complex *handshaking* process to determine the best data rate for transmission in order to minimize errors caused by lost bits.

DIGITAL AUDIO SYSTEMS

The Audio Engineering Society and European Broadcasting Union (AES/EBU) standards provide a benchmark for digital inputs and outputs. Fortunately, these standards provide a common denominator found on all professional equipment. AES/EBU, also known as AES3, created a balanced system that can transmit digital stereo audio up to 100 meters over a single shielded, twisted-pair wire. AES/EBU calls for internal transformer coupling, with dc blocking capacitors, on both input and output circuits. The circuit is designed for shielded audio cable with an impedance of 110 Ω.

Any digital input protocol must match the digital output of the source. AES3 provides assurance that any two pieces of equipment using this standard will work together.

The AES3-1992 Standard specifies a nominal signal voltage between 2 V and 7 V measured across a 110 Ω terminating resistor. An earlier standard (1985) allowed a 2 V to 10 V range. No compatibility problems exist between the 1985 and 1992 standards.

AES3 specifies connections using the familiar XLR three-pin audio connectors. Pins #2 and #3 carry the digital signal. Pin #1 is ground. This convention is exactly the same as used in wiring XLR connectors for microphone or balanced line-level audio. The connectors remain the same, but the wire does not.

Miniature broadcast audio cable (Belden 8451 or West Penn 291) does not meet the 110 Ω impedance specification. Remember, digital audio is actually computer data that runs at a rate of 64 Hz times the sample rate. Digital audio, sampling at a rate of 48 kHz, becomes a data stream running at 3.072 Mbps (64 Hz × 48 kHz = 3.072 MHz). Cable capacitance can rapidly degrade the 3 MHz signal. Belden, Gepco, Clark Wire & Cable and other cable manufacturers, offer low-capacitance, 110 Ω, digital audio cable that accomplish a satisfactory job of transferring the digital audio signal for the AES3 specified distance of 100 m (328 ft).

The need to transport digital audio further that 100 m resulted in a new standard using unbalanced coaxial cable. AES-3id-1995 allows transmission of a 1 V digital audio signal up to 1000 m (3280 ft). Considering the 3 MHz frequency of digital audio, 75 Ω coaxial cable makes a lot of sense. No knowledgeable engineer would suggest conducting a 3 MHz RF signal over twisted-pair audio cable. AES-3id calls for RG6A/U, or RG59B/U, cable with BNC connectors.

Television and video production facilities rapidly embraced this new standard. AES-3id not only allows for longer cable lengths, but permits the use of 75 Ω cable, terminated with BNC connectors, for both video and digital audio signals. You can expect the radio and studio engineers to retain AES3 and their trusty XLR connectors.

Sony and Phillips developed the Sony/Phillips Digital Interface Format (S/P DIF) a standard for consumer grade equipment. S/P DIF defines an unbalanced digital connection. S/P DIF and AES3 signals do not mix in all cases. An AES/EBU input will accept a S/P DIF output, but a S/P DIF input will not accept an AES/EBU output without an interface to correct the differences in the data formats and wiring.

S/P DIF specifies the old RCA phono pin connector. A 75 Ω coax works well as the conductor. The problem of yet another connector and cable type in the studio proves reason enough to standardize on AES3 digital equipment in the station.

The AES/EBU (AES3) Standard supports 16, 20 or 24 bit quantization formats. In theory, the 16 bit audio of a CD can communicate up to 96 dB of amplitude change (6 dB × 16 bits = 96 dB). 24 bit digital audio can reproduce a theoretical dynamic range of 144 dB (6 dB × 24 bits = 144 dB). In the real world, digital audio equipment achieves performance less than theoretically possible. 16 bit typically renders 90 dB of dynamic range due to the limitations of the analog to digital converters and digital to analog converters.

one or two of the on-air staff with a van full of prizes, amps, speakers and a microphone to Big Al's Used Car Lot. The primary concern is to transmit the voices of the talent from Big Al's back to the radio station with reasonable quality. The dial-up telephone network provides a cheap and easy solution.

The output of a simple microphone mixer, or small audio console, connected to a telephone line coupler provides the basis for the most elementary remote system. The person doing the remote calls the station, is connected to the control room console via the station's telephone hybrid, and monitors the off-air signal for cues. This system is easy to set up and operate but the dial-up phone system limits the audio quality. The telephone system, designed only to transmit voice from one telephone to another, limits the bandwidth to a range of 300–3200 Hz. The expensive air talent at the remote from Big Al's *sounds* like they called in on a telephone.

Telephone Frequency Extenders

The problem with using the dial-up telephone system for delivering broadcast audio is the limited frequency response. The fact that the telephone system rolls off all audio below 300 Hz costs 2.5 octaves of audio on the low end (50 Hz to 300 Hz). This tends to produce the tinny characteristic which makes unprocessed, dial-up, telephone remotes sound bad when compared to the full spectrum audio of regular programming. However, there is a solution.

Analog telephone frequency extenders trick the telephone system into passing audio with a bandwidth of 50–2900 Hz. An encoder-decoder process shifts audio frequencies upward by 250 Hz, sends the up-shifted audio over the phone line, then returns the audio to its normal frequencies on the receive end. The encoder travels to the location of the remote broadcast and serves the double duty of shifting the audio up by 250 Hz plus connecting the remote mixer to the dial-up telephone network. Most include telephone touchpads for dialing.

The encoder converts 50 Hz audio upward by 250 Hz to a frequency of 300 Hz. Audio at its natural frequency of 2950 Hz exits the encoder at a frequency of 3200 Hz which barely squeezes through the limited bandwidth of the phone system. The output of the frequency extender encoder sounds quite strange. Even the lowest baritone voice sounds like Donald Duck. Obviously, reverse treatment is required on the receiving end.

The frequency extender system's decoder shifts the audio which it receives down by 250 Hz, restoring it to the original frequencies. The analog frequency extension process delivers an audio bandwidth of 50–2950 Hz. The result is very pleasing voice transmission over a dial-up telephone circuit. The process sacrifices 1/7 of an octave between 2950 and 3200 Hz, but it restores 2.5 octaves between 50 and 300 Hz.

The system suffers from two disadvantages, First, analog frequency extension is a one-way system. When the remote is out of the range of the broadcast station's signal, a second telephone line is required for talkback and cueing. Second, compatible equipment is required on each end. A station in New York cannot send frequency extended audio to a station in Los Angeles unless both have identical equipment.

Digital Audio Codecs

The computer age has brought another means of transferring high-fidelity audio from one point to another. Broadcasters can now digitize the source audio, apply data compression techniques and send the audio over telephone lines via modems. Because computer modems operate bi-directionally, two-way audio communication can be achieved over a single phone line.

In brief, a digital audio codec (coder/decoder) consists of an analog-to-digital converter, a digital-to-analog converter, a modem and data compression software bundled into a single package. The modem is designed for Switched 56, ISDN or dial-up lines. Switched 56 service provides data transfer at a rate of 56 kbps. ISDN doubles the speed to 128 kbps.

Dial-up lines limit data transfer to no more than about 53 kbps on average and data rates will vary from line to line, with weather, and with telephone traffic conditions. 56 kb computer modems do not always connect at a speed of 56 kbps. Switched 56 and ISDN service are consistent. The trade-off for less audio bandwidth brings the ease of connection to any existing telephone line without extra line charges and construction delays. Four-hour commercial remotes make the use of a dial-up line an easy decision. Coverage of a week-long special event may justify the expense of an ISDN line.

Systems designed for Switched 56 lines provide a 7.0 kHz, bi-directional, audio circuit. ISDN service doubles the bandwidth to 14 kHz, or allows stereo 7.0 kHz audio transmission. Improvements in modem speed and technology now challenge these premium services with bi-directional audio bandwidth of up to 10 kHz over dial-up telephone lines. The program audio bandwidth capability not only depends upon the bandwidth of the telephone circuit, but with the data compression algorithm used in the codec.

The audio compression (data reduction) algorithms most frequently employed with Switched 56 and ISDN lines include ISO MPEG Layer II, ISO MPEG Layer III, apt-X, Musicam United States or the international telephone standard ITU G.722 (formerly, CCITT G.722). The rules of compatibility dictate that the codec on each end of the telephone line use the same algorithm. MPEG Layer III will operate with a Layer II device, but performance is limited to Layer II levels. MPEG is not compatible with ITU G.722. Likewise, apt-X only talks with apt-X. Musicam USA will converse with MPEG Layer II.

ITU G.722 introduces a minimal delay making it the most popular algorithm for talk shows and live remotes. Stations often find themselves using their top-of-the-line codecs in the ITU G.722 mode.

audio is canceled out by the out-of-phase wiring of secondaries #2. This leaves, in theory, only the receive audio, the caller's voice, on the primary of T2.

If the phone line exhibited a perfect 900 Ω resistive load, a 900 Ω resistor at the location of the equalization network would produce a perfect match. Telephone lines, however, do not represent a perfect world. Capacitance creeps into the mix because the phone company uses miles of #24 gauge twisted pair to connect to their central office. That much twisted wire forms a nice capacitor. The resistance of the circuit varies with the length of all that #24 gauge wire running back to the phone company. Loading coils, used in the telephone circuits to flatten frequency response add the inductance.

We connect our hybrid to what amounts to a RCL network when we plug into the phone line. The null created by the out-of-phase circuit created by the #2 secondaries no longer matches the amount of transmit audio induced into T2 through its #1 secondary. A tunable equalization network wired between the #2 secondaries compensates for the electrical characteristics of the phone line circuit. When improperly tuned, audible amounts of out-of-phase host audio mixes with the caller's voice making the host sound hollow. The hybrid circuit may cascade into feedback in extreme cases of mismatch.

An analog phone hybrid must be tuned for best performance for each phone line to which it will connect. The process involves transmitting pink noise during a call to an outside phone number then tuning the equalization network for a minimum level of pink noise at the hybrid's caller output. Digital phone hybrids accomplish this task with a short pink noise burst at the beginning of each phone call. The result is perfect separation of host and caller audio with excellent sounding talk show audio.

Telephone hybrid systems package multiple hybrids with call switching functions. The combined systems eliminate the challenge of building a talk show phone system from scratch with equipment from several manufacturers. Taking a system approach also solves the problem of creating multiple mix-minus feeds when using multiple hybrids to conference callers on the air. Time saved during installation usually justifies any extra cost of a combined hybrid and call switching system.

Broadcast Delay Units

Radio talk shows can be hazardous to a station's liability insurance. The spontaneity of a good talk show assure, that callers can, and will, say anything. This prompts the need for a system that allows time to pull the plug before certain words, or accusations, pass through the transmitter.

Before digital technology accomplished this task with no moving parts, there was tape. Tape delay systems employed a special cart machine with an erase head. A ten-second cart was inserted in the recorder. Real-time audio was recorded on the tape. It took ten seconds while the tape looped through the cart before reaching the playback head. The output audio emerged from the recorder ten seconds after it was recorded allowing time for the talk show producer to interrupt the delayed audio containing a profanity.

Simple digital delays perform this task without the worries of moving parts and broken tape. The device simply converts audio to a digital signal, records it in memory, then plays it back ten seconds later. The talk show producer mixes the program in the console's audition channel which feeds the input of the digital delay. The output of the delay routes to the program channel of the console and to the transmitter.

If things go wrong, the producer turns off the mixer carrying the delayed audio to the program channel and inserts fill music. The option also exists of switching the show host from the audition channel to the program channel after dropping the caller. The host then resumes the program in real-time.

Both tape delay and fixed-time digital delays pose the problem of transition in and out of delay. If the show host simply starts talking at the beginning of the program, their words will not exit the delay system until ten seconds later. Meanwhile, the audience is treated to ten seconds of silence. Most stations overcome this by playing a ten-second recorded introduction to the show on the program channel as the show host begins talking on the audition channel. The host's voice exits the delay precisely as the recorded message ends. If timed properly the transition is seamless.

A better approach to the problem of keeping talk show audio respectable is the digital delay unit that gradually builds the delay at the start of the program. This delay digitally records the real-time audio into memory and while it is building the delay time, it plays back the program audio slightly slower than it is being recorded. This process gradually fills the memory until the delay time reaches the maximum. After the memory fills, this delay operates just like the fixed-time delay; the audio appears at the output ten seconds after it is received at the input.

If the caller says something offensive, the host pushes a *dump* button which erases all, or part, of the audio in memory. Since the profanity was stored in memory, it disappears when the dump button is pushed. The program now is on the air in real-time and the delay begins the process of rebuilding the delay time again. After about a minute the host has enough delay in memory to begin taking callers on the air again.

This type of delay allows easy return to real-time at the end of the talk program. A few minutes before the show ends, the producer puts the delay in the *exit* mode. Now the delay records the program, but it plays back slightly faster than it is recording. This eventually depletes the audio stored in memory and the program returns to real-time. The best of these delays feature a relay bypass which takes the delay off-line when it is not in delay, or if it fails.

AUDIO REMOTE SYSTEMS

One of the most profitable activities for a radio station is the commercial remote. This consists of packing off

Reel-to-reel recorders operate by mixing the incoming audio with a high-frequency ac bias signal of fixed level and frequency. This combined signal magnetizes the tiny ferric oxide particles attached to the plastic tape as it moves past the record head. During playback, the play head converts the magnetic fields stored on the recorded tape to an audio voltage sonically equal to the signal originally recorded.

The bias signal assures that the record head creates a magnetic field sufficient to fully penetrate the ferric oxide portion of the audio tape. The frequency of the bias signal must be supersonic and typically is at least five times the frequency of the highest audio frequency recorded on the tape. The bias signal may be optimized for a particular audio tape by adjusting the bias level to produce minimum harmonic distortion when recording and reproducing a sine wave at a frequency in the range of 2–3 kHz. The operator's manual for the reel-to-reel recorder will contain instruction for optimization of the bias signal.

During playback, an equalization curve applied in the playback preamplifier insures that the reproduced audio produces a mirror image of the audio previously recorded. The equalization curve corrects inaccuracies related to the electrical characteristics of the record head, playback head and speed of the tape as it moves past the heads. Both low frequency and high frequency compensation perfect the playback process.

Proper alignment of both the record and playback heads is very important. Both heads must remain exactly perpendicular to the tape as it moves past them. Incorrect azimuth (side to side) alignment causes poor high frequency reproduction. Stereo recorders exhibit a loss of stereo separation when allowed to drift out of perfect 90° azimuth alignment. Improper zenith (front to back tilt) also contributes to the high frequency reproduction problem.

Professional machines include a third head, an erase head, in the tape recording process. This head uses the bias signal to clear any previously recorded audio from the tape during the recording process. If damaged, or not properly aligned, the erase head will leave remnants of audio beneath the new recording. In extreme cases, the old recording can be heard during silent, or low-level portions of the new recording.

In the radio station control room, the reel-to-reel records news feeds from networks and reporters in the field. FM stations record music requests and contest winners on a reel-to-reel for delayed playback. Some program material still arrives in the station on reel-to-reel tape. A two-track stereo deck with speeds of 7 1/2 IPS (inches per second) and 15 IPS fills the requirements of most control rooms.

Tape reels used to constantly turn in the typical production studio. Tape edit points, marked with a grease pencil, were cut with a razor blade and edited in a splicing block. Tape containing unwanted audio was discarded and the two edit points spliced together. Words were cut out and loose cues tightened using this method. This worked well with mono or two-track stereo formats. Nowadays, however, most radio studios either have already converted, or are in the process of converting to digital audio workstations. In many facilities reel-to-reel equipment is maintained only for backup purposes—or to retrieve archived material.

Telephone Hybrids

In many respects, the network between the telephone company's central office and the home, or business, remains largely the same as it was at the turn of the century. Broadcasters still depend on two copper wires to transfer voices from one place to another.

Both the voice being transmitted and the voice being received mingle back and forth on the same pair of wires. A telephone hybrid converts the two-wire system into a four-wire system which separates the caller's voice from that of the talk show host. Figure 3.5-6 shows the theory behind a telephone hybrid.

In this example, the core of the hybrid consists of two transformers, each having a single primary winding and two secondary windings. The talk show host's voice (transmit audio) feeds to the phone line from the primary of T1 and through secondary #1 of T1. The caller's voice (receive audio) travels from the phone line through secondary #1 of T2, then to the primary winding of T2. Note that the transmit audio also passes, in series, through secondary #1 of T2. This means that the transmit audio appears in T2.

Notice what is happening with secondary #2 on both T1 and T2; they are wired out-of-phase in relation to the first secondary windings. Although the transmit audio is introduced into T2 because secondaries #1 of both transformers are wired in series, the transmit

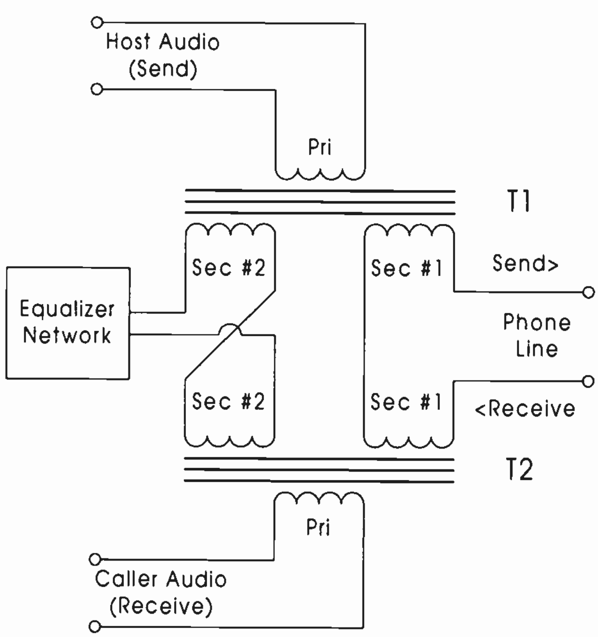

Figure 3.5-6. The telephone hybrid circuit converts the two-wire telephone line into a four-wire circuit. The hybrid creates individual send and receive audio connections separating the caller's voice from that of the host.

read by a laser beam focused on the spinning disc. Since nothing but the laser beam touches the disc, there is no wear.

Selecting the best equipment that the station can afford represents the best cost effective choice. Several manufacturers build CD players designed specifically for broadcast and professional use. If the station must use semi-pro players remember that their design considerations allowed for use in your living room a few hours a week. These consumer grade machines will not last indefinitely when run in a radio station 24 hours a day.

It is good practice to keep two spare (meaning new, unopened, in the box) semi-pro players in the station for quick replacement of a failed machine. Do not attempt to repair a failed consumer grade machine. They can be replaced with less hassle and expense than making repairs.

The output level and impedance of semi-pro CD players are not the same as their broadcast cousins. If your console inputs require +4 dB levels and present 600 Ω loads, use a matching interface. These matching boxes convert the −20 dB, high impedance, unbalanced output of the consumer grade CD player to a +4 dB, 600 Ω, balanced source. Consumer equipment can be difficult to cue and slow to start; evaluate units carefully before you commit to purchasing a quantity.

Turntables

Some unique source material remains available only on vinyl. This author disputed any remaining use of turntables in broadcast applications until the owner of one broadcast equipment manufacturing firm told me that he still sells 40–50 phono preamplifiers a month.

Turntables come in two varieties, the idler wheel design and direct drive. The once common broadcast turntable used a motor which turned at 1,800 RPM driving an idler wheel. The idler wheel in turn drove a large hub at the center of the platter. This design minimized wow and flutter caused by fluctuations in motor speed. The use of a heavy platter achieved further speed stability. Rapid starts necessary for tight cueing required a heavy, powerful motor.

The direct-drive turntable became more popular because of its reduced noise, wow and flutter. There is no idler wheel to replace or bearings to lubricate; the platter is the rotor of these slow turning electronic motors. The speed control circuits of direct-drive turntables constantly monitors and adjusts their speed, keeping it more accurate than if left to line voltage and frequency. Further contributing to the demise of the rim-drive tables, the speed control function made precise speed enhancement of music possible. Circuit repairs may be a problem because of the minimal documentation provided with most direct drive turntables.

No real broadcast tone arms remain; all current models are designed for consumer use. They track well and adjust easily but some prove difficult to cue and are not very rugged. A professional tone arm can be adjusted once and then left alone except for occasional testing. When installing a tone arm, use the template from the turntable manufacturer and follow the instructions supplied with the arm. Set the tracking weight as specified by the cartridge manufacturer.

The choice of the phono cartridge depends on the audio quality required. Rugged, less expensive models give the longest life in on-air use. Moving up to more expensive but less rugged models gains better separation and high frequency response. Avoid consumer grade phono cartridges.

Once mounted out of sight and never seen after installation, the turntable's preamplifier is easily neglected. The important specifications of noise, frequency response and separation need consideration. More expensive models offer filtering, high frequency cut or boost and adjustable cartridge loading.

Another pressing concern for the engineer is the preamp's resistance to radio frequency interference if the studio is co-located with the transmitter. RF easily makes itself known in these high gain amplifiers.

Audio Cart Machines

During the past forty years, cart machines proved invaluable for playing commercials, jingles and music. More importantly, cart machines removed the menace of 3 in. tape reels from the control room. Even stations that rely on digital audio storage systems will keep a few cart machines around as a backup system.

A mono machine utilizes two tracks, the upper track for program material and the lower for cueing. Stereo versions use three audio tracks on the endless loop of tape. Two of the tracks record stereo audio, the third carries cue tones. Trading recorded carts between mono and stereo players will not work because the tracks do not line up.

A brief 1000 Hz tone is recorded on the cue track at the beginning of the cart recording process. When the cart recorder is in the record mode, pushing the start button generates the 1000 Hz *stop tone* and begins the recording process. After the tape loop cycles through the cart and returns to the starting point, the playback head detects the 1000 Hz stop tone and stops the tape at the beginning of the recorded program material.

Most machines offer secondary and tertiary tones for cueing and starting the next tape. The secondary, or *aux tone*, is at 150 Hz tone and customarily triggers the next event in the program sequence of automation systems. The *tertiary tone* is an 8 kHz tone and triggers a cue light to warn air talent as the program material nears its end. The operator manually inserts the secondary and tertiary tones as the cart is recorded.

Although still a dependable and reasonably good storage medium for commercials and music, digital audio storage systems have moved essentially the cart machine out of the radio business.

Reel-To-Reel Tape Recorders

The reel-to-reel still remains a workhorse in some stations. Tape provides an economical means for storing longer program material without filling the hard drive of the station's digital audio storage system.

bility of a routing switcher provides the only practical solution when many audio sources must be switched frequently such as in a busy TV control room.

Size determines the cost of a routing switcher. A stereo switcher with 12 inputs and 12 outputs contains 288 cross-points (12 inputs × 12 outputs × 2 audio channels = 288). Visualize the switcher as two side-by-side matrices of 12 horizontal lines (inputs) intersected by 12 vertical lines (outputs). Each intersection becomes a possible connection point. One matrix represents left channel audio; the other represents the right channel.

In a television station, engineers must decide whether individual switchers handle left, right, mono, SAP, or if one large system routes all signals and audio. With the larger system approach, mono sources connect directly into left and right channels. The switcher may correct channel reversals and create mono mixes. A switcher with sufficient cross points to handle all switching tasks requires a larger investment than several smaller ones assigned to individual channels. The station planning for DTV is looking at a major investment in routing for the system's six channels of audio.

Distribution Amplifiers

When distributing audio to a number of locations on a continuous basis (without switching), a distribution amplifier (DA) proves invaluable. Sending a console's output to several recorders and other studios, or routing a satellite receiver's feed to all studios assure the distribution amplifier an important role in audio routing. A DA eliminates the need for constant patching and switching of various pieces of equipment. Distribution amplifiers represent the only practical solution when audio must be fed in multiple directions on a constant basis.

The typical DA provides six to eight stereo outputs for each channel. While there may be no input level adjustment, economical units should provide individual output trim pots. Modular distribution systems offer more versatility and avoid wasted, unused outputs. One model offers four stereo inputs, which can be assignable to any of its 14 stereo outputs by the use of jumpers. Popular DA options include metering, input level adjustment, audio compression, loss-of-signal alarms and redundant power supplies.

Studio Monitors

The control room audio monitoring system provides the first line of defense in spotting equipment failures and problems. For that reason, professional monitor speakers should be selected.

In choosing monitors, room size dictates cabinet size. In a large studio, invest in monitors with 12 in. woofers, 5 in. mid-range cones and horn or dome tweeters. Buy the best your budget will allow. Size limits small studios to a model with 5 or 6 in. woofers. Current speaker technology offers amazingly good sound quality from small cabinets. Look for low distortion and flat response.

A meticulous studio designer will consider background noise sources, reverberation time of the room, interaction from walls and ceiling and room equalization. Doing this properly means testing the control room with a real-time analyzer and positioning the monitors for best results. This is seldom practical.

When mounting the monitors on walls, use suspension mounts, preferably with vibration isolating components. Position each monitor an equal distance from the operator's normal position. Use sound proofing material on as much of the flat wall surfaces in the room as possible.

In small studios, *near-field* monitoring provides the best solution. Position the monitors in a triangular arrangement with equal distances between the monitors and the ears of the operator. Near-field monitoring assures that the monitors will be close enough to the listener that the direct audio from the speakers will overpower reflections and any undesirable acoustics of the room. Mounting solutions include a shelf, or wall brackets, above the console, suspension from the ceiling, or floor stands behind the console but directly in front of the operator. Position near-field monitors at, or just above, ear level.

The power amplifier becomes another vital consideration. Space and power requirements limit audio console internal monitor amplifiers to 10 W or less. Noise and distortion specifications may not be as good as those of stand-alone amplifiers.

Matching the power amplifier with the requirements of the monitors means another task in studio design. Pushing a low power amplifier to provide adequate listening levels can cause audio waveform clipping with distortion on peaks. Operating in this manner could damage the speakers. A better choice would be to operate a more powerful amplifier in a conservative manner.

To prevent rock-n-roll DJs from blowing the speaker voice coils with too much power, install fast-blowing fuses in the lines. Experiment with fuse values and listening levels to find the proper combination. Remember to stash a few spare fuses in the control room.

Just as important as amplifier power is the wiring between amplifier and monitors. Use at least #16 AWG for low-power amplifier and speaker combinations. Use heavier wire, up to #12 AWG, for combinations above 100 W or long runs of speaker wire. Consider that the cables from the amplifier, out of the rack, across the ceiling then down to the monitors may use 50 ft of wire even in a small studio. Audio purists insist that the wire length for both speakers remain equal.

AUDIO SOURCES

The CD player has been the audio source of choice in radio for nearly two decades. CD technology encodes audio as digital bits recorded as etched holes on the surface of the disc. A transparent plastic coating protects the surface so that only an accumulation of dirt or scratches affect the playback quality. The bits are rules still apply to these new boards. The only exception is that they pass along a digital signal rather than analog.

Audio Distribution and Routing

There are three basic types of patch panels (jack fields). The tip/sleeve 1/4 in. jack size is the oldest type, consisting of one conductor and one shield. This obsolete design dates back to the early days of radio. The tip/sleeve patch panel requires four single plug cords to patch a balanced stereo connection.

The tip/ring/sleeve 1/4 in. panel remains the most popular patch panel for radio. It offers two shielded conductors per cable. A pair of single-plug cords will complete a stereo circuit. Dual-plug cable assemblies allow the convenience of patching a stereo source with a single cable.

The most useful 1/4 in. patch panel design includes dual rows of 24 jacks. This configuration allows stereo pair spacing. These panels usually group their jacks in pairs with wider spacing between stereo pairs. This spacing technique, when used with a dual plug patch cord, makes it impossible to cross-patch an audio source. Cross-patching occurs when the user inserts the first single patch cord in one audio feed and the second patch cord in the adjacent audio feed on the patch panel. The dual plug will align only in paired jacks; cross-patching becomes impossible with these types of patch panels and dual plug cords.

Patch panel jack numbering follows the following convention: the jack in the top, left corner is identified as jack #1. Counting across and to the right, the last jack on the top row becomes jack #24. Jack #25 falls below jack #1 and is the first jack on the bottom row, starting on the left. Jack #48 is located on the bottom row at the right end and below jack #24. Although patch panels may contain more, or less, than 48 jacks, this numbering system remains the standard for identifying individual jacks.

Quarter inch patch panels also come in single rows of 26 jacks or dual rows of 52. These panels have standard spacing between all jacks and allow an additional stereo circuit on the 26 jack version and two additional stereo circuits on the 52 jack, dual row model.

Special configurations of the 1/4 in. jack field can create very useful designs. One version offers three rows of 26 jacks for a total of 78 jacks on the panel. The wiring scheme of the two lower rows create a conventional dual-row patch panel. Wiring the top row directly to the circuits of the middle row of jacks allows monitoring these equipment output circuits by patching between the top row jacks and the monitor amplifier inputs. Inserting a plug into the top row jacks does not interrupt the normal audio path through the patch panel.

Another custom item is a patch panel with special jacks that not only switch the conductors, but the shield also switches when a patch cord is inserted. Patching microphone circuits requires this seldom-used configuration.

One arrangement features patch panels built into a 19 in. rack mount chassis. The entire assembly mounts into the equipment rack just like the equipment that it connects. The jacks appear on the front of the rack and the rear termination points offer easy access to equipment wiring from the back of the rack. There remains a misconception that this design provides protection from RF. Do not count on it; the phenolic bay fronts provide no shielding of the jacks and some manufacturers even wire these designs with unshielded wire.

Rapidly making its way out of the recording studio and into broadcasting is the bantam or tiny-telephone jack field. These 0.175 in. in diameter plugs and jacks feature the tip/ring/sleeve configuration. The bantam patch panel consumes about half the space that a similar 1/4 in. jack panel would require in an equipment rack. Ninety-six jacks fit in a 1 3/4 in. by 19 in. rack space.

Patch Panel Wiring and Termination

Experienced engineers never connect patch panel jacks directly to equipment inputs and outputs. Termination blocks speed patch panel installation and offer flexibility when making wiring changes. Accepted practice mounts patch panel termination blocks in individual equipment racks, in a group in each studio, or in a central point in the engineering area.

Short jumpers between connections on the termination blocks complete the links between inputs and outputs. This allows wiring changes at a convenient, easy to reach location without pulling new wire between equipment. Terminations used include solder type *Christmas trees*, wire wrap, Type 66 telephone punch blocks or the newer types of punch blocks designed for stranded copper wire.

Christmas trees remain popular with engineers who trust only solder connections. They still serve well in remote trucks because of vibration concerns.

Broadcast engineers have switched to punch-type terminations. A specifically designed tool punches insulated wire into a slotted connector. The wire insulation strips away as the wire pinches into the connection. The process eliminates the soldering task associated with Christmas tree blocks. The "66" block accommodates #22 gauge solid wire used in telephone service. Using only solid #22 wire assures dependable connections. Stranded wire generally works but the stranded conductor may flatten out preventing removal of all insulation. Some strands may also break during the punch-down process.

Audio Routing Switchers

The audio routing switcher offers an alternative to patch panels. This unit accomplishes the same function by switching the audio with relays or solid-state switches rather than by plugs and jacks.

The system eliminates patch cords, can often be operated by remote control and may often route audio to more than one feed at a time. Some of the more elaborate systems feature computer control. The increased flexi-

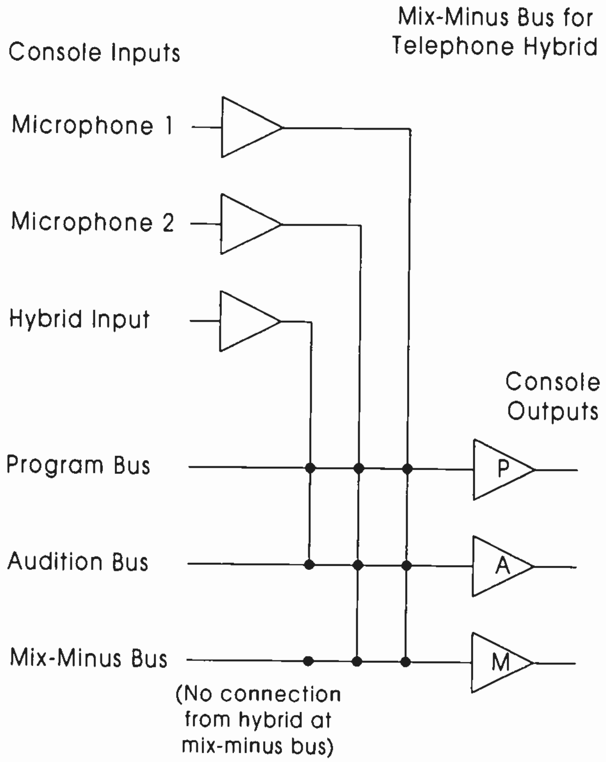

Figure 3.5-5. Broadcast consoles used with telephone hybrids require a mix-minus bus to feed the send input of the telephone hybrid. The mix-minus allows the caller to hear the talk show host's voice (Microphone #1 and Microphone #2) but prevents the caller's audio form being fed back into the hybrid.

1 and Input 2 (announcer microphones) connect to program, audition and mix-minus circuits.

If the studio contains multiple phone hybrids, a mix-minus feed for each hybrid is required so that callers will be able to hear each other's comments. In a television studio, a mix-minus feed provides on-air monitoring for talent on a live set. This feed includes program audio minus the talent's microphone preventing acoustic feedback while allowing the talent to hear program material and cues.

Consoles designed for radio production, and television, contain prefader processing patchpoints. These route the audio source compressors, equalizers or other signal processing devices before arriving at the mixing bus. These processing loops provide convenient connection points for microphone processing units.

Monitor amplifiers may be external or built into the console. Power and space limitations restrict built-in monitor amps to less than 10 W. Many engineers prefer to drive studio monitors with external, higher power amplifiers. The stereo monitor system should contain a stereo/mono switch. This allows the operator to check out-of-phase program material and misaligned tapes. A single-pole, single-throw switch wired between left and right channels at the monitor gain control accomplishes this function. At some stations, the control room monitors routinely operate in the mono mode. This immediately alerts station personnel to out of phase conditions.

A well designed console offers switchable input levels and impedance matching on each input module. This feature allows easy transfer of input sources to different mixers allowing for future changes in the studio. An input amplifier could then be used for either microphone or line level audio. A second best system would have interchangeable mixer input amplifiers which an engineer could shuffle between positions in the console mainframe.

Going one step further, some consoles offer programmable presets for input configuration. The engineer first stores pre-programmed console input settings in memory and then tells the console which program he plans to use. All of the input sources then automatically switch to the proper mixer resulting in fast and accurate setups.

Professional consoles feature balanced, bridging inputs. Bridging audio input circuits used in modern consoles handle a wider variety of input sources than possible when everything was designed with 600 Ω, +4 dBm terminations. A bridging input provides a 10,000 Ω, or greater, termination impedance which provides essentially no load to the source equipment. If an output requires a 600 Ω termination, a 620 Ω resistor tied across the input provides the necessary matching.

Remote start contacts for cart machines and other program sources became standard equipment in the 1980s. They allow the operator to start the equipment by simply turning on the appropriate channel. Some console manufacturers provide more flexibility by using logic circuits that allow the mixer to be turned on by pushing the start button on the cart player. When the cart machine recues the mixer automatically turns off. Look for automatic disabling of this logic when the input selector is switched to another input source. This eliminates the annoyance of having a cart machine start when the mixer is turned on for an auxiliary function.

Console manufacturers offer consoles with a choice of conventional analog VU meters or LED bar-graph metering. LED metering provides multiple color visual monitoring of root mean square (RMS) audio voltage plus peak values. One model shows left, right and peaks a single display. LED displays may make operators less likely to run a board with the meters buried in the red.

Multi-track recorders and digital workstations in the broadcast production environment require consoles with more than a single pair of left and right outputs. Four and eight channel consoles assist in producing award winning production. Channel assignment switches route the audio to the proper bus. Pan pots then shift it between left and right. Equalizers on each mixer allow adjustments to each audio source. Such production consoles resemble those once found only in recording studios.

Digital technology recently spread into the audio console industry in the mid-90s. The basic operating

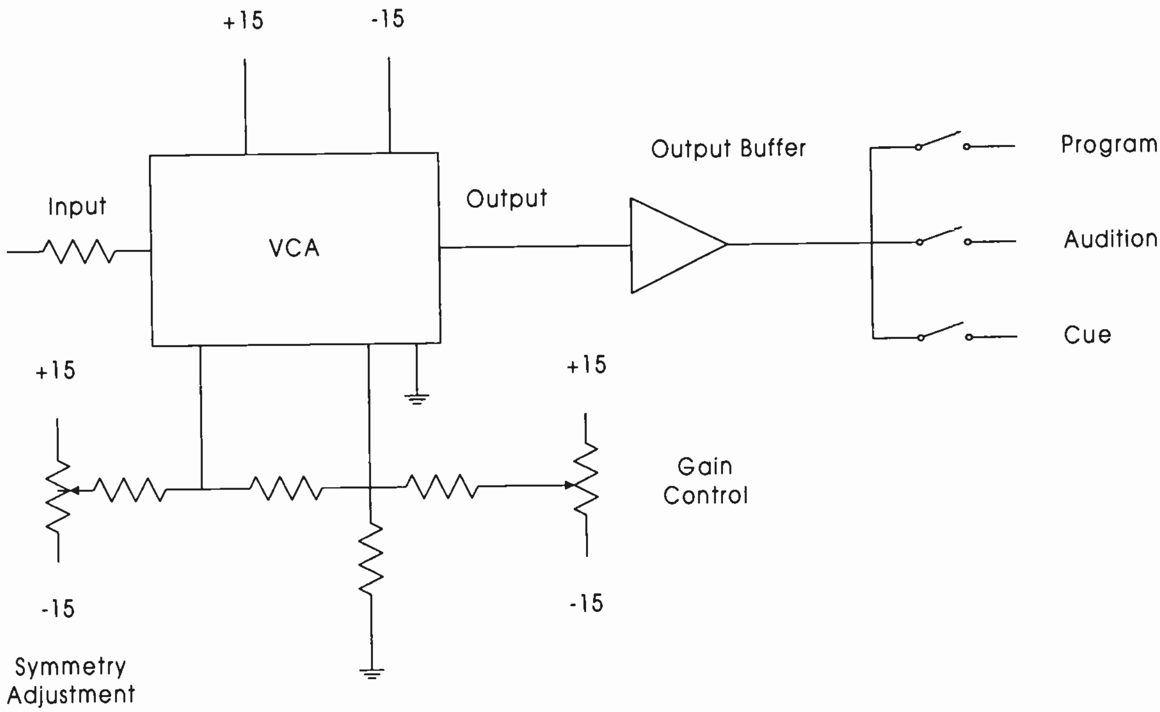

Figure 3.5-4. The voltage controlled amplifier (VCA) allows gain control via an adjustable dc voltage. This circuit is typical of those found in VCA controlled audio mixers.

In the early days of radio all program material was live and the audition channel served as the cue channel. Levels were set and program material was previewed using the audition channel. Today the audition channel records network feeds for later use while the program audio travels the program channels. The audition channel can monitor the audio quality and set levels of remote feeds using the studio monitor system.

Some consoles allow audio from the mixers to feed the program and audition channels simultaneously. This allows recording of on-air programming using the audition channel. In talk formats using fixed-time delay systems, the audition channel mixes the real-time program audio and feeds it to the delay. The output of the delay is brought back in to the console on the program channel, which then feeds the delayed program to the transmitter.

Television Audio Consoles

The requirements of TV audio are *compounded* because more live audio sources come into play (as opposed to radio, where most program material is recorded). In television installations additional monitoring requirements mean multiple output mixes. Television consoles include mono input modules for microphones, telephone hybrids and other mono sources. The inputs offer a gain control or switch to allow stepping between microphone and line-level input. These modules include a pan pot to allow left-right positioning of the apparent audio source. A mode switch may replace the pan pot, enabling selection of normal stereo, left channel only, right channel only, a mono mix or reversed channels. A cue channel feed plus a solo button permits stereo monitoring of a single audio source in the control room monitors. Audio sweetening requirements make equalization on each module a popular option.

The ability to create multiple audio feeds by the use of submaster mixing buses represents the major departure from radio consoles. The operator assigns mixer outputs to submaster buses and these submasters in turn create the master mix. This allows creation of several mix-minus feeds for special monitoring requirements.

Console Features and Options

A growing list of optional equipment available on audio consoles serve both radio and television audio mixing. These make them more user-friendly and provide expanded capabilities. Clocks and timers put timing functions in the immediate field of vision of the board operator. The timer resets to zero anytime that a new channel is selected so the operator will know how long a CD or cart has been running.

A mix-minus, program audio minus the caller's voice, feeds console to the telephone hybrid then down the line to the caller. If program audio, including the caller's voice, were fed to the phone hybrid a feedback path would exist. Figure 3.5-5 illustrates a block diagram of a mix-minus circuit for telephone hybrid. This example demonstrates that not all console inputs must route to the mix-minus bus. Notice that only Input

Studio Wiring Plan			
	Input Jack	Output Jack	
	Patch Panel #2	Patch Panel #2	
Program Output	Jacks 1 & 2	Jacks 25 & 26	AGC Amplifier Input
AGC Amplifier Out	Jacks 3 & 4	Jacks 27 & 28	Limiter Input
Limiter Output	Jacks 5 & 6	Jacks 29 & 30	STL Transmitter
Spare	Jacks 7 & 8	Jacks 31 & 32	Spare
Audition Output	Jacks 9 & 10	Jacks 33 & 34	Reel to Reel
Spare	Jacks 11 & 12	Jacks 35 & 36	Prod. Console In
Mono Output	Jacks 13 & 14	Jacks 37 & 38	Office Monitor
Mix-Minus Output	Jacks 15 & 16	Jacks 39 & 40	Telephone Hybrid
Spare	Jacks 17 & 18	Jacks 41 & 42	Spare
Prod. Console Out	Jacks 19 & 20	Jacks 43 & 44	Spare
Spare	Jacks 21 & 22	Jacks 45 & 46	Spare
Spare	Jacks 23 & 24	Jacks 47 & 48	Spare

Figure 3.5-3. This example of studio wiring of the console shows the versatility afforded by patch panels. Should the main console fail, patch cords can feed the production studio to the on-air processing and the transmitters.

Buying Equipment

Preparation of a shopping list and cost estimate for new equipment follows the design of the studio on paper. Choose the major components (console, cart players, professional CD players and furniture) early in the planning stage so that budget cuts will not compromise their quality. Allow for price increases, sales tax and shipping costs. Watch out for hidden handling or drop-shipment charges.

Each engineer should maintain a working relationship with a reputable broadcast equipment dealer. Absolute bottom dollar may not be the best deal. Consider the absence of real savings in paying $15.00 less for a CD player that fails to arrive in time to make the on-air date for the new studio. Experienced broadcast equipment salesmen offer their best deals and service to customers to whom they sell on a regular basis.

Fax the shopping list to the dealer at least a week before you need the cost estimate in order to allow the dealer time to research and work up a quote. Engineers who demand quotes on short notice seldom get serious attention by dealers. Competition in the broadcast supply business ensures that pricing between reputable dealers will vary by only a few percentage points.

If management insists on competitive bids limit this exercise to two bids. Time is more valuable than chasing nickels and dimes. If your regular dealer does not offer an item required for the project ask them to recommend a source. A salesperson will know all good suppliers and sometimes offer to get equipment not in the normal line for their best customers. This extra service can be worth a lot more than a few dollars when considering the big picture.

Audio Consoles

Centered in the radio studio, in front of the disc jockey sits the on-air audio console. An 8 to 12 mixer analog console typifies this unit. Smaller mixing consoles find their way into news editing rooms and production studios.

The number of mixing channels limits the number of audio events which can occur simultaneously or in rapid succession. The station format dictates its requirements. Although an operator-assisted easy listening or satellite based format may be able to use a four or five channel console; it would be out of the question for a fast-paced contemporary or rock program. These smaller consoles may not offer an audition bus or switchable inputs. The lack of multiple switched inputs requires one mixer for each audio source. External switchers can provide extra flexibility when required.

Wear and build-up of dirt plague console attenuators which depend on sliding a contact over a resistive element. The resistive element consists of either carbon, conductive plastic or metal film. Normal wear changes the element's resistance and build-up of worn-off carbon may cause erratic resistive changes in the contact between the slider and the element. Noise and uneven tracking between stereo channels results with age.

In years past noisy pots presented a major problem when the program audio ran directly through the potentiometer. Nowadays, however, most consoles employ voltage controlled amplifiers (VCAs) to avoid this problem. In modern consoles audio does not pass through the potentiometer. Instead, only a sample dc control voltage passes through it. This voltage controls the gain of an amplifier which carries the program audio. Figure 3.5-4 offers a schematic of a VCA control circuit.

VCA console design solves the problem of audible noise from defective attenuators, but the noisy attenuator will affect the accuracy of the control voltage. The audio passing through the VCA controlled circuit will become erratic and nonlinear as the noisy control moves through its range. Replacement of the defective attenuator prevents clumsy sounding cross-fades and stereo channel dropouts. This console design allows the use of cheaper rotary or straight-line (slider) attenuators. As with any amplifier, the VCA introduces some thermal noise and distortion. A good console has an overall distortion figure of 0.05% total harmonic distortion (THD) or less. The noise floor should be below −90 dBm.

Modular design consoles offer the engineer major advantages. Removing and swapping modules greatly simplifies troubleshooting. The layout of the console allows easy changes to keep up with station format undulations. The positioning of blank panels create dividers that neatly group sources together. Custom panels accommodate special functions such as reel-to-reel recorder control or telephone line selection. Extra space left in the mainframe offers expansion with additional mixers as the station's needs grow. These benefits justify the extra investment in a modular console.

For on-air use, a cue channel allows the operator to receive cue audio from remotes and networks and preview program material. Even if carts deliver all program material, a cue channel is a must. It serves as a valuable trouble-shooting tool.

Accepted engineering practice runs all line level inputs through patch panels on their way to console inputs. This allows rerouting special program audio and patching around any problems that may develop. The exception to the rule is microphone level audio. Directly wiring microphone outputs to the console input terminals remains the best option. Microphone input positions seldom change and the extra wiring through patch panel jacks invites noise problems. A possible exception is the television studio where the program must allow transfer from set to set, in which case adding a mic preamp to boost the signal to line level before patching may be appropriate.

Part of proper planning for a new console ensures that levels from all sources will be compatible with the input levels required by the console. If not properly matched, the operating positions of the potentiometers (pots) will be different for each mixer, making it difficult for the operator to run the board properly. The operator may open the pot only a fraction of a turn and drive the meters to the pin or may not get enough gain even with the control fully open. Either situation results in a poor audio mix with possible distortion and noise problems. Normal operation sets rotary attenuators at the two o'clock position and slider attenuators at a 70% position.

All studio sources should be adjusted to operate within their normal output range. Interface amplifiers (matching boxes) should be used to boost low level audio sources to the +4 dB levels required for most consoles. If the source signal overloads the console input an H-pad will drop it to gain a proper match.

An H-pad is a simple network of five resistors arranged in the shape of an "H" laid on its side. The resistors convert some of the audio energy into heat which drops the audio level by a predictable amount. At the same time, the H-pad maintains the impedance of the circuit. Pads of 10 dB, or greater, also correct impedance mismatches. Figure 3.5-1 illustrates the schematic of the resistive H-pad.

Pads are a must when directly connecting two audio transformers directly. If an output transformer directly feeds an input transformer, the output transformer sees a changing inductive load and frequency response and the system suffers. With an H-pad between them, the output transformer sees a linear resistive load. The H-pad can be mounted inside the equipment or at the studio punch blocks. Table 3.5-1 shows resistor values for commonly needed 600 Ω H-pads.

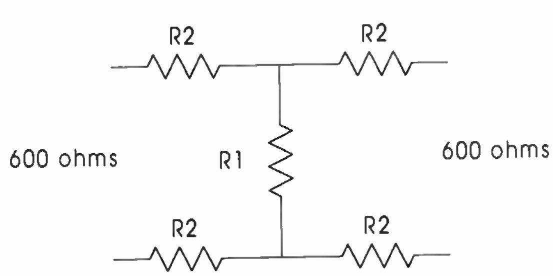

Figure 3.5-1. The H-pad resistive network reduces levels and matches impedances in balanced analog audio circuits.

Table 3.5-1
Typical H-Pad Values

Loss (in dB)	R1 (Ohms)	R2 (Ohms)
1	5100	18
3	1800	51
6	820	100
8	560	130
10	430	160
12	330	180
14	240	200
16	200	220
18	150	240
20	120	240
22	100	270
24	75	270
26	62	270
28	47	270
30	39	270
32	30	300
34	24	300
36	18	300
38	15	300
40	12	300

The worksheets in Figure 3.5-2 and Figure 3.5-3 offer an example of the starting point for designing a studio. Figure 3.5-2 illustrates wiring to the console inputs; Figure 3.5-3 designates the wiring path of the console outputs. Preparing customized worksheets for each studio saves false starts and wiring errors. Any computer spreadsheet program accommodates the task easily. Computer drafting programs offer another option for perfecting studio wiring prior to pulling cable.

The studio outlined in the worksheets is one of two in a station. A second studio serves as the production room. Patch panels route all audio. Outputs of both studios appear at the patch panel in the main studio as well as the production studio. If technical problems take the control room off-line the station can originate the program from the production console.

Studio Wiring Plan			
Audio Source	Input Jacks	Output Jacks	Console Inputs
	Patch Panel #1	Patch Panel #1	
Microphone #1			Mixer 1
Microphone #2			Mixer 2
CD #1	Jacks 1 & 2	Jacks 25 & 26	Mixer 3
CD #2	Jacks 3 & 4	Jacks 27 & 28	Mixer 4
Cart #1	Jacks 5 & 6	Jacks 29 & 30	Mixer 5
Cart #2	Jacks 7 & 8	Jacks 31 & 32	Mixer 6
Cart #3	Jacks 9 & 10	Jacks 33 & 34	Mixer 7
Satellite #1	Jacks 11 & 12	Jacks 35 & 36	Mixer 8
Satellite #2	Jacks 13 & 14	Jacks 37 & 38	Mixer 9
Reel to Reel	Jacks 15 & 16	Jacks 39 & 40	Mixer 10
Phone Hybrid	Jacks 17 & 18	Jacks 41 & 42	Mixer 11
EAS Receiver	Jacks 19 & 20	Jacks 43 & 44	Mixer 12
Production Studio	Jacks 21 & 22	Jacks 45 & 46	Mixer 13
Spare	Jacks 23 & 24	Jacks 47 & 48	Mixer 14

Figure 3.5-2. Careful planning of the console inputs prevents delays and rework during the installation process.

Digital audio equipment presents another level matching challenge. Headroom meters, not VU meters, monitor digital inputs. A headroom meter indicates how close the input signal comes to clipping in the analog to digital converter circuit. A 0 dBm signal fed to a digital recorder with 18 dB of headroom will appear on the headroom meter at − 18 dB. Headroom meters referencing a decibel value are identified as dBfs (*decibels* referenced to *full-scale*).

Analog circuits tolerate operation with the levels driven *in the red* above 0 dBm on their VU meters. Zero dBm is not the *clip point*. An analog circuit clips when the audio signal exceeds the voltage potential of the power supply. A sine wave then flattens on the peaks when the input signal reaches a level higher than the power supply voltage. This condition results in audio distortion.

Typically, analog audio equipment clips around + 24 dBu. If the manufacturer calibrated the VU meter to an output of + 4 dBu ("0" on the meters equals an output of + 4 dBu), the equipment is said to have 20 dB of headroom. Input audio reading an average value of 0 dB could contain audio peaks 20 dB higher without clipping and distorting as it passes through the equipment. It is easy to understand why analog equipment with 20 dB of headroom forgives trespasses into the *red* above 0 dB on the VU meter.

Digital equipment inputs demand closer attention. When a digital recorder, with a headroom meter, is driven above "0," the digital audio clips and the recording will contain non-repairable distortion, clicks or pops. Digital audio clips at the analog-to-digital converter (A/D). Digital clipping occurs when the analog input signal drives the A/D past its maximum output capability. Digital inputs should be operated as close to the "0" mark as possible, but do not clip! Good digital recording practice maintains peaks of − 6 dBfs.

Professional analog broadcast equipment features balanced inputs and outputs. A balanced audio output consists of two wires which carry the analog audio voltage to the next device. Neither of these wires connect to ground. Only the cable shield, which protects the audio from electrical noise and hum, is grounded. A balanced circuit can be run over properly shielded audio cables several hundred feet long.

When wiring balanced analog audio, use care to connect the high, or plus (+), terminals. Connect the low, or negative (−), only to similarly marked terminals. If you use 3-pin XLR connectors, pin #2 is always high (+). Pin #3 is always low (−). Pin #1 of an XLR connector is ground. When you use ¼ in. tip ring sleeve (TRS) plugs, the tip is high (+), the ring is low (−) and the sleeve is ground. Failure to follow the rules of polarity will result in out-of-phase audio. Stereo audio, wired out-of-phase, results in an audio dead spot centered in front of the speakers. Listeners with monaural radios hear only the difference between left channel and right channel if out-of-phase audio is fed to the transmitter.

An unbalanced audio circuit consists of a single conductor and grounded shield. Consumer electronic equipment uses unbalanced audio circuits easily identified by the single-pin, RCA phono plugs found on the connecting cables. An unbalanced circuit carries half of the power of a balanced circuit. It is more subject to hum and noise. Unbalanced circuits cannot support long runs of cable for this reason.

Bridging audio input circuits present no load to the source audio. Bridging inputs abandon the traditional 600 Ω, power-matching, input circuits found on older equipment. Without a load, no power transfer takes place. These bridging circuits simply transfer an audio voltage from output to input. A bridging input handles a wider variety of input sources than possible when everything terminated with a 600 Ω load. If an output requires a 600 Ω termination, a 620 Ω resistor tied across the input terminals provides a reasonable match.

In the old days of tube equipment, both inputs and outputs used transformers. Tubes could not drive 600 Ω loads directly; solid-state equipment could. Audio equipment manufacturers slandered the transformer with reports of poor performance as they removed them during the transition to solid-state design. Good transformers are expensive; manufacturers looked for ways to cut their costs and the audio transformer became a casualty.

Some applications still require the physical isolation that only a transformer can provide. Any time that audio equipment connects to a phone line, a transformer blocks the 48 V telco battery from entering the equipment. Unusually long audio cable runs operate best, with lower noise, when a transformer isolates the equipment on each end. The audio transformer provides best common mode rejection of electrical noise induced into long cable runs. Transformers still provide input termination on may high-end microphone preamplifiers. The transformer provides the required 150 Ω load for the microphone and isolates the preamp from the phantom voltage required to power condenser microphones. Common mode rejection of noise becomes even more important when dealing with the extremely low level output signals of dynamic microphones.

Step One: Where to Begin

Planning a new studio, or rebuilding an old one, begins with a layout on paper, or computer screen, of all of the required audio sources and feeds. The console inputs offer a good place to start. Working from a list of all possible sources the engineer assigns them priorities according to how often and how quickly the operator must put them on the air. This determines the number of mixing channels needed and how many switched inputs each mixer requires.

All frequently used audio sources should be assigned to individual console mixers. Keeping input switching and patching required of the operator to a minimum avoids errors and dead-air. A console with two or three more inputs and mixers than absolutely necessary provides inexpensive insurance against obsolescence and frequent studio rewiring jobs.

events around, control audio source equipment, adjust levels and even read copy and tags directly from the screen.

Talk formats require a studio for the show host and on-air guests. A large round table with the microphone booms mounted in the center allows the host and any guests working room plus affords eye contact. The show producer operates the mixing console and telephone hybrids in the control room. If not removed to an adjacent room, the show's call screener also shares the space in the control room.

Large market budgets afford lots of resources and first-class equipment. A visit to a small market talk show may reveal the show host running all of the control room equipment while talking with callers. The station's telephone receptionist works frantically screening calls and shuttling caller names on yellow Post-It-Notes® to the show host.

The Production Studio

A separate studio provides an area for commercial production work and transfer of music to cart or to a digital audio storage system. The production studio provides access to CD players, a digital audio workstation, cart recorders, equalization, patch panels, reel-to-reel recorders and possibly turntables. The production studio provides more flexibility and handles a wider variety of audio mediums than the on-air studio.

Four, eight and sixteen-track consoles and multi-track recorders found in major market production facilities often intimidate the typical disk jockey in segueing music and commercials. These consoles feature sub-master mixing busses allowing the mix down of multiple tracks of music, voice tracks and sound effects producing complex spots and promos. Special effects and equalization, not needed in the main studios, remain standard fare in production.

Production directors prefer digital workstations because they allow editing without splicing tape. Digital workstations bring to audio production the speed and versatility that word-processing brought to typing. Workstations allow editing of individual tracks, a feat impossible with multi-track reel-to-reel tape editing.

Since all material produced in the studio will eventually be played on the air, the quality of the equipment should be equal to, if not better than, that used in the main studio.

Typical Television Studio Layout

Audio for television stations can be challenging because of the need for many types of audio mixes. Multi-channel television sound (MTS) requires a stereo program feed to the transmitter, on-camera talent needs a monitor mix, programs with a studio audience require a mono PA mix, talk and news programs must have a mix-minus for telephone hybrids and possibly a mix in a different language for a second audio program (SAP) channel.

The ATSC DTV Standard will make life even more interesting. As the motion picture format 5.1 channel comes to television, the audio engineer must deal with left channel, center channel, right channel, two surround channels and a low-frequency effects (LFE) channel. The first five audio channels offer full 20 kHz bandwidth. The sub-woofer LFE channel provides response from 3 Hz–125 Hz. All of this arrives as digitally compressed audio in the Dolby AC-3 format.

Audio monitoring of the preview channel is accomplished through the mixer solo function. If a remote truck is involved, an interruptible foldback (IFB) system requires a program audio feed plus audio cues to the talent at the truck. The console to handle all this requires a design specifically for these complex tasks. An audio routing switcher tied to the video switcher assumes some of the work load.

STUDIO PLANNING

Analog audio signals consist of complex mixtures of alternating currents of different frequencies at different powers. In broadcasting, the decibel serves as one unit for measuring audio power. Power is measured with VU (volume units) meters, marked in decibels (dB), on broadcast equipment. The decibel is one tenth of the logarithm of the ratio of two powers. Volume units are referenced to the 1 mW of power produced by a 1 kHz audio tone across a 600 Ω load. This combination of audio power (1 mW) and load value (600 Ω) creates 0.775 V of audio and is represented by the "0" on the VU meter.

The designation "dBm" identifies all readings referenced above or below this power level. A signal of −3 dBm contains half of the energy of a signal measured at 0 dBm. A signal of +3 dBm is twice as loud as the 0 dBm signal. A signal of +10 dBm is 10 times as powerful.

Decibel values identified as "dBu," (decibels-unterminated) indicate an audio voltage of 0.775 V across an open circuit. Decibels measured in "dBv," (decibels-volts) are also measured across an open circuit, but are referenced to 1.0 V. Since the circuit lacks the traditional 600 Ω load, these are simple measurements of an audio voltage, not power. Modern analog equipment no longer uses 600 Ω, impedance matching, circuits; most references to decibels now carry the "dBu" or "dBv" notation.

Occasionally the 0 dBm output level on a console drives the input meter on a recorder to +4 dBm. Zero dBm still equals 0 dBm, but equipment manufacturers often calibrate their equipment to provide an output level of +4 dBm, or +8 dBm, when the output VU meter indicates 0 dBm. Engineers always standardize operating levels of all equipment in the station. This allows patching any output into any input without operating level problems.

Signal levels of 0 dBm, +4 dBm and +8 dBm are all valid operating levels. Each station may use a different level, but an engineer will calibrate all of the equipment in the station to one of these three standard operating levels. Someone bringing in equipment from outside the facility may find it necessary to recalibrate to the signal level used throughout the facility.

3.5
STUDIO AUDIO EQUIPMENT

WALT LOWERY
HARRIS CORP., QUINCY, IL

INTRODUCTION

The quality of a radio station's only distributed product, its sound, is determined by the events taking place in the studio. The best source material and the best air talent will produce only marginal results when burdened by inadequate equipment. Even in television, audio can no longer be treated as a secondary technology. State of the art equipment, properly used in the studio, equates to ratings and translates to revenue for the station.

Broadcast studios now take advantage of digital audio source material, digital audio processing equipment and digital consoles. As music CDs replaced vinyl discs as the standard source material for radio broadcasters over an alarmingly short period of time, digital broadcast equipment is poised to eclipse analog studio systems. We have the potential to reduce the radio studio to a touch-screen computer operation, but the trend in the industry remains loyal to familiar function and feel. Broadcasters prefer their digital equipment to emulate the friendly analog devices which they have used for decades.

TYPICAL RADIO STUDIO LAYOUTS

Many stations in active markets have suffered through changes in formats, managers and engineers leaving a crazy quilt of analog and digital equipment. The results have handicapped the station's ability to survive in a competitive market. Programming needs, available space and creativity of former engineers often dictated the design of a studio. Design du jour, compounded with galloping changes in technology, leaves many studios ripe for redesign and rebuilding.

The station's current format should dictate the main design parameters. The operational concepts will be much different for a music format than for a news/talk operation. It is possible to catalog radio station studios under a few general categories.

Music Formats

Studios built for music formats remain the most common, particularly in smaller markets. The basic configuration consists of an audio console, two or more CD players and multiple cart players arranged in a "U" or "L" shaped desk. Other necessary equipment might include audio routing, transmitter remote control and telephone interface equipment. Careful design places all equipment within arm's reach of the operator. This configuration handles the rather simple programming needs nicely. The announcer on duty mixes and switches audio, reads announcements, plays music from CD players, plays commercials from analog or digital cart players and switches news and network programming from a satellite receiver.

Some stations transfer music from CD to digital carts, making the studio an all-cart operation. In this situation the studio contains four to six cart playback decks and no CD players. Having all program material on cart makes the operation more simple. The operator needs only to talk, slam plastic discs into slots and push buttons.

Going one step further, some stations retrieve their program material from digital audio storage systems. Commercials and music are stored digitally on a hard drive, retrieved when required, converted back to analog audio and fed to the console. This eliminates the physical handling of any audio storage medium. The operator controls each audio event with a keyboard and mouse.

Music formats require positions for one combo operator and possibly an announce booth for news. With the popularity of the *Morning Zoo* format, many large market stations designed their studios for two or three on-air personalities. One member of the team operates the console, another juggles phone calls, pulling music and spots and the third handles news. The studio layout varies with the duties handled by each member of the team.

News/Talk Formats

All-news stations serve up information from live in-studio talent and short duration feeds from a large number of sources. Here the board operator functions as an engineer rather than on-air talent. Small studios orbit the central control room allowing eye contact between the board operator and on-air talent. The console provides more of a switching function than audio mixing. Live news or talk programs dictate a larger number of console inputs than the typical disk jockey operation. Digital audio storage systems help this format flow smoothly.

Technology now allows replacement of the audio console with a computerized audio switching system. Hard disk audio storage systems utilize multiple computers linked to a central network server through a local area network (LAN). Each studio retains access to all stored program material. The operator sees the log displayed on the screen. The operator can shift

This random access memory device has a capacity measured in hundreds of gigabytes. The data is stored as three-dimensional optical holograms, with data being written and retrieved as two dimensional patterns of laser light. A light sensitive crystal, (Holostore) serves as the medium for PVHS.

This form of crystal memory is non-volatile, removable, and achieves data transfer rates of 1 TB (terabyte) per second. Today's fastest magnetic disk would take five hours to resolve the same amount of data. It has been reported that a removable PVHS media of some 10 × 10 × .5 cm could store 100 GB—about a month's worth of continuous stereo digital audio. Over the coming decade the emergence of static optical storage may reduce moving magnetic media applications to antiquity.

and expansion, crossovers, reverberation, ambience processing, time alignment, acoustic noise cancellation, mixing and editing and acoustic analysis. Some DSP functions are embedded within other applications; for example, the error correction systems and oversampling filters found in CD players are examples of DSP. In other applications the user has control over the DSP functions.

Digital processing is more precise, repeatable and can perform operations that are impossible with analog techniques. Noise and distortion can be much lower with DSP thus audio fidelity is much higher. In addition, whereas analog circuits age, lose calibration and are susceptible to damage in harsh environments, DSP circuits do not age, cannot lose calibration and are much more robust. However DSP technology is an expensive technology to develop. Hardware engineers must design the circuit or employ a DSP chip, and software engineers must write appropriate programs. Special concerns must be addressed when writing the code needed to process the signal. For example, if a number is simply truncated without regard to its value, a significant error could occur, and the error would be compounded as many calculations take place, each using truncated results. The resulting numerical error would be manifested as distortion in the output signal. Thus all computations on the audio signal must be highly accurate. This requires long wordlengths; DSP chips employ digital words that are 32 bits in length, or longer.

In addition, even simple DSP operations may require several intermediate calculations and complex operations may require hundreds of operations. To accomplish this, the hardware must execute the steps very quickly. Because all computation must be accomplished in real time, that is, within the span of one sample period, the processing speed of the system is crucial. A DSP chip must often process 50–100 million instructions per second. This allows it to run complete software programs on every audio sample as it passes through the chip.

DSP products are more complicated than similar analog circuits, but DSP possesses an inherent advantage over analog technology—it is programmable. Using software, many complicated functions can be performed entirely with coded instructions. Figure 3.4-21(a) shows a band-pass filter using conventional analog components. Figure 3.4-21(b) shows the same filter, represented as a DSP circuit. It employs the three basic DSP operators of delay, addition and multiplication. However this DSP circuit may be realized in software terms. Figure 3.4-21(c) shows an example of the computer code (Motorola DSP56001) needed to perform band-pass filtering with a DSP chip. There are many advantages to this software implementation. Whereas hardware circuits would require new hardware components and new circuit design to change their processing tasks, the software implementation could be changed by altering parameters in the code. Moreover the program could be written so different parameters could be employed based on user control.

As noted, DSP can be used in lieu of most conventional analog processing circuits. The advantages of DSP are particularly apparent when various applications such as recording, mixing, equalization and editing are combined in a workstation. For example, a personal computer, combined with a DSP hardware card, hard disk drive, appropriate software and a DAT or CD recorder forms a complete post production system. Such a system allows comprehensive signal manipulation including ability to cut, paste, copy, replace, reverse, trim, invert, fade in, fade out, smooth, loop, mix, change gain and pitch, crossfade and equalize. The integrated nature of such a workstation, its low cost, and high processing fidelity make it clearly superior to analog techniques.

ADVANCED RESEARCH AND DEVELOPMENT

A continuing limitation of all common analog or digital audio systems is the requirement for moving media. The sophistication of high fidelity rotation and pickup devices inherently necessitate certain minimum sizes and production costs. Although some small solid-state storage media exist the volume of data and high price of memory prohibits today's technology being applied to professional audio recording systems.

Radical static storage approaches are being researched and at least one, photorefractive volume holographic storage (PVHS), shows impressive promise.

and odd data blocks, one for each head; half of each channel's samples are recorded by each head. All of the data are encoded with a doubly-encoded Reed-Solomon error correction code. The error correction system can correct any dropout error up to 2.6 mm in diameter, or a stripe 0.3 mm high. Dropouts up to 8.8 mm long and 1.0 mm high can be concealed with interpolation.

Serial Interfacing

Most professional digital audio devices employ an output protocol using the joint Audio Engineering Society (AES) and European Broadcasting Union (EBU) serial transmission format for digital audio data. It is known as the AES/EBU or AES3 format and is specified in the ANSI S4.40-1992 Standard. Manufacturers of consumer electronics have adopted a derivative transmission format that has been standardized by the International Electrotechnical Commission (IEC) and is commonly referred to as the SPDIF. It is specified in the IEC Report TC 84/WG11 and IEC Publication 958.

The AES/EBU digital audio format transmits and receives left and right channel data using one digital cable. The transmission rate corresponds exactly to the source sampling frequency. One frame consists of two subframes, labeled A (left channel) and B (right channel), each with 32 bits. Each subframe contains data for one audio channel. The first 4 bits are used for synchronization and identifying preambles. The next 24 bits carry audio data, with the MSB transmitted last; 16 bit audio data leaves 4 bits at zero; the first 4 bits in the field are set aside for auxiliary audio or other data, as shown in Figure 3.4-20.

The last 4 bits form a control field with the V, U, C, and P bits. The validity (V) bit indicates if the previous audio sample is error free. The user (U) bit can be used to form a block of user data associated with the audio channel. The channel (C) status bit is used to form a data block; for each channel, one block is formed from the channel status bit contained in 192 successive frames. The parity (P) bit is used to provide even parity for each subframe. The AES/EBU Standard specifies that data are transmitted over twisted pair conductors, with 3-pin XLR connectors. There is a supplemental document, called AES-3id–1995, that specifies the method for transmission of AES formatted data by unbalanced coaxial cable.

In the IEC or SPDIF serial format used in consumer digital audio equipment the first bit of the channel status byte is set to "0" to signify a consumer interface, and a different channel status specification is used. In addition, when interfacing CD data, provision is made to transmit the subcode data in the user bit channel. The consumer format also contains provision for SCMS in the channel status bits. In particular, bit 2 is used to flag copyrighted material, and bit 15 distinguishes between original and copied material. In the IEC or SPDIF format, video coaxial cable with phono plugs or fiber optic cables can be used to convey data.

Digital interconnection formats such as AES3 and SPDIF allow audio data to be transferred from one device to another without any generation loss whatsoever. For example, audio data from a DAT recording could be conveyed to a hard disk editing system, processed there, and returned to DAT without transmission error. However it is important to only connect AES/EBU outputs to AES/EBU inputs, and IEC/SPDIF outputs to IEC/SPDIF inputs. AES/EBU and IEC/SPDIF interfaces should not be interconnected. Transmitted data could be invalid, or lead to improper machine operation

Digital Signal Processing

Digital signal processing (DSP) has improved the performance of many existing audio functions such as equalization and dynamic range compression, and permits new functions such as ambience processing, dynamic noise cancellation and time alignment. DSP is a technology used to analyze, manipulate or generate signals in the digital domain. It uses the same principles as any digitization system however instead of a storage medium such as CD or DAT, it is a processing method.

DSP Applications and Design

DSP employs technology similar to that used in computers and microprocessor systems however there is an important distinction. A regular computer processes data, whereas a DSP system processes signals. It is accurate to say that an audio DSP system is in reality a computer dedicated to the processing of audio signals.

Some audio functions DSP can perform include: error correction, multiplexing, sample rate conversion, speech and music synthesis, data compression, filtering, adaptive equalization, dynamic range compression

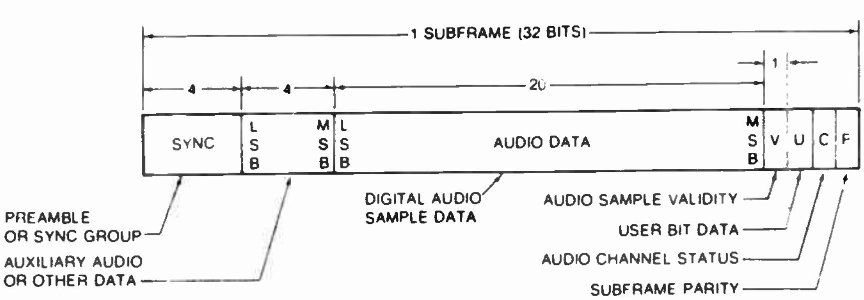

Figure 3.4-20. AES/EBU subframe format. (From Pohlmann, *Principles of Digital Audio.*)

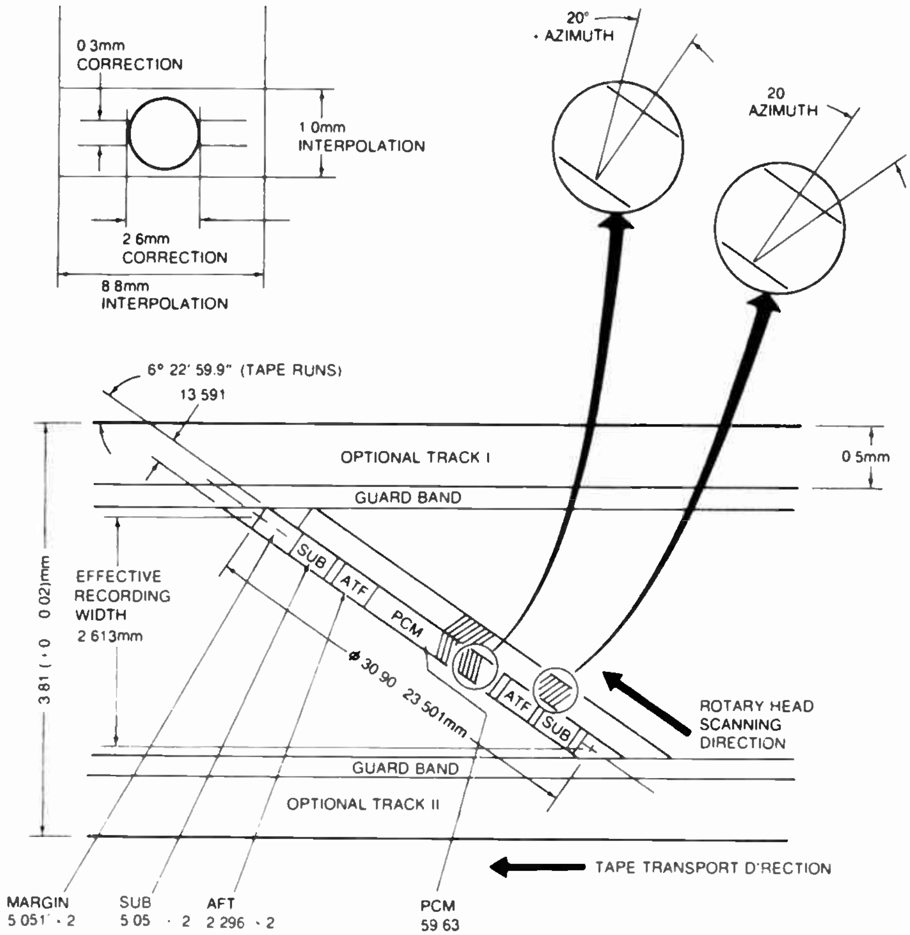

Figure 3.4-19. DAT track configuration. (From Pohlmann, *Principles of Digital Audio.*)

track types, sometimes referred to as A and B, with differing azimuth angles between successively recorded tracks. This ±20° azimuth angle means that the A head will read an adjacent B track at an attenuated level due to phase cancellation. This reduces crosstalk between adjacent tracks, eliminates the need for a guardband between tracks and promotes high density recording. Erasure is accomplished by overwriting new data to tape such that successive tracks partially write over previous tracks. Thus the head gaps (20.4 microns) are approximately 50% wider than the tracks (13.59 microns) recorded to tape.

The length of each track is 23.501 millimeters. Each bit of data occupies 0.67 microns, with an overall recording data density of 114 Mb per square inch. With a sampling rate of 48 kHz and 16 bit quantization, the audio data rate for two channels is 1.536 Mbps. However, error correction encoding adds extra information amounting to about 60% of the original, increasing the data rate to about 2.46 Mbps. Subcode raises the overall data rate to 2.77 Mbps.

The primary types of data recorded on each track are PCM audio, subcode and automatic track finding (ATF) patterns. Each data (or sync) block contains a sync byte, ID code byte, block address code byte, parity byte and 32 data bytes. In total, there are 288 bits per data block; following 8/10 modulation, this is increased to 360 channel bits. Four 8 bit bytes are used for sync and addressing. The ID code contains information on pre-emphasis, sampling frequency, quantization level, tape speed, copy-inhibit flag, channel number, etc. Subcode data are used primarily for program timing and selection numbering. The subcode capacity is 273.1 kbps. The parity byte is the exclusive or sum of the ID and block address bytes, and is used to error correct them.

Since the tape is always in contact with the rotating heads during record, playback and search modes, tape wear necessitates sophisticated error correction. DAT is thus designed to correct random and burst errors. Random errors are caused by crosstalk from an adjacent track, traces of an imperfectly erased signal or mechanical instability. Burst errors occur from dropouts caused by dust, scratches on the tape or by head clogging with dirt.

To facilitate error correction, each data track is split into halves, between left and right channels. In addition, data for each channel is interleaved into even

the helical scan track along with the audio signal, it is treated independently and can be rewritten without altering the audio program, and entered either during recording or playback. With the ID codes entered into the subcode area, desired points on the tape such as the beginning of selections can be searched for at high speed by detecting each ID code. During playback, if the skip ID is marked, playback is skipped to the point at which the next start ID is marked, and playback begins again.

In the DAT format, the recorded area is distinguished from a blank section of tape with no recorded signal, even if the recorded area does not contain an audio signal. Unlike blank areas, the track format is always encoded on the tape even if no signal is present. If these sections are mixed on a tape, search operations may be slowed. Hence, blank sections should be avoided. A consumer DAT deck with an interface meeting the specifications of the Sony Philips digital interface format (SPDIF) will identify when data have been recorded with a copy inhibit Serial Copy Management System (SCMS) flag in the subcode (ID6 in the main ID in the main data area) and will not digitally copy that recording. In other words, SCMS permits first generation digital copying, but not second generation copying. Analog copying is not inhibited.

DAT Recorder Design

From a hardware point of view, a DAT recorder utilizes many of the same elements as a CD-R recorder: A/D and D/A converters, modulators and demodulators, error correction encoding and decoding. Audio input is received in digital form, or is converted to digital by an A/D converter. Error correction code is added and interleaving is performed. As with any helical scan system, time compression must be used to separate the continuous input analog signal into segments prior to recording, then rejoin them upon playback with time expansion to form a continuous audio output signal. Subcode information is added to the bit stream, and it undergoes eight-to-ten (8/10) modulation. This signal is recorded via a recording amplifier and rotary transformer.

In the playback process the rotary head generates the record waveform. Track finding signals are derived from the tape and used to automatically adjust tracking. Eight-to-ten demodulation takes place and subcode data are separated and used for operator and servo control. A memory permits de-interleaving as well as time expansion and elimination of wow and flutter. Error correction is accomplished in the context of de- interleaving. Finally, the audio signal is output as a digital signal, or through D/A converters as an analog signal.

The DAT rotary head permits slow linear tape speed while achieving high bandwidth. Each track is discontinuously recorded as the tape runs past the tilted head drum spinning rapidly in the same direction as tape travel. The result are diagonal tracks at an angle of slightly more than 6° from the tape edge, as shown in Figure 3.4-19. Despite the slow linear tape speed of 8.15 mmps (1/4 in. per second), a high relative tape-to-head speed of about 3 msec (120 in. per second) is obtained. A DAT rotating drum (typically 30 mm in diameter) rotates at 2,000 rpm, typically has two heads placed 180° apart, and a tape wrap of only 90°. Four head designs provide direct read after write, so the recorded signal can be monitored.

Azimuth recording (*or guard-bandless recording*), is used in which the drum's two heads are angled differently with respect to the tape; this creates two these discs is vulnerable to sunlight thus discs should not be exposed to bright sun over a long period.

The CD-R format is defined in the *Orange Book Standard* authored by Philips and Sony. In CD recorders adhering to the *Orange Book I Standard*, a disc must be recorded in one pass—start-stop recording is not permitted. In recorders adhering to the *Orange Book II Standard*, recording may be stopped and started. In many players, tracks may be recorded at different times and replayed but because the disc lacks the final TOC, it can be played only on a CD-R recorder. When the entire disc is recorded the interim TOC data are transferred to a final TOC, and the disc may be played in any CD audio player. The program memory area (PMA) located at the inner portion of the disc contains the interim TOC record of the recorded tracks. In addition, discs contain a power calibration area (PCA); this allows recorders to automatically make test recordings to determine optimum laser power for recording. Some recorders exceed the *Orange Book II Standard*; they generate an interim TOC that allows partially recorded discs to be played on playback-only CD players.

CD-R recorders are useful because they eliminate the need to create an edited master tape prior to CD recording. If a passage is not wanted, it can be marked prior to writing the final TOC so that the recorder will not play it back. For example, dead air during a live performance can be marked so it is deleted whenever the disc is played back. The data physically continues to exist on the disc, however.

Erasable CD-E Format

CD systems that provide for both recording and erasing are known as *CD-E systems*. Erasable optical systems permit data to be written, read, erased and written again. Several recordable/erasable optical media have been introduced, most notably, magnetooptical (MO) media. Magnetooptical recording technology combines magnetic recording and laser optics, utilizing the record/erase benefits of magnetic materials with the high density and contactless pickup of optical materials.

With magnetooptics, a magnetic field is used to record data, but the applied magnetic field is much weaker than conventional recording fields. It is not strong enough to orient the magnetic particles. However the coercivity of the particles sharply decreases as they are heated to their Curie temperature. A laser beam focused through an objective lens heats a spot of magnetic material and only the particles in that spot are affected by the magnetic field from the recording coil, as shown in Figure 3.4-17(a). After the laser pulse is withdrawn, the temperature decreases and the orientation of the magnetic layer records the data. In this way, the laser beam creates a small recorded spot thus increasing recording density.

The Kerr effect may be used to read data; it describes the slight rotation of the plane of polarization of polarized light as it reflects from a magnetized material. The rotation of the plane of polarization of light re-

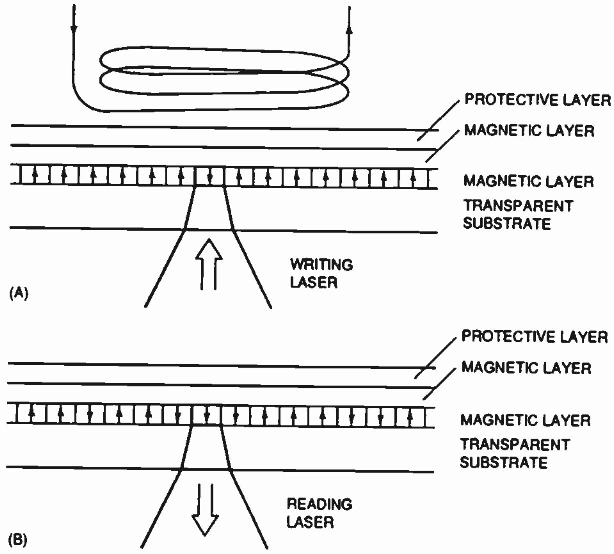

Figure 3.4-17. Magnetooptical recording (a) and playback (b).

flected from the reverse oriented regions differs from that reflected from unreversed regions, as shown in Figure 3.4-17(b). To read the disc, a low powered laser is focused on the data surface, and the angle of rotation of reflected light is monitored thus recovering data from the laser light. To erase data a magnetic field is applied to the disc, along with the laser heating spot. Tests indicate that MO media could be erased/recorded over 10 million times and would retain data for over 10 years.

Digital Audio Tape Format

The rotary-head digital audio tape (R-DAT or DAT) format was originally designed as a consumer medium to replace the analog cassette. However the format has found wider application as a low cost professional digital recording system.

Format Specifications

The DAT format supports four record/playback modes and two playback-only modes. The standard record/playback, and both playback-only modes, *wide* and *normal*, are implemented on every DAT recorder. The standard mode offers 16 bit linear quantization and 48 kHz sampling rate. Both playback-only modes use a 44.1 kHz sampling rate, for user- and prerecorded tapes. Three other record/playback modes, called Options 1, 2, and 3, all use 32 kHz sampling rates. Option 1 provides 2 hour recording time with 16 bit linear quantization. Option 2 provides 4 hours of recording time with 12 bit nonlinear quantization. Option 3 provides 4 channel recording and playback, also using 12 bit nonlinear quantization. These specifications are summarized in Figure 3.4-18.

The user can write and erase nonaudio information into the subcode area: start ID indicating the beginning of a selection, skip ID to skip over a selection, and program number indicating selection order. This subcode data permits rapid search and other functions. Although subcode data are recorded onto the tape in time constants of 15 and 50 μ sec. Upon playback, deemphasis is automatically carried out, resulting in an improvement in S/N.

Recordable CD-R Format

With a CD-R (or CD-WO) write-once optical disc recorder, the user may record data until the disc capacity is filled. Recorded CD-R discs are playable on conventional CD players. A block diagram of a CD-R recorder is shown in Figure 3.4-16. An encoder circuit accepts an input PCM signal and performs CIRC error correction encoding, EFM modulating, and other coding and directs the data stream to the recorder. The recorder accepts audio data and records up to 74 minutes in real time. In addition to audio data, a complete subcode table is written in the disc TOC, and appropriate flags are placed across the playing surface.

Write-once media is manufactured similarly to conventional playback-only discs. As with regular CDs, they employ a substrate, reflective layer and protective top layer. Sandwiched between the substrate and reflective layer, however, is a recording layer comprised of an organic dye. Together with the reflective layer it provides a typical in-groove reflectivity of 70% or more. Unlike playback-only CDs, a pregrooved spiral track is used to guide the recording laser along the spiral track; this greatly simplifies recorder hardware design and ensures disc compatibility. Shelf life of the media is said to be 10 years or more at 25° centigrade and 65% relative humidity. However the dye used in

darker rings, and spot dimensions are quoted as half-power levels.

When viewed from the laser's perspective, the pits appear as bumps with height between 0.11–0.13 mm. This dimension is slightly less than the laser beam's wavelength in polycarbonate of 500 nm. The height of the bumps is thus approximately 1/4 of the laser's wavelength in the substrate. The reflective flat surface of a CD is called *land*. Light striking land travels a distance one-half wavelength longer than light striking a bump, as shown in Figure 3.4-14. This creates an out-of-phase condition between the part of the beam reflected from the bump, and the part reflected from the surrounding land. The beam thus undergoes destructive interference, resulting in cancellation. Optically, if the CD pit surface is considered as a two-dimensional reflective grating, the focused laser beam diffracts into higher orders, resulting in interference. The disc surface data thus modulates the intensity of the reflected light beam. In this way the data physically encoded on the disc are recovered by the laser.

Data Decoding

A CD player's data path, shown in Figure 3.4-15, directs the modulated light from the pickup through a series of processing circuits, ultimately yielding a stereo analog signal. Data decoding follows a procedure which essentially duplicates, in reverse order, the encoding process. The pickup's photodiode array and its processing circuits output EFM data as a high frequency signal. The first data to be extracted from the signal are synchronization words. This information is used to synchronize the 33 symbols of channel information in each frame, and a synchronization pulse is generated to aid in locating the zero crossing of the EFM signal.

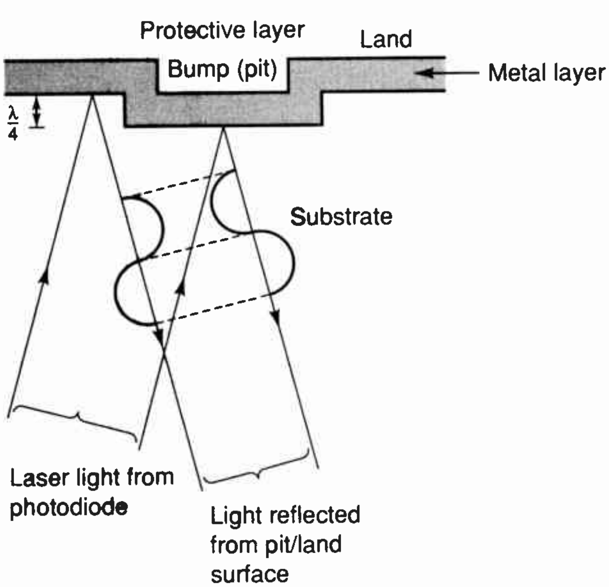

Figure 3.4-14. A pit causes cancellation through destructive interference.

The EFM signal is demodulated so that 17 bit EFM words again become 8 bits. A memory is used to buffer the effect of disc rotational wow and flutter. Following EFM demodulation, data are sent to a CIRC decoder for de-interleaving, and error detection and correction. The CIRC decoder accepts one frame of thirty two 8 bit symbols: 24 audio symbols and 8 parity symbols. One frame of twenty four 8 bit symbols are output. Parity from two Reed-Solomon decoders is utilized. The first error correction decoder corrects random errors and detects burst errors and flags them. The second decoder primarily corrects burst errors, as well as random errors that the first decoder was unable to correct. Error concealment algorithms employing interpolation and muting circuits follow CIRC decoding.

In most cases, the digital audio data are converted to a stereo analog signal. This reconstruction process requires one or two D/A converters, and low-pass filters to suppress high frequency image components. Rather than use an analog brickwall filter after the signal has been converted to analog form, the digitized signal is processed before D/A conversion using an oversampling digital filter. An oversampling filter uses samples from the disc as input, then computes interpolation samples, digitally implementing the response of an analog filter.

A *finite impulse response* (FIR) transversal filter is used in most CD players. Resampling is used to increase the sample rate; for example, in a four-times oversampling filter, three zero values are inserted for every data value output from the disc. This increases the data rate from 44.1 kHz–176.4 kHz. Interpolation is used to generate the values of intermediate sample points, for example, three intermediate samples for each original sample. These samples are computed using coefficients derived from a low-pass filter response.

The spectrum of the oversampled output waveform contains image spectra placed at multiples of the oversampling rate; for example, in a four-times oversampled signal, the first image is centered at 176.4 kHz. Because the audio baseband and sidebands are separated, a low order analog filter can be used to remove the images, without causing phase shift or other artifacts common to high order analog brickwall filters.

Traditionally, D/A conversion is performed with a multibit PCM converter. In theory, a 16 bit converter could perfectly process the 16 bit signal from the disc. However because of inaccuracies in converters, 18 bit D/A converters are often used because they can more accurately represent the signal. Alternatively, low bit (sometimes called 1 bit) D/A converters can be used. They minimize many problems inherent in multibit converters such as low level nonlinearity and zero-cross distortion. Low bit systems employ very high oversampling rates, noise shaping, and low bit conversion.

Also present in the audio output stage of every CD player is an audio deemphasis circuit. Some CDs are encoded with audio preemphasis characteristic with

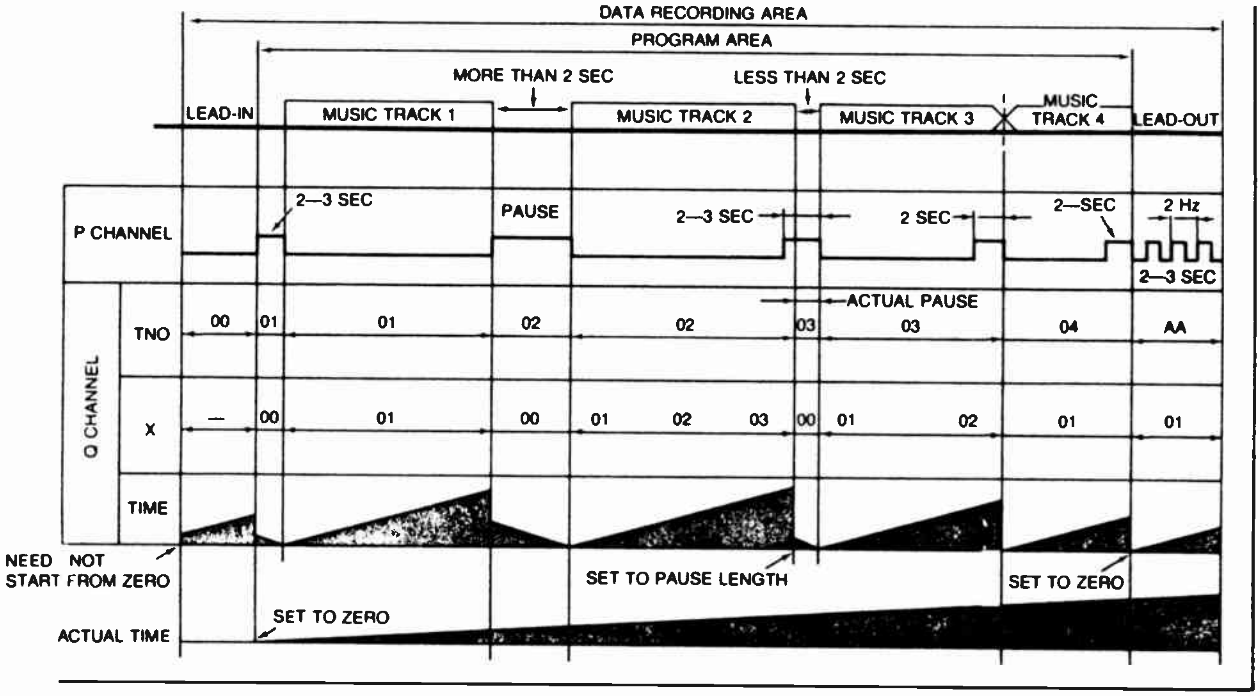

Figure 3.4-12. Typical subcode contents of the P and Q channels. (From Pohlmann, *The Compact Disc.*)

number of channel bits per frame after encoding is 588, comprised of: 24 synchronization bits, 336 ($12 \times 2 \times 14$) data bits, 112 ($4 \times 2 \times 14$) error correction bits, 14 subcode bits, and 102 (34×3) merging bits.

Data Readout

CD pickups use an aluminum gallium arsenide (AlGaAs) semiconductor laser generating laser light with a 780 nm wavelength. The beam passes through the substrate, is focused on the metalized pit surface and is reflected back. Because the disc data surface is physically separated from the reading side of the substrate, dust and surface damage on the substrate do not lie in the focal plane of the reading laser beam and hence their effect is minimized. The polycarbonate substrate has a refractive index of 1.55; because of the bending of the beam from the change in refractive index, thickness of the substrate, and the numerical aperture (0.45) of the laser pickup's lens, the size of the laser spot is reduced from approximately 0.8 mm on the disc surface to approximately 1.7 μm at the pit surface. The laser spot on the data surface is an Airy function with a bright central spot and successively

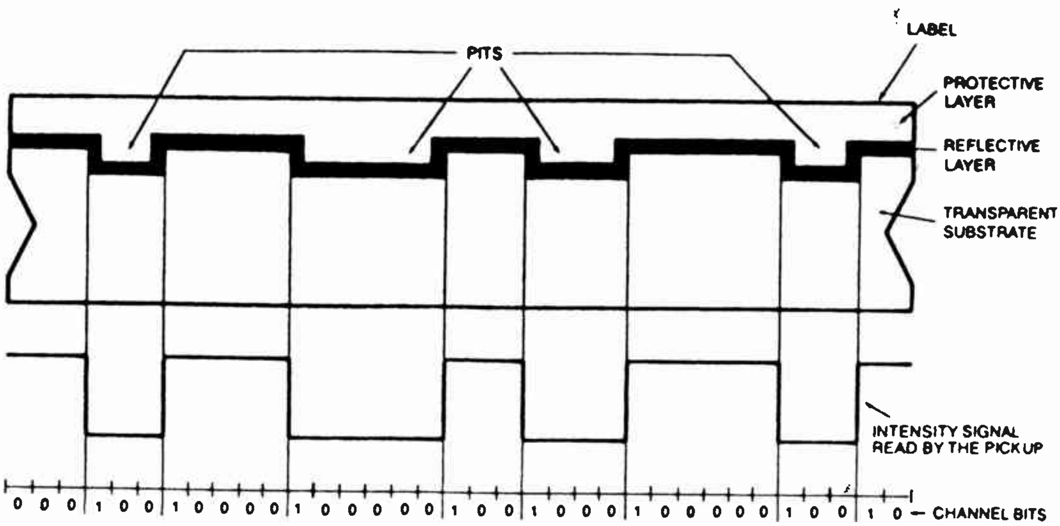

Figure 3.4-13. Channel bits as represented by the pit structure. (From Pohlmann, *Principles of Digital Audio.*)

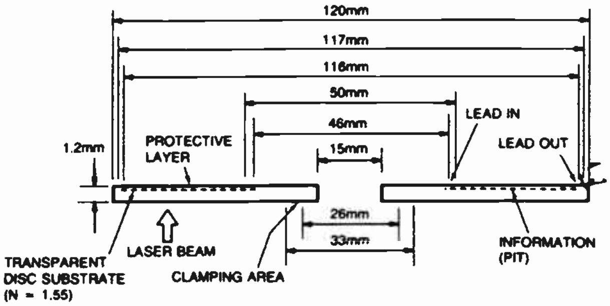

Figure 3.4-11. Compact disc physical specifications. (From Pohlmann, *The Compact Disc.*)

The disc rotates with a constant linear velocity (CLV) in which a uniform relative velocity is maintained between the disc and the pickup. To accomplish this, the rotation speed of the disc varies depending on the radial position of the pickup. The disc rotates at a speed of about 8 rev/s when the pickup is reading the inner circumference, and as the pickup moves outward, the rotational speed gradually decreases to about 3.5 rev/s. The player reads frame synchronization words from the data and adjusts the speed to maintain a constant data rate.

The CD standard permits a maximum of 74 minutes, 33 seconds of audio playing time on a disc. However by modifying encoding specifications such as track pitch and linear velocity, it is possible to manufacture discs with over 80 minutes of music. Although the linear velocity of the pit track on a given disc is constant, it can vary from 1.2–1.4 m/s, depending on disc playing time. All audio compact discs and players must be manufactured according to the *Red Book*, the CD standards document authored by Philips and Sony.

Compact Disc Encoding

CD encoding is the process of placing audio and other data in a frame format suitable for storage on the disc. The information contained in a CD frame prior to modulation consists of a 27 bit sync word, 8 bit subcode, 192 data bits and 64 parity bits. The input audio bit rate is 1.41×10^6 bps. Following encoding, the channel bit rate is 4.3218×10^6 bps. Premastered digital audio data are typically stored on a 3/4 in. U-matic video transport via a digital audio processor with a 44.1 kHz sampling rate and 16 bit linear quantization.

A frame is encoded with six 32 bit PCM audio sampling periods, alternating left and right channel 16 bit samples. Each 32 bit sampling period is divided to yield four 8 bit audio symbols. The CD system employs two error correction techniques: interleaving to distribute errors and parity to correct them. The standardized error correction algorithm used is the *Cross Interleave Reed-Solomon Code* (CIRC), developed specifically for the compact disc system. It uses two correction codes and three interleaving stages. With error correction, over 200 errors per second can be completely corrected.

Subcode Data

Following CIRC encoding, an 8 bit subcode symbol is added to each frame. The 8 subcode bits (designated as P,Q,R,S,T,U,V, and W) are used as 8 independent channels. Only the P or Q bits are required in the audio format; the other 6 bits are available for video or other information as defined by the CD+G/M (Graphics/MIDI) format. The CD player collects subcode symbols from 98 consecutive frames to form a subcode block with eight 98 bit words; blocks are output at a 75 Hz rate. A subcode block contains its own synchronization word, instruction and data, commands and parity. An example of P and Q data are shown in Figure 3.4-12.

The P channel contains a flag bit that can be used to identify disc data areas. Most players use information in the more comprehensive Q channel. The Q channel contains four types of information: control, address, data and *cyclic redundancy check code* (CRCC) for subcode error detection. The control bits specify several playback conditions: The number of audio channels (two/four); preemphasis (on/off); and digital copy prohibited (yes/no). The address information consists of 4 bits designating three modes for the Q data bits. Mode 1 data are contained in the table of contents (TOC) which is read during disc initialization. The TOC stores data indicating the number of music selections as a track number, and the starting points of the tracks in disc running time. In the program and lead-out areas, Mode 1 contains track numbers, indices within a track, track time, and disc time. The optional Mode 2 contains the catalog number of the disc. The optional Mode 3 contains a country code, owner code, year of the recording and serial number.

EFM Encoding and Frame Assembly

The audio, parity and subcode data are modulated using eight-to-fourteen modulation (EFM) in which symbols of 8 data bits are assigned an arbitrary word of 14 channel bits. By choosing 14 bit words with a low number and known rate of transitions, greater data density can be achieved. Each 14 bit word is linked by three merging bits. The 8 bit input symbols require 256 different 14 bit code patterns. To achieve pits of controlled length, only those patterns are used in which more than two but less than ten "0s" appear continuously. Two other patterns are used for subcode synchronization words. The selection of EFM bit patterns defines the physical relationship of the pit dimensions. The channel stream comprises a collection of 9 pits and 9 lands that range from 3–11T in length where T is one period. A 3T pit ranges in length from 0.833–0.972 μm and an 11T pit ranges in length from 3.054–3.560 μm, depending on pit track linear velocity. Each pit edge whether leading or trailing is a "1" and all increments in between, whether inside or outside a pit, are "0's," as shown in Figure 3.4-13.

The start of a frame is marked with a 24 bit synchronization pattern, plus three merging bits. The total

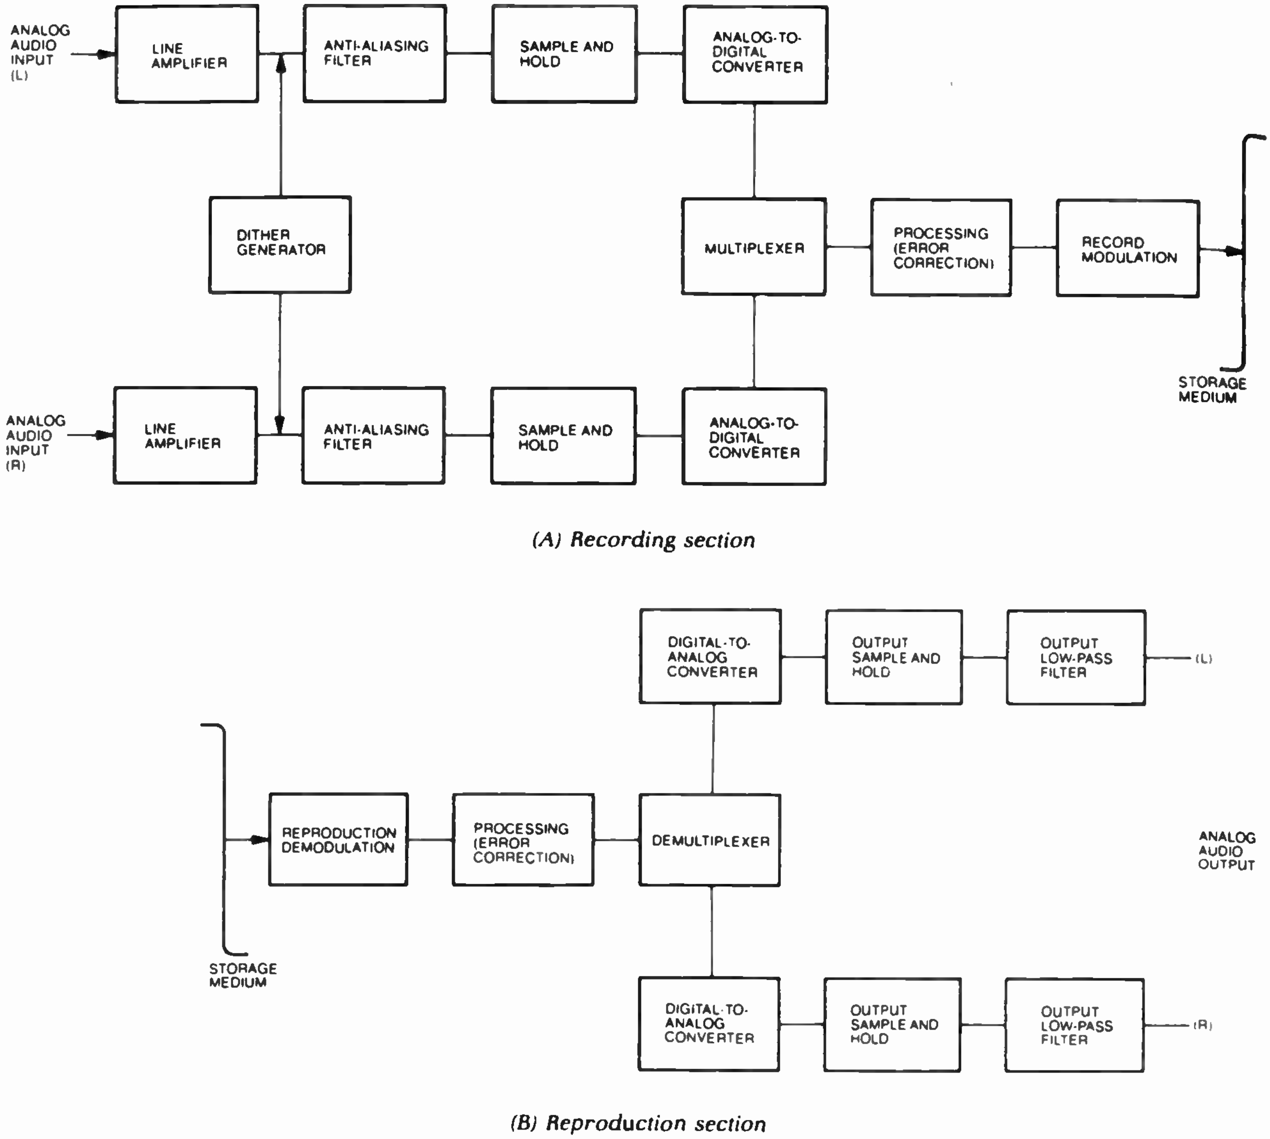

Figure 3.4-10. Block diagram of the recording (a) and reproduction (b) sections of a linear PCM system. (From Pohlmann, *Principles of Digital Audio.*)

Compact Disk Format

The Compact Disc (CD) format was developed to store up to 74 minutes of stereo digital audio program material of 16 bit PCM data sampled at 44.1 kHz. Total user capacity is over 650 Mb. In addition, for successful storage, error correction, synchronization, modulation and subcoding are required.

Compact Disc Physical Design

The diameter of a compact disc is 120 mm, its center hole diameter is 15 mm and its thickness is 1.2 mm. Data are recorded in an area 35.5 mm wide. It is bounded by a lead-in area, and a lead-out area which contain non-audio subcode data used to control the player's operation. The disc is constructed with a transparent polycarbonate substrate. Data are represented by pits that are impressed on the top of the substrate. The pit surface is covered with a thin metal (typically aluminum) layer 50–100 nm thick, and a plastic layer 10–30 μm thick. A label 5 μm thick is printed on top. Disc physical characteristics are shown in Figure 3.4-11.

Pits are configured in a continuous spiral from the inner circumference to the outer. The pit construction of the disc is diffraction-limited; the dimensions are as small as permitted by the wave nature of light at the wavelength of the readout laser. A pit is about 0.5 um wide. The track pitch is 1.6 um. There are a maximum of 20,188 revolutions across the disc's data area.

Figure 3.4-9. Summary of discrete-time sampling, shown in the time and frequency domains. (From Pohlmann, *Principles of Digital Audio*.)

When dither is added to a signal with amplitude on the order of a quantization step, the result is duty-cycle modulation that preserves the information of the original signal. The average value of the quantized signal can move continuously between two steps, thus the incremental effect of quantization has been alleviated. Audibly, the result is the original waveform, with added noise. That is more desirable than the clipped quantization waveform. With dither, the resolution of a digitization system is below the least significant bit.

The recording section of a pulse code modulation (PCM) system, shown in Figure 3.4-10(a), consists of input amplifiers, a dither generator, input (anti-aliasing) low-pass filters, sample- and hold-circuits, analog-to-digital converters, a multiplexer, digital processing circuits for error correction and modulation, and a storage medium such as digital tape. The reproduction section, shown in Figure 3.4-10(b), contains processing circuits for demodulation and error correction, a demultiplexer, digital-to-analog converters, output sample-and-hold circuits, output (anti-imaging) low-pass filters and output amplifiers. In most contemporary designs, digital filters are used in both the input and output stages. The output section forms the basis for a compact disc player.

heads the head never touches the tape and thus both head and media life is prolonged. Both crosstalk and signal-to-noise characteristics are excellent in such systems.

Isotropic recording utilizes longitudinal and vertical modes simultaneously. In isotropic recordings the vertical field erases the longitudinal fields near the tape's surface. Thus, the tape is recorded to saturation with longitudinal fields and is multiplexed with vertical fields near the surface. The longitudinal field is structured for dominance at low frequencies and the vertical field carries the higher frequencies. Because the head gaps in isotropic recordings are so minute there is essentially no intersymbol interference because only a small area at the trailing edge of the gap is recorded.

Additionally, because print-through effects are operationally nonexistent much thinner base thicknesses and oxide layers are commonly employed. Coercivity is much higher on digital magnetic media and typically ranges from 800–1500 Oe versus the more typical 300–400 Oe in analog recordings. Thus, digital recordings are deep and robust.

DIGITAL AUDIO RECORDING SYSTEMS[2]

Using the principles of discrete time sampling and quantization, a sampled signal can be processed transmitted or stored and through conversion can reconstruct an accurate representation of the original analog signal.

Discrete Time Sampling

An analog waveform such as an acoustic pressure function in air exists continuously in time over a continuously variable amplitude range. Such an analog function may be discrete time sampled; moreover, the sample points can be used to reconstruct the original analog waveform. This digitization of audio forms the basis for the encoding and decoding of the audio signals in any digital audio format.

The Nyquist theorem states that given correct, bandlimited conditions, sampling can be a lossless process. However the relationship between sampling frequency and audio frequencies must be observed. The Nyquist theorem defines the relationship: if the sampling frequency is at least twice the highest audio frequency, complete waveform reconstruction can be accomplished.

The choice of sampling frequency determines the frequency response of the digitization system; S samples per second are needed to represent a waveform with a bandwidth of S/2 Hz. As the sampled frequencies become higher, given a constant sampling rate, there will be fewer samples per period. At the theoretical limiting case of critical sampling, at an audio frequency of half the sampling frequency, there will be two samples per period. A low-pass filter is placed at the output of every audio digitization system to remove all frequencies above the half-sampling frequency. This is required because sampling, through modulation, generates new frequencies above the audio band. The output filter removes all spectra above the half-sampling frequency. This is summarized in Figure 3.4-9.

By definition audio samples contain all the information needed to provide complete reconstruction. However bandlimiting criteria must be strictly observed; a too high frequency would not be properly encoded, and would create a kind of distortion called *aliasing*. An input frequency higher than the half-sampling frequency would cause the digitization system to alias. If S is the sampling frequency and F is a frequency higher than half the sampling rate, then new frequencies are also created at S ± F, 2S ± F, 3S ± F, etc. An input low-pass filter will prevent aliasing if its cutoff frequency equals the half-sampling frequency. To achieve a maximum audio bandwidth for a given sampling rate, filters with a very sharp cutoff characteristic, *brickwall filters* are employed in either the analog or digital domain.

Amplitude Quantizing

The amplitude of each sample yields a number that represents the analog value at that instant. By definition, an analog waveform has an infinite number of amplitude values, however quantization selects from a finite number of digital values. Thus after sampling, the analog staircase signal is rounded to a numerical value closest to the analog value. The difference between the original values of the signal and values after quantization appears as error.

The number of quantization steps available is determined by the length of the data word in bits—the number of bits in a quantizer determines resolution. Sixteen bits yields $2^{16} = 65{,}536$ increments. Every added bit doubles the number of increments, hence the magnitude of the error is smaller. The accuracy of a quantizing system provides an important performance specification. In the worst case, there will be an error of one half the least significant bit of the quantization word. The ratio of maximum expressible amplitude to error determines the signal-to-error (S/E) ratio of the digitization system. The S/E relationship can be expressed in terms of word length as S/E (dB) = $6.02n + 1.76$ where "n" is the number of bits.

Although a 16 bit system would yield a theoretical S/E ratio of 98 dB, as the signal amplitude decreases, the relative error increases. Consider the example of a signal with amplitude on the order of one quantization step. The signal value crosses back and forth across the threshold, resulting in a square wave signal from the quantizer. *Dither* suppresses such quantization error. Dither is a low amplitude analog noise added to the input analog signal (similarly, digital dither must be employed in the context of digital computation when rounding occurs).

[2] This section contributed by Ken C. Pohlman. *NAB Engineering Handbook*, 8th edition, National Association of Broadcasters, pp. 863–875, 1992.

damage to tape and equipment. Thus, frequent cleaning of heads, guides, capstan, pinch roller required, typically after each recording or playback session is imperative. Freon TF and Ethyl alcohol are considered the most useful cleaners exhibiting very little health hazard, no perceptible solubility on magnetic tapes and virtually no effects on rubber pinch rollers or belts. Unlike Ethyl alcohol Freon TF is not flammable. Careful demagnetization of heads is also required for best performance, typically after each 8 hours of operation. Oils and salts from fingerprints will attract foreign particles and can themselves interfere with reliable head to tape interface.

Hydrolysis is a chemical reaction with water that affects polyester based recording tapes. High temperature and high humidity will accelerate hydrolysis reactions in any polyester based tape stock. However, from roughly 1977–1983 an industry wide polyester binder phenomena, referred to as sticky-shed syndrome, exacerbated the rate of hydrolysis reactivity.

Tapes from the sticky-shed era typically exhibit slip-stick phenomena as carboxylic acid and alcohol are sloughed from the binder as debris products. Tapes of this vintage are frequently unusable due to residue buildup that causes transports to squeal and bind. Fortunately, this phenomenon has been extensively documented and can be reversed temporarily with no apparent damage to the tape recording. The reversal process consists of warming (or *baking*) the tapes in a convection oven at 120°F for 24 hours. The tapes will then be usable upon cooling for several weeks before hydrolysis again sheds sufficient amounts of debris to interfere with transport functioning. Recommended humidity and temperature conditions are shown in Table 3.4-2, below.

Considerations Unique to Digital Recording Systems

Tribology (from the Greek word *tribos* meaning *rubbing*) is critical to high density magnetic recording applications such as digital audio. Thus magnetic tape tribology includes techniques to observe and classify surfaces, friction, lubrication, tape and head wear, contour effects, head-to-disk interface, disk surfaces, sliders, air bearings and contaminants.

Lubricants in magnetic media tend to result in drag forces proportional to media speed and head contact pressure. At higher velocities the coefficient of friction drops to zero at speeds near 80 ips due to the formation of a hydrodynamic air bearing. A friction rise below 1 Hz is due primarily to classic stick slip motions.

Table 3.4-2.
Recommended storage conditions.

Storage Temperature	Maximum Relative Humidity
50° C	39%
40° C	47%
30° C	60%
20° C	79%
10° C	100%

Sliding friction can generate significant heat. The temperature rise at the head/tape interface in helical recorders is typically only 5–7°, but can jump to a flash temperature of 1000° centigrade when an asperity, such as a protruding particle travels past the head.

A great advantage of digital recordings is that system performance is no longer limited by performance of the storage medium. Since transitions are the fundamental language of digital recording systems neither ac bias nor particularly high S/N are required. In fact distorted waveforms are the norm. However, since a massive amount of transition density must be stored for high fidelity audio, higher bandwidth and more precision magnetic emulsions are needed. Linear density, or kilobits per inch is the name of the game. Several techniques are employed to maximum density capabilities, as well as to minimize density requirements.

Error Control and Correction

The need for higher storage densities for digital audio has accelerated research and development in tape composition and magnetic head design. At higher recording densities error vulnerability requires ever smoother recording media and revolutionary designs of recording and playback heads.

Thus, in order to minimize damage and errors due to head to media contact a load-carrying air film is formed at the interface between record head and magnetic media. Physical contact should only occur as the media starts and stops its motion. The air film must be thick enough to conceal any near-contact surface irregularities and thin enough to provide a reliable record and playback signal. Head to medium separation ranges from about 50 nm to 0.3 μm, and the roughness of the head and medium surfaces ranges from 1.5 to 10 nm rms.[1]

Acicular magnetic particles are cigar-shaped particles employed in most magnetic digital recording. Because transitions are the basis of recording, saturation recording is employed and is typically of the traditional longitudinal format. However, for greater storage density the acicular particles can be oriented perpendicularly to the direction of the recording medium's travel. A balance between too low a density which requires excessive tape consumption and too high a density which requires additional error correction to combat drop-outs and intersymbol interference.

Thin film heads are of a substantially different design from analog heads. These heads are manufactured using photolithography to achieve a minute, precise shape. Multi-turn thin-film inductive record heads (IRH) are used for recording but do not have good playback characteristics at slow speeds. However, magneto-resistive (MR) heads are useful due to the output being independent of tape speed. With MR

[1] See Bhushan, Bharat, "Tribology of the Head-Medium Interface," *Magnetic Recording Technology*, Chapter 7, McGraw-Hill 1996.

where they are less noticeable. Clock synchronization techniques are commonly employed in digital audio equipment that correct for mechanically induced effects inherent in the recorder's drive mechanism.

The amounts of wow and flutter that are generally accepted to be just perceptible are:

Speech	.6% peak
Music	.3% peak
Classical Music	.15% peak

Tape Composition

Modern magnetic audio recording tape is of two basic types *particulate* and *thin film*. Particulate media are characterized by magnetic domains coated onto a flexible (polymer film) or rigid substrate (aluminum or glass/ceramic disks). As the name implies, thin film media consist of continuous films of magnetic materials deposited onto a substrate by vacuum techniques. Because thin film techniques yield a smoother and thinner medium than the particulate media, greater recording densities with lower error rates are achieved. Thin film techniques are almost universally used for hard disk storage and are beginning to be used for higher density tape stocks as well.

Particulate flexible media have a magnetic coating on both sides and the substrate is about 76 µm thick. The base film is typically polyethylene terephthalate (PET) film although polyethylene napthalate (PEN) polymers are becoming common for better dimensional stability in thinner tapes. (See Figure 3.4-7.)

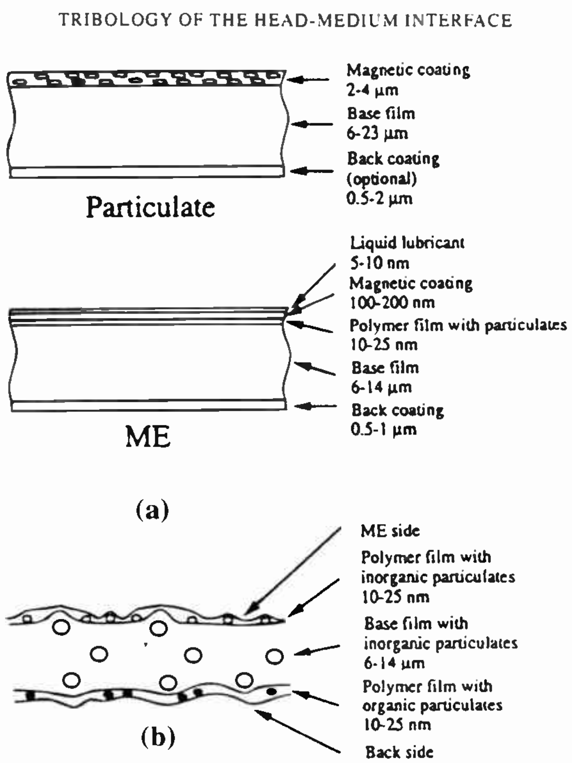

Figure 3.4-7. Sectional views of (a) a particulate and a metal evaporated magnetic tape and (b) coated PET substrate for metal evaporated (ME) tapes. ME is also referred to as thin film flexible media. (From Mee & Daniel, *Magnetic Recording Technology*, 2nd edition, McGraw-Hill, 1995. Reproduced with the permission of the McGraw-Hill Companies.)

Maintenance, Care & Storage of Audio Recordings

Although many analog recordings have held up in good condition for decades they are quite sensitive to permanent physical damage from improper handling, machine malfunction and environmental hazards. Winding tapes *tails out* immediately after complete playback is the most important safeguard in preventing edge damage to audiotapes. Cleanliness and controlled temperature and humidity are the most important factors in preventing environmental damage.

Tape wind or pack must be even to prevent protrusion scatter between layers that will crease and permanently damage tape edges during subsequent playback. Scatter wound tape is susceptible to edge damage from the pressure exerted on flanges during careless handling. For this reason, reels should be handled by their hubs rather than by the flanges. Similarly cinching of layers with actual foldover is possible during rapid acceleration/deceleration from jerky transport operation.

Many professional recorders have a *library wind* mode that operates at a higher than normal operating speed but with constant tension to assure a smooth pack. Tape libraries invariably have professional tape winding equipment that is optimized for gentle handling during higher speed precision winding. At professional libraries preventive maintenance includes periodic rewinding to minimize print-through, depletion of lubrication and to interrupt stiction buildup from adhesive action. Recommended periods between rewindings varies greatly with storage conditions. Tapes stored at 20°C should be rewound every 3,000 hours. Tapes stored at 30°C should be rewound roughly every 300 hours.

Minute particles can cause serious system degradation (see Figure 3.4-8). Static buildup, scraping, scratching of the tape surface and separation in pack and head contact can cause dropouts and permanent

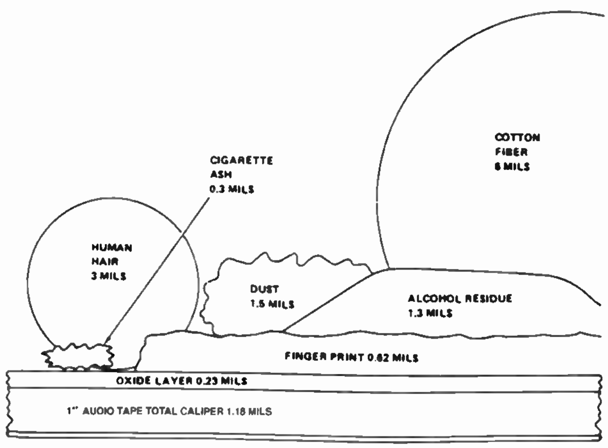

Figure 3.4-8. Relative size of various particulate debris. (From Ritter, *NAB Engineering Handbook*, 7th edition.)

tape move the frequency of maximum print-through lower. Because perpendicular susceptibility in modern audio tape formulations is approximately one-quarter of the longitudinal susceptibility one means to combat the more annoying pre-print effect is to wind tapes oxide out, as is common in European studios as well as standard in cassette tapes.

Velour Effect

As is the case for varying pre- and post-print effects, particle orientation has also been shown to exhibit different high frequency responses in forward versus reverse motion. When particles exist at a nearly right angle to the perpendicular recording field they may not be influenced strongly enough by the recording field. In general the very outermost layer of the coating surface exhibits less remanence. This is referred to as the *dead layer*. The dead layer is actually exploited in some digital recording systems with a longitudinal recording being multiplexed with a vertically recorded signal for greater information storage density. Stronger recordings result when the particle field is closer to agreement with the recorded field as shown in Figure 3.4-6.

Maximum Operating Level (MOL)

MOL_{333} is the maximum level output when the record level has been adjusted to produce 3% harmonic distortion. Some manufacturers use a 5% figure. MOL_{10} is the output between the normal reference level and the tape level at saturation recorded at 10 kHz. Operating levels are expressed in nano-Webers per meter (nWb/m) and are typically between 200–1000 nWb/m for audio tape. In broadcast environments a typical 15 ips setting may employ 320 nWb/m, with 7.5 ips levels set for 250 nWb/m.

Recorded levels depend on the amount of bias current. Each frequency will have an optimum bias current. High bias currents produce a clean, in-depth recording with low harmonic distortion, while a small bias current results in higher high frequency response and high distortion. A universal relationship regardless of tape formulation is that for tape stock with bias adjusted for maximum output at a 5 mil wavelength. One percent distortion is about 10 dB below tape saturation and the 5% distortion level is roughly 5 dB below saturation.

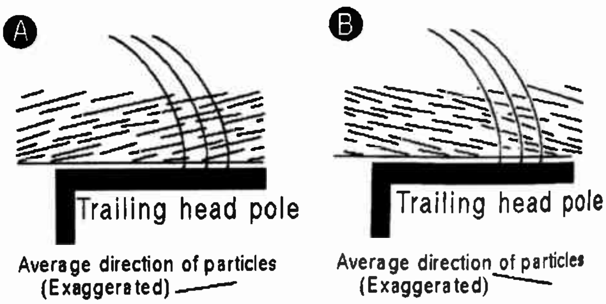

Figure 3.4-6. When particles are perpendicular to the recording field, a weak surface recording results (a); a stronger surface recording results when particles are not aligned perpendicularly to the field lines (b). (From Jorgensen, *The Complete Handbook of Magnetic Recording,* 4th edition, 1995, McGraw-Hill. Reproduced with the permission of the McGraw-Hill Companies.)

Table 3.4-1
Tape speed, coating thicknesses and time constants for audiotapes.

Application	Speed IPS	Coating δ μm	f_δ Hz	$\delta = 1/2\pi f_\delta$ μS	IEC/DIN μS	NAB μS
Studio	30	10	11,395	13	35	10
Professional	15	5	11,395	13	35	50
Home A	7½	5	5,970	27	50–70	50
Home B	3¾	5	2,985	54	90	90
Cassette	1⅞	2.5	2,985	54	120	90

(From Jorgensen, *The Complete Handbook of Magnetic Recording,* 4th edition, 1995, McGraw-Hill. Reproduced with the permission of the McGraw-Hill Companies.)

Coating thickness losses account for a 6 dB/octave increase in the voltage versus frequency response curve at low frequencies. Reproduce amplifiers must employ equalization circuits with a crossover frequency appropriate to the speed and coating thickness (see Table 3.4-1). Because relatively little high frequency energy is present in most music and speech, record current is boosted to achieve a uniform record level at high frequencies. The amount of boost is standardized in the United States according to NAB published criteria and DIN, CCIR and IEC in Europe.

Mechanical Considerations

High quality spooled recording media require precise speed stability and constant tension. In professional machines three motors are typically employed, one for the capstan speed, one for spooling the supply and one for the takeup reel. Most modern professional reel-to-reel analog tape recorders (ATRs) employ constant tension technology to minimize the possibility of stretching the magnetic tape stock. Constant tension is similarly important in achieving good tape pack to minimize cinching, debris pickup, and print-through. Most professional facilities store their tapes *tails out* not only to insure best pack but also to require a rewind prior to subsequent playback to shed any deposits or adhesion effects that can impair playback integrity.

The speed of the capstan must be precise and stable. The capstan's dimension must be perfectly concentric. Since perfection is hard to achieve in practice, mechanical variations that result in speed changes of up to 10 Hz are commonly referred to as *wow*, with speed variations above 10 Hz referred to as *flutter*. Wow is most typically caused by capstan shaft irregularities such as a shape eccentricity or debris pickup such as adhesives or dirt. Motor cogging and layer-to-layer adhesion in a tape pack can also contribute to wow.

Flutter is more typically generated by anomalies in the tape itself. Since magnetic tape has elastic properties, movement over tape guides and heads can cause minute longitudinal oscillations. Resonances set up in the tape medium by tension settings can also cause mechanical vibrations that will be exhibited as flutter. A variety of techniques have been devised to compensate for these effects, including simple masking techniques such as adding idler rollers along the tape path to shift the flutter resonances to higher frequencies

Considerations Unique to Analog Recording Systems

Decades of incremental refinements have been made in magnetic recording techniques. Bias, frequency response, signal-to-noise, print-through, oxide composition, backing media, lubrication and adhesive composition interact with one another and require trade-offs depending on the intended purpose of the recording. A wide range of tape formulations are available, with features specific to the application. Additionally, a wide range of speed, equalization, track widths, noise reduction and level standards have evolved on analog recorders for specific purposes.

Noise, Frequency Response and Bias

Because areas of magnetization increase as the square of the current value, the magnetization and recording process is nonlinear (see Figure 3.4-4). This nonlinearity presents innumerable challenges in reproducing high fidelity audio recordings. Early on it was discovered that when high frequency bias signals are added to the record head, the linearity of the magnetic recording process is improved. This is because the resulting heterodyned signal now moves into the more linear regions of the magnetization curve.

The mechanism of ac bias is familiar to anyone who has manually experimented with producing deep erasures on analog tape stock. The more smoothly the ac field is removed, the deeper the erasure. In practice this principle is applied as the ac bias field decays while the tape stock is moved past the trailing edge of the record gap at a constant velocity. Thus, the high frequency bias field causes the magnetization intensity to ramp down along a predictable hysteresis plot, leaving the tape in a final state that is proportional to the applied audio signal which is heterodyned with the bias signal (see Figure 3.4-5).

The remanence imprint is cleaner with higher frequency bias signals due to limited intermodulation. Thus, the bias frequency is generally set to at least five times the highest audio frequency to be recorded.

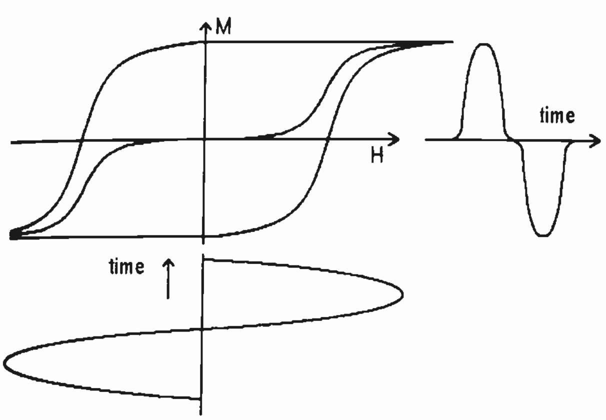

Figure 3.4-4. Zero crossing distortion is shown in a remanent magnetization coating. (From Jorgensen, *The Complete Handbook of Magnetic Recording,* 4th edition, 1995, McGraw-Hill. Reproduced with the permission of the McGraw-Hill Companies.)

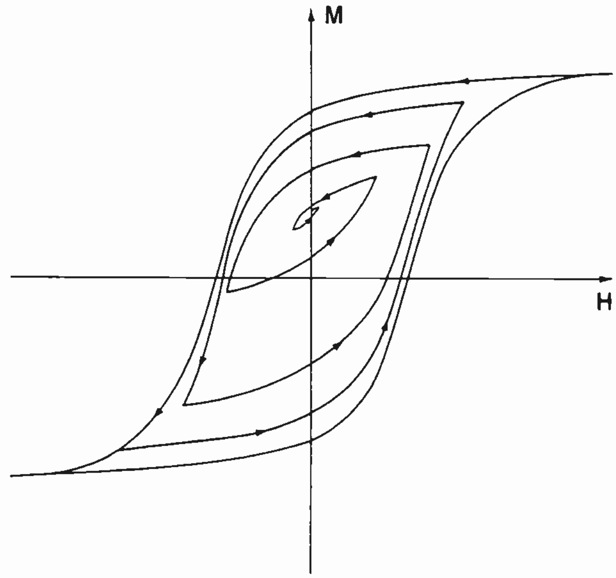

Figure 3.4-5. The principle of AC bias on a moving tape area, showing the decreasing magnetization swing of the high frequency bias signal, leaving the recorded intensity proportional to the superimposed signal field. (From Sharrock, NAB Engineering Handbook, 8th edition, 1992.)

The bias oscillator is also fed to the erase head, and for multitrack recorders a single oscillator is buffered and fed to each gap to prevent intermodulation. Bias current is typically 8–10 times the signal current. Normal bias is defined as the bias field which saturates the tape to its exact coating thickness. Overbias results in short wavelength losses but is frequently employed in professional audio recorders where equalization and higher tape speed maintain high frequency response; thus, even lower distortion is achieved.

Print-through

Print-through affects most magnetic tapes and is of major concern to archivists. As one would expect, print-through is more of an issue in thin base tapes, but coating techniques also affect print-through characteristics. Fe_2O_3 particle sizes can be problematic if too small or if oriented to be susceptible to magnetization levels in the adjacent contact layer. In some early oxide formulations 4% of the particles were small enough to be susceptible to magnetization by adjacent layers. Longer storage times as well as higher temperatures caused print-through to be increased. Typically, both a pre-print and post-print can be observed on each side of a strong signal in the quiet pauses around that signal.

Pre- and post-prints are typically of different magnitudes because the magnetization effect will be additive for one layer and subtractive for the other. When the wavelength of the recorded signal is equal to total tape thickness print-through is greatest. In practice a frequency of 1200 Hz on 2 mil tape at 15 ips combines for greatest print-through. Because this falls at the point of greatest aural sensitivity, methods to combat the effect are important. Slower speeds and thinner

Figure 3.4-2. Early German Magnetophone brought to the USA after capture by officers in the U.S. Army Signal Corps. (From Jorgensen. *The Complete Handbook of Magnetic Recording,* 4th edition, 1995, McGraw-Hill. Reproduced with the permission of the McGraw-Hill Companies.)

modern media to embrace digital techniques, professional archivists continue to prefer and insist on analog recordings due to known fault tolerances and stable format standards that will undoubtedly be readily available for the foreseeable future, even if they are fast losing favor in daily production.

MAGNETIC AUDIO RECORDING OVERVIEW

Domain theory is the basis for explaining ferromagnetic phenomena. In 1907, Pierre Weiss first posited the existence of *atomic magnets*, although Ampere had earlier theorized that magnetism in lodestones might be due to some molecular circulating currents inside the material.

At room temperature there are three materials where there are unpaired electron spins: four electrons in iron, three in cobalt, and two in nickel—precisely the materials in use in magnetic recording technology. These unpaired electrons will undergo exchange between adjacent atoms resulting in quantum mechanical forces of exchange. When the exchange value is positive, neighboring electron spins align and produce strong magnetization levels inside the ferromagnetic material. The spins will align themselves inside small volumes, called *domains* that can be as small as 1 μm or as large as 2 cm. At temperatures approaching absolute zero (0 degrees Kelvin) spin alignment becomes seemingly uniform and magnetization is highest. At higher temperatures thermal agitation causes excursions in the angle of mutual orientation as the exchange forces lose control. The temperature at which the material loses ferromagnetism and becomes diamagnetic is called the *Curie Temperature*. Upon cooling the material becomes ferromagnetic again, but has no memory of its prior magnetization. Typically, between 10^{12} and 10^{15} atomic moments comprise each magnetic domain.

The direction of magnetic domains varies from domain to domain, with net overall magnetization being zero in perfectly virgin ferromagnetic material, such as deeply erased audiotape. Domain behavior has been observed by applying a colloidal iron powder on the polished surface of a sample and viewing the resultant *bitter patterns*.

Magnetic fields are expressed as H, with flux lines shown by the symbol Ø. The intensity of the magnetic field is expressed in terms of flux density B and varies with the number of field lines. Flux density is measured in weber/m^2.

When a magnetic field is strong enough to realign the magnetic domains, even after the field is removed, the amount of magnetism remaining is called *retentivity* or *remanence*. The field required to oppose and reduce the retentivity to zero, or in other words to erase the magnetic field is called *coercivity* and is expressed as H_c.

Coercivity is measured in Oersteds (Oe), with typical analog tape stock requiring about 370 Oe for full erasure. Digital open reel tapes require over 700 Oe and metal particle tapes between 1,200–1,500 Oe for full erasure.

Hysteresis is the lagging of the magnetizing effect behind the magnetizing force as illustrated in Figure 3.4-3. Flux density (B) increases with the field intensity (H), but in a non-simultaneous fashion. As field intensity increases flux density increases reasonably uniformly until approaching saturation beyond which no further flux density is produced. Reducing the field intensity reduces the flux density, but note that when the field intensity is reduced to zero the flux density remains above zero. This is due to the magnetic material's *retentivity*. Only by applying an opposite polarity field of sufficient intensity will the flux density again reach zero. Hysterisis plots are unique for specific media samples due to vagaries in impurities, crystal structure, slip planes and stresses.

3.4
AUDIO RECORDING SYSTEMS

MICHAEL STARLING
NATIONAL PUBLIC RADIO, WASHINGTON, DC

INTRODUCTION

Until just over 100 years ago all sound was *live* sound. It was only with the harnessing and commercial use of electricity that amplification was developed and subsequently led to the widespread ability to store and reproduce sound waves. The faithful reproduction of sound waves is the goal of audio recording systems.

For most of the 20th century, analog magnetic tape has been the broadcaster's principal medium for audio recording. Magnetic recording is an interdisciplinary field of physics, chemical and material sciences, electronics and mechanical engineering. Current practice and research is focused on the implementation and standardization of digital recording techniques using magnetic, optical and even static storage media. The massive storage requirements for digital audio have led to significant advances in perceptual compression techniques and high-density research and development.

History

Audio recording preceded and helped fuel the introduction of broadcasting. The earliest recorded audio was Edison's 1877 cylindrical gramophone employing a constant velocity vertical recording groove. The gramophone's cylindrical media mandated that each recording be a master and stymied mass production. The flat disc recordings that dominated recorded audio for the next half century permitted impression duplication in mass quantities.

Early broadcast use of recorded media exploded in the late 1920's with the introduction of Berliner's mass-produced, laterally recorded flat disc. This development coincided with the rapid proliferation of AM broadcasting. Among the first actions of the Federal Radio Commission in 1928 was the deletion of several stations due to their heavy reliance on airing commercial records which the FRC cited as, "provision of a service which the public can readily enjoy without the service." The new FRC favored original programming and this too stimulated the use of recording lathes at the burgeoning population of radio stations. While many, if not most, early broadcast facilities acquired recording lathes for production of recorded audio, it was not until after World War II that saw the widespread debut of the more forgiving and affordable magnetic tape recording.

Danish telephone engineer Valdemar Poulsen demonstrated a magnetic wire recorder as early as 1898 as shown in Figure 3-4.1. Not until thirty years later did German researchers pioneer magnetically coated, paper-based tape for good quality recorder/reproducers.

By 1936, German scientists had advanced magnetic based recording using cellulose base-tape and achieved remarkably good sound quality. After the war, the AKG Magnetophone (see Figure 3.4-2) was copied and commercially exploited worldwide. Paper tape backing was immediately abandoned. A host of benefits including portability, immediacy of playback, ease of storage, wide dynamic range, low distortion and freedom from ticks and pops propelled magnetic recording to the forefront in broadcasting. Of paramount significance was the influence of a technology that no longer depended on laboratory processing. This was in modern terminology a democratizing development, much as is the current proliferation of digital audio workstations.

For nearly a half-century magnetic tape recording has dominated broadcast production. Even today audio archivists continue to insist that important original recordings come to them on analog reel-to-reel, rather than any of the multitude of recent digital media formats. Despite the inexorable and accelerating trend for

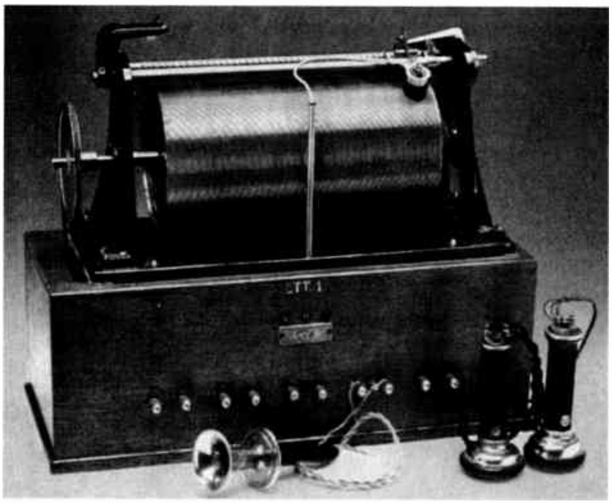

Figure 3.4-1. Valdemar Poulsen's Telegraphone won a Grand Prix Award at the 1900 Paris World's Fair. The device used pole pieces that attached to each side of the wire. Later improvements included a disk surface of 5.25 inches with longitudinal recording on both sides of the disk. (From Jorgensen, *The Complete Handbook of Magnetic Recording,* 4th edition, 1995, McGraw-Hill. Reproduced with the permission of the McGraw-Hill Companies.)

11. Avoid moisture in cables and connectors, particularly where phantom power is being used.

sound source is placed between the 90° arc of the front capsules of the two bidirectional elements. The stereo sound achieved by this approach can be very natural and mono integrity is well maintained. The Blumlein is more sensitive, however, to ambient noise and reverberation than the M–S and placement is critical.

CARE AND FEEDING

Microphones require a certain amount of care in their handling and storage. Here are some basic factors to consider and tips on microphone care. Misuse, or even some attempts to service or clean the microphone, could affect some manufacturers' warranties. When in doubt, ask or return microphones to the manufacturer's recommended service organization for maintenance.

1. Use a windscreen or pop filter to protect microphone if it is to be subjected to air-borne contaminates such as dust or smoke.
2. A foam windscreen will also protect a microphone from exposure to rain or snow for a surprising period of time. Over time, the cells will fill with water resulting in high-frequency loss and level drop. The foam may be quickly squeezed to reduce the moisture content or a dry screen substituted as required.
3. Foam windscreens will accumulate deposits of dust and other contaminates. The result will be a deterioration of frequency response and, perhaps, even altered polar response. Foam may be cleaned with soap and water. Rinse well to remove all residue. Non-detergent soaps work well.
4. Many microphones may be carefully opened to remove a foam pop filter and sometimes a cloth insert. Do so only in a very clean environment. These filters should be cleaned as detailed previously.
5. Avoid allowing dynamic microphones to be set on work benches or other areas where metal particles or metallic dust may be attracted to their internal magnet structures. Very small particles can work their way onto the diaphragm and alter the response greatly. In some cases, the dynamic microphone can be opened to reveal the diaphragm for examination. Metallic particles may be very carefully removed onto the magnetized tip of a screwdriver. The screwdriver shaft should be steadied on the edge of the microphone case and the tip very carefully lowered to attract particles which would likely be held immediately above the voice coil gap.
6. Avoid subjecting electret condenser microphones to high temperatures. This means do not store in the trunk or glove compartment of a car left in the sun on a hot day. Also avoid leaving the electret microphone on a boom very close to hot lights. The result may be a loss of charge on the capacitor element and a drop in level.
7. Avoid moisture with all microphones but especially with condenser microphones.
8. If given a choice between using mercury or alkaline batteries to power a microphone, remember that mercury cells die much more suddenly than alkalines. The gradual drop in level with an alkaline can be a life saver. Mercury batteries also drop in output level in cold weather. Furthermore, mercury batteries may give off a gas that can corrode the contacts.
9. Avoid unnecessary mechanical shocks. Store in clean, padded enclosures.
10. Moving a condenser microphone from a cold environment to a warm one may cause noise problems from condensation.

Figure 3.3-32. M–S microphone with internal matrix. (Courtesy of Shure Brothers Incorporated.)

A mixer may also be used for deriving L/R information from the M–S pair as shown in Figure 3.3-34.

The M–S technique offers several control capabilities. The first two of these controls may be exercised in either production or post production—another big bonus:

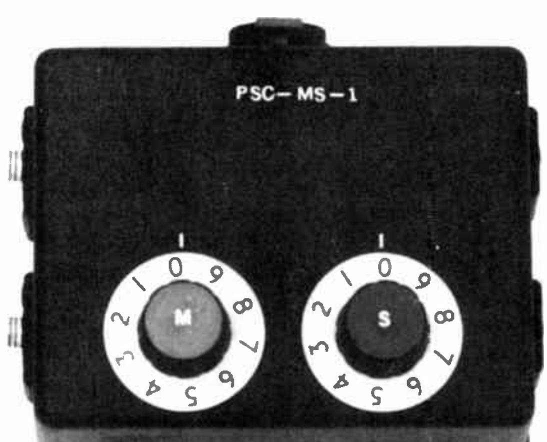

Figure 3.3-33. An M–S matrix decoder. (Courtesy of Audio Services Corporation.)

1. Adjusting the relative levels of the M and the S signals will narrow or broaden the perceived stereo image. This may be done in the field using the M–S microphone's matrix system or you may opt to record the outputs of the M and S capsules on separate tracks, saving the matrixing of them for post production. Matrixing in post will allow the audio perspective to be adjusted to make sense with the video.
2. Panning the M signal off-center may be done to deliberately shift the stereo image. For example, crowd noise at a sporting event may be shifted to appear more closely balanced left and right of a microphone position without moving either the microphone or several thousand fans.
3. Substituting various patterns, from omni to hypercardioid, for the mid microphone will affect the apparent microphone-to-sound source distance as well as the signal-to ambient or reverberant-noise ratio.

Blumlein Miking

The Blumlein technique employs coincident crossed bidirectional elements and, like the M–S, responds to amplitude differences to achieve stereo separation. The

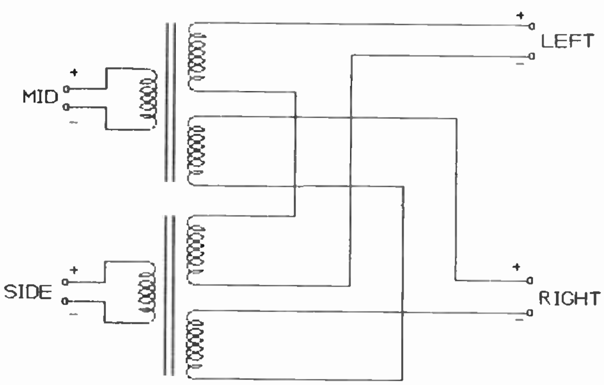

Figure 3.3-31. A passive M-S matrix.

Mid-Side Coincident Microphones

The most versatile of the coincident microphone types for stereo broadcasting is the M–S or "mid-side" microphone, whose polar pattern is shown in Figure 3.3-30. The M–S microphone is a combination of a *mid microphone*, typically a cardioid or hypercardioid, and a bidirectional, *side microphone*. The capsules of the two are placed as close together as possible. A matrixing network combines their outputs and decodes them as left and right channel information, as illustrated in Figure 3.3-31. The information derived from the matrix is nearly identical to that delivered by an X–Y pair, but with some important control advantages.

Sound originating from directly on-axis of the M–S microphone will be picked up by the mid element and delivered equally to left and right channels through the matrix. The mid microphone, which faces the left, with its rear lobe facing right, is insensitive to sound arriving from the center of the stereo stage as the sound is arriving at 90° off axis, where the null is deepest. It is, of course, sensitive to sound arriving from each side.

This is part of the process by which the M–S microphone derives directional cues. Sounds arriving from the left are picked up by the mid and side elements and, because they are in phase, are summed and sent to the left channel. Because the rear of the side element is out of phase with the mid microphone, their sum cannot be used to produce right channel information. Instead, an inverted-polarity version of the side microphone output is mixed with the mid microphone and delivered to the right channel. This processing happens in the sum-and-difference matrix according to the equations:

$$\text{Left} = \text{mid} + \text{side}$$
$$\text{Right} = \text{mid} - \text{side}$$

Commercially available M–S systems offer well-matched capsules, easy operation and considerable control flexibility. The model shown in Figure 3.3-32 incorporates the matrix system and offers a choice of outputs: mid and side or stereo. It also features a three-position control over the degree of stereo "spread" and stereo ambience pickup.

An M–S pair may be constructed using mid and side microphones from the station's collection plus a matrixing system. Several M–S matrices or decoders have been introduced for such use (see Figure 3.3-33).

tial for good stereo without adversely effecting the mono signal with the phase anomalies introduced by spaced microphones. Coincident microphones depend only upon amplitude differences for stereo separation and imaging and provide excellent mono compatibility. There are several coincident microphone schemes including X–Y, M–S, and Blumlein.

X–Y Microphones

The simplest of the coincident techniques is called "X–Y," which crosses two directional microphones so that their patterns meet at their 3 dB-down points (see Figure 3.3-27). The two microphones should be positioned so that one capsule is directly above the other, with the capsules on the same vertical axis. This minimizes any reflection or shadowing of high frequencies that each might contribute to sound arriving on the horizontal plane (see Figure 3.3-28).

An ideal cardioid microphone would have an acceptance angle of 131° and so would be 3 dB down at 65.5° off axis. If a pair of coincident cardioid capsules are rotated apart so as to overlap their polars at 65.5° off each microphone's axis, the resulting angle between the microphones' axes is 131°. If the angle is too great, sound sources at the center of the stereo image are placed farther off axis of each microphone and are thereby attenuated, making them sound as if they are farther away. Similarly, too narrow an angle results in near-center sources sounding louder, or appearing to be closer. Crossing the patterns to overlap at their 3 dB-down points insures that sound arriving from the center of the stereo stage will be summed such as to provide uniform sensitivity from left through center to right.

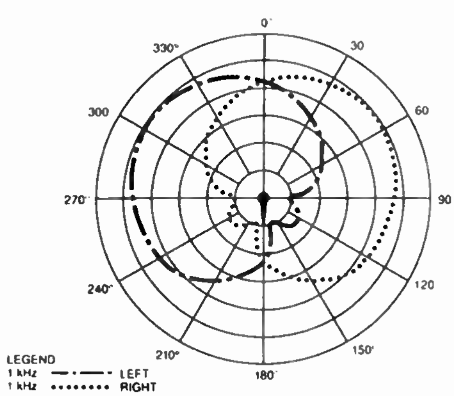

Figure 3.3-27. X–Y pattern orientation. (Courtesy of Audio-Technica U.S., Inc.)

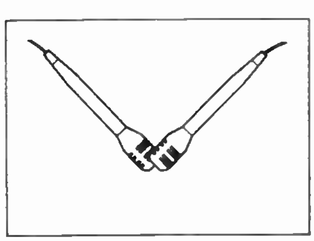

Figure 3.3-28. X–Y capsule orientation. (Courtesy of Audio-Technica U.S., Inc.)

While a 131° angle would be correct for ideal cardioid capsules, the optimum angle for real microphones will likely be somewhat less. It is very beneficial for the microphones used in X–Y to have uniform polar patterns. Because the polars of most cardioid microphones tend to collapse at higher frequencies, it is frequently recommended that X–Y positioning be 90°. This narrow spacing, however, often results in too much overlap of the polars. Stereo separation suffers and center-channel information tends to be brought forward of where it should lie in the stereo image.

The optimum angle for many cardioid elements will be approximately 120°. Experimentation and a thorough knowledge of the polars of the microphones you choose to use will help you get the best X–Y results. Even highly directional shotgun microphones may be used successfully in X–Y, particularly if you are careful to select some of the newer models that have greatly improved polar uniformity. Remember to cross the microphones at the elements, not the ends of the microphones.

A quick check outdoors can be made of the angle adjustment of an X–Y pair using the following procedure:

1. Sum the outputs of the two microphones into a mono audio monitor and provide equal gain for each.
2. Feed pink noise into a small powered speaker about 5 to 6 ft. in front of the shotgun microphones.
3. Rotate the X–Y pair horizontally at their capsules so that you can monitor the pink noise from far left channel to far right.
4. Pay particular attention to the amplitude at center. There should be a smooth transition from left to right channel. If there appears to be a hole in the middle, the angle is too great. If the noise seems suddenly closer at the center, try increasing the angle.

Several X–Y stereo microphones are available that integrate two directional elements into one housing (see Figure 3.3-29). These greatly simplify microphone placement. While easy to use, they should be handled with some measure of intelligence. It may seem obvious that in most cases the axes of the left and right microphones should be near horizontal. Some X–Y microphones, however, hide their capsules in round housings or windscreens that do not permit a quick visual indication of just what is horizontal.

It is not a good practice to use an X–Y microphone for a close-up announcer or reporter application. Even slight side-to-side head movements can cause the voice to shift dramatically from one channel to the other. A good example of a bad application would be to use an X–Y microphone vertically, hand-held, for a stand-up.

microphones are spaced, how closely matched their frequency responses are and the relative levels of the two mixed signals. It should be noted that the terms *phase* and *polarity* do not mean the same thing. Phase refers to a difference in the relative timing of two signals. Polarity refers to the wiring of a microphone or connectors in its circuit and, when reversed, results in a simple shift of 180° in the phase of the signal. Having noted this distinction, in common usage, the terms in phase and out of phase are often used to refer to matters of polarity. Most microphones will be wired to what is sometimes called the "RCA pin count" which is:

Pin #1 shield
Pin #2 high
Pin #3 low

This conforms to IEC standard 268-12 and 268-4. Refer also to EIA-221 (paragraph 3.3) which states that the in-phase terminal shall be the red (or other than black) conductor and that the out-of-phase terminal shall be the black conductor. The terms "in-phase terminal" or "high" (pin #2) indicate the terminal that has a positive voltage present when a positive pressure is applied to the microphone diaphragm.

Checking Polarity

While there are commercially available devices that use a pulse generator to check for polarity reversal, microphones and their cables may also be checked by simply bringing them together and summing their output while speaking into them from a foot or so away. Two microphones which are "in phase" will deliver a higher output under such a test; if they are reversed in polarity, the output should drop noticeably.

Polarity Reversal as a Tool

While inadvertent polarity reversal in a microphone line can result in some very bad audio, deliberate polarity reversal is sometimes employed as a problem solver.

Reducing Background Noise

A pair of microphones may be reversed in polarity to reduce the pick up of ambient noise. This technique is sometimes employed with two microphones in fixed locations, such as in a press box at a sporting event. If these microphones are brought together, a noise-canceling or differential microphone is created. The speaker must now talk into one of the microphones only, virtually in a lip-touching position. Because of the inverse-square law, the amplitude of the voice at that microphone will be much greater than at the other, resulting in reasonable output level. Distant sound will be picked up equally well, however, by both elements and canceled.

STEREO MICROPHONE TECHNIQUES FOR BROADCASTING

As a general rule, in producing stereo audio for broadcast, dialogue should be placed in the center channel, or perceived center, with only music and effects in stereo. Exceptions would be where spatial effects are important to the broadcast material.

Spaced-Pair Microphones

It is of utmost importance to provide high quality stereo audio without compromising mono audio quality. This importance of maintaining compatibility with monaural receivers (or stereo receivers operating in the monaural mode) normally excludes the use of spaced-pair microphone techniques involving omnidirectional or cardioid microphones. Spaced microphones depend upon a combination of amplitude and timing (phase) differences to provide stereo separation. They do not sum well for mono as the very phase differences that aid in separation result in multiple comb filter effects in the mono mix.

Coincident Microphone Techniques

Coincident microphone techniques utilize two microphones whose diaphragms are placed as near to the same point in space as possible. They offer the poten-

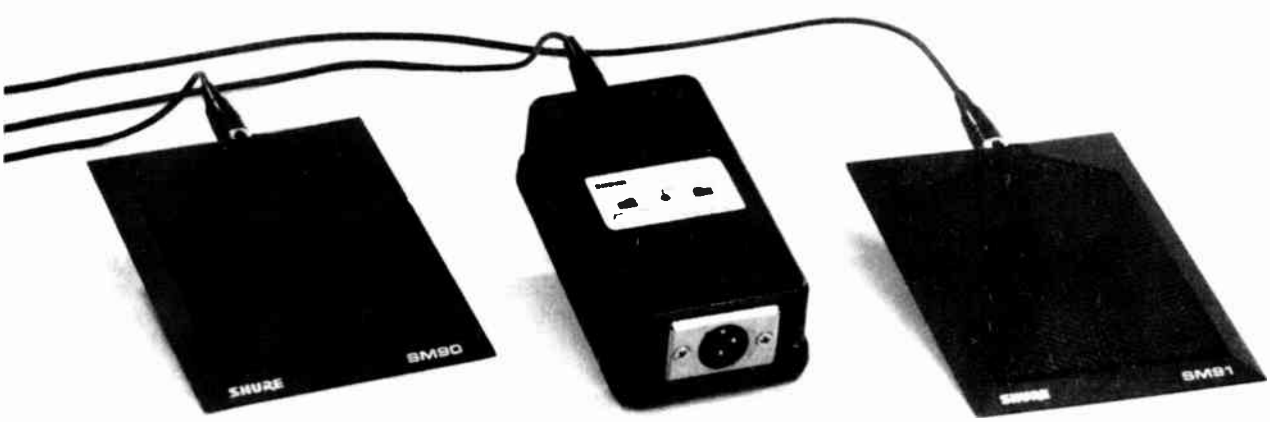

Figure 3.3-26. Cardioid and omni microphones designed for surface mounting. (Courtesy of Shure Brothers Incorporated.)

employed in this manner when redundancy miking is desired for critical applications. When two are used, place one above the other. Normally, only one of these microphones would be open at a time—the second is strictly a backup. Sometimes multiple microphones are used to feed separate systems, such as for house PA, government agencies, and broadcast. Each may still be used as a backup.

Adjacent pairs of cardioid microphones may at times be angled inwardly with their axes crossed and their diaphragms closely spaced. This may be done in order to broaden the acceptance angle of the two microphones while still maintaining some cancellation at the rear. The microphones' close proximity allows their diaphragms to occupy nearly the same point in space, thus reducing sonic time path differences. This ensures that negligible phase cancellation will occur should their output be summed. The same formation is often used as a 2-microphone stereo pickup technique and has the added benefit of good mono compatibility.

Obviously, there are many times when the outputs of two or more open microphones must be mixed. How, then, to avoid phase cancellation? Phase cancellation problems occur when identical signals, at the same or nearly the same amplitude, are allowed to combine at something other than zero phase angle. The result of reducing phase angle error by placing the two pickup elements close together has been shown. It is also possible to influence the amplitude difference between the two combined out-of-phase signals through careful microphone placement. The *3:1 ratio rule* is a good rule of thumb to follow in microphone placement.

To eliminate the problems demonstrated in Figures 3.3-23(a) to 3.3-23(e) by employing the 3:1 ratio rule, D3 must always be at least three times D1. Figure 3.3-25 shows examples of both the violation and enlistment of the 3:1 ratio rule. Subjective tests have shown that an amplitude difference of at least 9 dB between the two signals will reduce phase cancellation to an inaudible level. The 3:1 ratio rule is a means by which this 9 dB minimum difference may be quickly approximated in most multiple-microphone setups.

The amplitude variance desired may also be achieved by judicious use of the mixer's gain or fader controls. Only microphones in actual use should be opened to their normal operating levels; others should be lowered in level or preferably off. Attentive monitoring on an accurate control room speaker system or headphones will reveal audible phase problems, especially with relatively simple sound sources such as speaking voices or most solo instruments.

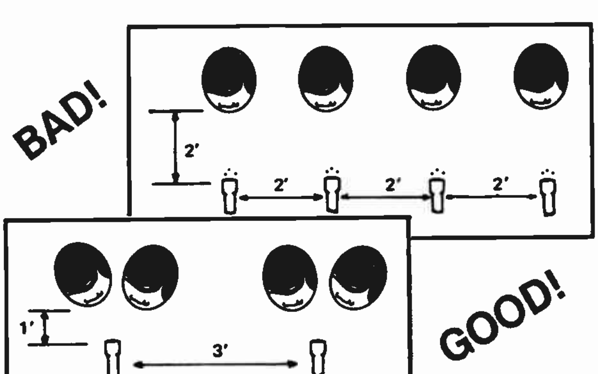

Figure 3.3-25. Obeying and violating the 3:1 ratio rule.

Acoustic Phase Cancellation with a Single Microphone

Acoustic phase cancellation can also occur in a single microphone system when reflected energy from a nearby barrier such as a music stand, podium, table or floor is introduced at the microphone's diaphragm at a sound pressure level within 9 dB of the direct sound. Such problems may be avoided by four different means:

1. Increase the reflected path length.
2. Shorten the direct sound path length.
3. Reduce the reflectivity of the barrier. It may be possible to cover the barrier with an acoustically absorptive material or construct it of an acoustically transparent material. For example, use an acoustically-transparent, visually-opaque screen in chroma keying to eliminate reflections into a weather person's lavaliere.
4. Position the microphone so close to the barrier surface that the direct and reflected sounds arrive at virtually the same time, causing them to be in phase. The latter method also results in higher microphone output because of the additive effect of the two in-phase signals. As discussed in the section on acoustic gain devices, the microphone is operating in (or nearly in) a *half-space environment*. This barrier (boundary layer) miking technique may be employed with omnidirectional or directional elements (see Figure 3.3-26). The omni may be recessed flush into the surface facing out for best performance.

The results of barrier miking will vary because of the following influences:

1. The size of the barrier. The barrier must be large to support low frequency response.
2. The size of the diaphragm. Very small diaphragms may be positioned extremely near the barrier, resulting in less high-frequency cancellation.
3. The reflectivity and resonant characteristics of the barrier.
4. Ambient noise or reverberant energy problems.
5. Reflections from other nearby reflective surfaces.

Microphone Polarity Reversal

Phase cancellation will also occur if the outputs of two microphones, positioned in the same sound field, are combined with their polarities reversed (pins 2 and 3 are reverse wired at one end of one cable). The frequencies canceled, and the degree to which cancellation will occur, will depend upon how far apart the

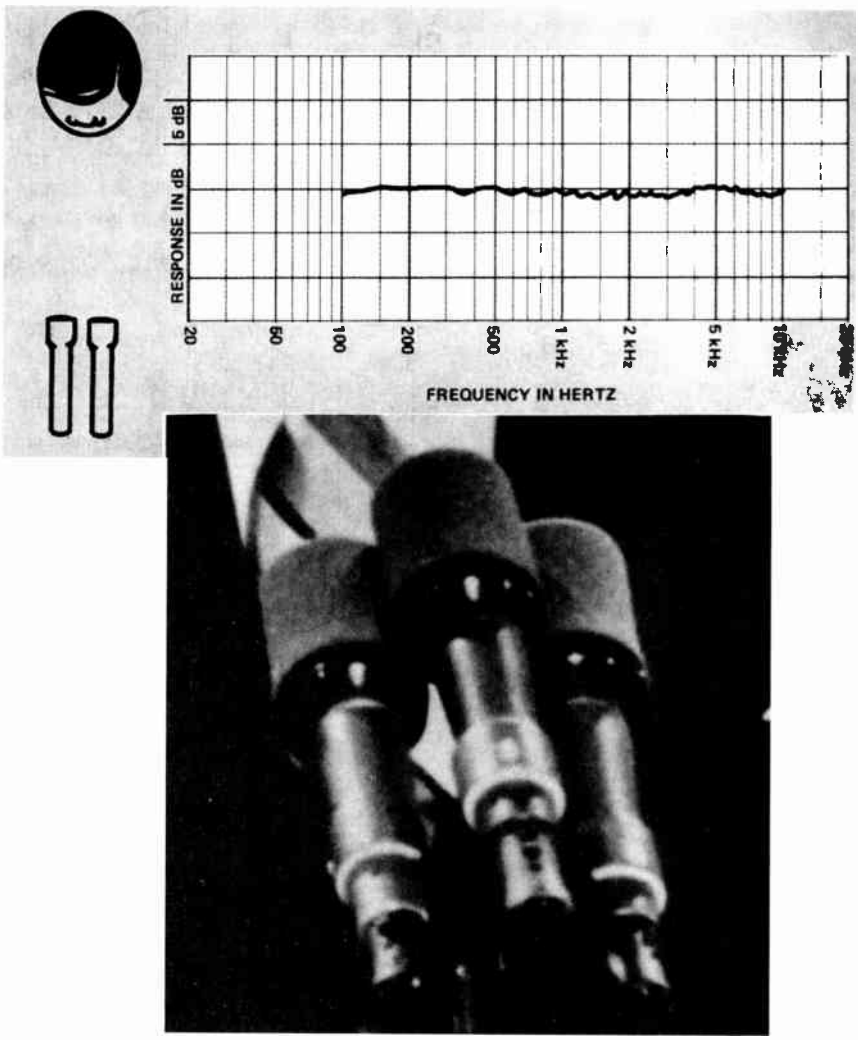

Figure 3.3-24. Redundancy miking. (Courtesy of Shure Brothers Incorporated.)

form (FFT)-derived displays of the actual frequency response of the two microphones combined, with respect to a sound source positioned as shown. The FFT analyzer and its companion microprocessor were used to compare the combined output of two matched, calibrated microphones to the output of one of the two microphones by itself. If no phase cancellation occurred, no trace variations would appear on the X/Y plot, as its plot would be a straight line.

It does not take much study of the response charts to see that, no matter which way the microphones and sound source are oriented, the summed response of the two microphones is poor. These experiments reveal quite graphically what the ear often perceives as a comb-filter or notch-filter effect that sweeps up and down in frequency (and even changes Q) as the variables D1, D2, and D3 change with the movement of the microphones or sound source. In more subjective terms, the resultant sound may be described as hollow, as if the sound is being forced through an empty cardboard tube.

Unfortunately, situations that cause acoustic phase cancellation arise quite frequently. One classic example occurs with a pair of microphones on a podium, spaced apart to provide on-microphone coverage as the speaker turns his head to address all of the audience in front. The curves shown in Figures 3.3-23(b) and 3.3-23(d) are typical of the problems caused by this approach. If the output of these two microphones is summed and fed simultaneously to a house sound system, there probably will be gain-before-feedback problems as well. Add the insistent creeping oscillation of a system on the brink of exceeding unity gain to the already intolerable frequency response of the microphone pair, and you'll have the quality of sound that makes the audience check the credits to see who handled the audio.

The simplest solution to the problems caused by this spaced-pair podium miking technique is to use one microphone only, placing it in front of the person speaking and toward the center of the podium. Figure 3.3-24 shows three microphones immediately adjacent to each other. Two (or three) microphones are often

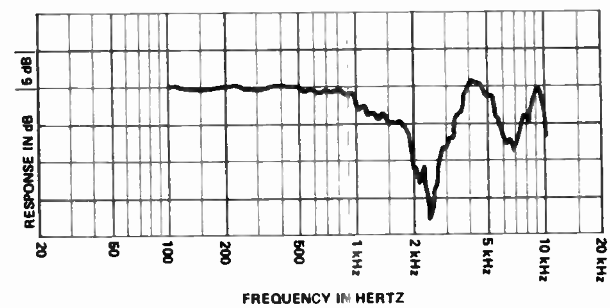

Figure 3.3-23(c). D_1 = 18″, D_2 = 21.6″, D_3 = 12″

to portions of the spectrum that are greatly attenuated. This change in the microphone's apparent frequency response is the result of acoustic phase cancellation. Acoustic phase cancellation may occur when two or more microphones are mixed, or even when a single microphone is subjected to an overdose of reflected sound. Figures 3.3-23(a) to 3.3-23(e) show the severe phase cancellation problems that can result from several typical miking situations.

Although sound arriving at each microphone is identical, originating at the same source, it arrives at the two microphones by paths of varying lengths. This causes a difference in the arrival times and results in phase cancellation of certain frequencies. The curves given for each of these examples are fast Fourier trans-

must cross microphone lines, separate the ac lines so that they cross at different points.

Use twisted pair cable Leads should be twisted inside the microphone and out. The virtually identical positioning this provides for the two conductors within the hum field, and the fact that they are out of phase with each other, will further increase induced hum cancellation.

Use well-shielded cable Installed cable may use a foil shield as flexibility and low flex memory are not a factor. Good stage and field cable, though, normally has a braided shield. Some of the cables which offer the best combinations of flexibility and good shielding use conductive cloth or conductive vinyl under the braided shield.

Follow good grounding practices, avoiding ground loops.

In general, dynamic microphones are much more sensitive to induced hum than are condenser microphones. The voice coil can be a very effective inductor. Hum-buck coils are employed in some designs that lower electromagnetic hum sensitivity by about 20 dB. The hum-buck coil is wrapped around the outside of the motor mechanism and wired in series with the voice coil but out of phase. When both coils are placed into an electro-magnetic field, equal energy is induced onto each. Because they are out of phase with each other, the offending signal is cancelled.

Transformers located within microphones should be avoided if electromagnetic hum is a possible problem. Some transformers are constructed with hum-bucking characteristics, however, to greatly reduce their hum induction potential.

In severe problem situations, operation at line level rather than microphone level may be required.

Acoustic Phase Interference

Another miking problem relates not to sounds that are added to the output, such as popping or hum, but

Figure 3.3-20. Zeppelin-type windscreens for shotgun microphones. (Courtesy of Audio-Technica U.S., Inc.)

duction of a transducer's sensitivity to such noise, or the improvement of its acoustic-to-mechanical-noise sensitivity ratio, starts with the basic element design.

First, omnidirectional microphones are lower in mechanical noise than comparable directional systems. Second, condenser microphones, because of their inherently lower diaphragm mass, are superior in this respect to dynamics. Also, as the size of a dynamic system is reduced (such as in dynamic lavalieres or some small hand-held systems) the acoustic sensitivity tends to decrease while the mechanical-noise sensitivity may remain fairly constant. When the resonant frequency of the microphone's mechanical sensitivity is low, a high-pass filter may be used.

Microphone elements are, of course, often internally shock-mounted by the manufacturer to avoid the transfer of noise from the case to the element. Lowest noise is achieved through the combining of omni or even omni condenser systems with internal shock mounts, as illustrated in Figure 3.3-21.

External shock mounts are often employed in stand or boom-mounted microphone applications. Properly designed shock mounts allow excursion on-axis, or perpendicular to the diaphragm plane. Excellent mechanical isolation may result from using an external shock mount on an internally shock-mounted microphone. Provided that the resonances of the two systems are dissimilar, they will stagger, increasing the effective isolation (see Figure 3.3-22).

Another method of reducing mechanical noise is to raise the resonant frequency of the mechanical drive system. An example would be that of bracing wooden platforms, tables or lecterns to eliminate the very audible, drum-like sound produced when they are struck. The use of very high-density materials for microphone support systems will result in a higher resonant frequency. A microphone stand set onto concrete or into sand gains advantage from this density.

Mechanical noise transfer to the diaphragm may also be reduced through decoupling the diaphragm from tensile forces, converting them to lateral forces. This may be illustrated as follows:

Select a microphone that has some noticeable handling noise problems and plug it into a talk-out system, raising the gain until the handling noise is evident. Now hold the microphone face up (diaphragm horizontal), with the cable hanging straight down, and tap on the cable. This should produce a low thump. Next rotate the microphone 90° so that the cable is hanging at a right angle to the microphone axis. Tap the cable again and the thump should be all but gone. The mechanical drive that takes place longitudinally on the cable is no longer easily transmitted to the diaphragm in the direction of its compliance. Output, therefore is greatly reduced. This principal may be applied to custom hardware designs and the dressing of cables as they enter stand or boom-mounted microphones. A loop of cable or a small coiled cord lowers mechanical noise transfer by this method. Direct interconnection of boom cabling and a shock-mounted microphone can create a direct mechanical short between the two, bypassing much of the shock mount's effectiveness. A coiled cord may be employed between these two points to eliminate this direct path.

AC Hum Rejection

Microphones may also be sensitive to noise induced in them and their cables by electromagnetic or electrostatic radiation. This may be the result of proximity to power transformers, fluorescent ballasts, high-voltage ac lines, SCR dimmers, and so on. The following points should be considered in attempting to avoid or eliminate induced ac hum:

Insure that lines are balanced low impedance The higher the impedance of the microphone, the greater the voltage of the electrostatically induced hum. The balanced line insures that nearly equal hum will be induced on each conductor. Little differential is seen, then, at the amplifier input, resulting in common mode rejection of the hum. Pins 2 and 3 of the 3-pin microphone connector should carry the signal, with pin 2 most often "high." This would mean that positive pressure on the diaphragm produces a positive voltage on pin 2. The shield connects to pin 1 (ground).

Route cables with caution If possible, do not run low-level cables near high-voltage lines, avoiding especially long parallel runs of adjacent microphone and ac power cables. When such cables must cross, they should do so at right angles. If more than one ac line

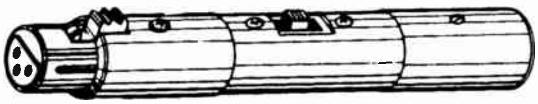

Figure 3.3-19. Microphone in-line attenuator. (Courtesy of Audio-Technica U.S., Inc.)

condenser microphones. A typical in-line attentuator is shown in Figure 3.3-19.

Durability and Reliability

Modern design and manufacturing techniques have provided the broadcaster with a variety of very durable microphone types. There are a few concepts that generally apply to a microphone design's potential durability, including the following:

The moving coil dynamic system offers more inherent durability than condenser or ribbon designs, although both of the latter systems have been employed recently in products that exhibit impressive durability. Also, if dropped on concrete, a lighter condenser microphone hits the surface with less momentum than its heavier dynamic counterpart.

Omnidirectional microphones are more easily built to be durable than are more complex directional designs.

Internally shock-mounted microphones may present a compromise in durability relative to rigidly mounted, nested designs.

Reliability is influenced by a variety of factors including design, construction, and quality control as well as the care that is taken in the use, transport, and storage of the microphone.

Voiding and Avoiding Noise Problems

Other unwanted signals include wind noise, "P-pop," mechanical or handling noise, AC hum and radio frequency interference (RFI). The reduction or elimination of each of these can be handled both through microphone design and user technique.

RFI problems can usually be traced to a point in the low level circuitry at which the signal leads are unbalanced, high-Z, or both. Condenser microphones, for example, may sometimes be sensitive to RFI at or around their impedance converter. In such an event, the manufacturer should be consulted for low-pass modifications or information.

P-pops may be reduced through several approaches:

Use an omni if possible Directional microphones are much more prone to P-pop problems than are omnidirectional ones.

Position the microphone out of the area of the breath blast In an announce application, speak across the microphone: on-axis but at a slight angle to the diaphragm. Stand-ups and hand-held interview miking should be done with the microphone capsule below the axis of the mouth.

Use a pop filter This is often the same as the manufacturer's windscreen. Avoid using foam filters that are not designed for the particular microphone model. If such a requirement arises, test the combination carefully for frequency response and directional characteristics before putting it into service. Windscreen/pop-filter foam is specially designed, reticulated foam that comes in a variety of densities. Even very acceptable open-cell foam may be too thick for use on some microphones. Nonreticulated foam (such as nerf balls) will roll-off high frequency response and alter the polar patterns of directional microphones.

Fashion a pop filter For radio and other off-camera miking, a piece of silk may be suspended a short distance in front of the microphone diaphragm. This is easily accomplished using a frame made of small, wooden hoops—the type used for embroidery. The outer of these concentric hoops expands for removal from the other ring. Surround the inner hoop with nylon hose material, pulling the fabric to one side where it may be sewn together with thread, and the excess cut off. Replace the outer ring and tighten it with the screw mechanism supplied. Attach the pop filter to an arm that will keep it positioned in front of the microphone. Adjust the distance between the two for best performance.

Use a high-pass filter Most of the disturbing explosive energy of a P-pop is very low in frequency. Try using a very abrupt high-pass (low-cut) filter in the microphone line. Rolling this energy off before it gets to the mixing board or recorder input will further reduce distortion in the audible range. Wind noise may be dealt with similarly to P-pop:

1. Omnis are preferred for low wind noise.
2. Use a properly designed windscreen. Most are made of reticulated foam. Superior results with shotgun microphones can be attained by using a well-engineered fabric/mesh cylindrical screen which provides an air space between the material and the microphone (see Figure 3.3-20). To handle severe cases (gale-force winds) special fur-like socks are available to wrap around the tubular windscreen. While this will result in some performance trade-offs, recordings made under such conditions are typically not intended for critical listening. Windscreens must cover all openings to the element: front and rear.
3. Use a high-pass filter.
4. A microphone with a limited low frequency response will help minimize wind noise. Extended-response condenser microphones can produce very high outputs of infrasonic energy when panned or when air around them is moved by air handling systems, etc. The result may be preamp overload or undesirable compressor or limiter action. Again, windscreens and or high-pass filters may solve these problems.

Handling or Mechanical Noise

The problem of mechanical, nonacoustic noise is one that plagues the user whether the microphone is hand held, body worn or hardware mounted. The re-

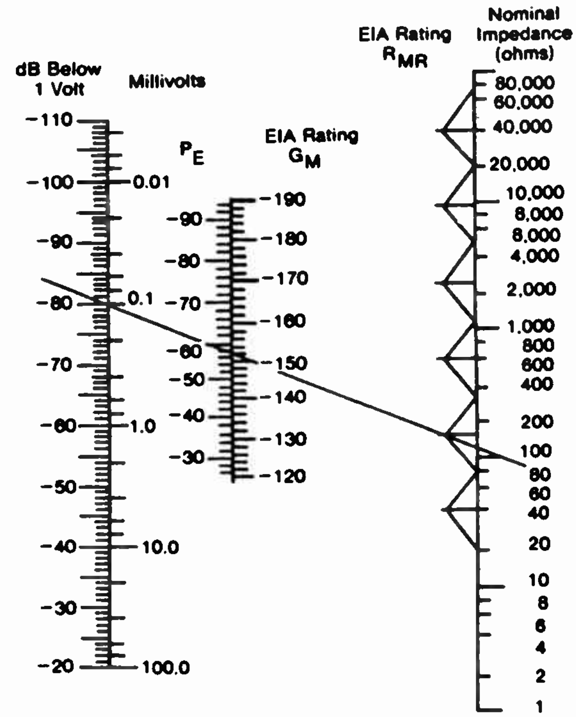

Figure 3.3-17. Nomograph: EIA sensitivity rating.

Figure 3.3-18. Microphone preamplifier. (Courtesy of Shure Brothers Incorporated.)

ance, ranging typically from 50 to 600 Ω. Dynamic moving-coil microphones achieve their low impedance by either a low-Z voice coil winding or a transformer. Condenser microphones use an impedance converter circuit to step-down the capacitor's high-Z output.

Low impedance offers the advantages of low susceptibility to hum and electrical noise pick-up, and the ability to use relatively long lines with a minimal loss of level or high-frequencies. Unlike matching power amplifier impedances to speaker systems, which may be desired for best power transfer, microphones need load impedances on the order of 10 times their internal impedance or even higher. This assures maximum voltage transfer. A microphone that looks like a resistive source of 150 Ω, looking into a load resistor of 150 Ω, for example, will suffer a 6 dB voltage drop compared to an open-circuit connection.

Dynamic Range

The difference between a microphone's own self noise and the maximum sound pressure level (SPL) it can handle is its *dynamic range*. In many field applications, ambient noise provides sufficient masking to make the self-noise specification of minor interest. The importance of this specification increases, of course, as greater working distances are demanded or ambient noise levels are lowered.

The impedance converter of condenser microphones, like any active circuit, will create some noise. The degree to which it does so will vary greatly from one design to another. The impedance converter design also determines the headroom, or maximum SPL that the condenser microphone can handle. A maximum SPL of as much as 141 dB is achieved in several high-quality condenser microphones. Such levels may never be encountered by lavalieres worn at a news desk or seldom by shotgun microphones that are more often attempting to pick up weak audio signals.

Dynamic microphones contribute virtually no self noise. When greatly amplified, only the noise of the thermal agitation of air molecules is detected. While this is very low in level, the dynamic microphone does not automatically rank as the first choice in a low-noise system. Because the output level of the dynamic is often lower than that of a condenser system, the user may end up working into the noise floor of the preamplifier in order to provide sufficient system gain.

Some new dynamic microphones employ powerful rare-earth magnets to increase the efficiency of their motor mechanisms. Their higher output, while still not as high as many condenser microphones, can provide a considerable S/N advantage over earlier designs.

Properly designed dynamic microphones are practically impossible to drive to audible distortion. The distortion heard when a dynamic microphone is subjected to the lips-touching proximity of a very loud rock and roll vocalist is usually the clipping of the electronics following the microphone. Outputs of 1 V or more may actually be delivered in such applications as rock and roll music. Preamp or amplifier clipping may be avoided by padding the microphone output or adjusting the trim (gain adjustment) of the mixer. Be aware that many mixers offer adjustment only after a gain stage or transformer, either of which may distort before any control is possible. In-line attenuators, or pads, are commercially available that allow the selection of 10, 20, or 30 dB of attenuation. These plug directly into the microphone line. Before using any in-line device, it is a good idea to verify that it is compatible with the powering system being used for

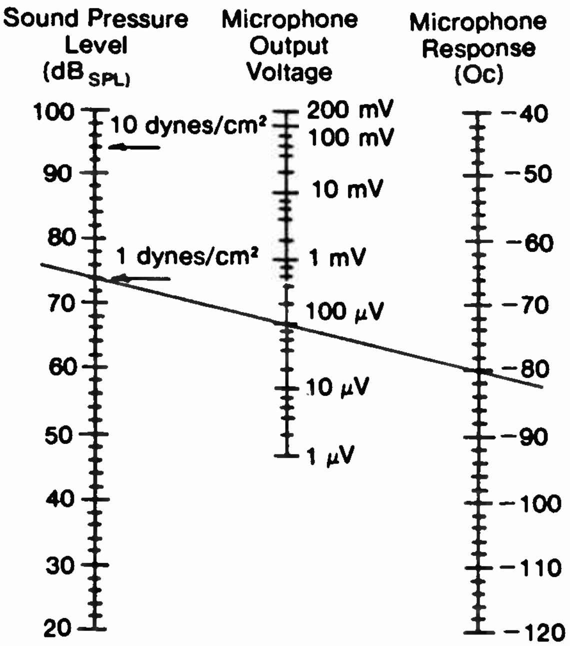

Figure 3.3-15. Nomograph: open circuit voltage rating.

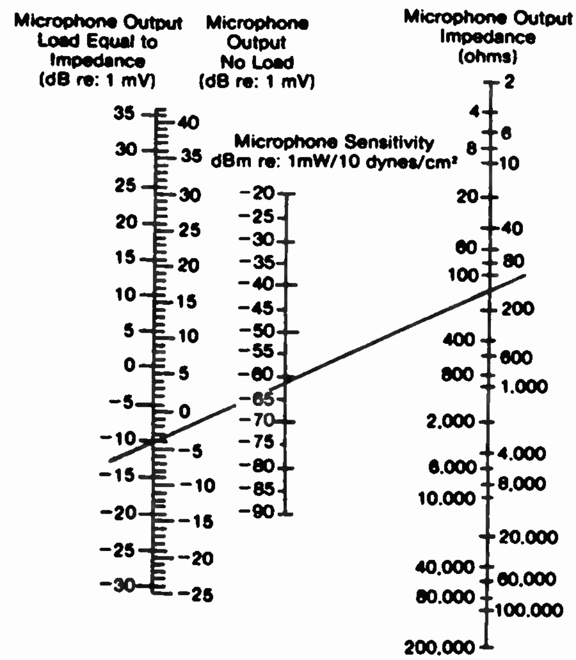

Figure 3.3-16. Nomograph: equivalent power rating.

Power Level

Microphone sensitivity may also be specified in terms of its output power level. This equivalent power level rating takes into consideration the open circuit rating and either the actual impedance of the microphone or the rated impedance. Specifications given would be in dBm (or just dB) referenced to 0 dB = 1 mW/10 dynes/cm² or 0 dB = 1 mW/Pa.

Calculating the power level rating may be done with the following formula:

$$P_E = V_{OC} - 10 \log_{10} Z + 44 \text{ dB}$$

where,

P_E = Equivalent power level
Z = Impedance of the microphone

A nomograph for determining the equivalent power rating is shown in Figure 3.3-16.

EIA Sensitivity Rating

The EIA sensitivity rating is one of those specifications that is sometimes specified but hardly ever used. The formula for determining EIA sensitivity is as follows:

$$ESR = V_{OC} - 10 \log_{10} R_{MR} R - 50\text{dB}$$

where,

ESR = EIA sensitivity rating
V_{OC} = Open circuit voltage in dB
R_{MR} = Center value of the nominal impedance range

Table 3.2-2 may be used for determining R_{MR}. An EIA sensitivity rating nomograph is given in Figure 3.3-17.

Table 3.3-2
Table for determining R_{MR}.

RANGE (in Ohms)	CENTER VALUE (in Ohms)
20–80	38
80–300	150
300–1,250	600
1,250–4,500	2,400
4,500–20,000	9,600
20,000–70,000	40,000

Line-Level Microphones

Line-level microphones designed for remote use incorporate a microphone, preamplifier, limiter, and power supply in one hand-held package. Line level may be required to get the signal above the level of induced noise to overcome resistive losses in long cable runs or merely to level-match to a system that does not provide a microphone preamp at its input. Applications of line-level microphones may include operation into extremely long lines, into unshielded twisted-pair cable, phone lines, or into line-level inputs such as those often found on microwave transmitters.

A line-level microphone is sometimes preferred over a separate microphone and preamp for simplicity of operation. A separate preamp, such as the one shown in Figure 3.3-18, however, allows use of a variety of microphones and offers several powering, control, and connection advantages.

Output Impedance

The impedance (Z) of a microphone is a measurement of its AC resistance looking back into the transducer. Broadcast microphones should be low impedoff-axis sounds originating from the microphone side of the window.

Acoustic Gain Devices

Shotgun microphones increase working distance by ignoring off-axis energy, thereby narrowing the acceptance angle. Some devices actually increase working distance by providing *acoustical gain.* Increased acoustical gain means less electrical gain is required and, therefore, less electronic noise is encountered. [If a satisfactory signal-to-ambient-noise ratio is obtained, the improved signal-to-electrical-noise ratio derived from the use of an acoustical gain device will increase the effective working distance of the overall system.]

The most commonly used acoustic gain device is the *parabola* or *parabolic reflector*, as shown in Figure 3.3-14. The parabolic reflector is shaped so that sound is reflected onto a focal point a short distance in front of the center-point of the dish. An omnidirectional microphone placed at this point receives multiple reflected sound waves in phase, which add to produce significant gain. The response of such systems is very ragged and limited. Low frequency response is extended as the dish diameter is increased. While totally unacceptable for most broadcast applications, the audio quality achieved with the parabolic microphone is often deemed adequate for sound effects pick-up such as at sporting events. In some situations, acceptable quality means the best level of performance possible through practical or affordable means.

A second type of acoustic gain device is the *horn.* Low cost re-entrant horns are often used for talk-back in paging systems. They can be quite directional and are extremely sensitive. Their audio quality as a microphone, however, is no better than a loudspeaker. Horns are sometimes used as microphones in surveillance applications where natural sound is secondary to sensitivity and intelligibility. Installed on the side of a building, the small horn is virtually as inconspicuous as a light fixture and is seldom thought of as a microphone. Some horns are built with 45 Ω voice coils, providing higher output signals to microphone inputs.

Acoustic gain is also realized by using a microphone in the very close vicinity of a large hard, reflective surface. Omnidirectional microphones may be flush-mounted into the barrier, facing out. In this position the microphone is in a half-space environment, or looking into only half the world. The output, for sound arriving on-axis, is increased by 6 dB. As the sound source is rotated off-axis, however, the microphone output drops. At 90° off-axis, the output is down 6 dB, or equal to the omni in free space. The resulting polar pattern resembles a cross-section of a cardioid cut through the microphone at 90°.

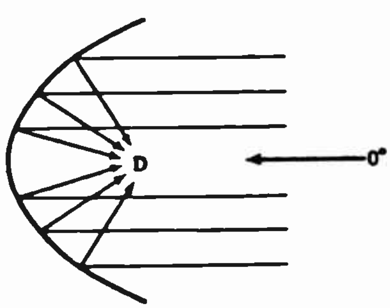

Figure 3.3-14. Parabola principle.

Frequency Response and Distant Miking

Distant miking may result in noticeable or even dramatic changes in the spectrum of the sound being recorded. High frequencies, attenuated by the air, may require boosting to restore a normal sound. Similarly, high-pass (low-cut) filters may prove helpful in reducing low frequency room reverberation or background noise, thereby extending the useful working distance. If possible, any boost in equalization (EQ) should be done in the recording process to minimize noise that would be amplified in post-production equalization. Microphones with rising high frequency response or a rolled-off low end will reduce the need for EQ.

Sensitivity Ratings

One of the greatest sources of confusion on a microphone specification sheet has to be the sensitivity rating. Several different rating systems are currently in use. Table 3-3.1 includes some figures to keep in mind when trying to interpret the ratings.

Open Circuit Output Voltage

Microphones are often specified as having a particular output voltage when looking into an open circuit. In most modern equipment, microphone inputs are at least 10 times the measured impedance of the microphone and may be regarded as an open circuit. Specifications may be given as an actual output voltage or as decibels below one volt at a sound pressure level of 74 dB (1 dyne/cm^2 or 0.1 Pa). These ratings are referred to as *the open circuit output voltage* rating or *open circuit sensitivity.*

The open circuit sensitivity may be expressed in dB by means of the following formula:

$$V_{OC} = 20 \log E_O - SPL + 74$$

where,

V_{OC} = Open circuit voltage in dB (referenced to 1V/0.1 Pa)
E_O = Microphone output in volts
SPL = Actual SPL at the microphone

The nomograph shown in Figure 3.3-15 provides an easy method of calculating the open circuit voltage.

Table 3.3-1
Converting specified parameters

10 dynes/cm^2	=	+94 dB SPL
	=	10 microbar
		1 pascal (Pa)
	=	newton/cm^2

NAB BROADCASTERS

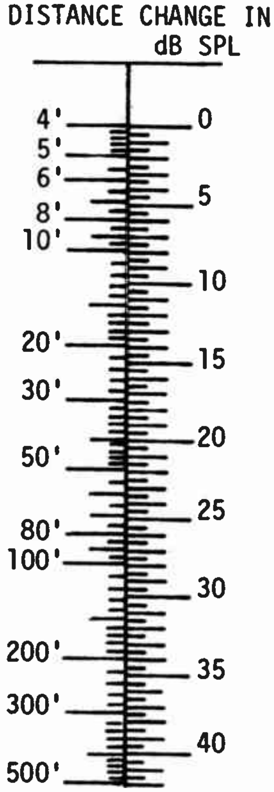

Figure 3.3-12. Inverse square law.

source of one half increases sound intensity at the microphone by a factor of 4 and the SPL by a factor of 2, or 6 dB, as illustrated in Figure 3.3-12. As the input sensitivity control of the mixer or recorder is lowered to compensate for the additional 6 dB available from the now-closer sound source, the microphone, in effect, becomes less sensitive to distant sounds.

Headset Microphones

Headset microphones provide benefits gained from always being a fixed distance from the speaker's mouth. Background noise is reduced (because of the inverse square law) and levels remain consistent. Omni, cardioid, and differential elements are available in headset systems. Cardioids offer the best combination of ambient noise suppression and acceptable broadcast quality.

Going For The Distance

In some distant-miking applications, the effective maximum working distance may be determined by the electronic signal-to-noise ratio of both the microphone and subsequent amplifiers. For example, the selection of an ideal boom microphone for picking up dialogue in a quiet environment, with no reverberation problems, may have little to do with polar patterns. Instead, the end user might look for a microphone with high output and extremely low self-noise. Most often, though, one is concerned with both electronic signal-to-noise and signal-to-ambient noise ratios.

Shotgun Microphones

Effective working distances beyond those afforded by cardioid, supercardioid, or hypercardioid systems may be realized through the use of a shotgun microphone. The shotgun microphone uses a slotted interference tube ahead of the element to provide a high degree of cancellation at the sides. Sound waves arriving on-axis are essentially unaffected by the tube. Sound arriving from slightly off-axis, however, is forced to turn and travel down the tube to the element. This results in numerous out-of-phase conditions being set up in the tube, with cancellation increasing as the microphone is rotated to 90°. The length of the tube will determine the low frequency limit to which this cancellation can be effective.

All things being equal, longer tubes are more likely to maintain their cancellation at lower frequencies than short tubes. Newer shotgun microphone designs from several manufacturers provide superior pattern control using shorter interference tubes than those required by older standards. The new generation of shorter, lighter products are much easier to handle in both fishpole and studio boom applications.

Some shotgun microphones are much less uniform in off-axis response than simpler, more conventional designs (see Figure 3.3-13). Even with their multi-lobed polar patterns, however, the very narrow acceptance angle can often save the day.

Shotguns work best outdoors and in controlled acoustic environments such as well-designed studios. They do not function properly near reflective surfaces. Distant miking down a hallway will not be assisted greatly by the use of a shotgun microphone. A shotgun microphone pointed toward an open window will see all sounds originating on the other side of that window as if they are coming from a source the size of the window. No directional advantage will be realized other than to reduce, perhaps, the level of some nearby

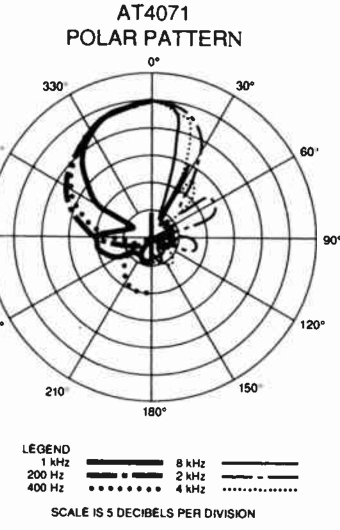

Figure 3.3-13. Shotgun polars. (Courtesy of Audio-Technica U.S., Inc.)

Omni vs. Cardioid

Compared to the omnidirectional microphone, the cardioid has several characteristics that should be noted:

- The cardioid reduces the pick-up of ambient noise and reverberant energy. A look at the comparison chart shows that the *random energy efficiency* (REE) of the cardioid is 0.333 (compared to a REE of 1 for the omni). The random energy efficiency is a measurement that compares a microphone's sensitivity to random (or reverberant) energy to its on-axis sensitivity. While this shows the cardioid to be one third as sensitive to random ambient noise as the omni, remember that discrete sound sources positioned at the null of the cardioid will be attenuated to a much greater extent. This will prove true outdoors where sounds arrive at the microphone directly with minimal reflections. Indoors, the advantage of the cardioid's deep rear null is only appreciated when the microphone is situated within *critical distance* of the offending sound source. Up to the critical distance, the direct sound is greater in intensity than the reflected energy; after that point, the two remain approximately equal.
- The cardioid is more susceptible to the problems of "P-pop" (the blast of explosives such as "P" and "T" in speech), wind noise, and handling or mechanical noise.
- The cardioid is more complex to design and construct. Therefore, expect to pay more, sometimes, for a cardioid microphone than for an omni of seemingly equal audio quality. The cardioid's more complex construction results in the omni often being the more rugged of the two as well.
- The cardioid offers greater resistance to feedback in most sound reinforcement applications. This results from its lower REE and is further aided by the proximity effect.
- The cardioid increases the effective working distance. The Figure 3.3-7 comparison chart lists a *distance factor* (DF) of 1.7 for the cardioid, meaning that a cardioid microphone has a working distance advantage over the omni of 1.7:1. This is calculated on the assumption of a perfect cardioid, in a totally diffuse noise field. An ideal cardioid, then, could be used at a distance of 1.7 times that of the omni for a given ratio of desired, on-axis signal to ambient noise.

In the real world, nonlinear polar response and the inability of cardioid microphones to achieve total cancellation at their null would seem to reduce greatly the cardioid's working distance advantage. It should be noted that in actual use, however, increasing the working distance often has more to do with attenuating a single, offending noise source than with overcoming a diffuse noise field. Directing the deep null of a good cardioid microphone at a whirring still-camera motor drive at a press conference may offer more than a 1.7:1 working distance advantage over an omni.

The cardioid exhibits proximity effect. While some designs are quite low in proximity effect, all exhibit some bass-boost phenomenon when used close. Although this may be considered an enhancement in many close-miking applications, care should be taken to avoid input overload or loss of intelligibility that may result from excessive proximity effect.

Other Patterns

An examination of Figure 3.3-7 will show how the three other polar patterns compare to the omni and the cardioid. The hypercardioid, for example, combines a tight acceptance angle with superior side rejection and offers the lowest REE. The result is a good pattern for distant miking (often required on a boom mount). Most short shotgun microphones approximate a hypercardioid pattern. Notice that the bidirectional pattern offers the best side rejection, but with no advantage over the cardioid in REE. Bidirectional microphones are typically ribbons or dual-diaphragm condensers. They are excellent for picking up two sound sources in music or dialogue miking with no phase problems. Compared to the omni, each of the directional patterns exhibits all six of the characteristics described previously.

Working Distance

Sometimes it is not sufficient to reduce ambient noise merely by using a polar pattern that offers the lowest REE. In very noisy environments (for example, in an aircraft, on a battlefield, in a factory, or at a sporting event) it may be desirable to differentiate between close sound (an announcer, for example) and distant sound. Microphones that offer considerable proximity effect may be used to advantage in these situations. Close-mic the talent and roll-off the low end as needed to flatten the response. In extreme situations, a noise-canceling (differential) microphone may be required.

Because of the special design (rear ports and back damping systems) of the differential microphone, sound arriving from a distance strikes both sides of the diaphragm with equal intensity and in phase. A positive pressure on the front, for example, would encounter a positive pressure on the rear of the diaphragm, causing the signal to be canceled. A combination of inverse square law and port damping causes sound that originates very close to the front of the noise-canceling microphone to be far lower in intensity and to exhibit some phase error by the time it arrives at the rear of the diaphragm. The result is diaphragm movement and maximum output. The noise-canceling microphone is able, therefore, to differentiate between close and distant sound sources. The audio quality of such systems normally limits them to voice communication applications.

Inverse Square Law

The easiest, and certainly the least expensive way to limit the apparent working distance of a microphone is by positioning the microphone very close to the sound source. Inverse square law shows that a decrease in the distance between the microphone and the sound

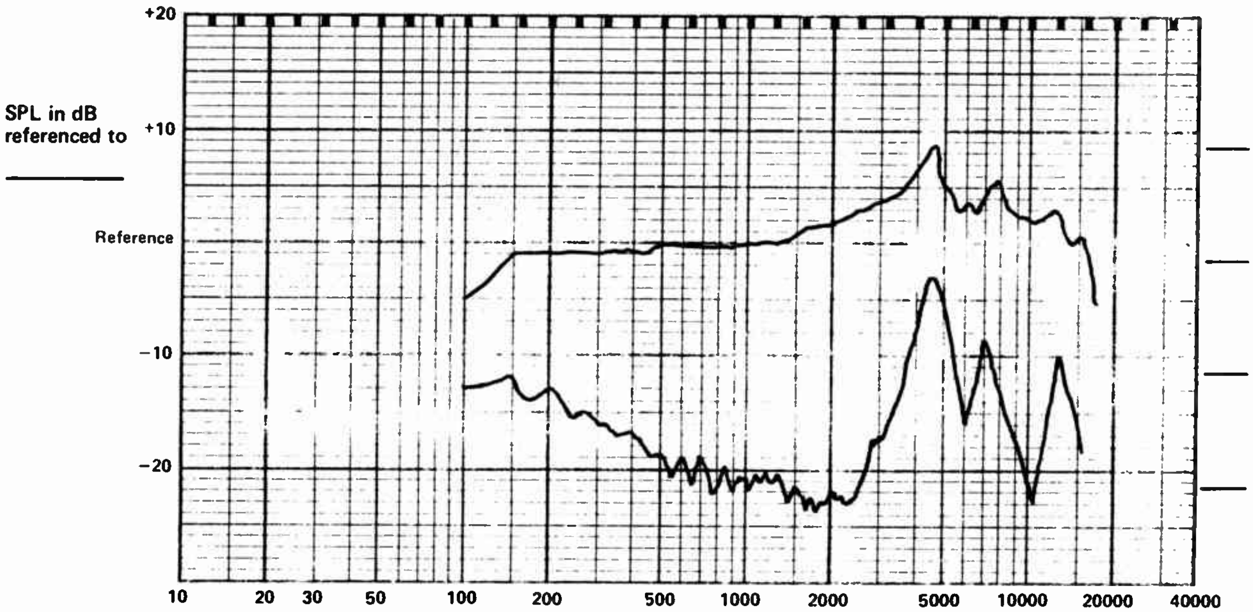

Figure 3.3-11(a). Front and back curves of a typical cardioid hand-held vocal microphone.

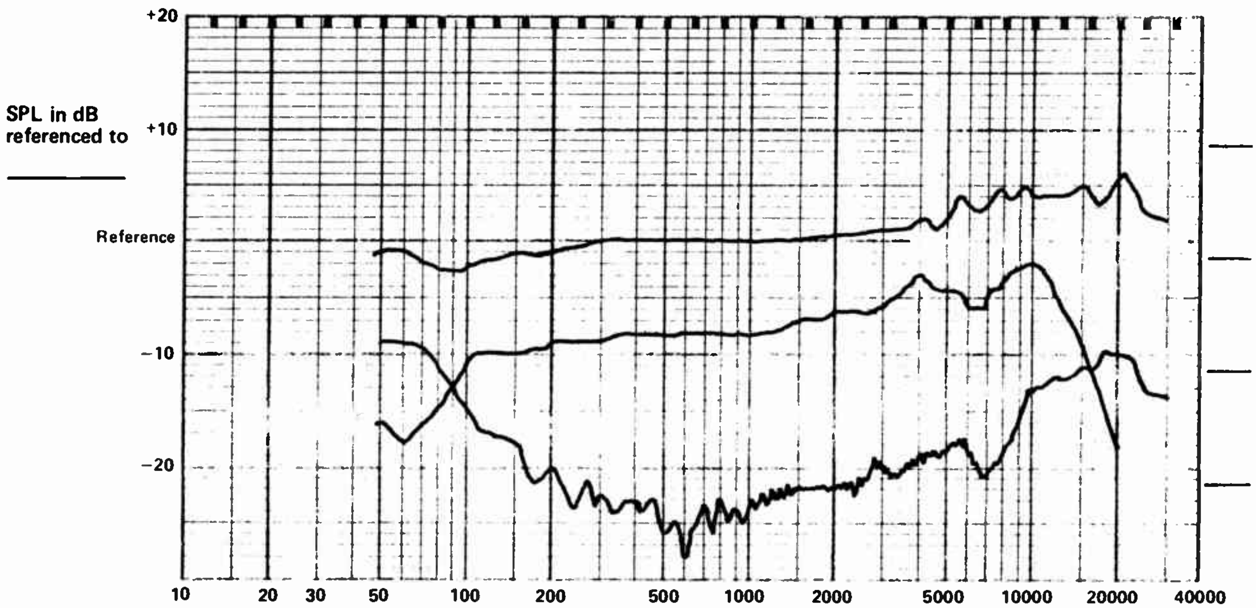

Figure 3.3-11(b). Front, side and back curves of a high- quality cardioid condenser microphone.

source at 90° off-axis. Here, a properly designed cardioid emulates well its mathematical model. At 180° off-axis, however, the cardioid can not live up to the equation. The chart indicates 0 output. In reality, well designed cardioids are capable of significant cancellation at 180° but, typically, only on the order of 20 dB. Still, a 20 dB drop in the level of some unwanted noise may be enjoyed simply by turning the cardioid to face directly away from the noise. That is equivalent to moving the sound source to ten times its actual distance from the microphone.

The 180° response curves (back curve) of many cardioid microphones show their tendency to more closely resemble omnis at both the low and high frequencies. The much more impressive cancellation in the midrange offers just the kind of temptation that sometimes causes a manufacturer to release a data sheet that shows one polar pattern only, and that at some unknown frequency. One of the most beneficial performance advantages an end-user should look for in a well-designed microphone is off-axis linearity, as illustrated in Figures 3.3-11 (a) and (b).

First, check to see whether the scaling is logarithmic or linear. A log scale (the most commonly used) will show a fairly modest inward curve of the cardioid pattern at 90°, indicating a 6 dB drop in level. The linear scale polar for the same microphone will show a polar pattern that appears much more directional. The outside circle of the linear polar represents 100% while the center of the circle equals 0 output. Because a 6 dB loss is equal to a 50% drop in voltage, the polar curve at 90° sweeps in to half the distance between the outside of the circle and its center. Second, determine the graduations between concentric circles. Are the darker lines 5 dB or 10 dB apart? Finally, take note of the dynamic range of the polar pattern. This may be determined by counting graduation lines inward from the point where the polar crosses 0°, in 5 or 10 dB steps (as marked) to the smallest inner circle. Polars may be found in most any range, with 25, 30 and 40 dB all being common. These differences will also alter the shape of a polar pattern.

Keep in mind that the polar pattern represents a cross-sectional, two dimensional diagram of a three dimensional function. The 131° arc, for example, that is described by the 3 dB down points on either side of the axis of the cardioid microphone can really best be thought of as a conical area within which the microphone is virtually uniformly sensitive. This area is often referred to as the microphone's *angle of acceptance or included angle.*

Omni Observations

The omnidirectional microphone is the easiest type to make. It consists of a diaphragm and generating element backed by a totally sealed case. When placed in a sound pressure field, the perfect omni disregards the direction of the sound's origin. A positive pressure (air expanding) at the diaphragm, for example, causes the diaphragm to move inward regardless of the sound's point of origin (see Figure 3.3-9). Such a microphone may also be referred to as a *pressure microphone.*

So it would be with the perfect omni. Most omnidirectional microphones, however, are not truly omnidirectional. The case of the microphone represents a barrier to higher frequencies arriving from off-axis. Because of this case effect, most omnis are increasingly directional at higher frequencies. The smaller the omni, the more truly omnidirectional it may be. In addition to the case effect, energy arriving at the diaphragm from on-axis is reinforced at those frequencies to which the size of this *baffle area* is significant. The baffle effect causes a rise in the microphone's high-frequency output, but only with respect to energy arriving on axis.

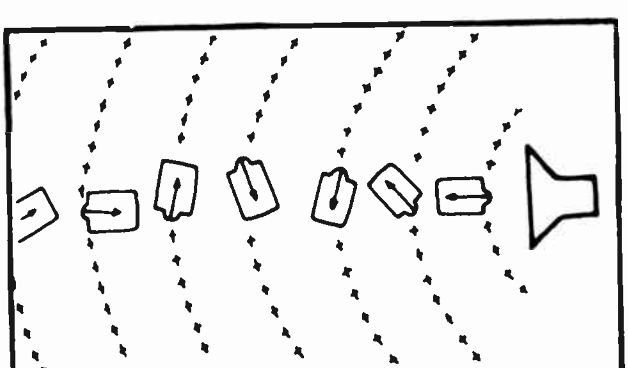

Figure 3.3-9. Omnidirectional microphone principle.

Cardioid Considerations

Directional microphones employ a damped porting system in their element design that allows sound waves to act upon the rear of the diaphragm as well as the front. The design introduces varying amounts of phase shift for sound arriving from off-axis, resulting in cancellation. The rear entry ports of most directional microphones are spaced at a single distance or "D" from the diaphragm (see Figure 3.3-10). Multiple port systems are also available and are designed to reduce the proximity effect.

Care should be taken when using any directional microphone not to obstruct the ports with the microphone clip, hand, clothing, gaffer's tape or logo flags. Covering even some of the ports may result in serious degradation of the microphone's directional characteristics and overall sound quality. The chart given in Figure 3.3-7 shows how the various patterns should relate to the reference omni in their ability to reject unwanted energy arriving from various points off-axis. A sound source that delivers 60 dB sound pressure level (SPL) to a cardioid on-axis from one foot away will sound to the microphone as if it has dropped in level to 54 dB (or been moved to two feet away) when the microphone is simply rotated to position the sound

amount of proximity effect that is possible to attain. The response curve of a particular directional microphone, tested at a specific (or perhaps even, unknown) distance may be of little value to someone who wishes to use the microphone at another distance. Ideally, directional microphone data should include close and distant curves, as illustrated in Figure 3.3-5.

Polar Patterns

As difficult as it might seem at times, to pick up a desired audio signal the real problem more often lies in eliminating unwanted sounds. Microphones with various directional patterns are often used to improve the ratio of desired signal to ambient noise or other unwanted sounds.

For most miking applications, a suitable on-axis curve alone may not be satisfactory. Ambient noise, leakage from other instruments in a band or orchestra, room reverberation and feedback potential from PA floor monitors are some of the reasons why it is important to know the off-axis response of a microphone.

The best view of the microphone's off-axis response is obtained by examining several different polar plots. These should be drawn at low, mid-band, and high frequencies. Overlaid, these plots should reveal how well the microphone maintains its directionality at each frequency (illustrated in Figure 3.3-6).

There are several broad classes based on fundamental polar patterns, to which most microphones directional characteristics conform, to some extent or another. These include:

Omnidirectional

- Bidirectional
- Cardioid
- Supercardioid
- Hypercardioid

Figure 3.3-7 shows the relative data for each of the patterns. The data, however, is taken from mathematical models representing the perfect polar characteristic for each example. Actual microphone polars may vary from near perfection to close resemblance. In the real world, the microphone design engineer must go beyond math equations to accomplish a desired axial response and sensitivity while maintaining polar uniformity. It is truly a blending of art and science.

Polar Scaling and Dynamic Range

Care should be taken when reading polar patterns to observe several variables in the way that they are represented. These variables can drastically alter one's perception of the microphone's directionality if they are not examined closely (see Figures 3.3-8 a-e).

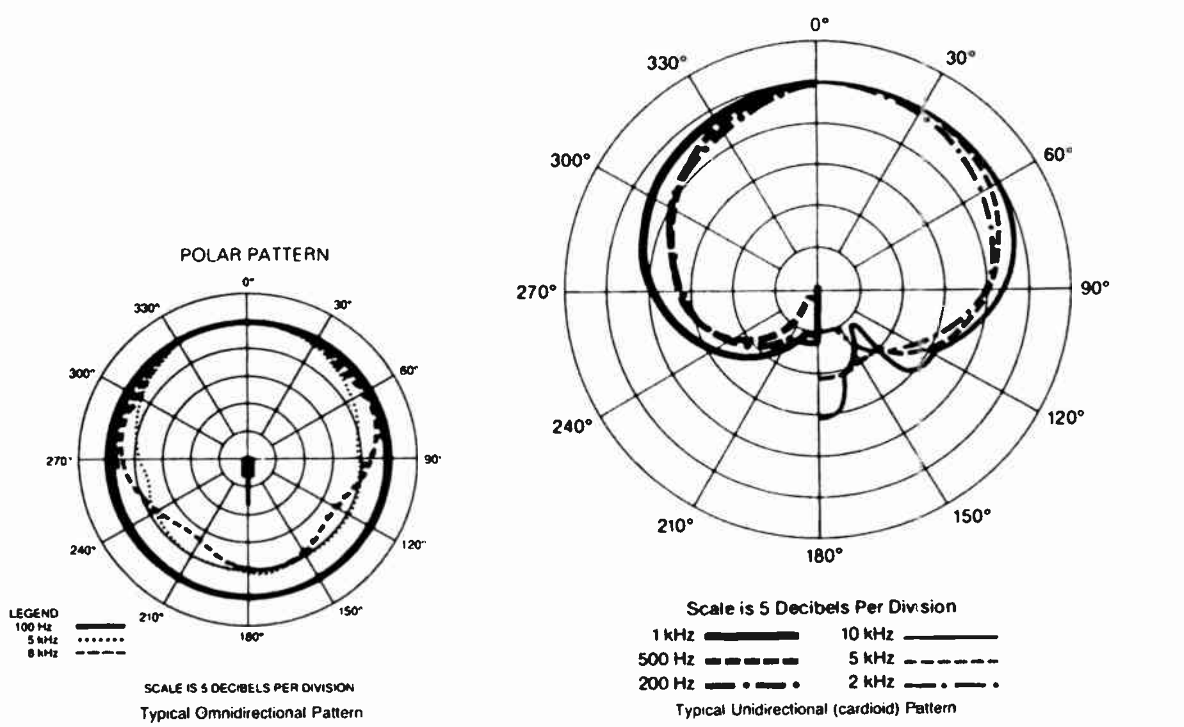

Figure 3.3-6. Polar patterns drawn at several frequencies. (Courtesy of Audio-Technica U.S., Inc.)

of these supplies, some modern discrete condenser designs require 48 V. The phantom supply voltage in nonelectret condenser microphones is often stepped-up by an internal circuit to provide a sufficient capacitor-polarizing charge for good signal-to-noise figures.

The amount of current delivered by the power supply is also a factor. While some condenser microphones can operate with less than a milliamp, others require up to 2.5 mA or more. When insufficient current is provided, the level of the microphone is reduced and the signal is distorted.

In a phantom power circuit, the plus side of the dc supply is applied equally to both of the signal conducting leads of a balanced microphone line. This may be done by means of either a build-out of matched precision resistors, or via a center-tapped transformer. In each case, the return path is the shield. In the microphone, the dc may be similarly tapped via the resistor or center-tapped transformer method to provide the power it needs. The dc is prevented from appearing at the impedance converter output by dc-blocking capacitors or the internal center-tapped transformer.

If a balanced-output dynamic microphone is connected to a line with phantom power present, performance should not be altered, nor should damage occur to the dynamic element. The voice coil or output transformer winding connects across the two signal leads and should see no potential difference between them. Because there is no connection between either lead and the shield (the dc return path), there is no circuit. If an unbalanced dynamic microphone is connected to a phantom supply, the dc will pass through the voice coil and probably destroy it. A less common powering system called "A/B" or "T" powering is not compatible with dynamic or phantom-powered microphones. A/B power puts the positive side of the dc on one signal lead and the negative on the other. This will damage even a balanced output dynamic microphone.

Microphone specifications

Charts, graphs and specifications are usually available for a professional microphone. Some microphones come with individual graphs for frequency response and polar pattern. While specs tell part of the story, there is nothing better than trying a microphone in a specific application. Be aware that the microphone preamp and microphone cable can both contribute to the sound of the microphone. The same microphone may sound different when amplified through another preamp.

Frequency Response

One of the first specifications considered on a microphone data sheet is the frequency response range or limits. The required low and high-frequency limits may depend upon the nature of the sound source that is being miked, the medium by which the signal is to be stored and transmitted and the environment in which the miking is to be done. Often, unfortunately, more attention is given to the response limits than to how the microphone actually sounds in its intended application. Nonlinearities of the response often contribute more to the listener's subjective impression of sound transmitted by the microphone than do the response limits. A specification that reads "frequency response 40 to 18,000 Hz," by itself, says little about a microphone's actual sound in use. Add to that some limits, like ± 3.0 dB, and one's knowledge of the microphone, while improved, is still lacking.

The shape of the response and polar response characteristics will tend to contribute to the character or personality of the microphone's sound. Response nonlinearities can create acoustic feedback in sound reinforcement, nasality, poor intelligibility, excessive sibilance, muffled sound or any of a variety of other acoustic problems. On the other hand, a microphone's response may be deliberately, carefully tailored by the design engineer to solve problems rather than create them. A rolled-off low frequency response and a rising high frequency response may be employed in a microphone that is intended for use at a considerable distance. This tailoring can reduce the effects of unwanted low frequency information, such as traffic noise or the rumble of air handling systems, while boosting the high frequencies that are normally attenuated with distance.

Some microphones that are intended to be worn on the body exhibit a response that compensates for the chest cavity resonance which they tend to pick up in a lavaliere mounting position. A rolled-off low end response may help considerably in attenuating handling or stand-born noise as well as wind noise or the breath blasts of plosives in speech.

Unfortunately, published specifications can serve as only one guide in understanding a microphone. The extent to which they serve any function at all is, of course, dependent upon the credibility of the source. This may help to explain why a very poor sounding \$50 microphone might show limited specifications that appear superior to an excellent sounding \$250 microphone. Certainly, a response curve drawn with the microphone directly facing the sound source (on axis response) will give us a clearer picture of the instrument than will a statement of its response limits. Even curves from well-respected manufacturers, however, may be difficult to compare due to the variety of test procedures and standards. For example, the frequency response chart is an X-Y graph that compares decibel output to frequency. If that chart is compressed vertically or stretched horizontally, the response curve will automatically appear more linear. Frequency response plots for the same microphone may also vary greatly when run on the same equipment, at the same scale. Such variables as the recording speed, damping or even the direction of the tone sweep (low to high or high to low) may result in vastly different curves.

Directional microphones present still another possible anomaly in the testing process. These microphones exhibit a phenomenon known as the *proximity effect,* which results in a bass-boosted output when close-miking a small sound source. Proximity effect is neither good nor bad; its value is dependent upon the intended application. Various designs will differ in the

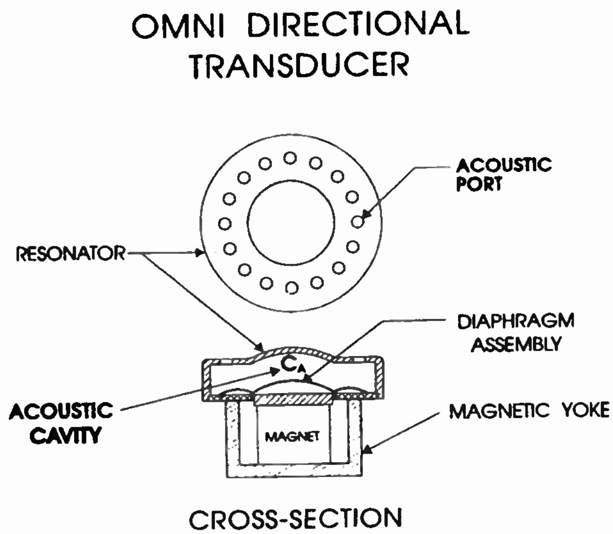

Figure 3.3-2. Cutaway drawing of a dynamic element showing helmholtz resonators. (Courtesy of Electro-Voice, Inc.)

transformer within their housing to correct for design trade-offs in their voice coil. The transformer adds to the microphone's cost and may also restrict performance if it is not a high quality unit, limiting the frequency response and possibly increasing distortion. But properly designed dynamic microphones can be the most rugged of the high-quality transducer types; some have truly become legendary for their ability to provide high quality broadcast audio with virtual bullet-proof construction.

Condenser Microphones

In the condenser microphone, a capacitor forms the generating element, as illustrated in Figure 3.3-3. One side of the capacitor is the diaphragm, the other is the fixed backplate. Air between these two plates acts as a dielectric. The capacitor, of course, must possess a positive electrical charge on one plate and a negative charge on the other. The conventional or discrete condenser receives this polarizing or bias voltage from an external dc power supply. In older condenser microphones, separate leads were required to deliver dc from the power supply to the microphone. Today, *phantom* power is used in most conventional condenser systems to deliver the required dc voltage to the microphone

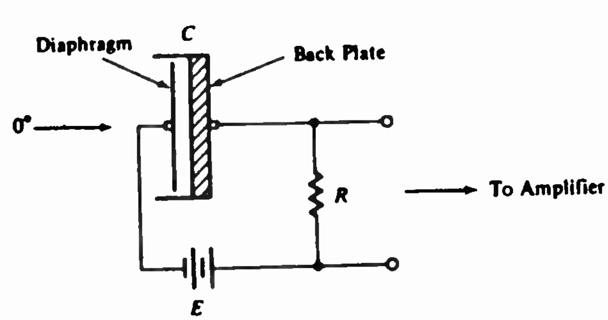

Figure 3.3-3. Conventional capacitor microphone system.

over the same conductors and their shield that are used to carry the audio signal.

Upon activation of the power supply, a positive voltage is quickly built up on the rear surface of the diaphragm. This causes an electrical current to flow through the resistor until the surface of the backplate finally receives a negative charge of equal value. As sound waves (air pressure changes) strike the diaphragm, causing it to move back and forth, the distance between the two plates rapidly increases and decreases. This causes proportional changes in the capacity of the condenser to hold a charge. The result is an ac current flow in the resistor and a voltage across the resistor that corresponds to the excursion of the diaphragm. While this voltage effectively represents the output voltage of the microphone, the source impedance is far too high to be carried for any distance over microphone cable. This output signal, then, is presented to an impedance converter circuit, usually a vacuum tube or FET inside the microphone. Power for the impedance converter is derived from the same source that provides the polarizing voltage for the element. The impedance converter delivers a low impedance output that can be fed down long microphone cables with minimal loss.

Electret Condenser

The electret condenser microphone utilizes a material which has the ability to hold a charge applied during the manufacturing process. Most high-quality electrets apply this material to the fixed back-plate of the capacitor, as shown in Figure 3.3-4. Some designs employ a charged diaphragm instead, but pay several performance penalties in doing so. Lowering the weight of the diaphragm by moving the electret material to the backplate results in lower handling noise, extended frequency response and improved transient response.

Although the electret functions much like the discrete condenser, but produces its output voltage without the need for an external high-voltage dc supply, an impedance converter is still required. The low voltage needed to power it, however, may be derived from internal or external batteries or an external ac-powered supply.

Phantom Power For Condenser Microphones

Phantom power, or *simplex power,* provides one means for remotely powering condenser microphones. Phantom power requirements of various microphones may fall anywhere between 9 and 48 V. External supplies are most often designed to deliver 9, 12, 18, 24, 30, or 48 V. While many electrets will operate on any

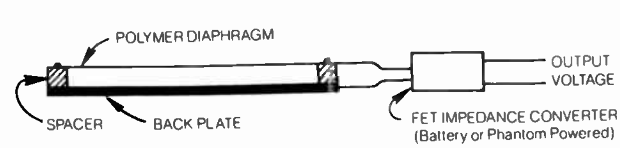

Figure 3.3-4. Electret condenser element. (Courtesy of Audio-Technica U.S., Inc.)

sympathetically-induced mechanical recreation of the amplitude and frequency of the sound presented to it.

The metallic ribbon's movement across the magnet's flux lines induces a small ac voltage onto the ribbon. The leads from the ribbon's ends connect it to a step-up transformer which converts the extremely low impedance of the ribbon (approximately 1 Ω) to a usable figure which might lie between 50 and 500 Ω. Ribbon microphones are available in a variety of fixed or variable patterns. They are known for delivering a very warm sound, due to the ribbon's sensitivity to low frequencies. They are also known for their fragility. Blowing into a ribbon microphone can destroy the ribbon. Some manufacturers suggest that ribbon microphones be stored in positions so as not to let the ribbon sag. Even rapid panning on a studio boom has caused ribbon failure. Newer designs, however, have provided considerable improvements in durability and a lower failure rate.

Some ribbon microphones should not be connected to a microphone preamp with active phantom or A/B powering. The voltage from these supplies can damage the ribbon.

Dynamic Moving Coil Microphones

Although the ribbon microphone is a type of dynamic microphone, in common usage, the term dynamic microphone usually refers to a microphone with a moving coil. The dynamic microphone has a diaphragm with its back attached to a voice coil, as illustrated in Figure 3.3-1. This extremely lightweight coil of wire is suspended in a magnetic field supplied by a permanent magnet structure. The ends of the voice coil are brought out to stronger leads, which connect either to a transformer or the microphone's output connector.

Sound waves reaching the diaphragm cause it to move back and forth in sympathy. The attached voice coil is then forced to cut the lines of flux in the magnetic field causing a small ac voltage to appear at the ends of the leads. This signal closely emulates the sound

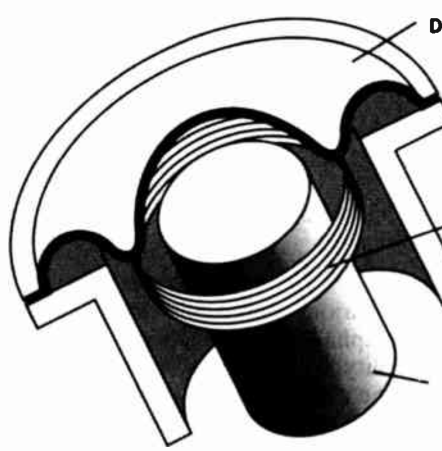

Figure 3.3-1. Dynamic moving coil element. (Courtesy of Shure Brothers Incorporated.)

waves in frequency and amplitude. The diaphragm design is crucial to good dynamic microphone performance. It must be highly compliant to allow effortless excursion at all frequencies of interest. In addition, this movement must be accomplished with maximum linearity and a minimum of break-up modes. Nonlinearities of diaphragm movement would include, for example, any tendency for a rocking motion to be set up which, at some frequencies, would allow one side of the voice coil to be travelling downward while the other side is moving upward. Such rocking results in phase cancellation and a dip in the frequency response. Break-up modes occur when a portion of the diaphragm resonates independently of the rest of the surface. Again, phase cancellation results and, with it, response anomalies occur.

The design and construction of a high quality dynamic microphone suitable for broadcasting use is a blending of science and art. As with other transducers, much of its design may be modeled by the use of equivalent electrical circuits. The process is similar to the computer-assisted design of loudspeakers using Thiel parameters. In the microphone, however, the seemingly infinite variety of complexities in certain parts of its design is so great that the artistry of the microphone engineer is constantly called upon. In the design process, the goals set before the microphone design engineer are sometimes all but impossible to achieve within the same product. As is true in other areas of engineering, design trade-offs are numerous and the laws of physics tend to win in the end.

Size plays an important role in the performance of the dynamic microphone. Small dynamic mechanisms tend to be very inefficient. Their acoustic sensitivity is low, while their mechanical sensitivity is high by comparison. The result may be a poor system signal-to-noise ratio (SNR) and a lot of handling or noise transmitted through the microphone stand. Internal shock-mount systems may be used to reduce the mechanical excitation but the design goal of small size may then be defeated. Small size usually means sacrificed low-frequency response in dynamic microphones. This is not to say that large dynamic microphones will always have an extended low frequency response. Very small dynamics will almost certainly, though, be lacking in low frequency output. Another physical characteristic of the dynamic microphone that affects its performance is the mass of the diaphragm/voice coil assembly. The greater the mass, the more limited will be the high frequency response. Common design practice includes the use of Helmholtz resonators immediately in front of the diaphragm. These create peaks and effectively extend high frequency response beyond the normal limits of the system (see Figure 3.3-2). Advances in metallurgy, specifically the use of stronger Neodymium magnets, has have resulted in dynamic microphones with higher outputs.

Most broadcast-quality dynamic low-Z microphones exhibit an impedance that is a function of the turns and gauge of their voice coil wire. Some older, more public address-oriented microphones employ a than directional microphones, however, some small-diaphragm condenser omni microphones are quite sensitive to popping.

Microphones with directional patterns, cardioid (heart-shaped) or figure-eight, are used in broadcasting to keep ambient noises from being picked up. Cardioid microphones are available by degree of directionality—cardioid, hypercardioid, supercardioid. Shotgun microphones, sometimes referred to as supercardioids, offer superior directionality. While their "reach," or ability to hear sounds at a distance is greater than hypercardioid patterns, shotgun microphones are omnidirectional at middle to lower frequencies. They are best used on a large well-damped sound stage or out in the open.

Figure-eight patterned microphones are useful when placed directly between two sound sources. Even so, cardioids are chosen over figure-eights in broadcasting because exact placement can be difficult and because two cardioids can be set at different levels to accommodate sound sources with different levels. Due to the physics of their design, cardioid microphones usually exhibit more bass response than omnis when the distance between microphone and person speaking is one foot or less. This phenomenon is called the *proximity effect*. If not abused, the proximity effect adds warmth and power to most voices. Directional microphones are also typically found in broadcast studios because they can be positioned to minimize noise from tape recorders, wire copy machines HVAC ducts, computer drives and fans and other noise generating devices.

Output Level

Output level is important because all microphone preamps add a certain amount of noise, especially at the upper end of their operating range. The higher the output of the microphone, the less amplification will be required from the microphone preamp. In general, condenser microphones have higher outputs than dynamic and ribbon microphones, although the use of higher flux magnets in both dynamic and ribbon microphones will increase their output.

Ruggedness is more important in ENG and electronic field production (EFP) recording. Microphones for these applications need to be able to withstand rough handling and harsh elements. Ribbon microphones are seldom used because of the fragility of the ribbon element. Some condenser microphones are better suited for highly controlled environments because they are sensitive to humidity, temperature changes and wind. Other condenser microphones are more tolerant of these conditions.

Hot Spot

The hot spot (sometimes called a sweet spot) of a microphone is that area within its pickup pattern in which a particular sound source sounds best. It is not an absolute position, but a relative one. In a very quiet and well-damped environment, the hot spot may be larger. However, if the sound source is thin and would benefit from more bass response, the hot spot for a cardioid microphone might be limited to an area within the range of its proximity effect. If the sound source has an overabundance of low frequencies, the area providing the proximity effect should be avoided.

If the sound source, an announcer for example, moves around too much, a hypercardioid pattern may provide too narrow a hot spot, resulting in noticeably uneven levels and sense of presence. If the announcer can not be trained to stay within the hotspot, a more forgiving cardioid pattern may be a better choice.

Regardless of the style or pattern of microphones chosen, the best results require the use of a high-quality, well-shielded microphone cable. Quality cable is more important here than anywhere in the audio chain because of the high amount of gain applied by the microphone preamplifier. The preamplifier raises the relatively low level of the microphone to line level. Poorly shielded, or low quality cable may not be able to reject electromagnetic or radio frequency induced noise. As a result, that low-level noise is amplified by the microphone preamplifier and can become audible. It is a good idea to start with well-shielded cables in which the shield is grounded at both ends to the XLR connectors. Using these cables to interconnect other pieces may result in ground loops, which can cause hums and buzzes. The most conservative solution is to keep microphone cables separate from those used to connect active, powered circuits.

MICROPHONES IN DETAIL

Microphones will be described in terms of their generating element (transducer) types:

- Ribbon
- Dynamic

Transducer Types

A microphone is a transducer: a device which, when activated by energy from one system, converts or transduces that energy to another form. In the microphone, acoustical energy (sound waves impinging on the diaphragm) is converted to a varying voltage that is the electrical analog of the sound. The method by which the microphone converts acoustical energy to electrical energy is one of the ways by which microphones are differentiated.

Dynamic Ribbon Microphones

The ribbon, or velocity microphone, utilizes a very thin, corrugated metallic foil ribbon suspended within the flux field of a permanent magnet. The ribbon microphone is also referred to as a *velocity* microphone because it responds to air particle velocity at the ribbon. The term *pressure gradient* is also used to denote that the pressure exerted on the ribbon is in proportion to the difference between the pressures present on each side. While the ribbon's ends are held in place, the rest of it is allowed to move freely back and forth in a

INTRODUCTION

Improving a broadcast facility's sound by choosing the right microphone is the direct result of knowing enough about microphones to make the right decisions. When considering both budget and application, there are usually a number of correct choices. This chapter is intended to provide you with information that will help you make the right choices. To that end, this chapter reviews the basic types of microphones, their construction, and how their different characteristics can be used in various applications for best results.

The successful use of any microphone also depends on the acoustic environment in which it is used and the particular voice or instrument on which the microphone is used. The problems of poor acoustic environments can not always be overcome by using more expensive microphones. Instead of great results, you might end up with technically excellent audio and a great performance in an obviously bad acoustical environment. In addition, individual voices vary greatly. The frequency response and texture of some voices seem to lend themselves to the electronic medium. Other voices with quirky frequency response, sibilance and other artifacts can be problematic, even after considerable processing. Great sounding audio, then, is the result of a great source, a great environment and the right microphone.

Of the many microphones available, broadcasters usually choose hand-held, boom-mounted and lavaliere styles. The hand held microphone is used for on-camera and electronic newsgathering (ENG). Boom-mounted microphones are usually found in the broadcast studio and some hand-held microphones also are boom-mounted. The lavaliere microphone is a small clip-on usually used in TV news, where a hand-held or boom-mounted microphone would be obtrusive. Lavaliere microphones can also be used in radio talk show programming where the guest may be unfamiliar with good microphone technique or intimidated by a large boom-mounted microphone.

The four attributes of a microphone most broadcasters need to consider are self-noise, directionality, output level, and ruggedness.

Self-Noise

Self-noise is normally perceived as a hiss. It is the electronic noise generated by the active circuitry of the microphone itself. Condenser microphones use a vacuum tube or field effect transistor (FET) circuitry to convert the high impedance of the condenser capsule to a lower impedance, more suited for the input of a microphone preamp. Vacuum tube condenser microphones are generally noisier than condenser microphones that use FETs. However, careful selection of the vacuum tube can result in a tube microphone being quieter than its FET counterpart.

Self-noise is an important factor in studio recordings, where every attempt to eliminate extraneous noise is important. Self-noise is less important in applications where the ambient noise level is considerably higher. The ambient noise level in a broadcast air studio may be quite low, equaling that of a well-designed music studio. It may also be rather high due to noise from HVAC systems, tape machines and computer hard drives and fans, wire copy machines and sound transferred through the structure from the surrounding environment. If the combined noise from any or all of these sources can not be reduced, spending extra money for a microphone with exceptionally self noise is not the best use of money. Finding the best sounding, most directional microphone and positioning it to reject as many of the ambient noises as possible is a better approach.

The self noise of dynamic or ribbon microphones is usually much less because these microphones do not use active electronics. However, the output of dynamic and ribbon microphones is usually lower than that of a condenser. Because of this, more gain is required of the microphone preamplifier to bring the dynamic and ribbon microphones up to the appropriate operating level. Less expensive or poorly designed microphone preamps also generate noise, usually perceived as hiss.

Directionality

Omnidirectional and directional microphones each have their place in broadcasting. Omnidirectional microphones pick up most sounds from all directions equally. However, they are usually directional at high frequencies. Omnidirectional microphones are usually used in news gathering interviews in which one or more voices are intended to be picked up. Their wide pattern is useful because the position of the microphone does not have to be moved from person to person. On the other hand, if there is a lot of ambient noise, or if only one voice is needed, a directional microphone may be more effective. In general, omnidirectional microphones are also usually less prone to "popping" achieved when the supply or return duct paths connecting two rooms are longer. The optimum situation is to have completely separate ducts back to the fan source; however, this may not be practical in some situations.

CONCLUSIONS

This chapter has presented basic principles of acoustic design that are relevant to the design or renovation of broadcast facilities. Hopefully, this material will offer some perspective and insight to the reader. There are, however, many different techniques of using these principles to achieve specific acoustic design goals and a wealth of literature and experience exists in this area. The value of a professional acoustical consultant in a major design or renovation project should not be underestimated. Acoustical design techniques can be very expensive and mistakes can be even costlier. With a basic understanding of acoustic principles, users will be better able to explain their needs to a consultant, understand the ramifications of various design trade-offs and develop the ability to make informed and competent decisions in the area of acoustics.

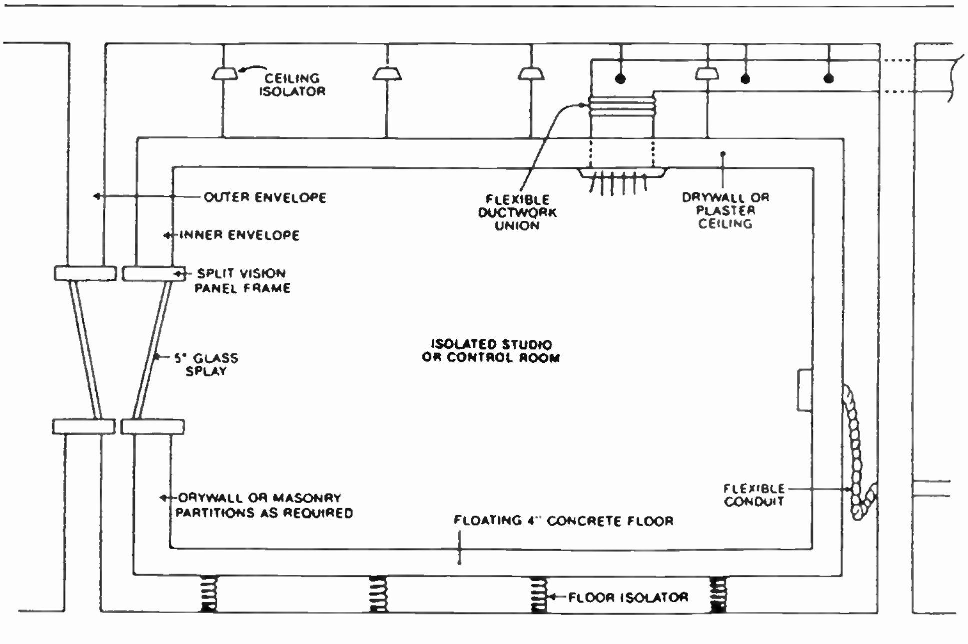

Figure 3.2-21. Floating construction technique.

Similar to the concept of STC, Impact Isolation Class (IIC) is a single number rating system to assess a barrier's effectiveness at arresting transmission of impact noise. The IIC method is based on the use of a standard *tapping machine* which supplies a known impact noise profile. SPL readings are then taken in one-third octave bands in the receiving room and compared with a standard contour to determine the IIC rating.

HVAC Considerations

Often the HVAC system in a room is the primary source for noise introduced into the room and also determines the level of acoustic leakage between rooms. With proper design, these limitations can in large measure be avoided.

A major contributor to HVAC noise is the fan noise itself which propagates down the supply ducts and subsequently enters the room. Ventilation ducts can be lined with absorbing material such as 1 in. glass fiber to reduce the noise at the end of the duct. Prefabricated duct silencers are also available which are placed in line with the duct and offer significant sound attenuation characteristics. Structure borne transmission of fan noise can be stopped by coupling the fan motor to the duct system via a canvas or rubber coupling to break up the vibration path.

The amount of noise in a duct system is also strongly dependent on the air velocity in the duct. Low noise design requires low air velocities which, for the same amount of total airflow, leads to the use of either multiple ducts or larger duct cross sections, both of which imply higher costs. Diffusor designs to minimize turbulence induced noise at the entry point to the room are also important.

The layout of supply and return ducts can be a hidden source of poor acoustic isolation between rooms. As shown in Figure 3.2-22, higher isolation is

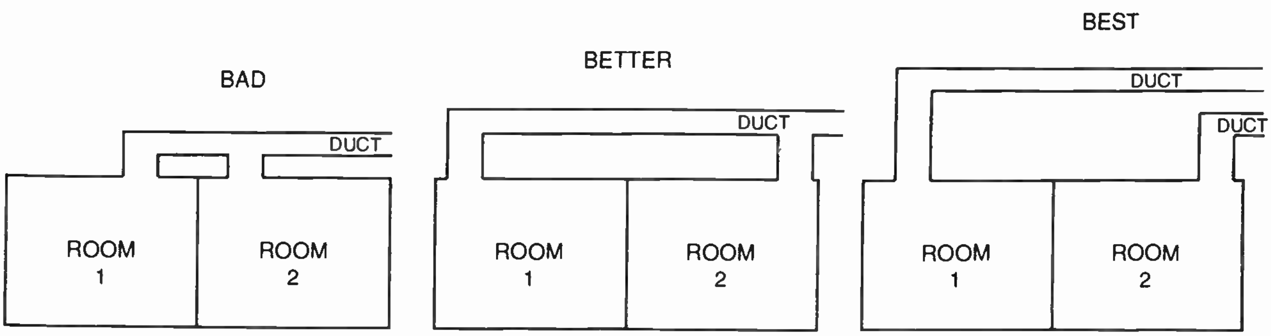

Figure 3.2-22. Effect of duct location on sound isolation.

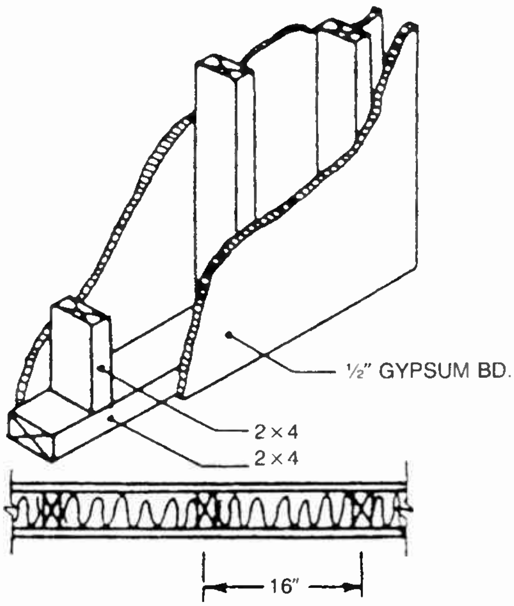

Construction—standard stud partition

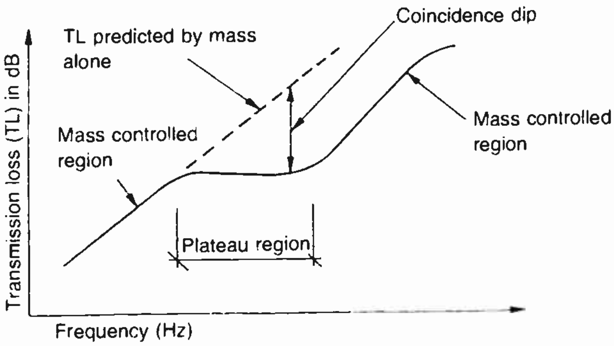

Figure 3.2-19. General transmission loss (TL) profile of solid materials.

(also known as a coincidence dip) and another mass controlled region above the plateau region. For rigid materials, especially at low frequencies, TL increases about 5 dB for each doubling of surface weight. In general, heavier materials have greater sound isolation capability.

Discontinuous Construction

Increasing the mass of a wall is an effective method of reducing the transmitted sound energy, but each doubling of mass will accomplish only about a 5 dB reduction in sound transmission. A more effective approach is the isolation of the two sides of the wall with an airspace and some form of resilient connection, often called discontinuous construction. It is important that the two sides of the wall not be rigidly tied together, as with wood studs, which will transmit sound energy as structure-borne sound.

Split or staggered wood studs (Figure 3.2-20C), lightweight metal studs, or resilient furring are all effective at isolating the two sides of a wall and reducing structure-borne sound. Within normal limits, the additional sound attenuation provided by an isolated airspace will also increase as the width of the airspace increases. Placing porous insulation (usually glass fiber) within the airspace can also increase the STC-rating by 3 to 6 dB, due to damping of the resonant coupling of the wall panels. The STC performance of common wall constructions is shown in Figure 3.2-20.

Windows

Achieving windows with high acoustic isolation requires a somewhat complex structure. A double pane with a 6 in. air gap between the panes is desirable. The glass must be resiliently mounted within the frame without cracks or air gaps. For best performance, the two panes should be different thicknesses and the perimeter of the air gap between the panes covered with sound absorbing material. Often one pane is angled with respect to the other, a characteristic which has more advantages in visual glare reduction than affecting the TL significantly.

Doors

High isolation doors are difficult to build and maintain since the gasketing and sealing of the door must be extremely precise and not degrade with time or wear and tear. Because of the difficulties of constructing and maintaining doors with high isolation, it is often more economical and reliable to create high isolation entry ways through use of a *sound lock,* that is, an outer door leading to a vestibule with an inner door.

The overall TL from the outside hall to the inside of the room via the vestibule can be very high even with only moderately stringent construction techniques. Also, by sequentially entering or exiting a sequence of doors, the room is never exposed to the total loss of isolation inherent to a single door partition.

Floating Construction

Floating construction is a combination of discontinuous construction and resilient mounting techniques. Floating floors are solid slab floors which are completely isolated from the structural floor by a resilient underlayment or resilient isolators. Walls may be built attached to the floating floor and a ceiling may be resiliently hung from the structural ceiling, resulting in an actual room-within-a-room with very high isolation possibilities. This is shown in Figure 3.2-21.

This type of construction can be extremely expensive but is sometimes the only avenue to achieving high levels of sound isolation, especially at low frequencies, in high noise environments or when very low ambient noise levels are required.

Vibration Isolation

Vibrations and sound energy produced by mechanical equipment can be transmitted throughout a building via vibration of the structure and reradiated as sound energy in a particular room. In general, vibrating equipment can be effectively isolated from the building structure by mounting the equipment on resilient mounts. The mass of the equipment and the compliance of the resilient mounting form a resonant system. Vibrations of the equipment at frequencies much higher than this resonant frequency will effectively be prevented from being transmitted into the building structure. As a rule of thumb, the resonant frequency should be one third or less than the lowest desired frequency of effective isolation. The lower the resonant frequency, the lower the level of transmitted vibrations for a given vibration frequency.

Impact Noise Reduction

Impact noise, as the name implies, refers to such mechanisms as footsteps, objects dropped on floors, slamming doors and so forth. Reduction of impact noise may in many cases be effectively treated by the obvious; a rug on the floor, castered chairs and other measures can drastically reduce impact problems by softening the blow. To obtain better improvements the same techniques to improve TL such as discontinuous construction can be effective.

Assessing Noise Levels

The Noise Criteria (NC) curves were developed through experimentation and knowledge of the sensitivities of the human hearing system to provide a single number figure of merit for maximum permissible noise level for a given activity. The NC number is given approximately by the value of the NC curve in the 1200–2400 Hz frequency band. Figure 3.2-18 shows the NC family of curves.

For assigning an NC rating to an arbitrary room:

- SPL readings are taken in the 8 octave bands from 63 to 8,000 Hz
- The NC rating is defined as the lowest value NC curve which lies wholly above the measured data.

For broadcast studios, a rating of NC-20 or less is desirable.

Airborne Noise Reduction

For sound energy striking a partition, one can define a transmission coefficient for the partition:

$$\tau = \frac{\textit{Energy transmitted through the partition}}{\textit{Energy incident on the partition}}$$

Transmission Loss (TL) is then defined as:

$$\text{TL} = 10 \log \left(\frac{1}{\tau}\right)$$

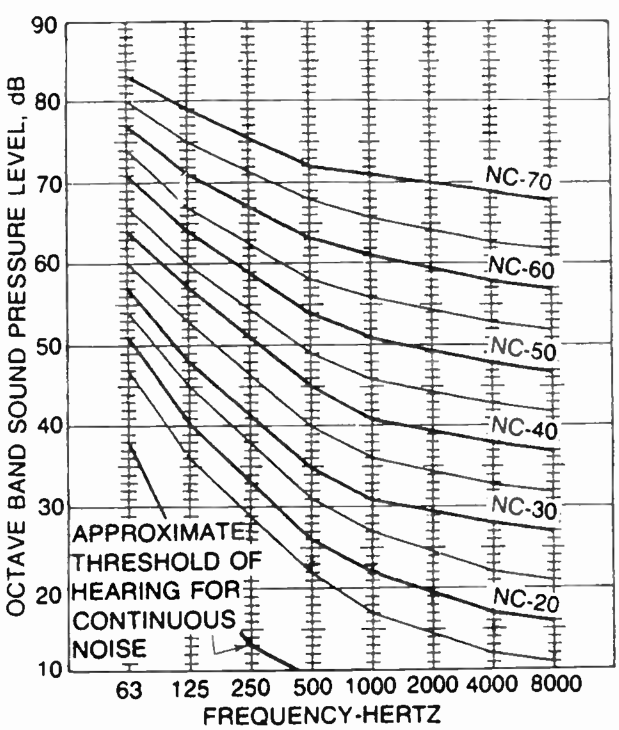

Figure 3.2-18. Noise Criteria (NC) curves. (L. Beranek, "Revised Criteria for Noise in Buildings." Noise Control, V. 3, N. 1, Jan. 1957, pp 19–27).[15]

and represents the decibel reduction of sound energy through the partition. The overall TL through a partition composed of several areas (for example, a wall with a door and window) can be calculated as follows:

$$\textit{Composite}\ \text{TL} = 10 \log \left[\frac{S_T}{\tau_1 s_1 + \tau_2 s_2 + \cdots \tau_n s_n}\right]$$

where

S_T = total surface area of partition
τ_n and s_n = the transmission coefficient and surface area of the nth element of the composite partition.

The disastrous effect of cracks and air gaps on achieving high TL partitions can easily be illustrated with this formula. For example, using $\tau = 1$ for a crack, consider the effect of a 1/8 in. crack under a door having a TL of 30 dB. The composite TL is then approximately 26 dB. Applying this same situation to a door with TL = 50 dB, yields a composite TL of approximately 28 dB, a 22 dB loss in isolation due to the air gap!

In partition design, the need for avoidance of cracks and gaps and the importance of gasketing and sealing cannot be over-stated—high sound isolation simply cannot be achieved if these factors are ignored or compromised.

Noise Reduction Between Rooms

Noise reduction (NR) is the actual difference in SPL measured in a room containing an offending noise source and the room under test. NR is determined by the area of the dividing partition (S), the total absorption in the receiving room (a), and the TL of the partition:

$$\text{NR} = \text{TL} + 10 \log \left(\frac{a}{S}\right)$$

Thus it can be seen that the actual isolation between rooms can vary both above and below the TL of the partition, although in practice, NR will typically be within 6 dB of the TL.

STC Rating

The Sound Transmission Class (STC) rating represents a single number figure of merit for overall acoustic isolation of a material. TL is plotted on ⅓ octave bands and compared with a standard contour curve to determine the STC rating. The higher the STC, the better the material for reducing sound transmission. While convenient as a figure of merit, in critical applications, such as broadcasting, it is always preferable to consider transmission loss at different frequencies to meet specific design objectives. There is no shortcut that can overcome the fact that transmission loss varies as a function of frequency.

Transmission Loss of Solid Materials

The TL of a solid wall tends to have three defined frequency regions as shown in Figure 3.2-19: a mass controlled region at low frequencies, a plateau region

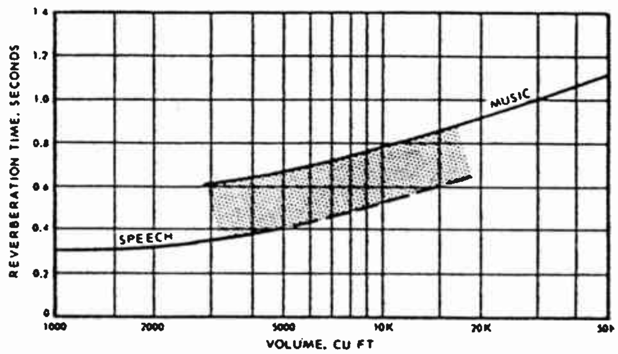

Figure 3.2-16. Optimum reverberation time (at mid-frequencies). (Reprinted with permission from book #1696 *Acoustic Techniques for Home and Studio*, 2nd Ed., by F. Alton Everest. Copyright 1984 by TAB Books, A Division of McGraw-Hill, Inc., Blue Ridge Summit, PA.

RT_{60} varies as a function of frequency. When not specified, mid frequencies around 500 Hz are usually the assumed frequency range. For critical listening applications, the optimum reverberation characteristic is sometimes deemed to be flat as a function of frequency. However, for a natural sounding environment with "warmth" it is often desirable to have higher RT_{60} at low frequencies compared to mid and high frequencies. Figure 3.2-17 shows the recommendations of the EBU in this regard.

Statistical Descriptors of Speech Intelligibility

Several statistical descriptors are used to classify the intelligibility of speech both in rooms and over audio networks. These include articulation index, speech transmission index, rapid speech transmission index and speech interference level.

Articulation index (AI) is the most often used of these metrics and can be measured using a simple sound source and sound level meter. It is the weighted proportion of speech which is usable to convey information and is calculated from the scores of a group of experienced listeners with normal hearing who write sentences, words or syllables read to them from specially-selected lists.

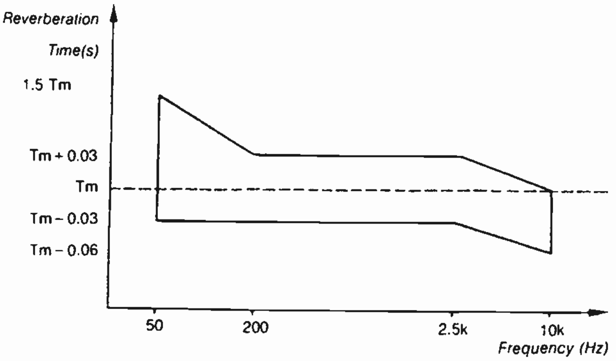

Figure 3.2-17. EBU recommendation on optimum reverberation time as a function of frequency. (Reprinted from EBU Technical Recommendation R22-1985: Acoustical properties of control rooms and listening rooms for the assessment of broadcast programs).

Speech transmission index (STI) is similar to AI but uses a modulation transfer function in its evaluation, and as such requires more sophisticated instrumentation, currently produced by only one manufacturer. It incorporates a procedure for expressing the loss in articulation produced by room reverberation.

The rapid speech transmission index (RASTI) is similar to STI, but uses fewer modulation frequencies and incorporates only speech and background sound levels in only two octave bands—500 Hz and 2000 Hz. Measurement of RASTI also requires sophisticated instrumentation.

A final descriptor, speech interference level (SIL) is the arithmetic average of the sound pressure level in four octave bands whose center frequencies are 500, 1000, 2000, and 4000 Hz.

NOISE CONTROL TECHNIQUES

Common sense is often the most important ingredient in acoustical room design and also the first forgotten concern when practical matters arise and introduce conflicts. In optimizing a room design for broadcast applications the following checklist identifies the highest priority items that should be considered, listed in approximate order of importance.

1. Select site for least noisy area
2. Perform noise survey to determine required acoustical isolation
3. Select position of room within building
4. Select sound isolation technique
5. Control noise within building including structure borne and airborne noise
6. Design room geometry for good diffusion and room mode spacing
7. Select and place sound absorbing material for optimum room acoustic response.

Numbers 1 through 5 refer to the control of noise and are intentionally a higher priority than criteria such as room shape and optimum reverberation time, especially for broadcast applications. A quiet room is both the most important design goal and also potentially the most expensive and difficult goal to achieve.

Below are four basic approaches to reducing noise within a room, listed in rough order of preference:

- Select room location
- Reduce output of noise source
- Design barrier partitions between noise source and room
- Reduce the noise energy existing within the room.

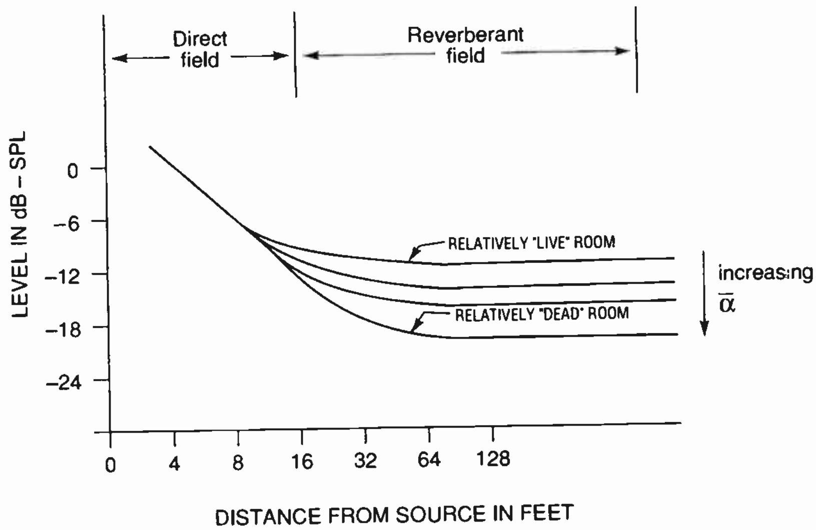

Figure 3.2-15. Sound attenuation as a function of distance and the amount of total room absorption.

Sound Decay in a Room

When a sound source stops in a room, the SPL at a given location will not decrease to zero instantaneously as in the free field case. Rather, the sound energy in the room will decay over a period of time due to reflected sound energy gradually dissipating as a result of the absorptive qualities of the room surfaces. This sound decay is called reverberation. The reverberation time of a room (RT_{60}) is defined to be the amount of time required for sound to decay 60 dB:

$$RT_{60} = \frac{0.049V}{S\overline{\alpha}} \quad (\text{when } \overline{\alpha} < 0.1)$$

where

V = room volume (ft^3)
S = surface area of room (ft^2)
$\overline{\alpha}$ = average absorption coefficient

This is the classic Sabine formula for RT_{60}.

For rooms in which the average absorption coefficient for all surfaces ($\overline{\alpha}$) is greater than 0.1 or where the absorption of various surfaces is significantly different, more complex equations govern. The reader is directed to *Acoustic Design and Noise Control*, by Michael Rettinger or other advanced texts on architectural acoustics.

In very large rooms or at high frequencies, the effect of excess absorption due to humidity and other effects must be taken into account:

$$RT_{60} = \frac{0.049V}{S\overline{\alpha} + 4\,m\mathrm{V}}$$

where m = excess sound attenuation in dB/ft (see Figure 3.2-2).

Limitations of RT_{60}

A basic premise of the RT_{60} formula is that the room exhibits a uniform rate of decay of sound. This in turn would require that the sound field is completely diffuse, an assumption generally more close to being true in large "live" rooms than small "dead" rooms. In small, very absorptive rooms, where all significant sound energy dies away in a few reflections, the validity of a statistically based tool like reverberation time becomes questionable. In these cases, the reflection profile itself must be considered on a more specific basis. In critical cases, in addition to addressing the statistical decay of the room versus frequency as represented by reverberation time, it is important to consider the strategic placement of absorptive, reflective and/or diffusive materials to provide control of first or second order reflections. For example, strategic reflection control may be important in a studio control room on the side walls and ceiling between the loudspeakers and listening position, as well as the front wall between the loudspeakers and the rear wall, which is often intentionally made diffusive according to several popular studio design philosophies.

Optimum reverberation time has received a lot of attention over the years. Being a subjective figure of merit, numbers that can be universally agreed upon for all circumstances will probably never exist. Certainly, the optimum RT_{60} varies with the size of the room and the intended application. For control rooms and listening rooms the European Broadcasting Union recommends an RT_{60} of .3 seconds ± .1 seconds at mid frequencies (200 Hz–2500 Hz). Figure 3.2-16 shows another example of optimum RT_{60} curves for small listening rooms and studios.

In general terms, most studio environments should have as little reverberation as possible. This is due to the simple fact that reverberation can be created electronically, but to date, it is virtually impossible to remove excess reverberation from an electronic signal.

the incident energy equally over a wide angular range and also corresponds to a widening of the energy received as a function of time.

Diffusing elements designed specifically for that purpose are available and the design of these units is quite refined. While traditional surface relief ornamentation, as referenced above, is useful as a diffusion element, it generally does not provide broad-bandwidth wide angle diffusion. An ideal diffusor would provide sound diffusion which is not a function of frequency, angle of incidence or observation angle. Examples of several commercially available products designed with these goals in mind are shown in Figure 3.2-14.

Based on the construction of a series of wells of different depths derived mathematically, the diffusors shown achieve a uniform angular distribution of reflected energy from a wide range of incident angles for mid and high frequencies.

Sound Level as a Function of Distance in an Enclosed Room

In an enclosed room, the situation is more complicated than the case of a free field—an environment with no reflected sound energy. The total SPL at any point in the room will be the result of contributions directly from the source (referred to as the direct sound field) and sound energy associated with multiple reflections from the room surfaces (referred to as the diffuse or reverberant sound field). The direct sound field varies inversely with the square of the distance from the source: the diffuse sound field is, by definition of being diffuse, equal at all points in the room. It can be theoretically shown that, for an enclosed room, at a distance r (in feet) from a sound source:

$$\mathrm{SPL} = \mathrm{PWL} + 10 \log \left[\frac{Q}{4\pi r^2} + \frac{4}{R} \right] + 10.5$$

where:

$R = \dfrac{S\overline{\alpha}}{1 - \overline{\alpha}}$

Q = Directivity of source

$\overline{\alpha}$ = Average absorption coefficient

S = Total room surface area

(R is sometimes called the Room Constant).

The graphical form of this equation is shown in Figure 3.2-15.

At distances remote from the sound source, the first fraction ($Q/4\pi r^2$) in the equation above becomes small as r^2 becomes large and the reverberant sound pressure level may be approximated as:

$$\mathrm{SPL} = \mathrm{PWL} - 10 \log R + 16.4$$

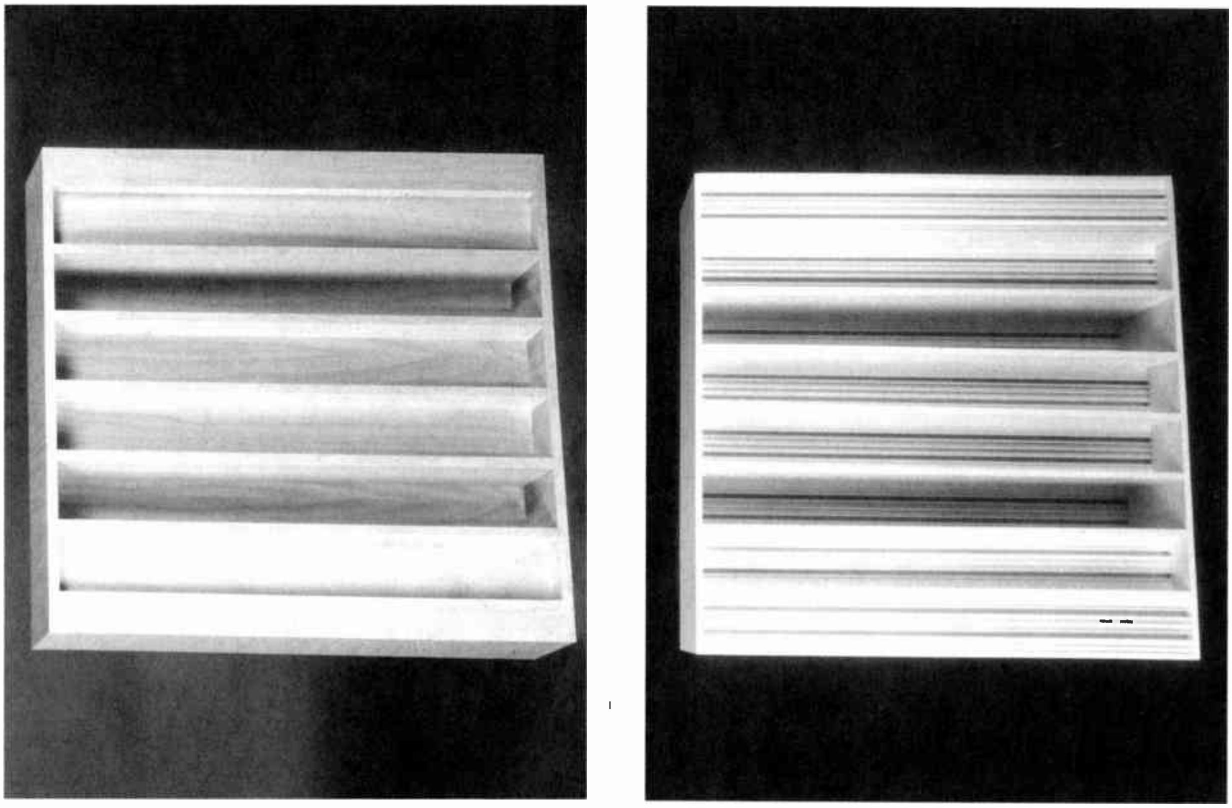

Figure 3.2-14. Examples of commercially available diffusors. (Photo courtesy of RPG Diffusor Systems.)

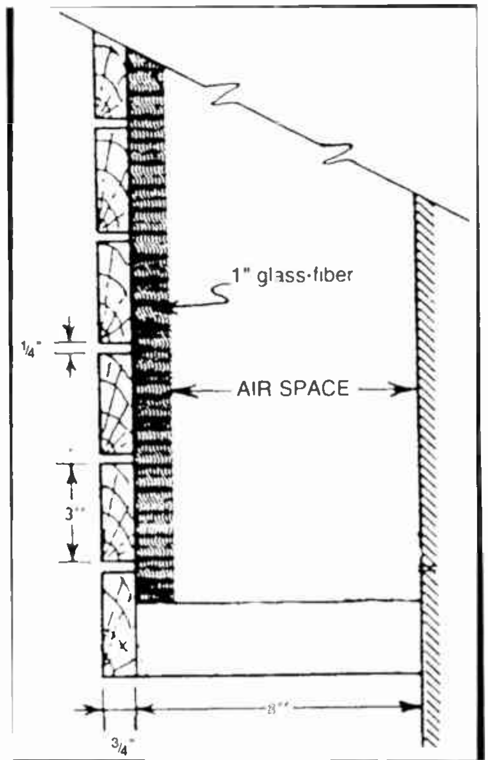

Figure 3.2-12. Example of a slit resonator.

success of many famous concert halls built in the 19th century can be largely attributed to the florid architectural features that offer diverse reflective and scattering properties for incident sound. Also, the intentionally irregular distribution of absorptive material in patches will increase diffusion. Increasing the randomness of the location of patches of absorptive material will also increase diffusion.

The range of possible effects of surface treatment on incident sound energy are shown in Figure 3.2-13. As shown in (b), a hard flat surface will reflect sound in a specular manner just as light is reflected from a mirror, following the relationship that the angle of incidence (relative to a line perpendicular to the surface) equals the angle of reflection and is equal in magnitude. At a location where both direct and reflected waves arrive, the reflected wave is a delayed replica of the incident wave. Similarly, sound absorptive material applied to a surface yields an attenuated and delayed replica of the incident wave as shown in (a). Finally, a diffusive surface, as shown in (c), reflects

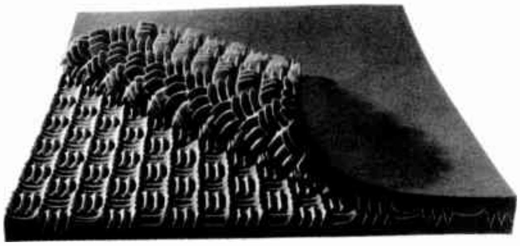

Figure 3.2-8. An open cell foam acoustical material. (SONEX photo courtesy of Illbruck, Inc.: SONEX Acoustical Products Div.)

Carpeting is often used as an absorber. However, absorption of carpeting at low frequencies is relatively poor. In general, a foam rubber or hair felt underlayment can improve low frequency absorption significantly. Typical absorption figures (with concrete as a reference) are listed in Table 3.2-3.

Effect of Mounting Method of Material on Absorption

Different methods of mounting a given material may give different absorption coefficient results. Tables of absorption coefficients must indicate the mounting method used when the absorption coefficient was measured to be useful.

In general terms, materials mounted against a hard backing will exhibit the lowest sound absorption coefficients. Sound absorption, particularly at low frequencies is increased by the presence of an airspace behind the absorptive material.

Figure 3.2-9 shows some of the various mounting designations used for standard measurements.

Acoustic Absorption Characteristics of People

Absorption by people and objects is specified in absorption tables as either the number of sabins per person or as an absorption coefficient provided by an audience based on normal seat and aisle spacings. Typical values are listed in Table 3.2-3.

Panel Absorbers

A panel with an enclosed air space behind it forms a resonant system with the air mass behaving as a spring and the panel as a mass. If the panel is thin, the resonant frequency and hence the frequency of maximum absorption coefficient can be shown to be:

$$f_{resonant} = \frac{170}{\sqrt{md}}$$

where

d = air space depth (in)
m = mass per unit area of panel (lb/sq. ft)

A broader absorption characteristic can be achieved by filling the air space with absorptive material, such as fiber glass.

Cavity Resonators

There are three basic types of cavity resonators:

- Individual units
- Perforated panels
- Slit resonators.

An example of an individual pre-fabricated cavity resonator is shown in Figure 3.2-10, which is essentially a slotted concrete block. Another type of commercially available individual unit is shown in Figure 3.2-11.

A perforated panel of significant thickness (greater than approximately 1/8 in.) spaced away from a rigid backing exhibits the absorptive behavior of a cavity resonator. The resonator has an approximate resonance frequency of:

$$f_{resonant} = 200\sqrt{\frac{p}{dt}}$$

where

p = percentage of open area of panel
d = air space depth (in.)
t = panel thickness + 0.8 × hole diameter (in.)

A slit resonator consists of a number of slats spaced away from a rigid backing with air spaces (slots) in between the slats as shown in Figure 3.2-12.

The resonant frequency can be calculated as follows:

$$f_{resonant} = 2{,}160\sqrt{\frac{s}{dD(w + s)}}$$

where

s = Width of slot (in.)
d = Thickness of slat (in.)
D = Depth of air space (in.)
w = Width of slat (in.)

In the example in Figure 3.2-12, a resonant frequency of about 250 Hz results. Broader absorption characteristics can be achieved by using slats and slots of varying widths or non-parallel air spaces.

Diffusion

Diffusion of sound in a room refers to the extent to which sound energy is uniformly distributed throughout a room. Making an analogy with baking a cake, diffusion would represent an indicated measure of how well the batter was mixed and individual ingredients of the recipe were dispersed throughout the mixture. In pursuing good room acoustics, maximum diffusion is desirable, all other things being equal. In a purely diffuse sound field:

- At a given location, sound waves are equally likely to be traveling in any direction
- The sound pressure will be equal at all locations throughout the room.

These criteria are determined by the pattern of reflections within the room. Diffusion in a room can be maximized in several ways. The introduction of oddly shaped protrusions aids in increasing diffusion. The

64. Water surface (swimming pool)	0.01	0.01	0.01	0.02	0.02	0.03	0.00

* NRC (noise reduction coefficient) is a single-number rating of the sound absorption coefficients of a material. It is an average that only includes the coefficients in the 250 to 2000 Hz frequency range and therefore should be used with caution.

†Refer to manufacturer's catalogs for absorption data which should be from up-to-date tests by independent acoustical laboratories according to current ASTM procedures.

‡Coefficients are per square foot of seating floor area or per unit. Where the audience is randomly spaced (e.g., courtroom, cafeteria), mid-frequency absorption can be estimated at about 5 sabins per person. To be precise, coefficients per person must be stated in relation to spacing pattern.

§The floor area occupid by the audience must be calculated to include an *edge effect* at aisles. For an aisle bounded on both sides by audience, include a strip 3 ft wide; for an aisle bounded on only one side by audience, including a strip 1½ ft wide. No edge effect is used when the seating abuts walls or balcony fronts (because the edge is shielded). The coefficients are also valid for orchestra and choral areas at 5 to 8 ft² per person. Orchestra areas include people, instruments, music racks, etc. No edge effects are used around musicians.

as a function of an airspace between the glass fiber and the wall. Figure 3.2-7 shows that the effect of packing density on the absorption performance is rather small.

Drapes and curtains are also often used to attenuate reflected sound energy. However, drapes also tend to have high absorption at high frequencies and low absorption at low frequencies. Listed below are some guidelines to increase the low frequency absorption:

- Use heavy base material with a lining
- Use 100% to 200% gathering of the drape
- Hang at least 6 in. from the wall.

Examples of the absorption of drapes are listed in Table 3.2-3.

An example of a commercially available cellular foam type of absorber is shown in Figure 3.2-8.

Although irregular configurated foam is popular for its appearance, the user should be aware that the geometric pattern of wedges and cavities does not increase the sound absorption of cellular foam except at very high frequencies, where the depth of the wedges is equal to $\lambda/2$, typically above 10,000 Hz. Foam of uniform thickness equal to the average thickness will be equally effective at most frequencies. Installing cellular foam over an airspace will be far more effective at increasing sound absorption coefficients than varying the surface of the foam.

Only open-cell (soft) foams are acoustically absorptive. Rigid, closed-cell foam, although a good thermal insulator, does not provide significant acoustical absorption.

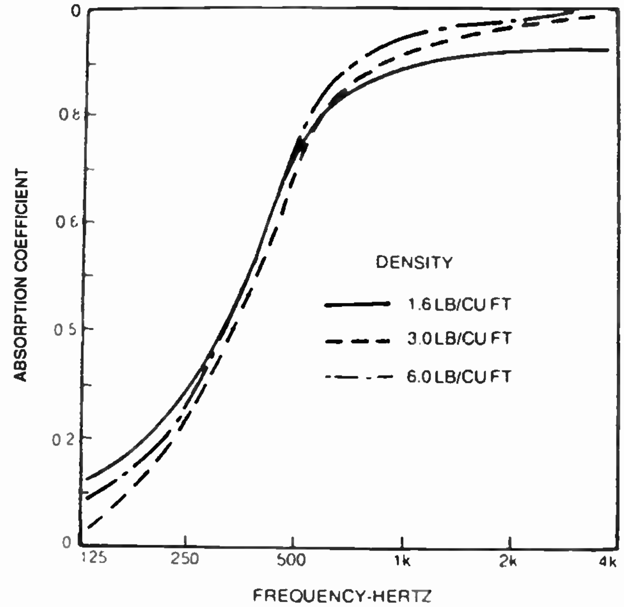

Figure 3.2-7. Effect of packing density on absorption characteristics of glass fiber (1 in. thickness). sign, an open window is considered a perfect absorber since no energy that strikes the opening is reflected back into the room.

The total absorption of a surface is defined as the product of its absorption coefficient and the surface area. The unit of absorption is the sabin, named for the early 20th Century acoustician, Wallace Clement Sabine.

In many applications, it is convenient to define the average absorption coefficient of the room, $\bar{\alpha}$. $\bar{\alpha}$ is defined as the total absorption in the room (in sabins) divided by the total surface area:

$$\bar{\alpha} = \frac{\alpha_1 s_1 + \alpha_2 s_2 + \cdots \alpha_n s_n}{s_1 + s_2 + \cdots s_n} = \frac{\sum_{i=1}^{n} \alpha_i s_i}{s_T}$$

where α_n and s_n are the absorption coefficient and surface area of a portion of the room, and s_T is the total surface area of the room.

The average absorption coefficient is accurate only for the frequencies at which the absorption coefficient values are valid.

Absorption coefficients vary as a function of frequency and are usually listed in tables at 125, 250, 500, 1,000 2,000, and 4,000 Hz.

Often materials are specified by their Noise Reduction Coefficient (NRC) value. NRC was intended to be a convenient single number index of average sound absorbing efficiency. It is defined as the arithmetic average of absorption coefficients at 250, 500, 1,000 and 2,000 Hz, rounded off to the closest multiple of .05.

$$\text{NRC} = \frac{\alpha_{250} + \alpha_{500} + \alpha_{1000} + \alpha_{2000}}{4}$$

While this has some merit, NRC has the considerable disadvantage that low (and high) frequency absorption is not considered, an important criteria to consider in critical broadcasting applications. Also, the variation of α with frequency is an important consideration as well in critical applications where optimizing the total absorption in a room at all frequencies is important. Since NRC is an unweighted average, two materials with the same NRC could have drastically different absorption versus frequency characteristics. Wherever possible, absorption in a room should be analyzed separately in the various frequency ranges of interest.

Table 3.2-3 shows the absorption coefficients of various commercial sound absorbers and general building materials.

Sound Absorbing Material Applications

Echo Control

Sound absorbing material can be used very effectively in specific trouble areas to stop echoes or flutter echoes (delayed sound reflections of sufficient intensity to be heard discretely above the general reverberant sound level).

Noise Reduction

Sound absorbing material can be used to control noise within a room by lessening the amount of reverberant (reflected) energy present.

$$\textit{Noise reduction (in dB)} = 10 \log \left(\frac{a_{after}}{a_{before}} \right)$$

where a is the total absorption in the room in sabins before and after room treatment.

Note that the total absorption must be doubled to lower the noise 3 dB and doubled again to achieve a total 6 dB reduction. A practical limit is quickly reached in attempting to achieve more than 6 to 10 dB of noise reduction using this technique.

Reverberation Control

The "liveness" or "deadness" of a room can be controlled by the introduction of sound absorbing material. This is perhaps the most common use of sound absorbing material.

Types of Absorbers

Porous absorbers. Characterized by a material with deep pores and cavities. Sound energy entering the pores is dissipated by frictional and viscous resistance and/or vibrations of fibers of the material. Glass fiber is a typical porous absorber.

Panel absorbers. Sound energy forces a panel into vibration. The vibrational activity converts the sound energy into heat.

Cavity (Helmholtz) resonator. Analogous to blowing air across the mouth of a jug. At the resonant frequency, air in the jug neck vibrates back and forth as a single air mass. Sound energy is dissipated by frictional resistance in and around the neck.

Examples of Porous Absorbers

Acoustical blankets such as glass fibers are common porous absorbers. The absorption of a given material depends on its thickness, density and relative porosity. In general,

- Increasing thickness increases absorption (mainly at low frequencies)
- Blankets of relatively low density have increased absorption as the density increases
- Blanket must be composed of interconnected open pores (closed cell foam is a poor absorber). As a guideline, if a blanket will pass smoke under moderate pressure, it will probably be a good absorber.

Glass fiber is certainly one of the workhorse materials for sound absorption applications. It is interesting to note the effect of thickness and mounting arrangement on the absorptive qualities of this material. Figure 3.2-5 shows that increased thickness mainly affects the low frequency performance. (High frequency absorption is more a function of the surface texture and relatively independent of thickness). Figure 3.2-6 shows the effect of increased low frequency absorption

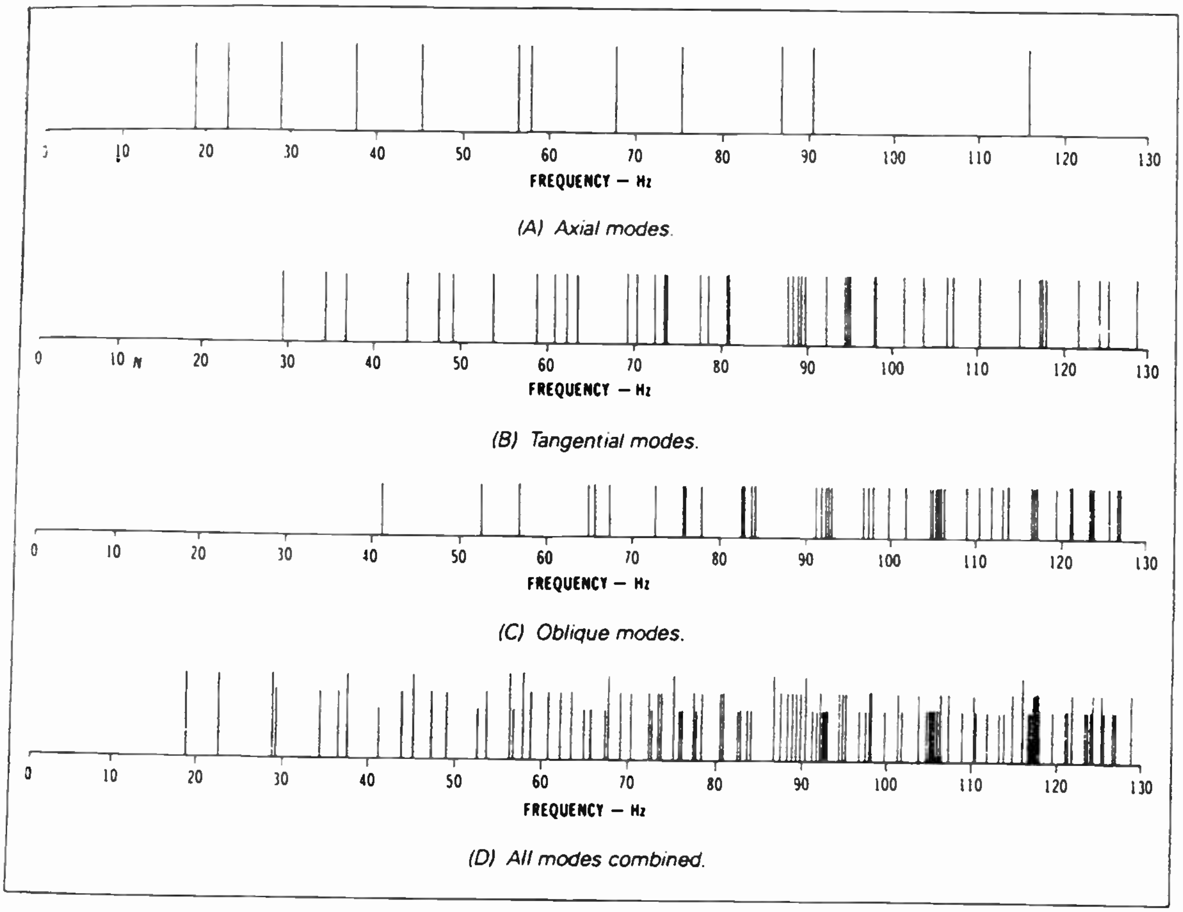

Figure 3.2-4. Modal frequencies for a room 30 ft × 25 ft × 19.5 ft (Glen Ballou: *Handbook for Sound Engineers, the New Audio Cyclopedia*, H. Sams, 1987).

pattern will lead to an overall optimized modal pattern since the tangential and oblique modes will tend to fill in the gaps between the axial modes.

Because of the resonance problems of small rooms, minimum sizes have been investigated over the years. The European Broadcast Union recommends a preferred volume of 80 cubic meters (2825 ft^3) for control rooms and 100 cubic meters (3500 ft^3) for listening rooms. Less than 40 cubic meters (1410 ft^3) is not recommended for use due to mode spacing problems.

Use of Nonparallel Walls

When the room is not rectangular, room mode problems do not vanish, they just become difficult to calculate. The modal distribution is certainly affected by room shape changes, but room resonances are not eliminated since the basic presence of room modes is more associated with volume as opposed to room shape. Nonparallel walls have been successfully used to promote good diffusion at higher frequencies and prevent flutter echoes. Flutter echoes are produced by repeated reflections from two flat parallel surfaces sufficiently distant from each other to produce a distinct echo. Usually an angle of 5° or a splay of one foot in 12 running feet is enough to destroy flutter echo problems. However, other more cost effective techniques exist to solve these problems.

Absorption of Sound

In general, when sound waves strike a surface:

- A portion of the energy is transmitted through the surface
- A portion of the energy is reflected back into the room
- A portion of the energy is absorbed.

The figure of merit for the absorptive quality of a material is called the absorption coefficient, α.

$$\alpha = \frac{\textit{Energy absorbed by the surface}}{\textit{Energy incident on the surface}}$$

α ranges between 0 and 1, 0 being a perfect reflector and 1 being a perfect absorber. In practical terms, absorption coefficients of surfaces are used in room design to aid in controlling reflections. For room de-

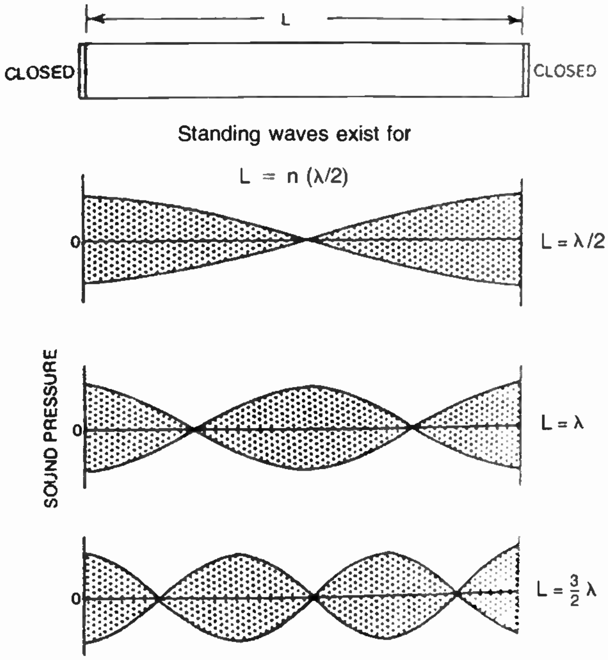

Figure 3.2-3. Standing waves in a closed tube.

three-dimensional instead of one-dimensional. Three types of resonance or room modes can be described:

- **Axial modes.** Resonant condition involving two parallel surfaces of room.
- **Tangential modes.** Resonant condition involving four surfaces and parallel to two surfaces of room.
- **Oblique modes.** Resonant condition involving all six surfaces of room.

The axial, tangential and oblique room modes for a rectangular room can be calculated as follows:

$$F = \frac{C}{2}\left[\left(\frac{p}{L}\right)^2 + \left(\frac{q}{W}\right)^2 + \left(\frac{r}{H}\right)^2\right]^{1/2}$$

where:

L, W, H = length, width and height of room
C = the speed of sound
p, q, r = integers 0, 1, 2, 3, . . .

A set of p, q and r represents one mode of vibration.

For the axial modes, only one of p, q or r will be non-zero. For tangential modes, two of p, q and r will be non-zero. Oblique modes have p, q and r all non-zero.

The above formula can be simplified for the axial modes:

$$\textit{Axial mode frequencies} = \frac{Cp}{2L}, \frac{Cq}{2W} \text{ and } \frac{Cr}{2H}$$

$$\text{for } p, q, r = 1, 2, 3, \ldots$$

At lower frequencies, modal frequencies are spaced farther apart. As frequency is increased, the modes become spaced very close together. At low frequencies, the distribution of modes with respect to frequency determines the coloration of room response. In general, room dimensions that leads to an even and uniform spacing of room modes leads to the most natural sounding environment. Room dimensions that lead to common modal frequencies should be avoided since increased response at these coincident frequencies may cause irregular boominess. Similarly, a situation with large spacings (approximately 20 Hz or larger) between adjacent modes will also result in unnatural response.

Rooms where ratios of length, width and height are related by small whole numbers should be avoided since this leads to coincident modes and consequent boominess at these frequencies. A room in the shape of a cube would be the worst case since axial modes associated with all three dimensions of the room would overlap. Beyond these simple guidelines, more concrete design criteria become complex. The search for optimum room ratios has been going on since the time of the 1940s. Recent trends suggest the use of a geometric series which closes upon an even number when continued past three dimensions. See Table 3.2-2, in which the first set is created from the square roots of successive numbers: $\sqrt{1}$, $\sqrt{2}$, $\sqrt{3}$, while the second set is the successive powers of the cube root of two: $\sqrt[3]{2^0}$, $\sqrt[3]{2^1}$, $\sqrt[3]{2^2}$. For rooms in which one or more dimensions must exceed twice the smallest dimension, even multiples of any of the preferred ratios can be used. Set 3 utilizes the ratios of set 2, but with the length and width each multiplied by 2.

Room mode analysis and optimization is particularly important in small rooms such as studios, control rooms, announce booths and so forth. A look at the example in Figure 3.2-4 shows why. Small rooms have few modes at the lowest audio frequencies and the spacing between them may be excessively large. The lowest mode in a room is equal to $565/L$ where L is the longest dimension of the room. This is $\lambda/2$ for a sound speed of 1130 ft/sec. Audio energy below this frequency will not be supported at all by resonance and room response at these frequencies will be attenuated.

As stated previously, three types of room modes exist. While all three are significant, a reasonable first-order design and /or analysis can be made using only the axial modes. The tangential and oblique modes involve four or six room surfaces respectively and are likely to suffer more attenuation due to the absorption of the surfaces and greater likelihood of meeting physical obstructions. In general, an optimized axial mode

Table 3.2-2
Recommended room dimension ratios for optimum mode spacing.

	Height	Width	Length
Set 1	1.00	1.41	1.73
Set 2	1.00	1.26	1.59
Set 3	1.00	1.52	3.18

SPL Attenuation as a Function of Distance

In a free field, sound intensity varies inversely with the square of the distance from the source. Hence, like light, sound follows so-called inverse square law. The difference in dB between the SPL at two different distances, d_1 and d_2, is then:

$$\textit{Difference in } \mathrm{dB} = 20 \log\left(\frac{d_2}{d_1}\right)$$

This is equivalent to a 6 dB loss per doubling of distance or a 20 dB loss per tenfold increase of distance.

Directivity of Sound Sources

In the practical case, sound sources are not omnidirectional and have an axis of main radiation. This can be quantified in the concept of directivity, or Q. Directivity (Q) is the ratio of intensity along a given axis to the intensity which would be measured at the same distance if the same quantity of total acoustic power were being radiated omnidirectionally. The designated axis is usually taken to be the axis of maximum radiation, so $Q \geq 1$. This can be expressed as:

$$Q = \frac{(\textit{On-axis pressure})^2 \textit{ at some distance}}{(\textit{Mean sound pressure})^2 \textit{ at same distance averaged over all directions}}$$

It can be shown that for a sound source having theoretical horizontal and vertical coverage angles of a and b,

$$Q = \frac{180}{\sin^{-1}\left(\sin\frac{a}{2}\sin\frac{b}{2}\right)}$$

Directivity is often expressed in decibel notation:

$$\textit{Directivity factor}\ (\mathrm{DF}) = 10 \log Q$$

The attenuation of SPL as a function of distance given previously can be modified to include the factor of source directionality:

$$\mathrm{SPL} = \mathrm{PWL} + \mathrm{DF} - 10 \log (4\pi r^2)$$

where r is the distance from the source in meters.

Effect of Humidity on Sound Level

Humidity in the air will increase sound level loss in excess of that predicted by inverse square law alone. Figure 3.2-2 shows a family of curves at different frequencies showing dB loss per 100 ft as a function of RH. In general, the attenuation increases with frequency and absorption is greatest between approximately 10% to 40% RH, decreasing above and below these levels for all frequencies.

The curves show why it is difficult to acoustically transmit high frequency energy long distances. For example, the SPL at a distance of 4 ft required to produce 80 dB SPL at 1000 ft for 10 kHz at 20% RH is:

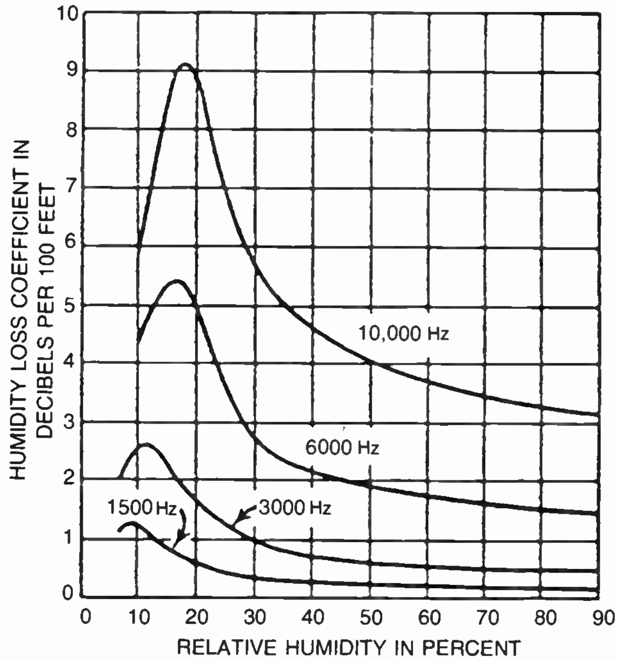

Figure 3.2-2. The effect of humidity on sound attenuation (dB loss per 100 ft).

$$\underbrace{80 + 20 \log\left(\frac{1000}{4}\right)}_{\textit{inverse square law term}} + \underbrace{9 \text{ dB}/100 \text{ ft} \times 10}_{\textit{humidity term}} = 218 \text{ dB SPL!}$$

SOUND IN ENCLOSED SPACES

Room Modes

It is well known that a guitar or violin string resonates at only selected discrete frequencies, determined by the length of the string and the tension on the string. It can be easily shown that these resonant frequencies include higher order harmonics, by placing a finger on the exact center of the string, damping out the fundamental frequency tone, but not the even harmonics, which continue to resonate.

Similarly, the resonant tone produced by an organ pipe is dependent upon the length of the tube, atmospheric pressure, and the end conditions; i.e., whether the pipe is open or closed. For a pipe closed at each end, the resonances are those of the standing waves in a closed tube, as shown in Figure 3.2-3. Once again, the resonant frequencies include the fundamental, for which the length of the pipe is one half the wavelength ($\lambda/2$) and other harmonics for which the length of the pipe is some multiple of one half of the wavelength (λ, $3\lambda/2$, 2λ, etc.)

Like closed tubes, rooms exhibit analogous characteristics of resonance . . . those frequencies at which sound is sustained or reinforced by the geometry and boundary conditions. However, the situation is now shown. As is evident, the air is alternately compressed and rarefied. In the second picture, at an instant of time later, it is apparent that the compression/rarefaction cycle is moving to the right.

The Speed of Sound

The speed of sound depends principally on the nature of the propagation medium in which it is traveling. Table 3.2-1 lists the speed of sound in various materials.

Looking at Table 3.2-1, it is easy to understand situations such as when banging on a pipe in the basement of a building results in the perception of a double bang in an upper floor room due to the arrival of sound energy transmitted via the pipe itself re-radiating in the room versus the slower airborne path through the room partitions and floor/ceiling structures. Also it is worth keeping in mind that loudspeakers closely coupled to a wall structure can in some cases transmit sound via the structure to be re-radiated from another point in the structure. Thus, since sound travels much faster in solid structures than in the air, sound energy can arrive at a listener or microphone before the direct sound path arrives, causing a weak but annoying pre-echo.

The speed of sound at normal room temperature is approximately 1130 ft/sec. However, the speed of sound is also dependent on temperature. At 32° F and 760 mm Hg the speed of sound has been experimentally verified to be approximately 1,087 ft per second. A reasonably accurate simplified formula for the speed of sound is to assume a 1.1 ft/sec increase or decrease for each degree F above or below 32°:

$$\textit{Speed of sound} = 1{,}087 + 1.1(T - 32)\ \text{ft/sec}$$

where T is temperature in degrees Fahrenheit

It is worth noting that the ambient air pressure is not a factor in the speed of sound.

Relative humidity changes the density of air and has a small effect on the speed of sound. At typical room temperatures, the percentage change in velocity between 0 and 100% RH is less than 0.5%. This factor is usually ignored in practical situations.

Definitions and Sound Measurements

A decibel (dB) is a mathematically convenient way for expressing the ratio of two power-like quantities:

$$\text{dB} = 10 \log \left(\frac{P_1}{P_2}\right)$$

where P_1 and P_2 are power quantities. Units expressed in decibels are designated as *levels* and are defined as follows:

$$\textit{Intensity level}\ \text{IL} = 10 \log \left(\frac{I}{I_{ref}}\right)$$

where

I = Sound intensity (watts/m^2)
$I_{ref} = 10^{-12}$ watts/m^2

$$\textit{Acoustic power level} = \text{PWL} = 10 \log \left(\frac{W}{W_{ref}}\right)$$

where

W = acoustic power (watts)
$W_{ref} = 10^{-12}$ watts

$$\textit{Sound pressure level} = \text{SPL} = 20 \log \left(\frac{p}{p_{ref}}\right)$$

where

p = Sound pressure (N/m^2)
$p_{ref} = 2 \times 10^{-5}$ N/m^2 or 0.0002 microbar

In a free field,

$$I = \frac{p^2}{\rho_o C}$$

where

ρ_o = Air density
C = Speed of sound
SPL $\approx$ IL in a free field.

In a diffuse field,

$$I = \frac{p^2}{4\rho_o C}$$

$$\text{SPL} = \text{PWL} - 10 \log (4\pi r^2) + .5$$

where

r = distance from the sound source in meters

and the source is omnidirectional.

When adding decibel quantities, it must be remembered that power levels themselves can be added directly but decibels cannot. To add decibel quantities, the decibel notation must be rearranged so that the associated power levels are added and then converted back to decibel form:

$$\text{dB}_{total} = 10 \log [10^{\text{dB}_1/10} + 10^{\text{dB}_2/10} + 10^{\text{dB}_n/10}]$$

For an approximate rule of thumb in adding decibels, refer to the following table:

When adding two dB values that differ by:	Add to the higher value to obtain the total:
0 or 1 dB	3 dB
2 or 3 dB	2 dB
4 to 8 dB	1 dB
9 or more dB	0 dB

Table 3.2-1
The speed of sound in different media.

Medium	Approximate Speed of Sound
Air (room temperature)	1,130 ft/sec
Soft Wood	11,000 ft/sec
Gypsum board	22,300 ft/sec
Steel	16,600 ft/sec
Water	4,900 ft/sec
Glass	17,000 ft/sec
Concrete	11,200 ft/sec
Hydrogen	4,100 ft/sec
Helium	3,000 ft/sec

3.2
PRINCIPLES OF ACOUSTICS FOR BROADCAST APPLICATIONS

LYNN D. CLAUDY*
NATIONAL ASSOCIATION OF BROADCASTERS, WASHINGTON, DC

INTRODUCTION

Acoustics—*the scientific study of sound, especially of its generation, propagation, perception and interaction with materials and other forms of radiation.*—American Heritage Dictionary.

Reducing the above definition to its basic core, acoustics encompasses essentially *the total effect of sound*, including the characteristics of the sound source, propagation medium and the reception of the transmitted sound. This chapter covers basic principles of acoustics relevant for broadcast applications. In addressing this subject, a review of the basics of sound wave propagation will first be presented. The behavior of sound in enclosed spaces will then be examined and design techniques for controlling sound within a room will be introduced. Sound isolation techniques, or controlling the intrusion of unwanted noises into enclosed spaces, will then be presented. The chapter offers a broad overview of acoustics, with a blend of theory and practice, with the goal of providing a balanced foundation on the subject. However, as the practice of acoustical design is still part science and part art form, the services of a professional consultant in this area will continue to be just as appropriate for the knowledgeable reader as for the layman.

THE NEED FOR ACOUSTICAL DESIGN IN BROADCASTING

The importance of the need for good acoustics in broadcasting applications cannot be overstated. Borrowing the garbage-in-garbage-out metaphor from the computing industry, it is easy to imagine that an excellent transmission system can be a wasted resource if the signal source itself is degraded. High ambient noise, improper acoustical treatment or poor noise isolation can quickly alienate, fatigue or annoy a listener. Common sense might lead one to a different conclusion: often one experiences poor acoustic environments in daily life and is not overly adversely affected: conversation does take place in noisy corridors, musical performances are well received in compromised settings, and so forth. Noise, excess reverberation or extraneous sounds are typically much less irritating to listeners when presented contextually in their original environments than when reproduced over radio or television. The human binaural sense of hearing, visual and other cues allow concentration on a desired source and inhibition of unwanted sounds. A simple experiment can be set up to prove this point. Carry a pocket tape recorder to a cocktail party and record the environment while moving from one conversation circle to another. While it is relatively easy to understand live conversations at the party, the recording will in all likelihood be a cacophony of jumbled sounds, indistinguishable one from another. The lesson: acoustics, while being of significant importance in live settings, is ever more so important for radio and television broadcasting because any defects that are present are magnified when the sounds are taken out of the originating environment and reproduced in another.

*Additional material provided by Eric Neil Angevine, Oklahoma State University, Stillwater, OK.

BASIC CHARACTERISTICS OF SOUND PROPAGATION

Sound is a wave phenomenon. The wave motion is of the longitudinal (as opposed to transverse) variety: the air molecules move back and forth in the same direction as the wave motion. All molecular motion occurs with respect to any motion of the air; there is no net motion of the air particles within the air. Figure 3.2-1 shows a sound wave traveling down a tube at two points in time: the distribution of air particles and regions of high and low pressure in the tube are also

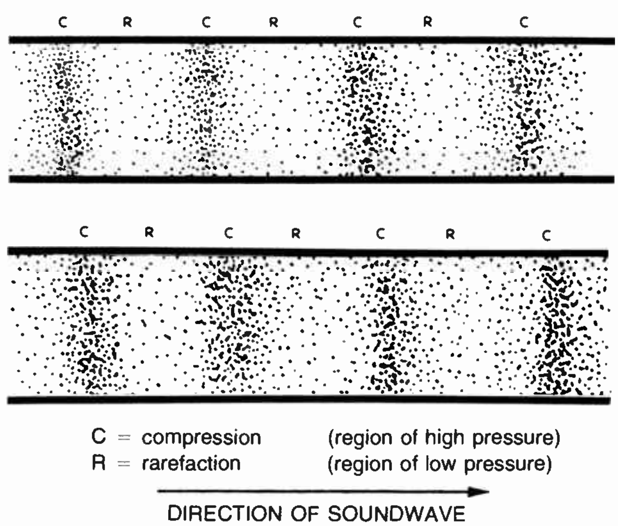

Figure 3.2-1. Illustration of sound wave propagation in a tube.

Doors to studios and control rooms should be of solid construction with weatherstripping (felt, not rubber that will squeak) and a good quality door closer. Do not use a latch on the door that will click each time the door is opened and closed. Doors should not open out into busy hallways where people will walk into them as they pass by. The average door in most stations is 3 ft wide. That can be reduced by 6 in. However, most furniture requires up to 30 in. to be moved through a doorway and more if it opens into a narrow corridor. The narrowest hallways should be no less than 3 ft 6 in. Note that hallways take up space. Every square foot of hallway that can be eliminated yields an equal amount of space that can be used for something productive.

Where the location of the facility allows, windows to the outside should be considered. This is particularly applicable for radio stations. In some instances studios are built in the interior of a building and exterior windows are not possible. However, when a radio studio or combo facility is built on an outside wall, a small exterior window will allow occupants to know a little more about the weather and have a connection with the outside world. Of course, if the facility is located next to an airport or major highway, the window invites more background noise than might be acceptable.

Sound locks, while desirable, are not essential, but can be combined with other purposes. Plan on plenty of lights but place the ballasts of fluorescent lights out of the production areas to eliminate acoustic noise and interference.

If the transmitter is at the studio site, locate it and the main control room so that meters on the transmitter and its associated monitoring equipment can easily be seen from the operating position.

Equipment

In a low-budget situation remember this rule of thumb: *Will the equipment to be bought pay for itself and make money for the station?* The purchase of a \$200 directional microphone to do a one-time remote broadcast that pays only \$100 is poor business.

Use this logic when equipping the station. Create a list of those functions you will have to perform and spend only what is needed to get on the air and function. However, plan for the future. Design around a console with enough inputs to accommodate those unanticipated needs. A four potentiometer board is not enough for most on-air operations except for simple production. Even the smallest stations should have provision for six or eight simultaneous inputs. Invest in a good quality telephone interface system. Virtually all stations now take phone calls for direct on-air use.

Consider used equipment with great care. While older equipment was built for long life, obtaining spare parts may be a problem and the general quality level may not meet today's needs.

Consider versatility and contingency in equipment configurations. The studio output can be operated through the automation system as a source. In the event of an emergency, the announcer can easily connect the output of the console to the studio-to-transmitter link (STL), bypassing the automation system. In the event of an STL failure, the audio can be patched directly to the transmitter via the remote control system line or a telephone line.

Do not forget the patch panel in the control room. There is a growing tendency among engineers today to eliminate this important switching center. All high level inputs and outputs should appear here. Even console inputs should show up. This also applies to all recorders, tuners and other audio sources. This practice makes for a very versatile operation and can save the embarrassment of dead air time if the console should fail. If this happens, a player can be patched directly to the transmitter, bypassing the defective elements in the system.

Consider every piece of equipment in the audio chain as a potential single point failure problem and address a plan on how to bypass it or do without while it is being repaired. Consider also a backup power generator. For a small station a modest sized generator can power the entire facility except for a central air conditioning system.

The construction of a new or renovated facility is a good time to implement a checklist approach to routine testing of all equipment on an annual, quarterly, monthly or weekly basis depending upon how often the equipment needs to be checked. The checklist should also include such items as the air conditioning and heating system, backup generator, tower, antenna, lights and the general condition of the facility and surrounding environment.

CONCLUSION

The planning of an audio production center is arduous at best. Every project reaches a point where the deadline is met and the budget must be closed. However, when everything is up and running the job may still not be done. It is not unusual to see 85% completion at this point. Those who control the purse strings will ask *we're in production, why go any further?*

The sheer exhilaration of a new facility will give the production and operations people the energy to carry on. When it wears off the end-users will tire of having to put up with inadequacies every working day. The product invariably suffers from lack of efficiency and enthusiasm.

The construction group will have moved on so the technical maintenance team is likely to handle the follow-up tasks. Because this must be done in addition to routine activities, budget some overtime for this purpose. The process will take three to six months. Keep communications open with the users. They will be patient if they see progress and know that someone is sweeping up corners and tying up loose ends.

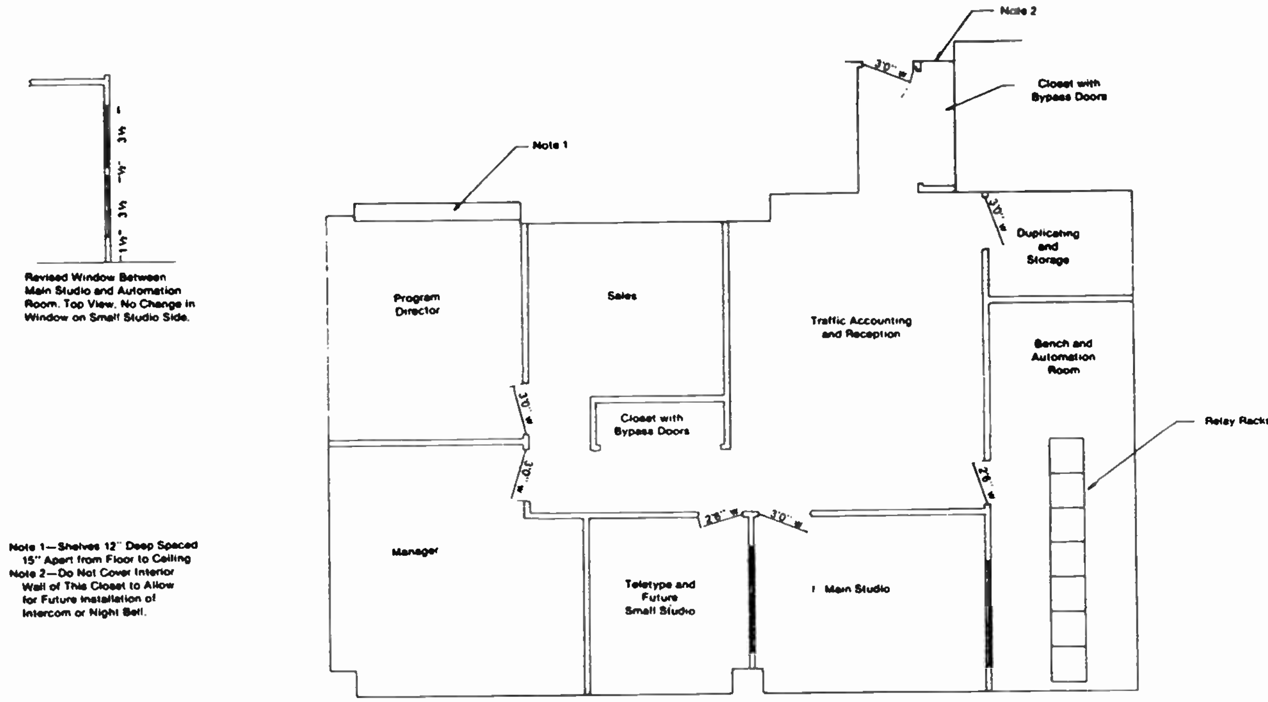

Figure 3.1-11. Studio layout for a small station.

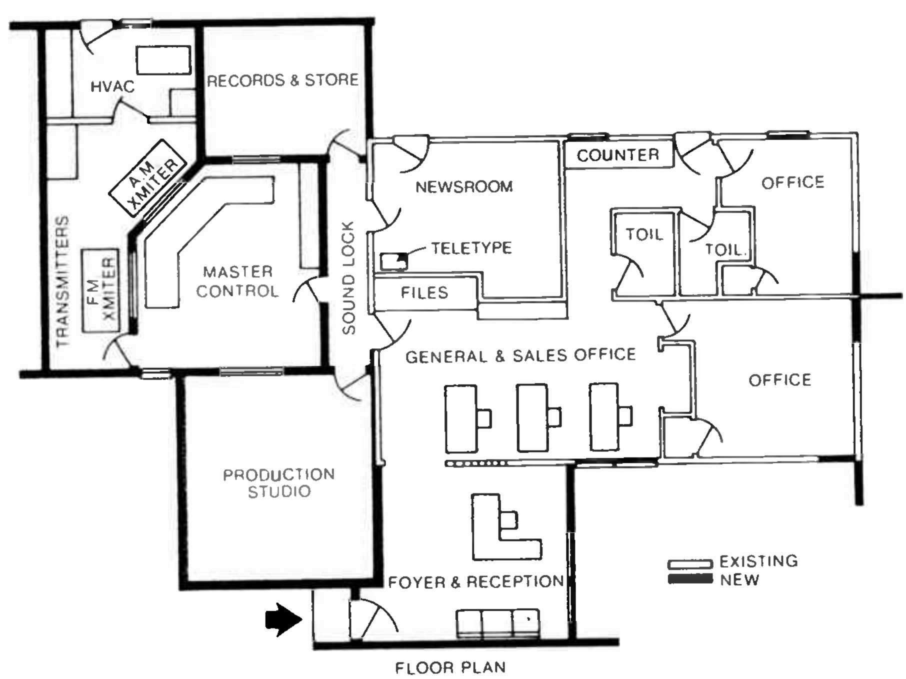

Figure 3.1-12. Renovated small station.

material is reinforced concrete. A wooden floor can be used if it is reinforced to prevent bouncing. Otherwise people walking on such a floor will cause problems with turntables and compact disc players. Sandbags or bricks in the base of the turntable cabinet will sometimes improve an otherwise bad situation.

Avoid placing the console up against a wall. In addition to being an acoustic problem, the operator will find looking at a wall to be uncomfortable. Locate the console in the middle of the room as a desk might be in an office. The wall space can be used for shelves, equipment, or other facilities.

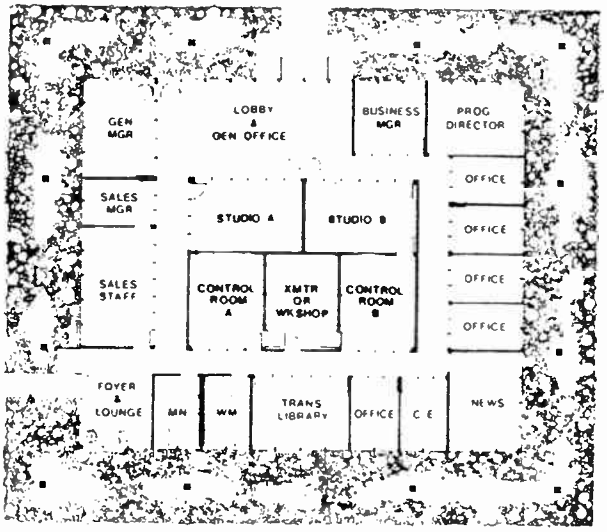

Figure 3.1-10. Large station. Metropolitan market full staff.

station's announcing is carried on and may be the only studio area in a station other than the production studio (also a combo). Combos usually contain most of the audio equipment of the station. Frequently, a transmitter and record library will also be located in the control room.

In many instances the news room will be used with live mics for late breaking news events. Both situations make the problem of acoustics more complex but, because radio sells with sound, good acoustic design is essential when the best sound possible is required.

Design factors of combo control rooms are at best a compromise of the several design factors:

- Location of the control room within the studio building
- Isolation. Elimination or substantial reduction of unwanted sound and noise, both internal and external
- Construction. Special walls, ceilings and floors may be required
- Reverberation control. Size the rooms and consider special wall and floor coverings to eliminate or reduce reflections and resonances that degrade the studio sound on the air
- Ventilation and air conditioning. Technical equipment generates more heat than normal office equipment and studio guests add to the heat load that must be accommodated with the HVAC facilities
- Size and arrangement of equipment. There are as many arrangements as there are designers—plan some flexibility for changes that will be needed after the facility is used for a while and for accommodating future needs.

RADIO STUDIOS ON A LOW BUDGET

Considerations Involved

Different sized stations require different construction criteria. A 50,000 W AM clear channel or Class C FM in a major market and a 250 W AM daytime or Class A FM in a rural area dictate that the small market station is going to be constructed quite different from its big city counterpart. In most cases, the selection of a studio site in a small market is dictated by what it costs to get the space. It is not unusual for space to be traded out in part or in full for advertising. Figures 3.1-11 and 3.1-12 show examples of small radio broadcast studio and office facilities.

For the construction or renovation of a smaller facility, the chief engineer (or engineering consultant) may be presented with an existing suite of offices, a store front or even an old house that must be converted into studios and control rooms. After determining the nature of programming management intends to offer the community, the facility can be designed to meet the requirements. Most smaller stations use combo control rooms and studios, a simple production facility (that can be used as an emergency control room) and a newsroom with recording and editing facilities capable of on-air use.

A larger studio can be fashioned from the lobby area, the general office area or by combining two or more management offices. With some advance planning, these areas can be acoustically treated and wired for use as acceptable studios for those occasional talent shows, church programs, talk shows or special group events that do not occur often enough to justify having a full-featured studio available. If the station is a new or growing operation and cannot afford to do all of the above, at least consider what functions may be required at a foreseeable future date. Plan now for what might be needed in two or three years.

Physical Layout

While the total amount of space may be limited, remember that combo control rooms are occupied for long periods by one or at most two people. Consider this as their office that should be large enough to house the equipment, move around, have visual access to other areas (including the outside) and be comfortable and well lit.

When laying out the studio location, draw a sketch of the available floor space and existing walls. Make a number of copies of this floor plan and start drawing in the studios, offices, newsroom, reception areas and engineering. Make three or four versions of the plan. If the existing layout will allow the installation of new walls, avoid perfectly square rooms. A room that is 8 ft × 8 ft × 8 ft is going to have a very definite and unpleasant resonance. Strive for 6 ft × 8 ft × 10 ft or dimensions in this proportion. Be sure to add extra wall thickness for the studios and control rooms.

Consider laying out the facility using scale cutouts of typical office furniture, studio equipment and consoles, plus storage cabinets and counter tops. Add some closets and undefined storage spaces for the future. Keep the main studio and control room from beneath heavily traveled stairways and corridors, air conditioners and front windows opening on busy streets. The control room floor should be very solid. The most desirable

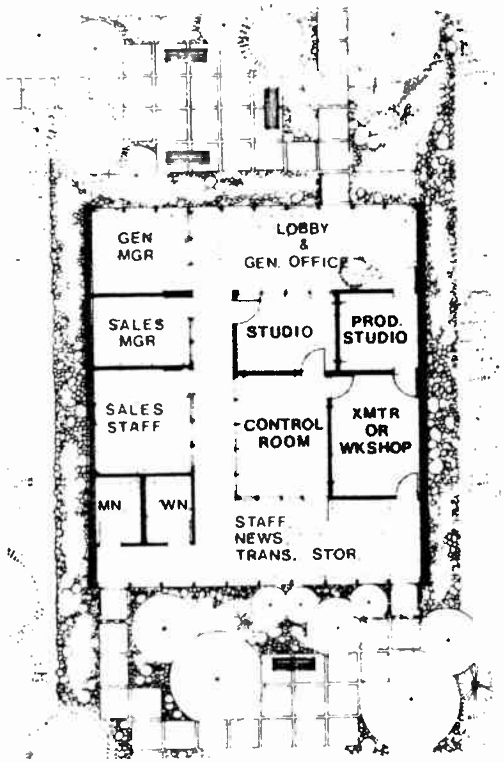

Figure 3.1-7. Small size AM station.

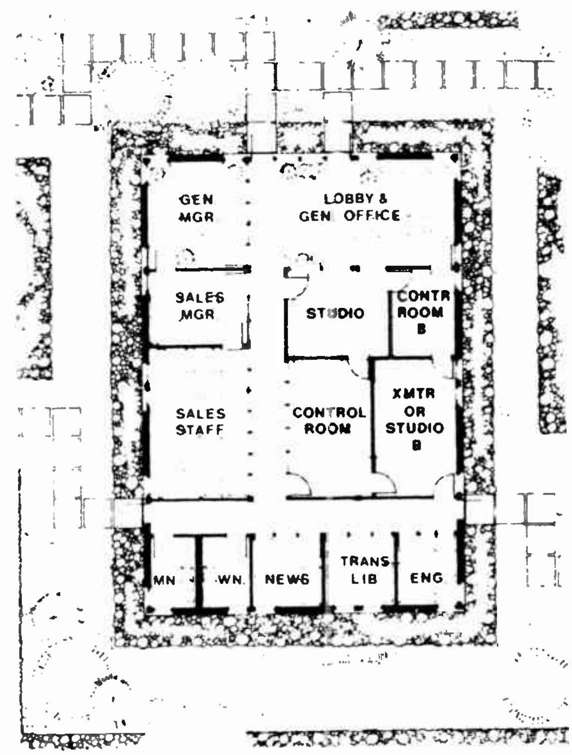

Figure 3.1-8. Medium size AM station.

ated studio (see Figure 3.1-9). Control rooms are separated by the transmitter, automation or engineering area. This floor plan includes approximately 3,150 sq. ft and is suggested for stations planning both AM and FM operations. Additional office space is also allocated for the larger staff in this station. This design features a mirror glass curtain wall building set in a reflecting pool. The building costs approximately $90,000 to $135,000.

Plan Four. Large Station

This 4,300 sq. ft studio/office complex is an impressive broadcast center (see Figure 3.1-10). Of primary importance is the location of all control room and studio space in the center of the building, eliminating the problem of outside traffic noise in a metropolitan area.

Operating personnel are assigned to the rear office areas and the news room is strategically located near the control rooms and an outside exit to the news cars and trucks.

The building is made of exposed concrete and features a dark glass curtain wall. The building cost is approximately $100,000 to $150,000.

CONTROL ROOM/STUDIO DESIGN

Many present day radio control rooms also double as studios and are called *combos* for combination control and studio. The combo room is where most of the

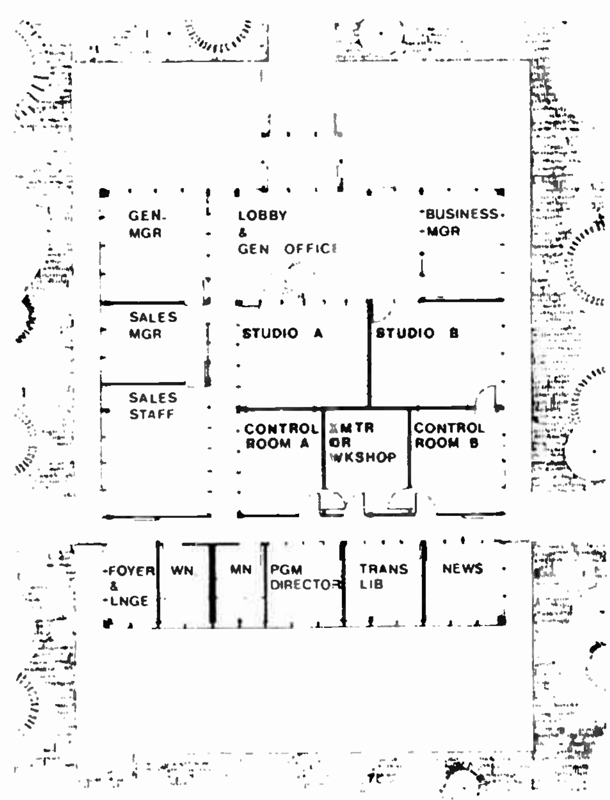

Figure 3.1-9. Large station AM/FM dual control room.

If 1/3 octave graphic EQ must be used, use smooth curves with no more than 2 dB difference between any two bands. Leave it bypassed for a few days, then switch it in to decide if you really like what it does.

STORAGE SYSTEMS

Professional CD, DAT and digital cart machines are the plow horses of most production centers. High quality R-DAT units offer economical multitrack operation for off-line production. Third generation computer based virtual multitrack systems are a good alternative but present the same DSP hazards as digital mixers.

Central digital storage systems are coming of age. They offer the advantage of simultaneous access to all material from every work station. These systems are worth considering for their ability to save large amounts of storage space. Redundancy is a given but no on-line operation should give up its traditional machines and one closet full of materials to play in them. Recordable CDRs offer a convenient backup of archival materials.

Processors

Every audio production benefits from a collection of processors. Tools that compress, limit, reduce noise and remove hum are useful in conditioning materials for the best sound. As with microphones, look at what others are using. Remember that newer gadgets may offer no real advantage over some of the old favorites.

Effects Devices

These are used to enhance the texture of sound or change its character. Reverb, delay, phasing, flanging and the like are enhancements. Pitch shifting often is used to disguise voices. Newer devices are highly sophisticated and may be able to do all of these effects. If more than one effect is needed on the same sound, multiple units may be required. Installations with multiple control rooms have the option of either moving effects gear around as needed or using tie trunks to access unused gear in other rooms.

ESTIMATING COSTS

Many of the factors that affect the costs of acoustic construction are actually under the station's control. A top 40 radio station whose talent works only a few inches from a single microphone, relies less on room acoustics for its live sound than does an all-talk format station requiring several open microphones to pickup guests at a variety of distances. Because broadcasting is considered high fidelity, studio acoustics must be closely controlled.

The more audio signal compression and limiting a station employs, the more evident will be the annoyance of poor studio acoustic characteristics. Conversely, the compression on stations with better studio acoustics will be less noticeable during live broadcasts and recordings.

AM AND FM STUDIO FACILITIES

Building Planning

One of the prime requisites for a successful broadcast station is the careful layout of studio, production and administrative areas to achieve maximum effectiveness of space and personnel. The following four typical layouts depict a range of facilities from a small market minimum staff facility to an arrangement suitable for a large metropolitan operation employing a full complement of personnel. Each floor plan is handled differently according to the needs of different size stations.

In these examples, the control room, studio and production facilities are in a centrally located core area although they need not necessarily be there. The suggested sizes of these areas should be considered as minimum from an operating standpoint with normal equipment complement. The layouts are presented as a guide for planning a modern, functional radio facility with considerations given to size of market, staff and programming requirements.

Plan One. Small Radio Station

With approximately 1,800 sq. ft, this floor plan provides adequate space for the small AM or FM station with a minimum staff (see Figure 3.1-7). Since smaller staffs have several responsibilities, partitioned general office space is omitted in favor of a large news, recording storage and general use areas at the rear of the building.

The transmitter and engineering workshop area is placed next to the control room with a window recommended for a clear view of the transmitter meters.

The building is of brick and plaster fascia and includes a glass curtain wall. The building price will vary considerably depending on area construction costs; but a typical range is $60,000 to $75,000.

Plan Two. Medium Radio Station

In medium-sized stations, office space is increased for sales, promotion and programming activities but without a substantially larger technical core area. This floor plan takes the small station layout and expands it to approximately 2,500 sq. ft (see Figure 3.1-8). More room is provided for the sales staff and clerical help and an impressive office for the general manager. Studio and control room space is slightly larger in anticipation of more equipment and activities in these areas. The news director, recording library and chief engineer gain office space. Alternate core area layouts may be employed.

The building includes brick walls, weathering steel columns and fascia with a dark glass entrance and glazing strips. Cost is approximately $65,000 to $90,000 but may vary considerably, depending on construction costs in a particular area.

Plan Three. Larger Radio Station

In this plan, the technical core area is adequate for two full-size control rooms, each with a large associto see microphones and processors dating from the 1950s and 1960s in photos of recording studios. The old favorites are still around because they are perceived to have personalities unmatched by newer choices. Surely this is true but as progress continues to peel back the veils of distortion, some of those characteristics will go out of favor.

Microphones

The electromechanical nature of microphones contributes to their imperfection. Each of the three basic types—dynamic units, condensers and ribbon microphones—has merits and disadvantages. Dynamic units are rugged and the best examples offer very smooth, wide frequency response. No power source is needed and their domed diaphragms diffuse reflected sound waves. Thus far, dynamics cannot be made as small and lightweight as required for body microphone uses.

Condenser (capacitor) microphones provide higher output, overcoming electronic noise but require a power source. Their necessarily flat diaphragm reflects arriving wave fronts resulting in cancellations. Large diaphragm condensers also create acoustical phase distortion as wave fronts arrive at different times across the element. This may be perceived as a slight harshness in the higher frequencies. Very sibilant voices risk digital overload from HF peakiness. Tiny clip-on condensers approach the theoretical perfection of a point in space.

Perhaps the best because of their ultra-lightweight element are ribbon microphones. Unfortunately they are extremely fragile and prone to damage from a mild breeze. Time will tell which type really is best. Find out what others are using and try one of these microphones first. When seeking a new microphone, look for units that sound good with minimum equalization (see also Chapter 3.3 "Microphones.")

Mixers

In addition to the human factors already discussed, the choice of a mixer must consider sonic quality. Low noise, good fidelity and resistance to interference are expected. Simple three-band quasi-parametric equalizers offer more than sufficient control in the hands of a knowledgeable user. Four-band EQ is more susceptible to abuse, causing irreversible phase shifts. Onboard gating and compression may be adequate. However, many users choose outboard equipment for these functions.

The dust cloud surrounding digital signal processing (DSP) is continuing to settle. Manufacturers and users are beginning to understand the subtle artifacts introduced by insufficient digital word size and improper dithering (rounding off of digital calculations). Even the ultimate high-end digital systems may still have some of these problems. Until everything is fully digital there will continue to be good arguments for a high quality hybrid system with pass-through digital inputs and both types of output.

Loudspeakers

In a production room the monitoring loudspeakers must be as accurate as possible. Too often program is over-equalized to make up for monitor problems. It is not sufficient to select a system because it is popular and found in similar facilities. Instead it is necessary to perform an objective evaluation of the potential choices and select one that is unquestionably the most accurate.

Evaluation of Loudspeakers

A/X/Y testing of loudspeakers maintains objectivity and overcomes the variables of other methods. *A* is a known, *X* and *Y* are unknowns to be compared to A and to each other. The testing may be done in a large room, parking lot or open field. If an existing control room is available, listening should be done there. Otherwise a small mixer, headphones and a few power amplifiers may be used.

The process consists of placing two candidate systems together and laying a microphone on the floor or other hard surface about 15 ft away. An omnidirectional dynamic microphone with wide, smooth frequency response is recommended.

Using program material containing music and speech, setup the mixer to compare direct program with that returning from the microphone. Switch repeatedly between the direct and each of the test loudspeakers. The more accurate one will reveal itself easily; replace the other with the next test unit. To ease any doubts about the control room monitor, use a similar monitor as a test system. Any inaccuracies will be magnified, not masked. Finally, rerun the test using the initial winner as a control room reference to check the top two or three candidates. The results should not vary significantly.

The theoretically best loudspeakers are coaxial in construction. Next are those with drivers aligned in a vertical array. There should be only one driver for each frequency range; two-way systems tend to be more accurate than those with three drivers. This is due to inevitable distortions in the crossover range. Systems with drivers horizontally offset create acoustical phase distortion. This is due to different arrival times, at the ears, of sounds in the crossover band. Loudspeakers built in mirror image pairs are the first to delete from the list.

Installation

Follow the manufacturer's recommendations for installation. Most systems are intended for 1/2-space mounting against or flush within a wall. Some are meant for 1/4-space locations such as wall-ceiling corners. Placement away from these solid surfaces results in reflections that damage low frequency performance.

Human hearing readily conditions to the nature of sound in a room. A friend's voice is as easily recognized in the kitchen as in the living room. Equalizers for voicing a monitor system may add more phase distortion than the response errors they correct. Confidence in the monitor's accuracy usually is sufficient.

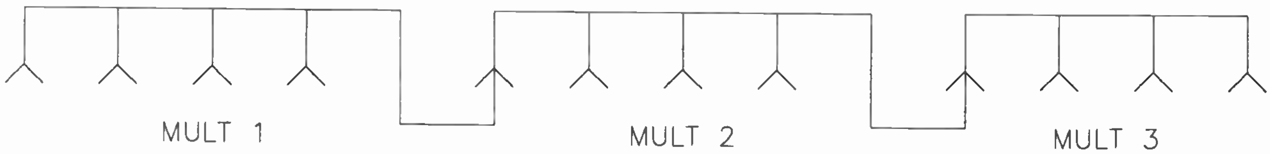

Figure 3.1-4. Half-normaled mult groups.

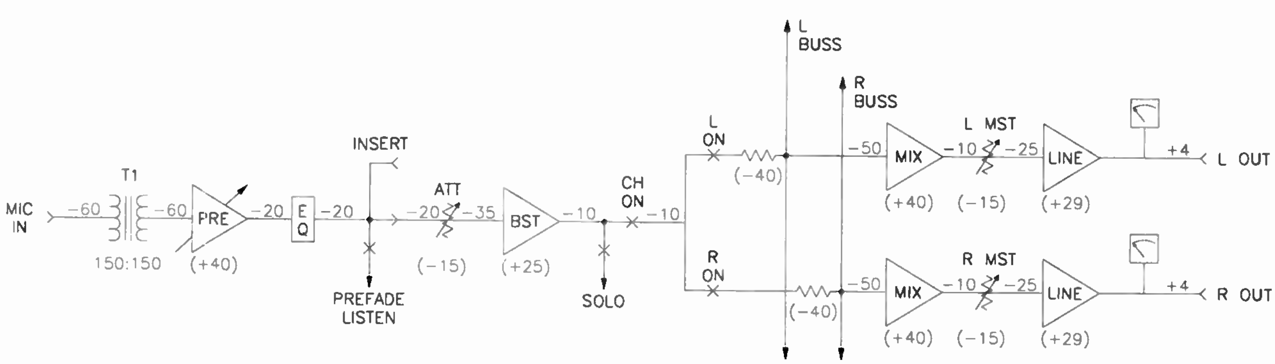

Figure 3.1-6. Single-line of typical channel path.

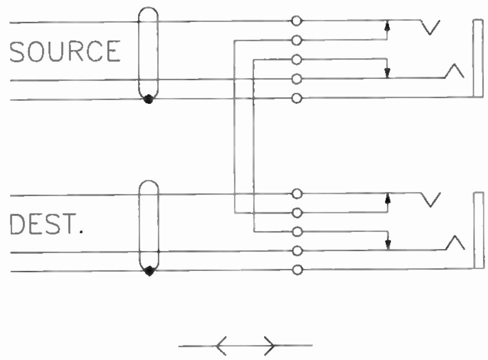

Figure 3.1-1. Schematic and symbol for full-normaled jacks.

plug in the destination jack breaks the path and injects a new source. The break jack may be identified by a dot in the lower left corner of its label. Of course, operators must be told of the dot's meaning.

A third configuration is called *blind normals*. Here the source is not available but a different source may be sent to the destination if necessary. This is useful when sufficient DA outputs are available and patchbay space is becoming limited. Figure 3.1-3 shows the scheme for using a blind normal for transmission. This method is preferred over half-normals because it avoids introducing a possible short circuit across a critical signal path.

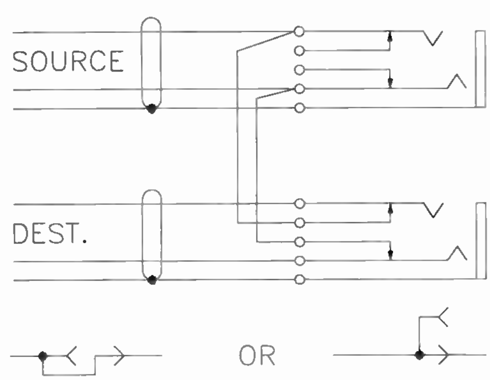

Figure 3.1-2. Schematic and symbols for half-normaled jacks.

Patchbay Utilities

Patchbay layout takes a special knack. Things that are alike should be kept together and multiple sources to a single destination should be grouped by destination not source. Some color-coding is helpful but not at the expense of legibility. White printing on bold colors is best because the eye irises to the white information rather than the darker background.

There are some less used utility devices and circuits that bring cheer to operators when they are needed:

- External device circuits connect to panels of XLR connectors near where a piece of equipment is likely to rest for temporary use. Six males and six females on each side of the room are a good minimum.
- Three-position stereo utility keys (4)
- Utility 600:600 transformers (4)
- Utility variable attenuators (4)
- Utility fixed attenuators (4 full-normaled sets—10 dB + 15 dB + 20 dB)

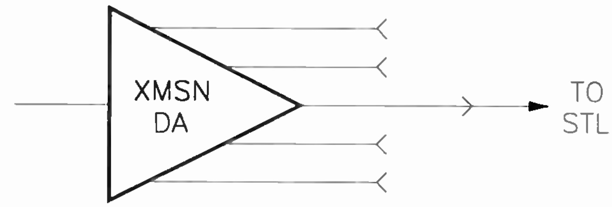

Figure 3.1-3. Symbol for using blind normals for transmission.

When all of the regular circuits are accounted for there will be gaps where some jacks have no assignments. The scattered sets of three or more jacks are suitable for creating *mult* (for multiple) *groups*. These are jacks wired in parallel and are useful for splitting a source to more than one destination. Although DAs are now more common for this purpose, some mult groups will always come in handy. An added convenience is obtained when the groups are consecutively numbered and half-normaled together as shown in Figure 3.1-4. This increases the available outputs without using cords to tie the groups together. Do not wire the last group back to the first one.

The Single-Line Diagram

When the facility is completed there will be many pages of detailed installation drawings. These will reside in the files of the technical maintenance shop. Each production room should have a simplified road map to help the operators find their way through the system. The audio single-line diagram minimizes the details in favor of clarity. Rather than every wire and connection, one line is used to represent a path.

A typical input channel will be shown along with master channel routing through the transmission DAs. Ancillary production equipment in the system should also be shown. The utility circuits and devices, along with their patch bay locations are also included. Figure 3.1-5 contains the symbols commonly used to abbreviate the components. Figure 3.1-6 is a very simple path from an input to the mixer's output. It shows how the gains, losses and nominal levels are indicated.

For a larger system it may take several hours to grasp the many paths and capabilities. For this reason it is helpful to find some convenient wall space to hang a copy of the single-line diagram. Remember it will become part of the room's acoustics. Sometimes there is a wall behind the equipment racks where such a reflector will do little harm.

PRODUCTION EQUIPMENT

Through the life of a production center there will always be a wide age range of equipment. It is common level. A pullout shelf at script apron height provides a place to put materials before and after use. The lower part of the rack may contain patch bays and distribution amplifiers (DAs). Computer or video monitors should be centered at or just below eye level. Continuous viewing of an object more than 15° above eye level can lead to nerve and muscle damage in the neck and shoulders.

Systems formed of conventional metal racks and cabinets are highly functional but somewhat sterile and mechanical in their appearance. Custom cabinetry using wood accents and plastic laminates is attractive but can be inflexible. Seek to use a modular approach with separate cabinets that fit together to form an integrated appearance. This will simplify changes of major elements as the installation evolves with production requirements and technology.

Communications

Good visual and verbal communications may be taken for granted but are not automatically inherent in a production facility. Some care should be taken to ensure open sight lines between the participants. A nod, wink or gesture might be critical to a project's success. The window between adjoining rooms must be wider and taller than normal. This is because the parties might be seated or standing and groups may spread out for comfort and ease of interaction. The basic assumption is that almost every place in each room should be visible to the other.

Voice communications range from the simple talkback built into most mixers to sophisticated multistation intercoms tailored to larger facilities. Almost every production center benefits from some form of modern matrix intercom with built-in *interrupted feed back* (IFB) and telephone interface. The advantage of a central matrix is that all users can be interconnected as production activities require. An important feature is separate volume controls on the master stations for each incoming channel.

AUDIO INFRASTRUCTURE

When the number of rooms in an audio production center exceeds two, a *master control* area is recommended. This creates a central place for access to the circuits that tie the rooms together. It offers a location for the intercom matrix and central digital storage systems. Sometimes called *central switching*, master control manages the incoming and outgoing broadcast feeds.

Cable Ways

Several miles of cable may be hidden away out of sight. Installations built with *computer floors* benefit from easy access to sub-floor cable raceways. However, a computer floor in an audio control room can be a disadvantage. The floor is resonant and sound isolation from adjacent rooms is more difficult. Building corridors on computer floors is one solution but few facilities have the luxury of combining solid floors with computer floors.

Suspended ceilings are a good alternative. A network of overhead raceways can follow the corridors, dropping down in closet spaces for passage into the rooms. Multiple 4 in. diameter thin wall conduits should be provided, not only for isolation of the various audio levels, but to ensure ample room for expansion. The traditional way to maintain acoustic integrity is to stuff the ends of the conduit with cloth. Remember to leave a nylon pull-rope in each conduit.

The following types of circuit should be kept separate:

- Microphone level audio
- Line level audio
- Digital audio and timecode
- ac power
- Loudspeaker level audio

Inside the control rooms a raised floor at the sides and behind the equipment provides a tidy way to route the cabling. Carpeted sections of 3/4 in. plywood resting on 4 in. × 4 in. boards make it easy to access the wiring when changes are needed. Whenever any set of circuits is permanently abandoned, remove the old cables to keep the area as open and clean as possible.

Patchbays

Practice has shown that eventually some operation will arise that exceeds the number of tie lines available. Amortized over the life of the system the cost of 24 rather than 12 trunks from every control room to master control is minimal. Add to these 12 AES/EBU digital trunks. (As digital audio settles into the broadcast world, they will become useful.) These are just the spares, not used for the normal operation. In addition, there will be the regular studio outputs, incoming sources from a central routing switcher and possibly a central digital storage vault.

Within the control room there should be patch bay access to every possible circuit:

- Incoming microphone circuits
- Line level sources
- Mixer inputs, inserts and outputs
- Machine inputs and outputs
- DA inputs and multiple outputs
- In-room trunks to a panel on the rear wall
- IFB program inputs
- IFB outputs
- Power amplifier inputs and outputs
- Loudspeaker inputs

Normaling Practices

Source and destination pairs of jacks that are wired together are called *normaled* because no patch cord is needed for their normal signal flow. Figure 3.1-1 shows the wiring for *full-normals* and indicates how a plug in either jack interrupts the circuit.

The impedance characteristics of contemporary audio devices have brought a newer practice called *half-normals* or *monitor* and *break* jacks. Figure 3.1-2 shows that a plug in the source jack does not break the circuit, but instead monitors the signal. A the control room. Here, extra care must be taken for acoustic isolation.

A good approach to layout places the sonically sensitive rooms in a central core surrounded by offices and other support areas. These serve as acoustic buffers against noise from outside the building. Production rooms may be thought of as islands in the core separated by corridors, equipment rooms and storage areas. It is helpful to provide access to control rooms from both sides of the core but not to the exclusion of a corridor across the core.

Traffic Patterns

Give careful attention to traffic patterns when determining where surrounding offices are located—the most used paths should be the shortest. Back-to-back control rooms may have doors to the perimeter corridors but this can lead to staff taking shortcuts instead of using the crossover corridor between them. If the control room doors are off of the crossover, they should not be opposite each other. Instead they should be offset by at least the width of one doorway.

A curious aspect of human nature is to congregate in the middle of high traffic areas. Two people will stand just outside a control room door and talk, with apparent disregard for those who would enter or leave the room until someone tries to get by. The intersection of two corridors is the same. Small groups will congregate in the middle of the crossroads, perhaps because the space seems large enough. Attempts to provide convenient alcoves for this purpose usually fail. The best solution is to make the corridors wider. Two or three people occupy a 4 ft diameter circle suggesting 6 ft 6 in. as a minimum corridor width.

HUMAN FACTORS

Ergonomics is the science of designing and arranging things people use for safe and efficient interaction. Each device in an audio system has been given some ergonomic consideration. When these elements are brought together to form a production facility it is easy to lose the efficiency each one may have on its own.

The Mixer

The mixer is the system of knobs, switches and sliders that is the heart of the facility. Products from various manufacturers may look alike at first glance. However, they can be quite different in detail. Look for good layout of most-used controls. On a larger mixer the operator may have to stand and lean to reach some of them. The switches and knobs that are used to configure the system for a project should be *presets*.

It is possible to have too many input channels. A simple rule suggests: *If you can't reach it, don't buy it.* Most mixer channels are on 1.5 in. centers. Thirty-six inputs are a reasonable limit to the average person's reach. Many input modules provide a selector to choose between two sources. A new generation of mini-mixers is on the market. These bring the controls closer together by using a monolithic rather than modular design. The hazard of this is that a single failure cannot be serviced without taking the whole package apart. However, these small mixers are a convenient and economical means of adding inputs when temporary expansion is required.

Another rule states: *If you can't see it, it isn't there.* Too many video production mixers become partially covered with scripts, schedules and other papers. The controls that are covered might just as well be gone. The provision of a sliding script holder is not a good choice. In a busy production room if the holder must be moved to change a setting, the operator may be half a page behind when the script is back in place. The best solution is a 12 in. apron between the operator and the mixer. It should be 1/2 in. below the lip of the mixer so that long pages will not easily slide up and push open some faders.

Height is important. If the equipment is too high, the operator is likely to raise the chair height. Unless a footrest is provided the user's upper legs will not be horizontal, leading to circulatory problems in the lower legs. The average desk or table is 30 in. high. A typewriter table is 27 in. high because the machine elevates the controls. The script apron is similar and provides full support for the operator's arms. Users not accustomed to this convenience soon learn its benefits over mixers with only a wrist rest.

Some mixers are built with a *scribble strip* between the faders and the input modules. Most faders have 1 in. of space at the top where labels can be placed. This makes the scribble strip area available for installation of controls that otherwise might be on the sides. If no scribble strip is provided, one or more input modules might be eliminated in favor of more convenient utility controls. Following is a list of functions that have been placed on these panels.

- Intercom
- Talkback
- Microphone on/off (privacy)
- Machine starts
- Announcer on/off
- On-air lights on/off
- Monitor stereo/mono
- Monitor dim and mute
- Phone coupler answer and release
- Silent signal lights
- Video monitor switching

Ancillary Equipment

In addition to the mixer there will be other equipment. Various players and recorders, processors and effects devices fill out the system for flexibility among projects. Some installations place these devices below and to the side of the mixer where the drawers of an office desk would be. This causes continual leaning and bending during normal operation, which is ergonomically unacceptable.

Ancillary equipment is better placed in a rack to the side of the operator from elbow height to just above eye

3.1 PLANNING AN AUDIO PRODUCTION CENTER

ROY W. RISING
ABC-TV, HOLLYWOOD, CA
ADDITIONAL MATERIAL PROVIDED BY MALCOLM M. BURLESON AND DAVID CARR
KHOU-TV, HOUSTON, TX

INTRODUCTION

Planning this chapter parallels planning an audio production center. One thing is likely—something will be overlooked. This chapter is a result of more than three decades of the author's involvement, both as a designer and an end-user of broadcast audio facilities. The subjects presented are those that should not be overlooked. Most of these will be covered in greater detail in following sections of this *Handbook.*

The objective of planning is to consider every possible detail and develop an integrated scheme that leads to the best final result. There will be tradeoffs; no single element is so important that it cannot yield to another's requirements. It helps to begin by giving equal weight to every aspect. In the end the larger and smaller issues will find their own places.

For example, every control room needs a pencil sharpener. Electric sharpeners are convenient but noisy and usually require a tabletop. Graphite dust is an enemy of electronic equipment because it conducts electricity. When the room is shut down, chances are the electric sharpener will not work until the correct circuit breaker is turned back on.

It may be better to choose a manual sharpener. It is quieter and can be wall-mounted away from the electronics. Experience has shown that installation near the entry of a room serves a third consideration. Personnel from adjacent areas can slip in and sharpen a few pencils without disturbing the operation. Those within the room should routinely sharpen two or more pencils each time. If the lead of a newly sharpened pencil breaks, find another brand.

Attention to this seemingly minor item reveals its larger importance. It is a good model for contemplation of the other details in systems design. An extension of the thinking mandates keeping a wastebasket below the sharpener.

Some things will be assumed. There should be an architect with a good understanding of acoustical considerations. A HVAC engineer will be needed to look after silent but effective ventilation systems. Keep in mind that although a solid-state device runs cooler than its vacuum tube ancestor, the equipment density is much higher and heat loads may be larger than expected. Electrical services are easily underestimated. The added cost of a larger entry capacity is small and will be welcome when future expansion presents new demands.

When initial sketches are completed and bids begin to arrive, establish a budget with about 20% slack for overruns. Watch expenditures for warning signs of underestimation. Setup a timetable based on realistic expectations. Track the progress and be alert for scheduling conflicts that might slow things down. Finally, if time permits and the budget is not depleted, have a party to toast your colleagues and yourself for a job well done.

USER INPUT

A very important part of the planning process is continuing dialog with the actual end-users. As plans for various elements of the facility begin to take shape, circulate sketches and descriptions among the users. Establish an open return channel for constructive criticism and follow-up for comments even when none are volunteered. Maintain a log of memos and conversations. This is helpful in resolving later disputes.

The end-users are justifiably nearsighted. Their focus is on those things that matter the most personally. Part of the planner's task is to moderate the areas where different user's needs overlap. First develop a consensus among users who share the same areas. Next design a proposed zone of transition between adjacent areas. Then circulate the proposal and make adjustments based on the responses.

LAYOUT

Very few production facilities have the good fortune to be built new from the ground up. More often an existing structure is used. By using an existing production center, broadcasters can benefit from the good aspects of the center and avoid its previous problems.

There are three types of audio production facilities: radio, TV and video postproduction. The audio control rooms and ancillary areas are similar and follow some common patterns. The first consideration for layout is sound isolation. Rooms with high level loudspeaker monitoring should not be adjacent to each other or to rooms with live microphones. The obvious exception is where a performance studio must be connected to

Section 3: Audio Production Facilities

Introduction by Randy Hoffner, ABC, New York, NY

Audio communication is the foundation of broadcasting. From early radio transmissions to 5.1-channel AC3 digital audio, sound has played a pivotal role in the growth of radio and, later, television. It was stereo that lifted FM from the "forgotten medium" of the 1960s to the prominent role that it enjoys today. Likewise, the DTV sound system—AC3—holds great promise for significantly enhancing the viewing experience of high-definition television. To enjoy the benefits of such advanced technologies, however, careful attention must be paid to the details of audio capture, storage, processing and transmission. The qualities and characteristics of aural signals have been hard to quantify, and even harder to preserve. Unlike video, where absolute references readily exist in the picture, audio is a tapestry of elements and nuances that will be irrevocably lost unless properly handled.

Roy W. Rising directs you through the planning of an audio production center from start to finish in his chapter, *Planning an Audio Production Center.*

Written by NAB Science & Technology Senior Vice President Lynn D. Claudy, the *Principles of Acoustics for Broadcast Applications* chapter offers a broad overview of acoustics, with a blend of theory and practice to provide readers with a balanced foundation on the subject.

Ty Ford's *Microphones* chapter is intended to provide engineers with information that will help them make the right choices. The chapter reviews the basic types of microphones, their construction and how their different characteristics can be used in various applications for best results.

As digital broadcast equipment is poised to eclipse analog studio systems, will your broadcast studio be ready for the change? Walt Lowery's *Studio Audio Equipment* chapter prepares broadcasters to take the leap into the digital future.

Michael Starling's *Audio Recording Systems* chapter illuminates the significant advances in audio compression techniques and the tremendous effects that such developments have had on the storage of digital audio.

David T. Turner examines the broad concept of station automation in his *Station Automation and Networking* chapter by providing a thorough overview of each component; thereby guiding the broadcast engineer through this seemingly daunting task.

The digital audio facility of the future will revolve around compressed signals. Therefore understanding the processing techniques is of great importance to broadcast engineers. Fred Wylie provides an overview of these technologies in his *Digital Audio Compression Technologies* chapter.

"One mark of the professionalism of a broadcast engineer is their mastery of the techniques of audio processing." Find out if you have what it takes in Robert Orban's *Transmission and Audio Processing* chapter.

Skip Pizzi and Jerry Whitaker's *Remote News and Production* chapter addresses the two most critical areas in remote broadcasting: portable production systems and backhaul.

Steve Church's *Telephone Network Interfacing* chapter explores the myriad of methods to integrate the telephone network into broadcast operations. Church covers the various services available from telephone companies and ways to interface them with station facilities.

Skip Pizzi contributes his expertise again in this section with his *Common Carrier Audio Program Services* chapter, which considers the opportunities for audio signal interconnections afforded to broadcasters by telephone companies and examines how broadcasters can implement these hookups.

Insulation Resistance Test

An insulation resistance test can be performed on a transmission line system after purging with dry gas to determine if it is sufficiently dry before applying power. The insulation resistance between the inner and outer conductors should be greater than 100,000 megohms. There are many inexpensive test units available to perform this test. This is especially critical when installing semi-flexible cable that has been stored outdoors for an extended length of time and it is unknown whether positive pressure has been maintained.

Operation and Maintenance

The following guidelines should be followed to ensure a long term and reliable operation of a coaxial transmission line system:

- Establish a baseline VSWR and time domain response of the system during installation
- Set and maintain all VSWR or reflected power protection devices at nominal levels. If a fault occurs, do not override these devices in order to continue transmitting at high power
- Always maintain positive pressure on the line system
- Do not exceed the pressure rating of the line or antenna. Damage to components and personnel may result
- Perform periodic maintenance checks on the pressurization system. Deviations from base line levels are a first indication of potential problems with the line
- Check for hot spots along the line during routine inspections. The outer conductor temperature is proportional to the inner temperature and excessive heating may indicate the beginning of a failure of the inner conductor connections
- Check the horizontal and vertical line sections for wear caused by thermal expansion
- Remeasure the system VSWR and time domain response on a regular basis and compare to previous results for changes.

Table 2.4-8
Recommended length of horizontal run.

Vertical Run (feet)	Recommended Length of Horizontal Run (feet) 3-1/8"	4-1/16"	6-1/8"	8-3/16"	9-3/16"
100	15	15	15	20	20
500	25	30	35	40	40
1000	35	40	50	60	60
1500	40	50	60	70	70
2000	45	60	70	80	80

all possible suppliers are aware of your system needs and individual component types so that the appropriate adapters can be supplied if needed.

MAINTENANCE AND TESTING

External air dielectric transmission lines must be kept under positive pressure using a dry gas to prevent moisture or other contaminants from entering the system. The moisture and contaminants can accumulate on the internal surfaces and connection joints of the transmission line causing oxidation and corrosion resulting in:

- increase in line attenuation
- increase in VSWR
- localized heating due to resistive losses
- voltage flashover at dielectric surfaces.

Transmission lines pressurized with dry gas maintain the initial performance of the system and reduce the risk of damage to the line and subsequent off-air situations. Dry gas is typically obtained from nitrogen bottles or a dehydrator system. Care must be taken not to exceed the lowest pressure rating of any of the system components.

Prior to applying power to the transmission line system, it should be sufficiently purged of environmental air acquired during installation. This normally can be accomplished by exchanging at least 3 volumes of dry gas through the system by opening a purge valve or joint at the far end of the system, and allowing the dry gas to pass through the system for a predetermined length of time based on the size of the system. Purging should also be performed anytime the system is opened to outside air or a positive pressure condition has not been maintained.

Electrical Testing

Electrical testing of the transmission line system should be performed for any of the following conditions:

- During initial installation
- After VSWR trips to determine the cause and location
- Periodically, to document performance
- At any time the performance of the system is in doubt.

Most conditions that result in less than optimal performance of the transmission line system can be detected immediately after installation. The most useful tests to determine performance are the VSWR/return loss sweep test and RF pulse testing. There are many types of equipment that can perform these tests. Over the past few years, the network analyzer with time domain transform capabilities has become the standard type of equipment.

The VSWR/return loss test is used to determine the composite input VSWR of the transmission line system terminated by a load or antenna as seen by the output of the transmitter. Normally, measurement is performed of the VSWR as a function of the frequency within the broadcast channel of interest; however, wider frequency sweeps are recommended to determine possible performance over wide temperature variations due to line length changes from thermal expansion/contraction or antenna VSWR changes due to environmental conditions such as icing.

Since the VSWR test is a composite, it presents an overall view of the system performance. System specifications for VSWR must take into account all the individual components, therefore, long complicated systems will typically have higher VSWR responses than short simple systems. Improvements can be made through the use of fine tuners installed near known contributors of VSWR, such as elbow complexes. Exceptional care must be taken during installation and tuning at the factory of elbows, adapters and transformers that will be used.

The RF pulse test displays reflections in the channel response as a function of time rather than frequency. This can be of great help in locating the cause of excessive VSWR or faults within the system. It is also used to identify the reflections from the antenna and other far end components to determine if ghosting conditions may be present. A typical far end reflection criteria to prevent most problems with the transmitted signal is −33 db return loss within the broadcast channel of interest.

Where the cause of high VSWR may be an improperly assembled flange or damaged conductor, the in channel RF pulse does not have the resolution to accurately locate the fault. Since the width of the pulse is inversely proportional to the frequency bandwidth, a narrower pulse for resolution requires wider bandwidth. With network analyzers presently on the market, the feature to change the bandwidth is readily available. These can be used in similar fashion to the time domain reflectometry (TDR) test. Bandwidths of 50–150 MHz centered on the channel will usually provide sufficient resolution to identify the above types of faults. It should be remembered that this test is not to determine the in channel characteristics of the system but rather to provide a more detailed look at the transmission line. In particular, components that are frequency sensitive, such as an antenna, may present a significant reflection when using wider bandwidths. These types of components should be identified ahead of time to prevent incorrect analysis of the data.

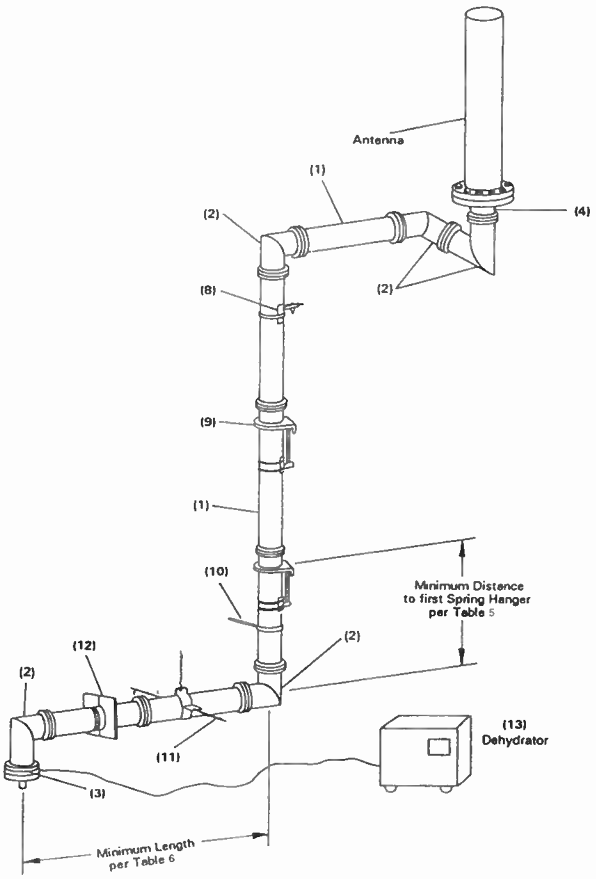

Figure 2.4-12. Typical broadcast rigid line system.

point of entry to the building, horizontal movement in and out of the tower must also be accounted for during installation (see Table 2.4-7 and 2.4-8).

Line Interfaces

Interface standards have been established by the Electronics Industries Association (EIA) for 50 Ω lines (RS-225) and 75 Ω lines (RS-259). The user should be aware, however, that many proprietary designs are used by suppliers that are not completely compatible with the EIA standards or other manufacturer's components. When purchasing components from different suppliers or making repairs to a system, be sure that

Table 2.4-7
Minimum distance to first vertical spring hanger versus length of horizontal run (refer to Fig. 2.4-12).

Horizontal Run (feet)	Minimum Distance to Lowest Hanger (feet) 3-1/8"	4-1/16"	6-1/8"	8-3/16"	9-3/16"
20	5	6	9	12	13
40	6	7	11	15	17
60	7	8	13	17	20
80	8	9	14	19	22
100	9	10	16	21	23

the movement to fall inside the inner conductor and not out into the main portion of the line. The spring is designed to be self-compensating in this process providing a constant contact pressure on the inner conductor. However, the mechanical wear does limit the reliable life of the spring, based on the conditions of operation for that particular line system.

The bellows device is built directly into the inner conductor (see Figure 2.4-10). Thermal compensation is achieved by the expansion and contraction of the corrugated section similar to the principal used in the construction of semi-flexible lines. The benefit of this design is that the bellows absorb all of the inner conductor movement and eliminate any wear at the bullet/inner conductor interface. The reliable life of the line is determined by the number of expansion/contraction cycles the bellows is designed to withstand.

The continuously corrugated inner conductor concept works on exactly the same principal as semi-flexible line. The entire inner conductor is corrugated allowing significant expansion and contraction capabilities (as shown in Figure 2.4-11). The inner conductors can now be bolted together with no possibility of a sliding contact point. Because the bolting process produces higher contact pressures, a significant reduction in resistance can be obtained resulting in a better electrical connection. In effect, after assembly of this type of system, there is one continuous inner conductor rather than multiple inners that have been spliced together.

The different compensation methods must be evaluated by the user relative to the specific environmental and operating conditions present at the broadcast site. Factors such as installation, maintenance requirements, extreme ambient temperatures, and high operating power levels can be significant in the determination of the proper concept needed for long term reliability at minimum costs.

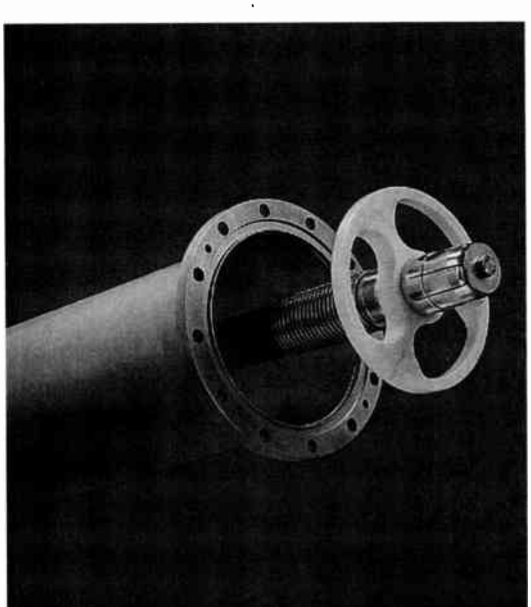

Figure 2.4-10. Bellows compensation approach to line length changes.

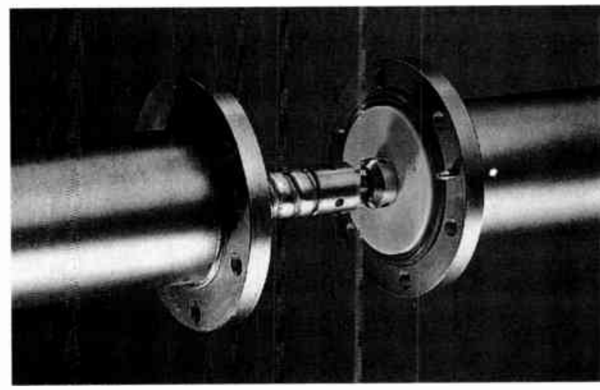

Figure 2.4-11. The use of a corrugated inner conductor for rigid line.

Rigid Line Systems

A rigid coaxial transmission line system is composed of a vertical exterior run and a horizontal run that will have some components inside the transmitter building and some attached to an exterior horizontal support bridge between the building and the tower. Because rigid lines are air-dielectric types, all components subject to contamination by outside air must be under constant pressurization.

Differential Thermal Expansion

The most important factor to consider in a rigid line installation is the difference in thermal expansion coefficients between the copper line and the steel support tower. For a 100°F change in ambient temperature, the differential expansion between the line and tower will be about 0.4 in. per 100 ft of length. For a 1000 ft. tower and a temperature change from 0°F to 100°F, this will result in the rigid line growing 4 in. relative to the tower. Provisions must be made to support the line within the tower and at the same time allow it to float to prevent severe buckling strains on the tower and line. This is accomplished through the use of vertical spring hangers which attach rigidly to the tower but support the weight of the line by springs and clamps (as illustrated in Figures 2.4-12 and 2.4-13).

To account for ice loads and possible failures of the spring hangers, a rigid hanger is attached near the top of the vertical run. It is important that it be placed as close to the antenna input as possible to prevent any thermal expansion conditions causing excessive force on the antenna input. Since the rigid connection is at the top of the run, the cumulative effects of the thermal expansion or contraction occur at the bottom of the vertical run. This is where care must be taken to allow sufficient clearance for the line to enter the tower from the horizontal run and not be damaged by tower members as the line moves up and down relative to the tower. And since the horizontal run is anchored at the

Table 2.4-5
EIA flange hardware requirements and recommended torque values

EIA Flange Size	Bolt Size	No. of Bolts	Recommended Torque Value
7/8"	1/4"	3	80 lb-in (9.0 N-m)
1-5/8"	5/16"	4	140 lb-in (15.8 N-m)
3-1/8"	3/8"	6	20 lb-ft (27.1 N-m)
6-1/8"	3/8"	12	20 lb-ft (27.1 N-m)
8-3/16"	3/8"	18	20 lb-ft (27.1 N-m)
9"	3/8"	20	25 lb-ft (34.0 N-m)
9-3/16"	3/8"	20	20 lb-ft (27.1 N-m)

produces a small reflection. At some frequency, the distance between flanges will become periodic and a VSWR spike will be generated. This spike will typically have a narrow frequency response but can be significant based on the number of discontinuities and the magnitude of the reflections. The frequency of the VSWR spike is determined by the following equation:

$$F_{\text{spike}}\,(\text{MHz}) = \frac{492.15 * V_p * N}{L}$$

where:

F_{spike} = Frequency of spikes (MHz)
N = Any integer
V_p = relative velocity of propagation
L = equal distance between discontinuities (ft.)

The response curve for this equation has a bandwidth of approximately ±2 MHz. Therefore, the line type must be chosen so that a critical frequency of operation is a minimum of 2 MHz from the spike frequency. Since many rigid line systems are several hundred feet in length, the amplitude of the VSWR spike can be quite large. Due to this, some manufacturers allow greater safety margins from the critical frequency when determining rigid line section lengths.

This equation is used to determine standard line lengths for rigid lines as shown in Table 2.4-6.

Internal Thermal Expansion

In a high power broadcast application, the inner conductor will run substantially hotter than the outer conductor. A typical difference in operating temperatures between the inner and outer is 70°F.

Because of this temperature difference, the inner conductor will expand to a longer length relative to the outer conductor. This difference can be calculated based on the thermal expansion of copper being 9.8×10^{-6} in/in/°F. With an overall length of 20 ft, the difference in lengths will be 0.174 in. In semi-flexible line, this difference would be absorbed by the corrugations in the conductors. For rigid lines, however, it must be compensated for at the inner conductor and inner connector (bullet) interface.

Without the thermal expansion, the inner conductor would be cut to exactly mate up to a shoulder on the bullet. This provides the optimum electrical contact and impedance match. To account for thermal expansion, the inner is cut back the distance needed to allow for the expansion under the maximum allowable operating temperature differential between the outer and inner. So, as the temperature varies between input power levels and ambient temperatures, the inner will move back and forth on the bullet. This will cause material deterioration from friction and ultimately will result in either mechanical or electrical failure at the contact points.

To accommodate this movement but minimize the degradation of the contact surface, compensation devices have been developed for rigid lines. They come in three concepts:

- Watchband spring attachment to the bullet
- A bellows attachment to the inner conductor
- A completely corrugated inner conductor using bolted joints between each section.

The watchband spring concept provides for a spring-like contact device that is attached circumferentially around one side of the bullet (as shown in Figure 2.4-9). The spring side is then inserted at the top of the lower inner conductor (the line section closer to the transmitter) such that the spring is below the insertion point. The insertion force of the upper side of the bullet is such that during thermal changes, the inner conductor movement is primarily on the lower spring section. This allows any shavings that are caused by

stranded wire is not recommended as they tend to deteriorate with time, reducing the effectiveness of the grounding connection. After installation, all ground connections should be weatherproofed to prevent degradation.

Phase Stabilized Lines

In some cases, such as AM directional antennas, it is necessary to use coaxial cables to sample current levels over time to confirm compliance with a broadcasting license. In this case, the phase stability of the cable over time is extremely important. Ordinary coaxial cable should not be used in these instances since it is subject to significant phase variation with temperature change during its initial usage. Instead, phase stabilized foam polyethylene dielectric or air dielectric cables should be specified. This cable has been subjected to a process that cycles the cable through a wide temperature range to remove the phase instability caused by hysteresis.

Rigid Line

Rigid lines have inherently high power handling and low attenuation and VSWR which make them ideal for high power broadcast applications. The line is typically fabricated from high conductivity oxygen-free hard copper tubing in nominal lengths of up to 20 ft. The inner conductor is supported in the outer conductor by peg or disk insulators. A PTFE compound is normally used for the insulating materials due to its extremely good electrical and mechanical properties.

The inner conductors of adjacent line sections are joined together by inner connector "bullets." These act as splices between the inner conductors and are designed with tension spring fingers to provide high insertion forces that produce low resistance electrical contacts. The high insertion force is also needed for good thermal conductivity. For added conductivity, the bullets are normally silver plated. An insulator is also attached to the middle of the bullet in order to anchor it between the outer conductor flanges. This provides mechanical stability when installing the line in a vertical position.

As mentioned above, the outer conductors are normally attached by bolting flanges together. The RF contact is accomplished through a raised contact surface near the inside diameter of the flange. A pressure seal is obtained through the use of an o-ring between the flanges. Flange types are typically governed by EIA standards RS-225 and RS-259, however, proprietary designs of various suppliers are also available. Important parameters for rigid coax are given in Tables 2.4-4 and 2.4-5.

Rigid Line Section Lengths

Because the connections between rigid line sections present an imperfect impedance transition, each flange

warpage. Application of silicone grease to the o-ring to hold it in place is a common practice. However, it should be remembered that silicone is an insulating material and excessive application of the grease can result in contamination of the contact surfaces. Excessive heating and damage to the o-ring can result.

Installation

A proper installation can be the difference between a smooth running transmitter site and a continuous effort to correct failures in the transmission line and antenna system. It should be remembered that the environmental forces acting on transmission lines installed outdoors and on tall towers are constantly changing. This results in extreme stress on the cable from corrosion, vibration, atmospheric contaminants and thermal changes that are not present with indoor installations. Following the manufacturer's recommended procedures for installation and maintenance can prevent catastrophic failures.

General guidelines for installation of semi-flexible cable systems primarily center around the handling of the cable. Upon delivery, the cable is usually shipped on reels or in cartons which should be inspected for shipping damage. In the case of air-dielectric cables, check to see that the cables are still holding pressure. In storage, allowable pressure drop is typically 1 psig (70 kPa) per 24 hours. If there is excessive leakage, the cause should be determined prior to installation. Reels should always be stored and moved on the flange edges. Storing on a flange side or dropping a reel can cause damage to the inside lengths of cable due to crushing from the outside.

The actual lifting and installation of the cable should only be performed by qualified installation crews. The proper use of lifting devices, such as hoisting grips, winches, load lines, etc. is required for safety (see Figure 2.4-7).

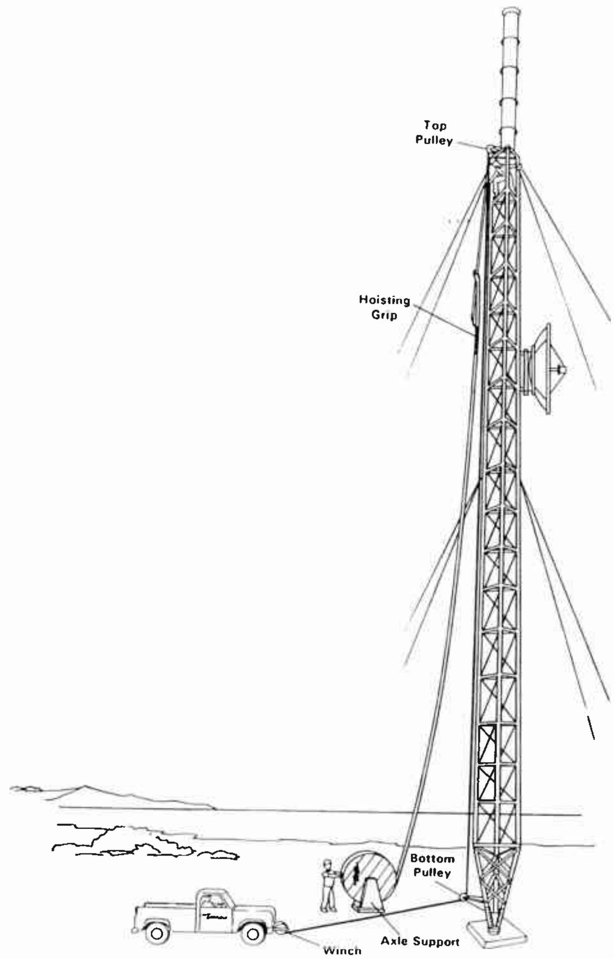

Figure 2.4-7. Installation of coaxial cable.

For long term reliability, proper installation of cable hangers is essential. The purpose of the hangers is to support the cable's weight and to prevent movement from wind, rain, ice and other forces. Excessive movement causes abrasion and damage to the outer conductor. To begin, the manufacturer's recommended hanger spacing should be considered. This spacing should be modified (typically twice as many hangers used) if the wind velocity will be consistently above 40 mph, peak winds exceed 125 mph or heavy ice is expected to form. (A common support system is shown in Figure 2.4-8).

A drip loop is recommended in the horizontal run to prevent moisture from using the line as a path to the building wall. Water can travel down the outside of the jacket and build up at the wall feed-through if a drip loop is not used and the line slopes toward the building. Water may also travel between the jacket and outer conductor if damage to the jacket has occurred. If this occurs, a small notch cut into the jacket at the bottom of the drip loop will allow for drainage.

Because the jacketed copper cables are very corrosion resistant, it is also possible to bury the horizontal run either directly or pulled through a conduit. Sharp objects must not come into contact with the cable or damage to the cable may occur. If installing within a conduit, do not exceed the tensile strength of the cable when pulling it through. Conduit pulling lubricants should be applied generously to the cable. Bends should be avoided if at all possible as the corrugations may cause excessive friction when pulling around a corner. Since a buried cable may occasionally become submerged, any buried connectors or splices should be well protected with a good weatherproofing kit.

Grounding

Since the cable represents a direct connection between the outside and the transmitter equipment, proper grounding is necessary to protect the equipment from the large currents caused by a lightning strike. Minimum grounding conditions are to ground the cable at the top and bottom of the vertical run as well as just before entry to the building. For long runs, additional grounding in 200 ft increments is recommended.

Ground connections must be made with high quality copper wire or straps. Braided copper straps or fine

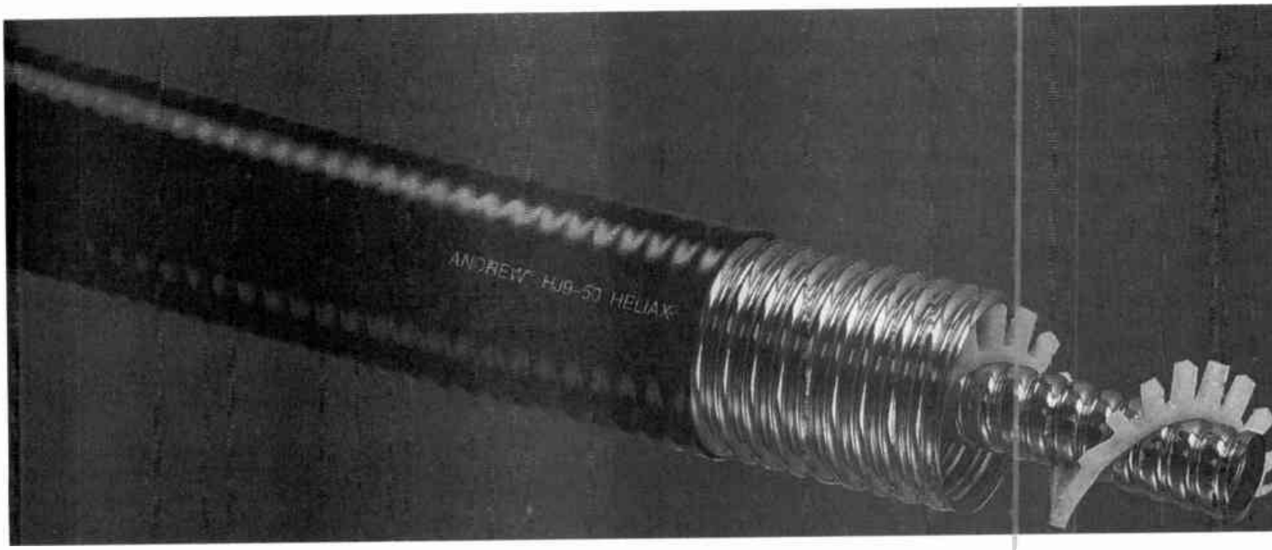

Figure 2.4-6. A section of high-power air dielectric semi-flexible coax. *(Courtesy of Andrew Corporation.)*

Connectors, Splices and Adaptors

Usually, the connector type is determined by the antenna and transmitter connection type and the power handling requirement of the transmission system. Once the decision has been made, then it is important to make the attachment properly. Close attention to the supplied assembly instructions, in particular the cable trimming dimensions, will assure a good connection. Clean mating surfaces and proper tightening is required for good electrical contact along the entire 360° of the cable edge.

It is highly recommended to make all connector and splice attachments with the cable end in a horizontal position. This minimizes the chance of metal chips falling into the cable during the trimming process. This will normally mean making connections on the ground, however, there may be times when there is no choice but to make the attachment on the tower. In that case, it is important to take precautions, such as stuffing cloth into the open cable end to prevent chips from falling into the cable. Care must be taken when removing the cloth so as not to drop any chips into the now open cable end.

Proper attachment of the finished connector to the antenna or transmitter prevents loosening of the connection from vibration or other stresses. It is important to recheck the cable assembly after attachment, specifically for connections using screw together interfaces. Twisting of the cable during attachment may cause the connection to loosen and result in poor performance and environmental damage to the cable. These connections should be securely taped to prevent loosening.

EIA style flange connectors must be carefully tightened to prevent distortion of the flanges. Tighten bolts that are opposite (not adjacent) to the proper torque specification. Overtightening can also result in flange

systems. The line achieves its flexibility through the use of corrugated copper conductors and can be fabricated in extremely long lengths. This eliminates the need for interconnecting joints therefore minimizing possible installation/assembly problems. They are also easier to install because the corrugations eliminate most of the need for hanger designs that permit independent movement of the line from the tower (differential thermal expansion).

Foam-Dielectric Cable

Foam-dielectric cables are designed for systems that do not require a pressure path to the antenna or other connected components. Typical applications include radio and low power television. Sizes range from 1/4" to 2-1/4". These cables are constructed with a closed-cell, low density foam dielectric which prevents water penetration while providing low attenuation and high relative velocity of propagation (see Figure 2.4-5).

The maximum diameter of foam-dielectric cables is limited by the manufacturing process of "coating" the inner conductor with the foam dielectric. The attachment process requires the foam to be applied to the inner in a liquid state and immediately cooling the foam to prevent distortion of the foam shape and movement of the inner conductor within the foam. As the diameter of the foam and inner conductor increases, the outer portion of the foam will harden and act as a thermal insulator for the inner portion of the foam. This action is much like the theory behind styrofoam insulated coolers. Whatever is inside the cooler is insulated from outside forces. Now, because the inner portion of foam is not hardened, the actual weight of the inner conductor can cause the conductor to sag in the liquid foam, resulting in a non-concentric configuration of the conductors. The characteristic impedance has now changed and the electrical performance has been compromised.

To produce larger diameter cables requires the use of spiral sections of dielectric wrapped around the inner conductor. This results in what is called an air dielectric cable.

Air-Dielectric Cable

Air-dielectric cables utilize a spiral dielectric material to separate the conductors. Because the majority of the volume between conductors is now air, these cables have slightly lower attenuation and higher average power handling than foam-dielectric cables. They require pressurization not only to prevent water ingress but also provide pressure to the antenna if needed. A benefit of the pressurization is that significant damage to the cable will usually result in a pressure leak allowing the damage to be detected before a more severe condition occurs as a result of voltage breakdown.

A spiral-wrapped air dielectric cable is shown in Figure 2.4-6. Table 2.4-3 compares common cables used in broadcasting.

Figure 2.4-5. A common type of foam-filled semi-flexible coaxial cable using a hollow center conductor. *(Courtesy of Andrew Corporation.)*

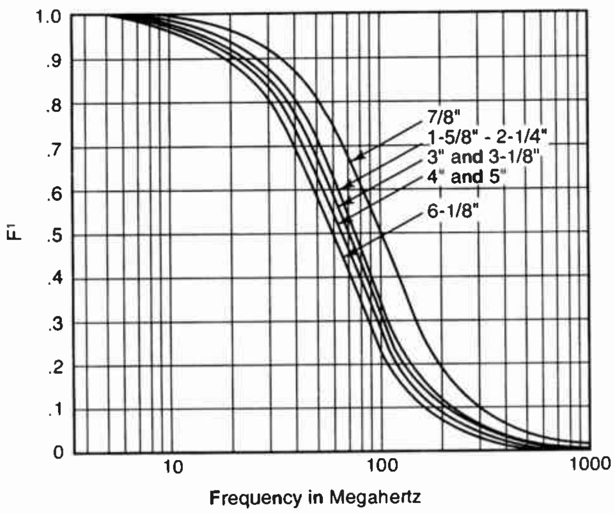

Figure 2.4-3. Derating factor for average power due to VSWR.

tween two or more lines is the velocity of propagation or phase velocity (V_p). It is expressed as a fraction of the speed of light in a vacuum and is determined by the dielectric constant of the insulating material:

$$V_p = \frac{c}{\sqrt{\epsilon'}}$$

$$\frac{1}{\sqrt{\epsilon'}} = \text{relative phase velocity}$$

where c = speed of light

The result of adding a dielectric material other than air is to "slow down" the TEM wave. For two coaxial lines having a different percentage of dielectric material there will be a difference in electrical phase between them even though they are physically the same length. This can be very important when using cables for sampling the relative phases of an antenna array, for example. Most manufacturers supply this factor with the other specifications for a transmission line.

Figure 2.4-4. A common type of semi-flexible foam-filled coaxial cable. *(Courtesy of Andrew Corporation.)*

Flexible RF Cables

Coaxial transmission lines used for short interconnections between equipment, typically inside buildings, have traditionally been called RF cables. They are small in diameter making them very flexible and very useful in areas with minimum space. The inner conductor is usually solid copper or a copper clad metal and the outer conductor a copper or aluminum braid. In order to maintain concentricity of the inner and outer conductors, the dielectric is a solid insulating material. The more commonly used cables are shown in Table 2.4-1.

With the introduction of more digital signals and multiple frequency grouping, the shielding performance of braided outer conductors may not be sufficient to prevent signal leakage. Interference between cables within an installation can be detrimental to signal quality and a frustrating condition to track down the cause. In these critical installations, cables that utilize a solid outer conductor will improve the system performance. Typical cables are listed in Table 2.4-2 and shown in Figure 2.4-4.

Semi-Flexible Cable

Globally, semi-flexible cables are the most popular choice for broadcasting applications. It is ideal for a wide variety of low and medium power transmission

Table 2.4-1

Average Power

The average power rating is limited by the amount of heat created due to line losses. The amount of heat allowable is primarily determined by the safe, long term performance of the dielectric material used. Since the loss and temperature rise of the inner conductor are greater than the outer conductor, the maximum allowable temperature of the inner conductor is normally used to determine the average power rating.

For typical conditions, the inner conductor is allowed to reach a temperature of 100°C with an ambient temperature of 40°C. This means the inner conductor temperature is allowed to rise 60°C above the ambient. Based on this standard condition, the average power can be calculated from the following:

$$P_{avg} = \frac{16{,}380 * \sigma * D}{M_{\alpha} * \alpha} \text{ watts}$$

where

P_{avg} = average power rating for 60°C rise of inner conductor temperature
D = outer conductor OD, in.
σ = heat emissivity coefficient of outer conductor, watts/in^2
M = correction factor for attenuation (relative to 20°C)
α = attenuation constant, db/100 ft at 20°C

It should be noted that the heat emissivity coefficient is derived from experimental data and there are no industry standards as to its value for various line sizes. Therefore, it is possible to have noticeable differences between published ratings due to slight differences in this factor. For example, a difference of only one hundredth of a watt/in^2 can result in a 10% difference in the average power rating.

Typical heat emissivity values for 50 ohm rigid transmission lines:

7/8"	0.120 watts/in^2
3-1/8"	0.107 watts/in^2
4-1/16"	0.104 watts/in^2
6-1/8"	0.097 watts/in^2

The average power is also frequency sensitive since the attenuation constant (α) is frequency dependent. At higher frequencies, the attenuation is greater, therefore the average power rating will be reduced.

If average power is the most significant factor in choosing a transmission line, it is suggested to review data sheets from several manufacturers and discuss any differences in average power ratings. Other factors that should be reviewed are flange connection types, inner connector design and method of thermal compensation for the inner conductor. In this way, all factors that may affect the long term performance of the transmission line are addressed and a sound engineering decision can be made.

For broadcasting, the average power is dependent on the nominal CW power of the transmitter and the type of modulation. For the primary broadcast modulation schemes, the average power can be calculated from:

$$\text{AM} \quad P_{avg} = P_c\left(1 + \frac{M^2}{2}\right)$$

$$\text{FM} \quad P_{avg} = P_T$$

$$\text{TV} \quad P_{avg} = (0.6 + AU)\,P_{TV}$$

P_{avg} = average transmitter power
P_c = carrier power
M = amplitude modulation index
P_T = FM transmitter power
P_{TV} = TV peak sync power
AU = Aural to visual ratio

As with peak power, the average power rating must also be adjusted for actual operating conditions. Since average power is based on ambient temperature, it must be adjusted for the actual operating ambient temperature. (Use Figure 2.4-2 to find the appropriate adjustment factor.)

Average power should also be derated for VSWR. The derating factor (*DF*) is calculated from the formula below where F^1 is a factor that varies with frequency and line size. Select the F^1 factor from Figure 2.4-3, calculate the *DF* and then divide the average power rating by the *DF*.

$$DF = \frac{\text{VSWR}^2 + 1}{2 * \text{VSWR}} + \frac{F^1 * (\text{VSWR}^2 - 1)}{2 * \text{VSWR}}$$

Increases in average power ratings can also be theoretically accomplished in a similar fashion as peak powers. The same cautions apply for average power as did for peak power.

Velocity of Propagation

A final performance characteristic that has primary importance when attempting to match the phases be-

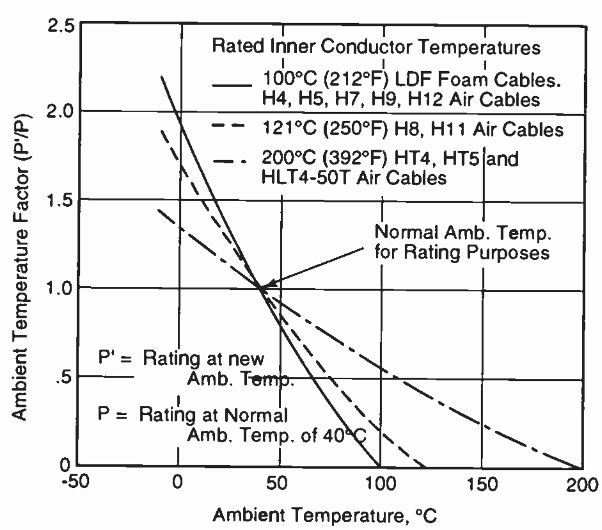

Figure 2.4-2. Variation of average power rating with ambient temperature.

modulation cycle. "Peak" refers to the peak amplitude of modulation and is not the instantaneous power when the RF voltage is at a maximum. In a continuous CW carrier such as FM, the peak power equals the average power. In 100% AM, the power rises to four times the carrier power at the peaks of the modulation envelope. So in this case, the peak power is four times the carrier power.

The peak power rating is dependent on voltage breakdown considerations, which are relatively frequency insensitive. Therefore, this rating is constant with frequency. It is, however, extremely sensitive to line size, physical conditions, pressure and the dielectric medium. It is important that the rating be based on a predetermined set of conditions that are clearly stated. Once a rating is determined for these conditions, it can be adjusted for other conditions.

The procedure for determining a peak power rating is to establish a peak voltage the line will withstand every time under normal manufacturing processes. Because voltage breakdown levels are extremely sensitive to effects such as dust, insulator condition and surface irregularities, the theoretical breakdown gradient cannot be used in practice. It has become standard procedure to derate the theoretical breakdown to 35% of its value to determine a production dc test voltage. This test voltage (E_p) is calculated using the following equation which is derived from the maximum voltage gradient in a coaxial line and includes the derating of 35%:

$$E_p = 3.17 * 10^4(d\delta)\left[\log\left(\frac{D}{d}\right)\right] * \left(1 + \frac{0.273}{\sqrt{d\delta}}\right)$$

where

E_p = production test voltage
d = inner conductor OD, in.
D = outer conductor ID, in.
δ = air density factor = 3.92B/T
B = absolute pressure, cm of mercury
T = temperature, °K

($\delta = 1$ for $B = 76$ cm and $T = 23°C = 296°K$)

Rounded off values for E_p for 50 Ω transmission lines are:

E_p DC Volts	Nominal Line OD inches
6,000	7/8
11,000	1-5/8
13,000	2-1/4
16,000	3
19,000	3-1/8
21,000	4
27,500	5
35,000	6-1/8

The production test voltage must now be converted to realistic RF rms operating voltage, E_{rf}:

$$E_{rf} = 0.7 * E_p * \frac{1}{\sqrt{2} * SF}$$

E_{rf} = maximum RF rms operating voltage with no derating for VSWR or modulation, but includes a safety factor

$1/\sqrt{2}$ = RMS Factor
0.7 = DC to RF factor
SF = safety factor for voltage (typically 1.4 or 2)

This voltage then determines the peak power rating, P_{pk}:

$$P_{pk} = (E_{rf})^2/Z_o \text{ watts}$$

or

$$P_{pk} = \frac{\left(\frac{E_p * 0.707 * 0.7}{SF}\right)^2}{Z_o}$$

An adequate safety factor on peak power is necessary to safeguard against voltage breakdown which can result in permanent damage to the line. Many manufacturers have settled on a power safety factor of 2 which is equivalent to a voltage safety factor (SF) of 1.4. When good conditions for installation or operation can not be maintained, it is good practice to apply a higher safety factor to prevent damage on initial startup of a system.

Once the peak power is determined, it must be further derated for the effects of modulation and VSWR. These deratings are calculated as follows:

AM:

$$P_{max} < \frac{P_{pk}}{(1 + M)^2 * \text{VSWR}}$$

FM:

$$P_{max} < \frac{P_{pk}}{\text{VSWR}}$$

TV:

$$P_{max} < \frac{P_{pk}}{(1 + AU + 2\sqrt{AU}) * \text{VSWR}}$$

P_{max} = derated maximum power
M = Amplitude modulation index (100% = 1)
AU = Aural to visual ratio (20% aural: AU = 0.2)

Much of the technical literature written on this topic discusses methods to increase the peak power rating through the use of increased pressure and high dielectric strength gases. While in theory a higher rating is possible, the system requires significant monitoring to prevent extensive damage due to breakdown if a failure in the pressurization integrity occurs. The decision to utilize these procedures requires extensive analysis of the proposed system and should not be used if other more stable configurations are available.

viewing various manufacturers' specifications. This is typically a result of a different safety factor used when deciding on the actual maximum frequency of operation. A 5–10% reduction in the calculated f_c is a normal safety factor and will account for manufacturing tolerances and the effects of connections and elbows. However, where numerous elbows assembled "back-to-back" will be used within a system, additional safety factors may be necessary to prevent the generation of higher order modes.

Voltage Standing Wave Ratio

Typically, it is important that the transfer of energy from the source (transmitter) to a load (antenna or receiver) be as efficient as possible. The attenuation constant is one factor in determining the efficiency as it represents a direct loss of energy. Another factor is the impedance mismatch between the line and the load. The greater the mismatch, the higher the reflected level of energy at the connection. This reflected energy reduces the amount of signal transmitted to the load and results in lower efficiency. The incident and reflected waves will combine to produce an uneven voltage distribution. Voltage and current maxima and minima occur resulting in a standing wave along the line. The VSWR is defined as the ratio of maximum to minimum voltage:

$$\mathrm{VSWR} = V_{max}/V_{min}$$

The effects of VSWR may be significant depending on the VSWR level and the specific conditions of operation. In general, as the VSWR increases, the maximum voltage levels increase and voltage breakdown may occur. Excessive heating along the line may also occur due to the current maxima and softening or melting of the dielectric insulating material may cause the inner conductor to shift in position.

In a simplified form, the impedance at any point along a transmission line is described as:

$$Z(s) = Z_o \times (1 + V^-/V^+)/(1 - V^-/V^+)$$

$Z(s)$ = resultant impedance at a point on the line
V^- = reflected voltage component
V^+ = forward voltage component
Z_o = characteristic impedance of the line
Z_L = impedance of the load

The reflection coefficient Γ_o at the load is defined as:

$$\Gamma_o = (Z_L - Z_o)/(Z_L + Z_o)$$

Then

$$\mathrm{VSWR} = V_{max}/V_{min} = (1 + \Gamma_o)/(1 - \Gamma_o)$$

or

$$\Gamma_o = (\mathrm{VSWR} - 1)/(\mathrm{VSWR} + 1)$$

Attenuation

Attenuation is defined as the loss created by the imperfect conductivity of the conductors and the imperfect insulating dielectric medium. In coaxial lines, losses come from both the inner and outer conductor materials and the material used to support the inner conductor. In solid dielectric cables, the dielectric loss can be appreciable and at higher frequencies actually exceed the conductor losses. For air dielectric lines, the insulating supports are a small percentage of the total dielectric space and their losses are generally negligible.

Attenuation and efficiency are directly related. Efficiency is defined as the ratio of power delivered to the load relative to the power input into the transmission line:

$$\text{Efficiency} = \text{Power out/Power in}$$

The efficiency is determined by calculating the total attenuation of the line based on its overall length. The total attenuation (in db) is then converted to efficiency:

$$\text{Efficiency \%} = 10^{-(\alpha_{total}/10)} * 100$$

Actual attenuation can be influenced by the VSWR of the line and the operating temperature. Except in cases of extreme VSWR or temperatures, these effects are insignificant to the performance of the system.

For VSWR, the loss is increased by the factor

$$\frac{1 + \mathrm{VSWR}^2}{2 * \mathrm{VSWR}}$$

For temperature, the greatest effect is a change in the temperature of the inner conductor since the conductivity of the material is affected by temperature. The adjustment factor for attenuation (M_a) is given by:

$$M_a = \sqrt{1 + \sigma_o(T_t - T_o)}$$

T_t = inner connector temperature °C
T_o = inner conductor temperature at standard rating °C
σ_o = temperature coefficient of resistance at standard rating

For standard temperature rating of 20°C, σ_o = 0.00393/°C. Then:

$$M_a = \sqrt{1 + 0.00393\,(T_t - 20)}$$

For an inner conductor temperature of 100°C, the attenuation will increase by a factor of 1.146.

Power Ratings

There are two primary ratings when discussing the power handling capabilities of coaxial transmission lines—average and peak power. The *average* power rating is based on the maximum internal heating the line construction can withstand. This is normally limited by the maximum safe operating temperature of the dielectric spacing material. The *peak* power rating is based on voltage breakdown characteristics.

Peak Power

Peak power is defined as the maximum RF power which can be reached in any interval, such as an RF in defined lengths, typically no longer than 20 feet. The individual lengths are then attached to each other through the use of flanges and the inner conductors are typically "spliced" together. Rigid coaxial lines can have diameters up to 14 inches. They have high power handling capabilities and low attenuation values.

Design Criteria: Electrical Parameter Optimization

A basic principle in the design of most transmission lines is to find the optimum configuration of inner conductor to outer conductor dimensions where the power handling is maximized and the attenuation minimized. Each configuration will then determine a characteristic impedance for the line.

Characteristic Impedance

The characteristic impedance is determined by the relative dimensions of the inner and outer conductors and the dielectric material between them. It can be expressed by the following equation:

$$Z_o = \frac{60}{\sqrt{\epsilon'}} * \ln\left(\frac{D}{d}\right)$$

where:

Z_o = characteristic impedance
ϵ' = dielectric constant or relative permittivity of dielectric to air
D = inside electrical diameter of outer conductor
d = outside electrical diameter of inner conductor

Attenuation

The attenuation of the line is normally expressed in terms of loss per unit length or db/100 ft (db/100 meters). The attenuation is due to dielectric losses and conductor losses. The dielectric material loss is directly proportional to frequency. For "air dielectric" lines where the majority of the volume of space between the inner and outer conductors is air, the most commonly used dielectric materials are TFE and polyethylene. These materials produce very small losses, and in the case of rigid coaxial lines, this loss is usually negligible relative to the conductor losses. Conductor losses are related to dimensions, permeability and conductivity of the material. The conductor loss varies with the square root of the frequency and for copper conductors:

$$\alpha = \frac{0.433}{Z_o} * \left(\frac{1}{D} + \frac{1}{d}\right) * \sqrt{f}$$

where

α = attenuation constant, db/100 ft
f = frequency, MHz

Attenuation is minimized when D/d is equal to 3.59, which results in an impedance of 77 Ω.

Power Handling

The power handling capabilities of coaxial lines are based on two factors: the maximum peak power (or maximum voltage that can be safely present) and the maximum average power, which is determined by the allowable temperature rise on the inner conductor.

Peak Power

The maximum electric field strength between two coaxial conductors can be calculated from:

$$E_{max} = \frac{0.278}{d} * \sqrt{\frac{P}{\ln\left(\frac{D}{d}\right)}}$$

where:

E_{max} = Maximum electrical field strength, volts/in
P = Power level of signal, watts

E_{max} is at a minimum when the ratio D/d is equal to 1.65. This results in a characteristic impedance for an air dielectric line of 30 Ω.

Determining the average power capability of a line requires extensive testing or the use of complex thermal models. It has been determined that the optimum ratio of D/d is approximately 2.72, resulting in a characteristic impedance of 60 Ω.

Summary

It can be seen from the previous analysis that there are tradeoffs between optimum configurations for attenuation, peak power and average power. Broadcast transmission lines have standardized on 50 and 75 Ω. The 50 Ω impedance is a balance between optimum peak power and average power. Typically, if power is the controlling factor, a 50 Ω line is used. If attenuation (efficiency) is more important, then a 75 Ω line should be used.

Design Criteria: Operational Parameters

With the characteristic impedances determined, the choice of line now is based on the desired frequency of operation (or limited by the cut-off frequency), and the actual power handling and attenuation ratings.

Cut-off Frequency

The cut-off frequency (f_c), is the frequency above which undesirable modes of propagation can be generated. The generation of these modes results in degraded efficiency, higher reflections (Voltage standing wave ratio—VSWR) and lowered power handling. Since larger coaxial transmission lines can handle more power, the (f_c) typically is the limiting factor where frequency of operation versus power handling is determined. The cut-off frequency is inversely proportional to the conductor dimensions and is determined by the following equation:

$$f_c\,(GHz) = \frac{7.52}{\sqrt{\epsilon'} * (D + d)}$$

Differences in the maximum operating frequency of specific line sizes are sometimes evident when re-

2.4
COAXIAL TRANSMISSION LINES

KERRY W. COZAD
ANDREW CORPORATION, ORLAND PARK, IL

INTRODUCTION

Transmission lines are one of the main components in the RF transmission plant of a broadcast station. Acting as the connecting link between the transmitter and the antenna, the transmission line plays a critical role in both the quality and reliability of the broadcast signal. Therefore, the proper choice of a transmission line type to be used can have a significant impact on the success of the station.

The choice of transmission line is typically decided based on the following criteria:

- Frequency of Operation
- Power Handling
- Attenuation (or efficiency)
- Characteristic Impedance
- Tower Loading (size and weight)

With the implementation of additional digital broadcast channels, other criteria such as installation costs, connector design, reliability and the effectiveness of transmitting multiple channels are receiving renewed attention from design and broadcast engineers. There are a wide variety of transmission line types and designs to choose from. This chapter reviews the attributes of the various types and describes performance comparisons to assist the broadcast engineer in the selection of the type best suited for a specific need.

COAXIAL TRANSMISSION LINE TYPES

A coaxial transmission line consists of two concentric conductors, the inner conductor being supported within the outer conductor through the use of a dielectric material (see Figure 2.4-1). The dielectric material may be continuous throughout the line or, as in the case of rigid coaxial lines, located at distinct points along the line in the shapes of "pegs" or cylindrical "beads." Some general characteristics from electromagnetic field theory are:

- An infinite number of electromagnetic field configurations (modes) are possible
- Propagating modes will be in a general form of waves traveling along the axis of the line
- The propagation constant is different for each mode
- There is a frequency called the cutoff frequency where the propagation constant is 0. Below this frequency, there is no propagation of that mode.

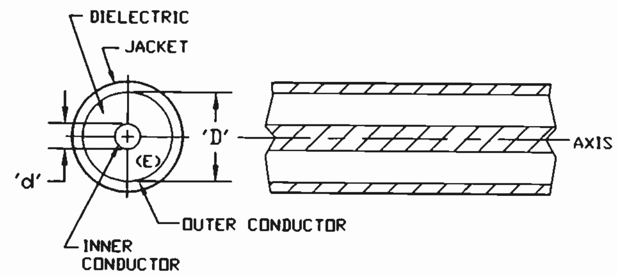

Figure 2.4-1. Coaxial cable cross section.

- There is one mode, transverse electromagnetic mode (TEM) for which the electromagnetic fields are transverse to the transmission line axis. The TEM has a cut-off frequency of 0 Hz. This is the mode that is primarily used for propagating signals within coaxial transmission lines.

Based on these common characteristics, coaxial transmission lines are usually divided into three primary groups: flexible (RF) cables, semiflexible cables and rigid coaxial lines.

RF cables are typically used for short interconnections between equipment. They consist of a solid or stranded inner conductor, solid plastic dielectric insulating material and a braided outer conductor sheath. It is coated with a plastic outer jacket to resist moisture and abrasion. Typically having outer conductor diameters of less than 0.5 inch, its attenuation characteristics restrict it to short runs and because it is highly susceptible to deterioration due to aging, it is normally only used indoors.

Semiflexible cables are designed with soft tempered copper inner and outer conductors. The dielectric material may be either solid (foam filled) or a spiral that has been wrapped in helical fashion around the inner conductor (air dielectric). Again, a plastic jacket is applied to the outer conductor to resist abrasion. One advantage of semiflexible cables is that they can be fabricated in diameters up to 9 inches and in continuous lengths of hundreds and even thousands of feet. This cable type is used extensively for radio and low power television broadcasting, as well as interelement feeders for some antenna types.

Rigid coaxial lines are designed with hard tempered inner and outer conductors. Discrete dielectric insulators are used to support the inner conductor within the outer conductor. Because it is rigid, it must be fabricated

CONCLUSION

This chapter has been written in tutorial form as every site is different and no single set of recommendations will apply to every situation. The principles set forth, while tailored to a broadcast environment, apply equally to other systems. There are still a few mysteries to be solved in completely understanding lightning, but once it enters a wiring system, it becomes an electrical current which is both predicable and understandable.

- All surge suppressors should be UL 1449 tested, approved and labeled
- Ask for published proof of testing to back up claims, especially clamping levels, energy handling capabilities (joules, watts or current) and speed of response
- Look for 3 to 5 years unconditional warranties
- Review the 6 major performance characteristics: Response time, voltage protection level, power dissipation, disturbance free operation, reliability and operating life. Make sure maximum power dissipation level and voltage protection level using specific waveforms, are stated at the same point to avoid misinterpretation
- Talk to other similar users for advice and recommendations
- Consult industry standards for performance requirements. At present, there is no testing or application standard for coaxial surge suppressors, so a comparative review of reputable manufacturer data will be necessary. Compare: impedance (50 or 75 Ω); clamping speed; frequency range; number of transmit, transceive or receive only signals; transmit power; presence of ac or dc power with the RF signals; mounting; connector type and sex.

Isolated Ground Receptacle

Figure 2.3-25 shows an isolated ground receptacle circuit commonly used in computer room grounding applications. The receptacles used in this type of circuit differ from the norm in that their ground pins are electrically isolated from their mounting tabs. They are therefore isolated from their outlet box and structural ground at each receptacle location. A dual system of grounding conductors ensures that equipment plugged into an isolated ground (IG) receptacle references ground first at the single point ground.

The use of isolated ground receptacles helps to ensure that plug-in terminals, printers, diagnostic and other ancillary equipment is properly referenced to the single point ground and not the local structure. It only takes one item of equipment connected between the protected equipment and a remotely grounded receptacle to compromise the integrity of the grounding system.

Figure 2.3-26 is a composite of the bonding and grounding recommendations for the typical broadcast site. While complicated in appearance, each component has its purpose as part of a simple-to-understand subsystem.

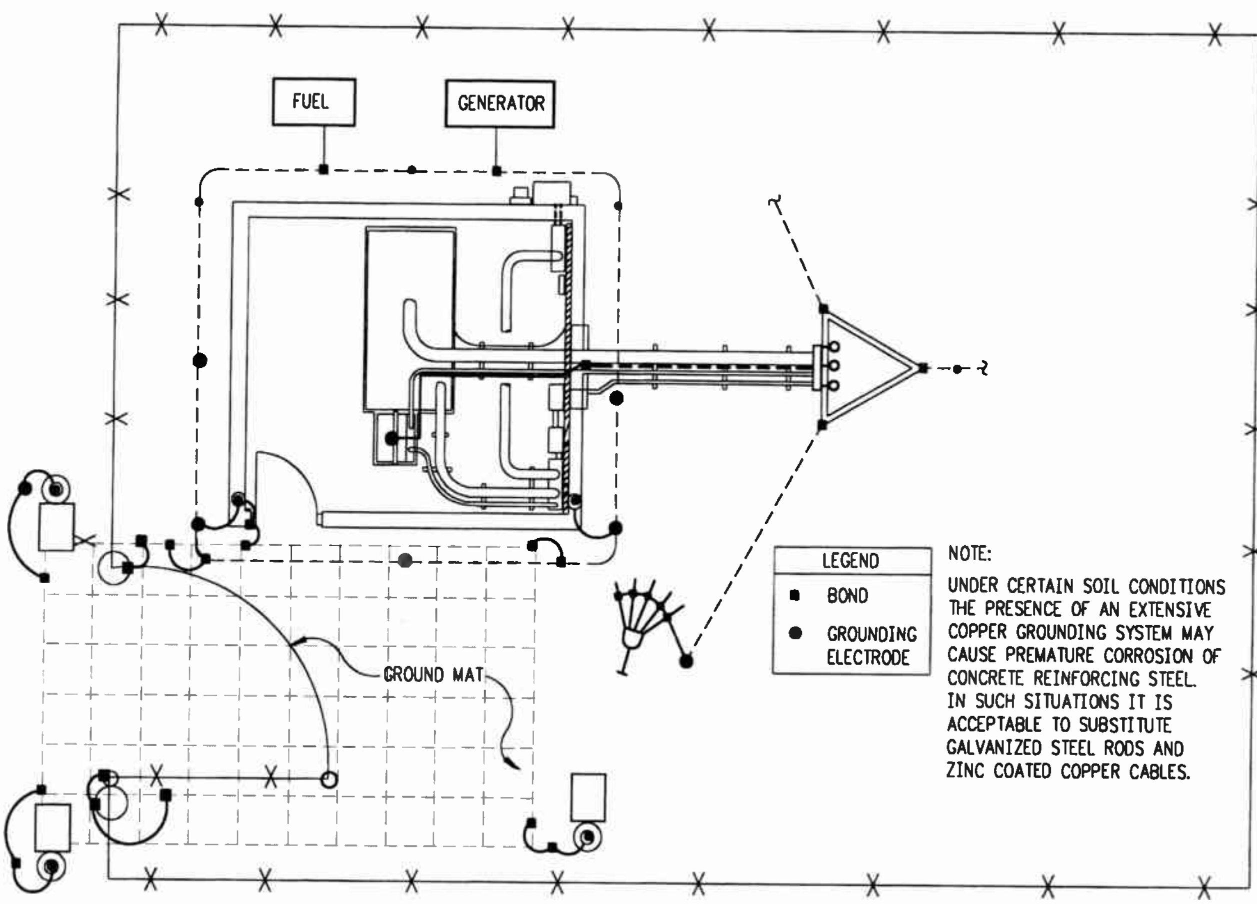

Figure 2.3-25. Isolated ground receptacle.

open during servicing and each condition can cause equipment flashover.

Flashover within electrical equipment is serious in itself, however, the problem is compounded when operating voltage is also present. The flashover arc provides a low impedance path for 60 Hz follow current and significant damage to the equipment may occur. The arrester will prevent this condition from occurring by limiting the travelling wave voltage.

Signal Line Suppressors

Figure 2.3-24 shows a common surge suppressor configuration for telephone signal line and coax applications. Most suppressors of this type are both shunt type and multi-stage hybrid devices utilizing a high-energy first stage, a fast acting second stage and impedance in series between the two stages to coordinate their clamping behavior. Because of the multi-stage design, these devices must be installed in series with the protected circuits.

The treatment of shields is often an issue when dealing with signal line surge suppressors. Figure 24 shows shields being bonded to the suppressor ground bus to force them to track the single point ground. If ground loop or other technical restrictions prevent direct bonding of the shields, they should be protected with suppressors as any other active circuit.

The bonding lead distance for signal line suppressors is often more critical than for power devices. Tolerance levels of signal circuits are normally lower than for power supply inputs, and the relatively small voltages developed in the suppressor ground leads can be become significant.

Signal line and coaxial surge suppressors are sold in a variety of shapes and sizes for different applications. The suppressors should generally clamp transient voltage on a circuit to within 150% of normal peak operating voltages and even lower in some applications. Since most signal line suppressors are inserted in series with the circuit being protected, it is wise to evaluate the effect of their series impedance and capacitance on the insertion loss of a circuit.

The effect of suppressor capacitance can be important in many high speed data, RF and video applications. One simple way of evaluating the effect of this capacitance is to equate it to equivalent cable feet. For example, if the desired suppressor exhibits capacitance of 100 picofarads, and the cable used in the circuit is rated at ten picofarads per foot. Will the circuit tolerate an additional 10 ft of cable? If so, the suppressor capacitance should produce no noticeable effect on the circuit.

Surge Suppressor Selection

Surge suppressors and lightning arresters come in all shapes, sizes, types and accessories. Contacting surge suppressor manufacturers may be extremely confusing due to the myriad of choices available, but eventually a choice must be made. Contacting the chairmen of the referenced IEEE, U.L. and IEC standard committees may also be helpful in understanding application issues. The following guidelines therefore may be helpful:

- Select suppressors and arresters based on IEEE C62.41 Categories (A, B or C)

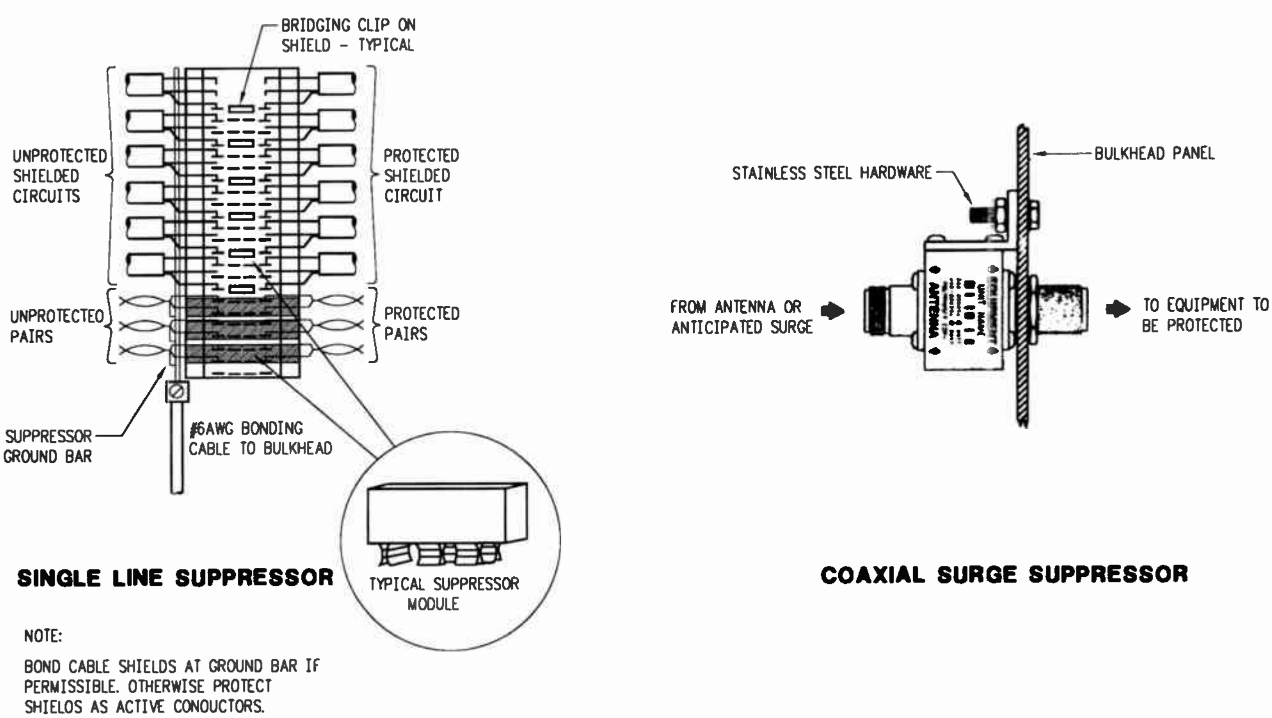

Figure 2.3-24. Common signal & coaxial suppressors.

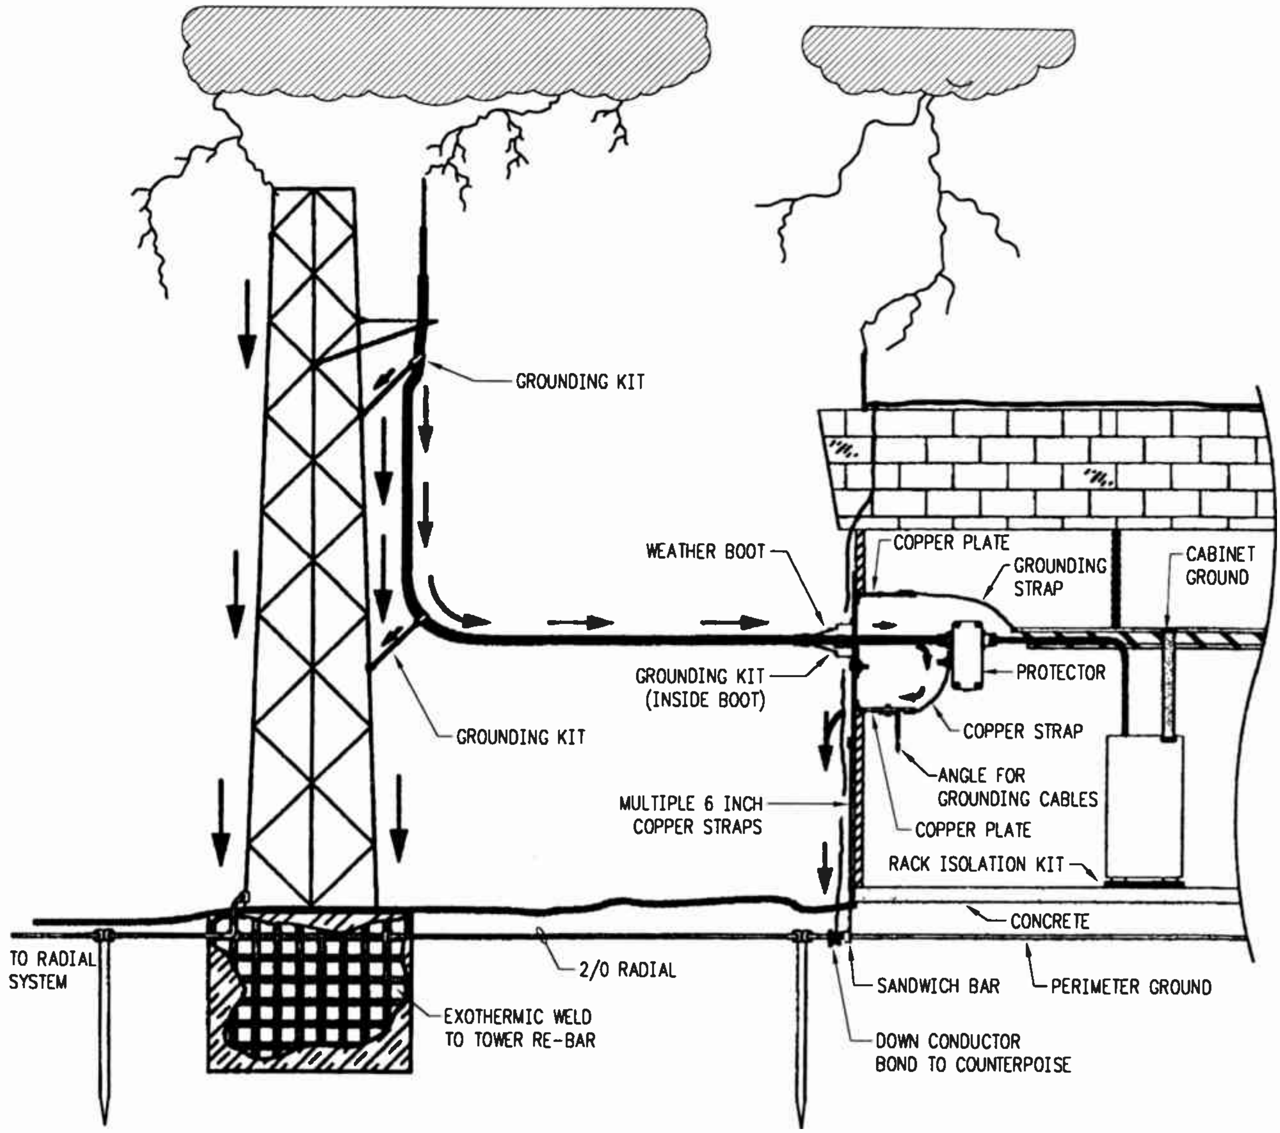

Figure 2.3-23. Typical bulkhead installation with single point grounding.

Surge Suppression

In Figure 2.3-22, surge suppressors are shown at the transfer switch emergency feed to protect the transfer switch from surges on the emergency power feeder whenever the feeder and generator starting controls are not run in rigid metal conduit. Where metal conduit is used, it must be bonded to the perimeter ground ring. Main service surge suppressors should be connected through individual or integral fused switches or breakers with short circuit interrupting ratings equal to or higher than the available service fault current. Also, a suppressor is installed on the circuit for tower lights. Both suppressors should be bonded to the grounding bus, keeping the length of their bonding lead as short as possible. Suppression should also be provided on all metallic, control, monitoring and communications lines and circuits serving lighting, winches and other electrical items outside the building. Again, locate these suppressors at the point of entry for the circuits and bond their ground leads to the bus with the shortest possible lead length.

The lightning arrester shown at the main disconnect outside the building serves an important purpose. Under normal operation, the main disconnect is closed and the transfer switch is connected to utility power. During operation on emergency power the normal transfer switch position is open. Potentially, a lightning strike to the utility line will propagate along the line as a travelling wave in both directions from the point of lightning contact. Upon reaching the open circuit input of the transfer switch, the wave will reflect back on itself, potentially doubling its initial crest value. The same condition can occur at the main utility company disconnect if it should be plex may be engineered with a single point grounding system and proper surge suppression on its external circuits. The terminals and their printers, however, are scattered throughout the building, referencing ground at each location through their power cords. It is possible to designate the ground pin on the receptacle for each terminal/printer combination as the single point ground for the equipment at that location. A combination power and data suppressor may be provided for each location which ensures that these conductors are held within safe limits of the receptacle ground pin and chassis of the equipment. The equipment is isolated from stray grounds by placement on a desk top.

Figures 2.3-22 and 2.3-23 are examples of how single point grounding applies to a typical broadcast tower-building installation. A bulkhead panel in the wall of the building serves as a single point ground reference for all equipment within the small facility. All coaxial cables, waveguides, and raceways from the tower are bonded to the bulkhead as they pass into the building.

The physical size of the electrical equipment dictates that it cannot be located directly at the bulkhead panel. To minimize the effect of bonding system inductance, a 6 in. wide bonding bus is extended to each side of the bulkhead or for large installations an overhead ground ring is provided (width of the strip provides the necessary low inductance). Its 1/4 in. thickness, while not necessary for electrical reasons, provides the installer with a bus which may be drilled and tapped to accept short bonding pigtails to the equipment.

Support hangers for cables and raceways serving the protected equipment are isolated from the roof structure to prevent inadvertent current flow through the raceways. Isolation is provided between the equipment feet and floor slab by a high dielectric polypropylene pad. Such isolation may not be necessary if adequate isolation is provided by the equipment feet. Nylon bolts may be used with conventional expansion anchors to secure equipment to the floor without violating the integrity of the single point grounding system.

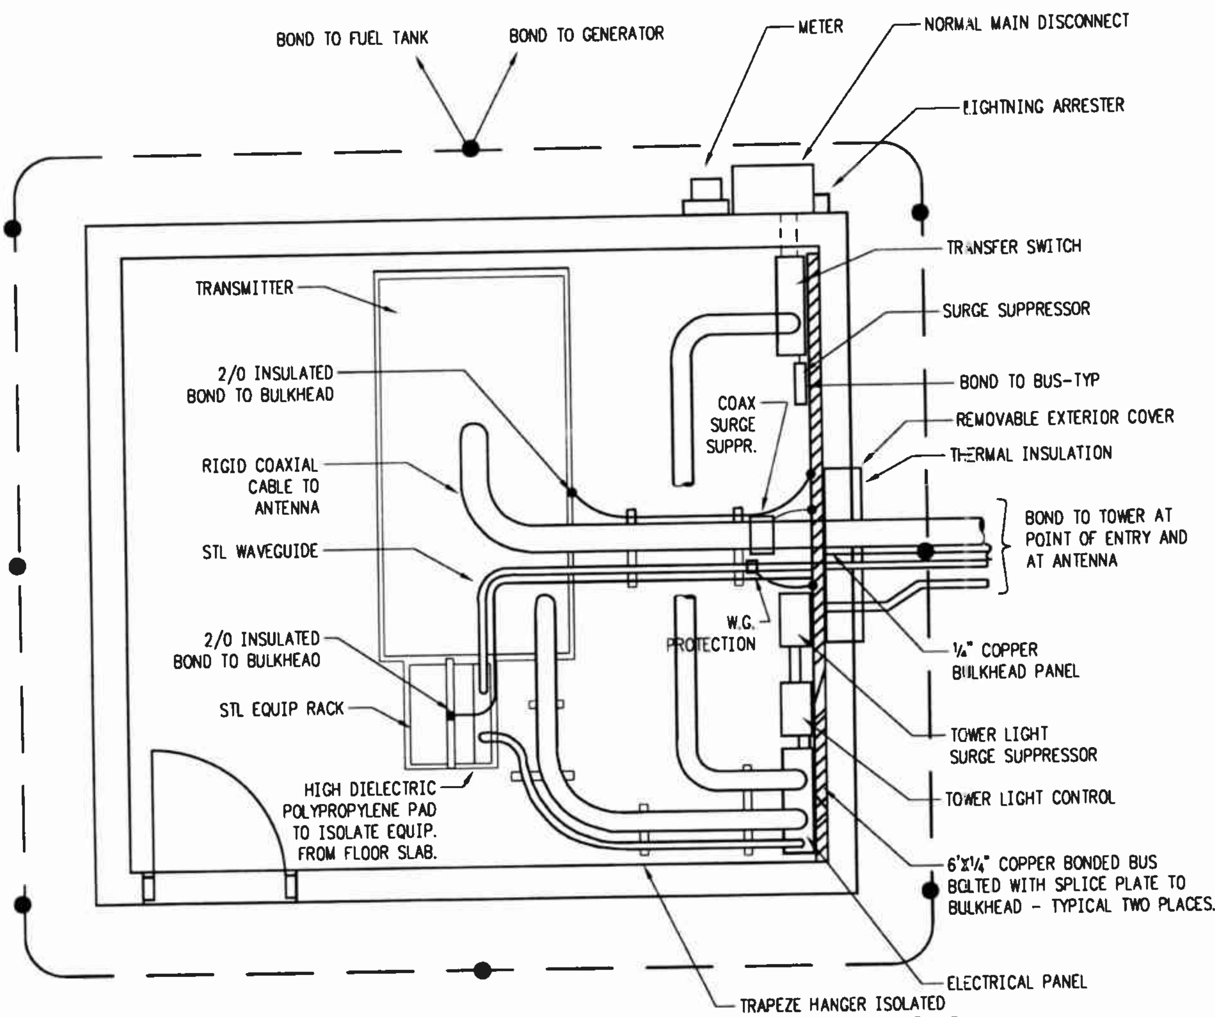

Figure 2.3-22. Single point transmitter building grounding.

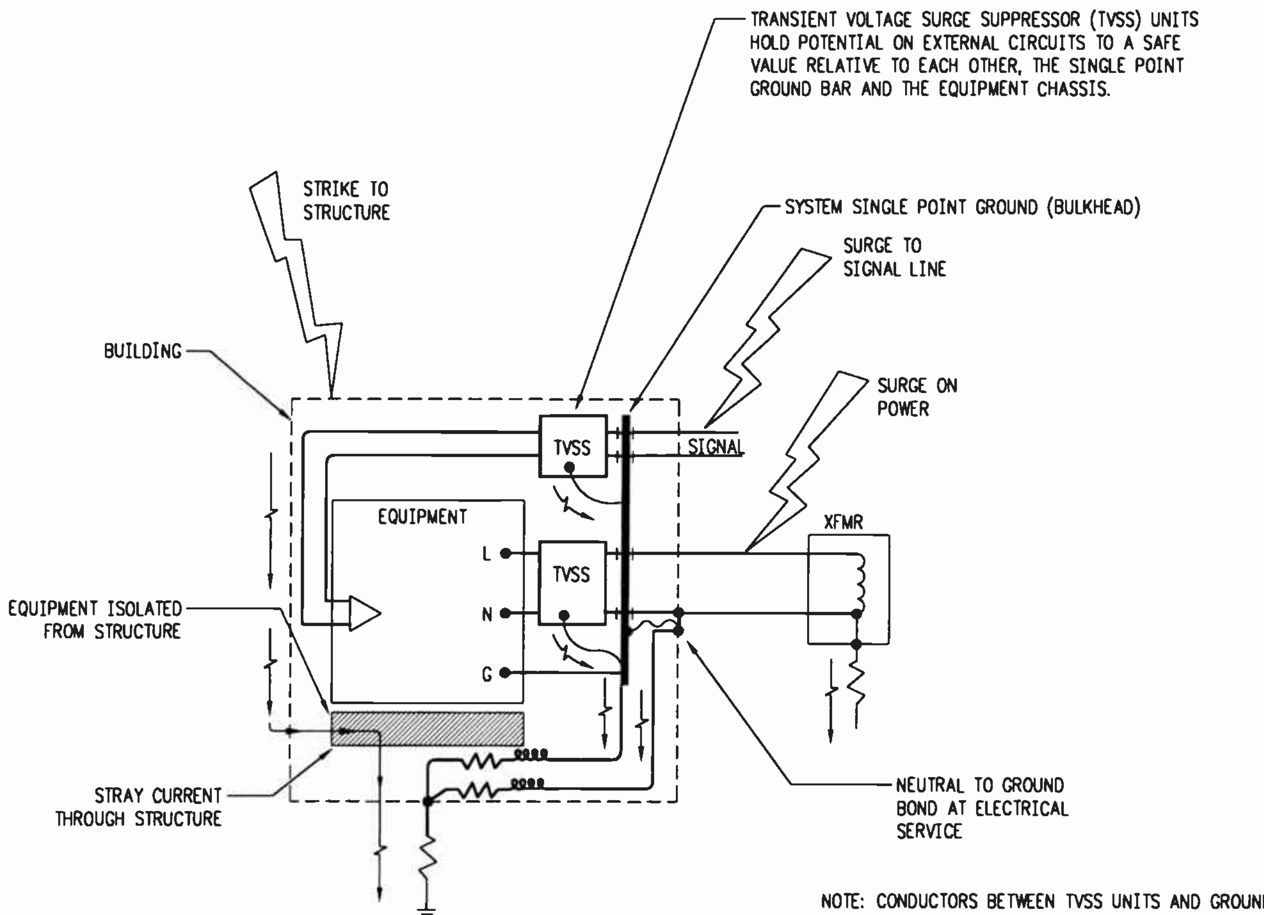

Figure 2.3-21. Practical application of single point grounding with TVSS.

chassis and all external metallic circuits are tied together at the single point ground. The only difficulty with the example in Figure 2.3-20 is that *nothing works*!

Figure 2.3-21 provides a more realistic approach to single point grounding. The only difference between Figure 2.3-21 and the preceding example is that Transient Voltage Surge Suppression (TVSS) devices are used on the active circuits, which, for obvious reasons, cannot be directly bonded to the single point ground.

For the purpose of this discussion, it is helpful to think of surge suppressors as a conditional bond, clamping or limiting the excursion of voltage on active circuits to a safe level relative to each other and to the single point ground. The single point ground may rise and fall in potential as the suppressors discharge current into it or during a strike to the building, but the difference in potential presented to the protected equipment is always held within safe limits.

It is worthwhile noting that TVSS devices will clamp in response to a rise in potential on their ground terminal as well as for legitimate transients on their active conductors. A strike to the building or nearby structure will cause a significant elevation in ground potential. The single point ground will rise in potential by virtue of its connection(s) to the building grounding system. The TVSS units, seeing their building ground terminals rise in potential above their remotely connected active circuits, will clamp, forcing the active circuits to track the potential of the single point ground and the chassis of the protected equipment. Again, the voltage excursion seen by the equipment is held to a safe level and no damage is sustained.

Applications of Single Point Grounding

The application of single point grounding is normally limited to equipment within a room or a group of rooms. While it is possible to design larger configurations, the need to bring circuits in at different locations soon dictates the need for multiple locations, each treated as an island of equipment with its own suppression devices and single point of ground reference. Larger single point grounding systems are also more susceptible to induced voltages from nearby lightning by virtue of their increased cable lengths.

As an example of two extremes in scale, a computer room which serves terminals throughout a station com-thickness is mechanical strength and mounting convenience.

As a final note on the inductance of bonding materials, *never expect an insulated conductor in steel conduit to carry lightning current effectively.* Ferrite beads make a reasonable effective low pass filter when placed around an insulated conductor. Steel conduit around an insulated cable creates the same effect, increasing the inductance of the cable within the conduit at least an order of magnitude similar to a choke coil. Where this condition exists (and there are many locations) a marginal compromise is to bond both ends of the cable to the conduit, permitting the conduit to serve as part of the circuit.

Single Point Grounding

If, after the exercise in bonding, you conclude there is no way of preventing potential differences in a conductor carrying lightning current, you are correct. There is, however, a method of preventing lightning current flow through a bonding circuit. With no current flow there can be no potential difference between the bonded items. This method is called *single point grounding.*

In Figure 2.3-20, the equipment chassis and all metallic circuits leaving the equipment for the outside world have been bonded together and to a ground conductor at a single point. There is no possibility of a difference in potential between the circuits entering the equipment or between these circuits and the chassis as they are all bonded together. There is also no possibility of current flow from the single point ground into the equipment through any of the circuits as the equipment is isolated from the structure.

A surge entering on the power or signal lines cannot present itself to the equipment in differential mode as the lines are all connected together. A common mode surge arriving at the single point ground will pass harmlessly to ground through the grounding conductor and ground electrode resistance. There will be potential rise at the single point ground due to inductance and resistance in the grounding circuit, however; no current can flow through the equipment as it remains isolated from other points of ground reference. The equipment will simply rise and fall in potential, tracking the potential of the single point ground.

A lightning strike to the building or other structures connected to its grounding system will also cause the single point ground to rise and fall in potential. The equipment, however, sees no potential difference as its

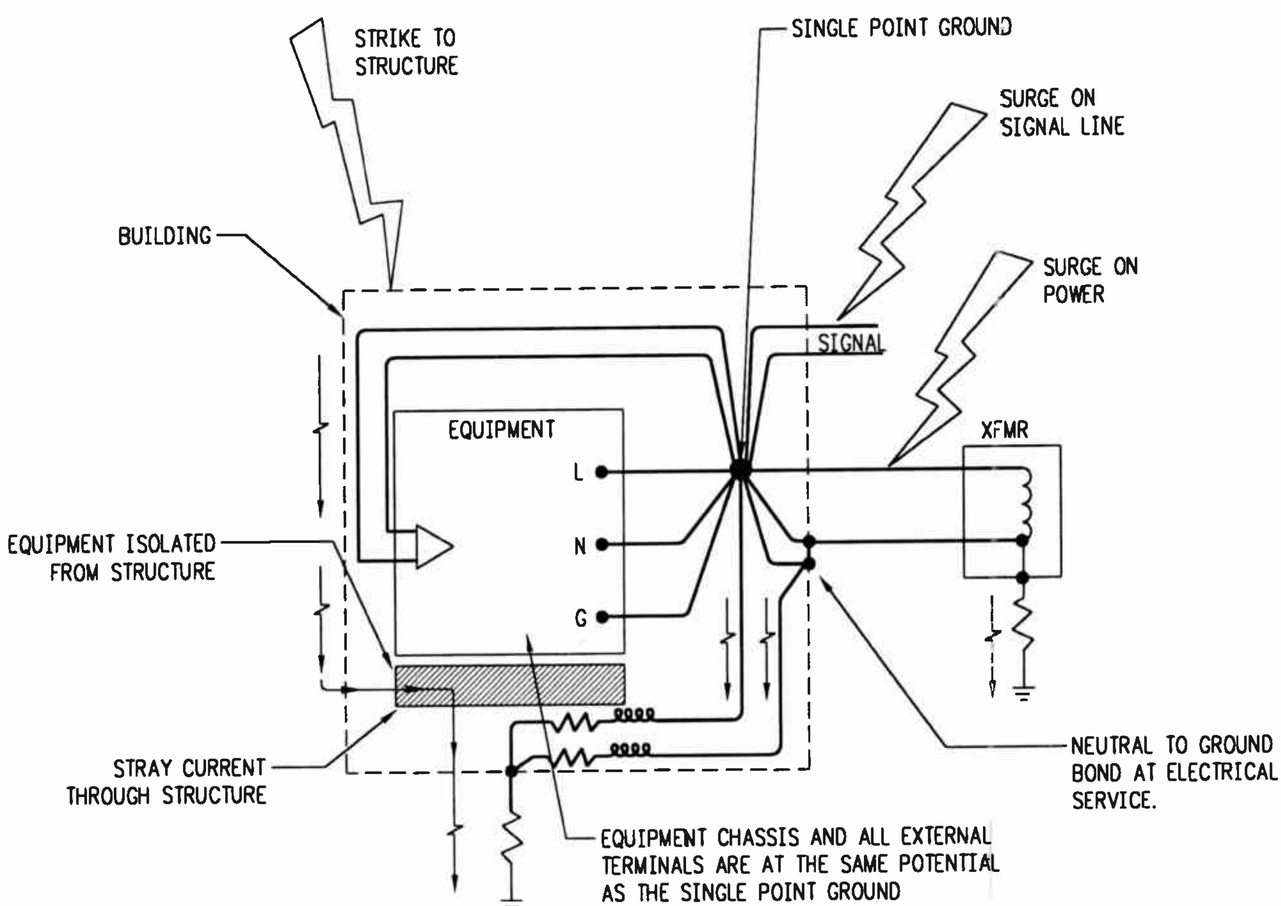

Figure 2.3-20. Single point grounding concept.

Kirchoff's law states that current will divide itself among all of the available parallel paths through a circuit in proportion to the impedance of each path. Lightning currents behave in the same way, flowing through all available paths to ground. In direct current circuits, the voltage produced across any circuit component is the product of current and resistance. When dealing with rapidly changing lightning current, inductance of the circuit plays a far larger role than simple resistance. Recall that an inductor tends to oppose any change in current until it has stabilized its magnetic field.

The bonding conductor shown in Figure 2.3-18 by virtue of its connection to ground at remote building A, serves as one of several paths for lightning current to follow on its way to ground. In this case, only 5% or 1,000 amperes of the lightning current flows through the 75 ft conductor with the remainder of the 20,000 A flowing into the grounding system of building B and its electrical service. Assuming a 1.5 μs risetime for the lightning current, the peak end-to-end voltage on the conductor is 15,030 V 15,000 V of the total is the result of inductance in the conductor. The remaining 30 V is the result of the conductor's resistance.

The normal reaction to lowering the potential difference between buildings in this example is to suggest a larger cable. After all, larger cables have less resistance and lower voltage drop. Changing to a larger cable, however, has little effect on the circuit inductance, affecting primarily the 30 V portion of the total.

Figure 2.3-19 provides a comparison of inductance values for a 1 ft. length of various sizes of round conductors, strip materials and coaxial cables. Strip materials are considerably more effective for the same cross sectional areas as a round conductor, making them more attractive as a bonding medium for lightning protection purposes and bulk head grounding. Another interesting property of strip material is that it reaches a width of about 4 in., the major reason for

Differential or normal mode surges are often more damaging than their common mode counterpart as most equipment is designed to operate in a differential fashion. In power circuits, a differential mode surge may appear on one or more phases relative to the neutral and ground conductors. In signal circuits, especially those operating on a balanced differential basis, the tolerance to differential mode surges is lower than for common mode. Common mode surges on electrical power systems are routinely converted to differential mode at electrical services where one side of the service is referenced to ground. The same conversion process can occur on a balanced circuit when an upstream transient voltage surge suppressor (TVSS) device clamps one side of a pair before the other.

Ground differential damage is a bit more obscure than either of the other mechanisms, however, it is responsible for a great deal of damage to systems with equipment in multiple locations. Equipment in different buildings, or even equipment within different areas of the same building can be damaged through ground differentials.

In the simple example of Figure 2.3-17, assume that building B receives a lightning strike of 20,000 amperes. Also assume the grounding system resistance is 2 Ω. As the lightning current flows into the earth through the 2 Ω grounding resistance, a 40,000 V potential rise will be produced in the building B grounding system. Since the equipment in building B references the local building through its power cord and bonding conductor, its chassis will rise to about the same potential.

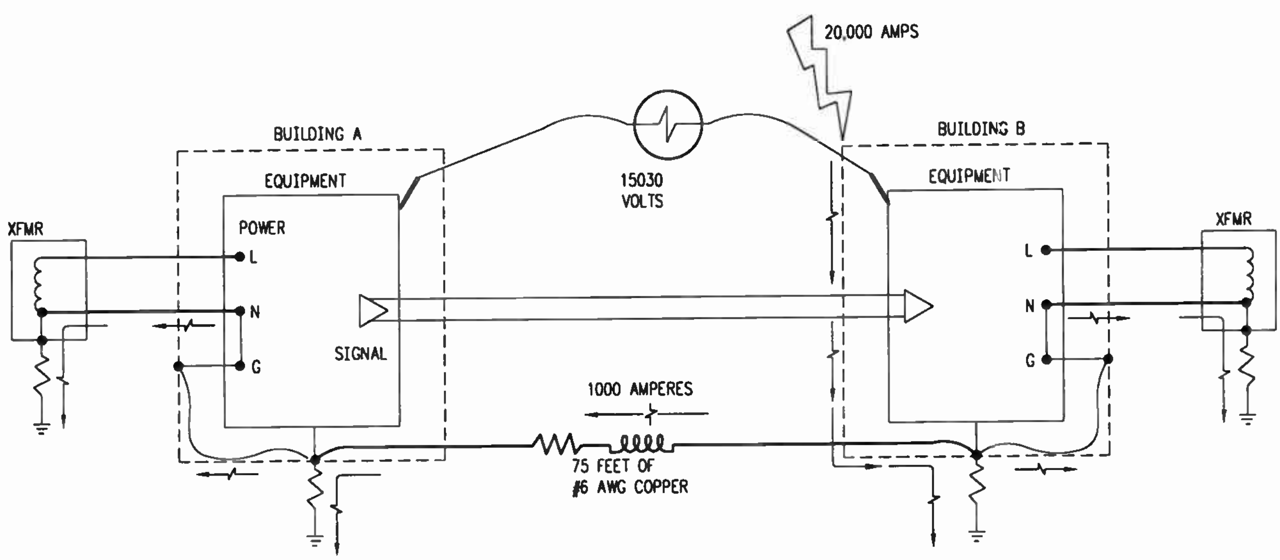
Circuitry within the building B equipment will attempt to track the building ground potential rise, except for the components which attach to wiring from building A. These components see a large difference in potential between the balance of their circuitry and the wiring to building A. Building A has not been involved in the ground potential rise so these circuits are still near ground potential.

Component breakdown occurs within the equipment in building B and a small fraction of the total lightning current attempts to find a path to ground through the wiring leaving for building A. Upon reaching the equipment at the remote building A, this current presents itself as a common mode surge causing damage to the equipment.

Equipment Protection Strategies

Protecting equipment from the effects of lightning involves a combination of grounding, bonding and surge suppression. Grounding provides a path to introduce lightning currents into the earth. Bonding serves to equalize lightning potential differences between various elements of equipment. Surge suppression limits differences in potential on active circuits which cannot be directly bonded.

Bonding is a means of equalizing potentials during a lightning strike. Figure 2.3-18 repeats the earlier example in Figure 2.3-17 regarding damage due to ground potential differences. This time, however, a bonding conductor is provided between the two grounding systems in an attempt to keep both at the same potential.



I = 1000 AMPERES

$$E = 30 = 15000$$

$$E = 15030 \text{ VOLTS}$$

Figure 2.3-18. Example of ground potential difference.

nearly equal potentials at both ends, additional bonding conductors between the radials will carry little or no current. There is only a slight advantage in bonding between radials for guy wire currents introduced into the grounding system at guy anchor points.

Figure 2.3-11 shows a perimeter ground ring or counterpoise which encircles the station building helping to equalize potential differences within the building. The station building ring also serves as a connection point for driven electrodes, fencing and other objects which must be bonded. A bonding conductor is shown between the station building ground ring and the tower base or grounding system. This conductor will equalize potentials and minimize the level of current carried between the tower and station building by the coaxial lines.

A commercially available bulkhead plate is shown on the side wall of the station building and is bonded to the station grounding ring. This plate serves as a single point ground for all equipment within the station building and the coax lines. In new construction, the steel reinforcing mesh in the station building floor should be bonded together to the bulkhead panel to minimize potential differences between the equipment and floor during a lightning strike.

EQUIPMENT DAMAGE PROCESS

Most lightning damage to equipment occurs as the result of potential differences which exceed the tolerance level of the equipment. These potential differences may be presented to the equipment or system through external metallic circuits as a conducted current or induced transient voltage surge. They may also occur as the result of differences in ground potential at various items of equipment which are connected together to form a system. (Figure 2.3-17 describes these situations in greater detail.)

Common mode surges, which are also referred to as *longitudinal mode*, arrive at the equipment with approximately equal potential on both sides of a balanced pair or on a number of circuits simultaneously. These surges may be induced into a wiring system by nearby lightning, directly coupled into the circuit or even created by the action of an upstream suppression device as it clamps two or more conductors together. Common mode surges may enter equipment on power phases, signal and other circuits. Damage is normally sustained due to potential differences between the affected circuit(s) and equipment chassis or other uninvolved circuits.

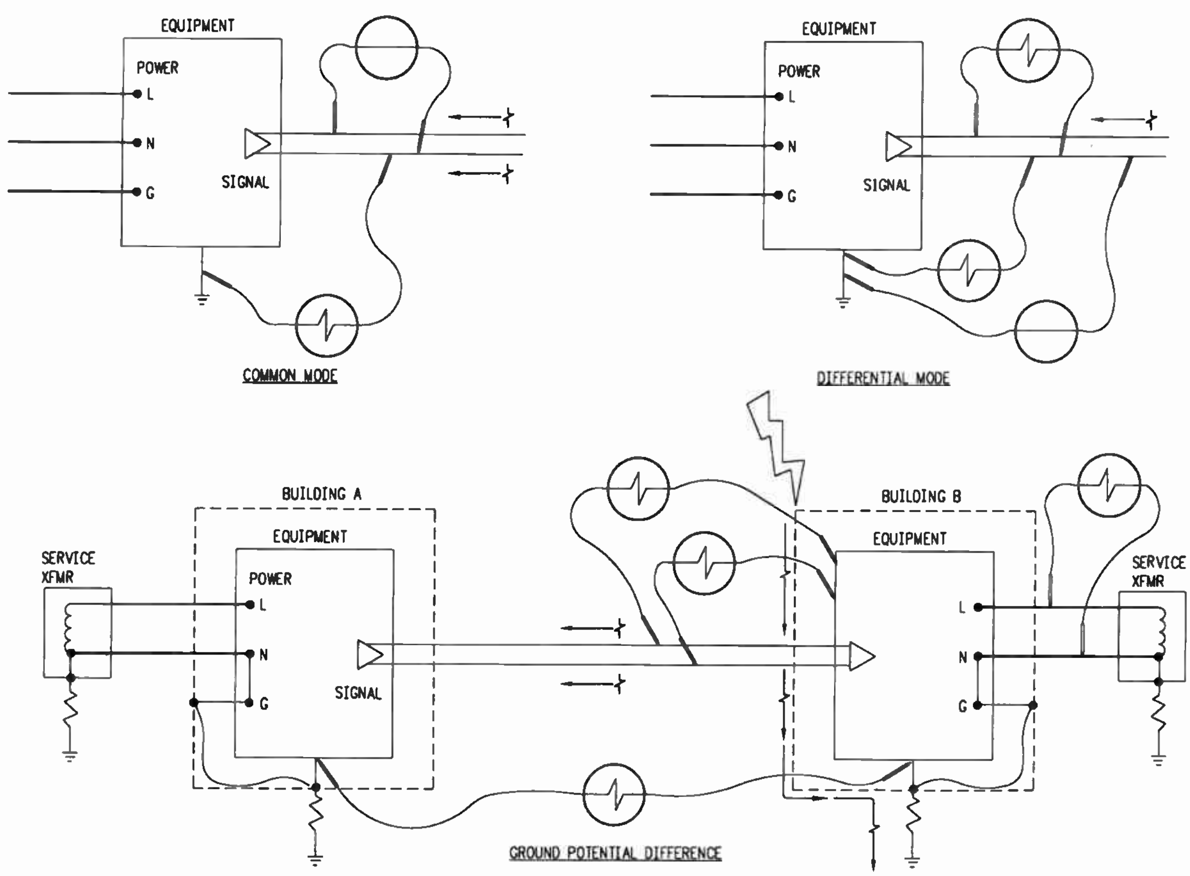

Figure 2.3-17. Typical equipment damage process.

current flowing between the tower and station building grounding systems, reducing potential differences between the two systems. The potential rise on the tower due to a lightning strike is a result of fast rising lightning current, tower inductance and ground resistance such that $E = IR + L\,di/dt$ where E is the potential rise from top of tower to ground, I is the magnitude of lightning current, R is the grounding resistance, L is the tower inductance and di/dt is the lightning current rise with respect to time. Tower structures have a certain amount of inductance per foot. The amount of this inductance is dependent upon the geometric configuration as well as the width of the tower. This width-to-height ratio will determine the total inductance of a tower. A 150 ft tower for instance, with 35 in. side widths can have an inductance of 40 μH. This value of inductance can be approximated ($W/H \leq 1\%$) by treating the tower as a 1/4 wave antenna using:

$$f = \frac{468 \times 10^6}{2(\text{H in feet})} \text{ then inductance } L = \frac{377}{2\pi f}$$

Therefore, there is not much that can be done about the tower inductance once the tower structure is known. Grounding, however, can be improved with proper grounding techniques.

Figure 2.3-16 describes a typical grounding configuration for a guyed tower and associated transmitter building. Tower grounding may be accomplished either by a system of interconnected driven electrodes between the tower base and guy anchor points or by radial counterpoise conductors without rods. The chosen method should be determined from previously described electrode calculations and earth resistivity testing. In the driven electrode configuration, one radial counterpoise conductor is extended from the base of the tower to each guy anchor point. This conductor interconnects driven electrodes near the tower base, at guy anchor locations and at intermediate points from any wire currents.

The rings shown feeding the system of radial conductors should stop within a few feet of the tower base. The complex mesh created by multiple bonds between the rings and radials will help to feed lightning current efficiently from the tower legs into each of the radial conductors. Apart from providing more copper in contact with the earth, there is no advantage in adding additional rings in the area between the tower base and guy anchor points. Current flowing from the tower base out on the radials will produce approximately equal potentials between adjacent radials. With

Figure 2.3-13. Formulas for calculation of resistances to ground.

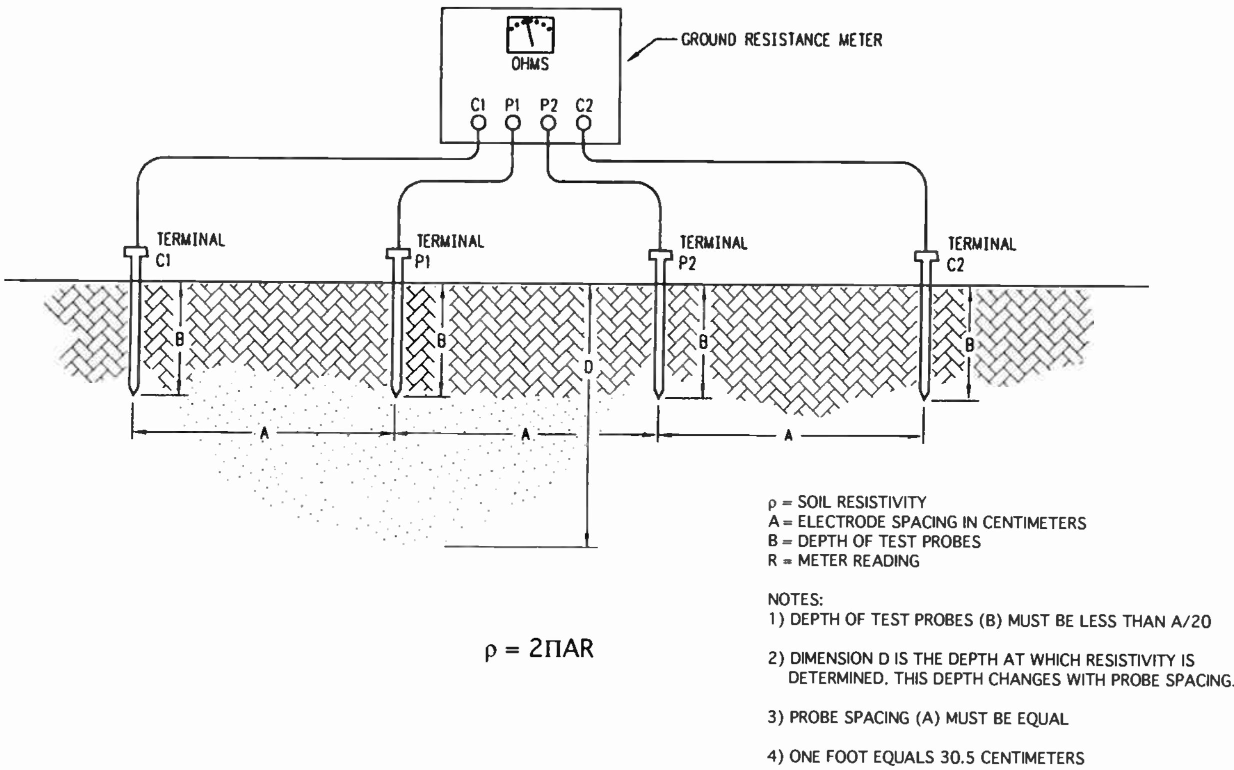

Figure 2.3-12. Soil resistivity test method.

frost line. They are often the only practical solution in areas with shallow subsurface rock. There have been instances at bald rock mountain top sites where radials were either grouted into saw cuts in the rock or simply pinned against the face of the rock.

The performance of a grounding system in high resistivity soil can often be improved through the addition of chemical salts. These salts leach into the soil, increasing the number of free ions with a proportionate decrease of soil resistivity in the area of the rod. Magnesium sulphate (Epsom salts), copper sulphate (blue virol), calcium chloride, sodium chloride (table salt), and potassium nitrate have been used for this purpose.

Figure 2.3-15 describes the trench and well methods for applying chemical treatment. A typical precharged chemical ground rod installation is also shown. In a precharged rod, moisture from the air enters the rod through breather holes at the top of the rod and leaches through chemicals inside, gradually exiting the rod through weep holes. As one might expect, chemically enriched grounds require recharging after a number of years to maintain their effectiveness. It is also wise to check with governing environmental agencies before introducing any foreign chemical into the soil.

The bentonite ground shown in Figure 2.3-15 is a popular way of decreasing grounding system resistance of a rod electrode in uniform soil by up to 30%. Instead of driving the rod, it is placed in the center of a 6 to 12 in. augured hole. A slurry consisting of bentonite clay and water (well drillers mud) is then poured around the rod. As the water settles out, the resulting clay remains moist through absorption of moisture from the surrounding soil. Popular additives to the slurry include up to 75% powdered gypsum (calcium sulphate) and up to 5% sodium sulphate (galvanic anode backfill).

Ground Electrode Testing

Testing of all grounding electrodes before they are connected to form a complex network is a fairly simple process that is well described in the documentation included with all ground electrode meters. The system as a whole, should be tested after all interconnections are made, providing a benchmark for future tests.

On a new site, it is often possible to perform ground system tests before the power company ground/neutral conductor is attached to the system. It is worthwhile to conduct a before and after test with probes in the same position to determine the influence of the power company attachment during future tests. It is also worthwhile to install permanent electrodes and marker monuments at the original P2 and C2 probe positions to ensure the repeatability of future tests.

Tower Building System

In typical tower building arrangements, the tower is normally subject to more frequent and larger lightning currents than the station building. It is therefore reasonable to place emphasis on the tower grounding system with less emphasis on that for the station building. Improved grounding at the tower will result in less

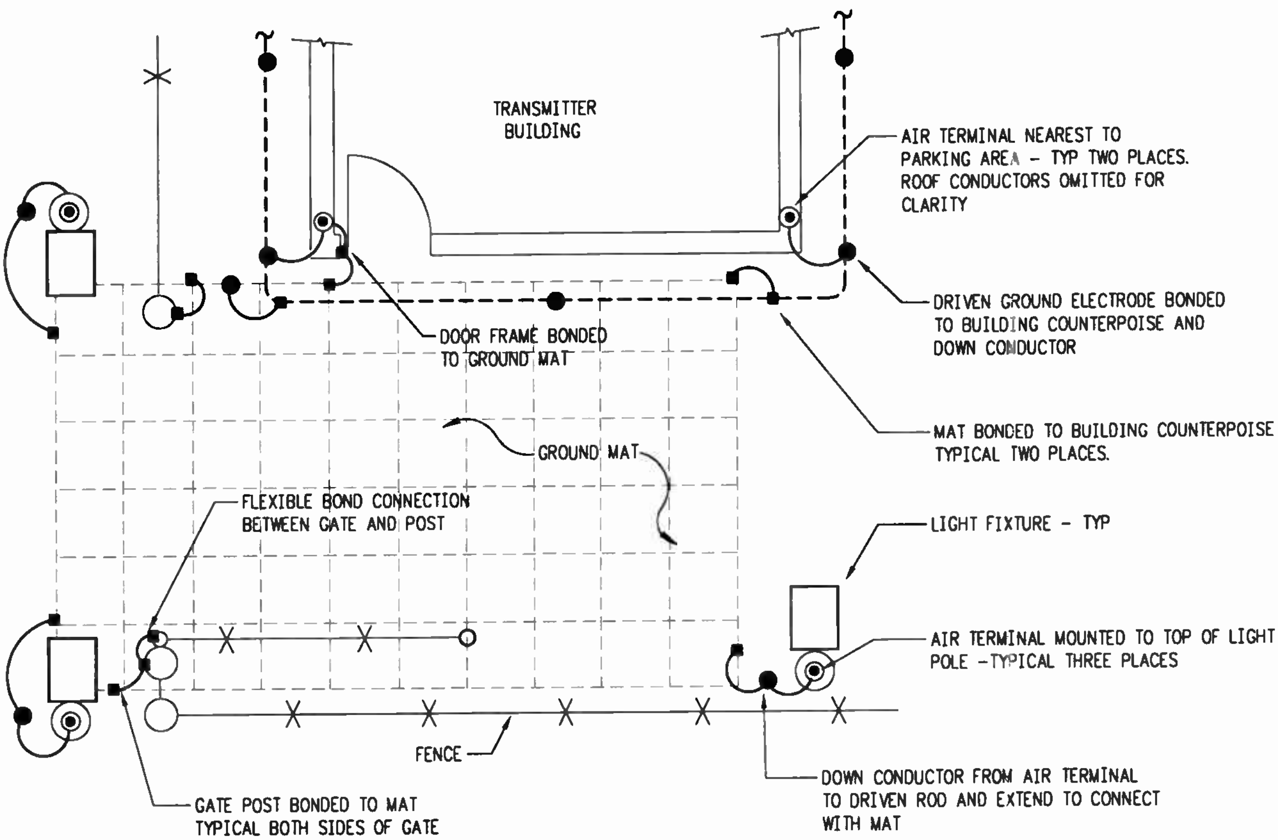

Figure 2.3-11. Personnel protection methods.

thermically welding a short length of flexible 2/0 AWG welding cable between the two elements.

The External Ground System

The effectiveness of a grounding system is a function of the type and extent of the electrode system used and resistivity of the surrounding soil. Soil resistivity is dependent on the quantity of free ions (chemical salts) in the soil, temperature and moisture content. The character of the soil below a particular site may also vary significantly with depth and location due to layering of different types of soil, the presence of hardpan layers, and subsurface rock.

Temperature is a major concern in shallow grounding systems because it has a major effect on soil resistivity. During winter months, the grounding system resistance may rise to unacceptable levels due to freezing of liquid water in the soil. The same shallow grounding system may also suffer from high resistance in the summer as moisture is evaporated from soil. It is wise to determine the natural frost line and moisture profile for an area before attempting design of a grounding system.

Figure 2.3-12 describes a four-point method for in place measurement of soil resistivity. Four uniformly spaced probes are placed in a linear arrangement and connected to a ground resistance test meter. An alternating current (at a frequency other than 60 Hz) is passed between the two most distant probes resulting in a potential difference between the center potential probes. The meter display in ohms of resistance may then be applied to the formula (shown in Figure 2.3-12) to determine the average soil resistivity in ohm-centimeters for the hemispherical area between the C1 and P2 probes.

Soil resistivity measurements should be repeated at a number of locations to establish a resistivity profile for the site. The depth of measurement may be controlled by varying the spacing between the probes. The probe length should not exceed 20% of the spacing between probes.

Once the soil resistivity for a site is known, calculations can be made to determine the effectiveness of a variety of grounding system configurations. Figure 2.3-13 presents equations for several driven rod and radial cable configurations which, after the solid resistivity is known, may be used for the purpose of estimating total system resistance. Generally, driven rod systems are appropriate where soil resistivity continues to improve with depth or where temperature extremes indicate seasonal frozen or dry soil conditions. (See Figure 2.3-14 for a typical U.S. soil resistivity map.)

Radials are also quite effective if placed below the

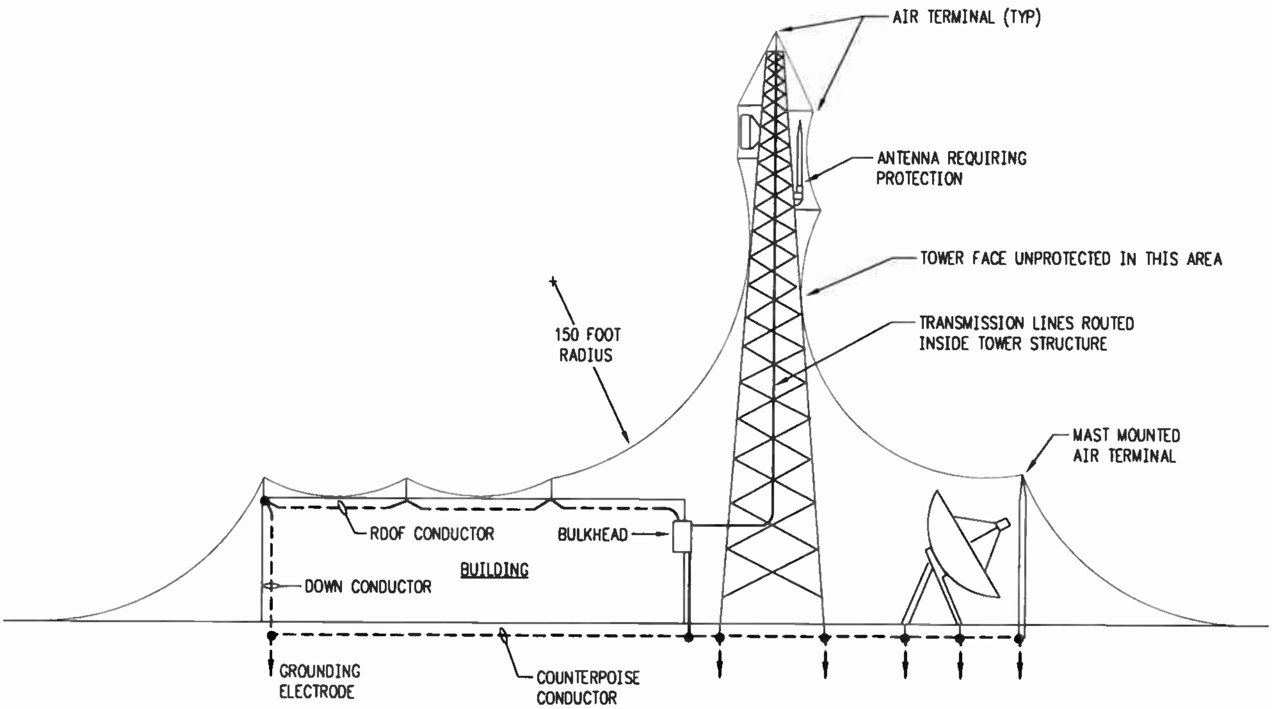

Figure 2.3-10. Example of *rolling ball theory* application.

Whenever practical, coaxial transmission lines and other wiring should be extended up the inside face of the tower to minimize the possibility of direct lightning contact.

Personnel Protection

The threat to personnel during a lightning strike ranges from the obvious danger of direct contact with a lightning strike to the more obscure effects of step and touch voltages. Protection from a direct strike when near or within structures is accomplished with traditional rolling sphere concept methods. However, to ensure that an adequate protective zone is provided in areas frequented by personnel the rolling sphere should be reduced to 100 ft radius.

Step and touch potentials are created as a lightning current passes through resistive soil and other available paths as it dissipates into the earth. A person in contact with only one point of the gradient will simply rise and fall in potential with the gradient without injury. A person in contact with multiple points on the earth or objects at different potentials along the gradient will become part of the current path and may sustain injury or death.

Figure 2.3-11 indicates a number of methods for protecting personnel from the direct and secondary effects of lightning.[2,9,17] A typical tower/transmitter site is used as an example. A technician responding to a service problem during a thunderstorm would likely exit his vehicle outside the gate, unlock and open the gate and move his vehicle into the inside yard. the technician would then leave the vehicle and enter the building.

The threat of a direct lightning strike to the technician has been minimized by establishing a protective zone over the areas to be traversed. This zone is created by the tower and air terminals mounted atop light poles.

Step potentials are minimized through the use of a ground mat buried just below the surface of the area where the technician is expected to be outside the vehicle. Ground mats are commercially available fabricated in 6 × 6 in. square pattern using #8 AWG bare copper wire. Each intersection is welded creating, for all practical purposes, an equipotential plan which short-circuits the step potential gradient in the area above the mat. The mat, as a whole, will rise and fall in potential due to lightning current discharges, however, there will be little difference in potential between the technician's feet. Mats should be covered with 6 in. of crushed stone or pavement.

The threat of dangerous touch potentials is minimized by bonding the ground mat to the building perimeter counterpoise, the fence at each side of the gate opening, bonding to the door frame of the transmitter building door, and providing a flexible bonding connection between the swing gate and its terminal post. Such bonding ensures that the object being touched by the technician is at or near the same potential as their feet.

Bonding both sides of the gate opening to the mat helps to ensure that the technician and both sides of the gate are at approximately the same potential while the gate is being handled. The flexible bond between the gate and its support post may be accomplished using a commercially available kit or by exo-

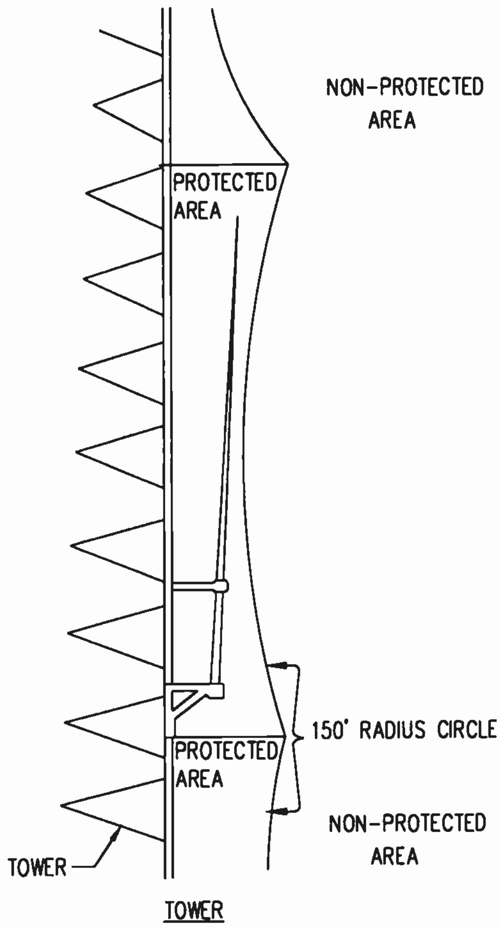

Figure 2.3-9. Side antenna protection method.

circuited in rigid metal galvanized conduit and the fixture itself should be constructed of metal to minimize surge currents on the wiring that would be difficult and expensive to eliminate from the source panelboard in the adjacent building. Surge suppression on the lighting circuit would still be required at the panelboard but it could be selected to handle minimal surge current.

A separate lightning protection *down conductor* is not necessary for adequate dissipation of lightning currents. The tower itself will always conduct the bulk of any lightning strike although a portion will travel on the coax shield and warning light conduit. An additional down conductor that is attached to the tower at intervals required by code will have a negligible effect on the division of current paths due to the inductance distribution of all components.

Lightning currents traveling down towers can, over time, cause arcing at tower joints, stripping away galvanizing and resulting in rusting. Maintenance, therefore of the tower system is important to long lasting, well performing components. Air terminals subject to heavy lightning currents of long duration can cause pitting and melting of points as well as severe mechanical stresses in mounting hardware. Bonding straps, cable fasteners and other miscellaneous hardware can loosen and allow movement or *whipping* of conductors from electromagnetic forces associated with unequal down currents in various components of the tower system. At least yearly maintenance is therefore recommended.

For guyed towers, guy wires can be very effective in dividing the lightning currents into additional paths to ground, therefore lowering the current and voltage stress to tower components and the service building bulkhead. Where guy wires contain insulators, special precautions must be observed. The insulators will be subject to voltage differences during lightning strikes occurring between guy to tower attachment points and the ground potential at the anchors due to ground currents and induced guy wire voltages. These voltage differences can reach hundreds of thousands of volts and can create arcing or *tracking* over insulators, resulting in ineffective isolation over time. Therefore, maintenance inspection of the insulators and selection of maximum insulative values for the insulators is very important.

The *Rolling Sphere Concept* is a protection strategy that is fully described in NFPA 780 and effectively applies to towers up to 150 ft high above level ground. (Figure 2.3-10 shows traditional lightning protection for a studio facility with an adjacent microwave relay tower.) Protective zones are based on an imaginary rolling sphere 150 ft in radius being passed over the structure. The sphere is also rolled around the structure tangent to earth. Air terminals are placed in such a way that the ball never contacts the structure or other objects requiring protection. Properly protected masts, light poles, and adjacent buildings may be taken into account when establishing zones of protection.

The protective zones created by the 150 ft radius sphere have proven statistically adequate for most facilities and are the basis behind most codes and standards.[6,7,8] An interesting way to think about structural lightning protection design is to imagine rolling an inked sphere of 150 ft radius around and over a structure. The ball should roll only on the earth, air terminals and other suitable metallic components which have been connected to the lightning protection system. Any other area which receives ink should be considered unprotected. Where grounded guy wires are present, the sphere rolls over the wire in similar fashion to protect items under the projected zone. This is similar to *overhead ground wire* protection described fully in NFPA 780.

Most broadcast towers, and much of the equipment they support, have sufficient mass and conductivity to resist damage from direct lightning contact. Localized burning, pitting and mechanical forces may occur in the immediate area of contact with the lightning channel; however, the brief duration of a lightning stroke creates little heating in areas away from the point of lightning contact. Figure 2.3-10 shows how air terminals, properly bonded to the tower, may be used to protect more sensitive objects.

Equipment Protection

Control of small potential differences that are deadly to electronic equipment and antenna cable, as measured between active circuitry and grounded media, is key to protecting equipment. Controlling the potential differences to a value below the equipment damage threshold will ensure that the equipment survives. Providing tighter voltage control to a value below the equipment upset threshold will help to ensure that the system rides through the lightning event without any noticeable effect. All protection, however, is predicated on the assumption of average or standard lightning strike parameters such as energy waveform and can therefore, never be 100% effective.

Personnel Protection

Protecting service personnel from the threat of a direct lightning strike, secondary flashing (sideflash), and controlling differences in potential (step and touch potentials) between different parts of their bodies during a lightning event must be integrated into any comprehensive tower protection scheme. Step potentials are voltage gradients seen along the surface or near surface of the earth as lightning current radiates hemispherically from its point of entry into the soil or grounding system. Touch potentials are voltage differences developed in horizontal and vertical elements of a structure, natural object, or system during the passage of lightning current. Both step and touch potentials can be hazardous and must be minimized.

Secondarily, the broadcast tower and associated building should also be reviewed for protection against lightning's effects. In most cases however, towers and equipment buildings will be self protected and provide a means to intercept lightning strikes, conduct the lightning current safely through or around the structure and dissipate the current into the earth. These characteristics however, are critical to personnel and equipment protection. Lightning current passing uncontrolled through a structure may result in deterioration of tower joints, ignition of combustible materials, generation of explosive forces in masonry and other moisture bearing materials and burning or tearing of roofing systems. Secondary flashing between the primary current path and nearby unbonded grounded objects may also pose a threat to persons in or near elements of the structure.

Protection Strategies

A typical broadcast tower installation will consist of an antenna tower in association with a studio building or an equipment hut for repeater locations. The preferred building type would consist of structural steel framing to maximize equipotential grounding and bonding characteristics. Where the buildings are not fully within the zone of protection provided by the tower or other adjacent structure, they must be provided with a Franklin Rod type system. Design requirements for this system are adequately documented and described in NFPA 780, Standard for the *Installation of Lighting Protection Systems*[6] and as supported by UL 96A[7].

Broadcast towers are normally 3 or 4 legged structures constructed of galvanized tubular or structural steel with sectional, vertical truss elements. They are either self-supporting or guyed and can be of various heights from a satellite dish near the ground to a 250 ft. or higher antenna support structure. Lately, however, some architecturally creative type towers of both steel and concrete have been introduced that cause some interesting challenges to lightning protection methodologies. Also, some towers are ground mounted, some are mounted on top of concrete or steel buildings of various heights and some are large enough to span, multi-legged over the broadcast building. It is therefore, impossible to describe detailed protection techniques for all types of towers. Basic requirements, however, will be presented so that application to any type tower can be easily extrapolated.

The tower structure itself is the basic lightning protection element that helps dissipate direct lighting strikes, minimizes voltage rise on associated antennas, coaxial cable and equipment and protects adjacent buildings. Where new towers are located in populated areas, increased lightning activity and dissipation of ground currents can cause local controversy, increased risks and can influence tower design complexity beyond the basic requirements presented herein.

Tower protection elements consist of the following:

- Grounding
- Coaxial cable shield bonding
- Enhanced strike attachment
- Warning light bonding
- Maintenance of joints
- Protection for side and top mounted antenna
- Grounded versus isolated guys

Proper tower grounding is essential to protection of all other systems and facilities interconnected with the tower. It should consist of exothermic weld connections between the tower base or legs and foundation reinforcing steel, anchor bolts, grounding radials, counterpoise rings, guy anchors and adjacent building counterpoise and fences.

Coaxial cable shields from antennas must be bonded to the tower at the top, near the antenna, and at the bottom where the cable leaves the tower. The cable should exit the tower as low as possible to minimize voltage gradient and current dissipation at the bulkhead panel on the building.

A 24 in. air terminal mounted on top of the tower will enhance the probability that the rod will be struck instead of the tower structure or any side mounted antennas, thereby minimizing maintenance from damaged antennas and pitting of tower steel. If the tower is over 150 ft high, side-mounted antennas above this level are vulnerable to direct hits and should be protected by mounting horizontal air terminals above and below the antennas, protruding at least six in. beyond the antenna. Since they are horizontal and located in the end nulls of the antenna pattern, the air terminals should not affect system performance. (see Figure 2.3-9). The warning light(s) on the tower must be

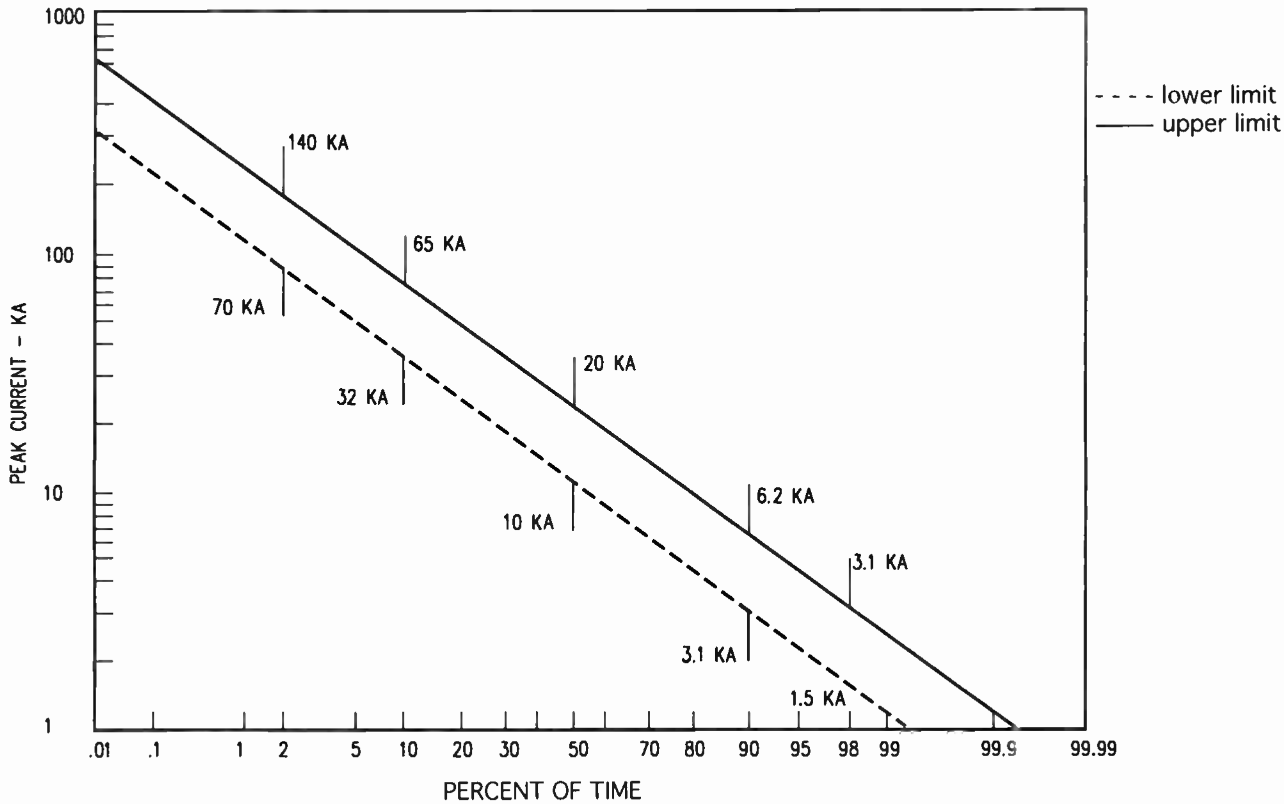

Figure 2.3-6. Lightning Stroke Intensity.

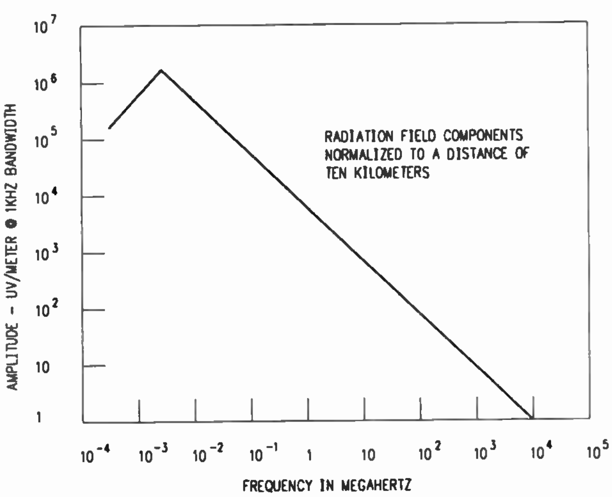

Figure 2.3-7. Lightning signal amplitude versus frequency.

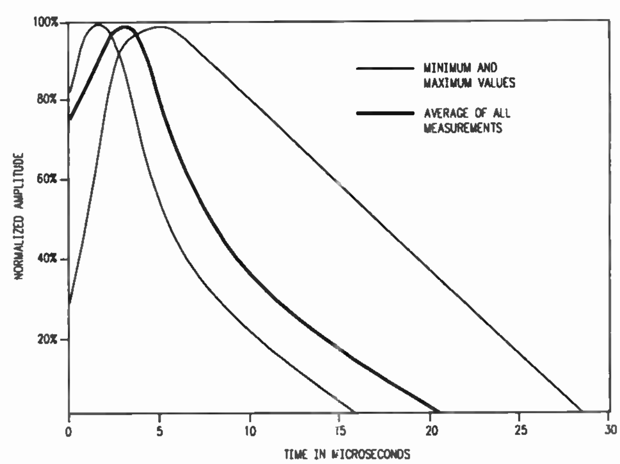

Figure 2.3-8. Typical lightning waveforms.

negative. As in remote strokes, inductive and capacitive properties of the wiring system may cause the circuit to act as a resonant tuned circuit, producing a ringing wave which alternates in polarity. References which categorize the waveforms and current levels for several types of circuits are listed at the end of this chapter.[12–16]

PROTECTION OBJECTIVES

Primary lightning protection objectives specifically for broadcast towers and associated building equipment wiring, may be grouped into two basic, primary categories—equipment protection and personnel protection.

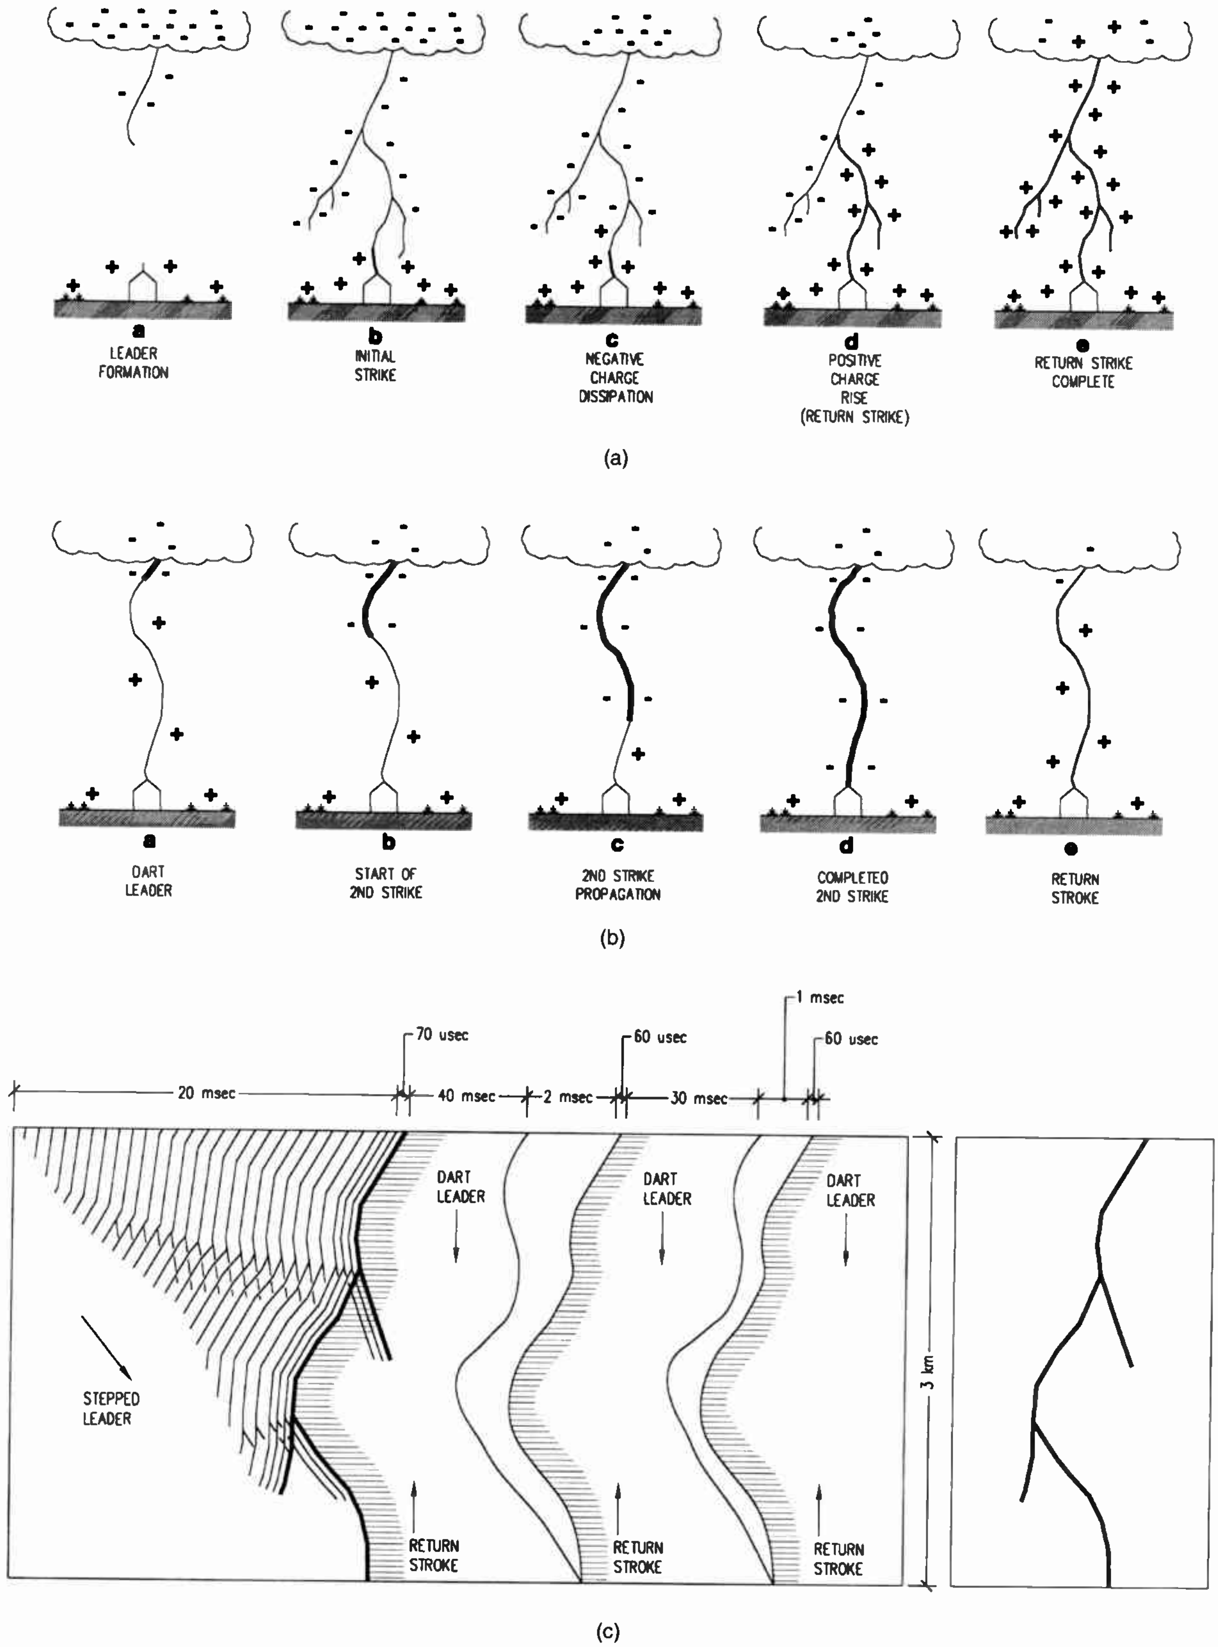

Figure 2.3-5. Typical lightning propagation development: (a and b) step-by-step process of a lightning strike, (c) time development of a stroke and the resulting composite.

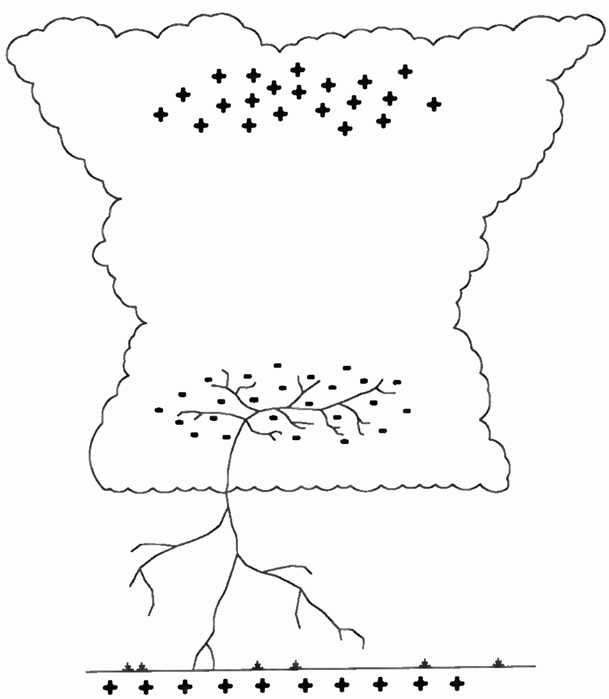

Figure 2.3-3. Typical mode of discharge in summer storms (Negative stroke predominance).

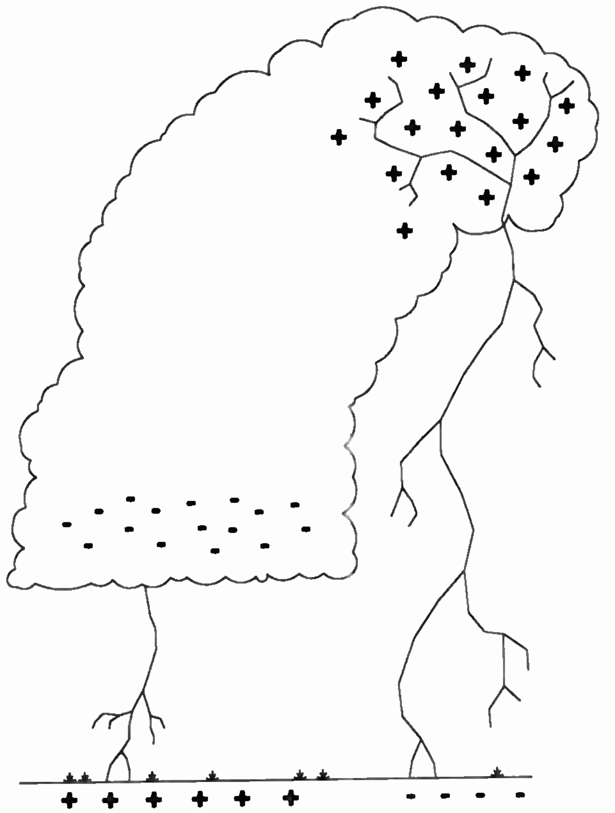

Figure 2.3-4. Typical discharge in winter storms (Positive stroke predominance).

strikes usually attach to the tower structure, building air terminals, tower mounted antennas and tower warning lighting. Remote lightning strikes can inductively couple the surge field into the tower structure, coaxial cable shields, warning lighting conduit systems, building rod systems and antennas. Both types of strikes can cause considerable damage if proper protection is not provided in the design of the tower/building system and in applied surge/lightning protection equipment. Design techniques include proper grounding and bonding, selection of tower/building location, coaxial cable routing and bulkhead design. Protection techniques include proper selection and placement of surge suppression devices for coaxial cables, lighting warning circuit, equipment building power service, tower mounted pre-amp equipment and emergency power equipment as well as air terminal protection for side mounted antennas mounted above 150 ft. and for the equipment building located outside the tower protected zone.

As mentioned above, the radiated impulse field from a remote lightning strike can pose a significant hazard to equipment and systems, particularly those which are interconnected by long lengths of cable. Figure 2.3-7 is a composite of lightning electromagnetic field measurements made by a number of researchers which have been normalized to a distance of 10 km. The figure shows a frequency domain distribution which peaks at about 10 kHz at an intensity of slightly more than 1 V per meter. It is important to realize that nearer strikes can create field strengths many orders of magnitude higher than those shown can. The predominant low frequency component is also very effective in coupling energy into systems of wiring, producing continuous frequency and ringing waveforms due to inductance, capacitance and resonant conditions, even if wiring is buried in the ground.

The time domain current waveform associated with a typical lightning strike is characterized by a very fast leading edge or risetime, followed by a more gradual decay. Technically, risetime is the period of time required for the wave to increase from 10 to 90% of its crest value. Decay time is normally expressed as the time measured between the wave crest and 50% of the crest value. A description of a waveform such as $1.5 \times 50\ \mu s$ for a 10 to 20 kA strike would indicate a single impulse waveform with a risetime of 1.5 μs and a decay time of 50 μs, to half peak value.

There are many variations on actual lightning waveforms seen in real world circuits. Waveforms such as those shown in Figure 2.3-8 may be found with risetimes measured in a fraction of a microsecond near the point of lightning entry to a circuit. Normally, however, the higher the lightning current, the slower the rise time and decay period such that a 250,000 amp strike will have a much slower rise time (30 μs) and 250 μs decay compared to a 10 to 20 kA strike. As a wave propagates through a wiring system, the risetime and the decay time will lengthen. The polarity of the impulse may be either positive or

Figure 2.3-2. 1989–1993 Composite of measured lightning flash density per year. Flashes per square kilometer. (Data supplied by the National Lightning Detection Network.)

field strengths of 100 kV per meter and higher. The field strength above the top of a 50 meter, well grounded, broadcast tower therefore could approach several million volts and result in upward charge streamers and corona discharge. A lightning strike to the tower is then a very real possibility.

The lightning process actually begins as a faintly visible stepped leader originating normally from the base of the storm cell. This leader carries the negative cloud charge toward the positive ground charge, forking and branching due to wind and random charge pockets in the air. As the leader nears the earth, one or more upward streamers will be initiated, usually from the tallest grounded bodies in near proximity to the downward leader. At some point, the downward leader will connect to an upward leader and return stroke currents flow in an effort to equalize the charge difference between the storm cell and the earth. The distance between the connection of the downward leader and the object producing the upward leader is called the *striking distance* and is the basis for the *Rolling Ball* theory. The striking distance is most greatly influenced by the amount of charge in the downward leader such that, the greater the charge, the greater the striking distance. Basically, the amount of leader charge and the surge impedance of the object being struck determine the value of lightning current.

In addition to *bottom of cloud* strikes, severe, long traveling lightning strokes can emanate from the positively charged top of storm cells to negative earth charges. Also grounded objects above 150 ft. tall can initiate upward leading charges, reversing the above process. Grounded objects, such as broadcast towers, taller than 150 ft., can be struck on the side of the tower instead of the top and can subject side-mounted antennas to direct strikes.

Lightning currents range from an average value of 20,000 amperes to a high recorded value of over 400,000 amperes. Many strikes contain up to 30 strokes just milli-seconds apart. These strokes appear to flicker or strobe, are usually wider, brighter and hotter than single strikes and can cause serious damage if not adequately, dissipated. (See Figures 2.3-5(a) through 2.3-5(c) for typical lightning propagation development. Figure 2.3-6 provides probability values of lightning stroke peak values.)

Lightning can affect broadcast tower structures and associated equipment or studio buildings in basically two ways—direct strikes and remote strikes. Direct

This reprinted material is not the complete and official position of the National Fire Protection Association, on the reference subject which is represented only by the standard in its entirety.

U.S.[1] and other countries have led to new maps depicting ground stroke intensity by location (see Figure 2.3-2). Data is now available in the U.S. and increasingly throughout the world to determine not only whether lightning occurred, but also stroke coordinates, discharge characteristics, flash density, direction of storm movement and other data that can be manipulated into very accurate charts, graphs, trend analysis, histographs, etc. Access to this extensive database can be secured through private and public sources via the Internet and may be useful in selection of broadcast antenna sites and level of protection.

Thunderstorms are of two general types—convection storms and frontal storms.

Convection storms are usually local in extent, of relatively short duration and account for the majority of storms in the U.S. They are caused by local heating of the air near the earth and therefore occur mainly during summer months and in warmer climates where moisture is present, although many convective storms are generated over mountainous areas. These storms can generate to great heights of over 40,000 ft. where vast amounts of moisture and high temperatures are present, producing intense lightning activity. However, they dissipate quickly as accompanying cloud shade and rain cools the earth and dissipates the clouds' source of energy.

Frontal type thunderstorms extend over greater areas, may continue for several hours and are usually more dangerous, causing greater damage than convection type storms. These storms develop from the meeting of a warm, moist weather front with a cold front which may at times extend for several hundred miles, exposing large areas to severe lightning discharges. (See Figures 2.3-3 and 2.3-4 for typical convection (summer) type discharges and frontal (winter) type discharges.)

The formation of lightning in all thunderstorms is generally believed[28] to be caused by ice/dust particles colliding with moisture particles in vertically generated air currents. The collisions create positive and negative charges within the cloud which eventually separate out so that negative charge concentration occurs near the bottom of the cloud and positive charges concentrate at the top. The negative charge at the bottom of the cloud causes a corresponding positive charge on the earth below the cloud. This charge difference between cloud and earth will commonly develop electrostatic

2.3
LIGHTNING PROTECTION FOR TOWER STRUCTURES

EDWARD A. LOBNITZ, P.E.
TILDEN LOBNITZ COOPER CONSULTING ENGINEERS, ORLANDO, FLORIDA

INTRODUCTION

Understanding how lightning works and its effects on tower structures, grounding and antenna systems is very helpful when trying to apply practical protection techniques. *Lightning protection* is never 100% and understanding the limitations or cost effective application of protection is an important part of the design process. Also, since no two installations are exactly alike, repetitive siting of towers will always require a review of *standard* protection to assure that expected protection has not been compromised.

Lightning is potentially one of the most hazardous natural occurrences on our planet. It can kill, maim, start fires, cause explosions, damage equipment, interrupt critical data transmissions, stop a shuttle from flying and cause many other disasters. It is also beautiful, awe inspiring, exciting, mysterious and challenging to all who are enchanted by its technical fascination. It is both predictable and unpredictable. The following statistics are surprising and sobering when we are asked to *protect* against such a power:

From 1959–1996	
Total injuries:	1,337
Fatalities by State:	
Florida:	374
Texas:	169
North Carolina:	168
New York:	128
Tennessee:	126

- A *typical* Florida thunderstorm can unleash 10,000 lightning strikes
- In Florida, lightning kills 10 and injures 35 people every year. It is more deadly, in recent years, than hurricanes, tornadoes or floods
- Nationally, about 90 people a year die from lightning and 300 are injured
- Lightning strikes the earth 100 times each second
- There are about 45,000 thunderstorms annually across the United States
- Property loss is estimated in the hundreds of millions of dollars annually.

Methods of protection from lightning have been changing ever since Benjamin Franklin's original studies of lightning and the creation of his lightning rod system—the Franklin Rod System. Although the exact physics of structure lightning rod protection originally was not fully understood, extensive research has greatly enhanced our understanding of lightning physics while also creating great controversies regarding theory and protection techniques. Also, electronic equipment has entered the picture in one of the fastest growing technologies of our century, but with inherent weaknesses to the effects of lighting. This has created even another huge industry known as surge suppression, with its own mix of technologies, theories, manufacturing methods and jargon to help further the protection methodologies and challenge *protection* designers with almost unlimited technical choices.

Fortunately, there are some standards to help *protection* designers through the maze of technologies available in order to evaluate effectiveness, technology comparisons, test results, performance claims and other criteria. Many of these standards are listed in the references at the end of this chapter.

These standards and publications are considered *consensus* standards since their committee members or testing agencies are comprised of members from across the industry or third party testing agencies. Only equipment that is verified to be in compliance with these standards and testing agencies should be used by protection designers. Claims by *other* equipment manufacturers regarding performance or construction should not be considered unless full verification and proof of claims by third party testing is provided. Lightning can cause great losses to life and property, and assumed protection must be equal to the task without question. More cannot be expected from lightning protection than it can be proven to provide, regardless of guarantee or guarantee claims.

LIGHTNING AND STORM DEVELOPMENT

The intensity of lightning storm activity throughout the world varies by location. Until recently, thunderstorm activity was measured by the number of *thunderstorm days* observed and reported. In the United States, data is reported through the National Weather Service and displayed on an isoceraunic map (see Figure 2.3-1). A thunderstorm day is defined as any day during which thunder is heard at a specific observation point. Since these observations merely confirm the presence of lightning and do not provide information regarding severity, number of ground strokes and stroke location, more complete data was needed to determine exposure risk. Recent atmospheric measurements throughout the

Base Insulator

The porcelain surface should be wiped clean with a soft cloth to remove accumulated dirt. A check should be made for cracks or chips on the porcelain surface. Scratches are often mistaken for cracks. Oil-filled insulators will display a wet surface or leak if cracked. If an oil stain or leak appears at the bottom of the porcelain on an oil-filled insulator and a crack cannot be found, incorrect loading possibly due to settlement of the pier should be suspected. A cracked base insulator should be replaced as soon as practical. Any sign of corrosion in the upper and lower bearing plates, rain shield, or lightning gap should be noted and corrected in a manner similar to that described for the tower structure. The lightning gap should be adjusted in accordance with instructions from the station engineer.

Tower Base and Guy Anchors

The tower base and guy anchors above grade should be visually inspected for spalling and cracking of the concrete. The soil surrounding the tower base foundation should be inspected for evidence of settlement. The anchor arms and surrounding soil should be examined for evidence of movement of the anchor. Any such settlement or movement should be noted.

Steel anchor shafts exposed directly to the soil should be inspected below grade for evidence of galvanic or electrolytic corrosion, especially in areas of high ground conductivity. Extreme caution should be exercised when excavating and backfilling during this inspection to ensure that the anchor's effectiveness is maintained.

Appurtenances

The ladder and its connections should be checked for corrosion and tightness along with the tower. The sleeve and belt of the safety device should be visually examined and tested near the ground level before each use.

Inspection and maintenance of the elevator system should be in accordance with the manufacturer's instructions. It is a good practice to operate the elevator at least once a month.

Inspection and maintenance of the lighting system should be in accordance with the manufacturer's instructions. Checks for corrosion in the conduit, junction boxes, and light fixtures should be made along with the tower inspection. Any obstructions in the breather or drain in the conduit should be removed. Broken or cracked glass and any leaking gaskets should be replaced.

If the tower is equipped with an isolation transformer, its surface should be inspected for cracking and splitting. The surface should be painted with a good quality alkyd varnish. Badly cracked surfaces should be filled with a mixture of varnish and microscopic glass ball powder and the area cotton taped over and varnished.

Frequency of Inspection and Maintenance

A suggested schedule for inspections and maintenance performance is shown in Figure 2.2-10.

A written report of each maintenance and inspection procedure performed should be made and filed with the station engineer.

SUGGESTED INSPECTION AND MAINTENANCE SCHEDULE

ITEM	Daily	Monthly	Before Each Use	Annually	After a major wind or ice storm	Manufacturer's Recommendation

Lighting System						x
Lamp Failure	x					
Conduit Systems, fixtures				x		

Figure 2.2-10. Suggested inspection and maintenance schedule.

Guys and Guy Insulators

Inspection of the guys can be done visually only for those portions adjacent to the anchors and tower. The range of this visual inspection can be extended by using binoculars, but its reliability is limited. If experienced riggers are available, it is possible to ride down the guy on a boson's chair, but this method should be used only under the supervision of qualified personnel.

Other maintenance requirements include the following: A visual inspection should be made of the guy cables, insulators and hardware. Cables and dead end grips should be checked for nicks or cuts in the individual strands. All porcelain insulators should be checked for chips, cracks and oil leaks where appropriate. Fiberglass rods should be checked for surface tracking (black carbon track marks on surface of the rod), breakdown of the epoxy surface and exposure of the individual glass strands. The manufacturers should be consulted with regard to corrective action.

- *Corrosion.* If the guy cables show signs of corrosion, consideration should be given to coating or replacing them. The cost of cleaning and coating the cables should be considered along with the life expectancy of the coating when comparing it to the cost of replacement. All guy hardware should be checked using the same procedures for inspection and corrective actions as previously described for the tower structure.
- *Connections.* All pins should be checked for tightness and the condition of the cotter keys. Dead end grips should be checked to ensure that their ends are completely snapped close, preventing any ice from forming inside. The surface appearance of the guy strand immediately next to the connections should be noted for evidence of slippage. Threads should be given a light petroleum coating.
- *Tensions.* Guy tensions should be checked in conjunction with the tower alignment. These tensions should be measured at the anchor end and compared to the specified values. It is important to remember that they are dependent upon the ambient temperature.
- *Compression* insulators are designed such that the porcelain element is in compression. Simple low voltage types are a single piece of porcelain placed between interlocking loops of the guy. Such insulators are available for mechanical working loads up to 40,000 lbs. For higher loads, oil filled and open types are used. The most common uses of compression insulators in broadcasting are for break-ups and as primary insulators (in-groups of three or four) on low-power antennas.
- *Tension* insulators come in many forms, including porcelain rods (not permitted in structural applications), fiberglass rods, synthetic ropes and oil filled safety core types. Tension insulators are used as primary insulators with corona rings to reduce the electrical field stress at the end fittings. One insulator is required at each guy attachment point. Since the voltage level is different at each point on the tower, different voltage ratings may be required for some insulators at certain guy attachment points. Tension insulators are available in a wide range of electrical and mechanical ratings to meet most needs.

For the usual guy arrangement with cables in three directions, it is necessary to measure the tensions in only one direction while keeping the tower plumb in all directions. For guy arrangements with cables in four or more directions, it is necessary to measure the tensions in only one of the two guys in the same vertical plane while keeping the tower plumb in that plane.

There are several methods of measuring guy tension with varying degrees of accuracy. For small guys up to 3/4 in., a shunt dynamometer calibrated for the size and type of strand is often used.

For larger guys, a series dynamometer may be placed in a temporary line between the anchor and a clamp on the cable. This line is then tightened until the permanent connection is relieved, and the tension is indicated on the dynamometer. Hydraulic jacks with a calibrated pressure gauge or load cells can be used in place of the temporary line and dynamometer. These are particularly effective for large guys attached with bridge sockets.

There are two indirect methods of measuring tensions in guys that do not have any large insulators or other loads in them. The intercept method consists of sighting along a straight bar attached at the bottom of the guy and measuring the vertical distance between the point when the line-of-sight intercepts the tower and the point where the guy is attached. This distance can be accurately estimated by counting the number of bracing panels. The tension in the guy is directly related to this intercept distance, the weight of the guy and its length and slope.

The tension in a guy cable is also directly related to its length, weight and natural frequency of free vibration. The national frequency can be determined by putting the guy in motion with your hand and measuring the fundamental period with a stopwatch. It should be noted that because a guy slopes, the tension on it varies along its length, and this method will only provide the average tension and not the tension at the anchor point. For long cables, this difference can be significant.

All tension measurements should be recorded along with temperature, wind speed and direction. If any substantial changes are noted from the values previously measured, careful checks for slippage of all connections should be made.

Tolerances for guy tensions should be as provided by the designer. In the absence of any other tolerance, tensions should be within plus or minus 5% of the specified values.

Any necessary adjustments in tensions can be made by adjusting the turnbuckle or bridge socket at the anchor. Make such adjustments slowly and carefully. Never leave less than three threads sticking through the turnbuckle body or nut on the socket U-bolt. Remember that the tower must be kept plumb.

isting structural components. The details and specifications for this work must be developed by the structural engineer who analyzes the tower.

Leg members may be strengthened by installing additional bracing or by field-welding additional material to them. Specific procedures in accordance with the American Welding Society *Structural Welding Code* must be provided and followed if field welding is required.

Bracing members and guy cables may be replaced with stronger components. Careful attention must be given to the connections for the new components to ensure their compatibility with the existing tower, as well as providing the required strength for the new components. When replacing components it is essential that temporary bracing or guy cables be installed before removing any existing component, and that it remain in place until the new component has been installed.

It is necessary that damage to the protective finish on existing members due to field welding or reaming be repaired. If required, the affected areas must be painted for aviation obstruction marking.

Foundations and guy anchors are the most difficult components to strengthen, and they may prove to be the limiting factor in determining a tower's capacity. The nature and feasibility of strengthening these components depend on the specific soil conditions.

INSPECTION AND MAINTENANCE PROCEDURES

To ensure trouble-free performance of a tower and its appurtenances, it is desirable to have a regular inspection and maintenance program. Portions of the program can be done by station personnel while others require experienced tower personnel.

Safety precautions should be observed at all times when working on or around the tower. If the tower itself is energized or if a high intensity RF field exists from antennas mounted on it, no work should be done on the tower without clearing it with the station engineer. When climbing the tower, safety belts and climbing devices should always be used. Automatic safety features on elevators should never be bypassed to save time. It is a good idea to never work alone. Failure to observe proper safety measures can result in serious injury or death.

Tower Structure

A visual inspection should be made of the entire tower structure to determine if any of the members have been deformed or damaged. Any bowed or kinked member should be noted as to type, location in tower, and nature and magnitude of deformation or damage. This information should be reported to the tower designer for evaluation and recommended action.

Condition of Paint

A visual inspection should be made of the entire tower structure to determine the condition of the paint. If the painting of the tower is for aircraft observation marking only, and not for corrosion protection, it is necessary only to note any general deterioration rather then small blemishes and scratches. If repainting is necessary, it is important to properly prepare all surfaces and select paints that are compatible with existing finish.

Corrosion

Small scratches in the galvanized surface are not detrimental as the exposed surfaces will be protected by cathodic action of the adjacent zinc. If corrosion is observed, the source should be determined and noted. The affected areas should be wire-brushed clean to bare metal then painted with a zinc-rich prime coat and, if necessary, a finish enamel coat of the appropriate color.

Connections

All bolts should be checked for tightness. Any loose bolts should be tightened in accordance with the original installation instructions.

Alignment

The tower structure should be checked for alignment using an engineer's transit. This check should be done only on a calm day (with wind velocity less than 10 mph), and in conjunction with measuring the guy tensions.

Both plumbness and twist of a tower can be calculated from the measured horizontal deviations of each tower leg member from true vertical. Thus three transit set-ups (one on each leg azimuth) are required for a triangular tower, and four for a square tower. When the transit has been properly leveled, set the vertical cross hair on the edge of the vertical leg at the tower base and lock the instrument in this position. By moving the telescope upward, it is then possible to observe the straightness of the leg over its entire height. The magnitude of misalignment can be accurately estimated by comparison with the tower leg diameter. A record should be made of the observations of each leg at each guy level.

Tolerances for plumbness and straightness should be provided by the designer. ANSI/TIA/EIA-222-F-1996 gives a plumbness tolerance that limits the horizontal distance between the vertical centerlines at any two elevations to 0.25% of the vertical distance between the two elevations. This should never be exceeded. A good rule of thumb in the absence of other data is to keep the tower plumb and straight within the diameter of the leg members. ANSI/TIA/EIA-222-F-1996 gives a twist tolerance of 0.5° in any 10 ft and total twist limit of 5°.

If straightening of the tower is required, it should be done by adjusting the guy wires.

When checking the plumbness of top mounted poles and pylon antennas, the effects of direct sunlight on them must be considered. It is best to make these checks early in the morning or on a cloudy day.

equipment and experienced rigging personnel. It is also important that the firm have adequate insurance coverage including workman's compensation, general and automobile liability, and builder's all-risk for direct damage to the tower and antennas being erected.

Owner's Preparation

Prior to the arrival on site of the erection crew, the site should be made ready for work to begin. These preparations include:

- *Access.* Suitable access from public roads for delivery of the tower materials and erection equipment is required. While a paved roadway is not necessary, the access must be able to handle heavy trucks and construction equipment.
- *Permits.* All necessary building and construction permits should be obtained and posted as required. Any inspections required during construction should be noted.
- *Clearing.* A work area must be cleared to permit unloading, sorting, and assembling the tower. Paths from the tower base to the guy anchors must be cleared for a width adequate to permit hauling the guy cables to the anchors and pulling them to the tower. Paths must also be cleared for the hoist line from the tower base to the hoist location, and for the tag line used to stabilize the loads as they are lifted. The sizes and locations of these cleared areas should be agreed upon beforehand with the erector. A typical layout is shown in Figure 2.2-8.
- *Electrical Power.* Power for operating temporary aircraft warning lights must be available before erection begins.

Assembly

The usual procedure for erecting a guyed tower is to assemble the individual sections on the ground and then lift them one at a time as an assembled unit. For a self-supporting tower, the wider sections near the bottom of the tower are often assembled in the air as the tower is constructed.

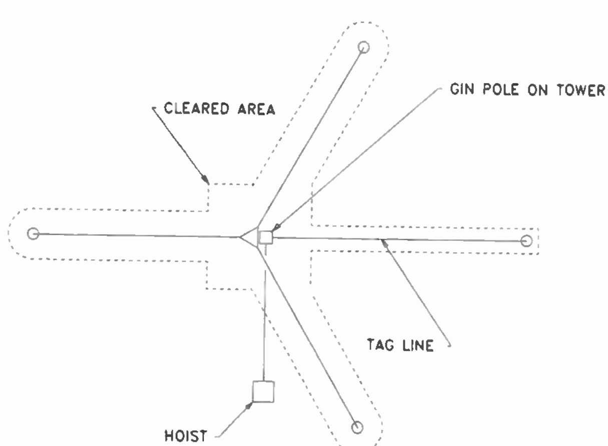

Figure 2.2-8. Typical layout for guyed tower.

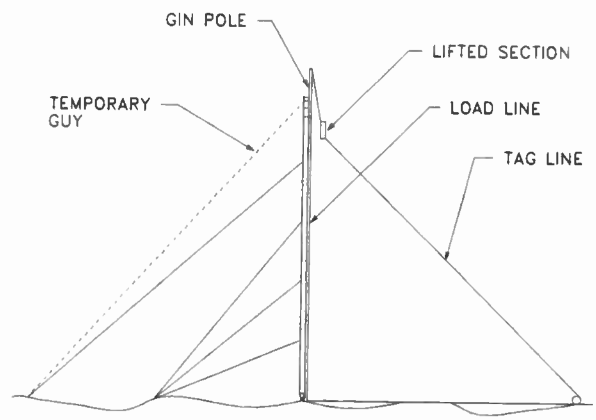

Figure 2.2-9. Typical erection setup for guyed tower.

Assembly of the tower sections should be done on a level bed to ensure that they will be straight and not racked or twisted. Bolts must be properly tightened and have a locking device. For high strength galvanized bolts, tightening by the *turn-of-the-nut* method is preferable to using a calibrated torque wrench.

Stacking

For a guyed tower, the first group of three to six sections are often joined together on the ground and then lifted into place using a crane. This portion of the tower is then guyed with temporary cables, and the remaining section are erected one at a time using a vertical boom or *gin pole*. This boom is moved or *jumped* up the tower as each section is installed. This arrangement is shown in Figure 2.2-9. Temporary guys to stabilize the tower should be used when instructed by the designer.

For a self-supporting tower, a crane is often used to lift as many of the tower sections as possible, after which a gin pole is installed and used for the upper sections beyond the crane's reach.

Temporary aircraft warning lights must be installed at the top of the construction at the end of each day.

The tower should be grounded as soon as the first section is in place.

Guy Installation

When the tower reaches a guy attachment level, the cables at that level are installed. The guys in all three directions should be pulled out simultaneously to prevent any large unbalanced loads on the tower.

The tower should be checked for plumbness as each set of guys is installed and tensioned. Maintaining a plumb tower during erection eliminates the need for time-consuming adjustments later. Final tensioning of the guy cables and a plumbness check are done after the entire tower is erected.

REINFORCEMENT AND MODIFICATIONS OF EXISTING TOWERS

When equipment is replaced, relocated or added to a tower it is often necessary to reinforce or replace ex-ing of the tower, showing where the transmissions lines, conduits, ladder, etc. are located, is also required. The use of presumptive values can result in an analysis with little value.

FOUNDATIONS AND ANCHORS

It is most difficult to predict the cost of the foundation system of a tower installation. This is due to the nonhomogeneous nature of soils, and the uncertainty of the conditions that may exist below grade. Therefore, it is necessary to have an investigation made of the subsurface soil conditions.

It is important to note that the soil design parameters given in the ANSI/TIA/EIA-222-F-1996 Standard are intended to serve only as a basis for preliminary design and estimating of foundation cost prior to obtaining specific soil data. They should not be used for the final design without verification by geotechnical investigation.

Soil Investigation

The soil investigation should be made by an engineering firm, which specializes in soil investigation and evaluation, and is familiar with the general area of the tower site. It should consist of making a test boring at each foundation and guy anchor location, analysis of soil samples taken from the borings, determination of ground water levels, recommendations of parameters for designing the foundations, identification of any special construction procedures required, and recommended backfill specifications. Other soil characteristics or properties may be required because of local conditions, such as the soil resistivity to determine if any special corrosion control methods should be implemented. If piles or rock anchors are necessary, recommendations related to these should be provided. It should also address requirements for frost protection and buoyancy effects.

Because the loads imposed on tower foundations are unique from those for conventional buildings (tower foundations have large uplift and horizontal components), it is important to provide the soil engineer with the loading conditions before they make their investigation. This will enable the engineer to plan their work in a manner suitable for obtaining and reporting the characteristics relevant to designing for the projected foundation loads.

Self-Supporting Tower Foundations

Except for relatively small towers with narrow base spreads, isolated foundations at each leg are usually more economical than a single mat for all legs. These foundations may be spread footings, drilled caissons or driven piles. If sound rock is present at shallow depths it is often economical to anchor the footing to the rock. These anchors should be proof-loaded to ensure their holding capacity in uplift.

Since these foundations are subjected to large uplift forces, it is important to consider buoyancy effects if ground water is present. Also, if driven or cast-in-place piles are used, they must be adequately anchored to the reinforced concrete cap.

Guyed Tower Base Foundations

These foundations may be spread footings, drilled caissons or driven piles. Since they are subject only to downloads with relatively small horizontal forces, they require no special anchorage details for uplift, unless they are placed above expansive soils. Buoyancy is usually not a problem.

Guy Anchors

Deadmen (buried reinforced concrete blocks), drilled caissons or driven piles may be used for these foundations. If sound rock is present at shallow depths it is often economical to anchor the foundation to the rock.

These foundations are subject to large horizontal forces as well as vertical uplift. Therefore, deadmen must have a large enough frontal area bearing against the soil to resist sliding; drilled caissons must have sufficient diameter and depth to prevent excessive lateral deflections as well as pull out from uplift; and driven piles must be sloped to prevent large lateral loads being imposed on them. Rock anchors may be installed along the slope of the resultant of the horizontal and vertical loads, or they may be installed vertically and post-tensioned to clamp the concrete cap to the rock to prevent sliding. Because of the uplift forces, it is important to consider buoyancy due to ground water and to provide adequate anchorage for driven or cast-in-place piles.

Construction

Since nearly the entire foundation system will be below finished grade and not subject to later inspection, it is important to carefully monitor its construction. The following items should be verified:

- Location and alignment of anchors in plan and elevation.
- Condition of excavation surfaces on which concrete will be placed.
- Position, size and grade of reinforcement steel.
- Placement of concrete to prevent voids and air pockets.
- Strength of concrete using test cylinders for 7 and 28 day break tests.
- Protection of concrete against freezing during the curing period.
- Placement and compaction of backfill.
- Driving records and/or load tests of piles.
- Proof loading and post-tensioning of rock anchors.

For towers with extensive foundation systems, it is advisable to retain an independent inspection service for this work. Often the firm making the subsurface soil investigation can also provide this service.

ERECTION

The erection of towers is a highly specialized field and should be performed only by firms having the proper easily controlled for lines installed in the future. Therefore, if the installation location of both the initially installed and future transmission lines can not be regulated, it may be prudent to prohibit the use of this procedure.

Width Restrictions

Some antennas impose restrictions on the width of the supporting tower. One common example is a side mounted FM antenna requiring a maximum width of 18 to 24 in. For antennas with more than eight bays, this results in a very slender structure. When placed at the top of a tall, guyed tower, the design of the guy system for this structure becomes extremely critical. Use of a cantilevered pole structure above the top of the main tower should be considered for these cases.

Another example of width restriction is a panel-type TV or FM antenna mounted on the faces of the tower. Here, too, it is often better to support these antennas on a cantilevered structure above the main tower rather than placing guys within the aperture of the antenna.

As previously mentioned, it is desirable to place large waveguides inside the tower near the vertical centroidal axis to prevent large torsional loads. This requires a tower having a minimum face width in the range of 7 to 8 ft to accommodate the waveguide and its supports.

Initial and Future Considerations

Because the antennas and transmission lines have such a significant effect on the tower design, it is important to consider all possible uses for a tower before it is designed. It is better to have unused capacity than to undergo expensive modifications or replacement in several years to obtain additional height or accommodate another antenna. This has become apparent in recent years with the proliferation of microwave, two-way communications, cellular and personal communication systems.

When providing for multiple antennas, it is important to determine not only the number and type of antennas and lines, but also their location on the tower. The distribution of load is equally important as magnitude.

Triangular top platforms (candelabras) to support broadcast antennas on each corner have been successfully used for many years. They have the advantage of placing all antennas at the same height. A variation of this platform to support only two antennas (tee-bars) has also been used. Both of these systems require multiple guy cables at the top platform to provide adequate torsional stability. It is possible to design the tower for a multiple antenna support platform without installing all antennas at the same time.

Another arrangement of multiple antennas is stacking (installing one antenna atop the tower and arranging others along the tower, one below the other). This arrangement can also be combined with a multiple antenna support platform.

If capacity for microwave antennas is required, it should be provided near guy levels and preferably above to minimize interference with the guy cables. The guy system and web bracing at these levels must be designed to provide adequate torsional rigidity.

Capacity for small antennas may be provided at various locations throughout the height of the tower. One arrangement for a large number of antennas is to provide a platform around the outside of the tower that is large enough to support the radio equipment for these antennas. The antennas can be mounted on the outside railing of the platform, thereby requiring only a short run of coax. Electrical power must be provided to the platform. This arrangement imposes a large concentrated load at the platform location with a relatively small uniform load between the tower base and the platform. If the same number of antennas were mounted along the tower and each fed by an individual coax line from the base, there would be only small concentrated loads at the antenna locations, but a relatively large uniform load due to the lines. This is an entirely different distribution of load, and would have a pronounced effect on the design.

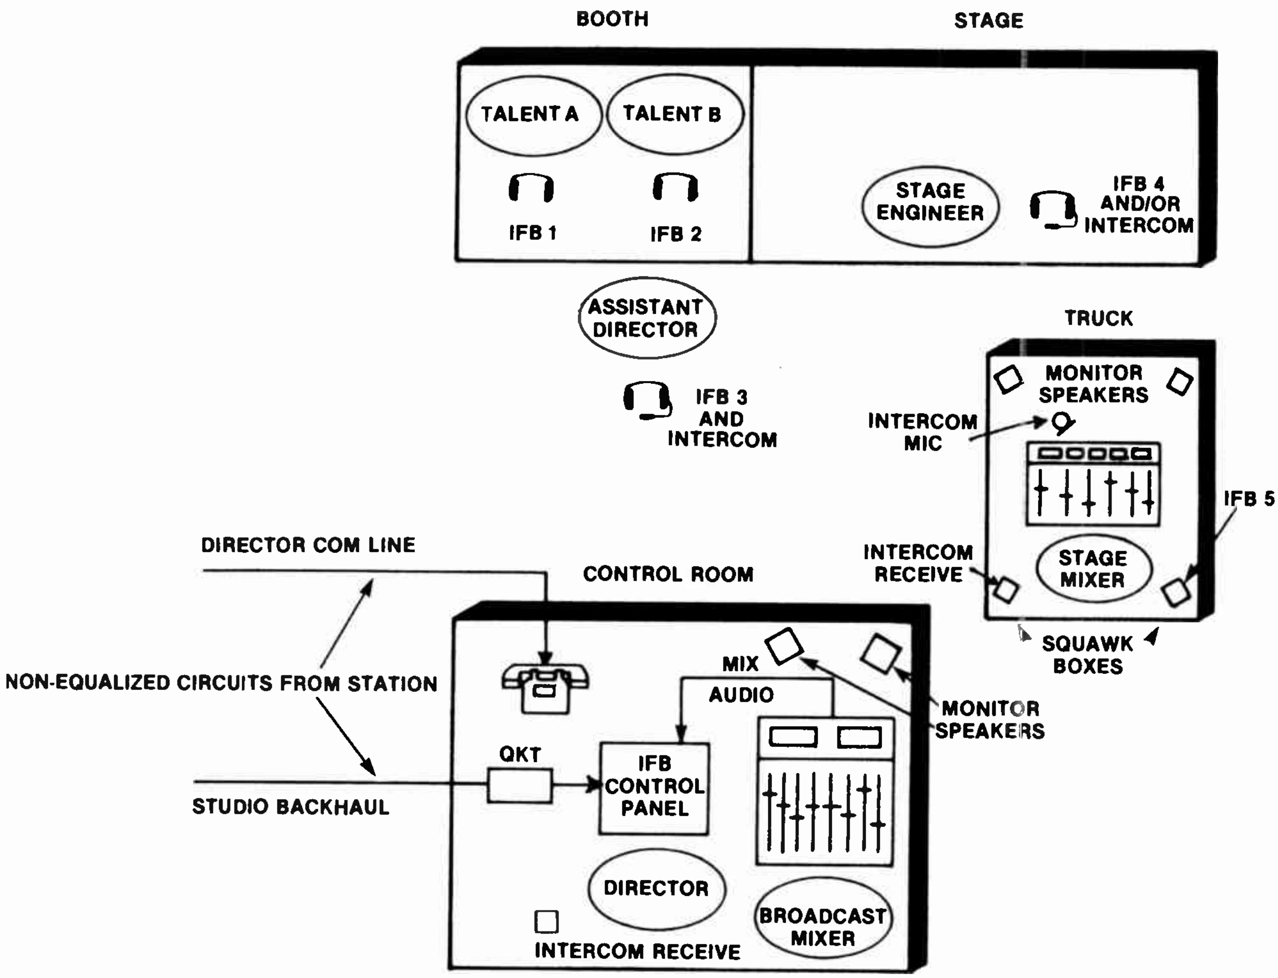
Another important consideration for future antennas or height extension is the electrical system. If an extension in height is planned, the wiring for the aircraft warning light system should be designed so that any additional lights can be connected to the system without adding or replacing wires in the existing conduit. The same holds true for any circuits required for future antennas. If the necessary wiring cannot be provided during the initial installations, capacity should be provided for additional conduits to hold the future circuits.

Replacement, Relocation, or Additions to Existing Towers

Since every tower has been designed for a specified arrangement of equipment, changes should not be made without considering their effects on the structural adequacy of the tower.

Two common misconceptions related to changes in equipment are "lower is better," and "smaller is better." Neither is necessarily correct, especially for guyed towers. Decisions based on these premises can have serious consequences.

It is much better to have a structural analysis of the tower made by a structural engineer experienced in tower design. Because of the significant changes that have been made in the methods of specifying loads in the various revisions of the design standard, the analysis should be made using the same criteria for wind and ice loads used for the original design and also for the current revision of the standard. This analysis will determine if any overstresses would occur in the tower or its foundations, and what modifications and reinforcing would be required to retain the structural integrity. To perform this analysis, it is necessary for the engineer to have complete data on the tower and its foundation including configuration, member sizes, and material strengths. It is also necessary for the customer to provide the engineer with a complete inventory of existing antennas and transmission lines on the tower along with the proposed equipment. A plan view draw-



NOTE: DIRECTOR'S CUES TO BROADCAST MIXER ARE ACOUSTICAL BECAUSE THEY ARE IN THE SAME ROOM AND NEITHER IS WEARING HEADPHONES. THE DIRECTOR CAN TALK TO ANY OF THE FIVE IFB STATIONS INDEPENDENTLY OR COLLECTIVELY. PROGRAM AUDIO SELECTION CAN BE VARIED BETWEEN EACH IFB STATION. ALL INTERCOM MICS ARE PUSH-TO-TALK.

Figure 3.9-15. Communications plot for a complex live remote broadcast. Stage mixer can use simple intercom (with no program audio) for communications to stage and other personnel, while main control room uses interruptible foldback system (IFB) to coordinate entire broadcast.

If critical, multi-station monitoring and communication is necessary at the remote site, an IFB system may be required. This device combines the function of intercom and monitor, such that a director, either on site or elsewhere, can communicate with and cue various personnel at the remote (talent, stage managers, floor directors, engineers) via headset or loudspeaker, using a multi-station intercom. The director's control panel for the IFB system is typically equipped with push-to-talk individual station and *all-call* (talk to all stations) buttons. What differentiates the IFB from a standard intercom is that when the director is not talking to an IFB station, that station receives program audio. The director's cues temporarily interrupt the program audio, which returns after the director's message has ended, hence the term IFB. Unlike a traditional intercom, the IFB system is usually not bidirectional, but rather feeds one-way from the director out to the various receive stations. Figure 3.9-15 shows a typical IFB layout in a complex remote situation.

Most IFB systems allow the use of two or more different program audio sources to be selectively routed to different stations, so that one station could be fed the dry stage mix, for example, while another station heard the whole remote transmission with continuity included. Both would hear the director when their channels were designated for communications, regardless of which program audio channel were selected. Off site IFB (in which the director is not at the remote location but back at the studio) is often referred to as a (PL) *private line*; dial-up or leased telco lines are used for PLs, along with wireless return links or cellular phones, in many ENG cases.

Some IFBs are stereo capable. Besides allowing the system to provide a stereo program feed to all stations, these systems are usually set up to place the director's communications into one channel only. This makes it easier for talent (listening on stereo headphones) to distinguish between program and communications audio. It can also allow the communications to interrupt only one channel, keeping program audio continuous (or only slightly attenuated, if desired) in the other channel.

Set-up and Testing Procedures

A tone oscillator is useful in setting up the remote broadcast. Most mixers designed for remote applications include an oscillator that can be switched on to the program channel. This feature is especially useful when a telco line is employed to return program audio to the studio. If the oscillator has multiple frequencies, so much the better. Phone line tests for frequency response, S/N, headroom, and relative polarity for stereo broadcasts should be performed. Phase response and distortion tests are also useful, if time and test equipment permit. (See Chapter 3.11, *Common Carrier Audio Program Services*, for detailed testing procedures.) If any noise reduction or other enhancement devices are being used across the line, testing should be performed with them bypassed. After the line proves satisfactory, engage these devices and recheck.

Multi-frequency checks are less critical with digital backhaul systems, because these are typically quite flat within the passband. Nevertheless, simple level and polarity checks are still worth performing with ISDN and T-1 services.

Having the proper monitoring facilities is important to the success of any remote broadcast. A loudspeaker (or well-matched pair for stereo broadcasts) and a set of headphones should be provided for the remote crew. Not all portable mixers can support a loudspeaker and multiple headphone outputs, and so a separate power amplifier and headphone booster may be needed. Speakers and headphones selected should be reliable and familiar. Crew members should listen to familiar music over these while setting up, to attune themselves to the speaker in this environment, however, since different rooms and speaker placements will produce drastic changes in the sound of any speaker.

After checking phone lines or wireless links for continuity back to the station, setup the monitoring system first, and check it for clean audio. Then add the other elements or subsystems of the setup one at a time, checking the monitors for continued clean response after each. In this way, when any deleterious effects are heard (hum, buzz, hiss, etc.), it will be fairly simple and quick to track down the offending hardware or interface method.

An off-air receiver is a requirement for nearly all live remote broadcasts. The receiver gives the remote crew a way of checking the total link and allows easy cueing of talent at the event.

A separate dedicated telephone set is suggested for complicated remote broadcasts. The phone provides an easy means of communicating with the studio. It can also serve as a backup line for program audio in case the RPU system or telco program service should fail. And in cases where the remote broadcast originates from outside the coverage area of the station, it is essential for monitoring as well as communicating. If digital telco service is employed, it is generally not much more expensive to have this return (or *backfeed*) line be of the same fidelity as the transmit circuit.

Wireless Microphones

The use of wireless microphones to free up the talent at a remote broadcast is gaining popularity with stations involved in RENG activity. The advantages to the talent are obvious: complete freedom of movement and nothing to carry around but a microphone and air monitor receiver. There are no controls or meters for talent to worry about. The range of a wireless mic is somewhat limited, but a properly designed system for remotes that are more or less stationary can provide simple setup and coverage of an event.

The receiver used in conjunction with the wireless microphone may use either diversity or non-diversity reception techniques. A non-diversity receiver is used where multipath cancellation is not a problem, such as in open areas or when conducting fixed position interviews. If, on the other hand, the wireless mic is to be used in several places and the possibility of multipath cancellation exists due to nearby reflective objects, a diversity receiver is recommended.

The diversity receiver uses two antennas that are physically separated by a distance varying between several inches to several dozen feet. In some diversity receivers, two complete RF sections are used. The diversity receiver automatically selects one of the two signals based on its criteria for better reception. (Some receivers combine the two signals through a phase shifting network.) The switching of RF sources occurs silently without any *squelch type* noise bursts.

Many wireless microphone systems include audio companding circuits to extend the dynamic range and lower the apparent noise floor. A properly engineered wireless microphone system can be treated by engineering personnel as essentially a piece of wire between the microphone and the audio console input. Both VHF and UHF frequencies are used. An often overlooked FCC regulation requires licensing of most wireless microphone systems.

EMERGING TECHNOLOGIES

As always, new technical developments will find their way into the radio remote kit. A number of these systems are emerging at this writing that will likely affect both backhaul and remote production systems.

Backhaul Systems

Under Part 15 of its Rules, the FCC has established two bands for unlicensed use of spread-spectrum transmission (§ 15.247), one in the VHF band (902–928 MHz) and one in the S-band (2400–2485 MHz). Some digital audio transmission equipment has become available for these bands, particularly the latter, which allows RPU-like operation without licensing or frequency coordination. With Yagi type antennas, these low power (<100 mW) systems can be used on line-of-sight paths of approximately 20 miles. Their use is not yet widespread in broadcasting, but other industries (primarily wireless computing) are beginning to use these bands. While spread-spectrum transmission is fairly resistant to interference, there is some concern that as the bands become more popular, the reliability of such audio links will not remain adequate for broadcast use. Nevertheless, in most cases, the audio quality and robustness of S-band spread-spectrum RPU has proven more than adequate for broadcaster's requirements, among the relatively few using the systems to date.

Another emerging telco technology is called *digital subscriber line* (DSL) technology, which extends the capacity of standard twisted pair circuits to T-1 data rates and higher. DSL is being implemented in a number of different forms. The most common to date is the *asymmetrical digital subscriber line* (ADSL), which provides high-speed service in one direction and lower speed service in both directions, plus bidirectional POTS service—all on standard copper telco loops (two twisted pairs). ADSL can provide speeds ranging from 1.5 Mb/s downstream and 64 kb/s upstream (plus POTS) up to 8 Mb/s downstream and 1 Mb/s upstream. *High-bit-rate DSL* (HDSL) is a symmetric service, offering from to 2 Mb/s to 6 Mb/s in both directions. *Very high-bit-rate DSL* (VDSL) offers extremely high data rates over shorter distances (13 Mb/s up to one mile, or up to 51 Mb/s at 1,000 ft.). DSL (particularly its HDSL variant) could have significant value for wired remote audio backhaul without data compression. (For more detail on DSL, see Chapter 3.11, *Common Carrier Audio Program Services*.)

Remote Production Equipment

In the area of location audio hardware, one new system that may have application is the *fiber optic snake*. Here, a single, robust, yet lightweight cable carries several dozen separate microphone or line level channels from one part of the remote site (typically the stage area) to another (typically the mix position), replacing the traditional heavy copper multipair cable. Also unlike its predecessor, the fiber optic system is impervious to the pickup of EMI, nor does it generate any. Microphone level audio is preamplified at the head or stage end, then digitally encoded and multiplexed, converted to the optical domain, and sent down the fiber. The reverse process takes place at the console end, terminating in line level analog balanced outputs, to be plugged into a conventional mixer's line inputs. Splitting can also be accomplished without difficulty or degradation in the digital (electrical, not optical) domain with these systems. A helpful feature is the addition of some remote control ability for microphone preamp gain from the mix position, since the preamps are located at the head end of the snake. Because this is an active rather than passive system, some provision must be built in for return signals running in reverse from the console back to the stage. A typical configuration is 56 send and 8 return paths on a single cable, about the size of a standard mic cable.

Also new and of potential future value is the digital wireless microphone. Using unlicensed S-band frequencies, these systems can improve the audio quality and coverage of wireless mics used by broadcast talent. Similar advantages may be applied to future digital wireless IFB systems.

CONCLUSION

A RENG network should be planned and constructed with long term service and frequency coordination requirements in mind. Areas that currently do not experience spectrum congestion problems may encounter them in the near future. It pays, therefore, to design a system that is spectrum efficient and relatively immune to interfering signals. New digital services, both telco supplied and of an RF variety, should also be considered, and the progress in these areas carefully monitored for application on future links. It is always easier—and cheaper—to do the job right the first time.

No matter how good the backhaul link, if the remote audio program is not properly created at the site, it will not make a successful broadcast. Well equipped, simple and reliable systems are essential for the remote crew to be able to setup quickly and make the instant creative decisions often required on location. The well engineered remote can make radio programming exciting and unique—the kind of compelling material that keeps listeners coming back for more.

3.10
TELEPHONE NETWORK INTERFACING

STEVE CHURCH
TELOS SYSTEMS, CLEVELAND, OH

INTRODUCTION

From earnest political talk presentations to raucous morning shows, listener involvement via telephone is an important programming element at many radio and television stations. When we want to create a two-way connection with our listeners, we will probably be using the dial-up telephone network.

Radio news departments rely extensively upon phoners to get reporters and newsmakers on the air in a timely fashion. Why are the people who run local TV news so concerned with avoiding the dreaded talking head—that is, the anchor simply reading a story into the camera? Because they've discovered that *being there* is better. The same is true for radio.

Today, integrated services digital network (ISDN) lines combined with modern audio compression techniques permit instant full fidelity remotes from almost anywhere in the world.

This chapter will explore all of the ways to integrate the ubiquitous telephone network into broadcast operations. First, we'll learn about the nature of the various services available from telephone companies. Then we'll investigate ways to interface them to our station facilities.

THE TELEPHONE NETWORK

As we transition our broadcast facilities to digital systems, it is interesting to note that the standard voice telephone network is almost entirely digitized and has been so for many years. The watershed event was Illinois Bell's 1962 installation of a T-carrier system—the first widespread commercial application of digital audio. Telephone engineers appreciate digital technology for the same reason broadcasters do: reduced susceptibility to noise and other disturbances, and improved ability to switch, monitor and maintain the circuits.

While the worldwide dial-up telephone network is an amazing achievement, it is mostly made from a simple ubiquitous element: digital circuit-switched channels of 64 kbps each. *Circuit-switched* means that the channel is connected end-to-end with the entire capacity available for the duration of the call. (This is in contrast to packet-switched systems, such as the Internet, where capacity is shared among users and there is usually no guaranteed bandwidth.)

While most of the network infrastructure is digital, the last-mile copper connections from the central office to the customer site mostly are not. The vast majority of users interface to the network via an analog technology that is little different from that employed in Alexander Bell's days. This is beginning to change with the introduction of digital last-mile technologies like ISDN, T-1, and an Asynchronous Digital Subscriber Line (ADSL).

Incidentally, in industry jargon, your local phone company is a local exchange carrier (LEC) or simply a telco. A long distance company is an inter-exchange carrier (IEC).

Speech Coding

The bit rate of 64 kbps was chosen to support phone-grade speech audio encoded using a modified pulse code modulation (PCM) technique. When we make a plain old telephone (POTS) call, our speech is sampled at an 8 kHz rate and encoded into a digital word 8 bits long. Telco engineers call this 64 kpbs bitstream a digital signal level 0 (DS-0) channel.

The word length is what determines dynamic range—and 8 bits would only permit 48 dB were it used in standard PCM linear fashion. A primitive kind of compression is used to stretch the dynamic range: μLaw in North America and much of Asia, and A-law in Europe (see Figure 3.10-1). This is a scheme that equalizes the step size in dB terms across the dynamic range—a smaller step size on low level signals reduces quantization noise and improves effective dynamic range to the equivalent of about 13 bits. Thus, the quantization noise (and distortion) is approximately a fixed percentage of the signal amplitude, regardless of its level.

The process of conversion and companding is done in specialized analog-to-digital (A/D) and digital-to-

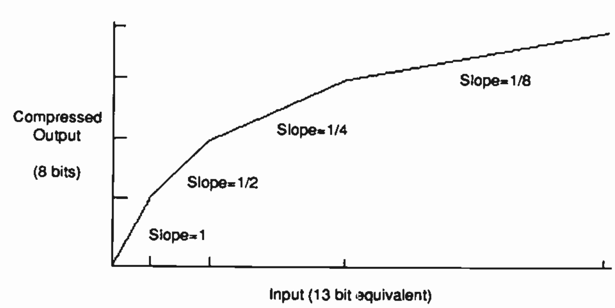

Figure 3.10-1. μLaw PCM coding within the telephone network causes the noise to be approximately a fixed percentage regardless of level.

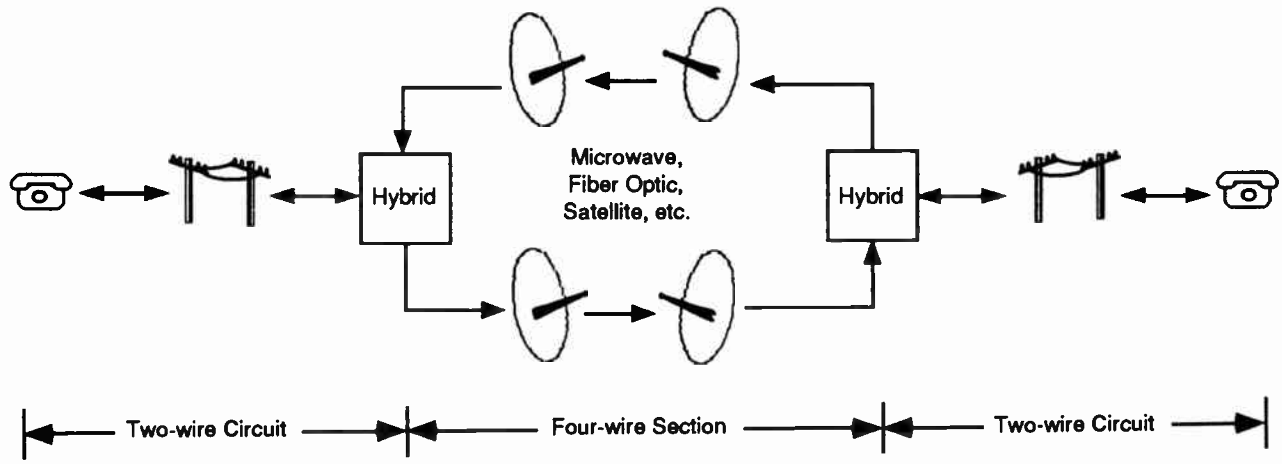

Figure 3.10-2. Two-wire circuits have both directions on a single pair of wires, which are separated for switching and long-distance transmission into 4-wire signals with hybrids.

analog (D/A) integrated circuits called *codecs* (CODer/DECoders). The method is specified by the International Telecommunications Union (ITU) as standard G.711.

2-Wire and 4-Wire

Both speech directions are mixed together on the usual analog lines with which we are most familiar, but this is not the way signals are handled within the telephone transmission and switching network. Non-copper transmission media such as microwave radio, satellite and fiber-optic cables are one-way only, so the paths must be kept independent. Even when copper is used, long-distance links are kept separated so that amplification can be inserted. A standard analog POTS circuit is *2-wire,* because it arrives on two wires. The network is internally *4-wire,* so named because in the past, a 4-wire circuit needed a separate wire pair for each of the send and receive transmission directions—four wires altogether.

The Traditional Analog Line

The traditional telephone lines provided by the phone company are known officially as subscriber loops, trunks or simply CO (central office) lines. (Trunks used to refer only to lines destined for private branch exchange (PBX) systems and may have included special signaling as well.)

Because these are 2-wire circuits, the CO uses a 2-to-4-wire converter (also called a *hybrid*) to interface the analog lines to its internal 4-wire system, as shown in Figure 3.10-2. This process happens on the *line card,* which is also responsible for digitization, talk battery insertion, off-hook detection, and ring generation.

Talk Battery and Ringing

The *talk battery* direct current (dc) voltage and the conversation audio appear together on the phone pair. The talk battery leaves the exchange at −48 V and is limited to 20–50 mA by a series resistor. The resistor's value is selected to complement the resistance of the loop. The dc resistance of the loop itself varies from a few to 1,300 Ω depending on length. Because of this series resistance, when a line is off-hook, its voltage at the customer equipment drops to around −12 V.

For ringing, an ac voltage of 90 vrms at 20 Hz is superimposed on the line. Talk battery is maintained during ringing, so that the resulting signal has a sinusoidal shape shifted 48 V to the negative.

Talk signals are ac coupled with nominal impedance of 600 Ω. However, some CO equipment uses complex impedance coupling, and the nature of the telephone network usually results in the actual impedance as presented to the user rarely being the specified simple 600 Ω. This turns out to be an important issue for broadcast interfacing, which we will discuss in detail later. The basic parameters are summarized in Table 3.10-1.

Frequency Response

For ordinary subscriber loops, the phone company specifies a frequency response of 300 Hz to 3.4 kHz. In the not-too-distant past when all local calls were connected at the exchange by metallic contacts, better

Table 3.10-1
Phone loop characteristics.

Parameter	Typical U.S. Values	Operating Limits
Talk Battery Voltage	−48 VDC	−47 to −105 VDC
Loop Current	20 to 80 mA	20 to 120 mA
Loop Resistance	O to 1300 ohms	0 to 3600 ohms
Loop Loss	8 dB	17 dB
Distortion	−50 dB	N.A.
Ringing Signal	20 Hz, 90 VRMS	16 to 60 Hz, 40 to 130 VRMS
Noise (objective)	−69 dBm0 to 180 mi, −50 dBm0 to 3000 mi (−16 dBm0 talk level) (C msg weight)	

frequency response was likely to be had on many conversations. Today almost all calls are digitized and are strictly limited to a 3.4 kHz bandwidth by the sharp low-pass filters required for proper digitization. The phone network's 8 kHz sampling rate permits a theoretical Nyquist frequency of 4 kHz, but a 600 Hz transition band is necessary for anti-aliasing and reconstruction filtering (see Figure 3.10-3).

Noise and Level

A 1971 Bell System survey of the phone network nationwide determined that the average conversation had a level of −16 dBm. Of course, as anyone who has wrestled with broadcast-to-telco interfacing knows, incoming level varies tremendously, with a range of perhaps −40 to −4 dBm, as illustrated in Figure 3.10-4.

Send audio (that is, audio fed into the telephone line) must be limited to −9 dBm as specified in Part 68 of the Federal Communication Commission (FCC) Rules. Audio loss on any given local loop is limited by tariff to 8 dB or less. This loss limit, however, applies only to the loop from the CO to the subscriber and does not include the rest of the signal path. Also, the 8 dB loss may occur at each end of a conversation path: once at the calling party end and again at the called party end, for a total loss of 16 dB.

The phone engineering people measure noise upside-down, defining a reference noise floor and then measuring *up* from there. The reference noise level is one picowatt, which corresponds to −90 dBm. Thus, a noise level of −60 dB relative to 0 dBm would be reported as 30 dBrn noise (dBrn = dB above reference noise). Note that, according to this method, the higher this number, the worse the noise.

Be aware also that when telephone people measure noise, they are measuring only *idle channel noise*. This is an important difference, since in digital systems idle channel noise is not the same as the traditional (S/N) measurement in analog systems. Noise in a digital system will generally increase when a signal is present. This effect is called *modulation* or *quantization* noise and is primarily dependent upon the number of bits used for quantization.

A *C-message weight* filter is employed when measuring phone line signal-to-noise ratio (S/N). (See Figure 3.10-5.) The C-message curve was developed years ago to simulate the frequency response of an old-style telephone earpiece and, accordingly, it has considerable low-frequency roll-off. This means that a line can have significant hum and other low frequency noise and can still meet the officially mandated noise specs. While this makes life easier for the phone company technicians, it can be troublesome when a broadcaster is trying to use phone audio on the air. If noise is a serious problem, try to get the technician to switch the noise meter to the flat position. The measuring set usually does have this option available.

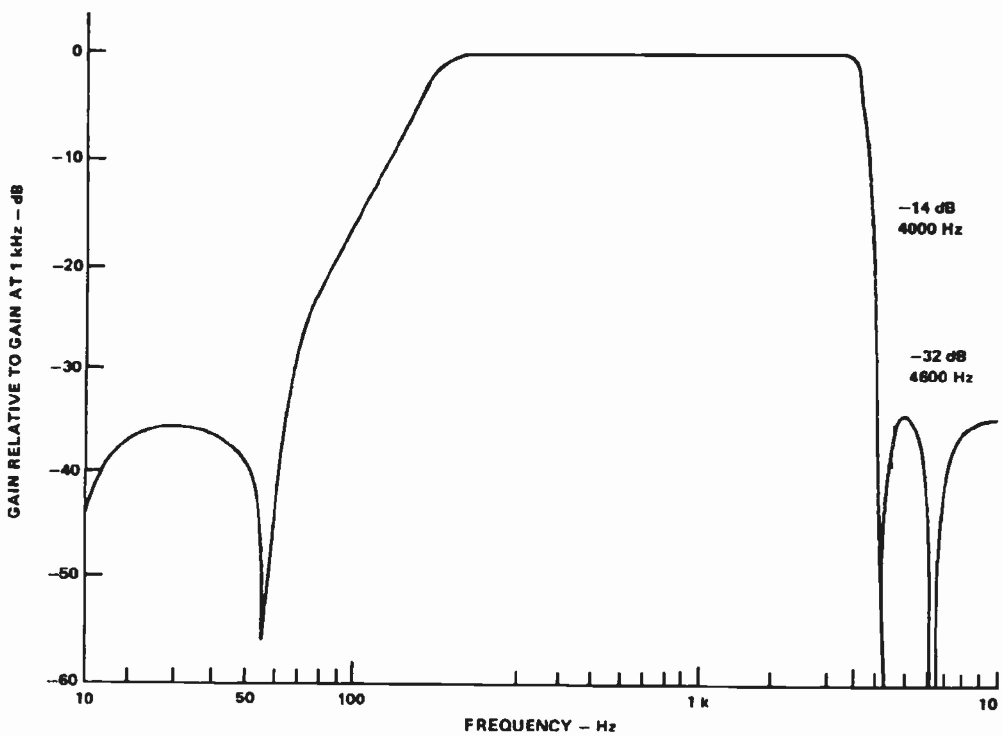

Figure 3.10-3. The low-pass filters required for digital transmission restrict frequency response. This response curve is for a codec that is widely used in the telephone network. (Note also the significant low frequency roll-off).

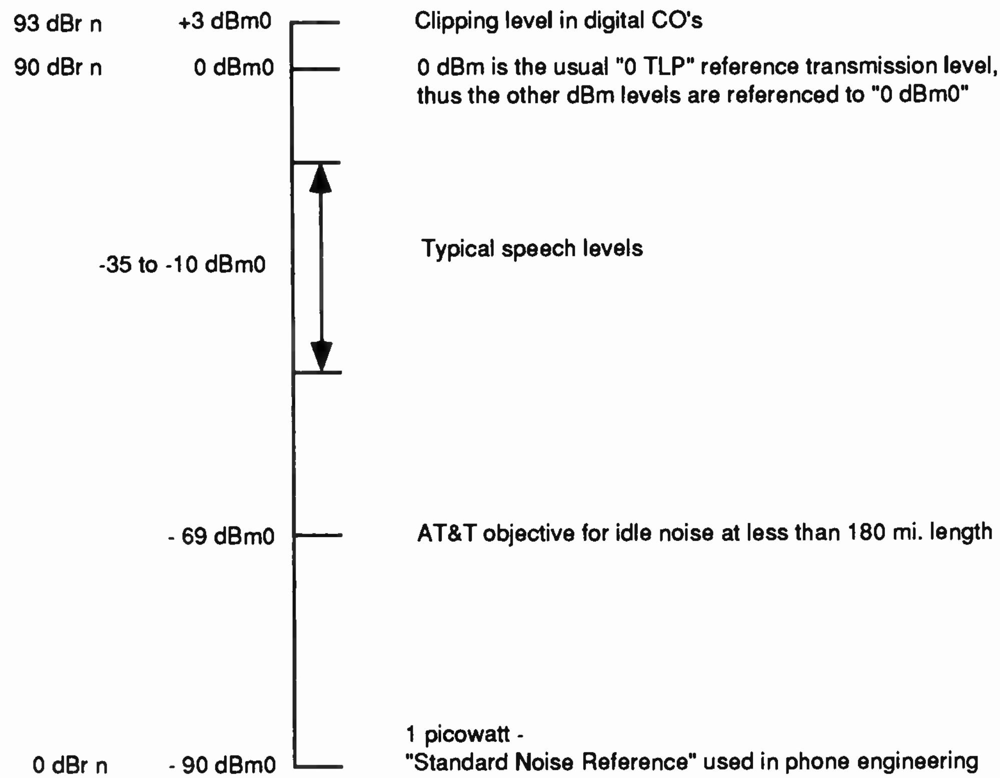

Figure 3.10-4. Signal and noise level references used in telephone engineering.

DTMF Tone Dialing

Dual Tone Multiple Frequency (DTMF) dialing uses two frequencies for each digit in order to avoid talk-off—that is, the tone detector accidentally sensing voice as a dial command. In addition, the frequencies were carefully chosen to avoid problems with harmonic distortion causing false detection. There are four low group frequencies, one for each button row, and four high group frequencies, with one assigned to each column as shown in Figure 3.10-6. Tolerance is ±1.5% for the encoder and ±2% for the digit receiver. The time required to recognize any digit tone is 50 msec with an interdigit interval of another 50 ms. Low group tones are supposed to be sent at a level between −10

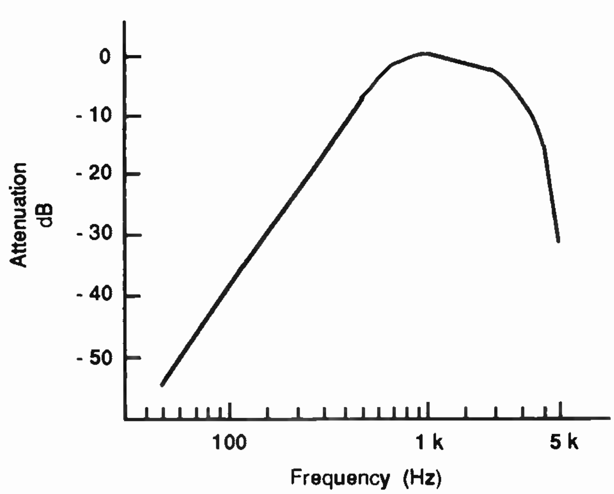

Figure 3.10-5. C-message weight frequency response curve.

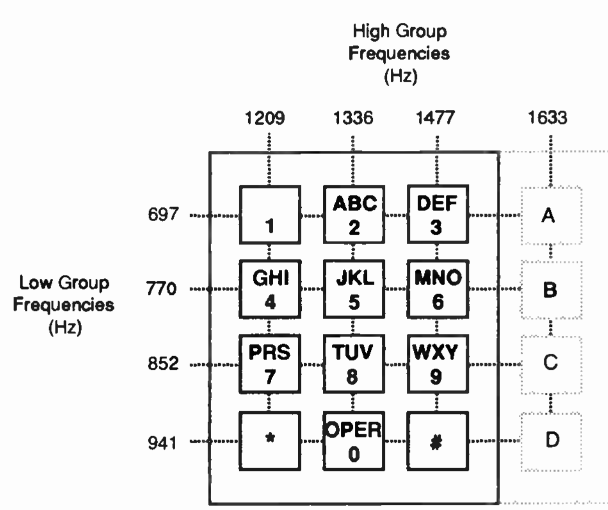

Figure 3.10-6. DTMF tone keypad frequency assignment. The four tone pairs in the last column are for special applications.

and −6 dBm; ideally, tones in the high group are transmitted with 2 dB greater level in order to compensate for high-frequency roll-off in the phone line.

Loop Start and Ground Start

Central office lines come in two basic configurations: loop start and ground start. Loop start is the kind that is most common. In this kind of circuit, the CO provides talk battery to the line at all times and detects that an off-hook condition is occurring when the terminal equipment connects and causes current to flow between the tip and ring. (Incidentally, the terms *tip* and *ring* originated with the description of the circuits being on the tip and ring of the patch cords that used to be used by telephone operators.) With ground start circuits, the CO waits for a connection from the ring wire to ground before connecting talk battery, at which time the terminal equipment removes the ground connection to establish a balanced talk path. When the calling party hangs up, a ground start circuit removes talk battery. A loop start circuit may or may not provide a momentary interruption or reversal of the talk battery when the calling party terminates.

Many PBXs are designed to work with the ground start circuits because the possibility of collision is reduced. Collision occurs when the phone system tries to seize a line for an outgoing call just as that line is ringing in.

Disconnection: Calling Party Control

Loop-current interruption occurs on most telco lines when the calling party hangs up. It is sometimes referred to as calling party control (CPC), since the *calling party* controls *your* equipment when he hangs up. The CPC may turn off an answering machine, for example, or extinguish the winking light on a held line on a key phone. The CPC interruption was probably never intentional, having been a by-product of early mechanically switched relay-controlled exchanges. Thus, some phone lines do not provide this function or they provide it unreliably. However, with the proliferation of answering machines that rely upon CPC, most central office equipment now has this capability designed in. In some cases, it is necessary to specifically request this feature from the phone company on a per line basis.

Loop-current *reversal,* on the other hand, has long been a phone company signaling method. First used between the telco's own central offices, loop-reversal was later employed to communicate with some large premises PBX systems. Thus, lines that are set up for PBX use, or originate at central offices with large concentrations of business customers, sometimes use this method. (However, the preferred and more modern situation for PBX control is to use ground-start lines.)

While most exchanges do provide CPC, there are some that do not reliably provide it or provide it after a variable time delay. Most PBXs do not generate it. However, every telco CO in the United States eventually returns dial tone to its lines when the calling party hangs up. Thus, we can use the presence of dial tone as a back up to cause a disconnect when the loop-current detection methods fail. An important consideration is to prevent false talk-off from noise, applause or other spectrally rich audio. Using software based statistical methods ensures that the dial tone is *really* present before terminating the connection.

Caller ID

Caller ID (CID) allows you to know the phone number of the caller. This capability is useful for call-in shows, where it might be desirable to deny access to problem callers. The technology is simple. Between the first and second ring, the information is sent in a packet using a 1200-baud modem. This is exactly the same modulation scheme used in normal computer modems operating at this rate. Customer equipment normally suppresses the first ring so that the answering user does not take the call before the CID information is fully transmitted.

Loading Coils

A typical #24 gauge phone pair attenuates a 3 kHz signal 2.5 dB per mile due to capacitive effects. On an 8 mile (12.9 km) long line, high-frequency attenuation would thus be 20 dB, a significant amplitude distortion. Loading coils are toroidal inductors, which counter the effects of the phone pair's natural capacitance. While the coils are effective at flattening out the response within the voice band, the roll-off above 3.5 kHz is devastating, as shown in Figure 3.10-7.

Physically, load coil banks are long cylinders, with the individual donut-like coils stacked one on top of the other inside. They are typically placed at 3,000 (.9 km), 4,500 (1.4 km), or 6,000 (1.8 km) ft intervals along the phone cables. Generally, loading coils are found only on cables of greater than 3 miles (4.8 km) in length.

As we shall see, loading coils can create problems for the hybrids used in broadcast interfaces.

4-Wire Circuits

It is possible to purchase analog 4-wire circuits from telcos. These are used where it is desirable to maintain

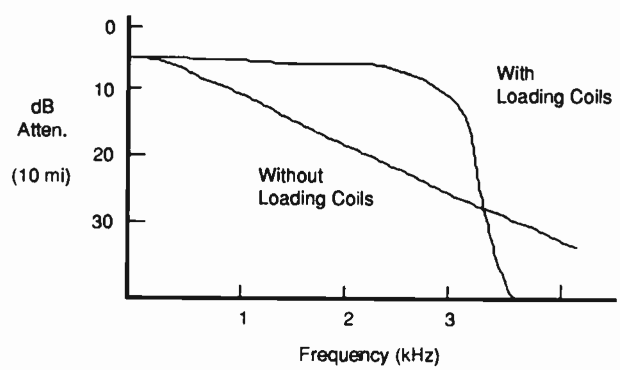

Figure 3.10-7. Frequency response with and without loading coils.

separation in the two speech paths. They are not dial-up, but rather end-to-end hardwired. This service has traditionally been used by television remote trucks for connection of remote production intercom systems. With the introduction of digital hybrid interfaces, use of this approach has been in decline. ISDN offers 4-wire capability at a lower cost and with fewer hassles, so it will probably supplant these analog lines over time.

Foreign Exchange (FX) Loops

FX provides local telephone service from a central office that is outside (foreign to) the subscriber's exchange area. If a station is located in the suburbs and the choke network central office is downtown, FX loops will be needed to connect your lines. When the phone is picked up, you get dial tone not from your local suburban CO, but from the downtown office. FX service is also sometimes used to extend your coverage into another city, so that people can call the station without paying a toll charge and calls can be made within that city without incurring toll charges. For instance, if the studio is in Cleveland and the goal is to serve listeners in Akron as if they were local, FX service could be the answer.

An FX loop is a 4-wire circuit with hybrids at each end, at each terminating central office. Since FX loops add an extra layer of hardware to the phone audio, they are another source of problems for on-air interfacing. They usually are engineered to have a few dB loss and they add to the impedance complexity of the line.

FX circuits are usually expensive and pose certain technical challenges. Since, as we will learn later in this chapter, hybrids are imperfect, a potential for a special kind of feedback called *singing* exists. This results from the inevitable leakage from the send to the receive ports at each hybrid. The phone people solve this problem by inserting a pad—anywhere from 5–8 dB is common.

Choke Networks

Most stations need special high volume exchanges for their contest and request lines. This requirement probably results from the days when aggressive program directors (PDs) desired the publicity that *burning out* a phone exchange would generate.

The choke network works by diverting calls beginning with the unique choke prefix around the local serving central office and sending them directly to the choke switching exchange, usually located downtown (see Figure 3.10-8). The phone company dedicates very few talk paths (wire trunks or special carrier equipment) to the task of connecting the caller's serving CO choke ports to the choke exchange. The usual switching and routing process is bypassed. Unfortunately, only a very limited number of paths are generally provided. In the densely populated Los Angeles area, for instance, only three connections exist from most central offices. In addition, the poorest facilities are often given over to the high volume service.

Generally, unless you are near the choke central office, the FX circuits previously described are employed to connect the choke CO to your serving CO. This is one of the reasons why choke circuits often have a lower level than standard lines. Because of their higher complexity, choke lines also usually have bumpier impedance curves, making good hybrid performance difficult to achieve due to the problem of finding appropriate balancing network values. This is especially a problem with simple analog hybrids.

In some areas, FX circuits are being replaced by internal call forwarding. This means that a published number is actually being software forwarded to a real number originating from your local serving CO. The main advantage to this approach is lower cost, since

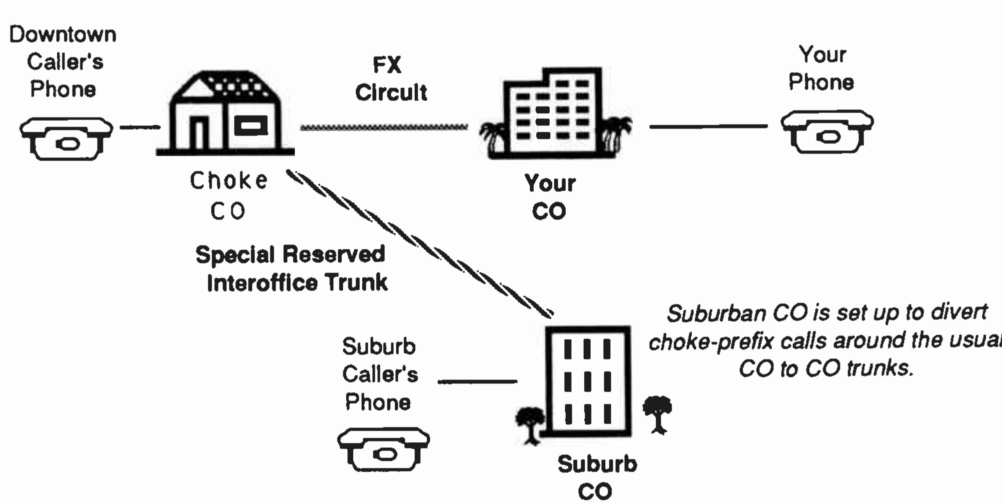

Figure 3.10-8. Typical choke network transmission path.

you do not have to pay the premium for the FX circuit. However, there usually is a smaller call-forwarding charge.

ISDN: Basic Rate Interface (BRI)

ISDN allows a direct digital connection to the telephone network. In addition to the quality advantages digital transmission offers for basic voice service, users may bypass the normal POTS speech coding methods and supply their own much better algorithms, such as those standardized by Moving Pictures Expert Group (MPEG). MPEG is an organization involved in standardizing audio coding. Another characteristic of ISDN important to broadcasters is that the B channels are true full-duplex, with absolutely no cross-connection between the send and receive signal paths.

ISDN is now widely available and is growing in popularity—mostly because of its value for high-speed Internet connectivity. Web surfers may implement direct digital links without the bottleneck caused by inefficient, slow modems. An ISDN BRI has 128 kbps raw capacity. Compare this to the speed possible with a 33.6 kbps modem and it becomes evident why the promise of ISDN creates so much excitement among people who need fast access to the net.

With a BRI line, you get two 64 kbps voice or data channels, called "B" or bearer channels, and one 16 kbps "D" or data channel on a single telephone pair (see Figure 3.10-9). The D data channel is the path between the central office and terminal equipment that is used for call set-up and status communication and is usually not available to the user.

The S and U Interfaces

The line from the central office is a single copper pair physically identical to a POTS line. When it arrives at the subscriber, this is called the "U" interface. The U interface converts to an S/T interface with a small box called an "NT-1." In the United States, NT-1 functionality is usually included in the terminal equipment. In Europe, the telephone company provides the NT-1. Only one NT-1 may be connected to a U interface, but as many as eight terminals may be paralleled onto an S bus.

Professional equipment should usually provide access to the S interface, making it possible to parallel multiple terminals. You can use either an external NT-1, or the equipment may have an internal NT-1 with both U and S/T connectors.

Terminal Adapters

A terminal adapter (TA) is the equipment that interfaces to the ISDN line, providing call set up and protocol conversion functions. A traditional TA has an ISDN connection on one end and one or two bit stream ports on the other, usually using the V.25 or X.21 connectors. Modern broadcast equipment combines this capability with the audio encoding equipment into one integrated unit.

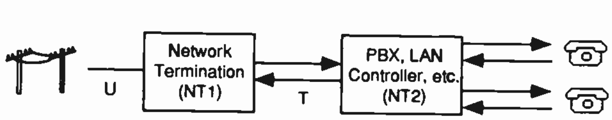

Figure 3.10-9. ISDN termination.

SPIDs

Service profile identification numbers (SPIDs) are only required when you are using the National I-1 ISDN protocol in the United States. This number is given to the user by the phone company and must be entered into the TA in order for the connection to function. SPIDs usually consist of the phone number plus a few prefix or suffix digits.

The intention of the SPID is to allow the telco equipment to automatically adapt to various user requirements by sensing different SPIDs from each type or configuration of user terminal. For instance, multi-button phones could retain function assignments when moving from line to line. In this case, the line number would probably not be used as the SPID. None of this matters with our application, but we must enter the SPIDs nevertheless. (Over time, it may be possible that a standard SPID could be used for all broadcast codec applications. A proposal that would allow this is being considered.)

If you are using the National I-1 protocol, your telco service representative must give you one or two SPID numbers for each line ordered. You will get one SPID for each B channel you need. Upon power-up, connection of the ISDN line or boot, the TA and the telco equipment go through an initialization/identification routine. The TA sends the SPID and, if it is correct, the network signals this fact. Thereafter, the SPID is not sent again to the switch. You must have this SPID number, and it must be 100% correct, or the system will not work. Do not let the installer depart without leaving your SPID number(s).

Directory Numbers (DNs)

Directory numbers (DNs) are the telephone numbers assigned to the ISDN line. You may be assigned one or two, depending upon the line configuration. If you have two active ISDN B channels, you will usually have two DNs. However, the physical channels are independent from the logical numbers. A call coming in on the second number will be assigned the first physical B channel, if it is not already occupied. Therefore, there must be some way for the TA to sort out which call goes to which channel/line. The DN is used for this function.

When a call rings in, it contains set-up information, which includes the DN that was dialed by the originating caller. The last seven digits are matched with the DNs programmed into the TA and the proper assignment is made. However, it is not usually necessary to explicitly enter them, as they are almost always contained within the SPID, and most TAs are smart enough to look there first. The only time a DN must be entered is in the very rare case where the last seven digits of the DN are not included somewhere within the SPID. When DNs are required, only the last seven digits need be entered.

Digital Long-Distance

Long-distance connectivity is routinely available in most parts of the United States from the big-three carriers: AT&T, Sprint and MCI. The "dial 1+" default carrier may be chosen at the time you order the line, just as with traditional voice lines. Also, just as with voice lines, you may usually choose a carrier on a per call basis by prefixing the number with the 1010XXX carrier selection code. You must dial the full number, including the 1 or 011 + country code following the prefix.

Here is a hot tip: You can save a lot of money by arranging a special plan with your long-distance (LD) carrier. When you use 1+ dialing without contacting your LD carrier, you are generally put into a standard rate plan that has the highest cost of any of the pricing tiers.

Some long-distance connections are limited to 56 kbps/channel. This arises from a quirk of the older telephone infrastructure. The channel banks that have been widely employed in the long-distance network have a native 64 kbps capability but rob the low order PCM bit on every sixth frame in order to convey supervision information (on-hook/off-hook and dial pulses). This limitation is becoming more rare as equipment is upgraded, but there is no way to know for sure in advance.

CSD and CSV

Recall that each ISDN BRI has two possible B channels. It is possible to order a line with one or both of the B channels enabled, and each may be enabled for voice and/or data use. Phone terminology for this class of service is circuit switched voice (CSV) and circuit switched data (CSD). (Both are in contrast to packet switched data (PSD) which is possible but irrelevant to this discussion.)

CSV is for standard voice phone service and allows ISDN to interwork with analog phone lines and phones. CSD is required for MPEG codec connections. Even though you may be sending voice, the codec bit stream output looks like computer data to the phone network.

Even for MPEG codec applications, you may want POTS speech capability, since some support this feature. Therefore, you may want to order CSV as well as CSD on one or both B channels. To get a line with one B channel to be used with either hi-fi or speech, you would request an ISDN BRI 1B+D line with CSV/CSD capability. For both B channels, you would order an ISDN BRI 2B+D line with CSV/CSD on both channels; if you do not need voice possibility on the channels, you want 2B+D with only CSD enabled.

Protocols

In a perfect world, all ISDN terminal equipment would work with all ISDN lines, without regard for such arcana as 5ESS, DMS100, CSV/CSD, SPIDs, etc. Unfortunately, the ISDN standard has been evolving for years and has only recently begun to settle down. And, sadly, there will remain different standards for the Unites States and Europe.

The telco network and the TA communicate via a *protocol*—the language the user equipment and the telephone network use to converse (on the D channel) for setting up calls and the like. This is where you will find differences, since the protocol depends upon the central office equipment and the standards that it follows.

In the United States, telephone companies use either AT&T 5ESS, Northern Telecom DMS100, or Siemens EWSD switches. Each of these can support the National I-1 protocol standard, which has been specified by Bellcore. However, both AT&T and Northern Telecom had versions of ISDN which pre-date the NI-1 standard and some switches have not been upgraded to the new format. There is also a newer NI-2 standard, but it is designed to be compatible with NI-1 for all of the basic functions.

In Europe, the common protocol is Euro-ISDN, following the ETS300 standards. It is an apparently successful attempt at having all of the European telephone networks use a single, compatible protocol. The telco authorities in most countries have adopted it already, with most of the rest planning to do so.

T-1 Digital Service

As with ISDN, T-1 is possible because an ordinary copper phone pair can carry a much wider signal than the 3.4 kHz required for a single voice conversation. Indeed, a pure metallic path of reasonable length is easily capable of passing frequencies in excess of 100 kHz. Thus, digitization and multiplexing can be used to carry a number of voice channels over a single pair of wires.

Introduction to T-1

To create the T-1 bit stream, 24 64 kbps DS-0 channels are assembled serially and the equivalent of another 8 kbps channel is added for synchronization (see Figure 3.10-10). Thus the ultimate data rate becomes 1.544 mbps, a rate also called DS-1. The signal is then converted into a digital bipolar bit stream in a special format called binary 8-zeroes suppression (B8ZS). The voltage is modulated between -3 V and $+3$ V.

Most LD carriers offer service on T-1 connected directly to their point of presence (POP). Because the LD carrier does not have to pay the usual fee to the local telco for routing over their CO and lines, the customer cost can be lower.

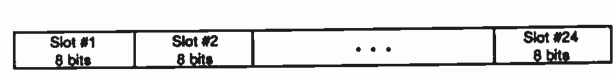

Figure 3.10-10. T-1 bit stream. 24 audio channels are transmitted sequentially.

Using T-1: The Customer Provided Equipment (CPE)

Despite the difference in capacity and service, T-1 arrives at the end user site as two conventional copper pairs: one for the data send and another for receive. The physical connector used to be a DB-15 type, but the current standard is the common RJ-48C, an 8-position modular plug. Figure 3.10-11 shows both types.

Here are the usual components of a terminal system for a T-1 circuit:

- *The CSU and DSU.* The T-1 line is first connected to a piece of equipment called the channel service unit (CSU). The CSU used to be considered part of the network, but is now almost always customer-provided and may also be merely included as an adjunct section in a complete T-1 interface solution. The CSU contains the last signal regenerator as well as a number of testing and maintenance features such as provision for loopback testing by the central office. It may also include a system to collect and report error statistics. The data service unit (DSU) handles the remaining digital housekeeping functions and data conversion from the bipolar T-1 format to standard serial data
- *The Multiplexer and Channel Cards.* The multiplexer, sometimes called a *channel bank,* is where the multiple voice (or data) channels are combined into the single bit stream required for T-1 transmission. Each voice channel is converted to and from digital using codecs. In order to simulate typical telco lines, talk battery is added, ringing voltage is generated and loop current is detected. Generally, multiplexers are constructed using a modular circuit card approach so that the available digital bandwidth may be configured as desired.

Many modern PBX systems and at least one broadcast on-air system are able to accept T-1 lines directly. This is a near ideal approach, since you get a low cost direct digital connection into the telco network. In this case, no multiplexer and channel cards are necessary, because the connection is made directly to the CSU/DSU. Some PBX equipment even incorporates the DSU.

T-1 and the Broadcast Interface

Generally, T-1 service appears to be a good idea for broadcasters, and many stations are using it successfully. However, be aware that some T-1 terminal equipment has problems in its analog conversion section, which cause the on-air hybrid interface to work very poorly with bad cancellation the result. Also keep in mind that, since all of your service will depend upon a single set of circuits, reliability could be reduced compared to individual analog lines. Consider having back-up circuits in place.

Primary Rate ISDN (PRI)

Primary rate ISDN has a data rate equivalent to T-1 circuits, providing 23B + D, or 23 64 kbps bearer channels and a 64 kbps D channel for control. (In Europe, PRIs have 31 bearer channels.) It is expected to replace T-1 eventually, since it speeds dialing and offers superior monitoring capabilities.

ADSL

Asymmetric digital subscriber lines (ADSL) promise connections at speeds of up to 3 mbps in the direction from the CO to the user. The upstream speed is limited to some much smaller value which is where the asymmetric part of the name comes from. An important advantage is the cost; it appears that this service may be priced at around the same level as ISDN BRI.

Initially, this technology was viewed by the telco industry as a way to compete with cable TV for the delivery of video services. Combined with an MPEG video/audio encoder, the bit rate offered by ADSL would permit full-quality National Television System Committee (NTSC) television. These projects now ap-

DB-15	PIN		PIN	RJ48-C

		(all others - no connection)		

Figure 3.10-11. T-1 connector pin-out. Either DB-15 or RJ48-C modular connectors may be used.

pear to be stalled and current efforts are being focused on high speed Internet connectivity. Since the Internet is a packet-based system with no bandwidth guarantee, the utility of this service for broadcast audio transmission is unclear.

Centrex

This service goes by various names, but the consistent principle is that the telco's CO equipment replaces customer-owned PBXs. Each phone set has a direct connection to the CO. The idea is to eliminate customer up-front costs and transfer maintenance responsibility to the telco. Varying requirements for numbers of lines or phones can be accommodated without customer equipment upgrades. Centrex is declining in popularity but seems to remain popular with universities.

Features in Centrex rely upon flashing the switchhook and the use of the normal dialpad keys, generally an awkward and confusing situation for users. This problem may be solved with ISDN Centrex, as this permits very sophisticated phones to be used with all of the usual PBX features.

Cellular Telephone

Cellular extends the dial-up network to many places where a wire connection would not be considered practical. Cellular transceivers operate in the 800 MHz range and automatically select the appropriate frequency from among the 666 FM channels assigned for this service. Low power is used so that the frequencies can be re-used in adjacent areas. The mobile phone varies its power according to the level of signal received at the base location. A useful feature for on-air use of a cellular phone is the signal strength meter provided on some units. Some phones also allow you to see the send power value. Often, the antenna's pattern is quite directional due to its position on the vehicle, so moving around while observing the level indication can help make remotes sound better. For fixed remotes, a Yagi antenna can be used with its benefits of higher gain and directionality. At 800 MHz, Yagis are very compact.

Most equipment designed for use with wired phone lines can be connected to cellular phones using an adapter provided by the phone manufacturer. Intended for laptop computer modems and portable fax machines, these adapters provide an interface to any broadcast equipment that can connect to a phone line. Units especially designed for broadcast use have provisions for audio input and output for direct connection to microphone mixers and the like.

Some new digital cellular systems have the capability to transfer data via a special interface. Unfortunately, the bit rate is limited to only 14.4 kbps—not sufficiently fast for digitized audio. The impetus from the Internet may cause cellular vendors to offer higher bit rate phones in the future, permitting broadcasters to use them for high-fidelity remotes.

A downside of the new digital phones is that speech quality may be poor. This results from the very low bit rate used by these systems and the extreme compression methods that are required to shoehorn audio into the channel.

FCC Regulations

FCC requirements for connecting equipment to phone lines are outlined in Title 47 of the Code of Federal Regulations (CFR), Part 68: Connection of Terminal Equipment to the Telephone Network. The CFR can be ordered from the Government Printing Office.

PBX AND KEY SYSTEMS

Now that we know a bit about the nature of the phone network, we can explore what happens after the lines become ours. We will want to use some of what the phone people refer to as CPE. That is all of the equipment connected to the phone line after the official demarcation point. We will survey the various styles of PBX systems available both for general office and on-air use, followed by a look at systems designed specifically for studio application.

Private branch exchanges (PBXs) are found where there is a need for a large number of extension phones. PBXs are miniature central office exchanges, allowing local phones to call each other as well as access trunk lines for incoming and outgoing calls. PBX systems often have a number of specialized features for call routing and control. Traditionally, PBX systems have used only single-line phone sets as terminals, with special functions like transferring and conferencing accessible by flashing the switch hook or by using the tone pad in a special way. Most PBXs now have available feature phones, which can button-access individual lines as well as provide numerous other advanced functions. Sometimes these systems are called key systems after the old multi-key 1A2 phones. (Why phone engineers called buttons keys remains a mystery.)

Modern Telephone Systems

While the systems are tremendously varied, most have in common that the cable from each phone set to the common equipment conveys:

- Power to operate the phone
- A two-way data path to signal user actions from the set to the switch and operational and display status from the switch to the set
- The speech audio.

Here are the usual approaches phone manufacturers employ for wiring and communication:

- *All Digital.* The most advanced systems use a pure digital bit stream for both voice and data. The phone set contains the codec for conversion to-and-from the analog and digital domains. The pure digital approach is used in the AT&T System 85, in the

Northern Telecom Meridian family, in the newer Mitel systems with the *Superset DN* phones and in the digital version of the NEC NEAX, among many others. The Siemens *Office Point* system claims to use standard ISDN protocol between the sets and the common equipment

- *Separate Pair per Function.* The early electronic phones used a separate pair for each of the three functions, and thus required three (or more) pairs. The AT&T Merlin system used this design. The center pair is the audio; another pair is for the serially transmitted control and display data and another handles the phone's power requirements
- *Two-Pair, Phantom Power.* This used to be the most common approach, but is now fading, as pure digital designs have become cost-effective. The AT&T Spirit system the popular NEC and TIE systems and many others use this approach. Talk and data each use one of the two pairs. The power is applied between the two pairs similar to the method used for phantom powering condenser microphones in recording studios. A transformer at each end of the audio pair permits the phantom power to be added. The data pair will probably use resistors to obtain a center tap, rather than transformers since the data signal has a dc component which could not pass through a transformer.
- *Two-Pair, Power not Phantom.* Some two-pair systems put the data on one pair and the audio on the other. Power may be on the data pair or on the audio pair. In the latter case, the audio pair resembles a central office line so that the phone ports may be universal: either single-line sets or feature phones can be plugged-in without hardware changes in the PBX. At least one of the Panasonic systems uses this technique. The center pair, again, is generally the audio
- *Data Over Voice.* The analog Mitel *Superset* phones use a unique scheme that requires only one pair for all three functions. The data is amplitude shift modulated onto a 32 kHz carrier *over voice* and then the combined voice and data are ac coupled across the dc power voltage.

Interfacing to PBX Phones

It is usually possible to interface to PBX phones for on-air use. However, this is best reserved for casual phone use such as for the occasional request or contest winner call. For applications where phone calls are a significant programming element, it is usually better to consider the specialized on-air systems from the broadcast-oriented manufacturers.

One reason is that the hybrid interface cannot determine when a new call is selected, so it can not adjust its null to the new line before the conversation starts. (However, since the hybrid can null on voice during conversation, null will be achieved in perhaps four seconds. This is acceptable if only a portion of the call is to be aired, as is common with on-air requests, contest winner calls and the like.) Another shortcoming of the direct-to-electronic phone approach is that the line switching clunk is not muted, although this is not a problem when calls are not aired directly and sequentially.

Another potential problem is audio quality. The primary impediment is usually noise, most often the result of the data signals cross-talking into the audio. Buzz from the power supply sometimes finds its way into the audio. Often, frequency response is limited by too small line coupling transformers or from other causes. Poorly designed digital systems may suffer from quantization and aliasing noise and distortion. Few PBX manufacturers publish specs on audio performance. Since, clearly, this is of importance to those of us who need to get decent quality from phones for on-air use, we'll want to make sure that the audio is at least reasonable. When choosing a new PBX, ask the phone system dealer for audio performance data or arrange to conduct at least a few simple tests yourself.

Direct Connection to the Skinny Wire

When the phone system uses the separate-pair approach previously described, the center two wires on the modular plug are usually the audio path. Since the phone's control functions stay active even when these connections are broken, it is possible to intercept the audio signal here for feed to the interface. Most broadcast interfaces provide a loop-through connection, which feeds the phone line back out when it's not active. Thus, the unit may be series connected with the audio pair. That way, you have normal telephone function preserved when the interface is not in use. When the interface is active, the phone serves merely as a controller, with no audio reaching the phone's network or handset. Wiring the hybrid's on/off functions to the console's switching logic accomplishes automatic operation.

When the phone uses the two-pair phantom approach previously described, the audio is again likely to be present on the inner pair and may be intercepted for interfacing use if the dc connection is maintained. One way to do this is to provide a bypass for dc with inductors. Two µH has proven acceptable in experiments performed on some phone systems As shown in Figure 3.10-12.

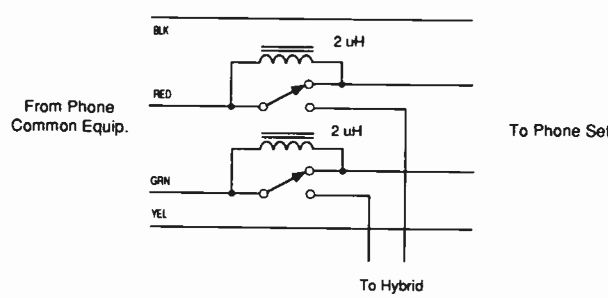

Figure 3.10-12. If the center two wires on many electronic phone systems convey audio, they may be used to feed broadcast equipment. The inductors bypass power to the phone set when the studio interface is active.

Special System Ports: Faux CO Lines

Since fax machines and modems need connections that look like central office lines, many systems provide ports for this use. They may be connected to broadcast interfacing gear as if they were CO lines. Sophisticated PBXs have programming features that allow these ports to be configured in various and potentially useful ways. For example, they may be set up for private line ringing (when a given incoming CO line rings, the call may be directly sent to the selected port). Unfortunately, with most PBX systems, awkward operation may result, since the only way to move a call from a phone set to the port may be to transfer it using multiple button punches, rather than the usual simple place-on-hold-and-pick-up-elsewhere operation. Taking calls in sequence on-air may be extremely difficult or impossible. Figure 3.1013 illustrates one possible solution.

Speakerphone Tap-Off

One way to get low cost interfacing is to take advantage of the switching-type interface that many phone set internal speakerphones provide. The procedure is to tap off the speaker with a transformer and pad to the console's required input level. You may continue to use the phone's internal microphone or you can provide an external send audio source to substitute for the phone's internal microphone. Again, you will certainly need a pad and probably a transformer. The input feed must be set so that appropriate switching action and proper send levels are obtained.

Handset Adapters

Adapters are available that plug into the phone set's handset modular jack and convert the microphone and earpiece signals into a signal that emulates a standard CO line. While useful in some applications, this approach is likely to offer a lower quality feed because the phone set's network remains in the signal path causing impedance bumps and other problems.

Intercepting the Serial Data Stream

Why can't we just emulate an electronic phone set by generating and decoding the phone system's serial data? It does seem that this would be a good solution. However, phone system manufacturers insist on keeping their data protocols a deep secret. That means that broadcast manufacturers are unable to design direct emulation equipment. Of course, even if we had the protocols, there is the problem of accommodating the dozens of communication methods employed by PBX designers.

1A2 Key Systems

While nearly all stations have gone to high-tech PBXs for the business office, many on-air installations continue to rely upon 1A2 key systems. Key systems offer the advantage of providing a direct metallic connection to the CO line. That means that no frequency response error, noise, distortion or time delay is introduced. Often, these issues are not fully considered in the design of the more complex business phone systems. In addition, costs are favorable, and full schematics and other documentation are readily available.

Leading from the key service unit (KSU) to each phone is a thick cable with 50 conductors (25 pairs). The *tip/ring* pair carries the telephone audio. As mentioned, these are direct connections to the telco CO lines. The *A leads* tell the key system which lines are in use and also signal a hold condition. Selecting a line causes a connection to be made in the phone set from the A lead to another wire, the *A-common*. The A lead is normally at -24 Vdc and A-common is at ground potential, so when a line is selected, the A lead goes from -24 Vdc to ground. If the A lead is broken before the tip/ring is disconnected, the system puts the

line on hold. The *lamp-leads* light the phone's line buttons with 10 Vac from the KSU's power supply and are returned via the *lamp grounds.* The standard color codes and pinout are given in Table 3.10-2.

The Evolving Phone

As time goes on, probably all but the most inexpensive systems will use the purely digital approach. As we've seen, these systems are difficult to interface to, but perhaps over time protocols will become standardized and maybe even based on ISDN. If this happens, broadcast interface manufacturers may be able to provide equipment that could directly connect to the PBX in place of, or in series with, the studio phone set.

Computer Telephony Integration (CTI)

With such a system, the PBX manufacturer provides complete documentation on an interface that can provide control of all of the important aspects of phone switching, including call set-up and routing functions. A standard data port is provided so that outside vendors may supply systems to work in concert with the phone equipment. These open PBXs may eventually offer a universal method for broadcast equipment to coordinate with the station's office phone system.

Another approach is to build a PBX using special cards and software installed in a standard PC. Systems of this type would use the Windows NT operating system along with other standard PC software components such as a database server to provide a very sophisticated package of features. It is possible, for instance, to dial using database name look-up on a networked PC. Ironically, most CTI systems use analog phone sets.

BROADCAST INTERFACING

This section describes the techniques necessary to achieve the best possible result from the phone-to-broadcast shotgun marriage.

One-way Interfacing

There is often a need to take audio from a phone or broadcast in only one direction at a time (newsroom phoners are a common application). If there is no requirement for a two-way conversation, a simple interface using a QKT will do. Formerly available from the phone company, this small box was permanently wired into a phone instrument or line and provided a quarter-inch (12.7 mm) phone jack output for feeding a line-level signal to a console or recorder input.

Since the QKT is nothing more than a transformer, a capacitor and a zener diode limiter, you can make your own (see Figure 3.10-14). The capacitor provides dc blocking so that the transformer does not become saturated with the phone line's dc potential. In order for the coupler to hold the line by drawing loop current, eliminate the capacitor and use a transformer that can withstand the loop current without producing distortion. (One such a transformer is the SPT117 from Prem Magnetics.) When sending audio into the phone line, remember audio level should be limited to −9 dBm. The QKT had back-to-back zeners for this purpose; you may want to add them to your homemade interface if you expect audio levels to get out of hand. Of course, commercial units are available that are a little fancier than the simple device described here. Some offer auto-answer and disconnect capability.

When using a coupler, it is most convenient to have the telephone instrument on-line and equipped with a push-to-talk switch on its receiver. This is because the phone's receiver has to be off-hook while a feed is coming in; the switch turns off the receiver's mouthpiece microphone when it is not depressed, thus insuring that noise from the studio side will not be included in the recording. Since this coupler works in both directions, it can be used to send audio down the phone as well—useful in the production studio for letting

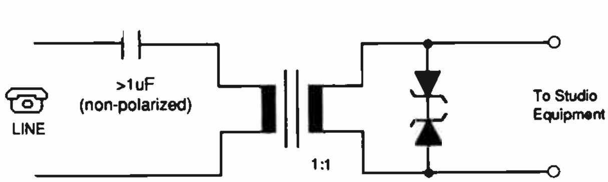

Figure 3.10-14. Simple one-way-at-a-time interface. The capacitor is for dc isolation and is not required when a transformer which can sink loop current is used. The zeners are chosen to properly limit transmission levels to the required −9 dBm.

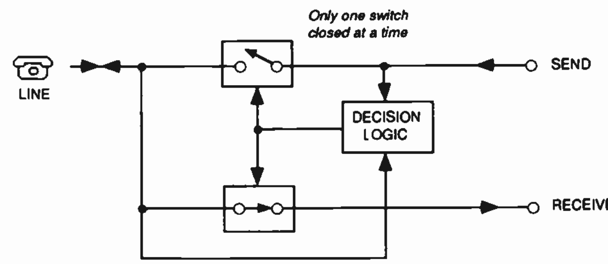

Figure 3.10-15. Switching interface allows two-way conversation, but only one way at a time.

clients hear their commercial masterpieces before they go into the control room.

When hooking up to a multi-line phone, connect to a point where the tip/ring is present after line selection. The most convenient place is usually right at the phone network. Use headphones to find the spot.

Two-way Interfacing

The simple coupler's limitations become apparent when it is necessary for the caller to hear the announcer and the audience to hear the caller simultaneously. A more sophisticated method is needed because of the requirement to have isolated send and receive audio signals.

Switching

This is what you get when you connect a speakerphone to your console input. No commercial broadcast interface uses this technique, which uses gain switching to keep the send audio from appearing at the receive output. Two electronic switches or voltage controlled amplifiers are used in such a way as to ensure that either the send or the receive path is closed at any given time, but never both simultaneously (see Figure 3.10-15). A decision circuit compares the send and receive levels, with the direction of transmission being determined by the relative signal strengths.

The disadvantage of the switching technique is its uni-directional nature. The caller cannot be heard while the announcer is speaking, and noises in the studio can sometimes cause a caller to disappear momentarily, especially on weak calls.

The Hybrid

Hybrids were invented long ago to separate the send and receive signals from the common two-way phone pair. Early hybrids were made from transformers with multiple windings. Nowadays, most hybrids are made with active components and are known as *active hybrids.* Both circuit types use the same principle and achieve the same effect.

In Figure 3.10-16, the first op-amp is simply a buffer. The second is used as a differential amplifier; the two inputs are added out-of-phase (subtracted). If the phone lines and the *balancing network* have identical characteristics, then the send signals at the second differential amp will be identical, and no send audio will appear at the output.

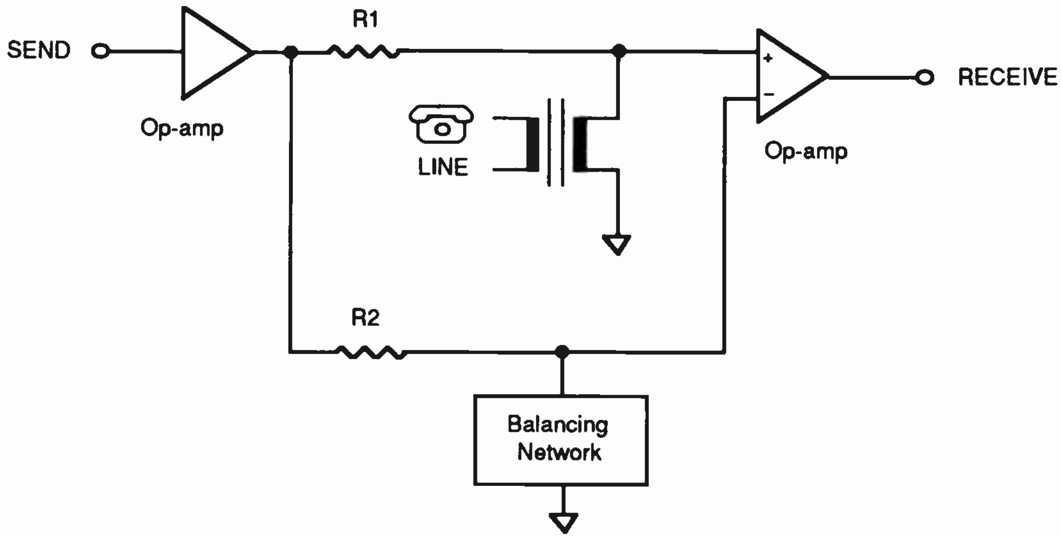

Figure 3.10-16. Op-amp hybrid. The second op-amp is used as a differential amplifier to perform the required subtraction for nulling.

The balancing network is a circuit consisting of capacitance, resistance and sometimes inductance, forming an impedance network. Depending on the hybrid's application, this circuit can be very simple or it can be comprised of a large number of components and have a very complex impedance characteristic.

R1 and the phone line form a voltage divider, as does R2 and the balancing network. If the phone line and balancing network are pure resistances, then, clearly, the phone line and the balancing network must have the same value in order for the signals at the differential amplifier to have the same amplitude and for complete cancellation to occur.

The phone line, however, is not purely resistive, but rather is complex impedance, causing both the amplitude and phase to vary as the send signal frequency varies. Two-to-four wire converters, transformers, repeaters, T-carrier systems and other telco systems are responsible for significant impedance bumps. Loading coils also usually have a deleterious effect on the performance of hybrid interfaces since the coils can create resonant peaks and phase anomalies in the phone line's impedance curve which are difficult to null out.

Only when the impedance of the balancing network is the same as the phone line, and the signals at the differential amplifier are matched in both amplitude and phase, will full cancellation of the send signal be achieved. Otherwise, leakage results—the scourge of hybrids.

Because the phone company's requirements are not generally too stringent, they usually use a simple network with compromise values of resistance and capacitance. Their goal is to get an average of about 12 dB rejection, with 6 dB acceptable on difficult lines—just enough to prevent feedback in a system with back-to-back hybrids. When the situation calls for better performance, modules with a number of R and C elements that can be switched in or out are employed, the switches being set to match the network to a particular line.

Broadcast Hybrid Application

In broadcast application, the studio mixing console combines the output of the hybrid and the announcer's microphone audio, as illustrated in Figure 3.10-17. As discussed previously, the hybrid output consists of both the desired caller audio and the undesired leakage—(the announcer audio but *phase-shifted because of the phone line's reactance*). If the amount of leakage is too great and the phase shift too extreme, the announcer sound will suffer degradation as the original and leakage audio combine in and out of phase at the various affected frequencies. When this occurs, the announcer sounds either hollow or tinny as the phase cancellation affects some frequencies more than others. Another effect of too little transhybrid loss is that feedback can result from the acoustic coupling created when callers must be heard on an open loudspeaker. Yet another problem can occur when lines are to be conferenced; when the gain around the loop of the multiple hybrids is greater than unity, feedback singing will be audible. So a hybrid will be useful for broadcast only when leakage is kept acceptably and consistently low.

The plots of phone line impedance vs. frequency and phase shift shown in Figure 3.10-18 are the result of measurements performed on phone lines at a radio station in the Midwest. They indicate the wide variation seen on typical telco lines as provided to broadcasters. The lines with smooth curves have impedance characteristics that could be emulated with a simple resistor-capacitor (RC) combination. These lines would work fairly well with a simple hybrid, since an RC balance network would match the impedance characteristic closely enough to make the cancellation of send audio at the hybrid output good enough to prevent coloration of the announcer audio.

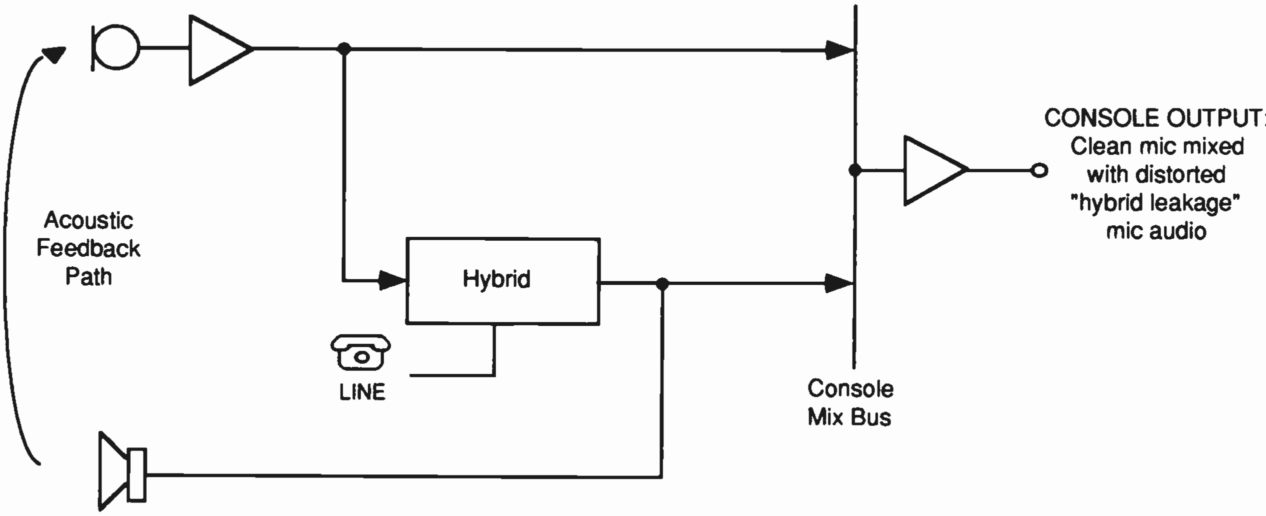

Figure 3.10-17. Block diagram of typical studio arrangement with telephone hybrid. Announcer audio is combined with hybrid output, potentially causing problems with announces voice distortion. The acoustic path is a possible source of audible feedback.

Those other lines are quite another story! While it would theoretically be possible to construct a balance network to match the difficult lines, practical considerations usually keep this approach from being used. The impedance characteristic required is too difficult to produce using resistors and capacitors. If the hybrid is to be switched among a number of lines, the line characteristic would have to be consistent from call-to-call and nearly the same impedance curve.

Digital Signal Processing Hybrids

Digital signal processing (DSP) offers a very powerful and effective technology to improve hybrids. DSP is the process of operating on analog signals that have been converted into the digital domain. Since the signals are numbers, mathematical operations can be performed to manipulate them before being returned to analog. Complex processing functions either impractical or impossible to be done with analog circuit elements are achievable in DSP.

With the DSP hybrid, natural simultaneous conversation is possible without distortion of the announcer audio. To accomplish this, the announcer and caller audio signals are digitized and processed in a system that makes use of a specialized DSP microprocessor. The digital hybrid incorporates software programmed to perform the hybrid cancellation function. The technique, *convolutional least mean square adaptive filtering*, is capable of very accurate synthesis of the required balancing transfer function for maximum nulling (see Figure 3.10-19). Unlike resistor/capacitor analog schemes, the adaptive filter can create the com-

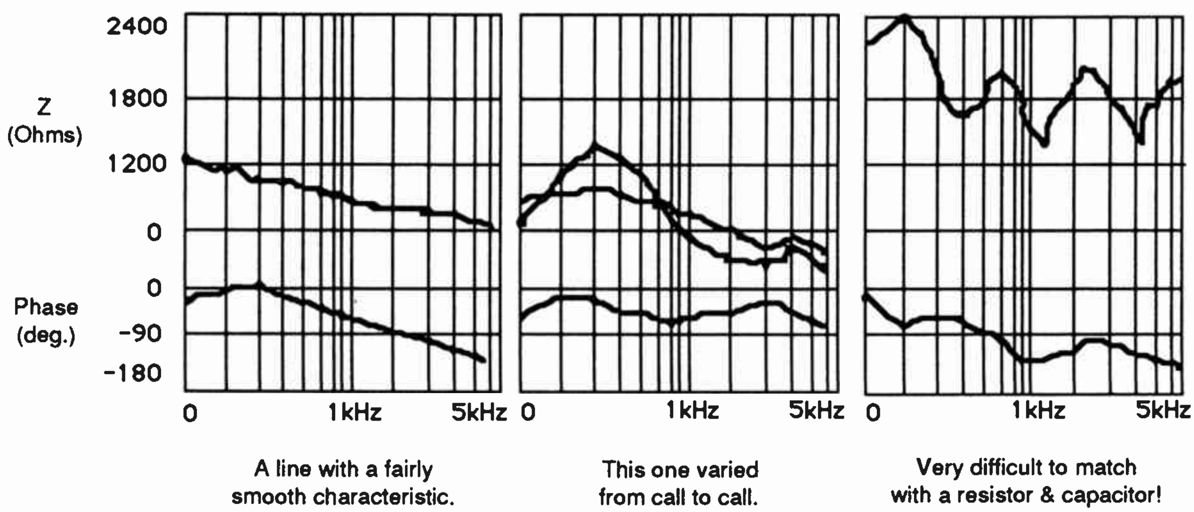

Figure 3.10-18. Impedance vs. frequency curves for some typical phone lines.

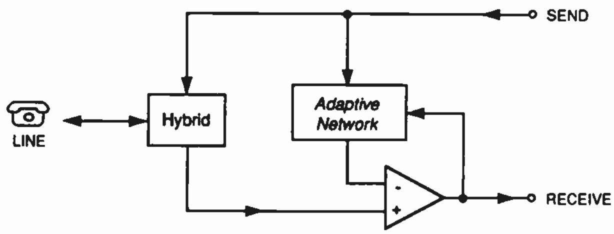

Figure 3.10-19. In the DSP hybrid, the digital balancing network continuously adjusts to the phone line impedance characteristic. When the adaptive network transfer function is identical to that of the phone line, perfect cancellation is achieved. Since the adaptive network is a digital filter than can create almost any required curve, performance is superior to the analog hybrid alone.

plex multiple break-point impedance vs. frequency curves required by difficult-to-match phone lines. The send and receive signals are constantly compared in a feedback loop with the leakage becoming an error control signal which drives adjustment of the *digital balancing network.*

The performance advantage of the digital hybrid technology is striking. On a typical phone line with a fairly smooth impedance curve, an analog hybrid might attain 15–20 dB transhybrid loss. A digital hybrid will likely produce 40 dB or better transhybrid loss. On lines with difficult impedance curves, the analog hybrid's performance will usually be so poor as to prevent its use, while a digital hybrid would perform acceptably.

When a call is initially established, a brief mute/adaption period provides an opportunity for the system to adjust to the phone line prior to the call going on air. The caller hears a noisy tone, but none of this tone is heard on the air since the output is muted. This has the incidental benefit of removing the line switching clunk. Adaption continues as the conversation proceeds, using voice as the reference signal.

While in the digital domain, other operations in addition to the hybrid adaptive balancing can be performed. Automatic gain control (AGC) can take advantage of digital techniques to significantly improve upon the functions implemented in analog. For instance, cross coupling to the hybrid section is possible in order to avoid the output AGC, confusing hybrid leakage with low level caller audio and inappropriately increasing gain. AGC may be smartened in other ways, as well. An adaptive floating expansion threshold, for example, improves noise-gating quality.

Evaluating Hybrid Performance

The amount of hybrid rejection—the transhybrid loss—directly affects the on-air audio and is the most critical measure of hybrid quality. The true test of hybrid performance is determined by measuring the amount of rejection across the entire audio frequency range, preferably with pink noise as a test signal at the send input. Any hybrid with an adjustable R and C balance network can produce high rejection at a single frequency, since both phase and amplitude at a single frequency can be adjusted for good cancellation.

Another thing to keep in mind—although the two are related, the transhybrid loss is not the same as the observed difference between the caller level and the leakage at the hybrid's output. That is because the typical phone call is maybe −20 to −25 dBm (on choke lines, even lower) and the send level (to the caller) from the hybrid should be −10 dBm. That means that the hybrid has to use up 10–15 dB of its transhybrid loss just to get even. The remainder becomes the observed difference.

Other important performance characteristics include S/N ratio, distortion and (for a digital unit) number of bits in the audio path. The operation of the dynamic functions—the AGC, noise gate and override ducking—make a significant contribution to a hybrid's effective performance.

Combining the Hybrid and Switching Techniques

This is the method used in nearly all commercial interfaces. The hybrid produces as much send-to-receive isolation as can be achieved. Then a ducking or *override* function causes the *dynamic* rejection to be greater than the hybrid alone can produce. When send audio is present, the receive gain is reduced. Thus, leakage also is minimized. However, since the level from the phone is also reduced when the announcer is speaking, there is a sacrifice of full-duplex operation. A user adjustment in the control signal path permits variation of the amount of receive ducking, allowing full duplex operation when the hybrid alone produces sufficient rejection, or speakerphone-like operation whereby the caller is turned almost completely off when the announcer speaks. As a practical matter, this control is usually set to provide the minimum amount of ducking which provides adequate send-to-receive leakage suppression.

ISDN For Studio Call-In Talk Systems

ISDN can provide a direct digital connection to the POTS analog network, so it can be used to enhance the quality of on-air calls. A call set-up message is sent from the customer equipment to the network to tell it to switch into POTS interworking mode. (This is in contrast to when an ISDN line is used with MPEG codecs. In that case, the line may be carrying voice signals but in a format that is incompatible with POTS phones. Instead, the network is providing a transparent end-to-end digital path.)

The cost of ISDN service is not a barrier. With ISDN lines costing about the same as analog in most parts of the United States. An ISDN BRI, with two channels, costs about twice as much as a POTS line. (Pricing varies depending on the telco but ranges from a 20% discount to a 30% premium. The average is probably around a 10% premium.

Broadcast interfaces may use either BRI or PRI. A simple interface for the newsroom could use a single BRI. Even sophisticated multiline systems could use

BRIs, with enough of them to achieve the desired number of lines. While PRIs would seem to be a more technically appropriate solution for a multiline system, BRIs may be more cost effective, more readily available and able to provide a measure of redundancy. A system using PRI or T-1s may be able to share lines among a number of studios, with connections to both hybrids and codecs.

ISDN Lines Are Inherently 4-Wire

As we have learned, analog lines use a single pair of wires for both signal directions, mixing the send and receive audio. This causes the famous leakage problem—where the announcer's audio is present on the interface output, instead of the desired caller only audio. Digital circuits inherently offer independent and separated signal paths.

While DSP based hybrids applied to the problem of separating the send/receive signals are dramatic improvement over analog systems, ISDN enables further improved performance. This is because it offers a fully independent path for each speech direction. In the case where both ends of a connection are digital, there is no mixing whatsoever. In the call-in application, the far-end from the studio will still be 2-wire, so the audio paths will not be fully independent and a digital hybrid function will still be necessary to cancel residual leakage. But moving the studio side connection away from mixed analog can help tremendously because it provides the hybrid a much better starting point.

Better Digital-Analog Conversion Quality

The codecs used in telephone central offices are not as good as the converters commonly used in audio equipment. Fidelity is not an important consideration when designers choose parts for this function. In a professional interface for studio application, we are able to design with much better converters than available in the telco's equipment. Noise-shaping functions permit a larger word-length converter to provide significantly better distortion and S/N performance.

In all digital installations, the phone interface can maintain a digital path all the way. Audio Engineering Society/European Broadcasting Union (AES/EBU) can be provided on the interface to accomplish the connection to the studio gear.

Lower Noise

As digital circuits, ISDN lines are not susceptible to induced noise. Analog lines are exposed to a wide variety of noise and impulse trouble-causers as they move across town on poles and through your building. Hum is the main one, given the line's proximity to transformers and ac power lines, but there are also sources of impulse noise from motors, switches and other sources. Digital lines convey the bits precisely and accurately from the network to your studio equipment without any perturbation—so the audio remains clean.

Call Setup and Supervision are Better

Analog lines use a strange mix of signaling to convey call status. Loop current drop and returned dialtone signal that a far-end caller has disconnected; blasts of 100 volts at 20 Hz mean someone wants you to answer. Why should we be using a mechanism designed to bang a gong against a metal bell to transmit network status information in the 1990s? ISDN uses a modern digital approach to controlling calls and conveying status information about them. The sophisticated transactions on the D channel are able to keep both ends of a call accurately informed about what is happening.

ISDN call set-up times are often a few tenths of milliseconds, enhancing production of a fast-paced show. Perhaps more importantly, when a caller disconnects while waiting on hold, the ISDN channel communicates this status change instantly. This contrasts with the usual 11 second delay on most analog lines. One of the most common complaints of talk hosts is that when they go to a line where they expect a caller to be waiting, they are met instead with a blaring, annoying dialtone. The chance of this happening with an ISDN line is reduced to near zero.

Another common error is when a talent goes to punch up a line that looks free, but is actually just about to begin ringing and connects to a surprised caller. This condition results from the delay in the ring signaling, which comes from the nature of the analog line's ringing cadence. This is much less likely with ISDN because the ambiguous status period is eliminated.

Levels

ISDN does not have the FCC-mandated -9 dBm send level limit. Audio may be adjusted to fill up the digital word, resulting in higher send signal volume.

Reduced Feedback During Multi-line Conferencing

When conferencing is required on 2-wire circuits, very good hybrids are needed to separate the two audio paths to add gain in each direction. When the gain around the loop exceeds unity, there is the possibility of feedback singing. Since the conference path usually includes four AGC functions, the hybrid must be sufficiently good to cover the additional gain that may be dynamically inserted. Because of the 4-wire nature of ISDN, the hybrid function is more effective and more reliably so across a variety of calls. That means more gain can be inserted between calls before feedback becomes a problem.

Line Monitoring

Since there is a full-time connection between the central office and the terminal on the D channel, it is possible to detect when a line is a not working. On an analog line, one discovers a problem only from a failed attempt to use the line.

The ISDN Broadcast Interface

Most of the functions performed by an ISDN interface are similar to that of an analog DSP hybrid, but there are some differences, both in the required functions and in the implementation of the common features.

Send/Receive Separation. This is the traditional hybrid function provided by broadcast telephone interfaces. Despite the fact that ISDN lines naturally have two independent send and receive paths, it is still necessary to provide additional functions to further reduce leakage. The reason is that almost all calls will originate with telephone sets connected via 2-wire analog lines, and so there will still be a mixing of both speech directions.

Acoustic Coupling Reduction. There is often an acoustic path between the received caller audio and the send audio signal. This results from having a loudspeaker in the studio that produces sound that couples into the microphones. When the talent use headphones for monitoring callers, this is not a problem. But sometimes it is not practical to convince guests to wear headphones, and television stations generally do not want talk show talent to wear earplugs. In these cases a combination of adaptive cancellation and dynamic gain reduction will reduce the coupling electronically.

High-grade Digital-to-Analog Conversion. When an analog connection to studio equipment is required, pro-grade converters can be used to provide much better quality than the usual telco conversion. At minimum, 16 bits should be used, but 18–20 bits may not be excessive.

Sampling-rate Conversion. When the studio connection is via a digital AES/EBU channel, no analog-digital conversion is required, but it will be necessary to adapt the sampling rate of the telephone network to the studio rate. telco sampling rate is 8 kHz, and studio equipment will usually operate at 32, 44.1 or 48 kHz. A process is required to perform the required up-and-down sampling, while suppressing aliasing and reconstruction audio components.

Automatic Gain Control. As with POTS hybrids, this function should be provided on both the send and receive audio paths. On the send side, it is necessary to smooth the wide level variations that arise from usual studio practices. Talent are used to having on-air processing take care of level variations and are generally not very careful at riding gain. On the receive side, AGC is essential to deal with the very different levels that can result from the many types of phone sets and telco analog network components.

Dynamic Equalization. With phone sets having a very wide variety of microphone characteristics, a multiband automatic equalizer helps callers have a reasonable spectral consistency.

Caller "Ducking." As with POTS hybrids, this can serve to reduce residual leakage. However, since ISDN hybrids have much better inherent transhybrid loss, this feature will be used mostly to satisfy a programming aesthetic requirement, reducing the level of the phone audio when the host talks and allowing her an automatic control over a caller who wants to carry on. This is a matter of taste; some talent and programmers prefer no ducking so that hosts and callers can conduct heated exchanges without impediment, while others want to exercise control.

Caller ID. ISDN naturally conveys caller ID information. This is transmitted instantly in the setup message and is much faster than the 1200-baud modem method used in analog caller ID.

Conference Linking. With two B channels available on one BRI line, broadcast interfaces will be dual units, making possible high quality conferencing between the two potential callers. Some systems will probably support larger numbers of conferenced callers.

BROADCAST ON-AIR SYSTEMS

With phones an important part of programming at many stations, systems to enable convenient, high quality on-air integration of phone conversations are essential.

On air phone systems are specifically designed for use in the broadcast studio environment. While many business phone systems offer similar functions—line selection and status indication, conferencing—they are generally awkward to operate in an on-air environment and may have other limitations such as the audio quality flaws described earlier.

While the phone network would not be considered to be a high fidelity source, it clearly does not help to degrade it further by adding additional noise, distortion or frequency response impediments. For that reason, broadcast phone systems are designed with these issues and other specialized requirements in mind. For example, a broadcast phone system output should be free of inappropriate switching sounds, and air talent should be able to access and manipulate lines live without any pops or clunks being audible to listeners.

Ergonomic Requirements

Line selection and other functions must be performed intuitively and with a minimum of hassle. Unlike a telephone set, broadcast line selection panels have large illuminated buttons. To avoid operator confusion, features are limited to those necessary for on-air application. One such example is panels that drop into an open position in the studio mixing console so that the line selection buttons are located near the channel on/off, fader, and audio switching functions.

Conferencing Capability

Most broadcast systems allow any number of lines to be switched to air, even if only a single hybrid is present. But, unless you are blessed with excellent phone lines, you will want additional hybrids with each connected to the other through a multiple mix-minus arrangement. That way, it will be possible to have amplification between callers. Without multiple hybrids, callers might have difficulty hearing each other, since you are at the mercy of the telco-delivered line level.

Special Features

Desirable features for an on-air phone switching system include:

Busy/unbusy. To prepare for a contest, all lines may be busied-out and then returned to readiness after the contest has been announced.

Automatic next line selection. Pressing the next button picks up the line that has been holding the longest. If no line has been holding, the longest ringing-in line is selected.

Call length timer. Displays call duration time.

Held caller timer. This tells which line has been holding longest and for how long.

Integration of On-Air Systems with PBXs

To interconnect the on-air system with the front office PBX, there are a number of possibilities.

Segregate the studio and office phone lines. Ports from the PBX configured to look like CO lines feed an input or two on the studio system so that that calls taken by the receptionist can be put on the air.

Route all lines through the PBX. The studio lines are programmed in the PBX to be forwarded to the ports that feed the studio system. Some audio degradation may result.

Simply parallel the two systems. With no cross-coupling of line status information, there could be trouble if a line is inadvertently picked up on one system while the other is being used.

Route the on-air lines through the broadcast system. Possible if the broadcast system brings out a loop-through connection. This scheme prevents PBX phones from picking up active on-air lines.

Improving Phone Audio Quality

Whether extracted from analog or digital lines, due to its limited frequency response and fairly high distortion, the audio from the phone has the poorest quality of our on-air sources. Thus, it generally pays to make telephone audio less of an earsore so that it does not stand out more than is necessary from other program material.

If the phone network is a digital system, why do phones still sometimes sound pretty awful on the air? The main problem is that phone engineers never designed the systems with a connection to full fidelity broadcast systems in mind. The 8/13 bit quantization scheme used for phone speech coding results in less than high fidelity. Often, the problem lies in the specific implementation rather than in any inherent shortcoming in the standard or the technology. One important quality limitation results from the anti-aliasing and reconstruction filters in the codecs. These filters usually have an ultimate roll-off of around 35 dB. Audio above the 4 kHz Nyquist frequency will alias and appear in the 300 Hz–3.4 kHz band as distortion. Thus, typical codecs have distortion of 2–3% from aliasing. The strange raspy noise that seems correlated with the speech sometimes heard on a telephone circuit is a result of the effects of this kind of distortion combined with audible quantization errors.

Also the codec filters generally use switched-capacitor technology, which tends to be fairly noisy. Some newer codecs avoid the switched-capacitor problems by employing the same *delta-sigma* over-sampling and digital decimation concept used for high performance digital audio conversion, but these are only rarely found in telco central office equipment.

What can we do? An ISDN connection solves half of the problem, since at least one of the telco's codecs is bypassed. We still have the other end to contend with, and the majority of broadcast connections will remain analog. Fortunately, there are some remediation possibilities. Filtering, equalization, gating and dynamics compression are the primary tools. Most of the commercial hybrid interfaces have at least some of these processes built-in.

Filtering

On a dial-up phone line, there is very little audio above 3.4 kHz—but there is noise. Thus, a filter with a very steep roll-off above the telephone passband will reduce phone line noise significantly without affecting conversation audio. The low-end can be improved as well. Low-frequency hum is often a problem—usually 60 Hz mixed with its second harmonic, 120 Hz. Thus, it is often a good idea to have a sharp roll-off starting at 200 Hz or so.

Equalization

An equalizer used to shape the frequency response of the phone line within its audio bandwidth can result in marked improvements in perceived quality. A typical phone line has an excess of energy at around 400 Hz and considerable roll-off at both the top and bottom ends of its passband, so the idea is to compensate by adding gain at both. Boosts at 2.5 kHz and 250 Hz and a cut at 400—500 Hz with a parametric equalizer will help achieve better sound. Since every phone line is different, the ear is usually the best instrument to evaluate the results.

When it is not possible or practical to make custom adjustments, an adaptive multiband EQ can be an effective tool. The principle is much the same as implemented in broadcast transmission processors. Audio is filtered into multiple bands, and an automatic gain adjustment is performed on each spectral segment. Given the limited frequency range of telephone calls, three bands are sufficient.

Noise Gating

Another effective processing device is the expander or noise gate. These devices may be used to reduce gain between the words of a conversation, thus making phone line noise less objectionable. On extremely noisy lines, however, the gating action can make noise more distracting by causing it to come and go with the words. In such cases, it might sound better to leave the gate off and let the noise remain present at a constant level. A unit with variable threshold and duck ratio can be adjusted so that the optimum compromise may be achieved between the benefit of reduced noise and audibility of the effect.

Dynamics Compression

Levels on phone calls vary widely, and it is not uncommon to see levels range from −40 to near −4 dBm as calls are switched into a given line. A compressor helps to smooth the levels. An AGC that maintains a constant compression ratio regardless of average gain reduction produces more consistency. Freeze gating is also important, so that gain does not increase during caller speech pauses.

Mix-Minus: Getting the Send Audio Feed

The feed-to-caller signal has come to be referred to as *mix-minus*, so called because it is often the *mix* of all of the console's active inputs *minus* the phone hybrid's output (see Figure 3.10-20). A mix-minus feed is necessary because the hybrid will create a feedback path if it is forced to chase its tail. Usually, the mix-minus is a mix of only the studio microphones, but it may sometimes include other audio that is to be sent to the phone such as contest sound effects from cart machines.

To create the required signal in simple installations, a feed taken from the main announce microphone may be all that is necessary. The patch send output available on many consoles is precisely what you need. In installations where multiple microphones are to be used, a combiner of some sort is required. This may be a small outboard mixer or a homemade op-amp summer or even a resistive combiner. Better consoles offer special purpose busses that may be used for mix-minus, often with provision for selective switching of sources into the phone feed. If you need to modify an older console that does not have special buses, a device (made by Henry Engineering) accomplishes the mix-minus by subtracting the hybrid audio from the console program output with a differential amp scheme. This unit generates a mix-minus signal true to its name—all sources except the phone itself will feed the phone.

Recording Phone Calls

Some stations may want to record calls for later playback. One technique is to have the mix-minus go to one track of a stereo tape machine, while the other channel gets the hybrid output with the caller audio. The result is a two-track tape with the announcer and caller separated. To play back, the console's input mode is set to mono; the relative balance, if need be, can be adjusted upon playback. The production department can use its tape to facilitate extraction of contest squeals.

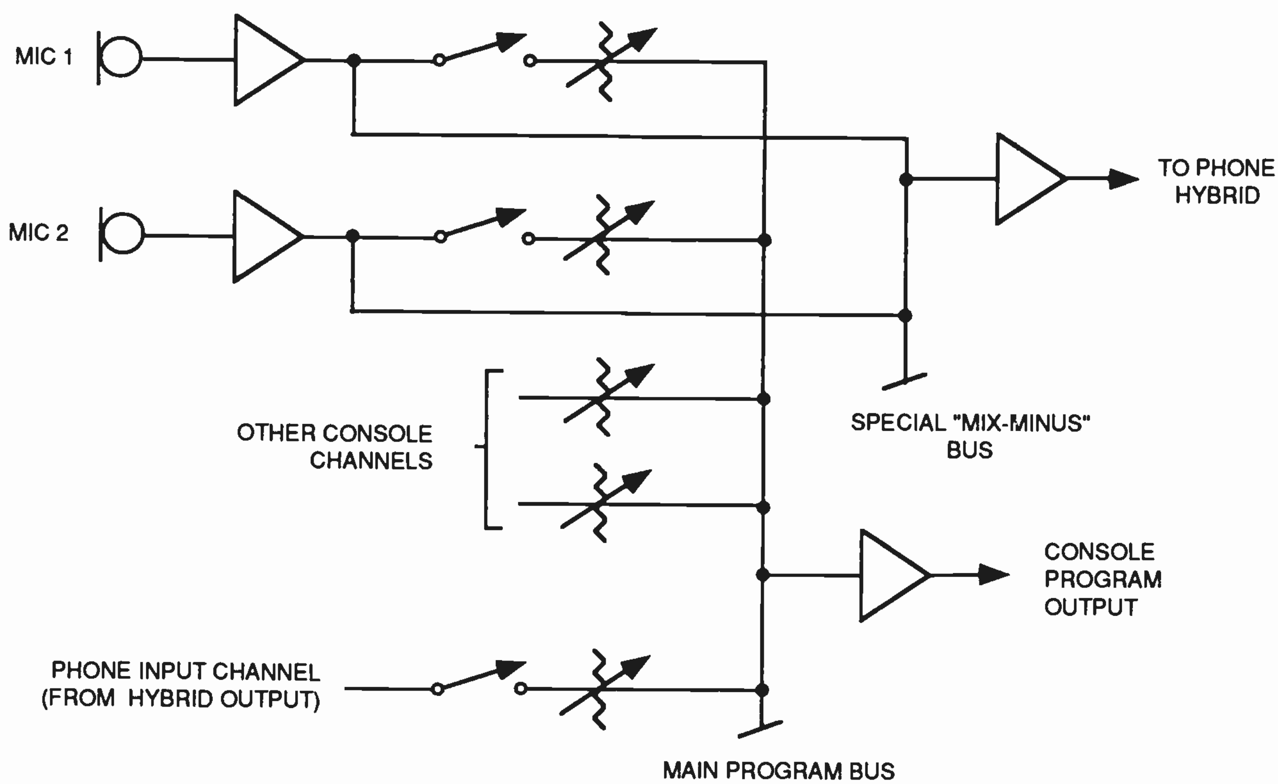

Figure 3.10-20. Simplified studio block diagram shows the mix-minus required for hybrid feed.

Talk-Show Screening Software

In its simplest form this personal computer software lets a talk show screener/producer communicate to the air talent who's on the line waiting to talk. It replaces the paper pieces on the window system employed for years at many talk stations. The better packages offer a number of convenient features: display of liner messages and other information, storage of caller data for demographic analysis and remote operation via modem.

An Ethernet or serial port on the broadcast system can let the computer display reflect current line status. New software enables laptop computers to extend full control capability and status display to a remote site, and modern systems even permit this function to be conveyed over the Internet.

ISDN: HI-FI REMOTES ON DIAL-UP LINES

ISDN makes high quality remotes possible with dial-up convenience. Convenient, reasonably priced studio-quality audio from almost anywhere in the world is now possible. The enabling technologies are digital telephone services like ISDN and audio compression or coding algorithms. Products offering this capability have burst onto the market in the last few years, and broadcasters have enthusiastically embraced the programming possibilities created by the new capability.

BROADCAST CODECS

Broadcast codecs have evolved rapidly over the past few years. Most are now single-box solutions that include an ISDN TA interface and a number of selectable coding algorithms. Some portable units even include a mixer for multiple audio inputs and outputs. Most are full duplex, with provision for transmitting and receiving simultaneously, and most offer the ADPCM G.722 and perceptual MPEG Layers 2 and 3 coding algorithms. Some offer a feature to allow dialing to POTS phones for low-grade voice communications. State-of-the-art systems include an auto-dial feature that adjusts the codec section settings, such as bit rate and transmit and receive coding choices, as well as the numbers for the codec you wish to dial.

In MPEG modes, many codecs permit bidirectional serial data at 9.6 kbps to be transmitted simultaneously with the audio. End-to-end parallel contact-closures offered by many codecs may be used to control recorders and other devices. Since codecs are inherently digital devices, it is only natural that AES/EBU digital inputs and outputs are usually available. Sample rate conversion is generally available on both input and output paths.

For many remotes, a receive-side mixer is required to combine the mix-minus signal from the studio with the local audio (see *Dealing with Delay*, below). In some cases, you will want to have two outputs: one for the talent, which can include cueing audio, and another for the public, who listens to PA loudspeakers. This is a common feature in portable units that are designed to be used in the field. Another valuable feature for remote applications is an input audio limiter to prevent digital nasties when the program signal peaks instantaneously, as might be the case on remotes hosted by excitable sports announcers.

The J.52 Protocol

While codec manufacturers have been remarkably successful at making their products inter-operate, it is often necessary to manually adjust a unit at one end or the other to a compatible mode. The J.52 standard addresses this problem by including information in the transmitted bit stream which identifies the details of the encoding method being used, allowing the receiver to automatically conform. J.52 also standardizes channel bonding.

ADPCM Coding

Adaptive delta pulse code modulation (ADPCM) pre-dates MPEG perceptual coding. It has been around as an international standard the longest and is probably the most widely used system. ADPCM is much simpler than the perceptual methods but suffers from poorer audio performance. It has the benefit of low cost and the unique advantage of low delay.

The most popular method, G.722, was invented in the late 1970s and adopted as a standard in 1984 by the Consultative Committee for International Telephony and Telegraphy (CCITT), a division of the United Nations. The technique used is Sub-Band ADPCM, which achieves data reduction by transmitting only the difference between successive samples. G.722 does this in two audio frequency sub-bands: 50 Hz–4 kHz and 4 kHz–7 kHz.

G.722 has a frequency response extending to 7 kHz at 56 or 64 kbps. Unless there is no alternative, it should be used only for voice feeds, as music transmitted via G.722 has a distinct fuzzy quality. It is good also for cueing and intercom channels. Only two bits are allocated per sample for audio frequencies above 4 kHz—sufficient for conveying the sibilance in voice signals but not very good for intricate musical sounds. Also, the *predictor model* used to determine the step size in the adaptive function is designed only for speech.

G.722 has the lowest delay of all popular coding methods, about 20 msec. For this reason, it often used as a return channel so that the round-trip delay is reduced, even when a higher fidelity method is used for the on-air feed.

Statistical Recovery Timing

G.722 uses a procedure called *statistical recovery timing* (SRT) or *statistical framing* to lock the decoder to the data stream. This procedure is specified in ANSI standard T1.306-1989.) The process usually happens instantaneously but can take up to 30 seconds.

The locking can be sensitive to audio present on the G.722 path, as it relies upon the properties of the audio bit stream itself. Some audio material and tones can prevent lock from ever happening. Silence is the most reliable signal for locking, and undistorted voice is usually acceptable. The most common problems are with sine tones and distorted voice or music signals, in which case, removing or lowering (to around −12 dB) the audio for a few seconds will generally cause lock to occur. In very rare cases, it may be necessary to disconnect and redial. Other strange effects may be observed. Tones and noises may be present before locking occurs, and some continuous audio tones may cause momentary unlocking.

Perceptual Coding

The broadcast world has been transformed by the introduction of perceptual audio coding techniques. Applying perceptual coding methods, it is possible to pass studio-quality 15 or 20 kHz bandwidth audio over ISDN channels.

Demystifying MPEG

By far, the most popular perceptual coders rely upon techniques developed under the MPEG umbrella. About a decade ago, when the CD had just been introduced, the first proposals for audio coding were greeted with suspicion and disbelief. There was widespread agreement that it would not be possible to satisfy golden ear listeners while deleting 80% or more of the digital audio data. In response, the MPEG was formed, and since 1988 the group has been working on the standardization of high quality low bit rate audio coding. Two standards have been completed: MPEG-1 (coding of mono and stereo signals at sampling rates of 32, 44.1 and 48 kHz) and MPEG-2 (ISO/MPEG IS-11172: coding of 5 + 1 multi-channel sound signals and low bit rate coding of mono and stereo audio at sampling rates of 16, 22.05 and 24 kHz). Today almost all agree not only that audio bit rate reduction is effective and useful, but that the MPEG process has been successful at picking the best technology and encouraging compatibility across a wide variety of equipment.

The MPEG process is open and competitive. A committee of industry representatives and researchers meet to determine goals for target bit rate, quality levels, application areas etc. Interested organizations that have something to contribute are invited to submit their best work. A careful, double blind listening test series is then conducted to determine which of the entrant's technologies delivers the highest performance. The subjective listening evaluations are done at various volunteer organizations around the world that have access to both experienced and inexperienced test subjects. Broadcasters are the most common participants with recent test series conducted at the BBC, the CBC, NHK. Finally, results are tabulated, a report is drafted and a standard is issued.

In 1992, this process resulted in the selection of three related audio coding methods, each targeted to different bit rates and applications. These are the famous layers. In 1997, another algorithm, advanced audio coding (AAC) was added to the MPEG standard.

Acoustic Masking

All of the MPEG codecs rely upon the celebrated *acoustic masking principle*—an amazing property of the human aural perception system. When a tone—called a *masker*—is presented at a particular frequency, we are unable to perceive audio at nearby frequencies that are sufficiently low in volume. As a result, it is not necessary to use precious bits to encode these inaudible, masked frequencies. In perceptual coders, a filter bank divides the audio into multiple bands. When audio in a particular band falls below the masking threshold, few or no bits are devoted to encoding that signal, resulting in a conservation of bits that can then be used for the bands where they are needed.

MPEG Layer 2

MPEG Layer 2 is the world's most popular perceptual coding method. It is the preferred choice for applications where greater than 120 kbps/channel is available, such as satellite links and high capacity terrestrial paths such as Primary ISDN or T1 channels. Layer 2 is the method used for satellite television audio and for many other applications such as hard disk storage. It is also used for European Eureka 147 terrestrial digital broadcasting.

Layer 2 offers a *joint stereo* technique to improve coding efficiency with stereo signals. The Layer 2 joint stereo mode uses an intensity coding method. This process has high coding power and is quite effective; however, it may impair stereo separation on some program material as audio above about 3 kHz is combined to mono and panned to one of seven positions across the stereo stage, at lower bit rates.

MPEG Layer 3

MPEG Layer 3 is perfectly matched to the bit rates available on ISDN BRI lines, permitting full FM broadcast quality. Full fidelity 15 kHz mono is possible on a single ISDN B channel and very near CD-quality 20 kHz stereo is achievable using both ISDN B channels. Until equipment supporting the new MPEG AAC standard arrives, Layer 3 is the most powerful method available to broadcasters. It is widely supported in broadcast codec equipment from a number of manufacturers.

MPEG Layer 3 uses a number of advanced techniques to achieve its power:

Psychoacoustic Masking. The audio is divided into 576 frequency bands. First, a polyphase filter bank performs a division into the 32 main bands, which correspond in frequency to those used by the less complex Layer 2. Filters are then used to further subdivide each of the main bands into 18 more. The resulting bandwidth of each sub-band is 27.78 Hz. A 32 kHz sampling rate allows very accurate calculation of the masking threshold values. Sufficient frequency resolution is available to exceed the width of the ear's critical bands (100 Hz below 500 Hz; 20% of the center frequency at higher frequencies) across the audible spectrum, resulting in better hiding of noise than would otherwise be possible.

Redundancy Reduction. A Huffman coding process accomplishes redundancy reduction. Values that appear more frequently are coded with shorter words, whereas values that appear only rarely are coded with longer words. This results in an overall decrease in the data rate with no degradation, since it is a lossless reduction scheme.

Bit Reservoir Buffering. Often, there are some critical parts in a piece of music that cannot be encoded at a given data rate without audible noise. These sequences require a higher data rate to avoid artifacts. Layer 3 uses a short time bit reservoir buffer to address that need.

Ancillary Data. The bit reservoir buffer offers an effective solution for the inclusion of such ancillary data as text or control signaling. The data is held in a separate buffer and gated onto the output bit stream using the bits allocated for the reservoir buffer when they are not required for audio.

Joint Stereo. A joint stereo mode different from that in Layer 2 permits advantage to be taken from the redundancy in stereo program material. The encoder switches from discrete L/R to a matrixed L + R/L − R mode dynamically, depending upon the program material.

MPEG AAC

The MPEG-2 AAC system is the newest audio coding method selected by MPEG and become an international standard in April 1997. It is a fully state-of-the-art audio compression tool kit that provides performance superior to any known approach at bit rates greater than 64 kbps and excellent performance relative to the alternatives at bit rates reaching as low as 16 kbps.

The development of AAC began when researchers became convinced that significant improvements would be possible by abandoning backward compatibility to the earlier MPEG layers. The idea was to start fresh and take the best work from the world's leading audio coding laboratories. Fraunhofer Institute, Dolby, Sony and AT&T were the primary collaborators. The hoped for result was *International Telecommunications Union (ITU)-R indistinguishable quality* at 64 kbps per mono channel. This was a fairly daunting requirement because it requires that no test item fall below the perceptible, but not annoying threshold in controlled listening tests. The test items include the most difficult-to-encode audio known to researchers—isolated pitch pipe, harpsichord and glockenspiel recordings, among others. The thinking was that if a coding system passes this requirement, it will almost certainly perform well with normal program material. Pop or western classical music is tremendously easier to encode.

Compared to the previous layers, AAC takes advantage of such new tools as temporal noise shaping, backward adaptive linear prediction and enhanced joint stereo coding techniques. AAC supports a wide range of sampling rates (8–96 kHz), bit rates (16–576 kbps) and from one to 48 audio channels.

The AAC system uses a modular approach. An implementer may pick and choose among the component tools to produce a system with appropriate performance-to-complexity ratios. Three default profiles have been defined, using different combinations of the available tools:

Main Profile. Uses all tools except the gain control module. Provides the highest quality for applications where the amount of random accessory memory (RAM) needed is not constrained.

Low-complexity Profile. Deletes the prediction tool and reduces the temporal noise-shaping tool in complexity.

Sample-rate Scaleable (SRS) Profile. Adds the gain control tool to the low complexity profile. Allows the least complex decoder.

AAC is the first codec system to fulfill the ITU-R/EBU requirements for indistinguishable quality at 128 kbps/stereo. It has approximately 100% more coding power than Layer 2 and 30% more power than the former MPEG performance leader, Layer 3.

Choosing the Coding Method Most Appropriate to Your Application

The following chart compares some of the important characteristics of G.722, Layer 2 and Layer 3.

One thing that should be apparent from Table 3.10-3

Table 3.10-3
Audio Coding Comparisons

	Layer 3	Layer 2	G.722
Method	Perceptual + Huffman	Perceptual	ADPCM
Audio Freq. Response/mono	15/20 kHz*	8/10 kHz**	7 kHz
Audio Freq. Response/stereo	15/20 kHz*	20 kHz	7 kHz
Delay at 32 kHz/mono	280 msec	—	20 ms
Delay at 48 kHz/mono	240 msec	150 msec	20 ms
Delay at 32 kHz/stereo	450 ms	—	20 ms
Delay at 48 kHz/stereo	340 ms	220 ms	20 ms
20 ms	MS Matrix	"Intensity Coding"	—
ISO Target Bit Rate	64 kbps/channel	128 kbps/channel	N/A
Coding "Power"	12:1	6-8:1***	4:1
Bands	576	32	2
Frequency Resolution (48 kHz)	42 Hz	750 Hz	—

* 15 kHz at 32 kHz sample rate; 20 kHz at 48 kHz sample rate.
** 8 kHz at a 56 kbps network rate; 10 kHz at 64 kbps.
*** 12:1 in intensity joint stereo mode.

is the trade-off between delay and audio performance. Layer 3's excellent audio performance requires a significant delay, because some of its power comes from the ability to analyze the audio over a relatively long period. Layer 2 requires the next longest delay, and G.722 has minimal delay.

The most flexible broadcast codecs permit the coding mode for the send and receive paths to be independently chosen, so the choice may be optimized for the specific requirement of each direction.

Dealing with Delay

All perceptual coders have too much delay for talent on remote to hear themselves via a round-trip loop. Therefore, a special mix-minus arrangement is required—exactly the same as has been used with satellite linked remotes for years. The principle is this: The remote talent does not hear himself via the studio cue return. Rather, his microphone is mixed locally with a studio feed that has everything but the remote audio thus the mix-minus designation. The announcer gets in his headphones a non-delayed version of himself and a slightly delayed version of all of the studio pieces.

To save money and hassle, callers are usually received at the studio, rather than at the remote site. In this situation, phones need to be fed to the remote talent so that they can hear and respond to callers, and the phone callers can hear them. In many cases, the remotes are sufficiently distant that the station cannot be monitored for the caller feed. Even if it could, the profanity delay would be a problem, since the talent needs to hear the phone pre-delay. Instead, the talent hears callers via the return path. As before, this return is fed with mix-minus: a mix of everything on the program bus minus the remote audio.

As for the second half of the equation, the callers hear the talent because the remote feed is added to the telephone mix-minus bus. This should be no problem if you have a setup that permits selective assignment to the phone mix-minus. The most common problem with this arrangement is a result of a phone hybrid with too much leakage combined with the system delay. If the hybrid isn't doing a good job of preventing the send audio from leaking to its output, the special remote send mix-minus is corrupted. Remember, if any of the announcer audio from the remote site is returned via the monitor feed, it will be delayed by the digital link, causing an echo effect. The answer is to make sure you have the best possible hybrid with the maximum transhybrid loss. If it has variable override (caller ducking), you could increase the amount when these remotes are in progress.

The round-trip delay in a typical remote broadcast may be reduced by using the G.722 algorithm for the return cueing path and MPEG for only the on-air direction.

Cascading Codecs

Coder cascading is an active field of investigation among algorithm designers, standards organizations and users.

Some of what we do know:

- Some International Consultative Committee for Radio (CCIR) tests have demonstrated that one pass of Layer 3 at 56/64 kbps can be cascaded with two-five passes of Layer 2 operating at high (112 kbps+/ per channel mono; 192 kbps+ joint stereo) bit rates with good results
- Informal tests at Telos with two passes of Layer 3 transmitted via Zephyr codecs have proven successful, with listeners noticing no audible degradation—even on difficult CDs
- One user has reported that two passes of Layer 3, followed by one pass of sedat, is acceptable (L3 in joint stereo mode).

SEDAT

The goal is to get as much coding headroom as possible at each stage. This is achieved by:

- Using the most possible bits at each stage—the least crunching—and/or
- Using the more powerful coding method of those available at each stage.

Here is some practical advice:

- Use coders only where necessary. Consider the alternatives at each stage. With the cost of hard disk capacity falling, is it really necessary to crunch at this point?
- Use the maximum bit rate you can afford at each stage. Hard disk recorders and other studio systems often have an option to adjust this. For very critical work, remember that some codecs may be used in a mode where a mono program is split over two digital network channels
- Use Layer 3 or AAC on low bit rate channels.

The staff at Fraunhofer Institute who developed the Layer 3 algorithm have introduced a computer based perceptual coding analyzer. This device has the potential of making objective measurements a reality and may help us learn about the effects of cascading with various coding methods and bit rates.

Mixed MPEG Layer 2 and Layer 3 Signal Chains

What about the case where you will be using L2 and L3 together in a signal chain? It turns out that the two methods are nicely complementary.

At low bit rates, Layer 3 gets more signal-to-mask margin than Layer 2. This is why it performs better in the low bit rate tests. It accomplishes this by using a filter bank with more bands, 576 vs. 32. One effect of this is time spread. (More frequency resolution requires a longer time window. This is a fundamental physical law.) For one or two passes, this is good, as the ear has masking in both the time and the frequency domains and L3 naturally exploits this additional dimension. The downside is that when many stages of L3 are used at low bit rates, the time spread can become audible (softening of transients and pre-echoes, mostly), and this is a bad thing. L2 does not have this problem. However because it is closer to the edge for S/N, multiple generations result in unmasking (noise and grit, mostly).

International Standards Organization (ISO)/MPEG proponents do not propose that a lot of passes of L3 be used. They advocate that L3 be used at ISDN bit rates for remotes and that L2 be used at higher bit rates in other parts of the signal chain. This is why ISO decided to recommend the layers as they did: L3 for 64 kbps/channel and L2 for equal to or greater than 120 kbps/mono channels.

My own experiments with codec cascading confirm that this is the right approach—the two coding methods seem to complement each other. Two passes of L3 sound noticeably better than two of L2; a pass of L3 followed by a pass of L2 also sounds better than two of L2.

DIAL-UP REMOTES ON POTS LINES

We can not always have an ISDN line at a remote site. Sometimes they are not available from the telco, or we just prefer not to use them because of the cost or the delay and trouble of getting one installed. Since cheap POTS dial-up lines are everywhere it makes sense to find ways to use them for program remotes. The problem is that the 300–3.4 kHz frequency response and limited dynamic range that the dial network provides are not generally adequate for modern broadcast needs.

Modem + Coding = Broadcast Audio on POTS Lines

A method that has emerged in the past few years is the so-called POTS codec. This piece of gear combines a high power coding algorithm with a fast modem. Of course fast is relative here. Recall that ISDN can supply a minimum 56 kbps bit rate, while the fastest modem is limited to 33.3 kbps—and very rarely achieves this speed, usually settling at around 24–26 kbps. (56 kbps modems have the fast rate only in the downstream direction; the upstream remains limited to 33.3 kbps.) Because our goal is to achieve something approaching broadcast quality, this is a very challenging bit rate for audio coding technology.

Generally, we employ a kind of coding that is optimized for speech and very low bit rates. The most common are taken from the code excited linear prediction (CELP) family, which have better audio quality for speech at very low bit rates than the MPEG perceptual coders used in ISDN equipment. They also have much lower delay, a critical characteristic when live interaction is required. Perceptual coders work by using an understanding of how the human ear works, while CELP algorithms model how the mouth produces voice sounds. Not surprisingly, CELP coders do a fairly poor job with musical signals. There can also be problems with background noises, such as applause.

Some equipment has the possibility to select from either CELP or an MPEG algorithm so that the user can decide which trade-off to make.

Frequency Shifting

Now that the digital systems previously described are available, the frequency shifting technique is used much less often. Nevertheless, it has its place, and many units are still in service. Frequency shifting offers a way to squeeze more high frequencies into a line than it will normally pass. More accurately, the process allows different frequencies than the usual 300–3.4 kHz to be passed through a POTS phone line.

Frequency-shifting units using a single phone line move all frequencies up by 250 Hz at the encode side and down by 250 Hz at the decoder as illustrated in Figure 3.10-21. The result is a 250 Hz improvement at the low end at the cost of a 250 Hz loss at the high end. This means a typical phone line's response will be changed after the shifting process to 50–3150 Hz. The 250 Hz loss at the top is not very significant due to the logarithmic nature of audio perception.

The shifting function is accomplished by heterodyning the input audio with a low-frequency carrier. The phasing single sideband (SSB) generation method is employed to allow only one sideband to emerge at the output—the carrier and other sideband having been cancelled in the SSB process. Encoding and decoding can easily be accomplished in the same unit, since only a simple signal path change is required for an encoder to decode, and vice versa. (See Figure 3.10-22.)

Subjectively, the resulting frequency-shifter-processed audio sounds less telephone like. However, the result of improvement at the low end without high end enhancement is often a somewhat muddy or flat sound. You can sometimes improve subjective quality by boosting the high end with a sharp EQ rise above 2 kHz. A parametric EQ or custom filter is preferred so that a high-Q curve can be obtained.

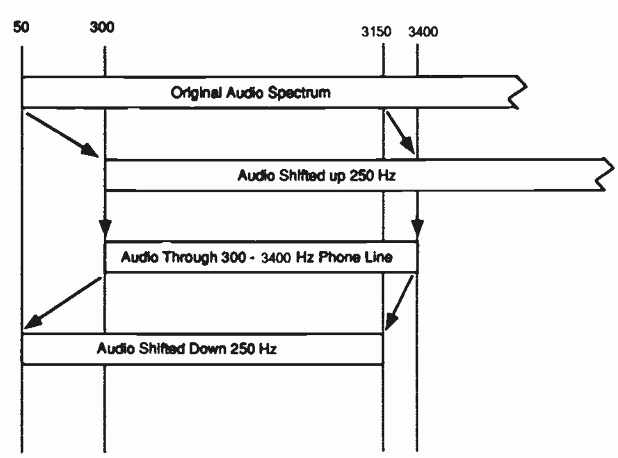

Figure 3.10-21. A frequency shifting bandwidth extender allows improved low end response at the expense of a small loss of high-frequency audio.

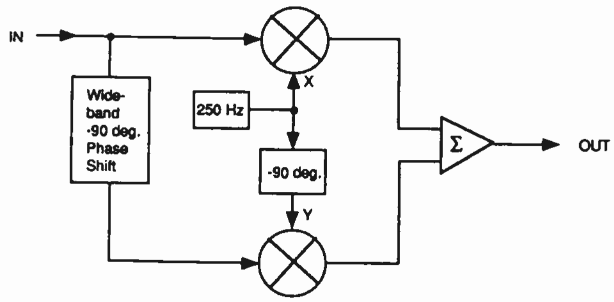

Figure 3.10-22. Single-line frequency extender uses SSB techniques to shift the audio 250 Hz at each end. A decode system is shown; signals at X and Y are reversed for encoding.

INTERFACING PRODUCTION INTERCOM SYSTEMS

To aid communication with the field crew during remote broadcast projects, connecting the production intercom system to dial-up telephone lines is often required. Smooth integration of live news remote feeds, for instance, requires that production personnel at all locations be able to communicate with each other in a simple, trouble-free fashion. This is especially true when multiple remote sites are involved, as for election coverage, major sporting events and telethons. Ideally, crews at each location would use the intercom system without regard for the distances involved. Most often, access to the dial-up phone network is available by wire or cellular, so an interconnection of the intercom system to the telephone network may be the solution.

4-Wire Intercom Systems

Four-wire systems are those in which the two speech directions are kept separated in the switching and distribution process. While it would be possible to use special four-wire telco circuits (or two standard loops) to maintain independent signal paths to remote sites, it is more economical and convenient to be able to use a single phone line. To accomplish this, we must create effective conversion between the 2-wire phone line and a port on the 4-wire intercom matrix. It will be necessary to separate the intermingled send and receive speech signals on the phone line with a 2-to-4-wire converter, or hybrid. One approach is given in Figure 3.10-23.

Transhybrid loss performance will be important when intercom stations with open loudspeakers and mics are to be used and when conferencing of multiple telephone lines is desired. In the first case, the acoustic coupling between the speaker and mic completes a feedback path which includes the hybrid. Clearly, the better the hybrid's isolation, the higher the feedback margin. In the second case, a feedback path exists from each active hybrid through all of the others that are conferenced to it. When the total gain exceeds unity, feedback results. The goal is to have the best possible transhybrid loss so that the maximum line-to-line gain may be achieved.

An auto-answer and disconnect function may be required for unattended operation. This circuit responds to a phone line ringing signal by activating the hybrid and de-activates the hybrid when the calling party hangs up. As discussed in the section on calling party control (CPC) a dial tone detector may be necessary to ensure reliable operation. The tone detectors are connected so as to respond to signals on the hybrid's separated telco receive audio signal. Were this not the case, and the detector was merely connected across the phone line, there would be a major problem when multiple lines are used together in a conference. Why? Because the tones would be conveyed to each line in use (through the intercom switching matrix) from every other line, causing all of

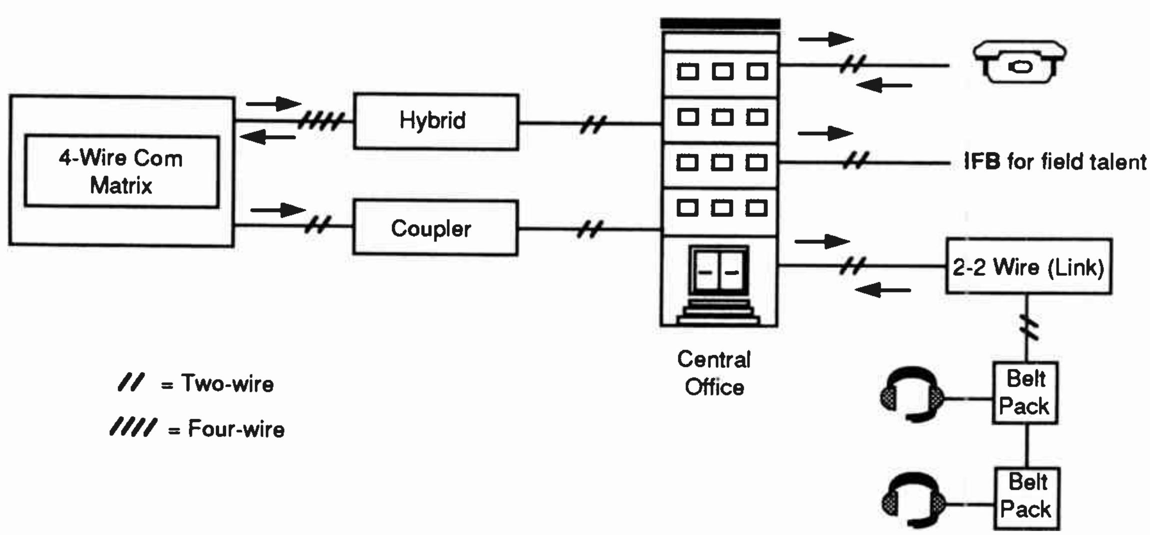

Figure 3.10-23. An arrangement which integrates a four-wire switching matrix with telco lines, an interruptible fold-back (IFB) feed, and a two-wire party-line intercom system for field production work.

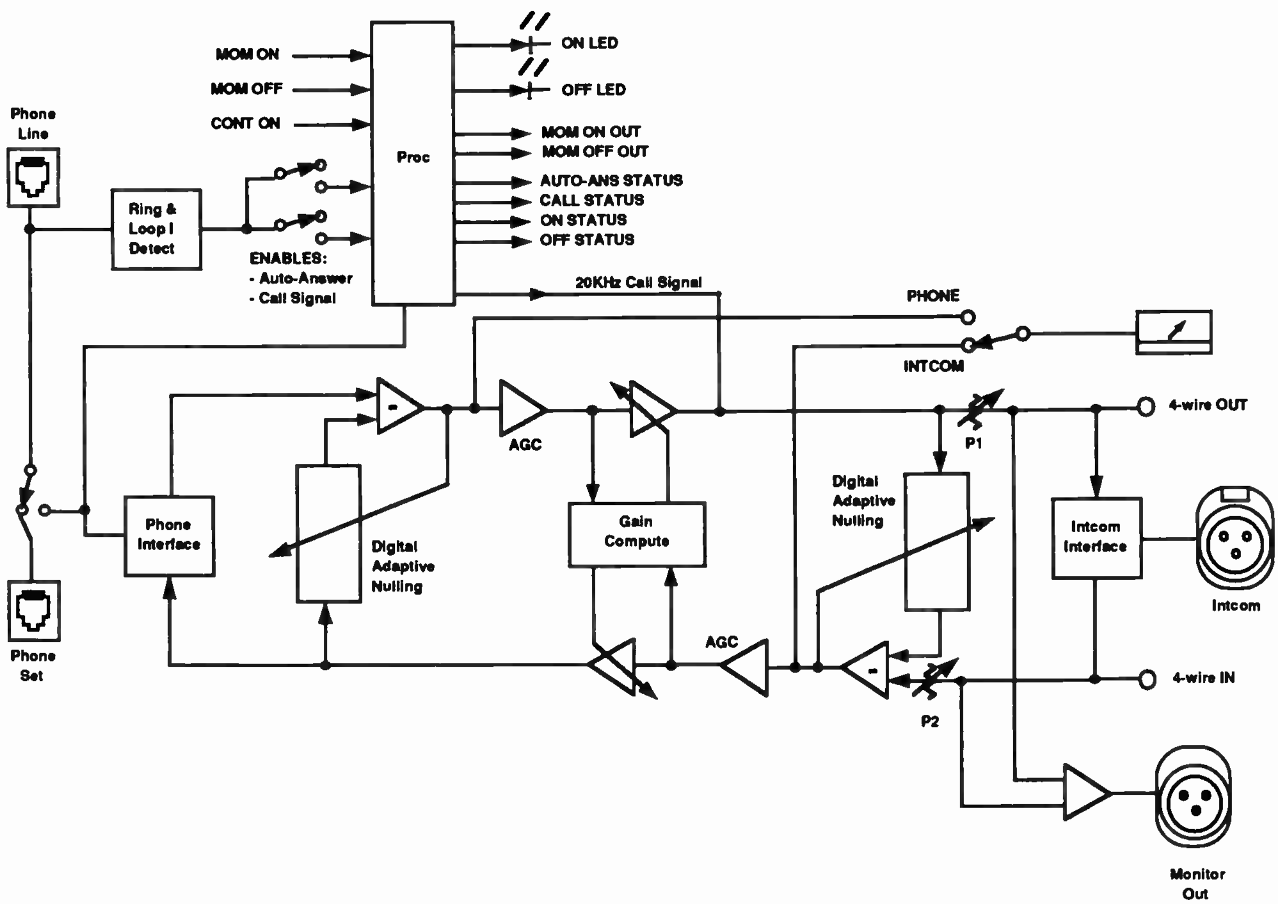

Figure 3.10-24. Two-wire intercom-to-telephone line interface (Telos "Link").

the detectors to respond to the tones from all of the other lines as well as its own. When one line's interface gets a disconnect, all of the others would turn off as well! Therefore, there is a critical requirement in this setup that transhybrid loss must be sufficient in order to be certain that any cross coupling is below the threshold of the tone detectors. The same situation applies with any DTMF detection that is used on a per-line basis.

2-Wire Systems

These are the popular party-line systems. Here, the interface to requires two hybrids. The hybrids are connected back-to-back so that the intercom hybrid's receive output is fed to the phone line hybrid's send input and vice versa. Appropriate gain and processing stages are inserted in the 4-wire path. This system is what telephone engineers call a 2-wire-to-2-wire repeater.

High quality hybrids are required to prevent feedback. As should be evident from Figure 3.10-24, the signals can feed around the loop and feedback could build up. This happens when the combined transhybrid loss of the hybrids is not at least as great as the gain in the two amplifiers.

As telephone circuits have widely varying and unpredictable end-to-end transmission characteristics, interfacing intercom systems to phone lines without gain and without AGC is not likely to work very well.

ISDN

Because ISDN circuits are inherently 4-wire, they are perfect for the intercom application. Used with a 4-wire intercom system, speech paths may be kept separated end-to-end. Applied to a 2-wire intercom system, the problem of maintaining sufficient hybrid balance is eased. ISDN lines are cheaper and easier to get than the special 4-wire lines sometimes used for intercom interconnection. Yet another benefit is that ISDN offers two channels so that production and talent feeds may be kept separate. Finally, a low delay coding method such as G.722 can be used to improve audio bandwidth in order to correspond more closely to the fidelity users are accustomed to on local links.

3.11
COMMON CARRIER AUDIO PROGRAM SERVICES

SKIP PIZZI
MICROSOFT CORPORATION, REDMOND, WA

INTRODUCTION

Broadcasters and the telephone company (telco) have been allied since the earliest days of both industries and will likely remain so. This chapter considers the opportunities for audio signal interconnections afforded to broadcasters by telcos, and examines how broadcasters can implement these hookups. At this writing, the telephone industry has nearly completed its quiet revolution from analog to digital distribution, so emphasis will be placed on the latter.

For clarity, the term circuit will be used to designate a telco audio path, supplanting the other commonly heard (and potentially confusing) synonyms of *loop, private line, leased line, program circuit,* and the like. Likewise, telco will be used to refer generically to all telephone companies, local, and long distance. LDS (long distance service) will be used to refer generically to all common carriers providing service between local telcos. General comments regarding telco service in this chapter will be limited to circuits used specifically for audio program transmission. For interfacing audio to/from the standard analog dial-up network (*Plain Old Telephone Service,* or POTS), see Chapter 3.10.

Dealing With Telco

The best way to minimize problems with your telco is to establish a good working relationship with the appropriate personnel, and to understand as much as possible about the company's service and operation. If the station's staff comes across as friendly and knowledgeable, but also professionally firm and businesslike, things should go well. If possible, keep the station's liaison to the telco limited to one staff member, and try to always deal with the same person at telco as well.

For ordering digital circuits, a recently instituted option is the data-line brokerage service. Here, the station gives its time, place, and quality of service requirements to a third party, who books the line for the station at no charge. (Like travel agents, these services receive commissions from the telcos whose circuits they book.) This service can be especially helpful in long distance applications, where two local telcos (one foreign to the station) and an LDS are involved. Following the travel-agent model, data line brokers may also be able to book the service at a lower cost. In some cases, any extra customer-provided equipment (CPE) required for the circuit may be rented from these brokers, as well.

ANALOG CIRCUITS

Analog audio circuits are still offered by some telcos under the schedule shown in Table 3.11-1, but in major metropolitan areas there are very few new lines being installed. Telcos are instead replacing the existing circuits that remain with digital equivalents. Meanwhile, LDSs have already phased out such analog services for their long-haul paths.

Where they are still offered, costs for both service and installation of analog program circuits continue to increase. (The exception is in some rural telephone service areas, where alternative digital service is not yet a viable option.) Installation of an analog program circuit generally requires several hours of an experienced technician's work to equalize the line, as opposed to digital services, which take much less time and trouble to pass spec at installation.

Past practice with local analog circuits often provided wider bandwidth than what was ordered, whereas digital services typically cut off exactly as specified. Increasingly, though, analog services that have to pass between telco central offices (COs) or switching centers will make the trip bundled on an interoffice digital carrier anyway, whereupon any excess bandwidth will likely be removed.

Obtaining and Testing Analog Telco Circuits

As Table 3.11-1 explains, analog circuits are available in a variety of bandwidths, and under temporary or permanent status. Check with your local telco to see which, if any, remain available and what they cost. Installation charges for permanent lines may be much higher than those for temporary service, because the

Table 3.11-1
Classes of service for analog telco audio circuits.

CLASS OF SERVICE	APPROX. BANDWIDTH	FULL- OR PART-TIME
Type 6002	200–3,500Hz	PT
Type 6003	200–3,500Hz	FT
Type 6004	100–5,000Hz	PT
Type 6005	100–5,000Hz	FT
Type 6006	50–8,000Hz	PT
Type 6007	50–8,000Hz	FT
Type 6008	50–15,000Hz	PT
Type 6009	50–15,000Hz	FT

telco may want to actually install new wiring rather than permanently occupy any pairs on its existing network cables. In an increasing number of areas, analog audio circuits will not be offered at all, in which case the reader may skip the remainder of this section. For those legacy users of analog audio program circuits, however, the following is provided.

Type 6008 and 6009 (15 kHz circuits) service may be ordered as a stereo pair, incurring a one time installation surcharge for *stereo conditioning*. (Some telcos also offer it for 6007/8 [8 kHz] service.) This ensures that both lines are routed together throughout their runs, so that interchannel phase differences will be minimized. A third line can be ordered for backup, and this too should be included in the stereo conditioning. Although billed routing (as the crow flies) may be a short distance, actual routing of the circuits may be much longer and indirect, providing ample opportunity for phase differences to occur. (Approximately 5 μsec time difference occurs for every mile of path length difference.)

Lines should be ordered well in advance of your need for them. Check with your telco for their preferred lead time. Always specify a start date at least one business day earlier than the actual requirement, to allow time for your own tests on the lines to be performed. Check frequency response, signal-to-noise ratio (S/N), distortion and headroom. For stereo pairs, check relative phase response and relative polarity.

Frequency response should be at least within ±3 dB of what was ordered. Be sure to check outside the passband, because response may not roll off but instead rise beyond the cutoff frequency. On occasion, in order to get a line to meet specifications, telco equalizers may be used to boost the extreme frequencies, and if done improperly, the response may indeed be flat to the cutoff frequency, but then increase for another octave or more before finally rolling off. This will result in audible consequences from the altered response and reduced headroom, particularly if a noise reduction system that preemphasizes high frequencies is used on the circuit.

(Use caution with any complementary analog noise reduction (NR) system used on a telco circuit. As a general rule, be sure that the audio fed to the NR encoder is pre-filtered to match the line's response, so that the audio passband seen by the encoder is relatively similar to that seen be the decoder after the audio has passed through the circuit. If the decoder sees a substantially narrower bandwidth than the encoder, it will not decode the noise reduction process in a complementary fashion.)

The proper procedure for calibrating levels on analog program circuits employs sinewave test tones of 400 Hz or lower, fed at the telco program operating level (POL) of +8 dBm. frequencies above 400 Hz must be sent at the telco test level of 0 dBm to minimize crosstalk into other circuits via capacitive coupling of higher frequencies. To keep things simple, you may want to run all frequency response tests at 0 dBm.

For measuring noise, telcos use a slightly unorthodox approach. They consider a noise level of −90 dBm to be *absolute quiet* or noise free, and measure noise from that reference point. The unit used is dBRN (RN for reference noise). Therefore, a −50 dBm noise level would be called 40 dBRN by telco. If the telco's specified audio reference level of +8 dBm is used by the customer on this circuit, a 58 dB SNR is achieved in this case.

The greater the distance an analog circuit travels, the noisier it becomes. The wider a circuit's bandwidth, the quieter it needs to be. Although specs vary between telcos, noise specifications generally reflect those observations. A typical noise level for local 15k Hz circuits is 33 dBRN or lower, providing 65 dB or better SNR. Long distance analog circuit noise levels generally hit 40 dBRN (58 dB SNR) for 15 kHz circuits. Noise levels for a 5 kHz service are around 46 dBRN (52 dB SNR) for local and 56 dBRN (42 dB SNR) for long distance service. Again check with your local telco for its specifications, and always verify that they are met.

Some telcos offer a lossless or zero loss option, in which the circuit acts as a unity gain device. This is contrasted to a standard circuit, which may exhibit up to 30 dB of loss. (Audio signals in copper cable drop at about 1 dB/mi from broadband resistive losses. Frequency selective reactive losses occur at greater rates, but these are remedied by receive end equalization.) The additional telco amplifiers required by lossless lines may have a detrimental effect on the distortion and headroom performance, and may not do much to reduce the overall static noise floor, but they are useful in densely trafficked urban areas where crosstalk and impulse noise is prevalent.

Static or random noise is far less objectionable than those coherent noises sometimes found on telco circuits. Such noises can be caused by capacitive coupling between adjacent pairs in multipair cable, dial pulses and other switching, inadequate common mode rejection, and carrier beating (causing high pitched sings or tones). Because of this, circuits should be carefully auditioned at the receive-end for a while after installation, without any audio on the line. Check circuits again prior to each on air use. Report any crosstalk or impulse noise problems to telco at the first sign of trouble.

Although there are usually no published specs for distortion or phase response on telco circuits, total harmonic distortion (THD) should be <0.25% on 15 kHz lines. For stereo pairs, relative phase response should be within 30° across the passband. Widely divergent frequency response between the two circuits in a stereo pair is a tip off to check phase response carefully. When a spare third circuit is ordered, the two closest to each other in frequency and phase response should be designated as the main pair, assuming distortion and noise are equivalent across the three.

The maximum level guaranteed on telco circuits is +18 dBm, which implies that only 10 dB of headroom will exist above the +8 dBm reference level. A sensible alternative is to use +4 dBm as a reference level (most professional audio hardware uses this level anyway), thus allowing a more realistic 14 dB of headroom, at the expense of 4 dB less SNR—generally a worthwhile tradeoff.

Interfacing Procedures

Figures 3.11-1 through 5 illustrate some do's and don'ts of audio interfacing to analog telco circuits. This is one area of today's audio where 600 Ω impedance matching is still important. Telco equalizes its circuits for flat response under the conditions of a 600 Ω source impedance and 600 Ω termination. Because of the reactive components in long wired paths (their transmission line behavior implies complex impedances), varying these impedances will affect the frequency response of audio carried on the circuit. Most contemporary audio equipment expects a bridging interface arrangement, so output source impedances are typically much lower than 600 Ω, and input impedances

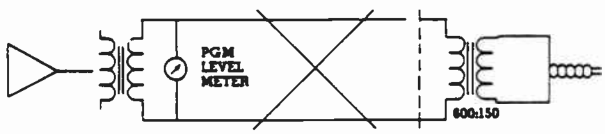

Figure 3.11-1. DON'T meter the signal across the input to the repeat coil (transformer at right) and DON'T feed the repeat coil directly from another transformer, if possible.

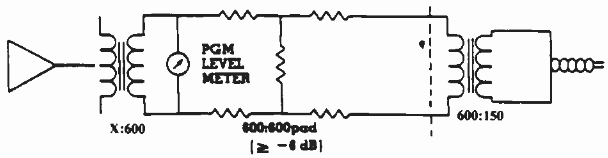

Figure 3.11-2. DO place a pad between the output device's transformer and the repeat coil; and DO place a level meter before the pad, calibrated for the voltage across the pad's output when terminated with a 600 Ω resistor.

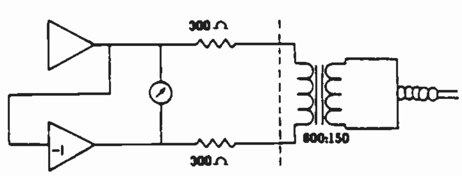

Figure 3.11-3. DO feed low-impedance sources (e.g. op-amps) through a 600 Ω differential balanced pad; and DO place the level meter before the pad, calibrated as Figure 3.11-2.

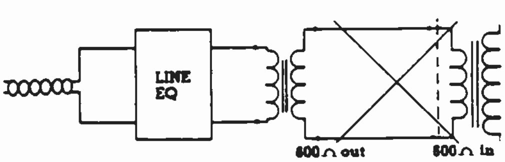

Figure 3.11-4. DON'T terminate the receive-end repeat coil (transformer at right) with another transformer, if possible. Its loading may vary with frequency from the true 600 Ω resistive termination used in line-up causing level and frequency response variations.

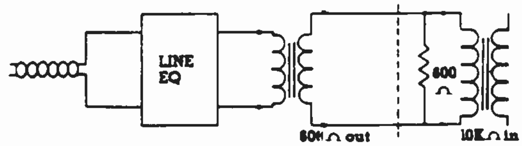

Figure 3.11-5. DO terminate the receive-end of a program circuit with a 600 Ω resistive load and bridge the load with a high-impedance transformer or active balanced input. Note: Common mode rejection of the transformer or active input must be considered if the distance from the repeat coil is great or is near other lines which induce cross-talk. Ideally, the secondary of the repeat coil should be resistively terminated. An active, balanced input circuit does this nicely, provided any RF is by-passed before the first stage of amplification. An alternative is the use of an input transformer with a high-impedance, bridging input. This allows the 600 Ω resistor, as show in Figure 3.11-5 to match the repeat coil. Another version, often seen on the input of broadcast line amps and modulation limiters is a 600 Ω h-pad; effectively the reverse of Figure 3.11-2. Following the steps shown in Figures 3.11-1–3.11-5 usually insures that transmission loss and frequency response closely match those of the phone company set up.

are much higher. Yet the telco does not guarantee flat response without 600 Ω matching conditions.

If a typical low impedance mixing console output is used to feed a telco circuit directly, it will generally cause a rising high frequency response to be received. This is not telco's responsibility, but rather the customer's. It is therefore essential that the device directly feeding the line have a 600 Ω source impedance, and be capable of driving such a balanced load to at least +18 dBm across the passband. Many mixers—even expensive ones—are not designed to do this, so an appropriate outboard line amp or distribution amplifier (DA) fed by the mixer should be used.

A DA will also provide isolation between the mixer and any other inputs, and more importantly, between all these devices and the telco circuit. Drive the telco circuit with its own DA output—no other inputs (even bridging ones) should be paralleled to it. DC voltages may appear on telco circuits, so this isolation is essential. For the same reason, a transformer coupled DA is the better choice over a transformerless design in this application. High quality transformers can be quite helpful on remotes, especially when interfacing with a telco. On most 15 kHz circuits (and some others), though, telco repeat coils appear at each end, providing this isolation for you. In this case, actively balanced outputs can be used safely, but flat frequency response is only guaranteed if they are interfaced to the repeat coil in the manner shown in Figure 3.11-3. A caveat here: remember that the active DA still has to drive a 600 Ω balanced load to +18 dBm across the passband, and many popular operational amplifiers do not have the current-drive capability to do so. To avoid crosstalk to other circuits, do not conduct lengthy tests at +18 dBm.

The "H" pad in Figure 3.11-2 does not provide a 600 Ω source to the line by itself. If the secondary of the output transformer on the left of the diagram were not 600 Ω, the pad would not set things right. The pad is there to provide isolation of the meter or a test oscillator from the repeat coil.

A simple test to determine the actual source impedance of a device's output is as follows. Place a bridging input voltmeter across the device's output while feeding 1 kHz at reference level. (No other inputs should be connected.) Terminate the output with various resistances, and watch the meter. The device's source impedance is the value of the resistor that drops the level by 6.02 dB. Then verify that this level drop is consistent at other frequencies.

Note also that the meter on the transmit end shown in Figures 3.11-2 and 3.11-3 should be used only for initial absolute level calibration, and not for relative levels in frequency response tests. For verification that consistent level is being transmitted at each frequency during response tests, and for realistic end-to-end results, put the oscillator further upstream, and use a more isolated meter for reference. This typically is done by feeding the oscillator into a properly telco interfaced mixer or DA input (or using the mixer's inboard multifrequency oscillator, if it has one), and recalibrating for oscillator drift using the meter on the oscillator, mixer, or DA, not the downstream meter shown in the figures.

Failure to follow the procedures outlined above will result in poor frequency response, distortion, calls from the telco warning of too high a level, too much noise and general unhappiness with the service.

DIGITAL AUDIO CIRCUITS

As with much of the technological progress in our industry, the digital audio revolution that is now taking place in the broadcast world began at the telco. The transmission of data is nothing new to telco but the high data rates required for digital audio transmissions had previously rendered the availability and cost of such service out of the practical range. Data compression (or bit-rate reduction) systems have made possible broadcast applications of data transmission paths that previously were only useful for computer interconnection. Reductions from earlier data rates for digital audio transmissions of 4:1 or higher have become commonplace and compression ratios of 12:1 without audible penalty are now emerging.

This implies that audio program circuits are ordered from telcos not as audio services per se, but simply as digital circuits with appropriate bandwidth for the transmission task at hand. The actual signal(s) passing through the line are of little consequence—a digital circuit cares not whether the program it carries is a symphony or a spreadsheet.

Data Compression

Although these data compression algorithms are viewed today as major breakthroughs, history will likely look upon them as natural evolutions, and consider the earlier linear pulse code modulation (PCM) systems as dinosaurs. While the straightforward nature of linear PCM may have been helpful in making the transition from analog systems, especially where bandwidth was cheap and available, it is an inefficient method for encoding digital audio. The resolutions of today's linear PCM systems are often overkill in terms of the actual needs of most listeners, and significant reductions in actual transmitted data can be achieved by applying data compression algorithms to the datastreams that linear PCM conversion produces. At present, linear PCM of as high a resolution as economically feasible is still a good idea for the original conversion of analog signals to the digital domain, and for any digital production or signal processing. But for signal delivery systems (and in some cases, for long-term storage), data compression is an appropriate tool.

Earlier compression systems (again pioneered by telcos) used a purely statistical or numerical analysis of the datastream's coding redundancies. These lossless systems could be used to reduce the data rate of any kind of data transmission. More recent lossy systems are designed for exclusive use on audio data. These coders acknowledge the limits of the human listener's sensory perception and exploit them for much higher compression ratios. Such perceptual coders are therefore based on psychoacoustic models, and owe their coding efficiencies to an appreciation of the audience's tolerances.

Data Rates

Like their analog counterparts, digital circuits come in various bandwidths. But rather than specifying cutoff frequencies of the audio passband, telcos specify digital circuits in terms of their data rates. Broadcasters now need to consider bandwidth requirements in two dimensions: that of the audio signal itself and the data-transmission path. The former is specified directly (in Hz), while the latter is specified as a data rate (in bps). The resultant audio quality through a digital transmission path is a function of the bandwidth of the digital circuit and the performance of the coding algorithm at that data rate. For example, linear PCM will provide only POTS-like results at 64 kb/s, but ISO/MPEG-1 Layer III Audio Coding can provide near CD-quality mono audio on the same 64 kb/s circuit.

Therefore, broadcasters must develop an acuity for the appraisal of various data rates capabilities, both with and without data compression. In the linear PCM (uncompressed) mode, the data rate requirement of a given audio signal is determined by simply multiplying its sampling frequency (in Hz) by its resolution (in bits/sample). For example, CD quality audio uses 44.1 kHz sampling at 16 bits/sample resolution, requiring a 705.6 kb/s data rate, per channel (stereo requires doubling that data rate to 1.411 Mb/s), before adding any error correction overhead. A digital audio compression algorithm capable of 4:1 data rate reduction can reduce that signal's resolution to an average of 4 bits/sample (while leaving its sampling frequency alone), therefore providing a 176 kb/s data rate for mono audio. Table 3.11-2 shows some other data compression ratios for audio, and their resultant data rates, at several common sampling frequencies.

Table 3.11-2

Data compression table showing a range of compression ratios and their resultant output data rates at a variety of sampling rates (fs). Audio bandwidth is approximately one half of fs. Data rates shown are for a single audio channel (mono).

RESOLUTION (avg. bits/sample)	COMP RATIO	OUTPUT DATA RATES (kbit/s) fs = 48 kHz	fs = 44.1 kHz	fs = 32 kHz
16	1:1	768	706	512
4	4:1	192	176	128
3	5.3:1	144	132	96
2.67	6:1	128	118	85
2	8:1	96	88	64
1.45	11:1	70	64	46
1.33	12:1	64	59	43

Because the sampling rate is not changed by a data compression system, frequency response and time domain performance retain the same specifications typical of most linear PCM conversions. Processing delay is introduced by these codecs, however, and its length is generally in direct proportion to the amount of data compression applied.

Telephone company installations and tariffs provide a variety of services, with more new services continually being deployed in many cities. Table 3.11-3 shows some current services and their data rates.

One of the most important differences to the broadcaster between analog and digital circuits is that most digital services are provided bidirectionally. This fact should not go unnoticed when making cost comparisons. Although interfacing hardware for return path channels must still be provided, their circuits require no separate costs or orders.

Note also that telcos have always had their own insider vocabulary and set of acronyms, but since the introduction of digital services, this has expanded dramatically. Many of these are explained in the *Glossary of Digital Telco Terms* at the end of this chapter.

For overseas links, rough equivalents to each of the domestic services shown in Table 3.11-3 do exist outside the U.S., but their actual data rates differ. Format conversions are therefore required for international transmissions, but most LDSs can handle this for the broadcaster. For example, European telcos offer an

Table 3.11-3

Some current U.S. digital telephone data services and their data rates. The ISDN data rates do not include the 16 kbps D channel (for BRI) or the 64 kbps D channel (for PRI), nor do they include framing, synchronization and other overhead bits.

SERVICE	DATA RATE (bits/sec)	MODE
Switched 56	56 k	Switched
DS 0	64 k	Dedicated
ISDN-BRI	128 k	Switched
ISDN-PRI	1.472 M	Switched
DS 1 (T-1)	1.544 M	Dedicated
DS 2	6.312 M	Dedicated
DS 3	44.736 M	Dedicated

E-1 rate of 2.0 Mb/s, in lieu of the North American T-1 rate of 1.5 Mb/s.

DS1 or T1 Service

Digital audio transmission on DS1 (or T1) lines has become widely available, and is often cheaper than standard analog circuits in both service and installation charges. (See *Glossary* for distinction between DS1 and T1 nomenclature.) DS1 is a bidirectional 1.544 Mb/s serial data link. The data rate calculations above show how DS1 can carry a single, linear PCM stereo audio signal, or several such compressed channels.

DS1 service is extremely reliable. Its bit error rate (BER) of 10^{-9} (the probability of error reflected by the specification of no more than one erroneous bit in 10^{-9} transmitted) is among the lowest available. By way of reference, IEEE and ITU-T have both established 106 as the BER required for data customer satisfaction.

The data carried on a DS1 circuit is actually a multiplex of 24 data channels, or slots, of 64 kb/s each. (An additional 8 kb/s is reserved for sync data.) These individual 64 kb/s slots are called DS0 channels. For standard telco T carrier use, each DS0 carries a digital voice grade circuit, using the so called μ Law (nonlinear 8 bit) algorithm on 8 kHz sampled audio. When a customer leases a DS1 circuit, it can be configured to carry any bandwidth channel that DS1 hardware is available for (3.5 kHz, 5 kHz, 7.5 kHz, 15 kHz) in any combination, up to the customer's payload data limit. When a customer leases a full DS1, the telco may use one DS0 slot for framing and other overhead, in addition to the 8 kb/s synchronization slot, leaving around 1.4 Mb/s for customer data. Check with your telco for its exact rate.

A rack of coding and multiplexing hardware appears on each end of the DS1 line, usually as customer provided equipment (CPE), and the circuit can be reconfigured simply by changing the appropriate cards in the proper slots in the racks at both ends. The customer can perform these reconfigurations at any time, without telco involvement or notification.

Unlike the labor intensive installation and equalization of an analog circuit, putting in a T1 circuit has become nearly as routine as a standard dial up telephone service installation. This and the capacity gluts in some areas continue to lower costs for DS1 service. Customers' use of digital compression systems on DS1 channels will only increase this economy. Whereas a 15 kHz audio channel had in the past typically required six DS0 slots, current hardware implementing perceptual coding reduces this to two (or even a single) DS0s.

Fractional T1

In some areas, Fractional T1 service is available, generally for intraLATA (local) applications only. This service allows a customer to lease only the number of DS0 slots on a DS1 circuit that are needed for a particular application. Although installation charges will be about the same as a full DS1, service charges may be substantially reduced for many remote audio applications.

Switched 56

Another telco digital offering that has been used by broadcasters is the Switched 56 service. This facility has been available for a number of years for local service in many metropolitan areas in the U.S., and from some long distance carriers. It provides a bidirectional 56 kb/s data path for use with dial up terminals. Like POTS, a monthly service/network access fee is charged (which often includes at least some free local calling), with long distance calls billed by the minute, at rates similar to regular dial up long distance service. In some cases, local calls are also billed for connect time. An installation fee is also typically charged for initiation of service.

A switched channel service unit (CSU)—the equivalent of a telephone instrument and data interface—is provided by the telco, or may be purchased by the customer. It allows voice or data interconnection, and dial up routing of the data path to any other similarly equipped destination on the network. For broadcast use, additional codecs are required, as shown in Figure 3.11-6, to feed wideband audio. These codecs are not available from telcos, and must be purchased by the customer. The typical codec used for Switched 56 service is ITU-T G.722, which provides 7.5 kHz mono audio (see Figure 3.11-6).

An obvious savings is possible with such a switched approach, since dedicated circuits need not be installed between a radio station and all of its remote sites. The station and each site need only to be wired for the switched service (with each line going to the telco CO only, and not end to end) and the station can dial up any remote site as needed. The station may require two or more lines for accessing multiple remote sites simultaneously or in quick succession.

CSUs are available in two wire or four wire versions, with two wire types costing less. The choice between two and four wire operation is not up to the customer, however, but to the local telco serving the area.

Switched 56 is available to Europe and Japan, as well, although it is a 64 kb/s service in most overseas locations. Conversion hardware is available for such an application. Like the higher speed channels mentioned above, no international standards exist for these switched services today, although they are currently under development.

Some telcos offer a similar unswitched service, in which a single DS0 channel can be leased on a monthly basis. For heavy point to point users, this may be more economical than a switched approach. As single DS0s, these circuits operate at 64 kb/s, and their terminal hardware is less expensive because it need not accommodate switch signalling.

New installations of Switched 56 service are now rare, with most telcos (and users) preferring the more recent Integrated Services Digital Network (ISDN).

ISDN Service

At this writing, ISDN is available in most urban centers, and will soon be universally deployed in the U.S. The most common variety of ISDN service is the Basic Rate Interface (BRI), which provides two 64 kb/s paths (bearer or "B"-channels) and one 16 kb/s circuit (data, delta or "D"-channel). As a result, this service is also referred to as 2 B + D. Bearer channels carry customer data, while data channels carry signalling and call routing data. This feature is a significant departure from POTS and Switched 56 service, in which the call signalling data is routed via the same data path as the program audio or data. (This is why DTMF tones and call-waiting beeps or pulses are audible on a POTS call, for example.) Such interruptions can cause problems to data communications, which benefit from continuous, bidirectional connections. ISDN's use of such *out-of-band signalling* provides significant improvement in speed, throughput and robustness for switched data communications.

ISDN-BRI is intended as a standard residential service, while business service is provided by ISDN's *Primary Rate Interface* (PRI). This service provides twenty-three 64 kb/s B channels, and one 64 kb/s D channel (23 B + D). (The ISDN-PRI D-channel operates at a higher rate than the BRI service because it has more B-channels to manage.) The data payload capacity of the ISDN PRI service (1.472 Mbits/s) is roughly equivalent to the data payload capacity of a T-1 circuit (1.536 Mb/s).

While the above data rates are common for ISDN, it should be noted that some ISDN systems in the U.S. offer users only 56 kb/s of payload data on their B-channels.

ISDN is a bidirectional, customer switched service,

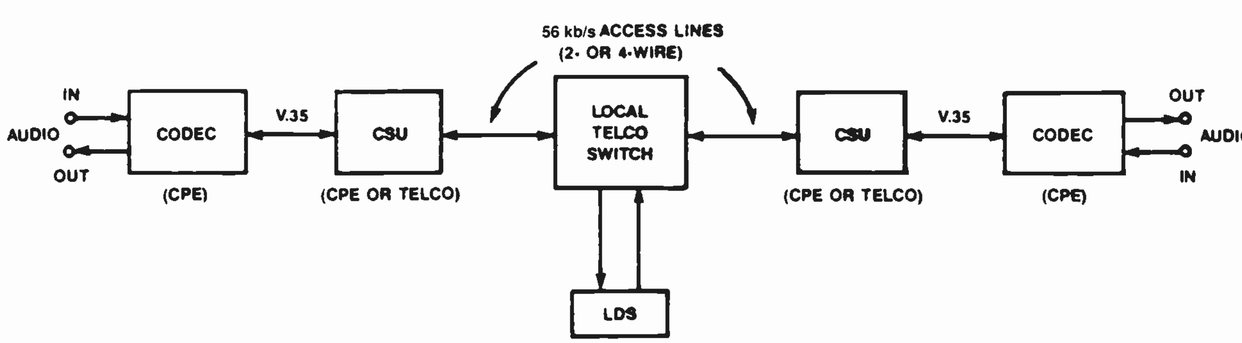

Figure 3.11-6. Block diagram of Switched 56 circuit path. (See Key Terms for acronym definitions.)

operating as a dial up, billed minute data network, allowing both circuit switched and packet switched operations. Its multichannel nature allows simultaneous voice and data to separate destinations (like multiline POTS service) or other applications in which multiple B-channels are combined to provide a single, higher-bandwidth call. This is done via a process called *inverse multiplex* (IMUX). Billing remains separate for each of the multiple lines in an IMUX, however.

The ISDN equivalent of the POTS telephone instrument is called the *terminal adapter* (TA), and it is available in several varieties, for the control of one or more BRIs or PRIs. Each TA is connected to the ISDN network via a standard *network termination* (NT), which varies with the type of terminal hardware and software installed by the local telco. In North America, all telcos have agreed to use a single standard interface, which requires the use of the NT-1 termination. While originally supplied as a separate unit for easier transport of a TA between service areas, the standardization has encouraged most manufacturers to include the NT-1 internally in most terminal equipment.

ISDN BRI has already become the delivery method of choice for many radio remotes, offering mono or stereo 15 kHz broadcast audio plus communications to/from a remote site. Often a single B-channel is used with one of several audio codecs capable of providing high-quality mono audio transport at a 56 or 64 kb/s rate. In other cases, two B-channels are IMUXed for high quality stereo at 112 or 128 kb/s. Numerous devices are available for such applications, and most include an integrated ISDN terminal adapter, NT-1 and codec, plus machine-control closures (see Figure 3.11-7). Most of these devices include codecs with variable data rates, and some may include multiple coding algorithms as well. Appropriate coding algorithms include ISO/MPEG-1 Audio Layers II and III, APT *x-100,* Dolby *AC-2,* Lucent PAC and MPEG *AAC.*

For more information on ISDN, including its use in voice transmission applications, see Chapter 3.10, "Telephone Network Interfacing." This chapter also contains information on the use of POTS codecs, which can provide moderate quality mono audio on standard dial-up phone lines.

DSL Service

An emerging technology that may play a role in future broadcast audio transport is the *Digital Subscriber Line* (DSL) service, which provides multimegabit connectivity over the telcos' existing twisted-pair infrastructures. It accomplishes this by implementing adaptive DSP at both ends of the signal path, thereby compensating for the distortion inherent in long copper lines. Path lengths for DSL are limited, but systems are designed to accommodate the typical telco customer-to-central-office runs of 12,000 to 18,000 ft.

DSL paths are dedicated, point-to-point services, and intermediate repeater amplification is not used. Two different transmission technologies are employed: *Discrete Multitone* (DMT, developed by Amati Communications), and *Carrierless Amplitude/Phase modulation* (CAP, from AT&T).

Several varieties of DSL are available. Of greatest interest to consumers is the *Asymmetrical Digital Subscriber Link* (ADSL), which offers a wider downstream bandwidth (from telco CO to customer) than its upstream capacity (from customer to CO). More important to broadcasters may be the *High-Speed Digital Subscriber Link* (HDSL), which provides equivalent capacity in both directions (up to 6 Mb/s). It may soon provide an economical alternative to T-1 service.

COMMUNICATION LINES

For remote broadcasts, circuits for transmission of program audio often must be complemented with separate communication interruptible fold-back (IFB) or talk-back lines. When analog program circuits are used, communications are usually carried on standard POTS lines. When digital services are used for program back-haul, their bidirectional nature usually allows monitoring and communications to be carried on the return side of the same lines. Nevertheless, it is still a good idea to have at least one POTS line on hand in such cases.

Communications lines may be used purely for talk-back if off-air monitoring is possible on site. Remember that the codecs used for digital services can add significant delay (on the order of 100 ms in each direction in some cases), as can studio-to-transmitter links and other components of the air chain. The cumulative delay from these devices can cause monitoring problems for talent listening to their own voices or in conversation with others. For this reason, dedicated (analog) communications lines may be useful even when air monitoring or digital return is possible.

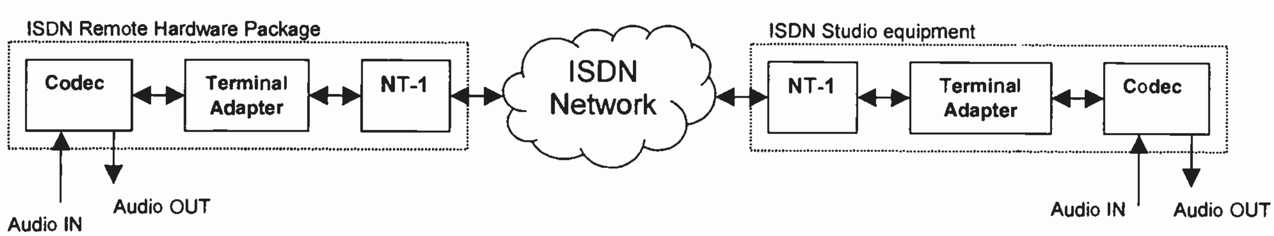

Figure 3.11-7. Block diagram of typical ISDN-BRI service used for a radio remote.

When using POTS communications lines, one or more standard dial up telephone circuits can be ordered for program audio monitoring and communications. Alternatively, an RF communication system (hand held radio or cellular phone) could be used. If wired telephone service is chosen, the station should provide its own instrument, which may be equipped with visual ring/bell cutoff and headset attachment.

There are also some variations to consider over a standard dial-up service. A communications phone line (comline) can be set up as an *off premises extension* (OPX) of the station's *private branch exchange* (PBX) system, or the line can be a dedicated *private line* (PL) that only runs between the station and remote site, in an unswitched form. In the latter case, such a PL is normally equipped with *automatic ringdown* (PLAR), in which special hotline type phones are installed by the telco, having no keypad or dial; the phone at one end rings whenever the phone at the other end is picked up. Services of this type (and their specific nomenclature) may vary among telcos. These services are also typically provided by a different department than the ones that handle program audio circuits or ISDN, so coordinate carefully. Typically, this part of the telco is the same one that handles all dial up installation and service calls from the general public, so lead time requirements and service call response time will often be longer than the program audio circuit or ISDN departments.

T-1 Applications

Using the return path on T-1 circuits for communications and backfeeding requires appropriate terminal hardware on each end. Channel configuration need not be the same as the circuit's other direction, and because narrowband (lower data rate) channels are usually all that are required, the number of communication channels on the return path can exceed the number of program audio channels on the transmit side, if necessary. Another possibility is the luxury of wideband backfeed and communications, such that the receive audio quality at the remote site is as good as the transmit quality.

For permanent interfacility hookups, a T-1 circuit could carry audio transmissions between sites plus telephone service, such that both locations can have their phones connected to the same PBX. If the locations are far apart, a *foreign exchange* (FX) arrangement can be established, whereby one facility can place calls to the other facility's telco service area without incurring toll charges. The PBX system is programmed to recognize area codes of the two cities involved (or special internal access codes), and it directs appropriate calls to FX lines on the T-1 rather than placing them as regular long distance calls.

COST OF SERVICES

For local service, there is normally only one provider of telco circuits, analog or digital, which is, of course, the local telephone operating company. So there is little competitive choice in the matter for intraLATA service pricing. Check with your local telco frequently, though, to see which services are more economical, for either permanent or temporary applications. Analog services continue to increase in price in most areas (if they are even available), while the cost of digital services declines at varying rates around the country. This makes it worthwhile to keep a close eye on these changing rates in your area.

For long distance paths, there is significant competition for interLATA digital service, so prices are kept low, and continue to drop. (There is little or no interLATA analog service available anymore.) Shop around for the best deal on interLATA digital service, or use a dataline broker. The list of common carriers in this business is long, and continues to grow. Secondary services may also be offered, such as switching and monitoring.

Back-up is also an important issue, particularly for live broadcasts. Many broadcasters establish primary and secondary backhaul and communications paths, using different services for each. (For example, ISDN primary and POTS secondary services.) This adds a level of redundancy because the services are typically routed differently. Costs of each service are an important factor, particularly when broadcasters are paying for something (the secondary service) that they hope they never have to use. The use of a lower-cost service for back-up therefore makes both technical and economic sense, and it is a highly recommended practice.

For those broadcasters who book a significant number of telco services, it also may be helpful to understand how telco billing works. Figure 3.11-8 shows the basic route-billing concepts followed by local and long distance common carriers for dedicated (non-switched) lines.

The importance to radio of interconnection, immediacy, and fidelity underscores the importance of a long term relationship between broadcasters and telcos. Good awareness of and rapport with telcos are essential to the daily work of the broadcaster. In today's context, that means keeping abreast with the changes in telecommunications that affect broadcasting as the digital revolution rolls along.

KEY TERMS

ADPCM. Adaptive Differential Pulse Code Modulation. A form of digital coding more efficient than linear PCM because it only codes the difference between one sample and the next, instead of assigning a fully discrete value to each sample. It also adapts its coding to the signal values currently under process. Considered a form of statistical data compression.

ADSL. Asymmetric Digital Subscriber Line. A high-speed digital service that uses telcos' existing copper (twisted-pair) infrastructure to provide data at a higher rate *to* the customer's premises than *from* it. For example, service may run 1.5 Mb/s from the telco CO to the customer, but only at 64 kb/s from customer to telco.

LEGEND

CM — Channel Mileage (per air-mile billing basis)
CO — Central Office (LEC switching center: also called SWC—Serving Wire Center)
CT — Channel Termination (flat rate billing)
IOC — Interoffice connection on LDS network (distance-sensitive)
LATA — Local Access and Transport Area (telco service zone)
LDS — Long-Distance Service (common carrier)
LEC — Local Exchange Company (local telco)
POP — Point of Presence [LDS's office in each LEC: also called SO (Serving Office)]

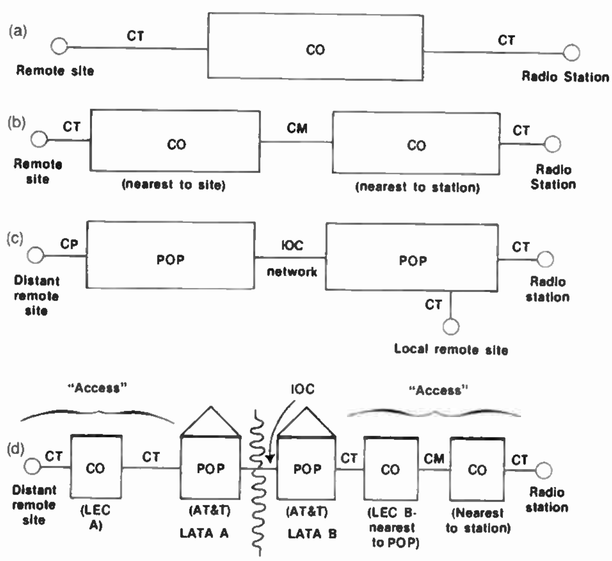

Figure 3.11-8. Billing methodology for dedicated telco circuits. In (a), the two ends of a local circuit are served by the same central office, or "rate center." In (b), two different central offices are involved. In (c) and (d), long distance service is depicted. LEC connections to LDS are referred to as "access." Access shown in LATA B will be more expensive because the radio station is in different rate center of LEC B than the long distance carrier's POP.

AMI. Alternate Mark Inversion. The binary modulation code used by the telephone company for data and digital voice transmission. It uses RZ coding in an alternate bipolar scheme, with logical zeros corresponding to zero volts, and logical ones alternating between +3V and −3V. (The first logical 1 produces a +3V output, the next 1 produces −3V, the next +3V, and so on.) Self synchronization is possible with this approach, but the number of continuous zeros must be limited.

B-channel. In ISDN service, a channel designated for customer data transmission, uninterrupted by any signalling data.

Bellcore. Bell Communications Research. The R&D firm that feeds technology and standards to the RBOCs, and is funded by them.

Carrier. In telco parlance, refers to a multiplexed digital interoffice signal, containing many individual calls or signals in a single cable or fiber.

CCITT. Consultative Committee of International Telephone and Telegraphy. The international standards setting organization for telephone systems, established by the UN.

Codec. Coder/decoder. Any device which includes digital transmission/encoding and reception/decoding circuitry in the same chassis.

CPE. Customer Provided Equipment. Refers to any network interface hardware not provided by telco.

CSU. Channel Service Unit. Terminal hardware for a telco data line, either CPE or telco provided. Also referred to as CSU/DSU (DSU = Data Service Unit) in T1 applications. Interfaces unipolar NRZ computer style datastreams to the RZ bipolar (AMI) telco data format. A switched CSU includes a keypad for call direction and other switch control.

D-channel. In ISDN service, a channel designated for signalling data only.

DDS. Dataphone Digital Service. The first telco data service in the U.S., originated in the mid 1970s by AT&T.

DS0. Digital Service 0. A 64 kb/s data channel.

DS1. Digital Service 1. A 1.544 Mb/s data service usually configured as 24 DS0 channels plus an 8 kb/s sync channel.

DS2. Digital Service 2. Four DS1 channels multiplexed together for transmission. Generally reserved for telco interoffice transmission, and not offered to customers directly.

DS3. Digital Service 3. Twenty eight DS1 channels multiplexed together with additional control data, providing a data rate of 44.736 Mb/s (generally quoted as 45 Mb/s). Used for compressed NTSC and high definition video distribution.

First-Mile. Refers to the signal path between a program's origination site and its entry point to a common carrier's network or a private satellite uplink. Usually a terrestrial RF link or a local telco circuit.

G.722. A CCITT standard for audio data compression. It uses two-subband ADPCM coding to put 7.5 kHz audio into 64 kb/s.

HDSL. High-speed Digital Subscriber Link. A digital service that uses telcos' existing copper (twisted-pair) infrastructure to provide high-speed bidirectional connectivity over limited distance. Adaptive terminal hardware allows higher speed than previous equipment was capable of on the same physical paths. Bidirectional rates of 6 Mb/s or higher are possible. The smart hardware allows quick installation without extensive testing and tweaking of lines. HDSL is replacing T-1 service in some areas.

InterLATA. Refers to telco service or rates between LATAs, or long distance service.

IntraLATA. Refers to telco service or rates within a LATA, or local service.

ISDN. Integrated Services Digital Network. A new telco service designed to eventually replace POTS with flexible digital service. It will be offered in basic rate (2 B + D) service, intended for home use, and primary rate (23 B + D) service for business customers.

J.41. A CCITT standard for digital audio encoding. Using 1411 PCM encoding (14 bits for lower level signals, 11 bits for higher level signals), it places 15 kHz audio on 384 kb/s.

Last mile. Refers to the short haul signal path between a long distance network terminal point (or private satellite downlink) and the customer's receive point. Usually a local telco circuit.

LATA. Local Access and Transport Area. The service area of a local exchange company (LEC).

LDS. Long Distance Service. A carrier of long distance (interLATA) telecommunications, such as AT&T, MCI, Sprint, and others.

LEC. Local Exchange Company. A local telco. Each RBOC contains one or more LECs. Also refers to independent, non Bell local telcos.

Mark. The telco term for high level data pulse, usually corresponding to logical 1. (See Space).

NRZ. Non-return-to-zero. The most basic form of binary modulation coding, in which logical 1s and 0s are directly represented by high and low levels respectively. Because no level transition occurs between continuous strings of like logical values, this form of modulation is not self synchronizing, and requires an external bit clock output for synchronous operation.

Packet switching. A sort of data partyline, in which data is transmitted in addressed bursts or packets, occupying the transmission channel only for the duration of the packet, after which the channel is free for other packets to or from the same or other users. Many users can be interconnected to the same line, but data can be sent discretely to each destination.

PDN. Public Data Network. Telco data services, including both switched and leased lines.

POTS. Plain Old Telephone Service. Refers to the public switched telephone network (PSTN).

PSTN. Public Switched Telephone Network. The standard dial-up phone system.

RBOC (or BOC). (Regional) Bell Operating Company. The seven Baby Bells created when AT&T divested itself of its local telephone operations.

RZ. Return-to-zero. A form of digital modulation coding in which logical ones and zeros are directly represented by high and low levels respectively, but where coding output returns to low level following each high pulse.

Slot (or Time-slot). Generally refers to a DS0 channel within a DS1 signal.

SMDS. Switched Multi Megabit Data Service. A high speed switched data network, operating at DS1 to DS3 rates.

SONET. Synchronous Optical Network. A telco standard for ultrafast data transmission, operating at speeds of 150 Mb/s to 2.4 Gbit/s.

Space. The telco term for low level data pulse, usually corresponding to logical 0 (see Mark).

Switch. Generic name for any telco call routing and connection hardware.

Switched 56. A switched digital service offering 56 kb/s data service on a dial up network.

TA. Terminal Adapter. The term for a CSU in an ISDN system.

Tariff. A schedule of services and their prices that a telco will provide to a given service area, subject to approval by the appropriate regulatory agency.

T-carrier. See Carrier.

T1. The copper network and hardware used to carry DS1 service.

VSAT. Very Small Aperture Terminal. Refers to Ku band satellite earth stations for fixed or portable use with dish diameters on the order of 1.5 m or less.

V.35. An older (but still common in the U.S.) CCITT telco standard for low speed data I/O to a CSU, with a unique multipin connector.

xDSL. Generic terminology for any of the variety of Digital Subscriber Link services offered by telcos, which provide high-speed connectivity across limited distances on the existing copper (twisted pair) infrastructure. (See ADSL, HDSL.)

Section 4: Radio Transmission Facilities

Introduction by Milford Smith, Greater Media, New Brunswick, NJ

Before radio is anything else it is, at its very essence, the transmission of electromagnetic waves from one place to another. Before we can play the hits, talk the talk or spread the news, the ability to manufacture, impart information to and launch these invisible wavelengths is essential and vital. Ironically, as time has passed and the machines associated with the radio frequency portion of radio stations have become infinitely more reliable, the relative level of expertise of the typical radio engineer in the RF domain has arguably diminished. This is in no way reflective of the overall expertise of the individual nor their desire to be knowledgeable in this important area, but is simply a result of the reality of today's staffing levels and the fact that other portions of the transmission chain are usually more demanding of immediate attention. It is for this reason that the material presented here is of such great value.

In the following chapters, experts from virtually every area of radio frequency transmission share their unique expertise with those of us charged with the day to day maintenance, trouble shooting upkeep and regulatory compliance of AM and FM RF plants.

The section begins with George Woodard's skillful discussion of the viability of AM transmission systems in the *AM Transmitters* chapter.

In the *AM Stereo* chapter, Edward J. Anthony discusses the more practical aspects of AM stereo preparation, installation and maintenance to aid the AM broadcaster in achieving a high quality stereo transmission.

Geoff Mendenhall's chapter, *FM Broadcast Transmitters,* deftly describes the advantages of stereo multiplex FM broadcasting. While, John Kean presents the reasons why most broadcasters agree that FM's resurgence and eventual dominance as an audio medium was due in large part to stereophonic transmission in his chapter, *FM Stereo and SCA Systems.*

Jerry Whitaker discusses the importance of the studio-to-transmitter link as digital technology becomes more prevalent in everyday radio operations in the *STL Systems* chapter. Continuing in the realm of digital technology's effect on radio broadcasting, Scott Wright unravels the mystery of the "chicken and the egg" problem that exists between radio broadcasters and RBDS manufacturers in his *Radio Broadcast Data System (RBDS)* chapter.

Harold Hallikanien walks novice and expert alike through the various meters and controls that the Federal Communications Commission requires broadcast transmitters to have in his *Transmission System Control and Monitoring* chapter.

Carl E. Smith's *AM Broadcast Antenna Systems* chapter provides station engineers with an understanding of some of the basic concepts of antenna design. Smith's chapter is followed by Ed Edison's *AM Antenna Coupling and Phasing Systems* chapter, which focuses on the function of such systems and their performance objectives, as well as the characteristics of basic networks, power dividers, transmission lines, sampling systems, detuning systems and transmitter load optimization.

James B. Hatfield's *Computer Simulation of AM Radio Antenna Systems* chapter teaches radio broadcasters how modeling an AM array can save a great deal of trial and error.

In the *Maintenance of AM Broadcast Antenna Systems* chapter, Ed Edison and Gerhard J. Straub team up to discuss the importance of maintenance attention in overcoming the normal effects of age and deterioration (routine maintenance), restoring proper operation after catastrophic failures (such as caused by lightning) and coping with new sources of reradiation that may develop within the environment in which the antenna system operates.

Written by Peter K. Onnigian, the *FM Broadcast Antennas* chapter is for broadcast engineers, technicians and station managers who must make important decisions regarding FM transmitting antennas.

Robert A. Surette details how filters and other components in FM combiners are used in transmitting several frequencies from a single broadband antenna system in the *FM Combining Systems* chapter.

In the *FM Translators and Boosters* chapter, Chip Morgan points out how proper translator and booster design and optimization methods can make the difference between a successful operation and a failure.

Finally, the section concludes with Donald Everist's chapter, *AM and FM Field Strength Measurements,* which explains the field strength measurements procedures for both types of stations.

The material presented is practical and ultimately usable by those of us in the trenches.

4.1 AM TRANSMITTERS

GEORGE W. WOODARD, P.E.
INTERNATIONAL BROADCASTING BUREAU, WASHINGTON, DC

INTRODUCTION

Broadcasting to the general public began with the process known as *amplitude modulation (AM)* near the start of the second decade of the twentieth century. Then, as now, the system of modulation chosen for transmission was heavily dependent on practical and economic aspects of receiver technology. The evidence is clear that amplitude detection was the only known practical method of signal demodulation when the ideas of radio communication began to be formulated in the late 1800s and early 1900s. It is apparent from some of the earliest technical writings on radio communications that a practical understanding of angular modulation (frequency and phase modulation) did not exist until the mid-1920s.[1] These modes of transmission and the necessary receiver technology were not to be proven practical until long after AM had become the standard of the radio and broadcasting technological art. AM in broadcasting is today more accurately referred to as DSB-FC-AM, an acronym for double sideband full carrier amplitude modulation, however, the abbreviation AM has been generally accepted to describe the mode of transmission currently used throughout the world in the standard broadcast AM band of 535 to 1705 kHz. In North America (ITU Region 2), the channel separation on the AM band is 10 kHz. In much of the rest of the world (ITU Regions 1 and 3), the channel separations are 9 kHz. In most of the rest of the world outside North and South America (ITU Regions 1 and 3), the AM band is more commonly known as the medium wave or MW band. The long-wave or LW band of 150 to 280 kHz, still popular in parts of ITU regions 1 and 3, also uses AM.

From almost the very beginning of radio communication, it was known that AM was not a very efficient mode of transmission, either in spectrum usage or in transmission of intelligence. The pioneers in AM broadcast transmitter and receiver engineering technology had a deep sense of responsibility toward developing this marvelous medium to enhance the lives of the general public with informative, educational, and entertaining programs. Some of the early communication technology pioneers in the U.S. and abroad had great vision for both the technical and programming aspects of public broadcasting.[2]

In the 1930s, when the telephone industry was planning a major switch from DSB-FC-AM in favor of single sideband suppressed carrier (SSB-SC) for both its long distance wire and wireless services because of its higher transmission efficiency and channel capacity,[3] the broadcast industry was committed to the continuance of conventional AM because of the economic need for public receiver compatibility. Therefore, the broadcast engineers' attention naturally turned to improvement of transmission standards such as fidelity, efficiency of transmission, reliability of transmission, and co-channel and adjacent channel interference, etc. Of these, efficiency and reliability of transmission have seen and continue to see the greatest improvement in the views of many transmitter designers and users. Transmission fidelity, always important, reached a plateau in the late 1940s of approximately 2–3% total harmonic distortion (THD), 10–15 kHz audio bandwidth, and −55 dB noise, which had not been significantly improved upon until the early to mid-1980s when totally solid-state transmitters began to appear on the AM transmitter market, yielding nominally 1% or less THD and −65 dB or better noise. In addition, pretransmitter audio program processing equipment and philosophy, which influence perceived reception fidelity, continue to improve and change through use of modern linear and digital circuit design techniques.

In the early 1980s, stereo transmission on the AM band became a reality. Some AM broadcasters saw AM stereo as a necessary means to compete with FM stereo. AM stereo transmission was approved on a general basis by the FCC in 1981, but unlike FM stereo or color television, the FCC did not adopt a transmission standard for this potentially revolutionary development in the standard broadcast band. Instead, the FCC allowed any commercially developed AM stereo transmission system, which would pass FCC type approval requirements regarding mono compatibility and interference, to compete for the broadcasters' and consumers' favor in order to establish a *defacto* standard for AM stereo transmission. This policy ultimately failed because receiver manufacturers could not justify the cost and complexity of receivers capable of receiving multiple AM stereo formats, and very few AM stereo receivers made it into the marketplace. Without many receivers, broadcasters had little incentive to begin or continue AM stereo transmissions. The FCC eventually recognized the failure of its policy and adopted a single AM stereo standard. However, as of this writing there are only a limited number of broadcasters and receiver manufacturers using this standard in the United States.

AMPLITUDE MODULATION THEORY

Amplitude modulation of a radio signal occurs in at least two basic forms, coded (digital) and linear (analog). The first AM processes for long distance communication involved on/off keying of a radio carrier wave. The pattern or *code* of the on/off keying process determined the content of the information being transmitted. In current state-of-the-art, linear or quasi-linear undulations are used to transmit the analog information present in speech and music. The radio carrier wave signal onto which the analog amplitude variations are to be impressed is expressed as:

$$e(t) = A*Ec*Cos(wct) \quad [1]$$

Where:

$e(t)$ = instantaneous amplitude of carrier wave as a function of time (t)
A = a factor of AM of the carrier wave
wc = angular frequency of carrier wave (radians/second)
Ec = peak amplitude of carrier wave

If A is a constant, the peak amplitude of the carrier wave is therefore constant and no modulation exists. Periodic modulation of the carrier wave exists if the magnitude of A is caused to vary with respect to time as, for instance, a sinusoidal wave.

$$A = 1 + (Em/Ec)*Cos(wmt) \quad [2]$$

Where: Em/Ec is the ratio of modulation amplitude to carrier amplitude
leading to:

$$e(t) = Ec*(1 + (Em/Ec)*Cos(wmt))*Cos(wct) \quad [3]$$

this is the well known basic equation for periodic (sinusoidal) AM and when all multiplications and a simple trigonometric identity are performed the result is:

$$\begin{aligned} e(t) = {} & Ec*Cos(wct) \\ & + (M/2)*Cos(wct + wmt) \\ & + (M/2)*Cos(wct - wmt) \quad [4] \end{aligned}$$

Where: M = the AM factor Em/Ec

Equation [4] can be represented graphically in at least two practical ways: in the time domain representation as shown in Figure 4.1-1, and in the frequency domain as shown in Figure 4.1-2. The graphical representations shown are for a single tone modulation index (M) of 0.7 (the peak modulating voltage is 70% of the peak carrier wave voltage (Em/Ec = 0.7)). Figure 4.1-2 shows the occupied bandwidth of an AM signal with single tone modulation. From this figure and its defining equation [4], it is clear that the bandwidth of an AM signal is equal to twice the highest modulating frequency when no system distortion is present. High quality music reproductions include frequency components as high as 15 kHz or higher and therefore the required theoretical bandwidth of a DSB-FC-AM signal capable of high quality music reproduction is at least 30 kHz. Harmonic and intermodulation system distortion have the effect of widening the effective occupied bandwidth of the system. However, most modern transmitters have sufficiently low distortion characteristics that bandwidth stretching due to system non-linear distortions is not normally a significant problem. The occupied bandwidth characteristics of an AM broadcast transmitter are discussed in more detail in the section on *factory tests* and *audio processing* and *pre-emphasis*.

Digital Radio Broadcasting

At this writing, research is well underway on several techniques to transmit digital audio broadcasting on the LW, MW, and SW-AM bands, as well as on VHF-FM bands. The technology for both compatible and discrete AM and FM digital broadcasting is still in its infancy and largely proprietary to the many competing proponents.

It is clear that digital radio broadcasting will soon be a reality with great promise for increased quality and reliability of signal delivery to the listening public. Because of the tremendous global economic investment in transmitting equipment, it is likely that any successful digital radio broadcasting system will, at least initially, use existing transmitting equipment in some relatively easily modified form. All proposed digital radio broadcast systems hold the promise of equal or greater current performance and coverage with considerably less than current transmitting power output levels.

RADIO FREQUENCY POWER AMPLIFIERS

The most important system component which is common to all AM systems is the high power final RF power amplifier. High power amplifiers that produce 0.25 to 50 kW of carrier power are common for AM broadcast transmitters in North America. Carrier power levels up to 1 MW and higher are not uncommon in other parts of the world for medium wave broadcasting. Transmitters delivering these high power levels should be designed for highest operating efficiency within the circuit constraints of the particular manufacturer and/or modulation system used. The most common amplifier used to meet the demands of high output power and high efficiency in modern transmitter designs is the class "C", "C/D", or "D" amplifier, either vacuum tube for large output powers from a single amplifier circuit or solid-state for large output powers derived from several combined lower power amplifier circuits. Class "B" RF power amplifiers, very popular in early broadcast transmitters, are still used occasionally at lower power levels and for driver stages of final class "C" or "D" stages. Solid-state class "D" amplifiers up to 5 kW are becoming the standard as driver stages for final vacuum tube amplifiers and for the final power amplifier modules in modern all solid-state AM transmitters. As stated in the introduction, the most common major concerns for both manufacturers and users of modern AM broadcast transmitters is operating relia-

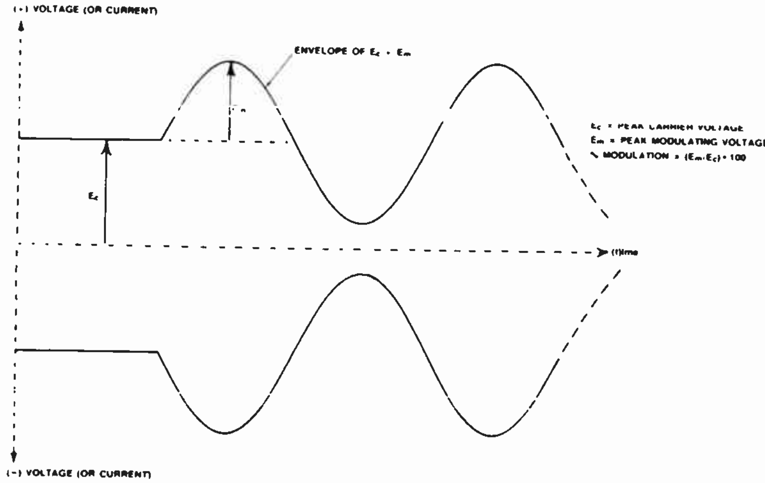

Figure 4.1-1. Time domain representation of a carrier wave signal amplitude.

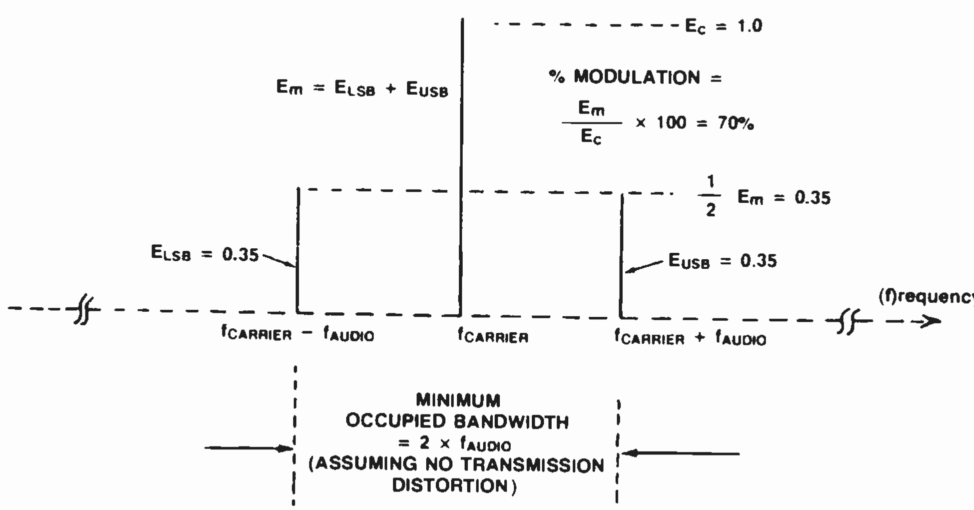

Figure 4.1-2. Frequency domain representation of an amplitude modulated signal showing the carrier wave signal and two resultant modulation sidebands at 70% modulation.

bility and efficiency, hence operating cost. To achieve high overall operating efficiency, the stages which consume the most power, the modulator and/or the final RF power amplifier stages must be designed for highest possible operating efficiency.

The basic tuned anode vacuum tube amplifier is described in graphical form in Figure 4.1-3. The vacuum tube shown can be either a triode, tetrode, or pentode, and can also be representative of transistor stages. Tetrode final amplifiers are most common in modern high power transmitter vacuum tube designs. The RF excitation voltage is supplied to the grid of the power amplifier tube and the ratio of dc grid bias voltage-to-peak RF excitation voltage, shown sinusoidal in Figure 4.1-3, determines the conduction angle (θc) of anode current, given as:

$$\theta c = 2*\text{Arc Cos}(Ecc/(Eg - Ecc)) \qquad [5]$$

where the exciting grid signal (Eg) is sinusoidal as shown in Figure 4.1-3(a).

The shape of the anode or transistor collector current pulse is determined by the device transfer characteristics and input waveshape. The pulse of current thus generated, Figure 4.1-3(c), is supplied by the dc power supply, E_{BB}, and passed through the resonant tank circuit shown in Figure 4.1-3(d). The resonant tank circuit is assumed to have sufficient operating "Q" to force anode or collector voltage (ep) to be essentially sinusoidal and of the same periodic frequency as the RF excitation voltage and resultant anode or collector current pulse. The instantaneous anode dissipation, shown in Figure 4.1-3(e), is the product of instantaneous tube anode voltage drop and anode current. The tube transfer characteristic is a variable dependent upon many tube factors as well as maximum drive signal (Eg). The exact shape and magnitude of the current waveform is

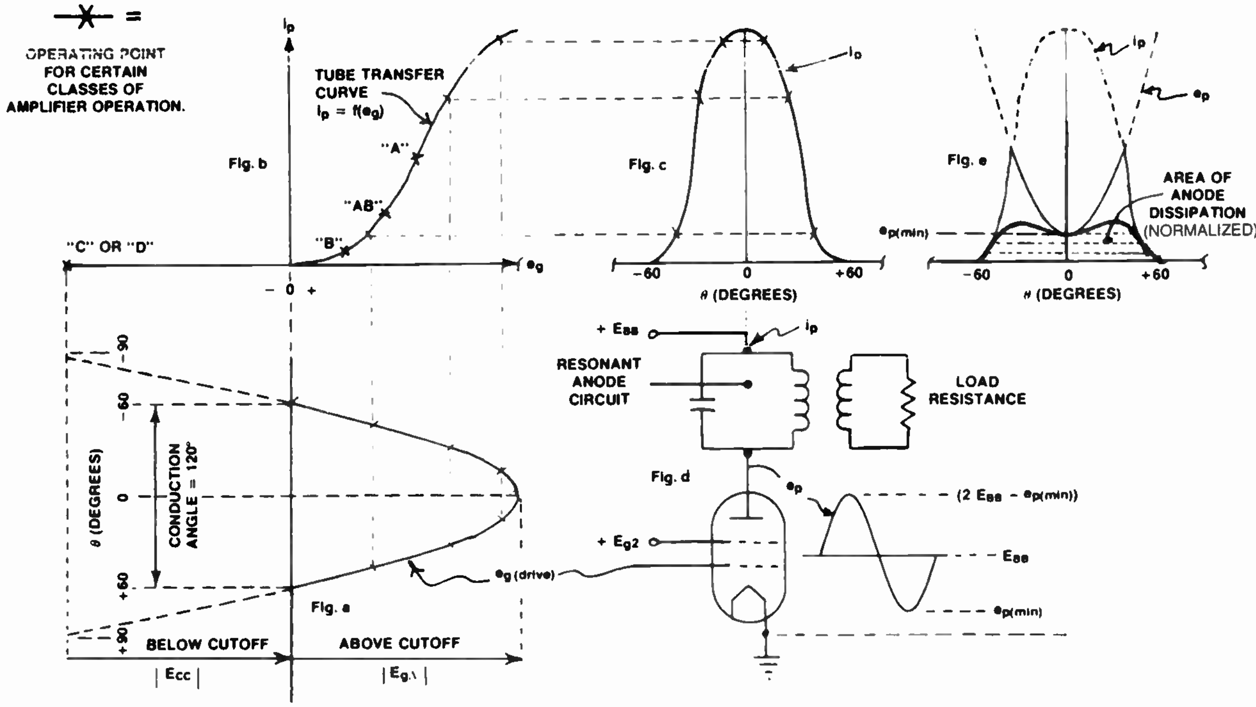

Figure 4.1-3. (a), (b), (c), (d) Classical vacuum tube class "C" amplifier with sinusoidal grid drive, 120° anode current conduction and resonant anode load.

normally obtained from a load line plot on constant current characteristic tube curves supplied by the tube manufacturer. The resonant anode load impedance is chosen and adjusted to allow ep (min) to be as low as possible without causing excessive screen grid (in the tetrode case) or control grid dissipation. Some manufacturers increase anode efficiency beyond the limits for typical Class "C" amplifiers by using a circuit employing a third harmonic resonator between the output anode connection and the fundamental resonant circuit. This has the effect of squaring up the anode voltage waveform (ep) thus causing the integral of the ep × ip product, or anode dissipation, to be smaller; resulting in lower anode dissipation for a given RF power output. An amplifier employing the third harmonic anode trap is commonly referred to as class "C-D;" suggesting an efficiency rating somewhere between conventional class "C" operation (nominal 120° conduction angle) and true class "D" operation with rectangular anode or collector voltage waveforms. Anode and collector efficiencies can be increased typically to values of 90% for transmitters up to approximately 10 kW carrier power and approximately 85% for transmitters higher than 10 kW carrier power by using the third harmonic trap technique. Table 4.1-1 shows a comparison of anode efficiency for six classes of high power tuned RF amplifiers under certain defined conditions.

Table 4.1-1

Comparison of Tuned RF Amplifier Efficiencies

Amplifier Class	Conduction Angle (degrees)	Anode Efficiency (%)	Defined Conditions of Operation
A	360	30	$E_{b(min)} = 0.10 \cdot E_{BB}$
A-B	240	60	$E_{b(min)} = 0.10 \cdot E_{BB}$
B	200	67	$E_{b(min)} = 0.10 \cdot E_{BB}$
C	120	84	$E_{b(min)} = 0.05 \cdot E_{BB}$
C-D	120	90	$E_{b(min)} = 0.05 \cdot E_{BB}$ (Odd Harmonic Resonators)
D	120	95	$E_{b(min)} = 0.05 \cdot E_{BB}$ (Square-wave voltage shape)

High Level Anode Modulation

The first practical method of generating the AM signal was Heising constant current, a method of applying audio modulation to the anode supply voltage of a class "C" RF amplifier.[4,5] This general type of modulation has since been known as high level anode (or plate, or collector) modulation (see Figure 4.1-4). The Heising modulator was used at least as early as 1920 and was usually used to modulate a low power RF amplifier or master oscillator stage which was followed by several linear amplifier stages until the desired power level was attained. In some cases the Heising modulator was used to modulate the final RF amplifier stage of lower power transmitters. The Heising shunt modulator operated in the class "A" mode and therefore was low in operating efficiency. The early linear amplifiers were tuned class "B" amplifiers operating with carrier level anode efficiencies of 30% maximum. The Heising and similar systems of audio amplification were also used to modulate the grid bias level of RF amplifier stages in order to obtain the

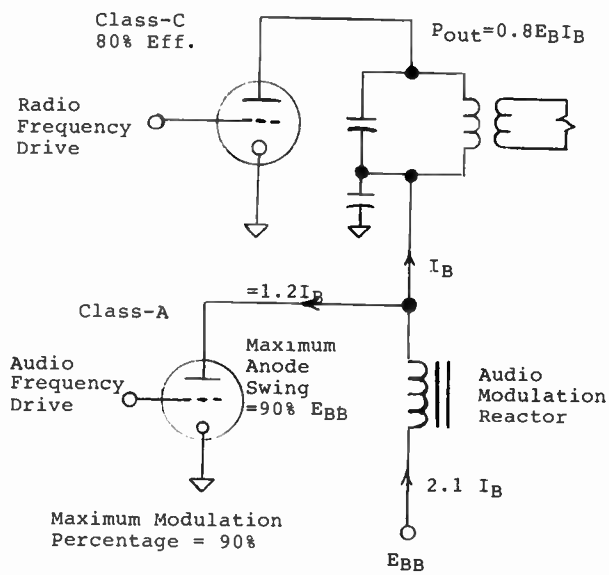

Figure 4.1-4. Heising Constant Current Modulator.

AM signal to be used for further linear amplification. Heising constant current anode modulation was also very popular in military and aviation radio sets used through the end of World War II.

Chireix Outphasing Modulation

Outphasing modulation was originally described in the literature by its inventor Henry Chireix in 1935.[6] It is a unique and ingenious method of obtaining the AM signal by use of counter phase modulation and vector addition of two separate radio frequency signals. It was marketed for many years by RCA under the trade name Ampliphase and many of those transmitters and some of European manufacture are on the air still today at power levels of 100 kW and higher. This system of modulation is described graphically in Figure 4.1-5. Two RF signals are derived from a common excitation source and then split into two separate channels. Each channel is shifted in phase, one positive and the other negative. The two channels are then each phase modulated by the modulating signal, again, in opposing polarity. The two channels are amplified and then recombined in a vector additive network which has the effect of producing the desired AM. The main advantage, as with all systems previously discussed, is in operating efficiency. The two independent channels contain only phase modulated RF signals and therefore each can be amplified to the desired power levels in high efficiency Class "C" or "D" amplifiers. The actual modulation process takes place both at low level, in the phase modulators, and at high level, in a passive output network combiner.

There are two major disadvantages of this system of modulation. First, the efficiency of the output power amplifiers is not quite as high as the previous description would imply, due to the fact that at all instantaneous levels of modulation, except one, the anode circuits must work into a reactive load. Secondly, output carrier power setting is sensitive to tuning of any stage anywhere down the chain; operators of early versions of this type of equipment soon learned of the potentially disastrous consequences of trimming a tuning control of some lower power stage. Later designs used broadband amplifying stages for the lower levels to circumvent the problem of tuning sensitivity of the lower power stages.

Another major disadvantage of the Chireix system in older transmitters was the generation of incidental phase modulation (IPM) in excessive amounts when the two low level phase modulators were not well balanced in opposing PM characteristics. It was common for such an unbalance to exist producing as much

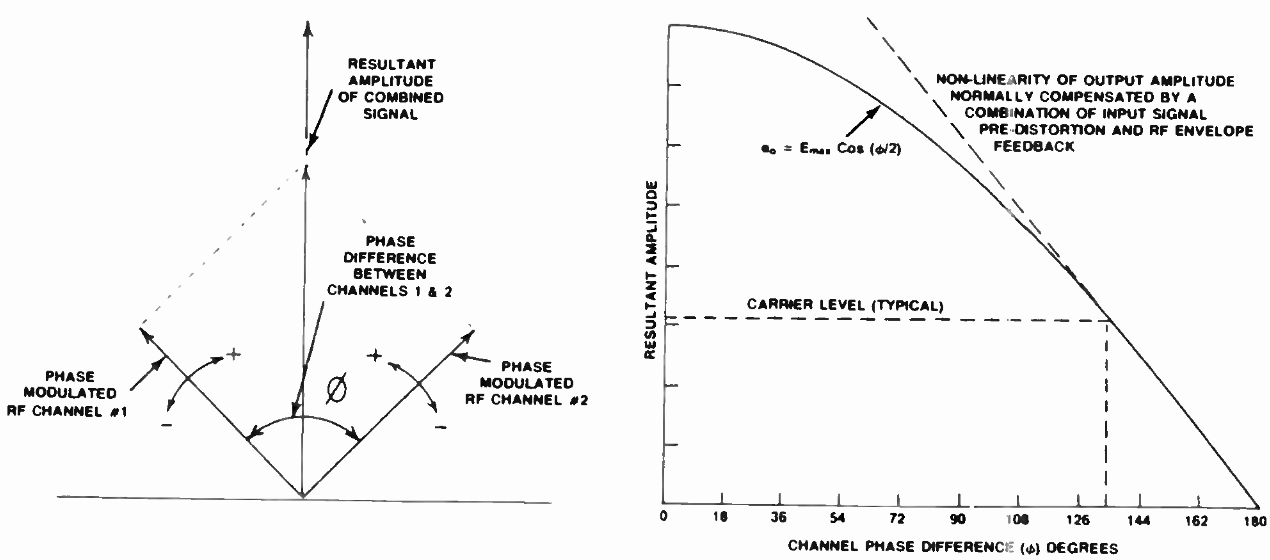

Figure 4.1-5. Principle of Chireix outphasing modulation.

as 12 to 18° of peak IPM at either 100% modulation crest or trough. Modern solid-state circuitry for the phase modulators using digital phase modulation techniques would completely remove this disadvantage were the system still being commercially produced. The outphasing system of AM ceased to be produced commercially when RCA discontinued its AM transmitter manufacturing in the mid-1970s.

Class "B" High Level Anode Modulation

Historically the most popular method of applying the audio modulating voltage to the anode circuit of a class "C" RF power amplifier was by a high power push-pull class "B" audio amplifier. This type of modulation was first used to improve the operating efficiency and to increase the output power of AM broadcast transmitters. Class "B" push-pull audio amplification was first used to improve distortion and output power of telephone transmission amplifiers. The invention was soon recognized by broadcast engineers and applied to high level anode modulation. With the final RF power amplifier operating at approximately 80% anode efficiency and the class "B" audio modulator total static currents approximately one-tenth that of an equivalent Heising modulator, total anode efficiencies at carrier level rose to approximately 72% compared to 37% for the Heising system and 30% for conventional linear amplification. A simplified drawing of a typical high level class "B" anode modulation system is shown in Figure 4.1-6. The vacuum tubes shown in Figure 4.1-6 may be either triodes, tetrodes or pentodes. The output circuit of the class-B modulator shows the output modulation transformer (MT), an audio coupling capacitor (C), and a dc shunt feed inductor (L).

This arrangement was used in all high level class-B high power broadcast transmitters until about 1960 because of a transformer design constraint that would not economically allow unbalanced direct currents to magnetize the transformer core material without poor low frequency distortion. Advanced technology core materials and careful magnetic transformer design allowed elimination of the coupling capacitor and the dc feed shunt inductor, first in some 100 kW European transmitter designs in the early 1960's, and in an American shortwave transmitter design in the later 1960's. Many of the more advanced modern AM broadcast transmitter designs still using high level class-B anode modulation have eliminated the extra C and L components from the modulator output circuitry, and the dc current to the modulated RF amplifier anode flows directly through the secondary of the output modulation transformer. Elimination of these C and L components is necessary for optimum operation of modern AM stations. With the extra C and L components, the modulator output is effectively a three-pole high pass filter which causes low frequency transient distortion to be generated when driven with the complex waveforms that are produced by many modern and popular program audio processors. Eliminating the C and second L component, causes the output modulator circuit to become a single-pole high pass filter, greatly reducing low frequency transient distortion.

Another problem with transformer coupled high level class-B anode modulation is with high frequency audio transient distortion. Stray internal winding capacitances and leakage inductances form multi-pole low pass filtering at the high frequency end of the audio spectrum. This equivalent multi-pole low pass

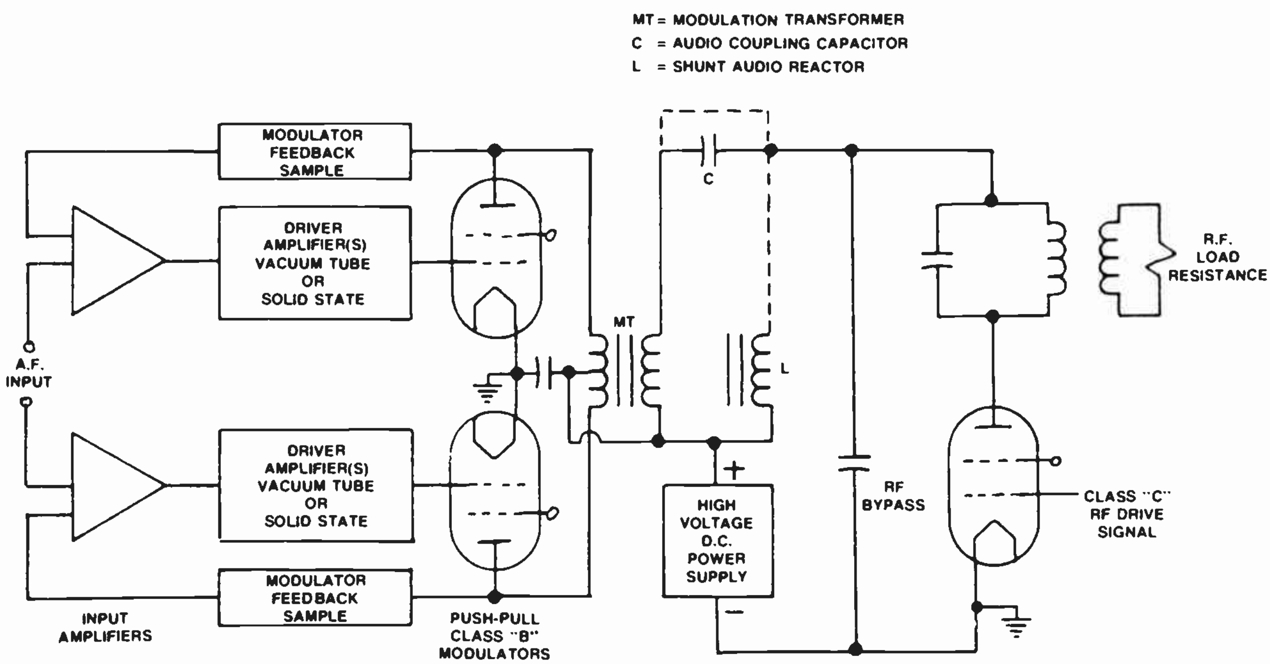

Figure 4.1-6. High Level anode modulation employing transformer coupled push-pull class-B modulators.

filter generates transient overshoot distortion when driven by the same type of processed complex program waveforms previously mentioned. Transient overshoot up to 12% is typical for square wave modulator input signals and results in a required modulation level reduction of the same 12% in order to maintain peak modulation levels within FCC allowed limits. This high frequency transient overshoot distortion can be effectively minimized by filtering the audio input to the transmitter with linear phase filters, resulting in somewhat lower high frequency audio response, and/or by careful control of the modulation transformer equivalent circuit yielding more linear audio phase characteristics for the entire modulator circuitry. Balanced modulator negative feedback is used to reduce modulator non-linear distortion and noise. Negative feedback, however, usually worsens high audio frequency transient distortion characteristics.

Doherty High Efficiency Linear Amplifier

The Doherty High Efficiency Linear Amplifier was first described in the technical literature in 1936 by its inventor, W.H. Doherty.[7] So contrary were the terms *linear* and *high efficiency*, in the context of amplitude modulated waves, that many engineers in broadcasting refused to accept the concept as workable, similar to the reaction Armstrong received when he proposed that frequency modulation was a practical mode of radio transmission. Nevertheless, the Doherty High Efficiency Linear Amplification System was soon proven to work by 1938 and has been used at power levels up to 1,000 kW carrier power in both the original and in the patented Weldon modified form in many installations throughout the world on the medium wave broadcast and international shortwave broadcast bands, as well as the long wave broadcast band in Europe.[8,9] Its implementation was the result of true inventive genius, using one or more known basic scientific principles to create a totally new and necessary product. The Doherty Linear Amplifier is described graphically in Figure 4.1-7. As with conventional linear amplifiers, the AM signal is generated at low levels and applied to the input of the final amplifier stage. The Doherty System employs two output amplifier stages, one defined as the carrier amplifier and the second as the peak amplifier.

The outputs of the two stages are combined in phase at the anode of the peak amplifier tube. At carrier level the carrier tube is operated as a nearly saturated Class "B" amplifier and thus delivers almost all of the carrier power at Class "B" efficiencies (approximately 70% anode efficiency). The peak tube at carrier condition is biased and driven just above cutoff and therefore supplies a small amount of carrier power (approx. 2 to 6%). The anodes of the two tubes are connected together through a 90° impedance inverting RF network. As the modulated signal increases in the positive direction to both peak and carrier tubes, the current supplied to the output load by the peak tube increases. The saturated voltage drop at the anode of the carrier tube remains constant over the entire positive modulation half-cycle, thus causing the current at the output of the interanode 90° network also to be constant during the same positive modulation half-cycle. The rising current from the peak tube anode has the effect of raising the impedance being presented to the interanode network. Since the current from the network is constant, the net effect is an increase in output power from the carrier tube ($I^2 \times R_L$ increases because R_L increases). At the 100% positive modulation crest, both tubes are producing exactly twice carrier power to the load, satisfying the requirement that peak envelope power (PEP) equals $4 \times P_{carrier}$. During the negative half-cycle of modulation, the peak tube is cut-off and the carrier tube behaves as a normal linear amplifier, allowing the envelope power output to drop linearly to zero at the 100% negative modulation trough. The anode efficiency of the Doherty High Efficiency Linear Amplifier at carrier level is more than twice the efficiency of conventional AM class "B" linear amplifiers.

The Doherty Linear Amplifier also has two other important advantages for high power broadcast transmitters. First, and most important, the peak anode voltage at either tube is only about one-half that required for an equivalent carrier power high level PWM or class "B" anode modulated transmitter thus allowing reliability and usable tube life to increase significantly. Secondly, no large modulation transformer or special filtering components are used in the final amplifier stages to cause transient overshoot distortion as previously discussed for Class "B" anode modulation or pulse width anode modulation. The main problems of the Doherty Linear Amplifier are non-linear distortion and an increase in the complexity of tuning. The major sources of non-linear distortion are the non-linearity of the carrier tube at or near the 100% negative modulation crest and the non-linearity of the peak tube at or near carrier level when it is just beginning to conduct. Both sources of distortion are effectively reduced by use of moderate amounts of overall envelope feedback. The tuning complexity problem is usually overcome by experienced and trained operators and simplified tuning procedures aided by built-in test equipment used in modern designs since approximately 1948.

Pulse Width High Level Anode Modulation

Pulse width modulation (PWM) of the dc anode voltage of a class-C RF amplifier was first used in commercial high power broadcast transmitters in Europe in the early 1960s. It was the first commercially successful attempt to significantly improve upon the efficiency of the popular high level class-B modulation system by applying and improving basic PWM concepts that were described by Heising decades earlier.[10] Since this first success, PWM has become a preferred method of high level anode modulation and is employed in several broadcast transmitter designs by several manufacturers worldwide. The basic PWM system and two ingenious improvements to the basic system are shown in Figure 4.1-8. The circuit in Figure 4.1-8(a) graphically describes the basic principle of

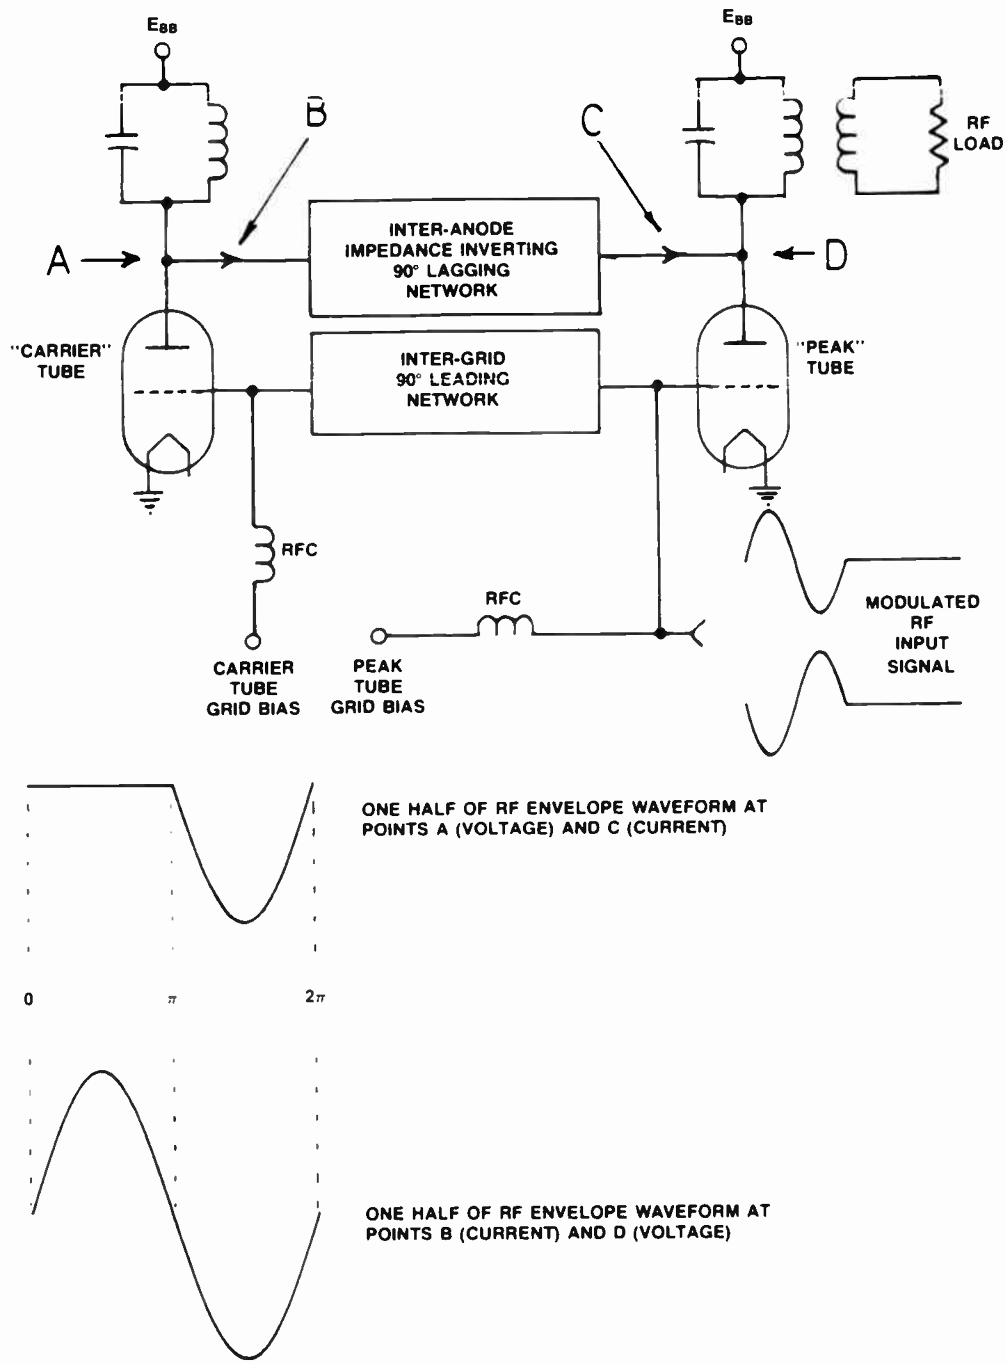

Figure 4.1-7. Doherty High Efficiency Linear Amplifier for modulated waves.

PWM. An inherent practical deficiency in the basic concept, Figure 4.1-8(a), is caused by the relatively high shunt circuit capacitance of the modulator tube filament transformer plus stray capacitances. Though special low capacitance isolation transformers can be used to supply modulator filament and auxiliary power to minimize shunt capacitance, typical realizable values of capacitance can cause excessive switching losses and audio distortion in lower power transmitters.

Besides causing switching losses, the high stray capacitance to ground is also a cause of major modulator distortion at high negative modulation indices.[11] The circuit shown in Figure 4.1-8(b) is one ingenious way to overcome the stray modulator capacitance problem.

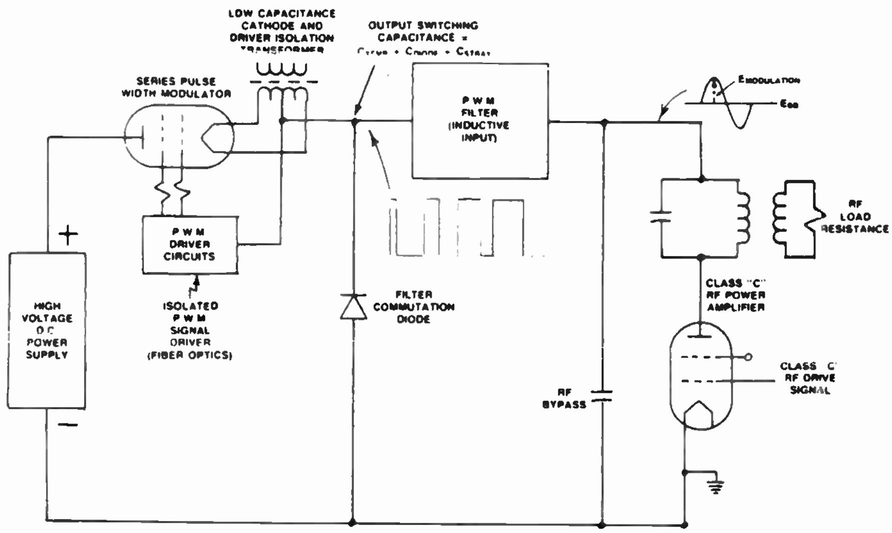

Figure 4.1-8(a). Basic classical high level anode pulse width modulation of a vacuum tube class "C" amplifier.

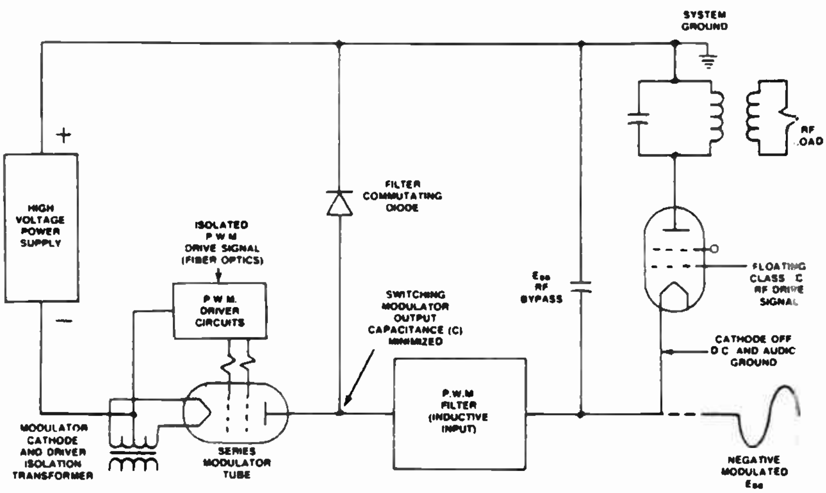

Figure 4.1-8(b). Collins Radio/Continental Electronics patented modification to basic high level PWM System to minimize modulator losses by minimizing switching modulator output capacitance.

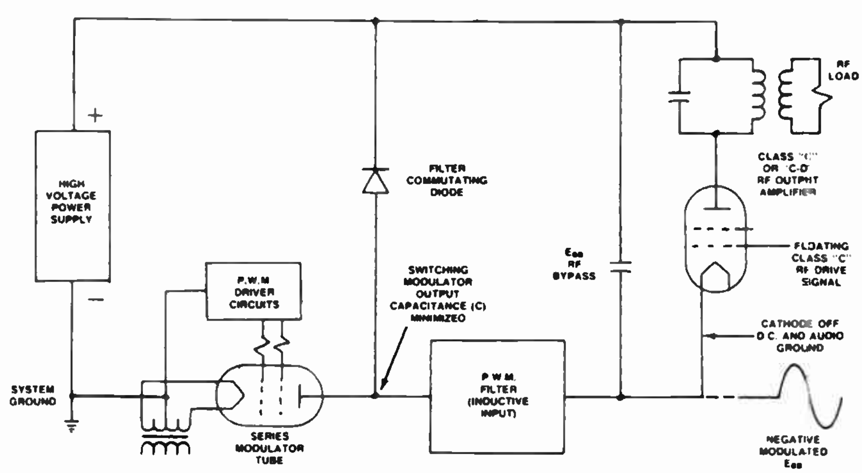

Figure 4.1-8(c). Harris corp. patented modification to basic high level PWM System to minimize modulator losses by minimizing switching modulator output capacitance.

It is identical to the circuit in Figure 4.1-8(a), in principle, except that the high voltage pulse modulated wave is at a point in the circuit where the shunt capacitances to ground are inherently minimized. The circuit in Figure 4.1-8(c) is basically the same as in 4.1-8(b) except the system ground has ingeniously been placed at another point in the circuit. PW Modulator anode efficiencies approach 92% in some higher power transmitter designs yielding a combined modulator and carrier tube anode efficiency of approximately 74% at all levels of modulation. An added efficiency advantage over high level class-B anode modulation is that a PWM transmitter may have only two high power vacuum tubes, one modulator and one final RF amplifier, thus eliminating the filament heating power of one large vacuum tube required in push-pull modulator designs. A significant disadvantage of PWM as described in Figure 4.1-8(b) and 4.1-8(c) is that the cathode and grid circuits of the modulated RF amplifier are operated at high voltage levels off ground, adding complications to the circuitry in these areas that are avoided with the classical PWM circuit of Figure 4.1-8(a) and conventional high level class-B anode modulation. Another major disadvantage of PWM in any form is that of transient distortion caused by the phase non-linearity of the multi-pole PWM filter, similar to that previously discussed for high level class-B anode modulation. The switching frequency is typically 70 kHz for most transmitters manufactured in North America. This frequency is chosen to ease compliance with FCC regulations which requires all spurious radiation more than 75 kHz removed from the carrier frequency to be 80 dB or more below the carrier level. In order to meet the spurious output requirements of paragraph 73.44 of the FCC regulations, a very steep cutoff low pass filter is required at the output of the PW modulator.

High Efficiency Screen/Impedance Modulation

In 1938, Terman and Woodyard described a modification to the basic Doherty High Efficiency Linear Amplification System previously described.[12] In the new system the grid bias level of two tubes operating class "C" is varied at the audio modulation rate thus creating a higher efficiency system of AM rather than amplification while still using the impedance inverting properties of the interanode network described by Doherty. The Terman-Woodyard system of modulation, however, was not extensively used in commercially successful high power transmitter designs.

High efficiency screen/impedance modulation is similar to the Terman-Woodyard modulation system except that the audio modulating signal is applied to the screen grids of two tetrode vacuum tubes operating as class "C" carrier and peak amplifiers. Invented by J.B. Sainton in 1965, the screen/impedance modulation system exhibits significant improvement to the Terman-Woodyard scheme due to the fact that RF excitation voltages and audio modulating voltages are isolated from each other thereby eliminating a troublesome source of tuning versus modulation interaction.[13]

The screen/impedance modulation system is shown in Figure 4.1-9. The peak and carrier tubes are biased and driven in quadrature as Class "C" amplifiers from the continuous wave RF drive source. At carrier level, the screen voltage of the carrier tube is adjusted so that the carrier tube is near anode saturation and delivering approximately 96% of the carrier power; while the screen voltage of the peak tube is adjusted so that the peak tube is just into conduction and supplying the remaining approximate 4% of carrier power. The combined anode efficiency at carrier level is better than 77% as shown in equation [7].

$$n_{at} = 1/(pc/n_{ac}) + (pp/n_{ap})$$
$$n_{at} = 1/(0.96/0.8) + (0.04/0.40) = 0.77 \qquad [7]$$

Where:

- pc = percent carrier power supplied by carrier tube (as a decimal)
- pp = percent carrier power supplied by peak tube (as a decimal)
- n_{ac} = carrier tube anode efficiency at carrier level (as a decimal)
- n_{ap} = peak tube anode efficiency at carrier level (as a decimal)
- n_{at} = total anode efficiency at carrier level (as a decimal)

The modulation of the RF carrier wave occurs when the screen voltage of the peak tube begins to rise during the positive modulation half-cycle, thus causing the peak tube to supply more RF current to the output load. This increase of current into the output network causes the resistance seen by the interanode network to increase and, due to the impedance inverting characteristic of the 90° interanode network, causes a proportional decrease in the load impedance presented to the carrier tube anode. The carrier tube resonant anode voltage drop is fully saturated over the entire positive modulation half-cycle and is therefore effectively a constant voltage source. The power output of the carrier tube thus increases during the positive modulation half-cycle due to the modulated decreasing impedance at its anode until both peak and carrier tubes deliver twice carrier power at the 100% positive modulation crest. During the negative modulation half-cycle, the peak tube is held out of conduction while the carrier tube output voltage decreases linearly to zero output at the 100% negative modulation trough. Simple alterations to the interanode 90° network characteristic impedance gives the screen/impedance modulation system the capability of full FCC allowed positive modulation up to 125% peak without added distortion. The advantages of screen/impedance modulation are the same as mentioned for the Doherty linear amplifier except that screen/impedance modulation has higher efficiency at all depths of modulation and, is less critical to misadjustment of RF amplifier tuning. Screen/impedance modulation has been successfully used in medium wave transmitters throughout the world at the 2 MW carrier power level and up to 250 kW in

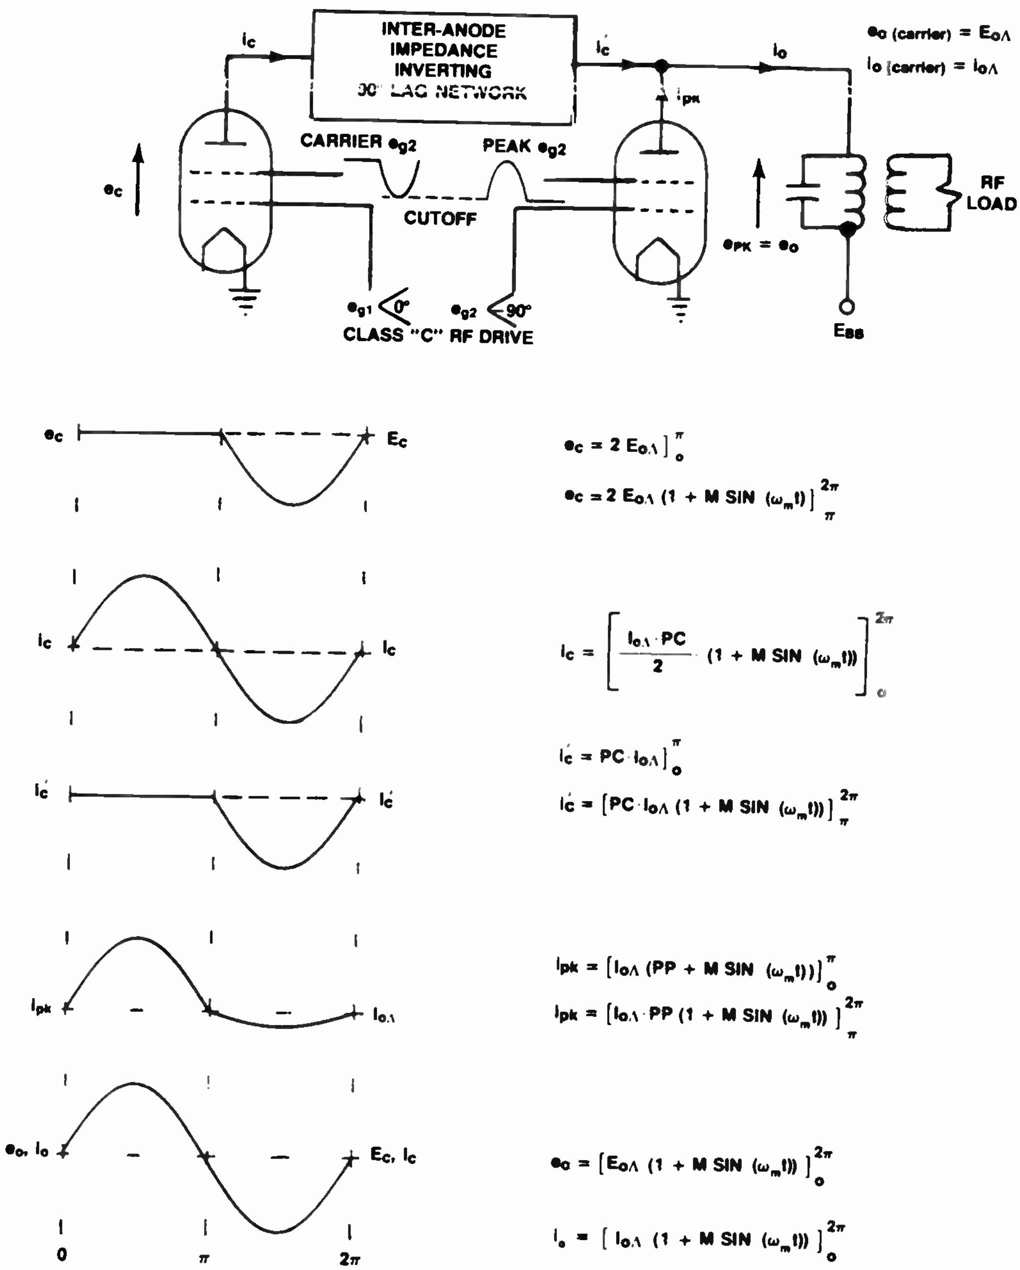

Figure 4.1-9. Principles of Sainton high efficiency screen/impedance modulation.

automatically tuned transmitters used for international shortwave broadcasting.

SOLID-STATE BROADCAST TRANSMITTERS

Developments in the application of solid-state technology to high power medium and shortwave AM broadcast transmitters have been prolific since about 1984 and continue to be a source of great cause for enthusiasm in the high power transmitter technological art. Concerns about the reliability of solid-state circuitry in high power environments has rapidly vanished as the new all solid-state designs and products have proved themselves worthy in the harsh environment of high power transient disturbances caused by gas arcs in associated vacuum tube circuitry and lightning strikes on antennas, power lines, buildings, etc. Current products available on the commercial transmitter market offer solid-state modulators for high level anode modulation of a vacuum tube final RF amplifier up to 600 kW on medium wave and shortwave transmitters. Other products are available utilizing fully solid-state designs up to 1,200 kW for medium wave transmitters. The vacuum tube power amplifier will still have a future for many years as a practical and economical source of radio frequency power generation for shortwave and some very high power lower frequency applications. However, the new all solid-state designs in the medium wave AM bands are achieving great commercial success because of their higher operating efficiencies, reliability, size, weight and superior modulation characteristics over competitive vacuum tube designs. Likewise, products and designs employing solid-state technology in the modulator circuitry for high level anode modulation of power grid vacuum tubes are also enjoying great commercial success worldwide for both medium wave and especially shortwave AM broadcast transmitters.

Solid-State Equipment and Circuitry

Solid-state designs of AM broadcast transmitters currently available on the commercial market fall basically into three categories: solid-state modulator circuitry supplying the audio modulating power for high-level anode modulation of a power grid vacuum tube RF power amplifier, solid-state high level collector modulation of solid-state RF power amplifiers and at least one unique product and design is commercially available in which the AM process is achieved by pseudo digital pulse-code modulation taking place directly in the RF power amplifier stages.

The main advantage of solid-state circuitry in high power AM broadcast transmitters is operating efficiency. It is still yet to be determined if the reliability of solid-state designs is distinctly advantageous over power grid vacuum tube circuitry, but the efficiency advantages are clear and proven. The efficiency of a single power grid vacuum tube pulse width modulator, including filament, control grid, and screen grid power losses is approximately 90% maximum for a 50 kW transmitter. Pulse-step/width modulator efficiency for a solid-state modulator at the same power level is approximately 95% or higher. When solid-state circuitry is also employed in the RF amplifier circuitry, the efficiency advantages are even greater. The typical maximum anode efficiency of a power grid vacuum tube Class-C RF power amplifier is 84% neglecting output network circuit losses. This efficiency can be improved to approximately 90% by anode voltage wave-shaping techniques such as 3rd and 5th harmonic traps in the output anode network. Therefore, the all tube pulse-width modulated transmitter overall modulator/RF power amplifier (RFPA) anode efficiency is 90%*90%, or approximately 81%. Transmitter designs employing solid-state circuitry in the RF power amplifiers typically use Class-D RF power amplifier circuitry which achieve approximately 95% RF collector efficiency at medium wave frequencies. Therefore, an all solid-state pulse-width modulated transmitter can have overall collector efficiency of 95%*95% = approximately 90%, 9% greater than the all tube transmitter. With energy costs constantly rising, the efficiency of broadcast transmitters will continue to be very important.

Thomcast Pulse-Step Modulator

Thomcast of France and Switzerland was one of the first companies to market a workable very high power solid-state modulator for use with their family of LF, MF, and SW transmitter products, from 100 to 1,200 kW of carrier power. The system employs several low voltage power supplies in series which are switched into operation in steps to provide the required anode modulation voltage, hence the term *step modulation*. The concept was first employed in a 500 kW shortwave transmitter design and later scaled down at LF, and MF, as well as other shortwave products of lower power levels to 100 kW, minimum. Typically the number of steps employed is approximately 28. Each step is pulse-width modulated to achieve the necessary total linearity required for broadcast transmitter modulation linearity characteristics. Each step represents approximately 1,000 V in modulator output, yielding a total modulator output capability of approximately 28,000 V at the 100% positive modulation crest.

The transmitters were designed to comply with the ITU international shortwave broadcast standard of 4.5 kHz audio bandwidth which is also compatible with the requirements for audio bandwidth of ITU region 2 and 3 medium and long wave transmissions.

To achieve high overall transmitter efficiency, Thomcast engineers concentrated not only on the solid-state modulator circuitry, but also on techniques to maximize the anode efficiency of the power grid vacuum tube final RF power amplifier and associated circuitry. Working closely with the power grid vacuum tube division of Asea Brown Boveri (ABB), they designed a tube with optimum circuit efficiency characteristics which operates with minimum grid drive power requirements, an anode conduction angle of approximately 110°, rather than the more conventional 120° standard for Class-C operation, yielding a total anode efficiency of approximately 87%, excluding circuit losses. Medium wave transmitter designs by Thomcast using pulse-step modulation employ similar technologies with the addition of anode wave-shaping circuitry, resulting in anode efficiencies exceeding approximately 92%. Overall, shortwave transmitter efficiency has been measured at greater than 76% on some international shortwave bands. Overall efficiency of Thomcast medium wave transmitters has been measured at greater than 77%.

Continental Electronics Corporation (CEC) Pulse-Step Modulator

Continental Electronics Corporation (CEC) introduced their own version of a high power pulse-step modulator system in 1990. The system is similar to the ABB Thomcast system in basic operating principle. The technique used to generate each step and the subsequent pulse-width modulation of each step is different than the system employed by Thomcast, but the net result is similar.

The CEC system for the basic step generation uses a modified flash A/D converter with an additional digital ring modulator system that electrically rotates the active steps equally among all available modules. This rotation provides equal power distribution among all system modules. Each step is pulse-width modulated by a linear mixing of a triangular dither signal to each A/D flash comparator.

The CEC system employs typically approximately 48 discrete steps of approximately 750 V each, and has been built for transmitter carrier power levels of 100 kW, 250 kW, 500 kW and higher, both medium wave and shortwave. The CEC design employs high speed IGBT insulated-gate-bipolar-transistors (IGBT) producing typical modulator efficiencies of 95% or higher, overall transmitter efficiencies of greater than 72%, and modulation bandwidth capabilities exceeding 10 kHz.

Nautel Corporation—AMPFET Transmitters

The Nautel Corporation of Nova Scotia, Canada was one of the first to introduce all solid-state transmitter designs on the commercial broadcast transmitter market. Initially available for only 1, 5, and 10 kW carrier powers, they have since added capability to 50 kW and to 100 kW by combining two 50 kW transmitters.

The Nautel design employs independent low power modules, each with Class-D RF power amplifiers with pulse-width modulation of the Class-D amplifier collector voltage. Each module contains its own RF power amplifier and pulse-width modulator and approximately 24 modules are then combined in an RF combining network to achieve the desired carrier power level. The collector efficiency of each Class-D RF Power amplifier (RFPA) is approximately 95% and the efficiency of the combining networks is greater than 99%, yielding a total RF system efficiency of approximately 94%. The efficiency of the pulse-width modulators is approximately 95% resulting in an overall collector efficiency of better than 89%. Nautel engineers then carefully selected and designed the remaining transmitter components to require no more than approximately 10% of nominal carrier power for all auxiliary transmitter functions, such as control circuitry, exciter and driver circuitry, cooling equipment, etc, thus achieving an overall transmitter efficiency of greater than 80%. The basic circuit concept of the Nautel design is shown in Figure 4.1-10.

Harris Broadcast Division, Polyphase Pulse-Width Modulation

In the late 1960s, Harris Corporation developed their version of pulse-width modulation—Pulse Duration Modulation (PDM). In the original configuration, audio information to be transmitted is sampled at a nominal 75 kHz rate. This creates a 75 kHz pulse train with its pulse width rate-of-change being equal to the audio frequency. Studies have determined that the time duration of the sample pulse is not critical. The sample rate is based on an upper frequency of 15 kHz sampled at five times that frequency to ensure broadcast quality bandwidth and distortion. In practice, most transmitters manufactured for use in North America employ a switching frequency of approximately 70 kHz, to simplify compliance with the FCC requirement for suppression of spurious emissions beyond 75 kHz from the carrier frequency.

The technique of polyphase pulse-width modulation (PPDM) was a further development to overcome the switching transition losses of the higher sampling frequency, the effective sample rate being four times normal, or approximately 280 kHz.

When extracting the long and short term dc average information from an encoded single phase PDM signal, a sharp filter roll off characteristic is required. This sharp attenuation characteristic generates overshoot due to the inherent group delay characteristic of the sharp roll off filter. The effective 280 kHz sampling rate of the Harris four phase sampling system, however, allows some relaxation in filter cutoff requirements that significantly reduce overshoots.

Harris Broadcast Division, DX Series Pulse-Code Modulation

One of the most exciting and truly innovative improvements to the AM broadcast transmitter art is the Harris Broadcast Division DX series of medium wave AM broadcast transmitters employing direct digital techniques to generate the amplitude modulated wave. The technique has no modulator as such and the complete AM wave, carrier and modulation sidebands, are produced by direct digital pulse-code control of several small power solid-state RF amplifier modules.

The DX system is employed in transmitters ranging in power from 5 to 50 kW for the domestic U.S. market, and has been sold at 1,000 kW power levels for the ITU Region 2 & 3 markets for which carrier powers up to 1 and 2 MW are not uncommon.

The system has many inherent advantages over conventional AM modulation systems.

- It is solid-state and employs no separate modulation of the final RF amplifiers (the amplitude modulated wave is directly achieved by digitally selecting series connected small RF output modules)
- Having no audio modulator, it is capable of high quality modulated wave characteristics such as lower modulation noise, distortion, and transient modulation characteristics
- Being basically a digital system, it is capable of directly receiving digital audio input from any variety of digital audio sources, such as CD's, RDAT, digital satellite program feeds, or future ISDN program distribution, without D/A conversion.

The Harris DX system is shown in Figure 4.1-11. The incoming analog signal is converted to digital code by conventional sample-and-hold and pulse-code modulation (PCM) techniques and circuitry. The top 6 (most

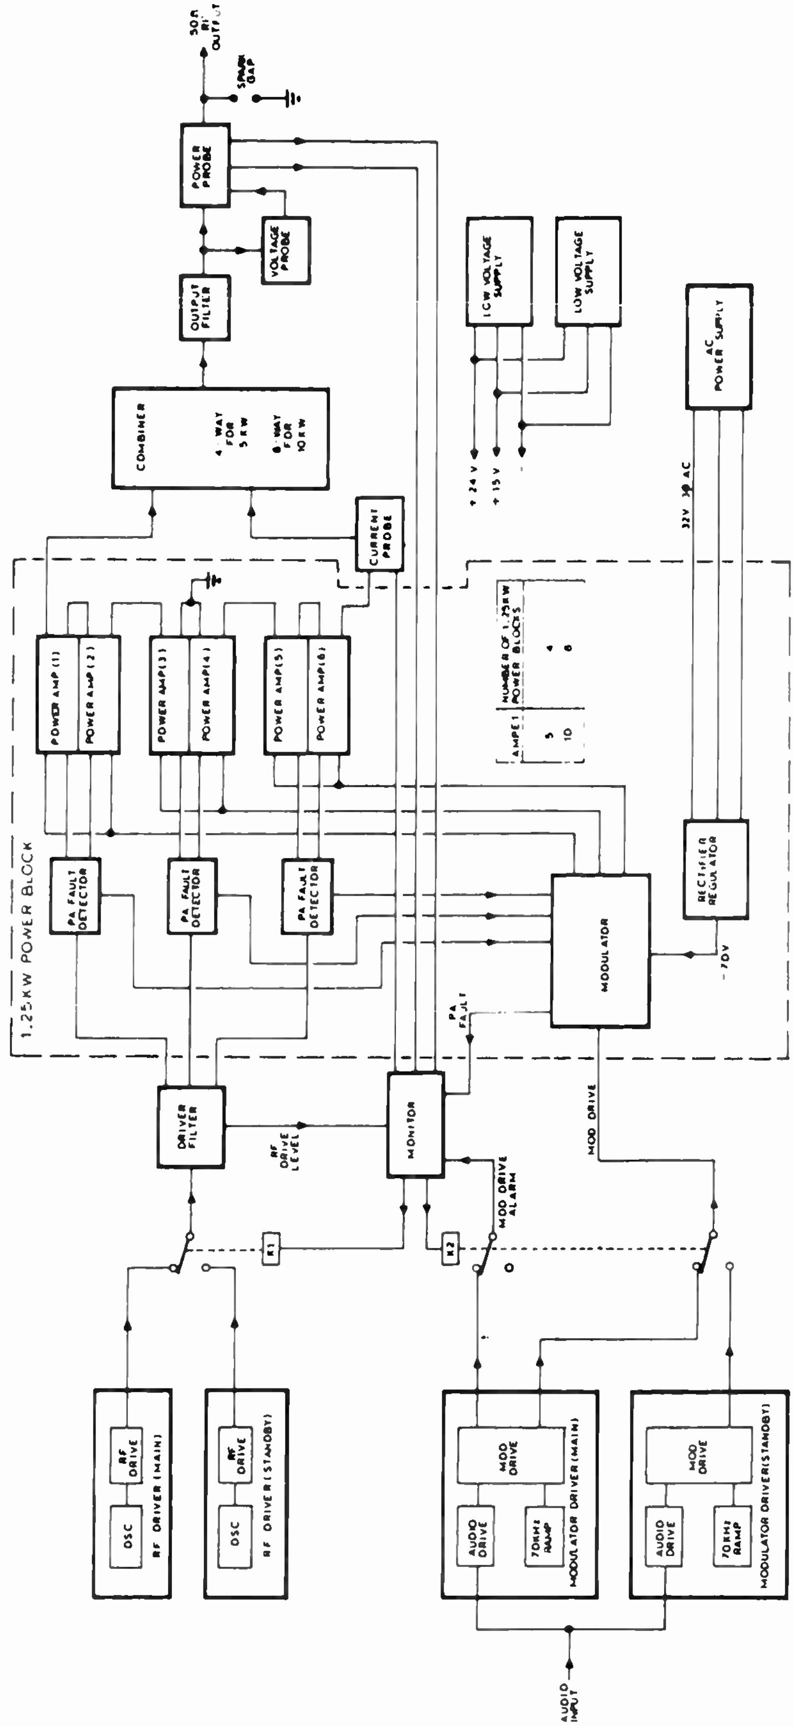

Figure 4.1-10. Block diagram, Nautel Model AMPFET 5 and AMPFET 10, 5 & 10 kW AM broadcast transmitters.

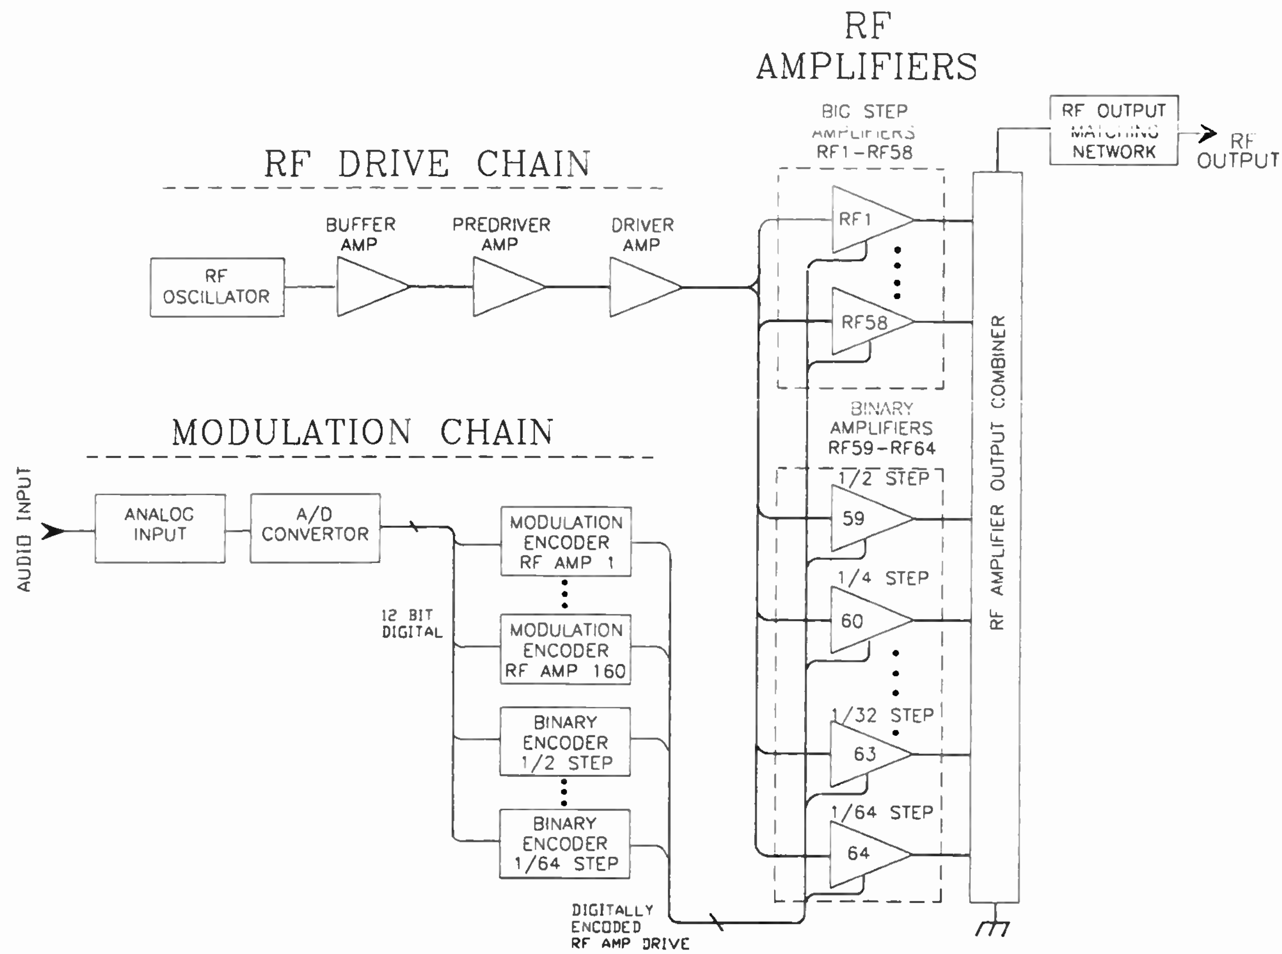

Figure 4.1-11. Harris DX system.

significant) bits of a twelve bit A/D PCM system are converted into 64 equal steps. The top 22 steps are not used leaving 42 equal steps which are used to control 42 equal output series RF amplifier modules. This is equivalent to keeping the lower 5.4 of the 6 top bits of the PCM digital code ($2^{5.4} \approx 42$). The bottom 6 (least significant) bits are then used to control 6 half-step RF amplifiers (amplifiers with outputs of 1/2, 1/4, 1/8, 1/16, 1/32, and 1/64th of the major 42 equal step amplifiers). In effect, this creates a digital reconstruction of the analog input waveform of 2709 discrete steps ($(42 + 1)*63 = 2709$). This is roughly equivalent to a PCM system with a total resolution of 11.4 bits ($2^{11.4} \approx 2702$). The theoretical capabilities of such a PCM system are well known yielding a theoretical harmonic distortion value of approximately 0.03% and audio noise of less than -70 dB referred to 100% modulation.[13] Typical measured values of THD are approximately 10 to 30 times this theoretical figure due to the practical difficulty in achieving balanced output contribution from all of the series output modules. However, even these levels of harmonic distortion (less than 1% maximum) are well below accepted norms for modern high power AM broadcast transmitters. Typical values of measured audio noise are typically very close to the theoretical maximum of -70 dB referred to 100% tone modulation at full carrier power.

Each high power amplifier module is a solid-state amplifier operating in the Class "D" mode having approximately 95% power efficiency, including output circuit losses. Since there is no additional modulator losses; (the modulation process takes place in the RF circuitry itself) the auxiliary circuits of cooling, control, excitation and drive, etc, represent the only other input power requirements. The total auxiliary input power of a 50 kW transmitter is approximately 5 kW. This means that the total input power of a 50 kW transmitter at carrier only power (no modulation) is approximately: $50/0.95 + 5 = 57.63$ kW, yielding an overall efficiency of approximately $(50/57.63)*100\% = 86.76\%$. Harris Broadcast Division claims 87% or greater overall efficiency for all their DX series transmitters greater than 5 kW carrier power, truly a remarkable achievement.

TRANSMITTER CIRCUITRY

Detailed transmitter circuit design is as varied as the individual designers. There is, however, some basic circuitry which is common to all transmitter types and models that will be briefly discussed in this section.

Carrier Frequency Generator/Exciter

The quartz crystal oscillator has been the stable frequency source for all transmitters manufactured since about 1930. The quartz crystals used in older model transmitters were large cuts of natural quartz, vacuum sealed in glass envelopes, similar to small power vacuum tube envelopes, and occasionally mounted in temperature controlled ovens to obtain the required FCC carrier frequency stability. It is more common in modern designs for the quartz crystals to be enclosed in small hermetic sealed metal cans made popular and proven reliable by the military and commercial communications equipment industry, and without special temperature controlled circuitry. Modern quartz crystal manufacturing technology and the use of proven solid-state crystal oscillator designs allows these types of small metal sealed units to adequately maintain the FCC's current requirement of ±20 Hz carrier frequency tolerance. Stability of the quartz oscillator circuits is normally adequate over the full lifetime of the equipment. Should frequency adjustment ever be required to bring a unit back inside the FCC limits, mechanically stable adjustment components, usually a glass or ceramic piston type of capacitor, are provided for use by a qualified station engineer using calibrated frequency measuring equipment. (See FCC Rules and Regulations Sections 73.1540 and 73.1545). Exciters for proposed AM stereos provide the carrier frequency excitation for the transmitter as well as the stereo generating circuitry. Because of manufacturing advantages, some manufacturers of AM stereo exciters generate the desired carrier signal with frequency synthesizer techniques. This method of generating the basic carrier frequency is generally equal to or better than the discrete quartz oscillator method with regard to frequency tolerance but can produce higher phase modulation noise if improperly designed or adjusted.

RF Power Amplifier

As discussed in earlier sections, all modern AM broadcast transmitters using power grid vacuum tube final RF amplifiers employ Class-C amplification. Some employ designs using third and fifth harmonic trap circuitry yielding quasi-class "D" operation for improved efficiency. All solid state transmitters use some form of Class "D" RF final power amplification.

RF Output Networks

The purpose of the RF output network is to match the impedance of the load (the common point impedance of one or more antenna matching and combining networks) to the impedance required by the final RF power amplifier tube or transistor to produce the desired carrier and sideband power. The output network circuit is also designed to provide the attenuation characteristics necessary to meet the FCC's requirements for spurious and harmonic output. There are many techniques to accomplish these basic tasks. One simple and effective method is shown in Figure 4.1-12. The terminating load impedance for the network shown in Figure 4.1-12 is defined by the Smith chart representation of Figure 4.1-13, which is a typical common point impedance characteristic of a multitower AM broadcast directional antenna array. Figure 4.1-14 shows the impedance versus frequency characteristics at the input of the network; at the anode of the final RF amplifier tube. The shape of the impedance curve in Figure 4.1-14 differs significantly from the shape of the terminating impedance curve shown in Figure 4.1-13 due to the narrowing of bandwidth caused by the output matching network. The VSWR (normalized to the resistive carrier impedance) at ±10 kHz is about 1.2 in both Figures 4.1-13 and 4.1-14 but at ±50 kHz the VSWR at the input to the network has increased from about 2.4 to approximately 3.0. The shape of the impedance versus frequency curve at the anode of the RF output amplifier tube (or transistor collector for the case of solid-state output devices) has an important role to play in the high audio frequency performance characteristics of the transmitter, such as frequency response and harmonic distortion.[14] The shape of the impedance versus frequency curve should be symmetrical about the resistive axis of the Smith Chart and should yield lowest practical VSWR values at the highest expected fundamental Sideband frequencies. Figure 4.1-15 shows the result of an attempt to lessen the magnitude of the mismatch at the input to the matching network by the addition of the dotted components shown in Figure 4.1-12. The result of adding the dotted components in Figure 4.1-12 is a significant reduction in tube anode load mismatch at sideband frequencies of ±10 kHz (from about 1.2 VSWR in Figure 4.1-14 to approximately 1.1 VSWR in Figure 4.1-15). The reduction of mismatch at ±10 kHz, however, comes at the expense of a worsening of mismatch at sideband frequencies greater than ±30 kHz. The worsening mismatch at higher sideband frequencies is normally not a problem and often tends to improve transmitter harmonic distortion performance, acting as an output bandpass filter to higher order harmonics. There is theoretically no limit to the amount of sideband mismatch correction that can be achieved with more complex network circuitry. The most important criteria is symmetry about the Smith Chart resistive axis. Station engineers or their engineering consultants should work with the transmitter manufacturers and antenna system designers to, first determine, then achieve the desired impedance versus frequency curve at the output RF amplifier tube anode connection. The example given for load sideband mismatch correction is for illustrative purposes only. It is quite common for the complex impedance at the sideband frequencies to present a more severe mismatch at the antenna common point

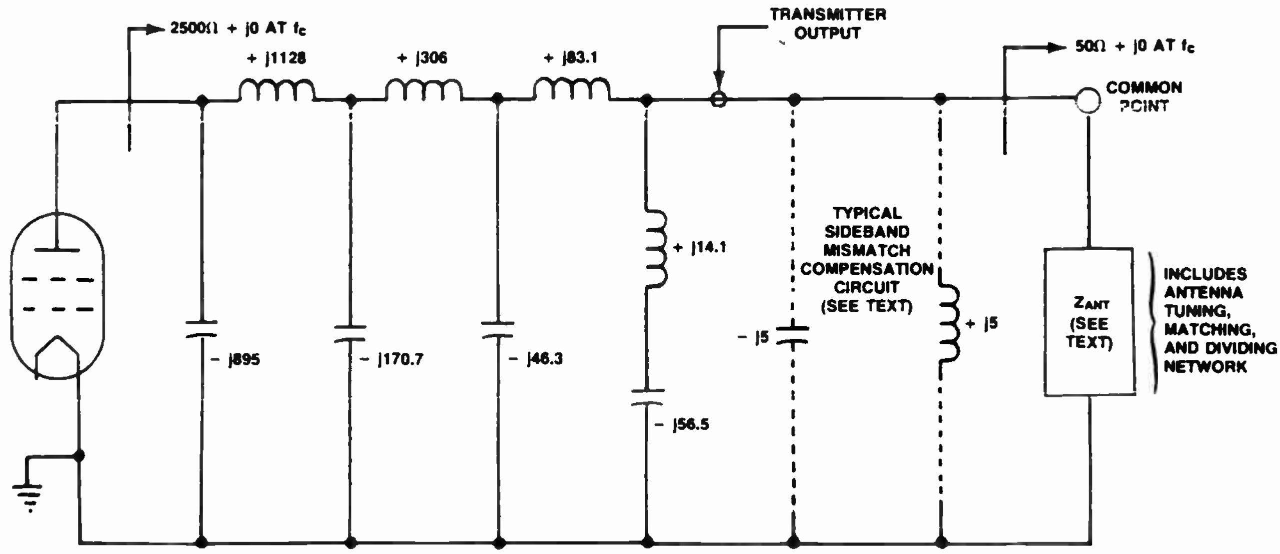

Figure 4.1-12. Typical output matching network yielding 80 dB or better harmonic attenuation and a compensated symmetrical sideband load at the anode(s) of the RF output amplifier.

than that shown in Figure 4.1-13. More severe mismatch and impedance dissymmetry requires more complex sideband mismatch corrective networking.

Transmitter Control and Monitoring

It is common to find the task of transmitter control performed with discrete digital IC logic circuitry in modern designs that used to be accomplished with simple relay control logic. Some manufacturers are incorporating microprocessor technology in their latest equipment designs to replace discrete digital logic circuitry. The aim of manufacturers is normally to provide the operating engineers and technicians with the most basic, reliable and easy to maintain and troubleshoot transmitter possible. Experience has shown that well designed relay control logic, discrete digital IC logic and microprocessor based logic are all about equal in terms of reliability and ability to perform the required basic transmitter control functions. Future microprocessor based transmitter control logic offers the promise to provide self and remote assisted diagnostics of transmitter problems and remote interrogation of transmitter operating parameters. Microprocessor based logic offers the added promise of altering the basic characteristics of a transmitter control system through software control, allowing the basic transmitter design to be more easily customized to individual users' operating requirements. Because of the high voltage and high current faults that can exist in any high power transmitter component, extra care must be taken by designers and manufacturers of high power AM broadcast transmitters to prevent the potential destructive energy in these faults from affecting the performance and operation of the relatively delicate solid-state control logic circuitry. High speed vacuum contactors and solid-state regulator/controllers are being used in many modern designs to control the high voltages and currents encountered in all levels of high power AM transmitters, which previously had been controlled by slower though equally reliable air-magnetic contactors and relays.

Remote control systems are commercially available that will allow remote control of almost any transmitter, old or new. These remote control systems, like the basic transmitter control system, use relay, discrete digital IC, microprocessor based logic circuitry, or combinations of these, depending on the manufacturer of the remote control equipment and the complexity of the remote control functions desired. Many transmitter equipment manufacturers provide limited built-in remote control functions and circuitry.

The FCC requires manufacturers of AM broadcast transmitters to provide certain basic monitoring functions for proof of certain performance parameters. These requirements are contained in the FCC Rules and Regulations Section 73.1215.

High and Low Voltage Direct Current Power Supplies

Direct current power supplies in AM broadcast transmitters must be designed to provide minimum acceptable performance in two basic areas: power supply ripple, which affects transmitter hum and noise output, and dynamic regulation, which affects low frequency modulation transient response. It is typical for transmitters of 5 kW carrier power and lower to operate from single phase ac power sources, usually 240 V in North America. Transmitters with carrier power ratings of 10 kW operate with single-phase or three-phase power sources, depending upon the manufacturer of the transmitter. Transmitters with carrier power ratings of greater than 10 kW operate only from three phase power sources, usually 480 V for power levels up to 100 kW and 4160 or 11,000 V in North America for higher carrier power levels. Three-phase power has the advantage of being easier to filter and usually provides better dynamic regulation of critical modulator voltages than single phase supplies. Single-phase power is more readily available which is the only reason it is used at the lower transmitter power levels, because initial installation cost would be disproportionately increased were three-phase power required. Single-phase rectifier power supply systems generally require L/C filtering to provide the necessary low ripple output for low transmitter hum and noise specifications. L/C filtering also creates, however, power supply resonances in the audible to sub-audible range of modulating frequencies and therefore is a source of poor dynamic power supply regulation when the modulator circuitry of the transmitter is excited by vowel sounds or musical percussion sounds. It has been common since about 1970 for higher power transmitters to use special high voltage supply transformers to generate a six-phase ac supply from the basic three-phase power source. The six-phase supply, when full wave rectified, yields a 12 pulse rectified dc waveform that has both lower ripple content and a higher ripple frequency than conventional three-phase full wave rectification. As a result, the output of the rectifier can be sufficiently filtered with no additional filter inductors, thus improving low audio modulating frequency dynamic power supply regulation and hence, low frequency transient distortion.

TRANSMITTER PERFORMANCE MEASUREMENTS

Certain basic AM transmitter performance parameters should be measured on a periodic basis in order to assure that certain minimum broadcast quality standards are provided to the listening public. Excluding the performance standards for AM stereo, these are listed below. Some are specifically required by the FCC, while others are a matter of good engineering practice.
