a) Spurious emissions (Section 73.44). This measurement must be made annually, with no more than 14 months between readings (Section 73.1590(a) (6)).
b) Operating power (Part 73.51)
c) Carrier output power delivered to the antenna system (Part 73.54)
d) Modulation capability

e) Total audio frequency distortion
f) System frequency response
g) Carrier-amplitude regulation (Carrier Shift)
h) Hum and noise output level
i) Carrier frequency tolerance [Part 73.1545(a)]

All audio measurements should be made from a demodulated voltage or current sample at the antenna system common point.

Regarding item c, the measurement of transmitter power output by the direct method described in Parts 73.51 and 73.1215 is subject to more than 13% error if allowed FCC measurement inaccuracies are taken to the limit. For example, assume that a common point impedance of 50 Ω resistive can be measured to within 2% accuracy with a radio frequency impedance bridge, a realistic tolerance. Further assume a direct reading RF ammeter having a full scale reading of 100 A and an FCC allowed tolerance of ±2% of full scale is used for this measurement and indicates 33.33 A of common point current (just meeting the minimum FCC accuracy and indication requirements in Part 73.1215(b)(2) and (3)). Under these conditions, the actual power delivered to the antenna is between the limits of (35.33 × 35.33 × 51) 63.65 kW, as a maximum, and (31.33 × 31.33 × 49) 48.10 kW, as a minimum; yielding a total measurement error of approximately +14/−13%. Using an RF ammeter with a 50 A full scale reading, the same FCC allowed inaccuracies, and the same meter indications as above, would result in power output measurement errors of approximately ±8%.

FACTORY TESTS

When looking for an AM broadcast transmitter to buy for replacement or new equipment, it is advisable to ask manufacturers for specific and detailed test and performance data at the start of the buy investigation. Before a final decision is made, specific and detailed tests should be made at the manufacturer's factory under strict control of an experienced engineer or engineering consultant. Most manufacturers of AM broadcast equipment welcome this kind of intelligent approach to the decision making process. Following are some hints on what kind of tests and a discussion on the details of each test.

Audio Frequency Response

In the early days of radio broadcasting, the term *broadcast quality audio* meant a standard to which all other system equipment, by comparison, was inferior. Today the audio quality of consumer high fidelity and stereo equipment surpasses, with one exception, the signal quality which can be broadcast by any AM transmitter manufactured today or likely to be made in the future. The one exception is audio frequency response. Practically all mass production AM receivers made in any country of the world have IF and audio amplifier bandpass characteristics that limit receiver −3 dB high end audio frequency response to between approximately 2,500 Hz and 5,000 Hz, with 2,500 Hz the more common of the two figures. (This poor high frequency response of the receiver is not a limitation of technical capability, rather a conscious decision on the part of receiver manufacturers to limit high end response in order to minimize perceived nighttime skywave co-channel and adjacent channel interference on the medium-frequency AM band.) Typical low end −3 dB frequency response of consumer AM radios is between 100 Hz and 300 Hz, with approximately 200 Hz a common value. AM transmitter frequency response characteristics, referred to a reference frequency of either 400 Hz or 1,000 Hz, typically are well within ±1 dB from 50 to 10,000 Hz at any depth of modulation, exclusive of antenna system characteristics which can and often do have a deleterious effect on many audio performance system characteristics.

Audio Harmonic and Intermodulation Distortion

Current production AM broadcast transmitters typically produce less than 2% (THD) up to 90% modulation at any frequency of modulation between 50 and 10,000 Hz for monophonic transmission. Most of the modern all solid-state digital systems produce typical audio distortion of less than 1% THD at most conditions of modulation.

Intermodulation distortion (IMD) has been known for years to be a more disturbing kind of distortion than harmonic distortion, though both are important. The ITU-R method of IMD measurement is the preferred method for radio broadcast transmitters. With this method, two equal audio tones separated by approximately 170 Hz are input to the transmitter and the peak modulation level adjusted to between 85 and 95% modulation. The level of odd and even order products are measured using an audio wave or spectrum analyzer connected to the test output terminals of a high quality modulation monitor. Two IMD measurements should be taken, one with the two tones near mid audio band (for example: 400 and 570 Hz) and one with the two tones near the upper audio end (7,000 and 7,170 Hz). High quality broadcast transmitters should produce odd order IM distortion products more than 30 dB below the level of either of the two modulating tones. The RSS value of all IM products, relative to the level of either modulating tone, should also be less than 5% at 90% peak modulation levels.

Residual AM Hum and Noise

The FCC requirement for AM noise of about 60 dB below the 400 Hz/100% modulation level can be achieved by most current production AM broadcast transmitters. The bandwidth of noise measuring equipment should be 20 kHz minimum. Typical modulation monitor demodulated audio bandwidth is approximately 25 kHz to accommodate both of these FCC bandwidth requirements.

Residual PM Hum and Noise

Residual phase modulation (PM) noise is normally not a problem for modern AM broadcast transmitter designs for monophonic broadcasting. The quartz crystal oscillator circuits and even moderately careful RF component mechanical designs produce quite acceptable phase noise characteristics. However, for AM stereo applications, where a frequency synthesizer may be used for the RF signal generation, is it wise to perform a test to determine the purity of the synthesizer circuitry. Very excessive residual PM noise can convert to AM noise over certain nighttime propagation paths and appear to distant listeners as objectionable AM hum and noise. An acceptable value of PM noise is −25 dB rms relative to one radian peak, measured in a 15 kHz bandwidth, for monophonic medium wave band AM transmission. Transmitters with quartz crystal oscillator exciters typically exceed this recommendation by 25 dB or more. Transmitters used for international shortwave broadcasting (4 to 26 MHz) require PM noise levels of approximately −45 dB relative to a one radian peak because of more severe sky-wave PM to AM conversion at higher frequencies.

Incidental Phase Modulation (IPM)

Like residual PM, IPM is more important in stations using or planning to use AM stereo transmission. IPM is defined as the peak phase deviation of the carrier frequency (in radians) resulting from the process of AM. IPM values of several radians were common in the very early days of broadcasting. Typical values of IPM for modern transmitters that have not been specifically designed or adjusted to minimize IPM range from about 0.1 to 0.5 radians peak (approx. 6 to 30°). A maximum acceptable value of IPM required for AM stereo operation is generally considered to be approximately 0.05 peak radians with a desired value of better than 0.02 peak radians. State-of-the-art modulation meters such as the Hewlett Packard model HP-8901B and other similar instruments are preferred for accurate PM and IPM measurements.

Carrier Amplitude Regulation (Carrier Shift)

The amount of carrier level shift in a given transmitter has more importance to overall transmitter performance than many broadcast engineers realize. Large values of negative carrier shift can have as much effect on effective transmitted sideband power as poor transient overshoot distortion. The term *carrier shift* may be somewhat confusing, especially to newcomers in radio broadcasting who often equate the terminology with frequency shift instead of level or amplitude shift, hence, the new terminology of *carrier amplitude regulation*. The ITU-R refers to the same characteristic as *carrier level shift*, which appeals to many engineers because of its closer adherence to the original terminology, but without the ambiguities. Carrier level shift is the effective shift in apparent carrier level due to the AM process. Carrier level shift can be caused by either poor power supply regulation, or modulation even order harmonic distortion, which generates a dc offset component in the modulated RF envelope, or both. Carrier level shift can be either positive or negative, though is usually negative because power supply regulation is most often the major source of carrier level shift and power supply regulation is most generally negative in sign (lower voltage output at higher current loads). Poor power supply regulation is not always caused by the transmitter power circuitry, it can also be, and often is, caused by poor supply line voltage regulation or, more generally a combination of the two.

Another common misconception regarding carrier level shift is that the defined level shift is a direct shift in carrier power. Actually, carrier level shift is defined as the shift in effective carrier *voltage or current* due to the process of modulation. This means that a carrier level shift of minus 5% is equivalent to a carrier power shift of approximately minus 10%.

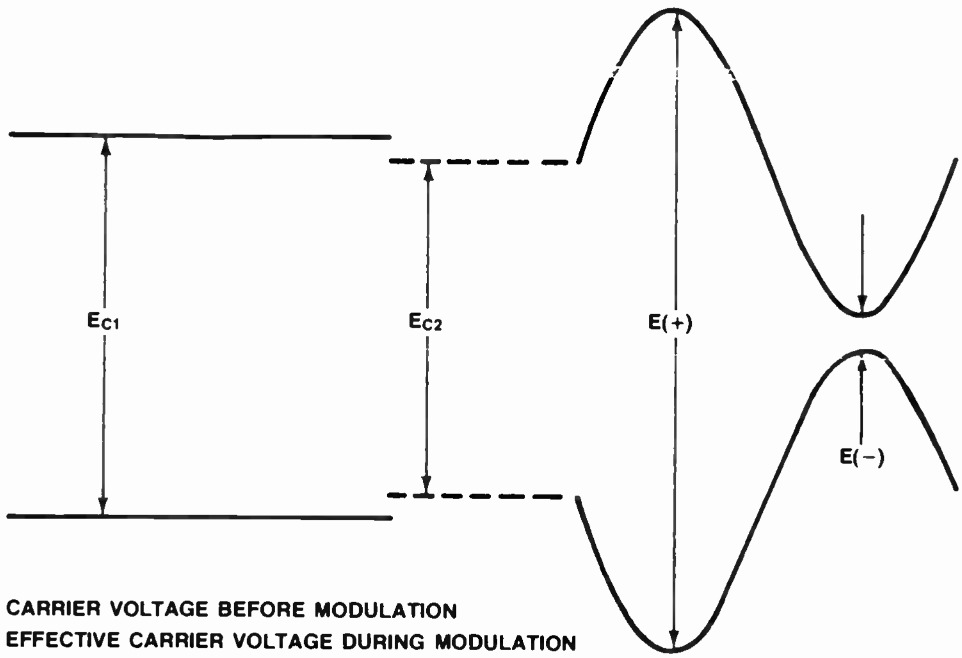
$$\begin{aligned} P_{carrier\,(mod)} &= P_{carrier} \times (1 - 0.05)^2 \\ &= 0.9025 \times P_{carrier} \end{aligned}$$

Transmitters having no carrier level shift produce an average output power of 1.5 times the carrier power level with 100% sinusoidal tone modulation. Transmitters that exhibit −5% carrier level shift produce an average output power only 1.35 times the carrier level at the same conditions of symmetrical sinusoidal tone modulation. A broadcast station engineer or engineering consultant needs to have complete understanding of these and other equally important transmitter characteristics in order to be able to make an intelligent buying decision based upon measurable and proven technical merit. Figure 4.1-16 gives a graphical representation of carrier level shift.

Audio Phase Linearity

Proper attention is given to phase linearity by most station engineers and engineering consultants. Station managers and engineers are usually properly concerned about the sound of their stations; and loudness, or perceived loudness, is a common criteria of quality in many stations with diverse programming formats. However, it is not uncommon to learn that many station engineers and program directors spend more time researching the various objective and subjective merits of program processing equipment than the one characteristic in their potentially more expensive transmitter purchase that could partially neutralize the potential advantage from a new or different program processor—that one characteristic is audio phase linearity.

Audio phase non-linearity and its major detrimental result, transient overshoot, have been discussed in previous sections of this chapter. Before the popularity of modern broadcast audio processing and some modern broadcast programming formats, audio phase linearity of a transmitter or any component in the program audio chain, was not as much of a concern as it is today. (Modern programming philosophy, and the resulting audio processors have made transmitter audio phase linearity characteristics a more important performance criteria.) In the late 1960s, at the long and persistent insistence of the AM broadcast industry, the FCC reluctantly authorized 125% positive program modula-



E_{C1} = CARRIER VOLTAGE BEFORE MODULATION
E_{C2} = EFFECTIVE CARRIER VOLTAGE DURING MODULATION

$$\text{CARRIER LEVEL SHIFT (CS)} = \frac{\frac{E(+) + E(-)}{2}}{E_{C1}}$$

$$\text{\% MODULATION} = \frac{E(+) - E(-)}{E(+) + E(-)} \times 100$$

Figure 4.1-16. Graphical representation of carrier level shift and formulas for calculation of carrier level shift and % modulation.

tion, allowing AM transmissions to accommodate certain naturally occurring asymmetry in voice and music thus achieving a gain of 2 dB of real loudness or actual program sideband power (20 log(1.25) = 2 dB). As stated earlier, some AM broadcast transmitters in present use exhibit as much as 12% overshoot of a squarewave input, due to phase non-linearity, which has the effect of taking away one of those 2 dB the industry tried so hard to get (20 log(1/1.12) = −1 dB).

A simple way to determine the effects of phase non-linearity, is to require the prospective transmitter manufacturer to demonstrate rectangular wave modulation characteristics of the transmitter under investigation. When such a test is performed, the overshoot produced by the transmitter will be directly visible and measurable on the oscillographic display of the transmitter output envelope. The station engineer or his engineering consultant should also investigate the effects that antenna system phase non-linearity may have on the total system transmission transient characteristics.

Occupied Bandwidth

Occupied bandwidth of an AM broadcast transmitter can best be measured with the use of a band limited colored gaussian noise source, similar to pink noise used in certain acoustical tests, to provide a continuous wideband modulating signal to the transmitter. Pink noise has an equal energy bandwidth ratio (equal energy per octave, per third octave, per tenth octave, etc.). White noise has equal energy per bandwidth (equal energy per Hz). Both noise signals can have a Gaussian or pseudo-Gaussian probability density function, a probability density function that closely resembles that of typical voice and music. Figure 4.1-17 shows a block diagram of the test procedure used to measure occupied bandwidth. (See CCIR recommendation 559-1 (Vol X Part 1 Geneva, 1982). The measurement of occupied bandwidth is a dynamic measurement which effectively summarizes two important transmitter static parameters: audio non-linear distortions, which are the source of IMD and THD, and IPM.

Harmonic and Spurious Output

Harmonic and spurious output of an AM broadcast transmitter or transmission system can only be effectively measured two ways. One way is to use a sample of the transmitter RF output signal when operating into a dummy load with a known or accurately measurable impedance characteristic out to approximately the tenth RF harmonic. Then, with a calibrated measuring system, measurements and calculations are made to

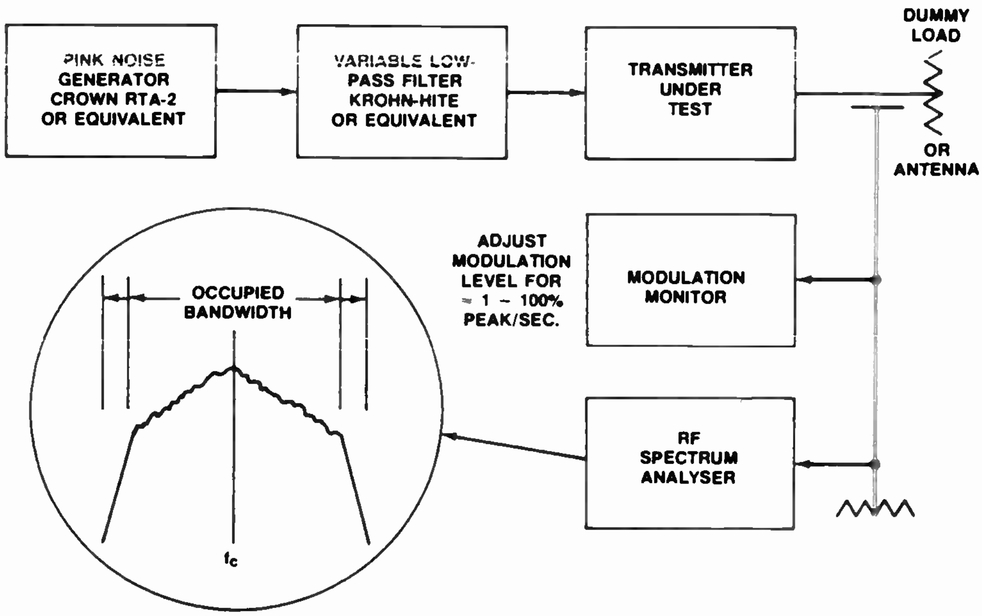


Figure 4.1-17. Block diagram test procedure for determining transmitter occupied bandwidth.

compute the output power of each harmonic according to the formula:

$$P_n = V_n^2 \times R_{pn} \qquad [8]$$

Where:

P_n = the power at the Nth harmonic
V_n = the corrected measured voltage of the Nth harmonic at the calibrated impedance point
R_{pn} = The parallel resistive component of the load impedance at the Nth harmonic

A second way to effectively determine the harmonic and spurious output of an AM broadcast transmitter is to measure the actual power radiated from the antenna system at each harmonic frequency or suspected spurious output frequency by standard field intensity measurement techniques. The field intensity method is the most meaningful of the two techniques because it allows the measurement to be made under actual conditions of operation with all systems interconnected. It is normally the new transmitter manufacturer and users joint responsibility to correct any actual interference problems to other broadcast or non-broadcast communication services even when the particular interfering signal meets the standard FCC requirements (see FCC Rules Section 73.44.(c)).

Carrier Output Power

The most accurate method of measuring the RF output power of a transmitter is by the calorimetric method, a method which uses the very accurately known and measurable physical and thermal characteristics of water or other similarly well defined liquids. This measurement is usually only done in a transmitter manufacturer's factory because the capital investment required to purchase and maintain calibration of this kind of infrequently used equipment is usually not justified for AM broadcasting operations.

Water is known to have a thermal capacity very close to 4.186 Joules per degree C per gram weight at a mean temperature of 60° centigrade. A Joule is equal to one watt-second. Therefore, the capacity of water to absorb power is 69.8 watts per degree C per liter of water flow per minute, or

$$\text{Power (kW)} = \text{Flow (lpm)}*\text{DT°C}*\ 0.0698$$

for water flow measured in liters per minute (lpm)

or,

$$\text{Power (kW)} = \text{Flow (gpm)} \times \text{DT°C} \times 0.2641$$

for water flow measured in U.S. gallons per minute (gpm)

The flow of water can be measured with an accuracy of approximately ±1%, by even the most common methods. Differential temperature measurement accuracy of approximately ±0.1°C is commonly practical, which, for temperature differentials of 20°C, is equivalent to ±0.5% accuracy. Therefore, using calorimetric measurement techniques, the output power of AM transmitters can be measured with total accuracies better than ±2%. The RF output amplifier efficiency factor F, referred to in FCC Rules Part 73.51(e), can then be determined for future operating and proof of performance reference. However, even with this method of determining the factor F, an accuracy of less than ±2% cannot be maintained over the life of the equipment. The required FCC transmitter voltage and current meters have a ±2% accuracy, in addition to the multiplied power accuracy of approximately ±4%. When accuracy levels are combined, this yields a total uncertainty of ±6% for the factor F. Still, this is considerably better than the accuracies obtainable by the direct measurement technique.

Operating Efficiency and Input Power

The determination of transmitter input power should be done under actual or simulated operating conditions. This requires program or simulated program signals for the transmitter modulating source during the period of power input measurement. The preferred method of measuring ac input power is by use of a standard rotating disk watt-hour meter. The measurement accuracy of these familiar watt-hour meters is typically better than 0.5%, better than four times the accuracy of any other conventional direct ac power measurement technique, and can be obtained with accuracies better than 0.1%. The watt-hour metering system should be connected in the main power feed line to the transmitter under test. Sinusoidal test signals, useful for other tests of transmitter performance, are not recommended for power consumption tests because of the distinctly opposite statistical characteristics of sinusoidal signals and typical voice and music program material and the effect this difference has on actual operating power consumption measurements. This difference between periodic sinusoidal signals and mathematically random types of signals such as human voice and/or music has been known for decades. The effect this difference produces in AM broadcast transmitter power consumption and operating efficiency measurements, however, was first documented in 1980, by investigators in Europe and was later verified and further explained by investigators in the US and other countries.[15,16]

The critical difference between sinusoidal signals and typical program types of signals is explained in Figure 4.1-18 which shows the amplitude density characteristics of a sinusoidal waveform (U-shaped curve) and an amplitude density characteristic of typical broadcast program modulation (pyramid curve). The totally different shapes of the two curves in Figure 4.1-18 cause the measured transmitter efficiency at identical RMS modulation levels also to be quite different. The pyramid shaped curve in Figure 4.1-16 was generated in 1984 from measurements taken off the air of five differently formatted FM radio stations in Dallas, TX. Data was taken for 24 hours continuous for each station and averaged for presentation as shown in Figure 4.1-18. FM stations were used in the collection of the data because of their consistent day/night signal levels, symmetrical modulation characteristics

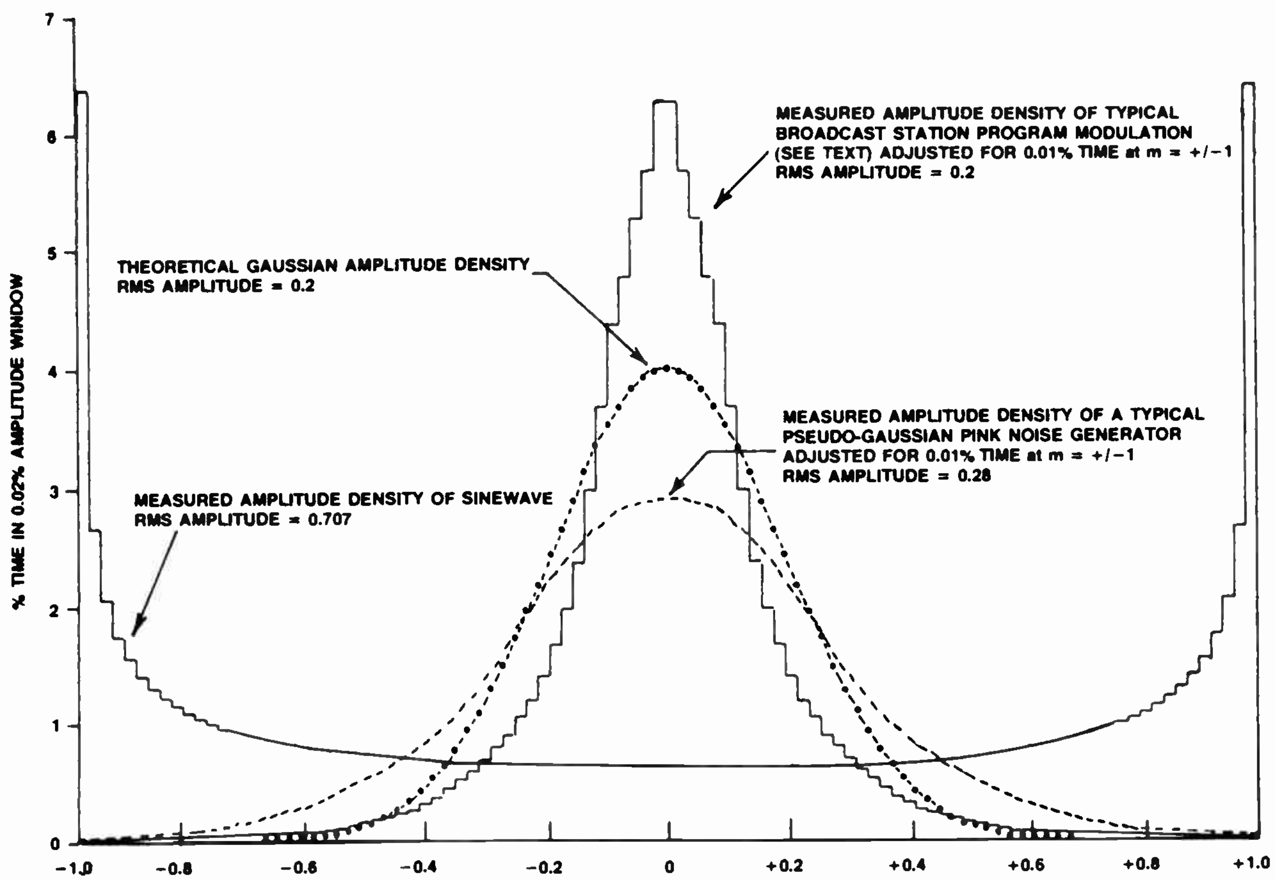

Figure 4.1-18. Amplitude density of sinusoidal test signals and typical program or noise test signals.

for easier comparison to the sine wave, and omnidirectional emission pattern. Some transmitters, or more correctly modulation systems, are more efficient with program modulation than with equivalent RMS sinusoidal test signals while others have poorer efficiency with program modulation. It has been effectively shown that modulation systems or techniques that yield higher carrier efficiencies also yield higher program efficiencies (lower program power consumption than with an equivalent RMS sinusoidal modulation test signal).[16] It is obvious that the program input power consumption test is the one most meaningful to broadcasters whose purpose it is to broadcast programs, rather than sinusoidal tones. In this discussion, the terms *program efficiency* and *program input power consumption* have generally been given equal weighted value. It is correct to equate the weighted value of these two parameters for transmitter to transmitter comparisons if it is assumed or defined that average transmitter-to-transmitter output power is constant for a defined program input. Such an assumption is correct except that transmitters with excessive transient overshoot will have correspondingly less average modulated RF power output for given peak levels of processed program modulation. Experimental methods have been devised to measure average long term transmitter output power (RF kilowatt-hour output).[17] With such equipment it would be convenient to accurately compute actual program efficiency knowing both kilowatt-hours input and kilowatt-hours output. Until such equipment becomes commercially available, however, only the transmitter energy input can be accurately measured with single-phase and multi-phase kilowatt-hour instruments.

Figure 4.1-18 also shows a third curve (dashed curve) which is the amplitude density function of a popular pink noise generator. It is recommended that either a pink noise signal with amplitude density characteristics similar to the curve in Figure 4.1-16 or a recording of actual program modulation be used as a program source for factory input power consumption tests. Program processing equipment, if used, and peak modulation levels should be adjusted to satisfy normal station operating procedures and transmitter input power measurements then taken during a 30 minute (minimum) segment of the program source material. (Refer to FCC Rules Section 73.1570(a) and (b) for modulation setup procedures.) The average input power determined by the method described will be very close to the transmitter power consumption during its total operating life and therefore can be used to accurately predict actual operating energy costs. This is the only method of transmitter power consumption tests that will provide accurate energy consumption forecasting data.

IMPORTANT AM STEREO TRANSMITTER CHARACTERISTICS

AM stereo utilizes a form of phase modulation for encoding the stereo signal onto the carrier of the AM signal. It is for this simple reason that the most important transmitter characteristic affecting AM stereo operation is IPM. Excessive IPM can affect stereo separation, single channel distortion and the occupied bandwidth of a stereo transmission—with the most significant of the three being single channel distortion.

Recognizing the various causes of IPM is the first step in correcting the trouble. There are many potential sources of IPM but the most common source is incorrect amplifier neutralization, either of a final modulated RF amplifier or of a lower power driver stage. The solution is, of course, to perform better neutralization of the offending amplifier stages. This is easier said than done in most cases. Since the inception of AM stereo broadcasting, manufacturers of the transmitters have paid more attention to the problems of IPM and in most cases have reduced levels of IPM in current production model transmitters to acceptable levels for AM stereo operation. In some cases, for especially difficult problems, field engineers from the manufacturers factory must make special on-site adjustment of individual transmitters which are particularly susceptible to excessive IPM. Several engineering consulting firms have developed special knowledge in the AM stereo field, having collected data on many transmitters in current use some of which have been out of production for several years. It is suggested that such a firm be contacted to solve particularly difficult neutralization procedures on old or new equipment which may not have been satisfactorily performed by the original manufacturer.

Phase Noise

Residual phase modulated noise cannot normally be detected by a standard AM broadcast receiver employing envelope detection, while stereophonic AM receivers are sensitive to PM noise. PM to AM conversion can occur on the medium wave band over multi-ionospheric *hops* (nighttime sky wave propagation) which can then be detected by receivers employing standard envelope detection. Very early transmitters sometimes produced more residual phase noise sidebands than those produced by the desired program AM. Nighttime reception of distant stations sometimes was accompanied by a 120–360 Hz roar which was caused by phase modulation from the master oscillator filament supply. A somewhat subdued roar can be heard even today from many shortwave stations using older transmitting equipment, especially on the higher shortwave bands where multihop propagation is more prevalent.

Significant phase modulated noise in modern transmitters is virtually nonexistent due to the use of high quality quartz crystal oscillator and synthesizer circuitry. Phase noise modulation of 0.6 degrees (0.01 rad) average is fully acceptable for monophonic AM broadcasting. Phase noise modulation of approximately 0.2° (0.0035 rad) average is usually considered acceptable for AM stereophonic broadcasting. As with measurements of IPM, an HP-8901, or equivalent, modulation analyzer is recommended for phase noise modulation measurements.

Stereophonic Phase/Gain Equalization

Standard production exciters for AM stereo systems may incorporate built-in circuitry designed to approximately match the phase and gain characteristics of the normal monophonic transmitter transmission path to the transmission path for the encoded stereo signal. Transmitters which have excessive in band non-linear phase characteristics sometimes require special outboarded phase/gain equalization networks to achieve optimum stereo performance.

International Shortwave Broadcast Transmitters

International shortwave broadcasting in the United States and North America began at about the same time as medium wave broadcasting, about 1920, but did not have any substantial growth until pre-World War II propaganda activities by the influential nations. Until this growth in the mid-1930's, shortwave broadcasting was done primarily by amateur and special industry groups using the higher frequency bands for experimentation and hobby interests. Almost immediately after the invasion of Pearl Harbor, accelerated shortwave broadcast activity in the United States began by the Office of War Information (OWI) which later assumed the wartime responsibility of the then inexperienced Voice of America in June 1942. Later, in mid-1943 the Armed Forces Radio Service began shortwave relay broadcasts to France and other parts of Europe from bases in England. After WWII, the VOA resumed control of their wartime expanded facilities and, together with virtually all nations, began continuous operations of native and foreign language broadcasts for information exchange and general entertainment purposes. Other private interest in shortwave broadcasting also began to expand after the war, primarily from various religious and politically based organizations seeking means to advance their cause or provide information and service not otherwise available by government operations. Commercial shortwave broadcasting in the United States has generally not been profitable primarily because of the limited audiences in North America given the popularity of AM, FM, and TV broadcasting. The quality of signal in shortwave listening is not of the same quality as in either of the three other more popular modes of broadcasting, due to the long distances covered and atmosphere-generated fading and noise. Therefore, shortwave broadcasting in North America attracts a different kind of listener, one who is more dedicated to the hobby of shortwave listening and therefore more willing to tolerate the disturbances associated with shortwave listening. Shortwave listening in the world outside North America is very popular, and necessary, among large segments of the population as a source of news, sociopolitical or religious viewpoint and entertainment.

Shortwave Transmitters

Shortwave broadcast transmitters are similar in many respects to medium wave transmitters and very different in others. The similarities are in methods of modulation, control, and monitoring. The differences are, generally, that shortwave transmitters are higher power, more complex in tuning, and more difficult to operate and maintain than medium wave standard broadcast transmitters. Although there are numerous exceptions, the general rule, is that the minimum usable carrier power level is 50 kW and the maximum economical carrier power level from a single transmitter is 250 kW to 500 kW.

It is not unusual for a shortwave transmitter to operate on five to ten separate frequencies every broadcast day. Modern broadcasting schedules of the prestigious broadcasting organizations are very tight, thus necessitating built-in automatic frequency changing circuitry which allows the transmitter to tune to several programmed frequencies in approximately 10 to 30 seconds, with minimum or no operator intervention. The trend in shortwave transmitter operation is toward unattended or minimum attended sites, with program and frequency changes done by remote and/or computer control.

Single Sideband and Digital Broadcasting on the International Shortwave Bands

Since about 1964, ITU has encouraged the adoption of a form of single sideband (SSB) as the standard modulation system for international shortwave broadcasting. This recommendation has been prompted due to the ever increasing congestion in the shortwave broadcast bands, the competitive increases in transmitter power levels, which contributes to the congestion and the realization of the increased efficiency of the SSB mode of transmission. A World Administrative Radio Conference Committee, meeting in Geneva in January and February 1984, adopted a specific and detailed 20-year plan for conversion to SSB on the international shortwave broadcast bands. The committee report addressed necessary changes in both transmitter and receiver technologies, thus creating the beginning and emphasizing the importance of the changes which can double the available channel space and improve reception quality in the current international broadcast bands.

Interest in compatible and discrete digital broadcasting on the international shortwave bands has been the natural outgrowth of similar interests in digital medium wave AM and VHF-FM broadcasting. The advantages of shortwave for cross-border broadcasting is well known. Since the end of the Cold War in the early 1990s, the popularity of shortwave broadcasting has declined in formerly closed societies, as reliable sources of independent news and thought have become more competitive in those countries. Nevertheless, almost every national administration has a desire to maintain short and long distance cross-border broadcasting capability in order to maintain stability in world politics. The popularity of shortwave dramatically increases whenever global or regional political instabilities develop, and digital shortwave broadcasting holds the promise to convert this medium to a higher technical quality. Various national administrations and private industry groups have begun independent as well as cooperative efforts to explore and develop the technology required for digital audio transmission and reception on the shortwave bands. Development of digital shortwave technologies could completely preempt the development of single sideband broadcasting.

AUDIO PROCESSING AND PREEMPHASIS

Audio processing technology progressed significantly in the 1980s. Manufacturing and research companies developed sophisticated circuitry to further enhance the state-of-the-art in speech and program audio processing toward the goal of producing maximum perceived loudness and quality by the listening public. It is not the intention here to discuss in detail the various processing schemes and advantages that each may offer. However, it is important that a discussion of AM transmitter technology also make mention of AM receivers, and the effect of audio processing on them.

Another important achievement in the 1980s was that the transmitter and audio processor equipment manufacturers, broadcasters, and receiver manufacturers came together in a forum group called the National Radio Systems Committee (NRSC), now jointly sponsored by the National Association of Broadcasters (NAB) and the Consumer Electronics Manufacturers Association (CEMA). Out of this forum came the definition and formal recognition of certain system inconsistencies that were a detriment to the growth of AM broadcasting. As a result of the NRSC's work, new and very important standards involving both the transmission and receiving ends of the system for AM broadcasting were developed.

The major system inconsistency that exists in AM broadcasting had been known for some time by many individuals in the industry. The offending system parameter could be called the transmitter/receiver interface. Because of the nature of nighttime skywave propagation on the standard medium wave AM band, and the adjacent and sometimes next adjacent and even not too uncommon next-next adjacent channel interference created by such propagation, receiver manufacturers had for many years severely restricted the intermediate frequency (i-f) and audio bandwidth of the receivers it produced for the AM band. In some cases the bandwidth restriction was severe (−20 to −30 dB frequency response at 5 kHz was not unusual). Yet, the broadcasters continued to broadcast wideband audio out to at least 10 and often 15 kHz in an effort to provide the public with the highest quality signal possible. The NRSC addressed the transmitter/receiver interface mismatch and produced a recommended standard of restricted transmitted bandwidth to 10 kHz which would encourage receiver manufacturers to widen the i-f and audio frequency response of the receivers correspondingly. The solution was the only one that could be made in light of the present usage and congestion in North America on the medium wave AM band. The standard that the NRSC proposed was a voluntary standard only and required the voluntary compliance of a majority of North American broadcasters and manufacturers of AM receiver products for the North American market. This voluntary compliance was enthusiastically instituted by more than 1,000 private AM broadcasters in the U.S. and Canada, prompting the FCC to make the NRSC standard a requirement by all U.S. AM broadcast stations. The FCC requirement took effect on June 30, 1990. Part of the standard generated by the NRSC involves the recommendation of an AM pre-emphasis curve to be used in the audio processing equipment at the transmitter end of the link. The proposed preemphasis curve is called a *Modified 75 Micro-second AM Preemphasis Curve* and exhibits approximately 1 dB boost at 1 kHz and approximately 10 dB boost at 10 kHz, but followed or accompanied by a single pole low pass filter with a break frequency of 8.7 kHz to reduce the peak boost at high frequencies (see Figure 4.1-19). The proposed matching deemphasis curve in the receiver can be achieved in the i-f or audio stages of the receiver, or a suitable combination of the two (see Figure 4.1-20).

The recommendation by the NRSC and following supportive action by the FCC is at least an important first step in achieving maximum system bandwidth on the North American AM broadcast band. The issue and subject of high audio frequency preemphasis is not without some controversy. Some broadcast engineers believe the standard is good in concept but does not go far enough, believing that high frequency boost should be limited somewhat lower than 10 kHz to further reduce or possibly eliminate adjacent channel interference. The European Broadcasting Union (EBU) in conjunction with the ITU-R in Geneva, Switzerland recommends moderate high frequency preemphasis to 4.5 kHz (European AM channels are spaced at 9 kHz intervals), followed by a sharp cutoff low pass filter

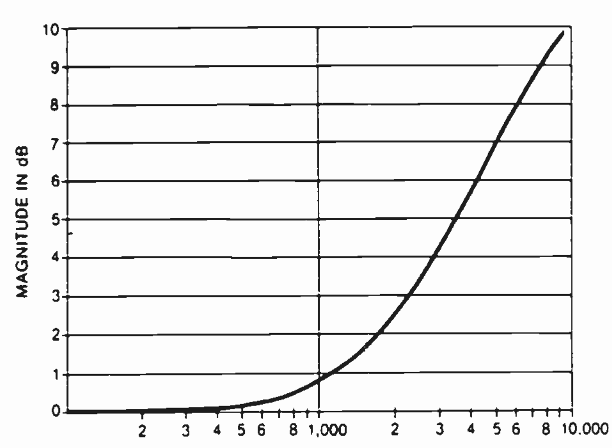

Figure 4.1-19. Modified 75 micro-second AM standard preemphasis curve.

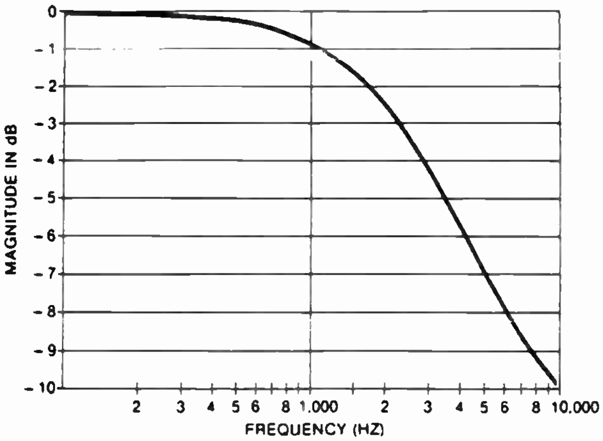

Figure 4.1-20. Modified 75 micro-second AM standard deemphasis curve.

at frequencies above 4.5 kHz. An identical standard of 4.5 kHz maximum sideband width is also recommended by the ITU-R for shortwave broadcasting where the channel spacing is 5 kHz.

The NRSC also generated a second standard pertaining to measurement of actual occupied bandwidth of a licensed AM broadcast station. The FCC ordered that all U.S. AM broadcast stations comply with this second standard, NRSC-2, by June 30, 1994. The full text of NRSC standards 1 and 2 follow as Appendices A and B.

TABLE OF CONTENTS

§ 1. SCOPE

The National Radio Systems Committee (NRSC) is a joint Committee composed of all interested parties including representatives of AM broadcast stations, AM receiver manufacturers, and broadcast equipment manufacturers. This document describes an interim[1] voluntary national standard that specifies the preemphasis of AM broadcasts, the deemphasis of AM receivers, and the audio bandwidth of AM stations prior to modulation. The standard applies to AM monophonic and AM stereo L+R transmissions, and to dual bandwidth and single bandwidth AM receivers. Compliance with the standard is strictly voluntary. To the NRSC's knowledge, no industry group or entity is or will be adversely affected by issuance of this document. Every effort has been made to inform and accommodate any and all interested parties. The NRSC believes that implementation of the standard will reduce AM interference, increase useful AM service areas, and encourage the production of higher fidelity AM receivers.

A five year review provision is established.

§ 2. INTRODUCTION

On September 5, 1985, the NRSC adopted a resolution to study proposals to standardize AM transmission preemphasis and AM receiver deemphasis with the objective of establishing an industry-wide AM preemphasis/deemphasis voluntary standard. After twelve months of study, on September 10, 1986 the NRSC released a draft voluntary standard that proposed a specific AM preemphasis/deemphasis curve as well as a 10 kHz standard AM bandwidth. The bandwidth specification evolved from NRSC deliberation on the causes and cures of AM interference, and ways to technically encourage the production of higher fidelity AM receivers. After a three month public comment period, the NRSC, on January 10, 1987, formally adopted this standard and authorized its publication by the National Association of Broadcasters and the Electronics Industries Association.

The purpose of the NRSC voluntary standard is to create a transmission/reception system where (1) AM broadcast stations will know, with certainty, the likely audio response characteristics of AM receivers, and (2) AM receiver manufacturers will know, with certainty, the likely audio response characteristics of AM broadcasts. A "matching" of preemphasis and deemphasis is expected to improve the consumer's overall satisfaction with the technical quality of listening to AM radio. The NRSC believes that the public interest is served by establishing a compatible transmission/reception system and the accompanying improvement of AM broadcasts and AM receivers.

This document also describes a specification for the maximum audio bandwidth transmitted by AM broadcast stations. Implementation of a bandwidth specification will reduce second-adjacent channel interference and thereby lead to (1) a significant reduction of second-adjacent channel interference as perceived on "wideband" AM receivers; (2) a corresponding increase in the interference-free service areas of AM stations; and (3) an incentive for the further building of dual bandwidth AM "wideband" receivers.[2] Analysis by a subgroup of the NRSC has shown that there would be little if any detrimental effect on today's "narrowband" AM receivers upon the implementation of this voluntary standard.

§ 3. BASIC DEFINITIONS

A. Preemphasis. The boosting of high audio frequencies prior to modulation and transmission.

B. Deemphasis. The attenuation of high audio frequencies during the process of reception and demodulation.

C. "Narrow" receivers. A subjective term to describe receivers with typical combined RF, IF and AF response characteristics of -10 dB at 4.2 kHz, -20 dB at 6.0 kHz. Response characteristics of narrow AM receivers are known to vary widely.

D. "Wideband" receivers. A subjective term to describe receivers with typical combined RF, IF, and AF response of -6 dB

---

1. The standard is described as "interim" until it is submitted and approved by the American National Standards Institute.

2. First Adjacent channel interference considerations may continue to discourage the building of single bandwidth "wideband" receivers; however, the extent and nature of this form of interference has not been fully studied by the NRSC.

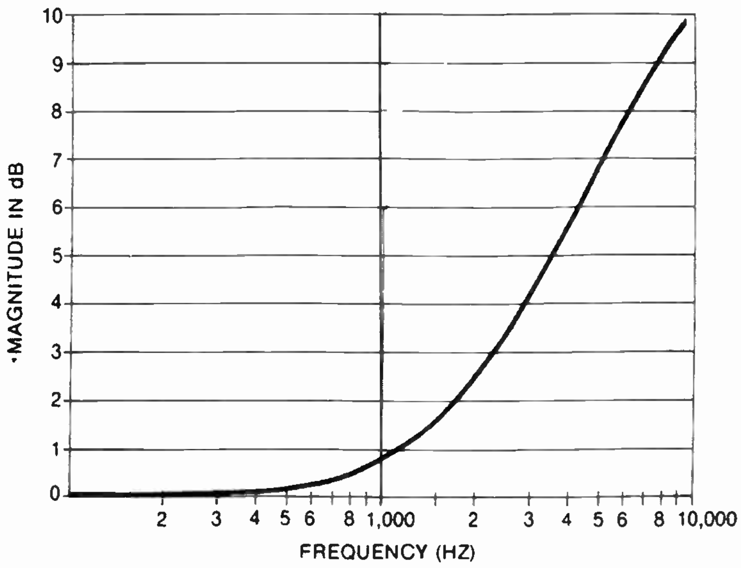

Figure 1. Modified 75μs AM Standard Preemphasis Curve

Technical Information

Frequency	Magnitude (dB)	Phase (deg)	Group Delay (sec)	Frequency	Magnitude (dB)	Phase (deg	Group Delay (sec)

at 6 kHz, -10 dB at 8 kHz. Response characteristics of wide AM receivers are known to vary widely.

E. "Excessive" Preemphasis. Preemphasis that produces no discernable benefit when received by a "narrow" receiver but increases interference to adjacent channel AM stations.

§ 4. AM TRANSMISSION PREEMPHASIS

§ 4.1. In General. AM preemphasis is the boosting of high audio frequencies prior to modulation and transmission. Today, most AM stations use preemphasis to varying extents. This preemphasis is employed in an attempt to compensate for the "narrow" response of most AM receivers. If AM preemphasis is not controlled, one station may interfere with AM receivers listening to neighboring stations located on adjacent AM channels. Whether such interference is objectionable will depend on (1) the response characteristics of the AM receiver, (2) the amount and nature of transmission preemphasis, (3) the extent to which the AM station is employing compression/ limiting techniques, and (4) whether the AM transmission system is bandlimited in the audio processor, transmitter or antenna.

Preemphasis is useful for improvement of the AM transmission-reception system audio response only to a limited extent for receivers using IF transformers. Many receivers using ceramic filters with narrow response characteristics can not be improved by use of excessive preemphasis. These receivers can not "hear" the transmission of preemphasized high audio frequencies. But excessive preemphasis will foster adjacent channel interference and cause wideband radios to sound shrill or strident.

§ 4.2. Description of the Modified 75 uS Preemphasis Curve. Each AM broadcast station shall broadcast with audio preemphasis as close as possible (within the capabilities of the station's transmission system) to the recommended standard, without exceeding it. The curve applies for audio frequencies up to 10 kHz.

The NRSC proposed standard AM transmission preemphasis curve is shown in Figure 1. The curve describes the recommended net transmission system static audio response of an AM station.

The recommended preemphasis curve is a single zero curve with a break frequency at 2122 Hz. It is similar to the 75 uS curve used for FM broadcasting. To reduce the peak boost at high frequencies, a single pole with a break frequency of 8700 Hz is employed. NRSC analysis has shown that the proposed curve is compatible with most existing AM receivers.

§ 4.3. Methods for Determining Performance. The NRSC AM preemphasis curve is a static curve, and cannot be measured dynamically. NRSC studies have shown that the dynamic and non-linear functions performed by most AM station audio processors will modify any given preemphasis curve. In addition, it is the audio response of the entire AM transmission system that indicates performance in accordance with the standard. For these reasons, measuring a station's preemphasis curve for the purpose of determining compliance with the NRSC standard shall be performed in accord with the following specifications:

§ 4.3.1. Use of Audio Tones. Compliance with the curve shall be measured by sweeping the station's transmission system with audio tones. The dynamic functions of the AM station's processor, but not the frequency shaping circuits, must be disabled (i.e., in "proof" mode).

§ 4.3.2. Location of Measurement. The net transmission system audio response is best measured by detecting the over-the-air signal. This will ensure that the AM transmitter and antenna combination is faithfully reproducing the preemphasized audio.[3] Alternatively, if the transmitter and antenna combination is reasonably broadband, performance can be determined by static measurement of the audio signal prior to modulation.

§ 5. AM RECEIVER DEEMPHASIS

§ 5.1. In General. Receiver deemphasis results from the selectivity

3.However, the deemphasis characteristics of the device used to demodulate the AM transmission must be accounted for. Additionally, some AM stations with transmitter or antenna problems may not be able to pass preemphasized audio without introducing "splatter" interference and/or overmodulation. If a particular AM station transmission system cannot "handle" the NRSC recommended curve, it is suggested that a lower amount of preemphasis be used until the system problems are corrected to allow the NRSC curve to be faithfully implemented.

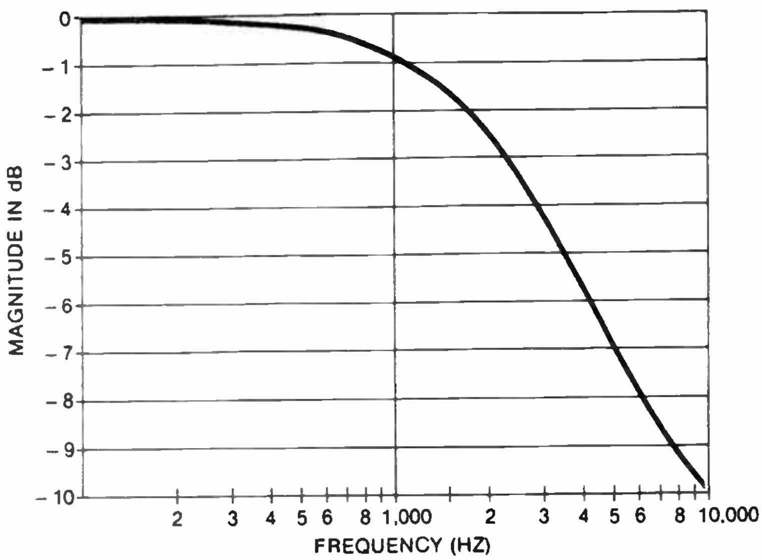

Figure 2. Modified 75µs AM Standard Deemphasis Curve

characteristics of a receiver's RF and IF stages and the response characteristics of the receiver AF section. A standard deemphasis curve permits AM stations to know, with certainty, the likely overall response characteristics of AM receivers.

§ 5.2. Description of the Standard Deemphasis Curve. AM receivers shall complement the recommended transmission preemphasis characteristic described in § 4 by incorporating a net receiver system audio response described in Figure 2. (The net system audio response of an AM receiver is the combined RF, IF, and AF audio response.) The NRSC deemphasis curve is characterized by a single pole at 2122 Hz and a single zero at 8700 Hz. It is the precise complement of the preemphasis standard described in § 4. The preemphasis/deemphasis voluntary standards apply only for audio frequencies below 10 kHz; the implementation of preemphasis/deemphasis standards produces a transmission/reception system that is essentially flat to nearly 10 kHz and limited only by the AM receiver's choice of bandwidth.

§ 5.3. Methods for Determining Performance. The deemphasis characteristic shall be determined by measuring the overall frequency response in accordance with International Electrotechnical Commission ("IEC") Publication 315.3, Clause 11.2:

(1) The receiver is brought under standard measuring conditions and the reference audio-frequency output voltage is noted. The modulation frequency is then varied and the output voltage at each frequency is noted and expressed in decibels relative to the reference voltage.

The modulation depth is adjusted at each frequency in accordance with the preemphasis characteristic of AM broadcast transmission. To avoid overmodulation at some frequencies it may be necessary to use a modulation factor of less than 30% at some frequencies.

(2) If overloading of the AF section of the receiver occurs, either the volume control attenuation should be increased or the modulation factor reduced, and a corresponding factor applied to the results.

(3) The measurements may be repeated with other values of RF input signal level and frequency.

The frequency response shall be measured for both monophonic and stereophonic reception, in accordance with the definition of the particular AM stereo system. For dual bandwidth receivers, the frequency response shall be measured in both bandwidth positions.

Results may be presented graphically, with modulation frequency plotted logarithmically as abscissa and the output in decibels as ordinate.

The frequency response can be stated as follows:

Selectivity	Frequency Response
Narrowband	50 Hz to 5000 Hz +/- X dB
Wideband or Stereo	50 Hz to 10,000 Hz +/- X dB

(Where X is the maximum deviation from the recommended frequency response, and 5000 Hz and 10,000 Hz are example frequency specifications.) The deviation X shall be of as low a value as practical. If a notch filter is used while the AM receiver is under test, the stated frequency response should be modified accordingly. Suggested modifications include (1) adding an appropriate footnote to the frequency response specification; and/or (2) lowering the upper limit value to the above "wideband" audio response specification.

§ 5.4. Notch Filters. A notch filter is a very selective filter that attenuates the spectrally pure carriers of first adjacent channel AM stations. Although an optional enhancement to an AM receiver, using notch filters is recommended. If used, the notch filter should (1) have as high a "Q" as is practical, (2) adequately suppress the interfering carriers, and (3) not unduly degrade the desired bandwidth performance of the AM receiver.

§ 6. 10 KHZ BANDWIDTH FOR AM TRANSMISSION

§ 6.1 In General. Each AM broadcast station shall modulate its transmitter with an audio bandwidth described by the specification in Figure 3. Appropriate and carefully designed audio low-pass filters as the final filtering prior to modulation can be used to implement this specification. The purpose of the bandwidth specification is to remove interference by controlling the occupied RF bandwidth of AM stations.[4]

§ 6.2. Description of the Standard. The audio bandwidth transmission standard is specified in Figure 3. The audio

4.It should be noted that the operation of non-linear AM Stereo systems theoretically may produce phase modulation components outside the desired RF bandwidth. The NRSC will examine this phenomena with the goal of determining whether such components exist and, if they do exist, whether they are objectionable. For a discussion of the detrimental effect of high audio frequencies on occupied RF bandwidth, see Klein, Modulation, Overmodulation, and Occupied Bandwidth: Recommendations for the AM Broadcast Industry, Proceedings of the 1987 NAB Engineering Conference, Dallas, Texas (April, 1987).

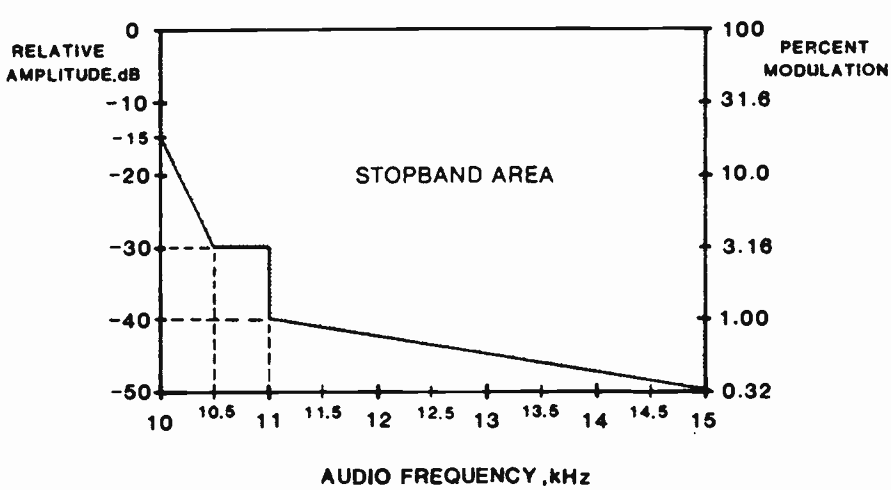

Figure 3. NRSC Stopband Specification
(Audio Envelope Input Spectrum To AM Transmitter)

envelope input spectrum to the AM transmitter shall be -15 dB at 10 kHz, smoothly decreasing to -30 dB at 10.5 kHz, then remaining at -30 dB from 10.5 kHz until 11.0 kHz. At 11.0 kHz, the audio bandwidth shall be -40 dB, smoothly decreasing to -50 dB at 15 kHz. Above 15 kHz, the audio bandwidth shall remain at least -50 dB. The reference level is 1 dB above a 200 Hz sine wave at 90% negative modulation. See Figure 3.

§ 6.3. Method for Determining Performance. An AM station is determined to be in compliance with the NRSC bandwidth characteristic by measurement of the station's audio bandwidth in accordance with the following parameters:

§ 6.3.1. Location of Measurement. Audio bandwidth measurements shall be obtained at the audio input terminals to the AM transmitter. For AM Stereo stations, audio bandwidth shall be measured at the L+R audio input terminals to the RF modulator. Note that the NRSC bandwidth standard characterizes an audio bandwidth that represents station program material that has been modified by possibly non-linear circuits in the station's audio processor. For this reason, the NRSC recommends use of a test signal that adequately characterizes typical audio program material, rather than relying on static audio test tones. However, it may still be useful to measure bandwidth statically at the time that AM preemphasis is measured.

§ 6.3.2. Use of Standard Test Signal. Audio bandwidth shall be measured using a test signal consisting of USASI (United States of America Standards Institute) noise that is pulsed by a frequency of 2.5 Hz at a duty cycle of 12.5%. See Figure 4. USASI noise is intended to simulate the long-term average spectra of typical audio program material. Pulsing of the noise is intended to simulate audio transients found in audio program material. USASI noise is a white noise source[5] (i.e. noise with equal energy at all frequencies) that is filtered by (1) a 100 Hz, 6 dB per octave high-pass network and (2) a 320 Hz, 6 dB per octave low-pass network. See Figure 4. A pulsed USASI noise generator is shown in Figures 5 and 6. Using the attenuator pad, the ratio of peak-to-average amplitude shall be 20 dB at the audio output of the pulser. The station's audio processor must be in normal operating mode.

§ 6.3.3. Use of Standard Measurement Devices. A suitable swept-frequency or FFT (Fast Fourier Transform) spectrum analyzer shall be used to measure compliance with the NRSC bandwidth specification.

(a) Spectrum Analyzer Setup. When a swept-frequency audio spectrum analyzer is used to measure compliance with the NRSC bandwidth specification, the analyzer's setup shall consist of:

a. 300 Hz resolution bandwidth.[6]
b. 2 kHz/horizontal division.
c. 10 dB/vertical division.
d. Reference: 1 dB above 200 Hz (sine wave) 90% negative modulation.
e. Display: maximum peak hold (or equivalent function).

The analyzer's operating span and sensitivity are adjusted as necessary to determine compliance.

(b) Fast Fourier Transform Analyzer. When a FFT analyzer is used to measure compliance with the NRSC bandwidth specification, the analyzer's setup shall consist of:

a. Reference: 1 dB above 200 Hz (sine wave) 90% negative modulation.
b. Window: Hanning.
c. Horiz. span: 20 kHz.
d. Dynamic range: 80 dB or available range.
e. Display: Maximum peak hold (or equivalent function).

5.Acceptable white noise sources include GenRad Models 1382 and 1390B; Bruel & Kjaer Model 1405; and National Semiconductor IC No. MM 5837N.

6.Note: if the audio bandwidth under test fails to meet the NRSC specification when a 300 Hz resolution bandwidth is employed, a narrower resolution bandwidth, such as 100 Hz, may be used to determine compliance; however, the sweep rate and the video bandwidth of the analyzer must be adjusted according to the manufacturer's instructions in order to assure accurate representation of the resolution bandwidth employed. If in doubt, check with the analyzer operating manual or the manufacturer. Further Note: the NRSC may suggest a different or more precise measurement standard as the industry gains experience. Spectrum analyzers that are capable of 300 Hz resolution bandwidths at audio frequencies include, but are not limited to, Tektronix Models 5L4N and 7L5; Hewlett-Packard Models 3580A, 3582A, 3585A, 8553A or B, 8566A or B, 8568A or B, 71100A; Marconi Models 2370, 2382; Rhode/Schwarz/Polarad Model CSA-240M; and a Techron Model TEF System 12.

§ 7. FIVE YEAR REVIEW PROVISION

It is the goal of the NRSC to increase the fidelity of the AM transmission and reception system from its present state to a quality level that approaches the quality available via FM broadcasting. Towards this end, the voluntary standards described in this document shall be in effect for five (5) years from the effective date of this standard. During the interim five year period, this voluntary standard will be reviewed at least once a year to determine whether the fidelity goals of the NRSC are being realized.

§ 8. EFFECTIVE DATES

These dates serve only as objectives. AM Broadcast stations and AM receiver manufacturers are expected to make a good faith effort to implement the NRSC standard.

A. AM Broadcast Stations. The effective date of this standard is January 10, 1987.

B. AM Receiver Manufacturers. The effective date of this standard is January 10, 1988.

Voluntary Standard No. NRSC-2

Sponsored by the Electronic Industries Association and the National Association of Broadcasters

TABLE OF CONTENTS

EMISSION LIMITATION FOR AM BROADCAST TRANSMISSION
(NRSC Voluntary Standard No. NRSC-2)

§ 1. Scope.

The National Radio Systems Committee (NRSC) is a joint committee composed of all interested parties including representatives of AM broadcast stations, AM receiver manufacturers, and broadcast equipment suppliers. This document describes an interim[1] voluntary national standard that specifies radio-frequency spectrum occupancy for AM broadcast stations. The standard applies to both AM monophonic and AM stereo transmissions. Compliance with the standard is strictly voluntary. To the NRSC's knowledge, no industry group or entity is or will be adversely affected by issuance of this document. Every effort has been made to inform and accommodate any and all interested parties. The NRSC believes that implementation of this standard will lead to reduced AM interference, thus providing increased service for all AM stations and an increase in quality of service to present and future AM listeners.

§ 2. Introduction.

On January 10, 1987, the NRSC authorized the National Association of Broadcasters and the Electronic Industries Association to publish an interim voluntary national standard specifying AM preemphasis, AM deemphasis and a 10 kHz AM audio bandwidth (Standard No. NRSC-1). The NRSC-1 audio standard applies to the audio signals that are intended to modulate the AM transmitter. Its purpose is to reduce second-adjacent channel interference by band limiting AM stations to a nominal

[1]The standard is described as "interim" until the test methods contained within the document can be fully verified through field tests. In addition, field test data of "splatter monitor" technology will be evaluated to determine the correlation between results obtained with such devices and the methods described within this document (see § 5.).

20 kHz occupied radio-frequency (RF) bandwidth (twice the 10 kHz audio bandwidth presented to the transmitter's modulation circuits). Implementation of the NRSC-1 audio standard alone largely achieves this purpose. However, there remain characteristics of the AM transmission process that may cause the RF occupied bandwidth to exceed a nominal 20 kHz. This document accommodates these transmission characteristics. It is in two Sections. Section 3 is a voluntary standard maximum RF occupied bandwidth of AM broadcast transmissions. Section 4 consists of a voluntary RF occupied bandwidth testing and control standard designed to insure repeatability and consistency of RF occupied bandwidth test measurements.

§ 3. RF Maximum Occupied Bandwidth Specification.

§ 3.1. Purpose. The purpose of an RF maximum occupied bandwidth specification is to control modulation products, desired or undesired, that fall outside the specified RF occupied bandwidth.

§ 3.2. Maximum Occupied Bandwidth. The maximum occupied RF bandwidth voluntary standard represents the maximum peak output of a swept-frequency spectrum analyzer IF over a minimum ten minute period.[2] The specification encompasses all spectral components caused by direct programming and all ancillary or data communications. AM broadcast stations shall occupy spectrum according to the following maximum specifications:

(see next page)

[2] It is recognized that the output of the spectrum analyzer depends on the shape of the analyzer's IF filters.

Table 1

Frequency Band Relative to Carrier (+/- kHz)	Attenuation Relative to Carrier (dB)
0 to 10	0
10 to 20	greater than -25[3]
20 to 30	greater than -35
30 to 60	greater than -(5 + 1 dB/kHz) from carrier[4]
60 to 75	-65[4]
above 75	-80[4]

(See Figures 1 and 1A (solid line) attached).

§ 3.3. Measurement Procedure.

§ 3.3.1. Use of Ordinary Program Material. Measurements of AM station spectrum occupancy shall be conducted using ordinary program material. All audio processing used in the AM station shall be in normal operating modes. The audio signal input to the AM transmitter shall conform to the NRSC audio standard adopted January 10, 1987.

§ 3.3.1.1. Use of Audio Tones. Sweeping a transmission system with audio tones is a widely accepted and respected method for gauging spectrum occupancy and for troubleshooting and adjusting AM transmission systems. The NRSC endorses audio tones for these purposes, but urges caution in the use and selection of audio tones particularly with AM stereo transmission.[5] It should be noted, however, that it is

[3] Note: the slope of occupied bandwidth in the transition region between 10 and 11 kHz is expected to parallel the NRSC-1 audio standard. Accordingly, attenuation levels in the region shall be 6 dB greater than described in the audio standard to adjust for carrier level reference.

[4] For carrier power levels between 50 and 5000 Watts, the maximum limit shall be $-(43 + 10 \log P_W)$ dB (where P_W is the carrier power in Watts) or as indicated in Table 1 and/or the attached Figure 1, whichever is lesser attenuation. For carrier power levels below 50 Watts, a -60 dBC maximum limit shall be used.

[5] The manufacturer of the particular AM stereo system employed should be consulted for the appropriate tone frequencies/modulation levels for "worst-case" condition testing.

difficult to infer the dynamic response of a transmission system while observing it in a steady-state condition.

§ 3.3.2. Use of Spectrum Analyzer. A suitable swept-frequency RF spectrum analyzer shall be used to measure compliance with the NRSC RF occupied bandwidth specification. The analyzer shall measure the over-the-air RF spectrum occupancy as perceived in the far field (i.e., at least 10 wavelengths from the antenna center). Some caution should be used in measuring spectrum occupancy with directional antennas.[6]

The analyzer's setup shall consist of:

a. 300 Hz resolution bandwidth.
b. 5, 10, or 20 kHz/horizontal division (as appropriate).
c. 10 dB/vertical division.
d. Reference: carrier peak.
e. Peak Hold: 10 minute duration minimum.
f. No Video Filter.

§ 4. RF Occupied Bandwidth Testing and Control Standard.

§ 4.1. Purpose. The NRSC recognizes that for the purposes of troubleshooting, design, and adjustment it may be desirable to use an occupied bandwidth emission standard that is coupled to a standard test signal and measurement procedure. This second measurement technique can also be utilized by transmitter manufacturers and broadcasters to provide results that may be directly correlated with each other. For these purposes, the NRSC proposes the following interim voluntary national test and control standard:

§ 4.2. Maximum Occupied Bandwidth. The RF occupied bandwidth test and control standard is a stored peak specification. With the standard test signals and measurement procedures specified below, AM stations shall occupy a maximum RF bandwidth that conforms to the following maximum specifications:

---

[6] *See* Klein, *Modulation, Overmodulation, and Occupied Bandwidth: Recommendations for the AM Broadcast Industry* (NAB, September 11, 1986) at 18-23.

Table 2

Frequency Band Relative to Carrier (+/- kHz)	Attenuation Relative to Carrier (dB)
0 to 10	0
10 to 13.5	Minimum is defined by a line with endpoints found at -25 dB/10 kHz and -35 dB/13.5 kHz[7]
13.5 to 54.5	Minimum is defined by a line with endpoints found at -35 dB/13.5 kHz and -65 dB/54.5 kHz[8]
54.5 to 75	-65[8]
above 75	-80[8]

(See Figures 1 and 1A (dotted line) attached).

§ 4.3. Measurement Procedure.

§ 4.3.1. Standard Noise Test. Measurements of AM station spectrum occupancy shall be conducted using a standard noise test signal described in the January 10, 1987 NRSC audio standard.[9] All audio processing employed in the AM station or test configuration shall be in a normal operating mode. The audio signal input to the AM transmitter shall conform to the NRSC audio standard adopted January 10, 1987.

§ 4.3.1.1. Monophonic conditions. The noise source is unmodified.

§ 4.3.1.2. Stereophonic conditions. Two independent but equivalently designed USASI-weighted noise sources are employed. Pulsing of the sources is controlled by a single control signal. The pulsed output of one noise generator is defined as L+R (mono, sum information) where the other is attenuated by 3 dB to

---

[7]See footnote 3.

[8]For carrier power levels between 50 and 5000 Watts, the maximum limit shall be $-(43 + 10 \log P_W)$ dB (where P_W is the carrier power in Watts) or as indicated in Table 2 and/or the attached Figure 1, whichever is lesser attenuation. For carrier power levels below 50 Watts, a -60 dBC maximum limit shall be used.

[9]*See National Radio Systems Committee, Interim Voluntary National Standard (NRSC-1)*, § 6.3.2 and Figures 4, 5, and 6 (January 10, 1987).

provide L-R (stereo, difference information). The signals are then matrixed to provide left and right channel information to be applied to the audio input terminals of the stereophonic audio processor employed.[10] See Figure 2 (attached).

§ 4.3.2. Use of Spectrum Analyzer. A suitable swept-frequency RF spectrum analyzer shall be used to measure compliance with the NRSC RF occupied bandwidth testing and control standard. The analyzer's setup shall consist of:

a. 300 Hz resolution bandwidth.
b. 5, 10, or 20 kHz/horizontal division (as appropriate).
c. 10 dB/vertical division.
d. Reference: carrier peak.
e. Peak Hold: 10 minute duration minimum.
f. No video filter.

§ 5. Splatter Monitor. It is understood that the NRSC does not anticipate a Spectrum Analyzer will be available for mask standard measurements in most AM radio stations. However, the current development of a low cost "splatter monitor" device may allow economical continuous monitoring of compliance with RF mask characteristics.

Such a device accommodates the following factors: (1) NRSC deemphasis, and (2) amplitude detection of in-phase and quadrature signal components found in the defined stopband region.

As these devices are evaluated and correlated with current spectrum analysis measurement techniques, a determination shall be made by the NRSC with respect to possible modification of RF mask compliance measurement methods.

§ 6. Effective Date. **June 1, 1988.**

§§§§

---

[10]The signal provided by the audio processor to the transmitter left and right audio input terminals shall not exceed single channel modulation limits as dictated by the constraints of the particular stereo system employed.

4.2
AM STEREO

EDWARD J. ANTHONY
QUINCY, IL

INTRODUCTION

The acceptance and implementation of AM stereo broadcasting in the United States has been a slow and difficult transition. Beginning with the now famous FCC marketplace decision in 1981, the field of prospective AM stereo system proponents had been reduced from five (Belar, Harris, Kahn Communications, Magnavox, and Motorola) to two, namely the Kahn Independent Sideband System (ISB) and the Motorola C-QUAM System, and then to one (C-QUAM).

Recent years have shown a quiet growth in AM stereo conversion, with less controversy than was experienced in the early and mid 1980's. The broadcaster's interest turned more toward proper installation and maintenance of AM stereo than on which system to use.

The proper operation of stereo transmission for AM is relatively more difficult than its FM counterpart. This chapter will discuss the more practical aspects of AM stereo preparation, installation, and maintenance to aid the AM broadcaster in achieving a high quality stereo transmission.

STATION PREPARATION FOR AM STEREO

Depending on the particular station, part or perhaps all areas of the operation will be affected during the AM stereo installation process. It is best to consider each section of the transmission path separately, so as to make a more thorough and logical conversion.

The Audio Chain

Unless the current AM studio is outfitted with stereo equipment, it will be necessary to install new stereo sources such as CD players, consoles and other distribution facilities. If good engineering practices are employed during the installation and layout phases, this portion of the process should not present major problems.

One area to be concerned about, however, is to ensure proper audio phase and amplitude matching of left and right channels throughout the facility. Without adequate tracking between both channels, proper monophonic frequency response and stereo imaging will not be maintained.

Figure 4.2-1 shows the resulting loss in monophonic frequency response due to improper phase relationship between the two audio channels. Another consequence of poor channel matching is a rapid degradation in L + R (monophonic) to L − R (stereo), and L − R to L + R crosstalk. This parameter typically degrades with frequency, reducing high frequency monophonic coverage and altering the high frequency stereo image.

Figure 4.2-2 graphically shows the degree of amplitude and phase matching required to obtain an arbitrary amount of crosstalk. For instance, a 0.1 dB amplitude error combined with 1° of phase mismatch will limit L + R to L − R and L − R to L + R crosstalk to about 40 dB. This relationship holds true for stereo separation during transmitter equalization.

AM Stereo Processing

Due to the nature of AM stereo transmission, the audio paths are different than its FM multiplex counterpart. Rather than operating in a discrete left and right channel mode, AM stereo transmission necessitates the use of matrix mode for transmission, since the amplitude modulation information comes from the combination of L + R (monophonic) audio and the RF carrier employs some form of phase modulation representative of the L − R (stereo) information. Unlike composite FM stereo, these paths are independent of each other and may also be processed independently. In fact, since the two audio paths are combined in matrix form before the actual modulation occurs, processing for AM stereo is most effective if it is also done in matrix form.

Figure 4.2-3 is a representation of a common and very effective tool used in AM stereo installation and maintenance: the X − Y or Lissajous pattern of a two channel oscilloscope. Standard operation is with the X input driven by the left channel, and the Y input driven by the right. This will produce a straight line display of 45° in the first and third quadrants for total L + R modulation, and a straight line display of 45° in the second and fourth quadrants for total L − R information.

If conventional left and right channel processing is used, the limiting must be done symmetrically, and at a level equivalent to 50% L + R and L − R modulation if only one channel were being applied. In this manner, proper 100% limiting will occur when L = R for the envelope (amplitude) modulation, and when L = (−R) for the phase modulation. However, under single channel conditions, there is a 6 dB loss in both monaural loudness and coverage. This undesired effect can be improved if the processing is done in matrix form.

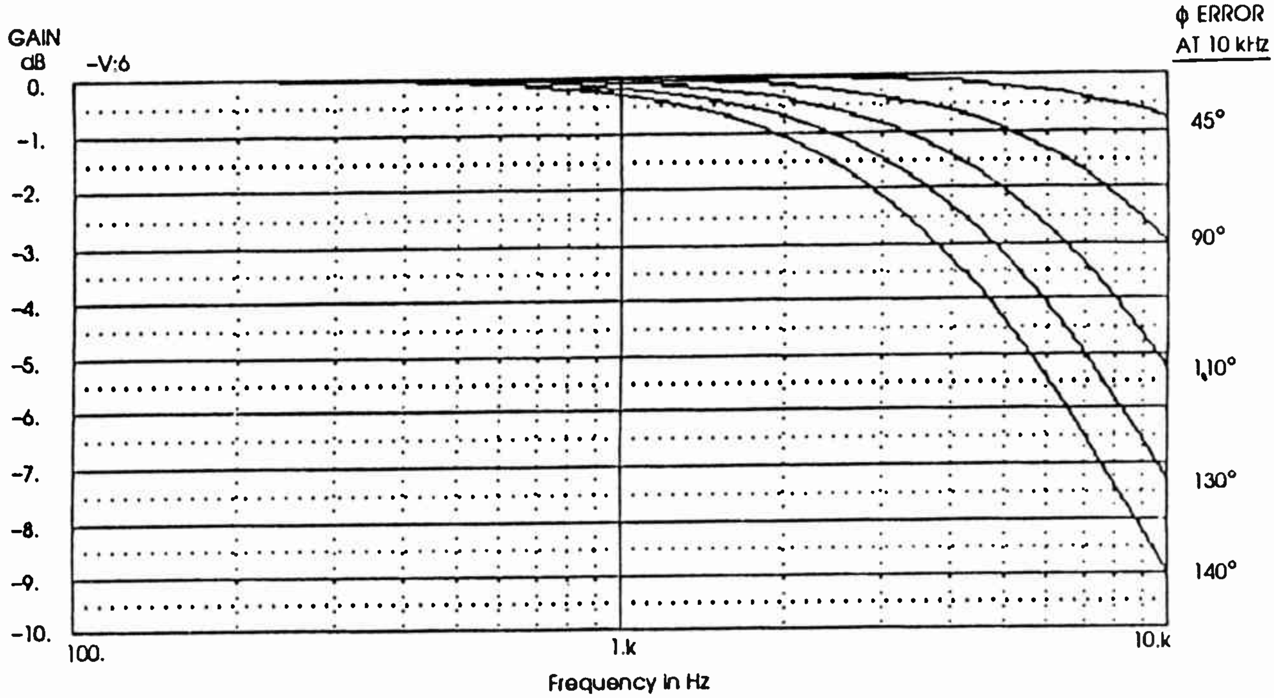

Figure 4.2-1. Loss in monaural frequency response due to phase errors.

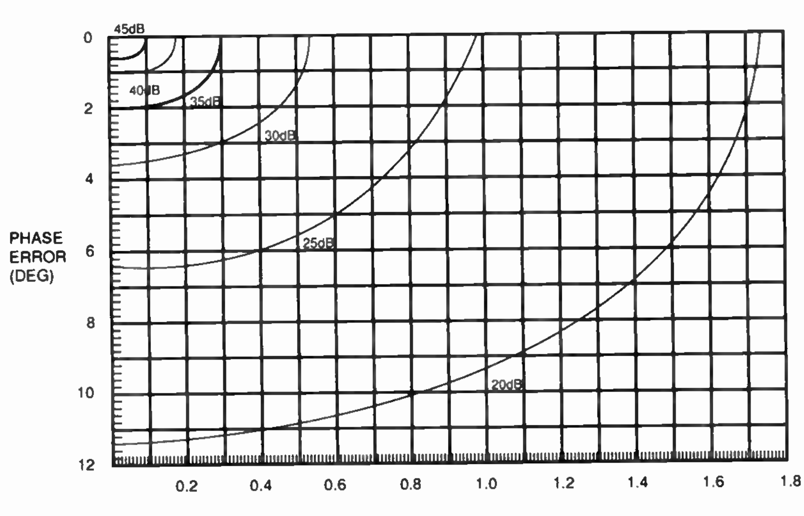
Figure 4.2-4 shows the classic diamond shape produced by full matrix stereo processing. With this method, left and right channels are increased under single channel conditions, and under heavy stereo conditions, to maintain full envelope modulation. This mode of operation is called *full monaural support matrix stereo limiting.*

Unfortunately, instead of the 6 dB loss in monaural loudness associated with the conventional processing method, the full matrix method results in a 6 dB *increase* in stereo single channel loudness. However, this has been found to be less objectionable than the alternative, and combined with the infrequent nature of single channel conditions, is a more desirable side effect for AM stereo.

There is still one aspect of full monaural support matrix stereo limiting that makes it unacceptable. The unique decoder requirements necessary for the C-QUAM AM stereo system necessitate that the left and right channels be limited to -75%, where -100% is



General Equation:

$$\text{Separation }(A,\theta) = \left[\frac{(\cos\theta + A)^2 + (\sin\theta)^2}{(\cos\theta - A)^2 + (\sin\theta)^2}\right]$$

Where: $A = \frac{L-R}{L+R}$ Amplitude ratio

$\theta = \frac{L-R}{L+R}$ Phase error in degrees

Figure 4.2-2. Crosstalk (separation) versus amplitude and phase errors in a matrix system.

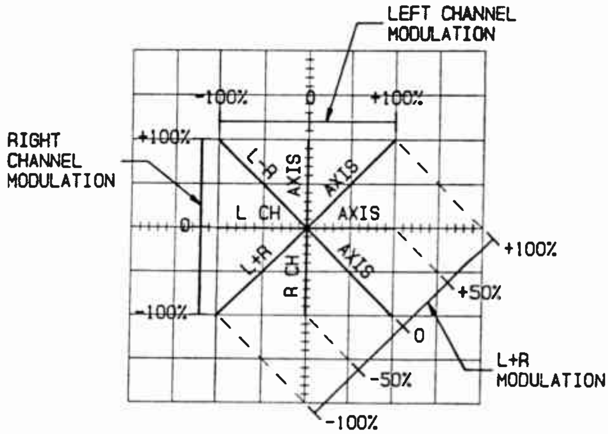


Figure 4.2-3. Conventional "X – Y" oscilloscope display.

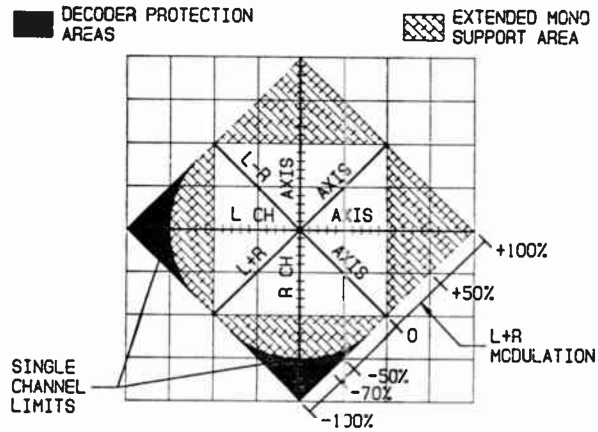

Figure 4.2-5. Modified matrix stereo processing.

equivalent to full envelope modulation caused by a single channel input. Therefore, all professional AM stereo matrix processors include a single channel limiter to prevent these problems. The new operational area is shown in Figure 4.2-5. Notice the protection areas that have been included to prevent non linear stereo operation. This style of AM stereo processing has been referred to as *modified* monaural support matrix stereo limiting.

Proper alignment and operation of any matrix AM stereo processor requires a thorough understanding of these departures from conventional FM stereo processing, as well as the practical limitations imposed by current AM stereo hardware designs. Without a proper grasp on these concepts, the processing can do more harm than good, and has often been the source of great frustration during installation and maintenance.[1]

Studio to Transmitter Link

Many AM stations operate studios at locations other than that of the transmitter. Therefore, there must be some form of studio to transmitter link (STL) to carry

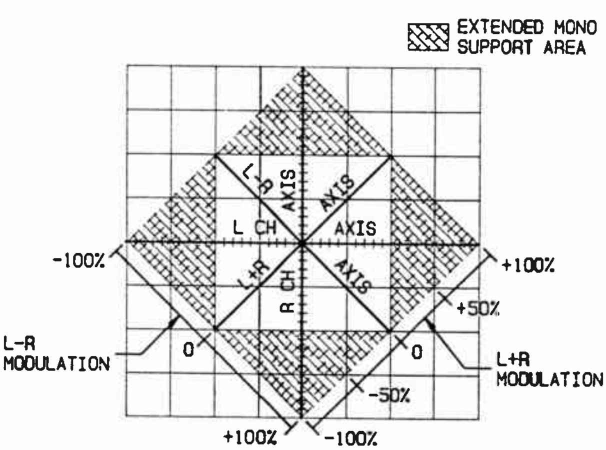

Figure 4.2-4. Full matrix stereo processing.

the audio information to the transmission facility. Traditionally, this has taken one of two forms: equalized phone lines or a microwave radio link.

Stereo transmission requires a second link to be installed. If this is not done carefully it can be a serious limitation to proper stereo operation.

Phone Lines

Installing a second phone line is often the first choice for AM stations that are currently using one. Two of the more common complaints with this approach are the increase in monthly fees associated with the second line and the troublesome problem of maintaining the amplitude and phase matching between the two lines.

Equalized phone lines typically have complex filters and frequency shaping equalizers. This makes them difficult to match and also prone to drift with time and temperature. The complexity of the circuits can also increase the total possible phase shift, making complete monophonic cancellation, or *combing*, a problem under extreme conditions. This same phenomenon will also cause complete mono to stereo image rotation, that will cause unexpected stereo imaging and excessive phase modulation.

Unfortunately, these paths are not under the direct control of the station, and one is often left to the mercy of the local telephone company for support. See Chapter 3.11, "Common Carrier Audio Program Services" for more information on current telco-based service options.

Radio Links

Installing a new radio link is generally considered a more favorable alternative, providing the frequency allocation is available. It also relieves the monthly financial burden associated with rented phone lines. However, discrete left and right STL transmission can suffer some of the same problems with amplitude and phase matching, but usually not to the same degree as phone lines. The STL transmitters and receivers will have audio, RF and IF filters, and depending on the design, construction and alignment, may not be well matched. It is best to consult the manufacturer to get an assurance that the two systems will track adequately.

There is a third approach that has been used in some locations with great success. An FM stereo generator can be used to create a baseband composite FM stereo signal that can then be transmitted on a single wideband STL link. The signal is then decoded back to left and right at the transmitter location using a high quality stereo decoder. This approach can be more expensive than discrete radio links, but results in a very high quality, reliable and stable way to provide the two channels to the transmitter.

Transmitter Preparation

Now that the studios are stereo ready, and the two channels are present at the transmitter site, the real job of installing AM stereo begins. Depending on the age and model of the current transmitter, preparing it to accept AM stereo can range from minor modifications to the nearly impossible.

Unfortunately, there are no absolutely defined procedures for making a transmitter stereo ready. It is highly recommended that a competent and reliable broadcast consultant be used to prepare the transmission chain. A reputable consultant with AM stereo installation experience can save time, trouble, and in the long run, money, since the consultant will know what is required for your unique set of circumstances and can implement them correctly.

In general, the work that will be required can be broken down into a few basic categories.

General Maintenance

The first step to high quality AM stereo is to have high quality AM monaural. Many AM transmitters have been neglected for years. A monaural proof-of-performance will show if the system is up to specifications. If not, it needs to be fixed so that it produces a decent proof. This is definitely money well spent, since it will improve your on air sound to all listeners, both monaural and stereo. It will also make the stereo installation easier, since there will be enough other problems to compensate for without the added burden of poor monaural performance.

Factory Modification Kits

Most manufacturers of AM transmitters will provide support to help upgrade their transmitters for AM stereo. Past experience has shown them where the stereo problems will be for any given model. In addition, some manufacturers have standard modification kits available, with instructions, to prepare the transmitter for stereo.

IPM Reduction

Incidental phase modulation (IPM) is broadly defined as any undesired angular phase shift of the RF carrier. It can be further broken down into two sub categories: IPM caused by power supply ripple (or induced magnetic fields), and IPM caused by envelope modulation.

The first form of IPM most often results from insufficient power supply bypassing. Before the advent of AM stereo, transmitter manufacturers were not concerned about IPM, since it was not decoded by conventional envelope detectors and generally did not affect the AM signal. It was simply not worth the additional cost to provide the extra bypassing.

Its main effect is to limit the decoded L − R signal-to-noise ratio (S/N), and is often the dominant stereo noise component. Any improvement in this area will improve the decoded stereo S/N. It should be possible to reduce this form of IPM to −45 to −55 dB below 100% L − R modulation.

The second form of IPM is much more troublesome to reduce and more detrimental to quality AM stereo. This mode of IPM is caused by amplitude modulation of the carrier, and can be caused by several mechanisms. For tube type transmitters, it is often the result of poor neutralization of the final PA stage, and can result in equivalent L − R modulation levels in excess of 25%.

The interelectrode capacitances found in vacuum tubes can cause instabilities. In particular, the plate to grid feedback capacitance provides a path for positive feedback. Figure 4.2-6 shows the static interelectrode capacitances found in a tetrode. The C_{g-c} and C_{g-p} are the two capacitances of importance for proper neutralization. The intent of neutralization is to cancel the C_{g-p}, so as to minimize its effect, both on stability and on IPM. The most popular method of neutralization is the *capacitance bridge*. Figure 4.2-7 shows a simplified tetrode configuration employing classic bridge neutralization. C_{g-p} and C_{g-c} are the grid to plate and grid to cathode interelectrode capacitances, respectively. C is comprised of any input capacitance, including stray capacitance, and is required for complete neutralization of C_{g-c}. C_n is the neutralization capaci-

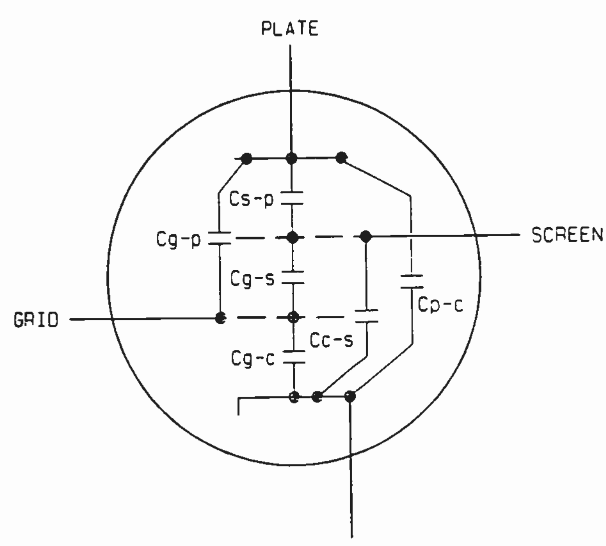

Figure 4.2-6. Static interelectrode capacitances of a tetrode tube.

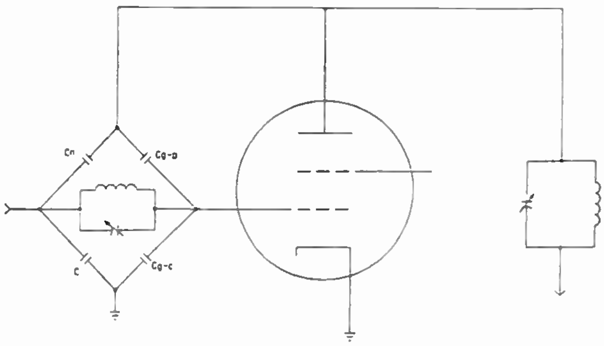

Figure 4.2-7. Bridge neutralization.

tance required to balance C_{g-p}. For proper balance (proper neutralization), the capacitor ratios must satisfy the following relationship:

$$\frac{C_n}{C} = \frac{C_{g-p}}{C_{g-c}}$$

With proper neutralization, IPM levels should be able to be reduced, typically, to -35 to -45 dB below 100% L − R modulation.[2,3]

For the solid-state transmitter, IPM is most often caused by the nonlinear output capacitance of the solid state device. The value of this capacitance is a function of the applied collector or drain voltage. Since most solid state transmitters use high level modulation, this voltage varies at the audio rate, that will affect the RF phase angle.

Fortunately, most solid state transmitters are relatively recent designs and steps have been taken to reduce this effect to an acceptable level. Many new transmitters are shipped stereo ready, requiring no additional effort to reduce IPM.

Tuned Circuits

Some older transmitters used narrow bandwidth tuned RF circuits as input, interstage and output coupling networks. Proper stereo operation requires that the amplitude and phase relationship of the L + R (envelope) information match that of the L − R (phase modulated) information. These narrowband tuned networks have three undesired effects. First, they introduce a non-uniform time delay to the RF carrier, resulting in complex phase equalization problems. Second, they result in L − R high frequency response problems, further aggravating the equalization requirements. Finally, the narrowband nature of the network alters the sideband structure of the phase modulation, resulting in increased distortion.

It is a fairly common practice to increase the bandwidths of these circuits to improve the stereo signal. A word of warning, however: reducing the Q of a tuned stage will result in a decrease in voltage at the output of the network. Care must be taken to ensure the resulting signal is adequate to drive the following stage. It is wise to consult the factory or a knowledgeable consultant before attempting this modification.

Antenna and Phasor Alignment

All AM stereo transmissions are sensitive to amplitude and phase non-linearities to one degree or another. For best performance, the antenna system should be as broadband as possible, and as symmetrical as possible. The C-QUAM system especially requires good transmission bandwidth and phase linearity.

If required, a consultant should be retained to broadband the antenna system and ensure its fitness for AM stereo transmission.

Monaural Proof of Performance

One final step should be carried out before the actual stereo conversion begins. A complete monaural proof of performance should be done to ensure the system is ready to accept stereo, and as a record to compare final monaural performance after installation.

STEREO EXCITER INSTALLATION

With a properly operating monaural transmission chain in place, the actual transmitter conversion to AM stereo may begin. Mount the AM stereo exciter close enough to the transmitter to allow proper interconnection. A general rule is the RF interconnection cable should be no more than 30 ft from the transmitter.

RF Interfacing

Since AM stereo transmission uses some form of phase modulation of the RF carrier, the AM stereo exciter will have a phase modulated RF output that will replace the transmitter's internal RF oscillator. The rated output power varies from exciter to exciter, from a few watts up to 10 W.

It will be necessary to pick a suitable RF insertion point to break the internal RF chain and replace it with the RF from the exciter. Stereo-ready transmitters will be outfitted with a BNC connector, usually requiring a transistor-transistor logic (TTL) level (5 V, peak-to-peak) signal for proper operation. Other transmitters require modification to provide a way into the RF sections.

If the particular type of transmitter uses narrow tuned RF stages, it is a good idea to pick the farthest point in the transmitter that the exciter can still provide adequate RF drive.

Many transmitters can accept a TTL level signal but are not outfitted with the necessary interface. Figure 4.2-8 shows a general purpose interfacing network that may be used in these transmitters.

Providing the Proper Termination

The RF output of an AM stereo exciter is designed to operate in a 50 Ω system. This is required due to the extended distances from the RF source to the transmitter. For proper operation, the transmitter end of the 50 Ω coax ***must*** be terminated with 50 Ω to prevent reflections on the line. This is especially important if the RF output is a square wave, which it is most likely to be. Improper termination will cause reflections on the line, that can cause excessive ringing

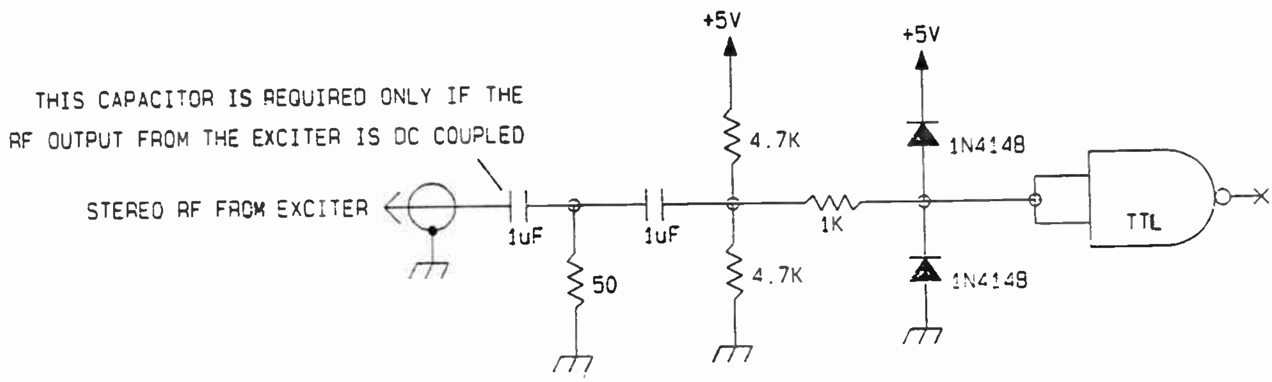

Figure 4.2-8. TTL RF interfacing.

and, for TTL inputs, improper logic operation. If the ringing is excessive, it is possible to damage the input stage due to excessive voltages. For TTL compatible input levels, a 1/4 W resistor is adequate, provided that the input to the transmitter is ac coupled, then dc restored (see Figure 4.2-8). If higher power levels are required, select the proper resistor power rating based on the following formulas:

$$P_{diss} = \frac{(V_{rms})^2}{50} \quad \text{(for sine wave input)}$$

$$P_{diss} = \frac{(V_{peak})^2}{50} \quad \text{(for square wave input)}$$

Internal RF Oscillator

Since the transmitter's original RF oscillator has been replaced by the AM stereo exciter, some possible problems may need to be dealt with. First, there may be some coupling between the original oscillator and the new RF signal. This coupling manifests itself most often in the form of a beat frequency equal to the difference in the two oscillators frequency calibration.

The most common cure is to simply remove the original crystal from the transmitter, or disable the power supply to the oscillator. This will prevent beat frequencies, and is a minor enough modification to allow quick replacement should the original oscillator be needed in an emergency.

If the old oscillator should be required due to a failure in the AM stereo exciter, it would be nice to be able to quickly switch back to the original oscillator and return to the air, in monaural, until the problem can be resolved. This can be done fairly easily with a relay. Figure 4.2-9 shows one possible implementation of an RF switching circuit. Notice the extra relay contact used to remove the power from the original oscilla-

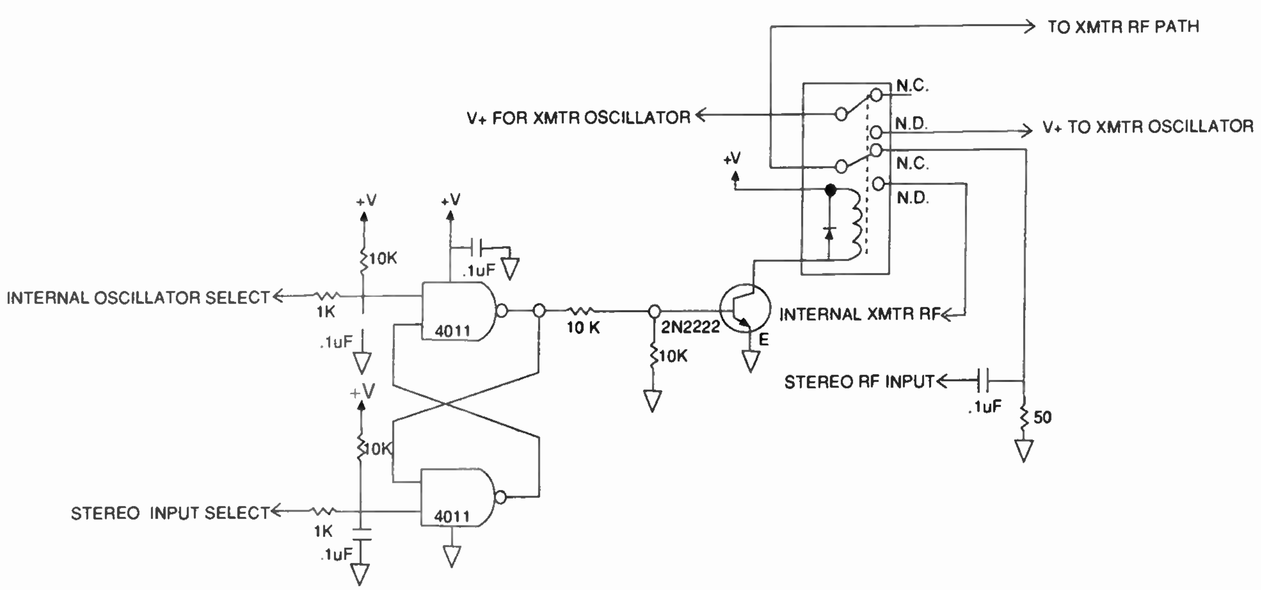

Figure 4.2-9. Mono/stereo emergency switching.

tor during normal stereo operation. Again, this eliminates the possibility of beat frequencies.

Audio Interfacing

The left and right channels must be connected to the exciter, and the levels set according to the manufacturers recommendations. The existing monaural input to the transmitter should be replaced by the monaural output from the AM stereo exciter. All audio connections should be made using a high quality shielded cable, such as Belden 8451. This is important to prevent RF pickup on the cable. To prevent ground loops, ground the shield at only one end.

AM STEREO EQUALIZATION

Now that all the necessary pieces are in place, the final part of the AM stereo installation can begin. Since half of the stereo information is contained in the monaural (L + R) connection to the transmitter, and the other half is in the form of phase modulated RF (L − R), they must arrive at the modulator portion of the transmitter at the same time. This is required so that proper left and right channels may be recovered in the receiver after de-matrixing. The amount of amplitude and phase (delay) matching required at the transmitter's modulator to produce a given amount of stereo separation after de-matrixing can be seen in Figure 4.2-2.

Without proper audio equalization, both stereo separation and distortion would suffer. Unfortunately, the amount of delay and amplitude equalization required for one type of transmitter is different from any other. In addition, the circuits in the transmitter that cause the problems are generally complex, so the best that any AM stereo exciter equalizer can do is to approximate the response shape. The effectiveness of the equalizer is dependant on the type of transmitter and the complexity of the antenna pattern at any given station.

For these reasons it is clear why there are no firm rules to follow during equalization. It is often a trial and error routine, especially at the higher audio frequencies where the response shape is most complex. If an AM stereo exciter was designed specifically for one brand of transmitter, it would be possible to equalize the two paths almost perfectly, but since it is a generic conversion tool, it can, at best, only come close.

Types of Equalization

There are three different equalization sections in an AM stereo exciter. Each is intended to fix a particular frequency range. Some installations require all three, others only two, and very rarely, only one will be needed.

Group Delay

The first section which is almost universally required is the *group delay equalizer*. Its purpose is to provide a constant time delay to either the L + R or L − R paths, depending on which one arrives at the modulator first. It is primarily used to equalize the low to mid frequencies (up to a few kilohertz). If the response shape of the offending path in the transmitter is low-pass (or bandpass for the RF path), the time delay for the lower frequencies will be constant, so the alternate path can include this equalizer to compensate adequately.

A common example would be any AM transmitter employing pulse width modulation (PWM), in that case the L + R path would include a PWM low pass filter in the modulator just ahead of the RF amplifier. The L + R audio will have significantly more delay than the L − R (RF phase modulation) path. In this case, the group delay equalizer would be added to the L − R path to slow it down so that it arrives at the RF amplifier at the same time the L + R signal does.

On the other hand, some transmitters will have more low/mid frequency delay in the L − R path due to several RF interstage bandpass filters. In this instance, the group delay equalizer would be added to the L + R path to compensate.

Low Frequency Equalization

The second type of equalizer found in the exciter is the least often used section. It is only necessary if the low frequency response of the L + R path is non-uniform. This is found primarily in older plate modulated transmitters where the reactance of the plate transformer causes phase, and to a lesser degree, amplitude nonlinearities.

Some transmitters will also include an active audio high-pass filter in the monaural input. This can also be effectively corrected by the low frequency equalizer.

High Frequency Equalization

The third audio equalizer is designed to approximately complement the complex high frequency response shape of most AM transmitters. The amount and shape of high frequency correction varies greatly from transmitter to transmitter, that makes this section the most difficult adjustment of the installation process.

Since this section is only meant to approximate the high frequency amplitude and delay characteristics, it will not correct at all frequencies. It is not uncommon to be caught in a seemingly endless loop of adjusting for one frequency, only to find out you have made another frequency worse. The key to a successful installation is the ability to recognize a good overall compromise and once you have quit. This is one area where a good engineering consultant with AM stereo installation practice will be helpful.

Figure 4.2-10 shows the various equalization adjustments found on one C-QUAM AM stereo exciter. Notice the additional set of equalization labeled *Night*. This is useful for stations utilizing a different transmitter, antenna pattern or both for part of the broadcast day. It can also be used to equalize an emergency backup transmitter.

Equalization Path Selection

The proper alignment of the three equalization sections is the key to high quality AM stereo. However, before they can be adjusted, they must be inserted into

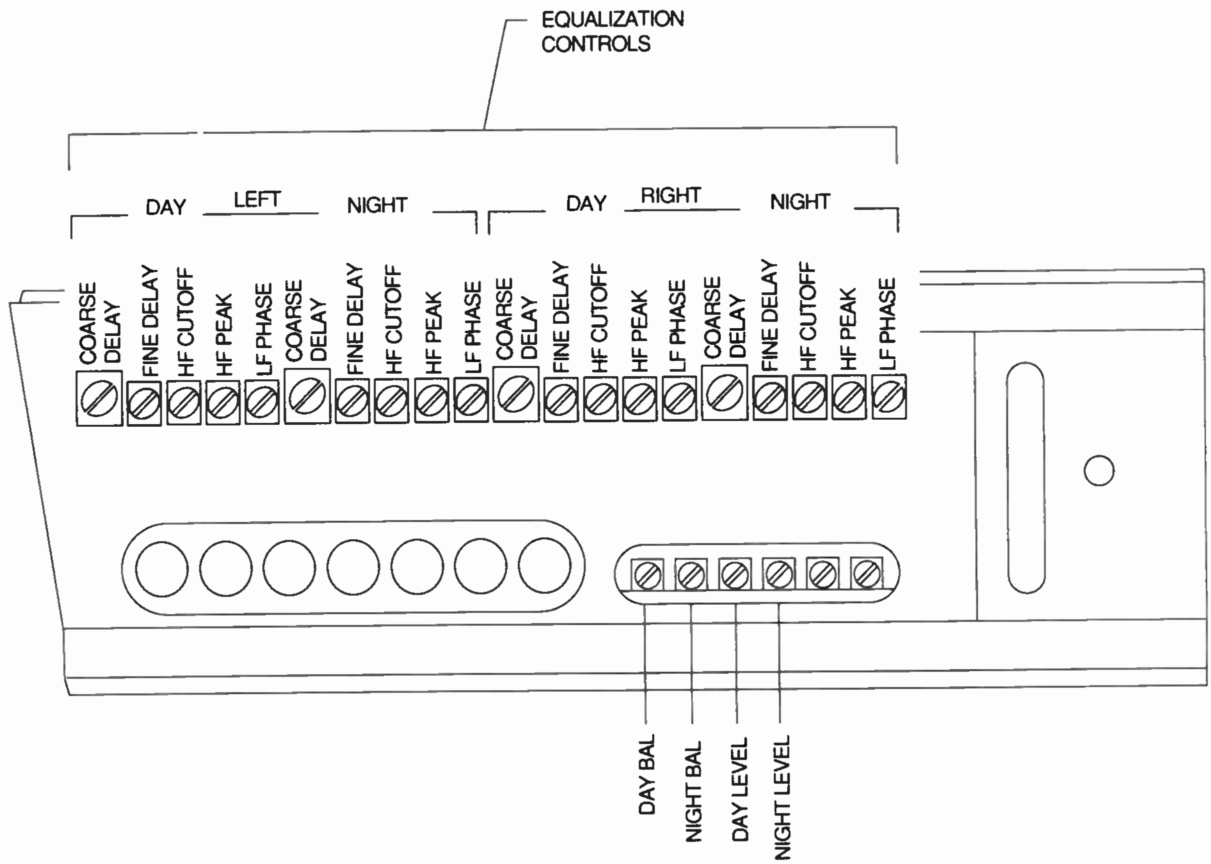

Figure 4.2-10. For a stereo exciter-stereo equalization control points.

either the L + R path or the L − R path, depending on where they are needed.

For someone with an intimate knowledge of the design of a particular transmitter, it may be possible to know for sure which path needs which equalizer. However, it is also possible that unique antenna characteristics could change what would be necessary into a 50 Ω resistive load. What results is a *try it and see* method. It may be necessary to change paths during the installation procedure as other equalizer sections are included. This will happen when, for instance, the inclusion of the high frequency equalizer in series with the group delay equalizer actually forces the constant delay to be added to the other path to compensate for low and mid frequency delay found in the high frequency equalization.

Figure 4.2-11 shows one method of selecting the proper path for any equalizer. This matrix switch is a flexible patch bay approach to inserting equalizers in series or parallel into either the L + R or L − R paths.

Equalization Procedure

Figure 4.2-12 outlines a typical test setup required for AM stereo equalization. Test equipment required for an adequate installation can be as simple as a low distortion audio oscillator/analyzer, an AM stereo modulation monitor and a dual trace oscilloscope with X − Y capability. In addition, a spectrum analyzer capable of resolving audio sidebands at the AM band frequencies can be very useful, but is not mandatory.

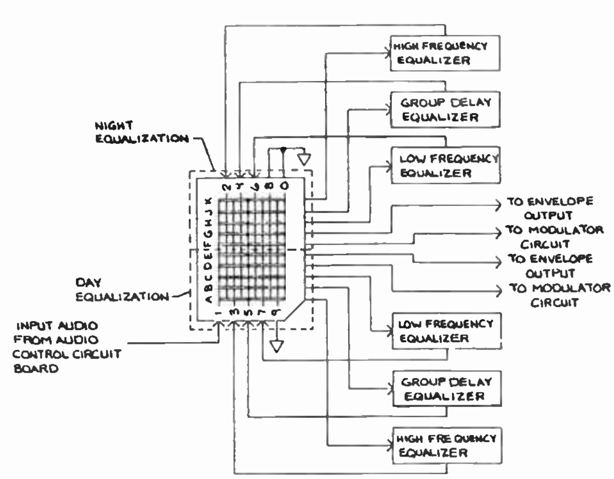

Figure 4.2-11. Stereo generator matrix switch.

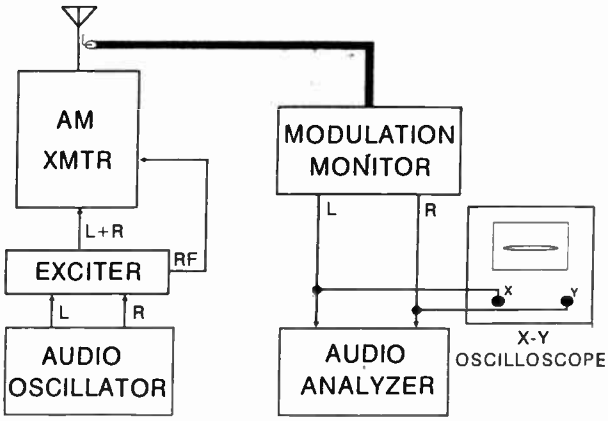

Figure 4.2-12. Stereo equalization test setup.

The X − Y Oscilloscope

The fundamental problem in AM stereo is determining the type and path of equalization required. In addition, it is necessary to determine if the system requires phase or amplitude equalization. A dual trace oscilloscope operating in the X − Y or Lissajous pattern mode is capable of resolving between amplitude and phase errors (or a combination thereof), as well as showing a multitude of additional information such as harmonic distortion, IPM, negative limiting, modulation compression and so on. To the trained eye, it is one of the most useful tools in AM stereo installation. Without this tool, it would be almost impossible to equalize the system.

AM Stereo Modulation Monitor

The final performance results of a stereo installation will only be as good as the equipment used to measure them. One of the most critical pieces of test equipment for proper installation, and just as important, routine maintenance, is the *AM stereo modulation monitor.* It should be a high quality piece of test equipment, and simple to use.

An Equalization Example

AM stereo exciters will have similar equalization adjustments, but may be labeled differently. The *day* adjustments are used in this example, though the *night* procedure is identical.

The first adjustment to be made is to set the exciter's L + R, or envelope, level to get the correct amplitude modulation for a corresponding L = R input. This is, at this stage, only a coarse adjustment. It can be done at any convenient modulation percentage. For instance, input 1 kHz L = R to the exciter such that the L + R meter on the exciter reads 80%. Then adjust the envelope output level of the exciter until the transmitter is modulating 80% as measured on the modulation monitor.

Next, apply a 1 kHz tone to the input of the left channel, only, at a level equivalent to 50% amplitude modulation. The oscilloscope should show a horizontal line (assuming the "X" input is the left channel). Most likely, it will be neither exactly on the X axis, nor a perfectly straight line. Figure 4.2-13(a) shows a typical display. If a display similar to Figure 4.2-13(b) is seen, the polarity of the L + R connection to the transmitter is wrong. This can easily be fixed by reversing the plus and minus terminals at the transmitter input. Figure 4.2-13(b) actually shows the high second harmonic distortion produced when the polarities of the amplitude modulation and phase modulation are not correct.

Next, the fine adjustments to maximize separation can be made. While monitoring both the residual right channel separation and the oscilloscope, insert the left channel group delay in either the L + R or L − R path (Figure 4.2-11) and adjust the coarse group delay. If the display opens up rather than closes, and the separation worsens, it has been inserted in the wrong path (see Figure 4.2-14). Reverse the location and adjust the coarse and fine group delay until the display closes (Figure 4.2-15). Then, fine tune the envelope level until the display lies exactly on the X axis and the left to right channel separation nulls (Figure 4.2-16).

Apply a 1 kHz tone to the input of the right channel,

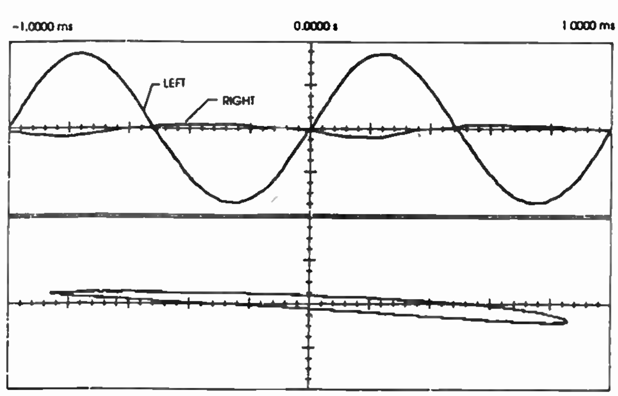

Figure 4.2-13(a). Typical left channel only display before equalization.

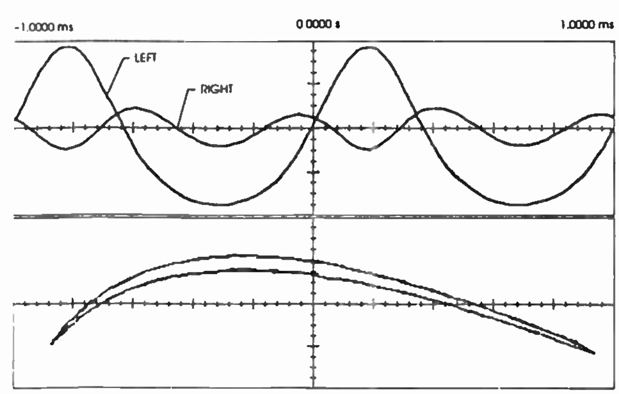

Figure 4.2-13(b). X − Y display caused by improper L + R polarity at transmitter.

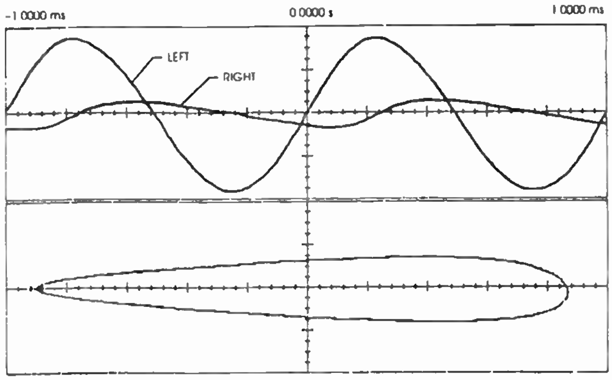

Figure 4.2-14. Left channel only with phase equalization error.

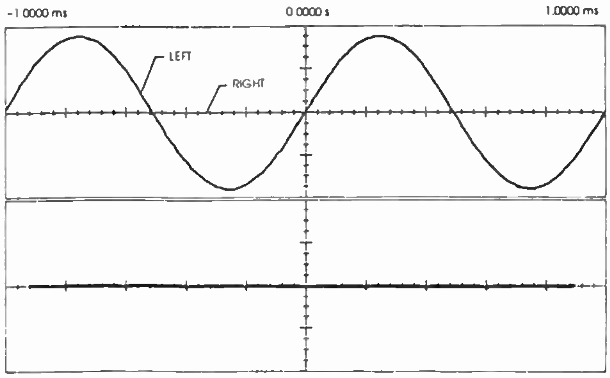

Figure 4.2-16. Left channel only, properly equalized.

only, at a level equivalent to 50% amplitude modulation. The oscilloscope should show a vertical display with only phase error. Insert the right channel group delay in the same path as the left channel and adjust until the display closes. The residual separation in the left channel will also null. Theoretically, the envelope level adjustment should not have to be adjusted for the right channel, but often the right to left separation can be improved slightly by fine tuning the level, at the expense of left to right separation. It is best to compromise the two to obtain the same amount of separation left to right as right to left. Some exciters are equipped with a balance control to help this problem. Refer to the individual service manual for the correct adjustment procedure.

The next step is to check the low frequency separation. A good frequency to look at is 100 Hz. If the separation has degraded significantly, the low frequency equalizer can be used to correct the problem. Again, this is usually only necessary in plate modulated transmitters, or ones that employ low level audio input high pass filters. The procedure is very similar to the group delay adjustment.

If low frequency equalization is used, re-check separation at 1 kHz and adjust the group delay, if necessary, to compensate.

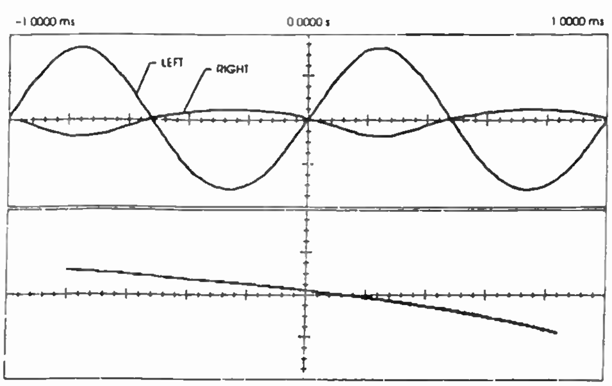

Figure 4.2-15. Left channel only with amplitude equalization error.

At this point, the transmitter should be equalized for good separation (30–40 dB) from 50 Hz to a few kilohertz. A quick check of separation at 5–10 kHz will most likely show a rapid degradation in separation performance.

With the left channel high frequency equalization controls set at minimum, insert the H.F. equalizer in one of the paths. Input 7.5 kHz left channel at a level sufficient to produce 50% envelope modulation. Observe the oscilloscope display while adjusting the H.F. cutoff control. If the phase degrades (display opens), then switch the paths. If it improves, adjust until it closes. Input 1 kHz and re-adjust the group delay to compensate for the added mid-frequency delay, and repeat until 1 kHz and 7.5 kHz are equalized for phase.

If the display at 7.5 kHz is not on the X axis, adjust the H.F. peaking and then the H.F. cutoff until the display lies on the X axis with minimum phase error. Again, adjust the group delay control at 1 kHz to compensate and repeat the procedure until maximum separation is achieved at both 1 kHz and 7.5 kHz. Repeat the procedure for the right channel.

Once this is done, spot check the separation performance from 1–10 kHz. Using good judgement, it may be necessary to compromise the performance at 7.5 kHz to improve it elsewhere. The procedure is identical with the exception of X kHz in place of 7.5 kHz. While there is no such thing as a typical proof, it should be possible to achieve greater than 20 dB separation out to 10 kHz.

The Stereo Proof

When satisfactory separation performance is obtained, the final step in the AM stereo installation is to run a full proof-of-performance, both monaural and stereo. In particular, pay attention to high frequency distortion. It may be necessary to fine tune the equalization to reduce distortion at the expense of a few dB of separation. An acceptable proof should show less than 3% THD and greater than 20 dB separation at all frequencies. This proof is a valuable tool during routine maintenance to gauge performance and to assess whether the equalization needs adjusting.

ROUTINE MAINTENANCE

Any change in the transmission system amplitude or phase response will cause a degradation in stereo performance. These changes will occur for several reasons including: seasonal environment changes, routine transmitter tuning and vacuum tube variations over its lifetime.

It is a good practice to include a spot check of stereo performance as a routine maintenance item. This should be done at an interval of no more than every six months. Left unattended, these normal system variations can cause a serious degradation in audio quality, but a small time investment will insure continued high quality AM stereo performance.

SUMMARY

Properly installed, AM stereo can offer many advantages to the AM broadcaster with the ever increasing pressure for high fidelity audio. Good planning, execution and follow up to the installation, are essential to avoiding the creation of new problems.

C-QUAM SYSTEM EQUATIONS

Any broadcast signal can be broken into three major components: amplitude, frequency and phase. The equation for a monophonic transmission can be described by:

$$E_R = (1 + L + R) \cos (\omega_c t + \varphi)$$

where 1 represents the carrier, L + R represents the monophonic (or left and right) information to be sent, $\omega_c t$ represents the carrier frequency, and φ represents phase modulation information that is, ideally, zero.

In fact as one uses ±100% modulation of L + R as an example and substitutes ±1 into the equation, it is obvious that at L + R = +1, the carrier level is instantaneously twice as high and at L + R = −1, the carrier level is instantaneously 0.0, or cutoff has occurred. From this equation it is also obvious why negative modulation is limited to 100% while positive modulation can exceed 100%. In the United States, the positive limit is 125% or 1.25 in the equation.

To insert stereophonic information, one could alter the amplitude, frequency or phase of the transmitted signal. Altering the amplitude is to be avoided since the envelope would no longer represent 1 + L + R, but instead, a distorted component containing L + R. Substantial alteration of the frequency is also to be avoided. This leaves only the phase component available for modulation.

One method of adding a second channel of information to an existing carrier and utilizing the same spectral assignment is to make use of Quadrature Modulation (QUAM) techniques. Linear QUAM, not unlike that used to convey the chroma information in NTSC color transmission, can be used to convey the second channel of information. Advantages of QUAM are:

- No increase in occupied bandwidth
- Little S/N degradation
- No loss of existing coverage
- The potential for synchronous reception techniques

However, the major disadvantage is that the envelope term is not 1 + L + R, but, instead is:

$$\sqrt{(1 + L + R)^2 + (L - R)^2}$$

leading to high levels of distortion in current monaural, envelope detector receivers and some difficulty in the conversion of existing broadcast transmitters due to additional requirements placed on the modulator stage.

The C-QUAM system was derived from QUAM, therefore it retains, to a large extent, the advantages of QUAM. In fact, C-QUAM can also use synchronous detection techniques particularly when conditions warrant. One difference between the generation of the C-QUAM signal versus the QUAM signal is found in the envelope audio term. By substituting the distorted term required by QUAM with the simple summation of the left and right channels, the envelope is made compatible with existing receivers. Mathematically, the system has been designed as follows.

The equation for the QUAM signal is:

$$E_R = \sqrt{(1 + L + R)^2 + (L - R)^2} \cos (\omega_c t + \phi)$$

$$\text{where } \phi = \tan^{-1}\left[\frac{L - R}{1 + L + R}\right]$$

The desired envelope component is: $E = (1 + L + R)$.

The cosine of the instantaneous phase modulation is:

$$\cos \phi = \frac{1 + L + R}{\sqrt{(1 + L + R)^2 + (L - R)^2}}$$

If QUAM is multiplied by cos φ:

$$\frac{1 + L + R}{\sqrt{(1 + L + R)^2 + (L - R)^2}} \times \sqrt{(1 + L + R)^2 + (L - R)^2} \cos(\omega_c t + \phi)$$

Then the resultant is:

$$E_R = (1 + L + R) \cos(\omega_c t + \phi)$$

$$\text{where } \phi = \tan^{-1}\left[\frac{L - R}{1 + L + R}\right]$$

In the process, the envelope term is made compatible by sending $1 + L + R$ while the in-phase (I) and quadrature (Q) components are multiplied by $\cos \phi$. Therefore the broadcast C-QUAM signal has the following characteristics:

Envelope (E) $= 1 + L + R$
In-phase (I) $= (1 + L + R) \cos \phi$
Quadrature (Q) $= (L - R) \cos \phi$

It can be seen that the mono, $1 + L + R$, signal may be directly derived from the envelope detector output, while a quadratine detector combined with division by $\cos \phi$ may be used to demodulate the $L - R$.

THE C-QUAM ENCODING SYSTEM

There are several forms by which the C-QUAM encoder may be implemented. In the first form, a series of linear, balanced multipliers is employed to generate a quadrature modulated signal. The signal is then amplified to the point of limiting in order to remove the QUAM envelope term. The summation of the left and right channels provides a distortion-free monophonic audio term which modulates the transmitter. The resultant phase modulated signal is used to replace the crystal oscillator stage of the transmitter. The existing broadcast transmitter conveys the L − R information in the form of complex phase modulation, and the envelope conveys the L + R information to both the existing monophonic as well as newer stereophonic receivers.

Other modulation techniques include the matrix switching method and the Time Division Multiplex method. The latter eliminates the need for audio matrices in the stereo modulator path.

To help visualize the generation of the signal, refer to Figure 4.2-A1, the block diagram for the exciter. Since the linear, balanced modulator technique is the easiest to understand, it will be described herein. Interested readers are encouraged to study literature produced by other C-QUAM broadcast equipment manufacturers to obtain a full understanding of the various modulation techniques.

Beginning with the RF stages, a crystal at four times the carrier frequency ($4F_c$) is fed to a digital divider circuit that results in an output that is an on-frequency carrier signal at 0°, 90°, 180° and 270°. These RF signals are utilized in pairs as differential references for three balanced modulators. The purpose of each balanced modulator is to suppress the carrier feedthrough and produce sideband information only when audio is present. It can be seen that the first two modulators are fed with the 0° and 180° reference signals. These modulators, therefore, produce an output referenced in-phase or synchronous to the carrier frequency. The third modulator is, conversely, fed with the 90° and 270° outputs from the RF divider and therefore forms a quadrature modulator stage. The first modulatory is fed with a dc voltage that causes a precise offset from the null of the 0° carrier reference, thereby producing a precise dc carrier term at its output. The second modulator is fed with L + R and therefore produces in-phase, L + R modulation sidebands. The final modulator is fed with L − R audio information and produces quadrature sidebands relating to the stereophonic information. It is important to note that the carrier-producing modulator is used in preference to simply unbalancing the in-phase (L + R) modulator for lower distortion.

The three balanced modulator outputs are summed and band-pass filtered to remove odd-ordered harmonics of the desired carrier frequency. Removal of odd order harmonics prior to limiting is important since odd ordered products represent a dc term that can unbalance the subsequent limiting stage, thereby introducing distortion. After band-pass filtering, the RF signal is amplitude limited by multiple stages that exhibit approximately 50 dB of limiting gain. The envelope component is therefore removed, leaving only the phase-modulated carrier component. This constant amplitude RF signal is then further amplified to a level adjustable from zero to 30 V, peak-to-peak. It is this amplified, constant amplitude carrier signal that is interfaced to the transmitter to create the composite stereo transmission.

Unlike FM stereo where a composite signal is fed into a wideband modulator input, the AM stereo signal is constructed at the power amplifier stage of the converted broadcast transmitter. A portion of the signal from the exciter enters the transmitter through an RF interface and follows one path to the RF power amplifier, while the remaining element, L + R, enters through the audio input terminals and follows a different path to the modulator where it is finally combined with the RF phase modulated information. Since two different circuit paths are used, the time delay along each path may be different, often by 40 μsec or greater. This level of delay can be understood when one considers the phase shift through the low pass filter in a conventional PDM transmitter that may exhibit a fifth or seventh order elliptical function. If the delay between the paths is not matched, both reduced separation and increased distortion will result. Loss of separation is easily understood since proper dematrixing of the

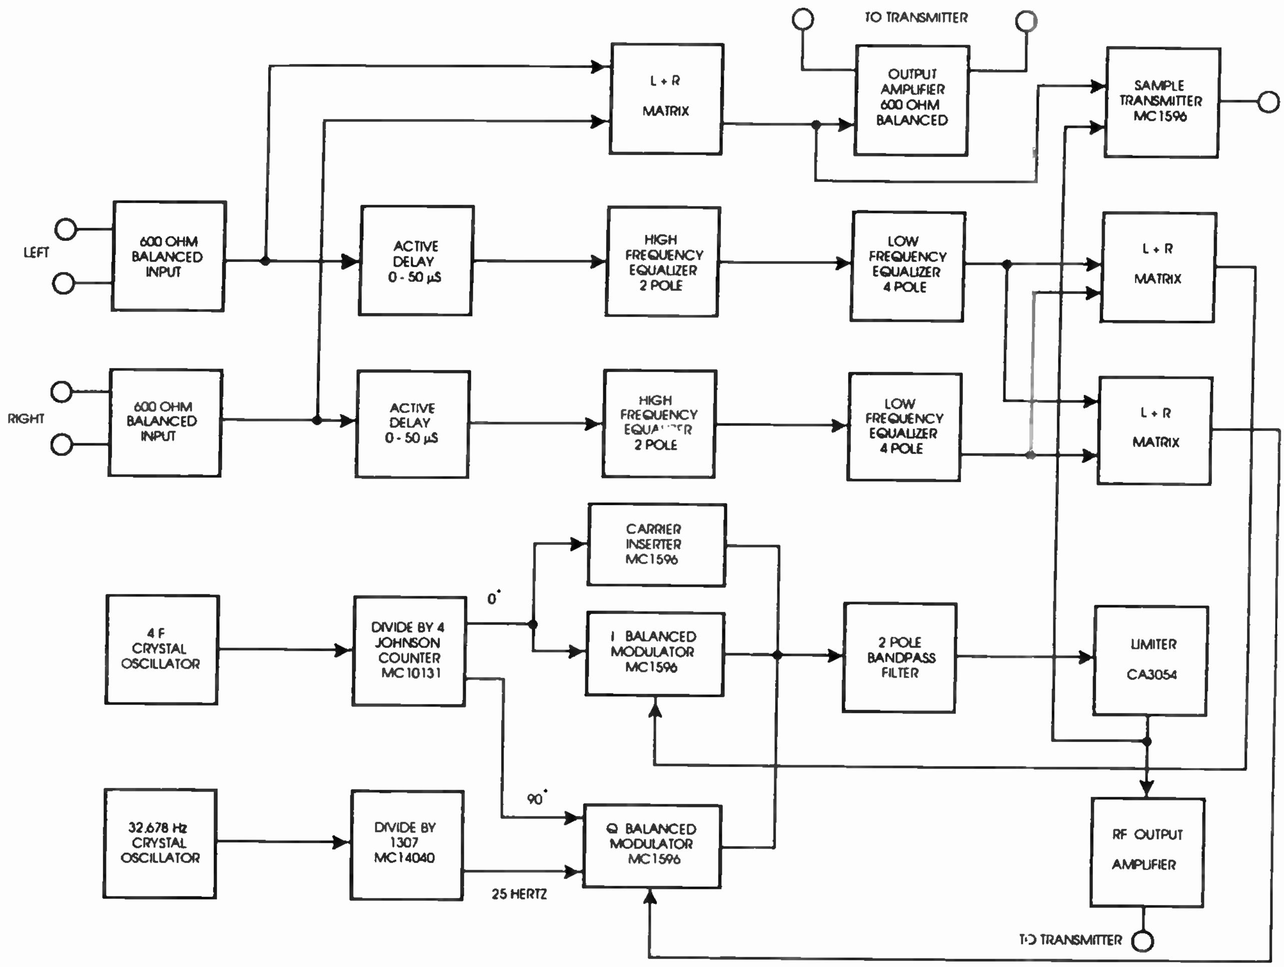

Figure 4.2-A1. Block diagram of C-QUAM exciter.

audio signals in the receiver will occur only if the phase and amplitude of L + R and L − R are closely matched. The increase in distortion is a concept that can only be clearly understood when one examines the phase modulated component of the signal and finds that an L + R term is found in the PM component. If this L + R term does not match the envelope term, an increase in distortion would result. Therefore, the audio equalizer is a very important section of the exciter.

In the simplest form of equalization, a delay circuit in the audio path to the quadrature modulator section of the exciter would be utilized, thereby introducing time delay into the L + R and L − R audio fed into the QUAM generator so that it matches the L + R audio delay through the broadcast transmitter. Although adequate results will occur with this approach, a modification of this approach allows for additional correction of the signal to compensate for bandwidth or sideband symmetry problems commonly associated with broadcast antenna systems, particularly directional arrays.

A once common form of single sideband generation particularly popular in the 1950s, utilized a scheme known as the *phasing method*. The process was simple because one could simultaneously amplitude and phase modulate a signal, essentially generating a QUAM signal. If the process is taken one step further so that both the RF terms and the audio terms fed to each modulator are shifted 90°, a single sideband transmission results without the use of expensive, sharp cutoff RF filters. The same holds true for AM stereo signal generation. If a small amount of phase shift is introduced into the audio driving the phase modulated path of the transmitter with reference to the envelope audio path, the signal will take on an unsymmetrical sideband structure. If the antenna system exhibits an overall tilt towards the upper sidebands, for example, one would only need to predistort the signal so the lower sidebands were favored in the transmitter, thereby restoring symmetry in the radiated signal.

The exciter can perform this task by inserting the delay sections into the left and right channels prior to matrixing. It is clear from Figure 4.2-A1 that this is the case for most C-QUAM exciters. The audio is delayed independently in the left and right channels. It is then matrixed to produce L + R and L − R that feed the QUAM generator. An uncompensated summation of L + R is used to feed the external broadcast transmitter. Such equalization, known as *differential equalization*, can be quite powerful in correcting situations where asymmetrical antenna sideband radiation would otherwise limit stereo performance.

The audio equalizer is broken into several components. The first is the *constant time delay circuitry* that is used to compensate for the bulk of differential transit delays through the transmitter. The second section is the *high frequency equalizer* that is used to compensate for additional phase shift (nonlinear group delay) characteristics in the broadcast transmitter audio path. These non-linear delay characteristics are introduced by rolloff in the modulator stages, phase shift in PDM filters, and reflected antenna impedances. The final section is the *low frequency equalizer* which, not unlike tilt correction commonly found in audio processors and limiters, anticipates the phase shifting and amplitude rolloff action of modulation transformers, reactors and coupling capacitors in older, plate modulated transmitters. By introducing a similar rolloff and phase shift into the phase modulated audio path, separation may be maintained at frequencies below 50 Hz.

The last section of the exciter to be discussed is the *pilot generator*. The *pilot tone*, a 25 Hz sine wave audio component, is injected into the L − R modulator at a 5% modulation level in the L − R channel. The purpose of the pilot tone is to indicate the presence of stereophonic information. This is different from the pilot tone signal in the FM stereo system where the 19 kHz signal is used as a synchronizing term in the demodulator. Indeed, AM stereo receivers could be built without the pilot tone detector, however, the consumer has grown accustomed to seeing a stereo indicator on the radio, hence it is incorporated into the system.

C-QUAM DECODING/RECEIVING TECHNIQUES

There are over a dozen ways to decode a C-QUAM transmission. The most common approach is the *feedback decoder* technique (see Figure 4.2-A2). In this drawing, there are three detectors: envelope, in-phase and quadrature.

The envelope detector demodulates the monophonic, L + R information. It may be a simple diode detector, however, most stereo demodulator integrated circuits utilize a limiter/multiplier approach that offers superior performance. Distortion measurements in the 0.1%–0.3% region are commonly found at 99% negative modulation when this technique is used.

The in-phase and quadrature demodulators are identical in action to the balanced modulators found in the exciter. Each has a reference signal, either 0° for the I detector, or 90° for the Q detector, and is phase

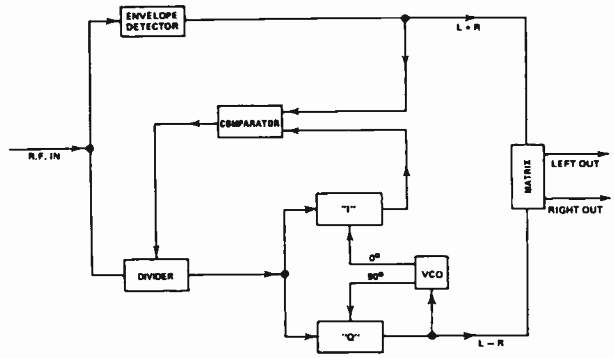

Figure 4.2-A2. Block diagram of feedback decoder.

locked to the incoming, received signal. However, referring back to the system equation, the actual received I signal is not 1 + L + R, but instead, (1 + L + R) cos ϕ, and the received quadrature signal is (L − R) cos ϕ rather than L − R as desired. In a proper C-QUAM decoder, the incoming RF/IF signal must be divided by the term cos ϕ, generally prior to quadrature demodulation. In the feedback decoder, the divider stage accomplishes this task. The derivation of the cos ϕ term conveyed in the phase modulated component is, however, an interesting process.

As indicated earlier, the I detector output would, since it is both phase and amplitude sensitive, be (1 + L + R) cos ϕ assuming no divider action. If the cos ϕ component is eliminated from the I detector output, the I detector would produce a signal identical in theory to the envelope detector. Assuming further that the I and Q detectors are fed from the same IF signal path, as cos ϕ is removed from the I detector output, it is also removed from the Q detector output, leaving L − R as the result. Since it is known that the IF signal must be divided by cos ϕ, a divider stage is placed in the IF path feeding the I and Q detectors. If the output of the I detector is then analyzed against the envelope detector output in a high gain comparator, the resultant is cos ϕ. By connecting the output of the comparator to the control port of the divider, a feedback loop results that will cause the cos ϕ signal normally found at the output of the I detector to be effectively transferred to the input of the divider. Since the IF path is therefore divided by cos ϕ, the Q detector performs the task of directly demodulating L − R.

The remaining circuitry in the decoder detects the pilot tone and dematrixes the L + R and L − R audio terms into the original left and right components.

PERFORMANCE CONSIDERATIONS

The C-QUAM system is capable of on-air performance figures in excess of 40 dB separation and under 1% distortion from 100–5000 Hz, particularly on newer solid state broadcast transmitters. It is not uncommon to obtain separation figures in excess of 30 dB from 50 Hz to the 10 kHz NRSC limit.

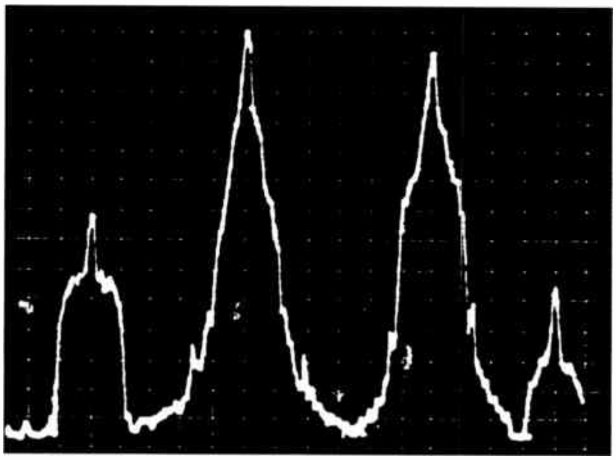

Figure 4.2-A3. Spectral photograph of four C-QUAM broadcasts.

RF spectra is also well controlled within the NRSC limits of occupied bandwidth now adopted by the FCC. A spectral photograph of four C-QUAM stations, three of which operate at a power level of 50 kW, depicts the spectral signal of C-QUAM broadcasts. It is virtually indistinguishable from monophonic broadcasts (see Figure 4.2-A3).

The broadcaster is free to choose the type of audio limiting desired for use with the C-QUAM signal with the exception that, if matrix type limiters are utilized, they must contain single channel limiting circuitry or the single channel limiter found in all C-QUAM exciters must be enabled. Since the L + R monophonic signal is summed and directly coupled to the broadcast transmitter, no additional tilt or overshoot is placed upon the audio allowing full modulation of the envelope component. The modulation constraints of the system are as follows:

- L + R (Monaural modulation) +125, −100% (FCC limits − higher mod is possible)
- L − R (stereo Difference channel only) ±100% (±45° phase modulation)
- L, R only (single channel, ref. to L + R) +125, −75% (limit of 71.56° phase modulation)
- *Pilot Tone* (injected into L − R channel) 25 Hz ± 0.1Hz, 5% +1/−0% injection level, sine wave.

In addition, audio preemphasis may be used. Motorola recommends use of the NRSC modified 75 μsec standard, however, tests with up to 30 dB preemphasis yield operation within FCC occupied bandwidth limits. The C-QUAM system has been used at audio bandwidths up to 15 kHz with excellent results, however, the FCC Rules limit audio bandwidth and subsequent RF emissions to 10 kHz as defined by the NRSC guidelines.

Use of the C-QUAM system will not reduce the monophonic coverage of the broadcast station. Since the envelope is sent as a compatible signal (the amplitude modulation of the station continues as 1 + L + R), the stereo component should pass undetected in existing mono receivers and full modulation of the envelope may be contemplated. The stereo receiver will experience a slight S/N degradation due to the fact that a second channel of information has been opened to allow passing of the stereo information. The degradation is usually under 3 dB and is typically 1.5 dB, which is nearly imperceptible under normal stereo programming conditions. All C-QUAM receivers contain circuitry that restores the receiver to mono reception when conditions warrant, thereby assuring no loss of coverage to the listener.

Receiver technology continues to expand with the advent of newer generation C-QUAM decoders. Original decoder IC's demodulated the incoming signal but performed very little conditioning of the signal to extend the performance of the receiver. Later generation decoders contain circuits that allow new receivers to be designed with adaptive bandwidth and synchronous detection features that improve reception under weak signal conditions. The MC13022 decoder IC, (see Figure 4.2-A4(a) and (b)), contains such circuitry that allows receiver designers to produce radios that operate at NRSC bandwidths under stronger signal conditions and automatically variable bandwidths sliding to 3–4 kHz under weak incoming signal conditions. The merits of such a system are obvious. The listener can enjoy wideband AM reception when signal conditions warrant while the receiver will automatically reduce the bandwidth under poor conditions, thereby retaining the listener. In addition, NRSC deemphasis is easily implemented with the MC13022.

INTRODUCTION

Although the mathematical principles explaining frequency modulation (FM) had been known for many years, the advantages and practical application to radio broadcasting were not realized until the 1930s, when Major Edwin H. Armstrong did extensive developmental work proving that FM radio transmissions were possible. Many theoreticians claimed to have proof that Armstrong's experiments were impossible based on mathematical models claiming that an infinite transmission bandwidth would be required. He never received proper credit for his many contributions to the radio communications industry during his lifetime.[1]

Among the advantages of FM are freedom from static, wide audio bandwidth and the ability of an FM receiver to capture the stronger of two signals transmitted on the same carrier frequency.

In 1940, following extensive public hearings, the Federal Communications Commission (FCC) established the FM Broadcast Service and set aside 40 channels in the 42 to 50 MHz band with commercial operation scheduled to begin January 1, 1941. Although World War II stopped all non-military radio construction, more than 40 FM stations continued to serve over 400,000 receivers. To eliminate the interference problems resulting from skywave reflection in the prewar FM band, the Commission moved the FM Broadcast Service to the 88 to 108 MHz band in 1945, thereby increasing the number of available channels to 100. However, the expected growth of FM broadcasting did not materialize. Since conversion of prewar FM receivers to the new band was not practical, purchase of a new receiver was the only way to receive the new FM stations. Television appeared to offer much more to the consumer than FM radio, since most FM stations merely duplicated the programming of an affiliated AM station.

Despite the potential for a higher quality broadcast service, there was little public demand for new FM receivers and virtually no public reaction when FM stations dropped popular programs from their schedule or were off the air due to equipment failures. It is not surprising, therefore, that in May 1950, there had been only 16 new FM license applications during the previous 15 months in which 259 FM stations ceased operations. It was not until after the introduction of stereo multiplex FM broadcasting that public awareness of the FM band increased and then skyrocketed in the 1970s to make FM the dominant medium for musical programming.

CHARACTERISTICS OF FM COMPARED TO AM

The 88–108 MHz FM broadcast band is relatively free of atmospheric and other noise interference. Emission at these frequencies is not propagated great distances by the ionosphere as it is in the 550–1600 kHz AM broadcast band. Therefore, noise from lightning discharges is limited to line-of-sight distances and is almost negligible. Man-made noise is a far greater source of interference, particularly in urban areas. The level of manmade noise falls off at increasing higher frequencies so that the microvolts-per-meter noise level is about one-tenth as great in the FM band as it is in the AM band.

In addition, FM has an improved noise threshold characteristic when compared to AM. Limiting circuitry symmetrically clips the RF waveform in an FM receiver to remove any amplitude variations produced by static or impulse noise before they reach the demodulator which responds only to phase or frequency changes in the signal. The FM improvement factor is illustrated in Figure 4.3-1. Note the sharp knee in the threshold curve above which noise and interference are suppressed, which results in an improved signal to noise (S/N) ratio. This same *capture* effect causes a weaker FM signal on the same channel to be suppressed, resulting in greatly reduced co-channel interference.

For even greater noise reduction, preemphasis (75 μsec time constant) is employed in the transmitter whereby the audio frequency components above about 2.1 kHz are boosted in amplitude at the rate of 6 dB per octave before being applied to the modulator. Flat frequency response is restored in the receiver's deemphasis network by attenuating the higher frequencies the same amount they were boosted in the transmitter. At the same time, the high frequency noise components which are characteristic to FM are also attenuated, resulting in greatly reduced background noise. Preemphasis is discussed in more detail in the FM theory and FM exciter sections of this chapter.

The net result of the above factors is a much better signal-to-noise ratio on FM than on AM. The lower background noise, along with the wider frequency response of FM versus AM (by virtue of its 200 kHz

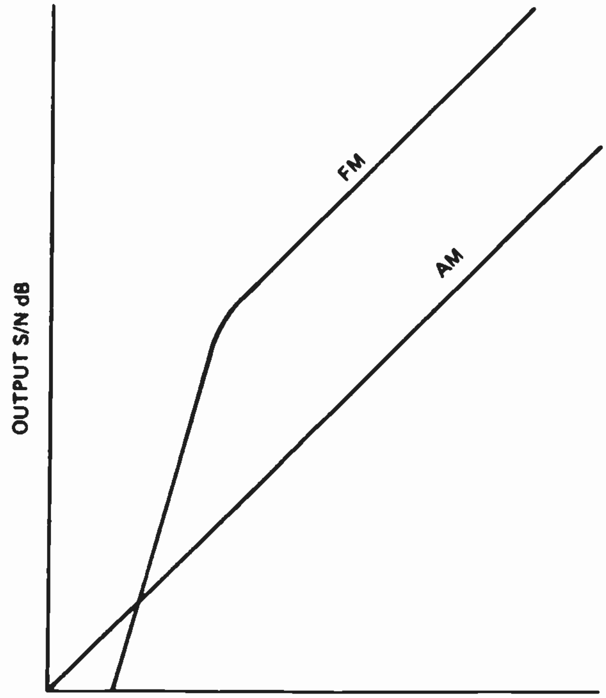

Figure 4.3-1. FM improvement factor.

channel bandwidth) means that a signal of higher quality and wider dynamic range can be enjoyed.

Occupied Bandwidth

The advantages of the FM broadcast medium over the AM broadcast medium do not come free of compromise. A standard FM broadcast channel occupies more than 10 times the bandwidth of an AM broadcast channel. This is because the more complicated nonlinear sideband structure of a frequency modulated carrier with wide deviation requires much more bandwidth than the simpler linear distribution of sidebands in an AM system. More details on the amplitude and spacing of FM sidebands are given in the section on FM modulation theory in this chapter.

High Fidelity

Uniform frequency response over the audible range of at least 50 Hz to 15 kHz, very low amplitude distortion (harmonic and intermodulation), very low noise level and good transient response (uniform time delay versus frequency) are necessary for hi-fi performance. The FM channel authorizations provide for adequate audio frequency response and a low-noise radio link to the listener. The rest of the performance is a matter of equipment design.

Stereophonic Transmission

The wide channel allocations and ability of FM to multiplex compatibly several audio channels on one carrier permitted development of a practical stereo broadcasting system. This has enabled the broadcast industry to provide the public with reproduction quality as good as or better than that which is available on stereo records or tapes. The advent of the compact disc and other digital audio source equipment will continue to challenge equipment manufacturers and station engineers further to improve the performance of the entire FM broadcast chain and to convert to an all digital audio transmission path. Recently introduced digital audio signal processing, uncompressed digital studio to transmitter links and digital DDS FM exciters now make it possible to 100% digitally convey the exact, "bit-for-bit," audio data from a compact disc to the FM transmitter power amplifier without any intervening analog to digital (A/D) conversions or distortions. Detailed technical information about stereophonic transmission theory and standards is provided in Chapter 4.4 "FM Stereo and SCA." See [27] at the end of this chapter for further information about digital FM exciter technology.

Subsidiary Communications Authorization (SCA)

The wide channel bandwidth authorized for FM broadcasting also makes it feasible to multiplex subsidiary audio or data channels commonly referred to by the FCC as Subsidiary Communications Authorization (SCA) together with the stereo transmission. SCA channels provide an important source of revenue to many stations as well as provide many useful audio and digital services to the community. Detailed technical information about SCA transmission theory and standards is provided in Chapter 4.4 "FM Stereo and SCA."

The AES/EBU Digital Serial Audio Data Interface Standard

Just as serial data can be used to pass information between computers, printers and modems, so various interconnect standards have been developed to transfer digitized audio data between components in an all-digital broadcast facility. AES3 is the digital audio data interface standard for audio sources, mixing equipment, audio processing equipment, studio to transmitter link (STL) equipment and transmitter inputs. The European Broadcasting Union (EBU) has republished a standard which is identical to the AES3 standards, except for the use of transformer-coupled inputs and outputs. The format of the AES3 data subframe is shown in Figure 4.3-2.

Some highlights of the AES3, 1992 (r1997) data format are:

- The interface format can accommodate 16, 20 or 24-bits of digital audio information
- The interface handles serial data transmission of two channels of digitized audio over distances of up to 500 ft using balanced cable specifically designed for the AES3 transmission standard. Transmission distances of up to 50 ft can be realized over a conventional shielded, twisted-pair, audio wire, when properly terminated

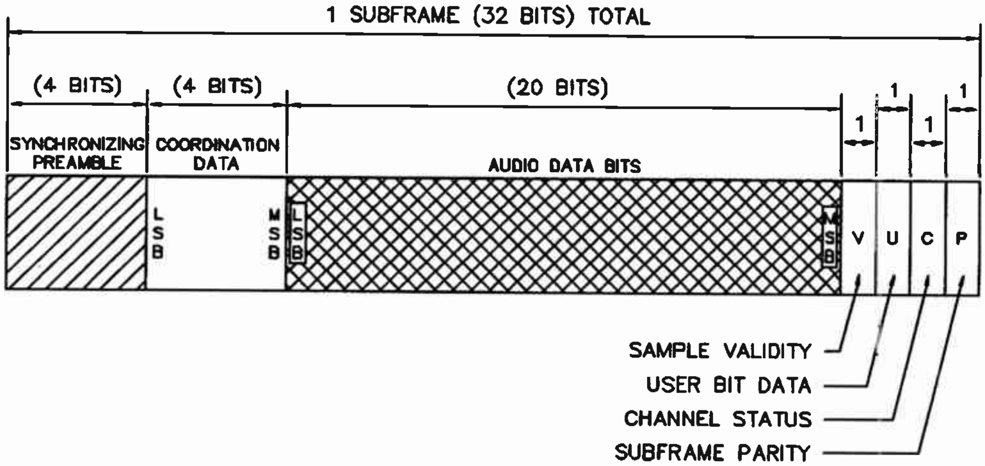

Figure 4.3-2. Thirty two-bit subframe format of AES/EBU serial data.

- The interface uses standard 3 pin, XLR-type connectors, carrying balanced, RS-422 compatible signals that are polarity independent. The input and output impedance for the interface is 110 ohms
- The data is sent least significant bit (LSB) first, with alternating subframes for Channel 1 and Channel 2
- The data is self-clocking and does not require an additional CLOCK connection to synchronize the source and destination. The SYNC data allows digital equipment to recognize the start of each 32-bit block of audio data and synchronize the master clocks
- There are four ancillary bits for validity, user bit, channel status and parity
- The validity bit indicates whether the audio sample data bits are valid and error free
- The user bit carries hardware or system specific information
- The channel status carries data concerning emphasis, sampling frequency and various other information
- The parity bit provides even parity over the current subframe, allowing simple detection of transmission errors.

The acceptance of the AES3 data interface standard by major broadcast equipment manufacturers makes it possible to build an all digital studio with an all digital link to the transmitter using standard off-the-shelf equipment. The standard AES3 transmit and receive chipsets support the three commonly used sampling rates of 48.0 kHz (studio), 44.1 kHz (consumer CD) and 32.0 kHz (broadcast transmission). Since the current FM stereo transmission standard limits the frequency response of the left and right channels to a maximum of 15 kHz, a 32.0 kHz sampling rate is often used. There are situations, particularly in the studio environment, where the higher 48.0 kHz sampling rate may be desired, so make sure that all the interfacing equipment has the ability to accept both the studio and broadcast transmission data rates. For further information on the AES3 standard and the transport of digital audio, see [28, 29, and 31].

FCC Transmission Standards

The FCC regulates and enforces the technical standards that apply to radio broadcasting in the United States. In theory, this ensures that the public is provided with a consistently high standard of transmission quality from station to station. The rules and regulations covering radio broadcast services, including those for FM broadcast transmitters are set forth in Part 73 of the Code of Federal Regulations (CFR) available from the U.S. Government Printing Office in Washington, D.C. The rules and regulations are changed from time to time to keep pace with new technology and changes within the broadcast industry. Every broadcast engineer should have access to a current copy these rules and regulations so that the station's technical performance is maintained within the prescribed limits.

FREQUENCY MODULATION THEORY

Angular Modulation

Frequency modulation (FM) and phase modulation (PM) are both special cases of angular modulation. In any angular modulation system both the frequency and phase of the carrier vary with time as a function of the modulating signal.

The relationship between the frequency deviation of the carrier, the phase deviation of the carrier and the sinusoidal modulating frequency is defined as the modulation index (m).

Where:

$$m = \frac{\text{frequency deviation (peak-to-peak Hertz)}}{\text{modulating frequency (Hertz)}} \quad (1)$$

Since frequency modulation and phase modulation are both subsets of angular modulation, they are virtually indistinguishable from one another except in the modulator characteristics.

In a PM system, the modulating signal causes the phase of the carrier wave to vary according to the instantaneous amplitude of the modulating signal. A phase modulator generates a constant amount of phase deviation of the carrier with a constant amplitude modulating signal independent of the frequency of the modulating signal. The frequency deviation of the carrier produced by a phase modulator does increase as the modulating frequency is increased even though the level of the modulating voltage is held constant. The net effect is that the phase modulator behaves as if it were a frequency modulator with a 6 dB/octave rising slope on the modulating signal input.

A frequency modulator generates a constant frequency deviation of the carrier with a constant amplitude modulating signal independent of the frequency of the modulating signal. The phase deviation of the carrier produced by a frequency modulator decreases as the modulating frequency is increased even the though the level of the modulating voltage is held constant. The net effect is that the frequency modulator behaves as if it were a phase modulator with a 6 dB/octave falling slope on the modulating signal input.

In FM broadcasting, the signal carrier should have frequency deviation that is proportional to the amplitude of the modulating signal, but independent of the frequency of the modulating signal as generated by a frequency modulator.

The instantaneous frequency (rate of change of phase) of the RF output wave differs from the carrier frequency by an amount proportional to the instantaneous amplitude of the modulating waveform. For example, consider a 100 MHz carrier wave frequency modulated by a 1,000 Hz audio tone and assume that a 1 volt input to the modulator causes ±20 kHz of frequency deviation on the positive and negative peaks of this tone. If the audio input amplitude is increased to 2 V, the peak deviation will become ±40 kHz varying in sine-wave fashion from one peak of deviation to the other and back again at the 1,000 Hz rate. In FM broadcasting, the FCC has defined 100% modulation as modulation which results in a peak frequency deviation of ±75 kHz of the RF carrier.

When preemphasis is used ahead of the frequency modulator, the system becomes a phase modulator at audio frequencies above the turnover point of the preemphasis network. This is because the frequency response of the preemphasis network rises at the rate of 6 dB/octave above this point. FM broadcasting with preemphasis really becomes a mixture of FM at low modulating frequencies and PM at high modulating frequencies.

FM Sideband Structure

The frequency modulated RF output spectrum contains many sideband frequency components, theoretically an infinite number. Consider, as an example, an RF carrier of frequency f_c modulated by a sinusoidal signal with frequency f_m ($f_m < f_c$). The spectrum consists of pairs of sideband components spaced from the carrier frequency by multiples of the modulating frequency. When the modulation index is small (m = 0.5), the amplitude of the second and higher order sidebands is small so that the output consists mainly of the carrier and the pair of first-order sidebands, as illustrated in Figure 4.3-3(a). The total transmitter RF output power remains constant for a given modulation waveform, but the distribution of that power into the sidebands varies with the modulation index such that power at the carrier frequency (and lower order sidebands) is reduced by the amount of power added to the higher order sidebands.

As the modulation index is increased (as in wide deviation FM broadcasting), the higher order sidebands become more prominent. The amplitude and phase of the carrier as well as the sidebands can be expressed mathematically by making the modulation index (m) the argument of a simplified Bessel function:

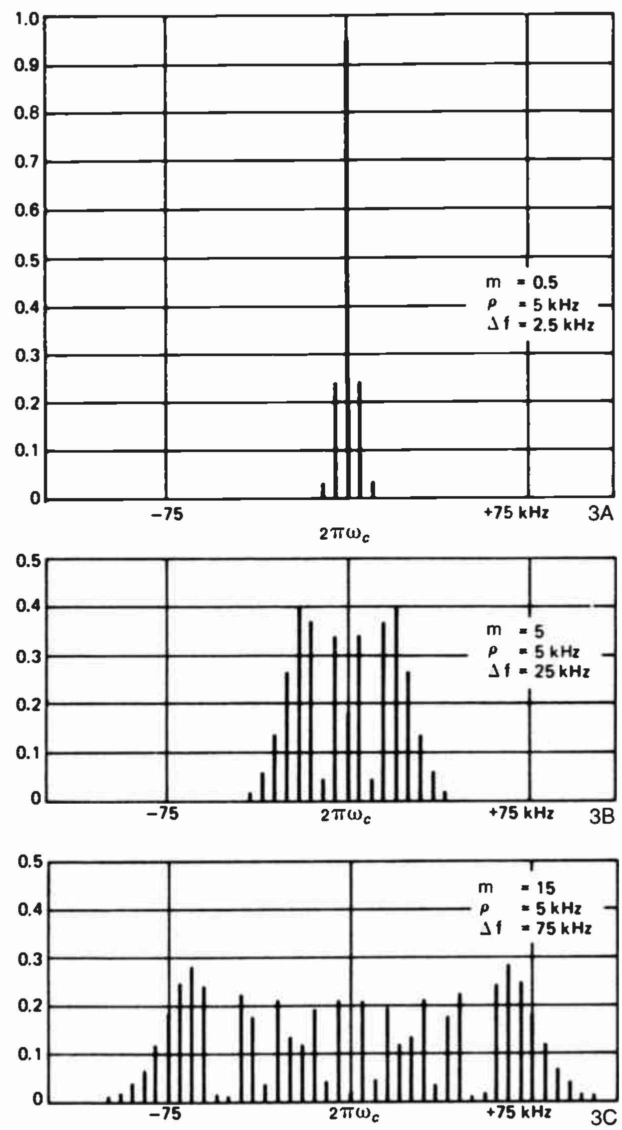

Figure 4.3-3(a), (b), (c). RF spectrum with modulation indexes of 0.5, 5.0 and 15.

$E(t)$ = Total RF Output Voltage (2)

$A[J_0(m) \sin \omega c(t)]$ carrier amplitude
$+[J_1(m) \sin (\omega c+\omega m)t]$ first order upper sideband
$-[J_1(m) \sin (\omega c-\omega m)t]$ first order lower sideband
$+[J_2(m) \sin (\omega c+2\omega m)t]$ second order upper sideband
$+[J_2(m) \sin (\omega c-2\omega m)t]$ second order lower sideband
$+[J_3(m) \sin (\omega c+3\omega m)t]$ third order upper sideband
$-[J_3(m) \sin (\omega c-3\omega m)t]$ third order lower sideband
$\pm[J_n(m) \sin (\omega c\pm n\omega m)t]$ higher order sidebands

where:

A = Unmodulated carrier amplitude constant
$J_0(m)$ = (modulated) carrier amplitude (a function of modulation index)
$J_1(m)$ = Amplitude of first order sidebands
$J_2(m)$ = Amplitude of second order sidebands
$J_n(m)$ = Amplitude of nth order sidebands
m = The modulation index
ωc = $2\pi F_c$ (The carrier frequency in radians/second)
ωm = $2\pi F_m$ (The modulating frequency in radians/second)

The numeric values of the Bessel functions, $J_0(m)$ through $J_n(m)$, which express the amplitudes of the various frequency components can be found in mathematical tables. Figure 4.3-4 shows a graphical representation of how the Bessel function values for the carrier and the first eight pairs of sidebands vary with the modulation index.

In a monophonic FM broadcast transmitter, the modulation index can become very high at low modulating frequencies. With a 50 Hz audio input signal of sufficient amplitude to produce 75 kHz deviation (100% modulation), the modulation index is:

$$m = \frac{75{,}000}{50} = 1{,}500 \qquad (3)$$

With a 15,000 Hz input at the same deviation (also 100% modulation), the modulation index is only:

$$m = \frac{75{,}000}{15{,}000} = 5 \qquad (4)$$

Figures 4.3-3(b) and 4.3-3(c) illustrate the frequency components present for modulation indices of 5 and 15. Note that the number of significant sideband components becomes very large with a high modulation index. For a given modulation index, the total bandwidth occupied can extend beyond ±75 kHz from the carrier depending upon the modulating frequency.

This single tone modulating frequency analysis is useful in understanding the general nature of FM and for making tests and measurements. When audio program modulation is applied, there are many more sideband components present. They vary so much that sideband energy becomes distributed over the entire occupied bandwidth rather than appearing at discrete frequencies.

Bessel Nulls

At certain modulation indices, the amplitude of the carrier component of the signal goes to zero, with all the transmitted power being distributed at frequencies other than the carrier frequency. This carrier null phenomenon is useful as an extremely accurate method for measuring the frequency deviation and to check the calibration of modulation monitors. Referring again to Figure 4.3-4, note that the carrier amplitude goes to zero and reverses sign at several values of modulation index including: 2.405, 5.520 and 8.654. Figure 4.3-5

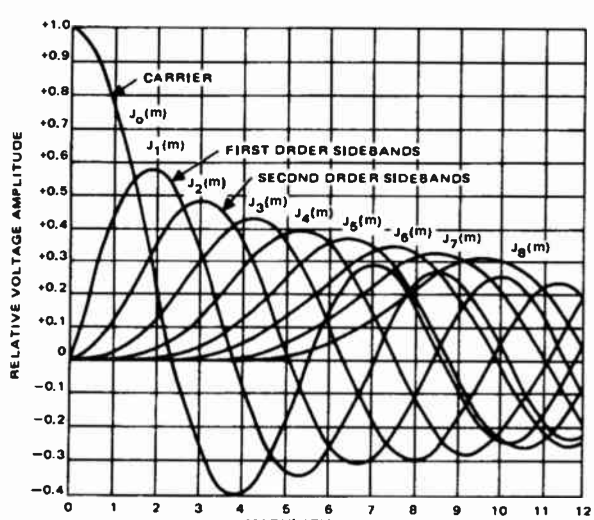

Figure 4.3-4. Relationship of carrier and sideband amplitudes to modulation index.

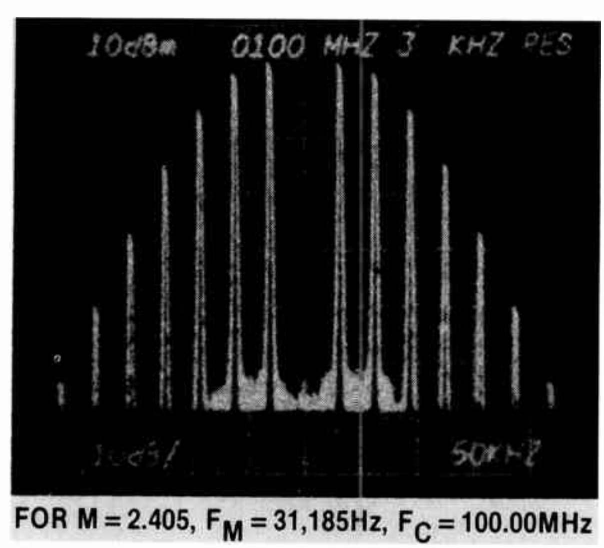

Figure 4.3-5. FM RF spectrum showing occupied bandwidth and Bessel Null of a single tone at ±75 kHz deviation.

Table 4.3-1
Sideband nulls as a function of modulation index and modulating frequency.

	Modulation Index (M)		(F_m) FOR 75 kHz Deviation	
Null	Carrier	First Sidebands	Carrier	First Sidebands
1ST	2.405	3.832	31,187	19,574
2ND	5.520	7.016	13,587*	10,690
3RD	8.654	10.174	8,667	7,372
4TH	11.792	13.324	6,361	5,629
5TH	14.943	16.471	5,023	4,554
6TH	18.071	19.616	4,150	3,823
7TH	21.212	22.759	3,536	3,295

* This tone is recorded on track 38 of the NAB Broadcast Audio System Test CD.

is a photograph taken from an RF spectrum analyzer showing the first Bessel null ($M = 2.405$) of a carrier at a frequency of 100 MHz.

To determine the audio input level required to achieve 75 kHz deviation, apply an audio tone of exactly 8,667 Hz (75,000 divided by 8.654). Starting from zero amplitude, increase the audio level until the carrier disappears for the third time (since 8.654 corresponds to the third Bessel null). At this audio level, the deviation is exactly 75 kHz. The carrier amplitude (null) detector must have sufficient selectivity to separate the carrier from the sidebands and could be a spectrum analyzer or a receiver with a narrow IF bandwidth. The FM signal can be heterodyned down to a convenient frequency for measurement, since heterodyning does not alter the modulation index. However, when a frequency (or phase) modulated wave is multiplied or divided, this also multiplies or divides the frequency deviation and the modulation index by the same amount.

A listing of useful carrier and first order sideband nulls as function of the modulation index (M) and the modulating frequency (F_m) is given in Table 4.3-1.

Occupied Bandwidth

After examining the Bessel functions and the resulting spectra, it becomes clear that the occupied band-width of an FM signal can be far greater than the frequency deviation of the signal. In fact, the occupied bandwidth is infinite (if all the sidebands are taken into account), so it is now clear that a frequency modulation system would require the transmission of an infinite number of sidebands for perfect demodulation of information. In practice, a signal of acceptable quality can

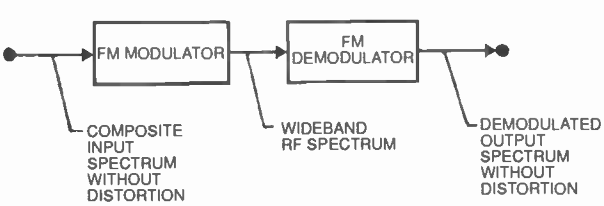

Figure 4.3-6(a). Wideband RF path.

be transmitted in the limited bandwidth assigned to an FM channel.

Effects of Bandwidth Limitation

Practical considerations in the transmitter RF circuitry make it necessary to restrict the RF bandwidth to less than infinity. As a result, the higher order sidebands will be altered in amplitude and group delay (time). Bandwidth limitation will cause distortion in any FM system.

Consider the block diagram shown in Figure 4.3-6(a), where a perfect FM modulator is connected to a perfect demodulator via an RF path of infinite bandwidth. The demodulated audio shown in Figure 4.3-6(b) contains no distortion components.

In Figure 4.3-7(a), a bandpass filter is inserted between the modulator and demodulator in order to restrict the bandwidth. Audio distortion products now appear at the output of our perfect demodulator as shown in Figure 4.3-7(b). These distortion products are due solely to the bandwidth restriction (300 kHz BW_3) imposed by the bandpass filter.

Figures 4.3-8(a) and 4.3-8(b) show the effects of a narrowband RF bandpass filter on the RF spectrum of a composite signal consisting of a stereophonic subcarrier modulated only on the left channel with 4.5 kHz plus a 67 kHz unmodulated SCA subcarrier. In Figure 4.3-8(a) through a wideband RF path, there are no baseband distortion products in the demodulated spectrum. Figure 4.3-8(b) shows the corresponding effects observed on the demodulated baseband spectrum for the same signal through a narrowband filter. The only distortion evident on the RF spectrogram is the loss of some sidebands greater than 150 kHz from the center frequency and some amplitude differences between the upper and lower sideband pairs. Note the creation of many undesired intermodulation terms in the demodulated baseband spectrum which cause crosstalk into both the stereophonic and SCA subcarrier bands. The change in the RF spectrum is subtle, but the resulting spectrum after demodulation is clearly modified.

As one can see, the distortion in any practical FM system will depend on the amount of bandwidth available as well as the modulation index being transmitted.

Group Delay Symmetry versus Amplitude Response Symmetry

While both the amplitude response and time response (group delay) have an effect on the amount of distortion added to the FM signal, the symmetry of the group delay response is more important than the total group delay variation or the amplitude response.

Best FM modulation performance is always obtained when the system is tuned for symmetrical group delay (time) response. Depending on the circuit topology, the tuning conditions for symmetrical group delay response may not coincide with the symmetrical amplitude response.

Limiting Factors within an FM Transmitter

Relating the specific quantitative effect of the bandwidth limitations imposed by a particular transmitter to the actual distortion of the demodulated composite baseband is a complicated problem indeed. Some of the factors involved are:

- Total number of tuned circuits involved
- Amplitude and group delay response of the total combination of tuned circuits in the RF path
- Amount of drive (saturation effects) to each Class C stage
- Nonlinear transfer function within each amplifier stage.

Improvement of the RF Path

The following design techniques can help improve the transmitter's bandwidth:

- Maximize bandwidth by using a broadband exciter and a broadband intermediate power amplifier (IPA) stage
- Use a single-tube design or a broadband, completely solid-state design where feasible
- Optimize both grid circuit and plate circuit of the tuned stage for the best possible bandwidth and symmetrical group delay response
- Minimize the number of interactive tuned networks
- Use a broadband antenna system that that provides a low standing wave ratio on the transmission line. For more detailed information about FM and digital modulation theory, see [2, 3, 4, 27, and 32].

PREEMPHASIS

The standards adopted for FM broadcasting in the U.S. require the use of preemphasis. The standard preemphasis curve is defined as an ideal RC network with a time constant of 75 microseconds. The 3 dB point is at a frequency of:

$$f = \frac{1}{2\pi(RC)} = \frac{1}{2\pi(75 \times 10^{-6})} = 2{,}122 \text{ Hz} \quad (5)$$

The 75 microsecond curve and the tolerance allowed by the FCC are shown in Figure 4.3-9. The frequency response characteristics in decibels for several popular preemphasis time constants are given in Table 4.3-2.

The reduction in receiver output noise due to the use of preemphasis in monophonic transmission is illustrated in Figure 4.3-10 (for 75 μsec preemphasis case). The noise voltage in a narrow bandwidth (for example, 1 Hz) increases directly with frequency, therefore, the power spectral density increases as the square of frequency as shown. When preemphasis is used, the noise voltage is attenuated above 2.1 kHz so that it remains constant with frequency. The power spectral density is also constant above 2.1 kHz. The area between these curves represents the noise power that is removed by the use of preemphasis. This diagram indicates the importance of preemphasis for high

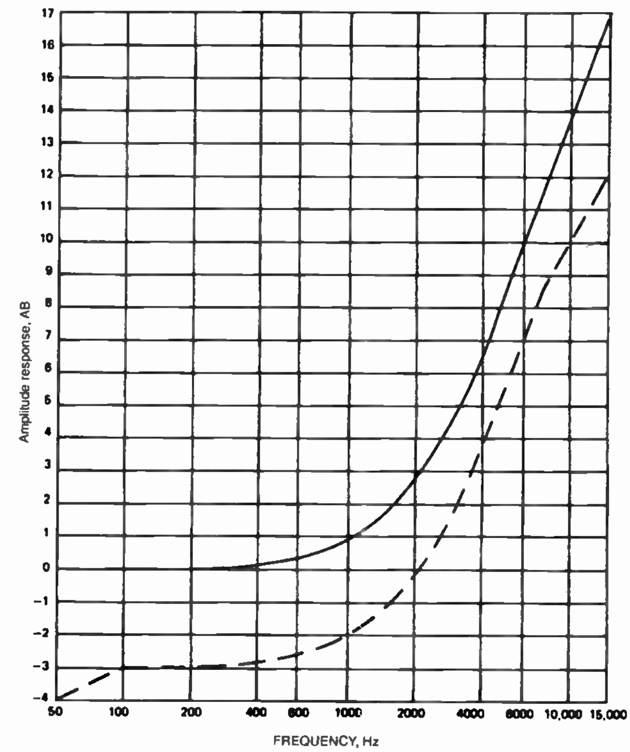

Figure 4.3-9. FCC Standard 75 microsecond preemphasis curve (solid line) and tolerance limits (solid and dashed lines).

Table 4.3-2
Precise amplitude response values for various amounts of preemphasis.

	Preemphasis Amplitude Response vs. Time Constant			
Freq (Hz)	25 μs	50 μs	75 μs	150 μs
50	0.000 dB	0.001 dB	0.002 dB	0.010 dB

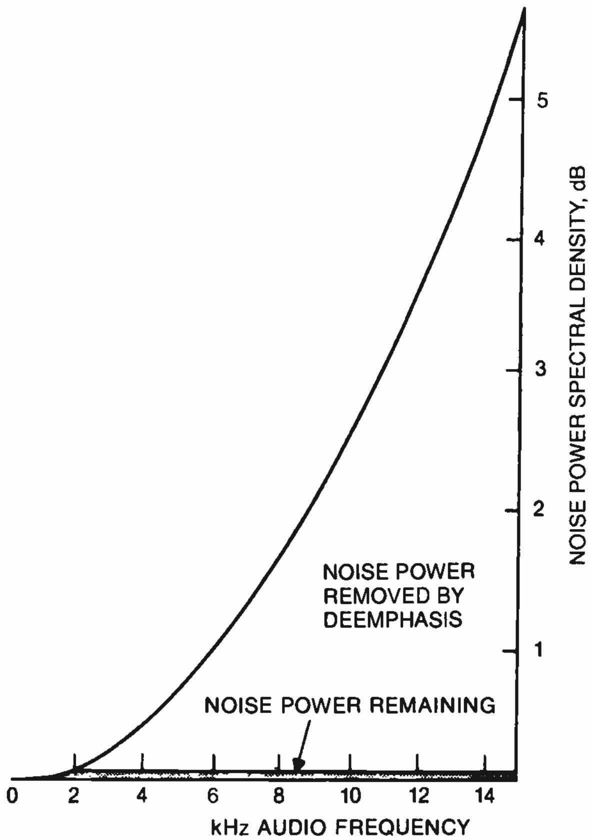

Figure 4.3-10. Noise power spectral density before and after deemphasis in receiver.

fidelity transmission because the high-frequency noise at the receiver would be very much greater without deemphasis.

Preemphasis is practical because program energy tends to peak at several kilohertz and then falls off fairly rapidly at the higher frequencies. For this reason, the higher frequencies can be boosted in amplitude without causing much increase in modulation level. There is some increase, however, so the net improvement due to preemphasis is the ratio of the areas under the two curves of the diagram less this reduction in audio input level required to keep within the 100% modulation limit. Modern audio processing equipment takes the preemphasis curve into account when controlling peak modulation levels.

In the section on FM modulation theory, it was mentioned that the use of preemphasis ahead of an FM modulator actually causes the system to behave like FM at low modulating frequencies and like PM at high modulating frequencies. The location of the preemphasis network in the system depends on whether the station is operating in the monaural or stereo mode. In the case of monaural transmission, the preemphasis network is usually located in the FM exciter just ahead of the modulator stage. Stereo transmission requires that the FM modulator have a flat response to the composite baseband signal from the stereo generator, so the individual preemphasis networks for the left and right channels are located in the stereo generator before the left and right audio channels are multiplexed into the composite baseband signal. In the case of a digital stereo generator, the AES3 serial audio data contains both the left and right channel information in alternating data frames. The digital stereo generator applies the preemphasis required and 15 kHz audio low pass filtering using Digital Signal Processing (DSP) techniques.

FM TRANSMITTER POWER OUTPUT REQUIREMENTS

The FCC regulates the power of FM broadcast stations in terms of effective radiated power (ERP) which is determined by the class of station and the antenna height above average terrain (HAAT). The authorized ERP applies only to the horizontally polarized component of radiation. Elliptical or circular polarization is also permitted, in which the ERP of the vertically polarized component may be as great as the authorized horizontal component. This means that twice as much total power may be radiated and twice as much transmitter power will be required.

The transmitter power requirement can be reduced by increasing the gain of the antenna. There is, of course, an economic trade off between the cost of a higher gain antenna versus the cost of a larger transmitter and the added primary power costs. For a high ERP, it is common to use antennas with up to 12 elements, providing a power gain of about 12.6 (or 6.3 in each polarization).

The long transmission lines associated with the tall towers commonly used are a source of considerable power loss. For example, the efficiency of 2,000 ft of 3⅛ in rigid coax at 100 MHz is only about 62%.

After the required ERP is determined, the transmitter power output (TPO) can be calculated taking into account the transmission line losses and the antenna array gain. Depending on the particular situation, the TPO could vary from as little as 50 W to as much as 70 kW.

FM transmitters are designed to operate over a wide range of power outputs so that with a few basic models any required power output can be furnished. Popular maximum ratings range from 250 W to 70 kW. Most installations use a maximum TPO of 30 kW or less because it is more economical to achieve the maximum 100 kW ERP with circular polarization by means of sufficient antenna gain.

THE FM TRANSMITTER

The purpose of the FM transmitter is to convert a main channel audio (mono or stereo) frequency signal and its associated audio or data subcarriers, or an AES3 serial digital audio data bitstream into a frequency modulated, radio frequency signal at the desired power output level to feed into the radiating antenna system. In its simplest form, it can be considered to be an FM modulator and an RF power amplifier packaged into one unit as shown in Figure 4.3-11.

Actually, the FM transmitter consists of a series of individual subsystems each having a specific function:

1. The FM exciter converts the analog audio baseband or serial digital audio data into frequency modulated RF and determines the key qualities of the signal
2. The IPA is required in some transmitters to boost the RF power level up to a level sufficient to drive the final stage
3. The final power amplifier further increases the signal level to the final value required to drive the antenna system
4. The transmitter control system monitors, protects and provides commands to each of these subsystems so that they work together to provide the desired result
5. The RF low pass filter removes undesired harmonic frequencies from the transmitter's output, leaving only the fundamental output frequency
6. The directional coupler provides an indication of the power being delivered to and reflected from the antenna system
7. The power supplies convert the input power from the ac line into the various dc or ac voltages and currents needed by each of these subsystems

FM Exciter

The heart of an FM broadcast transmitter is its exciter. The function of the exciter is to generate and modulate the carrier wave with one or more inputs (mono, stereo, SCA) in accordance with FCC standards. The FM modulated carrier is then amplified by a wideband amplifier to the level required by the transmitter's following stage.

Stereo transmission places the most stringent performance requirements upon the exciter. Since the exciter is the origin of the transmitter's signal, it determines most of the signal's technical characteristics including S/N, distortion, amplitude response, phase response and frequency stability. Waveform linearity, amplitude bandwidth and phase linearity must be maintained within acceptable limits throughout the analog baseband chain from the stereo and subcarrier generators to the analog FM exciter's modulated oscillator. The recent introduction of AES3 digital audio transport and all digital FM modulation techniques like DDS eliminate the distortions introduced by analog circuits. In a digital FM exciter, the left and right audio data is converted into a digital representation of stereo baseband by DSP. This data is then further converted into a frequency modulated carrier by a DDS numerically controlled oscillator (NCO). From here, the FM carrier is usually amplified in a series of Class C nonlinear power amplifiers, where any amplitude variation is removed. The amplitude and phase responses of all the RF networks which follow the exciter must also be controlled to minimize degradation of the signal quality.

Indirect FM

Before the advent of stereo broadcasting, most of the FM exciters employed phase modulation techniques. Some of these were adapted to stereo but it was difficult to achieve and maintain the performance requirements for stereo transmission.

In the FM modulation theory section of this chapter, the important relationship between PM and FM was discussed. If the audio frequency response is made to fall off at the rate of 6 dB/octave across the entire audio band at the input of a phase modulator, the resulting modulated output will be identical to that of a frequency modulated carrier. In 1948, James R. Day, an associate of Edwin H. Armstrong, demonstrated a Serrasoid phase modulator that used pulse circuits to achieve large phase shifts with low distortion. The Serrasoid modulation technique, in conjunction with the audio response shaping mentioned above, became the standard method of generating wide deviation FM with low distortion.

Known as indirect FM, this principle was used in many FM broadcast transmitters prior to the advent of stereo broadcasting. The advantage was that the carrier frequency could be generated by a stable crystal oscillator with the phase modulation occurring in later stages. The amount of phase deviation with low distortion was limited in most systems, so it was necessary to start with a low frequency oscillator and multiply its frequency and modulation index many times to achieve 75 kHz deviation at low modulating frequencies. This technique has been abandoned in favor of direct FM systems.

Direct FM

Direct FM is a modulation technique where the frequency of an oscillator can be made to change in proportion to an applied voltage. Such an oscillator, called a voltage tuned oscillator (VTO), was made possible by the development of varactor tuning diodes which change capacitance as their reverse bias voltage is varied (also known as a voltage controlled oscillator or VCO).

If the composite baseband signal is applied to the tuning terminal of a VTO, the result is a direct FM modulated oscillator. Figure 4.3-12 is a block diagram that fits most of the modern direct FM exciters on the market.

The S/N of an FM exciter is dependent on the short-term stability of the modulated oscillator. That stability is determined by factors such as operating level, noise figure of the oscillator transistor, circuit configuration, method of amplitude limiting, loaded "Q" of the oscillator tank circuit and the mechanical stability of components. Optimization of these factors has resulted in a S/N of better than 90 dB below 100% modulation in the current generation of analog FM exciters.

Analog FM Modulator Linearity

Nonlinearities in the FM oscillator can, by altering the waveform of the baseband signal, create distortion

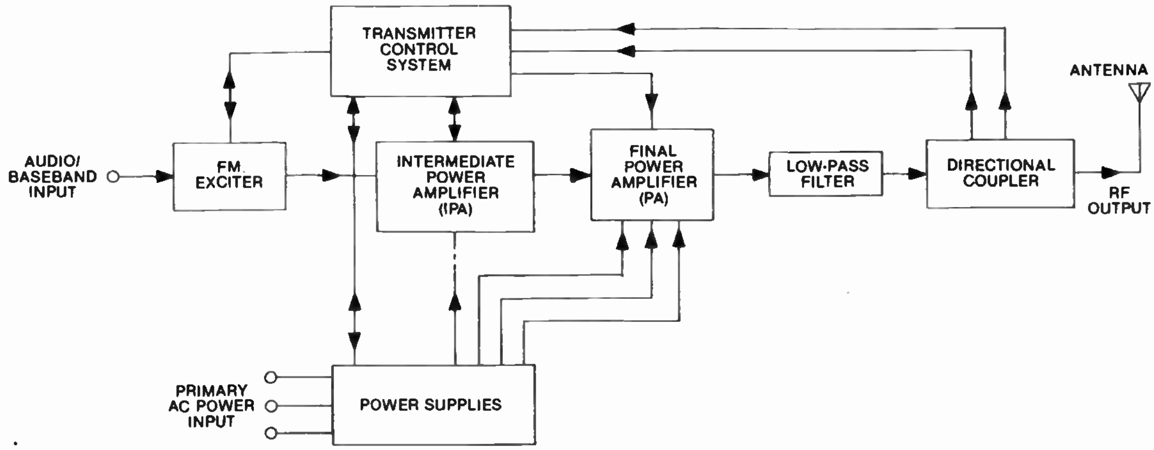

Figure 4.3-11. Simplified block diagram of an FM broadcast transmitter.

in the demodulated output at the receiver. A secondary effect of this distortion may include stereo crosstalk into the SCA, (subcarrier) signals.

The composite baseband signal is frequency modulated onto an RF carrier by the modulated oscillator (see Figure 4.3-12). Frequency modulation is achieved by applying the composite baseband signal to a voltage tunable RF oscillator. The modulated oscillator usually operates at the carrier frequency and is voltage tuned by varactor diodes operating in a parallel LC circuit.

To have perfect modulation linearity, the RF output frequency (F_c) must change in direct proportion to the composite modulating voltage (V_M) applied to the varactor diodes (C_v). This requirement implies that the capacitance of the varactor diodes must change as nearly the square of the modulating voltage as shown in following relationships:

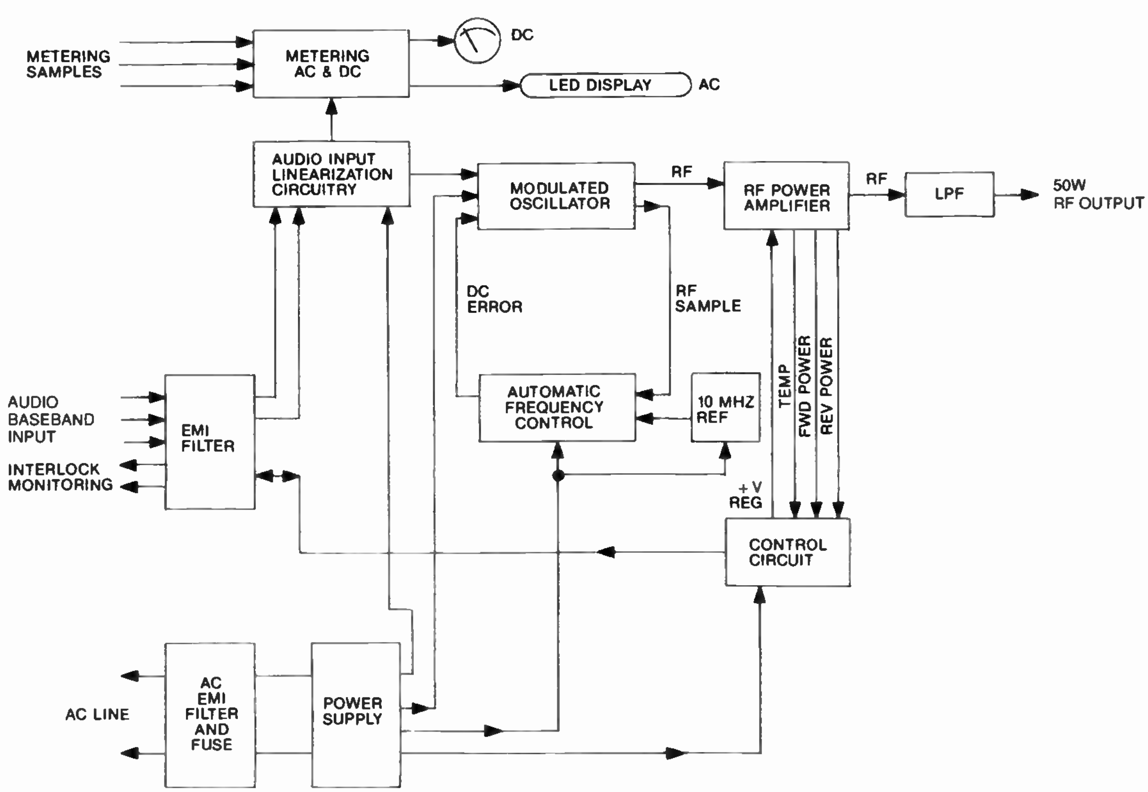

Figure 4.3-12. FM exciter block diagram using direct FM.

(F_c) is proportional to (V_M) if:

$$F_c = \frac{1}{2\pi\sqrt{(L)(C_t)}}$$

and:

$$C_v = \frac{K}{(V_m^2)} \qquad (\text{if } C_{\text{fixed}} = 0) \qquad (6)$$

(Desired linear voltage to frequency translation)

where:

F_c = Instantaneous carrier frequency
L = Inductance of resonant circuit
C_t = Total capacitance across L ($C_{\text{fixed}} + C_{\text{varactors}}$)
C_v = Capacitance of varactor tuning diodes
K = Varactor constant
V_M = Baseband modulating voltage

Unfortunately, the voltage versus capacitance characteristic of practical varactor diodes is not the desired square law relationship. All varactor-tuned oscillators have an inherently nonlinear modulating characteristic. This nonlinearity is very predictable and repeatable for a given circuit configuration, making correction by complementary predistortion of the modulating signal feasible. Suitable predistortion can be applied to the composite baseband signal by using a piece-wise linear approximation to produce the desired complementary transfer function. Figure 4.3-13 shows a typical network of switching diodes and resistors used for complementary predistortion of the composite baseband. Figure 4.3-14 shows how the predistortion network is cascaded with a nonlinear voltage-tuned oscillator to produce a linearized FM modulator.

It is also possible to improve both the linearity and S/N of the modulated oscillator by demodulating its RF output to baseband and then feeding some of this baseband with the proper phase relationship back into the composite input of the modulator. This type of configuration places the entire modulated oscillator within a negative feed back loop and transfers the responsibility for maintaining linearity to the demodulator. Digital demodulation schemes can be made very linear, but the additional complexity and the potential problems with loop stability have limited the applications of this approach to linearization.

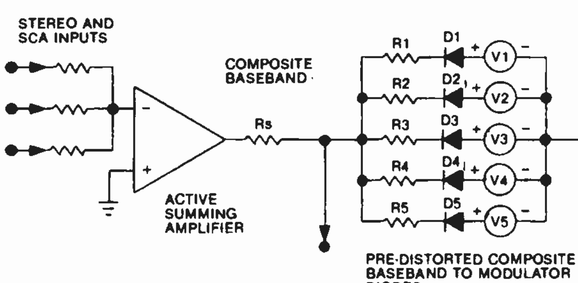

Figure 4.3-13. Predistortion network.

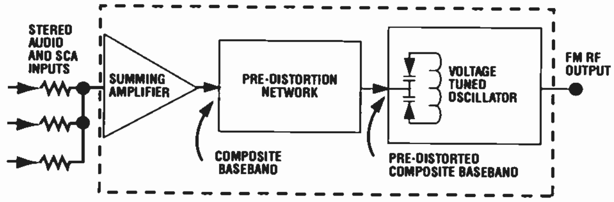

Figure 4.3-14. Linearized FM modulator block diagram.

Analog modulator linearization has reduced harmonic and intermodulation distortion to less than .01% in the current generation of equipment. Any distortion of the baseband signal caused by the modulated oscillator will have secondary effects on stereo and SCA crosstalk, which are quite noticeable at the receiver in spite of the rather small amounts of distortion to the baseband. For example, if the harmonic distortion to the baseband is increased from .05%–1.0%, as much as 26 dB of additional crosstalk into the SCA can be expected.

For illustrative purposes, Figures 4.3-15(a), 4.3-15(b) and 4.3-15(c) give representations of the fundamental and second order terms in the composite baseband spectrum with increasing amounts of harmonic distortion in the modulated oscillator. Figure 4.3-15(b) shows this spectrum after 0.05% harmonic distortion has been added to each component. Note that the second order stereo (L − R) sidebands are 78 dB below 100% modulation (about 58 dB below the 67 kHz SCA with a 10% injection). With normal (audio program) energy distribution in L − R and the SCA, crosstalk from stereo into the SCA will be more than 60 dB below the SCA subcarrier. Figure 4.3-15(c) shows the same baseband spectrum with 1.0% harmonic distortion. The second order stereo sidebands are now only 32 dB below the SCA, representing an increase of as much as 26 dB over the 0.05% distortion case, depending on the respective energy distributions in (L − R) and the SCA.

Transient intermodulation (TIM) distortion is usually not a factor in varactor-tuned modulated oscillators. The modulation bandwidth capability is generally more than ten times the composite bandwidth and no negative feed back is used to maintain linearity.

Ensuring that the composite baseband signal undergoes minimal distortion in the modulation process will suppress undesired harmonic and intermodulation products in the baseband, making the FM exciter transparent to the signals coupled into it. All exciter stages after the modulated oscillator operate as broad band amplifiers with minimal bandwidth limitations. The best analog FM exciter technology presently available is capable of transmitting near compact disk quality with less than .01% distortion and a S/N of better than 90 dB. Digital FM exciter technology utilizing DDS can now go beyond the limitations of analog modulators to provide the full 16bit digital performance of a compact disk.

Automatic Frequency Control

The frequency stability of direct FM oscillators is not good enough to meet the FCC frequency tolerance of ±2,000 Hz. This requires an automatic frequency control system (AFC) that uses a stable crystal oscillator as the reference frequency.

The modulated oscillator need not have good long-term stability since the AFC feed back loop will correct for long-term drift to keep the average carrier frequency within limits. The modulated oscillator does need excellent short-term (less than 1 sec) stability because the control loop time constant must be long enough so that the AFC circuit does not try to remove desired low frequency audio modulation. This means that the oscillator is essentially running open-loop at frequencies above a few hertz so that the noise performance of the modulator will also be determined by the short term stability characteristics of the oscillator.

Phase-Locked Loop Automatic Frequency Control

Phase-locked loop (PLL) technology has provided a means of precisely controlling the carrier's average frequency while permitting wide deviation of the carrier frequency at baseband modulating frequencies. This implies that a PLL system behaves like an audio high-pass filter with higher modulating frequencies being ignored by the control loop while lower frequencies are considered to be errors in the average frequency and are tracked out by the loop. An added advantage of the PLL is the ability to synthesize the desired frequency from a single reference oscillator, thereby eliminating the need to change crystals when changing the frequency of the exciter.

The block diagram shown in Figure 4.3-16 includes the key elements in the PLL. The output of the modulated oscillator operating at the carrier frequency is digitally divided down to a frequency of a few kilohertz or even less, called the comparison frequency. Likewise, the reference crystal oscillator is also digitally divided down to the reference frequency. The two frequencies are compared in a digital phase/frequency detector to develop an error voltage which corrects the carrier frequency of the modulated oscillator. The reason for dividing the modulated oscillator frequency so many times is to reduce the modulation index enough to limit the peak phase deviation at the reference frequency to a value that will not exceed the linear range of the phase/frequency detector. If the linear range is exceeded, the loop will lose lock. This is why some exciters may lose AFC lock in the presence of low frequency modulation components.

The phase detector output is integrated and low-pass filtered to remove the comparison frequency and all other frequency components above a few hertz so that the AFC circuit does not try to track-out low frequency modulation. Some FM exciters use a dual-speed PLL in order to keep the loop turn-over frequency low enough to maintain good amplitude and phase response at 30 Hz, while also providing quick lock-up time. The PLL error correction circuitry must respond quickly during the initial frequency scan of the FM band to achieve lock-up to the precision reference oscillator in a few seconds. The loop bandwidth is wide during acquisition and lock-up. After lock is achieved, the bandwidth is reduced to provide the optimum modulation characteristic.

The reference oscillator is usually temperature compensated and requires no warm-up to maintain ±3 PPM or better accuracy over the operating temperature range. Ten MHz is often selected as the reference frequency for convenient comparison to international znfrequency standards. For more information about PLL frequency synthesizers see [5].

Digital FM Exciter using Direct Digital Synthesis

DDS eliminates the need for a PLL in the FM modulation process. It does so, by directly synthesizing the carrier frequency, including FM modulation, from a

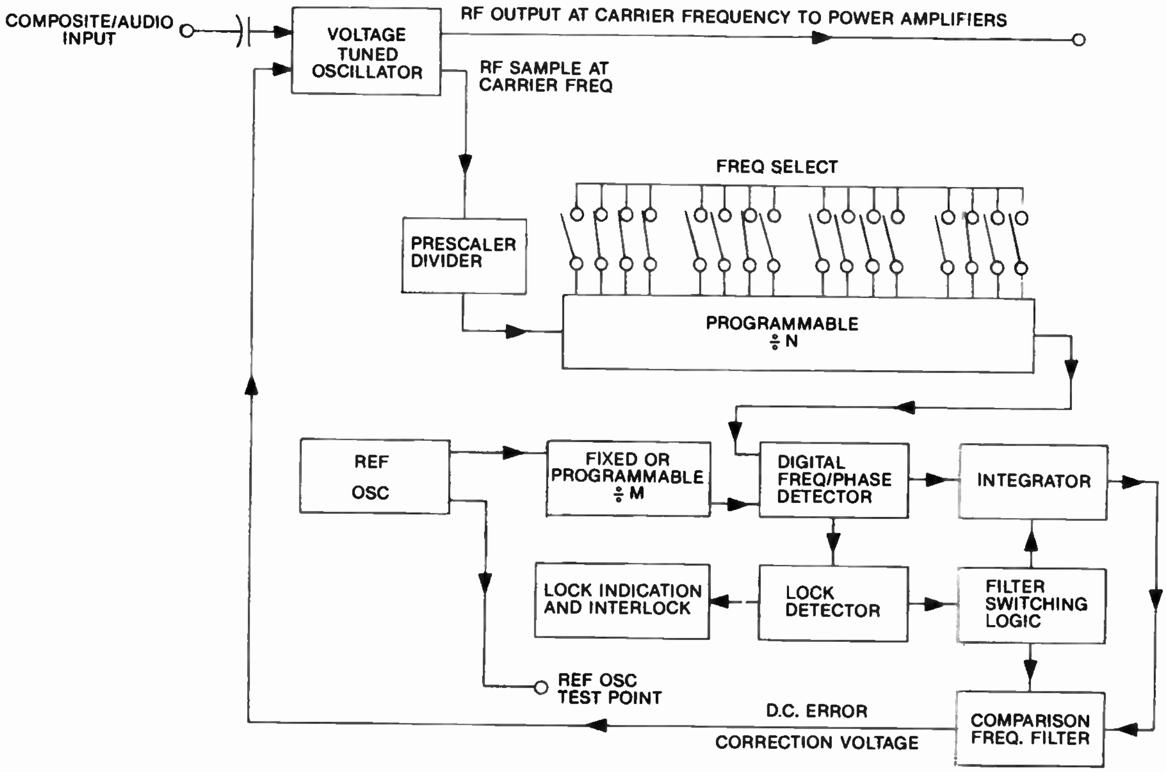

Figure 4.3-16. Phase-locked loop frequency synthesizer.

sinewave look-up table in a programmable read only memory device (PROM) operating in conjunction with a digital phase accumulator and a fast digital-to- analog (D/A) converter. When this technique is combined with DSP technology, the entire process of generating stereo baseband with SCAs and FM modulating this baseband information onto the RF carrier can be done entirely in the digital domain. The cost to performance ratio of DDS/DSP technology has made it competitive with the analog technology used in present exciters. The full benefit of DDS/DSP technology requires digital transmission of audio information as an uncompressed, digital, bit stream all the way from the digital audio source through a digital console, digital audio processing and an uncompressed, digital STL to the AES3 digital input port of the DSP/DDS exciter. This same technology is used in the fully digital audio broadcast (DAB) services including the Eureka 147 (EU-147) transmission standard and other technical standards presently being implemented worldwide.

With DDS, the completely modulated FM waveform, is generated totally in the digital domain. As digital modulation is an inherently linear process, no predistortion is required. The FM signal generated by a DDS device has extremely low noise and distortion for true 16 bit digital audio quality (−96 dB FM S/N and 0.0016% harmonic distortion for ±75 kHz deviation and 75 μsec preemphasis/deemphasis).

The current generation of DDS exciters use a 32 bit NCO. The basic resting frequency of the NCO is set by a 32 bit tuning word. Frequency modulation occurs when modulation data varies the structure of the tuning word within the phase accumulator section of the NCO. The modulated output of the NCO is converted to analog FM, upconverted, filtered and amplified to become the RF excitation for a conventional FM broadcast transmitter RF amplifier chain. A block diagram of a DDS digital FM exciter is shown in Figure 4.3-17.

DDS FM exciters also eliminate several basic limitations found in analog exciters using direct FM via the modulation of VCOs. Very low audio frequencies must be filtered from program signals to avoid affecting the AFC circuits of the analog exciter, which see very low modulating frequencies as an off-frequency condition that needs correction. A DDS based FM exciter has no such limitation and modulation response extends virtually to dc (zero hertz). These lower octaves of program material are important for sonic realism and to preserve the phase correlation existing in the original program.

Digital Modulator

The digital modulator which is the heart of a digital exciter, utilizes a 32 bit NCO to digitally generate the completely modulated FM waveform. Other supporting circuitry, including a digital peak detector, is used to drive the front panel modulation display. The block diagram in Figure 4.3-18 shows the functional subsystems of a digital modulator.

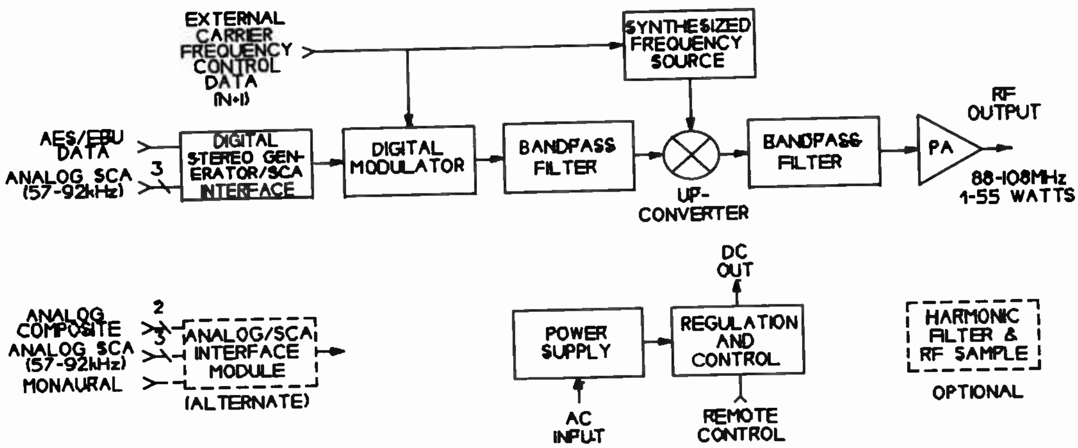

Figure 4.3-17. Harris DIGIT-CD DDS Digital FM exciter.

The input to the digital modulator is fed modulation data in the format and at the clock rate required. This data represents the stereo baseband created in the digital input module which contains the DSP digital stereo generator and subcarrier input circuitry.

The digital modulator module includes a precise, digital peak detector to provide the drive for the front panel peak modulation display. This circuit is driven by the same data as the NCO modulator. Therefore, the modulation indication on the front panel of the digital exciter has very high accuracy to within 0.25% of the true FM deviation value at any modulation index or frequency.

The output of the NCO is then D/A converted to a precise, conventional FM signal at an intermediate frequency and passed through a bandpass filter to remove the images produced in the DDS process.

Digital Input and DSP Stereo Generator

DDS techniques are compatible with standard AES3 digital audio, which provides the last link in maintaining a 100% digital audio path from the program source through the generation of the modulated FM carrier, with no intervening A/D or D/A conversions to add noise and distortion. The DDS exciter includes a built-in DSP stereo generator to convert the incoming AES3 digital stereo into the digital stereo modulation data needed for the NCO to generate FM stereo. Most DDS exciters also offer as an option a high-quality A/D converter that will convert the analog baseband output of an analog stereo generator into the digital data format needed by the NCO. The same high-quality modulation performance as for digital input signals is provided under these conditions. Auxiliary signals such as SCA and Radio Broadcast Data Service (RBDS)/RDS are accepted as modulated analog waveforms from external devices, then A/D converted to digital data and applied to the NCO for simultaneous transmission with normal stereo program material. Figure 4.3-19 shows the major signal blocks in the digital input module.

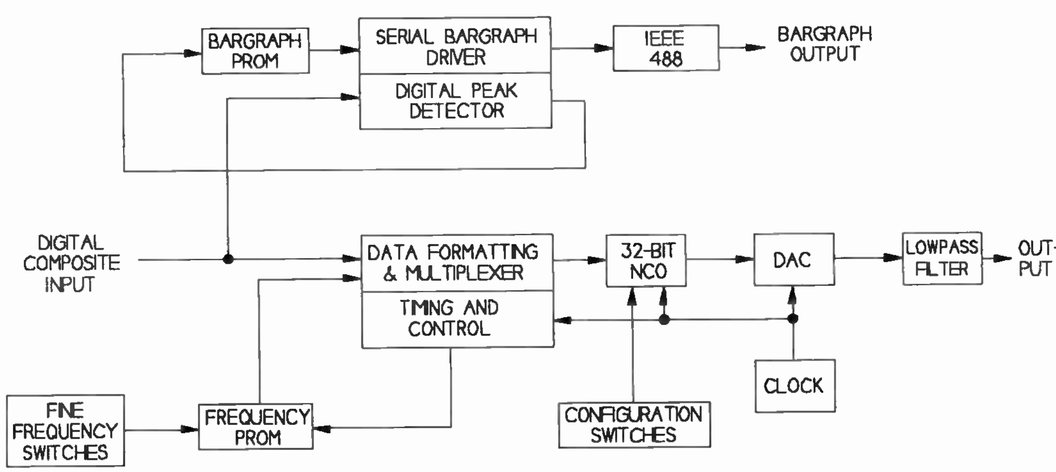

Figure 4.3-18. Digital Modulator in the Harris DIGIT-CD FM exciter.

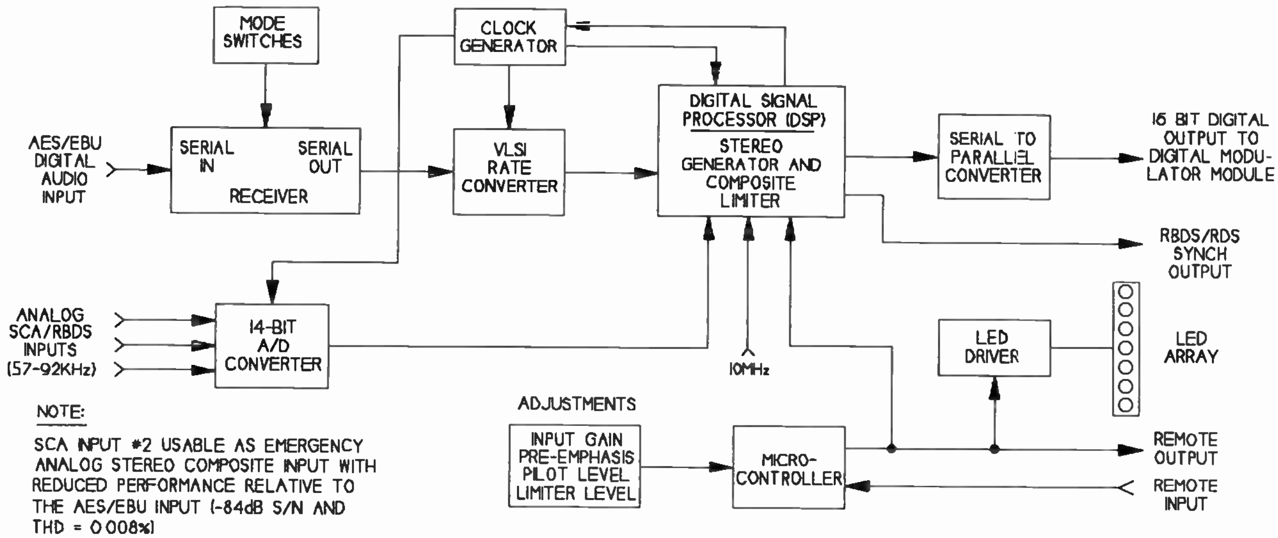

Figure 4.3-19. Harris DIGIT-CD Digital input module and DSP stereo generator.

The digital input module provides the interface, monitoring and control circuitry for these functions:

- Accepts standard AES/EBU stereo digital data at any rate from 20.8 kHz–56 kHz, normally 32 kHz. Rate conversion is automatic (self-clocking)
- Accepts up to three analog subcarriers in the range 57–92 kHz
- Converts all input signals to the composite digital format needed by the digital modulator
- Provides a 19 kHz output to synchronize an external RBDS/RDS generator
- Supplies digital composite limiting using a special implementation of "lookahead" digital technology
- Provides gain adjustment for summed SCA, overall deviation, limiting level and pilot level
- Provides switchable LED display showing either total peak deviation or limiting level
- Allows user selection of program channel mode (AES/EBU or analog), preemphasis on/off/time-constant, mono on/off and data error detection mode. For more detailed information about digital modulators and other aspects of digital FM exciter design and performance see [27, 30, 31, and 32].

FM by I/Q Modulation Techniques

Another method used to generate FM is the quasi digital, in-phase/quadrature (I/Q), RF modem technique. Two identical analog RF mixers are fed in-phase (I) and quadrature (Q) analog baseband signals derived from two separate D/A converters at the output of a DSP digital stereo generator. The (I) mixer is also fed the in-phase carrier frequency while the (Q) mixer is fed the carrier frequency phase shifted by 90° from the (I) mixer. When the RF outputs of these two mixers are summed the desired FM RF spectrum is produced if everything is perfectly balanced and matched. Practical limitations in the matching of these mixers require that feed back incorporating sophisticated nonlinear DSP adaptive correction be placed around these mixers and the (I) and (Q) (D/A) converters driving them. This technique has the advantage of producing FM at the carrier frequency instead of at an IF frequency but has limited modulation performance and spectral purity.

Exciter Metering

Metering of important operating parameters can be provided by a combination of analog metering and a digital LED display. Steady-state parameters are usually selected by a multiposition switch and displayed on an analog or LCD multimeter. Typical steady state functions include regulated, preregulated and unregulated supply voltages; the AFC control voltage; RF power amplifier collector voltage and current; forward output power and reflected power.

A color-coded peak reading display is usually provided to constantly monitor the peak FM deviation. A high-speed peak detector gives accurate peak readings on signals from dc to 100 kHz. A one-shot multivibrator circuit can provide a clear indication of short transient peaks exceeding 100% modulation. Digital exciters can directly read the peak values of the modulation data producing the FM deviation in the NCO.

Exciter Packaging

Protection of sensitive circuits within an FM exciter from external electromagnetic interference (EMI) is important because the unit is often located in the near field of multiple broadcast antennas operating over a broad range of frequencies. The exciter should be protected from conducted EMI by use of RC and/or LC filters on all leads entering the cabinet, including the ac line. Additionally, the power transformer may have an electrostatic shield between the primary and secondary windings. The modulated oscillator is often shock mounted to prevent the transmission of mechanical vibrations from the transmitter's blower. This avoids microphonic pick-up by the modulator that would degrade the FM S/N. Magnetic shielding of the analog FM modulator is also used to prevent hum pick-up from nearby transformers. In some cases, a hum-bucking circuit is provided to help cancel hum induced into the analog modulator.

The mechanical construction of most present day exciters is designed around a plug-in modular or semi-modular approach, which allows easy removal of subassemblies for repair or replacement.

The exciter chassis may be mounted on pull-out slides so that all subassemblies are accessible while the unit continues to operate.

Exciter Output Stage

The broad band RF amplifier in the exciter amplifies the output of the modulated oscillator from a power level of a few milliwatts up to an output level in the range of 5–50 W. The output stage is usually protected against damage that could be caused by an infinite voltage standing wave ratio (VSWR) (on the output) at any phase angle.

The typical RF amplifier is designed to have a bandwidth of at least 20 MHz, using successive broad band impedance matching sections for each stage. Each group of matching sections consists of micro strip or lumped elements.

The broad band performance of the RF amplifier eliminates the need for adjustments to any particular frequency within the FM band. The exciter output is transparent to the signal generated by the modulated oscillator, and the amplifier stability is enhanced under varying load conditions.

A micro strip directional coupler is often incorporated in the RF amplifier output network. This coupler supplies information to the exciter control circuitry which provides automatic control of power output level and provides protection against operation under high VSWR conditions.

All current-generation FM exciters typically produce at least 50 W of RF output so they can be used as a complete transmitter for educational stations (with the addition of a harmonic filter at the output). For higher power level requirements, the exciter is used to drive an external power amplifier.

RF Power Amplifiers

The remainder of the FM transmitter consists of a chain of power amplifiers, each having from 8–20 dB of power gain. Ideally, the transmitter should have as wide a bandwidth as practical with a minimum of tuned stages. Broad band solid-state amplifiers are preferred to eliminate tuned networks in the RF path. Higher powered transmitters in the multikilowatt range may use multiple tube stages each with fairly low gain such as in the grounded grid configuration or a single grid driven power amplifier (PA) stage with high gain and efficiency. The cost, redundancy and wide bandwidth benefits of solid-state transmitters has made them attractive at power levels up to 20 kW. At higher power levels, beyond 20 kW, the lower cost per watt of high power, single-tube transmitters still make them attractive even though the modulation performance and reliability is less than that of a solid-state transmitter. Design improvements in tube-type power amplifiers have concentrated on improving bandwidth, reliability and cost effectiveness while design improvements in solid-state amplifiers have focused on continuous cost reduction to make them competitive with tube technology at ever increasing power levels.

RF Power Amplifier Performance Requirements

The basic function of the power amplifier is to amplify the power of the exciter output to the desired transmitter power output level. Most of the overall transmitter performance characteristics are determined by the exciter, but a few are established or affected by the following power amplifier characteristics:

- The RF output level at harmonics of the carrier frequency is almost completely a function of the attenuation provided by the power amplifier output matching circuit and output low-pass/notch filters. The FCC limit in decibels is [43 dB + 10 · log (pwr in watts) dB] or 80 dB whichever is less (73 dB for 1 kW output or 80 dB for 5 kW and higher)
- The major source of AM noise usually originates in the last power amplifier stage. The FCC limit is 50 dB below 100% equivalent AM modulation.
- The RF power output control system which must keep the output within +5% and −10% of authorized output is usually achieved in the final power amplifier
- Inadequate power amplifier RF bandwidth, particularly with respect to phase linearity (constant time delay) across the signal bandwidth, can reduce stereo separation and cause SCA crosstalk
- The presence of standing waves on the transmission line from the power amplifier to the antenna may also interact with the power amplifier to cause degraded stereo separation and SCA crosstalk.

The power amplifier should provide trouble-free service and be easy to maintain and repair. Good overall efficiency is also desirable to reduce the primary power consumption and heat load released into the transmitter room.

Power Amplifier Bandwidth Considerations

As mentioned earlier, the FM signal theoretically occupies infinite bandwidth. In practice, however, truncation of the insignificant sidebands (typically less than 1% of the carrier power) makes the system practical by accepting a certain degree of signal degradation. The transmitter power amplifier bandwidth affects the modulation performance. Available bandwidth determines the amplitude response and group delay response. There is a trade-off involved between the bandwidth, gain and efficiency in the design of a power amplifier.

The bandwidth of an amplifier is determined by the load resistance across the tuned circuit and the output or input capacitance of the amplifier. For a single-tuned circuit, the bandwidth is proportional to the ratio of capacitive reactance to resistance:

$$BW \propto \frac{K}{2\pi f_c R_L(C)} = \frac{K(X_C)}{R_L} \tag{7}$$

where:

BW = Bandwidth between half-power points (BW_{3dB})
K = Proportionality constant
R_L = Load resistance (appearing across tuned circuit)
C = Total capacitance of tuned circuit (includes stray capacitances plus output or input capacitances of the tube)
X_C = Capacitive reactance of C
f_c = Carrier frequency

The load resistance is directly related to the RF voltage swing on the tube element. For the same power and efficiency, the bandwidth can be increased if the capacitance is reduced.

Effects Of Circuit Topology And Tuning On FM Modulation Performance

FM broadcast transmitter RF power amplifiers are typically adjusted for minimum synchronous AM (incidental amplitude modulation) which results in symmetrical amplitude response. This ensures that the transmitter's amplitude passband is properly centered on the FM channel. The upper and lower sidebands will be attenuated equally or symmetrically which is assumed to result in optimum FM modulation performance. This is true only if the RF power amplifier circuit topology results in simultaneous symmetry of both amplitude and group delay responses.

The tuning points for symmetrical amplitude response and symmetrical group delay response usually do not coincide, depending on the circuit topology. Therefore, simply tuning for minimum synchronous AM (symmetrical amplitude response) does not necessarily result in best FM modulation performance.

Actually, symmetry of the group delay response has a much greater effect on FM modulation distortion than does the amplitude response. Tuning for symmetrical group delay will cause the phase/time delay errors to affect the upper and lower sidebands equally or symmetrically. The group delay response is constant if the phase shift versus frequency is linear. In this case, all components of the signal are delayed in time, but no phase distortion occurs.

Measurements taken on a typical FM transmitter as well as computer simulations showed that tuning the RF power amplifier for symmetrical group delay response resulted in minimum distortion and crosstalk. [23] It confirmed that group delay response asymmetry causes higher FM modulation distortion and crosstalk than amplitude response asymmetry. The transmitter should be tuned for symmetrical group delay response which results in best FM modulation performance rather than symmetrical amplitude response which results in minimum synchronous AM.

Power Amplifier Output Source Impedance

At the milliwatt levels used in RF test equipment, it is customary to use 50 Ω as the standard impedance. Consequently, test equipment is typically designed to provide both 50 Ω source and load impedances to systems under test. This approach minimizes any reflections to systems under test since both the transmitter (source) and the termination (load) will absorb reflected energy. A 50 Ω source impedance is usually provided by placing a 50 Ω build out resistor in series with a low impedance voltage source (Thévenin equivalent). The closed circuit voltage with this configuration is exactly ½ of the open circuit voltage, meaning that half of the total available RF power is dissipated in the source resistance. The best possible efficiency for this system is 50% assuming the voltage source is 100% efficient without the source resistance.

It becomes obvious that while an FM transmitter is designed to drive a 50 Ω load, it does not itself have an output source impedance of 50 Ω. In order to achieve high efficiency, the transmitter must have a very low output source impedance so that nearly all of the power is delivered to the load. The plate dissipation indirectly represents some of the power lost within the low source resistance. Since the low source impedance of the transmitter provides a mismatch to reflected power from the load, this power is almost totally reflected back from the transmitter output stage toward the load again.

Intermediate Power Amplifiers

The IPA is located between the exciter and the final amplifier in higher power transmitters that require more than about 50 W of drive to the final amplifier. The IPA may consist of one or more tubes or solid-state amplifier modules.

Interstage Coupling Circuits

The separate IPA output circuit and the final amplifier input circuit are often coupled together by a coaxial transmission line. Impedance matching is usually accomplished at either end by one of the configurations shown in Figures 4.3-20(a), 4.3-20(b), 4.3-20(c) and 4.3-20(d).

The interconnecting transmission line between the coupling circuits should be properly matched to avoid a high VSWR. Directional wattmeters are normally placed in the line to measure forward and reflected power from which standing wave ratio can be established. The VSWR is established by the match at the load end of the transmission line.

Solid-state RF power devices possess a very low load impedance at the device output terminal, so that an impedance transformation that goes through the 50 Ω intermediate impedance level is required to couple these devices into the relatively high impedance of the final amplifier grid circuit. Therefore, virtually all solid-state IPA systems have a 50 Ω impedance point within the system that can be used to feed the antenna in an emergency.

The tube in the final amplifier stage of most newer design high power transmitters only requires between 150–600 W of drive. This permits the use of solid-

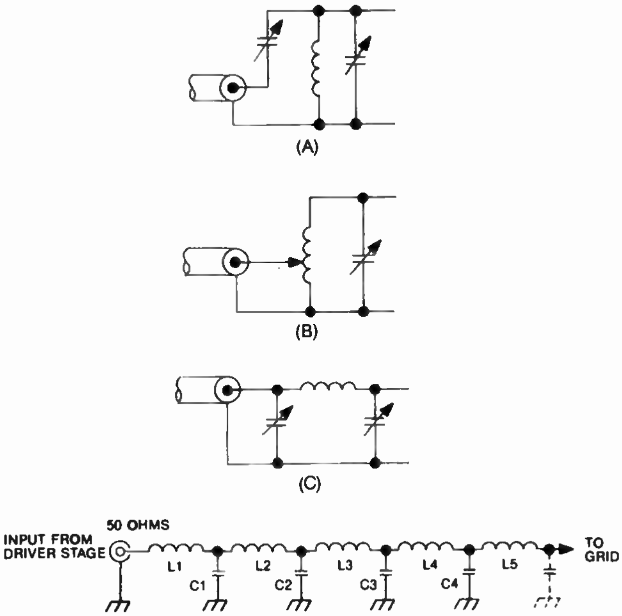

Figure 4.3-20(a–d). Interstate RF coupling circuits.

state, wideband, power amplifier modules to boost the exciter's power up to the level required to drive the grid of the final tube.

Solid-State RF Power Amplifier Systems

A solid-state RF power amplifier almost always consists of a system of individual amplifier modules that are combined to provide the desired power output. The advantages of using several lower power modules instead of a single high power amplifier include:

- Redundancy is provided by isolating the input and output of each module, permitting uninterrupted operation at reduced power if one or more of the modules fails.
- The ability to repair or replace failed modules without having to go "off-the-air"
- More effective cooling of each power device by splitting the concentration of heat to be dissipated into several areas instead of one small area
- Better isolation between the amplifier modules and the input circuit of the final power amplifier or antenna is provided by the combiner/isolator
- Redundant power supplies and air cooling systems for each module improve overall reliability.

Each RF power amplifier module consists of one or more solid-state devices with broad band impedance transformation networks for input and output matching. A new generation of Metal Oxide Semiconductor Field Effect Transistor (MOSFET) devices permits the design of broad band amplifier stages that exhibit both high efficiency and the wide bandwidth necessary to cover the FM broadcast band.

The input impedance to the solid-state device is always lower than the desired 50 Ω input impedance, so a broad band impedance transformation scheme is required. This is usually accomplished by a combination of coaxial baluns and push-pull coaxial line sections that are cross-coupled to provide 4:1 or higher transformation ratios over the FM band.

By operating two devices in push-pull, the input impedance (differential) is double that of a single ended circuit, and the suppression of even order harmonics is enhanced. Two devices fed in this manner also provide some degree of redundancy within the module itself since partial RF output can be obtained with one device failed. In a similar manner, the low output impedance of these solid-state devices can be transformed up to the desired 50 Ω module output impedance where combining occurs. Figure 4.3-21(a) illustrates a simplified schematic of a broad band,

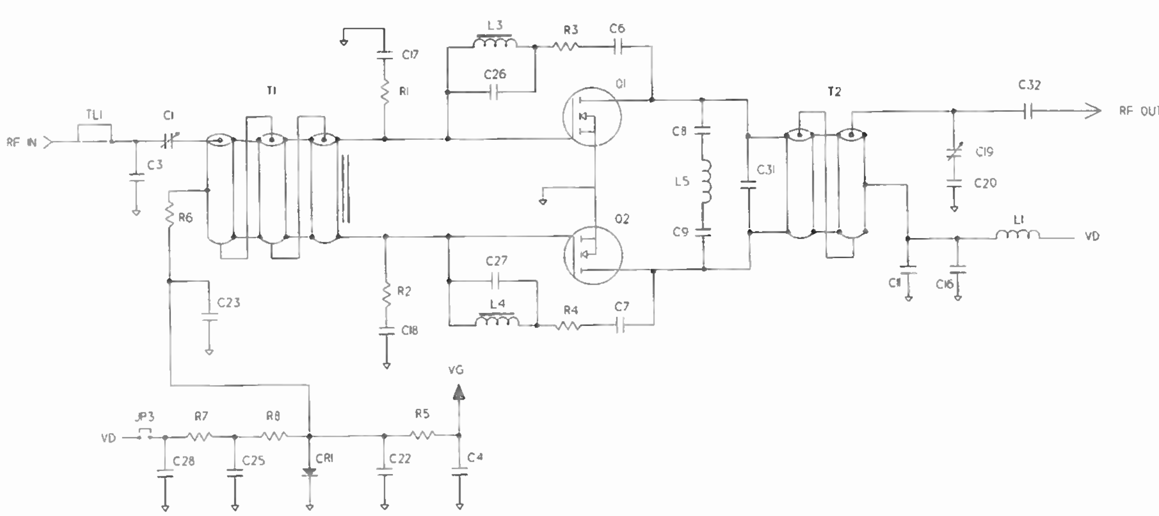

Figure 4.3-21(a). Schematic of broadband, 425 W, MOSFET, RF power amplifier module.

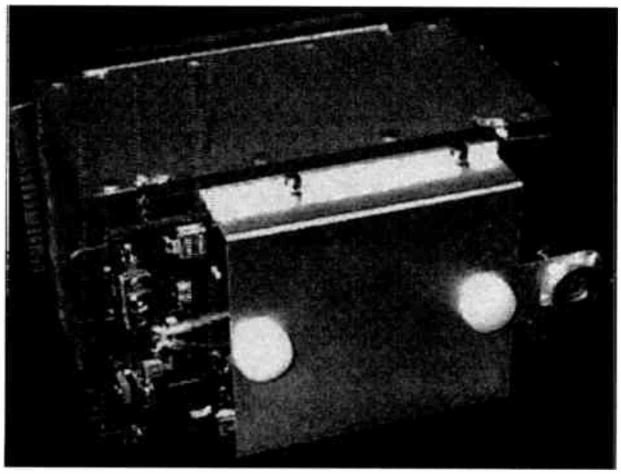

Figure 4.3-21(b). Broadband, 850 W, MOSFET, RF power amplifier module.

425 W, MOSFET, RF amplifier module utilizing the push-pull configuration. Figure 4.3-21(b) is a photograph of this RF amplifier module.

Solid-State Amplifier Splitting and Combining

Two frequently used types of splitting/combining schemes are:

- A 90° hybrid splitter or combiner ("N-1" hybrids required to split or combine "N" inputs). (See the section on transmitter output combining.)
- A Wilkinson "N-way" in-phase splitter or combiner.

Either type of splitter/combiner must provide isolation between the individual power amplifier modules and low loss splitting or combining of the total power.

The cascaded 90° hybrid system shown in Figure 4.3-22 provides double isolation between the power amplifiers and the load by first combining the two pairs of amplifiers and then combining the outputs of the first two combiners. A portion of the reflected power, caused by a mismatch at the output, will be dissipated in the reject loads so that the power amplifier modules will operate into a lower VSWR than exists at the output. The unbalanced 50 Ω reject loads are accessible for monitoring of reject load power which is useful in determining the balance of the system.

Wilkinson system shown in Figure 4.3-23 is a simple and effective way to split and combine modules operating in phase, but usually requires a balanced reject load making reject power measurements more difficult. By adding additional coaxial balun sections to the Wilkinson (Wilkinson/Gysel), it is possible to use unbalanced reject loads.

Adaptive Control of the Combiner Configuration

Both the 90° hybrid and Wilkinson combining systems require resistive RF power reject loads to provide isolation between the amplifier modules in the event that one or more of the modules fail. A portion of the RF power from the remaining modules is wasted in the reject loads instead of being delivered to the output. Recent developments have made it possible to have a microcomputer monitor the degree of imbalance in the system and adaptively change the configuration of the combiner to losslessly compensate for the failure of one or more power amplifier modules. This is accomplished by having the microcomputer substitute the appropriate reactances in place of the resistive reject loads to maintain enough isolation for the remaining power amplifiers to work efficiently. This technique is used in the Harris "Z" plane combiner.

Since most splitter/combiner systems are designed around a 50 Ω input and output impedance level, these systems can be easily used as a low power stand-by transmitter by routing the output to the antenna system.

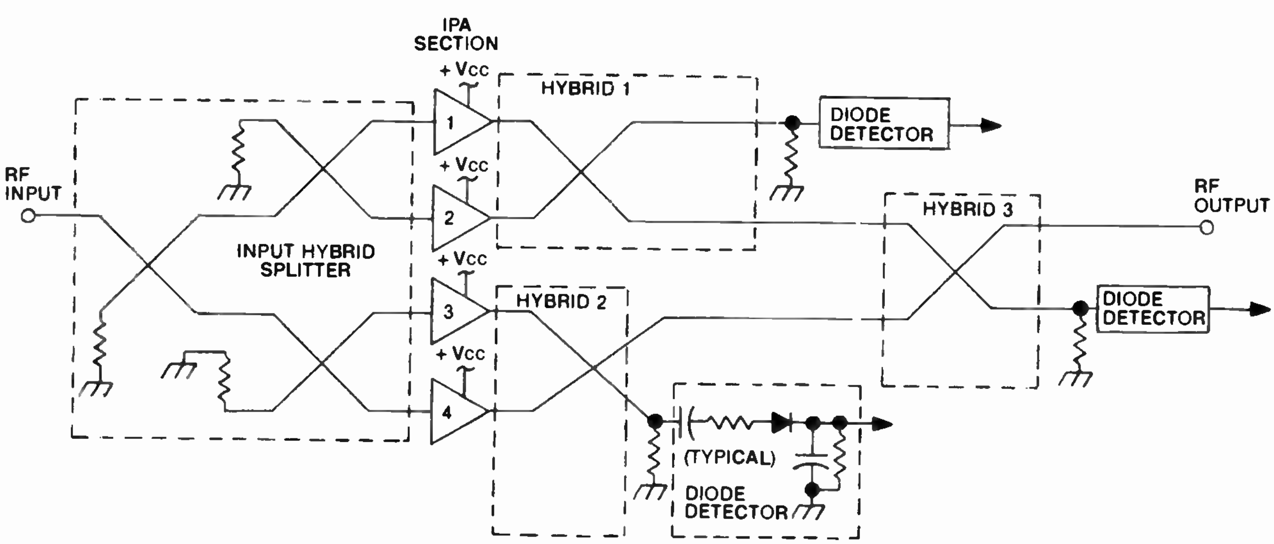

Figure 4.3-22. Cascaded 90° hybrid splitting/combining system.

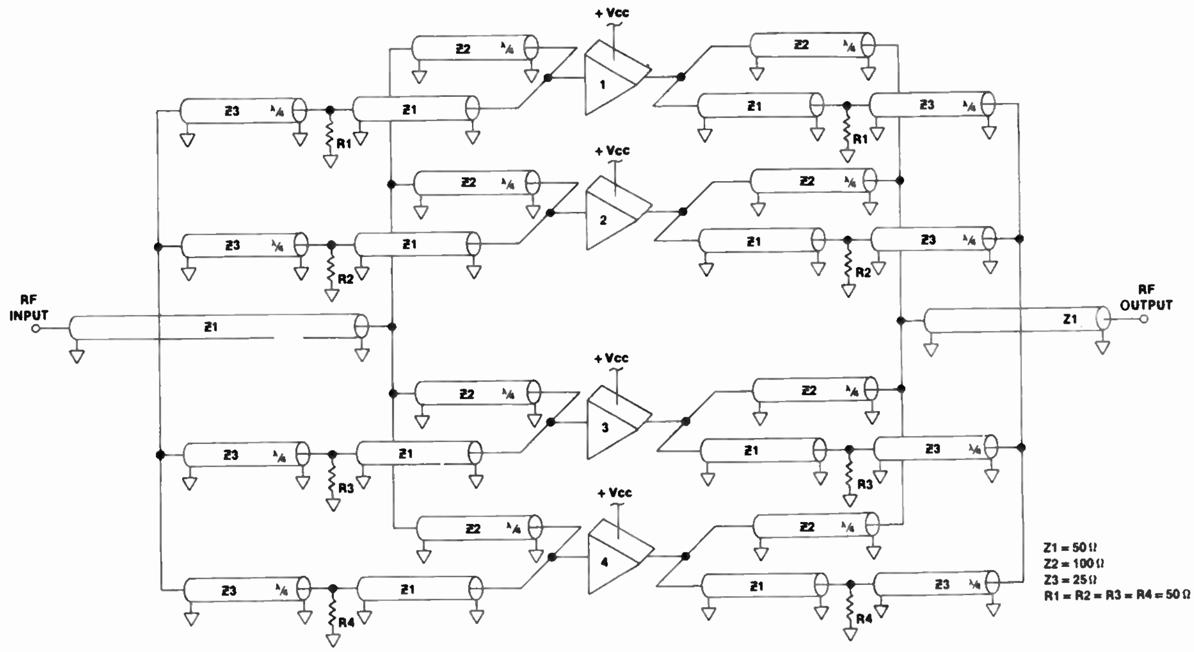

Figure 4.3-23. Wilkinson/Gysel in-phase splitting/combining system with unbalanced reject loads.

An RF low pass filter (LPF) is required only when directly feeding the antenna system. The harmonic suppression of the IPA is not as critical when driving a nonlinear power amplifier that also generates harmonics, because this stage will have its own LPF.

SOLID-STATE FM BROADCAST TRANSMITTERS

The techniques used to construct IPA systems can also be used to construct a completely solid-state transmitter using arrays of combined modules for the final output stage. An additional RF low pass filter is usually required to meet FCC emission requirements.

Advantages of Solid-State Transmitters

The primary advantages of a solid-state transmitter are the built-in amplifier and power supply redundancy, superior FM modulation performance, the ability to cover the entire FM band without the need for re-tuning, and elimination of tube replacement costs. A tubeless transmitter is nearly maintenance free.

Solid-State Transmitter Design Considerations

Several manufacturers offer solid-state FM broadcast transmitters with power outputs ranging from 100 W up to 20 kW, but present economic factors still favor the single tube FM transmitter for power levels above 20 kW.

In order for a solid-state transmitter to be cost and power consumption competitive with a single tube transmitter, the efficiency of the solid-state RF power amplifiers and combining system have to approach the 80% efficiency obtainable from tube type RF amplifiers. This high efficiency has been achieved with MOSFET solid-state devices at VHF frequencies.

Solid-state designs can provide high ac/RF efficiencies, with up to 80% dc to RF efficiency at the MOSFET device level and over 62% overall efficiency, from ac line in to RF output. This is actually better ac to RF efficiency at the 5 kW level than a typical single tube transmitter, which is normally less than 60%.

Some solid-state designs have added a few percentages to their overall ac to RF efficiency by optimizing their RF circuits over narrow band sections of the FM band. This approach is beneficial to the user who is certain there will not be a need to change the transmitter's frequency, or who is prepared to provide the transmitter modifications needed to do so.

Trends in the newest solid-state FM transmitters are to supply redundant RF, power supply and control circuits so as to keep the transmitter on the air at reduced power in the event one or more components should fail. Identical and interchangeable IPA and PA modules offer additional redundancy. RF modules that can be removed and inserted in an operating transmitter also provide the advantage of not requiring an off-air period for some maintenance services.

Solid-state transmitter layouts using direct, cable-free connection of the RF modules to the RF combiner have also been introduced and further enhance transmitter reliability and stability. Another enhancement provided in some current solid-state FM transmitters is an advanced, microprocessor based control system that can monitor detailed parameters within the transmitter and provide "intelligent control" of the transmitter system, including the RF combiner. This maximizes output power and minimizes reject load power under

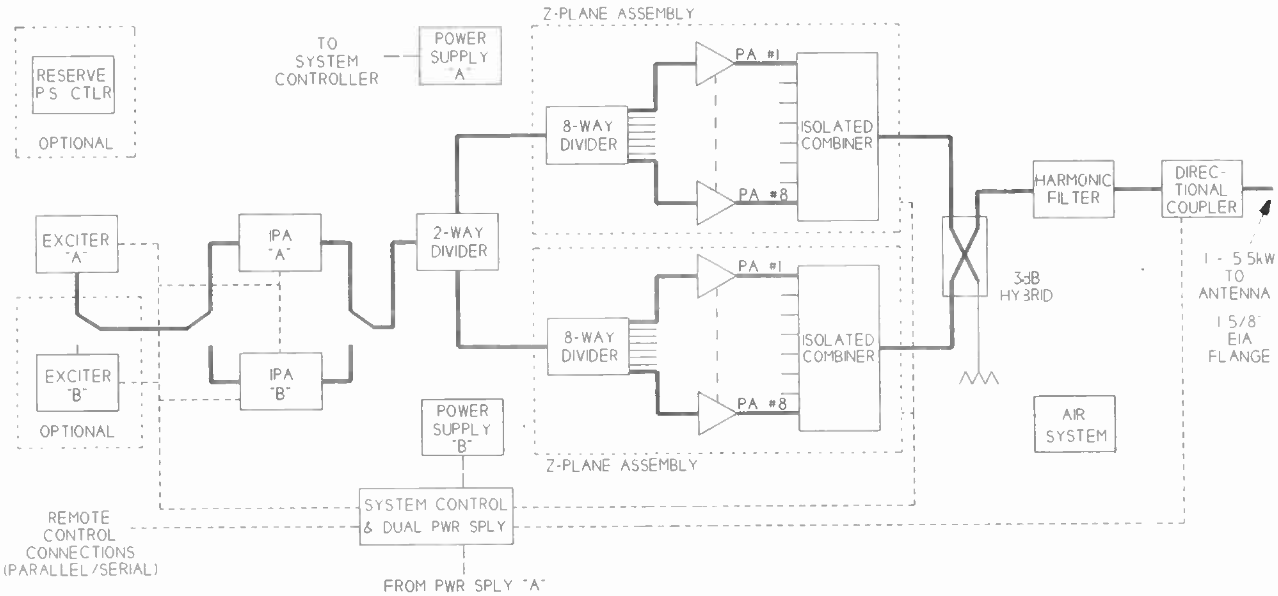

Figure 4.3-24. Harris "Z" 5 kW solid-state FM transmitter.

various combinations of active and inactive modules. Figure 4.3-24 shows a block diagram of a 5 kW solid state transmitter.

Solid-State Versus Single Tube Transmitter Purchase Cost

There is no engineering reason why a solid-state FM transmitter of 20–40 kW output power cannot be produced. The only economic factor at the present time is the cost premium, which tends to rise linearly with power for solid-state transmitters, while leveling off exponentially for high-power single tube transmitters. Figure 4.3-25 graphically shows that at power levels below approximately 8 kW, solid-state transmitters are less expensive to purchase than transmitters that use a tube. As the power level increases, the cost of a single tube transmitter increases incrementally, but not in direct proportion to the power increase. If the power output of a solid-state transmitter is doubled, it requires twice as many power amplifiers, power supplies, combiner ports etc., so that the cost very nearly doubles.

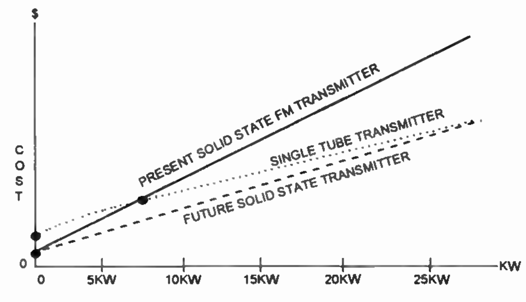

Figure 4.3-25. Solid-state versus single tube transmitter purchase cost.

Since the cost of a solid-state transmitter increases proportionately to the power output, the only way to make solid-state technology cost competitive with high power tube technology is to reduce the slope of the solid-state curve by driving the cost of solid-state devices down while simultaneously increasing the power density per RF device. This trend will continue, eventually making high power solid-state transmitters more economical to purchase.

Purchase price alone does not determine the overall economics of buying a solid-state FM transmitter. When the reduced cost of installation, maintenance, elimination of PA tube replacement cost and the overall cost of ownership are included in the comparison, a high-power, solid-state FM transmitter can become a good value. [6, 7, 8, and 9]

VACUUM TUBE POWER AMPLIFIER CIRCUITS

The amplitude of an FM signal remains constant with modulation so that efficient, nonlinear, Class C, amplifiers can be used.

FM broadcast vacuum tube power amplifier circuits have evolved into two basic types. One type uses a tetrode or pentode tube in a grid driven circuit while the other uses a high-mu triode in a cathode driven (grounded grid) circuit.

Cathode Driven Triode Amplifiers

The high-mu triodes used in cathode driven (grounded-grid) FM amplifiers were originally developed for linear single side band (SSB) amplifiers. Their characteristics are well adapted to FM broadcast use because the circuit is very simple, and no screen or grid bias power supplies are required. Figure 4.3-26 shows the basic circuit configuration. In this case, the

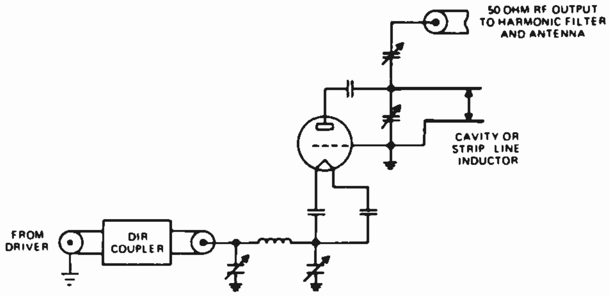

Figure 4.3-26. Cathode driven triode power amplifier.

grid is connected directly to chassis ground. Direct current grid current is the difference between dc cathode current and dc plate current. The output tank circuit is a shorted coaxial cavity which is capacitively loaded by the tube output and stray circuit capacitance. A small capacitor is used for trimming the tuning, and another small variable capacitor is used for adjusting the loading. A pi-network matches the 50 Ω input to the tube cathode.

The triodes are usually operated in the less efficient, Class B mode in order to achieve maximum power gain, which is on the order of 20 (13 dB). They can be driven into high efficiency, Class C operation by providing negative grid bias. This increases the plate efficiency but also requires increased drive power.

Most of the drive power into a grounded-grid amplifier is fed through the tube and appears in the stage's output. This increases the apparent efficiency so that the efficiency factor given by the manufacturer may be higher than the actual plate efficiency of the tube. The true plate efficiency is determined by dividing the output power by the total input power, which includes both the dc plate input power (Ip × Ep) and the RF drive power. Since most of the drive power is fed through the tube, any changes in loading of the output circuit will also affect the input tuning and driver stage.

With RF drive voltage on the cathode (filament) of the tube, some means of de-coupling must be used to block it from the filament transformer. One method employs high current RF chokes since the inductance can be very low at this frequency range. The other commonly used method feeds the filament power through the input tank circuit inductor.

Cathode driven stages are normally used only for the higher power stages. The first stage in a multitube transmitter is nearly always a tetrode because of its higher power gain.

Grounded-Grid Versus Grid Driven Tetrode Operation

Tetrodes may also be operated in the grounded-grid configuration by placing both the control grid and the screen grid at RF ground. Higher efficiency and gain can be achieved by placing negative bias on the control grid while placing a positive voltage on the screen grid of a cathode driven tetrode.

The input capacitance of a tetrode in a grounded-grid configuration is much less than a grid driven configuration and the input impedance is lower providing better bandwidth.

Approximate input capacitances of typical tubes:

	C input (pf)	
Tube Type	Grounded Grid	Grounded Cathode
4CX 3,000A	67	140
4CX 3,500A	59	111
4CX 5,000A	53	115
4CX15,000A	67	161
4CX20,000A/8990	83	190

Typical drive power requirements, as a function of plate voltage, for a 5 kW power amplifier:

	4500 V	5200 V
Configuration	Drive Power	Drive Power
Grounded Grid	340 W	280 W
Grid Driven	190 W	140 W

There are several trade-offs between the performance of grounded-grid and grid driven operations of a tetrode PA with respect to gain, efficiency, amplitude bandwidth, phase bandwidth and synchronous AM under equivalent operating conditions:

- When driving the PA into saturation, the bandwidth of the PA is limited by the output cavity bandwidth in the grounded-grid amplifier. The PA bandwidth in the grid driven amplifier is limited by the input circuit "Q," which is basically determined by the amount of swamping resistance
- Output bandwidth under saturation can be improved in either configuration by reducing the plate voltage. This involves a trade-off in efficiency with a smaller voltage swing. The bandwidth improvement can be obtained with a loss of PA gain and efficiency
- A grounded-grid saturated PA improves bandwidth over a grid driven saturated PA at the expense of amplifier gain. Best performance for FM operation is obtained when the amplifier is driven into saturation where little change in output power occurs with increasing drive power. Maximum efficiency also occurs at this point
- The phase linearity in the 0.5 dB bandwidth is better in a grid driven configuration. The Class C, grounded-grid, PA exhibits a more nonlinear phase slope within the passband, yet has a wider amplitude bandwidth. This phenomenon is due to interaction of the input and output circuits because they are effectively connected in series in the grounded-grid configuration. The neutralized, grid driven, PA provides more isolation between these networks, so they behave more like independent filters.

Grid Driven Tetrode and Pentode Amplifiers

A small tetrode tube such as the 4CX250B is commonly used as the only amplifier stage in 250 W transmitters and as the driver for higher power stages.

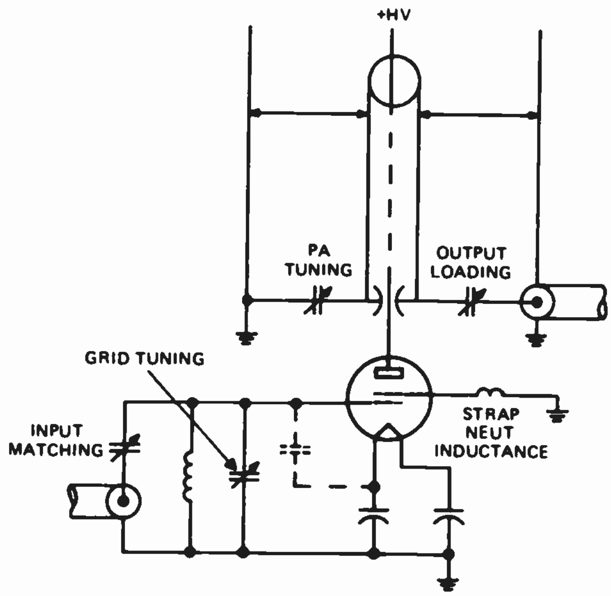

Figure 4.3-27. Grid driven grounded screen tetrode power amplifier.

Transmitters using tetrode amplifiers throughout usually have one less stage than those using triodes. Since tetrodes have higher power gain, they are driven into Class C operation for high plate efficiency. Against these advantages is the requirement for neutralization, along with screen and bias power supplies.

Figure 4.3-27 shows a schematic of a grid driven tetrode amplifier. In this example, the screen is operated at dc ground potential and the cathode (filament) is operated below ground by the amount of screen voltage required. This grounded-screen operation has the advantage of eliminating stability problems due to undesired resonances in the screen bypass capacitors. With directly heated tubes, it is necessary to use filament bypass capacitors. During grounded-screen operation, these bypass capacitors will need to have a higher breakdown voltage rating since they will have the dc screen voltage across them. The filament transformer must have additional insulation to withstand the dc screen voltage. The screen power supply provides a negative voltage in series with the cathode to ground and must have the additional capacity to handle the sum of the plate and screen currents. A coaxial cavity is used in the output circuit so that the circulating current is spread over large surfaces, keeping the losses very low. This cavity is a shorted quarter-wavelength transmission line section which resonates the tube's output capacitance. The length is preset to the desired carrier frequency, and then a small value variable capacitor is used to trim the system to resonance. Capacitive output coupling is used from the high RF voltage point to the 50 Ω transmission line. The 50 Ω input is capacitively coupled into the grid circuit inductor to provide the correct impedance match.

Pentode amplifiers have even higher gain than their tetrode counterparts. The circuit configuration and bias supply requirements for the pentode are similar to the tetrode since the third (suppressor) grid is tied directly to ground. The additional isolating effect of the (suppressor) grid eliminates the need for neutralization in the pentode amplifier.

Impedance Matching Into The Grid

The grid circuit is usually loaded (swamped) with added resistance. The purpose of this resistance is to broaden the bandwidth of the circuit by lowering the circuit "Q" and to provide a more constant load to the driver. It also makes neutralizing less critical so that the amplifier is less likely to become unstable with varying output circuit loading.

Cathode or filament lead inductance from inside the tube, through the socket and filament capacitors to ground can heavily load the input circuit. This is caused by RF current flowing from grid to filament through the tube capacitance and then through the filament lead inductance to ground. An RF voltage is developed on the filament which in effect causes the tube to be partly cathode driven. This undesirable extra drive power requirement can be minimized by series resonating the cathode return path with the filament bypass capacitors or by minimizing the cathode to ground inductance by using a specially designed tube socket using thin-film dielectric "sandwich" capacitors for coupling and bypassing.

High-power, grid driven, Class C, amplifiers require a swing of several hundred RF volts on the grid. To develop this high voltage swing, the input impedance of the grid must be increased by the grid input matching circuit. Since the capacitance between the grid and the other tube elements may be 100 picofarads (pF) or more, the capacitive reactance at 100 MHz will be very low unless the input capacitance is parallel resonated with an inductor. Figure 4.3-28(a) and 28(b) show two popular methods of resonating and matching into the grid of a high power tube. Both methods can be analyzed by recognizing that the desired impedance transformation is produced by an equivalent "L" network.

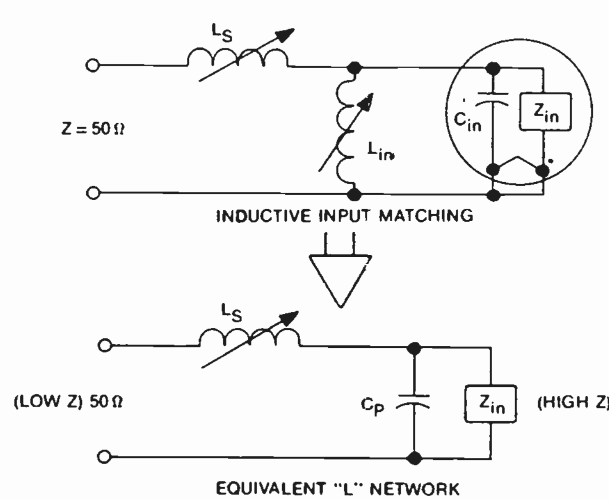

Figure 4.3-28(a). Inductive input matching.

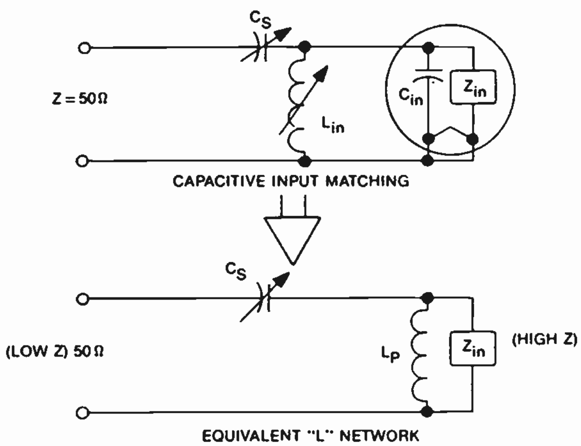

Figure 4.3-28(b). Capacitive input matching.

In Figure 4.3-28(a), a variable inductor (L_{in}) is used to raise the input reactance of the tube by bringing the tube input capacitance (C_{in}) almost to parallel resonance. Parallel resonance is not reached since a small amount of parallel capacitance (C_p) is required by the equivalent "L" network to transform the high impedance (Z_{in}) of the tube down to a lower value through the series matching inductor (L_s). This configuration provides a low-pass filter by using part of the tube's input capacitance to form (C_p).

Figure 4.3-28(b) uses variable inductor (L_{in}) to take the input capacitance (C_{in}) past parallel resonance so that the tube's input impedance becomes slightly inductive. The variable series matching capacitor (C_s) forms the rest of the equivalent "L" network. This configuration is a high-pass filter.

Neutralization

Cathode driven, grounded-grid amplifiers utilizing triodes do not require neutralization. The grid-to-ground inductance, both internal and external to the tube should be kept very low to maintain this advantage. Omission of neutralization will allow a small amount of interaction between the output circuit and the input circuit through the plate-to-filament capacitance. This effect is not very noticeable because of the large coupling between the input and output circuits through the electron beam of the tube. Cathode-driven tetrodes have higher gain and therefore require some form of neutralization.

Grid driven, high gain tetrodes need accurate neutralization for best stability and performance. Self-neutralization can be accomplished very simply by placing a small amount of inductance between the tube screen grid and ground. This inductance is usually in the form of several short, adjustable-length straps. The RF current flowing from plate to screen in the tube also flows through this screen lead inductance. This develops a small RF voltage on the screen, of the opposite phase, which cancels the voltage fed back through the plate-to-grid capacitance. This method of lowering the self-neutralizing frequency of the tube works only if the self-neutralizing frequency of the tube/socket combination is above the desired operating frequency before the inductance is added. Feedback neutralization utilizes a small coupling capacitor, usually in the form of a small plate located near the anode of the tube. The sample of the RF voltage from the anode intercepted by this plate is coupled through a 180 phase shift network into the grid circuit. This technique has the advantage of providing neutralization over a very broad range of frequencies, if implemented correctly and stray reactances are minimized.

Special attention must also be given to minimizing the inductances in the tube socket by integrating distributed bypass capacitors into the socket and cavity deck assembly. Pentodes normally do not require neutralization because the suppressor grid effectively isolates the plate from the grieed. [10]

Power Amplifier Output Circuits

Usually the output circuit consists of a "high-Q" (low loss) transmission line cavity, strip line or a lumped inductor that resonates the tube output capacitance. A means of trimming the tuning and a means of adjusting the coupling to the output transmission line must also be provided by the output circuit. The tank circuit loaded "Q" is kept as low as practical to minimize circuit loss and to maintain as wide an RF bandwidth as possible.

Power Amplifier Cavity

The vacuum tube power amplifier is constructed in an enclosure containing distributed tank circuit elements for minimum loss. The efficiency of the PA depends on the RF plate voltage swing, the plate current conduction angle and the cavity efficiency. The cavity efficiency is related to the ratio of the loaded to unloaded "Q" as follows:

$$N = \left[1 - \left(\frac{Q_L}{Q_U}\right)\right] \times 100 \qquad (8)$$

where:

N = Efficiency in percent
Q_L = Loaded "Q" of cavity
Q_U = Unloaded "Q" of cavity

The loaded "Q" depends on the plate load impedance and output circuit capacitance. Unloaded "Q" depends on the cavity volume and the RF resistivity of the conductors due to skin effects. For best efficiency, a high unloaded "Q" is desirable, as is a low loaded "Q." As the loaded "Q" goes up, the bandwidth decreases. For a given tube output capacitance and power level, loaded "Q" decreases (and bandwidth consequently increases) with decreasing plate voltage or with increasing plate current. The increase in bandwidth at reduced plate voltage occurs because the load resistance is directly related to the RF voltage swing on the tube element. For the same power and efficiency, the bandwidth can also be increased if the output capacitance is reduced. Power tube selection and minimization of stray capacitance are areas of prime concern when designing for maximum bandwidth.

Quarter-Wavelength Cavity

The quarter-wavelength coaxial cavity is the compact and popular PA output circuit illustrated in Figure 4.3-29. The tube anode is coupled through a dc blocking capacitor to a shortened quarter-wave length transmission line. The tube's output capacitance is brought to resonance by the inductive component of the transmission line that is physically less than a quarter-wavelength long. Plate tuning can be accomplished either by adding end-loading capacitance at the high impedance end of the line with a variable capacitor or by changing the position of the ground plane at the low impedance end of the line. The plate tuning capacitor may be a sliding or rotating plate near the anode of the tube. The center conductor of the transmission line (air exhaust chimney) is at dc ground while the anode of the tube operates at a high RF and dc potential. Direct current voltage is fed through an isolated quarter-wavelength de-coupling network inside the chimney to the anode of the tube, while the plate blocking capacitor prevents dc current flow from the anode into the chimney. The quarter-wavelength cavity has approximately twice the operating bandwidth of the half-wavelength cavity.

Folded-Half-Wavelength Cavity

Another approach to VHF power amplification uses the re-entrant, folded-half-wave cavity design illustrated in Figure 4.3-30. The dc anode voltage is applied to the lower portion of the plate line through a choke at the RF voltage null point. The half-wave line is tuned by mechanically expanding or contracting the physical length of a flexible extension (bellows) on the end of the secondary transmission line stub, which is located concentrically within the primary transmission line (air exhaust chimney). Coarse frequency adjustment is accomplished by presetting the depth of the top secondary section of plate line into the tank cavity.

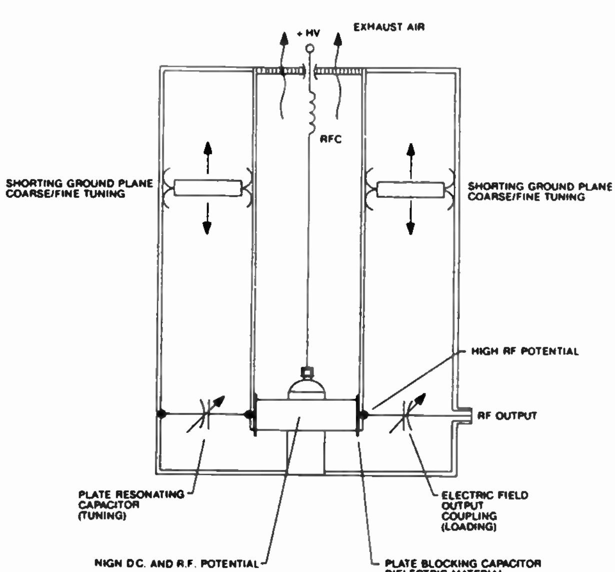

Figure 4.3-29. The quarter-wavelength cavity.

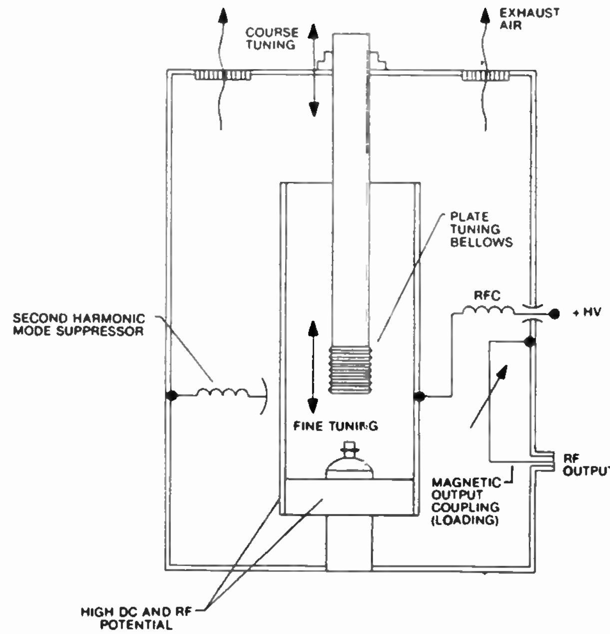

Figure 4.3-30. The folded half wavelength cavity.

Other power amplifier configurations may use lumped components or hybrid combinations with distributed transmission line elements to achieve similar results. The discrete circuit elements are chosen for their individual inductance or capacitance instead of being operated in a purely quarter-wave or half-wave mode. Stray inductance and capacitance add to the component values resulting in the hybrid nature of these circuits.

The RF voltage and current distributions for the quarter-wavelength and the folded-half-wavelength cavities are shown in Figure 4.3-31.

Regardless of the specific configuration, the output circuit must transform the high resonant plate impedance down to the output transmission line impedance of 50 Ω.

The bandwidth of a transmission line cavity is optimized by using a quarter-wavelength and by choosing the highest characteristic impedance mechanically and electrically allowable. [10 and 16] at the end of this chapter give detailed information about the design of tube type RF power amplifiers.

Output Coupling

Power may be coupled from a quarter-wavelength cavity to the transmission line by a capacitive probe located at the high RF voltage point located at the anode end of the quarter-wave line as shown in Figure 4.3-29. The loaded "Q" of this circuit varies with the degree capacitive coupling. Another method of coupling power from the quarter-wavelength cavity uses a tuned loop located near the grounded (high current) end of the line.

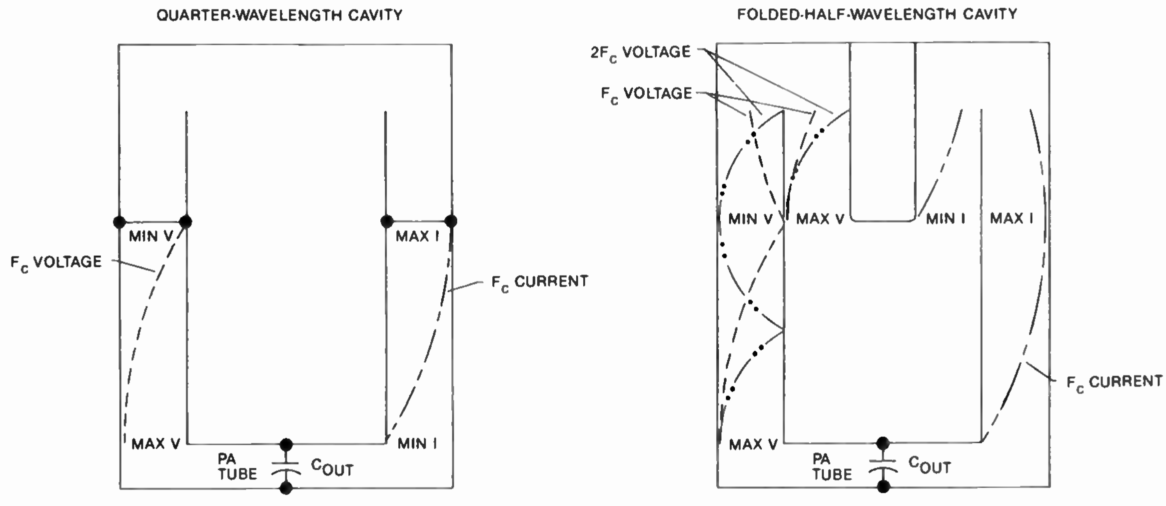

Figure 4.3-31. Cavity RF voltage and current distributions.

In this case, the tuned loop operates both as an inductive and a capacitive pick-up device. Power may be coupled from the half-wave line by an inductive loop located in the strong fundamental magnetic field near the center of the cavity (see Figure 4.3-30).

Power Supplies

Power supplies provide the appropriate dc or ac voltages to the various subsystems with the transmitter. In a typical FM transmitter, the voltages and currents can range from less than 5 V at a few milliamperes to over 10,000 V at several amperes. Safety must therefore be a prime consideration when working around potentially lethal power supplies. Power supplies must be designed with adequate bleeder resistors and interlocks to discharge high voltages before an operator can come in contact with these circuits. The degree to which the ac components are filtered out of the dc outputs of the power supplies will, in large part, determine the "asynchronous" (without FM modulation) AM noise of the FM transmitter.

FM transmitters usually contain multiple power supplies for each of the functional blocks within the system. These power supplies fall into two general categories:

- Single-phase supplies (single input winding on the transformer)
- Polyphase supplies (three or more input windings on the transformer).

Single-Phase Power Supplies

Single-phase power supplies with conventional full-wave rectification and filtering are most often used for the FM exciter, the control system, bias supplies and the IPA. A single-phase supply requires a larger filter choke to achieve the "critical inductance" requirement and a greater value of filter capacitance to maintain acceptably low ripple content compared to a polyphase supply. Large value filter components also mean that the greater stored energy in these components can have a more destructive effect if an arc-over occurs. Choke-input filter sections are normally used to help limit the in-rush current while the shunt capacitor is charging during turn-on. This also maximizes utilization of the transformer and rectifiers by keeping the charging current nearly constant, providing the best filtering action. Choke-input filters have the undesirable characteristic of poor voltage regulation over a wide range of loads. The output voltage will "soar" above the nominal value with no load unless there is enough current through the "bleeder" resistor to keep the choke in the constant current range. Fortunately, in a FM transmitter application, the load on the power supply is fairly constant since the power output of the transmitter does not vary significantly with FM modulation. In higher power transmitters with a three-phase main power source, care must be taken to balance each of the individual single-phase loads among the three phases so that the total load on each of the individual phases is equal.

Polyphase Power Supplies

Polyphase power supplies are used for the final power amplifier, high- voltage supply in high power transmitters. Sometimes they are also used for tube or solid-state IPA supplies. Large blowers used to cool transmitters are usually operated from a three-phase power source. Care must be taken to make the three-line connections to the blower motor in the proper sequence so that the motor will turn in the proper direction.

The most common type of polyphase supply is three-phase with full-wave rectification and LC filtering. Other polyphase systems encountered in broadcast equipment are usually multiples of the three phases with twelve phase rectifiers becoming more popular. The main advantages of a polyphase power supply are:

- Division of the load current between three or more lines to reduce line losses and the size of each of the lines

- Greatly reduced filtering requirements after rectification due to the low ripple at the output of a polyphase full-wave rectifier
- Better voltage regulation with a choke input filter with typically 6% or less "soaring" from no load to full load
- Greater choice of output voltages from a given transformer by selection of either a DELTA or WYE configuration.

The main disadvantage of polyphase systems is their susceptibility to phase imbalance which causes degraded performance of the power supply. If significant imbalance exists in a polyphase system, ripple rejection will be reduced in the polyphase rectifier with a resulting increase in AM noise.

The broadcast engineer should be particularly careful to be sure that the local utility does, in fact, provide true three-phase power to the transmitter site. This can usually be verified by making sure that there are three transformers on the utility pole feeding the transmitter site. In many rural areas, the utilities are still synthesizing pseudo-three-phase service by providing the so-called open-delta (V-V) or Scott (T-T) connection with two transformers instead of true three-phase service. Operation on an open-delta service will degrade the transmitter's performance and increase the susceptibility of the transmitter to damage from transients on the line. Most transmitter manufacturers state that their warranty is void if the transmitter is connected to an open-delta system.

Regulated Power Supplies

In some cases, phase control switching regulation is applied to the high voltage power supply feeding the final output tube. The regulation is accomplished by switching thyristors in the ac mains ahead of the primary winding of the transformer. As the switching duty cycle is reduced, the plate voltage is also reduced. Care must be taken to protect solid-state devices connected to the main power line from transients. Heavy-duty transient suppressors are available for this purpose.

Completely solid-state power amplifiers demand lower voltages at much higher currents. Voltage regulation of these high current supplies is necessary to suppress ripple, but the design of these specialized regulators is different from the typical high voltage power supply. Linear regulators are used at the lower power levels because they are low in efficiency, but they are simple and provide excellent ripple rejection without the need for suppression of switching transients. The linear regulators use series or shunt devices which change resistance dynamically to provide regulation with changes in load and therefore dissipate some of the power within the dynamic resistance.

Switch-mode regulators are used at higher power levels because they are high in efficiency, but they are more complicated and require additional suppression of the switching transients. The high efficiency comes from the digital "on" or "off" nature of the switching regulator which reduces resistive losses by using low loss reactive components to store energy during switching.

Switched tap power supplies can provide good voltage regulation over a limited range at higher efficiency than a switch-mode regulated supply. A solid-state controller switches banks of silicon controlled rectifier (SCRs) between several taps on the secondary of the power transformer to maintain a constant output voltage with changes in load. This type of power supply is simple, efficient and has an excellent power factor (PF). Figure 4.3-32 shows the switching arrangement for the switched tap supply.

Low voltage high current power supplies contain extremely large amounts of stored energy. This can be dangerous due to the high peak currents that can occur during a short circuit across a component with high stored energy. For this reason, special attention must be paid to methods of safely discharging these circuits without damaging components or injuring the operator.

The voltage regulator should provide short-circuit protection with some type of current limiting. The main danger to the operator from this type of power supply is burns due to the nearly instantaneous heating of metallic tools and other conductors (like a metal watchband or ring) that accidentally get into a high current path (such as a short across the filter capacitor).

Power Factor

The PF of a power supply is the measurement of how reactive the input impedance of the power supply appears to the ac power line feeding it and/or how nonlinear this load impedance is. PF is usually specified as a decimal value of less than 1.0 which is the cosine of the phase angle between the voltage and current waveforms on the ac line feeding the input to the power supply.

$$PF = \cos\phi \qquad (9)$$

Where: ϕ is the angle between the voltage and current waveforms

The power utility prefers a resistive load with a unity power factor and minimum disturbance to the voltage waveform on the ac line. A non-unity power factor can be the result of either an inductive or capacitive load. Transmitter power supplies usually have an inductive power factor. Generally, it is desirable to have a power factor of greater than 0.9 which means that the current waveform is displaced less than 26° from the voltage waveform. Minimizing the harmonic content of the waveforms impressed across the ac power line by the power supply is important to prevent interference to other equipment connected to the same power line. If there is high harmonic content in the current waveform, it will degrade the power factor measurement. However, since it is possible with certain linear, reactive loads to have a low power factor with low harmonic content, it is best to measure and specify both the power factor and harmonic content separately from each other. [2, 12, 13]

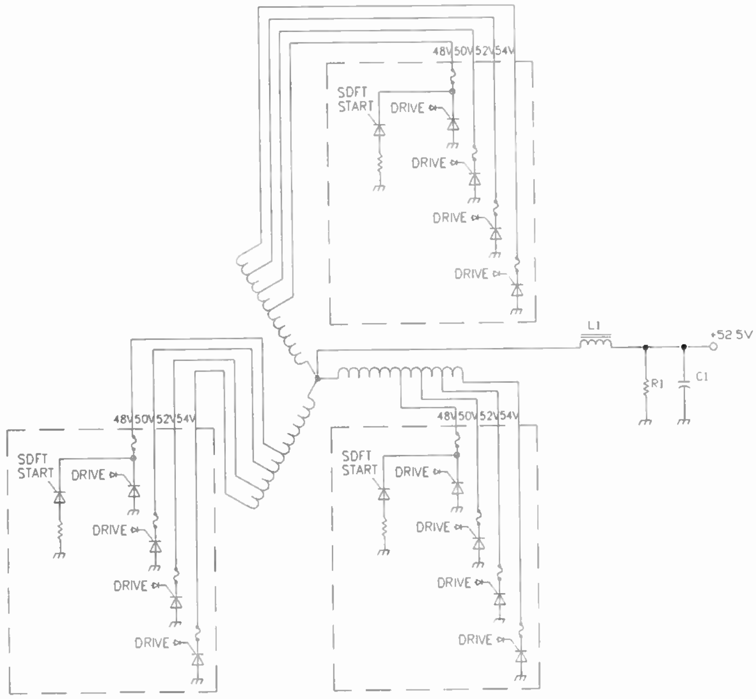

Figure 4.3-32. Switched tap power supply in Harris "Z" solid-state FM transmitter.

Step-Start

Step-start is often used in large power supplies where peak in-rush currents become high when the power supply is first turned on. These peak currents are caused by the need to overcome the hysteresis effect (to initially magnetize the core of the transformer) when ac power is first applied, and to charge the filter capacitor. Step-start systems temporarily insert a resistance or reactance in series with the power lines to limit the current to a reasonable value until initial magnetization of the core and filter charging are completed.

Transmitter Control Systems

Transmitter control systems are often overlooked or given little priority in the selection and maintenance of a broadcast transmitter. The transmitter's control system does, however, serve several important purposes. It provides for:

- Basic on/off control of the transmitter
- Overload protection to protect the transmitter from damage
- Safety interlock protection to prevent injury to people and accessory equipment such as RF switching equipment or RF loads
- A means of controlling the transmitter output power
- Remote control capability and interfacing at installations where the transmitter is not at the same location as the control operator
- Warm-up and cool-down timing sequences of filaments or other time sensitive operations

Additionally, a transmitter control system may provide for:

- Status indications of overloads or other critical parameters
- Automatic regulation of the transmitter output power
- Diagnostic indications to aid in adjustment and maintenance
- Totally automatic operation of the transmitter plant
- Integrated remote control capability.

The transmitter's ability to stay on-the-air will only be as good as the reliability of the control system. So selection and correct operation of the transmitter control system are important.

Early transmitter technology relied on simple relay logic combined with electromechanical contactors to control the transmitter. The speed and variety of overload protection was limited, and diagnostics were not available. While these systems had the virtue of being simple and immune to RFI, the relay logic required continuing maintenance in order to keep the contacts clean and properly adjusted.

Later, transmitter control logic relays were replaced by solid-state digital logic. This provided much more flexibility and reliability, but also raised concerns about the ruggedness and ability of solid-state logic to survive lightning strikes. Although this concern is valid, modern solid-state logic and microprocessor control systems are well protected against damage by optical isolation, shunt protection techniques and radio frequency interference (RFI) filtering. Operating experience with the current generation of transmitters has proven that a properly designed solid-state control system is far more reliable than its relay predecessors.

Automatic Power Control

Many transmitters also provide automatic power control (APC) circuitry to maintain the transmitter's power output within preset limits by correcting for changes in line voltage, component aging or small amounts of drift in operating parameters. The APC circuitry compares a sample of the transmitter output power to a reference and then adjusts the RF drive or other voltages within the transmitter to bring the output power within tolerance.

Some of the more sophisticated APC circuits also provide proportional VSWR fold-back of the transmitter output power. If a sample of the reflected power on the transmission line exceeds a safe limit, the transmitter output power is proportionally reduced to a safe level until the problem is resolved. This feature prevents lost air time during antenna icing or other limited VSWR situations. All standard APC circuits should provide fast-acting shutdown of the transmitter during a catastrophic failure of the antenna system such as a short or open circuit.

Microprocessor Control Systems

Microprocessor technology is now commonly applied to broadcast transmitter control systems. Microprocessor based control systems expand the functions of the transmitter controller from basic housekeeping duties into powerful self-diagnostics, controller redundancy, adaptive control of amplifier combining systems, integrated remote control, user customization and even self-correction of operational problems.

Microprocessor technology lends itself well to industrial control applications like broadcast transmitters. The hardware can be made just as reliable as hard-wired digital logic, allow changes and growth in the operational features by simple modifications in software instructions rather than a complete redesign of the hardware.

Several transmitter manufacturers are marketing transmitters with microprocessor based control systems. Some of the typical features that distinguish these control systems from non microprocessor systems are:

- Built-in "trouble tree" with fault location and diagnostic read-outs with user-friendly messages
- Simultaneous read-outs of all operating parameters
- Real time calculation of efficiency, dissipation, VSWR and other parameters requiring mathematical operations
- Adjustment of parameters to maximize efficiency and minimize reject load dissipation
- Built-in clock/calendar for logging changes in operating status, power failures and overloads
- Tolerance flagging on key operating parameters as warnings for logging and for preventive maintenance
- Ability to communicate with the outside world for remote control or logging purposes through a standard serial interface or TCP/IP
- Integrated remote control capability without external remote control equipment and interfacing
- Provision to customize the system features to the station's individual requirements through the use of software menus
- Tuning aids which allow the operator to adjust the system for peak efficiency, minimum dissipation and minimum VSWR by means of a real time display of these calculated parameters

The method of communicating information to the operator varies among systems, but most use LED or LCD read-outs with codes or alphanumeric messages. Microprocessor controllers can also be equipped with large graphic displays so that a large amount of information can be displayed in several different graphical formats.

Controller Back-Up Systems

A certain degree of redundancy is desirable in the transmitter control system so that the transmitter can stay on-the-air even if a portion of the system fails. There are several approaches currently in use to provide back-up systems. A multi-level hierarchy can be used which automatically hands over basic control functions to a primary "life support" controller in the event of microprocessor hardware or software problems. Good systems design separates diagnostic and supervisory functions from basic control functions so that a failure in a higher level function will not affect the ability of the system to remain on-the-air without interruption. Watchdog circuits and software are embedded within the control system to detect failures and initiate corrective action before an interruption in service occurs.

It is also possible to have distributed microprocessor systems with multiple processors that can automatically pick up the tasks of a failed processor without affecting the ability of the transmitter to remain on the air. The ability to quickly replace a controller subsystem while remaining on the air is an advantage of the latest generation of transmitter control systems.

Remote Control Interfacing

Regardless of the type of control system used, the ability to interface easily with standard remote control systems is very important. Most modern systems interface with parallel control lines for each individual function requiring a momentary contact closure of 24 V or less at a current of 50 milliamperes or less. These levels are compatible with relay logic or optically isolated solid-state logic. Analog levels output from the transmitter for remote meter readings generally are fully buffered and fall into the range of 0–5 V dc for a full scale reading at an impedance level of less than 10 KΩ.

The advent of microprocessor based control systems has been accompanied by a trend toward using standard computer asynchronous serial interfacing instead of parallel interfacing. Serial interfacing reduces the number of connections to the transmitter and can carry both control functions and digitized meter readings through the same interface. By converting analog information into digital information before transmission to the remote control point, the need for calibration and recalibration of the remote metering point is reduced. The current trend is toward open, nonproprietary, serial data protocols and interface standards such as Internet SNMP and TCP/IP. This allows the user maximum flexibility in choosing dedicated remote control equipment or using software based network management tools. Microprocessor based control systems also allow the remote control system to have access to more in-depth information about the transmitter than is possible by parallel interfacing with an external remote control system. A personal computer or laptop computer can be used to control the transmitter through an ordinary dial-up phone line, Internet IP address or radio link.

For more specific information, see Chapter 4.7 "Transmitter Remote Control Systems."

RF Output and Systems Filters

The high efficiency, nonlinear RF power amplifiers used in FM broadcast transmitters generate significant amounts of energy on frequencies that are integer multiples (harmonics) of the desired fundamental frequency. The output circuit alone does not provide enough harmonic attenuation to meet FCC regulations. To comply with Part 73 of the CFR and to prevent interference to other services, a low-pass filter must be installed in the transmission line at the output of the transmitter. The FM band is narrow enough that one low-pass filter design can be used for any FM channel carrier frequency. These filters usually consist of multiple LC sections arranged so that frequencies within the FM band are passed with little attenuation (typically 0.1 dB or less) while frequencies above the FM band are highly attenuated (60 dB or more).

The most common type of filter used in this application is a reflective filter. This means that the frequency components outside the passband are reflected back out of the filter toward the source because the filter provides a mismatch at these undesired frequencies. The filter can be constructed using either lumped inductors and capacitors or by using a section of nonconstant impedance transmission line to form distributed inductors and capacitors. The filters designed for low power transmitters often employ "lumped" elements (coils and capacitors) because these elements are compact and can be integrated into the transmitter cabinet. The distributed type of filter is most often used with high power-FM broadcast transmitters because of its simplicity, extreme ruggedness and ability to handle higher power levels. The distributed filter does have the disadvantage of having larger physical dimensions than a similar lumped filter, which may necessitate mounting the filter external to the transmitter cabinet. Figure 4.3-33 shows a cut-away view of a typical distributed low-pass filter. Note that the areas where the center conductor of the transmission line is smaller than that required for the input Z_0 are inductive, while the areas where the center conductor is larger in diameter are capacitive.

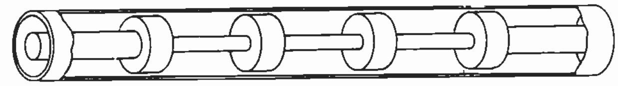

Figure 4.3-33. Cut-away view of a distributed low pass filter.

When two filters (such as the output cavity and the harmonic filter) are connected together by a transmission line, the total harmonic attenuation will vary with interconnecting line length. The attenuation characteristics of the harmonic filter are specified for the condition where both the source and load impedances are equal to the desired transmission line impedance.

In actual use, the source impedance at the output of the tank circuit is much less than the 50 Ω load impedance presented by a properly terminated filter. If an incorrect length of line is selected, the harmonic attenuation may be insufficient and the transmitter tuning may be affected. This undesirable condition can be corrected by changing the line length by approximately one-quarter wavelength. The line length between the tank circuit and harmonic filter is usually supplied precut to a value satisfactory to the transmitter manufacturer.

Harmonic Notch Filters

In some cases, a second harmonic notch filter is required in addition to the low-pass filter because the second harmonic component from the amplifier is high and the cut-off slope of the low-pass filter is not steep enough to provide sufficient second harmonic attenuation. The additional attenuation required (typically 30 dB) can be provided by a notch filter which places a short circuit across the transmission line at the second harmonic while providing a high impedance at the fundamental. A one-quarter wavelength (at the fundamental frequency) shorted coaxial stub is often used for this function. The second harmonic energy is partially reflected back into the power amplifier and partially dissipated in the equivalent series resistance of the series-tuned circuit formed by the stub. This shorted stub provides a very low inductance and a dc path from the center conductor of the transmission line to ground, providing a separate, protective advantage by shunting static discharges, such as lightning, to ground. Some transmitters have internal second harmonic suppressors which eliminate the need for an external notch filter.

Transmission Line Power and SWR Measurements

Directional wattmeters are instruments that measure the forward power (P_f) and reflected power (P_r) in a transmission line. The net power delivered to the load (antenna) is ($P_f - P_r$). If the transmission line is perfectly matched, all the forward power will be absorbed by the load and there will be no reflected power. The peak voltage at each point along the line will be the same value; similarly, the current at each point along the line will also have a uniform value. If the transmission line is mismatched, there will be reflected power with a resulting standing wave on the line. This means that the voltage and current distributions along the line will no longer be uniform with high values at certain points on the line and low values at points one-quarter wavelength away. The ratio of high value to the low value is called the standing wave ratio (SWR).

SWR

The SWR on the transmission line is related to the ratio of the forward to reflected power by the following formula:

$$\mathrm{SWR} = \frac{1 + \sqrt{(P_r/P_f)}}{1 - \sqrt{(P_r/P_f)}} \qquad (10)$$

This relationship is shown graphically in Figure 4.3-34 so the approximate SWR can be obtained without computation.

The standing wave is due to the presence of two components of power, one traveling toward the load and the other reflected by the load mismatch, traveling back toward the generator.

These components are defined as:

$$P_f = \frac{E_f^2}{Z_o} = I_f^2(Z_o) \qquad (11)$$

$$P_r = \frac{E_r^2}{Z_o} = I_r^2(Z_o) \qquad (12)$$

$$P_n = (P_f - P_r) \qquad (13)$$

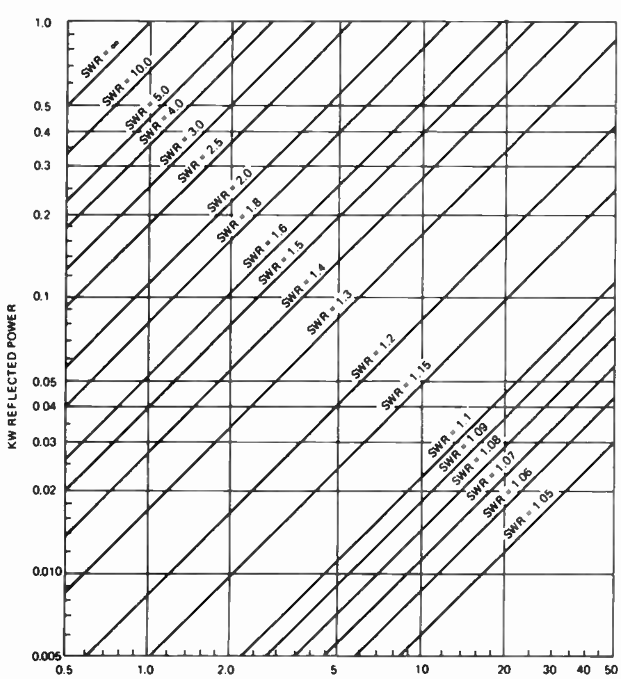

Figure 4.3-34. Chart of SWR versus forward and reflected power.

The subscripts ($_f$) and ($_r$) are used to denote the forward and reflected values of power, voltage and current; while Z_o is the characteristic impedance of the transmission line. (P_n) is the net power absorbed by the load (transmission line loss and antenna radiation).

Since the forward and reflected voltage and currents are traveling in opposite directions, they will add in phase at some point along the line length to produce a voltage maximum. One-quarter wave length along the line in either direction from this maximum, the forward and reflected components are out of phase and produce a voltage minimum. The forward and reflected components of current also add vectorially to produce a current standing wave. The magnitude of the standing wave is defined as:

$$\mathrm{SWR} = \frac{E_{\max}}{E_{\min}} = \frac{I_{\max}}{I_{\min}} \qquad (14)$$

The ratio of the highest voltage point on the line to the lowest voltage point on the line is a commonly used measure of system performance defined as the VSWR. A VSWR of 1.0:1 means that a perfect match has been achieved, while a VSWR of 2.0:1 means that a mismatch is causing approximately 11% of the power to be reflected.

At the point of reflection (the load mismatch), the phase of the reflected current is reversed 180 from the forward current. The reflected voltage does not have this phase reversal. This displaces the voltage and current standing waves by 90° along the line so that the ($E_{\max}$) and ($I_{\min}$) occur at the same points while ($E_{\min}$) and ($I_{\max}$) occur 90° (one-quarter wavelength) away, in either direction from ($E_{\max}$) and ($I_{\min}$).

Since the reflected current is reversed in phase a directional coupler can measure forward and reflected power separately. A small voltage is obtained by inductive coupling which represents the current in the transmission line. To this is added a sample of the voltage across the line that is simultaneously obtained by capacitive coupling. These two samples are adjusted to be exactly equal when the line is terminated with its characteristic impedance (no standing waves and no reflected components). The two RF samples are added, which gives a resultant RF voltage proportional to the forward components of voltage and current as illustrated in Figure 4.3-35(a).

The forward components of the samples are equal and in phase, but the reflected components of voltage and current balance out. By having a second coupling section physically turned around in the opposite direction, the phase of the current sample is reversed; the reflected components add while the forward components balance out as illustrated by the vector diagram in Figure 4.3-35(b). The voltages representing the forward and reflected powers output by the directional coupler are usually rectified and buffered to feed the automatic power controller and a power indicating meter. Since power is proportional to the square of the voltage on the transmission line, the meter scale is calibrated to read the square of its input. It also has

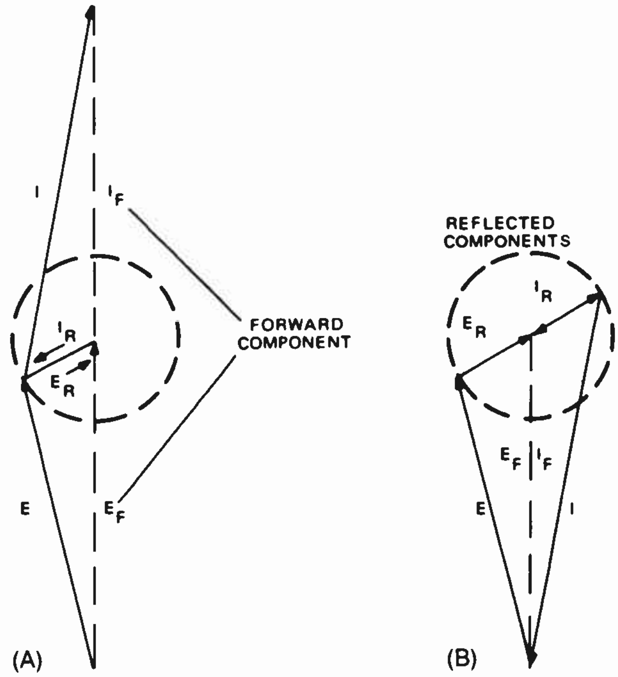

Figure 4.3-35. Phasor addition of voltage and current samples to separate forward and reflected components.

a diode correction factor so that forward and reflected power are read out directly.

VSWR Measurement

Although some FM transmitters can operate into a VSWR of greater than 1.8:1, the VSWR on an FM antenna transmission line should normally be kept to a value of 1.1:1 or less for good stereo performance. It takes very little reflected power to produce substantial VSWR (see Figure 4.3-34). For this reason, the reflected power is usually read on a more sensitive meter position. Problems in the antenna system, such as loose connections or icing, may cause excessive VSWR. Instruments external to the transmitter are available that monitor reflected power and energize an alarm if it becomes excessive. As long as the transmitter power output is fairly constant, the use of reflected power to indicate excessive VSWR is simple and adequate.

Combined Transmitters

It is possible to combine the output of two RF power amplifiers for higher power levels. The important advantage is that the broadcast transmission is not interrupted if one amplifier fails. The radiated signal strength merely drops 6 dB until the failed amplifier is repaired and put back on the air. A dual amplifier system costs more than a single amplifier for a given total power output, but there are the economic advantages of reducing lost air time and eliminating the need for a separate standby transmitter. Automatic or manual output switching can be used to route the full power of the remaining amplifier directly to the antenna.

Two methods may be used to bypass the output combining hybrid to allow 100% of the power of the remaining transmitter to be sent to the antenna if one transmitter of a combined pair should fail.

The first method uses three motorized switches (or patch panels) to bypass the 3 dB hybrid while connecting the operating transmitter directly to the antenna and the failed transmitter directly to the test load. This allows recovery of the 50% power lost in the reject load when one transmitter is off the air. One disadvantage is that the system must be taken off the air for several seconds for operation of the coax switches.

A second method provided by some transmitter suppliers uses a pair of 3 dB hybrids interconnected with one fixed and one variable RF phasing section. The phasing section is constructed to operate while under RF power and can re-direct the full output of either transmitter directly to the antenna and place the other transmitter into the test load without taking the system off the air. A dedicated system controller allows automatic or manual control. This so-called switchless combiner offers the highest possible on-air availability for combined FM transmitters. With complete redundancy in the RF power amplifier chain, some stations go one step further and also install dual exciters with automatic switching so that if one exciter fails, the other unit is quickly switched into service.

Hybrid Couplers

Hybrid couplers are reciprocal four-port devices that can be used either for splitting or combining RF sources over a wide frequency range. Figure 4.3-36 shows an exploded view of a typical 3 dB, 90°, hybrid coupler. The coupler consists of two identical parallel transmission lines that are coupled over a distance of approximately one-quarter wavelength and are enclosed within a single outer conductor. Ports at the same end of the coupler are in-phase while ports at opposite ends of the coupler are in quadrature (90° phase shift) with respect to each other.

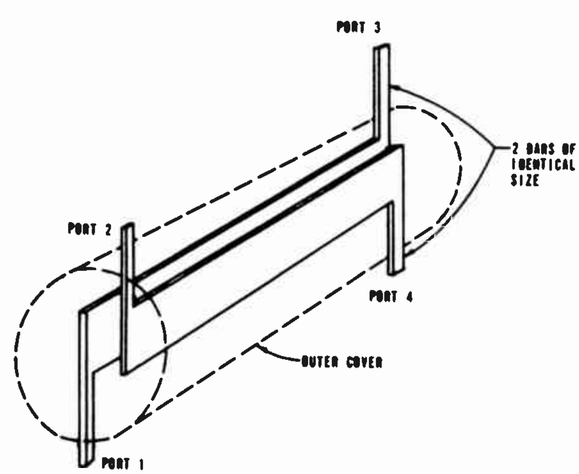

Figure 4.3-36. Physical model of 90° hybrid coupler.

The phase-shift between the two inputs or outputs is always 90° and is almost independent of frequency. If the coupler is being used to combine two signals into one output, these two signals must be fed to the hybrid coupler in phase quadrature. The reason this type of coupler is also called a 3 dB coupler is that when used as a power splitter, the split is equal or half-power (3 dB) between the two outputs.

Hybrid Combiners

The output hybrid combiner effectively isolates the two amplifiers from each other. Tuning adjustments can be made on one amplifier, including turning it on and off, without appreciably affecting the operation of the other amplifier. Good isolation is necessary so that if one transmitter fails, the other will continue to operate normally instead of in a mistuned condition. Two of the ports on the hybrid coupler are the inputs from the power amplifiers. The sum port is the antenna output terminal and the difference port goes to a resistive dummy load called the "reject load" since only the rejected power due to imbalance appears here. When the power fed to each of the two inputs is equal in amplitude with a phase difference of 90° the total power is delivered to the sum port (antenna). Very little of the power appears at the reject load if the phase relationship and power balance are correct. If the phase relationship is reversed between the two amplifiers, all the power is delivered to the reject load, so care must be taken to be sure that the proper one of the two possible 90° phase relationships is used. When all the ports on the hybrid combiner are properly terminated, isolation of 30 dB or more can be achieved between the power amplifiers. For perfect isolation between the amplifiers, the load impedance on the sum and difference ports must be exactly the same. This is approached in practice by providing a 1.0:1 VSWR with a resistive 50 Ω load for the termination (reject load) on the difference port and then reducing the VSWR on the antenna transmission line as low as possible by trimming the antenna match. This will keep the input port impedances from changing very much when one amplifier is not operating.

The input ports will present a load to each transmitter with a VSWR that is lower than the VSWR on the output transmission line. This is because part of the reflected power coming into the output port will be directed to the reject load and only a portion will be fed back into the transmitters. Figure 4.3-37 shows the effect of output port VSWR on the input port VSWR and on the isolation between ports.

If the two inputs from the separate amplifiers are not equal in amplitude or exactly in phase quadrature, some of the power will be dissipated in the difference port reject load. The match in input power and phase is not extremely critical. See Figures 4.3-38 and 4.3-39.

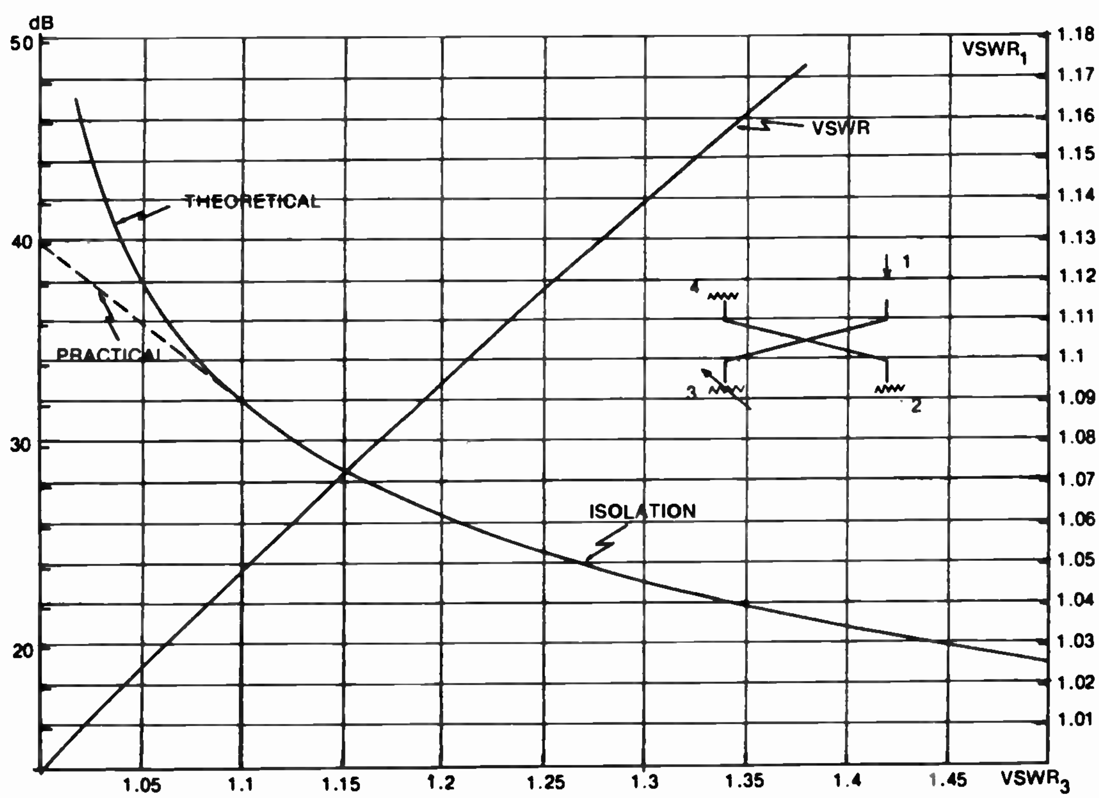

Figure 4.3-37. Isolation of hybrid coupler.

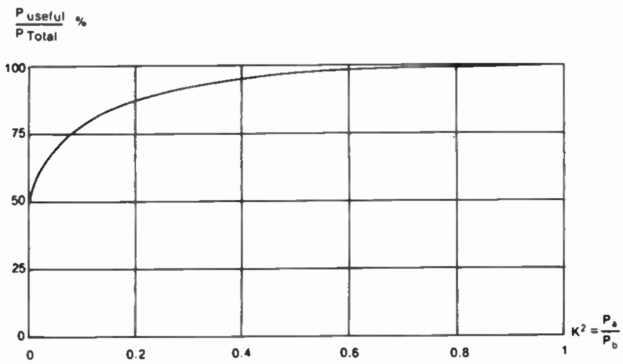

Figure 4.3-38. Power imbalance in hybrid couplers.

The power lost in the difference port reject load can be easily reduced to a negligible value by touching up the amplifier tuning and by adjusting the phase shift. For example, if one amplifier is delivering only half the power of the other amplifier, only about 3% of the total available power will be dissipated in the reject load; 97% is still fed to the output transmission line.

If one transmitter fails completely, half of the working amplifier's output goes to the antenna, and the other half is dissipated in the difference port reject load. This is why the radiated output drops by 6 dB or to one-fourth of the original combined power. The reject load must be rated to handle a minimum of one-fourth of the total combined power, but often the reject load is rated to handle one-half the total power so that it can also be used as a test load for one of the transmitters.

Hybrid Splitting of Exciter Power

Figure 4.3-40 shows a block diagram of a pair of combined amplifiers with dual exciters. The exciters cannot be operated in parallel like the amplifiers because their RF outputs would have to be on exactly the same carrier frequency and almost exactly in phase under all modulation conditions. An automatic or manual exciter switcher is used to direct the output of the

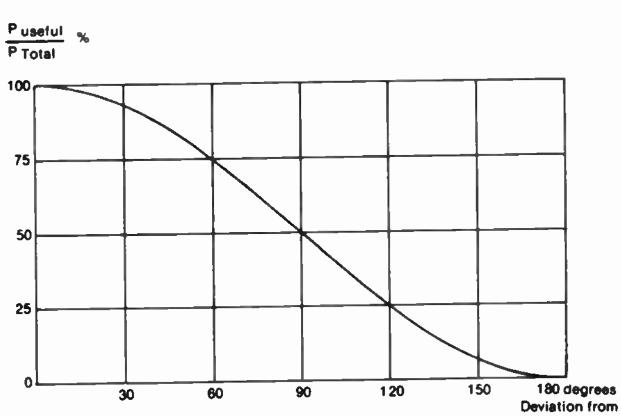

Figure 4.3-39. Phase sensitivity, hybrid coupler.

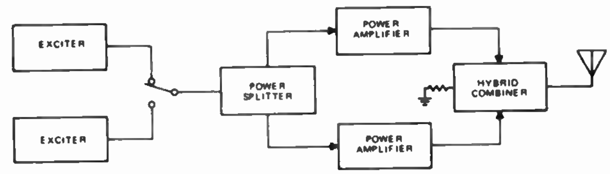

Figure 4.3-40. Block diagram of transmitter with two power amplifiers, a hybrid combiner and dual exciters.

desired exciter to the combined transmitter while the other stand-by exciter is routed to a dummy load. The one exciter in use feeds a hybrid splitter/phase shifter which transforms one 50 Ω input into two isolated 50 Ω outputs that have a 90° phase shift between them with half the power going to each output. The operation of this hybrid splitter is the reciprocal of the hybrid combiner described above. The exciter must have enough power output capability to drive both power amplifiers. In some cases, an additional IPA is required between the exciter and the splitter to boost the drive level. The length of coax from the power splitter to each amplifier input must be cut to a precise length so that the amplifiers will be fed in the proper phase relationship.

Each of the power amplifiers is assumed to have equal gain and phase shift. In practice, it may be difficult to get the amplifiers tuned so that their gains and phase shifts are equal at the same time. For this reason, a line stretcher or variable phase shift network is usually included with the exciter splitter so that the station engineer will have the ability to adjust phasing independent of amplifier tuning. For more detailed information on the theory of hybrid couplers, see the chapter on television transmitters and [7].

Filterplexing

Having several FM stations share a single broad band antenna system is becoming more and more popular. A special device called a filterplexer (also known as an RF multiplexer) is used to connect several transmitters on different frequencies together onto one antenna system. The filterplexer provides isolation between the various transmitters while efficiently combining their power into a single transmission line. This is usually accomplished by a system of band-pass filters, band-reject filters and hybrid combiners. The isolation is required to prevent power from one transmitter from entering another transmitter with resulting spurious emissions as well as to keep the rest of the system running in the event of the failure of one or more transmitters.

An important consideration in the design of a filterplexing system is the effect on the phase response (group delay characteristic in the passband) of each of the signals passing through the system due to individual bandwidth limitations on each of the inputs.

RF Intermodulation Between FM Broadcast Transmitters

Interference to other stations within the FM broadcast band, as well as to other services outside the broadcast band, can be caused by RF intermodulation

3rd ORDER INTERMODULATION PRODUCTS

f_1=100.3 MHz. f_2=101.1 MHz.

$2f_1$-f_2=[2(100.3)-(101.1)]=[200.6-101.1]=99.5 MHz.

$2f_2$-f_1=[2(101.1)-(100.3)]=[202.2-100.3]=101.9 MHz.

OR

[f_1-(f_2-f_1)]=[100.3-(101.1-100.3)]=[100.3-0.8]= 99.5 MHz.

[f_2+(f_2-f_1)]=[101.1+(101.1-100.3)]=[101.1+0.8]=101.9 MHz.

4.3-41. Example of how the intermodulation product frequencies may be calculated.

between two or more FM broadcast transmitters. Transmitter manufacturers have begun to characterize the susceptibility of their equipment to RF intermodulation so this information is becoming available to the designers of filterplexing equipment.

The degree of intermodulation interference generated within a given system can be accurately predicted before the system is built if the actual mixing loss of the transmitters is available when the system is designed. Accurate data on *"Mixing Loss" or "Turn-Around-Loss"* not only speeds the design of filterplexing equipment, but also results in higher performance and more cost-effective designs because the exact degree of isolation required is known before the system is designed. Filterplexer characteristics, as well as antenna isolation requirements, can be tailored to the specific requirements of the transmitters being used. The end user is assured in advance of construction that the system will perform to specification without fear of overdesign or underdesign of the components within the system.

Mechanisms that Generate RF Intermodulation Products

When two or more transmitters are coupled to each other, new spectral components are produced by mixing the fundamental and harmonic terms of each of the desired output frequencies. For example, if only two transmitters are involved, the third order intermodulation (IM_3) terms could be generated in the following way. The output of the first transmitter (f_1) is coupled into the nonlinear output stage of the second transmitter (f_2) because there is not complete isolation between the two output stages. The (f_1) will mix with the second harmonic of (f_2), producing an in-band third order term with a frequency of $[2(f_2) - (f_1)]$. In a similar fashion the other third order term will be produced at a frequency of $[2(f_1) - (f_2)]$. This implies that the second harmonic content within each transmitter's output stage, along with the specific nonlinear characteristics of the output stage, will have an effect on the value of the mixing loss.

It is possible, however, to generate these same third order terms in another way. If the difference frequency between the two transmitters $[(f_2) - (f_1)]$, which is an out-of-band frequency, re-mixes with either (f_1) or (f_2), the same third order intermodulation frequencies are produced.

Empirical measurements indicate that the $[2(f_2) - (f_1)]$ type of mechanism is the dominant mode generating third order IM products in modern transmitters using a tuned cavity for the output network.

Figure 4.3-41 shows an example of how the intermodulation product frequencies may be calculated. Figures 4.3-42 and 4.3-43 show the resulting frequency spectra.

Intermodulation as a Function of "Turn-Around Loss"

Turn around loss or mixing loss describes the phenomenon whereby the interfering signal mixes with the fundamental and its harmonics within the nonlinear output device. This mixing occurs with a net conversion loss; hence, the term turn around loss has become widely used to quantify the ratio of the interfering level to the resulting IM_3 level. A turn around loss of

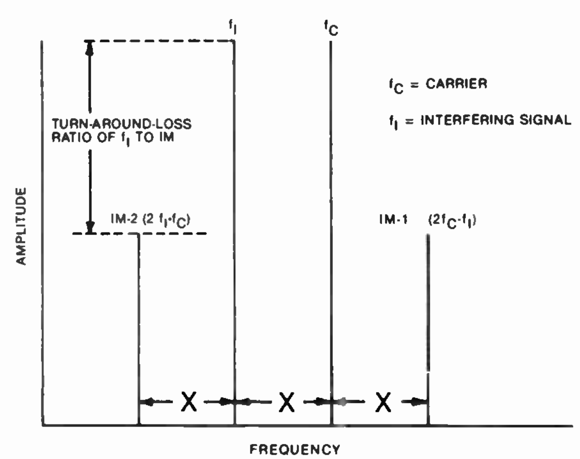

Figure 4.3-42. Frequency spectrum of third order IM with the interfering signal level equal to the carrier level.

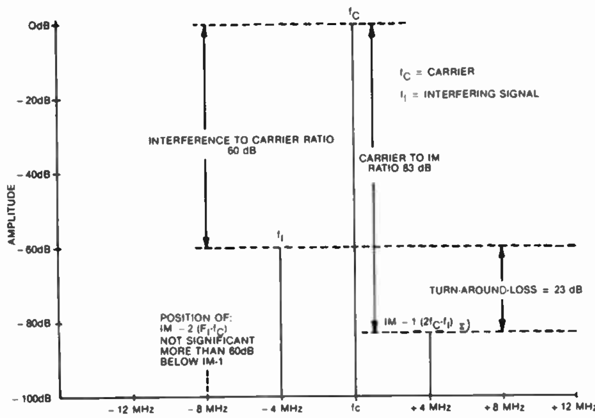

Figure 4.3-43. Typical frequency spectrum of third order IM of a broadcast FM transmitter.

10 dB means that the IM_3 product fed back to the antenna system will be 10 dB below the interfering signal fed into the transmitter's output stage.

Turn around loss will increase if the interfering signal falls outside the passband of the transmitter's output circuit, varying with the frequency separation of the desired signal and the interfering signal. This is because the interfering signal is first attenuated by the selectivity going into the nonlinear device; the IM_3 product is then further attenuated as it comes back out through the frequency selective circuit.

Turn around loss consists of three components:

1. The basic in-band conversion loss of the nonlinear device
2. The attenuation of the out-of-band interfering signal due to the selectivity of the output stage
3. The attenuation of the resulting out-of-band IM_3 products due to the selectivity of the output stage.

As the turn around loss increases, the level of undesirable intermodulation products is reduced, and the amount of isolation required between transmitters is also reduced.

The transmitter output circuit loading control directly affects the source impedance. This therefore affects the efficiency of coupling the interfering signal into the output circuit where it mixes with the other frequencies present to produce IM_3 products. Light loading reduces the amount of interference that enters the output circuit with a resulting increase in turn around loss. In addition, the output loading control setting will change the output circuit bandwidth (loaded "Q") and therefore will also affect the amount of attenuation that out-of-band signals will encounter passing into and out of the output circuit.

Second harmonic traps or low-pass filters in the transmission line of either transmitter have little effect on the generation of intermodulation products. This is because the harmonic content of the interfering signal entering the output circuit of the transmitter has much less effect on IM_3 generation than the harmonic content within the nonlinear device itself. The resulting IM_3 products fall within the passband of the low-pass filters and outside the reject band of the second harmonic traps, so these devices offer no attenuation to RF intermodulation products.

Figure 4.3-44 gives an overview of the various filtering options to prevent excessive IM_3 products.

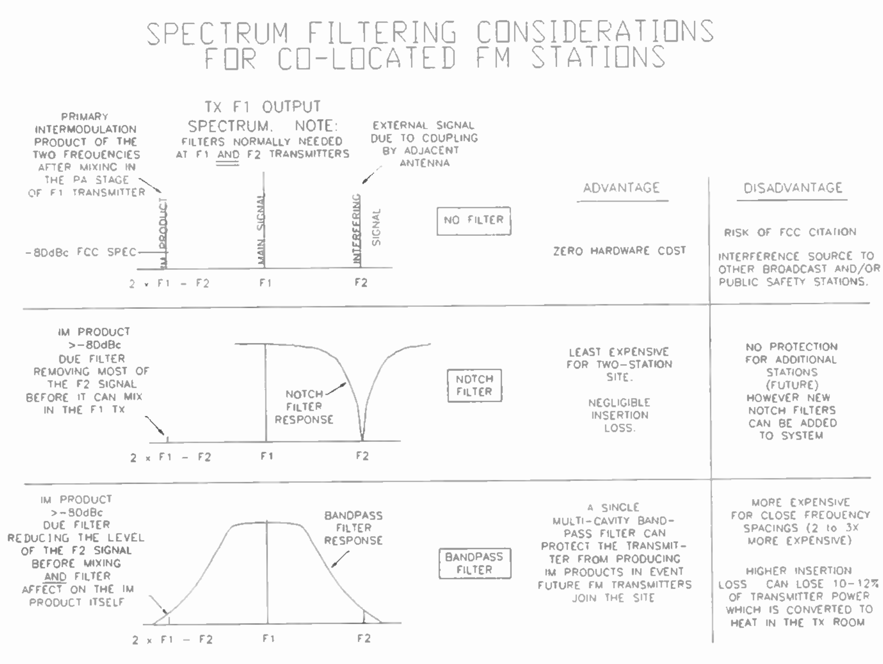

Figure 4.3-44. RF filtering requirements.

Reduction of RF Intermodulation in Solid-State Transmitters

Depending on the topology of the combining system, broad band, solid-state transmitters are more likely to generate RF intermodulation products than single-tube transmitters which have a narrow band, selective cavity in the output stage. However, some modern solid-state designs use balanced "N-way" module combiners together with a conventional 3 dB hybrid as the final output combining stage. This topology tends to provide a rather uniform 15 dB turnaround loss to incoming RF interference, regardless of the frequency separation of the solid-state transmitter's FM carrier from an interfering carrier. For frequency spacings closer than about 5 MHz from the interfering carrier, a solid-state transmitter using this combining technique actually produces fewer RF intermodulation IM_3 products than a single tube FM transmitter whose close in turnaround loss can be less than 6 dB. In some cases, a solid-state FM transmitter of this design may not require as much (or any) external RF filtering. In other cases, it may require more RF filtering than a tube/cavity transmitter. The turnaround loss of a narrow band tube/cavity transmitter is usually better than a broad band, solid-state transmitter when there is a large frequency separation (>5 MHz) between the carrier frequency and the interfering frequency. This is due to the skirt selectivity of the narrowband final amplifier cavity. Co-sited FM transmitters are likely to need external RF filtering to prevent the generation or transmission of unacceptable RF intermodulation products, regardless of whether they are of tube/cavity or of solid-state design. For more detailed information about RF intermodulation between transmitters, see the chapters on FM and TV antenna systems and [14].

Synchronous FM Boosters

According to FCC rules, FM stations may operate on frequency booster facilities up to 20% of the maximum permissible ERP for the class of primary station they rebroadcast. The booster station may not, however, transmit beyond the predicted 1 mv/m contour of the main transmitter for Class A and Class C stations, the 0.5 mV/m contour for Class B, or the 0.7 mV/m contour for Class B1 stations.

Effects of Adding a Booster

For the purpose of analyzing the effects of a second carrier, the addition of a booster signal can be treated as interference. A second interfering carrier will both amplitude and phase (frequency) modulate an existing desired carrier. The characteristics of this apparent modulation are given by Equation 15.

$$F_m = |f_c - f_i| \qquad B = A_i/A_c \tag{15}$$

Where:

F_m = Frequency separation of the carriers
f_c = Main carrier frequency
f_i = Booster (interfering) carrier frequency
A_i = Booster (interfering) carrier amplitude
A_c = Main carrier amplitude
B = Percentage of amplitude modulation

Equation 15: Characteristics of an Interfering Signal Modulating a Desired Signal.

In other words, an FM receiver detecting two carriers (unmodulated for simplicity), decodes a modulation tone equal in frequency to the absolute value of the frequency separation between the carriers. Moreover, the modulation index (both AM and FM) is simply the ratio of the carrier amplitudes. Note, however, that the modulation index is never more than one, since increasing the amplitude of the interfering signal over that of the original carrier simply makes the carrier the interfering signal to the booster. For FM, B is measured in radians (see Equation 15), while for AM, B is the percentage of amplitude modulation produced.

Synchronous Carriers

This gives necessitates the need for synchronizing carrier frequencies. An analysis of the equation for B (FM) shows, given a fixed carrier ratio (fixed modulation index), an increase in carrier frequency separation is equivalent to an increase in Δf. For FM this is equivalent to an increase in detected signal amplitude (see Equation 16).

If, given $B = \Delta f/F_m$, B is held constant and F_m is the frequency separation of the carriers, then:

$$\Delta f = B \times F_m \tag{16}$$

Equation 16: FM modulation index, alternate form. This phenomenon is shown graphically in Figure 4.3-45.

Figure 4.3-45 illustrates the relationship of carrier frequency separation to equivalent carrier frequency deviation (B = 1).

Knowing this, the advantages of frequency locking the carriers becomes obvious. By taking the limit as the difference in carrier frequency approaches zero, two things happen. First, the frequency of the detected tone approaches zero and the equivalent FM deviation

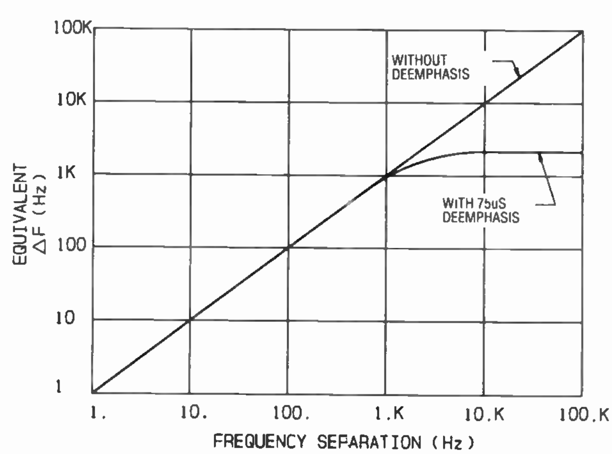

Figure 4.3-45. Relationship of carrier frequency separation to equivalent carrier frequency deviation (B = 1).

produced by that tone approaches zero. In other words, the interference disappears.

The Resultant Carrier

This leaves us with a single frequency carrier whose amplitude depends on the relative phase relationship between the two signals at any given reception point. If the signals are in phase and the carrier ratio is one (0 dB), then the resultant amplitude is twice that of either carrier. On the other hand, if the carriers are 180° (out of phase), the net result is zero. Between these two extremes, the resultant amplitude and phase are given by Equation 17 and 18 respectively.

$$A_r = \sqrt{[A_c + A_i \text{ Cos } \omega_i(t))^2 + (A_i \text{ Sin } \omega_i(t))^2]} \tag{17}$$

where:

A_r = Resultant Carrier Amplitude
A_c = Main Carrier Amplitude
A_i = Booster Carrier Amplitude
$\omega_i(t)$ = Angle between A_i and A_c

and:

$$\Phi_r = \text{Arctan} \frac{A_i \text{ Sin } \omega_i(t)}{A_r + A_i \text{ Cos } \omega_i(t)} \tag{18}$$

where: Φ_r = Resultant Carrier Phase Angle

Figure 4.3-46 shows this vector summation.

Resultant Effect on Receivers

All the conditions for adequate reception would be met if we were in a reception area of equal in phase and frequency locked carriers, located on a straight line between the two transmitting antennas and the information on each carrier were occurring at the same time.

However, if we were to move 2.5 ft toward either transmitter (roughly equivalent to one-quarter wavelength at 100 MHz), we would now be in an area where the two signals are 180° out of phase and there is no longer a signal to detect. Notice that we have only moved one-quarter wavelength, yet have actually moved into a null! This is because we have moved one-quarter wavelength away from one transmitter and one-quarter wavelength closer to the other, giving a total one-half wavelength change. In a mobile receiver,

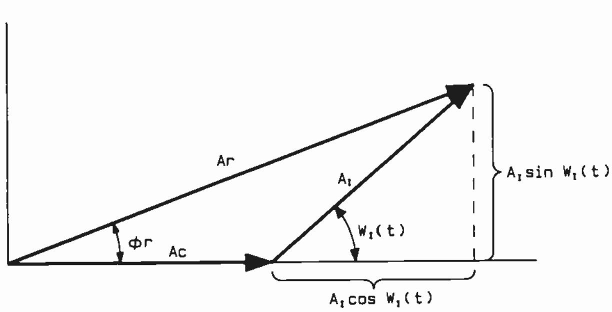

Figure 4.3-46. Vector summation of two carriers.

this phenomenon is virtually identical to the "picket fencing" of multipath, except that the interfering signal is not reflected but rather is a duplicate transmission from a booster site.

For the stationary receiver in an additive state, this is not a problem, and, in fact, gross modulation problems can be effectively covered up by virtue of the capture effect of an FM receiver, provided the carrier ratios are adequate to accomplish this. This ratio depends on the particular receiver, but it is a smaller ratio than is required to maintain adequate reception with a mobile receiver.

Even relatively small fluctuations in signal strength due to the adding and subtracting of carriers will cause a noticeable fluctuation in receiver S/N, unless the residual signal strength in the null area is adequate to keep the receiver well into quieting.

This effect, more than any other, makes the areas of inadequate carrier ratios unlistenable. It is important to note that for the mobile receiver, the picket fencing problem is present whether or not the carriers are locked.

Modulation Effects

So far, we have dealt primarily with the effect of adding a second unmodulated carrier onto a main unmodulated carrier. At best, understanding the consequences of imperfectly correlated modulation superimposed on two carriers is difficult, if not futile. There are, however, two areas of modulation equalization which are fairly straightforward.

Time Delay Equalization

For two identical signals that have a constant time delay between them, at any (base band) frequency where the time delay is equivalent to 180° or *N* multiples of 180°, there will be complete cancellation, producing a combing effect. This is especially destructive to composite FM stereo and subcarrier performance. In fact, a 7.5 μsec group delay addition to one composite signal will cancel a 67 kHz subcarrier. Likewise, a 26.3 μsec delay will cancel the stereo pilot tone.

Unfortunately, time delay equalization cannot eliminate cancellation of modulation components in equal carrier areas, since differences in propagation times between the main and the booster will be adequate in some cases to cause the cancellation. At best, the use of group delay can move the location of the nulls relative to the transmitters. Care must be taken to insure the network exhibits a constant group delay, as nonlinear delay can seriously degrade stereo performance, especially stereo separation.

Deviation Calibration

If the frequency deviation of both modulators is not precisely calibrated, a condition of dynamic interference will occur during modulation. For example, two separate modulators are fed identical amplitude, delay equalized sine waves. The level is adjusted to produce a nominal 100% (±75 kHz) modulation. The first modulator swings the carrier exactly ±75 kHz, as predicted, but the second modulator only modulates its carrier ±74 kHz (98.67%).

Careful examination shows that the second carrier will interfere with the first in the following manner. Assuming equal carriers in an additive RF location and starting at time zero, we have two carriers of exact frequency producing a single carrier whose amplitude is derived from Equation 15. As we move positively in frequency with the modulation, the carrier frequencies diverge until, at the peak of modulation, the carriers are 1 kHz apart. From Equation 15, this produces a 1 kHz FM modulation at a B of 1 (1 kHz deviation) and an AM modulation equivalent to 100% at 1 kHz.

Actually, the detected interference is a frequency sweep from dc to 1 kHz to dc and back to 1 kHz for each complete cycle of modulation applied. Subjectively, this type of interference sounds similar to white noise, but it is only present during modulation. It is also most prevalent during the maximum modulation peaks, as this is the point of maximum carrier divergence with maximum detected loudness. This relationship of maximum interference during the periods of maximum modulation tends to mask the noise.

Correcting the Interference

Both forms of modulation related interference are most prevalent in areas of nearly equal carriers. With adequate carrier ratios, both types are effectively eliminated by the capture effect in the FM receiver. It is also important to keep the proper perspective in assessing the importance of these forms of interference. Remember, these are most prevalent in areas where, even without modulation, the carriers are adding and subtracting, tending to make the signal unlistenable as the receiver location is moved.

Booster Systems

Two main components must be present at the booster station. Station program material must be transmitted either in the form of composite stereo or as AES3 serial audio data. In addition, some form of frequency locking information must also be present.

Using a Radio Link

One method of interconnection is by the use of a radio link, such as a composite STL between the main transmitter and the booster. This method has several advantages, including high quality transmission, reliability, total signal control and economy. It is also capable of transmitting the frequency reference signal with the composite stereo via subcarrier. In this way, one radio link supplies both the station programming and reference information.

Synchronization to GPS Satellite Atomic Timebase

Some digital FM exciters include the capability to lock the FM carrier frequency and stereo pilot tone frequency to an external 10MHz reference signal derived from a Global Positioning System (GPS) satellite receiver. This high accuracy, external reference takes the place of the internal 10 MHz carrier reference in the exciter. When two or more exciters are locked to a GPS source, they become frequency-locked to a very high degree of stability. They also eliminate the need for an STL subcarrier or land line to convey a synchronizing signal since all timebases within the digital FM exciters inherit the accuracy of the atomic clock aboard the GPS satellites. In addition, the FM deviation of all the digital exciters in the network will be exactly matched if the audio is transported via an uncompressed AES3 serial data link since all digital modulators will be fed identical audio data. If the AES3 transport is through T1/E1 data lines via data format conversion, the time delay variations in the T1/E1 link must be dynamically compensated. The SynchoCast system recently introduced by Intraplex uses GPS timing to allow precision differential delay adjustments between multiple T1/E1 links and to maintain the delay compensation over time.

OPERATIONAL MEASUREMENTS

The FCC considers certain parameters to be important enough to justify almost continuous observation. Especially important are the modulation level, carrier frequency, and output power level. Consult the current revision of Part 73 of the CFR because there may have been changes since this chapter was printed.

FM Modulation Measurement

Measuring FM modulation can be accomplished with a broadcast type modulation monitor or with a so-called modulation analyzer test instrument. Some FM exciters have built-in peak modulation displays for convenient setup and adjustment. Once the initial levels are correctly set, modern audio processing equipment will usually hold the modulation levels within the desired window.

The broadcasting industry has been interested in the best method to determine the modulation percentage for complex program material. The inability of mechanical meter movements to follow short-duration, nonrepetitive peaks accurately has received special attention. Standard modulation meter movements cannot follow modulation peaks with the required accuracy. For this reason, modulation monitors have a peak-indicating device that can be preset to flash at the particular level of interest. This device should be used instead of the meter to determine peak modulation conditions of the transmitter.

The reason for setting a peak deviation limit is so the related occupied bandwidth does not increase to the point of interfering with stations on adjacent channels and causing excessive audio distortion in the FM receiver by exceeding the receiver's IF bandwidth. The FCC presently enforces the modulation limit by monitoring the instantaneous peak deviation of the station as displayed on an oscilloscope. This method of measurement does not exactly correlate with the station's occupied bandwidth because the duty-cycle of the modulation peaks is not taken into account. As a result, many sophisticated peak limiting and overshoot control devices have appeared on the market to maximize loudness without exceeding the peak deviation limit. These devices remove the low energy peaks that would extend beyond 100% modulation. The use of these devices does cause some degradation of the audio quality, they would not be used if the method of modulation measurement were changed to one based on occupied bandwidth. Recently introduced modulation measurement devices ignore short duration overshoots and provide modulation level indications that more accurately reflect the resulting occupied bandwidth. The FCC now enforces occupied bandwidth requirements for the FM band by measuring compliance with the FM emissions mask defined in Section 73.317 of the CFR.

Carrier Frequency Measurement

The average carrier frequency must be measured with an accurate frequency monitor and maintained to within ±2,000 Hz of the assigned channel. These monitors fall into two categories: analog display of the frequency error from the nominal carrier frequency and digital display of the absolute carrier frequency. The trend is toward the digital counter because of its accuracy and ease of use.

Historically, the FCC required FM stations to utilize type-approved modulation and frequency monitors, but this requirement has since been eliminated. Each station is still required to maintain its frequency, modulation and audio performance within the FCC limits defined in Part 73 of the CFR, but the responsibility for selecting the method of measurement and type of measuring equipment is now up to the station operator. Every quality conscious station will want to have the necessary equipment to accurately evaluate the signal being broadcast. New options are available in high performance yet general purpose test equipment, now that monitor type approval is no longer required. For instance, modern modulation analyzers provide frequency agility as well as greater measurement capability than the more specialized modulation monitors. General purpose frequency counters are now available with sufficient accuracy to measure the carrier, subcarrier and stereo pilot frequencies directly. Spectrum analyzers provide a wide range of capability including the measurement of harmonic and spurious frequencies at the carrier frequency, composite baseband, Bessel nulls, occupied bandwidth, stereophonic and SCA crosstalk and synchronous AM.

Measurement of RF Power Output

The methods for determining RF output power are specified in Part 73 of the CFR. An accurately calibrated directional wattmeter provides an excellent means of making a direct measurement of RF output power. Until recently, the directional wattmeter was seldom used as the primary RF power determining method because of the requirement for recalibration to a traceable standard at regular intervals. Use of the indirect method of power measurement avoided this requirement. The FCC now permits the use of the transmitter power output meter directly, if it is periodically calibrated by comparison with the indirect method, instead of with a dummy load and standard wattmeter.

Using the indirect method, the output power is calculated from a measurement of the dc input power multiplied by the efficiency factor of the final amplifier stage. The efficiency factor is provided by the transmitter manufacturer on the final test data sheet or in the instruction manual and must be applicable to the particular frequency and power level in use. The power input to the final amplifier stage is normally defined as the product of plate voltage and plate current to this stage. Multiple output stages which are combined for the total power must have their individual dc power inputs arithmetically summed to obtain the total power input.

The directional wattmeter can be used as a check when compared to the power output calculated by the indirect method to determine if the efficiency factor has changed due to incorrect tuning, changing antenna conditions or a weak output device.

Logging of Transmitter Operating Parameters

Although the FCC has deleted specific logging requirements, FM stations may still wish to log certain transmitter parameters at three-hour intervals to track equipment performance trends. The minimum suggested entries are:

- Final amplifier plate/drain voltage
- Final amplifier plate/drain current
- RF transmission line current, voltage or direct power.

The carrier frequency, stereo pilot frequency and SCA subcarrier frequency require less frequent measurement and logging. Microprocessor based control systems often provide automatic logging of all transmitter parameters, including overloads and tolerance flagging.

Proof of Performance Measurements

While the FCC no longer requires proof of performance tests, it is advisable to conduct such tests periodically to ensure the equipment is operating properly. These tests should include:

- Audio frequency response
- Audio frequency harmonic distortion
- FM signal-to-noise ratio
- AM noise level.

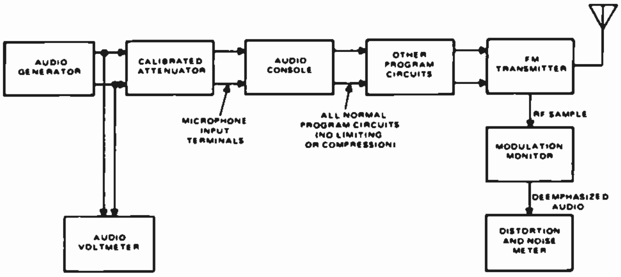

Figure 4.3-47. Block diagram of test setup for audio performance measurements.

Figure 4.3-47 is a block diagram of a typical test set-up for proof-of-performance measurements.

Measurement of Audio Frequency Response

The audio frequency response of the system is measured in reverse, that is, a constant percentage of modulation is maintained for all modulating frequencies by adjusting the amount of attenuation between the audio generator and the microphone input terminals. This is necessary because of the rising response due to preemphasis. Frequency response data is taken at three levels of modulation: 25%, 50% and 100%. The audio voltmeter which measures the audio generator output voltage is used to maintain a constant voltage level versus frequency at the generator output terminals. The precision attenuator dials are adjusted for each modulating frequency to maintain the desired modulating level, and the attenuator readings, in decibels, are recorded. Readings should be taken for the following modulating frequencies: 50, 100, 400, 1,000, 5,000, 7,500, 10,000 and 15,000 Hz. When the attenuation, in decibels, is plotted versus frequency, the 75 microsecond preemphasis curve is obtained if the system frequency response is perfect. Deviations from the ideal response are permitted to the extent that allows the measured curve to be fitted between the upper and lower limit curves shown in Figure 4.3-9(a). The procedure for doing this is to offset the measured curve by subtracting or adding the same number of decibels from each of the measured values. This process may be repeated until a fit is obtained. If it is impossible to obtain a fit within the limits by subtracting or adding the same value of attenuation from all measured values, the system frequency response is inadequate and corrections must be made.

Measurement of Audio Harmonic Distortion

Total harmonic distortion (THD) of the system from microphone input terminals to transmitter output is measured by modulating the transmitter with sinusoidal modulating signals having low distortion and observing the harmonic content at the output of the modulation monitor. For this measurement, preemphasis is used in the transmitter and deemphasis is used in the monitor. The distortion analyzer must respond to deemphasized harmonics through 30 kHz.

The type of distortion meter normally used in this test reads not only harmonic distortion but also noise in the audio passband. For this reason, THD measurements above 5 kHz may be noise limited due to the effect of deemphasis. A more accurate method of distortion measurement in the presence of noise is to use an audio frequency spectrum analyzer to determine the total RMS value of the individual distortion products.

The THD is typically measured under the following conditions:

- For modulating frequencies of 50, 100, 400, 1,000 and 5,000 Hz at modulating levels of 25, 50 and 100% modulation
- For modulating frequencies of 10 kHz and 15 kHz at a modulating level of 100%.

The preceding measurements must show that the system THD is less than 3.5% for modulating frequencies between 50 and 100 Hz, less than 2.5% for modulating frequencies between 100 and 7,500 Hz, and less than 3.0% for modulating frequencies between 7,500 and 15,000 Hz. Most modern equipment will pass these tests by a wide margin. If distortion levels greater than these are measured, the system requires adjustment or repair. Tuning the transmitter for minimum even order harmonic distortion will result in a symmetrical group delay response and optimum FM modulation performance. This can be accomplished either by observing the even order harmonics in the demodulated baseband or by placing an audio bandpass filter tuned to the second harmonic or other even order harmonic of the modulating frequency ahead of the audio distortion analyzer. If the transmitter is modulated by a single monaural tone of 9.5 kHz, the 19 kHz (2 × 9.5 kHz) bandpass filter in the stereo modulation monitor's pilot injection metering circuit can be used to tune the transmitter for minimum second harmonic distortion.

Measurement of Two-Tone Intermodulation Distortion

Audio intermodulation distortion (IMD) measurements are a quick and accurate way to evaluate the system performance before a complete set of THD measurements are made. If the system will pass a single 60 Hz/7 kHz, 4:1 (Society of Motion Picture and Television Engineering (SMPTE)-IMD) measurement at 100% modulation, it will probably pass all of the THD measurements up to 10 kHz. This dual frequency test signal (SMPTE-IMD) is on track 30 of the *NAB Broadcast and Audio System Test CD.*

Other types of difference-tone, swept two-tone and sinewave/squarewave IMD measurements can reveal more subtle problems in the system such as transient IMD due to insufficient audio feed back bandwidth in the audio amplifier stages.

Measurement of FM S/N

The FM signal-to-noise ratio of the system is also measured from the microphone input terminals to the transmitter output. The residual noise level at the monitor output is measured with an audio voltmeter. For this measurement, preemphasis is employed in the transmitter and deemphasis in the monitor. The residual audio noise level is referenced to the signal level produced by 400 Hz (L + R, mono) modulation at the 100% level (±75 kHz deviation).

The procedure for making the FM S/N measurement is:

- Modulate the transmitter with a 400 Hz sine wave applied at the microphone input terminals of the console and set the level for 100% modulation
- Read and record the audio signal level appearing at the modulation monitor output terminals. If the monitor has audio metering capability, the meter gain should be set for a 0.0 dB reference level according to the manufacturer's instructions

- Remove the modulation and terminate the console audio input terminals with a resistor equal to the normal microphone output impedance
- Read and record the residual audio noise voltage in decibels below the 400 Hz reference signal level. The measured S/N must be at least 60 dB. State-of-the-art equipment can provide a S/N of better than 90 dB, so it is relatively easy to meet the FCC requirement of 60 dB.

Measurement of AM S/N

The perfect FM transmitter will have an absolutely constant output, regardless of FM modulation or power supply variations. In practice, there is always some residual amplitude modulation of the FM transmitter. Two types of AM S/N are of interest to the FM broadcast engineer:

1. Asynchronous AM S/N measured without FM modulation is required by the FCC Rules and is primarily related to power supply ripple.
2. Synchronous AM S/N or incidental carrier AM (ICAM) measured with FM modulation is not required by the FCC Rules and is related to the tuning and overall bandwidth of the system.

Asynchronous AM

Residual amplitude modulation of the transmitter output without FM modulation, due primarily to power supply ripple, is measured with an AM envelope detector. Most FM modulation monitors include an AM detector for this purpose. The detector must include 75 microsecond deemphasis of its output. AM noise measurements must be made directly at the transmitter output (or an accurate sample of its output). No amplifying or limiting equipment may be used between the transmitter output and the AM detector since this equipment would modify the residual AM noise level present. The FCC Rules require residual AM noise to be 50 dB below the level which would represent 100% amplitude modulation of the carrier. Since the transmitter cannot be amplitude modulated, this reference must be established indirectly by a measurement of the RF carrier voltage. (Refer to the instructions of the detector manufacturer to determine the reference level. Generally, the reference level is determined by setting a carrier level meter to a specified reading. If the transmitter is unable to meet the 50 dB requirement, the problem can usually be traced to a power supply component or to line imbalance in a three phase system.)

Synchronous AM

Synchronous AM is a measure of the amount of incidental amplitude modulation introduced onto the carrier by the presence of FM modulation. Although this measurement is not required by the FCC Rules, it provides information about the amplitude response and tuning of the transmitter. Measurement of synchronous AM also gives the station engineer an idea of the overall system bandwidth and whether the passband is positioned correctly. Since all transmitters have limited bandwidth, there will be a slight drop-off in power output as the carrier frequency is swept to either side of the center frequency. This slight change in RF output level follows the waveform of the signal being applied to the FM modulator causing AM modulation in synchronization with the FM modulation. The concept is similar to the slope detection of FM by an AM detector used in conjunction with a tuned circuit.

Synchronous AM measurements are made directly at the transmitter output (or an accurate sample of its output). No amplifying or limiting equipment may be used between the transmitter output and the AM detector since nonlinearities in this equipment could modify the synchronous AM level present. Since the transmitter cannot be fully amplitude modulated, an equivalent reference level must be established indirectly by a measurement of the RF carrier voltage. (Refer to the instructions of the detector manufacturer to determine this reference level. Generally, the reference level is determined by setting a carrier level meter to a specified reading or to obtain a specific dc voltage level at the output of the detector diode without modulation. Care must be taken when making these measurements that the test setup does not introduce synchronous AM and give erroneous readings which would cause the operator to mistune the transmitter to compensate for errors in the measuring equipment.)

The input impedance of the envelope detector must provide a nearly perfect match so that there is a very low VSWR on the sampling line. Any significant VSWR on the sampling line will produce synchronous AM at the detector because the position of the voltage peak caused by the standing wave moves along this line with FM modulation. A thru-line type of directional coupler normally used to drive the wattmeter movement has the envelope detector diode built into the sampling element. This provides a dc component that the meter movement responds to plus the demodulated synchronous AM component that the meter movement does not respond to. If the thru-line element output is fed to an oscilloscope instead of the wattmeter movement, the synchronous AM waveform can be accurately measured. This approach eliminates the errors due to VSWR on the sampling line, since the detector is located at the sampling point. The manufacturer of the thru-line coupler can supply the special connectors and/or cables to connect its output to the oscilloscope. Care must be taken to avoid hum pick-up from ac ground loops while making these low level measurements. Both the thru-line element detector and the precision envelope detectors have some residual RF on their dc output, so an RF filter network may be required between the detector and the input the oscilloscope.

Most FM demodulators cannot be relied upon to make accurate synchronous AM noise measurements, so it is a good idea to cross-check the demodulator reading directly against the demodulated output of a precision envelope detector. This can be done by first measuring the dc component of the waveform with a voltmeter or by dc coupling the scope input. The scope is then ac coupled, and the input sensitivity is increased until an accurate peak to peak measurement of the ac modulation component can be made. The peak-to-peak ac voltage is then divided by twice the dc component to obtain the voltage ratio. Twenty times the log (base 10) of the voltage ratio is the actual synchronous AM noise level in dB below equivalent 100% AM modulation. Multiplying the voltage ratio by one hundred yields the percent of AM modulation. Note that the peak detected value of the carrier must be doubled to convert it to the peak-to-peak value of the carrier. The ratio of the peak-to-peak modulation component to the peak-to-peak carrier is then used to calculate the percentage of synchronous AM modulation.

What is an Acceptable Level of Synchronous AM?

Synchronous AM of 35 dB or more below equivalent 100% AM is considered to be acceptable since the limited bandwidth of the IF filter in the receiver will reintroduce higher levels of synchronous AM to the FM signal before demodulation. Higher levels of synchronous AM can cause increased "chopping" of the signal at the receiver near limiting threshold under weak signal fringe area conditions and can exacerbate multipath problems. Excessive synchronous AM is also an indirect indication of passband-induced distortion problems that degrade stereo performance and SCA crosstalk.

Many older multitube transmitter designs presently in use will have as much as 6% (−30 dB) synchronous AM when simply tuned for best power output and efficiency even though the asynchronous AM (without modulation) may be better than −50 dB. Some of the newer single tube transmitters can be adjusted for 50 dB or more suppression of synchronous AM. The synchronous AM level of virtually any FM transmitter can be improved by proper tuning techniques. An approximation to the overall system bandwidth can be related to the synchronous AM as shown in Table 4.3-3.

Limitations of Synchronous AM Measurements

Synchronous AM measurements are an indirect way of evaluating and optimizing FM performance. Even though synchronous AM measurements are a helpful aid to correctly tune an FM transmitter, these measurements tell only the amplitude response half of the total story. Transmitter tuning also affects the group delay (time) response which in turn affects the relative time delays of the higher order FM sidebands. Even though the amplitude response appears flattened when the grid is heavily driven, the group delay (time) response still has a serious effect on the higher order FM sidebands.

Table 4.3-3

Approximate system bandwidth as related to synchronous AM.

Synchronous AM (Below 100% AM) (+75 kHz@1 kHz FM)	Approximate Bandwidth of Transmitters (−3 dB)	RF Level Variation at Receiver Limiter (%)	(dB)
−30 dB	410 kHz	6.32%	0.57 dB
−35 dB	550 kHz	3.54%	0.31 dB
−40 dB	730 kHz	2.00%	0.18 dB
−45 dB	1.00 MHz	1.12%	0.10 dB
−50 dB	1.34 MHz	0.64%	0.06 dB
−55 dB	1.82 MHz	0.36%	0.03 dB
−60 dB	2.46 MHz	0.20%	0.02 dB

Synchronous AM versus Symmetrical Group Delay Response

Computer simulations as well as empirical measurements made on FM transmitters showed that group delay asymmetry results in much more distortion than asymmetrical amplitude response. [23] As long as the group delay response is symmetrical, the amount of synchronous AM will have little effect on the FM modulation performance and distortion. Most FM transmitters will exhibit a significant increase in synchronous AM when tuned for symmetrical group delay response even though this results in best FM modulation performance. Tuning for minimum synchronous AM is a good starting point, but it is more desirable to finish tuning at the symmetrical group delay point.

Fine tuning the input and output for minimum even-order harmonic distortion will optimize the group delay (time) response. Transmitters that utilize wideband solid-state IPAs will add less distortion to the FM signal because both the amplitude and group delay (time) response will be better than systems utilizing several tuned stages.

Tuning The Transmitter for Best Performance

If properly adjusted, modern power amplifiers discussed in the preceding sections can operate with high reliability and power efficiency without compromising subcarrier performance. All optimization should be done with the APC system disabled so that the APC will not chase the adjustment to keep the output power constant. The transmitter should be connected to the normal antenna system rather than to a dummy load. This is because the resistance and reactance of the antenna will be different from the dummy load, and the optimum tuning point of the transmitter will shift between the two different loads. The tuning sequence is described below.

Initial Tuning and Loading

The transmitter is first tuned for normal output power and proper efficiency according to the manufacturer's instructions. The meter readings should closely agree with those listed on the manufacturer's final test data sheet if the transmitter is being operated at the same frequency and power level into an acceptable load.

Input Tuning and Matching

The input tuning control should first be adjusted for maximum grid current and then fine-tuned interactively with the input matching control for minimum reflected power to the driver stage. Note that the point of maximum grid current may not coincide with the minimum reflected power to a solid-state driver. This is because a solid-state driver may actually output more power at certain complex load impedances than into a 50 Ω resistive load. The main objective during input tuning is to obtain adequate grid current while providing a good match (minimum reflected power) to the coaxial transmission line from the driver. In the case of an older transmitter with a tube driver integrated into the grid circuit of the final amplifier, the driver plate tuning and the final grid tuning will be combined into one control that is adjusted for maximum grid current.

Output Tuning

The output tuning control adjusts the resonant frequency of the output circuit to match the carrier frequency. As resonance is reached, the plate current will drop while both the output power and screen current rise together. Under heavily loaded conditions this dip in plate current is not very pronounced, so tuning for a peak in screen current is often a more sensitive indicator of resonance.

Output Loading

There is a delicate balance between screen voltage and output loading for amplifiers utilizing a tetrode tube. Generally, there is one combination of screen voltage and output loading where peak efficiency occurs. At a given screen voltage, increasing the amplifier loading will result in a decrease in screen current, while a decrease in loading will result in an increase in screen current. As the screen voltage is increased to get more output power, the loading must also be increased to prevent the screen current from reaching excessive levels. Further increases in screen voltage without increased loading will result in a screen overload without an increase in output power.

Automatic Power Control Headroom

APC feed back systems are utilized in many transmitters to regulate the power output around a predetermined setpoint with variations in ac line voltage or changes in other operating parameters. Modern FM broadcast transmitters may utilize a high gain tetrode as the final amplifier stage with adjustment of the screen voltage providing fine adjustment of the output power.

For each power output level there is one unique combination of screen voltage and output loading that will provide peak operating efficiency. If the screen voltage is raised above this point without a corresponding increase in loading, there will be no further increase in power output with rising screen voltage and screen current. If the screen voltage is raised without sufficient loading, a screen current overload will occur before the upward adjustment in power output is obtained. To avoid this problem, tune the transmitter with slightly heavier loading than necessary to achieve the desired power output level and allow for about 5% headroom in adjustment range. The output loading can be adjusted for a peak in output power of 5% over the desired level, and then the screen voltage can be reduced enough to return to the desired level. This procedure will allow headroom for an APC system controlling screen voltage and will result in about a 1% compromise in efficiency, but it will ensure the ability to increase power output up to 5% without encountering a screen overload.

Centering the Passband

A simple method for centering the transmitter passband on the carrier frequency involves adjustment for minimum synchronous AM. If the bandpass is narrow or skewed, increasing synchronous amplitude modulation of the carrier will result. A typical adjustment procedure is to FM modulate 100% at 1 kHz and fine-adjust the transmitter's grid tuning and output tuning controls for minimum 1 kHz AM modulation as detected by a wideband envelope detector (diode and line probe). One kHz is used as the FM modulating frequency rather than 400 Hz so that the audio highpass filter in the audio analyzer can be used to eliminate the ac line frequency related asynchronous component from the synchronous AM component. It is helpful to display the demodulated output from the AM detector on an oscilloscope while making this adjustment. Note that as the minimum point of synchronous AM is reached, the demodulated output from the AM detector will double in frequency to 2 kHz. This is because the fall-off in output power is symmetrical about the center frequency causing the amplitude variations to go through two complete cycles for every one FM sweep cycle (see Figure 4.3-48). It should be possible to minimize synchronous AM while maintaining output power and efficiency in a properly designed power amplifier.

Effect of Transmitter Tuning on the FM Side Bands

The higher-order FM side bands will be slightly attenuated in amplitude and shifted in time (group delay) as they pass through the final amplifier stage. The alterations in the side band structure that are introduced by the amplifier passband result in distortion after FM demodulation at the receiver. The amount of

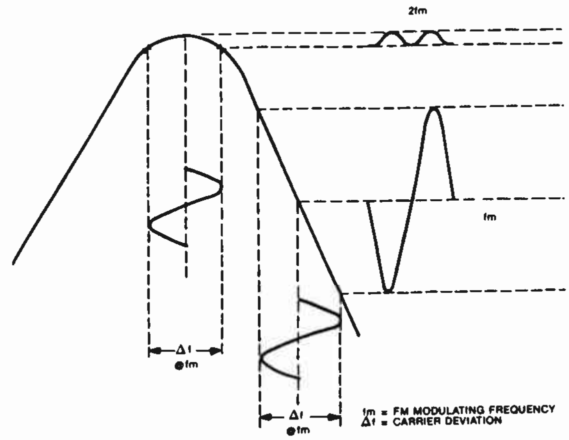

Figure 4.3-48. Synchronous AM waveforms.

distortion depends on the available bandwidth versus the modulation index being transmitted. For a given bandwidth limitation, the distortion can be minimized by centering the passband of the amplifier around the signal being transmitted. This will cause the amplitude and group delay errors to affect both the upper and lower sidebands equally (symmetrically). Tuning an amplifier for minimum plate current or for best efficiency does not necessarily result in a centered passband. One way to center the amplitude passband is to tune the amplifier for minimum synchronous AM modulation while applying FM modulation to the transmitter. Since the circuit topology of most transmitters exhibits a difference in tuning between the symmetrical amplitude response and the symmetrical group delay response, FM modulation performance can be further improved by tuning for symmetrical group delay rather than for minimum synchronous AM. The symmetrical group delay tuning point usually does not coincide exactly with the symmetrical amplitude tuning point but rather falls between the point of minimum synchronous AM and the point of maximum efficiency.

The transmitter may be tuned for minimum intermodulation distortion in left-only or right-only stereo transmissions. Stereo separation will also vary with tuning. For stations employing a 67 kHz SCA, transmitter tuning becomes very critical to minimizing crosstalk into the SCA. Modulate one channel only on the stereo generator to 100% with a 4.5 kHz tone. This will place the lower second harmonic (L − R) stereo sideband on top of 67 kHz SCA. Activate the SCA at normal injection level without modulation on the SCA. Tune the transmitter for minimum output from the SCA demodulator. This adjustment can also be made by listening to the residual SCA audio while normal stereo programming is being broadcast.

A more sensitive test is to tune for minimum even order harmonic distortion which will result in a symmetrical group delay response and will optimize distortion, separation and crosstalk.

Modern power amplifiers have been designed to operate without compromising subcarrier performance. By providing broad band matching circuits, adjustment of these transmitters for optimum FM modulation performance (minimum distortion, minimum crosstalk, maximum separation etc.) is very repeatable and stable.

The following field adjustment techniques are listed in ascending order of sensitivity:

- Tune for minimum synchronous AM noise
- Tune for minimum IMD in the left or right channel only
- Tune for minimum crosstalk into the unmodulated SCA subcarrier
- Tune for minimum even order harmonic distortion (symmetrical group delay). (See page 000)

In any of these tests, the grid tuning is frequently more critical than the plate tuning. This is because the impedance match into the input capacitance of the grid becomes the bandwidth limiting factor. Even though the amplitude response appears flattened when the grid is heavily driven, the group delay (time) response has a serious effect on the higher order FM sidebands. For more information about tuning an FM transmitter for optimum performance, see [14, 15, 20, and 22].

OPTIMUM TUNING VERSUS EFFICIENCY

VHF amplifiers often exhibit a somewhat unusual characteristic when tuning for maximum efficiency. The highest efficiency operating point does not exactly coincide with the lowest plate current because the power output continues to rise on the inductive side of resonance coming out of the dip in plate current. If the amplifier is tuned exactly to resonance, the plate load impedance will be purely resistive, and the load line will be linear. As the output circuit is tuned to the inductive side of resonance, the plate load impedance becomes complex, and the load line becomes elliptic instead of linear since the plate current and plate voltage are no longer in phase. Apparently, best efficiency occurs when the phase of the instantaneous plate voltage slightly leads the plate current. This effect is believed to be caused by the nonlinear gain characteristics of the power amplifier tube operating on an elliptic load line.

INSTALLATION CONSIDERATIONS

Adequate planning and care in the installation of an FM broadcast transmitter and associated equipment will help avoid many problems that may be difficult and expensive to correct later. For example, poor grounds and ground loops may cause high noise levels.

Wiring the Transmitter Plant

Separate metallic shielded conduits or troughs should be provided for the audio and the ac wiring. A third conduit should be used if computer logic levels are employed for equipment control. These conduits or wiring troughs may be either overhead or below the cabinets. The ac wiring should be well separated from the audio pairs to prevent the induction of unwanted hum and noise into the audio circuits.

Audio shields should be grounded at only one point to prevent ground loops in the shields. This point may have to be found experimentally to give the lowest noise pickup. The equipment racks and transmitter should be connected together by copper straps at least two in. wide, tied to a good earth ground at one point. If a good ground screen is not available, a satisfactory ground can be provided by driving four or five copper ground rods 8-10 ft long into the ground with a spacing of about three ft. These ground rods should be tied together with a wide copper strap. The straps connecting the equipment to the earth ground should be as short and direct as practical.

It is often difficult to remove VHF-RF from the equipment by grounding because at FM carrier frequencies nearly any connection to an earth ground has an appreciable impedance. The best way to keep RF out of sensitive low level circuits is by keeping them enclosed within an RF shield and by filtering leads that enter the shielded unit when necessary. Filters in the audio lines may be made up of small bi-filar RF chokes and disc capacitors.

For stereo transmission, it is necessary to keep the L and R audio lines phased properly. To insure proper monaural compatibility, correct audio polarity must be maintained throughout the station from the microphones, tape machines and turntables through all of the audio equipment to the stereo generator audio input terminals. Stereo phone line pairs or separate RF studio-to-transmitter links (STL) should also be checked for proper polarity and equal phase delay.

The transmitter equipment should be located and arranged to provide sufficient clearance around the front, sides and rear for easy access during servicing and maintenance.

Transmitter Cooling

Almost all FM broadcast transmitters require forced air cooling to remove heat from the output stage and other assemblies within the cabinet. A very important consideration in locating the transmitter is the provision for adequate cooling air. Assuming that the overall efficiency of the transmitter is about 50%, the transmitter will generate about the same number of kilowatts of heat as it does RF power output.

Figure 4.3-49(a) shows a transmitter located in an air conditioned room. This type of closed-loop system requires no special ducting and has the advantage that the transmitter intake air is usually much cleaner than outside air. The transmitter exhaust air places a substantial heat load on the air conditioner during the summer, but it becomes a source of heat in the winter. The transmitter manufacturer can usually supply data on the number of cooling BTUs required, so that the proper size air conditioner can be selected. This method is frequently used with the lower power transmitters. A protective system should be provided to prevent over heating of the transmitter if the air conditioner fails.

Figure 4.3-49(b) shows a transmitter located in a wall separating an air conditioned room and a ventilated, but not air conditioned room. A large exhaust fan is provided in the ceiling to remove the rising hot air while an adequate cool air intake is provided in the lower portion of an outside wall. Adequate air filtering is required to keep the transmitter interior clean.

Figure 4.3-49(c) shows a transmitter located in an air conditioned room with intake and exhaust air ducts to the outside. An auxiliary blower or fan is normally required to overcome pressure drop in the ducting. This type of system requires careful design to make sure the air flow through the transmitter is not impeded by the duct work. Additional air interlocks may be required to protect the transmitter from a failure of the external fan. The air intake and exhaust openings to the outside should be provided with rain shields, insect screens and dust filters as dictated by the environment.

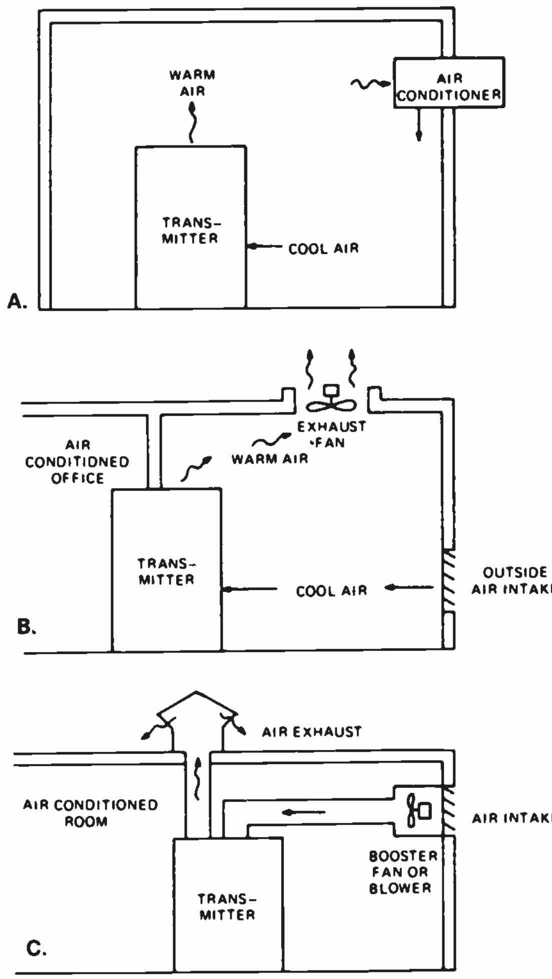

Figure 4.3-49(a–c). Three methods of providing cooling air for the transmitter.

The location of the air intake and exhaust openings should be arranged so that wind pressure will not impede the air flow.

Air filters should be periodically cleaned or replaced according to the transmitter manufacturer's instructions. This is very important because dust- or insect-clogged air filters may reduce the cooling air flow enough to cause overheating of some components. The probability of component failure increases very rapidly when cooling is insufficient. Particular attention should be paid to removing dirt and dust from high voltage components during regular maintenance after all power is removed and all components are discharged.

Dust should be cleaned from the transmitter with a suitable brush and vacuum cleaner or as otherwise recommended by the transmitter manufacturer. Usually weekly cleaning is sufficient.

Care of Power Tubes

The operating life of high power vacuum tubes can be extended by proper care. Most high power tubes utilize a directly heated cathode composed of a thoriated tungsten filament structure.

The key points to extending the life of RF power tubes are:

- Store tubes upright (upside-down or right-side-up) along the axis of symmetry, not on their side, to keep the internal elements concentrically aligned
- Use care when handling tubes to prevent mechanical shocks to the delicate internal structure. Don't set a tube on a hard surface without padding
- Keep the tube seals and anode cooler free of dust and dirt by weekly cleaning even in a clean environment
- Keep a spare tube on hand and rotate the tubes every few months to help keep the chemical "gas-getter" active so that the tubes remain gas free
- Keep a regular record of all tube operating parameters so that any trend of changes will be noticeable. If a tube fails during the warranty period, this data will be necessary to receive credit on a replacement tube
- Monitor the filament voltage on a true RMS responding instrument and log any changes for future reference. The sampling point for this voltage measurement should be located as close to the tube's filament contacts as possible to minimize errors due to voltage drops in the filament wiring.

Even a tube that has been properly operated should gradually lose emission from the cathode until it is no longer useful because the emissive material is gradually consumed. The carcass of the tube can then be rebuilt with a new cathode and recycled back into service. Tube life is not directly related to plate dissipation (within the ratings) but is related to the filament operating temperature (filament voltage) and the current density (milliamperes per heater watt) emitted by a given size filament. This means that operating a given tube type at a lower filament voltage and plate current will proportionately increase the life of the tube. For directly heated thoriated tungsten filaments, the plate current should be less than 4 milliamperes per watt of heater power for extended life.

Normally a new tube will deliver full output at a reduced filament voltage. By operating the tube at the optimum filament voltage, the filament life can be significantly extended. The optimum value may be found by slowly reducing the filament voltage from the manufacturer's rated value until the RF power output drops about 2% and then increasing the filament voltage until the RF power increases back up 1%. Recent informational bulletins on extending tube life from tube manufacturers permit the filament voltage to be reduced more than 5% below the manufacturer's rating as long as operation is closely monitored to stay above the point where there is a 1% drop in power output. [26] A brand new tube should be operated at the full rated filament voltage for the first 200 hours before the voltage is reduced to the optimum value for long life. This will assure that the gas-getter is properly activated. As the tube ages, the filament voltage will have to be increased to stay at the optimum value, until RF output power cannot be maintained at or above the rated value of filament voltage. At this point, the tube's useful life comes to an end. Check the manufacturer's data sheets and most recent application notes which are often enclosed with the tube for detailed information. An excellent guide to the proper care of power tubes is listed in references [10 and 26]. [17] gives detailed information about how to specify a proper forced-air cooling system for power tubes.

Preventive Maintenance

Preventive maintenance is equipment inspection and maintenance performed at regular intervals before an operational problem develops. The long term benefits are great because potential problems are discovered and solved while they are still easily manageable. A checklist of a few typical preventive maintenance items for an FM transmitter plant might include:

- Weekly overall internal and external cleaning and inspecting for damage or excessive wear
- Lubricate motors, tuning gears, and other moving parts at intervals recommended by the manufacturer
- Checking and logging all meter readings, including filament voltage, daily. Then compare these readings with the previous set of readings as an aid to diagnosing a developing problem
- Regularly exercising the automatic power control and any other servo systems.
- Checking the antenna lighting and de-icer systems
- Checking the transmission line pressurization and VSWR
- Checking all air filters in the transmitter plant and clean or replace as required
- Checking the proper operation of all monitoring and remote control equipment.

In addition, good overall housekeeping will pay big dividends in the long run by keeping equipment clean and free of problems that would otherwise be caused by dirt build-up.

Maintenance Systems

The key to making any maintenance program work is to set up formal checklist, logging, parts inventory management and repair scheduling systems. These systems provide the discipline required to keep the maintenance routine accurate and complete. Each station should develop a system suited for the particular physical plant involved. When there is more maintenance and repair work needing attention than there is time to do it all, set priorities for completing each item so no item gets forgotten. Accurate notebooks describing all installation and maintenance work are a very helpful part of any maintenance system especially when work spans many years.

4.4
FM STEREO AND SCA SYSTEMS

JOHN KEAN
MOFFET, LARSON & JOHNSON, INC., FALLS CHURCH, VA

INTRODUCTION

Stereophonic sound FM broadcasting and Subsidiary Communications Authorization (SCA) services are a form of multiplexing that had its origins over 60 years ago, when high-fidelity audio and facsimile messages were simultaneously transmitted from the Empire State Building in New York City to experimental receive sites in New Jersey.[1] Those historic multiplexing efforts demonstrated the value of wideband frequency *modulation*, allowing modern FM broadcasting to provide services to the public of both quality and variety.

Despite its illustrious start, FM broadcasting in the 1950's was a marginal business. The number of operating FM's declined annually from about 700 in 1947 to slightly over 500 in 1957. Many depended on additional income from their SCA services, which offered background music and other programs to stores and offices over medium fidelity audio subcarriers. The FCC gave the then struggling industry a boost by granting something AM and TV didn't have—stereo. The FCC's April 1961 ***Report and Order*** authorized transmission of a stereophonic sound system that combined the system proposals of Zenith Radio Corp., Chicago and General Electric Co.

FM broadcasters did not show much excitement for their new capability, but the growing availability of stereophonic LP records and home stereo equipment created a natural market for FM stereo. Most agree that FM's resurgence and eventual dominance as an audio medium was due in large part to stereophonic transmission. FM licensees, as well, still actively employ SCA.

THE COMPOSITE BASEBAND

This section contains definitions of the terms commonly used in the FM stereo and SCA systems.[2] Since some of these terms are misused or ambiguous, the intention here is to establish meanings that will be used throughout this chapter.[3] The list was selected to clarify certain terms and is not a complete glossary.

Key Terms For Stereo and SCA

Multiplexing. In its simplest sense, multiplexing implies that two or more independent sources of information are combined for carriage over a single medium, namely, the radio frequency *carrier*, and then are separated at the receiving end. In stereophonic broadcasting, for example, program information consisting of left and right audio signals are multiplexed onto an FM carrier for transmission to receivers which subsequently recover the original audio signals.

Channel. A transmission path. The usage herein distinguishes between the concept of a channel and a signal (main channel, stereophonic subchannel, etc., and left and right audio *signals*).

Composite Baseband Signal. A signal which is the sum of all signals that frequency modulate the main carrier. The signal includes the main channel signal, the modulated stereophonic subcarrier, the pilot subcarrier and the SCA subcarriers.

FM Baseband. The frequency band from 0 Hz to a specified upper frequency which contains the composite baseband signal.

Main Channel. The band of frequencies from 50 (or less) Hz to 15,000 Hz on the FM baseband which contains the main channel signal.

Main Channel Signal. A specified combination of the monophonic or left and right audio signals which frequency modulates the main carrier.

Stereophonic Sound. The audio information carried by a plurality of channels arranged to afford the listener as sense of the spatial distribution of sound sources. Stereophonic sound includes, but is not limited to, biphonic (two channel), triphonic (three channel) and quadraphonic (four channel) services.

Stereophonic Sound Subchannel. The band of frequencies from 23 kHz to 99 kHz (53 kHz for two channel transmission) containing sound subcarriers and their associated sidebands.

Subchannel. A transmission path specified by a subchannel signal occupying a specified band of frequencies.

Subchannel Signal. Subcarriers and associated sidebands which frequency modulate the main carrier. It is synonymous with subcarrier, as in the stereophonic subcarrier or SCA subcarrier.

Frequency Deviation. The peak difference between the instantaneous frequency of the modulated wave and the average carrier frequency.

Percentage Modulation. The ratio of the actual frequency swing of the carrier to the frequency swing defined as 100% modulation, expressed in percentage. Although current FCC rules conditionally permit greater than 100% modulation when SCAs are transmitted, a frequency swing of ±75 kHz is still defined as 100 percent modulation.

Injection. The ratio of the frequency swing of the FM carrier by a subchannel signal to the frequency swing defined as 100% modulation, expressed in percentage. The total injection of more than one subchannel signal is the arithmetic sum of each subchannel injection.

Crosstalk. An undesired signal occurring in one channel caused by an electrical signal in another channel.

Linear Crosstalk. A form of crosstalk in which the undesired signals are created by phase or gain inequalities in another channel or channels. Such crosstalk may be due to causes external to the stereophonic generator; consequently it is sometimes referred to as system crosstalk.

Nonlinear Crosstalk. A form of crosstalk in which the undesired signals are created by harmonic distortion or intermodulation of electrical signals in another channel or channels. Such crosstalk may be due to distortion within the stereophonic generator or FM transmitter; consequently it is sometimes referred to as transmitter crosstalk.

Frequency Spectrum And Modulation Limits

The FCC's stereophonic transmission standards are contained in Section 73.322 of the FCC Rules, and the SCA transmission standards are contained in Section 73.319. Readers should refer to the Commission's rules for a listing of its standards.

The composite baseband extends to 99 kHz and may be used in support of either stereophonic or SCA multiplex services. Stereophonic broadcasting includes, but is not limited to, biphonic service. Within the frequency range of 23 kHz to 99 kHz any form of amplitude modulation (DSB, SSB, etc.), angle modulation (FM or PM) or frequency shift keying of a multiplex subchannel is permitted.

An actual authorization, called an SCA, was once required in order for a station to begin broadcasting a multiplex service. Although the familiar term SCA is still used, the authorization is no longer required. Broadcast licensees may begin transmitting multiplex services without prior notification of or authorization from the FCC.

Under certain conditions when SCA multiplex subcarriers are operated, a total modulation of up to 110% is legal. Figure 4.4-1 shows the baseband frequency ranges and modulation limits for various modes, from monophonic to stereophonic plus fully loaded SCA operation.

Figure 4.4-1(a) represents the basic monophonic program mode, where the baseband width is limited to approximately 15 kHz and no other signals are multiplexed. In this case all the modulating energy is contributed by the main channel. Not more than 100% modulation is permitted in this case.

Figure 4.4-1(b) shows the baseband with SCA operation in addition to monophonic main channel service. Total SCA injection up to 30% is permitted within the band from 20 kHz to 99 kHz. This injection figure may be contributed by one or more SCA subcarriers. To insure that the bandwidth of the main carrier (and its interference to other stations on adjacent and alternate channels) is not significantly increased, the arithmetic sum of all modulation must not exceed 100% plus 1/2 of the SCA injection, subject to a total modulation limit of 110%. SCA injection between 75 kHz and 99 kHz may not exceed 10% under any conditions.

Note that the Commission Rules permit transmission of multiplex subcarriers when *no* broadcast program service is carried on the main channel, provided that the above modulation rules are met.

Figure 4.4-1(c) shows the basic stereophonic sound program mode, without SCA operation. As is the case for monophonic program operation, the modulation must be limited to 100%.

Figure 4.4-1(d) adds a single band for SCA operation to the stereophonic mode. While total SCA injection may be up to 20%, no more than 20% total injection may be employed within the frequency bands from 53 kHz to 75 kHz and 10% from 75 kHz to 99 kHz. (There is one exception to determining total SCA injection involving subcarriers that are multiples of and synchronous to the stereophonic pilot. This is discussed in the SCA multiplex section of the chapter.) The modulation contributed by the main channel and stereophonic subchannel signals must be no more than 100% minus 1/2 the total SCA injection. Since the total SCA injection may be up to 20%, total modulation may be up to 110%.[4]

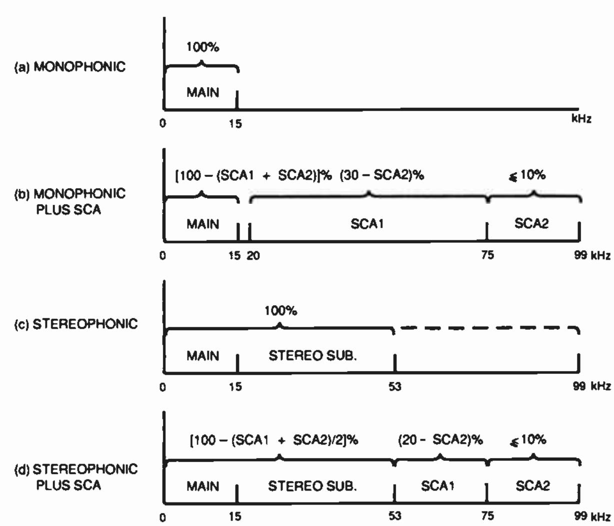

Figure 4.4-1. FM baseband scenarios with allowable modulation limits for monophonic, stereophonic, and SCA operation. Modulation percentages are referred to 75 kHz carrier deviation.

Generating The Stereophonic Baseband Signal

Figure 4.4-2 shows the composite baseband that modulates the FM carrier for biphonic broadcasting. (SCA multiplex subchannels are not part of this band and will be discussed later.)

The two channel stereo baseband has a bandwidth of 53 kHz, and consists of:

- A main channel ($L+R$) which consists of the sum of left plus right audio signals. This is the same signal broadcast by a monaural FM station, but it is reduced by approximately 10% to allow for the stereo pilot injection.
- A stereophonic sound subchannel ($L-R$) is required, consisting of a double sideband amplitude modulated subcarrier with a 38 kHz center frequency. The modulating signal is equal to the instantaneous difference of the left and right audio signals. The subcarrier is suppressed to maximize modulation capability. The pairs of AM sidebands have the same peak modulation potential as the main channel.
- A 19 kHz subcarrier *pilot* which must be exactly 1/2 the frequency of the stereophonic subcarrier and very nearly in phase to it. It supplies the reference signal needed to synchronize the decoder circuitry in receivers. The frequency tolerance of the pilot is ± 2 Hz and it must modulate the main carrier between 8 and 10%.

In general two principles have been used to generate the stereophonic subchannel—*time division multiplex* (TDM) or switching method and *frequency division multiplexing* (FDM) or matrix method.

Frequency Division Multiplexing

A basic method for generating the stereophonic baseband involves the direct generation of the double sideband suppressed $L-R$ subchannel along with the $L+R$ channel.

A simplified block diagram of the FDM system is shown in Figure 4.4-3. Both left and right audio channels are pre-emphasized and low pass filtered. In the matrix the left and right audio signals are both added and subtracted. The audio signals are added to form the $L+R$ main channel which is also used as the monaural broadcast signal.

The subtracted signals are fed to a balanced modulator which generates the $L-R$ subchannel. Since a balanced modulator is used, the carrier at 38 kHz will be suppressed, leaving only the modulated sidebands.

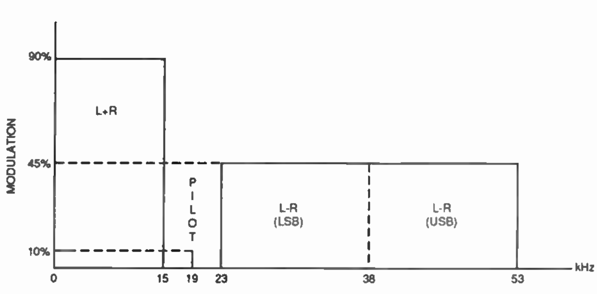

Figure 4.4-2. Biphonic (two-channel) stereo baseband.

The 38 kHz oscillator is divided by 2 to make the 19 kHz pilot tone. Finally, the main channel, stereophonic subchannel and pilot are combined in the proper proportions (45 + 45 + 10) to form the composite output.

An examination of the composite stereo waveform in the time domain, such as displayed by an oscilloscope, is helpful. First consider a 1 kHz sine wave applied equally to the L and R audio inputs. This is shown in Figure 4.4-4(a) without a pilot signal. The only frequency present in the spectrum graph is 1 kHz, since the matrix produces no difference signal necessary to generate sidebands in the stereophonic subchannel.

Figure 4.4-4(b) illustrates the ideal composite signal when the same 1 kHz tone is applied to the L and R inputs but exactly out of phase. With the pilot still off, two frequency components at 37 kHz and 39 kHz are generated. No $L+R$ signal appears from the matrix, thus only the sidebands of the modulated 38 kHz subchannel are present.

The symmetrical envelope shown represents a double-sideband suppressed carrier (DSBSC) AM signal. Note that the amplitude of each sideband is 1/2 that of the $L+R$ component in Figure 4.4-4(a). In the receiver's stereo decoder the sidebands are added together to produce an output equal to the full left signal.

Finally, consider the waveform in Figure 4.4-4(c), when the composite signal (still without pilot) is generated by applying a 1 kHz tone to the L input alone. The baseline of the waveform envelope will be a straight line if there is no amplitude or phase difference between the main channel and subchannel. Three frequency components are present: 1 kHz, 37 kHz and 39 kHz. These sidebands are each 1/2 the voltage amplitude of the 1 kHz signal in the main channel; together they equal the energy of the main channel in this instance.

The last diagram looks the same when an R-only 1 kHz tone is applied, but the phase of the two sidebands would be reversed with respect to the 38 kHz subcarrier (and the pilot). Adding the pilot at 8-10% produces similar waveforms, but oscilloscope display of the waveform baseline is fuzzier. For this reason, most stereo generators allow the pilot to be turned off for baseline measurements.

Time Division Multiplex

A different type of stereo generator is in use which produces a result similar to frequency division multiplexing by using a switching technique.

Generation of the both the $L+R$ and $L-R$ channels is accomplished by an electronic switch that is toggled by a 38 kHz signal. The switch alternately samples one audio channel and then the other, as shown in Figure 4.4-5. According to Nyquist criteria, the original signal can be reconstructed from periodic samples, provided that the samples are taken at a rate at least twice the frequency of the highest audio frequency component (approximately 15 kHz in broadcast FM).

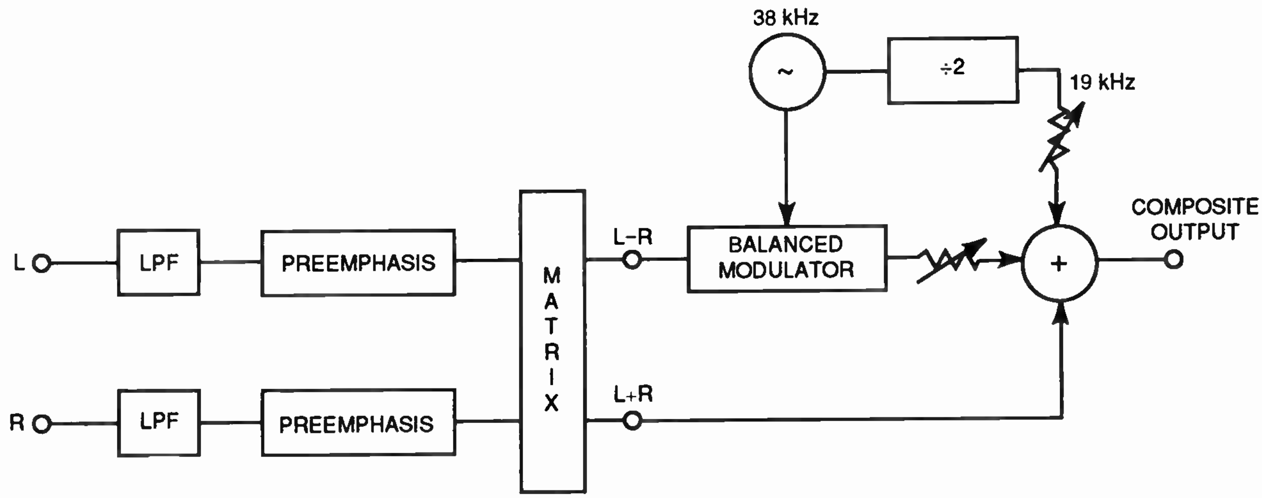

Figure 4.4-3. Functional blocks of a frequency division multiplex stereo generator.

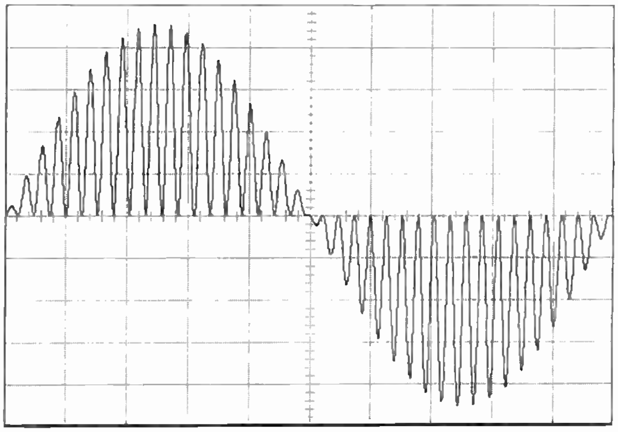

Figure 4.4-4c1. 1 kHz Left at 91%, 19 kHz at 0%. Sinusoidal L input at 90% modulation. (Courtesy of Quantics.)

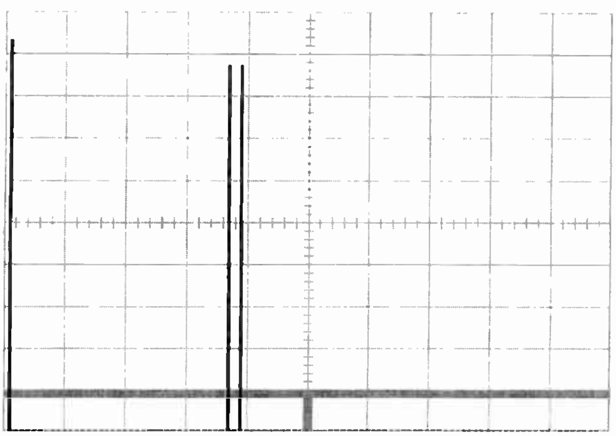

Figure 4.4-4c2. Baseband spectrum of 4c; modulation of 1 kHz signal appears a fundamental frequency at 45% level and as upper and lower sidebands of 38 kHz subcarrier at 22.5% each (−13.0 dB). (Courtesy of Quantics.)

Figure 4.4-6 shows the output waveform for the TDM generator in the time domain (as an oscilloscope would display the signal) for a sequence of input signals. The diagrams at the right of the waveform show the same signal in the frequency domain (as would be displayed on a spectrum analyzer).

In Figure 4.4-6(a), there are no input signals present. Ideally, no output signals are possible, and in practice only a small amount of leakage of the switching transients are present. Since the transfer time of the switching signal is extremely quick, harmonics of the fundamental 38 kHz are possible.

A 9 kHz audio tone is applied to the L and R inputs in Figure 4.4-6(b). The 9 kHz input signals are combined at full amplitude (90% modulation) and no subchannel sidebands are generated.

In Figure 4.4-6(c), only the left channel has a signal present. As the switch selects the L audio line, samples are passed along to the composite output. Therefore, the output waveform shows the same signal, chopped into segments of 1/38,000th of a second. Since the total area under the waveform has been divided in half, it should be apparent that the energy of the 9 kHz signal in the $L+R$ channel is only half the amplitude that it would be if an equal 9 kHz signal were also present at the right channel. The equation for the output signal e for an input signal σ at any instant t is:

$$\begin{aligned} e &= 1/2 \sin \sigma t \\ &\text{(main ch. audio)} \\ &+ 1/\pi[\sin(\phi + \sigma)t + \sin(\phi - \sigma)t] \\ &\text{(DSBSC)} \\ &- 1/3\pi[\sin(3\phi + \sigma)t + \sin(3\phi - \sigma)t] \\ &\text{(3rd harmonic)} \\ &\ldots \text{etc. (higher harmonics)} \end{aligned} \qquad [1]$$

Figure 4.4-6(c) shows the original 9 kHz signal (at half amplitude), and a pair of sidebands centered about the 38 kHz switching frequency. No 38 kHz signal

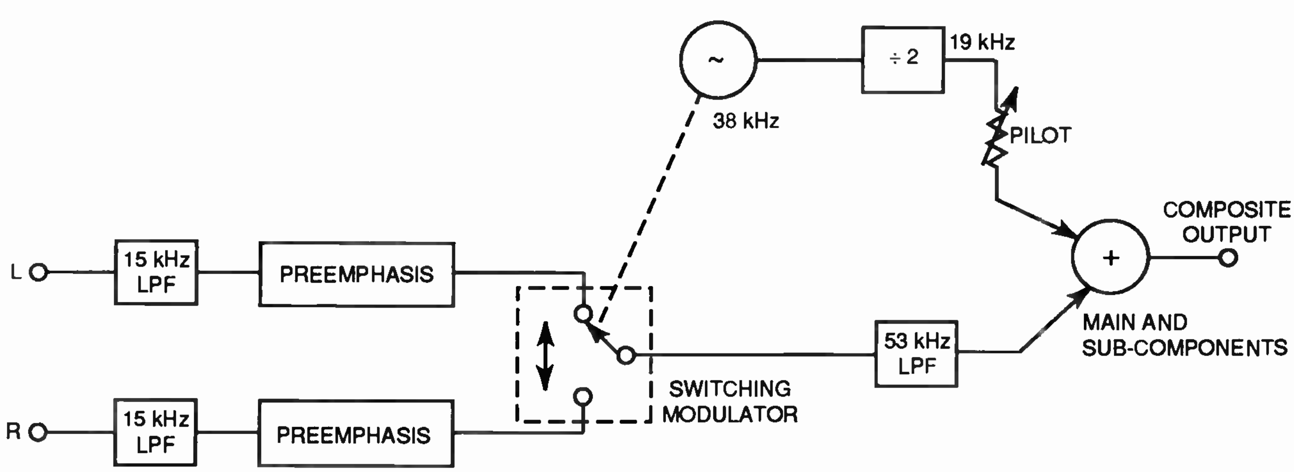

Figure 4.4-5. Functional blocks of a time division multiplex stereo generator.

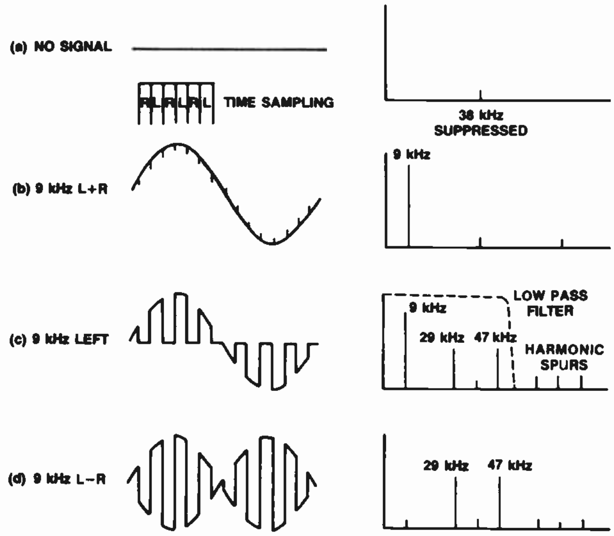

Figure 4.4-6. Time domain and frequency domain diagrams of stereo baseband signals.

is generated if the switching waveform has perfect symmetry, that is, if the switch is connected to the left and right channels for precisely equal periods. Note that a harmonic of the stereophonic subcarrier is shown, centered around 114 kHz which is three times the switching frequency. Only one extra term was shown in the equation; however, other terms at the 5th, 7th are present.

In addition to the odd order harmonics of the 38 kHz subchannel, asymmetry in the switching signal or other circuit imbalances can create some sidebands centered about the second harmonic at 76 kHz. All these harmonics must be removed by filtering, as shown in the diagram.

When the odd harmonics are filtered out the proper DSBSC waveform results. However, it is slightly greater in amplitude than the $L+R$ signal because the fundamental component of the square wave is $4/\pi$ or 1.27 times larger than the square wave amplitude. This is easily corrected by adding enough of the L and R audio to the output to equalize the amplitude.

In Figure 4.4-6d, the TDM signal is shown when the L and R signals are equal in amplitude and exactly reversed in phase. This waveform matches the composite stereo signal shown in Figure 4.4-4b.

The composite lowpass filter must have very steep cutoff characteristics but should have flat amplitude response and linear phase shift with frequency (equal time delay at all frequencies) below 53 kHz. While this approach to stereophonic generation is simple and stable, the filter can degrade stereo separation, especially at higher audio frequencies.

The 19 kHz pilot squarewave from the ÷2 digital divider must also be filtered to remove harmonics. This additional time delay (phase shift) of the pilot with respect to the 38 kHz information must be compensated to have optimum channel separation.

A significant improvement on the original switching concept is shown in Figure 4.4-7. As mentioned earlier, the higher order terms of the square wave-driven switch are responsible for generating the harmonics of the 38 kHz subchannel which must be removed by filtering. By using a *soft switch* to connect back and forth between the L and R channels it is possible to eliminate the lowpass filter and its side effects.

This is accomplished by using the electrical equivalent of a variable attenuator, shown in the diagram by a potentiometer. The slider is driven from end to end of the potentiometer by a sinewave. Since a sinewave is represented only by a single, fundamental frequency, the signal output at the slider has the proper DSBSC characteristics without the harmonics. The equation for the composite signal generated in this way is:

$$e = \underbrace{1/2 \sin \sigma t}_{(L+R\ audio)} + \underbrace{1/\pi[\sin(\phi + \sigma)t + \sin(\phi - \sigma)t]}_{(38\ kHz\ DSBSC)} \qquad [2]$$

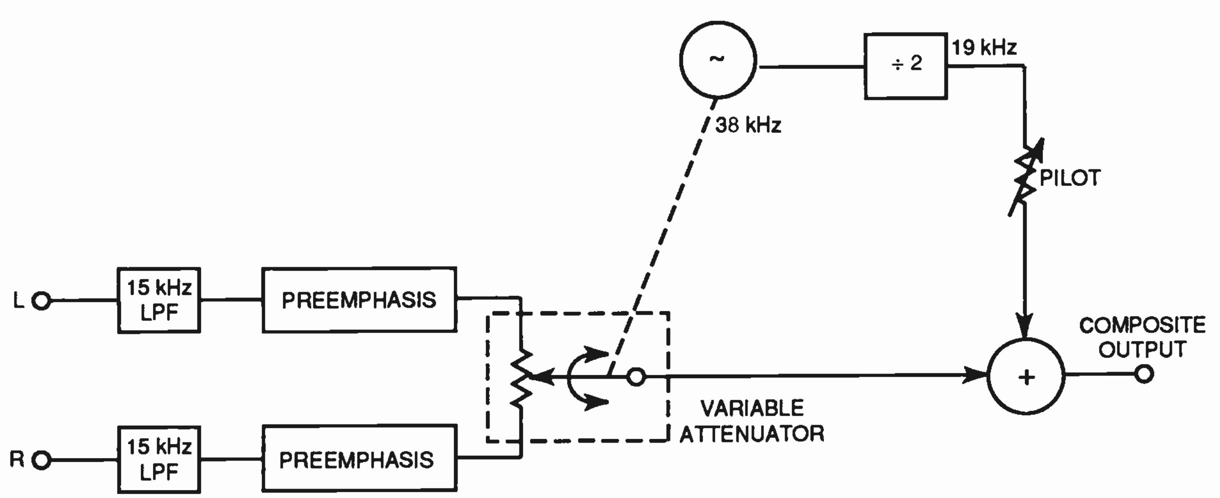

Figure 4.4-7. Functional blocks of a time division multiplex stereo generator using a variable attenuator.

As the equation shows, only the fundamental sidebands of 38 kHz are present in the sampled signal, along with the main channel component. Like the fast switching TDM system, the $L+R$ and $L-R$ channels are generated in one operation so that the circuit remains relatively simple. No filter of the output is required, provided that the 38 kHz sinewave is free from harmonics and the variable attenuator has good linearity.

Digital Stereo Generation

The major manufacturers of stereo generators have moved to all digital composite generator designs. These units carry out the same functions as analog stereo generators, but with the flexibility and consistency commonly expected of digital audio systems. Some generators also perform all the audio compression and peak limiting functions in the digital domain. This chapter is confined to a discussion of digital stereo generation techniques.

Digital implementation is made easier if the output sampling rate is a binary multiple of either of the two steady state vectors in the composite signal: the stereo pilot or the $L-R$ subcarrier. For example, an oversampling rate of 304 kHz is sometimes employed (this is eight times the subcarrier frequency, and 16 times the pilot).

The input sampling rate is also an important consideration. The reader will note that switching type stereo generators, discussed earlier, operate at only 38 kHz. While higher rates do not yield any additional improvement in fidelity, it is desirable to use a higher rate throughout the generator system.

While Digital Compact Discs© are fixed at 16-bit quantization precision, most digital stereo generator designs use more bits per sample. This is because analog-to-digital (A/D) conversion devices do not perform to the theoretical limits of 16 bits, and because the mathematical precision of the processing architecture can produce rounding errors that contribute noise and distortion to the processed signal. Eighteen to 24 bit data paths are generally chosen.

Analog audio for each channel is passed through an anti-aliasing lowpass filter and is then A/D converted into digital data streams. At this point, generators with audio processing carry out algorithms that gain-control, pre-emphasize, limit and filter the digital audio stream. The dynamic effects are very similar to analog processors even though the treatment is entirely digital.

The processed L and R signals are then numerically matrixed using simple addition into $L+R$ and $L-R$ channels. The digitized 38 kHz sinewave is derived from a look up table and digitally multiplied by the $L-R$ channel to produce the 38 kHz DSBSC. The 19 kHz pilot is generated by another look up table that is locked via software control so that the phasing relative to the 38 kHz subchannel is perfect. The pilot and 38 kHz subchannel are finally summed and applied to a digital-to-analog (D/A) converter to form the complete composite stereo signal. Some manufacturers provide a separate digital output port for digital FM exciters.

Stereo Decoder Circuits

Stereo FM receivers include a circuit to convert the multiplexed composite signal at the FM detector into the original left and right audio channels transmitted by the FM station. There are at least as many ways to decode the stereophonic signal as there are ways to encode (generate) the composite signal. In practice, only one type of decoder is commonly used, the *phase-locked loop* (PLL) integrated circuit.

The circuit in Figure 4.4-8a is seldom used, but is shown for comparison. It is the closest complement to stereo generators using frequency division multiplexing. At the input, the composite signal is split with three equal time-delay filters into the main $(L+R)$ channel, pilot signal and stereo $(L-R)$ subchannel. Next, the pilot is doubled to 38 kHz and this regenerated carrier is reinserted into the double-sideband AM signal from the subchannel filter. This AM signal is demodulated to yield the $L-R$ (difference) audio. Finally, the $L+R$ and $L-R$ signals are combined in a sum and difference matrix to produce the original L and R audio channels.

Because of the costly filters needed to separate the composite spectrum, the frequency division multiplex circuit is not used in consumer equipment. Similar circuits have been used in broadcast modulation monitors, where metering of the separate channels is required.

The circuit shown in Figure 4.4-8b is universally used, due to its simplicity, high performance and low cost. While this stereo decoder is commonly referred to by its internal PLL, its performance is really distinguished by its time division demultiplexer (shown in the dashed box as a toggle switch).

Following a buffer amplifier, the composite baseband signal is sampled by a PLL within the IC. A voltage controlled oscillator, usually running at 76 kHz (four times the pilot frequency) is held in phase with the pilot by a reference signal from the phase comparator and loop filter. When divided by two, the result is a square wave at 38 kHz having nearly perfect duty cycle (high and low states have equal timing) and very fast rise and fall times. This signal is ideal for driving the output audio switcher (demultiplexer). This stage is a transistor matrix designed to rapidly transfer the composite baseband to the L and R audio output in time with the switch in the station's stereo generator. Fast, clean audio switches are relatively easy to make and do not drift.

Because PLL stereo decoders normally use square wave switching, the circuit is able to demodulate baseband signals that are odd harmonics of 38 kHz. The third harmonic (114 kHz) is most troublesome, since noise and spurious signals near this frequency are shifted to the audio baseband, as is the 38 kHz stereophonic subchannel. Engineers should be watchful of the frequency band centered on 114 kHz in their transmitted signal since audible noise may occur in consumer receivers.

Recent stereo decoder designs have reduced sensitivity to energy outside the composite baseband. One

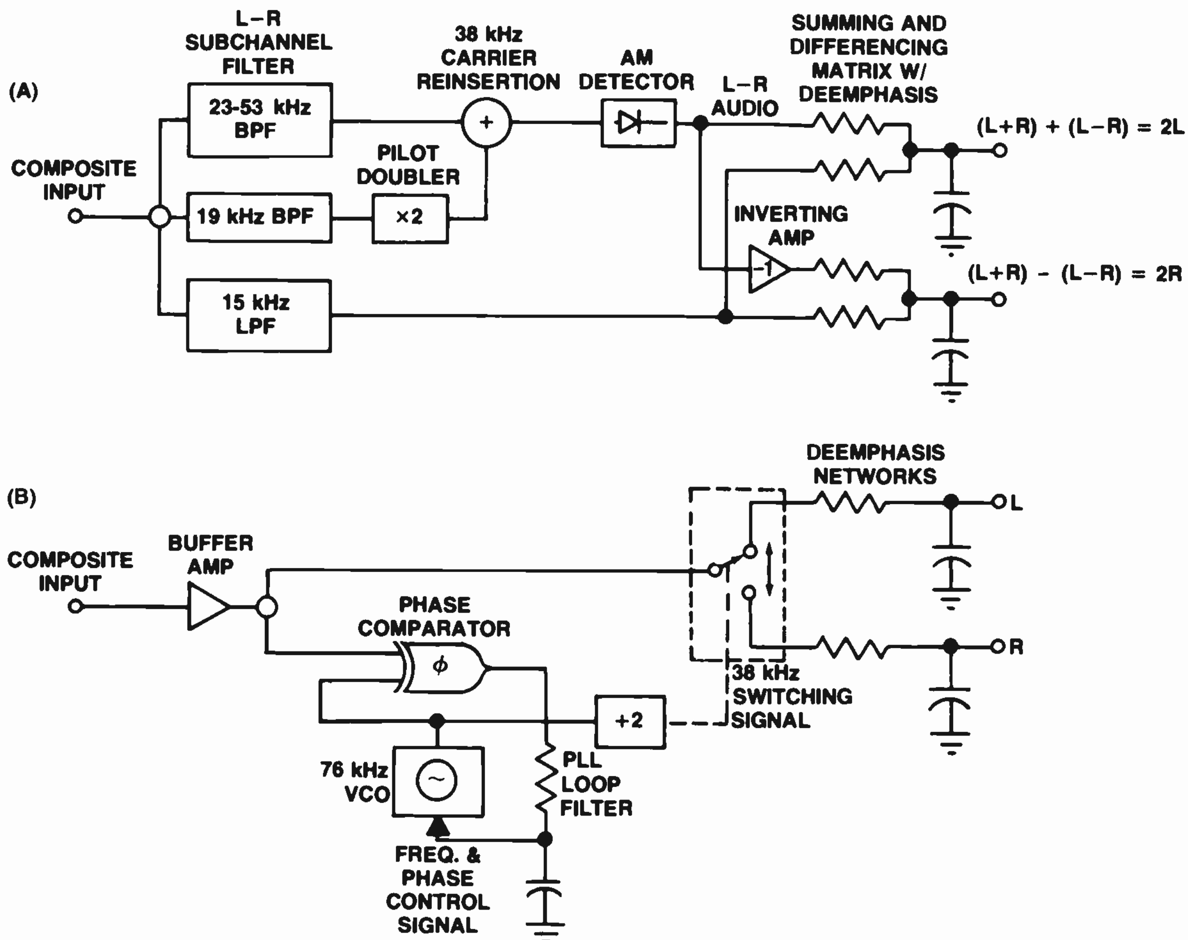

Figure 4.4-8. Functional blocks of stereo decoders using (A) $L+R$ and $L-R$ matrixing and (B) phase-locked time-division multiplexing.

approach utilizes a second composite audio toggle switch operated at 114 kHz. The demodulated product is inverted and mixed equally with the 38 kHz switching outputs, canceling the response to signals in the 114 kHz range. The other approach—Walsh demodulator—applies a properly timed stair step imitation of a sinusoid to a digital multiplier in the output signal path.[5] This reduces sensitivity to 3rd and 5th harmonics, as well as adjacent channel noise and interference, by up to 20 dB.

FM SCA TRANSMISSION

From its beginning as a broadcast service, people have recognized the potential of FM for multiplexed services. As early as 1940, the FCC permitted multiplex facsimile transmission on FM stations, but not until much later did auxiliary FM services attain a wide acceptance among FM broadcasters.

In 1955, the FCC established the SCA and created an entirely new industry. The original intent of the authorization was to permit programming of background music to offices, stores, restaurants, etc., where it was uneconomical to provide this service via telephone lines. For many commercial FM stations, the SCA operation became a major source of revenue which enabled them to survive in the 1950s.

By the early 1980s, improvements in transmitter and receiver technology and the desire for new revenue prompted commercial and noncommercial broadcasters to seek changes in the SCA rules. In a series of rulemakings in 1982 and 1983 the Commission made numerous changes to expand technical opportunities and reduce legal regulation.[6] These changes extended the baseband frequency limit from 75 kHz to 99 kHz, allowed any type of subcarrier modulation to be used, changed the subcarrier injection requirements to permit multiple services and increased limits for the total modulation during SCA multiplex operation to reduce main channel modulation loss.

FCC Rule Requirements For SCA Operation

Section 73.319 of the FCC Rules sets forth the technical standards for FM multiplex subcarriers. However, the Commission does not set standards for mini-

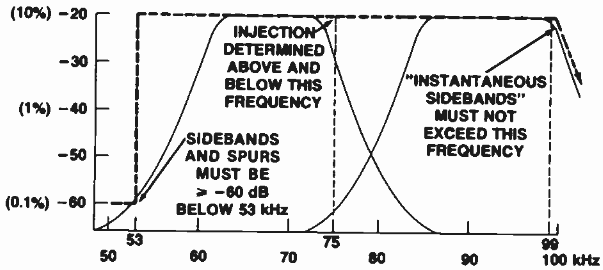

Figure 4.4-9. Injection, channel bandwidths and spurs limits for SCA operation when stereo is transmitted. Two possible subcarriers (at 67 and 92 kHz) are shown.

mum SCA subcarrier performance. This is left for the broadcaster or lessee of the service to determine. In its rules, the Commission defines the transmission conditions under which subcarriers may be operated, to minimize interference to the main channel and stereophonic subchannel and to other FM stations.

In this chapter, subcarrier injection and bandwidth are considered here only with stereophonic operation, since this is by far the most common FM mode. Figure 4.4-9 shows the upper portion of the composite baseband, from approximately 50 kHz to 100 kHz. This is the same as the upper portion of Figure 4.4-2 with the addition of two hypothetical subcarriers centered at 67 kHz and 92 kHz. Any number of SCA subcarriers may be operated in this frequency range provided that total bandwidth and injection limits are met.

On the baseline are several frequency markers at the upper and lower frequency limits of the two subcarrier ranges. The actual frequencies of the subcarriers are not specified.

Alongside each subcarrier are arrows marking the level in dB below 100% modulation of the main carrier. For example, -20 dB marks the injection at the center frequency of both subcarriers. Since 10% is the maximum injection permitted under the Commission rules within each SCA subchannel.

$$\text{Injection} = 20 \times \log_{10}(0.1) = 20(-1) = -20 \text{ dB} \quad [3]$$

At 53 kHz, an arrow marks a level of -60dB. The FCC requires that any frequency modulation of the main carrier due to the SCA operation shall be at least 60 dB below 100% modulation in the frequency range of 50 Hz to 53 kHz when stereo is transmitted. This figure must include spurious and intermodulation products as well as subcarrier sideband energy.

At 99 kHz, the level of -20 dB is marked, denoting the FCC requirement that "instantaneous sidebands" be restricted within this frequency limit. The Commission has not officially defined instantaneous sidebands, but it is normally considered to be the instantaneous frequency of the subcarrier at its peak deviation (for frequency modulated subcarriers) or the highest sideband frequency (for amplitude modulated subcarriers).

Interference Between FM SCA Subcarriers

In practice, two subcarriers should be separated as far apart in frequency as possible, while observing the limit of spurious energy below 53 kHz and the instantaneous sidebands at 99 kHz. While the FCC Rules are silent on the choice of SCA frequencies, 67 kHz and 92 kHz have become the defacto standards for FM subcarriers. The first frequency was adopted when the original stereophonic standards restricted the subcarrier spectrum between 53 kHz and 75 kHz. The second frequency was recommended to situate the instantaneous sidebands below 99 kHz while maintaining a safe separation from a 67 kHz subcarrier.

Some overlap of the subcarrier sidebands does occur, as depicted in Figure 4.4-10. This does not cause significant interference between the two SCA subchannels when the systems use frequency modulation. Following is a list of bench test results of a standard table model SCA receiver:

- Unweighted 67 kHz SCA S/N ratio at 65 dBf, referred to 5 kHz deviation: 57.5 dB.
- Same, with 4 kHz tone modulation of 92 kHz subcarrier at 7 kHz deviation: 56.5.
- Same as first case with tone modulation of main channel at 67.5 deviation: 52.5.

The above data shows that crosstalk is greater from main-to-67 kHz subcarrier than from a 92 kHz subcarrier into the 67 kHz subchannel demodulator.

Other Types of Analog Subcarrier Modulation

Other frequencies and total number of subchannels are permissible, according to the occupied bandwidths and interference margins required. A hypothetical SCA baseband spectrum combining five amplitude-modulated subcarriers is shown in Figure 4.4-11. A variety of bandwidths and injection levels are used.

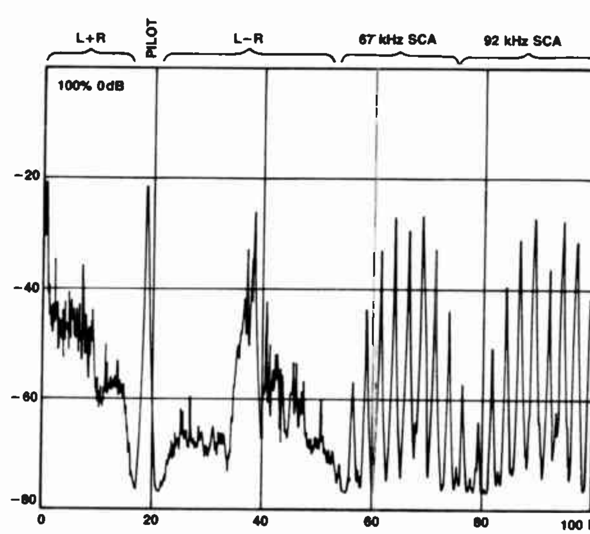

Figure 4.4-10. Composite baseband of FM station with 67 kHz and 92 kHz FM-SCAs, modulated with 2.5 kHz tone at 5 kHz and 7 kHz peak deviation, respectively. Note overlap of sidebands between subcarriers. Station is carrying stereo programming.

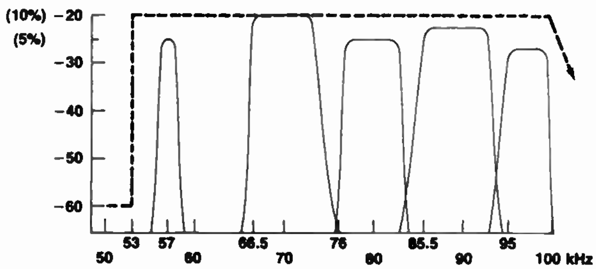

Figure 4.4-11. Carrier envelope spectrum, DSB-AM and SSB-AM SCA subcarriers. Vertical markings are dB referred to 75 kHz deviation.

In Figure 4.4-11 note that single sideband suppressed carrier (SSBSC) AM systems are used for the four other subchannels. On the first (at 66.5 kHz), 10% peak envelope injection is being used, while the other three use levels which bring the total to 20%.

At 57 kHz, the envelope of a narrow subcarrier is shown. Actually, standards exist to interleave two subcarriers within the same channel. One is the *Radio Data System* (RDS) which is in use by a large number of Western European countries for personal paging, station and program identification, emergency alerting, etc. This 57 kHz system is currently used by over 700 stations in the U.S. The modulated carrier spectrum resembles suppressed-carrier double sideband AM that is locked to the third harmonic of the pilot. The digital data rate is 1187.5 bits/sec and nominal deviation of the carrier is 2.67% (±2.0 kHz).

Automotive Road Information (ARI) is another 57 kHz system developed in Europe. It is used to identify stations that broadcast traffic information and to activate specially equipped FM car radios during traffic announcements. ARI is a slow rate signaling system with very narrow bandwidth. The 57 kHz ARI carrier is centered within the suppressed carrier region of the RDS signal (if RDS is transmitted).

Examples Of Analog SCA Operation

Figure 4.4-12a shows the functional blocks of a standard aural SCA generator using frequency modulation. At the input, audio is lowpass filtered to limit the modulation sidebands that could interfere with the stereophonic subchannel or an upper SCA subchannel.

A 5 kHz audio cutoff is frequently used so that fidelity compares favorably to unequalized telephone service. Using a Bessel function analysis one can determine the peak deviation which may be used to maintain FM sidebands below 53 kHz within FCC limits:

Sinusoidal SCA Modulating Frequency	Maximum SCA Peak Deviation
3.5 kHz	5.0 kHz
5.0	3.5
7.5	2.0

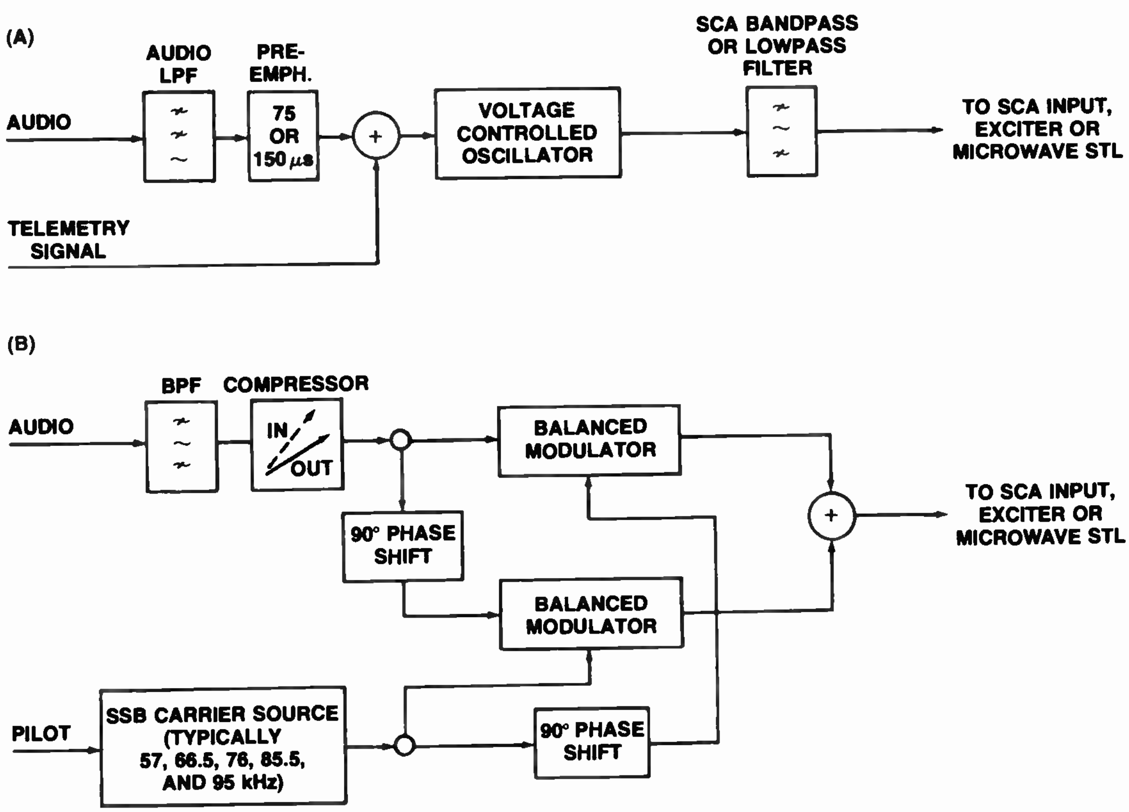

Figure 4.4-12. Functional blocks of (A) a frequency-modulated SCA subcarrier generator, and (B) a single-sideband AM subcarrier generator.

For the protection requirements, equipment manufacturers often recommend 3.5 or 4.0 kHz peak deviation with a 5 kHz lowpass filter when stereo is transmitted. In practice, slightly higher deviation may be used since the calculations assume single tone modulation which has greater modulation power than program audio.

Pre-emphasis follows the lowpass filter in the sample FM SCA generator. A value of 150 μsec is commonly used to combat the rising high frequency noise characteristic in the FM SCA channel. Unfortunately, this extreme boost (almost 17 dB at 5 kHz, compared to 400 Hz) requires substantial amounts of peak limiting to allow full modulation at low and middle audio frequencies.

The processed audio signal is fed to the FM modulator, usually with a provision for a subaudible (less than 30 Hz) channel for telemetering return. The telemetry channel takes advantage of the extended low frequency response capability of FM subcarriers by sending tone signals in the 10 to 30 Hz range at a level of 15 to 25 dB below reference peak deviation. A highpass filter is inserted ahead of the audio input when subaudible telemetry is used to avoid interference to the low frequency channel.[8]

Ideally, no filtering of the frequency modulated subchannel is required. However, some of the FM generator circuits produce spurious or harmonic energy. For this reason, a bandpass or lowpass filter is used that passes all the significant sidebands but suppresses spurious signals to acceptable levels. The modulated subchannel signal is amplified to a level required by the subcarrier input of the FM exciter or studio transmitter link equipment.

A simplified block diagram of a SSBSC AM subchannel generator is shown in Figure 4.4-12b. The input audio is bandpass filtered to control subchannel bandwidth (to 5 kHz, for example), and may be compressed according to specific amplitude and spectral standards. A complementary expander circuit in the receiver restores the original program dynamics and reduces noise in the channel. Large amounts of pre-emphasis are not as important since the spectral characteristic of the noise is flat with a linear modulation system, not rising with frequency as in angular modulation systems.

The processed audio signal is fed to a pair of balanced modulators, one path going through an all-pass filter which shifts the audio phase 90° throughout the required audio range. The balanced modulators are driven by a subcarrier frequency source which may be frequency locked to a harmonic of the stereophonic pilot (and its half frequency of 9.5 kHz, as shown). One of the modulators is driven by a carrier signal which is shifted 90°. When the two modulated carriers are summed, cancellation of the lower (or upper) sidebands creates the desired single sideband signal.

Since SSBSC AM requires a carrier for detection, the pilot provides an excellent source for reinsertion at the receiver. With monophonic audio no pilot is transmitted, so another carrier reference must be used. One approach is to carry the 19 kHz reference at a reduced level which will not trigger the stereophonic decoders in FM receivers.

SCA DATA SYSTEMS

SCA subchannels have characteristics that are quite favorable for transmitting data. While the channels are noisy for high fidelity audio services, they can provide good to excellent data error performance, and moderately fast data rates are possible without complicated or expensive receivers. Combined with the high power and elevation of FM broadcast stations, SCA data systems may be operated over large service areas.

There are many methods of putting data on an SCA subchannel, the simplest being *audio frequency shift keying* (AFSK)—the connection of a telephone type data modem to the audio terminals of the SCA generator.

The cost and complexity of this form of SCA data broadcasting is low. However, this technique occupies the bandwidth of a standard audio subcarrier and the highest practical speed is about 2,400 bps. This may be acceptable where the hardware must be off-the-shelf and data capacity of baseband spectrum is not a consideration.

Direct Data Modulation

Direct data modulation eliminates the intermediate steps that convert the data into audio signals, allowing the subcarrier to be directly modulated by the binary data. This efficiency allows a greater amount of data to transmitted within the available SCA subchannel bandwidth.

In *non-return-to-zero frequency shift keying* (NRZ/FSK), the two binary states are represented by two different subcarrier frequencies. For example, a "0" could be 65 kHz and a "1" 69 kHz. FSK is the most popular form of direct data modulation at this writing, probably because of its robust performance, simplicity and low cost. Using careful design, a modulated bandwidth similar to that of background music services (about ±16 kHz at −25 dB below subcarrier injection) and a maximum speed of 19 kbps are currently possible.[9]

Data FSK systems must use filtering methods to control occupied bandwidth, since the rapid frequency transitions generate high order sidebands that could interfere with adjacent subchannels. Filtering is accomplished by either or both of the following methods shown in Figure 4.4-13:

- Where a pair of oscillators are alternately toggled by the data states, filtering must be done to the output spectrum to directly reduce occupied bandwidth.
- Where analog FM modulators are used, filtering the slew rate of the switching signal tends to reduce high order sidebands indirectly.

The spectrum of the composite baseband of a FM station is shown in Figure 4.4-14, carrying a 19 kbps

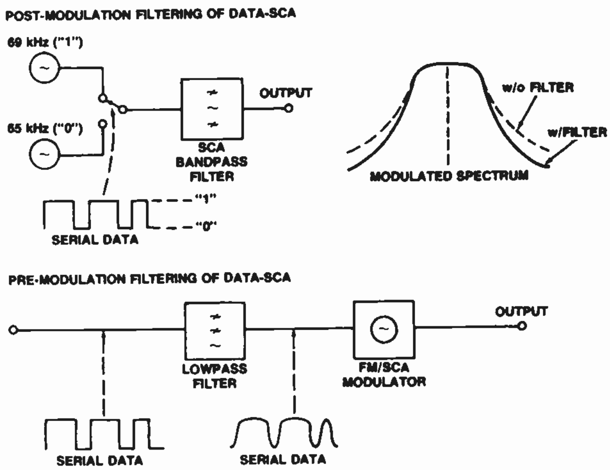

Figure 4.4-13. Two basic methods for generating and controlling the bandwidth of data subcarriers used for SCA.

data signal. The spectrum was generated by a specially designed SCA generator employing both pre- and post-modulation filtering.

Phase Shift Keying (PSK) is another technique for transmitting high speed data. With PSK, one phase of the carrier represents one binary state and a second phase (usually 180° apart) is used for the second state. High speed data transmission is possible, up to 56,000 bps, although most of the 53 to 99 kHz bandwidth might be required and receiver/decoders would be much more expensive than those for moderate speed FSK systems.

Radio Broadcast Data System

The United States Radio Broadcast Data System (RBDS) Standard was first adopted by the National Radio Systems Committee in 1993. A revised edition of this standard was adopted in 1998. The RBDS Standard uses an FM data subcarrier at 57 kHz in the FM baseband to transmit information like call sign, format type, song title, artist, and emergency information to RBDS-equipped receivers. This standard is explored in more detail in Chapter 4.6, *Radio Data Broadcasting*.

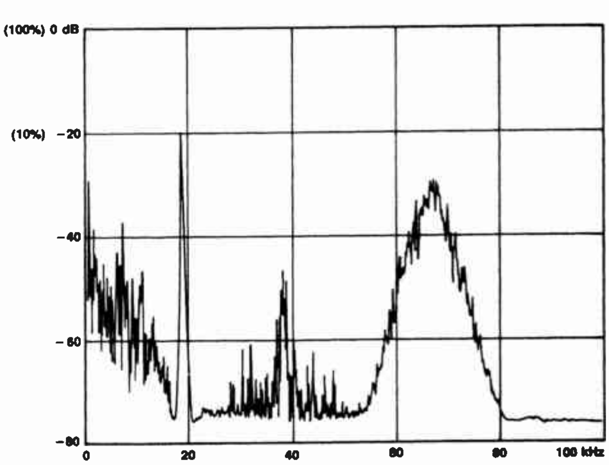

Figure 4.4-14. Composite baseband of an FM station carrying a 19 kbps frequency-shift keyed data subcarrier. Center frequency of the subcarrier is 67 kHz, with an injection of 9%. Station is carrying stereo programming.

MONOPHONIC, STEREOPHONIC & SCA PERFORMANCE

While monophonic, stereophonic and various SCA services are conveyed by the same FM carrier, performance varies considerably due to the relative carrier deviation of each and the particular frequency span occupied within the composite baseband. The performance of a channel may be expressed in terms of demodulated S/N ratio for a given radio frequency carrier level, or, conversely, coverage range for a given signal to noise ratio.

The performance of a conventional FM receiver in the presence of random (thermal) noise is commonly judged on the basis of the variation of the output S/N power ratio as a function of the carrier to noise power ratio contained within the receiver bandwidth, usually determined by the IF bandwidth. An estimate of the IF bandwidth required for transmission of (monophonic) broadcast FM is given by the following equation:[10]

$$\beta_{IF} = 2(F_{dev} + 2f_m) \qquad [4]$$

Where:

F_{dev} = the peak frequency deviation (75 kHz), and
f_m = the highest baseband modulating frequency (15 kHz).

This β_{IF} figure is rounded to 200 kHz for later use.

The equivalent input noise power in a bandwidth β launched into a noise free (cool) receiver is:

$$\begin{aligned} rB &= 4 \times 10^{-21}\beta f_N \\ &= 8 \times 10^{-16} f_N \text{ W} \end{aligned} \qquad [5]$$

Where:

f_N = the receiver noise figure, and
β = nominal noise bandwidth in Hz.

The carrier power is:

$$C = (V_{\mu V^2}/R) \times 10^{-2} \text{ W} \qquad [6]$$

Where:

$V_{\mu V^2}$ = the rms input voltage in microvolts
R = the receiver r.f. input resistance.

For R = 75 Ω the CNR in decibels is:

$$\begin{aligned} CNR &= 10 \log_{10}(C/rB) \\ &= 12.2 + 20 \log_{10} V_{\mu V} - 10 \log_{10} f_N \end{aligned} \qquad [7]$$

For example, for a 10 dB noise figure the carrier to noise ratio is 0 dB for an input voltage of 0.77 μV over 75 Ω (1.55 μV over 300 Ω).

For a half-wave dipole antenna matched to a 75 Ω receiver the input voltage is related to the field strength as:

$$V_{\mu V} = 48.5E_{\mu V}/f_{MHz} \qquad [8]$$

Where:

$E_{\mu V}$ = the field strength in μVμ
f_{MHz} = the carrier frequency in MHz.[11]

Thus, for 98 MHz (middle of the FM band)

$$V_{\mu V} = \frac{E_{\mu V}}{2} \qquad [9]$$

With the FCC F(50,50) field strength curves it is possible to relate μV to the distance to the transmitter, effective radiated power and antenna heights. Ultimately, it is possible to predict the CNR for a given broadcast system. For a 200 kHz nominal bandwidth the CNR in dB can be shown to be:

$$\begin{aligned} \text{CNR} = E_0 + P + G - F \\ + 20 \log_{10}(h/30 \times 98/f) + 6 \end{aligned} \qquad [10]$$

where

E_0 = field strength for 1 kW ERP 1000′ HAAT, in dB μV/m
P = ERP in dBkW
G = receiver antenna gain relative to dipole, in dB
h = receiving antenna height above ground, in ft
F = receiver noise figure in dB
f = frequency in MHz.

For example, if $F = 10$, $P = 10$, $G = 0$, $h = 30$, and $f = 98$, then CNR $= E_0 + 6$.

Next, the S/N ratio is established by the CNR:

$$\text{SNR} = 40 + 10 \log_{10} \text{CNR dB} \qquad [11]$$

This expression assumes a peak deviation of 75 kHz, a de-emphasis corner frequency of 2.1 kHz (75 μS) and a nominal intermediate frequency noise bandwidth of 200 kHz.[12]

Using the previous equation, a carrier to noise ratio of 0 dB would result in a signal to noise ratio of 40 dB. However, standard FM demodulators typically exhibit a threshold at about 12 dB CNR, below which the noise floor changes from a hiss to a raspy kind of noise with noticeable clicks jutting above the noise. For this reason, the monophonic channel actually deteriorates below a signal to noise ratio of about 52 dB.

A well known effect of FM demodulation is that the noise voltage in a narrow band (for example, 1 Hz) increases with frequency. This has important implications for systems which employ subchannels since both the bandwidth and center frequency affect the S/N ratios. For example, the stereophonic $(L-R)$ subchannel shown in Figure 4.4-2 extends nominally from 23 kHz to 53 kHz and occupies twice the bandwidth of the main $(L+R)$ channel. When the noise of the $L-R$ subchannel is combined during stereo decoding, the unweighted noise floor is 23.1 dB higher than the monophonic system under the same conditions.[13]

The S/N ratio of an SCA subcarrier, relative to the main channel, is a function of a number of variables and is:

$$N_S/N_O = (2f_c^2/m^2D^2)\frac{f_1^3(b_1 - \arctan b_1)}{f_0^3(b_0 - \arctan b_0)} \qquad [12]$$

Where:

f_c = subcarrier frequency
m = injection level as a percent of 75 kHz
D = deviation of FM subcarrier
f_0 = −3 dB freq. of de-emphasis in main audio channel (2.12 kHz)
f_1 = −3 dB freq. of de-emphasis in SCA audio channel (1.06 kHz)
b_0 = main channel audio output bandwidth (15 kHz)/f_0
b_1 = SCA channel audio output bandwidth (5 kHz)/f_1

Following is an example of the excess noise in the 5 kHz SCA audio channel, compared to the 15 kHz main channel, if $m = 0.1$ (10%). Note that the noise level of a 67 kHz subcarrier with 5 kHz deviation and a 92 kHz subcarrier with 7 kHz deviation are nearly equal. Comparative tests by the author have indicated that susceptibility to impulse noise (gasoline engine ignition radiation) is greater at the higher subcarrier frequency even though Gaussian noise levels are approximately the same. This may be due to a higher noise threshold in the 92 kHz demodulator (due to a wider pre-detection bandwidth than the 67 kHz demodulator) or to differences in the spectral distribution of impulse noise compared to Gaussian noise in the IF (composite) demodulator.[14]

f_c (SCA freq., kHz)	67	92	92
D (deviation, kHz)	5	5	7
N_S/N_o (above main, dB)	36.4	39.2	36.2

Figure 4.4-15 graphs the relative subcarrier noise level against increasing frequency of a subcarrier, compared to the main (monophonic) channel for the same receive conditions. Shown are two peak deviations (5 kHz and 7 kHz) for FM SCA, and SSBSC AM SCA with 10% peak envelope injection. The graph segment representing 7 kHz deviation is dashed below 70 kHz since excessive interference to the $L-R$ subchannel is possible in this frequency range when stereo is transmitted.

Single Sideband AM Subcarriers

The conditions under which standard SCA subcarriers are operated are quite close to those existing with narrow band frequency modulation. For example, when a maximum audio bandwidth f_m of 5 kHz and peak deviation f_d of 5 kHz are used, the modulation index is 1.

$$i = f_d/f_m = 5/5 = 1 \qquad [13]$$

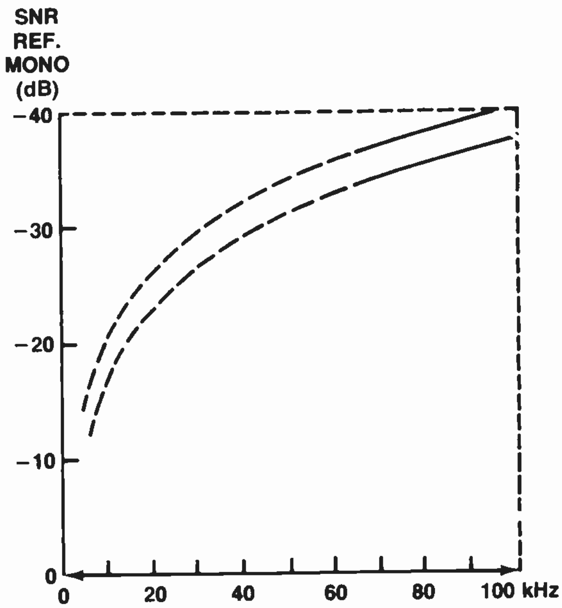

Figure 4.4-15. SNR of FM/SCA audio (5 kHz bandwidth) versus subcarrier frequency, compared to monophonic reception, referred to 5 kHz and 7 kHz deviation.

After frequency demodulation, the SNR power ratio will be:[15]

$$\mathrm{SNR} = \frac{3i^2}{\mathrm{CNR}} = \frac{3\,(1)^2}{\mathrm{CNR}} \qquad [14]$$

where CNR is the carrier to noise power ratio in the bandwidth occupied by the modulated signal. The noise power bandwidth B_n is difficult to predict for two reasons. First, the (usually) inexpensive SCA predetection filter has sloping skirt selectivity, thus departing from the ideal rectangular shape assumed in the calculation. Second, the actual bandwidth may vary, depending on the amount of audio distortion to be tolerated. The extremes of choice may be:

$$i \le 1,\ B_n = 2f_m = 10\ \text{kHz} \qquad [15]$$

$$i > 1,\ B_n = 2(f_d + f_m) = 20\ \text{kHz} \qquad [16]$$

A noise power bandwidth of 15 kHz is a compromise value that happens to represent the measured performance in some common FM SCA receivers.

In single sideband systems, one is simply frequency shifting the modulation passband to a particular frequency in the composite baseband. There is no inherent noise reduction effect; the recovered audio S/N ratio is approximately equivalent to the noise contained within the subchannel bandwidth.While the FM subcarrier system improves S/N, its greater bandwidth admits about three times the noise power. At a modulation index of one, FM improvement is approximately 10 log (1) or 0 dB for an ideal detector. The use of pre-emphasis and de-emphasis improves the FM system S/N without significantly affecting the subcarrier's occupied bandwidth. The use of 150 μsec de-emphasis, common in FM subcarrier demodulators, reduces RMS noise in a 5 kHz channel by 8.8 dB. The practical improvement in S/N ratio measured by the author is more typically 4 dB. This is because the extreme high frequency boost is not a good fit to the program material.[16]

Since single sideband modulation is spectrally efficient, even when compared to narrow band FM, it is practical to divide the 53–99 kHz range into a number of independent subchannels. In the one system, five subchannels each having a 5 kHz baseband are operated at 57, 66.5, 76, 85.5 and 95 kHz. These are shown in Figure 4.4-11.

Twenty percent peak injection is the maximum permitted by the FCC Rules when stereo is transmitted, therefore, each subchannel would receive 4% injection (20/5 = 4). It is reasonable to assume that slightly higher injection could be permitted for each subchannel due to the random interleaving of the total subchannel injection. If 5% were employed, then, the S/N would be lower than that for a channel using ten percent peak injection.

$$\text{change in SNR} = 20\log(10/5) = -6\ \text{dB} \qquad [17]$$

Assuming an approximated improvement of 4 dB for a standard FM subchannel, and a reduction of 6 dB for one of five single sideband subchannels, there is an estimated difference in S/N, assuming the same center frequency of both subchannels and flat noise density over this spectrum.

$$\mathrm{SNR_{FM}} - \mathrm{SNR_{SSD}} = 4 - (-6) \approx 10\ \text{dB} \qquad [18]$$

The power density from an AM demodulator remains uniform across the baseband (unlike FM demodulators, in which noise density rises in proportion to frequency). Therefore, pre-emphasis/de-emphasis is not as necessary to combat noise. The use of a complementary noise reduction system (compandor) can significantly improve the S/N ratio of either system.

Using the previous estimates, the performance of the (uncompandored) single sideband and (de-emphasized) FM subchannels is compared to main channel and stereo in Figure 4.4-16. The coverage radii are based on the FCC F(50,50) field strength predictions for an FM station having 10 kW ERP, 1000 ft height above average terrain (HAAT) and a dipole receiving antenna at 30 ft above ground level into a receiver having a 10 dB noise figure.

SCA-TO-STEREO INTERFERENCE CONSIDERATIONS

Introduction of new signals into the modulating baseband of an FM station requires attention to their possible interactions with existing baseband signals, as well as its chosen performance characteristics.

FM stereo receivers having stereo decoders with diode switching bridges driven by a high level 38 kHz sinusoid (usually identified by discrete component con-

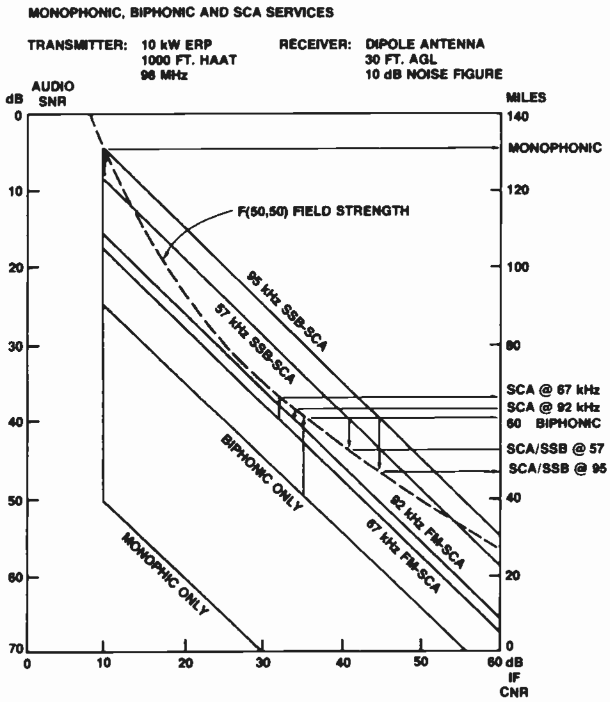

Figure 4.4-16. Predicted serviced distances for 50 dB monophonic and biphonic SNR, and 40 dB SCA SNR. To use, find intersection of desired SNR with service (diagonal) line; next move up (or down) to F(50,50) dashed line; then read across to mileage scale.

struction and tuned transformer stages) were responsible for the original birdie or beat note interference in early SCA/stereo broadcast systems. For historical perspective, the sources of this interference were:

- nonlinearity in the diode bridge due to the conduction characteristics of the diodes and the sinusoidal drive signal
- imbalance in the center tapped transformer driving the diode bridge and second harmonics of the 38 kHz sinusoid at this point

The result caused a second order intermodulation (mixing) of twice the 38 kHz switching frequency minus the instantaneous frequency of the SCA subcarrier as:

$$9\text{ kHz} = [38\text{ kHz} \times 2] - 67\text{ kHz} \qquad [19]$$

The product is not 10 kHz as was often believed. Today, the small amount of beat note interference that results from a 67 kHz subcarrier is 10 kHz, but due to an entirely different mechanism.

Over the past decade these receivers have been entirely replaced by sets with integrated circuit decoders, which have virtually no internally generated beat note problem. As a result, the interference to stereo service from SCA operation has dropped significantly.

Contemporary receivers create very little beat note interference from SCA operation because of the type of stereo decoding done within the integrated circuit. The fact that the circuit contains a PLL has little to do with this improvement. Modern decoders derive their 38 kHz signal by a digital technique, which is well suited to circuit integration. This results in a 38 kHz square wave of fast rise time and balanced duty cycle (equal time in high and low states). The output circuit is usually a differential transistor pair configured as a balanced demodulator. When driven by the 38 kHz square wave (which has virtually no even order harmonics), very little mixing is possible which can result in the product shown in the above equation.

If SCA beat notes created within stereo receivers was the only source of interference, there would be virtually no problem with SCA operation. However, experience shows that a minor source of interference remains when certain SCA frequencies are used. The source of this interference is *external* to the receiver: multipath distortion of the radio frequency signal itself.

Large obstructions such as mountains, hills and tall buildings can reflect VHF broadcast waves well enough to create the simultaneous reception of a direct and one or more reflected path signals. Upon demodulation the baseband signals will include a combination of linear, second and third order distortion products, as shown in Figure 4.4-17. Higher order distortions are negligible when the distortion is small. Hence, these products take the form:

2A, 2B, 2C, etc. (where A, B, and C are the fundamentals)

A + B, A − B, A + C, A − C, B + C, B − C, . . . etc.

2A + B, 2A − B, 2B + A, 2B − A, . . . etc.

Second order distortion (frequency sum and difference) is the most troublesome, because new product frequencies are created which may fall within the main and stereophonic channels where they can become audible. This is illustrated in Figure 4.4-18, which shows the baseband of an actual FM station. The only modulation present in the transmitter is the stereo pilot and unmodulated SCA subcarriers at 67 kHz and 92 kHz, plus a small amount of noise from the audio chain which can be seen from zero to 15 kHz and centered around 38 kHz in the $L-R$ subchannel.

Several second order products are visible in the spectrum graph. This distortion takes the form:

$$f_{SCA1} \pm f_{SCA2} = f_{IM} \text{ product, or} \qquad [20]$$
$$f_{SCA} \pm \text{pilot} = f_{IM} \text{ product}$$

In the case of 67 and 92 kHz subcarriers, significant products are:

92 − 67 = 25 kHz
67 − 19 = 48 kHz
92 − 19 = 73 kHz
67 + 19 = 86 kHz
92 + 19 = 111 kHz

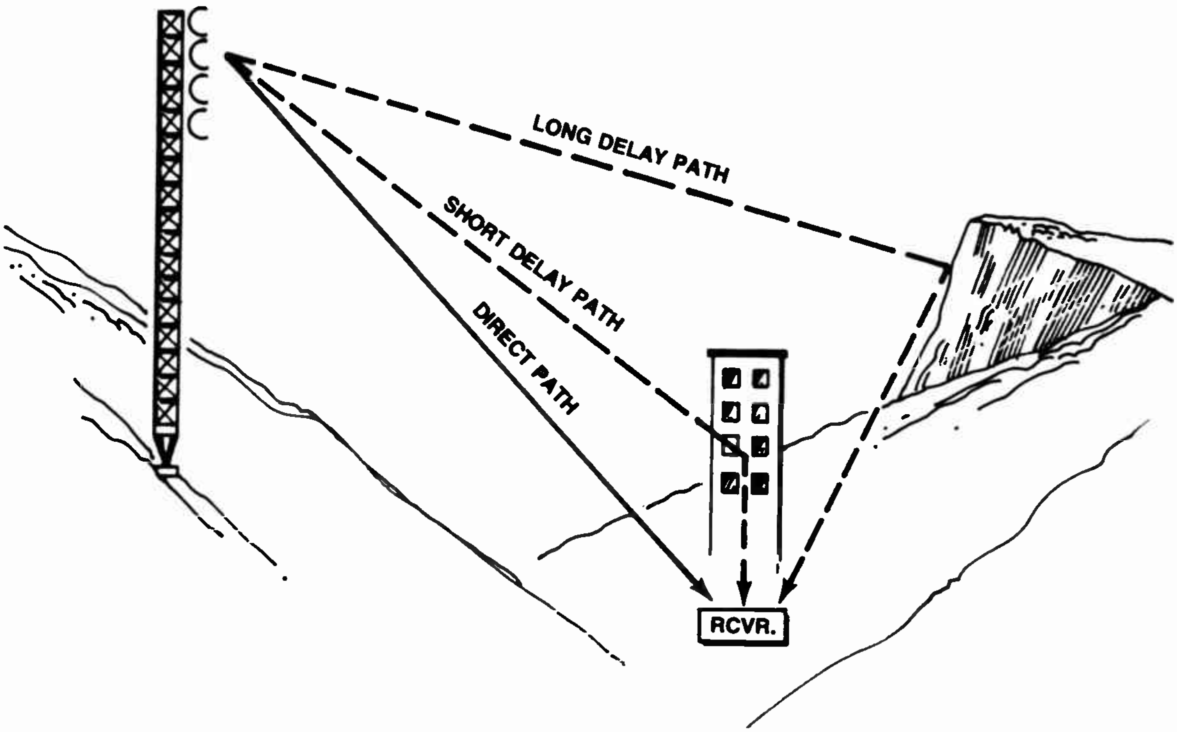

Figure 4.4-17. Examples of reflected signals arriving at an FM receiver, along with a direct path RF signal. Distortion of the demodulated FM signal is related to both the direct/reflected signal ratio and delay time of the reflected signal; distortion increases as the signal ratio approaches 1:1 and as the secondary path delay time rises.

While these IM products are not directly audible, some may be once they are demodulated by a stereo decoder:

$$25 - 38 = 13 \text{ kHz}$$
$$48 - 38 = 10 \text{ kHz}$$
$$111 - 114 = 3 \text{ kHz}$$

(The last product could be demodulated by IC stereo decoders using a 38 kHz square wave switching signal. However, sensitivity to a 111 kHz product is rare.)

Some other general findings about multipath effects are:[18]

- Multipath distortion is almost inversely proportional to the DU (desired-to-undesired path signal ratio) if the ratio is greater than about 10 dB
- Baseband signal distortion increases almost proportionally to the delay time up to about 10 μsec, then increases with delay time at a slower rate
- A high DU ratio required to suppress the beat note interference to stereo program reception from an SCA subcarrier (about 20 dB at a delay time of around 5 μsec and about 30 dB at around 20 μsec).

It should be emphasized that the perceptibility of this form of beat note interference depends on the loudness and consistency of main channel programming (program audio in most broadcast FM stations is capable of masking the beat note). Generally, only stations which do light amounts of audio processing and broadcast programming with wide dynamic range are even aware of an occasional case of interference.

The *type* of SCA modulation or the subcarrier frequency may significantly affect the perceptibility of any beat note. For example, properly encoded high speed data subcarriers using FSK or PSK spread the carrier energy in such a way that it sounds like faint, band limited noise which is most easily masked. Fur-

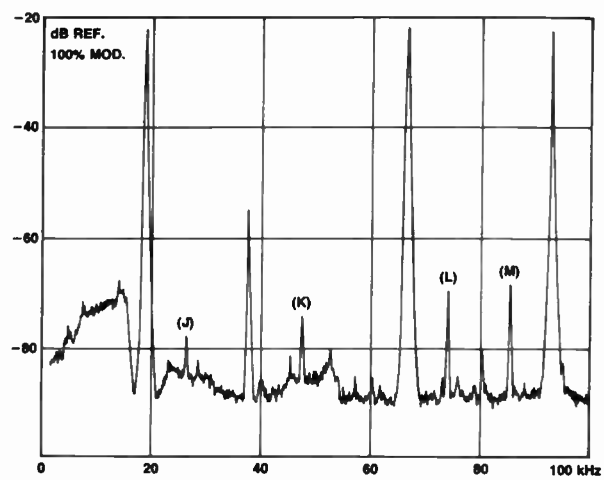

Figure 4.4-18. Composite baseband of an FM transmitter system with pilot, 67 kHz, and 92 kHz SCAs at 9% injection. IM products are identified by letters and are described in the text.

thermore, higher subcarrier frequencies will shift the beat-note image out of the audible range. Experience has shown that 92 to 95 kHz subcarriers have little problem in this regard.

Crosstalk From Main Channel Program Into SCA Subchannels

Crosstalk remains a problem for audio SCA services, despite the development of low distortion receivers for SCA use. The cause is the same as SCA-to-stereo beat notes: multipath distortion.

In the reference case illustrated in Figure 4.4-19, the baseband signal consists of one low frequency sinewave of frequency F (1 kHz), which modulates the main carrier by a deviation D (95% or 71.25 kHz for broadcast FM) and a sinewave subcarrier at a variable frequency f Hz which modulates the main carrier with a very small deviation d, having a modulation index less than 0.3.

Second order distortion will cause sidebands at frequencies of $f-F$ and $f+F$ with an output injection $d_2(f-F)$ and $d_2(f+F)$. The sum of the sideband amplitudes is:

$$d_2(f) = d_2(f - F) + d_2(f + F) \qquad [21]$$

The distortion is defined as the ratio of the sum of the sidebands to the amplitude of the subcarrier d_1 is:

$$\delta = d_2(f)/d_1(f) \qquad [22]$$

This distortion is easily measured as a function of the subcarrier frequency f with a spectrum analyzer. If the sidebands are equal they may in the extreme either amplitude modulate or phase modulate the subcarrier. In general there is a combination of amplitude and phase modulation.

Third order distortion is similarly defined by the sidebands created at frequencies $f-2F$ and $f+2F$.

While FM SCA detectors usually include amplitude limiting, they are intended to convert any angular modulation, whether program audio or not, into an output signal. Thus any phase non-linearity in the RF system or multipath will generate second and higher order sidebands around the subcarrier, causing main-to-SCA crosstalk at audio modulating frequencies.

Figure 4.4-20 shows the relationship between main-to-SCA crosstalk, subcarrier frequency, and maximum

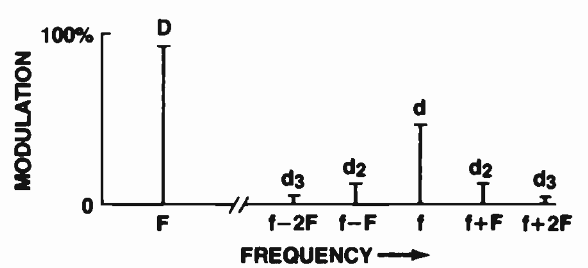

Figure 4.4-19. Spectrum of a subcarrier "f" shown with second and third order distortion products resulting from low frequency modulation "f".

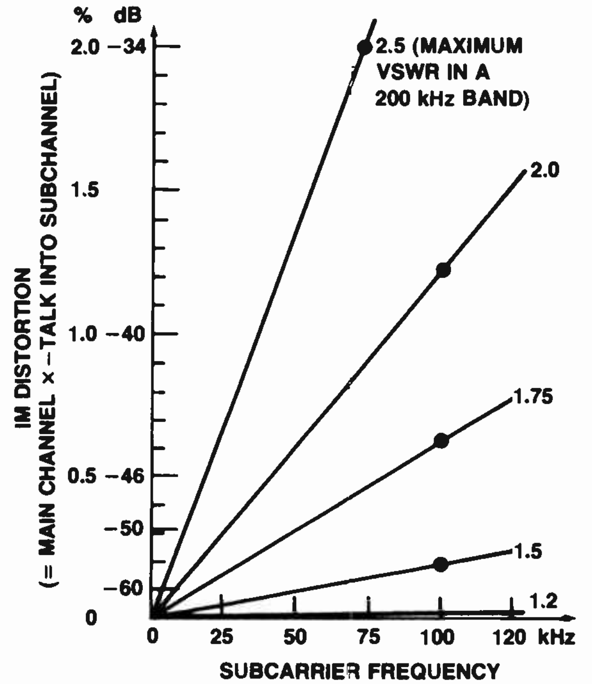

Figure 4.4-20. Distortion due to limited antenna bandwidth vs. frequency of subcarrier with max VSWR in 200 kHz band as parameter.

antenna VSWR in a 200 kHz band. It is evident that higher frequency subcarriers require somewhat larger, but not very much larger bandwidth. It has also been determined that antenna matching must be improved as the transmission line becomes longer. This is especially important for higher frequency subcarriers since the phase error is compounded rapidly with an increase in subcarrier frequency. Distortion is proportional to the subcarrier frequency. Thus, for equal distortion, doubling the subcarrier frequency requires halving the reflection coefficient.[19]

4.5
STL SYSTEMS

JERRY C. WHITAKER
EDITOR-IN-CHIEF

INTRODUCTION

One of the major concerns in the design and operation of a radio broadcasting facility is the means by which the program audio from the studio is conveyed to the transmitter site. As illustrated in Figure 4.5-1, this link represents an important element in the overall reliability of the transmission chain. Furthermore, as digital technology continues to move into daily radio station operation, the *studio-to-transmitter link* (STL) must become as transparent as possible. An inferior link will impose an unacceptable limit on overall audio quality. The requirements for reliability and transparent program relay have led to the development of new STL systems based on digital technology.

Changes in FCC broadcast ownership rules and the popularity of *local marketing agreements* (LMAs) have reshaped radio broadcasting. The need for high quality audio programming is one outgrowth of new competition and new alliances and STL systems are an important component of these audio improvement efforts. Furthermore, increasing numbers of stations are using *intercity relay* (ICR) facilities to share programming. Unfortunately, in many areas of the United States, the demand for 950 MHz STL channels has far outstripped the available supply. The Federal Communication Commission's (FCC) Part 74 bandwidth allocations for STL systems, therefore, necessitate highly efficient designs to meet the needs of radio broadcasters today.

Market demand for STL systems is not limited to North America. The commercialization of radio broadcasting in Europe and elsewhere has led to increased use of radio links to relay programming from one studio to the next, and from the studio to the transmitter site. In some areas, repeated use of the same frequency places stringent demands on system design.

Radio vs. Landline Links

The arguments over which approach—radio STL or landline (telco)—is the better way to convey program audio from the studio to the transmitter is as old as radio broadcasting itself. Now, however, a new element has been added to the equation that makes the landline option considerably more attractive. That new element is digital technology.

For years, broadcasters were limited in their choice of STL equipment to two main options: 950 MHz radio and equalized analog telephone lines. Today, a third approach, T1 digital transmission, is rapidly becoming the system of choice for many radio stations.[1] The decision to use T1 may be based on several factors, including:

- Necessity. The station has no line-of-sight to the transmitter, or suitable frequencies are unavailable

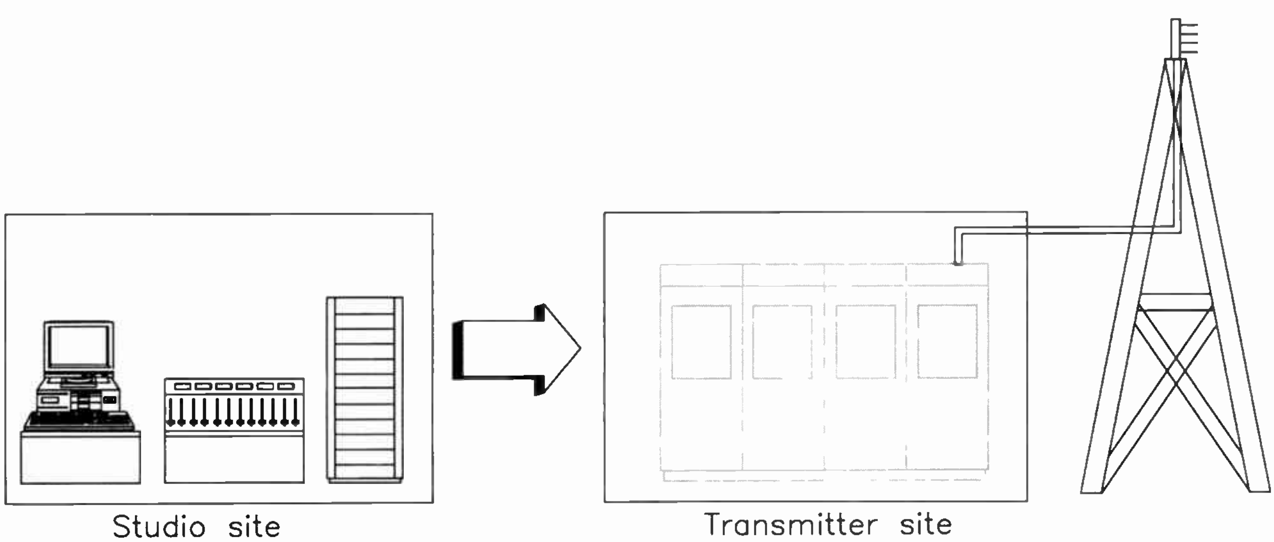

Figure 4.5-1. The basic function of a studio-to-transmitter link.[2]

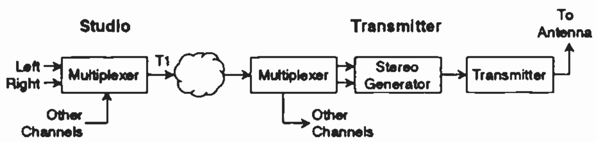

Figure 4.5-2. Discrete channel T1 digital audio STL system.[1]

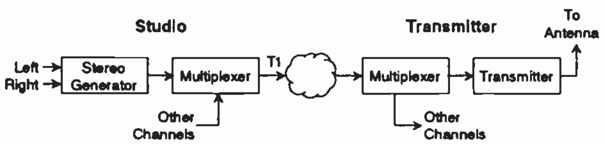

Figure 4.5-3. Composite T1 digital audio STL system.[1]

- Sound quality. A digital STL can sound better than even the best analog systems
- Cost. A single leased T1 line can cost less than multiple leased analog lines.

Whatever the reasons, a broadcaster who decides to use T1 transmission must then choose what type of system to implement. Digital T1 STL systems can be designed either to transmit discrete left and right channel stereo, as shown in Figure 4.5-2, or to transmit a composite stereo signal as illustrated in Figure 4.5-3.

One of the advantages to a broadcaster in using a T1 digital STL is the ability to multiplex several signals together. Subsidiary Communications Authority (SCA), second audio program (SAP) channels, transmitter remote control signals, data and voice can all be combined with the broadcast audio signal for transmission on a single T1 circuit. The duplex nature of T1 permits use of the same system for both STL and *transmitter-to-studio* (TSL) functions as well. Table 4.5-1 compares T1 bandwidth usage for various circuit implementations.

A detailed discussion of telco based STL systems is beyond the scope of this chapter. Interested readers are referred to Chapter 3.11, *Common Carrier Audio Program Services*, for a discussion of this subject.

STL SYSTEM CONFIGURATION

The frequency range used by aural STL systems in the United States is 944.5–951.5 MHz. Frequencies ranging from 200–940 MHz are used in other parts of the world. STL systems are also operated above these traditional bands, however, such links often face difficulties associated with increased susceptibility to signal loss as a result of precipitation, foliage and fog, which limit usage to short path lengths. Frequency modulation is used for analog STL systems.

The vast majority of radio STL systems in operation today carry a composite stereo baseband signal from the studio to the transmitter. An alternative approach, and one that may be used for monaural AM stations, involves the use of one or two narrowband STL systems. The two approaches are compared in Figure 4.5-4.

The monaural STL typically has an audio bandwidth of up to 15 kHz for program signals and usually can accommodate a single FM subcarrier at approximately 39 kHz as shown in Figure 4.5-5(a). For stereo or dual mono installations, a common antenna can be used at the transmitter and at the receiver. At the transmit site, a combiner/isolator adds the signals and prevents the generation of intermodulation products. At the receive site, a low-noise antenna splitter feeds the individual receivers.

The composite STL has sufficient bandwidth (220 kHz) to accommodate the output of a stereo FM generator and usually several separate subcarriers. A low pass filter generally is used at the output of the receiver to separate the signals to be broadcast over-the-air from the non broadcast (or closed-circuit) signals. A typical configuration is illustrated in Figure 4.5-5(b). The composite STL provides superior stereo performance compared to dual monaural radio links in several respects, including:

- Elimination of interchannel phase and amplitude errors that can arise in a dual channel system
- Elimination of audio headroom considerations because the STL input signal has already been passed through the station's audio processing system and the stereo generator, which are located at the studio.

For FM applications, the composite signal from the

Table 4.5-1
Digital Audio Sampling Size vs. T1 Bandwidth Usage.[1]

System Type	Samples/s (for 15 kHz stereo)	Sample Size	Digital Transmission Rate	Number of TI Time Slots Used for Broadcast Audio	Number of T1 Time Slots Available for Other Channels
Discrete	32,000 × 2	16 bit	1.152 Mbits/s	18	6
Composite	112,000	16 bit	1.792 Mbits/s	Not usable	—
		15 bit	1.680 Mbits/s	Not usable	—
		14 bit	1.568 Mbits/s	Not usable	—
		13 bit	1.456 Mbits/s	23	1
		12 bit	1.344 Mbits/s	21	3

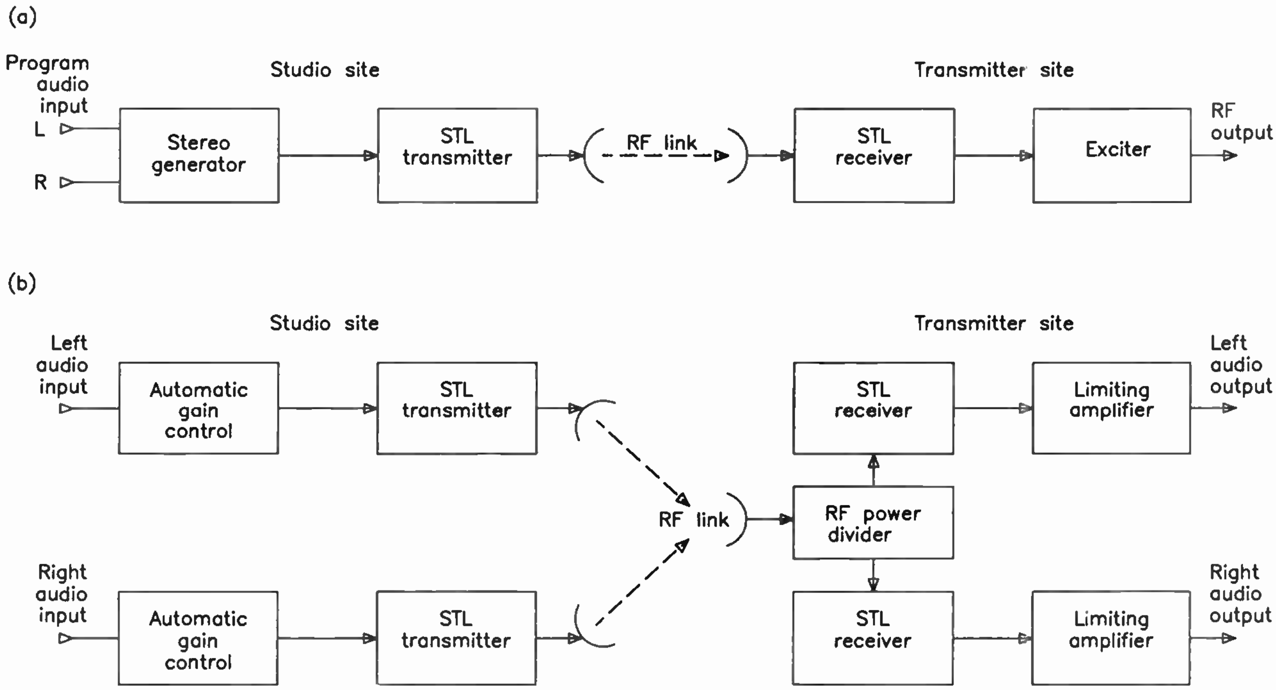

Figure 4.5-4. Comparison of STL systems: (*a*) composite transmitter-receiver system, (*b*) dual monaural transmitter-receiver system.[2]

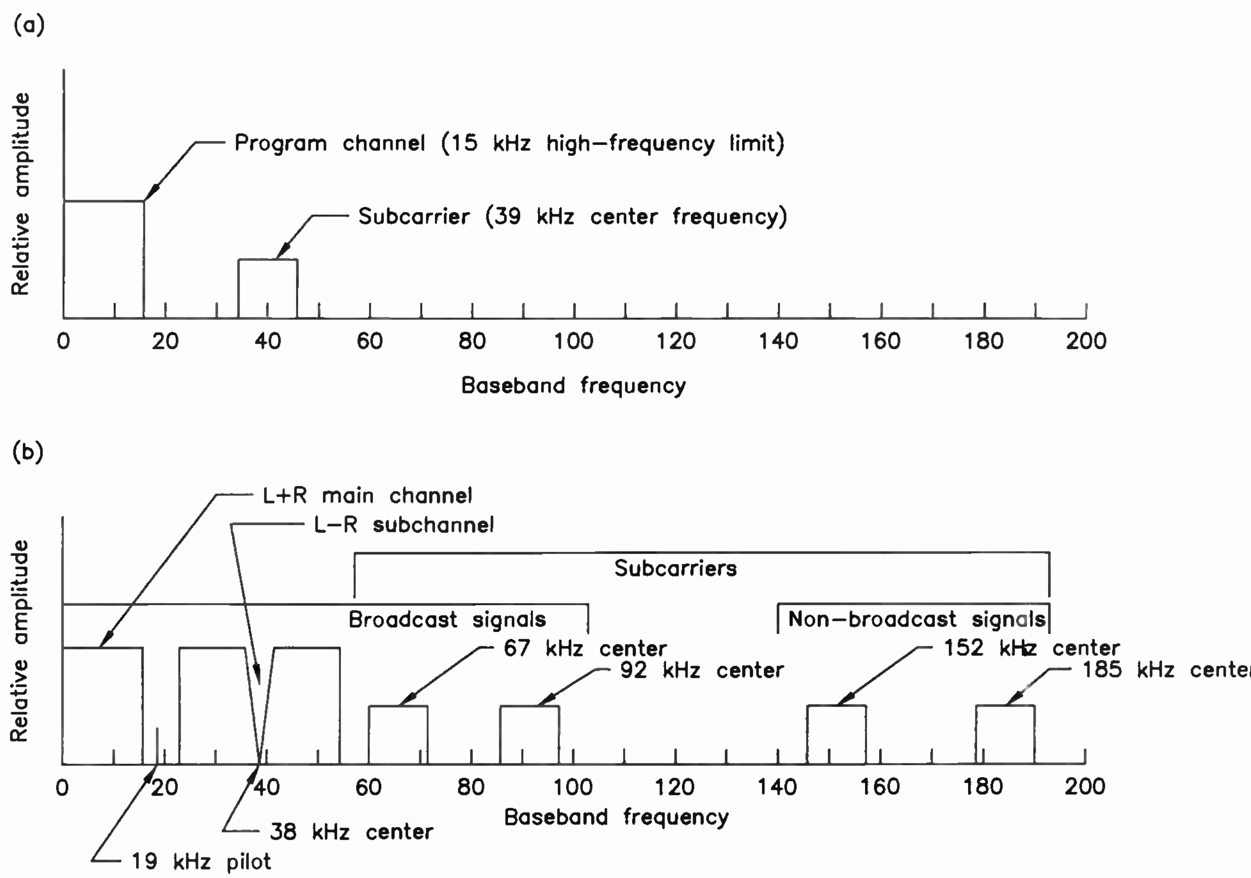

Figure 4.5-5. Baseband spectrum of STL systems: (*a*) monaural, (*b*) composite.[2]

STL receiver is fed directly into the FM transmitter exciter. An alternate method involves the use of a *Reciter*, which functions as an STL receiver and FM exciter but with an IF interface rather than a baseband interface.[2] The elimination of one stage of demodulation and remodulation reduces noise and distortion in the transmitted FM signals.

Because AM stereo exciters require discrete right and left channel audio inputs, a complementary stereo decoder is used to recover the left and right channel audio if a composite STL (fed by a stereo generator) is used.

Digital STL vs. Analog STL Link

Digital signal encoding of audio frequency information provides a number of advantages over conventional analog systems. The principal strengths of digital coding for transmission and storage vs. analog methods include the following:

- Greater immunity to noise and interference in the transmission path. Differences of 50 dB SNR vs. 76 dB are common
- Elimination of transmission-path-dependent distortion mechanisms, such as harmonic distortion, intermodulation distortion, and crosstalk
- Efficient use of baseband and radio frequency (RF) spectrum
- Efficient and predictable regeneration of the digital signal
- Easy and effective encryption for security and coding purposes
- Uniformity in transmitting audio and data signals.

The last item merits additional consideration. Intense development has been underway for a number of years to develop efficient and cost-effective digital coding and compression systems for audio frequency signals. The results of this work can be seen in everything from personal computer soundboards to recordable CD type minidisks. This technology, obviously, has many spinoff effects that can be used to advantage by radio broadcasters. Advanced digital devices and algorithms are now being adapted for use in a wide variety of broadcast products, most notably studio storage and mixing systems and STL systems.

The use of digital coding and modulation in an STL system provides the user a number of benefits in terms of performance and path reliability. By its nature, digital coding offers a more robust link. As long as the received signal strength and carrier-to-noise exceed a defined minimum value, the *bit error rate* remains relatively constant, and the decoded baseband signal is an exact duplicate of the input signal at the studio (see Figure 4.5-6). With adequate error correction, signals can be received error-free. With a digital STL, multiple links are practical because signal degradations are not additive, as in an analog system.

It is fair to point out that digitization of the input audio signal always brings with it a measure of degra-

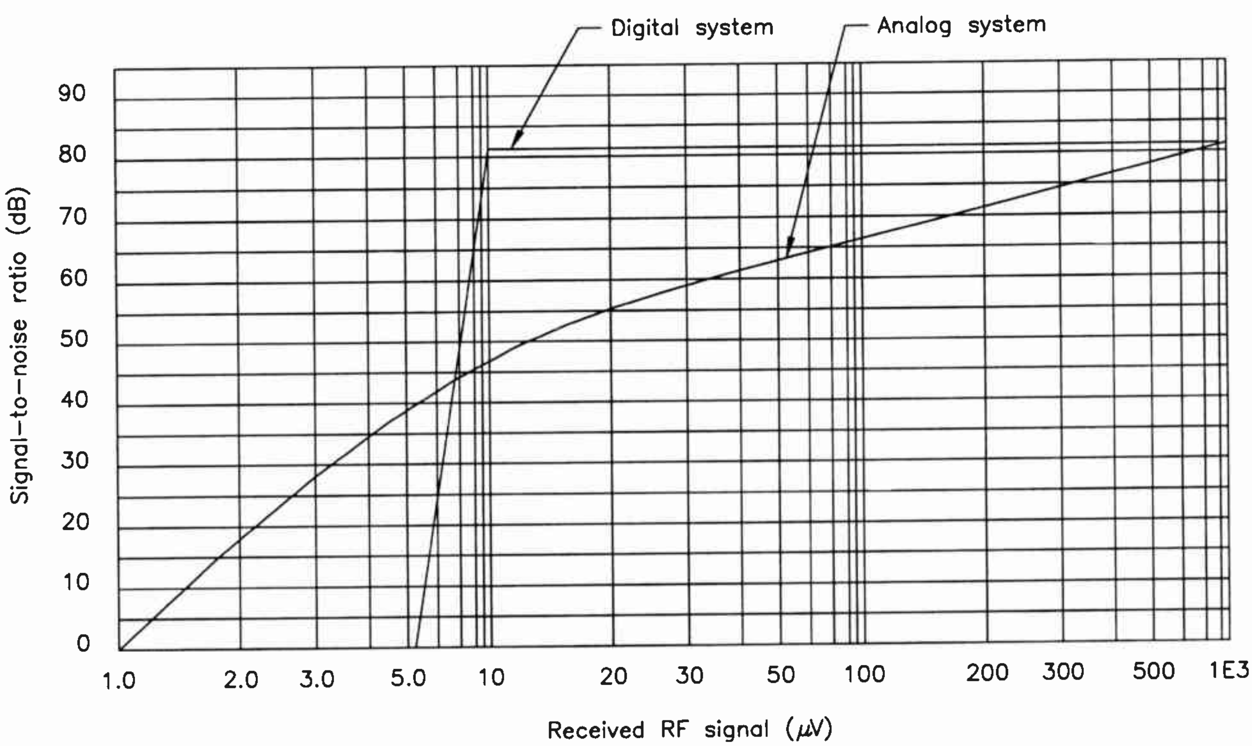

Figure 4.5-6. The benefits of digital vs. analog STL systems in terms of S/N and received RF level.[2]

dation in the form of quantization errors. However, with the high sampling rates typically used for professional audio applications, such degradation is minor and almost always completely inaudible.

The process of quantization is illustrated in Figure 4.5-7. The sampling rate and quality of the sampling circuit determine, in large part, the overall quality of the digital system. A properly operating transmission channel can be assumed to provide error-free throughput. This being the case, the digital signal can be regenerated at the receiving point as an exact duplicate of the input waveform, quantization errors excepted. Figure 4.5-8 shows a general representation of a digital communications channel. In the case of a radio link, such as an STL, the transmission medium is analog in nature (FM). The circuits used to excite the modulator, however, are essentially identical to those used for an all-digital link, such as fiber optic cable.

The functions of the encoder and decoder, shown in Figure 4.5-8(a), usually are formed into a single device, or set of devices (a chip set), known as a *codec* (*coding and decoding* device). At the transmission end, the codec provides the necessary filtering to band-limit the analog signal to avoid aliasing, thereby preventing *analog-to-digital* (A/D) conversion errors. At the receiver, the codec performs the reciprocal *digital-to-analog* (D/A) conversion and interpolates (smoothes) the resulting analog waveform.

Digital STL Performance

The benefits of a digital STL for radio broadcasters can best be appreciated by comparing the performance of a digital system and an analog system. A digital STL typically permits broadcasters to extend the fade margin of an existing analog link by 20 dB or more. Furthermore, audio *signal-to-noise* (S/N) improvements of at least 10 dB can be expected for a given RF signal strength. Alternatively, for the same S/N, the maximum possible path distance of a given composite STL transmitter and receiver can be extended. These features could, in some cases, mean the difference between a one-hop system and a two-hop system.

The spectrum-efficiency of a digital STL is of great importance today in highly congested markets. The system may, for example, be capable of relaying four program channels and two voice-grade channels. The use of digital coding also makes the signals more tolerant of co-channel interference than a comparable analog STL.

Coding System

Several approaches may be used to digitize or encode the input audio signals. The complexity of the method used is a function of the availability of processing power and encoder memory and determines the resulting delay incurred due to the encoding/decoding process. For a real-time function such as an STL, significant encoding/decoding delay is unacceptable. *Pulse code modulation* (PCM) is a common scheme that meets the requirements for speed and accuracy. In the PCM process, the sampled analog values of the input waveform are coded into unique and discrete values. This quantization may be uniform, as illustrated in Figure 4.5-7, or nonuniform. With nonuniform quantization, compression at the coder and subsequent expansion at the decoder is performed. By using larger quantization steps for high energy signals and smaller steps for low energy signals, efficient use is made of the data bits, while maintaining a specified signal-to-quantization noise level. This process is known as *companding* (compression and expansion).

PCM encoding, in a simple real-time system, provides a high-speed string of discrete digital values that represent the input audio waveform. Each value is independent of all previous samples. No encoder memory is required. This approach, while simple and fast, is not particularly efficient insofar as the transmission channel is concerned. There are many redundancies in any given input signal. By eliminating the redundancies, and taking advantage of the *masking* effects of human hearing, greater transmission efficiency can be realized. Viewed from another perspective, for a given radio transmission bandwidth, more information can be transferred by using a compression system that

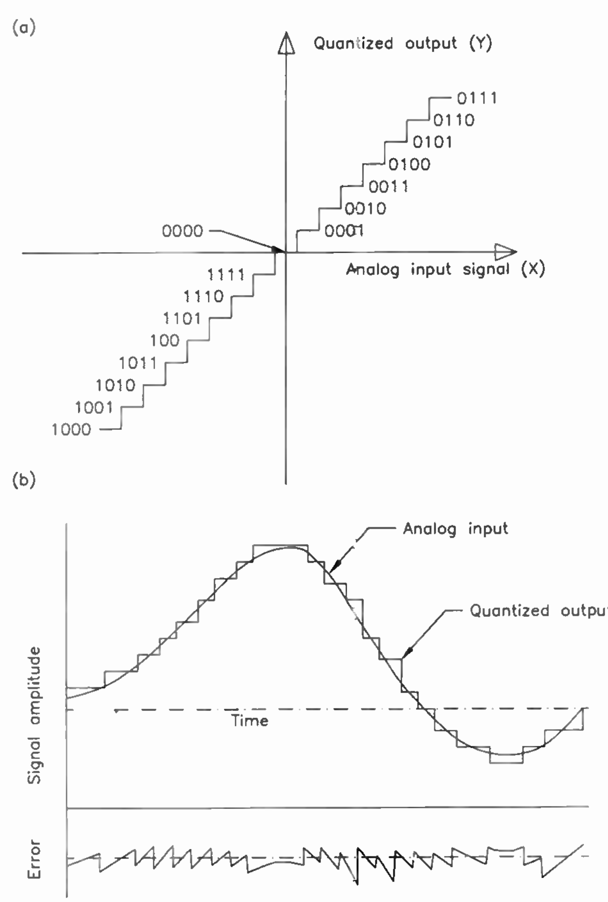

Figure 4.5-7. Quantization of an input signal: (*a*) quantization steps, (*b*) quantization error signal.[2]

removes nonessential data bits. (Audio compression systems are discussed in Chapter 3.7, *Digital Audio Compression Technologies.*)

Analog Composite STL Transmitter and Receiver Characteristics

As mentioned previously, the composite aural STL is the workhorse of the radio industry. A number of hardware variations can be found in transmitter and receiver systems, but all are designed to accomplish basically the same goal: relay of a baseband signal from the studio site to the transmitter. Figure 4.5-9 illustrates the basic STL configurations for an AM stereo (Figure 4.5-9(a)) and FM stereo (Figure 4.59(b)) application. A block diagram of a representative composite STL is given in Figure 4.5-10.

The RF carrier is generated by a *voltage-controlled oscillator* (VCO) that is phase-locked to a modulating VCO operating at an intermediate frequency of approximately 70 MHz. Direct composite FM modulation takes place at the IF VCO, which is also phase-locked to an oven-controlled crystal oscillator that serves as the master timebase for the transmitter. Because fre-

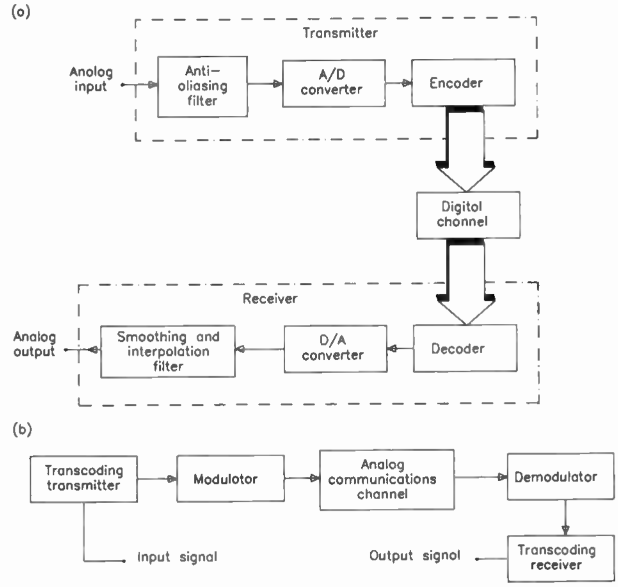

Figure 4.5-8. Digital transmission system: (*a*) coding/decoding functions, (*b*) overall communications link.[2]

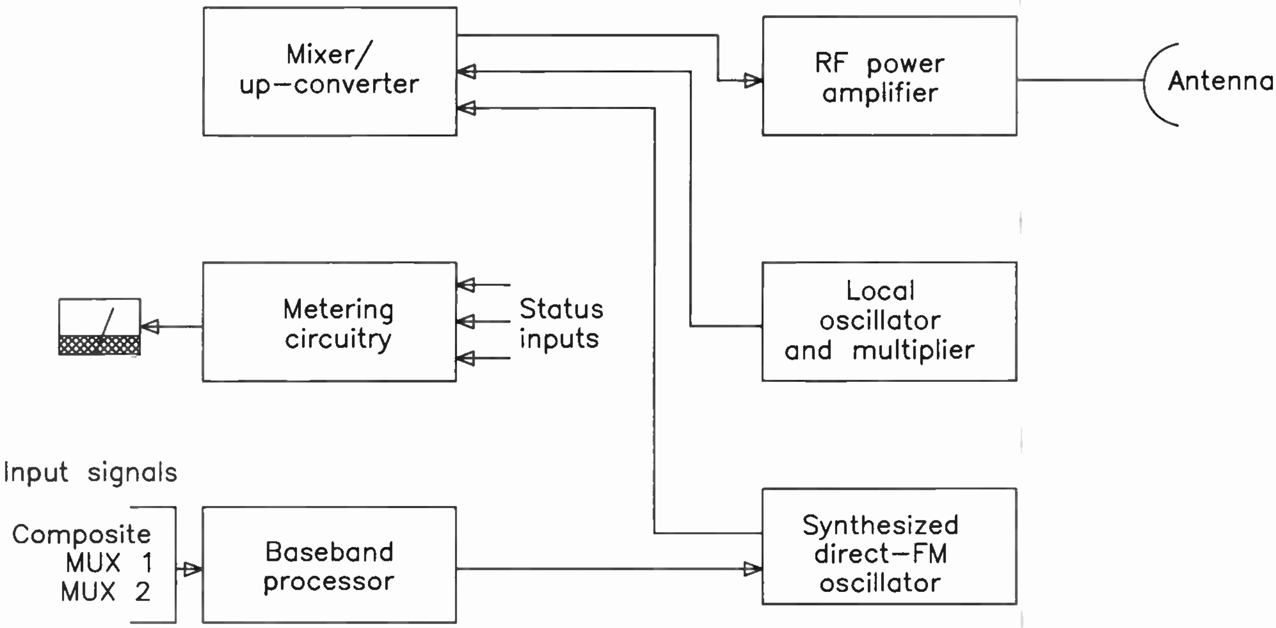

Figure 4.5-10. Block diagram of a composite STL transmitter.[2]

quency multiplication is not used, the RF carrier is an exact reproduction of the IF VCO. Therefore, a number of potential compromises resulting from frequency-multiplication and post-heterodyne filtering are eliminated, including:

- Degradation of S/N
- Generation of spurious signals
- Degraded stereo performance

IF modulation provides excellent overall stereo performance, as documented in Table 4.5-2.

In this design, the operating frequency of the transmitter is programmable by DIP switches in 12.5 kHz steps, so that frequency changes may be made in the field. The composite baseband signal accommodates the full stereo baseband, including two SCA and/or multiplex (MUX) channels. These features permit all processing equipment for analog operation to be located at the studio. An illustration of the composite baseband of such a system is shown in Figure 4.5-11.

Table 4.5-2
Specifications for a Typical Composite STL System.[2]

Parameter	Specification
Power output	6 to 8 W
Frequency stability	±0.0002%, 0 to 50°C
Spurious emissions	60 dB below maximum carrier power
Baseband frequency response	±0.1 dB or less, 30 Hz to 75 kHz
Stereo separation	Greater than 55 dB at 1 kHz
Total harmonic distortion	0.02%, 75 μs deemphasis
S/N	85 dB below ±75 kHz deviation, 75 μs deemphasis
Nonlinear crosstalk	50 dB or less
Subchannel-to-main crosstalk	60 dB or less

A block diagram of the companion composite STL receiver is shown in Figure 4.5-12. Like the transmitter, the receiver is user-programmable in 12.5 kHz

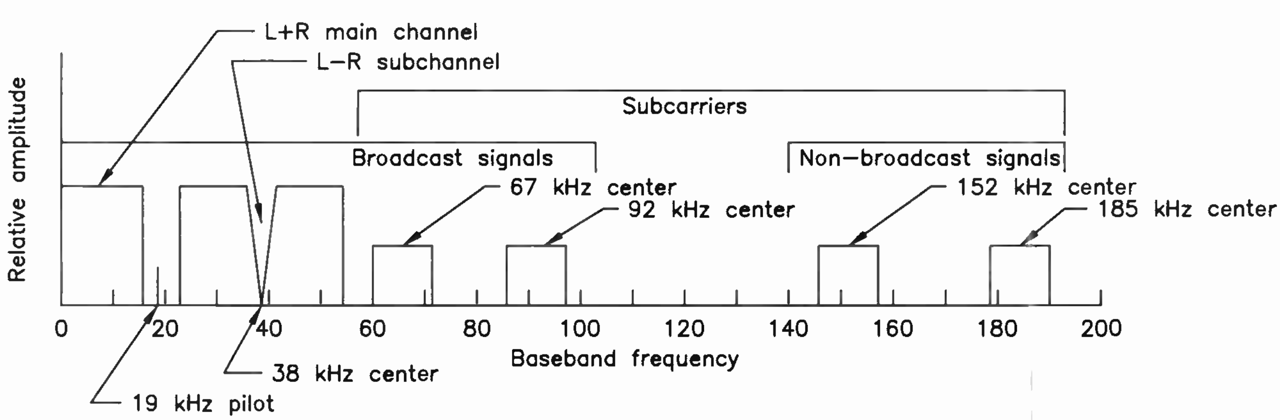

Figure 4.5-11. The baseband of a composite STL transmitter.[2]

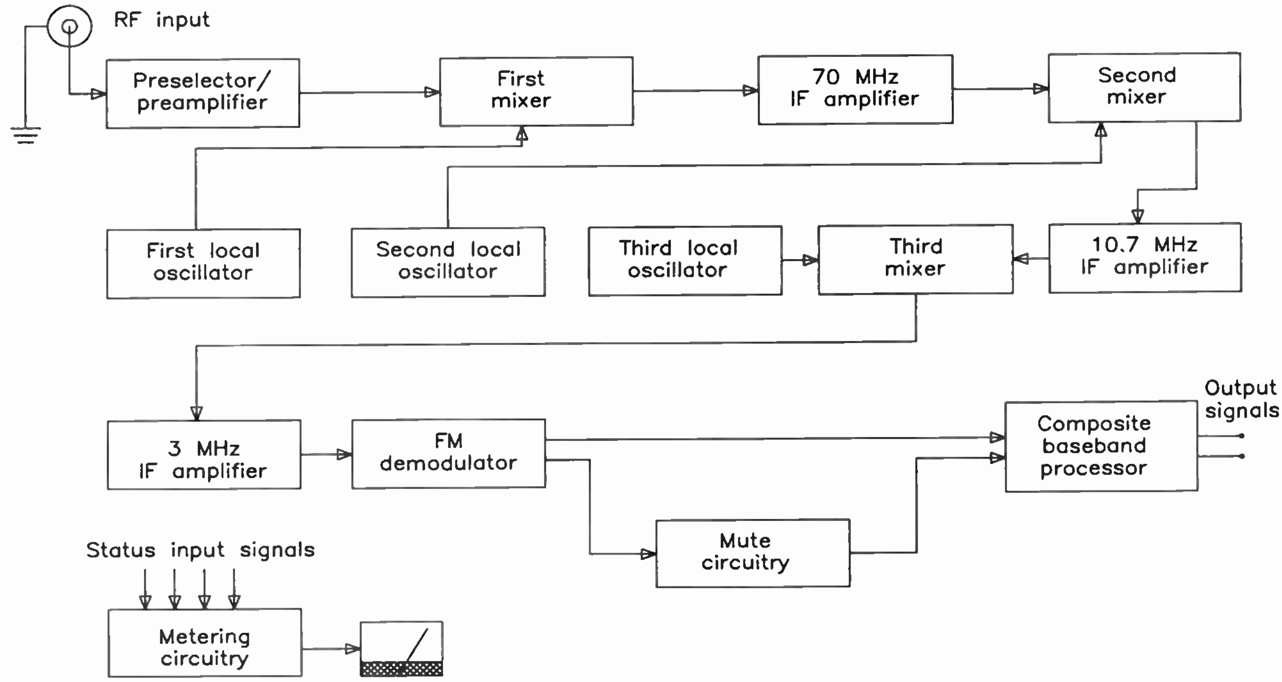

Figure 4.5-12. Block diagram of a composite STL receiver.[2]

steps typically through the use of internal dual inline package (DIP) switches. The front-end uses cascaded high-*Q* cavity filters and *surface acoustic wave* (SAW) IF filters to provide high selectivity and phase linearity. Triple conversion IF is used to feed a pulse-counting discriminator for linear baseband demodulation.

Components of an STL System

An STL installation is only as good as the hardware used to interconnect the link. All components, from the transmitter to the output connectors, must be carefully chosen and properly installed. A well-designed system will provide years of trouble-free service. A poorly designed system will cause problems on a regular basis.

Transmitter and Receiver Requirements

When choosing an STL transmitter, it will be necessary to select a unit that will deliver sufficient power to overcome the losses determined by path gain/loss calculations. Figure 4.5-13 provides a starting point for system planning. In cases where additional power is needed, a separate power amplifier may be used. For convenience in manipulating figures, the transmitter power output should be converted to gain in decibels above a 1 mW reference (dBm) (see Table 4.5-3).

When choosing an STL receiver, specifications should be carefully analyzed, particularly receiver sensitivity. This figure, necessary in STL path calculations, is usually specified as a signal level required for a specified S/N. This value should be converted to dBm (see Table 4.5-4). For example, a receiver may require 100 μV for 60 dB S/N. This is equivalent to −66.9 dBm. In receiver design, sensitivity, S/N, selectivity and the method of demodulation are deter-

Example: H_T = 60 feet. H_R = 500 feet. Radio path length = 41.5 miles

25	−79	8000	−28.9
30	−77.25	9000	−27.9
35	−76	10,000	−26.9

mining factors of receiver quality. The use of SAW filters provides sharper selectivity and more linear phase response. These attributes yield better stereo separation and lower distortion. A pulse-counting discriminator also provides low distortion and accurate demodulation of the received signal. Phase-linear low-pass filtering is critical for best stereo separation.

A low-noise RF preamplifier may be added to the system when the received signal level is low. For best performance, the preamplifier should be mounted directly at the receive antenna. Care must be taken, however, to prevent overloading the receiver front-end by unwanted, and often strong, interfering signals.

In areas of frequency congestion, narrowband receivers are important in preventing interference from other transmitters. STL manufacturers have responded to the needs of broadcasters in congested RF environments by providing suitable narrowband STL systems. Such receivers typically incorporate bandpass cavity filters, helical resonators or mechanical coaxial filters. SAW filters and ceramic filters in IF stages also may be included to improve selectivity.

Choose a monaural, composite or digital STL as needed. Compare performance specifications and carefully analyze the long-term benefits of each system. Examine what the STL will need to handle two or five years from now.

Transmission Lines

Figure 4.5-14 shows the primary hardware elements required for an aural STL. Transmission line sections, connections and strain-relief provisions are important for long-term reliability. The main criteria in the selection of transmission line include the following:

- Amount of signal attenuation
- Physical parameters (dielectric material and size)
- Purchase and installation cost.

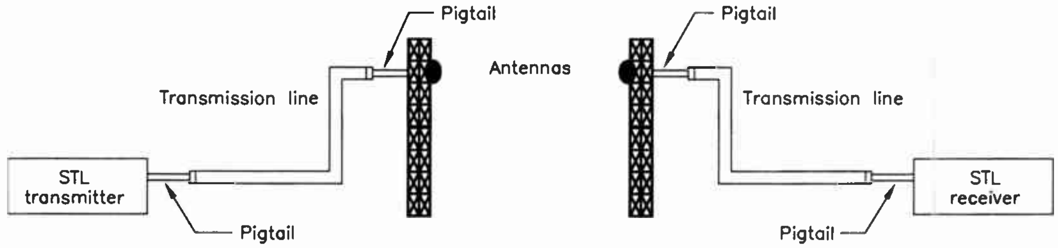

Figure 4.5-14. Principal physical components of an STL system.[2]

In general, the larger the diameter of the transmission line, the lower the loss, and the greater the cost of the line. Loss is also affected by the type of dielectric material used. The most common types of dielectric are air and foam. Air dielectric cable typically requires pressurization and is, therefore, seldom used for 950 MHz installations. For the purpose of gain/loss calculations, cable loss for a particular installation can be determined from the transmission line manufacturer's specification table, given in decibels per unit of measure. Attenuation for common types of coaxial line are given in Table 4.5-5.

Other electrical and mechanical specifications (primarily cable size and impedance) must be compatible with the transmitter, receiver and antennas to be used. Connector loss must also be considered. It is important to minimize each potential source of signal loss when assembling the system. There are no "minor details" in the installation of an STL.

Stain relief must be provided on each end of the cable run (at the transmitter and at the receiver). So-called pigtail or jumper cables are commonly used for this purpose. They permit movement without straining cable and chassis connections. Because the pigtails commonly are terminated with *N*-type male connectors on both ends, the main transmission line must be configured with female *N*-type connectors on both ends if a pair of pigtails are used.

Antenna System

At the frequencies commonly used for STL operation, antennas can readily focus the signal into a narrow beam. This focusing, required for point-to-point communications, provides high gain at both the transmitter and the receiver. Several types of antennas are available, including parabolic and parabolic section. Parabolic antennas are available in solid or grid styles, while parabolic section antennas usually are grid type in design. Antenna models differ in a number of respects, including:

- Gain (directly proportional to size)
- Operating frequency range
- Polarization (most antennas can be set for either horizontal or vertical polarization using universal mounting hardware kits)
- Beamwidth
- Front-to-back ratio
- Wind loading
- Structural strength.

Table 4.5-5
Typical Coaxial Transmission Line Loss at 950 MHz.

Cable Type	Loss (dB/100 Feet)
RG-8/U	8.5
RG-218/U	3.8
1/2-in foam dielectric	3.0
7/8-in foam dielectric	2.0
1/2-in low-loss foam dielectric	2.4
7/8-in low-loss foam dielectric	1.4
1-5/8-in foam dielectric	1.4
1/2-in air dielectric	2.7
7/8-in air dielectric	1.4
1-5/8-in air dielectric	0.7

Environmental factors may also need to be considered so that suitable antenna accessories, such as de-icers and/or radomes, are included.

Antenna gain is specified in decibels referenced to an isotropic antenna (dBi) or decibels referenced to a dipole antenna (dBd). Conversion from dBd to dBi is as follows:

$$\text{dBi} = 2.2 + \text{dBd}$$

For path analysis calculations of system gains and losses, dBi is used.

Figure 4.5-15 plots the response of a common type of STL antenna. Note the high directivity provided by the device and the difference in gain between operation in the 450 MHz band as opposed to the 950 MHz band. Table 4.5-6 lists the typical gain provided by antennas of different physical size.

Mounting Structures

Each antenna requires a mounting structure, such as the side of a roof or building, or an existing or custom-built tower. The structure must be sufficiently high to mount the antenna at the minimum elevation determined by STL path calculations. The structure must also be capable of supporting the weight of the antenna and transmission line, as well as withstanding any forces that affect the antenna tower, such as wind and the weight of snow and ice. Be certain to take into account the mounting hardware used with the antenna, which typically accommodates pipe up to a diameter of 3.5 in. (9 cm). Provisions must be made to secure the transmission line. The structure may also be subject to local building and zoning codes. Strict adherence to these codes is mandatory. Adequate physical clearance must be considered to allow for proper horizontal and vertical alignment during installation.

Hardware Considerations

Depending on the complexity of the STL system, additional hardware may be required. Where more than one transmitter or receiver is used with a single antenna, a combiner, splitter or duplexer will be needed. These items contribute additional loss and must be accounted for in path calculations.

Certain installations may require the installation of an external power amplifier in cases where the output of a standard STL transmitter is insufficient for a particular path. In path calculations, the power output of the external power amplifier (converted to dBm) is substituted for the output of the STL transmitter. In general practice, most engineers choose to use an external power amplifier only as a last resort. Higher gain antennas usually are a more attractive alternative.

SYSTEM PLANNING

The ultimate goal in selecting STL equipment is to choose a combination of STL transmitter, transmission

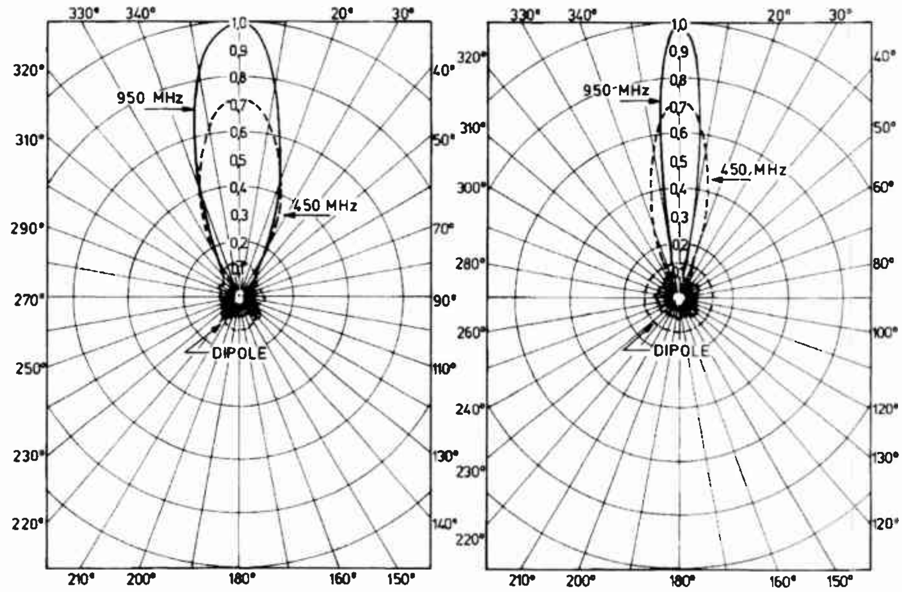

Figure 4.5-15. Radiating plots for a parabolic section antenna at 450 MHz and 950 MHz: (*a*) horizontal response, (*b*) vertical response.[2]

line, antennas and STL receiver that will give adequate quieting (S/N) when transmitting over the path between the studio and the station transmitter. Allowance in the form of *fade margin* must also be made for the uncertainties that the path imposes on the received signal.

The STL transmitter supplies the operating power that drives the system. The transmit and receive antennas add gain to the link. All remaining components add loss. By far the greatest loss results from the path itself. Passive components of the system, including the transmission line, connectors and pigtail cables, also add loss. All gains and losses must be taken into account to ensure that the RF level at the receiver input is adequate. Losses should be minimized wherever possible.

Frequency Selection

Frequency selection would be a relatively simple procedure were it not for other broadcasters, who also may be using STL frequencies and perhaps sharing the same transmitter site. In practice, the choice of operating frequency is governed by the availability of unused STL channels in the area. It is further dictated by the need to avoid interference with other STL users. The local frequency coordinator (under the auspices of the Society of Broadcast Engineers in most areas of the United States) usually can provide information on available frequencies and potential frequency conflicts.

Table 4.5-6
Typical Isotropic Gain for Full Parabolic Antennas at 950 MHz.

Antenna Diameter	Isotropic Gain
4 feet	18.9 dBi
5 feet	21.0 dBi
6 feet	22.0 dBi
8 feet	25.0 dBi
10 feet	27.0 dBi

STL engineering can be divided into three broad categories:

- Frequency selection
- Path layout
- Path gain/loss calculations

Path layout concerns the factors affecting the physical location of the STL transmitter and receiver as well as the intended path. The goal in path layout is to ensure a correctly oriented and unobstructed route for unhampered propagation of the radio wave. Path gain/loss calculations involve analyzing RF power levels from the transmitter output to the receiver input so that an adequate receive level is provided.

Spectrum Considerations

In view of the serious spectrum congestion problems that exist today in many areas of the United States, an STL system should be designed to be as spectrum efficient as possible and—equally important—to be as immune to undesired transmissions as possible. Even if the system will be operated in an area that currently does not have a spectrum congestion problem, there is no guarantee that such a situation will not surface in the near future. In any event, a well-engineered system is also a spectrum-efficient system.

The first rule of spectrum efficiency is to use only the *effective radiated power* (ERP) necessary to do the job. There is no justification for putting 15 W into the air when 5 W will provide the required receiver quieting and fade margin.

A simple and sometimes effective spectrum coordination tool is cross-polarization. Two stations on nearby frequencies may achieve as much as 25 dB RF isolation through the use of different polarizations of transmit antennas, matched by like polarization at their respective receive antennas. Cross-polarization results in varying degrees of success, depending upon the frequency of operation and the surrounding terrain.

Path Layout

Careful path engineering should be performed prior to any licensing work to determine if the proposed locations of the STL transmitter and receiver will be able to achieve the desired results. There is much more to path engineering than simply pointing the transmitting and receiving antennas at each other and turning the equipment on. Antennas cannot always be located in the best possible geographic points because of space availability problems, excessive construction or site rental costs or local/federal licensing difficulties. In such cases, the required path is not the ideal path, and the link will have to be engineered around these fixed points.

Planning for any STL system should begin with an accurate, detailed U.S. Geological Survey (USGS) map covering the proposed path. Note should be made of any natural obstructions (such as mountains, hills or vegetation) or man-made obstructions (such as buildings, water tanks or transmitting towers) in the path.

Line of Sight

Because microwave frequencies are used for STL systems, the signal path is theoretically limited to the line-of-sight between the studio and transmitter locations. In reality, the *radio horizon* is frequently situated beyond the visual horizon. This is the result of the gradual decrease in the refractive index of the atmosphere with increasing altitude above the earth. This effect bends radio waves downward. The degree of bending is characterized by the *K factor*, which is the ratio of the effective earth radius to the true earth radius. A typical value for *K* is 4/3, or 1.33, valid over 90% of the time in most parts of the world. For long paths, consult a map showing the minimum *K* factor occurring in the specific area so that proper antenna heights can be planned. Figure 4.5-16 plots an example path on 4/3 earth graph paper.

STL Site Selection

Usually, there is little choice for the STL transmitter and receiver locations, because most STL systems will be required to provide a path between already determined studio and transmitter points. If, however, a new studio location is being planned, the possible STL path is an important consideration. Figure 4.5-17(a)

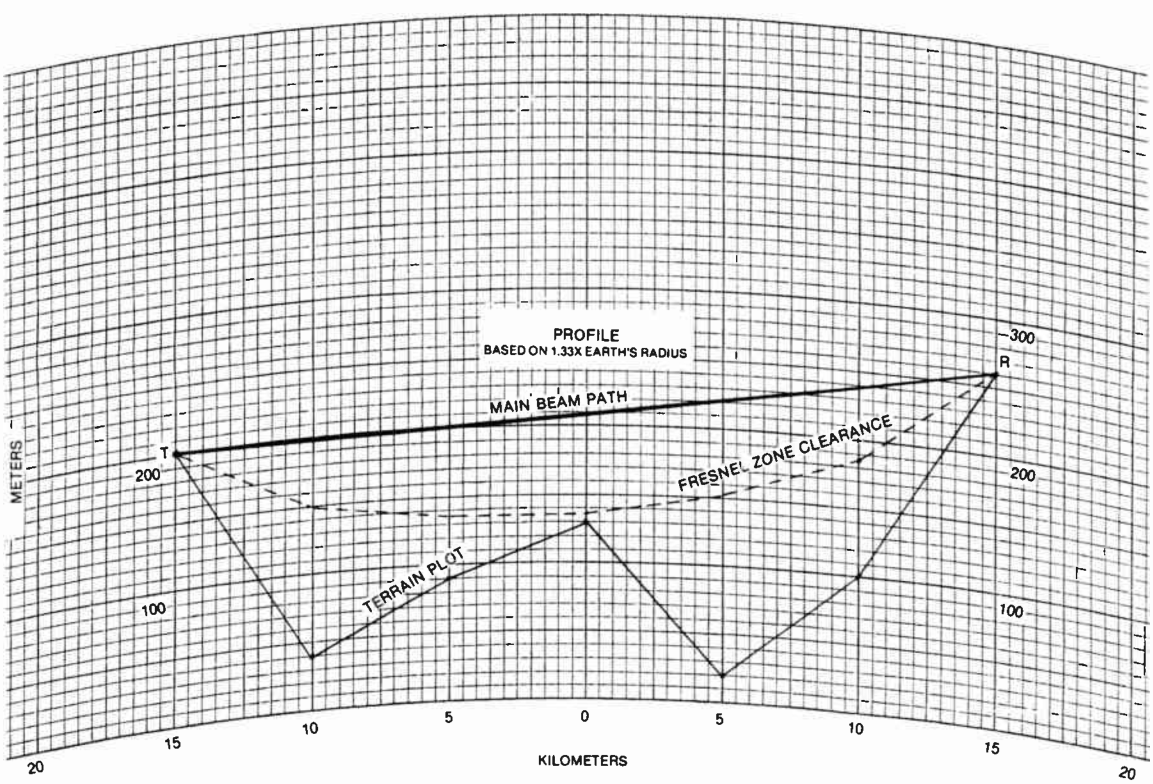

Figure 4.5-16. An aural STL path profile drawn on true-earth radius graph paper.[2]

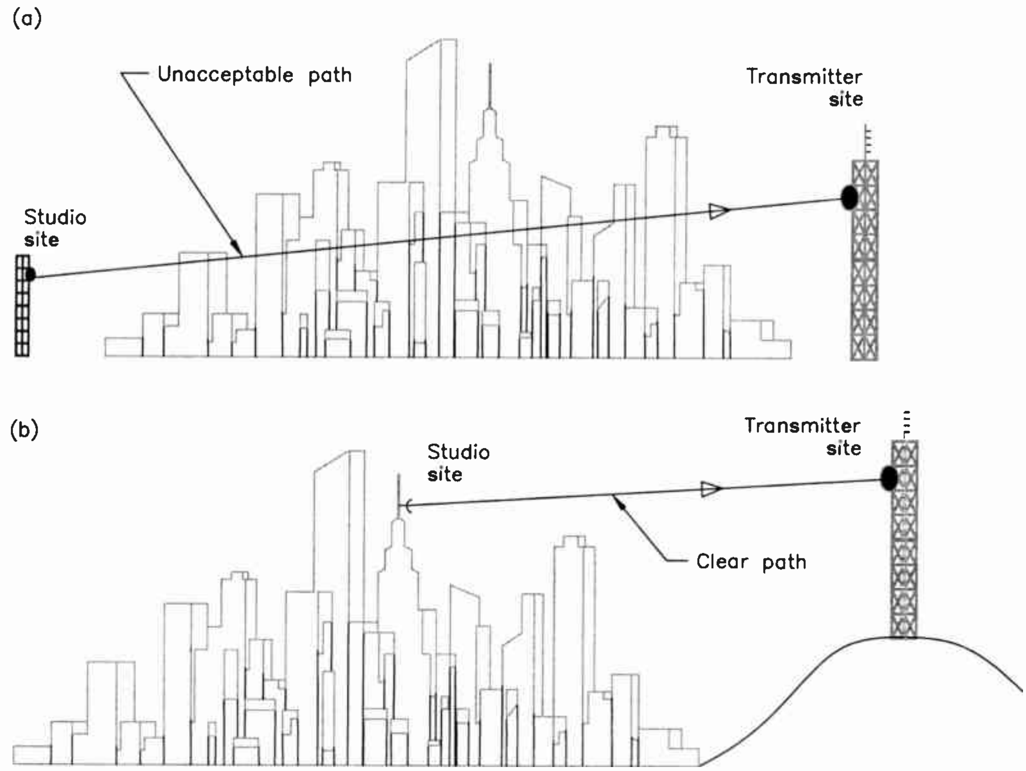

Figure 4.5-17. Path considerations in planning an STL: (*a*) unacceptable path because of obstructions, (*b*) usable path.[2]

illustrates a poor path. Generally speaking, a good path is literally line-of-sight, with no obstructions to block the signal and no other terrestrial or atmospheric conditions that would compromise the path (see Figure 4.5-17(b)).

Terrain Considerations

One of the major tasks required to engineer an STL system is the path analysis between the STL transmitter at the studio and the STL receiver location. To determine what constitutes a clear path, the concept of Fresnel zones for optical theory is applied to radio waves. Most of the electromagnetic energy at a receiving point is concentrated in an elliptical volume that is a function of the distance between the transmit and receive points and the wavelength. The energy outside this volume either cancels or reinforces the energy within the volume, depending on whether the distance that the energy travels to the receive point is longer by an even or odd number of 1/4 wavelengths. Even distances result in radio wave cancellations; odd distances result in radio wave reinforcement (see Figure 4.5-18). The radius of the first Fresnel zone, which defines the boundary of the elliptical volume, is given by the following:

$$F_1 = 72.1\sqrt{\frac{d_1 d_2}{fD}}$$

Where:

F_1 = first Fresnel zone radius in feet
d_1 = distance from the transmitting antenna to the obstruction in miles
D = total path length in miles
d_2 = $D - d_1$ in miles
f = frequency in GHz
H = distance from the top of the obstruction to the radio path

For reliable operation, obstructions should not project into the area thus defined. Empirical studies, however, have shown that performance is substantially the same for H greater than 0.6 F_1.

The first step in evaluating the path is to make a subjective check of the planned route. First, determine that a reasonable possibility of success exists. Next, draw a best-case route for the path. If obstructions are found, consider accomplishing the path by using a repeater system or by shifting the location of the STL transmit antenna. Although a detailed path analysis may not be required in cases where line-of-sight is clearly present and the distance is less than about 10 miles (16.1 km), it is still good engineering practice to review some of the basic elements of the evaluation.

Obtain an accurate map showing the topography between the STL transmitter and receiver locations. After determining the transmitter and receiver sites on

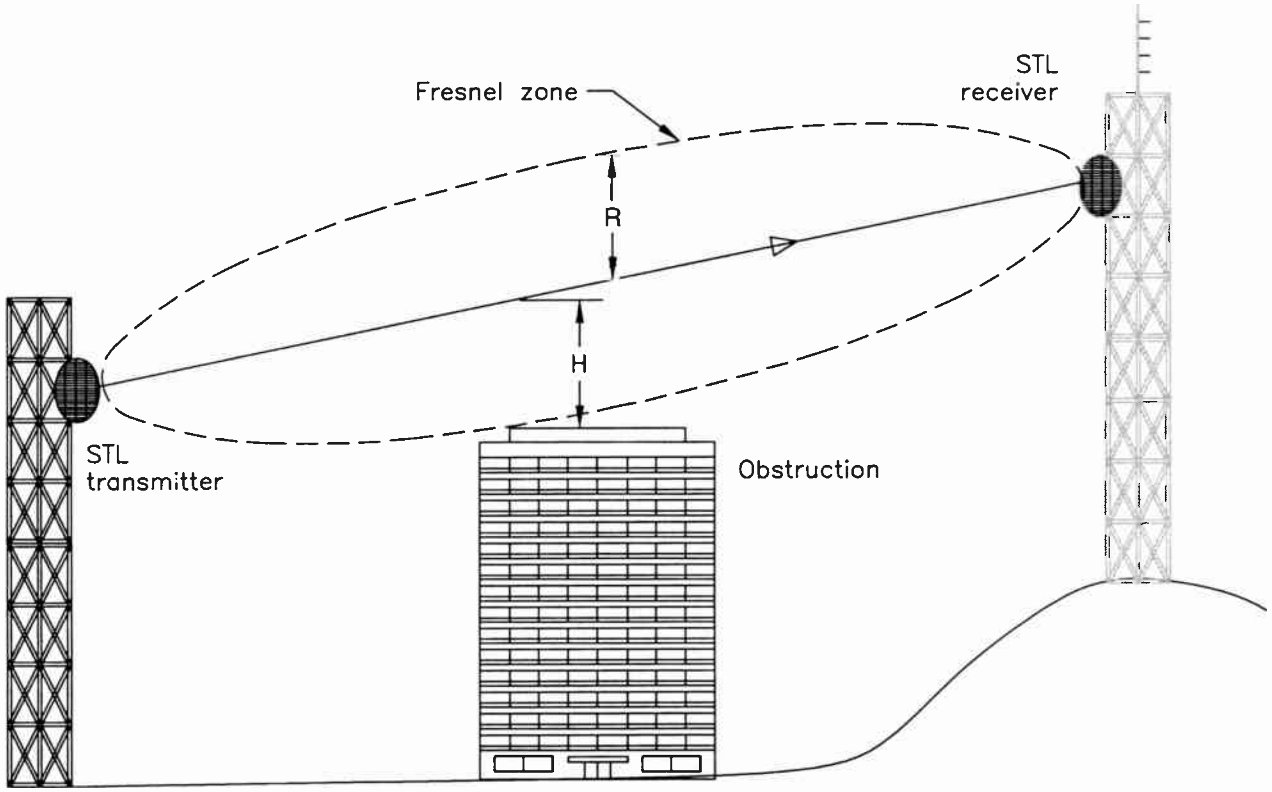

Figure 4.5-18. Fresnel zone clearance for an STL path.[2]

the map, connect them with a straight line showing the proposed path. After the path has been drawn, a protractor can be used to determine the direction (azimuth) of the path in degrees from true North. This data will later assist in antenna setup and is necessary for filling out the appropriate FCC application.

Using the scale of miles on the map, measure the distance between the transmitter and receiver sites. Determine the altitude of the proposed transmit antenna location from the contour lines on the map and add to that the height of the building or other structure on which the antenna will be mounted. Make a similar determination for the receive antenna location. Adjust the heights to ensure that all obstructions are cleared. Depending on the path length and the height of the antennas, it may be necessary to take the curvature of the earth into account. If so, use true-earth radius graph paper to plot a cross-section of the path.

Study the map to see what terrain features are between the path points. Prior to making any other evaluations, conduct a visual field survey. Check for any structures or features not listed on the map. Anticipate any possible new construction or tree growth that may cause problems in the future.

The terrain from the transmitting antenna to the receiving antenna must be examined not only for obstructions, but for reflection possibilities as well. A large body of water will usually cause problems for an STL system. If the water is an even number of Fresnel zones from the direct path, signal attenuation will likely occur at the receiver. Temperature changes and tidal conditions will also have an effect. Likewise, thick vegetation or forested areas can be reflective to RF signals when wet, creating a similar (but not so troublesome) problem. Generally, the solution to reflection conditions is to change either the transmitting or receiving antenna height. In extreme cases, a diversity reception system may also be used.

Path Reliability

The long term reliability of an STL path is determined in large part by the initial engineering work done before the system is installed. Figure 4.5-19 charts gains and losses through a typical system. The most important factors are free space loss and allowance for fade margin. Thereafter, effects such as diffraction, reflection, refraction, absorption, scattering and terrain loss must be considered.

A gain and loss balance sheet should be computed to determine the fade margin of the planned STL system. An adequate fade margin is vital to reliable performance because a link that is operating on the edge of the minimum acceptable receiver quieting will likely encounter problems at some point. Normal component aging in the receiver or transmitter can cause a loss in received signal level and, thus, degrade system performance. Atmospheric conditions, such as severe weather in the area or ice on the transmitting or receiv-

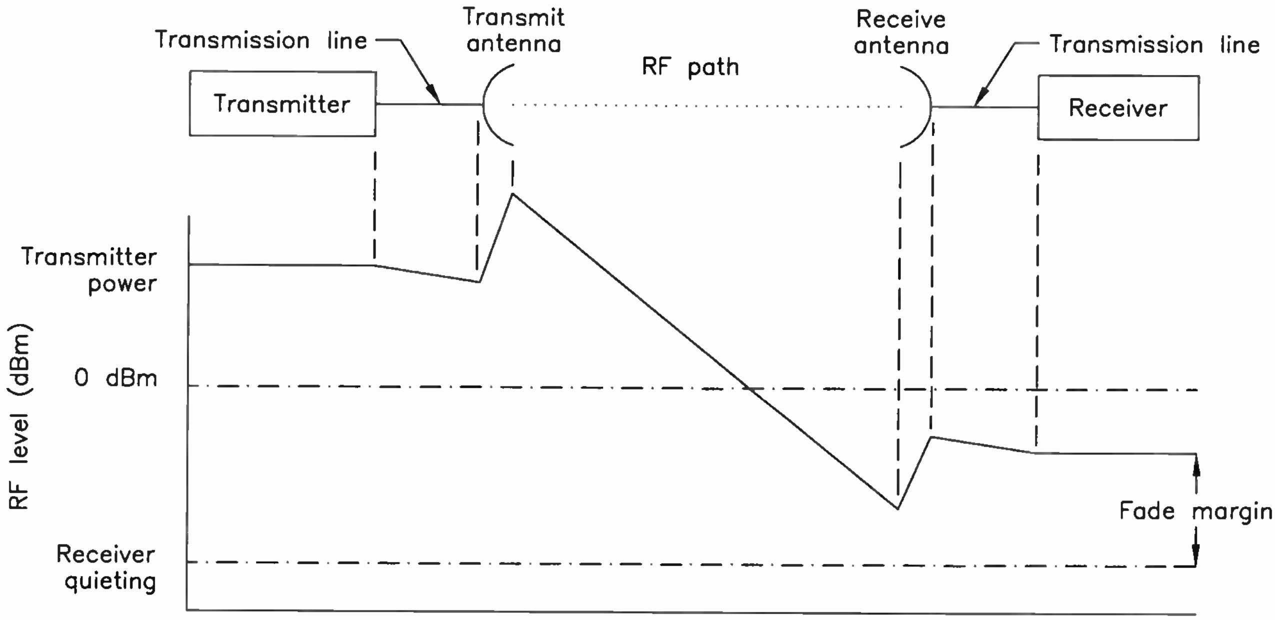

Figure 4.5-19. Path analysis of plotting gains vs. losses for an STL.[2]

ing antennas, can also cause sharp fading and even a complete loss of signal if an adequate fade margin above minimum receiver quieting is not provided. The STL fade margin can be computed using the following equations:

$$G_s = G_t + G_{ta} + G_{ra}$$

Where:

G_s = total system gain in decibels
G_t = transmitter power output in dBm
G_{ta} = transmit antenna gain in dBi
G_{ra} = receive antenna gain in dBi

The values for G_{ta} and G_{ra} are gathered from the antenna manufacturer's literature.

The value for G_t is given by the following:

$$G_t = 30 + 10 \log P_o$$

Where:

G_t = transmitter power output in dBm
P_o = transmitter power output in watts

The total system losses are then computed:

$$L_s = L_p + L_l + L_c + L_m$$

Where:

L_s = total system losses in decibels
L_p = path loss in dB
L_l = transmission line loss in dB
L_c = connector losses in dB
L_m = miscellaneous losses in dB

The values for L_l and L_c can be determined from manufacturer's literature. Figure 4.5-20 shows typical loss values for 0.5 in. (1 cm) foam-filled transmission line. A reasonable value for connector loss with components normally used in 0.5 in. (1 cm) coax installations is 0.5 dB. The value for L_p can be determined by using the following formula:

$$L_p = 36.6 + 20 \log F + 20 \log D$$

Where:

L_p = free space attenuation loss between two isotropic radiators (in dB)
F = frequency of operation in megahertz
D = distance between the antennas in statute miles

Free space loss can also be found using a table of approximate values, as given in Table 4.5-7.

With the foregoing information available, the fade margin can then be calculated:

$$M_f = G_s - L_s - R_m$$

Where:

M_f = fade margin (in dB)
G_s = total system gain (dB)
L_s = total system losses (dB)
R_m = minimum signal strength required for the target S/N in dBm (a negative number)

G_s and L_s are determined by the equations given previously. R_m (receiver sensitivity) is determined from the receiver manufacturer's specifications. If the manufacturer gives a receiver sensitivity figure in microvolts, the following formula can be used to convert to dBm:

$$R_m = 20 \log\left(\frac{V_r \times 10^{-6}}{0.7746}\right)$$

Where:

R_m = minimum required signal strength (in dBm)
V_r = receiver sensitivity (in μV)

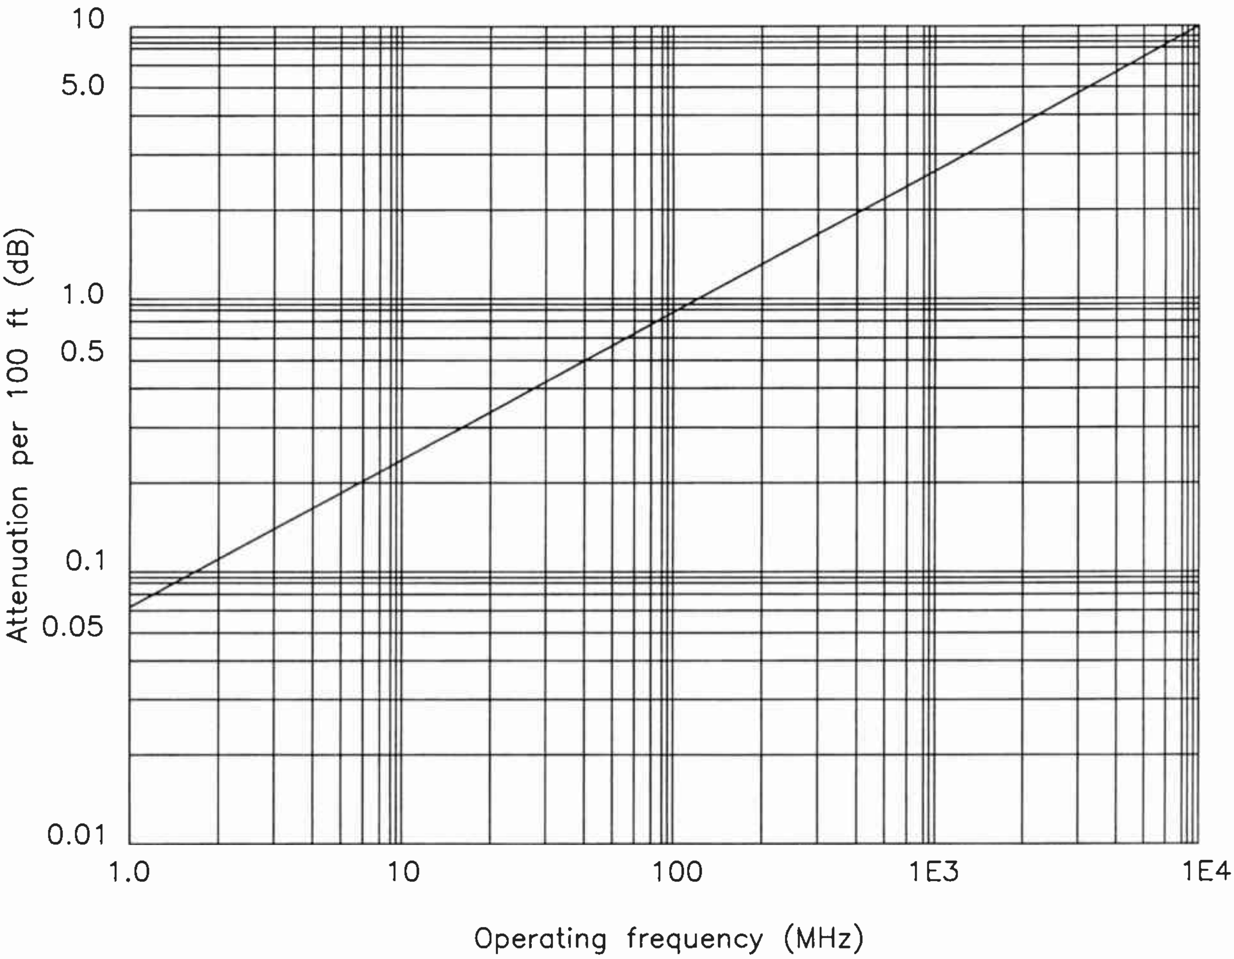

Figure 4.5-20. Loss vs. frequency for 1/2 in. foam dielectric transmission line.[2]

In order to predict accurately the performance of the STL radio link, the value of R_m must be determined carefully. For maximum system performance and reliability, the fade margin determination should be made based upon the signal level required to provide the minimum acceptable receiver S/N performance. Longer paths require greater margins for fade.

Table 4.5-7
Path Attenuation at 950 MHz.

Distance in Miles	Loss in dB	Distance in Miles	Loss in dB
1	−96.2	16	−120.2
2	−102.2	17	−120.7
3	−105.7	18	−121.3

5	−110.1	20	−122.2
6	−111.7	21	−122.6
7	−113.1	22	−123.0
8	−114.2	23	−123.4
9	−115.3	24	−123.8
10	−116.2	25	−124.1
11	−116.9	26	−124.5
12	−117.7	27	−124.8
13	−118.4	28	−125.1
14	−119.1	29	−125.4
15	−119.7	30	−125.7

The primary cause of signal fade in an STL system below 1.0 GHz is changes in the refractive indexes of the atmosphere along the signal path. These fluctuations affect the path of reflected or refracted signals differently from the direct, line-of-sight signal. When the interfering signals combine with the direct signal, the level at the receiver increases or decreases depending upon the degree of reinforcement or cancellation. Because atmospheric conditions are seldom stable, some fade margin is always necessary.

Another cause of signal fade is *earth bulge* (or *inverse beam*) fading, where the overall refractive index in the vicinity of the signal path decreases, thus hindering the full signal from reaching the receive antenna. Again, allowance for signal fade will minimize degradation. Precipitation is another potential cause of signal fading, although it is not generally considered significant at frequencies below 1.0 GHz.

Approximate fade margin also can be determined from Table 4.5-8. The relationship between system reliability and fade margin is detailed in Table 4.5-9.

Table 4.5-8

Recommended Fade Margin as a Function of Path Length.

Path Length	Fade Margin
5 mile	5 dB
10 mile	7 dB
15 mile	15 dB
20 mile	22 dB
25 mile	27 dB
30 mile	30 dB

Dealing with Problem Paths

The STL systems described thus far have been simple installations with a transmitter at the studio and a receiver at the broadcast transmitter site. There are cases, however, where a simple, single-hop STL is not be practical. Reasons include the following:

- The distance is too great to be reasonably covered by a single-hop system
- A direct path cannot be used because of obstructions of some type
- An unusually large fade margin is required for the application.

Figure 4.5-21 shows three instances where a two-hop system is required. A two-hop repeater uses two transmitters and two receivers, with one pair located at the intermediate site. As shown in Figure 4.5-21(c), interference avoidance is another practical application of a multi-hop system.

With a conventional active repeater, the received signal is demodulated down to the baseband at the intermediate site before being retransmitted. This approach is shown in Figure 4.5-22. Unfortunately, this method results in inevitable degradation of the analog signal. A better approach, an IF repeater, is shown in Figure 4.5-23. Instead of being demodulated to the baseband level, the received signal is brought down to the IF level before being injected into the repeater transmitter.

Hot-Standby Redundant Systems

The importance of continuous, uninterrupted service from an STL system cannot be overstated. Modern STL equipment is stable and reliable; failures rarely occur. However, a station may elect to install a hot-standby redundant system to ensure zero downtime from the STL. Figure 4.5-24 shows a block diagram of a common hot-standby system. The installation includes a second transmitter and a second receiver. An automatic changeover unit is included for switching purposes. The changeover system monitors each transmitter and receiver pair to sense critical parameters. If a failure occurs, the changeover controller switches from the faulty transmitter to the standby transmitter, or from the faulty receiver to the standby receiver. The changeover units work independently.

This system can be simplified to include only hot-standby provisions at the transmitter site or at the receiver site. If this approach is taken, a case can be

Table 4.5-9

Relationship between Fade Margin, Reliability and Outage Time for Rayleigh Distributed Paths.

Fade Margin (dB)	Path Reliability/ Availability	Outage Hours per Year	Outage Minutes per Month	Outage Seconds per Day
10	90.4837	834.20	4170.98	8222.05

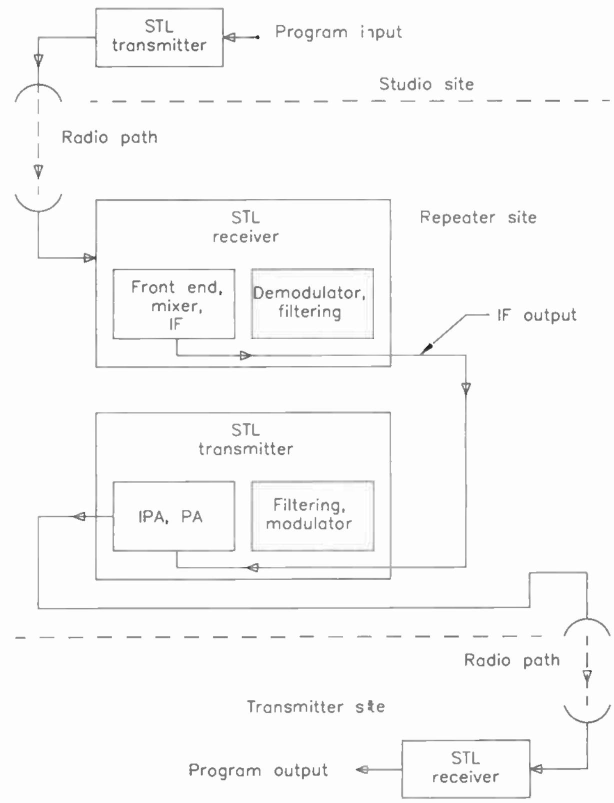

Figure 4.5-23. Repeater link using IF transfer of the composite signal.[2]

made for either backup system. One argument states that the transmitter is more likely to fail because it contains high-power stages, which typically are more prone to problems than low-power circuits. On the other hand, the transmitter is almost always more accessible for repair—being at the studio site—than the receiver.

Pre-installation Checkout

The best planned STL system, well engineered and comprised of the finest equipment, will not perform properly if incorrectly installed. Quality control steps taken before installation actually begins is an important part of the installation process. Delivery schedules for STL hardware vary widely. After all the equipment is ordered, components will arrive, typically, over a period of some weeks. Good engineering practice dictates that each component is checked or inspected as it arrives. This process is preferable to waiting for all of the components to arrive on site because any problems discovered at that point will delay the project.

The STL transmitter can be operated into a dummy load to confirm proper operation. With an ideal load, the transmitter front panel readings should correspond closely with the final test sheet supplied by the manufacturer. Modulation can be applied to the transmitter to ensure proper operation.

The STL receiver is more difficult to test effectively with the instruments typically available at a radio station. The engineer can, however, bench test the receiver by operating the transmitter into a dummy load and attaching a short wire to the receiver antenna input. Be sure to use the proper connector on the receiver to avoid possible damage to the center pin. Maintain sufficient separation of the transmitter and receiver to prevent overloading the receiver front-end. Arranged in this manner, the STL system can be checked from end-to-end with a signal generator (or program material) on the bench.

For a digital STL, the transmitter, receiver and modem/multiplexer can be tested in a similar way. Bench tests before installation usually resolve hidden or unexpected problems associated with equipment operation and/or interfacing. Functionality of the transmitter and receiver should be checked before adding the encoder to the system. In this manner, any problems detected can be readily pinpointed.

An STL using one or more subcarriers for program relay, closed-circuit communications or remote control functions can be bench tested in a similar manner. Having all hardware on one bench and easily accessible makes adjustment of levels and other parameters much easier than when the units are separated by many miles.

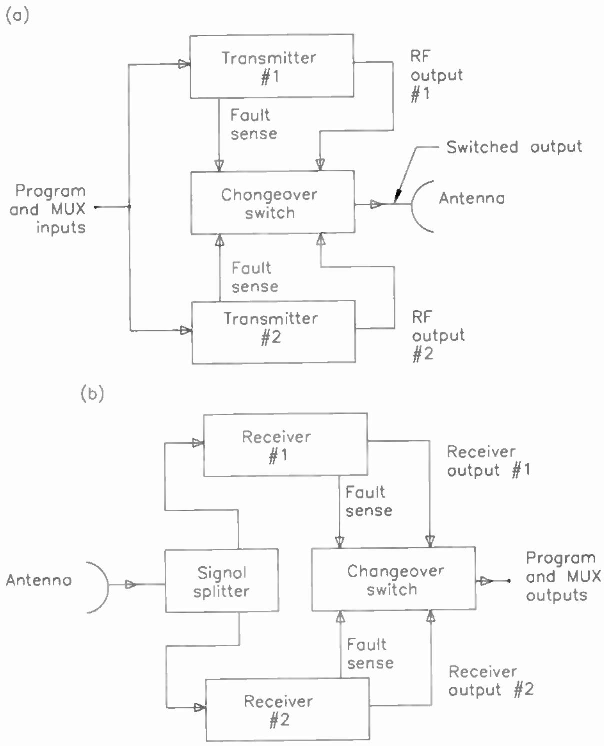

Figure 4.5-24. Equipment configuration for a hot-standby system: (*a*) studio site, (*b*) broadcast transmitter site.[2]

Nearly all STL systems checked in this manner pass specification testing with no problem. Still, there may be instances where a unit is damaged during shipment. It is far easier to solve such problems before the hardware is installed.

Antennas should be given a close visual inspection. Many antenna models used for STL work are shipped partially assembled. Final assembly of the antennas should be completed before the installation process is begun. Pay particular attention to mounting brackets; make sure the hardware will mate properly with the tower or structure on which the antennas will be mounted. Check carefully for missing parts.

The transmission line and connectors require no pre-installation quality control however, it is suggested that as many connectors as possible be installed in the shop, rather than at the site. *N*-type connectors require patience and skill to install. If possible, have the cable supplier attach the proper connectors to both ends of the cable reel. In this way, only two connectors will need to be installed in the field. Always place the manufacturer-installed connector ends at the antennas. This provides the best assurance of trouble-free operation in an exposed environment. Consider ordering a couple of extra connectors just in case a part is lost or damaged during construction. The engineer may also want to use one connector as a test case to become more familiar with the required installation technique.

The test equipment required for pre-installation checkout is usually readily available in the radio station shop. Basic items include the following:

- A high quality 50 Ω dummy load capable of dissipating approximately 25 W
- An in-line RF power output meter capable of reading forward and reverse power at 1.0 GHz
- Audio frequency signal generator
- Audio frequency distortion analyzer
- Frequency counter accurate to 1.0 GHz.

If possible, a spectrum analyzer also should be available. Although most radio stations do not own a spectrum analyzer, engineers in a given market sometimes rent one to be shared among the stations for a period of several weeks.

Figure 4.5-25 shows a typical bench test setup for an STL system.

Planning Cable Runs

Routing of the transmission line from the transmitter to the antenna is an often overlooked element of STL installation. Confirm that there is a practical route for the coax from the transmitter to the rooftop or tower location. Double-check the length of the transmission line path at both the studio site and the station transmitter site. If the actual run is longer than predicted during fade margin calculations, run the numbers again to be certain that a problem will not develop during system commissioning. Confirm also that the pigtail cables to be used are sufficiently long and have the proper connector terminations.

Installation

The locations commonly used for broadcast transmitter sites are seldom ideal from an environmental standpoint. The site may be difficult to reach during certain parts of the year, very hot during the summer and very cold during the winter. For these reasons, rugged equipment should be chosen and properly installed. Temperature extremes can cause problems for frequency-determining elements, as well as accessories such as cavity filters, preselectors and preamplifiers. Environmental control at the broadcast transmitter site, therefore, is highly recommended.

The STL transmitter and receiver should be mounted in an equipment rack in a protected location adjacent to the stereo generator at the studio site and adjacent to the exciter at the broadcast transmitter site. Keep all cable runs as short and direct as possible. Excessive cable lengths between the stereo generator and the STL transmitter, or between the STL receiver and the exciter, can degrade stereo separation and frequency response. Follow good grounding practices at all times.

The antenna presents probably the greatest installation challenge. Because of its directional nature, the antenna must be properly oriented. Compass bearings are desirable along with whatever visual sightings are practical. The received signal strength at the broadcast transmitter site can be used as an indication of proper orientation of the STL receive antenna. Ensure also

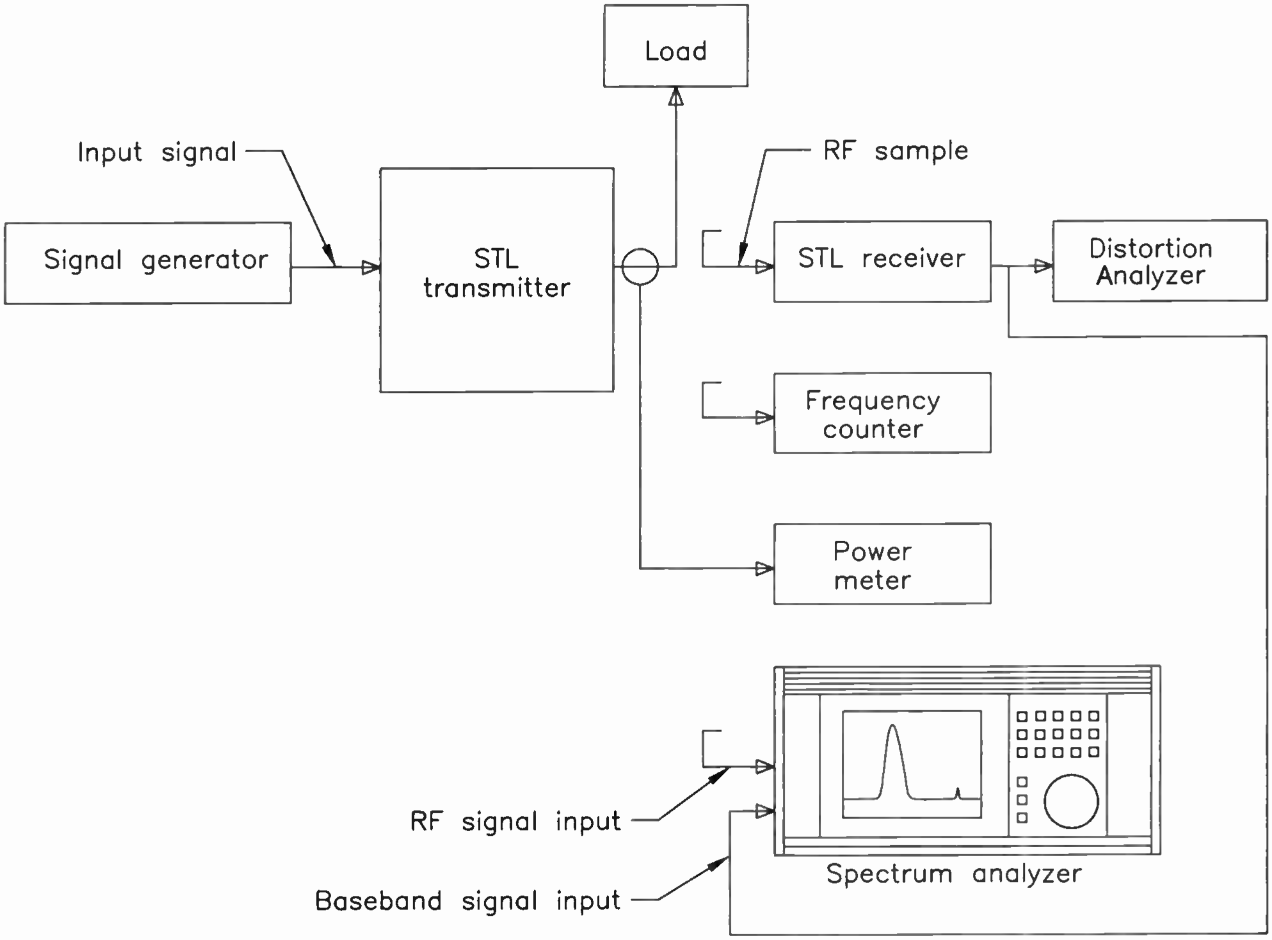

Figure 4.5-25. Equipment setup for bench testing an STL system prior to installation.[2]

that the antenna is set to the proper angle relative to the horizon. Because the STL antennas may be located high on a tower or building, a professional tower crew may be required to mount the devices. Make certain that all cables on the tower are securely fastened to prevent stress and wear. Seal the external connections with sealant made for that purpose and completely wrap the connection joints with tape.

While it is desirable to mount the receive antenna high on a tower to ensure a good path, it is also good engineering practice to keep the antenna as far as possible from radiating elements on the structure, such as the station's main broadcast antenna. Other potential sources of RF problems include two-way radio, cellular radio and TSL systems. If the STL receive antenna is located in a strong RF field, the front-end may be overloaded or *desensitized*. Placing the STL antenna close to other antennas on the structure also can detune the antennas, degrading the performance of both systems.

One of the most common problems encountered during installation is damage to the transmission line. Lines must not be twisted or bent beyond their minimum bending radius. To retain its characteristic impedance, the line must be treated with care. A line damaged by carelessness can cause poor performance of the system.

The transmission line must be properly grounded. As illustrated in Figure 4.5-26, grounding typically is performed at the point where the line leaves the tower and at the point where it enters the building. This procedure, obviously, applies only to grounded tower systems. Grounding kits are available for this purpose.

In situations where the STL antenna is to be mounted on an AM antenna tower, which typically is insulated from ground, an *isocoupler* will need to be installed where the line begins its run up the tower. The isocoupler will pass the STL signal efficiently, while providing a high impedance to ground for the tower at the AM frequency. When this is done, the base impedance of the tower should be expected to change slightly.

Checking System Operation

After all of the components of the STL system have been installed, checkout can begin. Begin by powering

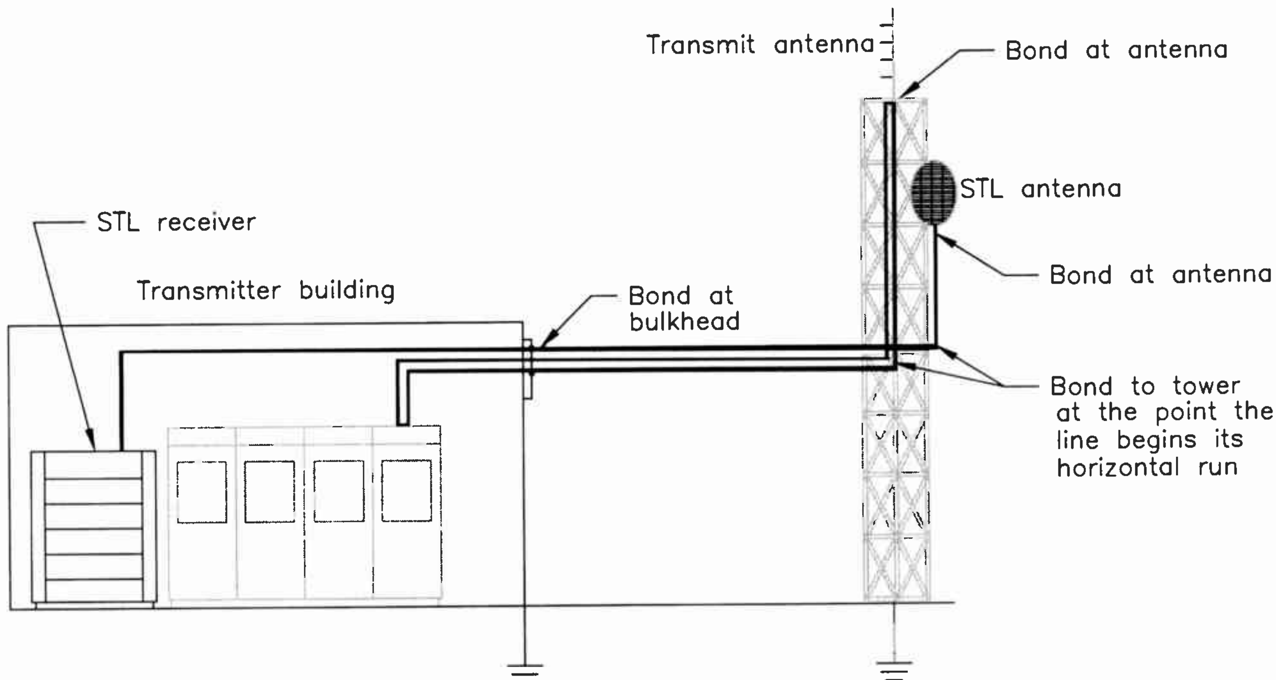

Figure 4.5-26. Grounding practice for an STL transmission line on a tower.[2]

up the STL transmitter. Confirm that all meter readings are within normal parameters. If any problems are detected, shut the system down immediately and troubleshoot the failure.

After proper operation has been confirmed, adjust the modulation levels into the STL transmitter according to the instructions given with the unit. If a digital modem/multiplexer is used, make the necessary adjustments on that unit.

Let the transmitter run for a period of time—several hours or so—and check the operating parameters regularly to be certain that no problems develop. Pay particular attention to voltage standing wave radio (VSWR) and internal high-temperature alarms. If abnormal operation is suspected, consult the manufacturer's equipment manual.

After checkout of the STL transmitter is complete, power up the STL receiver and confirm correct parameters on the front-panel meter. Check and adjust program levels as needed. If a digital modem/multiplexer is used in the installation, check the status monitors on the unit. If displayed, observe the bit error rate monitor to be sure the link is operating properly.

Using an accurate modulation monitor at the broadcast transmitter site, adjust the modulation level of the transmitter. Check operation of the STL system carefully for an hour or so before committing the system to the air.

After the link is operating properly, run a complete proof-of-performance on the broadcast chain. Document the measured parameters so they can be used as a benchmark for later reference.

Troubleshooting

The most common problem associated with STL commissioning is high VSWR. If the indicated VSWR is outside normal limits, the transmission line, a connector or an antenna usually is at fault. A dummy load may be used to determine where the fault lies. Begin at the first pigtail and substitute the dummy load for the transmission line. At each point the load is substituted for the line and antenna, check the displayed VSWR on the transmitter. It is necessary, of course, to power down the transmitter while the dummy load is moved from one point to the next.

Operating the System

Regular performance tests should be made on the STL system. Routine inspections allow the engineer to spot potential problems that could cause a system failure if left unattended.

The STL transmitter and receiver should provide trouble-free performance for many years. If problems develop, the likely trouble areas will be the antennas and transmission lines—the components exposed to the elements. The best check of system performance at the studio is the STL transmitter multimeter. A periodic check of the meter will help to spot oncoming problems. Readings that change gradually can provide clues that will help prevent a failure. Many users will wish to monitor forward power continuously. Reverse power also should be checked regularly to monitor the condition of the line and antennas, as discussed previously. Compare the test data taken after system commissioning with the operating parameters observed during routine checks. They should closely agree.

Operation of the receiver is best checked with its built-in multimeter. The RF level indication should be carefully noted during initial installation and subsequent observations should be compared with this reference. Remember that there will be some change in signal strength readings because of weather conditions and temperature variations. Consider the fade margin conditions used in the path analysis calculations when making judgments about the observed readings. Be aware of unusual variations resulting from temperature inversions, if they are common in the area. If trouble is experienced with the receiver, the possibility of interference from another STL or another service should not be overlooked. A spectrum analyzer is invaluable for such troubleshooting.

For digital STL systems, error rate monitors are provided to assess overall performance. As long as the status indicators on the front panel indicate proper operation, the system usually can be considered to be transparent to the program material.

The most definitive overall check of the system will be the audio proof-of-performance. Primary attention should be given to the noise measurement. If this is not satisfactory, it will be impossible to achieve meaningful distortion measurements because noise will be indicated as distortion by the analyzer. For dual monaural systems, the engineer will need to carefully check left and right channel balance.

A broadcast system is only as strong as its weakest component. Before placing blame for poor performance on the STL, start at the beginning of the broadcast chain and follow the signal step-by-step to the point where it deteriorates.

4.6 RADIO BROADCAST DATA SYSTEM (RBDS)

SCOTT A. WRIGHT
DELPHI DELCO ELECTRONICS SYSTEMS, KOKOMO, IN

INTRODUCTION

Since the adoption of the Radio Broadcast Data System (RBDS) standard in 1993, much debate has surrounded the success of this system. RBDS is the classical *chicken and egg* problem whereby broadcasters debate purchasing equipment when so few receivers are available, and receiver manufacturers debate introducing capable receivers with so few broadcasters on the air. However, the tides have turned recently and broadcasters have little to fear about making the decision to broadcast RBDS. Currently, RDS is standard or optional in automobiles from General Motors, Ford, Porsche, Audi, Volvo, Jaguar, SAAB, and Mazda. RDS receivers are also available for home, car aftermarket, portable and personal computer use, offered by manufacturers such as Denon, Pioneer, Kenwood, Blaupunkt, Becker, Sangean, Onkyo, and ADS Technologies. While RDS is being introduced into premium systems, its application in many new models is a given *if* more broadcasters get on the air. The risk is low with broadcast encoders available starting at under $400. As of this writing, broadcast equipment manufacturers include RE America, Inovonics, Belar, Rohde and Schwartz, Modulation Sciences and Circuit Research Labs. RDS equipment is available through a number of broadcast supply houses as well, and other manufacturers may have, or be planning to offer, RDS equipment. RDS certainly is accepted by consumers in Europe, where it was introduced in 1982. Since that time over 50 million receivers have been sold, and over 500 different models are currently available.

THE RBDS AND RDS STANDARDS

The Radio Broadcast Data System (RBDS) Standard was adopted in January 1993. It was produced by the National Radio Systems Committee (NRSC) which is a joint committee of the National Association of Broadcasters (NAB) and the Consumer Electronics Manufacturers Association (CEMA). Thus, RBDS is an agreed upon standard between broadcasters and receiver manufacturers. The U.S. RBDS Standard is largely based on the European RDS Standard which was adopted in 1982.

Revised editions of both the European RDS Standard, and the U.S. RBDS Standard, were adopted in 1998. To obtain a copy of the U.S. RBDS Standard contact either the NAB or CEMA for ordering information. The European RDS Standard is formally issued by the European Committee for Electrotechnical Standardization (CENELEC) and is issued under Document Number EN 50067.

In the U.S. all references to RDS/RBDS technology generally use the term RDS rather than RBDS. This is because products can be marked with a special RDS logo. RBDS is generally used only to refer to the actual NRSC Standards document. The NRSC felt that it was important to distinguish the U.S. Standard from its European counterpart by giving it a slightly different name. The U.S. standard includes a few features that the European standard does not. One of these is a specification for transmitting Emergency Alert System information via the RDS signal.

The RDS Subcarrier

The FCC has deregulated subcarrier usage allowing almost any technology to be used as long as certain criteria are met. This means that analog or digital or a mixture of both may exist within the subcarrier frequency range as long as the total modulation does not exceed 110%. RDS has proven to be compatible with existing services due to its low injection requirements and narrow bandwidth. In addition, by phase locking the AM double sideband suppressed carrier signal with the stereo pilot signal, there is little risk of interference to the main audio program, even under multipath conditions. RDS is carried on many classical networks throughout Europe and the U.S. with no degradation to the audio quality. Figure 4.6-1 depicts the baseband audio spectrum of a FM broadcast station. RDS nests into the 57 kHz position between the stereo multiplex and the 67 and 92 kHz subcarrier channels. Injection levels as low as 1.3 kHz allow RDS to be easily implemented without giving up program audio power. Since RDS lies at 57 kHz it is compatible with nearly every subcarrier in use or development today. Due to the low implementation cost of RDS, it is not likely to be displaced by another system for many years.

RDS Data Structure

The RDS signal is modulated and demodulated as an asynchronous bit stream. The RDS baud rate is

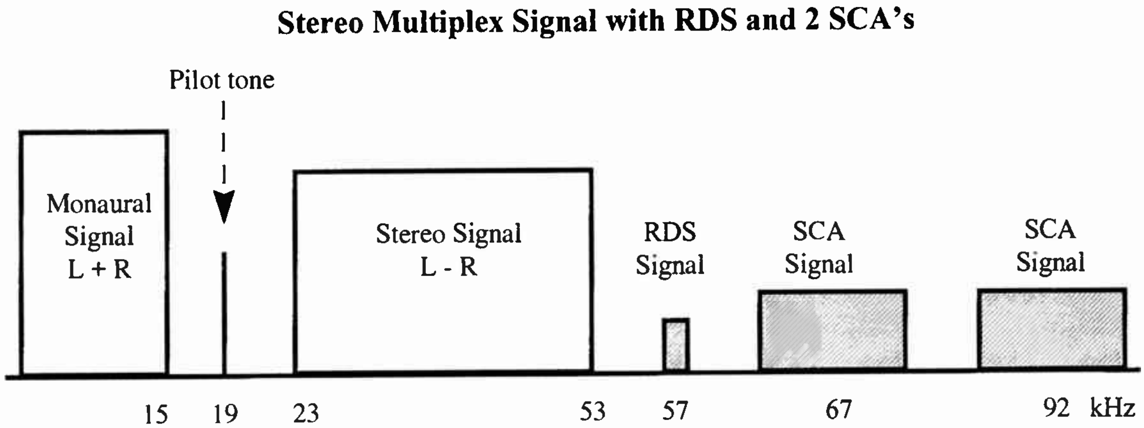

Figure 4.6-1. A typical broadcast system.

1187.5 bits per second. The data transmission is fully asynchronous and there are no gaps between the groups or blocks. The RDS group structure or baseband coding is depicted in Figure 4.6-2. This baseband structure is described as follows:

- The largest element in the structure is called a group (104 bits).
- Each group comprises 4 blocks of 26 bits each.
- Each block comprises an information word and a checkword.
- Each information word comprises 16 bits.
- Each checkword comprises 10 bits.
- All information words, checkwords, binary numbers or binary address values have their most significant bit (msb) transmitted first.

Information Word

The *information word* contains the actual data for each block. This information word is comprised of 16 bits. The most significant bit (m_{15}) is transmitted first.

Checkword and Offset Word

The *checkword and offset word* consist of 10 bits. The most significant bit (c_9) is transmitted first. The checkword allows the receiver to detect and correct errors that occur during data reception. The error-protecting code has the following error-checking capabilities:

- Detects all single and double bit errors in a block.
- Detects any single error burst spanning 10 bits or less.
- Detects about 99.8% of bursts spanning 11 bits and about 99.9% of all longer bursts.
- The code is also an optimal burst error *correcting* code and is capable of *correcting* any single burst of span 5 bits or less.

Figure 4.6-3 shows the possible offset words. The offset word allows detection of the block number within the data group. This allows critical data such as the PI, PTY and TP codes to be decoded without reference to

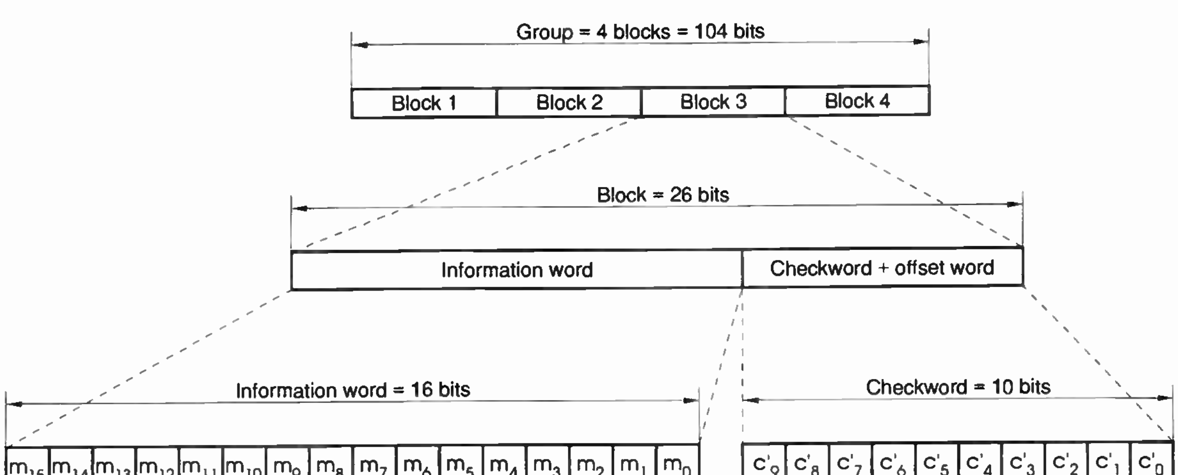

Figure 4.6-2. Structure of the baseband coding.

Offset Word	Binary value d_9	d_8	d_7	d_6	d_5	d_4	d_3	d_2	d_1	d_0
A	0	0	1	1	1	1	1	1	0	0
B	0	1	1	0	0	1	1	0	0	0
C	0	1	0	1	1	0	1	0	0	0
C	1	1	0	1	0	1	0	0	0	0
D	0	1	1	0	1	1	0	1	0	0
E	0	0	0	0	0	0	0	0	0	0

Figure 4.6-3. Offset words.

any block outside the one that contains the information. This is essential to minimize acquisition time for these kinds of messages and to retain the advantages of the short (26-bit) block length. To permit this to be done for the PI codes in block 3 of version B groups, a special offset word (C′) is used in block 3 of version B groups. The occurrence of offset C′ in block 3 of any group can then be used to indicate directly that block 3 is a PI code, without any reference to the value of B_0 in block 2. Offset word E is only transmitted by Mobile Broadcast System (MBS) or RDS/MBS time multiplexing (MMBS) stations. This allows receivers to maintain synchronization in MMBS applications.

Synchronization of Blocks and Groups

The blocks within each group are identified by their offset words A, B, C or C′ and D. The beginning and end of the data blocks may be recognized in the receiver decoder by using the fact that the error-checking decoder will, with a high level of confidence, detect block synchronization slip as well as additive errors. This system of block synchronization is made reliable by the addition of the offset words (which also serve to identify the blocks within the group). These offset words destroy the cyclic property of the basic code so that in the modified code, cyclic shifts of codewords do not give rise to other codewords. A detailed explanation of a technique for extracting the block synchronization information at the receiver is given in Annex C of the U.S. RBDS Standard.

Group Structure

The information coded into each group has a common fixed structure as depicted in Figure 4.6-4.

All data groups share a common fixed structure of information coding to allow critical data to be transmitted in a fixed, highly repetitive pattern to ensure the best reception even under adverse reception conditions. This fixed structure is described as follows:

Block 1—Block 1 of every RDS data group contains only the program identification or PI code.

a) Block 1 is identified by offset word A.

Block 2—Block 2 contains the group type code, version code, traffic program code, and program type (PTY) code. All codes are binary coded with the msb transmitted first.

a) Group type code—The data groups are identified through the 4 bit group type code identified as A3-A0, along with the 1 bit version code, B0. The bits A3-A0 yield decimal values 0 through 15.
b) Version code—Each group then has an "A" version and a "B" version based upon the state of B0 where:
   i) B0 = 0 is identified as group type A
   ii) B0 = 1 is identified as group type B
   iii) All B type groups repeat the program identification (PI) code in blocks 1 and 3.
c) Traffic Program (TP) code—This single bit code is utilized with the traffic announcement (TA) code to provide the traffic feature.

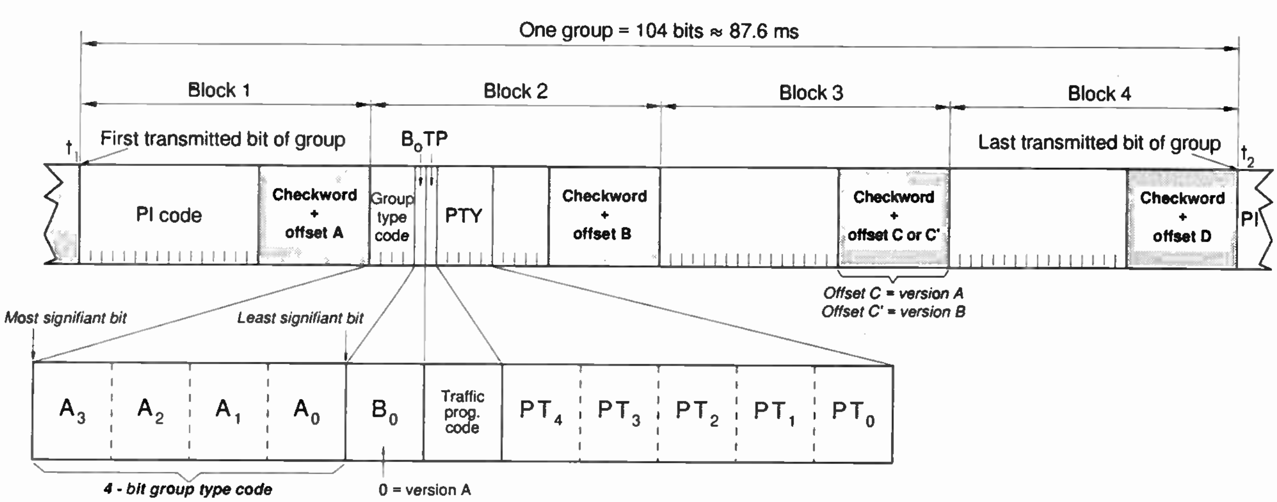

Figure 4.6-4. RDS group coding structure.

d) Program type (PTY) code—This five bit code describes the current audio program being aired. There are 31 possible PTY's available.
e) Block 2 is identified by offset word B.

Block 3—Dependent upon the group version code (A or B) or offset word (C or C'), block 3 may carry two distinct types of data.

a) Version code A—This block carries data defined by the group type code.

Block 3 is identified by offset word C for version code A groups.

b) Version B type groups carry only the PI code.

Block 3 is identified by offset word C' for version code B groups.

Block 4—This block carries data defined by the group type code.

a) Block 4 is identified by offset word D.

RDS Group Types

RDS data groups are referred to by both the group type and version, (0A, 14B). Taking into account both the group type and version codes, there are 32 defined data groups. Some of the group features are defined in their entirety and cannot be defined in any other way, while other data groups are openly defined such that the actual data contained in the group can be defined by the operator. The group type code defines the basic function of the data group. The "A" and "B" versions differ only in the coding of the data for the group. Because RDS data is transmitted in functional groups that share a common structure, the operator can select from these groups types and transmit all or only a portion of them depending upon the features in use. In this manner, there is no need to transmit data which is not in use, thereby maximizing data throughput. Figure 4.6-5 summarizes the possible applications for all possible group types. Only group type 0A or 0B must be included in the transmission sequence.

RDS FEATURES

RDS involves the use of primary and secondary features. Primary features are either contained in every information group or are included in type OA or OB groups, which are always transmitted. Secondary features are transmitted only when necessary or desired. This prevents data capacity from being wasted on unused features. The following is a summary of RDS features.

Primary Features

Program Identification (PI) Code The PI code is a four digit hexadecimal code that is unique for each station. The PI code is calculated from the station's call

Group Type	Group type code/version A_3	A_2	A_1	A_0	B_0	Flagged in type 1A groups	Description
0A	0	0	0	0	0		Basic tuning and switching information only
0B	0	0	0	0	1		Basic tuning and switching information only
1A	0	0	0	1	0		Program Item Number and slow labeling codes only
1B	0	0	0	1	1		Program Item Number
2A	0	0	1	0	0		Radiotext only
2B	0	0	1	0	1		Radiotext only
3A	0	0	1	1	0		Applications Identification for ODA
3B	0	0	1	1	1		Open Data Applications
4A	0	1	0	0	0		Clock-time and date only
4B	0	1	0	0	1		Open Data Applications
5A	0	1	0	1	0		Transparent Data Channels or ODA
5B	0	1	0	1	1		Transparent Data Channels or ODA
6A	0	1	1	0	0		In House applications or ODA
6B	0	1	1	0	1		In House applications or ODA
7A	0	1	1	1	0	Y	Radio Paging or ODA
7B	0	1	1	1	1		Open Data Applications
8A	1	0	0	0	0	Y	Traffic Message Channel or ODA
8B	1	0	0	0	1		Open Data Applications
9A	1	0	0	1	0	Y	Emergency Warning System or ODA
9B	1	0	0	1	1		Open Data Applications
10A	1	0	1	0	0		Program Type Name
10B	1	0	1	0	1		Open Data Applications
11A	1	0	1	1	0		Open Data Applications
11B	1	0	1	1	1		Open Data Applications
12A	1	1	0	0	0		Open Data Applications
12B	1	1	0	0	1		Open Data Applications
13A	1	1	0	1	0	Y	Enhanced Radio Paging or ODA
13B	1	1	0	1	1		Open Data Applications
14A	1	1	1	0	0		Enhanced Other Networks information only
14B	1	1	1	0	1		Enhanced Other Networks information only
15A	1	1	1	1	0		Do not use; Fast PS being phased out.
15B	1	1	1	1	1		Fast switching information only

Figure 4.6-5. RDS group types.

letters, thus no two are alike. The receiver uses the PI code to identify a station rather than frequency. RDS allows frequency diversity such that if a station simulcasts on another frequency, the receiver can automatically tune to the strongest station. If a station simulcasts, then it must pick one station's PI code and use it on all of the simulcasting stations. While the PI code is transparent to the user, its proper use is vital to proper receiver operation. Specialized PI codes are available for use for networked programming as well.

Program Service (PS) Name The PS Name is whatever name the station chooses to present to its listeners. It can be call letters like "WZWZ-FM," or a slogan like "Z-93." The PS Name is displayed instead of frequency on an RDS receiver. When the listener tunes to an RDS station the station's name will be shown on the radio display. The PS Name cannot be longer than eight characters. Any character referenced in the RBDS Standard may be used, but special characters might not be displayable on certain low cost displays. The note appearing at the bottom of Table E.1 of the RBDS Standard details which characters are most commonly displayable.

Traffic Program (TP) If a station offers listeners traffic bulletins then it should pay particular attention to this feature. The TP identifies the transmitting station to the listener as a station that offers traffic programs. RDS receivers can automatically tune to stations that offer traffic programs when the user turns on the traffic announcement feature of the radio. A broadcaster should not set TP high unless it actually uses the TA feature.

Traffic Announcement (TA) When an actual traffic bulletin is broadcast this information bit must be set to a logic "1." The RDS receiver detects this and will automatically stop any playback device that may be in use, and will return to the FM tuner mode. Audio adjustments are also automatically made so that, if the user had the volume muted for instance, the receiver will adjust the volume to a user preset level. Some means must be employed to control the state of this information bit coincident with the beginning and ending of the actual traffic announcement. Figure 4.6-6 depicts the proper usage of the TP and TA bits during a traffic announcement.

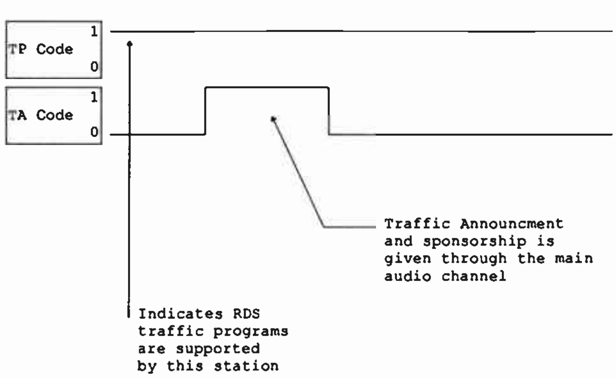

Figure 4.6-6. A typical non-EON traffic announcement.

Program Type Codes (PTY) This code is used to identify the type of program material being broadcast. There are pre-defined codes for *Country, Rock, Top 40* etc. The RDS receiver can automatically search for stations by PTY, thus allowing listeners to find their favorite type of programming without tuning to all available stations. Advanced receivers can even interrupt listeners when, for example the *News* is broadcast. A definition of the terms used to denote North American Program Types is given in Table 4.6-1.

Alternate Frequencies (AF) This feature allows the RDS receiver to automatically tune to the best signal when multiple transmitters or translators are broadcasting the same program. Regional or national programs that are broadcast over large areas can even be linked together, providing the listener with the illusion of one very powerful transmitter. It is also possible to only link stations during specific times when the program material is common (perhaps during a sporting event) using the linkage actuation feature. Competitors cannot steal listeners away using this feature because an RDS receiver will only look for alternative frequencies that are specified by the station that is currently tuned in. An example of an AF network is shown in Figure 4.6-7.

Secondary Features

Program Type Name (PTYN) This feature allows the ultimate in flexibility for the broadcaster who wants to stand out from competitors. While the PTY codes are predefined, the PTYN can be any eight characters the broadcaster desires to further describe the current program. For example, a broadcaster who is currently using the PTY "Personality" may set the PTYN to "Limbaugh" to further describe the current program. A "Rock" station may set the PTYN to "Bob & Tom" to describe their morning team. An RDS receiver cannot search by PTYN, but will display the PTYN in place of the PTY once tuned to a particular station.

Radiotext (RT) Radiotext allows a station to transmit up to 64 characters of information to the listener. Information such as the current artist and song title, station promotional information, local events, and even additional information about the advertiser whose commercial is currently playing can be sent.

Clock Time and Date This feature enables broadcasters to transmit the current date and time once every minute, thus enabling RDS equipped clock radios, car radios, etc., to be automatically set after a power failure, time zone change, etc. Broadcasters should not use this feature unless they can ensure the accuracy of the transmitted information within ± 2 sec.

Emergency Warning System (EWS) The EWS feature allows the transmission of coded emergency information intended for specialized receivers. The FCC has recognized the capability of this feature, and permits broadcasters to use RDS to transmit Emergency Alert System information. Broadcast EAS equipment can be linked to an RDS encoder for automatic retransmission of EAS information. (However, this does not eliminate the requirement to transmit EAS information in the main program channel as well.)

Table 4.6-1

Program Type	Name	Description
1	News	News reports, either local or network in origin.
2	Information	Programming that is intended to impart advice.
3	Sports	Sports reporting, commentary, and/or live event coverage, either local network in origin.
4	Talk	Call-in and/or interview talk shows either local or national in origin.
5	Rock	Album cuts.
6	Classic Rock	Rock oriented oldies, often mixed with hit oldies, from a decade or more ago.
7	Adult Hits	An up-tempo contemporary hits format with no hard rock and no rap.
8	Soft Rock	Album cuts with a generally soft tempo.
9	Top 40	Current hits, often encompassing a variety of rock styles.
10	Country	Country music, including contemporary and traditional styles.
11	Oldies	Popular music, usually rock, with 80% or greater non-current music.
12	Soft	A cross between adult hits and classical, primarily non-current soft rock originals
13	Nosotalgia	Big band music.
14	Jazz	Mostly instrumental, includes both traditional jazz and more modern smooth jazz.
15	Classical	Mostly instrumentals, usually orchestral or symphonic music.
16	Rhythm And Blues	A wide range of musical styles, often called *urban contemporary*.
17	Soft Rhythm	Rhythm and blues with a generally soft tempo.
18	Foreign Language	Any programming format in a language other than English.
19	Religious Music	Music programming with religious lyrics.
20	Religious Talk	Call-in shows, interview programs, etc. with a religious theme.
21	Personality	A radio show where the on-air personality is the main attraction.
22	Public	Programming that is supported by listeners and/or corporate sponsors instead of advertising.
23	College	Programming produced by a college or university radio station.
24-28		Unassigned.
29	Weather	Weather forecasts or bulletins that are non-emergency in nature.
30	Emergency Test	Broadcast when testing emergency broadcast equipment or receivers. Not intended for searching or dynamic switching for consumer receivers.
31	Emergency	Emergency announcement made under exception circumstances to give warning of events causing danger of a general nature. Not to be used for searching—only used in a receiver for dynamic switching.

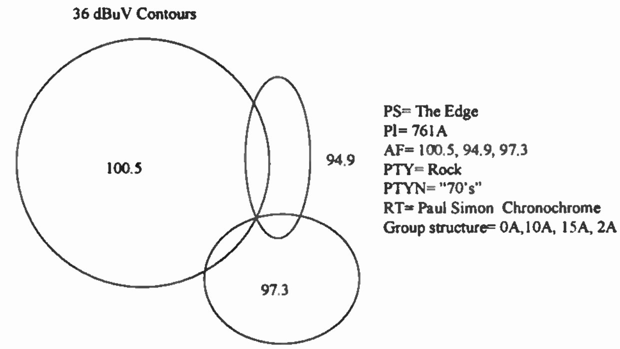

Figure 4.6-7. A typical RDS alternate frequency network.

An alert feature contained within consumer receivers will be activated when an alert code is transmitted. The U.S. RBDS Standard includes an entire annex devoted to implementing EAS within RDS.

Open Data Channel (ODC) This is the latest and most flexible addition to the RDS Standard. In previous years working groups were formed to determine the best way to add additional data services such as *differential correction* for the Global Positioning System (DGPS), and even the EAS. These systems needed both public (free) and private (fee) based delivery. Using the remaining few undefined RDS data groups to perform these services proved too much, as coordinated systems could not be agreed upon. However, it was agreed that each data group left undefined was worth its weight in gold, since once all the groups were defined, that meant the end of any future expansion to the system. Thus was born the concept of the open data channel.

The open data channel allows the definition of an unused RDS data group based solely on the Application Identification (AID) code. Thousands of AID codes are available meaning that the remaining data groups could be defined thousands of different ways. The AID codes are internationally assigned and coordinated so that anyone can apply for an AID code and start their very own data service. The ODC is much more flexible than other data only groups such as the transparent data channel because it can be automatically tuned (by use of the AID) and tracked regardless of any other data being transmitted. This is a dynamic, and potentially very profitable, data group.

Transparent Data Channel (TDC) For specialized applications, information of any type can be transmitted by use of this data group. For instance, advertising messages could be sent to an electronic billboard using this feature. Virtually any way that data is sold can be supported by the TDC. Normal car and home receivers do not decode this information.

In-House Application Data contained in this group is to be used only by the broadcaster. Remote control applications, station telemetry, or paging applications can be supported using this data group.

Radio Paging (RP) Paging services including numeric or alphanumeric can be supported by RDS.

Traffic Message Channel (TMC) This feature allows traffic information to be coded and displayed on consumer receivers so that normal audio bulletins are not required

SUMMARY OF CHANGES IN THE NEW STANDARD

The newly revised European RDS and U.S. RBDS Standards move forward into a new era for FM data services. All changes have been devised to be fully backwards compatible with the old standard while offering a tremendous amount of growth. The prior standards were:

- United States RBDS Standard—January 8, 1993. Issued by the National Radio Systems Committee (NRSC)
- EN50067, Specification of the radio data system (RDS)—April 1992. Issued by the European Committee for Electrotechnical Standardization (CENELEC)

While these standards shared much commonality, the newly revised standards are almost completely identical in form. To utilize the new features contained in the 1998 version of the U.S. RBDS Standard, a software upgrade must be made to existing broadcast encoders. It is a good idea to inquire about upgrades before making a purchase of new equipment as well. The following features were modified in the new RBDS Standard:

- Program Type Name (PTYN)
- Fast Program Service Name (Fast PS)
- Location and Navigation (LN)
- Open Data Applications (ODA)
- Enhanced Radiopaging Protocol (EPP)
- Language Identification (LI)
- Decoder Information (DI)
- Extended Country Code (ECC)
- PI structure from B000-FFFF
- Analog SCA cross referencing
- IRDS Updating
- PTY code table
- MBS EAS

Program Type Name (PTYN)

The PTYN contained within group 10A has been added to the RDS standard. This feature was previously defined only within the RBDS Standard. The feature has been slightly modified with the addition of a text A/B Flag, but is still backwards compatible with the previous definition. The A/B flag is located in the unused 4 bit region and shares the same bit position as the A/B flag in Radiotext group 2A. The usage is the same in both groups in that the A/B flag should be toggled whenever the PTYN is changed. Within the receiver, the PTYN text buffer should be cleared when the A/B flag is toggled to prevent *mixing* of old and new PTYN's. The rationale is that the PTYN is designed to be semi-dynamic, potentially changing whenever the program changes from "news" to "weather" to "sports"). Newly designed receivers can take advantage of the A/B flag without effects from existing encoders that do not incorporate this change.

Fast Program Service (PS) Name

The Fast PS is currently defined in group type 15A of the RBDS Standard and is not defined in the RDS Standard. This group will not be adopted in Europe. In North America there will be a phase out of all transmissions within 10 years, and 2 years for new encoders. The elimination of this group can be included in encoder upgrades to the new standard. This group will not be defined for any use and could later be reallocated as open data. This will not adversely affect the existing receiver base as only Delco Electronics, Grundig, Blaupunkt, and Becker have produced receivers for North America with this feature. The rationale for this change is that it will not cause significant performance degradation in the receivers as the PS is also located in groups 0A, and 0B. The PS is transmitted two characters at a time in these groups and will be received in 348 ms versus 174 ms using the fast PS feature. Since the PS is typically static and is often stored in receiver memory for instant recall following PI reception, the only time that slower PS acquisition will be noticed is when tuning to a station for the first time. There are over 35 million receivers in use worldwide that would not be able to receive the fast PS. Once broadcasters begin using Fast PS, acquisition times of PS in existing receivers would be adversely impacted since they would not be able to decode this data. Therefore as a feature, Fast PS cannot be considered fully backwards compatible. The Fast PS would be of minor benefit especially in Europe where most broadcasts are network based and hence require frequent repetition of AF information (0A). So in consideration for phase out in North America, the Europeans have agreed to coordinate the future use of 15A.

Location and Navigation (LN)

LN was defined in Group 3A in the RBDS Standard only. This usage will be immediately deleted and reassigned to the Open Data Application (ODA). This was recommended since there were no LN transmissions within North America and this feature was no longer required for ID Logic receivers. The definition as LN was found to be inadequate by the Differential Global Positioning System (DGPS) Working Group of the NRSC. This group along with its European counterpart determined that the LN structure could not meet current needs of private and public service providers. It was recommended that the ODA be used for LN and DGPS services.

Open Data Applications (ODA)

Group 3A was redefined for ODA. Other, previously unused groups were assigned for ODAs as well. The use of an "A" type group allows low data capacity application to exist entirely within Group 3A. The ODA allows multiple reuse of unused data groups rather than fixed definitions, ensuring a long future for RDS. The actual use of data can be either public or private. The ODA allows encryption of data for fee based services. Data groups referenced via slow labeling (Group 1A) can also be used for ODA when not specifically referenced for use. Specific uses are identified by application identification codes (AID). Over 65,000 internationally allocated AID Codes are available. This allows anyone to start their own datacasting business locally, nationally, or internationally. ODA are already defined or proposed for EAS, DGPS, DAB cross referencing and enhanced TMC.

Enhanced Radiopaging

To enhance the existing paging capabilities of RDS, the enhanced radiopaging protocol was developed. This protocol is contained within Groups 13A and 1A. Annex M of the U.S. RBDS Standard contains the protocol definitions. With the enhanced protocol the possibility of international RDS paging has been added. The prior definition of RDS paging was based upon the usage of PI codes only. This worked well in network based broadcasts as found in many parts of Europe, but offered no solution where non-network based broadcasts are employed, such as in the U.S. The enhanced radiopaging protocol now opens local, national and international paging opportunities.

Language Identification

To aid the international traveler, the language identification feature located in Group 1A Variant 3 has been expanded to include most world languages. The list of covered languages is located in Annex J of the Standard. The feature enables the broadcaster to indicate the spoken language being broadcast thus allowing listeners to search for their native language on local broadcasts.

Decoder Identification (DI)

The decoder information feature has been modified to enable the identification of stations that perform dynamic PTY switching. This allows the broadcaster to indicate that it dynamically switches the program type (PTY) based on the current audio program thus supporting the use of PTY interrupts in consumer receivers. Prior to this, there was no way to tell if the broadcaster would ever change the PTY. The dynamic PTY indicator is analogous in use to the TP bit of the traffic announcement feature.

Extended Country Codes (ECC)

ECC allow receivers to identify the country that the broadcast is coming from. Since PI codes are limited in number, they must be repeated throughout the world, when the PI code is received in conjunction with the ECC, the exact country of origin can be identified. The updated ECC code table has been expanded to be international in scope. It is contained in Annex D and Annex N of the Standard. ECC should be transmitted by all broadcasters, and it is recommended that it be a default automatic transmission in encoders.

Program Identification (PI) Codes

In the U.S. PI codes are based on call letters rather than being assigned by any organization as is done in Europe. A portion of the PI codes are reserved for network usage and also for assignment to stations in Canada and Mexico. During the upgrade to the U.S. RBDS Standard, several mistakes were discovered in the non-call based PI codes which had to be corrected. The changes to the PI code assignment are summarized as follows:

- PI assignments below B000 will remain as is, allowing AF switching but no regionalization. PI codes "_0__", and "__00" are re-mapped into the "A" range of PI's.
- C000-CFFF assigned to Canada. Allows AF switching, but no regionalization. PI codes C0xx, and Cx00 are excluded from use.
- F000-FFFF assigned to Mexico. Allows AF switching, but no regionalization. PI codes F0xx , and Fx00 are excluded from use.
- B_FF, D_01-E_FF assigned for national networks in U.S. and Canada, Mexico. Regionalization allowed. NRSC to provide assignments for all three countries.

The ECC code table was modified for these changes as well. The rationale for these changes was that the current definitions for PI's above BFFF were contradictory. Also, the present PI code structure above BFFF were inadequate for the needs of Canada and Mexico because the existing PI structure only allowed 256 PI's for Canada and Mexico. The new PI assignments yield 3,584 possible non-regional PI's for Canada and Mexico. As well as 765 national network PI"s for all three countries.

Analog SCA Cross Referencing

This feature was devised to allow RDS signaling to receivers equipped with analog subcarrier decoders to switch over automatically. This feature was defined in section 3.1.3.6, Note 3 as part of the transparent data channel (TDC), Group 5A Channel 2. This feature has been deleted from the revised standard because: a) it is not in use; b) it prevents harmonization with the European RDS Standard; and, c) it can be easily converted over to the ODA channel.

ID Logic RDS (IRDS) Updating

This feature was previously defined in section 3.1.3.6 Notes 1 and 2 as a reservation of the transparent data channel (TDC), Group 5A Channel 0 and 1. This was reserved for updating ID Logic receiver databases through RDS. The TDC reference was deleted from the revised standard. The rationale behind this change was that it was not currently in use and it prevented harmonization with the European RDS Standard. ODA will now be used for updating ID Logic receiver databases. The use of AID codes will provide better protection and international usage of the IRDS feature.

PTY Code Table

Both the RDS and RBDS Standards have included additional definitions for previously undefined PTY codes. RBDS has defined two new codes:

- PTY-29, Weather. It is defined for non-emergency weather related information such as forecasts, watches, and advisories. Weather is a popular listener feature that can be supported with the PTY "Watch" mode to interrupt playback similar to traffic announcements and News PTY.
- PTY-23, College. Is intended to be used to identify broadcasts oriented to college students that often contain a variety of formats and information. It is one of the top three non-commercial formats. The other two, Public and Religious, already had PTY definitions.

In the European RDS Standard all the PTY codes have now been defined. The main reason for this was to ensure coordination with the development of the digital audio broadcasting system being rolled out throughout Europe known as the Eureka 147 Standard. Previously, codes 16 through 30 had no definition. These codes have all been defined in the new standard.

DIFFERENCES BETWEEN RDS AND RBDS

With all the changes to the two standards, there still remain differences. These differences are mainly market driven. From a listener point of view, most of these differences are transparent. In exploring these differences it will become evident that the receiver manufacturer must be well versed in the differences to ensure proper receiver operation. When these differences are properly employed by the receiver manufacturer, it is possible to construct a truly global receiver. If broadcasters and receivers make use of the ECC feature, it is possible that the receivers could self-configure automatically. The problem of course, is getting broadcasters to utilize the ECC feature since it is not a required broadcast feature.

Summary of Differences Between European RDS and U.S. RBDS

- Program Type Definitions (PTY)—To conform with differing broadcast styles, the PTY code definitions are different. These differences may be accounted for through the use of a look-up table within the receiver. Annex F of the U.S. RBDS Standard includes both the European and North American PTY definitions.
- Program Identification Coding (PI)—Due to the high penetration of network based programming throughout Europe as compared to the largely independent single transmitter structure of North America, the derivation of PI codes is different. In the RBDS Standard, PI codes are based on call letters from 0000-AFFF, and are network based from B000-FFFF. This means that PI codes above B000 in North America are treated by the receiver the same way that all PI codes are treated in Europe. Below B000, PI codes in North America do not employ the regionalization feature. While alternate frequency switching is still employed below B000, variants based upon changes in the second nibble of the PI code, do not exist, and should be ignored. PI code definitions can be found in Annex D of the Standard.
- Mobile broadcast system (MBS) and RDS/MBS time multiplexing (MMBS)—The predecessor to RDS, MBS, still thrives throughout North America. MBS is mainly used as a paging system through a network of approximately 500 stations within the U.S. The MBS system utilizes the same modulation and data structure as RDS, but employs a different data protocol. An MBS broadcast is identified through the offset word E. Since there are similarities between the two systems, it is possible to time multiplex MBS and RDS data. This time sharing is known as MMBS. Receiver manufacturers must be able to differentiate between RDS and MBS, as well as accommodate MMBS broadcasts. Internal MBS/MMBS cross references can be found throughout the new RBDS Standard as a reminder of particular system requirements and as a possible alternative to RDS. A public domain EAS protocol is also contained within the MBS/MMBS annex.
- EAS ODA Protocol—Within the U.S. RBDS Standard, the EAS ODA protocol is defined for use in the U.S. This optional feature set is constructed around the Federal Communication Commission's EAS protocol and is open for public use. RDS allows the silent retransmission of emergency information. This has been combined with existing consumer oriented emergency features to allow additional feature functionality to consumer receivers as well. The EAS ODA can also accommodate private emergency systems.
- ID Logic (IDL) in — Receiver database updates via RDS (IRDS) ODA Protocol—The ID logic feature is a licensed technology that allows the incorporation of an in receiver database that contains format type and call letters for all AM and FM stations. When combined with RDS, IDL can provided similar data and features for non-RDS and AM stations. The IRDS feature allows the database to be updated through an RDS ODA so that the information can be updated and maintained automatically. The introduction of ID Logic is contained in Section 7 of the U.S. RBDS Standard, and the IRDS ODA is described in detail in Annex R.
- AM RDS (Future System)—Although a suitable data transmission system has yet to be developed that is compatible with the C QUAM AM stereo system, there is a separate section in the U.S. RBDS Standard where such a system can be defined or referenced. The NRSC remains interested in the development of an AM RDS system.

4.7
TRANSMISSION SYSTEM CONTROL AND MONITORING

HAROLD HALLIKAINEN
HALLIKAINEN & FRIENDS, INC., SAN LUIS OBISPO, CA

INTRODUCTION

The Federal Communications Commission (FCC) requires broadcast transmitters to have various meters and controls. The required meters include those necessary to determine the transmitter power output (or input to the antenna system) by the direct and/or indirect methods. These are normally those instruments necessary to determine the transmitter final amplifier input power (final amplifier voltage and current) and the output power (transmission line meters for FM and TV, base or common point meters for AM).

On some transmitters, measurement of the final amplifier voltage and current is meaningless. In these cases, the transmitter manual should describe what the FCC required for acceptance of the transmitter.

The required controls include those necessary to insure that the transmitter is operating within the terms of the station license. These controls have traditionally included a carrier on/off control, a day/night control for AM stations (power and/or pattern change) and a *power trim* control. Directional AM stations and television stations must have additional monitors. Directional AM stations are required to have an FCC authorized antenna monitor (Section 73.69). This monitor indicates the current ratios and phases for each tower, relative to a reference tower. Television stations are required to have a monitor capable of determining whether the transmitted visual signal meets FCC specifications (Section 73.691).

In 1995, the FCC made major changes to its requirements for transmitter control. (see *Report and Order*, MM Docket 94-130, 60 FR 55476). Section 73.1400 was rewritten and renamed *Transmission system monitoring and control*. The revised rules allow stations to be operated in either an *attended* or *unattended* mode.

Stations operating attended have a *designated person* in charge of the transmitter. There is no longer a requirement that the person controlling the transmitter have an FCC operator's license. The person in charge of the transmitter may observe and control it directly (if the transmitter is nearby) or by using a remote control. Finally, the person in charge may merely supervise an *automatic transmission system* (ATS) (Section 73.1400(a)(2)). The ATS is required to monitor and control (licensee determined) critical parameters that would cause interference should they be out of tolerance. Should an interference causing condition exist that the ATS cannot correct, the ATS is required to notify the person in charge of the transmitter. The previous requirement that an ATS shut down a transmitter has been removed for stations operating in an attended mode with an ATS.

Stations operating unattended rely upon stable equipment or an ATS instead of relying upon a person to insure the transmitter operates within limits. If an ATS is used, it monitors and controls licensee determined critical parameters. Should an interference causing condition exist, the ATS shuts down the station within three hours. ATS systems at unattended stations are not required to notify anyone before shutting the transmitter down. However, most stations want someone to be notified if the transmitter is going to be shut down, so they set up their ATS systems to do this anyway.

FCC rules previously authorized *extension metering*. Extension metering was a form of remote telemetry where a dedicated circuit was used for each parameter being monitored. No control functions were required to be extended. Instead, a distance limit on extension metering permitted the transmitter controls to be reached quickly. The adoption of the rules permitting unattended operation deleted the extension metering provisions.

This chapter discusses the sampling and control of various transmitter parameters. These sampling and control concepts can be applied to remote control (including *extension metering*) and ATS. The discussion then moves on to data conversion and transmission subjects important to remote control and remote ATS. This is followed by a discussion of the operator interface, and data analysis. Although the vast majority of transmitter control systems available today are microprocessor based, nonprocessor based systems are presented to develop the concepts common to all systems and to provide an historical perspective. The chapter organization can be thought of as starting at a transmitter and working back to the control point.

PARAMETER SAMPLING CIRCUITRY

Most transmitter parameters can be reduced to a *sample voltage* by using voltage dividers or current sense resistors. *Remote metering* is accomplished by sending a signal representing this sample voltage to the remote metering point, then displaying a value representing the original parameter. The concept of sample voltages is important. Although the parameter could be measured directly from the remote metering point, wiring costs often make this impractical. For example, it would be impractical to send 5,000 V to the remote metering point to measure the final amplifier plate voltage of a vacuum tube transmitter. Nor would it be practical to send several amperes of plate current or antenna current to the remote metering point. Instead, voltages (typically dc) representing the values of these parameters are sent. The scale of the remote meter can be calibrated such that every volt of sample voltage represents another kilovolt of plate voltage. The remote meter can directly indicate the transmitter plate voltage without having to deal with high voltages.

In practice, the actual sampling ratio (sample voltage/parameter value) is not important as long as the sampling ratio is stable and the sample voltage is reasonable (low enough to be easily handled, high enough to not get lost in noise). Most transmitter manufacturers provide remote samples for the FCC required indicating instruments. Figure 4.7-1 shows some typical voltage sampling circuits.

DC Voltage Sampling Circuits

Figure 4.7-1(a) shows how a voltage divider may be used to divide the plate voltage down to a safe sample voltage. This circuit is independent of the transmitter front panel plate voltage meter.

In extension meter applications, broadcasters may want to adjust R2 to provide a voltage that is an integer order of magnitude below the actual plate voltage. For example, the extension meter could be a 3.5 digit digital panel meter (a DPM that reads between −1,999 and +1.999), which typically reads in millivolts. R2 is adjusted such that the sample voltage is 300 mV when the plate voltage is 3.00 kV. The appropriate decimal point on the display can be enabled to directly indicate the plate voltage in kilovolts with a resolution of 0.01 kV.

Figure 4.7-1 (b) shows how the existing plate voltmeter *multiplier resistor* (R1) can be used to drive the front panel meter and provide a sample voltage. The additional 1K sampling resistor (R2) decreases the reading of the local meter by 0.01% (which is negligible).

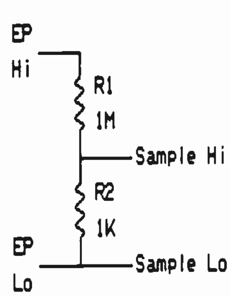

Figure 4.7-1(a). Unbalanced plate voltage sampling circuit. Sample voltage = EP/1001.

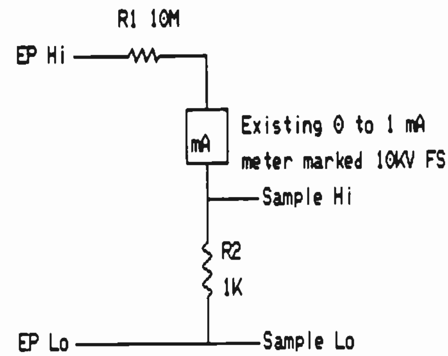

Figure 4.7-1(b). Adding resistor to existing plate voltmeter circuit provides a remote sample.

Clamp Diode for Safety

In each of the sampling circuits shown in Figure 4.7-1, the full plate voltage would be supplied to the remote indicator should the shunt resistor (R2) open (assuming minimal loading by the remote indicator). To protect wiring and personnel, it is common practice to add a *zener diode* across R2. Should R2 open, the sample voltage is clamped to the zener voltage. The zener will typically fail to a short, protecting the external sampling equipment. This zener is commonly damaged in lightning storms, causing a loss of plate voltage sampling.

Common Mode Voltages

Input and output terminals in the circuits of Figure 4.7-1 are labeled "high" and "low." The low terminal is the one whose voltage is closest to ground. In many cases, the low terminal connects directly to ground, allowing the sample voltage to be measured between sample high and ground. Many transmitters, however, do not measure the plate voltage between the plate supply and ground. These transmitters often have resistors between the final amplifier tube cathode (or transistor emitter or source) and ground. These resistors are used to provide protective bias, cathode current sampling and output power trimming. The final amplifier input voltage is then measured between the plate supply to the tube (generally +3 kV to +10 kV) and the cathode of the tube (0 V to +250 V). The circuits of Figure 4.7-1 could possibly place the low side of the sample 250 V above ground. This hazardous voltage would require special precautions in wiring. Further, many remote control systems assume the low side of the sample is grounded. Connecting such a remote control to such a transmitter would short out the circuitry in the cathode circuit, disabling the tube protective bias and current overload protection and causing the transmitter to run maximum power, regardless of the power trim setting.

Common Mode Attenuator

Figure 4.7-2(a) shows circuitry similar to that presented so far. It is driven by +5 kV from the plate of

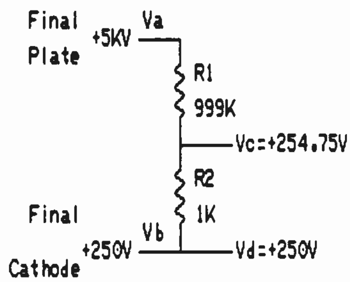

Figure 4.7-2(a). Plate voltage sampling circuit without common mode attenuation gives dangerous sample voltage.

the amplifier and +250 V from the cathode. The *plate voltage* is the differential voltage (Va − Vb). The differential voltage is attenuated (multiplied by 0.001) to arrive at the differential sample voltage. Unfortunately, the circuitry shown does not attenuate the common mode voltage ((Va + Vb)/2) as much, multiplying it by 0.096. This yields the dangerously high common mode voltage.

Figure 4.7-2(b) shows a sampling circuit that attenuates both the common mode and differential mode voltages equally. As in Figure 4.7-2(a), the differential mode sample voltage is 0.001 times the differential mode input voltage (0.001 times 4.75 kV or 4.75 V, in this case). However, the common mode sample voltage is also multiplied by .001, reducing it from 2.625 kV to 2.625 V. This circuit can be used to sample high voltages that are not measured with respect to ground provided the remote metering equipment has differential inputs.

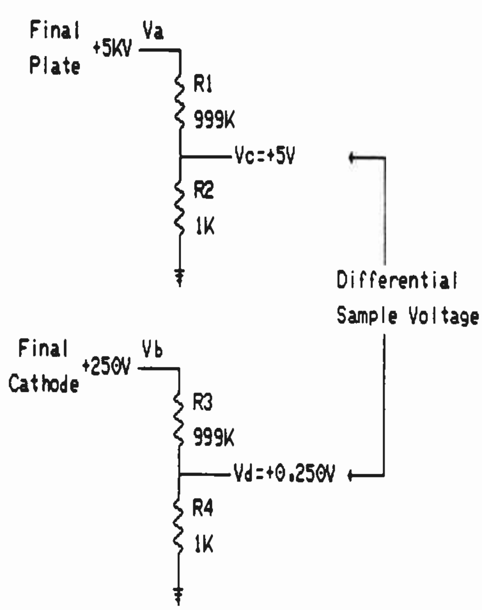

Figure 4.7-2(b). This voltage divider reduces common mode voltage to a safe +2.65 V.

Common Mode Rejection

The differential output voltage of Figure 4.7-2(b) (Vc − Vd) is independent of the common mode input voltage ((Va + Vb)/2) if all the resistors are precisely matched. This can be checked by applying a high common mode voltage with no differential voltage. When both Va and Vb are connected to the high voltage supply (+5 kV), one of the 1K resistors can be adjusted as needed to give no voltage between Vc and Vd.

Differential Input Circuitry

Several techniques are available for dealing with differential sampling voltages (where neither side of the sample is grounded). For circuit simplicity, many remote control systems assume one side of the sample voltage is grounded. Other systems provide differential inputs. If differential samples must be measured, additional circuitry may be added outside the remote control to convert the sample to a ground referenced sample. Typical approaches to dealing with a differential input voltage include: use of an isolation amplifier, use of a differential amplifier, floating the remote control analog to digital converter and calculating the differential voltage.

Isolation Amplifier

An *isolation amplifier* may be included inside a transmitter, a remote control, or between the two units. Isolation amplifiers provide isolation between the input and output by using magnetic, capacitive, optical or thermal coupling between input and output. Many isolation amplifiers require a floating power supply to drive the input circuitry, which considerably adds to cost. Careful design is required to insure that the *encode* and *decode* processes track each other (the output voltage is indeed proportional to the input voltage). Some isolation amplifiers use feedback techniques to reduce the nonlinearities induced by the coupling method.

Differential Amplifier

In most cases, electrical isolation between the sampling circuitry and the remote metering equipment is not required. Instead, a differential voltage must be changed to a *single ended* voltage (one side grounded). This can be accomplished using one of the differential amplifiers shown in Figure 4.7-3. Figure 4.7-3(a) is a basic differential amplifier. If the resistors are precisely matched, the output voltage will be a constant (the differential gain) times the differential input voltage. If the resistors are not precisely matched, the amplifier will have a *common mode gain* other than 0. The output voltage is (Va − Vb)Ad + ((Va + Vb)/2)Acm, where Ad is the differential gain (amplification factor) and Acm is the common mode gain. If the resistors are precisely matched, Acm = 0.

The circuit of Figure 4.7-3(a) suffers from a limited input voltage range. If the amplifier is setup for a gain of 1 (R1 = Rf), the circuit will only accept about twice the input range of the operational amplifier. The circuit of Figure 4.7-3(b) allows up to 200 V of common mode input voltage.

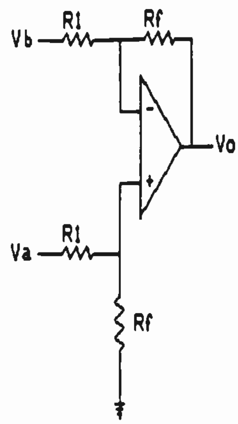

Figure 4.7-3(a). Basic differential amplifier. Vo = (Rf/R1)(Va – Vb).

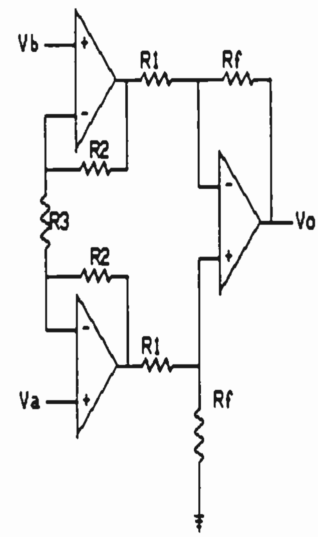

Figure 4.7-3(c). Standard instrumentation amplifier. Gain can be varied by changing R3.

The circuit of Figure 4.7-3(c) (the instrumentation amplifier) loads the sample circuitry less than the other circuits, has better common mode rejection (lower common mode gain), and the gain can be altered by changing only one resistor (R3). The input voltage range is, however, limited to the voltage range of the operational amplifiers.

Calculated Differential Voltage

Each of the schemes so far has been directly measuring the differential voltage or calculating it using operational amplifier (analog computer) techniques. By reconsidering Figure 4.7-2(b) and measuring the sample voltages at points C and D with respect to ground (Vc and Vd), the differential voltage can be calculated. A typical remote control could put Vc on one channel and Vd on another channel. The remote indication would show Vc at 5 V, which indicates Va is 5 kV. The remote indication would show Vd at 0.250 V, which indicates that Vb is 250 V (0.250 kV). By subtracting, the transmitter operator could determine the plate voltage (5.000 kV − 0.250 kV = 4.750 kV). If the remote control has a software subtraction capability, the differential plate voltage could be displayed directly.

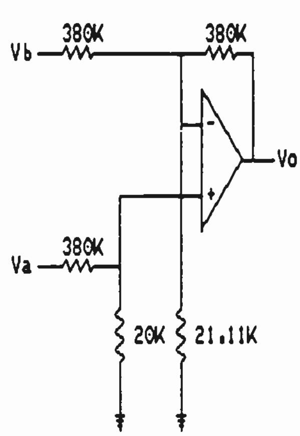

Figure 4.7-3(b). Burr-Brown INA117 differential amplifier with 200 V input range. V0 = Va − Vb.

This approach does require the voltages to be relatively stable, as most systems do not sample all the channels simultaneously.

DC Current Samples

Figure 4.7-4(a) shows the use of a current sense resistor to give a voltage sample that is proportional to current. Unfortunately, the common mode voltage of this sample is very high (about 5 kV). An isolation amplifier would probably be required to safely utilize this sample.

Of course, the plate current also flows through the cathode, so a ground referenced sample is available there. However, the cathode current also includes the control grid current and screen grid current (if the tube has a screen grid). If the grid and screen circuits are returned above the sense resistor, an isolated sample of plate current is available (as shown in Figure 4.7-4(b)). If these circuits are not returned above the sense resistor, samples for each of these currents can also be derived. These currents can then be subtracted from the measured cathode current using analog or software techniques.

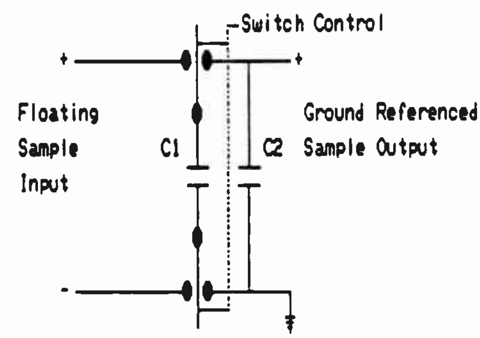

Figure 4.7-3(d). Flying capacitor isolator.

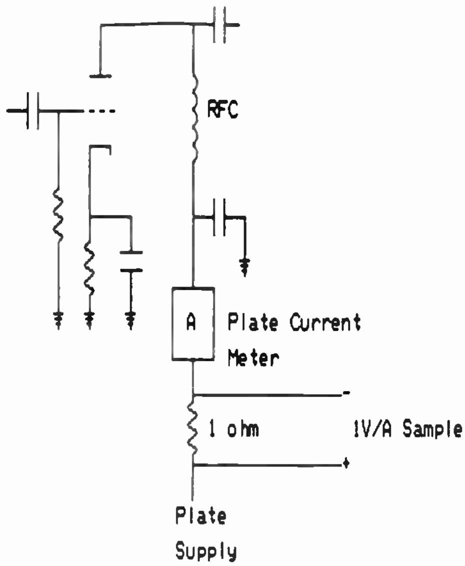

Figure 4.7-4(a). Plate current sample with dangerously high common mode voltage.

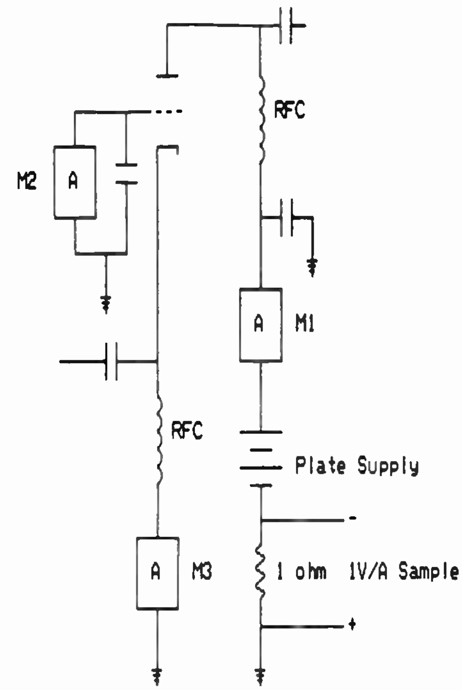

Figure 4.7-4(c). Plate current sampling in negative side of plate supply.

If a high voltage supply is powering only the plate of the RF amplifier (such as the grounded grid amplifier shown in Figure 4.7-4(c)), it is possible to measure the plate current by measuring the current into the negative side of the supply. Instead of grounding the negative side of the supply (as is typically done), a current sense resistor is placed between the supply and ground. The voltage across this resistor is proportional to the plate current. Note that the current through this resistor is the same as the plate current indicated by Ml, while M3 (the cathode current) is the plate current (Ml) plus the grid current (M2). Note also that the sample voltage is negative. Most (though not all) remote control equipment can handle bipolar sample voltages.

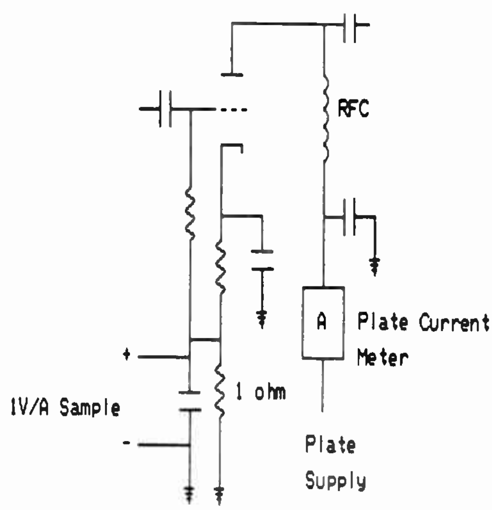

Figure 4.7-4(b). Plate current sampling in cathode circuit. Note that grid is returned above sample resistor.

Some pulse duration modulated AM transmitters operate with the plate of the final amplifier at dc ground potential. The cathode of the final idles at -7.5 kV and peaks at -15 kV on $+100\%$ modulation peaks. The same sampling techniques can be used.

Resistor Stability

The initial tolerance of resistors used as current sense resistors or in voltage dividers is not critical. An inexact resistance will cause the sample voltage to be other than that expected. Whatever sample voltage appears, the remote meter can be calibrated to agree with the local meter. The resistance of resistors changes with time and temperature. The variation with temperature is the major error contributor.

A carbon composition resistor may have a temperature coefficient of about ±600 ppm/°C for resistors up to 1 kΩ. This increases to ±1875 ppm/°C for resistors up to 1 MΩ. If these resistors were used in the plate voltage sampler of Figure 4.7-1(a), the sample voltage *could* change 22% over a 0° to 50°C temperature range. Carbon film resistors are available with temperature coefficients that range from 0 to -300 ppm/°C for low resistance values to 0 to -1000 ppm/°C for high resistance values. Metal film resistors are available with temperature coefficients down to 15 ppm/°C. Bulk metal resistors are available with temperature coefficients of 5 ppm/°C. If the resistors in a voltage divider are at the same temperature, the matching between the temperature coefficient of resistance (TCRs) is more important than the actual TCR. Since the TCR matching is generally better than the TCR of an individual resistor, sampling systems should be designed to keep the resistors in the network at the same temperature.

In differential amplifiers, the matching of resistor values is very critical. To ensure the resistance values track with temperature, it is common to use a resistor network made using hybrid film techniques or integrated circuit techniques. Since the resistors are made at the same time and of the same materials, the TCRs will match closely. Since they are on the same substrate, they will be at about the same temperature.

Other considerations in resistor selection include the power and voltage rating of the resistors. For example, a typical 2 W carbon film resistor is rated at 750 V. A resistor with a higher voltage rating, or several in series, would be needed to sample a high voltage.

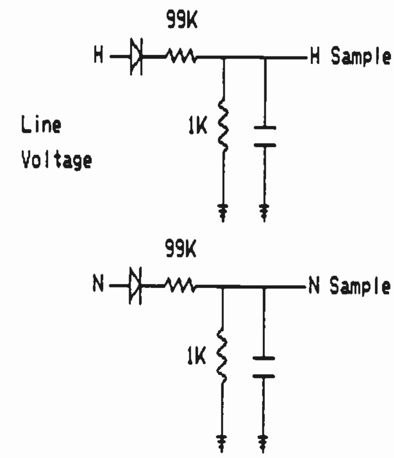

Figure 4.7-5(b). Non isolated line voltage sampler with differential sample output.

AC Voltage Sampling Circuits

Figure 4.7-5(a) shows a simple transformer isolated ac line voltage sensor. The dc output voltage will be approximately proportional to the differential line voltage (as measured between hot and neutral). The linearity of the sample is limited by the diode knee voltage as a proportion of the transformer secondary voltage. This line voltage sampler may be as simple as a calculator supply directly driving the analog input of the remote control.

Figure 4.7-5(b) shows another line voltage sampling circuit. This circuit provides a differential output. Ideally, the neutral line voltage is about zero, so that portion of the circuit may be deleted. If the circuit is used with a remote control that does not have differential inputs, an external differential amplifier may be used, or the hot and neutral samples can drive two input channels of the remote control. The operator or the remote control software can then calculate the actual differential voltage.

Three-Phase Line Voltage Sampling

The *hot* portion of the circuit in Figure 4.7-5(b) can be duplicated for each phase of a three-phase system. The remote control is then presented with four samples, one for each phase voltage referenced to ground, and one for the neutral line voltage. Note, however, that this circuitry will not necessarily indicate a loss of phase. Should a phase open, a load between two phases may pull them together, causing the correct voltage to be on each phase, but the proper phase relationship would not be present. Such an open phase can be detected with the *phase imbalance detector* of Figure 4.7-6.

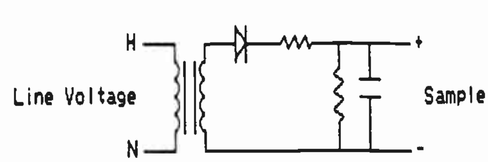

Figure 4.7-5(a). Transformer isolated line voltage sampler.

Figure 4.7-6 shows the circuit driven by a three-phase wye source. The three 10K, 2 W resistors form an averaging circuit, adding the three voltages and dividing the result by three. In a 3 phase wye circuit, Va = 120 V at 0°, Vb = 120 V at 120°, and Vc = 120 V at 240°. These three voltages add up to 0 V at V1, indicating the circuit is balanced.

If a line imbalance occurs (such as a phase being lost where phase B follows phase A), the input voltages are 120 V at 0° on phases A and B, and 120 V at 240° on phase C. Averaging these voltages results in 69.28 V at −30° at V1. The remaining circuitry provides a dc voltage proportional to the half wave average of the voltage at V1. Use of this simple circuit detects loss of a phase while merely measuring phase voltages does not. Note that the standard wiring of a three-phase delta source results in voltages that are not balanced with respect to ground. The typical voltages are 120 V at 0°, 120 V at 180°, and 208 V at 90°. If these are fed to the circuit of Figure 4.7-6, the yield is V1 = 69 V at 90° and a sample output of 13.13 VDC. This

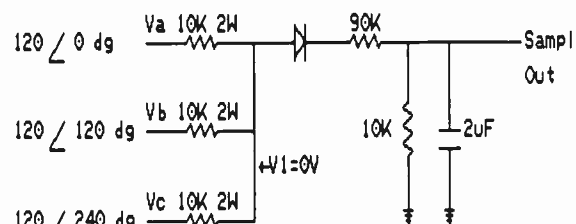

Figure 4.7-6(a). Alternate current line phase imbalance detector. Note that the sample output voltage is 0 volts when ac line is balanced.

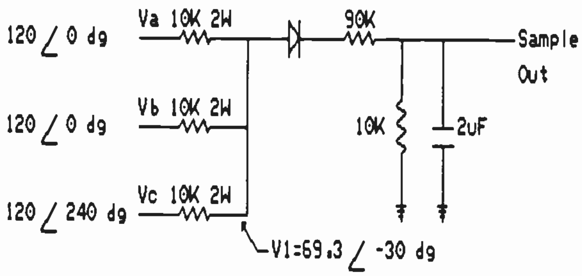

Figure 4.7-6(b). A current line phase imbalance detector with phase B shorted to phase A, giving sample voltage representing imbalance.

sample voltage could be monitored. Significant deviation would indicate a power line problem. Another approach would be to add three transformers between the line and the phase imbalance detector to change the delta source to a wye.

Note that in all of these circuits, the diode is placed before the voltage divider (the 90K and 10K resistors) to minimize the nonlinearity due to the diode knee voltage.

Finally, none of these circuits will detect a phase reversal. The actual phase sequence is generally unimportant to transmitter power supplies. However, many transmitters use three-phase blowers. A phase reversal will cause the blower to rotate the wrong way, severely deteriorating the transmitter cooling. Phase sequence detecting relays that will release a set of contacts on a missing phase or a phase reversal are available. These contacts could drive an analog or a status input of a remote control.

Filament Voltage Sampling

Filament voltage sampling can be done using the same techniques previously described for line voltage sampling. If an isolation transformer is used, the voltage ratio would need to be adjusted to yield the proper sample voltage. If an isolation transformer is not used (instead, just a diode and voltage divider are used), care must be taken to ensure that only the filament voltage is sampled. Grounded grid amplifiers have a high RF voltage on the filaments, so the filament voltage must be measured before the RF isolation inductors. AM transmitters often have a dc common mode voltage on the filament (typically due to circuitry for protective bias, cathode current sensing, and power trim). This can be removed by using an isolation transformer or capacitively coupling the ac voltage to the sampling circuitry.

Tower Light Sampling

The monitoring of tower lighting systems is required by Section 17.47 of the FCC Rules. This section requires a daily observation of either the tower lights or a properly operating tower light indicator by the tower owner. Section 17.47(a)(1) requires the remote indicator (or alarm) to indicate the failure of any lamp on the tower. Section 17.48(a) requires the failure of a

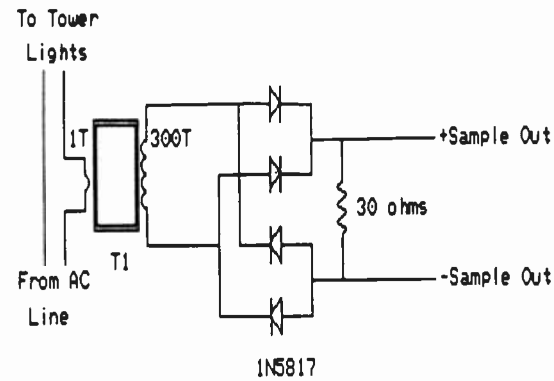

Figure 4.7-7(a). Tower light current sampler provides 84 mV dc average/RMS ac amp.

steady burning lamp at the top of a tower or the failure of any flashing obstruction lamp to be reported to the FAA. A daily observation of tower lights requires that the lights be viewed directly from a location which would allow any lighting failure to be observed. A properly operating tower light indicator is one that will report the proper operation of the lighting system as well as the failure of a required light. Such systems usually operate by sensing the current driving the tower lights. Stations operating by remote control often read this sensed current at the remote control point and interpret proper operation by observing the indicated current.

Figure 4.7-7(a) shows a possible tower light sensor. T1 is a current sensing transformer (Toroid Corporation of Maryland TR-3025) with a primary to secondary current ratio of 300. Ideally, the secondary current is the primary current divided by 300. As circuitry is added to the secondary (secondary not shorted), the secondary current decreases and the linearity of the secondary versus primary current curve decreases. This is due to the output voltage limitations of the transformer (it is not an ideal current source).

Figure 4.7-7(b) shows the peak voltage output of the circuit when measuring the current driving two flashing 620 W lamps and two steady 116 W lamps (all rated at and driven with 130 VAC). Note the high

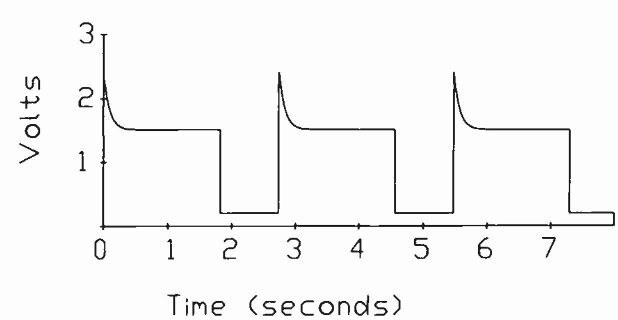

Figure 4.7-7(b). Tower light sample output waveform.

output when the beacon is first lit. This high inrush current (due to the filament cold resistance) increases the initial beacon current by about 70% (generally limited by the resistance of the wiring feeding the lamp). The time constant for the exponential decay down to the steady state current is about 91 ms. If the remote control system uses an integrating (dual slope) analog to digital converter, it will measure the average dc voltage across the resistor during the sample time. A typical dual slope A/D does between 3 and 30 conversions per second. It is not sampling the input during the total conversion time (time is spent in the autozero and reference integrate phases). Assuming 3 conversions per second, 2.73 conversions can be done during the beacon off time (using the typical flash rate and duty cycle) and 5.46 conversions can be completed during the beacon on time. By watching the minimum and maximum conversions, it is possible to determine if all lamps are working properly. Many people will be tempted to add a capacitor across the output of the sampler to provide a dc sample to the remote control. This, however, will cause samples taken during the beacon off time to include a component due to the beacon on current and vice versa. This interference between the measured on and off currents is eliminated by allowing the A/D integrator to remove the ac line frequency (actually twice line frequency, since it is full wave rectified) component, though there is still some interaction possible due to a conversion starting when the lamp is on and completing when the lamp is off. A/D sampling rates on dual slope converters are typically chosen to minimize the effects of 60 Hz and its harmonics.

Table 4.7-1 shows typical minimum, maximum, and average for a series of samples taken over a one minute period with 3 conversions per second. Note that these voltages are less than the peak voltages shown in Figure 4.7-7(b) (measured with an oscilloscope), since the voltages in Table 4.7-1 are average dc voltages, measured with an integrating A/D converter.

Note that the circuit of Figure 4.7-7(a) measures tower light current, which will vary with tower light voltage. FCC Rule Section 17.54 requires the voltage at the base of tower lamps during normal operation to be at least 97% of the rated lamp voltage. Tower lamps tend to be constant current devices. As the line voltage drops, the filament cools, decreasing the filament resistance and increasing the current, though not back to the original value. With a typical tower lighting load (two 620 W lamps and two 116 W lamps) a 3% decrease in line voltage causes a 1.57% decrease in lamp current. A 6% decrease in line voltage causes a 3.30% decrease in line current. Since these variations due to line voltage fluctuations (staying within FCC required line voltage limits) are much less than the variations due to a lamp failure, it is simple to differentiate between lamp failures and permissible line voltage variations.

Table 4.7-1

Average dc voltages (as opposed to RMS) from circuit of Figure 4.7-7(a) under various tower lamp failures, 3 samples per second for 60 seconds.

Light Condition	Minimum Volts	Maximum Volts	Average Volts
All ok	0.132 (100%)	1.402 (100%)	0.766 (100%)
Side light out	0.060 (45.5%)	1.217 (86.8%)	0.687 (89.7%)
Beacon out	0.132 (100%)	0.776 (54.6%)	0.465 (60.7%)

If a remote control returns voltage indications corresponding to tower light current (using a circuit similar to that suggested), minimums and maximums can be checked by an operator or system software to determine if the tower lights are operating properly. If the output of the circuit is run through a low pass filter with a cutoff frequency well below the beacon flash rate, a steady dc voltage corresponding to the average voltage would be available. This voltage is proportional to the current drawn by the steady burning lamps plus the product of the current drawn by the flashing beacons and the duty cycle of the flashing beacons. A variation of more than 5% in this voltage would indicate a lamp failure.

All the discussion has been based on a standard tower lighting load. This consists of two flashing 620 W lamps and two steady 116 W lamps. Tall towers require more lamps. It is suggested that the lighting circuits for such towers be sampled individually, breaking the system down to several standard lighting loads. Increasing the load substantially will make it difficult to detect the loss of one small lamp.

No matter what approach is used to do tower light sampling, it is suggested that a single 116 W lamp be added to each lighting circuit. This light should remain on at all times or switch on when the other tower lights are turned on. For AM stations, this lamp might be in the antenna tuning unit at the base of each tower. FM and TV stations might use it as a transmitter site nightlight. The tower light sensing circuitry and software can be tested by turning off this lamp, simulating the failure of a steady burning lamp. An operator, system hardware, or system software should be able to detect this tower lamp failure. This is an easier method of testing the system than climbing the tower to unscrew a lightbulb!

The FCC permits the use of high intensity (strobe) lighting as an alternative to tower painting and standard lighting. Due to the complexity of the required control circuitry, strobe control systems typically provide outputs that can be used to determine the state of the system (high/medium/low intensity and failure of any lamp). These outputs can be returned to the transmitter operator using standard status monitoring circuitry.

In addition, several manufacturers offer tower light alarm systems for incandescent tower light systems.

FM AND TV OUTPUT POWER SAMPLING

FM and TV transmitters are required to have a metering circuit that measures the output power. Most transmitters have a remote output of this sensor that can be used to drive remote meters. These meters are generally directional couplers that sample the forward and reflected power at the transmitter output. For those transmitters without a remote output power sample (or those stations using combined transmitters), a transmission line directional coupler with an associated wattmeter (with remote sample) can be added. NTSC television transmitter output power meters include a peak detector circuit, since the RMS output power varies substantially with picture content. The NTSC peak amplitude (tip of sync) should be a constant power. Different power measurement techniques are used with the newly adopted digital television standard.

The dc output of the reflectometer has a relatively high source impedance and is easily loaded. Many transmitters include isolation circuitry so the remote or extension meter does not load the directional coupler, causing inaccurate indications on the transmitter front panel meter.

The sample voltage out of a directional coupler is proportional to the square root of the power (directly proportional to the voltage or current), except at very low powers, where the diode knee voltage again causes additional nonlinearities. The output power meter on most transmitters is a mechanical meter with a nonlinear scale, allowing it to read output power directly. An analog remote meter can also use the same scale, allowing direct reading of the transmitter output power. Digital meters, however, generally use a linear A/D converter. Getting an accurate remote indication involves squaring the sample voltage either before or after the A/D converter. The sample voltage can be squared prior to the A/D using an analog multiplier (or balanced modulator) and tying the two inputs together (multiplying the sample voltage by itself). Devices that handle this analog squaring are often called *power to linear converters*.

The sample voltage can also be squared after the A/D converter. This may be done by giving the transmitter operator a chart (indicated power versus actual power). Finally, most microprocessor based remote controls make this calculation automatically.

AM POWER SAMPLING

AM stations generally determine power by measuring the RF current into the antenna system. For nondirectional stations, this is the base current of a series fed antenna or the feedwire current of a shunt fed antenna. A directional station measures the current into the common point of the array. In each case, the measured current is squared and multiplied by the resistance (base, feed wire or common point) to arrive at the power into the antenna. Section 73.51(a)(1) of the FCC Rules also permits the use of direct reading power meters that measure the voltage, current and phase relationship between them to determine the power, but these meters are rare.

RF currents have traditionally been measured with thermocouple meters, which measure the true RMS current. Remote thermocouple meters are available, but suffer from nonlinearity between the RF current and the sample voltage. Further, when an AM transmitter is modulated, the RMS current into the antenna increases (corresponding with the addition of power to the AM sidebands). The FCC places limits on the unmodulated antenna current. Having the antenna current indication vary substantially with modulation would require checking the antenna current without modulation. For these reasons, diode meters are now generally used for remote RF current indications.

Diode meters utilize an RF current sensing transformer to develop a dc voltage that is proportional to the RF current. The dc sample is obtained by running the rectified RF through a low pass filter that removes the ac components (RF and audio). Ideally, the dc component of the rectified RF is constant, since the transmitter ac couples the audio into the final amplifier (using typical modulation techniques). The sample voltage will be the same with or without modulation, allowing measurement of the unmodulated antenna current without interrupting modulation. Again, there are potential nonlinearities due to diode knee voltages. However, these may be overcome by placing the current sense transformer terminating resistor after the rectifier, as was done in the tower light sensor previously described. Other techniques are available to eliminate this nonlinearity. These include developing a bias voltage to get over the knee and the use of zero crossing driven FET switches (similar to a synchronous rectifier).

A well designed diode meter (such as the Delta TCA series) also serves well as the local antenna current meter. These meters provide a local indication and a sample voltage suitable for driving remote metering.

In practice, the indication of a diode type RF ammeter will vary with modulation. This is generally due to less than perfect carrier amplitude regulation (carrier shift) in the transmitter. Often the transmitter high voltage power supply is loaded by the modulators as the modulation level is increased, decreasing the high voltage available for the final amplifier. This can cause a decrease in the indicated antenna current. Variations in the antenna impedance with frequency may also cause carrier shift, as the various sideband frequencies see a varying load impedance. If these variations in indicated antenna current are excessive (remote antenna current meters are required to agree with the local meter within 2% [Section 73.57(d)]), the readings would have to be taken without modulation, or perhaps some electrical compensation could be added (see *Carrier Shift Compensation*).

Some stations take a sample of the RF voltage at the antenna input (base, feed wire or common point) and calibrate the remote indication to agree with the local ammeter. Assuming the impedance of the antenna is constant, then the RF voltage will indeed be proportional to the current. This approach uses the antenna itself as a *current to voltage converter*.

Finally, directional stations are equipped with a very high quality RF detector circuit in their antenna monitor. Stations that operate nondirectional some portion of the time may use the indication of the antenna monitor current sample for the nondirectional tower as a remote base current sample. The actual RF sample is typically from an RF current transformer at the base of the tower or a current sampling loop part way up the tower. Stations can also add a current sense transformer just prior to the common point meter. This transformer can drive the antenna monitor to give a remote sample of the common point current.

Carrier Shift Compensation

The circuit of Figure 4.7-8 may be added between a Delta TCA RF ammeter and a remote control (input resistance of 1 M or MΩ greater) to compensate for variations in indicated antenna current due to carrier amplitude shift with modulation. Figure 4.7-9 shows the remote sample voltage out of a Delta TCA2OEXR with modulation. Normally, the ac component (due to modulation) is removed by a low pass filter in the remote control or the *mechanical low pass filter* created by the movement of mass in a meter movement. If R2 is set to the center of its range, the circuit of Figure 4.7-8 forms a low pass filter (Fh = .034 Hz). The output voltage will be the dc component of the input, regardless of any ac component (due to modulation). If, during modulation, the dc component drops (due to carrier shift), the dc output voltage will drop. If, however, the wiper of R2 is moved towards Dl, Cl will tend to charge to the peak input voltage instead of the average voltage. If the output voltage without modulation is measured (remote control calibrated without modulation), then R2 adjusted for the same indication with modulation, most of the effects of carrier shift can be removed. Testing of the circuit on a 5 kW plate modulated transmitter operating into a three tower directional array reduced variations in indicated common point current from ±1.2% to ±0.1%.

Note that the circuit must not be loaded by the remote metering circuitry. If a low resistance (less than 1M or MΩ) is to be driven, a standard operational amplifier voltage follower circuit should be added between the carrier shift compensator and the remote metering system.

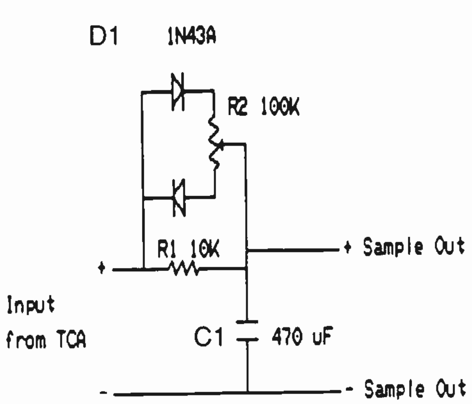

Figure 4.7-8. Remote ammeter carrier shift compensator.

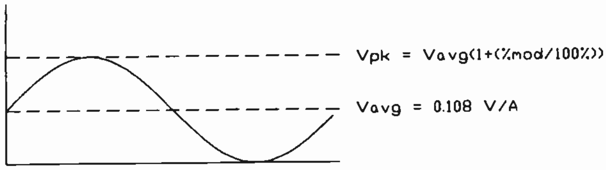

Figure 4.7-9. Remote sampler output waveform of Delta TCA20EXR. Note that Varg will typically decrease with modulation due to carrier shift. Vpk increases with modulation.

DIRECTIONAL ANTENNA MONITOR

AM radio stations with directional antenna systems must have an antenna monitor to verify the proper operation of the antenna system when operated in a directional mode. The indications of a directional antenna monitor may also drive remote meters when designed for such use and when authorized by the FCC (Section 73.53(a)(9)). Most antenna monitors require a tower select input and usually a pattern select input in order to measure the amplitude (or ratio) and phase of the selected tower, though some more recent monitors provide continuous outputs of all samples. Additional difficulties are caused by the necessity to properly indicate phase relationships that may be positive, negative or very close to 0°. In extension metering systems, the tower select controls can be extended to the metering point, allowing the operator to select which tower the monitor will measure.

Most (though not all) antenna monitors use one or two amplitude detectors and one phase detector. This technique requires that the detector circuitry be shared among several towers through the use of an RF multiplexer which selects the desired tower input samples. Monitors with two amplitude detectors leave one connected to the reference tower at all times. The other (or only) amplitude detector is switched between the RF samples from the various towers in the antenna system. One input of the phase detector is also constantly connected to the reference tower. The other input of the phase detector follows the amplitude detector, connecting to one tower sample at a time. When a tower is selected on such an antenna monitor, the response time of the RF multiplexer and the settling time of the detection circuitry prevent an accurate indication from being immediately available. At least one antenna monitor avoids this problem by providing complete detector circuitry for each tower input sample. This approach eliminates the need for tower input selection and can provide continuous indications of all ratios and phases to remote control equipment.

In remote control applications, when tower select inputs are required, the control outputs of the remote control system are typically used to drive the tower select inputs of the antenna monitor. A fairly common practice has been to assign a tower to a channel, then use the *raise* control to read the phase and the *lower* control to read the loop current or ratio. This technique, however, requires interface circuitry between the remote control and the antenna monitor (the control contacts are selecting which indication, phase or ratio, as well as the tower to be sampled) and may result in calibration difficulties, since two dissimilar readings will need to be calibrated on a single analog telemetry input. A simpler approach is to have one or more channels assigned to phase and one or more channels assigned to loop current. The analog inputs of these channels can connect directly to the antenna monitor phase and loop current sample outputs, and each channel will be calibrated to only one type of indication. The *raise* and *lower* control lines then drive the tower select inputs of the antenna monitor. Table 4.7-2 lists some sample channel assignments for such a system.

This arrangement removes the requirement for interface relays between the antenna monitor and the remote control. The current indications may be sample currents (typically from sampling transformers at the tower base or a sampling loop on the tower) or may be current ratios.

Some remote controls provide a channel selected output that notifies external sampling equipment that the channel is selected. With such a system, the channel selected output can directly drive the tower select input of the antenna monitor, allowing the operator to get an antenna monitor reading in the same manner as any other reading (by simply selecting a channel). Such systems can also scan the monitor channels automatically. In this case the response time of the RF multiplexer and settling time of the detector circuits must be considered. Most antenna monitors will present a valid sample about one second after a tower is selected.

To simplify the remote interface of antenna monitors, *sample and hold* devices are available. These devices scan through the tower selects on the antenna monitor and store the resulting sample voltages. The device then provides a steady output sample voltage for the phase and loop current (or ratio) for each tower in the system. This makes the antenna monitor appear like other samples at a transmitter site (continuously available). Operators and system software must allow for the possibility that such a sample and hold system may have acquired some data with the station operating in one pattern, and the remainder of the data in another pattern. This is also a possibility in any system that scans the antenna monitor parameters. Some system software checks the pattern select (day/night) before scanning the antenna monitor and again after scanning the antenna monitor. If these samples of the pattern select disagree, the monitor is scanned again.

Table 4.7-2
Suggested channel assignments for remote monitoring of a 4-tower DA.

Parameter	Control (channel)
Tower 1 phase	Raise (10)
Tower 2 phase	Lower (10)
Tower 3 phase	Raise (11)
Tower 4 phase	Lower (11)
Tower 1 current	Raise (12)
Tower 2 current	Lower (12)
Tower 3 current	Raise (13)
Tower 4 current	Lower (13)

Getting a remote indication of the sign of the phase angle indication on some antenna monitors is difficult. Most antenna monitors output a positive voltage (typically 0 to 1.800 V for 0° to 180°), whether the sign of the phase is positive or negative. Some antenna monitors introduce a delay in the reference tower circuitry when a phase sign switch is pressed. This delay will cause an increase in the phase indication if the phase is positive (selected tower leads reference tower), or a decrease in the phase indication if the phase is negative. Although this switch could potentially be remote, it rarely is. Some antenna monitors use digital techniques (such as a D flip-flop) to detect the sign of the phase. While the phase sign is brought out for remote display (typically as a TTL level), the analog output for driving the remote control still outputs a positive voltage regardless of the phase sign. This phase sign logic level can be returned to the operator through a remote control status channel. The operator (or system software) can negate the phase indication, when appropriate.

Since it is rare to have the sign of a DA tower phase change (unless it is very near 0° or 180°), many stations wire the antenna monitor to the remote control such that the proper sign is indicated (reverse input leads to get a negative reading), if the remote control has a floating analog input. Others may merely note the sign of the phase for each tower in the operator instructions at the remote control point. Microprocessor based remote controls may use a negative calibration or scaling factor to cause a positive input voltage to display a negative value (corresponding to a negative phase).

Finally, note that most antenna monitors will require a *pattern select* control input. This input may change reference levels and/or reference towers. This input is typically driven by the antenna phasing equipment control system. This insures that the antenna monitor and the antenna system agree on the pattern.

PROBLEMS IN ANALOG SAMPLING INTERFACING

Although standards for interfacing transmitters and monitoring equipment exist (see IEC 60864), they are not widely used in the U.S. One cannot always connect the remote outputs of a transmitter directly to a remote control. A few typical problems and suggested solutions are listed here.

Sample Voltage Too High

To eliminate errors contributed by voltage dividers inside a remote control, many manufacturers run the sample voltage directly through an analog multiplexer into the A/D converter. Voltage limitations on the multiplexer and the A/D converter limit the maximum sample voltage the system will accept. Exceeding the multiplexer maximum voltage will often introduce leakage into other channels, making all readings appear to be out of calibration. Exceeding the A/D maximum input voltage will cause an erroneous reading on that channel (or an overrange indication) and may cause erroneous readings on other channels (due to A/D overload recovery time).

Some transmitters provide adjustable sample voltages. In this case, the sample voltage should be adjusted down to match the optimum input of the remote control.

Sometimes a voltage divider can be modified by adding an external resistor across the remote output of the transmitter, reducing the sample voltage. This will not be the case if the transmitter includes an isolation amplifier for the metering circuitry. The added shunt resistor should be of high quality with a low temperature coefficient of resistance (TCR).

The sample voltage output of the transmitter can be run through another voltage divider, reducing the sample down to the optimum for the remote control. Again, high quality, low TCR resistors should be used.

Sample Voltage Too Low

Too low a sample voltage will cause a lack of resolution in remote metering circuitry. Many systems will not allow calibration if the sample voltage is less than 100 times the A/D step size, since this would give a resolution of less than 1%. The only solution to low sample voltages is the addition of an amplifier between the sample and the remote control. This may be required on FM or TV power meters (reflectometers or directional couplers).

Some parameters are ideally zero (such as reference tower phase, three-phase line imbalance, or reflected power). The sample voltage for these parameters are also ideally zero, making it difficult to calibrate remote metering. If the antenna monitor has a *180° calibrate* button, this switch can be held while the remote control is being calibrated. The system is calibrated to the indicated 180°. When the calibrate button is released, the remote control should agree with the local meter.

A three-phase balance detector can be calibrated by purposely unbalancing the three-phase input. This is typically accomplished by disconnecting one input of the detector and grounding it (setting it at 0 V). The unbalance can be measured with a voltmeter. The remote metering can then be calibrated to agree with this indication.

The remote indication of a reflected power sample can be calibrated by calibrating it to the forward power. If the transmitter uses the same circuitry (same size power sampler) for forward and reflected power, the input of the remote control can be temporarily connected to the forward power sample. The remote metering is then calibrated to agree with the forward power indication. The remote control input is then reconnected to the proper point.

Some transmitters utilize rotatable *slugs* to sample the forward and reflected power. The reflected power slug can be rotated to measure forward power. If the reflected power slug is more sensitive than the forward power slug (full-scale reflected is less than full-scale forward), then the transmitter power should first be trimmed down to the maximum the reflected sampler can handle. If the transmitter includes VSWR shutdown circuitry, it will have to be disabled during this adjustment. Otherwise, the transmitter will immediately shut down.

Similarly, some transmitters have coaxial cables going out to external forward and reflected power samplers. These cables can be temporarily reversed, giving a high reflected power indication, allowing calibration. Again, VSWR shutdown circuitry would have to be disabled during this time.

Sample Voltage Differential, Remote Single Ended

Often a transmitter provides differential sample voltages while the remote control expects one side of a sample voltage to be grounded. There are various techniques for handling this. One solution (the historically typical approach) is to add a differential amplifier between the transmitter and the remote control. Another solution involves measuring each side of the differential voltage with respect to ground, then determining the differential voltage through calculation (either an operator calculation or a computer calculation).

Sample Voltage Not Linear

Generally, the sample voltage is the measured parameter multiplied by a constant. Sometimes it is the square root of the measured parameter (typically for power indicators). Other times it may be linearly related to the parameter, but offset (zero sample voltage does not correspond to zero parameter, often the case for temperature indicators).

In each case, the calculation required to convert the sample voltage back to the parameter can be done before the remote control, in the remote control or after the remote control. *Power-to-linear converters* can square the sample voltage so it linearly tracks the power. Differential amplifiers often include an offset control that can be used to subtract whatever may be necessary to make the sample voltage track the parameter properly. The remote control itself may contain calculation software to perform these calculations after the A/D conversion. Finally, the remote control may just indicate the sample voltage. The operator may use a calculator or a look-up table to determine the actual parameter.

STATUS SAMPLING

It is often desirable to remotely indicate the status of on/off indicators. Many transmitters utilize back lit push button switches for local control and status indication. The switch that corresponds to the current status is lit. For example, if there are a pair of switches marked *plate off* and *plate on*, pressing the *plate on* switch will cause the indicator in the *plate off* switch to extinguish, while the indicator in the *plate on* switch will be illuminated. This sort of indication is very user-friendly. An operator could determine that the plates had been turned on by looking at the plate voltage or current meter, but seeing that the button lit is a more intuitive indication that the desired action took place.

Other status indications that are often available at a transmitter site include filaments on/off, power high/low, stereo/mono, overload tally, RF switch settings (including DA pattern select relays, transmitter select relays, and combiner relays), STL carrier presence, STL selected, audio processor selected, fire alarm and burglar alarm. Each of these is an on/off indication. Many are isolated switch contact closures. Some are switch (or open collector transistor) closures to ground. Some are switch (or open collector) closures to some supply voltage. Most remote controls accept closures to ground. If the status input is open, the remote control pulls the status line to +5 V. This input design is generally used due to low cost. The inputs drive complementary metal oxide semiconductor (CMOS) or transistor transistor logic (TTL) inputs through input protection circuitry. If a transmitter status output is not compatible with the remote control status inputs, additional interface circuitry may be added. This circuitry may consist of relays or optical couplers, which provide complete isolation between the transmitter and the remote control. Resistor/transistor circuits or integrated circuits may also be used for *level translation*, converting the transmitter's status levels to levels appropriate for the remote control.

Finally, the transmitter status outputs can drive analog inputs to the remote control. These analog samples can be compared with a threshold (by the operator or system limit checking software) to determine whether the status is true or false. Use of analog inputs with appropriate software support allows *universal inputs* that can serve as either analog or status inputs. Note that a status input usually includes a *pull-up* resistor (so the input can detect a closure to ground), while analog inputs do not. A universal input system can provide a single pull-up after the analog multiplexer and enable or disable the pull-up under program control.

CONTROL OUTPUTS

Transmitter remote controls have traditionally provided momentary isolated relay contact closures for control. Two control outputs were provided for each analog input. These outputs were designated *raise* and *lower*. If the operator had analog channel 1 selected (perhaps plate voltage), pressing the *raise* button closed a pair of contacts that were wired to the plates on control input of the transmitter. The transmitter plates would go on, and the operator would see the plate voltage go up. Pressing *lower* while plate voltage was selected turned the plates off. If channel 2 were selected (perhaps plate current), *raise* and *lower* might change the transmitter between high and low power.

Use of momentary controls allows the remote control to be connected in parallel with the local control (transmitter front panel) while allowing control from both locations simultaneously. Latched control lines (non-momentary) would disallow control from more than one location.

Use of isolated relay contacts allows the remote control to drive a variety of control circuits. Older transmitters used 120 to 240 V ac to drive the control relays. Isolated relay contacts were suitable for driving these transmitters, though such transmitters did place hazardous voltages on the remote control. Some current transmitters are expecting the remote control to provide a momentary contact closure to some positive voltage (generally +12 or +28 V). Again, remote controls with isolated relay contacts can drive these directly. Many remote control systems provide open collector control outputs. This is generally a cost saving technique. A single integrated circuit may provide four, eight or even 32 open collector outputs. This compares quite favorably to one control output per relay. Further, open collector outputs that all switch to a common ground also allow a higher wiring density. Figure 4.7-10 shows the interconnection of a remote control open collector output to a transmitter control input. The diode across the relay coil clamps the control voltage when the transistor turns off, preventing the transistor from breaking down due to excessive voltage. A remote control may include clamp circuitry to protect the control output transistors.

If a transmitter uses high side control switching (expecting a closure to a positive voltage), it may be possible to reverse the power supply leads to the control interface portion of the transmitter, converting it to ground switching. This eliminates the need for repeat relays between a remote control with open collector outputs and the transmitter. If the control relays include clamp diodes across the coils, they will have to be reversed. Further, if the transmitter uses magnetic

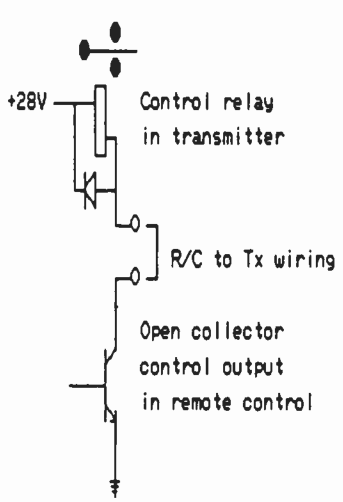

Figure 4.7-10. Open collector remote control output driving a transmitter control relay.

latching relays in the control circuit, their actions will probably reverse due to the change in current direction. Finally, at least one transmitter expects contact closures to ground, but interrupts the ground with the local/remote switch. If the remote control uses relay outputs to switch the control inputs to the switched ground of the transmitter, all works fine. However, if the remote control switches the control lines directly to ground (as an open collector output would), the remote/local switch is bypassed. This presents a safety problem to someone unfamiliar with the transmitter site. The remote control would still be able to turn on the transmitter, even though the local/remote switch was in local. It may be possible to move the wiring of the remote/local switch to the top of the control relay coils. The switch would then interrupt the positive supply to the relays when the switch was in local.

It would seem, from a remote control manufacturer's point of view, that all control and status should rely upon closures to ground via mechanical contacts or open collector (or drain) transistors. However, transmitter manufacturers point to safety advantages in using high side switching in control circuits. It is, as they point out, far less likely for a control wire to accidentally short to +24 V than it is for that wire to short to ground, possibly activating a transmitter. Further the standard IEC 60864 requires control outputs to be "earth free." (See the section on IEC 60864.)

Control Interface Panel

In all but the simplest transmitter sites, it is common to have a relay interface panel between the remote control and the various pieces of transmitter site equipment. Besides any repeat relays that may be required to convert from open collector drive to whatever the transmitters may require, such a relay interface panel will generally use relay ladder logic to interlock various transmitter site functions. Such an interface panel may handle the sequencing of RF switches in transmitter or DA switching, and ensure that a transmitter drives a load before it can be enabled and that dummy load cooling is on before power is sent to a dummy load.

In the design of a transmitter site, there is an interesting division of responsibility problem. Various portions of the site control and monitoring can be assigned to the remote control, control interface or the transmitter. It has been common practice to have a transmitter accept control pulses and report its current status back to external equipment. Many transmitters now include an automatic power control, which moves some of the control into the transmitter. Some other transmitters have moved much or all of what has typically been considered a remote control's job into the transmitter itself. In most stations, however, there is a fair amount of decision making required outside the transmitter. A fairly common decision problem is the RF sequencing of an AM station pattern change. Similar sequences are required for transmitter changes in other AM stations, FM stations and TV stations.

AM Pattern Change Sequencing

Many stations have used time delay sequencing circuitry to do a pattern change while insuring the RF relays did a *cold switch* (switching while no RF present). A typical sequence might be:

1. Drop transmitter carrier.
2. Wait one second.
3. Switch RF relays.
4. Wait one second.
5. Bring up transmitter carrier.

There is another approach that results in faster pattern changes and ensures the station will not come back up if all the RF relays do not operate properly. This interlocking of DA RF relays was an FCC requirement (under the operator requirement rules) when the FCC first reduced operator requirements for DA stations to less than a First Class Radiotelephone Operator. The interlocking rule has been deleted, but is still good practice (ensuring against operation with other than the desired pattern, and protecting equipment from excessive currents or voltages should a relay stick). An interlocking and sequencing system can be easily setup using relay ladder logic in a remote control interface panel. In relay ladder logic, logical *and* gates are formed by wiring relay contacts in series, while logical *or* gates are formed by wiring relay contacts in parallel. It is also fairly common to form *or* gates using diodes in combination with the relays, reducing the number of contacts a relay may require. The logic for a typical DA pattern change is listed below.

```
IF NightSelected AND OnDayPattern AND PlatesOn
THEN CommandPlatesOff
IF NightSelected AND OnDayPattern AND PlatesOff
THEN RFSwitchToNight
IF NightSelected AND OnNightPattern AND PlatesOff
THEN CommandPlatesOn
```

This represents three series strings of relay contacts.

NightSelected is the pattern change command from the operator. OnDayPattern and OnNightPattern represent the current condition of all the RF relays. Neither will be true during the switch (as the relays change the system configuration). The PlatesOn and PlatesOff status lines correspond to the transmitter's state. Actually, operators are interested in whether there is any RF in the system. An interface panel may use an RF sample from the final amplifier of the transmitter (often a modulation monitor tap) to drive a relay that indicates whether RF is present or not.

Some AM transmitters have a very fast carrier interrupt input. This on/off input drives the modulator to 100% (envelope voltage zero) in pulse duration, digital and series modulated transmitters. On receiving a carrier drop command, the transmitter drops the carrier in 100 μsec or less. Since it takes substantially longer than this for an RF relay to open a contact, the carrier drop and relay drive signals can be supplied simultaneously.

The carrier interrupt input on some pulse duration modulated transmitters expects a floating short (in a switched +28 V dc line) to keep the carrier up, and an open to drop the carrier. This can be driven with floating relay contacts. In many cases, a resistor (10 kΩ typical) may be added across the carrier interrupt terminals. The carrier drop circuit input (the side of the resistor that is driven by the +28 V, not the side that provides the voltage) may be grounded with a relay contact or an open collector driver to interrupt the carrier.

Finally, in the design of the control system for AM directional stations, it is suggested that the relay interface panel send low voltage dc (typically 24 V) to repeat relays in the tuning units at the base of each tower. Standard 25 pair telephone cable can be looped past each tower. This cable carries these low voltage control signals. It also carries the status of each RF contactor in each antenna coupling unit. The cable can also be used to send sample voltages for RF base currents, tower light sample currents and to provide a telephone at the base of each tower. The pattern change repeat relays switch the coil voltage to the RF contactors. The contactors can be powered by the same wiring used to drive any tower lights, reducing the requirements for heavy wiring. It is suggested that the contactors be run on the highest voltage available (typically 208 or 240 V), reducing the current requirements and the resulting voltage drop in the power wiring.

IEC 60864

This standard (available from the International Electrotechnical Commission at http://www.iec.ch) covers the *Standardization of Interconnection between Broadcasting Transmitters or Transmitter Systems and Supervisory Equipment.* The standard is broken into two parts—part 1 covers *dedicated interconnections* (similar to that discussed above), and part 2 discusses a data bus for interconnecting equipment.

With this standard, a transmitter supervisor box is driving a system logic unit that actually drives the transmitters and changeover relays. The *transmitter supervisory equipment* would be a remote control, while the *system logic unit* could be a relay interface panel. Part 2 of the standard puts a bit more intelligence in the system logic unit than can be accomplished with relays.

Even though part 1 of the standard was adopted in 1986, it is not widely used in the U.S. The standard allows the use of relays, semiconductors or optocouplers for the control or status (binary) interface. When a relay interface is used, commands may be presented as momentary (100 to 500 ms) closures or continuous closures (latched). Indications (status) lines are to remain activated as long as the status is true. The standard states that the circuits shall be *earth free* (ungrounded) and may be independent pairs or utilize a common return wire (which, again, must not be grounded). These circuits utilize a nominal open circuit voltage of 24 V dc and have a maximum operating current of 25 mA.

When semiconductor or optocoupler techniques are used, the output device (whether a control system command output or a transmitter status output) must be *earth free*, handle a nominal 24 VDC open circuit voltage and a nominal 8 mA closed circuit current (with a maximum voltage drop of 3 V). The circuitry must withstand the transient of a 33 μF capacitor charged to 250 V being discharged into the circuit.

For analog samples (though analog signals *may* be used for control as well as telemetry), sample voltages are specified as being 0 V to +10 V. The minimum load resistance is to be 1 kΩ. The maximum source resistance is to be 100 Ω. The maximum positive or negative common mode voltage is to be 25 V. The standard also requires analog interface terminals to be *earth free*, requiring the use of isolation amplifiers. Analog wiring between supervisory equipment and the transmitters is to be done with shielded pair cables.

The standard also allows for a current loop analog interface. This interface is standard in industrial control, but is rarely used in the U.S. broadcast industry. With this standard, an indication of zero is represented by a current of 4 mA. Full-scale is represented by a current of 20 mA. A current sensor is allowed to have a maximum resistance of 1 kΩ. The current generator is to have a high resistance making the loop current independent of load resistances.

Part 2 of the standard (adopted in 1997) establishes a digital interface standard between supervisory equipment and a *system logic unit.* The system logic unit provides the actual hardware interface to multiple transmitters at the site using discrete wire techniques (as specified in part 1 of the standard). The digital interface is based on the IEEE 1118 *bit bus* standard with the IEC 8482 electrical specifications. The standard provides for a wide variety of digital codes for commands, telemetry and status messages.

As mentioned previously, this standard is not widely used in the U.S. Earth free requirements increase system costs (due to the additional cost of relays and isolation amplifiers) and decreases system wiring density. As the industry becomes more international, this equipment will probably be introduced to the U.S.

REMOTE CONTROL HARDWARE DESIGN

The basic purpose of a transmitter remote control system is to extend the transmitter metering and control from the transmitter site to the operator. This may be accomplished by running a pair of wires for each meter and another for each control. This is the technique used in extension metering. It can be used in remote control also, but it is generally more economical to combine several functions onto a single pair of wires. The basic transmitter site remote control unit multiplexes the metering, status, and control signals onto a single communications circuit. This circuit may be a dc circuit, voice grade circuit or digital circuit.

A dc circuit is a pair of wires that has dc continuity from one end to the other (a *metallic pair*). Direct current and low frequency ac (typically to 3 kHz) may be sent through these circuits. Early broadcast remote controls used two dc circuits one for control and the other for metering. The metering sample selected by the operator is put directly on the metering pair. A current or voltage meter at the control point displayed the transmitter parameter. The various control functions could be sent over a single control pair by feeding various levels and polarities of voltages between the control conductors, or between each conductor and ground.

Later single pair remote control systems utilized audible tones for control and continued to use dc for metering. This allowed both signals to be on the same pair of wires using a form of frequency division multiplexing.

Voice grade circuits typically pass a 300 Hz to 3 kHz band of frequencies. Voice grade circuits are available over a very wide range of media including telephone lines, radio links, subcarriers on microwave, broadcast and satellite systems. Most broadcast remote control equipment is designed to work over voice grade circuits, since they are so widely available. Many signaling techniques are available using voice grade circuits.

Digital circuits are circuits that present a digital interface to the customer provided equipment, at each end of the circuit. Between the customer terminations, the circuit may have taken any of several forms. It may have been run through modems, converting the data for transmission over a voice grade circuit. It may have been combined with other digital data into a high speed data stream for transmission over microwave, satellite, or fiber optic cable. At the other end of the high speed medium, the data are split off to each customer. A remote control must combine the various control and telemetry signals, then encode them in a manner suitable for transmission over the medium available.

Analog Multiplexing

Since several sample voltages are generally sent over one available circuit, a switch is used to select the sample voltages, one at a time, for transmission to the control point. In many remote control systems, this switch is under the direct control of the operator. When the operator selects a metering channel, the switch at the transmitter site selects the appropriate sample and sends the result to the control point for display. These systems may be thought of as a voltmeter with very long leads. Just as a technician moves voltmeter probes from point to point in a circuit to get an overview of circuit operation, a transmitter operator remotely selects which sample to monitor. Early remote control systems used the electromechanical stepper switch from the telephone industry to select among the metering samples. The step pulses for the stepper were generated with a mechanical telephone dial. More recent remote controls use individual mechanical relays (reed relays or other relays designed for dry switching) for analog multiplexing. The most recent remote control designs use integrated circuit multiplexers for analog multiplexing. These circuits act like a mechanical rotary switch. A typical multiplexer may accept three address inputs to determine which one of eight inputs will be connected to the output. The IC multiplexers cost less than relays, are faster, do not have a cycle limit, and take less space. They do, however, have a higher leakage current than relays and do not tolerate voltages higher than the supply voltage. If the voltage on an input is higher than the supply voltage, stray currents will generally develop in the circuit, causing erroneous readings on all inputs. With appropriate precautions, however, integrated circuit multiplexing is well suited to the job.

Telemetry Encoding

Once the analog multiplexer has selected a sample for transmission to the control point, it is necessary to encode the data into a form suitable for the communications medium involved. If the circuit has dc continuity, the output of the multiplexer can be applied directly to the circuit. If the circuit does not have dc continuity, further encoding is necessary.

Analog FM Encoding of Telemetry

A low cost method of converting a dc sample voltage to a form suitable for transmission over a voice grade or other ac circuit (such as subcarrier) is to use the sample voltage to drive a voltage-to-frequency converter (V/F) or frequency modulated oscillator. A block diagram for a system using this technique is shown in Figure 4.7-11. A zero sample voltage results in one frequency, full-scale results in another. A half-scale sample results in a frequency halfway between the two. One such system utilizes 800 Hz for zero sample voltage and 1200 Hz for full-scale. This is suitable for transmission over any voice grade circuit. A similar scheme uses 20 Hz to 30 Hz to transmit analog metering below program audio on AM stations or subcarriers. This system can also be used to generate higher frequencies for use as subcarriers. It is more common, however, to use the audible or subaudible metering as input to a subcarrier generator. This may result in FM (the remote control V/F converter) on FM (the subcarrier generator) on FM (an FM broadcast or TV aural transmitter). This approach is used because of the common voice grade interface.

At the control point, an F/V converter (or FM demodulator) develops a dc voltage that corresponds to the sample voltage. This voltage drives the meter or display at the control point. Accuracy of these systems is limited by the tracking between the V/F and F/V converters. Typical errors include zero drift, gain drift, and nonlinearity. The zero and gain errors can he minimized by frequently adjusting the F/V converter offset and gain while driving the V/F with zero and full scale samples.

Calibration of these systems typically involves a transmitter technician using the telephone to call the operator at the remote control point. The transmitter

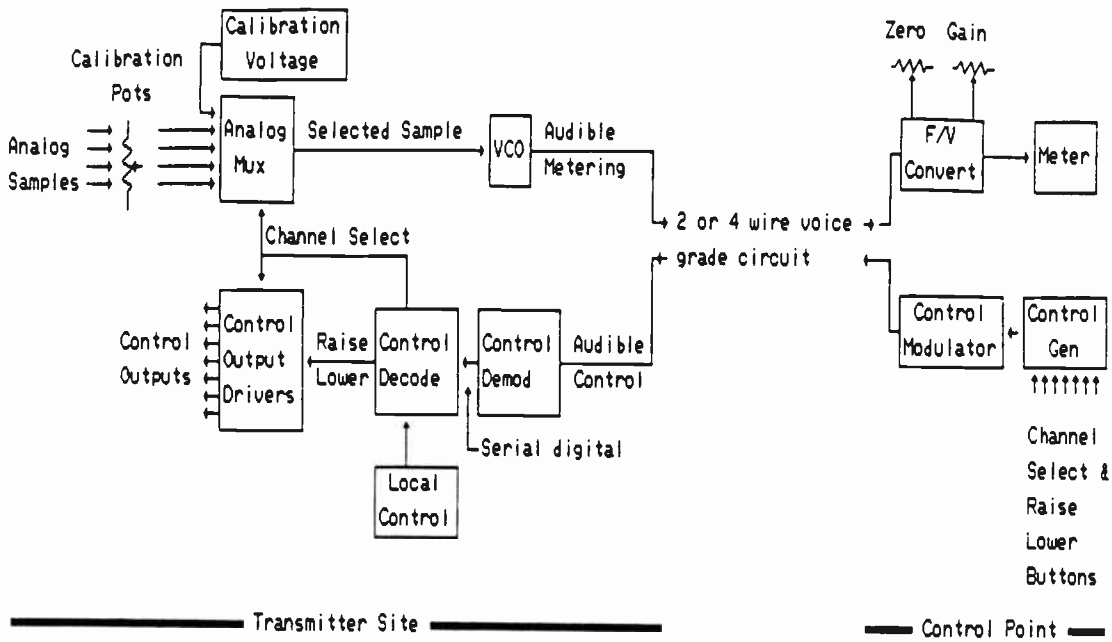

Figure 4.7-11. Typical analog remote control block diagram.

technician then adjusts calibration controls at the transmitter site until the operator at the control point says the reading matches the reading at the transmitter site.

A/D with FSK Transmission

Another method of transmitting the analog sample voltage to the control point consists of splitting a digital voltmeter into two parts (see Figure 4.7-12). The A/D converter is put at the transmitter site, and the display is put at the control point. This typically involves adding some data formatting circuitry to the output of the A/D converter and driving the transmit side of a universal asynchronous receiver transmitter (UART). The serial data out of the UART drives the transmit side of a modem. This modem typically uses frequency shift keying at 300 to 1,200 bps. The digital output of the A/D also drives a local display, allowing calibration at the transmitter site.

At the control point, the incoming audible FSK data is demodulated back to the original serial digital form. The serial digital data then drives the receive portion of a UART. The parallel output of the UART then drives data decoding and display circuitry. Since digital coding was used in transmitting the output of the A/D to the control point, the control point display will indicate the same as the transmitter site display. If there is an error in the received digital data (which is generally detected by a parity check on each byte received), the display is blanked and an error lamp is lit.

Control Encoding

As mentioned previously, if dc circuits are available, pulses of loop current or voltage may be used to send control to the transmitter site. Many recent systems use some form of tone encoding.

Frequency Shift Keyed Control

The ready availability of voice grade circuits has encouraged the design of systems utilizing audio tones for the transmission of control signals. The most common technique is the use of frequency shift keying (FSK), the same technique described in the A/D with FSK section. Early systems utilized a telephone dial or integrated circuits emulating a telephone dial to generate a string of pulses. The number of pulses in the string determined what channel was selected. More recent systems utilize binary coding. Since a UART normally sends eight data bits, six could be allocated to channel select, and two to control (one raise, one lower). This allows a simple 64 channel system to be built (since six bits can code decimal numbers 0 to 63). Since an error in a control byte transmitted can have serious consequences (turning transmitters on and off), many systems send the data at least twice and only accept it as error-free if the two transmissions agree.

Typical Nonprocessor-Based Design

Figure 4.7-11 shows the design of a typical analog remote control system. Digital circuitry is used to encode operator instructions through the channel select and raise/lower buttons. The serialized control data is sent to an FSK oscillator (the control modulator). This generates an audio tone at 400 Hz for one digital input level and 300 Hz for the other digital input level.

This audio control signal may be applied directly to a two-wire or four-wire telephone line (or other

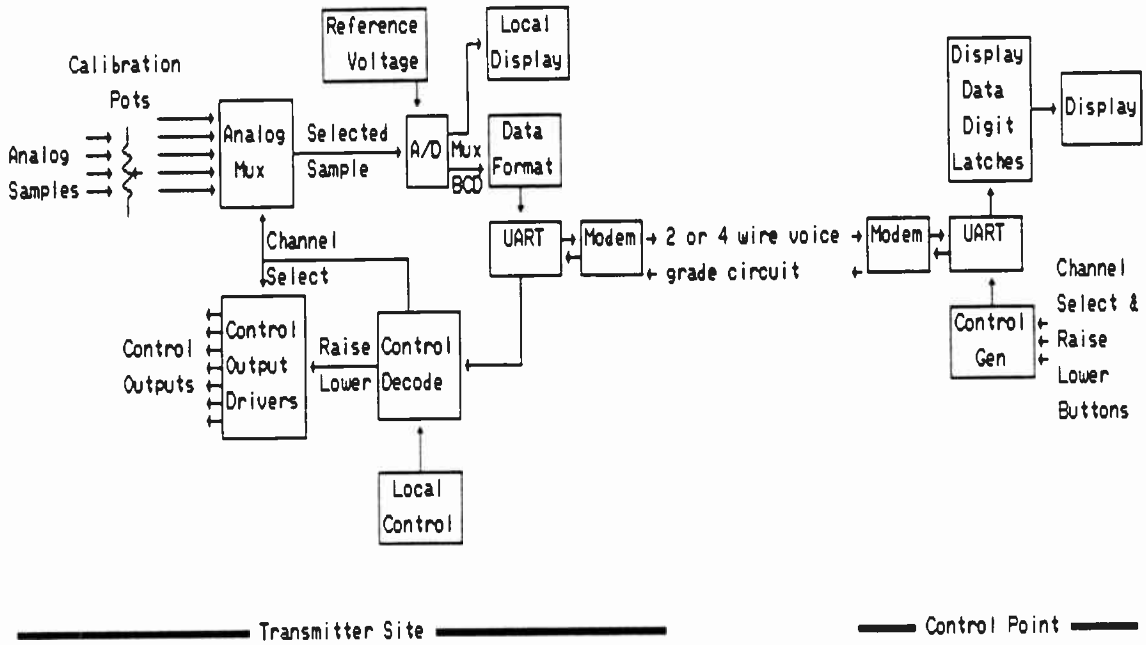

Figure 4.7-12. Typical digital remote control without processor.

audio circuit). It may also be further modulated onto a subcarrier for carriage above programming on an STL transmitter.

At the transmitter site, the FSK audio is demodulated back to the original serial control data stream. This drives the control decode circuitry, which determines which channel the operator selected and whether a raise or lower button was pushed. The channel number is sent to the analog multiplexer (which may be relays or an integrated circuit analog multiplexer) and the control output drivers (which may be transistors, integrated circuit output drivers, or relays). When a channel is selected and a raise or lower button is pressed, the selected channel control line is enabled.

Sample voltages from transmitters and other site equipment are scaled (multiplied by a constant) by *calibration pots*. During system calibration, these are adjusted so the control point meter reads the same as the meters at the transmitter site. The outputs of the calibration pots drive the analog multiplexer. This sends the sample voltage selected by the operator to the voltage controlled oscillator (VCO). Note that a calibration voltage is also shown. Such systems will typically allocate one or two channels of the analog multiplexer to a zero and full-scale (occasionally half-scale) voltage. These reference voltages allow the operator at the control point to adjust the F/V converter offset (zero) and gain controls to compensate for drift in the VCO and F/V.

The output of the analog multiplexer drives a VCO. The VCO will typically generate 800 Hz for a zero reading and 1,200 Hz for full-scale. If subaudible metering is used, 20 Hz represents zero and 30 Hz full-scale. The 800 Hz–1200 Hz metering frequency range is well separated from the 300 Hz–400 Hz control frequency range, allowing both signals to be put on a single two wire telephone line, yet be easily separated at each end using filters. This combining of two signals onto a single circuit by using different frequencies is a form of frequency division multiplexing.

Finally, the 800 Hz–1,200 Hz metering signal gets back to the F/V converter at the control point. The dc output voltage (proportional to the deviation from the nominal frequency) drives a front panel meter, which the operator reads. By selecting each channel and noting the meter indication, the operator can monitor several transmitter site parameters. Further, by selecting a channel and using the raise and lower controls, various transmitter site controls may be activated.

Nonprocessor Digital Remote Control

Figure 4.7-12 shows the design of a typical digital remote control that does not use a microprocessor. It is quite similar to the analog system described previously.

The calibration pots, analog multiplexer and control output drivers are the same as the analog system. The digital system does not, however, require calibration voltages to be sent to the analog multiplexer. The A/D converter typically accepts a reference voltage (its output is the ratio of the unknown voltage to the reference voltage). The A/D automatically calibrates and zeroes itself during each conversion.

The output of the A/D in most such systems is multiplexed *binary coded decimal* (BCD). The decimal code for each digit is represented as a 4 bit number on four wires. The code for each digit is multiplexed onto these same four wires. Digit select lines out of the A/D tell the outside circuitry which digit's data is present at any particular time. This data may be latched and decoded to drive LCD or LED displays. It may also be merely decoded (not latched) to drive multiplexed LED displays. The output of the A/D drives a display at the transmitter site, allowing the calibration pots to be adjusted at the transmitter site, since the transmitter site display will exactly track the control point display.

The output of the A/D also drives data formatting circuitry which converts the multiplexed BCD to something suitable for the UART. The transmit side of the UART accepts up to 8 bits of parallel data and a strobe pulse. It then serially sends the data bits (along with some synchronizing bits). Typical data formatting circuitry selectively gates the digit select outputs of the A/D to the transmit strobe input of the UART, causing each digit of BCD data to be transmitted. The multiplexed BCD is connected directly to four input lines of the UART. The digit select gating allows the A/D data to be sent to the UART without latching the multiplexed BCD data out to parallel BCD (which would take lots of parts). Typically, a couple more bits of the UART are used to transmit a *digit identification code,* corresponding to the digit being transmitted. At the receive end, the digit identification code is used to route the incoming BCD data to the proper digit of the display.

The output of the UART is serial digital data. This data is sent to a modem for transmission over a voice grade circuit. Often, Bell 103 modem tones are used. These modem tones allow the transmission of 300 bps in each direction over a single two wire voice grade circuit (again, using frequency division multiplexing). Bell 103 uses FSK with 1,270 Hz representing a 1 and 1,070 Hz representing a 0 in one direction. Data going the other direction uses 2,225 Hz for 1, 2025 Hz for 0.

The audible metering data is received by the modem at the control point. It is converted back to serial digital data by the receive side of the modem. The UART changes the serial digital data back to the original parallel form (up to 8 data bits plus a strobe). If the previously described encoding scheme was used (4 bits of BCD, 2 bits of digit select), the digit select code bits may be used to drive a demultiplexer integrated circuit. This *demux* routes the receive data strobe from the UART to the clock input of a latched display driver for each digit. The latched display drivers for each digit are being fed the received BCD data from the UART, but only capture the data for the appropriate digit when the strobe for that digit is presented.

In a similar manner, front panel controls may be sent to the transmit side of the UART, where the data is serialized for transmission to the transmitter site. The transmit side of the control point modem converts the data to a form suitable for transmission over a voice grade circuit. At the transmitter site, the receive side of the modem converts the control data back to the original serial digital form. The receive side of the UART converts the control data back to the original parallel form.

Microprocessor Based Remote Control

Each of the techniques described so far has used standard nonprogramable integrated circuits to build a system dedicated to transmitter control. Each system was a digital voltmeter with a remote input select switch and display

Microprocessors greatly enhanced the capabilities of transmitter remote control systems. In microprocessor based systems the basic components of the remote control remain the same. There is still an analog multiplexer, an A/D converter and a modem. Instead of being connected in a manner fixed in hardware, they are all connected as input/output (I/O) devices on a computer bus. The computer processor then addresses each of these devices, telling them what to do and picking up data. The complexity of the system is moved from hardware to software. The use of computer techniques allows features to be added to the system at very low production cost (as compared to providing the same features with dedicated hardware).

Figure 4.7-13 shows a block diagram of a rather large microprocessor based remote control transmitter site unit. Most systems will not contain all of these elements, but processor based systems can be designed to allow for substantial expansion.

Processor

The *processor* executes a computer program. It reads instructions and data from the system memory. It can read data from input ports and write data to output ports (commonly combined into I/O ports). It can make calculations and decisions based on those calculations. It can also write the results of calculations back out to memory or I/O.

The processor has three buses to communicate with the rest of the system—the *control bus, address bus* and *data bus.* In simple systems (such as a typical remote control), the address bus is driven only by the processor. The processor uses this bus to tell memory and I/O devices what location is to be read or written. In transmitter remote control equipment, the address bus is normally between 11 and 20 bits wide.

The data bus is a bidirectional bus. It is driven by the processor when the processor is writing (sending) data to a memory location or an I/O device. It is driven by the memory or I/O device when the processor is reading data. The data bus in transmitter remote control equipment is generally 8 or 16 bits wide. The processor uses the address bus and the control bus to tell other devices on the data bus whether data is for that particular device, and where in that device the data is supposed to go or be read from.

The control bus varies between different processor types. In Motorola style processors, a +read/−write line has the same timing as the address lines. It is high during a processor read and low during a processor write. These processors then have a common (between read and write) strobe line (called E or phase 2). This

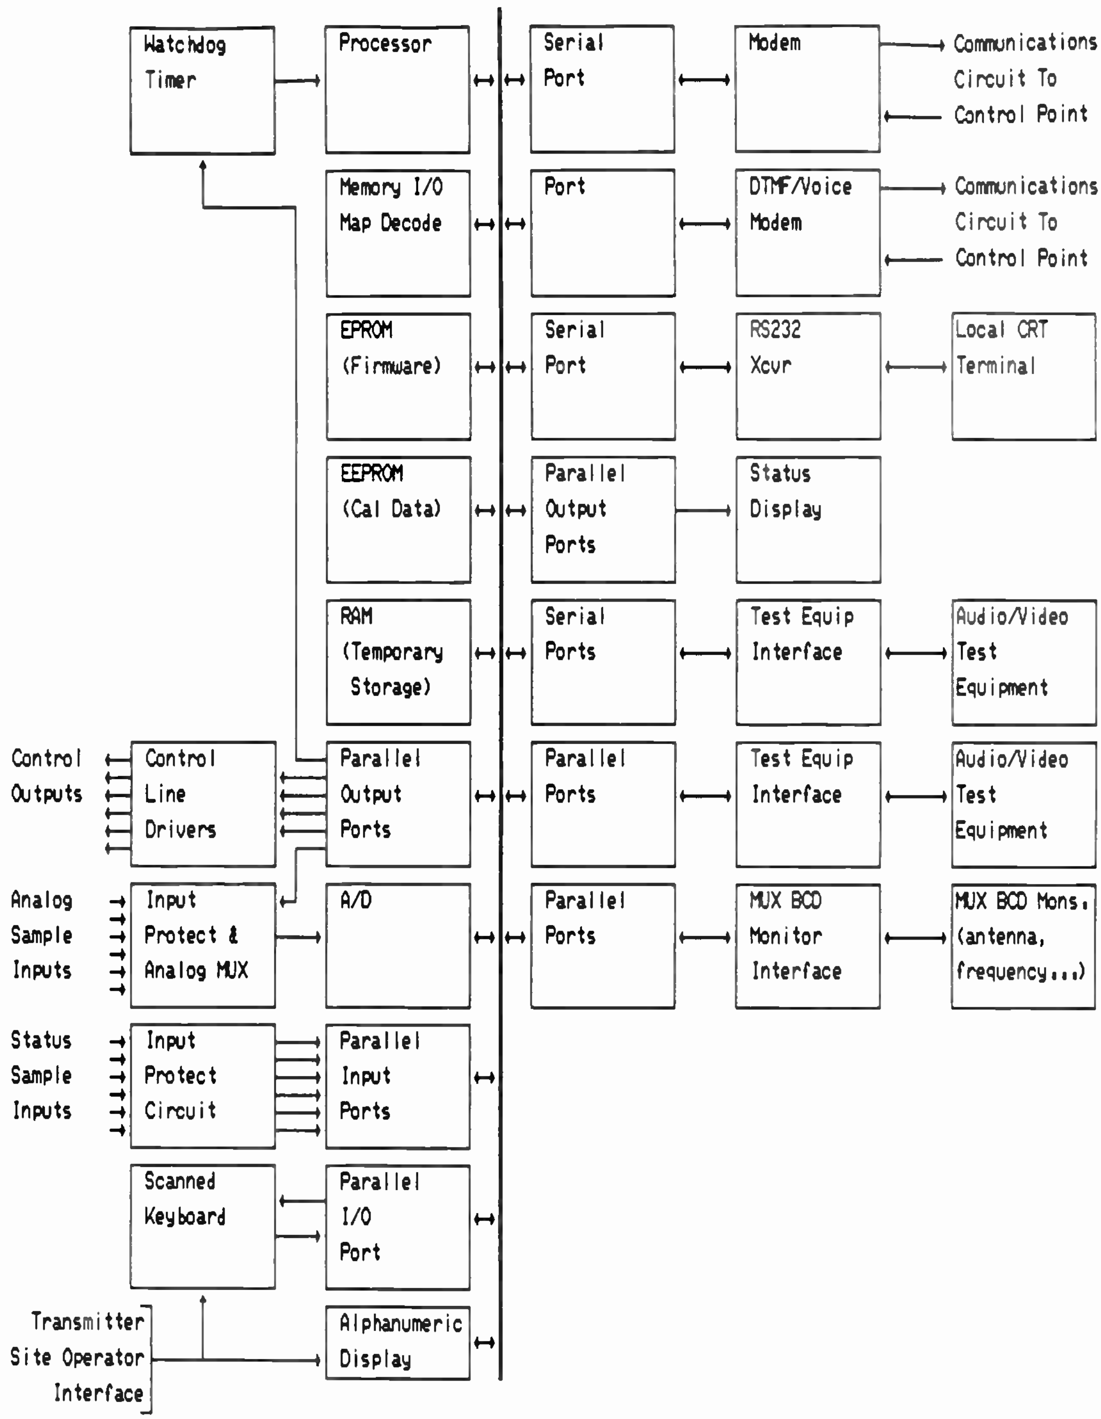

Figure 4.7-13. Transmitter site unit of microprocessor-based remote control.

line goes high during a read or write. Data is enabled on the leading edge of the strobe and latched and disabled on the trailing edge. Intel style processors use two separate strobes, one for read and one for write. These have about the same timing as the common strobe in Motorola style processors.

Another variation in the control buses deals with how I/O devices are handled. Motorola style processors have no I/O instructions. Instead, memory instructions are used for I/O. If the address that data is sent to has an I/O device instead of a memory device, the data is output. The processor does not know where the data is sent. It just puts an address on the address bus, puts the data on the data bus, then strobes the enable line. What device (if any) picks up the data is not important to the processor. Similarly, the processor can read data from either memory or I/O. Motorola style processors use the same instructions for both. This is called *memory mapped I/O.*

Intel style processors have a *separate I/O map*. Separate I/O instructions setup the address bus and put data on the data bus, just as memory write instructions. However, an I/O write strobes the I/O write strobe instead of the memory write strobe, allowing I/O data to go to the I/O device instead of a memory device, which may be at the same address. Systems based on Intel style processors may also use memory mapped I/O.

The other main control bus lines are the *interrupt lines*. When an I/O device enables an interrupt line, the processor stores away its current state, then executes an *interrupt service routine* (ISR). The number of interrupt lines varies from processor to processor. When a particular interrupt line is enabled, the processor vectors to a particular address to find the ISR for that device. Several I/O devices may share the same interrupt line. When this is the case, the ISR polls each device using that interrupt line to determine which one generated the interrupt. On completion of the ISR, the processor executes a *return from interrupt* instruction, which restores the processor state to what it was prior to the interrupt. The main program continues on as though nothing happened. Interrupts are commonly used to allow a processor to appear to multitask.

Watchdog Timer

Occasionally, something will go wrong in a computer system. When this occurs, the processor must be reset. The reset loads the program counter (or instruction pointer) with the beginning address of the system program, allowing it to start over. System programs typically include an instruction to set a bit of an output port high at one point in the program, then set it low at another point. If this fails to occur within some time period, the *watchdog timer* times out resetting the system. This ensures that a system crash will not disable the system.

Memory-I/O Map Decode

This portion of the remote control may be done in one chip, or may be spread over several chips. The map decoder recognizes when particular addresses are present on the address bus, then generates a *chip select* for the device that is to be selected.

Erasable Programmable Read Only Memory

The *erasable programmable read only memory* (EPROM) holds the program the system executes when the power is first applied. Depending upon the system, this may be the only program the system ever executes. Some systems may hold additional software in EEPROM or RAM. The program that tells the system how to be a remote broadcast transmitter controller (instead of, say, a microwave oven controller) is held in this EPROM. The program is just a series of binary numbers. Under direction of the processor, the EPROM puts the contents of its various memory locations (more than 1,000,000 8 bit locations are available in today's EPROMS) on the processor bus. The processor reads these instructions, then executes them.

The program in the EPROM is often called *firmware*. The firmware may be written in one or more of several computer languages. In each case, a program (either an assembler or a compiler) converts the program into a series of binary numbers. These binary numbers are programmed into the system EPROM. The processor reads the program from the EPROM and executes the program.

Electrically Erasable Programmable Read Only Memory

Most systems now include *electrically erasable programmable read only* memory (EEPROM) or battery backed RAM to hold system setup information. Some systems may also run firmware from EEPROM, allowing field upgrade of the firmware without opening the box. Such upgrades can be accomplished by downloading from an external computer, an internal floppy drive or through the dial-up modem.

EEPROM is similar to EPROM in that it is nonvolatile (it retains the stored data when power is lost). It is similar to RAM since it can be reprogrammed in circuit (EPROM is typically removed from the circuit, erased with ultraviolet light, reprogrammed, then put back in the circuit). Most recent EEPROMs use the same bus interface as static RAMs, easing system design considerably. EEPROMs can be written to, the same as RAM, except that a time delay of 1 msec to 10 msec is required before another read or write to the chip. The system firmware must take the EEPROM write delay into account (it cannot stuff calibration data into the chip at a typical processor speed of a byte per microsecond or faster).

The ease of programmability of system EEPROM has its drawbacks. If there is a processor crash, it is easy for the processor to write garbage into the EEPROM, causing loss of calibration data. Most systems, therefore, include extra write protect hardware for the EEPROM. This hardware typically consists of an output port that drives gating circuitry for the write to the EEPROM. Prior to writing data to the EEPROM, the processor must write a specific code to the write protect port. After the data has been sent to the EEPROM, the processor writes another code to the write protect port, disabling further write strobes from reaching the EEPROM. It is unlikely that a crashed processor would write the proper code to the write protect port, thus protecting the EEPROM data until a watchdog timeout resets the system. The only other limitation on EEPROM is the limited number of write cycles. Each byte of EEPROM may typically be written 10,000 to 100,000 times. Since calibration and setup of transmitter control systems is typically done no more than once a week, this limitation is generally not serious.

Some systems use battery backed CMOS RAM to hold system calibration data. This has several advantages over EEPROM. The RAM can operate at full processor speed (writes at more than one byte per microsecond) and there is no limit on the number of write cycles. The RAM is normally battery backed with a lithium battery, which has an expected shelf life of ten years. The addition of the battery and other power switching circuitry makes the system design more complex, though some companies sell battery backed RAM subsystems (the memory, battery and all support circuitry contained in a standard 24 pin package, the same package used by RAM or EEPROM). One battery backed RAM subsystem also includes a battery backed real time clock and all associated circuitry, again in the 24 pin package. Use of this chip further simplifies system design, when a real time clock is required. The battery backed RAM suffers the same too easy to write problem as EEPROM. Many systems, therefore, include write protect circuitry for the battery backed RAM.

The use of nonvolatile memory for system calibration and setup has vastly increased the capabilities of transmitter control systems. A calibration pot may be replaced with 4 bytes of EEPROM. A single byte of EEPROM can replace 8 DIP switches.

EEPROMS (or battery backed RAM) in transmitter control systems typically include 2 kB to 32 kB of nonvolatile memory (where 1 kB is 1,024 bytes). The data included in the nonvolatile memory may include the following for each analog channel:

- A scaling factor, replacing the calibration pot and decimal point positioning logic.
- An alphanumeric label identifying the parameter (such as ICP for common point current).
- An alphanumeric units identifier (such as kV for kiloV).
- A curve or formula identifier (such as linear or square law).
- A *sample delay* to allow for the settling time of external monitoring equipment (such as AM antenna monitors).
- Alarm and action limits on the parameter.
- Alarm and action codes for each limit. These may adjust transmitter power on one set of limits and alarm on another set of limits.

For each status input:

- Active high or low (light indicator when input high or low).
- Latch or momentary. It may be desirable to have some status indicators remain on even after the status input has gone back to the false state. The status indicators are then reset by operator command.
- Status change alarm or action code. A status change may cause some control command to be issued or enable an audible alarm.

Other site specific data:

- Communications parameters for intersite communications (typically between the transmitter and the transmitter control point).
- Site identification number. Many systems use the same firmware in control point and transmitter site equipment. The site identification number tells the processor which portions of the firmware apply to this site. This site number is also used to recognize messages intended for this site in multisite systems.
- In multisite systems, site intercommunication data such as site access slot timing, highest site number, and site message routing tables. Communications parameters for any other serial devices (such as CRT terminals, test equipment, video monitors, etc.).
- Coding for interface to specific monitors at the site (such as those connected to the remote control through RS232 or other serial links, IEEE488 or other parallel links, and multiplexed BCD).
- Time specific data, such as generating control pulses at specific times (perhaps AM pattern change), or changing limit tables based on time (different limits used day or night).

The variety of data held in the system nonvolatile memory is limited only by the system firmware. The use of specific locations can be changed through system firmware updates (EPROM swaps), allowing features to be added later with no hardware changes. Finally, the packages and pinouts for all byte-wide memory devices have been standardized. This allows more memory to be added to the system (through addition of chips or the substitution of larger chips in the same sockets) or the memory balance (between EPROM, RAM, and nonvolatile memory) to be adjusted as the system design advances. This is a vast improvement over calibration pots and DIP switches!

Random Access Memory

Random access memory (RAM) is used for temporary storage in the processor based system. The two major RAM types are *static* and *dynamic*. Static memory remembers data as long as the power is applied. Dynamic memory remembers data for about 2 msec. After 2 msec, dynamic memory must be refreshed. Due to the simplicity of design of systems utilizing static memory, it is commonly used where 64 kB of RAM or less is required. In larger systems, the added expense of refresh circuitry is offset by the lower cost of dynamic RAM.

The processor uses RAM to hold *return addresses* so it can find its way back after a subroutine call or interrupt. RAM is also used to form buffers for I/O devices. With appropriate firmware, the system can send large blocks of data (such as a full screen of characters) to a *device driver*. This firmware then holds the data in RAM and sends it to the output device (such as a serial port or modem) one byte at a time, as the port is ready to receive more data.

RAM buffers may also be used in receiving data from an input port. This allows more flexibility in the system firmware, since it need not continuously poll a specific input device. Without an input buffer or continuous polling, some input data could be lost (the firmware may be dealing with the A/D converter when data arrives from the modem, causing modem data to be lost). The RAM input buffer holds received data until the main firmware is ready to deal with it. Another RAM input buffer is used with the communications port that receives data from the control point.

To ensure data is received error-free, it is typically sent in *packets*. Each packet of data includes error detecting data at the end of the packet. The packet cannot be dealt with until the entire packet is received. The RAM buffer holds received packets until they are complete. The system firmware then determines if the packet is error-free. If so, the packet may be acknowledged (depending on system design) and passed on to other sites or firmware at this site. If a packet has an error, a negative acknowledgement is typically passed back to the originating site.

The amazing flexibility of processor based systems is again evident in the uses of system RAM. All of these uses (and more) may reside in the same chip. The allocation of that memory may change under program control and with system firmware upgrades (EPROM swap). In a pure hardware (nonprogrammed) system, each buffer would probably be implemented using another chip, considerably adding to hardware complexity.

Parallel Output Ports

A parallel output port may consist of an 8 bit latch. When the processor does a write to the appropriate address, the memory I/O map decoder clocks the latch, causing it to capture the data then on the data bus. This data is held until the processor does another write to the same address. As can be seen from Figure 4.7-13, parallel output ports serve several purposes. Whenever an operator needs to generate a logic level under program control, a parallel output port is used.

One bit of a parallel output port is used to drive the watchdog timer. Additional lines of a parallel output port (not shown) drive the EEPROM write protect circuit.

Additional port outputs drive the control line drivers. The output port itself is typically a low power Schottky transistor logic (LS) or high speed complementary metal oxide semiconductor (HC) compatible device, which has limited driving capabilities. The port outputs drive control line drivers, which may be discrete transistors or peripheral driver chips. These open collector control outputs may be sent directly to the rear panel (through RF filters) to drive transmitter site equipment, or may drive interface relays within or outside the remote control unit. Under firmware control, these control lines may be set high or low or pulsed high or low. How these lines are pulsed or set is typically a combination of user action (command keystrokes), system parameters (automatic control) and user data in the EEPROM. These lines replace the raise and lower control lines of nonprocessor based systems. For convenience, many processor based systems still refer to the control lines by a raise/lower designation.

Additional parallel output ports may be used to drive status indicators (typically LEDs). These may be driven directly by the output port or may be driven by a peripheral driver chip. The various LEDs can be lit or extinguished under processor control. These may reflect the status inputs at this site or another site, or other on/off conditions.

Additional parallel output port lines drive the address lines of the analog multiplexer. These determine which of the many analog samples are routed to the A/D converter.

A/D Converter and Analog Multiplexer

The A/D converter serves the same purpose as that in the nonprocessor based digital remote control. It converts the analog sample voltage from the analog multiplexer to a digital code. Of the several A/D techniques available, transmitter control systems typically use integrating (dual slope or residue multiplication) or successive approximation. For the same cost, an integrating A/D offers higher resolution (12 bits versus 8) while the successive approximation A/D is faster (50,000 conversions per second versus 20). Although the same A/D used in the nonprocessor based system could be used with a processor, A/Ds are available that are designed to interface directly with processor buses. The processor may read the A/D to see if a conversion is complete and to pick up the converted data. It may write to the A/D to start a conversion, select an input range, select ac or dc or select an input (some include analog multiplexers).

The A/D is driven by the analog multiplexer. Any of the previously described analog multiplexing techniques may be used. Further, the sample selected by the multiplexer may be directly selected by the operator (who may be interested in only a particular channel at the moment), or may be scanned through all the inputs that are used. When the multiplexer is scanned, the resulting conversions are usually held in RAM, making them immediately available to the firmware and the operator.

Solid-state analog multiplexers typically will not accept voltages higher than the supply voltages (either positive or negative). Many multiplexers are protected from damage due to higher than supply input; however, they will typically have excessive leakage into other channels under this condition, causing erroneous readings. The input protect circuitry typically protects the multiplexer from damaging voltages and those voltages that may cause improper operation.

Scanned Keyboard Port

A transmitter site operator needs to interact with the system for setup and calibration. The local display and keyboard serve this purpose. With the addition of four pullup resistors, a single parallel I/O port (4 bits input, 4 output) can be used to scan a 16-key keyboard (typically arranged as four rows and four columns).

Alphanumeric Display

This display is used by the processor to talk to the operator. In simpler systems, the display may only display numeric data. In more complex systems, the display typically displays 32 alphanumeric characters. The use of a full alphanumeric display allows the processor to explain the operation of the system. Each key may have several uses (reducing the keyboard hardware required). The display allows the processor to inform the operator the meaning of each key at this particular point in the operation of the system.

Many systems use alphanumeric display modules that interface directly to the processor bus. A write by the processor to the display may put a character on the display, position the cursor, clear the display or various other control functions. The processor can also read data from the display module. It can typically read a status bit indicating whether the display controller is ready for another character (the display controller is generally slower than the system processor), read the cursor position and various other parameters of the display controller.

Alternate Display Techniques

When large amounts of information are to be displayed, it is difficult to beat the economics of a CRT display. Transmitter and control point operator interaction with the system can be accomplished with a full alphanumeric keyboard and CRT at the site.

Alternate Interaction Techniques

Some remote control systems do all operator interaction (including transmitter site setup and calibration) without a display. All operator interaction with the system is through dual tone multifrequency (DTMF) or Touch-Tone and voice. A standard telephone replaces the keyboard and display previously described. The processor either synthesizes voice in software or sends recorded speech to a (relatively) high speed D/A converter. The output of the D/A is sent to the local (or a distant) telephone. The operator responds to inquiries from the system using the DTMF keyboard on the telephone. This technique has proved quite popular and has been awarded an U.S. patent. Again, however, when large amounts of data are to be displayed, it is hard to top a CRT display. Most systems with DTMF/Voice also offer serial ASCII interfaces (to drive a CRT) as an option.

Digital Monitor Interface

Not all transmitter site parameters monitored by the remote control system can be easily changed to dc voltages. Some monitors digitally derive a parameter, then convert it to an analog sample for interface to the remote control. This is a rather indirect method of getting data from one instrument to another (digital data converted to an analog voltage, then digitized again). A direct digital connection would be simpler and more error-free (no D/A, A/D tracking problems). Several methods exist for handling the digital interface. These can be divided into serial and parallel interfaces.

Serial Monitor Interface

Various serial interface standards exist. The most common is EIA-232-D (RS232) with asynchronous data. Typically, not all the EIA-232-D lines are used. The two signal lines most commonly used are *transmit serial data* and *receive serial data*. The remote control processor can send requests to the external monitor by writing to the appropriate serial port in the remote control. The monitor sends data back to the remote control through the same serial port. The processor can read this data from the same serial port.

More and more transmitter site monitoring equipment is equipped with an EIA-232-D port. That equipment is often designed to be directly connected to a modem, allowing remote access to the equipment. If each piece of equipment got its own phone line, a transmitter site could end up with many dial-up lines. A *mini private branch exchange* (PBX) is now available to serve this need. An operator can call the site, key in an extension number and be connected to the appropriate piece of equipment (whether it be the transmitter control, the modulation monitor, a video signal analyzer etc.). A similar RS232 switch is available. It would be placed between the modem and the transmitter site equipment. Finally, transmitter remote controls may serve as multiplexers or routers for RS232 data from transmitter site test equipment.

EIA-232-D allows one port to talk to one device. It also uses single ended data transmission (one signal line fed against ground). EIA-422-A (an electrical specification that is part of EIA-449), however, uses balanced lines (two wires driven differentially). Some EIA-422-A applications operate in a *multidrop mode*, allowing several devices to share the same port. When operating in a multidrop mode, each device connected to the port is addressed by the processor (polled) when the processor needs data from that device. This technique allows several devices to share a single serial port, saving on hardware.

Parallel Monitor Interface

Various parallel interfaces exist. For example, a frequency monitor may present its data in parallel BCD, where each digit of its indication is transmitted over four wires. Obviously, this requires a lot of wires and a lot of interface hardware.

An antenna monitor may provide multiplexed BCD data. Four wires carry all the BCD data and additional *digit select* lines identify the digits. An antenna monitor will also require various control signals, such as tower selects. Again, a lot of wires and interface hardware are required.

Further complicating the BCD interface is the wide variety of software that would be required to deal with each instrument. Hewlett Packard recognized the problem with existing test equipment interfaces and invented the Hewlett Packard Interface Bus (HPIB). This eventually became the IEEE488 bus, also known as the general purpose interface bus (GPIB). The IEEE488 bus standard includes well-defined hardware specifications and addressing specifications (it is a multidrop parallel bus). Some standards also exist for command and response messages. At this writing, the IEEE488 bus is not widely used in broadcast remote control applications.

Intersite Communications

Most transmitter remote control systems utilize low speed (300–1,200 bps) asynchronous data to communicate between the control point and the transmitter. In Figure 4.7-13, this is shown as a serial port driving a modem. Some systems offer a variety of modems that plug into the system. One modem may be optimized for two-wire full duplex voice grade circuits. Another may be optimized for four-wire voice grade circuits. Another may directly generate signals suitable for use as subcarriers on STL and broadcast transmitters. It is also possible to bring out a serial digital interface to communicate with the control point. The station can then transmit the data digitally to the control point. This digital transmission may involve the use of external modems, a fiber optic link or multiplexing the data into a higher speed digital link (such as a digital STL).

The data that is sent to the control point must, of course, be of a form that the control point equipment can handle. This data may be ASCII data ready for immediate screen display (directly driving a CRT terminal) or a stream of site data where the control point equipment does error checking and extracts the required data for display. In each case, the data and its encoding (modem type) is optimized for the control point equipment and the communications channel. One widely available piece or control point equipment is the standard DTMF telephone. Since this does not have a display, data is sent to it using voice synthesis. Commands from the phone are sent to the transmitter site using the DTMF tones. The voice synthesizer/DTMF detector can be thought of as another modem that takes digital data and formats it for transmission over a voice grade circuit.

Summarizing Transmitter Site Hardware

Figure 4.7-13 shows many of the elements that *may* be present in the transmitter site unit of a transmitter control system. Some systems may have more I/O devices hung on the bus, others may have less. There are microcontrollers available that combine many of the hardware requirements for such a system on one chip. Some microcontrollers contain a processor, EPROM, EEPROM, A/D converter, analog multiplexer, watchdog timer, serial port and parallel I/O on one chip. If one of these chips can meet system requirements, a very low chip count system can be built. However, once the design does not fit on a single chip, the system design may become more complex using microcontrollers in their expanded mode as opposed to using a standard processor.

Control Point Hardware Design

The *control point equipment* is used to display data gathered by the transmitter site equipment (or announce it, in a voice/DTMF system), and transmit operator commands back to the transmitter site. In most cases (again, excepting voice/DTMF systems), the control point hardware is another microprocessor based system using many of the same components as the transmitter site equipment. It has been fairly standard practice to use the same hardware for control point and transmitter site equipment, generally eliminating the analog inputs and control outputs and some other special I/O at the control point. The control point equipment would include the processor, memory, a display, a keyboard, status display and modem (for communicating with the transmitter site).

If the system were to drive a control point CRT terminal, typically the intelligence for driving the terminal would be located in the control point end of the remote control system. Since the CRT terminal is also a microprocessor based system that displays received data and transmits operator keystrokes, it appears possible to replace the control point end of the system with a standard CRT terminal and a modem. This is the basis of some more recent remote control systems. The use of a standard CRT terminal as the control point equipment reduces the system cost. However, most standard CRT terminals do not include a watchdog timer, allowing the terminal processor to crash in a power dip. An external watchdog timer may be added, if desired.

Use of Standard Hardware

Broadcast transmitter control equipment has typically been designed specifically for the industry. Standard components are used, but the circuit boards are designed by the equipment manufacturer. Computer hardware, however, has become somewhat generic. In many cases, it is more cost effective for a manufacturer to buy standard computer hardware (that uses either the Industry Standard Architecture bus or another industrial computer bus). In such cases, the manufacturer may buy the processor board, video boards, serial and parallel I/O boards, modems, disk interfaces, etc. While standard A/D, status in and control output boards exist, the required additional RF filtering required for operation in a broadcast environment normally makes it more cost effective for the equipment manufacturer to design and build this board. The distinction between different systems becomes a matter of which standard hardware has been plugged into a standard system board along with the unique software for each system. Product differentiation has moved from hardware to software.

Lower cost systems, especially those based on a microcontroller with the majority of the hardware on one chip, continue to be based on custom hardware.

System Firmware Considerations

The firmware design of a minimum system (one emulating the nonprocessor based system of Figure 4.7-12) can be implemented relatively easily. However, in an effort to reduce parts count (and manufacturing costs), there is a trend towards moving as much of the design as possible from hardware to software.

For example, the calibration pots are replaced with scaling factors and multiplication routines. Analog multipliers (power-to-linear converters) are replaced with software. Once the system includes a processor, powerful features can be added with minimal manufacturing cost (though the design cost may be the same or higher than designing a similar feature in hardware). These added features may include automatic limit checking, transmitter adjustment, transmitter logging, full screen display, etc.

Intersite Communications

In a simple system with a single control point and a single transmitter site, data sent by the transmitter site to the control point is displayed and operator keystrokes are sent to the transmitter site for appropriate action. These communications are normally carried out using simple data packet techniques so that any erroneous data is ignored. If an error-free data link can be established, the display (perhaps a CRT terminal) can be connected directly to the link. Such an error-free link can be established by moving the error correction responsibility from the control point box to the modem. All modems currently on the market include error correction firmware. Even a noisy line should not cause erroneous data.

It gets more interesting when there are multiple transmitter sites. If dial-up lines are used, the telephone company handles all the site selection and data contention problems. DTMF/voice systems may use a single telephone with an automatic dialer. If a site has a problem to report, it calls it in. If the operator wants to poll a site, a single key on the dialer is pressed, and the operator is shortly in communication with that site.

A similar approach may be used with CRT terminal based dial-up systems. In such systems, programmable function keys on the terminal may be used to generate modem dialing codes for each of the transmitter sites. If a transmitter site calls in with an alarm report, the modem answers and puts the site information on the screen. The dial-up phone system is handling all the data routing problems. Further, only the data from one site at a time is displayed. If the CRT terminal is replaced with a computer and a modem, it can gather the last reported data from each site and put together a display showing a summary of the site information.

If dedicated circuits are used to interconnect the sites, it is the remote control's responsibility to route the data to the appropriate site. Two major methods exist. The first utilizes half duplex modems and is similar in design to local area networks (LANs) and packet radio data transmission. The second approach uses full time digital links (which may include modems to allow use of voice grade or other analog circuits) and is more similar to the switched telephone network or wire line (or fiber optic) packet data networks.

Multisite Data Packet Communications

In multisite communications, a single link is used to carry messages that may originate from any of several sites and be sent to any of several sites. To keep the messages straight, each one is put in a packet that includes the number of the originating site and the destination site. This information is included in the message header. The header consists of a flag identifying the beginning of a packet, the address information, and a message length count. A flag consists of a sequence of bits or bytes that is unique and guaranteed to not occur in the data stream (which would cause a false begin of header detection).

The structure of the header varies from system to system, but will often include the destination address (site number), the return address (site number), and a byte count for the message being sent in the packet. The destination address is used by each site in determining whether to accept a message, route the message to another site or ignore the message. The return address is used by the destination site to send back any requested data, a message acknowledgement, or a negative acknowledgement. The message byte count is used to determine where the end of the packet is. An alternative method is to use another flag sequence to identify the end of the packet. The header may also include a sequence number. As each packet is transmitted, the sequence number is incremented (and rolls over, back to zero). The receive site can then acknowledge a whole sequence of packets instead of each one individually. This generally speeds up the data transmission (a bunch of packets can be sent in one burst instead of sending them one at a time and waiting for acknowledgements). The actual contents of the data field of the packet may have varying meaning. Often one byte of the packet will identify the type of data contained in the packet. This packet type byte is then used to identify the contents of various fields of the data packet. The data packet ends with a frame check sequence (FCS). This is generally an 8 bit or 16 bit error detecting sequence, often a checksum, cyclic redundancy check or some similar error detection system.

Multisite Half Duplex Communications

Half duplex multisite systems have a single analog communications link between all sites in the system, so that all sites can hear all other sites. A message transmitted by any site is heard by all other sites in the system. This is similar to many LAN and packet radio systems. Each site receives all the packets that are exchanged in the system, but ignores all packets except those where the destination address matches the site number of that site. This is a fast communications system, since the message immediately goes to the desired site (and all others). Some method of keeping the sites from interfering with each other is required. Each site operates half duplex, keeping its modem carrier off line unless it has some data to transmit. Each site is continuously listening to the line. As such, it is somewhat similar to a tristate bus in a computer system (each device listens to the bus, but only the addressed device puts data on the bus). A variety of techniques are available to coordinate the data transmission on the channel. These include *master/slave, token passing, aloha, carrier sense multiple access* *with collision detection* (CSMA/CD) and *minislotted access.*

Multisite Full Duplex Communications

Another approach to routing data packets among several sites in a system is based on a continuous two-way data link linking each site to at least one other site in the system (a mesh topology). When a packet is received from any of the incoming links, the packet is first checked for errors. If the packet is error-free, the destination address is examined. If the destination address matches this site, the message is passed to the remainder of the firmware at this site (perhaps requesting a parameter from the A/D handler, etc.).

If the destination address does not match this site, a routing table (typically in EEPROM) is consulted. Based on the destination address, the routing table information and circuit loading, the received packet is placed in the output buffer for a particular output port, which drives a communications link to another site in the system. The routing table holds one or more port numbers for each site in the system. Where more than one port number is assigned, the system makes a decision as to which port is to be used based on system traffic. If the first choice port (the most direct path) has a lot of data in its output buffer, the second choice port may be used, spreading the traffic for optimum transmission speed (is it faster to use the indirect route or get in line for the busy port?).

On receiving a packet, a site does a similar evaluation. Note that a particular communications link will be carrying data destined for many different sites. A properly received packet that needs to be relayed to another site is put into a FIFO buffer for transmission to that site. Since each message must be fully received (for error detection) before it is passed on, the delay in getting a message from one end of the system will be more than in the previously described half duplex systems. This delay can be reduced by using smaller packets, though the header overhead then reduces overall system efficiency. This routed system does result in higher overall throughput since the system may carry more than one message at a time, while half duplex systems carry only one message at a time.

Further, there are no delays due to carrier bring up, shut down and carrier sense delays. Each site acts as a data switch and multiplexer along with its normal data acquisition and control activities. Each message is fully demodulated, error checked, retimed and remodulated when sent on to another site. This digital repeating prevents the accumulation of noise, distortion, and errors in the data.

Internet Protocol

The Internet Protocol (IP) defines a structure for data packets to be sent over a variety of circuits from any point (or site) to any other point (or site). At this writing, the IP is not widely used in broadcast transmitter control. However, use of this protocol would allow use of mass market hardware and software in broadcast transmitter control. The IP can be used on circuits owned by the broadcaster (such as subcarriers or other data channels on an STL) or dedicated circuits from a telecommunications carrier. The transmitter control data can stay entirely within a private network or can be introduced to the Internet, allowing control and monitoring of the transmitter from anywhere the Internet is available. In such instances, use of a secure IP is, of course, suggested. In such systems, the broadcast transmitter control unit becomes an *embedded server,* responding to requests from client units elsewhere on the network, just as other Internet servers respond to client requests.

Parameter Limit Checking

A simple transmitter control system (such as a non-processor based system) typically extends all the transmitter site meter indications to the control point, but makes no evaluations of these indications. Once a processor is added to the system, parameter limit checking can be accomplished with no additional hardware. After each parameter (or the whole group of parameters) is acquired by the A/D converter, each reading is compared with various limits. If a reading is above or below a specified limit, a specified action is taken. The software to accomplish this limit checking may reside at any point in the system (such as the transmitter site or the control point). Further, the limit checking may reside in the remote control system or may be in a computer that gathers data from the remote control system.

Remote control equipment is not legally required to have limit alarms. If, however, the station utilizes an automatic transmission system (ATS) for *attended* operation, then Section 73.1400(a)(2) requires the system to contact the operator in case of a technical problem. Early systems used analog comparator integrated circuits to detect a sample going over an alarm limit. A potentiometer adjusted the threshold voltage for the comparator. Current systems handle the problem in software (although many automatic power control systems in transmitters themselves utilize a pair of analog comparators). A typical remote control system will assign four limits to each analog channel. These limits divide the total possible range of the parameter into five bands. Limit codes may be assigned to these bands as shown Table 4.7-3 below.

A system may allow for different limit tables depending upon the state of the transmitter site. For example, different limits will apply depending on whether an AM antenna system is in day or night pattern. Different limits will apply if a different trans-

Table 4.7-3
Limit codes.

Limit	Code Description
+2	Above upper upper limit
+1	Below upper upper limit, but above upper limit
0	Inside all limits
−1	Below lower limit, but above lower lower limit
−2	Below lower lower limit

mitter is on the air. Different limits will apply if no transmitter is on the air (after station sign off, we don't care if the antenna current is below the licensed minimum!). A system could evaluate the state of the transmitter site and determine which limit table to use based on the state discovered. This may, however, cause some problems. If a transmitter goes off the air and the *Determine State* software determines that the current state is off air, it may decide to use the off air limit table (ignoring all alarms except tower lights, burglar alarm and fire alarm). For this reason, a system will often change state based only on operator commands or automatic commands (scheduled pattern changes, etc.).

Associated with each limit code and state is a *limit action*. The limit action tells the system software what to do when this limit code occurs. For example, a limit code of +1 may cause the system to trim down the transmitter power while a limit code of +2 may shut down the transmitter (if the transmitter got to this limit code, the power trim must have not been successful). A system will also typically store the previous limit code for each parameter so that transitions can be detected. A system should log the transition of a limit boundary rather than continuously printing that the power is too low. One log entry when the power went out of limits and another when the power went back in is generally sufficient. Of course, one of the limit actions will be to alert the operator of the limit transition (alarm on limit transition).

A system may highlight the out of tolerance parameter on a display, display a user specified alarm message, or some other action. In some systems the out of tolerance parameter or alarm message will flash and an audible alarm will sound until the operator acknowledges the alarm by pressing a key. Once the alarm is acknowledged, the audible alarm and flash stop, but the alarm message remains visible as long as the parameter is out of tolerance.

Time of Day Actions

If the time of day (along with day of week and date) are stored in the system as a number (generally integers), then the same limit checking routines used for analog parameters can be used for time of day automatic control. If a lower limit is set to the sunrise time, and the upper limit is set to sunset time, actions (pattern/power changes) can be generated by the limit checking software. Many systems allow for time of day programming using this or similar techniques.

Operator Interface

A wide variety of operator interface options are available. These range from the numeric display of a single metering channel along with channel select and raise/lower buttons through DTMF/voice to CRT screen displays. The single channel display is traditional (processor based systems emulating nonprocessor based systems) and quite adequate where a small number of parameters are to be monitored.

The DTMF/voice interface has proven quite popular due to the ready availability of Touch-Tone phones—a station technician already has a control point terminal at home and perhaps even in the car. With a large number of parameters to be monitored this interface can become awkward, but it is certainly better than no interface at all.

Parameter Display

Parameter display started with analog meters (either a meter for each parameter or a single meter with a function select switch). A major improvement was the introduction of digital displays in both processor and nonprocessor based systems. Voice display of parameters extends the precision and readability of digital displays to anywhere there is a telephone.

When a large number of parameters are to be displayed, it is difficult to beat a CRT screen. A typical screen would include each analog parameter along with a label and units identifying the parameter. Out of tolerance analog parameters can be identified through distinctive text (inverse video, flashing or a color such as red). Transmitter site status can similarly be displayed with a label and an indicator of the current status. An operator can view this one screen and have a good idea of the overall condition of the transmitter site. One screen may give an overview of the entire system (several transmitter sites), while additional screens give details of specific sites. Additional screens may give details of a specific piece of equipment at a specific site.

Operator Command Input

Operator command input started with the switches on the front of the transmitter. These switches may be extended to a remote location giving a switch per function. Early in the history of the remote control industry, control took the form of a channel select switch (or even a telephone dial in the very early units) with *raise* and *lower* buttons. The channel select switch acts as a function select switch, determining what the raise or lower key does. This approach continues to be used in many systems, both those with dedicated control point terminals and those that use a DTMF telephone as the control terminal.

Systems that utilize a CRT display often use an associated alphanumeric keyboard for control input. Hitting various keys sends the control functions identified on the screen or changes the screen to display additional pages of information. Use of multiple screen pages allows a limited number of keys to serve many purposes, since the function of the key varies depending upon which screenpage is visible.

Systems utilizing a CRT display may also use a *touch screen* to simulate a transmitter front panel. The screen can use boxes of varying video brightness or color to simulate back lit pushbutton controls. The operator can push the simulated transmitter button, the transmitter comes on, and the button turns green. Additional buttons provide other control functions and select other screen pages.

A control system may also utilize a computer mouse for operator control input. The operator uses the mouse to click buttons for desired commands or to select screen pages.

Automatic Logging

The FCC used to require broadcast stations to maintain an operating log, program log and maintenance log. The Commission has dropped the requirement for a program log and combined the operating and maintenance logs into the *station log*. The requirements for a station log are discussed in Section 73.1820 of the Rules. These rules include a provision for automatic logging.

Early automatic logging systems consisted of chart recorders that would plot the several transmitter parameters on a single roll of paper. This was often done by multiplexing several analog samples into a single channel recorder, then enabling and disabling the marking of the recorder as each channel stabilized. As digital circuitry was introduced to transmitter control systems, the chart recorder was replaced with a printer based on an electric typewriter. As microprocessors were introduced to transmitter control systems, standard computer printers (generally dot matrix) were put into service printing logs showing transmitter parameters.

Each of these logging systems satisfied the then existent FCC requirements for operating or station logs. At this point, required parameter logging for most stations is minimal, though a paper trail of parameter logging is still useful in showing a history of compliance with FCC requirements. Logs now serve as an indicator of drift or possible future failures in the transmission system. Having these logs as columns of numbers on a piece of paper may not be the most useful form. Further, the log printing interval may at times be too frequent (wasting paper) and at other times not frequent enough.

For these reasons, some systems now save the log to a hard drive in a form that is easy for other software to analyze. Due to the ever increasing capacity of hard drives, a relatively high log frequency can be used without generating lots of wasted paper. For example, a transmitter site might transmit a data record to all sites in the system on a user defined significant change in any parameter at the site. The record would consist of the site identification, date, time and all site parameters (typically analog, status, and other system inputs). Each site in the system captures this data to its hard drive. Each site can then build screens based on the latest data from each site in the system. The sites can also build printed logs based on the current data from multiple sites. Users can scroll back through data on each user screen, showing the history of the particular site. Finally, the log data can be exported to other software for further analysis, perhaps graphing parameters against time, emulating the chart recorders that served as the first automatic logging systems.

Programming the System

Prior to processor based remote controls, system setup and calibration consisted of adjusting the calibration pots. As features are added to processor based systems, more and more user input is required to describe how the system is to act. Keeping the system flexible while not overwhelming the user is a challenge for system designers. As with any other computer program, various methods of user data entry exist. Most systems utilize a series of menus, data tables or an adaptation of a standard computer language.

Providing flexibility in the design of user screens and printed log formats has proved challenging. Forms and menus give the user a certain amount of flexibility and ease of use. A programming language provides more flexibility and is generally less easy to use. In recent years, however, the World Wide Web has become extremely popular. The design of web pages is similar to the design of user screens in a transmitter control system. At this writing, embedded web servers are among the most popular topics at conferences dedicated to embedded system design. Simple web servers have been built into soft drink vending machines, copiers and other appliances. It is expected that transmitter control systems will also become embedded web servers, allowing the user to design screens using the standard hypertext markup language (HTML). With HTML, the user interface software becomes a standard web browser, currently available for free or at low cost. User screens can include graphics, menus, tables and other elements to make the display more understandable. These screens can be hand coded in HTML or standard HTML editors can be used to design fancy pages with little or no HTML coding by the user.

HTML pages are generally transmitted by the server in a ready to display form except for graphics. Graphics are referenced in the received page. The browser then uses these image references to request the individual graphics files. In transmitter control systems, it is not possible to have a ready built page ready to send, since the transmitter parameters vary with time. Such pages could be built on the fly by the server (a transmitter site unit), inserting current transmitter parameters into a predefined page. However, higher speed and greater user flexibility is probably available by handling transmitter parameters in a manner similar to images in standard HTML pages. The user screens can be defined as standard HTML files on the local unit, eliminating the need for transmitting the page from the server (the transmitter) to the client browser (the studio). The local page would include image tags that would request the individual transmitter parameters, similar to the way page hit counts are handled in pages on the World Wide Web. Finally, these transmitter parameters could be dropped into the page by sending individual requests to the appropriate transmitter site and waiting for the parameter to be returned over the communications link.

As an alternative, transmitter sites can send all the site parameters to all sites in the system on a significant change (as discussed in logging). The local browser responsible for building the user screens then refers to this log file for the latest data. In this manner, screens can be built quickly, as there is no wait for the data to be sent down a possibly slow and congested communications link. The studio unit is maintaining an updated cache of the information it needs, or is acting as its own *proxy server*.

Mouse clicks on screens on a web browser are generally used to bring up other pages through hypertext links. However, mouse clicks can also send commands to a program running on the server (generally referred to as a common gateway interface (CGI) script). Use of similar commands allows user interaction with the transmitter site (making adjustments, turning equipment on and off, etc.). Thus, it appears that use of a standard web browser can serve as the user interface in a transmitter control system.

Standard web browsers and the IP can be used on private networks for transmitter control. With appropriate security measures, this data can be dropped onto the Internet allowing transmitter monitoring and control from anywhere in the world at very low communications costs.

TRANSMITTER CONTROL DIVISION OF RESPONSIBILITY

Automatic transmitter control systems are often divided into several hardware boxes, each responsible for a portion of the job. Some of the control responsibility resides in the transmitter. Some resides in a remote control transmitter site unit. Some resides in a remote control control point unit. Some may reside in a control point computer.

Extended Voltmeter

The simplest remote control systems utilize an *extended voltmeter* for telemetry. In response to operator requests, the transmitter site analog multiplexer connects the voltmeter input to the various parameter samples. The operator logs the resulting readings, does limit checking and makes required adjustments. The transmitter site equipment has minimal responsibility.

Transmitter Site Polling

Automatic equipment may be placed at the control point to poll the various transmitter parameter samples (just as the operator did). This equipment may then log the readings, do limit checking and make adjustments. The intelligence of the system is at the transmitter control point and may be in the remote control unit itself, or in an external computer (through a computer interface on the remote control).

Continuous Telemetry Transmission

Another design approach calls for the transmitter site equipment to continuously scan all the parameter samples and send the resulting data to the control point. This data is then held in memory by the control point. As new data for a specific parameter is received, the old data is overwritten. The operator may then select (through a standard *channel select switch*) which parameter is to be displayed. The data is immediately pulled from local RAM. If a CRT display is used at the control point, the screen is continuously updated with the received data, giving a full screen display of all transmitter site data.

Exception Reporting

In the previously described systems, telemetry data is continuously transmitted, even if it duplicates data that was sent a few seconds earlier. Another approach is to send only the data that has changed (requiring parameter identification to be sent with each parameter), or to send the entire status of the site (all analog and status parameters) upon a significant change in any parameter. Either approach allows the introduction of noncontinuous data communications between the control point and the transmitter. The typical noncontinuous data communications link utilized is the dial-up telephone. The telephone company charges for the line during the time it is used. A dedicated circuit is assumed to be used at all times. The break even point between dial-up and dedicated voice grade circuits is typically at two to three hours per day.

By placing some of the intelligence at the transmitter site, the amount of information transmitted to the control point can be reduced considerably (through exception reporting). This allows more sites to share a dedicated circuit (due to lesser loading of the circuit), or allows the use of noncontinuous circuits, such as dial-up circuits. A transmitter site may transmit the status of the site due to any of several conditions. These include the existence of an alarm condition, a change in a parameter or a scheduled report. Systems that have dedicated circuits to the control point may immediately transmit the current state of the site based on any of these conditions. Systems that utilize dial-up circuits will typically originate a call only on an alarm condition. These systems may buffer all the parameter changes. This buffer is dumped to the control point on it filling, on an alarm condition (requiring immediate notification of the operator), and on a scheduled basis. One multisite dial-up system utilized by a television network has each transmitter site do a buffer dump each morning between 6:00 and 7:00. If all goes well, this may be the only report from the site during that day. It occurs when the telephone charges are the lowest. It also confirms that each site is operating properly as the broadcast day begins.

Data Analysis

Each week, the designated chief operator of a broadcast station is required to review the station logs and certify that the station operation was in complince with FCC requirements (FCC Rule Section 73.1870(c)(3)). In addition, the chief operator will typically look for drift in parameters in an effort to anticipate problems at the transmitter site. Statistics gathering may be done by hand (looking at manually or automatically printed logs), by the remote control (especially programmable systems) or by a separate computer. If either the remote control or an attached computer saves data to a hard drive, another program (either on the same computer or on a local area network) can access this data to build reports on the status of the system.

Data Reporting

Various devices may be used at the control point to make the transmitter site data available to the operator. These include a visual display (whether a small single channel display or a CRT display), printer, DTMF/voice interface (through a telephone) and fax machine. Visual displays show the last data received. Printers show all the data received, forming a printed log. DTMF/voice systems report the current data and alarm conditions. Systems with visual displays often include printers to generate a printed log. DTMF/voice systems typically do not generate a printed log (the Touch-Tone phone does not have a printer port). However, most stations now have facsimile machines connected to the dial up telephone network. These may be utilized by DTMF/voice systems to generate a printed log. The transmitter site equipment buffers all parameter changes, alarm conditions, operator alarm acknowledgements, automatic adjustments and operator adjustments. After each day is completed (some time after midnight), the transmitter site unit calls the fax machine and prints the log. If several transmitter sites are reporting, these calls may be scheduled to avoid conflicts. The use of the fax machine allows a station to get an automatically printed log using existing equipment.

Remote Diagnostics

The systems discussed so far have merely presented the transmitter site data to an operator. They have done minimal analysis of the data. One broadcast software company has developed transmitter analysis software. Through extensive analysis of the failure modes of transmitters, the system is able to determine what component most likely failed to cause the existing transmitter parameters. This approach is an automated *logic tree*, similar to the flow charts equipment manufacturers supply to aid in the troubleshooting of equipment.

COMMUNICATIONS CIRCUITS

Various circuits are available to connect a control point with transmitter sites. They include the following:

- Telco metallic pair
- Telco voice grade pair
- Telco dial-up voice grade
- Telco digital circuits
- STL subcarrier (voice grade or digital)
- Digital STL datastream
- FM subcarrier
- TV aural subcarrier
- TV vertical blanking interval
- AM subaudible
- Dedicated radio link (P channel)
- FM squared satellite
- SCPC satellite; Satellite VSAT
- Digital satellite datastream
- Unlicensed radio link

Telco Metallic Pair

The telephone system is designed for voice communications. Individual pairs of wires connect each telephone instrument to the local central office. Once the pair is terminated in the central office, the voice is generally digitized (8 bits per sample, 8,000 samples per second) for switching and transmission to other central offices. The links between central offices are now high speed digital lines. As such, it is very difficult to get long distance metallic pairs (dc continuity end-to-end). Within the coverage area of a single central office, however, these lines are sometimes available. They may be ordered as a *3002 local area data channel* line with dc continuity. These lines are suitable for dc metering and control. They can also be used to transmit digital telemetry and control by using short haul modems or line drivers. These condition the data for transmission over the long distance balanced lines where there is likely to be substantial common mode voltage. A low cost, short haul modem can typically transmit 9,600 bps data 2.2 miles. At 1,200 bps, this increases to 6 miles. These short haul modems normally require a four-wire circuit (one pair in each direction), though, with appropriate drivers and software, it is possible to set-up a single half duplex current loop circuit that allows communications in one direction at a time over the single pair.

Telco Voice Grade Pair

If a 3002 local area data channel goes through more than one central office, it will probably not have dc continuity. The link between central offices was multiplexed onto wire pairs, coaxial cable, microwave, or optical fiber. The telephone company can multiplex 24 voice grade circuits onto a single pair, so it is not economical for them to allocate a pair to one voice grade circuit. The voice grade circuit can, of course, carry voice DTMF, making it suitable for DTMF/voice control. It can also carry analog remote control telemetry that is based on audible tones. Finally, with the addition of modems (whether inside the remote control or outside), it can carry digital data, allowing its use on microprocessor and nonprocessor based digital control systems.

Note that the telephone company central office normally digitizes the incoming voice grade circuit at 64,000 bps. Based on this, an operator should be able to send 64 kbps through a voice grade circuit. However, due to noise distortion and delay distortion on the local loop between the customer and the central office, current modems are limited to about 56,000 bps. In one direction with 33,300 bps in the other direction over dial-up telephone lines. These modems use pulse amplitude modulation.

Other high speed digital transmission techniques are available for use over standard telephone company twisted pairs. These include integrated services digital network (ISDN) and asymmetrical digital subscriber line (ADSL). The twisted pair is not dead!

Telco Dial-up Voice Grade Circuit

In December 1984, the FCC dropped the failsafe requirement from its rules, making the use of temporary circuits legal for the control of broadcast transmitters (further, in 1995, they dropped the requirement that there be an operator present to supervise the transmitter (unattended operation) making the use of *no* communications circuit possible). These *plain old telephone* circuits are inexpensive, reliable and very widespread. They are voice grade, allowing various data encoding techniques. The most common data encoding techniques for dial-up lines are standard dial-up modems (for digital data) and DTMF/voice. The wide availability of personal computers has reduced the cost on dial-up modems, making them suitable for driving control point terminals and computers.

DTMF/voice systems utilize dual-tone, multifrequency (Touch-Tone) signals for control and synthesized (or digitally recorded) voice for telemetry and status reporting.

Use of the dial-up telephone network allows large transmitter control networks to be built, since the telephone company equipment handles all the data routing between the transmitter sites and the control points. The FCC does, however, require the broadcast transmitter operator (assuming attended operation) to have the capability to turn off the transmitter at any time. In the *Report and Order* (see 60 FR 55481) adopting the unattended operation rules, the FCC states that a dial-up line dedicated to the transmitter control system is sufficiently reliable. If, however, the line serves other purposes, an alternate means must be available for shutting down the transmitter, since emergency shutdowns cannot be scheduled for when the dial-up line is not in use. (For more information on this subject, see the *NAB Guide to Unattended Station Operation.*)

Telco Digital Circuits

The digital circuits available from telephone companies are based on the 64 kbps rate used to encode voice. Allocating a full voice grade digital circuit to broadcast transmitter telemetry severely underutilizes the circuit. However, some stations are now utilizing T1 circuits (1.544 Mbps, designed to carry 24 voice circuits) as a digital STL. With appropriate encoding, it is possible to run composite or discrete program quality stereo through a single T1 circuit. A small portion of the T1 circuit is typically allocated to be a low quality voice circuit or low speed digital circuit for transmitter control and telemetry. In each case, the 1.544 Mbps circuit is broken into several lower speed data channels suitable for carrying the digitized audio and/or other data.

Optical fiber is being utilized throughout the telephone industry. It is typically used between central offices to handle very high speed digital data (generally representing many voice circuits). At this time, most telephone subscribers do not require sufficient data bandwidth to extend the fiber the last mile to customer premises. The one possible exception is where television stations utilize digital fiber for the transmission of digitized video. As with T1, some data capacity can be stolen from the digitized video channel to provide a digital data circuit between the studio and the transmitter, suitable for transmitter control and telemetry.

STL Subcarrier

Many stations use an aural or television STL to get programming from the studio to the transmitter. There is usually bandwidth available for the addition of a voice grade or digital data channel. In addition, television stations may insert control data in the vertical blanking interval of the video going to the transmitter site. This data may be replaced with telemetry data prior to being fed to the broadcast transmitter. The most common technique of sending control data over an analog aural STL is to use an FM subcarrier to establish a voice grade circuit. Standard modems (inside or outside the remote control) then drive this new voice grade circuit. Other modulation techniques are available, including FSK of the subcarrier, and quadrature amplitude modulating the subcarrier with digital data. The following frequencies are typically used:

- 26 kHz: Monaural or discrete stereo aural STLs
- 110 kHz: Composite stereo aural STLs
- 135 kHz: Composite stereo aural STLs
- 152 kHz: Composite stereo aural STLs
- 185 kHz: Composite stereo aural STLs
- 7.5 MHz: Video STLs
- 8.3 MHz: Video STLs

Digital STL Datastream

Digital STLs (whether for radio or television) provide a high speed digital link from the studio to the transmitter. Some of this bandwidth is used to transmit program material to the transmitter site after the programming has been encoded to a suitable digital form. Additional data bandwidth is generally available for a low speed digital channel or voice grade audio channel to send control information to the transmitter site. In transmitter to studio link (TSL) and intercity relay (ICR) applications, these links can also carry telemetry information.

FM Subcarrier

Transmitter site telemetry may be returned to the control point (and anywhere else there is a subcarrier receiver) over a subcarrier on the FM broadcast channel. This is generally a voice grade FM subcarrier driven by a modem in the remote control. Other modulation techniques are available, including FSK and quadrature amplitude modulation. In addition, the subcarrier is sometimes further multiplexed by using the 20–30 Hz range to return the metering (either analog or digital) and the range above 50 Hz for other programming. Typical FM broadcast subcarrier frequencies are (assuming stereo operation) 67 kHz and 92 kHz.

TV Aural Subcarrier

In 1971, the FCC authorized TV stations to use an aural subcarrier with an instantaneous frequency between 20–50 kHz. Much of this spectrum is now taken by BTSC stereo. BTSC does, however, set aside a subcarrier frequency for station use (the PRO channel). This is at 6.5 times the horizontal scan rate. It is frequency modulated with a voice grade signal, or may be frequency shift keyed with a digital signal.

Vertical Blanking Interval

FCC Rule Section 73.682(a)(21) allows lines 17 through 20 (except line 19, which is reserved for the standard ghost canceling signal) of both fields for test, cue, control and identification signals. On an STL, these may be used to send transmitter control information. The data could be replaced with telemetry data at the transmitter site.

AM Subaudible

In 1969, the FCC authorized AM stations to use frequencies below 30 Hz on the AM carrier for telemetry. The modulation level of the telemetry signal was limited to 6%. Analog metering systems typically use 20 Hz to 30 Hz (20 Hz representing zero, 30 Hz representing full-scale). Subaudible signaling may also be used to transmit digital data (although at a low rate, on the order of tens of bps). The subaudible digital signaling may use any of various modulation techniques. FSK and phase shift keying have been used. The low speed capability of the data channel may be a limiting factor, but over a full day, a lot of data can be sent. If the telemetry system sends only the changes in parameters while the control point terminal stores the most recently received data (perhaps using a standard CRT terminal), a reasonable telemetry system is possible.

The current FCC rule Section 73.127 governs this multiplex use of AM carriers. It allows the use of either amplitude or phase modulation (the original rule required the use of AM). The rules no longer set a maximum injection level or frequency, though the multiplex signal must not be audible or cause radiation outside the channel. AM multiplex signals are also finding other applications. One such application is electric utility load management. The subaudible band is also used by the AM stereo system for a pilot signal to trigger the operation of stereo demodulators. These other applications may limit the use of this range of frequencies for transmitter telemetry.

Digital Television

As digital television is introduced, various other circuits become available for the transmission of control and telemetry signals. Both the digital STL and the digital television transmitter provide a high speed digital circuit that may be divided into various lower speed channels. Further, since both video and telemetry/control data tend to be *bursty* (the peak bandwidth is higher than the average bandwidth), higher transmission rates are available for the various services through the use of statistical multiplexing or use of data packet transmission instead of allocating fixed data rate channels to each application.

Both the STL and the broadcast transmitter datastreams may make some data capacity available for telemetry and control.

Broadcast Subcarrier Limitations

Broadcast subcarrier (whether AM subaudible, FM or TV aural subcarrier, TV VBI, or digital TV subchannel) telemetry transmission is low cost, but has one serious limitation. When there are problems with the broadcast transmitter, no telemetry is available, making remote diagnostics and troubleshooting difficult. For this reason, many prefer to use a telemetry link that will continue to operate on failure of the broadcast transmitter.

Dedicated Radio Link (P Channel)

The FCC has set aside eight frequencies in the 450–455 MHz area for operational communications, including telemetry and control (see FCC Rules Sections 74.402(e)(9), 74.462(b), and 74.482(d)). It is most common to treat these radio links as a voice grade circuit, then use standard voice grade modem techniques to send data. It is also possible to directly digitally modulate the UHF carrier using any of the standard techniques (FSK, etc.). Many stations leave the transmitter up continuously, making the frequency unavailable to other stations in the area. Simple circuitry can be added between a standard remote control and the TRL transmitter to only key the transmitter when readings are being taken. Such systems could also use the dial-up technique of holding all the data changes in a buffer until the buffer fills, an alarm condition occurs or a scheduled report time.

Another technique available for frequency sharing is *packet radio*. Here, a terminal node controller (TNC), packet modem or packet assembler/disassembler (PAD) coordinates the use of the RF frequency, adds addressing to the packets (setting up *virtual circuits* between sites in the system) and adds error correction. The RF packet communications system provides a transparent serial digital circuit between two points over a shared RF channel. Some remote control equipment includes packet hardware and software in its design. Other systems may be adapted to packet radio by adding an external packet modem. Finally, note that Section 74.482(d) outlines the specifications for automatically identifying the P channel radio link. Some remote control systems include the ID system. Some P channel transmitters also include an ID system.

FM Squared Satellite

Some satellite networks providing transmitter operating services rely on dial-up telephone lines for routine control and telemetry of transmitters. To provide an independent method of shutting down transmitters on the failure of the dial-up system, the networks may use subaudible tones on the program channel or interrupt the program audio. This is typically used on *FM squared* satellite channels where the program audio is carried as an FM subcarrier above video (which is also frequency modulated on the satellite, although some systems delete the video, just running an FM carrier with several FM subcarriers). Since subaudible data channels can only handle low data rates, some FM squared systems run a separate data channel (on another video subcarrier). This data channel normally handles addressed packet data. It includes program cues, individual station transmitter commands and text messages to subscriber stations (electronic mail). Loss of the data channel may be used as a failsafe way of shutting down the transmitters.

SCPC Satellite

Single channel per carrier (SCPC) satellite systems run several FM audio carriers in a single video transponder, as opposed to carrying the audio as subcarriers on a single video carrier. The bandwidth of the SCPC carriers normally allows the addition of a subcarrier immediately above the program audio for each channel. Through the use of data packets and addressing, this data channel may be used for program cues, individual station transmitter commands and text messages to subscribers. Again, routine transmitter control and telemetry is accomplished over dial-up telephone lines, since each station has a receive-only earth station.

Digital Satellite

Many program networks have changed to digital distribution of their programming. A portion of the high speed datastream utilized for audio distribution can also be utilized for program control (local ad insertion, etc.) and transmitter control. This one-way link can be supplemented with a dial-up telephone as a return link for telemetry.

VSAT Satellite

Very small aperture terminal (VSAT) satellite systems are widely used for point-to-point and point-to-multipoint data distribution. These differ from the previously discussed satellite systems in that a transmit/receive terminal is put at each station. Through data packet switching, the VSAT system sets up a large number of virtual circuits through a single satellite transponder, on a single frequency. The techniques are similar to those used in packet radio. The single RF channel is divided among several users through time division multiplexing. However, instead or allocating a fixed time slot to each user, a time slot large enough to handle the data a site needs to transmit at that particular time is allocated (as in statistical multiplexing). The VSAT system appears to the user as a very long RS-232 cable. Data put in one end comes out the other. The complexity in the middle is handled by someone else. This very long RS-232 cable allows the control terminal or the transmitter control system to be located almost anywhere. To decrease the amount of time utilized on the satellite circuit, the remote control (or an interface computer) uses exception reporting, reporting only changes in system parameters (and often updating the data every half hour). Sending the same data over and over again (as would result from a stable transmitter) wastes time on the satellite that would otherwise be available to other users. The two-way satellite link allows the complete control and telemetry of the broadcast transmitter to be handled by the satellite circuit. The previously described receive-only satellite systems relied on dialup telephone circuits to get telemetry back to the control point.

Unlicensed Radio Link

Part 15 of the FCC Rules sets aside various bands of frequencies that can be used by low power communications devices without any licensing. Users of these frequencies are not protected from interference. Some stations have utilized Part 15 spread spectrum digital radio links to provide control and telemetry communications between sites. These systems can work well in uncongested areas. In other areas, the shared use of the frequencies limits their usefulness.

MANY OPTIONS

Recent revision of the Communications Act of 1934 and the subsequent elimination of the FCC requirement that an operator be in charge of a broadcast transmitter is a radical change from the traditional approach to the supervision of broadcast transmitters. Further, relaxation of the ownership limits can result in a single licensee owning several stations in one market and hundreds of stations in the country. These licensees may choose to run the transmitters unattended relying upon transmitter stability, automate the supervision of the transmitter or have a person keep a close watch on transmitters throughout the country. The degree of supervision is now up to the station licensee, *as long as the transmitters continue to operate within licensed parameters.* Stations may use the techniques discussed in this chapter (as well as other techniques) to maintain the degree of supervision desired.

4.8
AM BROADCAST ANTENNA SYSTEMS

CARL E. SMITH

INTRODUCTION

Standard broadcast (AM) antenna systems can reach a high degree of sophistication, much of which is based on advanced mathematics. The purpose of this chapter is to provide the station engineer with an understanding of some of the basic concepts of antenna design and an appreciation for the complexities of this specialty. An extensive bibliography is included for those who wish to pursue further study.

The chief purpose of a broadcasting antenna system is to radiate efficiently the power supplied to it by the transmitter. A simple antenna can do this job quite well. This is often a single vertical tower that radiates its signal equally in all directions along the ground in a so-called nondirectional or omnidirectional pattern. A second purpose of an AM antenna system is often to concentrate the power in desired directions to cover populated areas and to suppress it in other directions to protect the coverage of other stations sharing the same or closely-adjacent channels. This directionality may require a very complicated antenna system with several towers if the requirements are stringent.

The antenna is the last point in the system under the control of the broadcaster. The signals radiated from the antenna are propagated through space to each receiving antenna. The factors affecting the strength of the received signal include the strength of the signal radiated by the broadcasting station in a particular direction, the distance to the receiving site, losses incurred by the less-than-perfect conductivity of the ground along the propagation path, terrain obstructions, (large hills cast shadows even at AM frequencies) and, in the case of skywave transmission, the ionospheric conditions that determine how much of the radiated signal will be reflected back to each distant receiving location. Signal strength in a particular direction can also be affected by the presence of structures such as buildings or towers near the radiation system.

The polarization of the transmitted waves is also a factor; for standard broadcast stations vertical polarization is used because of its superior groundwave propagation and the simplicity of antenna design. The FCC has established maximum transmitter power limits for each of the four classes of AM channels—A, B, C and D so the only variables available to the design engineer attempting to maximize the coverage of a radio station involve the antenna location, the pattern design, and a limited choice of power levels. These factors go hand in hand when designing a directional antenna system. Severe constraints are usually imposed on transmitter site selection because of aeronautical, zoning, environmental, and coverage requirements. The constraints encountered in the pattern design relate to the size and shape of the transmitter site, the extent to which the necessary signal suppression can be achieved at the desired transmitter power level and the cost of design, construction, adjustment, and maintenance of multi-tower systems. The pattern design can also seriously affect the stability, efficiency and bandwidth of the completed system. These factors will be discussed later.

RADIATION VERSUS FIELD STRENGTH

Two independent factors determine the signal strength at any given point within a station's service area. First is the strength of the signal radiated in that direction; second is the path attenuation between the transmitting and receiving antennas. Attenuation is determined by both distance and ground conductivity. It is customary to express the radiation in units of millivolts-per-meter at 1 km unattenuated. This is the field that would exist at 1 km over perfectly conducting earth. In this case the field strength would be inversely proportional to the distance from the transmitting antenna; hence, the radiation is also described as the "inverse distance field." The unattenuated radiation cannot be measured directly but can be inferred with great accuracy if sufficient field strength measurements are made to determine the ground conductivity. Field strength measurements are always dependent on radiation, distance, and ground conductivity.

THE SINGLE TOWER NONDIRECTIONAL ANTENNA

The majority of single-tower antennas are neither top-loaded nor sectionalized and most of them are insulated from ground. For such simple towers, the current is a maximum 90 electrical degrees down from the top (or at the base if the tower is shorter than 90° in height). A typical guyed tower that is 90° high physically is about 95° high electrically, because the velocity of propagation is less in the tower than in air and is a function of the tower cross-section, slowing down as the cross-section is increased. The approximate shape

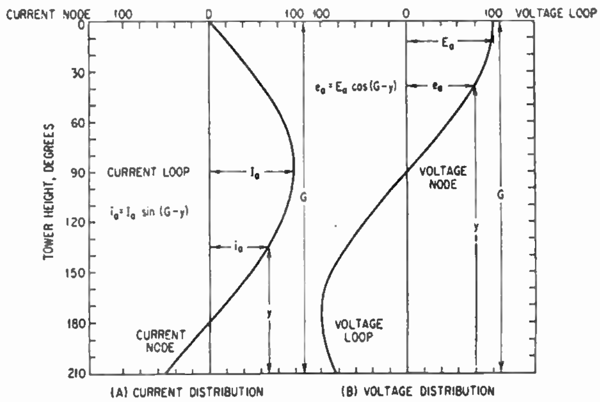

Figure 4.8-1. Theoretical current and voltage distribution on a vertical radiator.

of the current distribution on a thin tower of uniform cross-section is given by

$$i_a = I_a \sin(G - y)$$

Where: i_a is current in amperes at height y
I_a is the maximum current in amperes
G is the tower height in degrees
y is the height in degrees of the current element i_a

As an example, the general shape of the current and voltage distribution on a thin tower 210 electrical degrees high is shown in Figure 4.8-1. For shorter towers, the distribution would approximate that shown, but with the lower portions cut off; there always being a current node and a voltage maximum at the top of any such tower that does not employ top loading. It is important to visualize the shape of the voltage distribution along the tower because of the need of good insulators at the high-voltage points. Otherwise corona or arc-overs may result to disrupt broadcasting service.

The tower current and voltage are not zero at the nodes shown along the tower. Rather, they reach minimum values and shift rapidly approximately 180° in phase in traversing the node region. When towers considerably taller than 180° in height are considered, the current near the base is in the opposite direction from that in the upper portion of the tower. Under these conditions, when viewed in the horizontal plane, the radiation from the lowest part of the tower is canceling a portion of the radiation from the part above the current minimum. Any increase in tower height above the optimum would actually reduce horizontal plane radiation.

VERTICAL RADIATION CHARACTERISTICS

Maximum groundwave radiation occurs for a tower 225 electrical degrees high (5/8 wavelength). The variations in tower current distribution with increasing tower height defines the shape of the radiation characteristic in the vertical plane. Figure 4.8-2 shows the size and shape of the vertical plane radiation patterns for a single tower of various heights atop a perfect ground system, fed with 1 kW of power.

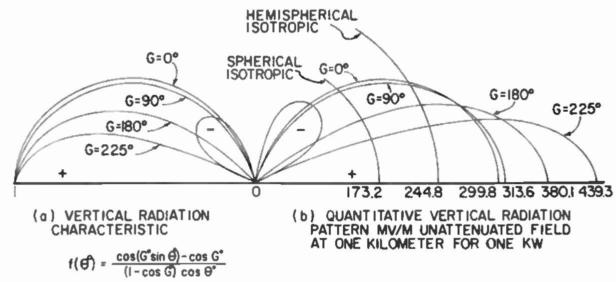

Figure 4.8-2. Radiation characteristics in vertical plane.

Insulated Tower Base Impedance

The base impedance of a single nondirectional tower is determined principally by its electrical height, its cross-section, the extent of the ground system, and the elevation of the feed point above ground. For typical guyed towers of uniform cross-section, which are base insulated and fed 4 or 5 ft above ground level, the resistive and reactive components of the base impedance approximate the values shown in Figure 4.8-3. The base impedance of self-supporting towers departs radically from the values shown, not only because of their large and tapering cross-section, but also because of the capacitance of the base insulators necessary to support each leg of such towers.

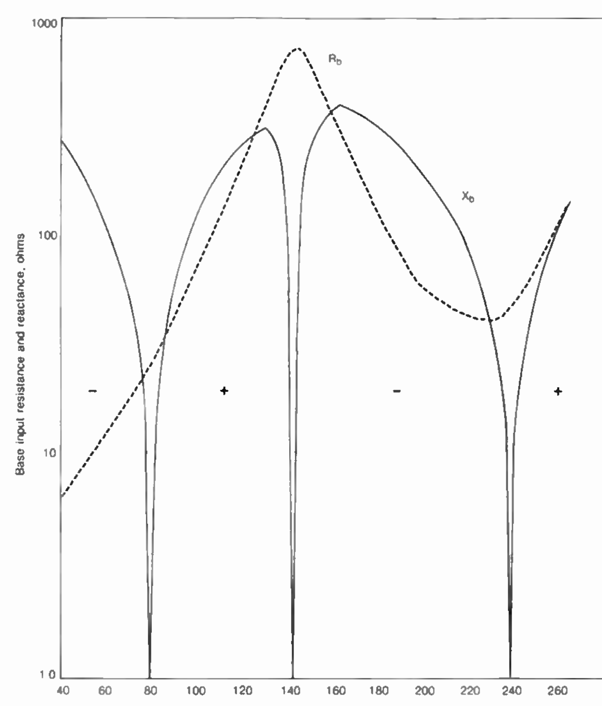

Figure 4.8-3. typical base input resistance and reactance of a uniform cross-section base insulated guyed tower.

Electrically short towers are inefficient radiators, not only because of the shape of their vertical radiation characteristics as shown in Figure 4.8-2, but also because of proportionately higher ground losses. For example, a tower 48° high with a base resistance of only 9 Ω will have approximately 10% of the available power wasted in the ground system resistance losses (typically 1 Ω).

Grounded Towers, Shunt Fed and Folded Monopoles

Occasionally towers without insulated bases must be utilized as AM radiators. Such structures include FM or TV towers, water tanks and ornamental flag poles. Although the impedance at the base of such a tower is necessarily essentially zero, the impedance rises with increasing height of the feed point. It is a simple matter to determine experimentally the height at which a shunt fed tower must be driven to provide a desirable input impedance. A common technique is a *slant-wire*[1] feed in which a wire is attached to the tower at a selected height above ground and brought down to near ground level at an angle approximating 45°, to serve as the antenna input terminal. A slant-wire feed distorts the otherwise omnidirectional pattern of a single tower and tends to suppress radiation over the sector on the side where the slant-wire is attached. This effect can be avoided if, instead of the slant-wire, the feed conductors are insulated at the base, brought up outside of the tower and bonded to the tower, for example, 90° above ground to form a folded monopole. The conductors, in this concentric arrangement, in effect form the outer conductor of a coaxial transmission line with a short to the tower at the 90° point and an open at the base insulators. This quarter-wave open circuit transmission line in effect puts an insulator at the tower base. The current up on the outer conductors and down on the tower essentially cancel so far as radiation is concerned. The tower with this insulated skirt performs like a base insulated tower. The concentric arrangement of conductors, usually six, are tied together above the conductor base insulators and fed like a base insulated tower. There is a small amount of power loss in the 90° concentric transmission line shorted at the top and used to produce the open circuit at the bottom. The radiation current is up on the outer conductors, to where they are connected to the tower at the 90° point, and then on up to the top of the tower where the current is zero as on a base fed insulated tower.

Folded Conical Monopole

The folded conical monopole shown in Figure 4.8-4 broadbands the input impedance. For a 90° tower the vertical radiation characteristic is that of a 75° tower but with an increased value of input resistance and reactance of about 50%. These results were obtained by applying the method of moments to compute the base impedance, current distribution and vertical pattern.

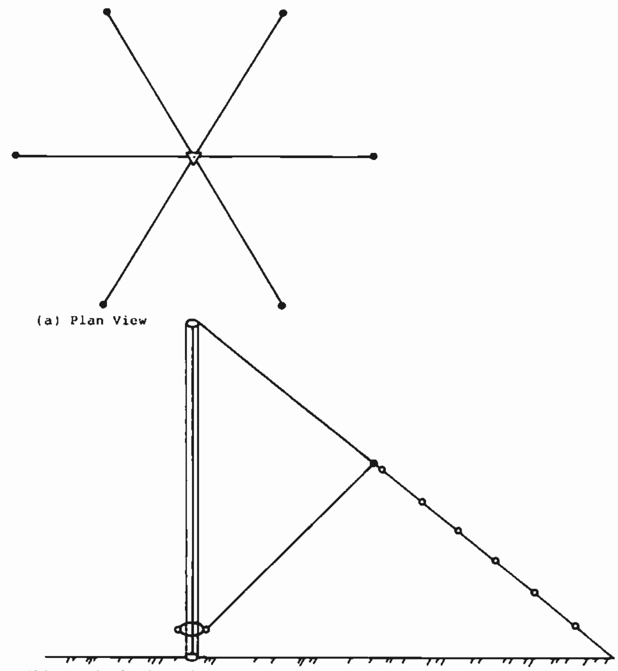

Figure 4.8-4. Sketch of folded conical monopole antenna.

Top Loading

The performance of an electrically short tower (significantly less than 90°) can be improved, both as to radiation efficiency and bandwidth by means of top loading. This consists of increasing the capacitance to ground from the top of the tower. This loading can take the form of either a flat, more-or-less circular horizontal disk attached to the top of the tower (called a top hat) or as sections of guy wires bonded to the top of the tower and extending down a useful distance before encountering the first of the guy wire insulators. Many variations are possible. Some installations use 3, 6, or even 12 nonstructural guys for top loading that are very effective. By interconnecting the lower ends of the top loading cables, the capacitive loading is increased some, but this method or spider web connections between the top loading cables increases the construction and maintenance problems. These problems can be eliminated by just increasing the top loading cables a small amount to give the same increase in capacity effect. Top loading is electrically less desirable than increased tower height, but is useful where towers must be electrically short due to either extremely low carrier frequencies or to aeronautical limitations. Top loading increases the base resistance and lowers the capacitive base reactance thus reducing the Q and improving the bandwidth on towers less than 90° high. When the tower height is of the order of 130°, top loading can be used to increase the tower's

[1] Slant wire feeds are no longer accepted by the FCC for critical hours and night operation.

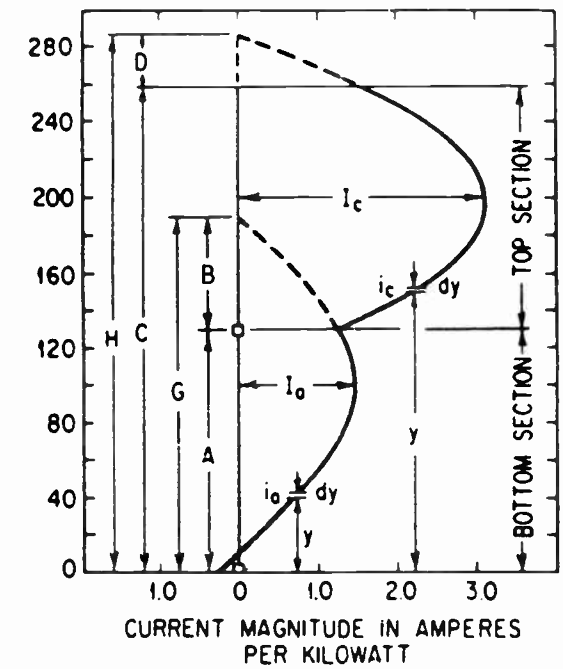

Figure 4.8-5. Theoretical current distribution on top-loaded sectionalized tower.

electrical height to give maximum groundwave radiation and minimum skywave radiation.

Sectionalized Towers

A utopian vertical radiator would have a constant current throughout its height, but in real life the current must ultimately reduce to zero at the tower top or at the end of the top loading cables. The current can be made to diminish less rapidly by inserting an inductance in series with the tower at a point part way up its height. This is the same technique as the familiar "loading coil" near the center of the vertical whips often used for mobile radio systems.

Top Loaded Sectionalized Tower

For a simple vertical radiator the radiation characteristic can be improved by increasing the tower height up to 225° for maximum ground wave or by top loading. This in effect raises the position of the current loop with respect to the ground. This principle can also be applied to the top section of a sectionalized tower.

The purpose of top loading a sectionalized tower is to provide a means of further controlling the current distribution on the lower section only. Considering efficiency and stability, it is usually possible to achieve a more favorable radiation characteristic of the whole tower by employing top loading and sectionalization (see Figure 4.8-5). In the case of tall towers used to support FM or TV antennas, it may not be practical to employ top loading.

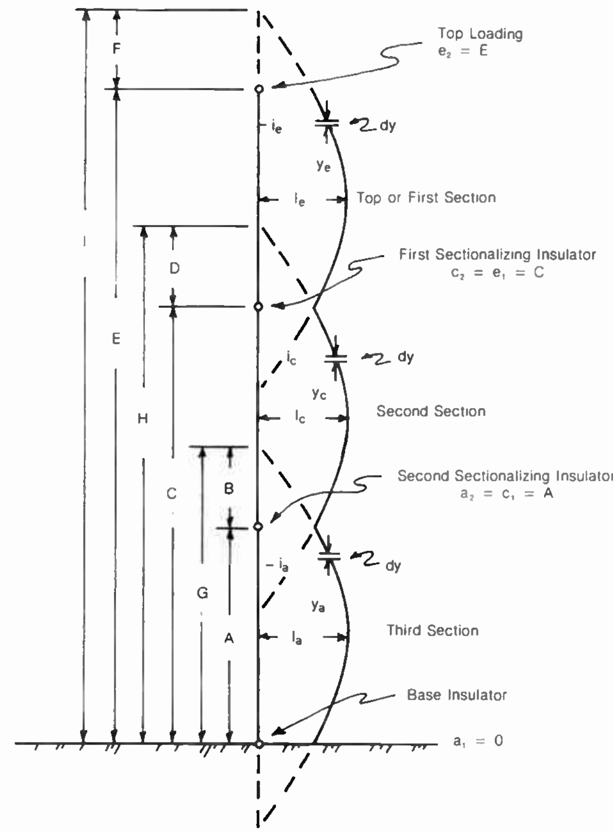

Figure 4.8-6. Theoretical current distribution on three section top loaded tower.

Depending on the height, of tower in wavelengths, the tower can be sectionalized at one or more points to accomplish the highest efficiency consistent with good operating stability (see Figure 4.8-6).

Short Low-Loss Antenna with Insulated Counterpoise

Short low-loss antennas are useful for standby use and regular use where height is limited. By using optimum top loading and a tuned counterpoise, the field strength is maximized by adjusting the counterpoise inductor in Figure 4.8-7 to minimize the top hat field through the counterpoise to the lossy ground.

Ground Systems

The current on a tower does not simply "disappear," rather it returns to earth through the capacitance between the earth and each incremental element of the tower or the top loading. For towers not exceeding 90° in height, the tower current is greatest at the base. For such towers the radial ground current is greatest near the tower and decreases with increasing distance from the tower. For single towers the ground currents are radial from the tower base. The ground losses are greatly reduced if the tower has a radial copper ground system, so the ground current will be in the low-loss

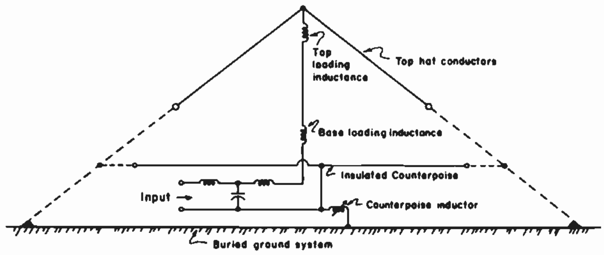

Figure 4.8-7. Short, low-loss antenna with counterpoise.

copper ground system rather than in the earth which has a much higher resistance. A solid copper sheet of infinite radius would be the ultimate ground system, but experiments and experience have defined the dimensions of an adequate ground system. A system of 120 radial ground wires, each 90° long (140° is considered optimum), and equally spaced out from the tower base, constitutes a "standard" ground system. This is often augmented with an additional 120 interspersed radials 50 ft long, or an expanded copper mesh ground screen 25 to 50 ft square centered at the tower. A superior ground screen material is the copperweld, mesh ground mat often utilized by power companies for lightning protection under electrical substations.

Where the antenna site is too small to accommodate all the ground radials at full length, a compromise often used, if easement can not be obtained beyond the property line, is to increase the number of radials by placing them 1 or 2° apart rather than the standard 3° separation.

There is no magic in a "standard" ground system for nondirectional towers; it simply represents a reasonable balance between cost and radiation efficiency.

The antenna system loss including the tower and ground system is normally assumed to be 1 Ω and is added to the tower base resistance.

Most ground systems under directional antenna arrays consist of the usual 120 radials per tower truncated and bonded to traverse copper straps where the radials from the several towers would otherwise intersect. Stability considerations may dictate larger than standards ground systems under critical directional antenna arrays; changes in soil conditions beyond the ground system can result in small changes in tower base impedance.

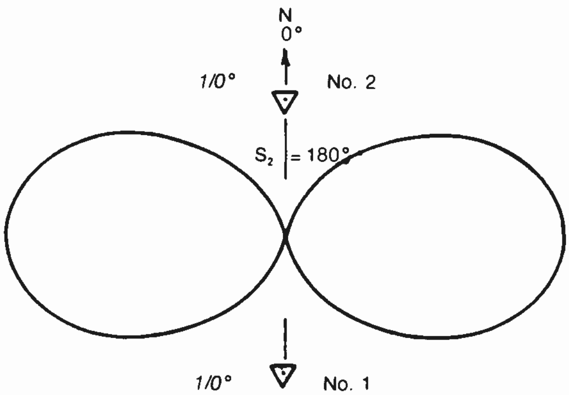
Ground system losses are minimized if the radial wires are placed above ground, thus the E-field voltage from the tower and top loading cables terminate on these radial conductors so the H-field current can return to the tower base without penetrating the lossy earth. Ground radials are usually buried 6 to 8 in. for mechanical protection. Burial up to 24 in. is feasible where necessary to permit deep plowing for agricultural crops. However, the ground system should be very near the earth surface in the immediate vicinity of the tower. The earth losses are greater for the buried ground system. Changes in weather conditions change the dielectric constant and conductivity of any unshielded earth to the detriment of base current stability.

TWO-TOWER DIRECTIONAL ANTENNA

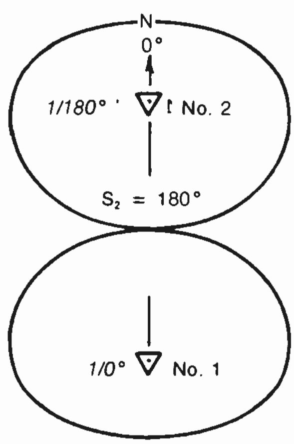
When a nondirectional antenna, with a given power, does not radiate enough field strength to serve the community of interest and/or fails to protect other radio stations, then it is logical to resort to a directional antenna system to achieve these objectives. FCC Rules spell out the protection requirements to be provided to the various classes of stations, both daytime and nighttime on the same and adjacent channels. These limits, which must be met in the directional antenna design, tend to define the shape and size of the most desirable antenna pattern. Since the distances and directions to the other stations requiring protection are rarely the same, most directional antenna patterns are tailored to meet the specific requirements. A directional antenna functions by carefully controlling the amplitude and phase of the radio frequency currents fed to each tower. The resulting field in any direction is the vector sum of the individual tower radiation components. To visualize the resulting pattern in the horizontal plane, one must consider the individual tower radiation components when viewed from distant points in different directions. The relative amplitudes from the individual towers remain unchanged, but the relative phases shift with azimuth because the signal from the closest tower arrives first. In a directional antenna system, one tower is usually defined as the reference tower, and the amplitude and phase of each other tower is measured relative to this reference. The reference tower usually has the greatest current, thus the ratio of the current in each other tower relative to the reference tower current is a fractional number often expressed as a percent of the reference tower current. The relative amplitude and phase of the tower currents is measured by means of an antenna monitor.

The phase of the field, radiated by each tower relative to the reference tower, has two components when viewed from any distant point of observation. The relative electrical magnitude of the current fed to the tower is one component, and is adjustable. The second component is the phase which appears to lead or lag the reference tower by virtue of being more distant or closer than the reference tower to the point of observation. This is termed the space phase component and varies continuously for each tower in a sinusoidal manner as the observation point is moved in azimuth along a distant circle around the array.

Figure 4.8-8 shows three simple directional antennas and their resulting patterns which are easy to visualize. Figure 4.8-8(a) shows two towers arranged along a north-south line separated by 180° and fed with equal currents in phase. When viewed from the east or west, the fields from the two towers are in phase and the maximum field strength results. When viewed from the north or south, the field from the more distant tower is delayed by the 180° of additional distance,



(a) Broadside Array



(b) End Fire Array

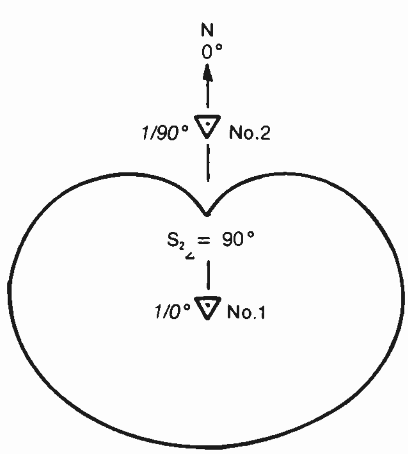


Figure 4.8-8. Three simple directional antenna patterns.

thus canceling the field of the closer tower so as to result in a minimum or null. The deepest minimum or null occurs only when the fields are exactly equal in amplitude and opposite in phase.

Figure 4.8-8(a) is termed a broadside array because the maximum radiation is broadside to a line through the towers. Figure 4.8-8(b) shows a similar arrangement, but with the phase of the current in the north tower shifted by 180°. Then the fields from the two towers cancel each other when viewed from the east or west, but would produce maximum radiation from north or south. This would be termed an end-fire array, because maximum radiation coincides with a line through the ends of the array. Figure 4.8-8(c) alters the spacing to 90° and phasing to 90° so as to produce a cardioid pattern. Other combinations of tower spacing and phasing can produce a great variety of pattern shapes. See Appendix B.

Multiplication of Two Tower Patterns

Perhaps the most widely used method of controlling pattern shape involves the multiplication of two-tower patterns. This illustrated in Figure 4.8-9. When a two-tower pattern such as pattern Number 1 with nulls at $\pm 0_{n1}$ is multiplied by pattern Number 2 with nulls at $\pm 0_{n2}$ the result is pattern Number 3 in a three-tower array. The directions of all of the two-tower array nulls are maintained in the three-tower array. This is a very powerful design technique for protecting other stations and still serving a desired service area. In this special case the spacings S_2 and S_3 are equal, resulting in an in-line array with fields of towers Number 2 and Number 3 being added in the center tower, and the end tower of the three-tower array is the multiplication of these fields as shown in pattern Number 3 of Figure 4.8-9.

In the event that the protection directions are not symmetrically located, the two-tower arrays can be placed on different azimuth angles to produce a four-tower parallelogram array (as shown in Figure 4.8-10). The nulls of the Number 1 pattern are maintained and the nulls of Number 2 pattern are maintained in the four-tower parallelogram array. Furthermore, the spacing from Number 1 tower to Number 2 and Number 3 towers does not have to be the same. By this approach of using one or more parallelograms, a wide variety of asymmetrical patterns are possible with relative simplicity of pattern calculations. However, modern computer techniques can optimize individual tower locations, currents and phases so as to produce an efficient pattern, frequently using fewer towers than required with the parallelogram approach.

Systematization of Patterns

The pattern possibilities resulting from variations in spacing and phasing have been systematized and a sample of two-tower patterns is shown in Appendix B. (See Reference 1 for three-tower patterns.)

Radiation Pattern Size

The pattern size is usually determined by integrating the energy flow outward through an imaginary hemispherical surface surrounding the directional antenna array. This method does not give information regarding the distribution of power radiated from the various towers of the directional antenna array, however, it is very useful for making comparisons of pattern size.

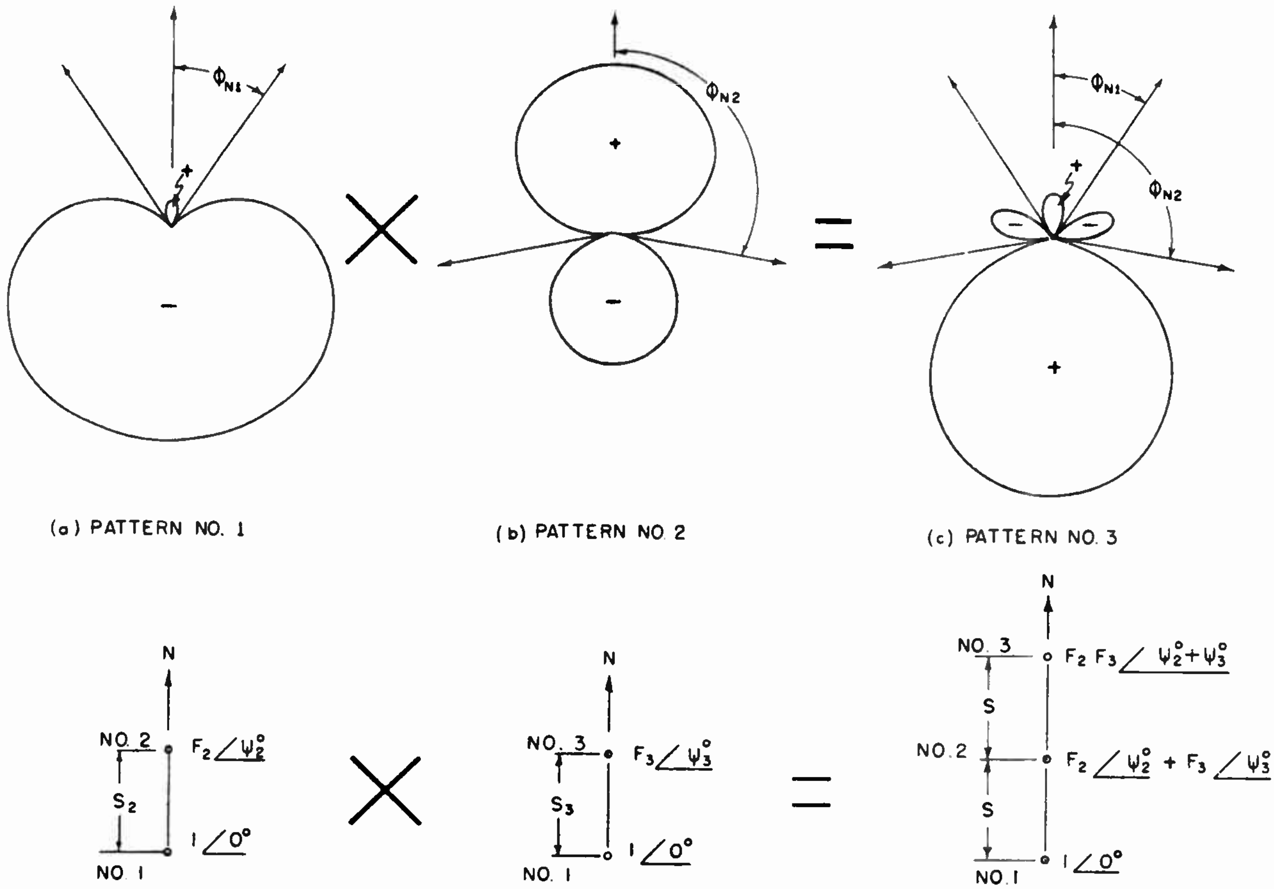

Figure 4.8-9. Multiplications of patterns to produce a three tower in line array.

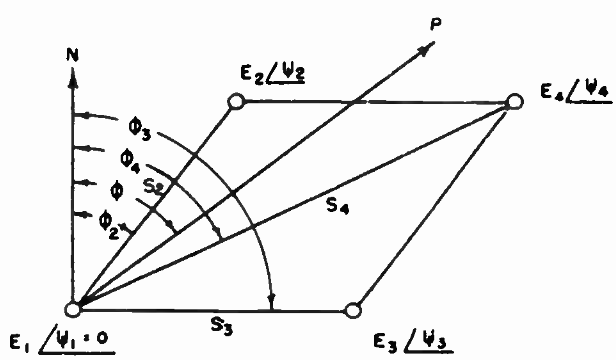

Figure 4.8-10. Multiplication of two patterns to produce a four tower parallelogram array.

This computation method is available in digital computer programs and is used by the FCC.

There are other methods of determining pattern size, such as the *mutual resistance method* which employs Bessel functions, and the *driving point impedance method* which uses mesh circuit equations with self and mutual impedance information.

The "method of moments" is now available in large computer programs to determine current distribution on towers and top loading cables, base driving point impedances and the vertical pattern of directional antenna arrays.

Driving Point Impedance

The input impedance of each tower in an array (*driving point impedance*) is not that of the nondirectional tower. The driving point impedance contains the self impedance plus the mutual impedance multiplied by the current ratios that exist in the array as driven to produce the desired pattern. The driving point impedance will modify the self impedance, depending on the array parameters, and can even make the base resistance negative so that the tower draws power, from the other towers and dissipates the power into a load resistor or delivers it back to the phasing system. Because the driving point impedance is affected by the currents in the other towers, it can only be measured by an operating bridge inserted in the tower feed point, while the other towers are operating with their correct current magnitude and phase.

Base Currents Versus Radiated Fields

In a directional array, the tower base current ratios will usually depart substantially from the calculated radiated field ratios when the pattern is correctly adjusted. This is caused by the mutual coupling between

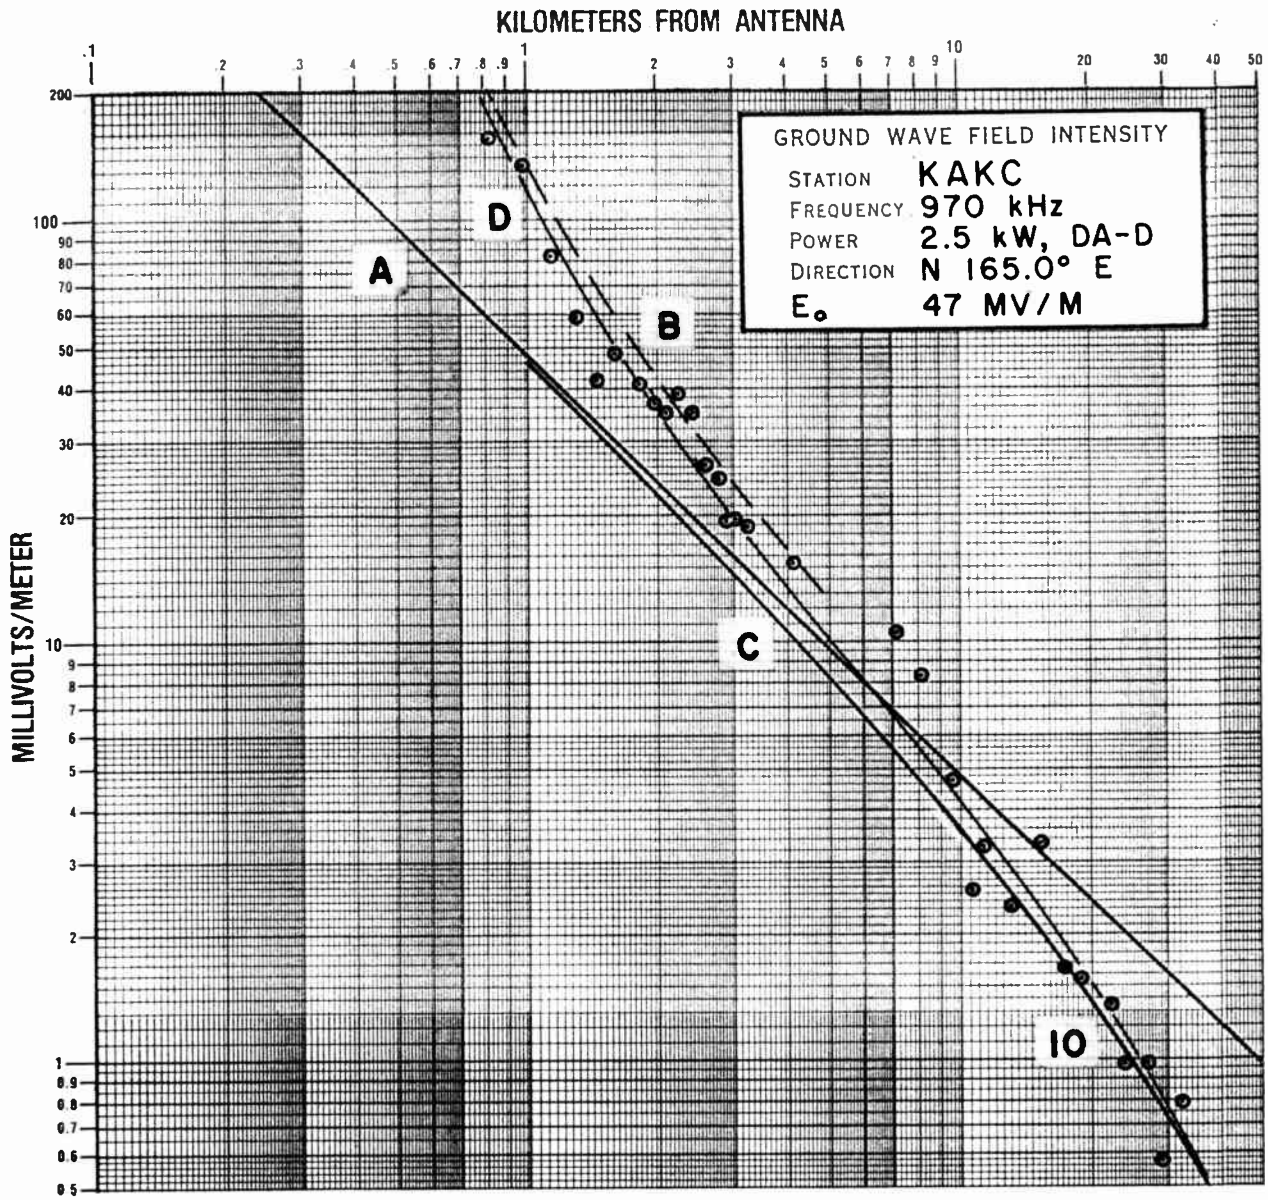

Figure 4.8-11. Near-field effects.

towers which distorts the sinusoidal current distribution otherwise assumed for each tower. Thus, the correct pattern is initially proved by means of a series of field strength measurements in significant radial directions from the station rather than by assuming that measurement of tower currents and phases can establish the correct pattern.

Near-Field Versus Far-Field Conditions

Theoretically a directional antenna pattern is not fully formed except at an infinite distance, where the separate towers can be considered as point sources. As a practical matter, near-field effects can persist as far as 32 km (20 miles) from an antenna before far-field conditions prevail. This is especially true in the deep minimums of wide-spaced arrays; however, misleading measurement results can often occur under apparently innocent circumstances. Near-field calculations involve consideration of the actual inverse distance attenuation and the actual phase delay from each antenna element to a series of observation points along a radial.

Figure 4.8-11 shows the results of such calculations on a minimum radial and the resulting analysis of field strength measurements. Line A is the inverse distance line for the theoretical unattenuated radiation at 1 km. Line B is the result of the near-field calculations assuming only inverse distance attenuation, that is, no soil losses. It converges with the inverse distance line with increasing distance. Line C represents a soil conductivity of 10 mmhos/m as drawn in the conventional manner from analysis of nondirectional measurements on the radial. Line D is a composite of lines B and C. It includes the near-field calculations and is attenuated with distance in accordance with the soil conductivity previously established. This composite line converges with the near-field calculations at short distances where soil attenuation is negligible and converges with the soil conductivity line at great distances where near-field effects disappear. Since curve D accounts for both near-field effects and soil losses, it is the proper curve against which the directional field strength measurement data should be fitted. Note the good fit to the measurement data, both close to the array and at distant points even though the first 19 measurement points fall considerably above the inverse distance line A.

Pattern Size Versus Pattern Shape

The shape of a directional antenna pattern is determined by the adjustment of the phase and ratio parameters, whereas the pattern size is a measure of the power radiated and is affected by the transmitter power output and the losses within the phasing system and the ground system. Since pattern size and shape are essentially independent, it is most expeditious to adjust an array to get the correct shape before expending much concern on the size.

Field strength measurements on a previously-licensed directional antenna may appear to indicate a change in pattern shape or size when the change was in fact due to changes in soil conductivity. Such changes affect distant measurements more than close-in measurements. In some areas of the United States, the conductivity is typically higher during winter and spring months when the soil is more moist than in summer and fall months.

Seasonal conductivity variations are not observable in some portions of the country, yet are extreme in other areas. One well-documented case showed a seasonal doubling of signal strength at 32 km (20 miles) in the main lobe of a correctly adjusted system operating on 1380 kHz. To avoid the misleading effects of seasonal conductivity changes that might appear to distort measured directional antenna patterns in size or shape, the FCC requires that all the field strength measurements in a directional antenna proof of performance be made under "similar environmental conditions."

Standard Patterns

Theoretical (calculated) patterns can have nulls wherein the radiation at specific azimuths goes completely to zero. In practice, it is not possible to prove by field strength measurements that a null exists. Reradiation and scatter from objects external to the array limit the depth to which a pattern minimum can be proven. Additionally, operational variations in phase and ratio parameters will increase radiation in any direction where the deepest possible minimum has been previously established. To accommodate these limitations, the FCC authorizes a *standard pattern* for each directional antenna station. Standard patterns exceed the theoretical pattern at all azimuths by specified and easily calculated amounts. It is required that the radiation from a directional station not exceed its standard pattern. All U.S. stations employing directional antennas have FCC specified standard patterns. These supersede all earlier patterns based on theoretical calculations or on field strength measurements. The standard pattern radiation values are now used exclusively in all calculations of coverage and interference.

Augmented Patterns

Augmentation is applied to the standard pattern when the measured field strength is exceeded in discrete directions but does not cause interference to other stations. When augmentation is desired, it is achieved by applying Equation (C-9) in Appendix C.

APPENDIX A
DIRECTIONAL ANTENNAS FOR PATTERN SHAPE

Space Configuration

The Plan configuration of the k^{th} tower in an array is shown in Figure 4.8-A-1. A space view of the k^{th} tower and observation point P is shown in Figure 4.8-A-2.

Vector Diagram

The field strength at the point P in space for the k^{th} tower is shown in Figure 4.8-A-3. The space phasing in the horizontal plane is shown in Figure 4.8-A-4 and in the elevation plane the space phasing is reduced further as shown in Figure 4.8-A-5.

Generalized Equation

The vector equation to express the vectors in Figure 4.8-A-6 is the generalized equation that can be used to express the pattern shape for a directional antenna array of n towers. The equation in condensed form is,

$$E = \sum_{k=1}^{k=n} E_k f_k(\Theta)\beta_k \qquad \text{[A-1]}$$

where:

E = the total effective field strength vector at unit distance (P) for the antenna array with respect to the voltage vector reference axis. This vector makes the angle β with respect to this axis as shown in Figure 4.8-A-6.
k = the k^{th} tower in the directional antenna system
n = the total number of towers in the directional antenna array
E_k = the magnitude of the field strength at unit distance in the horizontal plane produced by the k^{th} tower acting alone
$f_k(\Theta)$ = vertical radiation characteristic of the k^{th} antenna as given in Equation A-3
Θ = elevation angle of the observation point P measured up from the horizon in degrees

$$\beta_k = S_k \cos\Theta \cos(\phi_k - \phi) + \psi_k \qquad \text{[A-2]}$$

is the phase relation of the field strength at the observation point P for the k^{th} tower taken with respect to the voltage vector reference axis

$$S_k \cos(\phi_k - \phi)\cos\Theta$$

is the space phasing portion of β_k due to the location of the k^{th} tower and ψ_k is the phasing portion of β_k

S_k = electrical length of spacing of the k^{th} tower in the horizontal plane from the space reference point
ϕ_k = true horizontal azimuth orientation of k^{th} tower with respect to the space reference axis
ϕ = true horizontal azimuth angle of the direction to the observation point P (measured clockwise from true north)
ψ_k = time phasing portion of β_k due to the electrical phase angle of the voltage (or current) in the k^{th} tower taken with respect to the voltage vector reference axis

The shape of any directional antenna pattern can be computed by applying the above equations, however, many directional antenna arrays can be designed by simplified versions of this equation.

For a vertical antenna having a sinusoidal current distribution with a current node at the top, the vertical radiation characteristic takes on the form

$$f(\Theta) = \frac{\cos(G\sin\Theta) - \cos G}{(1 - \cos G)\cos\Theta} \qquad \text{[A-3]}$$

where

$f(\Theta)$ = vertical radiation characteristic
G = electrical height of the antenna in electrical degrees
Θ = elevation angle of the observation point measured up from the horizon in degrees

The vertical radiation characteristics in Equation A-3 are graphed in Figure 4.8-A-7.

For a top-loaded tower the formula is:

$$f(\Theta) = \frac{\cos B\cos(A\sin\Theta) - \cos G - \sin B\sin\Theta\sin(A\sin\Theta)}{\cos\Theta(\cos B - \cos G)}$$

This is the vertical radiation characteristic for a top-loaded tower of height A and top-loaded to a height of $G = A + B$.

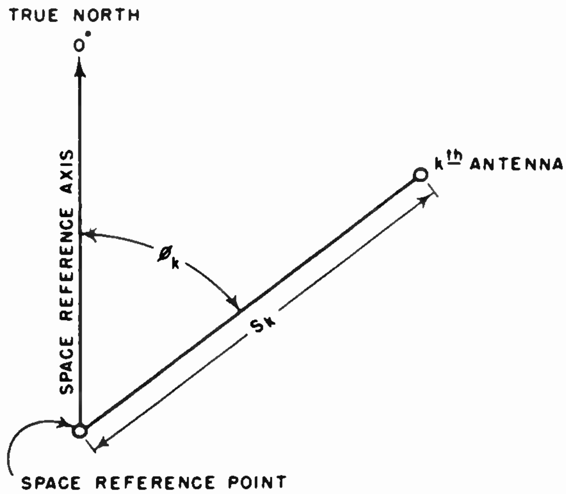

Figure 4.8-A-1. Plan view of space configuration of k^{th} antenna.

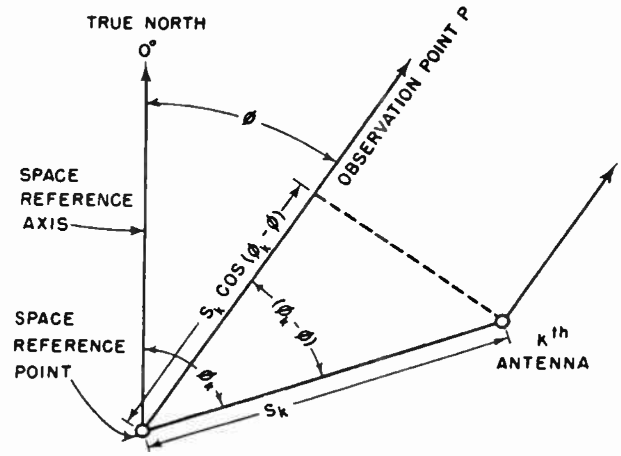

Figure 4.8-A-4. Plan view of k^{th} antenna showing space phasing in the horizontal plane.

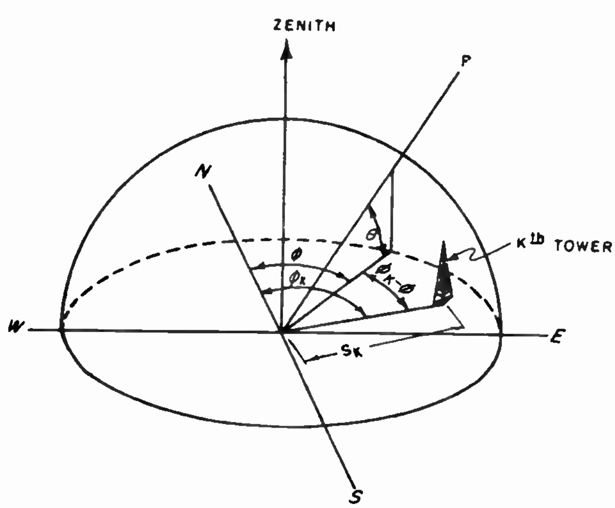

Figure 4.8-A-2. Space view of observation point P and the k^{th}.

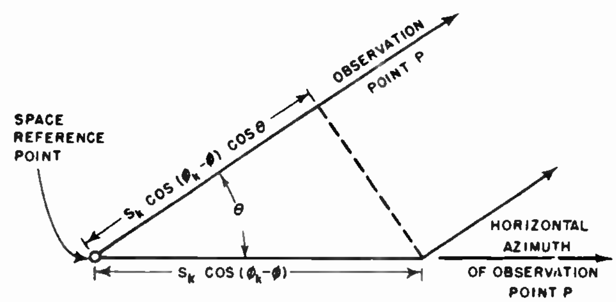

Figure 4.8-A-5. Elevation angle θ shortens the spacing S^k to the value of $S^k \cos\theta$.

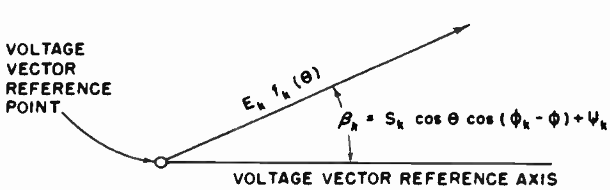

Figure 4.8-A-3. Voltage vector diagram for the k^{th} antenna.

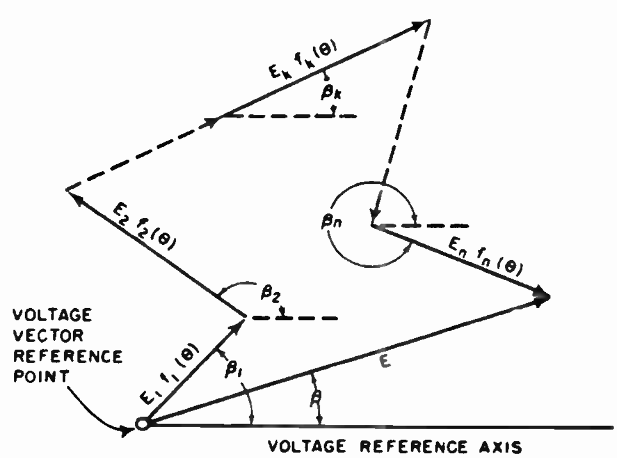

Figure 4.8-A-6. Summation of field strength vectors for n antennas in the directional antenna array.

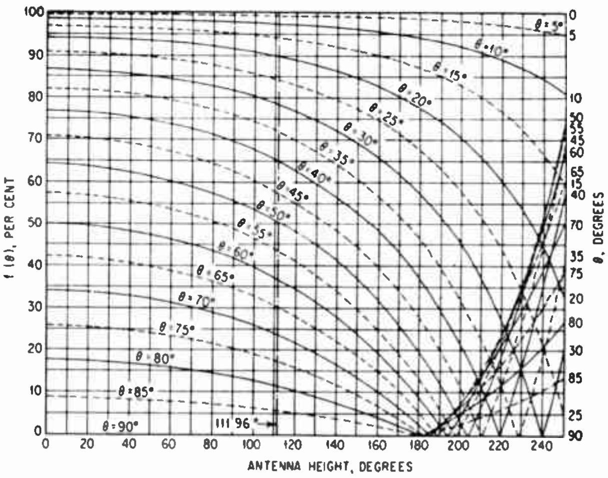

Figure 4.8-A-7. Vertical-radiation characteristics as a function of electrical tower height for various values of elevation angle.

For a two section top-loaded tower as shown in Figure 4.8-5, the formula is:

$$\cos B \cos(A \sin \Theta) - \cos G + \frac{\sin B \cos(H - C)\,\cos(C \sin \Theta)}{\sin(H - A)}$$

$$f(\Theta) = \frac{-\dfrac{\sin B \sin \Theta \sin (H - C) \sin(C \sin \Theta)}{\sin(H - A)} - \dfrac{\sin B \cos (H - A) \cos(A - \Theta)}{\sin(H - A)}}{\cos\{\cos B - \cos G + [\sin B/\sin(H - A)]\,(\cos \overline{H - C} \cos \overline{H - A})\}} \qquad \text{[A-4]}$$

This is the vertical radiation characteristic equation for a two-section sectionalized tower. The same procedure can be applied if more than two sections are involved, such as shown in Figure 4.8-6.

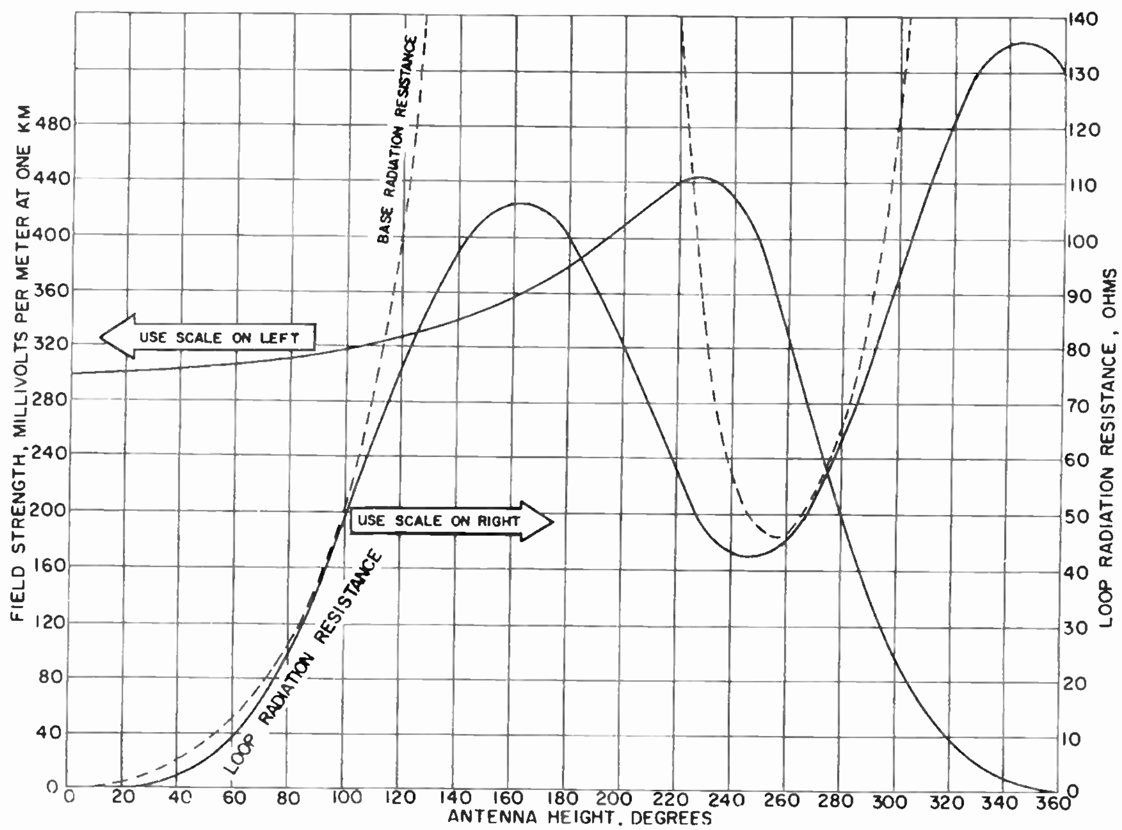

Figure 4.8-A-8. Inverse field strength at 1 km for 1 kW, loop and base radiation resistance as a function of tower height over a perfectly conducting earth.

Theoretical Self-Loop and Base-Radiation Resistance

It is useful to know the theoretical loop and base resistance of a vertical radiator. This information is presented graphically in Figure 4.8-A-8 along with the theoretical inverse field strength at 1 km.

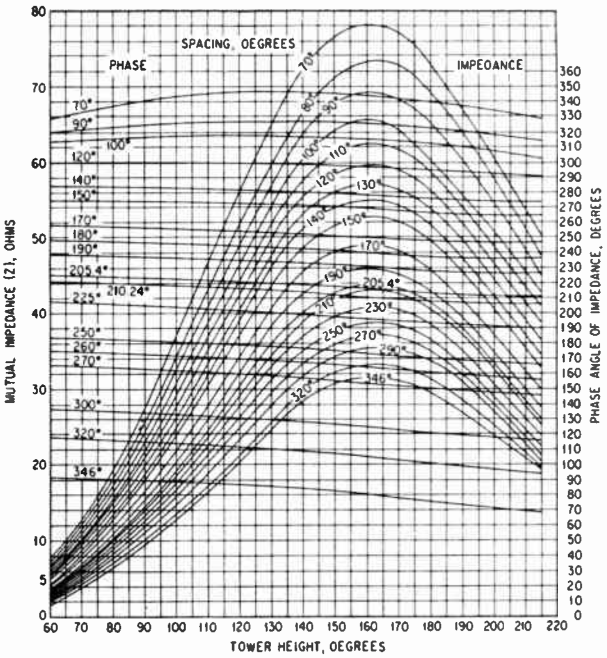

Figure 4.8-A-9. Loop mutual impedance and phase angle between two towers of equal height.

Mutual Impedance Curves

The value of mutual impedance for most tower heights and spacing is given in Figure 4.8-A-9. The loop mutual impedance between quarter-wave towers is shown in Figure 4.8-A-10.

Horizontal RMS Field Strength

The field strength gain or loss of a two-tower array for various values of phasing and spacing is shown in Figure 4.8-A-11.

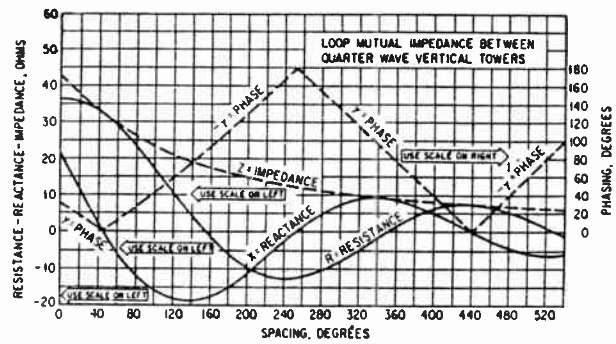

Figure 4.8-A-10. Loop mutual impedance between quarter-wave vertical towers.

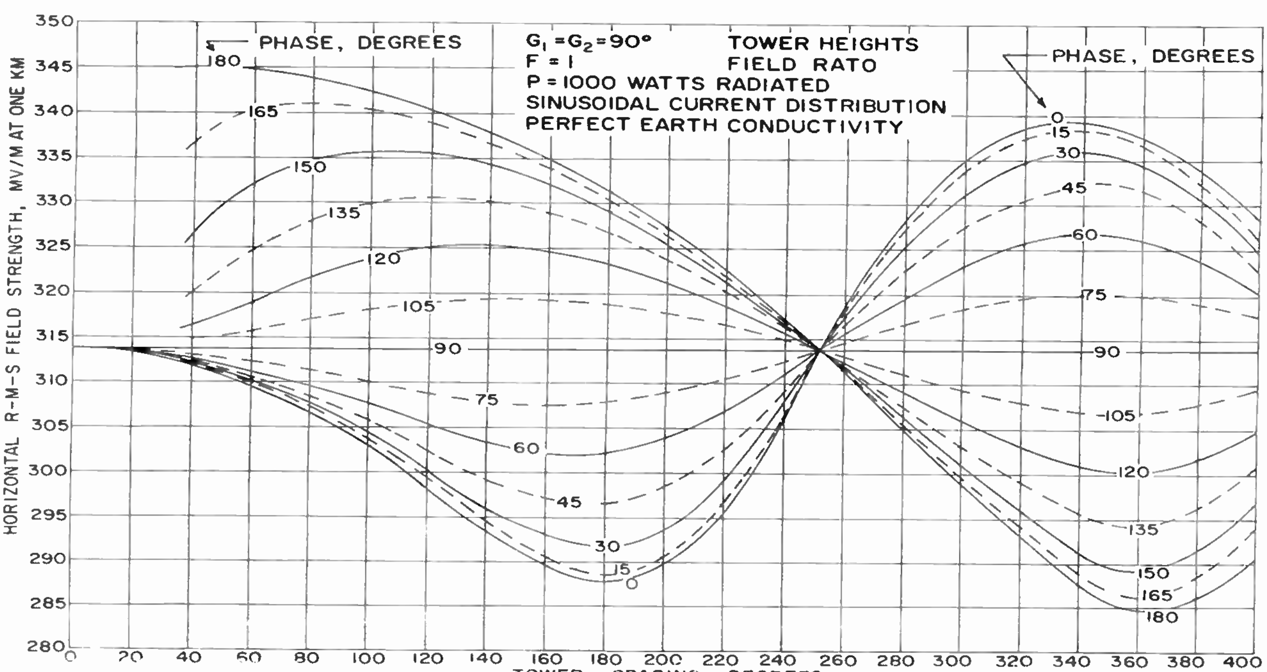

Figure 4.8-A-11. Horizontal RMS field strength of two-tower directional antenna.

APPENDIX B
SYSTEMATIZATION OF TWO TOWER PATTERNS

The pattern numbering system has been devised to furnish the antenna parameters in an orderly fashion as described at the bottom of each Figure. To simplify the numbering system, the spacing and phasing of each antenna is shifted in steps of 45°. The spacing varies from 45° in Figures 4.8-B-1 to 1,440 in Figure 4.8-B-4 while the phasing varies from 0° to 315° in each figure. The field strength of each antenna, E1 and E2, is expressed in percent of the maximum lobe field strength (50%) of the horizontal pattern. Finally, the last two digits specify, in percent, the RMS field strength in the horizontal plane of the two tower directional antenna array.

The detailed patterns which follow are for spacings in steps of 15° up to 360° degrees. The phasings are only presented from 0° to 180° since the same patterns, turned 180°, give the results for phasings from 180° to 360°.

APPENDIX C
PATTERN DEVELOPMENT OF DIRECTIONAL ANTENNAS

Theoretical Pattern Equation

The theoretical pattern equation of Appendix A can be written as follows by changing the k^{th} tower to the i^{th} tower to conform with the FCC practice, thus:

$$E(\phi, \Theta)_{th} = \left| k \sum_{i=1}^{n} F_i(\Theta) \underline{/ S_i \cos\Theta \cos(\Phi_i - \Phi) + \Psi_i} \right| \quad [C-1]$$

where:

k = multiplying constant which determines pattern size

Standard Pattern Equation

The standard pattern equation is obtained from Equation C-1 by adding the quadrature term Q to fill minimums and increase the size by 5%, thus:

$$E(\Phi, \Theta)_{std} = 1.05\sqrt{[E(\Phi, \Theta)_{th}]^2 + Q^2} \quad [C-2]$$

where Q is the greater of the quantities:

$$0.025g(\Theta)E_{rss} \quad [C-3]$$

or

$$10.0g(\Theta)\sqrt{P_{kw}} \quad [C-4]$$

where $g(\Theta)$ is the vertical plane distribution factor, $f(\Theta)$, for the shortest element in the array (see Equation C-2 above; also see FCC Rules Section 73.190, Figure 5).

If the shortest element has an electrical height in excess of 0.5 wavelength, $g(\Theta)$ shall be computed as follows:

$$g(\Theta) = \frac{\sqrt{\{f(\Theta)\} + 0.0625}}{1.030776} \quad [C-5]$$

$$E_{rss} = \sqrt{\sum_{i=1}^{n} E_i^2} \quad [C-6]$$

As an example, consider a two-tower array. The theoretical pattern equation (Equation C-1) becomes:

$$E = E_1 f_1(\Theta) \ \underline{/0^\circ} + E^2 f_2(\Theta) \ \underline{/ S_2 \cos\Theta \cos(\phi_2 - \phi) + \psi_2} \quad [C-7]$$

Now, for 5 kW, 90° towers, and the following parameters:

Tower number	Height G^0	Field Ratio	Spacing S^0	True Bearing ϕ^0	Phase ψ
1	90	1.0	0	0	0
2	90	1.0	90	0	−90

E_{rss} (theoretical pattern) = 691.92 mV/m
Q (quadrature term) = 21.60 mV/m
E_{rms} (standard pattern) = 726.87 mV/m

A plot of the theoretical and standard patterns is shown in Figure 4.8-C-1.

The minimum horizontal field strength (at one km) when the theoretical field strength goes to zero is given by Equation C-2 for a standard pattern along the ground using Equation C-4 with g(Θ) = 1.0. For 1 kW and under, Q is 6 according to FCC Rules. For various FCC licensed values of power, the minimum field strength values are as follows:

P_{kw}	Q	E_{mvm}
0.25	6.0	10.14
0.50	6.0	10.14
1.00	6.0	10.14
2.50	9.49	16.03
5.00	13.42	22.67
10.00	18.97	32.06
25.00	30.00	50.69
50.00	42.43	71.69

The minimum field strength (at 1 kW) for any elevation of a standard pattern, by Equation C-5, is:

$$g(\Theta) = \frac{\sqrt{0 + 0.0625}}{1.030776} = 0.2425$$

Augmented Pattern Equation

The augmented pattern equation is obtained by adding an augmentation quadrature term to the standard pattern as given here:

$$E_{(\phi,\Theta)aug} = \sqrt{\{E_{(\phi,\Theta)std}\}^2 + A\left\{g(\Theta)\cos\left(180\frac{D_A}{S}\right)\right\}} \quad [C-8]$$

where:

$E_{(\phi,\Theta)aug}$ = augmented pattern radiation value at azimuth, elevation
$E_{(\phi,\Theta)std}$ = standard pattern radiation value at azimuth, elevation
A = augmentation constant (insert equation C-10)

$$g(\Theta) = \frac{\sqrt{\{f(\Theta)\}^2 + 0.0625}}{1.030776} \quad [C-9]$$

S = span of augmentation in degrees
D_A = angular distance from center of span

The principle of augmentation is illustrated in the cardioid pattern of Figure 4.8-C-2.

The FCC has converted all augmented directional patterns to a table for each station as shown in the example of Figure 4.8-C-3. In this case there were six augmentations as tabulated in Figure 4.8-C-4 and shown on the polar chart of Figure 4.8-C-5.

It should be noted that where the spans overlap, Equation C-9 is applied repeatedly, once for each augmentation, proceeding clockwise from true north.

AM ANTENNA COUPLING AND PHASING SYSTEMS

EDWARD EDISON, P.E. & GERHARD J. STRAUB, P.E.
HAMMETT & EDISON, INC., SAN FRANCISCO, CALIFORNIA

INTRODUCTION

AM broadcast antenna coupling and phasing systems consist principally of passive networks of inductors, capacitors, transmission lines, and auxiliary components such as lightning gaps, meters, jacks and relays. This equipment can range from simple (such as a nondirectional station having the transmitter building located adjacent to the tower base) to complex (such as a multi-tower directional array requiring different patterns day and night). To understand AM antenna systems and their environment, we must consider the function of such systems and their performance objectives, as well as the characteristics of basic networks, power dividers, transmission lines, sampling systems, detuning systems, and transmitter load optimization.

It is not the intent of this chapter to make directional antenna experts out of its readers. However, in providing a broad perspective of the design of such systems, we hope to encourage a rational approach to the everyday problems of directional antenna operation and maintenance. The design and adjustment of the more complex directional arrays require considerable knowledge and experience that is beyond the training of almost all chief engineers and contract engineers. When unusual problems arise that do not yield to reasonable efforts at repair and adjustment, it is time to call in an expert; preferably the consulting engineer or firm that designed or previously adjusted the system.

THE FUNCTION OF A DIRECTIONAL ANTENNA PHASING SYSTEM

The function of a directional antenna phasing system is to distribute current to each tower with controllable phase and amplitude so as to generate the desired directional radiation pattern. This function is accomplished typically by means of the following:

1. A network at each tower matches each tower load to its transmission line (see Figure 4.9-1). This network is typically in a weatherproof box, termed an antenna coupling unit (ACU) or antenna tuning unit (ATU), or within a small building called a *doghouse.*
2. The remaining equipment, usually housed in one or more indoor cabinets, is termed a *phasor.*

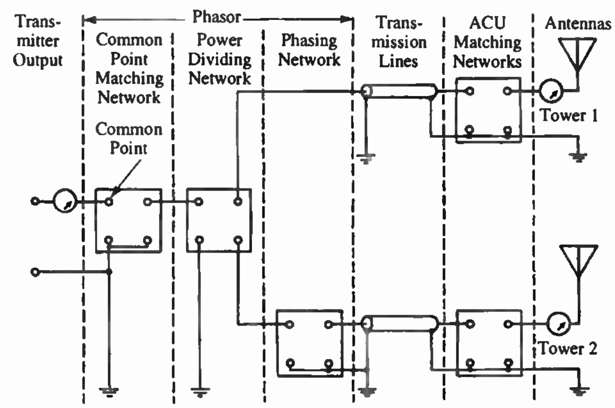

Figure 4.9-1. Block diagram of a directional antenna.

a) Within the phasor cabinet (usually located in the transmitter building), networks control the phase of the current into each transmission line.
b) Power divider circuits control the current amplitude in each transmission line.
c) A common point matching network adjusts the phasor input impedance to a desirable resistive value (typically 50 Ω) without disturbing the phase or amplitude of the tower currents.

Figure 4.9-1 shows a system with only two towers—each additional tower requires its own antenna coupling unit, transmission line, and phasing network, as well as additional components in the power divider.

PHASOR PERFORMANCE OBJECTIVES

The essential performance objective is to have both the phasor input impedance and the directional antenna radiation pattern remain essentially constant at all frequencies within ± 10 kHz of the assigned channel. The performance may be disappointing if the design process proceeds by a piecemeal approach, where subsystems are independently designed for each of the functions illustrated in Figure 4.9-1 and are then connected together. It is better to use a systems approach that considers the entire collection of components between the transmitter and the towers as a whole rather than by the *building block* approach implicit in Figure 4.9-1. No one subsystem in an array can be treated in isolation. While it is a simple matter to design a series of subsystems to provide the desired phase and amplitude parameters, these subsystems must properly complement each other if optimum performance is to be achieved.

Phasor Input Impedance

An ideal phasor would present a load to the transmitter that is the same pure resistance at all sideband frequencies. However, phasors consist of coils and capacitors whose reactance varies with frequency; therefore, this ideal cannot be achieved. The term *impedance bandwidth* describes the degree of constancy of the phasor input impedance across the entire range of sideband frequencies. A useful figure of merit to express the impedance bandwidth as a single number is the worst case voltage standing wave ratio (VSWR) existing at either of the two 10 kHz sideband frequencies when the system is perfectly matched at the carrier frequency. This approach yields VSWR numbers that are related to antenna performance just as television and FM transmitting antenna performance is described by VSWR limits at various sideband frequencies. The sideband VSWR can be determined by analysis of common point impedance measurements. The resistance and reactance at each sideband frequency of interest are expressed as a percentage of the measured carrier frequency resistance, usually 50 Ω, and are then plotted on a Smith Chart. A Smith Chart depicts the relationship between the load impedances at sideband frequencies and the ideal matched load. The distance from the center of the chart for each sideband frequency is a measure of the VSWR at that frequency. Figure 4.9-2 shows a Smith Chart showing a VSWR circle of 2.0. All impedances, when normalized to the chart center, resulting in a VSWR of 2.0 or less will plot within this circle of radius 2.0.

Bandwidth

Bandwidth requirements for each channel change greatly across the broadcast band. At 1600 kHz, a total

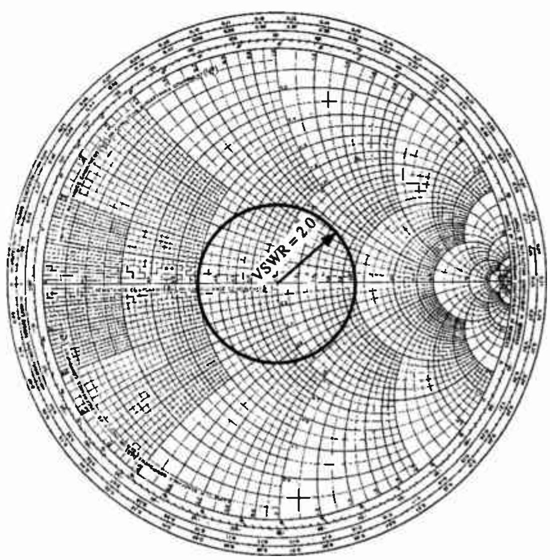

Figure 4.9-2. Smith Chart with VSWR circle.

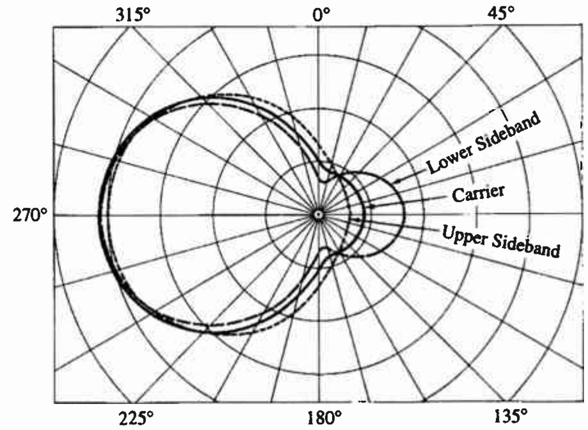

Figure 4.9-3. Example of poor pattern bandwidth.

bandwidth of 20kHz corresponds to about 1% of the center frequency whereas, at 540 kHz, 20 kHz corresponds to nearly 4% of the center frequency. Comparatively, an AM station at the lower frequencies has a more stringent bandwidth requirement than is needed for acceptable visual transmitter performance on VHF TV channels 7 through 13 or on any of the UHF channels.

The common point VSWR at 10 kHz above and below carrier is often better than 1.1:1 in good phasor designs. Poor designs can be worse than 3:1. Poor phasor designs manifest themselves by poor audio performance, which may result in limited frequency respons.

Radiation Pattern

An ideal phasor would produce an antenna radiation pattern that remains unchanged across the channel. Variations in the phase and ratio of tower currents at the sideband frequencies can result in changes in the location and depth of the intended pattern minimums. The frequencies for which the pattern remains useful describe the *pattern bandwidth.* Pattern bandwidth cannot be quantified by simple numbers, but the concept is useful in comparing alternative designs.

The example of poor pattern bandwidth shown in Figure 4.9-3 is for the three tower daytime pattern of an actual station at its carrier frequency and at the 10 kHz sideband frequencies. The sideband patterns were calculated from the actual measured ratios and phases of tower currents at both sideband frequencies. This directional antenna system did not adequately protect an adjacent channel station even though conventional field strength measurements indicated proper operation. A spectrum analyzer displaying the received signal confirmed the extreme sideband asymmetry in critical directions. In deep pattern minima, poor pattern bandwidth can result in severe distortion of the audio signal. Essentially, the carrier has been removed and what is left is effectively a distorted double sideband, suppressed carrier signal that will have an audio effect at the receiver similar to overmodulation.

BASIC NETWORKS

The networks used for matching impedances and for shifting phase are typically "T" or "L" configurations. "Pi" networks having shunt elements at the input and output and a central series element can be made electrically identical to any T network but T networks are easier to adjust.

The networks at the left in Figure 4.9-4 offer large phase shifts, while the configurations on the right offer small phase shifts. Intermediate between these two conditions are L networks which can be considered as T networks with one zero reactance arm. L networks do not permit independent adjustment of impedance match and phase shift; however, the resulting phase delay or advance can be calculated easily, with the result often being a value that is compatible with the overall phasor design.

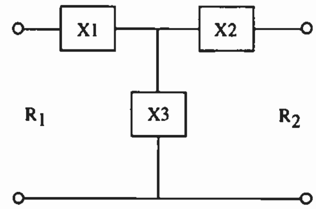
The formulas for these networks are all based on matching into resistive loads. The loads presented by antenna towers usually have a reactive component; therefore, the output arm of the matching network is modified from the calculated value to cancel the tower reactance. When this modification is made, the output arm will occasionally assume the opposite reactance sign, as shown in the parentheses in Figure 4.9-4.

T Networks

The reactances of the input, output and shunt arms of a T network can be calculated quickly, once the desired input and output resistances and the phase shift (β) are specified, by using the formulas shown in Figure 4.9-5. The formulas are equally applicable for leading ($+\beta$) and lagging ($-\beta$) networks.

L Networks

Conventional L networks can provide a match between any two resistance values. The formula for such networks is shown in Figure 4.9-6, which presumes a non-reactive load. If an L network is used to match a tower to a transmission line, the reactive component of the tower impedance must be considered. If the tower resistance is lower than the line impedance, the series arm of the L network is connected to the tower.



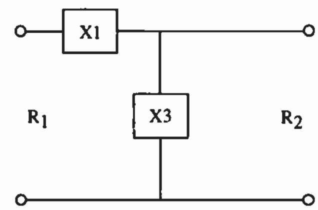
$$X_3 = \frac{\sqrt{R_1 R_2}}{\sin\beta}$$

$$X_2 = \frac{R_2}{\tan\beta} - X_3$$

$$X_1 = \frac{R_1}{\tan\beta} - X_3$$

R_1 = Input resistance
R_2 = Output (load) resistance
β = Phase shift (output - input)

Figure 4.9-5. "T" network formulas.



$$X_1 = \pm\sqrt{R_1 R_2 - R_1^2}$$

$$X_3 = \pm\frac{R_1 \; R_2}{X_1}$$

$$\beta = \cos^{-1}\sqrt{\frac{R_1}{R_2}}$$

R_2 must be greater than R_1
X_1 is inductive (+J) for lagging network
X_1 is capacitive (-J) for leading network
X_3 must have sign opposite to X_1

Figure 4.9-6. "L" network formulas.

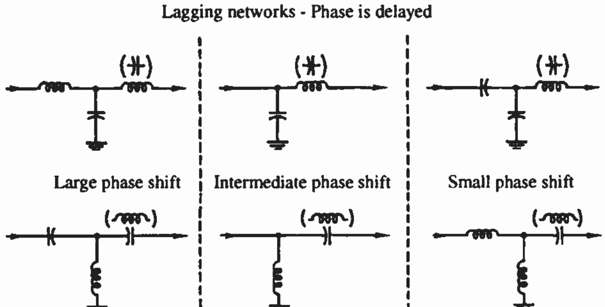


Figure 4.9-4. Conventional "T" and "L" networks.

This arm can then be modified from the value calculated by the formula so as to also cancel the tower reactance.

An L network can also be used to match a tower having a resistance higher than the transmission line impedance, but in this case the formula in Figure 4.9-6 does not apply unless the tower impedance contains no reactance. In the usual case, where the tower impedance is reactive, an L network cannot be so easily calculated. The shunt arm (which is in parallel with the reactive tower load) must be one which makes the resistive component of the parallel combination equal to the transmission line impedance. Then the resulting reactance of the parallel combination is canceled by the series input arm of the L network. Such networks are easy to adjust; the shunt arm of the L network is adjusted to make the input resistance match the transmission line characteristic impedance, and the series arm is then adjusted to cancel the resulting reactive component. The two adjustments are substantially independent of each other. If the tower is one element of a directional array, an operating impedance bridge (hot bridge) at the network input must be used and the phase and ratio parameters must be approximately correct in order for the tower operating impedance to be that which will exist when the directional antenna array is operating normally.

When the tower resistance is higher than the line impedance, there are two different values of shunt arm reactance (one capacitive and one inductive) that can satisfy the conditions necessary for a match with an L network. If the shunt arm is of the same sign as the tower reactance, the required series arm will be of opposite sign and the phase shift will be small. If the shunt arm is opposite in sign to the tower reactance, the required reactance in the series arm will have the same sign as the tower reactance and the phase shift will be large.

An alternative way to design such L networks (rather than by calculating the shunt arm reactance necessary to produce the desired resistive component for the parallel combination) is to think of them as T networks in which the output arm is represented by the reactive component of the tower load. As such, these networks can be described as *Phantom T Networks.*

Phantom T Networks

A phantom T network utilizes the tower reactance itself as the output arm (X_2) of the network. It is electrically equivalent to a conventional T network but requires one less circuit element. Because it has only two adjustable elements, the phase shift of a phantom T cannot be independently selected but two choices are possible, corresponding to T networks with small and large phase shifts. When the input resistance and reactance are properly adjusted, the resultant phase shift is then defined. Phantom T networks can be calculated quickly by the T network formulas while using cut-and-try variations of the phase shift until X_2 exactly equals the tower reactance. Phantom T networks with small phase shifts exhibit excellent bandwidth. Those with large phase shifts are somewhat poorer.

POWER DIVIDERS

In many phasors, separate components are used to accomplish the power division function; but the same networks that control phase shift can also control the division of power, if desired. It is important to remember, when comparing different towers in an array, that the power delivered to a tower is not in proportion to the base current; a low base resistance tower may consume very little power (I^2R) even if the current is relatively high. The actual power division is defined by the required base current ratios and the base resistances. An example of power division calculations is shown in Figure 4.9-7.

Given: Total power is 1000 watts with base current ratios and resistances as shown. I = Current in Tower 3.

Tower No.	Base Current Ratio	Base Resistance	Power
1	0.20	25 ohms	$(0.20\ I)^2 \times (25) = 1.0\ I^2$
2	0.70	130	$(0.70\ I)^2 \times (130) = 63.7\ I^2$
3	1.00	40	$(1.00\ I)^2 \times (40) = 40.0\ I^2$
4	0.50	10	$(0.50\ I)^2 \times (10) = 2.5\ I^2$
			$107.2\ I^2 = 1000$ watts; $I = 3.054$ amps

Tower No.	Base Current	Base Power
1	0.20 x 3.054 = 0.611 amps	$(0.611)^2 \times (25) =$ 9.3 watts
2	0.70 x 3.054 = 2.138	$(2.138)^2 \times (130) =$ 594.2
3	1.00 x 3.054 = 3.054	$(3.054)^2 \times (40) =$ 373.1
4	0.50 x 3.054 = 1.527	$(1.527)^2 \times (10) =$ 23.4
		1000.0 watts

Figure 4.9-7. Example of power division calculations.

Tank-Type Divider

In a tank type power divider, as shown in Figure 4.9-8, roller coils L2 and L3 (termed *jeep* coils in this configuration) adjust the power; the combination of L1, L2, and L3 is tuned close to resonance by capacitors C1 and C2. The input tap on L1 adjusts the common point resistance; L4 adjusts the common point reactance. This system is no longer popular because it is difficult to adjust and because bandwidth is limited by the excessive stored energy.

Shunt-Type Divider

A common type of divider is the *shunt* design shown in Figure 4.9-9, which uses several adjustable coils in parallel, each of which controls the current to an individual tower. The reactance of the L1, L2, L3 combination is then tuned to resonance with C1. Component values are selected so that the impedance at point A is on the order of 400 Ω. A conventional T network then matches this load to the desired common point impedance. This design is easy to adjust. L2 and L3 may be tapped or variable inductors, however, the rollers on the variable coils may tend to bind and develop intermittent contacts after several years of use.

T Network Power Division

A phasor can be designed to exploit the input impedance of conventional T networks to achieve control of both power division and phase, as shown in Figure 4.9-10. In such a system, each T network presents a load at its input which is appropriate to divert the required power to its corresponding tower.

Once such a phasor is properly adjusted, the small changes in phase and ratio that may later be required to maintain an array within tolerances are easily accomplished with very small adjustments in only the shunt and input or output arms of each individual tower network in the phasor. Although the phase and ratio adjustments interact (as with all phasors, due to the

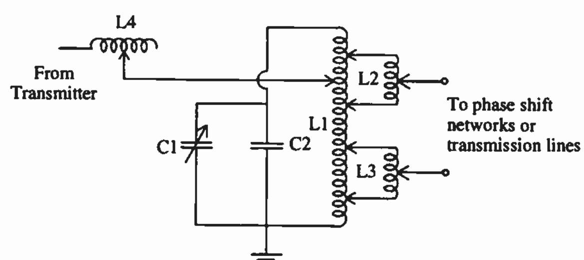

Figure 4.9-8. Typical tank-type power divider.

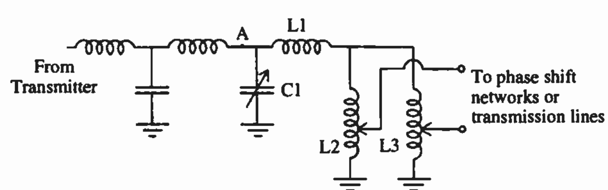

Figure 4.9-9. Typical shunt power divider.

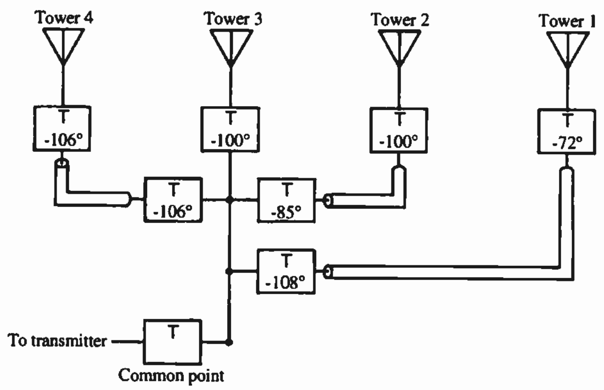

Figure 4.9-10. Typical phasor with "T" net power division.

mutual coupling between towers), the shunt arms tend mostly to control power division, whereas the series input arms tend mostly to control phase. By noting which parameters are farthest out of tolerance, it is a simple matter to make small adjustments in the networks, observe the results of each change, and expeditiously restore such a phasor to the desired parameters.

Simplified Power Division

For two tower directional systems, some very simple configurations can permit adjustment of both power division and phase shift with very few circuit elements. One such simplified system is a *back-to-back* phasor, shown in Figure 4.9-11.

Components "C" and "L" are connected back-to-back at the output of the common point matching network. In this example (which assumes matched transmission lines with resistive inputs), reducing L to zero would yield a current into transmission Line 2 that is in phase with the applied voltage, E_0. As L is increased, the current into Line 2 diminishes and lags the applied voltage. As L is varied from zero to infinity, the locus of all possible Line 2 currents is the semi-circle on the lower half of the diagram. Similarly, as C is reduced, the amplitude of the current in Line 1 is reduced and its phase is advanced relative to the

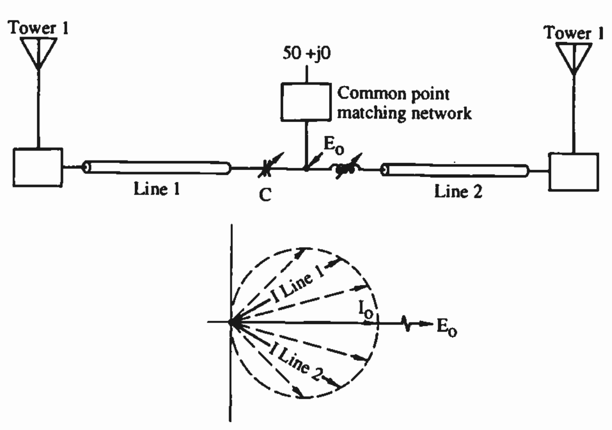

Figure 4.9-11. Example of back-to-back phasor.

applied voltage. The locus of all the possible currents into Line 1, as C is varied from infinity to zero, is the upper semi-circle of the vector diagram. The ranges of adjustment of C and L need only be sufficient to reach the desired phase and ratio parameters, not the entire semi-circular gamut.

Independence of adjustment of phase and ratio is completely lacking in a back-to-back design, yet the phasor is easy to adjust. If one wants to change the ratio, an arbitrary change is first made in either component, phase is restored to the initial value by adjustment of the opposite component, and then the direction of ratio change is noted. It becomes a very simple cut-and-dry process, not unlike that required to maximize transmitter efficiency by adjusting transmitter tuning and loading.

It is not always necessary to employ a coil and a capacitor in a back-to-back phasor. Often, the phase shift in the transmission lines and ACU networks can be tailored to provide the desired parameters with a series capacitor on the input to each line, rather than one capacitor and one coil. This arrangement permits a two-tower phasor in which both power division and phase adjustment are accomplished by only a pair of variable vacuum capacitors offering excellent stability and resetability. This arrangement also provides excellent impedance bandwidth.

TRANSMISSION LINES

Many of the requirements for AM broadcast transmission lines differ from those used in FM and TV installations; the similarities and differences are discussed in the following paragraphs.

Line Losses

The losses in transmission lines at AM broadcast frequencies are largely in the copper, not in the dielectric. For this reason, and for mechanical convenience, semi-flexible foam filled lines are the most popular. Air dielectric lines are needed only when power levels exceed the ratings of available foam filled lines.

Jacketing

All lines should include a black polyethylene outer jacket. Unjacketed lines can result in inadvertent poor contacts to other metallic conductors, which can be a source of minute arcs that can cause spurious emissions. Jacketed lines are particularly suitable for direct burial. Burying the lines greatly reduces the daily and seasonal temperature extremes they encounter, yielding greater stability relative to above ground installations.

Although jacketed lines have an indefinitely long life when buried, they are vulnerable to attack by rodents, that can gnaw through the vinyl jacket and have been known to consume portions of the copper outer conductor, as well. The possible need to replace buried lines in the future should be considered at the time of initial construction. Protecting the lines in PVC conduits and/or installing spare lines are desirable options. At the minimum, PVC sweep elbows should be in place before concrete floors or foundations are poured for buried transmission lines and sampling lines that exit the transmitter building or doghouses.

Characteristic Impedance

A characteristic impedance of 50 Ω is the industry standard for radio frequency transmission lines. Such lines can be expected to be more easily available than other impedances in future years, should a replacement line be needed. The velocity of propagation in transmission lines is less than the velocity in air. Therefore, the electrical length of any line is somewhat greater than its physical length. This increase must be considered in any phasor design. Typical values of transmission line velocity constants are listed below:

Obsolete solid dielectric flexible lines	68%
Original foam filled lines	79%
Low density foam (LDF) lines	88%
Semi-flexible air dielectric lines	90–93%
Modern rigid copper lines	99.8%

Phase Stabilized Line

In its first year, a new directional array will usually experience small drifts in indicated phase and ratio parameters that will not be repeated seasonally thereafter. This initial drift is caused by the minor mechanical stresses remaining in the feed lines and sampling lines following manufacture and installation; these stresses are slowly relieved with temperature cycling. The result is a small initial change in characteristics following installation that will not be repeated. Phase stabilized lines, which will reduce the initial drift, are available. Such lines have been temperature cycled in an oven to relieve residual mechanical stresses. Within about a year following installation, no observable differences in stability exist between regular lines and those that were initially phase stabilized.

Transmission Line Fittings

All modern transmission lines can be equipped with EIA standard flanged fittings to mate with connecting equipment. Although the impedance continuity provided by such fittings is essential at FM and TV frequencies, such fittings are unnecessary for foam line antenna feeds at AM broadcast frequencies. However, adequate electrical bonds are essential between the transmission line conductors and the adjoining equipment. The dielectric in foam filled lines is a better insulator than air. However, catalogs show such lines as having the same voltage breakdown rating as air dielectric lines because of the limited air gap within the end fittings. For AM broadcast use, the power rating of foam lines can be increased by avoiding the use of end fittings and stripping back the outer conductor (while leaving the foam) to increase the air gap on both ends of each line.

Line Mismatch

At AM broadcast frequencies, the effects of a transmission line mismatch are quite different from the electrically long transmission lines used for FM and television antennas, where mismatches can cause reflections back into a transmitter and result in crosstalk or ghosts. At AM broadcast frequencies, transmission lines are rarely longer than a wavelength. A mismatched transmission line yields an input impedance that is dependent on both the load impedance and the length of the line. Thus a transmission line can act as a simple impedance transformer and can be designed to exhibit a desired input impedance through proper choice of load impedance. This characteristic is occasionally exploited in designing phasing systems.

Perfect transmission line matches are not critical to overall system bandwidth. Although most phasing and coupling systems are designed with the intent that the transmission lines to the towers be matched, the consequences of substantially mismatched lines are usually trivial. Improving the match on any transmission line between the phasor and tower may improve or may impair the bandwidth. Because the lines are electrically short, their behavior is more akin to that of a simple network than to the transmission lines in FM and television systems, which are often hundreds or thousands of wavelengths long. As a general rule, if lines to towers that handle 25% or more of the transmitter power are matched to a VSWR of 1.5:1 or better (at the carrier frequency) and any remaining lines are matched within 2:1, further efforts at improving matches may give only trivial reductions in line losses and trivial changes (for better or worse) in the bandwidth.

Even though a line may be perfectly matched at the carrier frequency, it will never be perfectly matched at the sideband frequencies because no antenna load is absolutely constant over the desired bandwidth of ±10 kHz. The effects of the less than perfect sideband matches can be minimized by proper proportioning of the phase shifts between the phasor networks and the ACU networks. It is important to avoid confusion between transmission line VSWR at the carrier frequency and common point VSWR at sideband frequencies.

Voltage and Power Ratings

With 100% modulation, the voltage on a matched lossless transmission line varies from zero on a modulation trough to twice the unmodulated value on modulation crests. This is quite unlike the situation in FM where every radio frequency cycle has the same amplitude. In FM and TV systems, the dielectric losses (because of the higher frequencies) cause the power rating to be limited by the heat generated within the dielectric, as well as by the copper losses; power ratings are accordingly based on the ability of the transmission line to dissipate the heat resulting from the losses. At AM frequencies the dielectric losses are minor while the instantaneous voltages during modulation peaks can be very high. As a result, the power handling ability of AM transmission lines is usually limited by the voltage breakdown rating of the line. With 125% positive modulation, the maximum instantaneous peak voltage becomes more than three times the unmodulated RMS voltage and the instantaneous peak power becomes more than 10 times the unmodulated power. An additional allowance must also be made to accommodate the increased voltage maximum along each line due to standing waves caused by any less than perfect transmission line match.

Under transient conditions (such as can be caused by lightning strikes or sudden component failures) the VSWR overload protection designed within all modern transmitters may not trip and the power distribution among the towers may be drastically altered in unpredictable ways. This can lead to voltage breakdowns within buried transmission lines which are difficult to locate and repair. For this reason it is good engineering practice to employ equal size transmission lines to all towers that are capable of handling the full modulated output of the transmitter even though the power delivered to particular towers may be only a few percent of the total power during normal operation. This design factor will also be greatly appreciated in the event of an emergency requiring non-directional operation on one of the low power towers.

ANTENNA MONITOR AND SAMPLING SYSTEM

A directional antenna sampling system consists of current sampling transformers at the base of or sampling loops on each tower to provide a sample of the tower current, transmission lines which return the samples, and an antenna monitor which measures the amplitude and phase of each sample relative to that of the reference tower.

Sampling Loops

A sampling loop consists of a rigid single turn coil permanently attached to each tower. Because sampling system stability is essential, the loops are typically made of galvanized or stainless angle iron or rigid copper water pipe. The loops must be at least 10 ft. above ground and may be insulated from the tower and kept at ground potential. However, it is more common practice to use loops at tower potential and return the sample to ground potential through an isolation coil (*isocoil*) formed by coiling up the sampling coax so as to form a high impedance across the tower base insulator while not disturbing the current sample carried within the coax.

Sampling Transformers

An alternative method of obtaining tower current samples is to use shielded current sampling transformers in the feeds to each tower. These have much to recommend them if the tower heights do not exceed approximately 130°. Although a transformer will sample both the current going up the tower and a lesser component that flows to ground through the base insulator capacitance, the sampling error is usually inconsequential. The advantages to using sampling transformers are stability, a sampling device that is protected inside the ACU instead of being exposed to the weather, and elimination of the isocoils that are otherwise usually required at each tower.

Stability and Accuracy

Sampling system stability is vital, but accuracy is not critical because the proper phases and currents to generate a directional antenna pattern are determined by means of field strength measurements. The sampling system is required to detect changes from the original adjustments of indicated phase and ratio. The accuracy of a sampling system in measuring the absolute amplitude of radiation from each tower is inherently poor.

Even though the sampling loops may be carefully adjusted so that each has exactly the same area in its single turn coil and all are mounted at the same height, the samples will not necessarily be a measure of the relative radiation from each tower. The mutual impedances between towers can seriously distort the sinusoidal current distribution which would otherwise exist throughout the height of each tower. Thus the indicated antenna monitor ratios are not an absolute measure of the relative radiation from each tower. The monitor ratios may also differ substantially from the base current ratios, particularly when the loops are a considerable distance above ground level or towers of unequal height are employed. The indications of phase from a good monitoring system are considerably more accurate than the ratio indications. Arrays with unequal height towers usually require sampling loops that are all located approximately a quarter wavelength below each tower top if the indications of phase and ratio are to be the best approximation of the actual radiation from each tower.

Recently, there has been some activity directed at simplifying the proof-of-performance of directional arrays by eliminating or at least reducing the requirement for field strength measurements. With the computer power available today, it is possible to calculate relatively accurately the current distribution on a given tower in an array and to determine in advance what monitor values are needed to produce the required pattern. In order to do this, the absolute accuracy of the sampling system becomes an important concern. As a result, it would be necessary to characterize the sampling system prior to array adjustment so that the target monitor values could be adjusted accordingly. Even with a perfect sampling system, however, some field strength measurements would be necessary, as the sampling system can not determine the effect of external factors located near the array.

DETUNING AND DECOUPLING SYSTEMS

The most common occasion for detuning towers arises within directional arrays themselves, wherein unused towers must be placed in a non-radiating condition. This is necessary in all arrays when nondirectional proof-of-performance field strength measurements

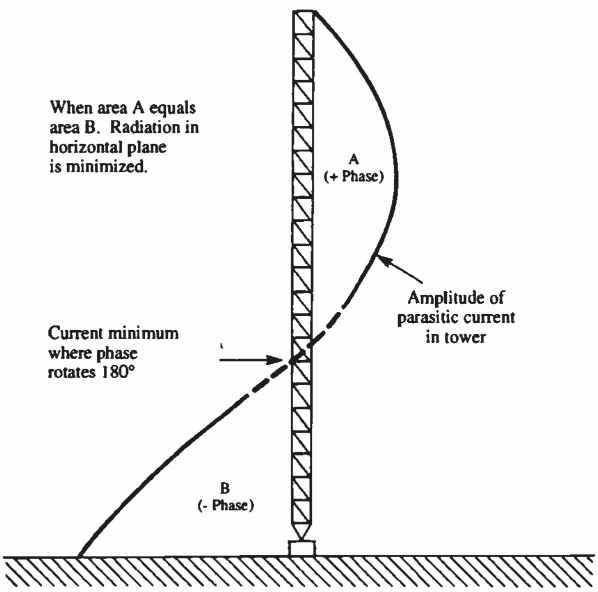

Figure 4.9-12. Current distribution on detuned tower.

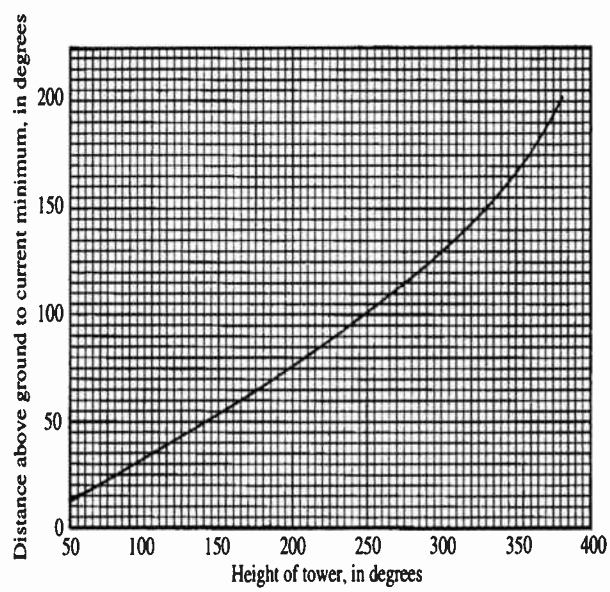

Figure 4.9-13. Approximate height of required current minimum to detune guyed towers.

must be made, where nondirectional daytime operation is permitted, or where one or more towers are not used for daytime or nighttime modes when two patterns are authorized. In more critical situations, or with taller towers, more effective detuning is required than simply disconnecting the unused towers to reduce the radiation (reradiation) caused by parasitic currents that flow in them due to the mutual coupling to adjacent driven towers. Disconnecting a tower will not eliminate the component of induced tower current flowing to ground through the capacitance of the tower base and base insulator. An inductive reactance of the proper value (often formed in part by the isocoil if sampling loops are employed) can be added across the base to resonate the base capacitance and essentially eliminate all current flowing to ground.

The optimum detuning (even for short towers, as well as for towers up to a wavelength tall) results when an inductive reactance across the base insulator produces a tower current distribution as shown in Figure 4.9-12. Because there is a phase reversal at the elevation of minimum current, it is necessary to position a current minimum on the tower so that area A equals area B. In the horizontal plane, the radiation from the portion of the tower above the minimum will then cancel that from the portion below the minimum. The proper height for the tower current minimum (typically about 1/3 the tower height) is as shown on Figure 4.9-13. The minimum can be achieved easily by climbing the tower with a field strength meter (or other current sampler and detector) and adjusting the reactance shunting the base insulator until a current null is obtained. Although the shunt reactance necessary to detune a tower is always inductive, the reactance may be so high as to not be within range of a coil of reasonable size. A vacuum variable capacitor in parallel with the coil then provides a convenient and precise way of adjusting the shunt reactance so as to detune the tower.

Tower Sectionalization

Occasionally, when it is necessary to use a tower that is too tall, sectionalization of the tower is required. For example, it may be desired to share an FM tower with an AM station. If the overall tower height were to exceed about 225° at the AM frequency, the tower would be a poor radiator, putting more AM signal up into the sky than along the ground. The preferred solution for such a tall tower is to include insulators in the tower legs (and an isocoupler in the FM feedline at the same height) so as to open circuit the tower at the height needed to make it a good AM radiator. A parallel resonant circuit (an impedance pole) across the insulators can then resonate the insulator and stray capacitances to effectively decouple the upper portion of the tower. In cases where structural considerations prevent the sectionalizing of a tower by means of insulators, a workable solution can be to use detuning *skirts* to decouple the top portion of the tower.

A tower skirt is an insulated wire cage constructed outside of a tower. The skirt is formed of wires that surround the tower and are spaced a foot or two away. All skirt wires are bonded to the tower at one end and can be connected in parallel at the other end so as to be tuned with a single capacitor. Electrically, the skirt can be considered as forming a shorted quarter wave coaxial transmission line which is slightly foreshortened and loaded with a variable capacitor at its open end for easy adjustment. The tower forms the center conductor of the coax and the skirt wires approximate an outer conductor. Adjustment of the skirt tuning places a high impedance at the capacitor end of the

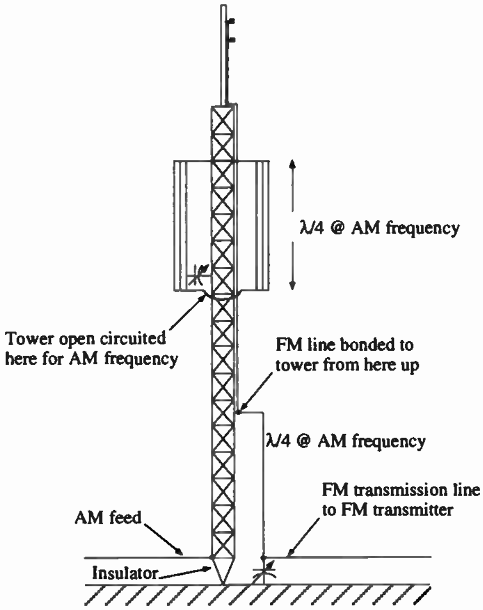

Figure 4.9-14. AM/FM tower sectionalized with skirt wires and with decoupled FM transmission line.

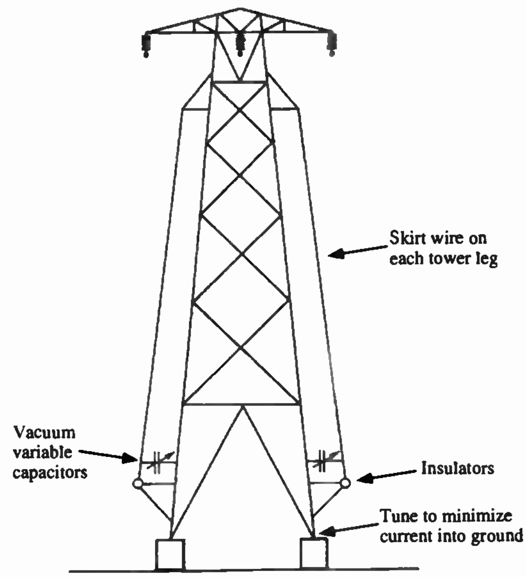

Figure 4.9-15. Skirts used to detune power-line towers.

skirt with a result that the tower is effectively open-circuited at that elevation.

The effectiveness of such a tower skirt is determined by the characteristic impedance and losses in the transmission line section formed by the tower and the skirt. The most effective skirt will necessarily have a high Q, which is realized by using reasonably heavy skirt wires spaced as far as mechanically feasible away from the tower. For guyed triangular towers of uniform cross section, combinations of three or six skirt wires are common. Inasmuch as the most effective skirt will necessarily have a high Q, it will best decouple the portion of the tower above its open end only at the frequency to which it is tuned. As a result, the tower base may exhibit a steep impedance versus frequency characteristic which can impair bandwidth.

Another way of visualizing the operation of a skirt is to think of the tower and skirt wires as forming an inductive loop which is tuned to resonance so that the current flowing up the tower is effectively canceled by a substantially equal and opposite current flowing down the skirt wires. Figure 4.9-14 shows an example of the use of skirt wires to sectionalize a tower and to decouple a transmission line for the FM station located at the top.

Detuning Power Lines

The detuning techniques previously described can be applied to steel power line towers or to other tall metallic structures in order to reduce the radio frequency currents in them, currents that would otherwise cause reradiation and distort the desired directional antenna pattern of a nearby radio station.

Figure 4.9-15 shows such an arrangement with each skirt wire on each tower leg separately tuned. Again, the effectiveness of the skirt depends on the length of the skirt section and the number, diameter and spacing of the skirt wires.

Filter Systems

If it is necessary to control the current distribution on an AM tower at a different frequency from the operating frequency in order to avoid disturbing the pattern of a nearby directional station, a filter system is needed to permit control of the impedance shunting the tower base at the other station's frequency. The control should be independent of routine phasor adjustments. Such an arrangement is shown in Figure 4.9-16 for each tower of a station operating on 630 kHz. The 630 kHz station must control tower current distribution at 950 kHz in order to protect the directional antenna operation of the nearby station on that frequency.

For filters in series with antenna feeds (such as the C3/L7, C4/L8 combination), it is desirable to provide an impedance zero at the pass frequency as well as the impedance pole at the reject frequency. Even when

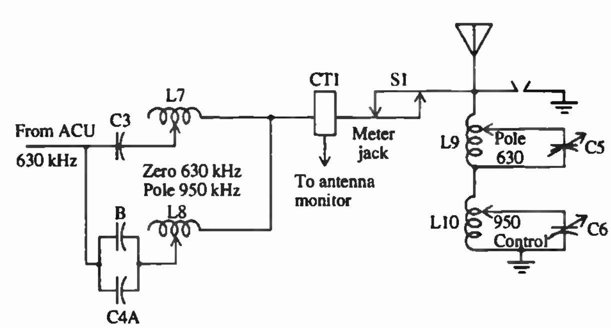

Figure 4.9-16. Independent control of tower current distribution at a second frequency.

the pass and reject frequencies are widely separated, failure to provide the impedance zero with a reasonably low L/C ratio can result in excessive losses.

Intermodulation

Filters to control spurious emissions resulting from intermodulation products generated within the final stage of a transmitter can have the same configuration as filters used to control tower current distribution for a nearby station. Before such filters are designed, a knowledge of the frequencies that generate the intermod is essential. The second, third, and higher harmonic frequencies are strong components in a transmitter output stage and can generate intermod products there even though these harmonics are suppressed to acceptably low levels when measured at the transmitter output. In the general case, an unwanted incoming signal from some other station can be coupled into the final amplifier through the antenna system to mix with the fundamental or any harmonic to produce a spurious output frequency.

Effective filters can take the form of either traps to prevent an unwanted signal from getting into the transmitter or traps to prevent the resulting spurious emission from getting out (or both). Filters can be series resonant shunt elements that short the unwanted incoming signal (or the spurious emission) to ground, or they can be parallel resonant elements in series with the transmitter output to present a high impedance to either the unwanted incoming signal or the spurious emission.

One clever and expeditious arrangement, when a single spurious frequency must be eliminated, may be to modify the shunt arm of the common-point matching network to consist of a series-resonant L/C circuit that simultaneously has a very low impedance at the undesired frequency and the proper reactance at the station carrier frequency.

Many modern transmitters have exceedingly broadband output coupling networks which, together with improved antenna bandwidths, permit unwanted signals from other radio stations to get back into the final stage of the transmitter to produce spurious intermod products. Signals thus entering the transmitter need not be particularly strong. Many cases are known where the offending input that caused an objectionable spur originated from a radio station 20, 30, or even 40 miles away. Be aware that the intermodulation products may fall in the marine and beacon bands below the AM broadcast band.

Broadbanding

The term *broadbanding* can be quite confusing. Frequently it is applied to any circuit modifications that are intended to improve the impedance bandwidth of an antenna system. A *broadbander* is a circuit that improves the impedance bandwidth, thus reducing the VSWR at the sidebands. A *broadbander* typically consists of the series combination of a coil and a capacitor which is inserted in series with the load to be improved (usually immediately before or after the common point) and is adjusted to series resonance at the carrier frequency. Such a circuit is capacitive below the carrier frequency and inductive above the carrier frequency. Before a broadbander can function as intended, the load it sees must be inductive at the lower sideband frequencies and capacitive at the upper sideband frequencies. This condition is achieved by altering the phase shift in the common point matching network (or inserting an additional phase shifting network) so that the Smith Chart plot is *horns up*, as is shown in Curve A, Figure 4.9-17. Then the uncorrected load reactance (which is inductive for the lower sideband) can be canceled by the capacitive reactance of the broadbander and the capacitive reactance of the upper sideband load can be canceled by the inductive reactance of the broadbander. The result is that the load reactance can be effectively canceled at any pair of sideband frequencies as determined by L/C ratio of the broadbander. For such a *broadbander* to function as intended, it is essential that it be effectively shielded so that there is no stray coupling between it and the other components in the phasor. When properly designed and adjusted, it can *wrap up* the common point impedance, as shown in Curve B, Figure 4.9-17.

Such a broadbanding circuit should not be viewed as a cure-all, but it can provide a useful reduction in sideband VSWR once all other reasonable efforts at improvement have been applied.

TRANSMITTER LOAD OPTIMIZATION

A transmitter can deliver equal power to both sidebands when the upper and lower sideband load resistances are equal and the upper and lower sideband load reactances are equal. If the transmitter load VSWR at ±10 kHz from carrier is rather good (perhaps 1.2:1 or better), further adjustments to improve load symmetry may not be warranted. However, if the ±10 kHz sideband loads are rather poor (e.g., 1.5:1 or greater) sideband load symmetry can become an important matter. Symmetry is achieved by adjusting the phase shift in the common point matching network so that the load resistances at the ±10 kHz sideband frequencies are essentially equal and the reactances are equal but opposite in sign as measured at the anode (or collectors) of the transmitter output stage.

Because different manufacturers use different output circuitry with different phase shifts, and because some have not published information as to optimum load orientation at the transmitter output terminal, the necessary measurements usually must be made on the load seen by the final amplifier stage anode or collector. Figure 4.9-17 shows the Smith Chart orientation for the two conditions that satisfy symmetrical loading requirements. For tube type transmitters (whose output stage functions substantially like a constant current generator), Curve C, which shows equal sideband resistances higher than at carrier, tends to emphasize the high frequency response. Curve A also shows equal sideband resistances, but lower than at carrier; this orientation tends to show reduced 10 kHz distortion.

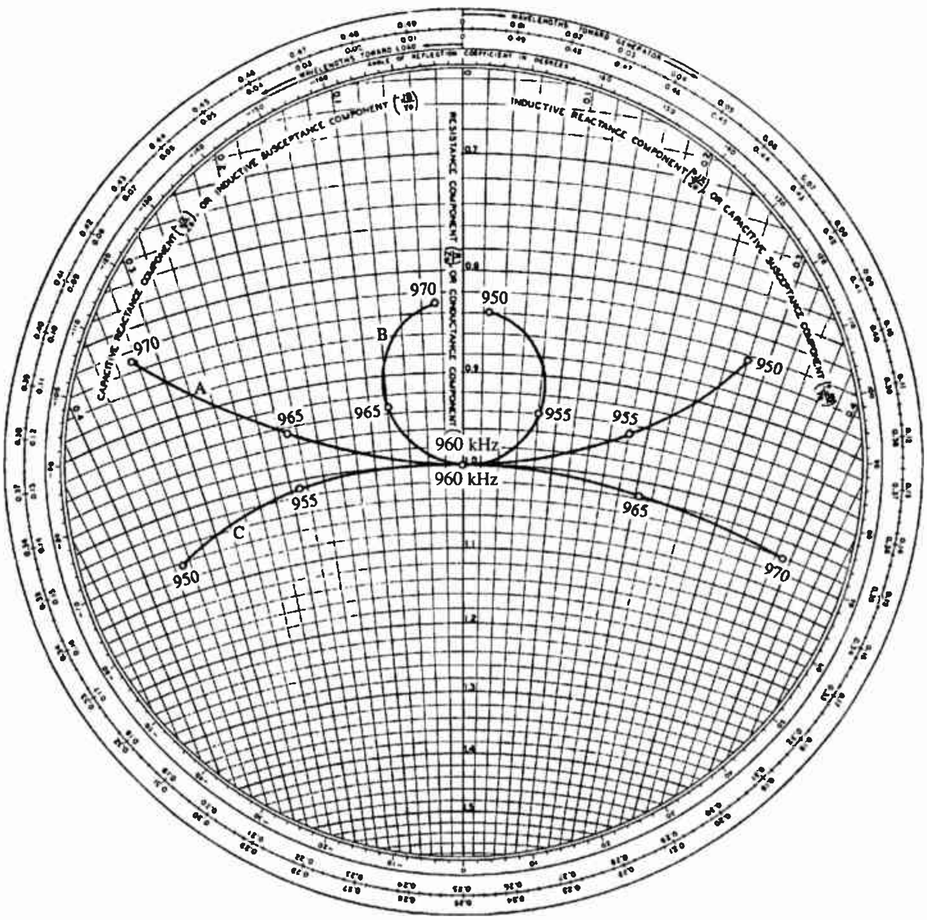

Figure 4.9-17. Proper load impedance at final amplifier plate or collector.

Either of the two conditions is preferable to intermediate conditions that yield asymmetrical load resistances at the two 10 kHz sideband frequencies.

Transmitter manufacturers are now more sensitive to the fact that all antenna systems provide less than perfect loads at the sideband frequencies and that load orientation (as displayed on a Smith Chart) can be critical to overall system performance. Most manufactures can now supply information as to optimum load orientation (referred to the transmitter output terminals) for each specific transmitter. Experience has also shown that audio intermodulation distortion varies with load orientation, so intermod should be measured and minimized.

DIPLEXERS AND MULTIPLEXERS

Two, three, or more AM stations can be combined on a single tower, provided that sufficient frequency separation exists between the channels and the electrical height of the tower is not unreasonably short or tall at any of the channels. Depending upon the transmitter characteristics, only 35 dB or less of RF isolation is typically required between the transmitters to avoid generation of spurious emissions and to permit completely independent operation. Diplexer adequacy is assured when each station:

- Has no objectionable spurious emissions.
- Can conduct an acceptable audio proof, including distortion and noise measurements, while the other station is in operation.
- Has no observable change in its indicated antenna current when the other station's transmitter is turned on and off.

The losses in diplexing and multiplexing filters can become crucial to a successful design. Since the tower impedance and required tower current at each frequency are known, the losses can be calculated with good accuracy. Capacitor losses are negligible. Coil losses can be calculated using an assumed coil Q of 300, which is a conservative approximation for typical silver-plated RF inductors in shielded enclosures. Diplexer losses can be minimized if the reactive component of base impedance can be eliminated by means of networks at the tower base. Then the shunt elements in the diplexing filters operate at lower voltage levels.

Two stations having directional antenna patterns can be diplexed on common towers provided the tower spacing and orientation permit acceptable directional patterns for both stations and the compatibility requirements previously mentioned for combining nondirectional stations are met.

Ground Systems

The current that flows into a tower does not simply disappear; it all flows back to ground through the capacitance that exists between each incremental length of the tower and the ground. (This makes the tower and ground system an integral part of the coupling and phasing system.) When this current reaches the ground, it must be collected and returned to the ground side of the ACU network to complete the circuit. The ground currents are usually strongest close to the base of the tower where the capacitance between the tower and incremental ground segments is greatest. If the ground resistance is substantial, the ground current (equal to the antenna current) will simply heat the ground and represents a power loss. To return the antenna current from the ground surrounding the tower to the ground terminal of the ACU network, a system of radial ground wires is employed. For nondirectional towers a series of early day experiments established that 120 radial ground wires uniformly distributed at 3° intervals and extending a quarter-wavelength (90 electrical degrees) from the tower base was a reasonable limit beyond which the reduced losses to be realized from incremental increases in the number or length of the radials did not warrant the incremental increases in cost required for a more extensive ground system. As a result ground systems consisting of 120 radials extending a quarter wavelength from each tower (or foreshortened and bonded to a transverse copper strap where radials from adjacent towers overlap) have become the *de facto* industry standard, even though it is recognized that in directional arrays the ground currents do not always flow along radial lines, due to the effects of adjacent towers.

Near the base of each radio tower, there are both electromagnetic and electrostatic fields. With reasonably low base impedances (such as a quarter wave tower), the electromagnetic field predominates. Near towers with a high base impedance (such as a half wave tower), the electrostatic field predominates. The radial wire ground system minimizes the I^2R losses but not the E^2/R electrostatic losses which can occur in all materials near the tower base with less-than-perfect dielectric constants. The electrostatic losses are usually inconsequential in a nondirectional operation but can become critical in a directional array. Dielectric materials in the vicinity of the tower base can include wooden fences, wooden or cement block tuning houses, and the earth that is on top of a buried ground system. The changing dielectric constant in these materials between wet and dry conditions can make enough difference in base impedance to cause substantial changes in base current ratios and phases. For these reasons the ground wires should be kept on top of the soil in the immediate vicinity of each tower base or covered with only a thin layer of gravel or paving. Beyond about 20 ft. from each tower base the fields are less intense and the remaining portions of each ground radial are usually buried 6-8 in for mechanical protection. Deeper burial is called for only if the land is to be cultivated or is so soft that farm animals or machinery can sink into the soil and break the ground wires.

Metal fences surrounding each tower base are quite superior to wooden fences, whose dielectric constant can change greatly when wet. If non-metallic doghouses are employed in critical arrays, it may be necessary to provide an electrostatic shield of expanded copper mesh or Copperweld wire mesh up the side of the dog house adjacent to the tower and across its roof. The ultimate electrostatic shield takes the form of an elevated radial ground system which typically extends to a radius of 10 to 30 ft. at a height of 6 ft. or more above ground and effectively shields everything beneath it.

Number 10 AWG soft-drawn copper wire is the most common material for ground radials. Copperweld mesh ground screens, such as are employed for lighting protection under electric power substations, are suitable for the area immediately surrounding each tower, and the radial wires can be connected to the edge of such a screen. Frequently an additional 120 radials, each 50 ft. long, are interspersed between the longer radials where a ground screen is not used. All connections within a ground system must be silver-soldered or brazed, as soft tin/lead solder deteriorates rapidly when buried.

OVERALL SYSTEM PERFORMANCE

Directional antenna pattern design and phasor design go hand-in-hand. Given a poor pattern design, no amount of clever circuit design in the phasor can provide an excellent system. Following are some considerations that can lead to an excellent antenna system.

In the Pattern Design

- Avoid closely spaced towers; 90 electrical degrees or more should be the objective.
- Avoid broadside minimums without ample spacing between towers, otherwise the driving point resistances can become very low.
- Check to see that the individual tower radiation vectors add in-phase (or very nearly in-phase) in the pattern maximum, otherwise excessive circulating currents, poor bandwidth, and pattern instability can result.
- Unless other considerations dictate, choose tower heights in the range of 100 to 130°. Shorter towers exhibit lower driving point resistances and poorer bandwidth. Taller towers may require excessively large impedance transformations in the ACU networks; this condition can add another bandwidth limitation.

In the Phasor Design

- Minimize reactive power (I^2X) in the phasor components. This will avoid high Q circuits.
- Avoid excessive use of series (trim) coils to adjust the reactance of fixed capacitors. Such coil/capacitor combinations necessarily have a steeper impedance versus frequency characteristic than a capacitor alone having the proper reactance.
- Consider alternative phasor designs. The design with the fewest parts usually has the best bandwidth unless specific broadbanding circuits are incorporated.
- Derate coil current ratings by 40% and mica capacitor current and voltage ratings by 50%. Remember that RF currents under heavy asymmetrical modulation can exceed 130% of the unmodulated current and that peak voltages can exceed 300% of the unmodulated RMS voltages.

A SIMPLE BANDWIDTH TEST

A simple test can evaluate the performance of the individual towers in an existing directional antenna system. The object is to determine the amplitude of each 10 kHz sideband component as radiated by each tower. This test is possible with any common field strength meter because the selectivity of such meters is just sufficient to resolve sideband components that are 10 kHz removed from the carrier. The procedure is as follows:

1. Keep the sampling lines terminated into the antenna monitor, but add "T" connectors to bridge off samples into a field strength meter operating as a linear tuned voltmeter. Be certain the samples do not exceed the safe voltage input for the field strength meter.
2. Modulate the transmitter 50% with 10 kHz sinewaves.
3. For each tower sample, first adjust the field strength meter gain so as to set the carrier level full scale (100%). Then tune in each sideband in turn and log each sideband amplitude as a percent of full scale. In a perfect system, this would result in sideband amplitudes equal to 25% of the carrier level in each tower.
4. Repeat the process for each tower.

In the best antenna systems, all 10 kHz sideband components will range between 23% and 27% with 50% modulation at 10 kHz. Poor systems have been observed to have individual tower sideband components as low as 5% or as high as 40% in this test.

In the main lobe of a directional antenna pattern, deficient 10 kHz sideband amplitudes do not usually result in measurable distortion because the radiation components from the individual towers add approximately in phase and the sideband deficiencies of any one tower are masked by the total radiation from all of the other towers. This test is useful in pinpointing limitations in existing systems.

Sampling Source to Feed a Modulation Monitor

The indications of a modulation monitor may be inaccurate at high modulation frequencies if the modulation sample is taken from a less than perfect antenna system. In an antenna system with a high VSWR at the 10 kHz sidebands, the voltage sampled for the modulation monitor may be higher or lower at the 10 kHz sidebands than at low modulating frequencies.

The best measure of 100% modulation is at a remote point in the main lobe of the antenna pattern. Various sampling points within the transmitter or phasor can be tried until a sample source is found that matches the percentage modulation at high modulating frequencies observed in the far field of the main lobe.

CONCLUSION

When the complexities in the design of directional antenna patterns and circuitry are considered together, the need for specialists in this field is evident. However, these chapters should have increased the reader's understanding of the complexities and thus assisted in the maintenance and improvement of AM directional antenna systems.

COMPUTER SIMULATION OF AM RADIO ANTENNA SYSTEMS

JAMES B. HATFIELD
HATFIELD AND DAWSON CONSULTING ENGINEERS, LLP, SEATTLE, WA

INTRODUCTION

Antenna systems have been analyzed and designed using computer simulation for many years by academics and those designing antennas for the military. By comparison to electromagnetic simulation of aircraft and ship structures, modeling medium wave antenna systems is an almost trivial exercise. It has been this writer's, and other consultants', experience that a relatively short time spent modeling an AM array can save a great deal of trial and error standing out in the rain and cold with two-way radios tuning up a directional array (DA).

FCC EQUATIONS AND MOMENT METHODS

The two pages of equations labeled Figure 4.10-1, published by the FCC in the *Code of Federal Regulations*, have been the basis of AM DA design, with few modifications, since the 1940's. *Equation (1)* of this Figure determines the basic pattern shape, while the other formulas deal with pattern size, vertical angle and standard pattern computations.

The term *moment methods* refers to the fact that electromagnetic fields from antennas are proportional to the area under the tower current distribution curve. The units of this area are (amperes) × (length) which is of the same form as the mechanical turning moment used in civil engineering. Moment method programs find the area under the current distribution curve by a process of numerical integration where the incremental area is the product of the tower current at a point and an incremental distance.[1]

Most moment method programs compute far field horizontal plane pattern shape by using the same mathematical expressions as FCC *Equation (1)*, although with different notation. The major difference between moment method computations and the FCC equations shown in Figure 4.10-1 is that the FCC formulas for vertical plane field and pattern size computations assume sinusoidal tower current distributions, while all moment method field and pattern size computations are derived from Maxwell's equations in integral form and are scaled to the specified input power.

The moment method equation for the horizontal plane far fields from a tower can be boiled down to:

$$E = \frac{\pi}{3}\sum i \cdot \Delta l$$

The inverse distance field, in mV/m, at 1 km, from a tower is 1.0472 times the sum of the incremental tower current moments in amp-degrees. This summation of incremental current moments over the length of the tower is usually called the *tower moment*.

Since the field from each tower in an array is 1.0472 times the tower moment of that tower, the field ratio of each tower is the ratio of the tower moment of that tower to the tower moment of the reference tower. The tower moment is a polar number, with a magnitude and angle. The phase angle of the field ratio is found by subtracting the angle of the reference tower moment from the tower moment angle of the tower in question.

PRODUCING THE CORRECT PATTERN WITH MOMENT METHOD PROGRAMS

The FCC equations use variables called *field ratios* and *current phases*. These field parameters are specified in FCC Form 301 applications and on licenses as *theoretical parameters*. The current phase, in practice, refers to the relative phase angle of the *antenna loop* current. The loop current refers to the maximum antenna current. The FCC equations are based upon the assumption that the loop current phase angle and the phase angle of the contribution of the tower to the far field are the same. It is important to note that FCC *Equation (1)* uses the field ratio as the relative contribution of the tower in question to the far field. The phase angle used in the equation is the phase angle of that far field contribution. In fact, the ratio and phase angle of the field parameters are determined by the behavior of the tower as a whole. The ratio and phase angle of the tower loop current is seldom, if ever, the same as the actual field ratio and phase angle. This difference is the reason that antenna monitor readings do not usually match the theoretical parameters. If we can compute what the antenna monitor ratios and phase angles should be we can avoid a great deal of trial and error.

The antenna system can be thought of as a black box where the inputs are voltages and the outputs are fields. The antenna system is linear, so the inputs and outputs can be related by a series of constants even if the towers are not all of the same height.

If one includes mutual impedance, the relationship between the voltage drives and fields for a two tower array is of the following form:

$$E_1 = V_{11}T_{11} + V_{12}T_{12}$$
$$E_2 = C_{21}T_{21} + V_{22}T_{22}$$

"E" represents the FCC field parameters (ratios and phases), "V_{11}", "V_{22}", are the tower base drive voltages, "V_{12}", "V_{21}", are the tower base voltages induced by the other towers, and the "T" is the constant that relate them. The "T" constants are found by shorting the respective towers to set the pertinent base voltages to zero.

Moment method computer programs devoted to broadcast antennas solve these equations for the base voltages necessary to produce the proper pattern. Base drive parameters for the correct FCC pattern can be computed by some method moment programs for top loaded or self supporting towers.

Antenna monitor ratios and phase angles can be found by calculating the ratios and relative phase angles of the computed tower currents at the location on the tower where the antenna monitor samples the current.

Some programs include a provision for current drives. If the antenna sample system is well characterized (sample line lengths and sample transformer sensitivities are known) the correct base current ratios and phases can be determined and used as base drives for computation of the pattern as adjusted.

Near-Fields and Proximity Effect

FCC *Equation (1)* calculates the pattern shape using the assumption that lines are parallel between the towers and the location where the field is being calculated. This assumption is true only at some distance from the array. Closer than this to the towers the pattern is not properly formed. The measured fields close to the antenna on null radials will not be the same as FCC *Equation (1)* would predict even though the patten is properly adjusted. This has been called the *proximity effect* and may, or may not, be an important factor depending upon array geometry.

The proximity effect occurs in an area called the *array near-field*. Accurate computations of the fields in the array near-field region can be made with moment method programs. These near-fields can then be compared to FCC *Equation (1)* fields computed at the same locations for analysis.

Field strength meters use shielded magnetic field sensing loops and convert the magnetic field component of the radiated signal to equivalent electric field units. The magnetic field is multiplied by 377 to A/m to V/m. The conversion factor of 377 only applies to plane wave fields and, in the presence of reradiating objects, may result in an improper indication of the equivalent electric field. Magnetic fields and electric fields are computed separately by the near-field computational portion of the NEC and MININEC family of programs. As a result measurement anomalies resulting from non-plane-wave conditions can be determined.

Impedance

Tower self impedances computed by method of moment program are benchmarked to values computed in R.W.P. Kings' *Theory Of Linear Antennas*. The King values for monopole antennas are based upon measurements made at high frequencies using the center conductor of a coaxial cable projecting through a copper sheet ground plane to which the outer conductor is connected. This results in resistance and reactance values that differ significantly from the resistance and reactance of a base insulated guyed tower over a radial wire ground system. The shunt capacitance of the tower base insulator can have a significant transforming effect upon high tower base impedances. Tower feed connections also add a significant inductive reactance to the tower reactance.

These defects in the computation of tower impedance can be corrected by the addition of reactance to the tower model (Figure 4.10-3) or by increasing the tower height by about 6.7%. It must be noted, however, that the fields and tower radiation efficiencies computed by moment method programs for actual tower heights are close to measured values and also to those shown by FCC graphs (see Figure 4.10-2).

Detuning Towers

When making field strength readings it is sometimes necessary to detune nearby reradiating objects which cause localized perturbations in the measured fields. The moment method programs can be used to determine whether the reradiating object affects the station's pattern or only the measurements near the reradiating object.

An effective method for detuning towers is to treat the tower as a part of the array. The field parameters for the detuned tower are set to zero as a program data input. When the computed drive voltage (and phase) are applied to the tower to be detuned, along with the proper drives to the array, and the computation is performed, the impedance of the tower to be detuned is noted. If the reactive component is approximately ten times the resistive component for the detuned tower it can be detuned by loading it with the conjugate of the computed impedance. If the computed reactance is $-j450\ \Omega$ the tower would be detuned by $+j450\ \Omega$ across its base to ground.

If the resistive part of the detuned tower impedance is large, and negative, it may, in addition, have to be loaded by a resistance in series with the detuning reactance. If the resistive component of the detuned tower impedance is large and positive it will have to be driven with a small amount of power.

The effects of the shunt capacitive reactance of the tower base insulator must be taken into account when detuning a tower. The best procedure for being sure that a tower is properly detuned is to send someone a third of the way up the tower with a current sensing device (if the tower is over about 130° tall the height will be greater, see Figure 4.10-6). The detuning reactance is adjusted until a tower current minimum is observed at the detuning point. A field set with the

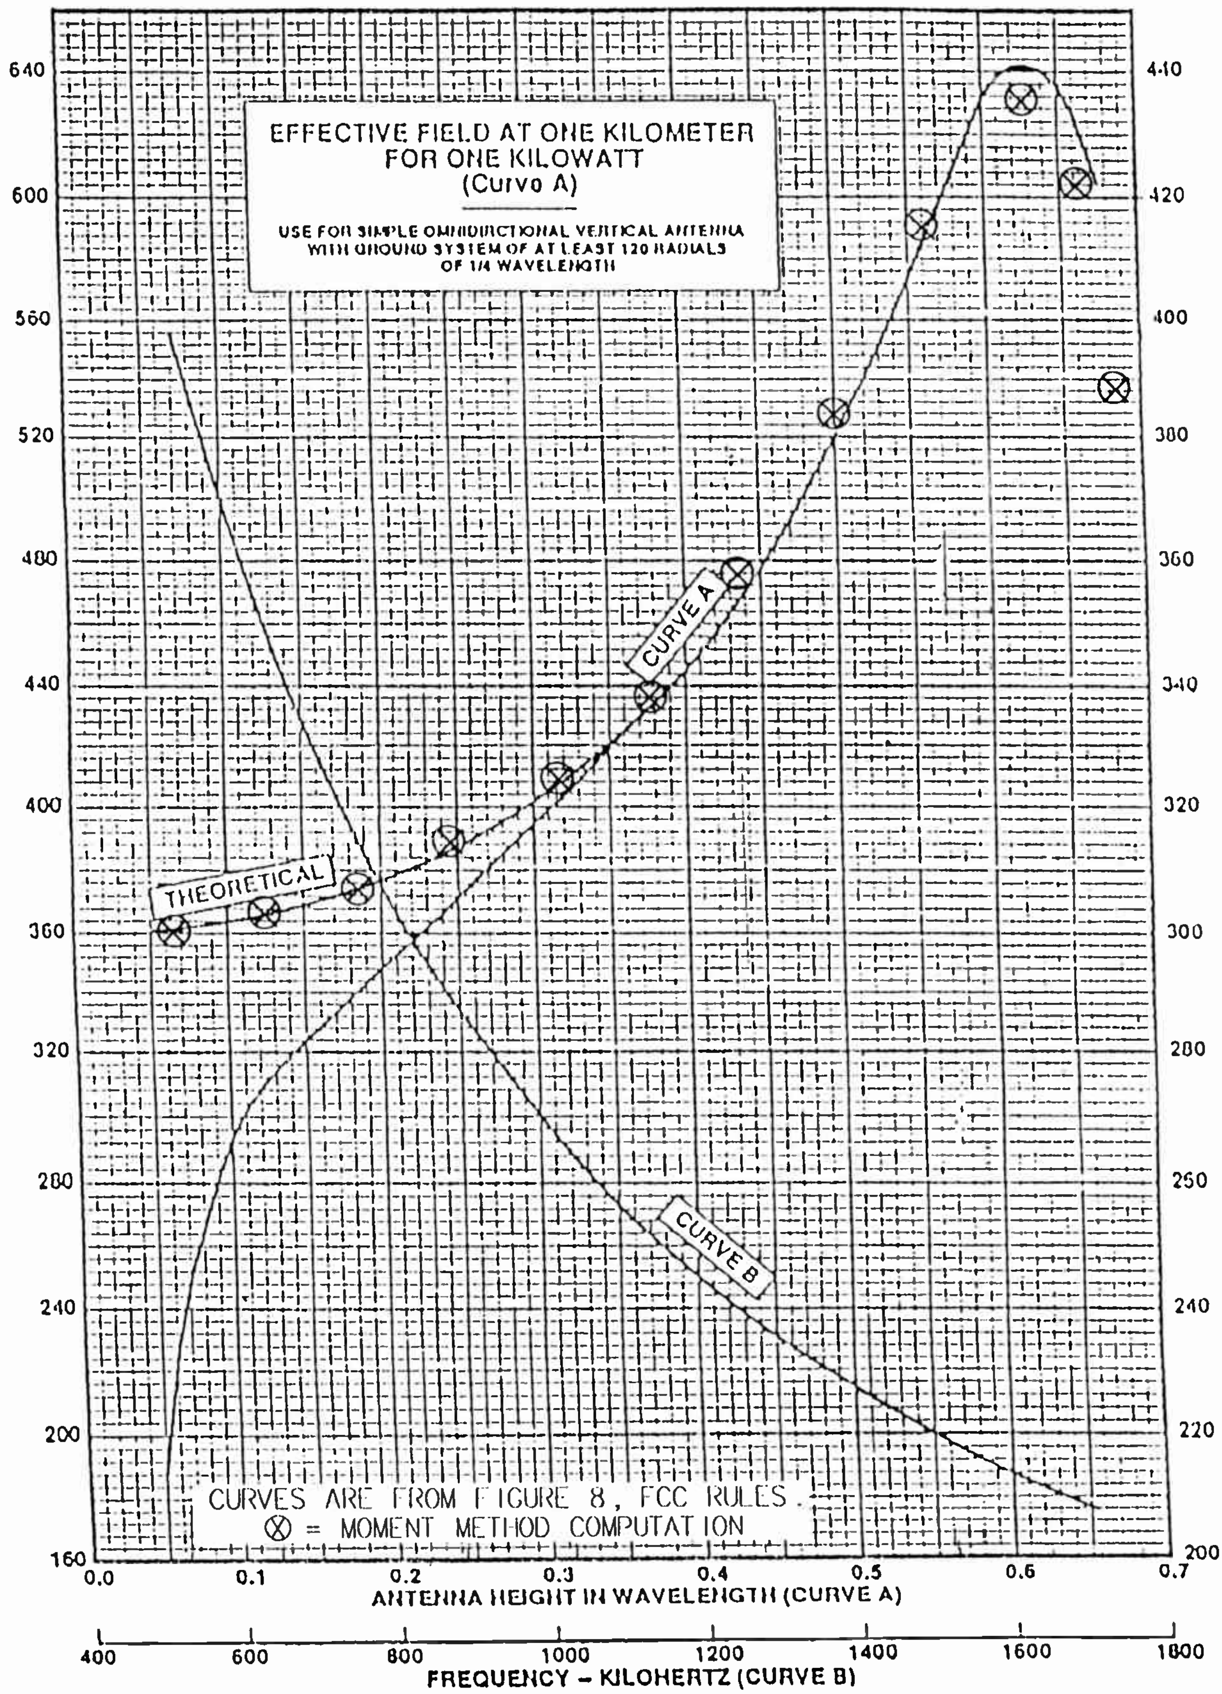

Figure 4.10-2. Lossless inverse field at one kilometer.

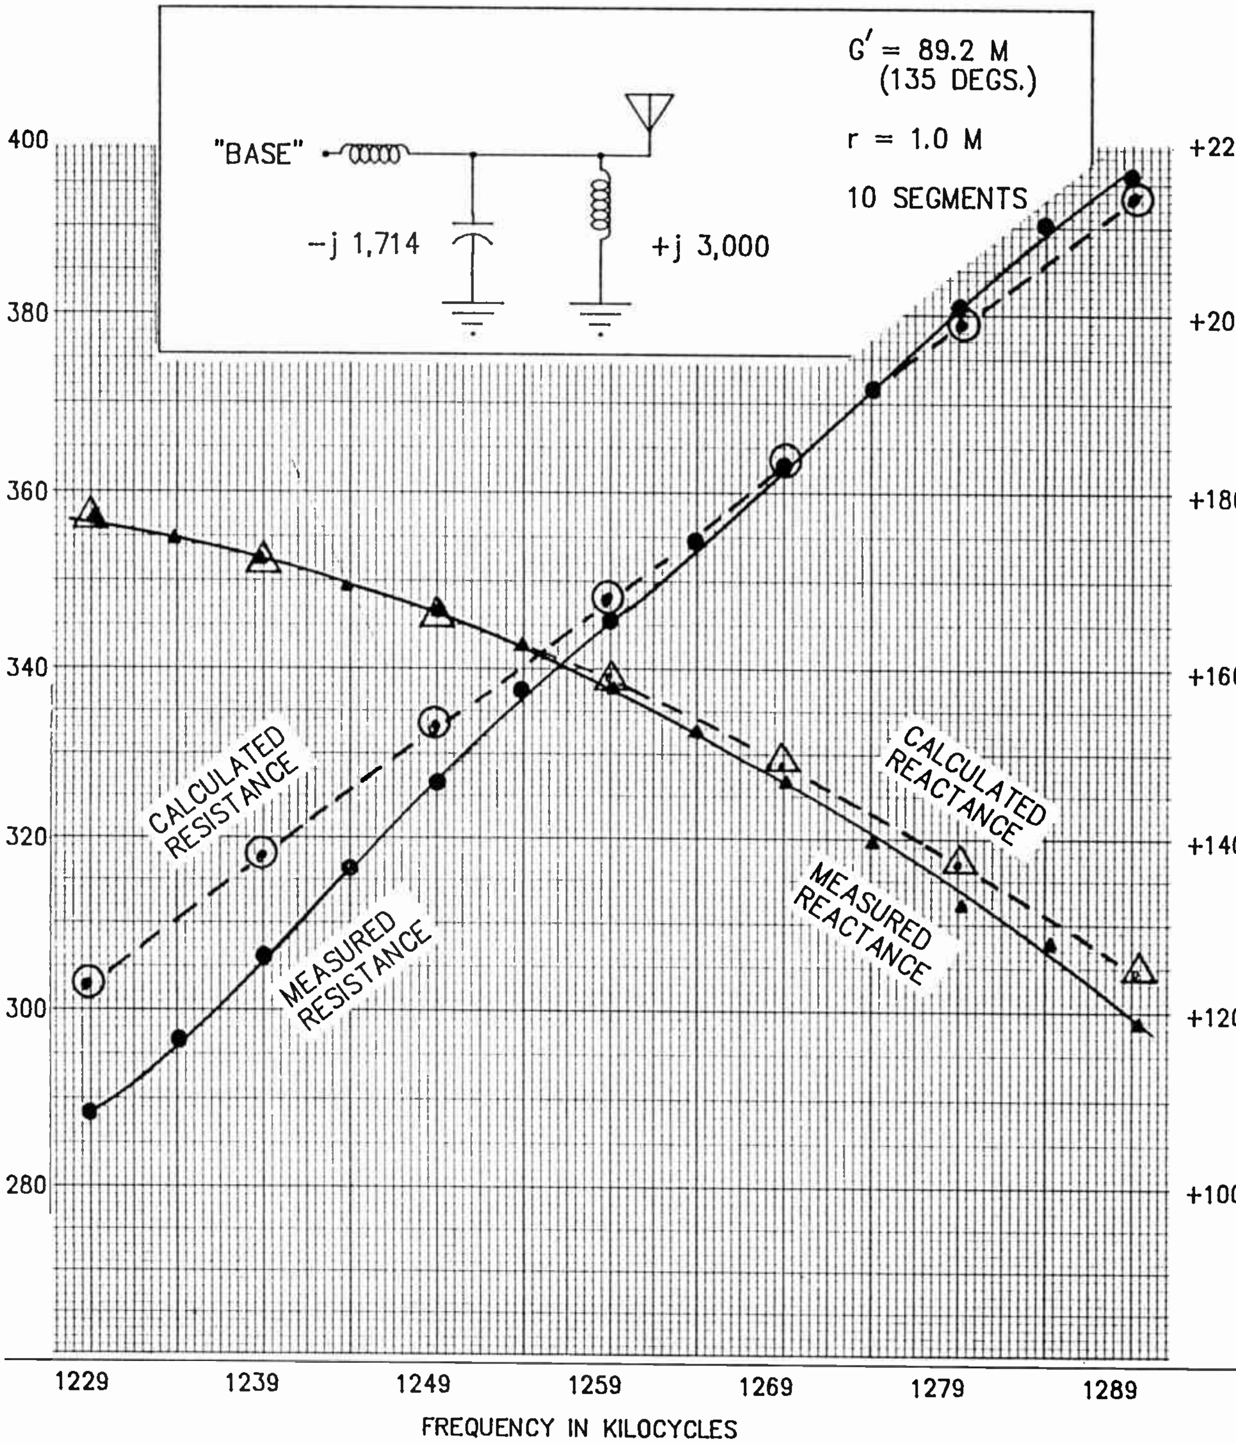

Figure 4.10-3. Rhodes, Greece tower model measurement and analysis by Ron Rackley.

loop shield shorted out through use of a screw can provide a sensitive indication of when the tower current minimum is reached.

This procedure is based upon the fact that towers are detuned in the horizontal plane by having the area under two-halves of the tower current distribution curve being equal and opposite in phase. If the current on a 90° tower is nearly sinusoidal the area under the curve is given by the cosine function. On a per unit basis the cosine is 0.5 at 30° and one-half of the area is one-third of the way up the tower.

Figure 4.10-4 shows the effects upon the nondirec-

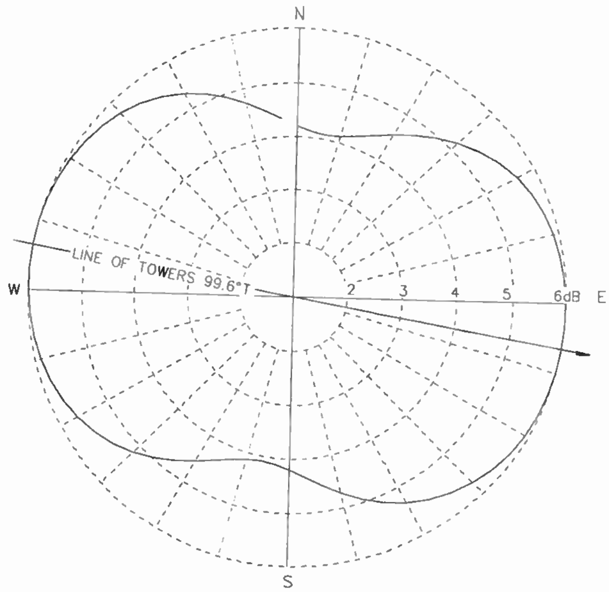

Figure 4.10-4. Non-directional patter, 3-tower array center tower driven, end tower floated, 100 pf to ground.

tional fields of the center tower of a 90° tall three tower array when the end towers are not detuned.

While detuning drastically lowers the fields in the horizontal plane it can cause large increases in vertical plane fields. Figure 4.10-5 illustrates this effect upon a four tower 110° array near a tall (5/8 wave) detuned tower. For a daytime directional, this effect may not be important, but it could have a disastrous effect upon radiation minima at night at high pertinent vertical angles.

Matching Antenna Monitor and Theoretical Field Parameters

The location on a detuned tower where the antenna current goes through a minimum and a reversal of phase angle is at the center of the area of the current distribution curve. The current at this location is proportional to the tower moment and hence the radiated field from the tower. If a sample loop is placed at this location and the sample system is the same for all towers of equal height, then the antenna monitor parameters will be the same as the theoretical field parameters.

The sample loop location for identical antenna monitor and theoretical field ratios and phase angles is shown in Figure 4.10-6 as a function of antenna height. For towers below 110° the sample loop should be placed one-third of the way up the tower. It is necessary, of course, that the rest of the sample system be identical, with equal length, same type, sample lines up to the loops and identical sample loops on all towers, with all loops oriented in the same direction.

When the towers are of different heights, the monitor ratios can be determined by taking the ratios of the computed currents one-third of the way up the towers. The monitor phase angle relative to the reference tower will be the same as the relative theoretical field phase angle.

The ratio of the current at a point on a tower to the tower moment is nearly constant for varying drive conditions. For different height towers the monitor ratio one third of the way up the tower for tower two of a two tower array is $(M_1/I_1) \times (I_2/M_2) \times F_2$. "M" refers to the tower moment for the respective numbered towers, "I" is the current on the tower one third of the way up the tower (slightly higher for towers over 130°) and "F" is the field ratio for the non-reference tower, while the monitor phase angle for the non reference tower is the same as the theoretical field phase angle. The tower moment and corresponding sample current can be calculated for each tower separately, independently of drive conditions, and the correction factor for the antenna monitor current ratio of the non-reference tower will be accurate for all field parameters.

When the antenna monitor sample loops are located at the tower height shown in Figure 4.10-6, the correction to the antenna monitor sample current ratio for

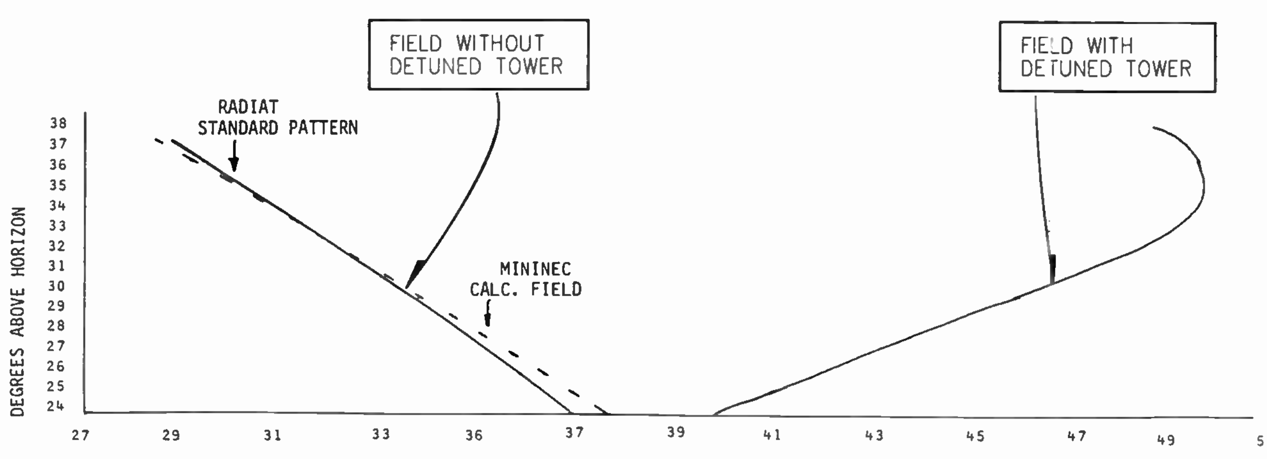

Figure 4.10-5. Effect of detuned tower on vertical angle radiation.

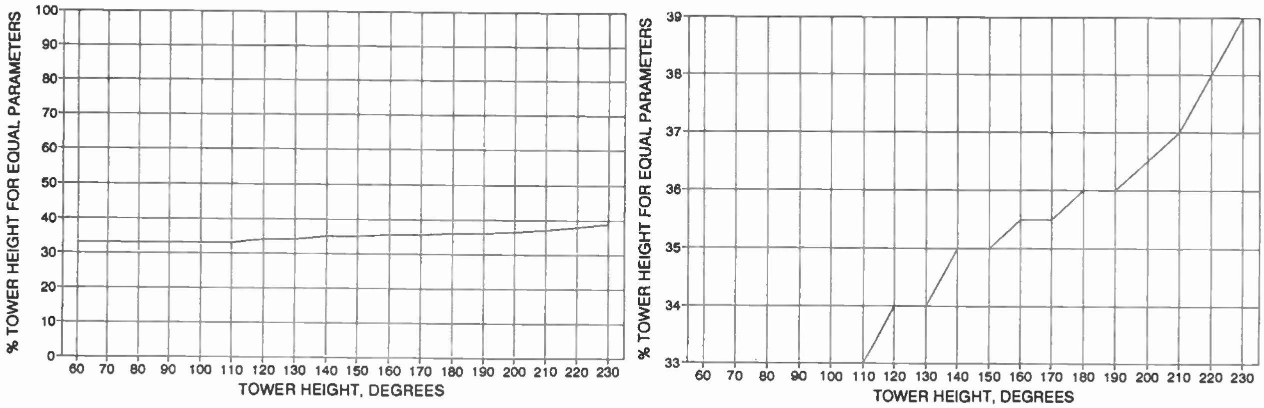

Figure 4.10-6. Percent of tower height where current ratios are same as field ratios and location of detuning current minimum.

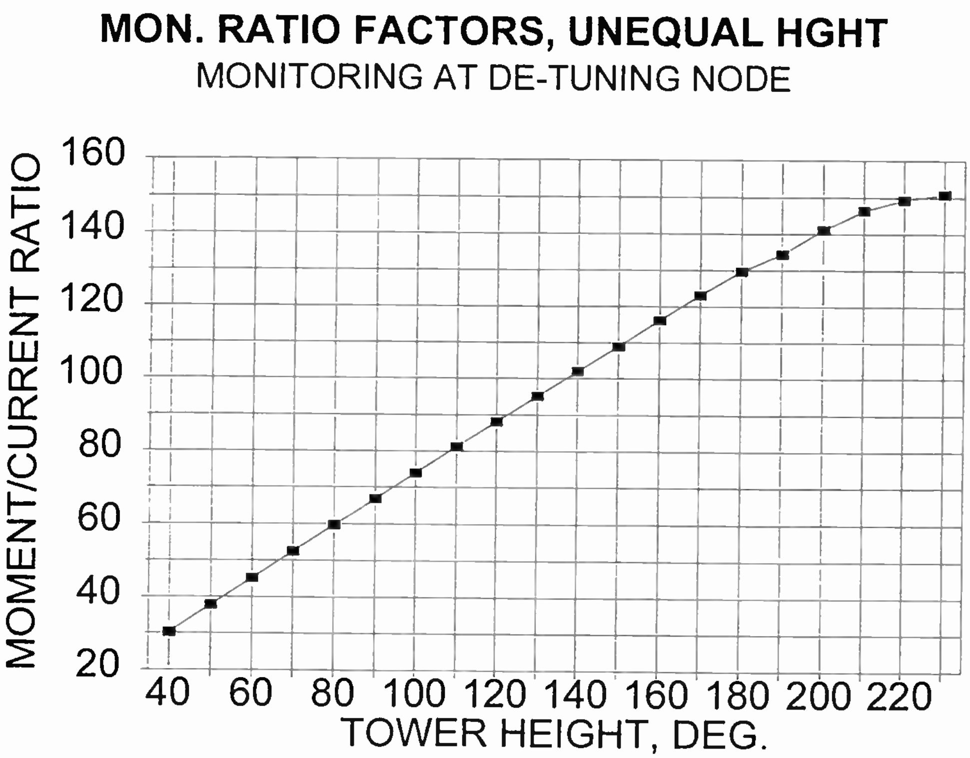
towers whose height is different from the reference tower can be found by using the tower moment to sample current ratio factors (M/I) shown in Figure 4.10-7. To find the correct antenna monitor current ratio for a tower that differs in height from the reference tower, multiply the reciprocal of the M/I factor for tower height by the M/I factor for the tower height. This result is multiplied by the theoretical field ratio of the tower in question to determine the corrected antenna monitor current ratio for that tower.

Since the fields differ from "M" by a constant, one could, in theory, determine the correction to the monitor ratio for unequal height towers by measuring the tower currents at the sample location and the fields at the same distance from each tower (or use FCC *Figure 8* from Section 73.190, shown as Figure 4.10-2) under identical tower drive conditions, and compute the correction to the antenna monitor current ratio from the above relationship. This is not always a practical procedure, however, due to the limitations of measurement accuracy and the difficulty of isolating the tower to be measured.



HEIGHT, DEGREES	FACTOR
40	30.28
50	37.72
60	45.09

Arrays Near Reradiating Objects

Figure 4.10-8 shows a typical problem that arises when an AM array is near a power transmission line. There are several effects that occur simultaneously:

- The current flowing through the transmission line towers and skywires causes large changes to the ratio of the electric and magnetic components of the radiated field of the array
- The power line may only affect the accuracy of nearby field strength readings but not the inverse distance pattern of the station
- The power line may affect both the field strength readings and the station pattern.

These effects can be separated out by modeling the power line and the AM array and then computing the near electric and magnetic fields along with the far-field pattern as influenced by the power line. A 1 Ω loss pattern can be computed by subtracting the square of the loop currents (maximum currents on the print-out) from the station input power. Corrections to the field strength meter readings can be calculated from the magnetic near-field data.

In one instance there were three tall guyed communications towers within a mile of an AM array. The array and the guyed towers were modeled and the stations pattern was scalloped as shown in Figure 4.10-9. The computed pattern did not exceed the standard pattern so no attempt was made to detune the communications towers.

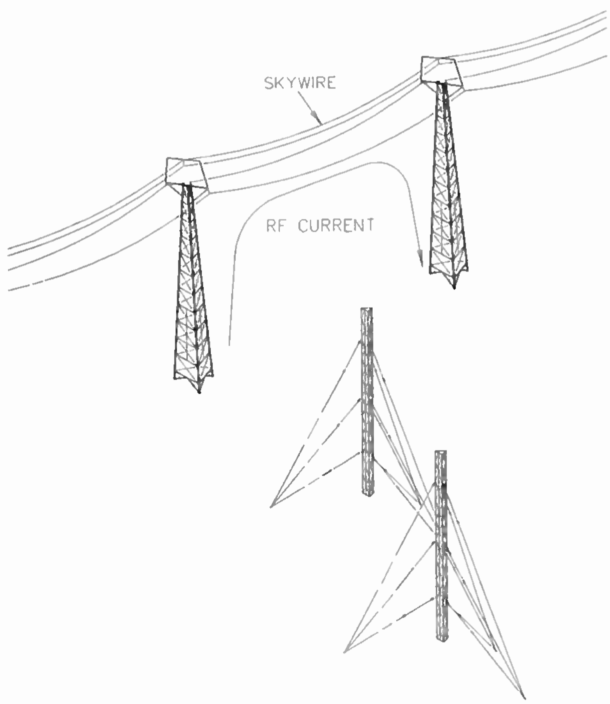

Figure 4.10-8. Two tower array with power line and skywire.

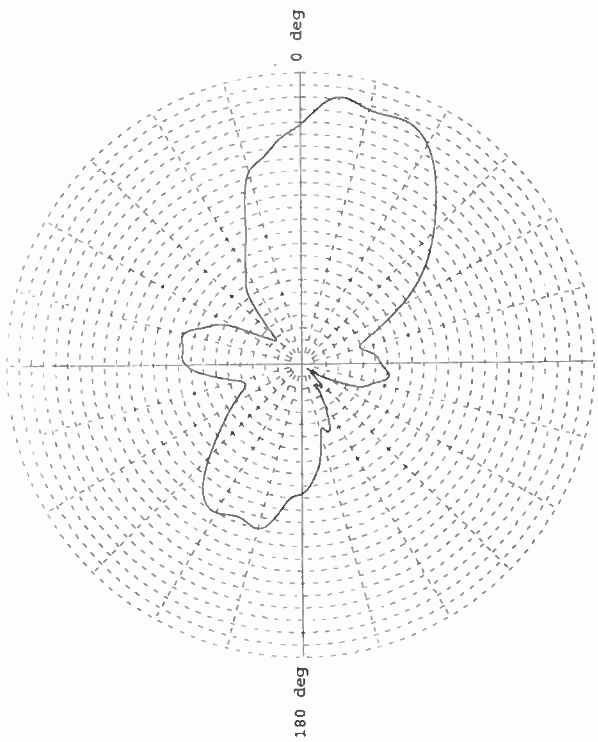

Figure 4.10-9. Example of the effect of a nearby reradiation on a DA pattern.

Top Loading

To determine the effects of modest amounts of guy wire top loading, a 76° non-directional tower was modeled as top loaded to 8° and 14°. The top loading, in electrical degrees, was simply the length of uninsulated guy wire connected to the top of the tower. Horizontal skirts were also added to the ends of the guy sections to determine their effects.

Eight degrees of top loading increased the resistive component of the base impedance by 45% while the reactance was reduced to 12% of the un-top loaded base reactance and went from capacitive to inductive. Adding horizontal skirts caused a further 16% increase in base resistance while the reactance became more inductive by a factor of five.

Fourteen degrees of top loading produces results that are, practically speaking, indistinguishable from skirted 8° of top loading with regard to resistance and reactance. Adding skirts to 14° of top loading tripled the inductive reactance and increased the resistance by 28%.

The conclusions are: top loading makes short antennas more inductive; the Q of the antenna is worse with skirted top loading and optimum with modest (8°) unskirted top loading. For all top loading from 0° to 14°, skirted or not, the inverse field at 1 km. only varied from 310 to 314 mV/m. So one can conclude that 8° to 14° of top loading has only a minor effect on tower radiation efficiency.

COMPUTING HUMAN EXPOSURE TO RF FIELDS FROM AM ARRAYS

Human exposure to magnetic and electric fields from AM towers can be computed using moment method programs. Licensed facilities in this country are restricted to a maximum power of 50 kW, so the FCC exposure limits are reached at a distance from each tower that is much less than the distance between adjacent towers. For this reason each tower can be treated as a separate case if no other sources of exposure are present at the site.

Tables 1 through 4 of distances to fences around AM towers shown in *Supplement A to OET Bulletin 65 (Edition 97-01)* were based upon moment method computations. The Commission has accepted such computations for RF guidance level determination for many years.

Figure 4.10-10 shows a computation of the electric and magnetic fields around an AM tower. The measured fields agree quite closely with the computed values. The figure also shows that one must model the tower carefully if correct results are to be achieved.

KEY TERMS

Antenna Monitor Parameters. The relative antenna current magnitudes and phase angles at a specified location on the towers.

Current Loop. The maximum current location on a tower. This is at the base of the tower for tower heights of a quarter wave or less.

Electrical Degrees. A unit of distance proportional to the free space wavelength at the frequency of interest. One wavelength is 360° and a quarter wave tower has an electrical height of 90°.

Field Parameters. The relative magnitude and phase of the contribution to the far electric field of each tower in an AM array.

Inverse Field. The electric far field of an AM antenna at 1 km that is not attenuated by earth losses and varies with distance R proportional to 1/R.

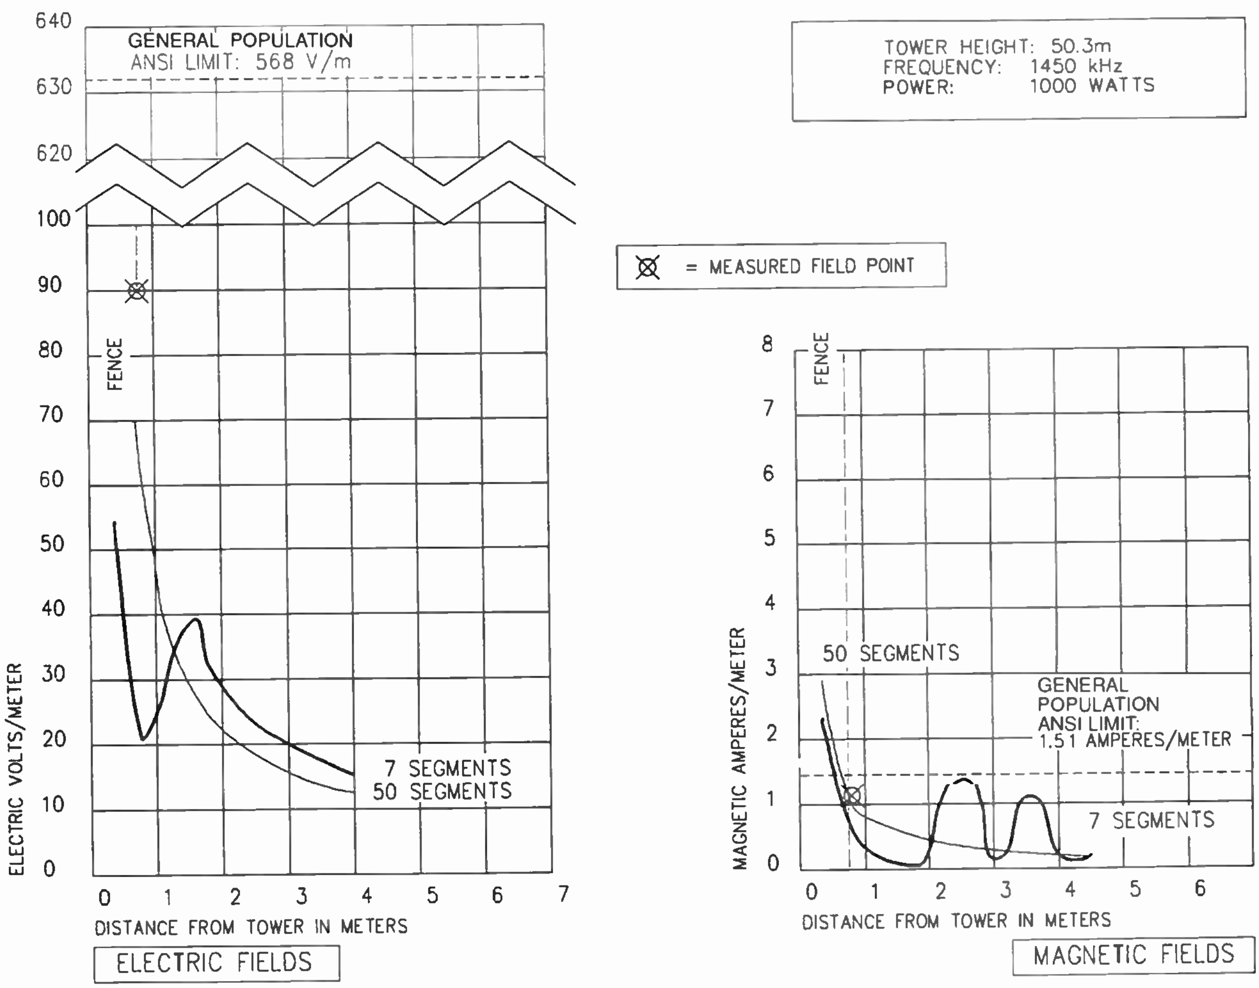

Figure 4.10-10. Electric and magnetic fields at 1 meter above ground near an AM tower.

Method of Moments. In the method of moments the integral equations relating antenna currents to radiated electric and magnetic fields is approximated by a set of linear equations. In these equations the differential distance is expanded to finite size, (segment) and the integral is replaced by a summation of a fixed number of current-segment products. When the matrix formed by these linear equations is inverted, the unknown variables can be expressed in terms of known input variables and numerically evaluated.

Sinusoidal Current Distribution. Antenna current that varies with antenna height proportional to the sine or cosine of the antenna height in electrical degrees.

RULES AND REGULATIONS

(Eq. 1)

$$E(\phi, \theta)_{th} \left| k \sum_{i=1}^{n} F_i f_i(\theta) \underline{/S_i \cos\theta \cos(\phi_i - \phi) + \psi_i} \right|$$

where:

- $E(\phi, \theta)_{th}$ Represents the theoretical inverse distance field at one kilometer for the given azimuth and elevation.
- k Represents the multiplying constant which determines the basic pattern size. It shall be chosen so that the effective field (RMS) of the theoretical pattern in the horizontal plane shall be no greater than the value computed on the assumption that nominal station power (see 73.14(c)) is delivered to the directional array, and that a lumped loss resistance of one ohm exists at the current loop of each element of the array, or at the base of each element of electrical height lower than 0.25 wavelength, and no less than the value required by § 73.189(b)(2) if this part for a station of the class and nominal power for which the pattern is designed.
- n Represents the number of elements (towers) in the directional array.
- i Represents the element in the array.
- F_i Represents the field ratio of the i[th] element in the array.
- θ Represents the vertical elevation angle measured from the horizontal plane.
- $f_i(\theta)$ Represents the vertical plane distribution factor of the i[th] antenna.

  For a typical vertical antenna with a sinusoidal current distribution:

  $$f(\theta) = \frac{\cos(G \sin\theta) - \cos G}{(1 - \cos G)\cos\theta}$$

  where G is the electrical height of the tower.

  See also Section 73.190, Figure 5.
- S_i Represents the electrical spacing of the i[th] tower from the reference point.
- ϕ_i Represents the orientation (with respect to true north) of the i[th] tower.
- ϕ Represents the azimuth (with respect to true north).

Figure 4.10-1(a). Formulas given by the FCC for determining directional antenna pattern size and shape taken from the Federal Register.

ψ_i Represents the electrical phase angle of the current in the i[th] tower.

The standard radiation pattern shall be constructed in accordance with the following mathematical expression:

(Eq. 2) $$E(\phi, \theta)_{std} = 1.05\sqrt{\{E(\phi, \theta)_{th}\}^2 + Q^2}$$

where:

$E(\phi, \theta)_{std}$ Represents the inverse distance fields at 1 km which are deemed to be produced by the directional antenna in the horizontal and vertical planes.

$E(\phi, \theta)_{th}$ Represents the theoretical inverse distance fields at 1 km as computed in accordance with Eq. 1.

Q is the greater of the following two quantities:

$$0.025g(\theta)E_{rss}$$

or:

$$10.0g(\theta)\sqrt{P_{kw}}$$

where:

$g(\theta)$ Is the vertical plane distribution factor, $f(\theta)$, for the shortest element in the array (see Eq. 2, also see Section 73.190, Figure 5). If the shortest element has an electrical height in excess of 0.5 wavelength, $g(\theta)$ shall be computed as follows:

$$g(\theta) = \frac{\sqrt{\{f(\theta)\}^2 + 0.0625}}{1.030776}$$

E_{rss} Is the root sum square of the amplitudes of the inverse fields of the elements of the array in the horizontal plane, as used in the expression for $E(\phi, \theta)_{th}$ (see Eq. 1), and is computed as follows:

$$E_{rss} = k\sqrt{\sum_{i=1}^{n} F_i^2}$$

P_{kw} Is the nominal station power, expressed in kw; see Section 73.14. If the nominal power is less than 1 kw, $P_{kw} = 1$.

$$K = \frac{(C1)(\sqrt{P_{nom}})}{rms_{hem}}$$

where:

K = the no-loss multiplying constant;

$C1$ = 244.86422 mV/m; this is the horizontal radiation from a standard hemispherical radiator in mV/m at 1 km.

P_{nom} = the nominal power in kw;

rms_{hem} = the root mean square effective field intensity over the hemisphere, which may be obtained by integrating the rms at each vertical elevation angle over the hemisphere. The Commission's computer performs the integration using the trapezoidal method of approximation:

$$rms_{hem} \cong \sqrt{\frac{\pi\Delta}{180}\left[\frac{rms_0^2}{2} + \sum_{m=1}^{l} rms_{m\Delta}^2 \cos m\Delta\right]}$$

where:

Δ = the interval, in degrees, between the equally spaced sampling points at the different vertical elevation angles θ;

m = integers from 1 to I, which give the elevation angle θ in degrees when multiplied by Δ;

l = one less than the number of intervals; it is equal to $90/\Delta - 1$;

rms_θ = the root mean square field intensity at the specified elevation angle θ:

$$rms_\theta = \sqrt{\sum_{i=1}^{n}\sum_{j=1}^{n} F_i f_i(\theta)\, F_j f_i(\theta) \cos\psi_{ij} J_s(S_{ij}\cos\theta)}$$

where:

i = i_{th} tower;

j = j_{th} tower;

n = number of towers in the array;

F_i = field ratio of the i_{th} tower;

$f_i(\theta)$ = vertical radiation characteristics of the j_{th} tower;

F_j = field ratio of the j_{th} tower;

$f_j(\theta)$ = vertical radiation characteristics of the j_{th} tower;

ψ_{ij} = difference in the electrical phase angles of the currents in the i_{th} and j_{th} towers in the array;

S_{ij} = spacing in degrees between the ith and jth towers in the array;

$J_o(S_{ij}\cos\theta)$ = Bessel function of the first kind and zero order of the apparent spacing between the i_{th} and j_{th} towers.

Next, the no-loss loop current (the current at the current maxima) for a typical tower is computed:

$$I_i = \frac{KF_i}{(C2)(1 - \cos G_i)}$$

where:

I_i = the loop current in amperes in the i_{th} tower;

K = the no-loss multiplying constant computed above;

F_i = the field ratio for the i_{th} tower;

$C2$ = 37.256479; this was derived in Constants for Directional Antenna Computer Programs;

G_i = the height, in electrical degrees, of the i_{th} tower.

Figure 4.10-1(b). Formulas given by the FCC for determining directional antenna pattern size and shape. Taken from the Federal Register.

Note: If non-typical towers are used; different loop current equations may be required. If the tower is less than 90 electrical degrees in height, the base current is computed by multiplying the sine of the tower height by the loop current. Using the no-loss currents, the total power loss would be:

$$P_{loss} = \frac{R}{1000} \sum_{i=1}^{n} I_i^2$$

where:

P_{loss} = the total power loss in kw;
R = the assumed resistance in Ω; for standard pattern calculations this would be at least 1 Ω;
i = the i_{th} tower;
n = the number of towers in the array;
I_i = the loop current (or base current if the tower is less than 90 electrical degrees in height) for the i_{th} tower.

Finally, the multiplying constant must be adjusted to change the assumption from nominal power being radiated to nominal power being the input power to the array prior to taking account of the assumed loss resistance:

$$K_\Omega = K\sqrt{\frac{P_{nom}}{P_{nom} + P_{loss}}}$$

where:

K_Ω = the multiplying constant after adjustment for the assumed loss resistance;
K = the no-loss multiplying constant;
P_{nom} = the nominal power in kw;
P_{loss} = the total power loss in kw.

The multiplying constant $K\Omega$ is the used to compute the theoretical pattern used in generating the standard pattern.

4.11
MAINTENANCE OF AM BROADCAST ANTENNA SYSTEMS

EDWARD EDISON, P.E. & GERHARD J. STRAUB, P.E.
HAMMETT & EDISON, INC., SAN FRANCISCO, CA

INTRODUCTION

Many stable directional arrays, being electrically passive devices, operate for 10 or more years without any readjustment. However, maintenance attention will be needed to overcome the normal effects of age and deterioration (routine maintenance), to restore proper operation after catastrophic failures (such as caused by lightning), and to cope with new sources of reradiation that may develop within the environment in which the antenna system operates. Infrequently, readjustment and relicensing with new pattern parameters may be required.

ROUTINE MAINTENANCE

Routine mechanical and electrical maintenance is required to offset the effects of age and deterioration. Mechanical maintenance includes the attention necessary to keep the moving parts functioning and the tower painted and in good repair. Electrical maintenance may involve replacement or recalibration of base current meters; checks on the continuing proper performance of the phasor components, transmission lines, and ground system; and infrequent readjustment of the antenna phase and ratio parameters as necessary to ensure operation within licensed limits with the proper directional antenna pattern.

Mechanical Maintenance

The moving components within an antenna system may include RF relays, meter switches, dial drives and the rollers on variable coils.

The contacts on RF relays that carry substantial currents may eventually wear out and require replacement. It is vital that such relays be interlocked so they cannot be switched while transmitter power is applied. Relay maintenance problems are reduced when vacuum relays are employed.

Meter switches, that disconnect thermocouple-type ammeters from the circuit when not being read, are subject to considerable mechanical wear and tear. Occasional lubrication and tightening of the components are necessary if the parts are to function properly. Replacement of thermocouple ammeters with modern transformer type meters eliminates the need for RF meter switches and their associated maintenance requirements.

Dial drives on variable coils and capacitors, once properly adjusted, require little attention except infrequent lubrication. The thrust bearings on vacuum variable capacitors are factory lubricated and should not require maintenance attention. However, the rollers on variable coils are often a source of mechanical difficulties (particularly in older coils) and periodic maintenance is required if they are to operate smoothly and without excessive arcing. Networks that are designed to utilize variable vacuum capacitors instead of variable coils are superior in this regard.

Electrical Maintenance

Thermocouple RF ammeters that measure base currents and common point currents are a frequent problem due to failure or changes in calibration. If such meters cannot be replaced with modern transformer type units, an intermediate improvement can be effected by substituting make-before-break meter jacks at the base of each tower (in lieu of the original permanent thermocouple meters and associated protective switches). The meters can then be stored in a dry environment and taken to the towers only when base current readings are required. The effects of calibration errors are reduced if the same meter is used to measure all base currents (provided all currents fall within an acceptable range on the meter scale).

Thermocouple ammeters can be calibrated with 60 Hz current. A useful procedure is to remove all such meters from the system and to connect them in series for testing. A high quality dynamometer or soft iron type meter should also be included as a calibration standard. A filament transformer having adequate secondary current rating can be used to drive current through all of the meters connected in series. Current amplitude is easily controlled by supplying the filament transformer from an adjustable ac supply such as a Variac.

Modern current transformer RF ammeters cannot be calibrated with 60 Hz and, if defective, must be returned to the manufacturer for repair and recalibration. The transformer, meter and interconnecting cable are calibrated as a unit. The cable length should not be changed without recalibration by the manufacturer.

Occasionally loose connections or deteriorating phasor components will produce abnormal heating. Failures from these causes can be anticipated by simply feeling all RF connections and components for warmth immediately after sign-off.

Transmission Lines

Air or foam dielectric lines in continuous lengths rarely develop troubles, but pressure should be maintained on air dielectric lines in order to prevent the accumulation of moisture. Breaks in the outer conductor of foam filled lines that are buried may cause obscure symptoms and prove difficult to locate. In extreme situations, a time-domain reflectometer is the best tool to pinpoint the problem.

Ground System

Significant deterioration of a ground system can manifest itself in two ways. The first indications may be unusual changes in the phase and ratio parameters between wet and dry conditions. These changes depend upon the nature of the directional array and the character of the ground. When ground systems are installed in shallow tidewater or saltwater marshes, the inherent ground conductivity is so good that even drastic changes of the ground system may produce negligible effects.

A second, more obvious symptom of a deteriorating ground system, is a reduction in antenna radiation and a reduction in base currents. It is not uncommon in older arrays to find that the absolute value of each base current has fallen off since the time of the initial installation, even though the base current ratios remain correct. With the available common point power remaining constant, any increase in ground system losses must necessarily reduce the base currents.

It is essential that all joints in a ground system be made by brazing or silver soldering. Soft solder consisting only of lead and tin deteriorates quickly when buried.

The existence and continuity of buried ground radials is best checked by using an underground cable locator of the type used by utility companies to locate buried cables and pipes. These devices consist of a transmitter, that can be located at the tower base to place a modulated low-frequency signal on all connected ground wires and a receiver that detects the unique modulation. While in use, the receiver can be carried in a circle with a radius of 100 ft or more about each tower, so that the radial wires that are intact can easily be detected and counted.

Alternatively, if a cable locator is not available, a shielded pickup loop held near the ground and connected to the external input of a field strength meter may suffice to detect the current in individual radial ground wires. Even when a radial is broken, the current beyond the break tends to concentrate in the wire instead of the adjacent earth. A most definitive check is to uncover the distant ends of adjacent radials and check for continuity between them with a dc ohmmeter.

Towers

Towers require occasional attention to ensure their structural integrity. Periodic inspections by an experienced tower contractor are desirable. Guyed towers should be checked to confirm that they are straight and plumb and that the guy tension is correct. Towers with tubular legs can rust from the inside out; a close inspection is necessary to detect this condition while repairs are still feasible. Towers with solid legs avoid the hazards of internal rust. Galvanized towers must be painted only if required for aeronautical safety. Nongalvanized towers should be avoided, not only because rusting makes the maintenance problem more severe, but also because of their inferior electrical conductivity.

Lightning strikes and target shooters may destroy guy wire insulators. Such failures can usually be discovered with the aid of field glasses or a telescope. The electrical field gradient can be very high adjacent to a tower, particularly near the top. Arc overs and corona can be avoided by cascading guy wire insulators (johnny balls) immediately adjacent to the tower. Under severe conditions, fiberglass rod insulators or dielectric guy cables are a preferred solution. In an existing system with marginal insulation, any dirt or salt deposits on the insulators may cause corona and arc overs. Washing the insulators and coating them with silicone grease may provide a temporary remedy.

SUDDEN COMPONENT FAILURES

Lightning strikes are the most common cause of component failure in a well designed antenna system. Lightning that strikes a tower should be conducted directly to ground through the ball gap that is typically part of each tower installation. However, lightning has been known to destroy components in what appear to be well protected systems.

Damaged components can most usually be located by a careful visual inspection. Lightning currents flowing through adjacent coil turns tend to collapse them; therefore, coils should be inspected to confirm that all turns are in their original uniform alignment. The forces generated by lightning traveling through the coil strap and clip on a ribbon coil may dislodge the clip and leave the strap hanging in nearly its original position. Careful visual inspection is needed to locate dislodged coil clips.

Although vacuum capacitors are usually self healing if subjected to minor over voltages that cause internal arcing, the extremely high currents from a lightning strike can melt the plates together and short the capacitor, necessitating replacement.

If lightning damage is a recurring problem that warrants additional protection, the following steps are suggested:

1. Check the ball gap at the tower base. The balls should be arranged side-by-side so that dirt and

water will not bridge the gap with the first rain of the season. The balls should be on the same radial line through the tower axis because towers tend to twist in high winds; this twisting could otherwise change the gap between the balls. The gap should be as narrow as possible.

2. Provide a two-or-three turn choke coil in the RF feed from the antenna coupling unit (ACU) to the tower if one is not already installed. The coil can be from 5 to 10 in. in diameter depending on the station power level and the feedline size. Its function is to present a high impedance to lightning strikes so they will jump the ball gap rather than enter the ACU. Readjustment of the output arm of the matching network will be required to offset the added inductance of the lightning choke.
3. Provide a horn type lightning gap within the ACU similar to the design shown in Figure 4.11-1. The relatively clean, dry and insect-free environment inside the ACU permits a tighter gap setting and increased lightning protection than can be accomplished with an exterior gap. The path for lightning currents from the tower to the gap within the ACU should be very direct with minimum inductance and no sharp bends. Similar lightning gaps also can be installed at both ends of all transmission lines to help prevent lightning currents from getting into the phasor.
4. Adjust each gap individually by reducing the spacing until it arcs on the heaviest modulation peaks. The spacing should then be doubled for the permanent adjustment. This will be a much smaller gap spacing than is usually encountered on external gaps at the tower base.
5. Check to see that there is a dc path from each tower to ground, either through a phase sampling isolation coil, a separate static drain coil or resistor, a spare winding on a tower lightning choke, or the network circuitry within the ACU itself. Without a static drain, static charges may build up on a tower and then discharge with a small arc that may be sufficient to trip protective circuits and take the transmitter off the air.

ENVIRONMENTAL CHANGES

The ideal environment for a directional antenna system is a flat plane of high conductivity with no tall structures in the general vicinity, such as buildings, power line towers, water tanks or oil wells. Such structures (or any metallic objects of substantial vertical dimension) will have currents induced in them. These currents are dependent upon the size and shape of the structure, the frequency, and the ambient field strength with which they are illuminated. The currents in such objects make them parasitic antennas. The resulting

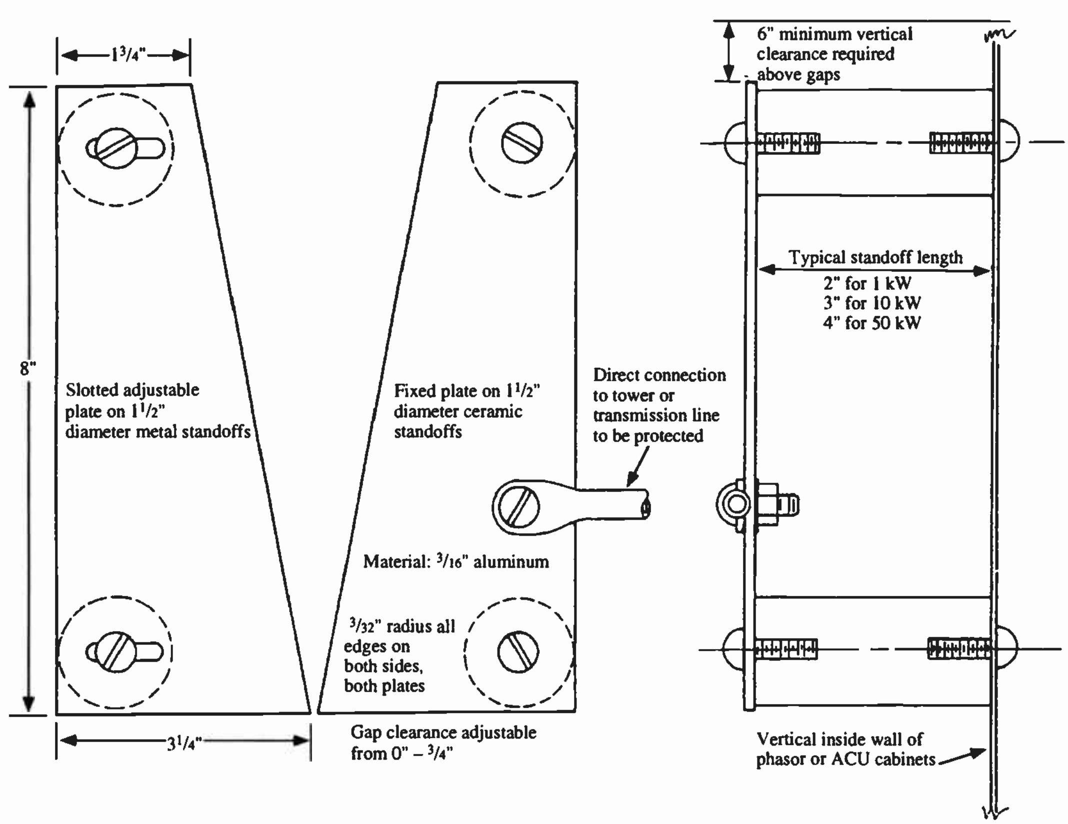

Figure 4.11-1. Suggested lightning gap design.

reradiation can severely distort the pattern of a directional antenna array.

Reradiating objects located in the main lobe of an antenna pattern are of greater consequence than those located in or near pattern minimums where their illumination is substantially less. The reradiation from reasonably slim and electrically short objects (where the overall height is substantially less than a quarter wavelength) can be calculated with useful accuracy by means of the approximate formula,

$$|E_r| = \frac{|E_i| \left[\frac{\cos(1.2\,hf) - 1}{\cos(1.2\,hf)}\right] h}{2000\left[\left(ln\,\frac{2h}{a}\right) - 1\right]}$$

Where: E_r = Reradiated field in mV/m at 1 km
E_i = Incident field in mV/m at location of reradiator
h = height of reradiator in meters
a = effective radius of reradiator in meters
f = frequency in MHz
ln = natural logarithm
cos = cosine of angle in degrees

Reradiation can also be calculated using commercially available software.

If feasible, a more accurate assessment of the reradiation can be obtained by measuring the RF current flowing in the reradiating object. If the object is reasonably thin (such as a guyed communications tower, a cable television headend tower, or the four individual legs of self-supporting power line towers) measurement of the current flowing from the tower to ground is not difficult. For this measurement, a toroidal pickup coil formed by the spiral steel wire in a length of clothes dryer exhaust hose (or even better, some types of vacuum cleaner hose) is useful. The hose section should be long enough to encircle the tower or current carrying conductor to be measured and to have its ends attached to a field strength meter operating as a linear voltmeter. Such a pickup coil can be calibrated by encircling a conductor carrying a known current, such as the feed to the base of a radio tower.

It is not necessary to measure the current distribution throughout the height of electrically short objects. The current distribution can be assumed to be triangular, decreasing to zero at the top of the tower if it is freestanding; or the current can be assumed to be uniform throughout the entire height of the tower as a worst case assumption where power line towers exhibit heavy toploading due to the capacitance to ground of the conductors they support. Once the current is measured the reradiation can be calculated by relating the *ampere feet* of current in the reradiator to that in a quarter-wave tower at the same frequency. For example, a quarter wave tower at 1,000 kHz is 246 ft high, has a base resistance of approximately 50 Ω, and a base current of about 4.5 A for 1 kW. With sinusoidal current distribution on the tower, the average current throughout its height would be 64% of the base current or about 2.9 A. Thus, at 1,000 kHz about 700 A-ft of current would produce about 190 mV per meter of radiation at one mile or 300 mV per meter at one kilometer. This corresponds to a radiation (or reradiation) in the order of 0.5 mV per meter at 1 km for each A-ft of current in the reradiator. This rule-of-thumb as to the resulting reradiation from short towers is proportional to frequency when applied to channels removed from 1,000 kHz.

CELLULAR AND PCS TOWERS

Perhaps becoming the most prevalent potential reradiating structures these days are the ubiquitous cellular and PCS towers. The FCC has codified the requirement for these facilities to notify and to conduct measurements on AM radio stations located near potential tower sites to ensure that the antenna pattern of the AM radio station is not affected by parasitic radiation from the cellular or PCS tower. The FCC requires that directional AM stations within 3 km and nondirectional AM stations within 1 km be notified. Additionally, measurements must be conducted on the AM station both before and after construction of the new tower to ensure that no adverse effects have occurred. If there have been any significant effects, the burden is on the cellular or PCS provider to remedy the problem, including detuning if necessary.

Measurements on the AM station may take a number of forms. FCC policy requires a partial proof on each pattern of a directional station, although fewer measurements may be acceptable if the station and the cellular provider agree. It is important to note that this requirement implies required cooperation on the part of the AM station, including operating with nighttime pattern during the day in order to allow field strength measurements to be made with the absence of skywave and in accordance with FCC policy for AM field strength measurements. The FCC has intervened on occasion and reminded the reluctant AM station that it has the authority to request a partial proof-of-performance from the station at any time.

Measurements on nondirectional stations should consist of approximately ten points between 3 and 16 km from the station. The measurements should be made on eight evenly spaced radials beginning with true north. The first set of measurements, for both directional and nondirectional stations, are made prior to the new tower being erected. The second set of measurements should be made after the tower has been erected and all antennas and appurtenances have been installed. The measured field strength before and after construction are then compared to look for significant changes. To avoid potential environmental changes, it is desirable to conduct the before and after measurements with as little time between them as possible. A new tower constructed very close to a nondirectional station may also affect the base impedance of the tower. In such cases, the base impedance may need to be remeasured to ensure accurate power measurement.

Even with the proliferation of these towers, there are relatively few cases where the new tower is really a problem. Most of these towers are electrically short and are such inefficient radiators that they cause no problems. For example, a typical 60 ft monopole is approximately 37 electrical degrees tall at 1700 kHz and proportionately shorter at lower frequencies in the band. It is nearly impossible for such a tower to have a significant effect on a nondirectional station at any reasonable distance from the AM tower. Such a tower located very close to a directional AM array with a very deep pattern minimum, if the tower is located in the main lobe of the AM pattern, may be able to cause some measurable effect. The same tower located in the pattern minimum would have little effect, since it is not heavily illuminated by the AM radiation.

By all means, AM broadcasters should keep diligent watch for new towers near their transmitter sites and have these evaluated by a competent engineer. However, unless the tower is relatively tall, in terms of wavelength at the AM frequency, unless the tower is located close to the AM array, or unless the AM pattern has very deep minima, it is unlikely that the tower will cause a significant effect. In cases where there is a significant effect, simple detuning measures described previously will usually remedy the problem.

RADIATION HAZARDS

In 1986, the FCC promulgated rules limiting human exposure to radio frequency fields at all AM, FM, and TV broadcast sites. In 1997, these rules were further revised. This subject is covered in detail in Chapter 9.4, *Non-Ionizing Radiation.* At AM broadcast frequencies the potential for human exposure in excess of the radiation limits exists only in the immediate vicinity of radio tower bases and in the vicinity of phasors and antenna coupling units that are not in fully enclosed cabinets. Phasors and ACUs employing open panel construction can exceed exposure limits at distances up to about 5 ft depending upon the station power level. Metallic fences surrounding each tower base form excellent shields at AM broadcast frequencies and greatly reduce the area exceeding exposure limits when compared to unprotected towers or towers within wooden fences. One useful arrangement when weatherproof ACUs are employed is to mount them so that their locked front door is in the plane of the fence surrounding the tower and is accessible without entering the fenced enclosure.

Compliance with radiation hazard limits effectively prevents maintenance or painting of a tower while it is in use. Therefore it is now highly desirable to provide for nondirectional operation on either of two towers so that every tower can be deenergized in turn when required for maintenance without taking the station completely off the air.

Although the FCC has not adopted the induced or contact RF current limits of any standard, there is the potential for creating a situation that would exceed recognized current limits near AM facilities. Tall, ungrounded, conductive structures near an AM transmitter site could have substantial current induced by the AM radiation. A person contacting the structure and ground could draw significant current from the structure. With high powers, it may even be possible to create an arc and receive an RF burn.

Large cranes are the most troublesome, as the crane, boom, and cable create a large loop antenna capable of intercepting significant energy from a nearby AM station. Contact currents on large cranes near a 50 kW facility were measured to exceed one ampere in at least one case and significant arcs could be drawn from ungrounded and uninsulated hooks. It is important to realize that this is not only a high power concern, as currents in excess of the applicable ANSI standard were measured on a large crane over 800 ft away from a 1 kW facility. While siting near cranes is not usually desirable because of the pattern distortion that they may create, if it is necessary to locate a facility near large cranes, or other objects, it may be necessary to utilize insulated hooks or other mitigation techniques on the crane or other structure.

READJUSTING AN ARRAY

Any readjustment of a directional antenna array should be undertaken only by personnel who have a basic understanding of directional antenna theory and practice. At the minimum, the material in the preceding two chapters should be read and understood. Before any array adjustments are attempted, considerable information needs to be collected and analyzed.

Four conditions for proper array performance are explained below. All of these conditions should be met simultaneously in normal operation.

- The antenna monitor indications should agree with the station license within the FCC tolerances of 5% for tower current ratios and 3° for phase. A special case is a *critical* array which has been assigned tighter tolerances by the FCC.
- Changes in base current ratios should be consistent with changes in antenna monitor ratios. Although the base current ratios and antenna monitor ratios are rarely in exact agreement (and will differ greatly in arrays with unequal height towers), these ratios should change by essentially the same percentage for small changes in the actual base current ratios. In other words, when the monitor indications match those shown in the license or the most recent proof, the base current ratios should also match what is shown in the same license or proof. Discrepancies are an indication of changes in the sampling system or in the base current metering and should be investigated.
- The reradiation environment must be essentially unchanged from that in which the array was last in proper adjustment. Any substantial structures such as power line towers or steel frame buildings recently constructed in the vicinity of the array, particularly in the main lobe of the pattern, can cause trouble.

Grounded structures approaching a quarter-wave high can distort critical antenna patterns even if located one or two miles away in the main lobe of radiation.

- The monitoring points should be within the limits shown on the station license. A high monitoring point may result from a changed environment due to the construction of buildings or power lines near the monitoring point. If a high monitoring point does not correlate with observed changes in antenna monitor parameters, the point is suspect and should be checked by measuring and analyzing 10 or more of the other points on the same radial that had been measured and recorded in the most recent proof or partial proof. Readjustment to reduce excessive radiation is indicated only if the analysis of 10 or more points confirms that the radiation in that direction is in fact in excess of the standard pattern limit.

SOIL CONDUCTIVITY

The analysis of a radial may be misleading due to changes in soil conductivity. Increased soil conductivity during wet seasons may cause substantial increases in signal strength at distant measuring points when compared to the same measurements during dry seasons. This phenomenon varies with distance, with season, and with differing geographical regions. These effects may not exist in some regions, but in extreme cases may show 2:1 changes in field strength at a distance of 20 miles. When analyzing field measurements, soil conductivity variations can be eliminated by comparing the present ratio of directional to nondirectional field strength at each measurement point to the same ratio in previous complete or partial proofs. Because new nondirectional measurements may be needed at a future date, it is important to incorporate in the phasing system a switching capability to permit reversion to nondirectional operation at those stations which do not normally have a licensed nondirectional mode.

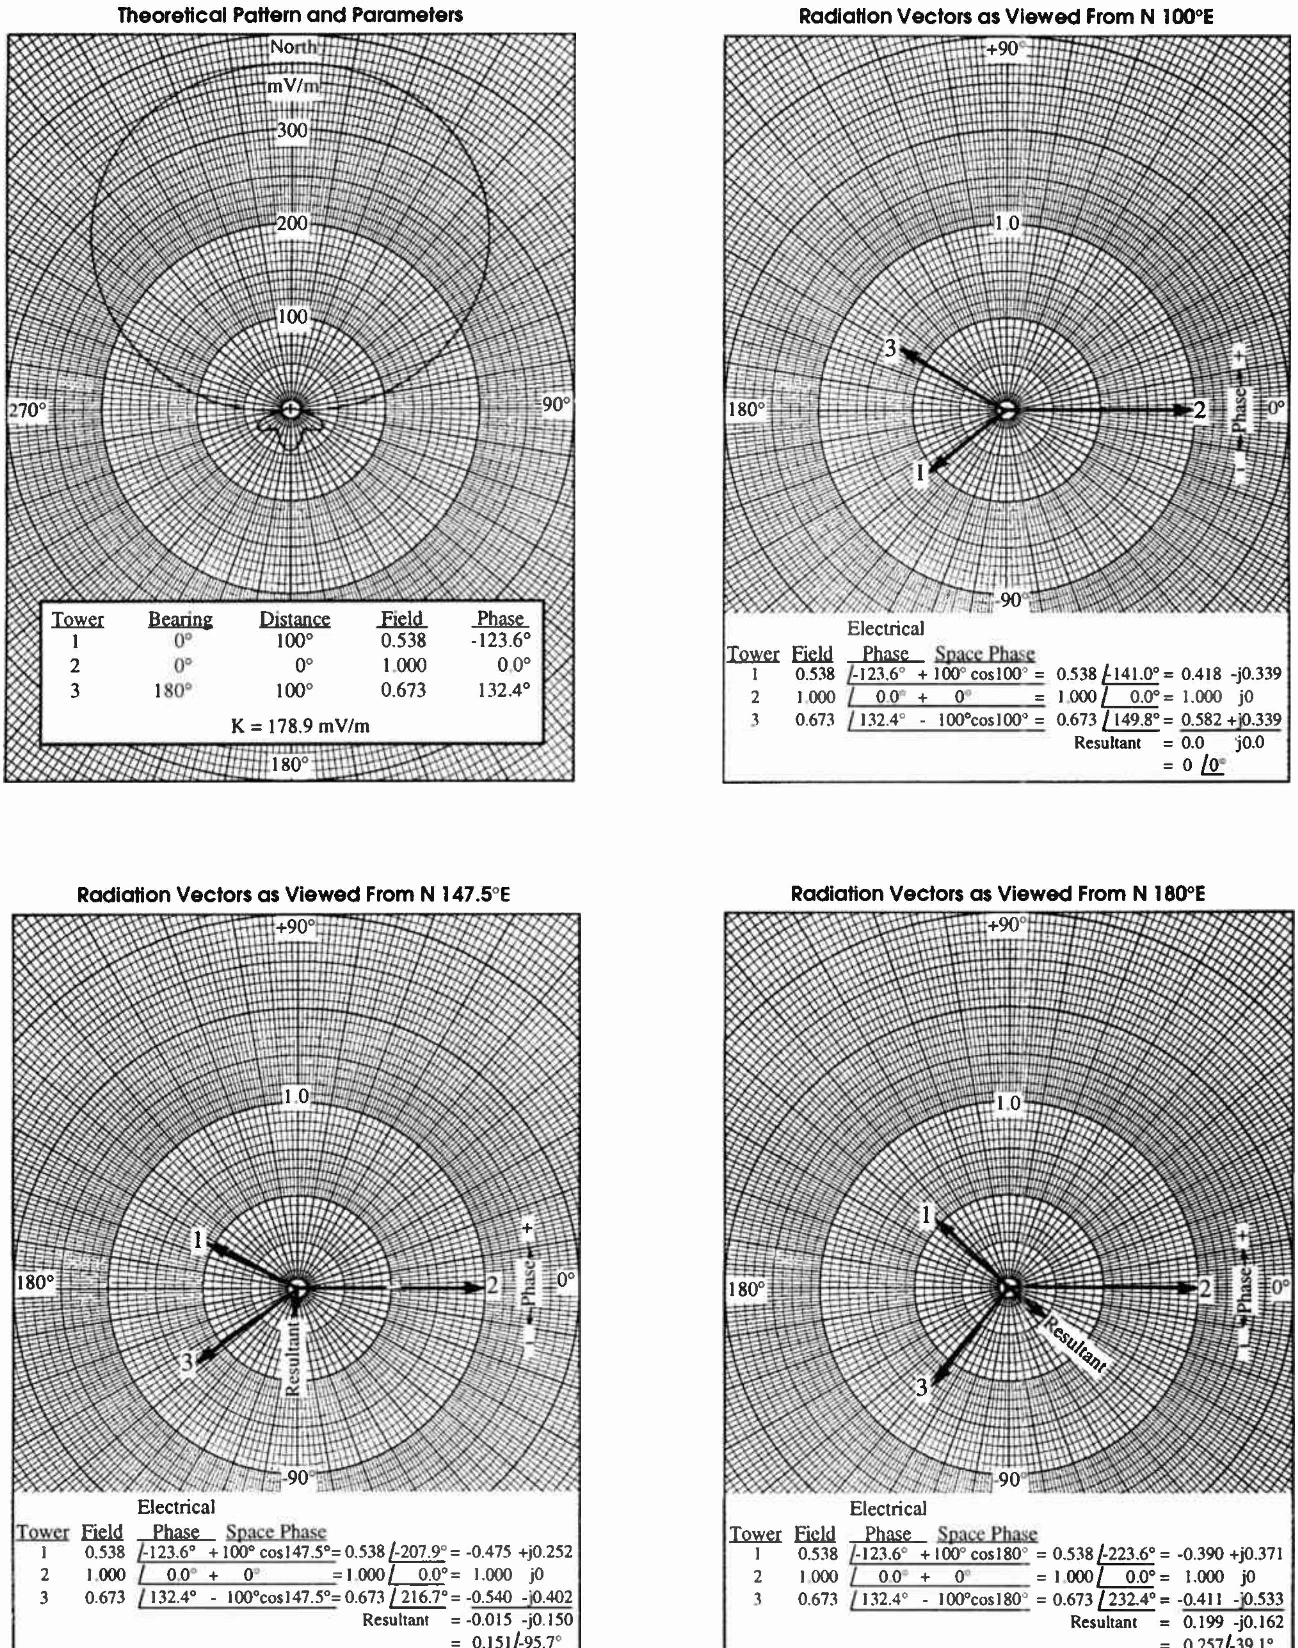
READJUSTMENT DATA AND ANALYSIS

Directional antenna arrays vary so much in pattern shape, suppression requirements, and phasor circuitry that precise readjustment instructions cannot be described. If possible, the consulting engineer who adjusted the array before its last proof of performance should be consulted on the problem. The following guidelines should prove helpful:

- Carefully log all dial settings and all coil tap locations before making any changes. Keep in mind what parameter you are trying to change before twisting any knobs or changing any coil taps.
- Make changes only in small increments, typically never more than about 1° or 1% in phase or ratio.
- Keep a step-by-step record of each change as it is made so that the array can be restored to intermediate or initial conditions, if necessary.
- Remember that even small adjustments of phase or ratio can have a measurable effect on the common point resistance. The power fed to the antenna system is only correct if the common point resistance and current are essentially correct. A permanently installed common point operating impedance bridge is a convenience not only for keeping track of the common point impedance during adjustments but also for continuing confirmation of the licensed common point value in day-to-day operation.
- Construct vector diagrams for each important direction. Samples of such diagrams are shown in Figure 4.11-2. The phase relationships must include both the electrical phase of the currents fed to the towers and the space phase component for each tower relative to the reference tower as viewed from each direction. Such diagrams will assist in visualizing what effect any contemplated changes in phase or ratio for any tower will have on the resultant field in each direction. The vector diagram amplitudes may be in terms of the individual tower field ratios (such as in Figure 4.11-2) or in terms of the theoretical unattenuated radiation. The theoretical unattenuated radiation from each tower (expressed in millivolts-per-meter at one km or one mi) is obtained by multiplying the theoretical pattern field ratio for each tower by the pattern constant K, which is also usually shown in each theoretical pattern.
- If the pattern includes essentially zero minimums (which need to be as deep as possible), make *talkdown* adjustments at a series of the most distant points on the null radial from which adequate two-way communications can be obtained. At each talkdown location, adjust the phasor for any combination of tower currents and phases that gives the deepest possible minimum. (A deep minimum can usually be confirmed by rotating the field strength meter 90° on a vertical axis and noting that the signal received from scattered reradiators is stronger than that received from the station when the meter is in its normal measurement orientation.)

Construct the vector resultant for each talkdown on a vector diagram similar to that shown in Figure 4.11-2, but use the antenna monitor indications of phase and ratio instead of the theoretical parameters. The vector resultant will probably not be zero because of errors in the antenna monitoring system, non sinusoidal current distribution on the towers, and reradiation from objects external to the array. However, the resultants so plotted from a series of talkdowns along a radial will enclose an area in which the optimum adjustment has its vector resultant at its center. Knowing the desired resultant for each critical radial direction, one may then be able to infer a set of phase and ratio parameters to satisfy conditions in all directions simultaneously.

For simple arrays, a pragmatic approach that often yields effective results, is to station observers with



Theoretical Pattern and Parameters

Tower	Bearing	Distance	Field	Phase
1	0°	100°	0.538	-123.6°

field strength meters at each of the several monitoring points or in other critical directions. By using a two-way radio to learn the effect on field strength, cut-and-try adjustments of the phasor can yield a set of phase and ratio parameters that satisfy all conditions simultaneously.

Following readjustment, if any of the new phase and ratio parameters exceed the 3° phase and 5% ratio tolerances permitted by the FCC when applied to the parameters shown on the current station license, a partial proof-of-performance will be required before the FCC will license the new parameters. If the new parameters are within tolerance of the licensed values, a partial proof and application for changed parameters may still be desirable in order to avoid long-term operation uncomfortably close to the tolerance limits.

4.12
FM BROADCAST ANTENNAS

PETER K. ONNIGIAN, P.E.
ERIC DYE

INTRODUCTION

This chapter is for broadcast engineers, technicians and station managers who must make important decisions regarding FM transmitting antennas. To ensure the best possible signal strength in the station's service areas, the site location, antenna height, antenna type and propagation conditions must all be considered.

FM broadcasting was first authorized in the United States in 1940 by the Federal Communications Commission (FCC). The first FM station began operation in 1941. In 1945, the FM service was assigned to the 88 to 108 MHz band and divided into 100 channels, each 200 kHz wide. In 1991, there were over 5,400 commercial and 1,700 educational FM stations.

Most FM antennas are nonsymmetrical, that is they are mounted on one side of a steel supporting tower or pole. FM antennas outside the western hemisphere on the other hand are usually symmetrical, that is installed on all faces of a tower. However, both methods are capable of providing excellent omnidirectional azimuth patterns.

Antennas for FM broadcasting use horizontal polarization (H-pol), vertical polarization (V-pol), or circular polarization (CP).[1] Cross polarization is used as a means to prevent co-channel interference in some European countries but not in the western hemisphere. CP, together with its special form, elliptical polarization (E-pol), was introduced in the United States in the early 1960s as a means to provide greater signal penetration into the many different forms of FM receiving antennas, which are now found in the service area. H-pol is the standard in the United States, CP or E-pol may be used if desired. V-pol only is permitted for noncommercial FM stations seeking to limit interference to TV channel 6.

Between 1980 and 1990 there were over 300 million radios sold in the United States. Over 140 million were automobile AM/FM radios.[2] FM radio receivers use a variety of antennas including extendable monopoles (whips), dipoles and capacitive coupling to power lines and headphone leads.

Antennas for FM broadcasting must be chosen carefully in order to cover the service areas properly with adequate level and quality signals. For economic and technical reasons, the desired effective radiated power (ERP) should be produced with a balance between antenna gain and transmitter power. It is the purpose of this chapter to provide sufficient technical information for the broadcaster to achieve this.

The height of the antenna over the service area, distances to areas of population, the ERP and the economics are items that must be considered.

Antennas currently available in the United States differ considerably from those to be found in Europe. The various American types are discussed so that the engineer will be informed on the subject. Considerable advances have been made in recent years in the design and fabrication of FM antennas. These improvements provide greater penetration of signals into automobile FM radios as well as popular small FM transistor radios of all kinds.[3] The newer FM broadcasting antennas must meet the more stringent requirements for FM stereo and subcarrier broadcasting. Most FM stations in the United States are using CP antennas.

PROPAGATION

FM broadcasting has some distinct advantages over AM (medium wave) broadcast service. These advantages stem from the propagation characteristics of FM frequencies as well as the modulation system.

There is essentially no difference between day and night FM propagation conditions. FM stations have relatively uniform day and night service areas. FM propagation loss includes everything that can happen to the energy radiated from the transmitting antenna during its journey to the receiving antennas. It includes the free space path attenuation of the wave and such factors as refraction, reflection, depolarization, diffraction, absorption, scattering, Fresnel zone clearances, grazing, and Brewster angle problems.

Propagation is dependent upon all these properties out to approximately 40 miles (65 km). Some additional factors enter the picture at greater distances. Radio wave propagation is further complicated because some of these propagation variables are functions of frequency, polarization, or both, and many have location and time variations.

The technical intent of the broadcaster is to put a signal into FM receivers of sufficient strength to overcome noise and to provide at least 20 dB carrier-to-noise ratio, which will provide at least 30 dB of stereo separation. The required RF signal level varies from about 2 μV/m (microvolt per meter) for high sensitivity FM stereo tuners in the suburbs to about 500 μV/m for less sensitive transistorized portables.

Automobile receivers have wide ranged sensitivity values.

FM antenna manufacturers do not guarantee coverage. They supply antennas which meet certain radiation pattern requirements and gain. Many of the antennas assume an omnidirectional pattern. Although reasonable in free space, it is never fully achieved in practice due to sources of distortion (support structure, feed lines, etc.)

Some manufacturers in the United States provide azimuth pattern adjustment service to insure a horizontal plane pattern circularity of ± 3 dB when mounted on the side of a specific tower or pole. It must be pointed out that this radiation pattern and gain are for free-space conditions and may not relate directly to signal strengths measured at or near ground level, well away from the antenna.

Radiation pattern and propagation are two distinctly separate conditions. The pattern is the radiation which is transmitted by a given antenna in any given direction, without any propagation limitations, as measured on a good antenna test range. Propagation depends on path and environmental conditions existing between the transmitting antenna and the receivers.

The actual service area signal strength contours are based upon two probability factors. Contours are not solid signal areas. For example, the FCC signal coverage charts referred to as the F(50/50) curves, are based upon a probability of occurrence of certain voltage levels at 50% of the locations, 50% of the time. This means that at any given location, 30 ft above ground, the signal has a 50% chance to measure up to the predicted contour level. Furthermore, half the time at that location, it may reach or exceed the level predicted while at other times it may be lower in strength.

These FCC charts (FCC Rules, Section 73.333) are based upon the assumption that average propagation conditions exist. One or more of the conditions mentioned in the second paragraph under this heading may reduce the measured signal strength from the predicted values substantially.

Propagation Loss

The power radiated from a FM transmitting station is spread over a relatively large area, somewhat like an outdoor, bare light bulb on top of a tall pole. The power reaching the receiving antenna is a very small percentage of the total radiated power.

At 100 MHz and a distance of 30 miles (48 km) the figures indicate the free-space path loss to be 106 dB.[4] The formula used to compute free-space loss is:

$$FSL = 36.6 + 20 \log D(\text{miles}) + 20 \log F(\text{MHz})$$

Doubling the distance increases the space loss by 6 dB. The path loss does not attenuate the signal with distance as much as some other factors. Path loss between an earth station and a satellite is a classic text book example of a 6 dB loss every time the distance is doubled. But a typical FM station signal travels through a nearly perfect dielectric (air) and over the imperfect earth's surface (ground). Herein lies the FM radio propagation loss problem.

Refraction, diffraction, and reflection from scores of objects such as hills and buildings may occur in the propagation path between the transmitting and the receiving antennas. These, along with absorption, scattering, lack of Fresnel zone clearances, and other factors, all reduce the signal strengths.

Signal loss due to foliage has been well known to UHF TV broadcasters for many years.[5] This same condition exists to a lesser degree for FM broadcasting. Trees, shrubs, and other foliage on hills or smooth terrain affect the reflected as well as the lateral signal loss with distance. With average values of permittivity and conductivity in both foliage and ground, a loss of about 2.5 dB was found to exist in a ten-mile path, at FM frequencies.[6] The height gain factor is increased with heights above the foliage.

Considerable depolarization takes place because the transmission through or reflections from ground foliage is a diffracted field contribution.

Multipath Problems

The ideal reception condition is a strong direct single source signal. When energy from two or more paths reaches the receiver, (due to reflections) a condition called multipath reception occurs. Poor reception is experienced when there is insufficient strength difference between the direct and the reflected signals, because they can cancel each other where the geometry places them out of phase.

Nothing is more important in the way of broadcasting facilities than the location of the transmitting antenna. Great care must be exercised to find a suitable site. Poor selection of the transmitter point can result in unfavorable signal propagation and negate the entire project. One very serious result of poor site selection is multipath propagation in some directions.

As an example, the transmitter should not be located so that strong reflections take place from nearby hills or mountains. This can happen when the transmitter is placed on one side of a large city and the other side of the city has a high mountain range. Radiation into the city directly from the transmitting antenna, as well as reflections from the nearby hills and mountains will create two or more signal paths to many receivers. These reflections can be so strong that only a 10 dB difference may exist between the direct and the reflected condition which causes severe multipath problems.

A TV station at this same location would experience unusable signals due to heavy ghosting, even with directional receiving antennas, which exhibit moderate signal pickup from their back. This is illustrated in Figure 4.12-1 where a mountain range causes reflections back into a large city.

The multipath example shown in the sketch was an actual case. The site was chosen by the FM broadcaster, without proper engineering guidance, simply because the hill had a tower, building, power, and a road was in place. Later, the broadcaster learned why the original

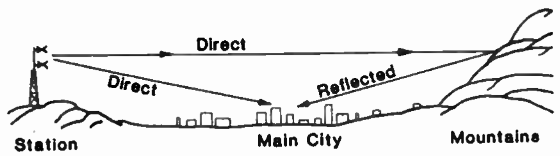

Figure 4.12-1. Example of poor station location causing severe multipath conditions due to delayed reflections from mountains on the right. Not to any scale.

owner, a television station, had abandoned the site: the TV station had failed in part due to extremely heavy ghosting into the principal city.

A much better FM transmitting site was located on the hills between the high mountain range and the city. Using a directional transmitting antenna with very little radiation towards the high mountains, reflections were satisfactorily reduced, and the FM station is now operating successfully.

Multipath reflections are easy to identify. On an automobile radio, the signal will drop out, sometimes abruptly, as the car moves. This effect may be rhythmic with distance while traveling slowly. It is sometimes called picketing as it acts like a picket fence alternately blocking and letting the signal pass. A field strength meter will usually reveal great variations of signal when moving, say, 100 ft (30 m) in a line with the transmitter. Cyclic variations over quite uniformly spaced intervals on the ground as great as 40 dB have been observed by the author.

This variation in signal levels is caused by the reflections adding and subtracting from direct and reflected signals caused by propagation problems existing in the path between transmitter and receiver. It usually has nothing to do with the qualities of the transmitting antenna. It is a function of site selection. This should not be confused with a similar effect observed near the base of the tower supporting a high-gain antenna. Nulls produced by stacking bays for gain are found near the antenna and may be filled-in if needed. (See Beam Tilt and Null Fill in this chapter.)

Ground Reflections

In the elevation plane between transmitter and receiver, nearly all FM signal coverage lies between the horizon and 10° below. Called the *grazing angle*, it lies between the horizontal plane and the earth's surface. Generally the higher the transmitting antenna above the service area, the greater this angle will be.

The angle of incidence and reflection are not the same, as shown in Figure 4.12-2. The depression angle and the grazing angle are not equal as would be the case for a flat earth. Reflections from these angles play an important part in the strength and the quality of the signal in FM broadcasting with circular polarization.

The ground, which causes reflections at these grazing angles does not treat H-pol and V-pol in the same manner. The V-pol is attenuated considerably more than the H-pol as shown in Figure 4.12-3. The phase of the V-pol changes substantially with angle, while H-pol remains nearly the same. At these useful low

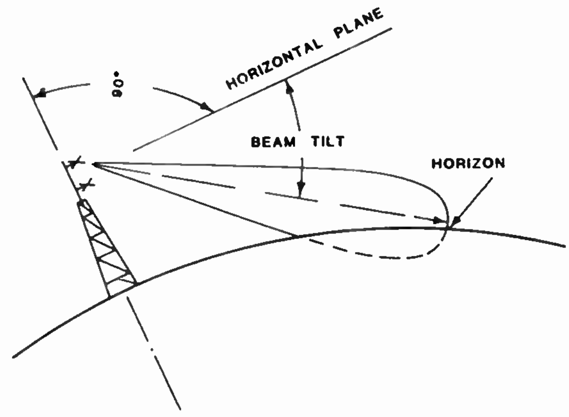

Figure 4.12-2. Beam tilt to radiate maximum ERP at the horizon. Not to any scale and exaggerated for illustration.

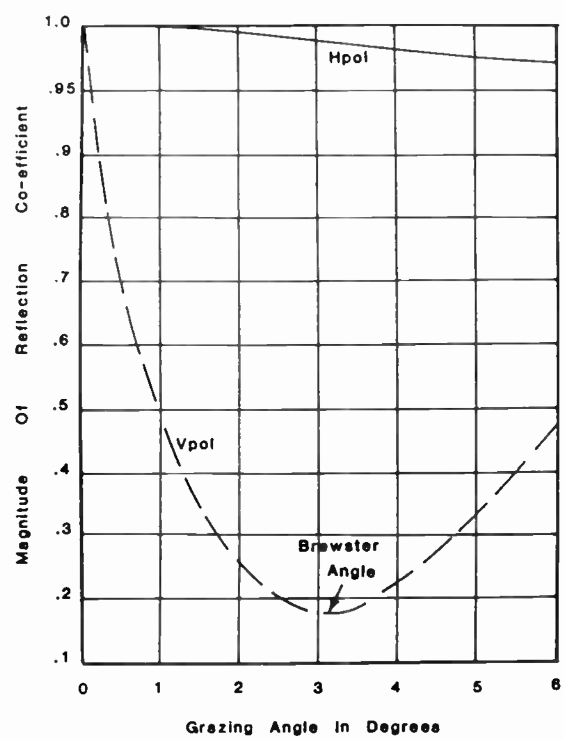

Figure 4.12-3. Magnitude of reflection coefficients showing differences for H-pol and V-pol, and the Brewster angle.

propagation angles, there is considerably less V-pol signal reflected than H-pol, when grazing takes place. Field measurements confirm this fact.[7] For this reason, it is impossible to measure accurately axial ratios in the service area. To be meaningful, the H-pol and V-pol ratios must be measured on a good antenna test range.

It is quite difficult to predict accurately the reflection coefficient (efficiency), which varies considerably as a function of polarization, frequency, grazing angle, surface roughness, soil type, moisture content, vegetation growth, weather and the season. There are complex formulas for predicting the ground conductivity at the frequency of interest. For 100 MHz, a value of 10 millimhos per meter ground conductivity is often used, with a permittivity of 25, as being about the average for the continental United States.[6]

Brewster Angle

For polarization with the electric field normal to the plane of incidence, there is no angle that will yield an equality of impedances for earth materials with different dielectric constants but like permeabilities. An incident wave with both polarizations present will have some of the one polarization component but little of the other reflected. The reflected wave at this angle is thus plane polarized with the electric field normal to the plane of incidence, and the angle is the polarizing angle.

Notice that in Figure 4.12-3 the minimum reflection coefficient occurs at a grazing angle of about 2°. Below this angle, the reflection coefficient rapidly increases to unity. The angle at which the minimum reflection coefficient occurs is called the ***Brewster*** or *polarizing angle,* after the Englishman who first discovered this phenomenon.

For ground reflections occurring near the Brewster angle, the reflection coefficient is much smaller for V-pol than the H-pol. Therefore, the reflected V-pol signal component of CP are attenuated considerably. The greatest attenuation for V-pol from ground reflection occurs at this angle.

Field measurement of V-pol signals will usually show a significant variability of H-pol to V-pol ratios due to this Brewster angle phenomenon. The Brewster angle is a function of soil conductivity and may change from place to place, as well as from season to season.[8]

It is important, then, that the antenna height above the service area results in grazing angles which are less than the Brewster angle. Otherwise the V-pol will be reduced and the radiation will be much more elliptical than circular in polarization.

Fresnel Zone Clearance

A much neglected consideration in FM transmitting antenna location and height is *Fresnel zone* radius clearance in the path to the service area. Microwave engineers always make certain that their signal paths have this important clearance.

The effect of clearance above ground or other obstacles was studied by August Jean Fresnel, a French scientist who first discovered this phenomenon in optics. Fresnel zones are circular areas surrounding the direct line-of-sight path of a radius such that the difference between the direct and the indirect path length to the zone perimeter is a multiple of half-wavelength longer than the direct path. This is illustrated in Figure 4.12-4. The zone diameter varies with frequency and path length. The greater the path length, the larger the required mid-path clearance required for full signal.

Fresnel also discovered that the entire first zone

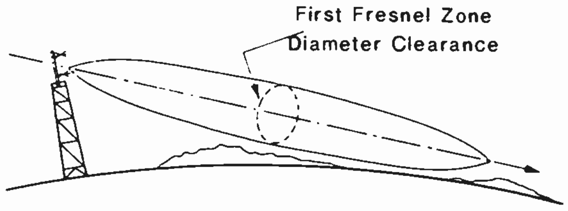

Figure 4.12-4. First Fresnel zone clearance occurs as shown above, but only six-tenths is required for full free space signal level. Not to any scale.

radius is not required for full signal strength. Six-tenths of the first zone would suffice, which is fortunate since the radius is quite large at the FM frequencies. The equation for determining the first Fresnel zone radius for 4/3rd earth curvature is:

$$R = 1140\sqrt{d/f}$$

where d is the path length in miles, f is in MHz and R is in feet for the first radius.

In Table 4.12-1 the required 0.6 first Fresnel zone radii clearances at the middle of the path are shown for 98 MHz and service areas up to 52 miles (92 km) from the transmitter. The idea is to raise the height of the transmitting antenna so that the mid-path height is as high as or higher than shown in the table. Due to the geometry of the Fresnel zone, if the terrain is relatively flat, the mid-path radius will control and be larger than that required elsewhere along the path. If the mid-path clearance is less than the values shown, the FM signal will be attenuated in accordance with the curve shown in Figure 4.12-5, presuming ideal reflection off the ground or obstructions.

The center-of-radiation heights of the antennas in Table 4.12-1 are actual and not height above average terrain (HAAT). Some of these recommended heights will reduce the allowable ERP in accordance with FCC 73.211 (b), depending on the class of station and the zone. However, it is better to have the Fresnel clearance than the maximum low height ERP values, as the higher heights will produce stronger signals.

It is a well known propagation axiom that greater heights are more useful in producing higher signal strengths far from the antenna than ERP levels, everything else being equal.

Without the first Fresnel clearance of 60% the signal level at the distant point may suffer. This reduction will follow the curve shown in Figure 4.12-5 for different values of clearance and worst case reflection conditions.

In order for the FCC prediction curves to be valid, the recommended minimum antenna heights should be achieved. These heights not only provide line-of-sight conditions to the service limits but also proper Fresnel clearances. Both conditions are required for the FCC F(50,50) curves to be valid.

The values in Table 4.12-1 are for relatively flat

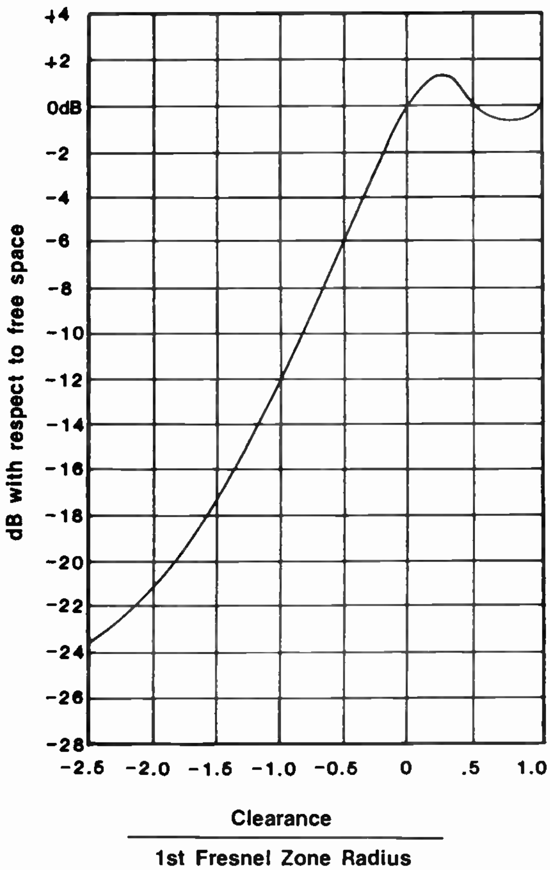

Figure 4.12-5. Attenuation of FM propagation when the path between transmitter and receiver lacks Fresnel zone clearance in the ratios shown.

terrain, but take into consideration the FCC suggested roughness factor of up to ±150 ft (50 m). Where the tower height is limited by HAAT values or other limitations, the signal strength will suffer due to those factors.

Soil Conductivity

The conductivity and permittivity of the soil, together with the vegetation on it, play a small part in the attenuation of FM signal strength. Average soil has a dielectric constant of about 15 millisiemens per meter at 100 MHz.[9]

Linear Height Gain Effect

By raising the receiving antenna above the immediate effects of the soil, the signal level will be increased. Actual field measurements have proven a 9 dB increase in signal when the dipole was raised from 3.28 ft (1 m) to a level of 30 ft (9.1 m). This is due to reflection phenomena in the foreground of the receiver, not ground conductivity.

FCC Service Contours

From the FCC coverage prediction charts, it is possible to draw contours of the various grades of service for a given ERP and antenna height above average terrain. These predictions, at 50% of the locations, 50% of the time, constitute the basis for the service contours. The city grade contour is 70 dBμ (3.16 millivolts per meter) and primary service contour is 60 dBμ (1.0 millivolts per meter).

The FCC Rules, Section 73.333 charts for these predictions have a built-in terrain roughness factor, as explained above.

GENERAL COVERAGE STANDARDS

There are certain height and power levels fixed by the FCC for various classes of stations. The United States has been divided into three different geographical areas based on population density as well as propagation refractive index levels. These ERP and height values have been set to prevent co-channel and adjacent channel interference.

Zone I, generally speaking, is the northeastern part of the United States. Zone I-A includes Puerto Rico,

Table 4.12-1

Virgin Islands, and that portion of California lying below the 40th parallel. Zone II includes Alaska, Hawaii, and the remainder of the United States not in the above two zones. This is more fully described in FCC Rules Section 73.205.

Under the FCC Rules which resulted from Docket 80–90: *Modification of FM Broadcast Station Rules to Increase the Availability of Commercial FM Broadcast Assignments*, in 1983, new ERP levels and additional classes of stations were created. The distance to the 60 dBu (1 mV/m) signal contour is the controlling factor so that the ERP based on the HAAT is adjusted to produce that level and no more at a specific distance for a particular class station.

Table 4.12-2 shows for each FM class station, the zone, the maximum ERP, the maximum HAAT, and the distance to the 60 dBu contour calculated by using the maximum ERP and HAAT, and then rounding to the nearest kilometer and mile.

Under the Rules, Class C stations are required to have at least 100 kW ERP and an antenna height of more than 984 ft (300 m) above average terrain. Class C-1 stations are now permitted a maximum of 100 kW ERP with an antenna maximum HAAT of 984 (300 m), while C-2 stations may go to 50 kW at a maximum HAAT of 492 ft (150 m). Higher HAAT may be used with reduced ERP values, in accordance with equivalent 60 dBu coverage. Class C and C-1 stations may thus share the same antenna and tower.

Stations may be upgraded using the easiest method, which is to increase existing location tower height. Such factors as local zoning laws and aircraft flight patterns may preclude this approach, however.

FM Signal Measurements

The signal strength received at 5 ft (1.5 m) above ground, which is about average for auto whip antennas, is several times lower in level than at the standard FCC measurement height of 30 ft (9.1 m). This fact should be taken into consideration when comparing low height measurements with the FCC Rules Section 73.333 prediction charts, which are based on a 30 ft receiving height, where signals are considerably stronger.[10]

Signal levels inside houses, apartments, offices, and other structures vary greatly. Levels depend on the type of building construction, but in nearly all cases will be lower than those outdoors. Reflections inside the building reduce stereo separation, and cause cross-talk problems with SCA channels. Outside FM receiving antennas generally provide good reception.

Field strength measurements should not be used to determine the transmitting antenna radiation pattern or efficiency except under carefully controlled conditions. The propagation factors discussed previously camouflage the true antenna performance. The only technically acceptable way to determine the antenna's characteristics is on an antenna test range.

See Chapter 4.15, *AM and FM Field Strength Measurements* for more information. This information may be used to determine the actual quality of service and the areas where useable signal levels in fact exist. Predicted contours may be considerably different from actual measured values.

Required Signal Strength

What is the minimum satisfactory signal strength? What is the maximum above which it is wasteful? The history of FCC proceedings provides some of the following levels:

34 dBu = 0.05 mV/m For rural areas
60 dBu = 1.00 mV/m Suburban areas
70 dBu = 3.16 mV/m Principal community
82 dBu = 12.64 mV/m Highest useful level

The first three levels were set by the FCC in the early 1950s when tube receivers and H-pol antennas were popular. Modern day transistor radios have much greater sensitivity. CP has added greater signal penetrating power than H-pol when the levels were first established.

The FCC defines two grades of signal contours on its applications. The first is based on the 70 dBu contour (3.16 mV/m) required to cover the principal community of license. The second is the 60 dBu contour (1 mV/m) which defines the primary service area.

The FCC also stated that, in rural areas, levels as low as 50 μV/m were useful. Indeed current home stereo tuners and FM auto radios operate very well with only 25 μV/m. In practice, 50 mV/m (0.05 mV/m) provides good quieting in nearly all automobile and transistor radios receiving a stereo signal from a CP station antenna. Therefore 50 mV/m should be considered the minimum useful signal level.

If the highest level of 3.16 mV/m is quadrupled, it will be 12.64 mV/m. This is a 12 dB increase, equal to increasing the FCC power level by more than 15 times. It can be safely said that this level of 12.64 mV/m is considerably more signal than necessary by any present day working FM radio. Any signal level higher than this at the receiving antenna has not proven to be of significant value.

Blanketing

Excessive RF signals can overload the front end of receivers and make satisfactory reception impossible. The FCC in Section 73.318 defines the 115 dBu (562 mV/m) level as the *blanketing contour*, and adopted the free-space prediction method to predict how far this contour extends.

New or modified FM stations have the responsibility to satisfy all complaints at no cost to the complainant, of blanketing-related interference inside this contour within one year of commencement of operations.

The distance to the 115 dBu contour is determined using the following equation:

$$\text{d (in kilometers)} = 0.394\sqrt{P}$$
$$\text{D (in miles)} = 0.245\sqrt{P}$$

where P is the maximum ERP, measured in kilowatts of the maximum radiated lobe, irrespective of vertical directivity. For directional antennas, the horizontal directivity shall be used.

ANTENNA CHARACTERISTICS

Antenna gain can be increased by adding additional radiating elements (bays) to the antenna at the cost of narrowing the radiated beam. High-gain antennas concentrate the energy into such a narrow beam that often null fill must be employed to achieve the desired signal strength within the first few miles to the tower.

Directional antennas achieve increased gain over nondirectional antennas by limiting the radiated energy in various directions. Directional antennas are useful when the tower is located near a large body of water, mountain range, or other areas where energy radiated in those directions is otherwise wasted. They are also employed to avoid interference where stations are insufficient distances apart.

Antenna gain is expressed in power ratio or in dB. For example, an antenna with a power gain of 2 is also said to have a gain of 3.0 dB.

FCC Rules, Section 73.310(a) defines antenna gain as the inverse of the square of the root mean square value of the free-space field strength produced at one mile in the horizontal plane, in millivolts per meter for 1 kW antenna input power to 137.6 mV/m. (In metric units, 1 km and 221.4 mV/m).

Notice that this gain is in reference to a horizontally polarized half-wave dipole. For a CP antenna, the gain is half for the same input power.

A two-bay H-pol antenna has a power gain of approximately two. But a two-bay CP antenna in FCC terminology has a gain of about one because the other half of the power is V-pol and is not considered in the gain calculations. Only the horizontal polarization mode is used by the Commission. The vertically polarized energy must not exceed the H-pol (except for noncommercial, educational FM facilities attempting to minimize interference to TV channel 6 reception).

The power gain of an antenna is used with the transmitter gain and transmission line loss when determining the ERP. Consider for example a 10 kW transmitter and an antenna power gain of 5. Neglecting transmission line loss, the ERP is 10 kW × 5 = 50 kW ERP. If the antenna gain were 10 and the transmitter power was 5 kW, we would have the same ERP of 50 kW. (5 kW × 10 = 50 kW ERP)

The FCC defines EPR to mean the product of the antenna input power (transmitter output power less transmission line loss) times the antenna power gain. Where circular polarization is used, the term ERP is applied separately to the H-pol and V-pol of radiation. For allocation purposes, the ERP is the H-pol component of radiation only. The V-pol component power normally must not exceed the H-pol power.

Beam Tilt

FM broadcasting antennas are normally mounted on towers which are plumb, so the peak power beam in the elevation pattern is perpendicular to the tower axis. A standard FM antenna without any beam tilt radiates more than one half of the total radiated power above the horizon. All this power is lost.

The higher the antenna is above its average terrain, the larger the predicted coverage area. Since the earth is curved, the service horizon is bent lower than a perpendicular angle from the earth's surface. Thus the strongest portion of the signal is aimed above the horizon. It also follows that the higher the antenna above the terrain, the greater the elevation angle down to the earth's horizon.

In order to strike the farthest service area from a high HAAT, the beam may need to be tilted down towards the earth. Electrical beam tilt lowers the beam angle equally in all azimuth headings and is chosen more frequently than mechanical tilting, which exhibits different effects in different directions. Choose enough tilt to position the center of the main beam on the furthest edge of the desired coverage area or just below the horizon, whichever is closer.

For low gain antennas (two to four bays), the main beam is very broad, and if the antenna HAAT is less than 500 ft there is little to be gained with beam tilt. On the other hand, beam tilt makes a large difference on high-gain antennas mounted on towers with a high HAAT.

Figure 4.12-6 shows the comparison between elevation angle path and coverage distance. It incorporates the curvature of the earth. This chart can be used to determine the optimum beam tilt. Follow the curve which is closest to actual HAAT, and mark the point where it intersects the horizon or crosses the distance of furthest desired coverage area (vertical axis). Read the beam tilt on the horizontal axis. Round this value up to the nearest ¼°.

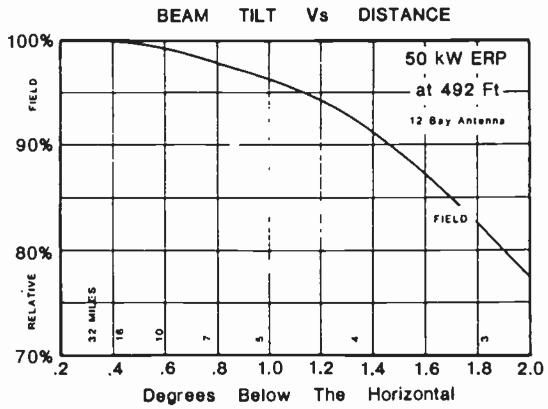

Figure 4.12-6. Twelve bay Cpol antenna with 0.3° beam tilt showing ERP distribution with coverage from 492 foot (150 m) tower over flat land. Degrees below the horizon are based on 4/3rd earths curvature. Horizon is −0.341° at 32 miles (52 km).

Consulting engineers, familiar with this problem, can easily work out the required amount of beam tilt, if it is necessary. Typical values are one-half to one degree of tilt, depending on the antenna height, distance to the far service area, and the antenna elevation pattern.

Beam tilt is usually accomplished electrically, by delaying the currents to the lower bays, and advancing the phase of the upper bay currents during the design and construction of the antenna at the factory.

Null Fill

While the beam tilt puts more signal into the far reaches of the service area, it does not solve the problem sometimes caused by high-gain antennas within several miles of the transmitter. Elevation angle nulls common to all antennas with two or more bays appear farther and farther away from the antenna as its gain is increased with more bays.

When multiple bay arrays are employed, lobes and nulls occur in the elevation pattern. As the number of bays increases, the main beam narrows and the first null radius increases. The advantage of beam tilt and null fill varies depending on factors such as tower height, site elevation, number of bays, and relative locations of communities to be served.

A simple rule-of-thumb is that null fill is beneficial when there is desired service area within the radius of the first null. The equation below gives the approximate radius of the first null for multiple bay antennas.

$$\text{Null Radius (miles)} \cong \frac{H_{(ft)}}{\text{Number of Bays}/5280\ \text{ft/mi}}$$

where H is the height (ft) of antenna above radius ring.

In most FM applications, the null is very close to the antenna, thus a small amount of null fill (5–10%) takes care of the problem. Larger amounts of null fill are unnecessary and reduce the gain of the antenna. Note that null fill has no effect on distant coverage.

VSWR Bandwidth

According to theory, the bandwidth of an FM signal is infinite if all the sidebands are taken into account. Also, at certain modulation indices, the carrier amplitude goes to zero and all the transmitted power is on frequencies (sidebands) other than the carrier frequency. Practical considerations in the transmitter and receiver circuitry make it necessary to restrict the RF bandwidth to less than infinity.

Prior to 1984 the maximum deviation for FM stations was 75 kHz, representing 100% modulation. In that year the FCC changed the maximum deviation to 82.5 kHz (110%) for those stations with 10% injection of subcarrier channels. This additional deviation requires greater antenna system bandwidth than previously needed.

System bandwidth is measured at the point in the antenna system where the transmitter is connected. This usually includes the harmonic filter, the main coaxial transmission line, and the antenna.

The significant sidebands are usually considered to be those whose amplitude exceeds one percent of the unmodulated carrier. With 110% modulation (82.5 kHz deviation) these side bands produce a bandwidth of 260 kHz.[11,12]

The VSWR bandwidth is the range over which the system under consideration has a reflection coefficient of less than five percent; a VSWR of 1.1:1.

Checking System VSWR

From time to time, the VSWR of the narrow-band antenna system should be checked and adjusted. If the exciter has thumb wheel exciter frequency adjustability in 10 kHz or 50 kHz steps, it can be used to change the frequency to check VSWR on different frequencies (with the transmitter operating at low power during the overnight experimental period). The reflectometer may be used as the indicator.

Alternately one of several methods for checking VSWR in coaxial line systems using test equipment may be used. These include a signal generator test setup, an impedance test set, or a network analyzer.

The VSWR should be measured to ensure that the reflection response is balanced to 130 kHz on each side of the carrier frequency. With transmission lines longer than 300 ft (100 m) it is suggested that the VSWR bandwidth be under 1.08:1 all the way out to ±130 kHz. The additional delay due to increasing line length becomes more of a problem, so the amplitude of the reflection must be reduced, for best operational results.

Importance of Low VSWR

The VSWR shown by the transmitter reflectometer does not increase or decrease the range of the signal. It has nothing to do with coverage. But VSWR values above 1.1:1 may decrease the final amplifier efficiency. Other definite negative effects of VSWR are increased intermodulation products and AM synchronous noise. Stereo separation is also degraded with increased VSWR.[13]

Intermodulation and SAM Distortion

Intermodulation distortion and synchronous AM (SAM) noise can be caused by narrow VSWR bandwidth in the antenna system, as well as by final amplifier circuitry all the way to and including the antenna.[14]

SAM is extremely important in FM transmitter facilities employing subcarriers. SAM is AM modulation of the carrier caused by frequency modulation of the carrier frequency in the VSWR notch. At the notch the reflected energy is the lowest. As the deviation takes place, the greater the frequency swing, the greater will be the reflections, due to the VSWR notch. With a flat VSWR curve, SAM does not take place. If the VSWR curve is skewed, SAM will occur and intermod and stereo crosstalk will increase.

Directional Antennas

The FCC sometimes requires that the azimuth radiation pattern be directionalized to reduce normally allocated ERP towards a given short-spaced station, or for other reasons. (See the FCC Rules Section 73.213, 215, and 316(b) and (c).) To conform to these specifications, most broadcasters order antennas which are pattern adjusted, measured, and certified to the Commission's requirements.

Directional antennas are licensed for peak ERP values based on the azimuth pattern. The V-pol gain may not exceed the H-pol gain in a CP directional array nor may V-pol exceed the H-pol in the protection direction (except in the case of FM protection to TV Channel 6, mentioned elsewhere). The amplitude away from the null cannot climb more than 2 dB per 10° of azimuth.

Directional antennas are usually mounted on poles although some have been tower mounted. Since the support affects the pattern, they are specified and measured with the pole or tower on which they are mounted. Most firms will make the antenna meet the specific pattern requirements.

Directionalizing is a combination of the natural pattern resulting from sidemounting and the use of parasitic elements. Using the two factors, virtually any directional pattern can be produced.

Antenna gain is calculated differently for directional antennas. The azimuth directivity increases the gain value to correspond to the pattern. If all elements/bays are the same (the typical case), pattern multiplication can be used to determine gain. For linearly polarized antennas, the gain is simply the product of the azimuth directivity, the array factor, and the efficiency factor. The array factor is referenced to an ideal dipole. For directional CP antennas, the power distribution between polarizations must be taken into account.

Antenna Gain (H-pol)

$$= g_H \times \text{array factor} \times \text{efficiency}$$

$$\text{V-pol} = g_V \times \text{array factor} \times \text{efficiency}$$

$$\text{where: } g_H = \frac{D_H \times D_V \times GA}{D_H + D_V \times GA}$$

$$g_V = g_H / GA$$

D_H and D_V are the directivities of the H-pol and V-pol azimuth patterns, while GA is the gain if the H-pol over the V-pol pattern.

Due to the gain of its azimuth patterns, directional antennas have gains which are typically 2 dB to 6 dB higher than their nondirectional counterparts of equal number of bays.

ANTENNA POLARIZATION

Radio waves are composed of electric and magnetic fields at right angles to each other and to the direction of propagation. When the electric component (E) is horizontal, the wave is said to be horizontally polarized, as shown in Figures 4.12-7(b) and 4.12-7(d). Such a wave is radiated from a horizontal dipole. References are with respect to the earth plane. If the desired electric component is vertical as in Figures 4.12-7(a) and 4.12-7(e), a vertical dipole could be used to produce the vertically polarized wave.

Circular Polarization

When the two plane waves are equal in magnitude, and if one plane wave lags or leads the other by 90 electrical degrees, the field will rotate as shown in Figure 4.12-7, at the speed of the carrier frequency and will be polarized circularly.

Only in the special case where the horizontal and vertical components are equal in strength with a 90° phase difference is the radiation said to be CP.

The direction of rotation shown by the vector arrows in Figure 4.12-7 depends on the relative phase of the two components. Thus the polarization of the wave will appear to have either clockwise or counter-clockwise rotation, as shown. The FCC has set clockwise rotation as the technical standard, in order that similar sense of rotation antennas may be used for reception in the future.

Notice that in Figure 4.12-7 the polarization rotates as the field propagates in time and space. Importantly, vertical and horizontal components are in quadrature phase. It is this rotation which enhances the signal penetrating qualities of CP, so useful in FM broadcasting.

The axial ratio as shown in Figure 4.12-8 is that between the maximum and minimum voltage component at any orientation of the reference measuring test

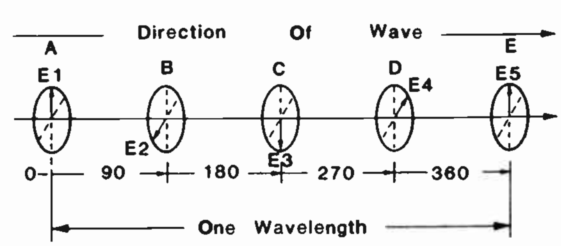

Figure 4.12-7. Circularly polarized wave propagation in one wavelength of travel, showing right hand rotation. Note vector rotation with wave travel.

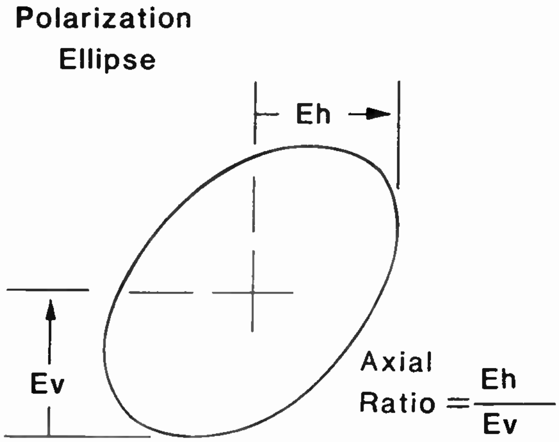

Figure 4.12-8. Axial ratio expressed in dB is the ratio of the larger polarized component divided by the smaller at any reference dipole orientation, where the maximum ratio occurs.

dipole which is placed perpendicular to the direction of propagation. An axial ratio of 1:1 (0 dB) is perfect. In practice, axial ratios of 2 dB or better are considered to be excellent and commercially available. Axial ratios over 4.9 dB (1.75 to 1 voltage ratio) are considered to be elliptically polarized, a hybrid form and not as good in signal penetrating qualities as CP.

Since receiving antennas are linearly polarized, the introduction of CP does not increase the net power received since the vertical and horizontal components never occur during the same instant. Thus, CP does not necessarily mean an increase in coverage. However, the introduction of CP eliminates the requirement of the receiving antenna to have a specific polarization. Thus, CP allows more consistent coverage within the contour. Its rotating vector can penetrate areas where linear polarization is stopped, shadowed, or canceled due to out-of-phase reflections.

MATCHING COVERAGE AND ANTENNAS

Table 4.12-3 shows the FCC predicted signal strengths for a typical Class A facility on a relatively flat plane, with the antenna center 328 ft (100 m) HAAT. A power of 3 kW is used. The first two columns show the distances, with the farthest being the horizon from this height. The third column indicates the true earth angle from the antenna to the distances shown. From the elevation information the ERP from each antenna was determined at each vertical angle. This ERP value was used to find the signal strength from the FCC F(50,50) FM prediction chart, FCC Rules Section 73.333, Figure 1.

Under the signal level in millivolts-per-meter (mV/m) column, the predicted field strengths shown in this Table are based on the above procedure. From 5 miles (8 km) to the horizon, the signal strengths are identical. This is due to the shape of the antenna elevation pattern near the maximum.

Departure occurs as the depression angle to the receiver becomes larger. Beyond 4 miles (6.4 km), the one-bay antenna and the six-bay antenna produce nearly the same signal level.

Going towards the transmitter from 4 miles (6.4 km), the field increases in favor of the one-bay antenna. In this example, the table clearly indicates that the high-power transmitter low-gain antenna does not improve the signal strength available to the receivers beyond about 4.5 miles (7.25 km). The signal level starts to increase between 4 miles and 5 miles (6.4 and 8 km). Any increase above this level is useless because full limiting has certainly taken place in even

the poorest FM receiver. (See Required Signal Strength in this chapter.)

In Table 4.12-3 the same signal strength of (16 mV/m) at 5 miles (8 km) comes from either transmitter-antenna combination. This is due to the fact that the ERP power at the vertical angle of −0.74° is about the same from both antennas. The ERP at 0.0° elevation pattern will of course be exactly the same for both combinations. The field does not change measurably until observation is made beyond 1.5° from the peak 100% value in a six-bay antenna.

The signal strengths in this table were based on relatively flat terrain for an antenna 328 ft (100 m) HAAT. The true earth curvature distance to the horizon is 25.56 miles (41.23 km). Therefore the outer reaches of useful signal drop off very rapidly beyond this point in the typical Class A station.

There are no nulls in a one-bay antenna pattern. In a six-bay antenna the first null occurs at about −10°, approximately 0.37 miles (0.6 km) from the tower. Antenna arrays are never perfect so the null is never zero power. With a minimum radiation of 5 W in the first null, the predicted signal would be 31 mV/m. The second null is closer to the tower and with the same 5 W ERP would be even stronger in this example. So in practice there may be no need to fill in the nulls of the six-bay antenna.

Another consideration is that the nulls may fall very close to the tower and the number of people occupying the null areas may be small. Thus problems resulting from these close-in nulls would be minor.

Typical Class B and C-2 Station Coverage

The same comparisons of transmitter-antenna combinations can be made for Class B and the new Class C-2 stations, operating with a HAAT of 492 ft (150 m) with 50 kW ERP. This is shown in Table 4.12-4. A 55 kW transmitter with a 2-bay CP antenna would provide the 50 kW ERP, with high efficiency coaxial lines. It is compared with a 10 kW transmitter feeding a 10-bay CP antenna. The terrain flatness is assumed not to exceed ±150 ft (50 m).

Table 4.12-4 indicates that the signal levels are the same from 4.6 miles (7.4 km) out to 35 miles (56 km) under similar columns as for the Class A station comparisons. The FCC uses a receiving height of 30 ft (10 m) so the horizon is a bit further away, at 31.3 miles (50.5 km).

From the transmitter out to about 2 miles (3.2 km), the signal rises much more rapidly in the 2-bay antenna than in the 10-bay, the latter being somewhat similar to a cosecant curve. There is surplus signal close in and more than is needed or can be tolerated.

Therein lies one of several problems with high transmitter power and low-gain antennas as seen in Table 4.12-4. With the 2-bay antenna there is 900 mV/m at one mile (1.6 km) and 562 mV/m as far out as 1.55 miles (2.5 km). This is above, or at, the blanketing level of 562 m/Vm. (See Blanketing in this chapter.) The high-gain antenna does not cause this type of problem under identical conditions.

The signals from both combinations are much more than necessary for present day FM receivers out to about 10 miles (16 km). There is no practical difference technically in useable signal strengths presented to receivers in the entire market area, from either antenna. There is, however, a great deal of savings in capital costs as well as operating expenses between the two combinations.

One antenna factor is not clearly indicated in Table 4.12-4. The two antennas have elevation pattern nulls. The 2-bay antenna null at −30° falls 852 ft (260 m) from the base of the tower and can be disregarded. The ten-bay antenna nulls can be filled to as little as 2½% field, which will not affect its gain. This would represent a minimum ERP at the nulls of 31 W. Although seemingly very small, it is very effective as shown in Table 4.12-5.

It is obvious that the 10-bay antenna nulls can easily

Third	−17.25°	31 w	1,512 Ft	109 mV/m

be filled to produce signal levels in excess of those required. If the transmitter is located in a populated area, these high levels prevent the loss of stereo separation and noise in the SCA (if there are reflections from high level lobes in the built up areas). This problem is common to TV transmitters which produce ghosts from high signal level lobe areas reflecting into null areas. This problem is greatly and satisfactorily reduced with null fill as shown in Table 4.12-5.

MATCHING TRANSMITTER POWER AND ANTENNAS

Several available combinations of antenna gain and transmitter power will provide the necessary ERP. But which combination is the best? The choice is further complicated by the nature of the terrain in the service area. Is it all flat, some rolling hills, mountainous or a large valley? What are the regulatory limitations on the antenna supporting tower height?

Important considerations when choosing the transmitter power and the gain combination to produce a given ERP are as follows:

- Transmitter
- Feed system
- Antenna
- Final amplifier
- Tower
- ac power consumption

The transmitter, antenna, tower, and coaxial feed line are one-time capital costs for the station. Tube costs and commercial power use, however, are a continuing hour-by-hour cost factor. From the above it is apparent that a low-power transmitter is much more economical than a high-power transmitter. But is there a difference in signal strength?

The ERP is the product of the antenna power gain and the antenna input power. Many different combinations of power gain and input power will yield the same ERP. The azimuth pattern will be quite similar for many different antenna power gains.

The only difference in various combinations is the elevation pattern. As discussed previously, there is no momentous or important difference in serving listeners from very different transmitter/antenna ratios.

The signal strength at any given location is a direct function of the ERP from the antenna elevation pattern angle to that location, the height of the antenna, and the propagation path. The ERP at the pertinent angle is the product of the elevation pattern relative amplitude at that angle squared, times the maximum ERP. In practice there is no significant difference between a 3 kW ERP Class A station using a 7.5 kW transmitter and a 1-bay CP antenna, or, one using a 1 kW transmitter and a 6-bay CP antenna, all other factors being equal.

Normally, all the power radiated above the antenna elevation pattern to the horizon is wasted. It is the radiated power below the angle to the horizon that strikes the earth with all its FM receivers. Therefore only the radiated power towards the earth should be considered useful.

The ideal antenna system would put the same signal level from the base of the tower all the way out to the horizon. This requires an antenna whose elevation pattern is a cosecant curve, the normalized reciprocal of sine. It would be the most efficient antenna elevation pattern. Although this curve is impossible to achieve, it is approached as the antenna gain becomes greater.

ANTENNA SITE SELECTION

The transmitter location must be carefully chosen. Site economics should be secondary to the technical advantages of a particular site. Fresnel zone clearances and other factors outlined in this chapter should be considered. A site with an operating FM or VHF TV station makes an excellent source of signals to check propagation for a new station. If the existing station is FM, make certain that its antenna pattern has been optimized to provide as much circularity as possible.

A good field strength meter should be used to measure the actual signal from the existing station. Relative readings are important, not the absolute. Check for reflections as well as level changes within a short walking area of about 100 ft (30 m). Check for stereo separation. Using this information, the operation of a new station near the one being checked can be compared before moving or submitting the FCC application. The consulting engineer may find it useful to consider this information to evaluate the suitability of the new site.

High-Gain Antenna Contradictions

The many advantages of high-gain, low-power transmitter combinations to produce the ERP have been shown. Their superiority in relatively flat land applications cannot be disputed.

There is, however, the matter of unusual height over average terrain to be considered. As examples, if the transmitter is located on Mt. Wilson, in California, on a very tall building in Chicago, or New York, the elevation pattern problem can become serious. This is true particularly when there are listeners near the sites as is the case for these three locations.

Mt. Wilson which serves the greater Los Angeles metropolitan area is more than 1 mile (1.6 km) above most of its listeners. In fact coverage is required from 11 miles (17.75 km) out to the horizon which is −0.57° at 105 miles (168 km). Pasadena, the nearest city, is 13° below the horizon. A high gain antenna tilted down

0.5° would serve the far reaches well, but would not lay down a moderate signal at −13°.

Section 73.211 of the FCC's Rules limits the ERP for overheight antennas such as those on Mt. Wilson with 2,900 ft (884 m) HAAT. New stations using that height must reduce ERP in accordance with the equivalence calculation, so that the predicted signal at the 1 mV/m contour does not extend beyond 32 miles (52 km) for Class B stations.

In these situations a moderate gain antenna should be considered. From Mt. Wilson several existing four and 5-bay antennas now provide excellent service.

TV CHANNEL 6/FM ANTENNA PROBLEM

Television Channel 6 occupies the band from 82 MHz to 88 MHz. The FM broadcast band extends from 88 MHz to 108 MHz. Noncommercial educational FM stations are assigned from 88 MHz to 92 MHz. Interference can exist between the two, with the TV station viewers receiving interference from the FM stations. The FM receiver is relatively selective with a response to about 200 kHz, but the TV receiver has a bandwidth of at least 6 MHz. However, more than TV receiver selectivity is involved in this interference problem. (See FCC Rules Section 73.525.)

Three principal techniques can be employed to minimize Channel 6 interference from FM stations: (1) collocation, (2) where collocation is not feasible, location of the FM station in an area of low population density, and (3) antenna cross polarization.

Co-location

The purpose of co-location (that is, placing the FM transmitter at the Channel 6 transmitter site) is to achieve the same propagation path for both TV and FM stations, thus maintaining a nearly constant desired-to-undesired signal ratio in the service area. If possible, both antennas should be mounted on the same tower. If not, a maximum separation of 0.25 miles (400 m) between the two is still considered as co-location.

The horizontal and vertical plane radiation patterns of both antennas should be similar because the objective is to maintain a near constant desired-to-undesired signal ratio. The HAAT should be similar, thus the desirability of collocating on the same tower. The maximum ERP of the FM stations operating on this basis is in Section 73.525(d) of the FCC Rules.

Alternate Locations

The FM station may not be intended to serve the same community as the TV station, or collation may not be possible. In this event, the FM broadcaster should locate in an area of relatively low population density by imposing a limit on the population which may be included within that area where a particular undesired-to-desired protection ratio is exceeded.

Two ratios were proposed by a committee which studied this problem in 1983.[15] Their recommendation varied according to the educational station frequency separation from the channel 6 aural frequency of 87.75 MHz. In any event, the interference area should not have more than 3,000 people living in it. (See FCC Rules Section 73.525(c) and (e).)

Cross Polarization

Several organizations have made discrimination tests in the United States and in Europe with cross-polarized antennas. It has thus been well established that discrimination of 16 dB is to be expected in rural areas and 10 dB in urban areas between two stations one using the V-pol and the other using H-pol, and the receiving antenna being similarly polarized. This is sufficient in most cases to resolve the FM-Channel 6 problem.

While technically, cross polarization will help solve the problem, the Commissions Rules do not require it. This is left as an option for the FM applicant to use. Most TV channel 6 receiving antennas will remain H-pol, while automobile FM antennas will stay V-pol. So if the TV station remains H-pol, this interference problem may be cleared up if the FM station will switch to V-pol. (See FCC Rules Section 73.525(e)(4).)

Rejection Filters

The FCC believes that rejection filters installed at the TV receiver would be helpful, while others think this is not a satisfactory solution. Unfortunately, many viewers do not sufficiently understand this problem and are thus not motivated to have the necessary filter installed.

It is further complicated by the fact that many of the existing TV receivers still have balanced antenna inputs (300 Ω) and filters designed for them that do not usually provide the necessary amount of rejection. As more TV receivers with coaxial inputs are purchased by the TV viewing public, this situation could change. Coaxial (75 Ω) filters with 20 dB of attenuation of the FM signal are readily available.

COMMERCIALLY AVAILABLE ANTENNAS

There are several basic classes of antennas available for FM broadcasting. These and variations of them are made by several manufacturers in different models, gains, and input power ratings. They may be broken down into the following classes:

- Ring stub and twisted ring
- Shunt and series fed slanted dipole
- Multi-arm short helix
- Panel with crossed dipoles

These antennas have many things in common. For example, nonsymmetrical antennas are designed for sidemounting to a steel tower or pole. Radiating elements are shunted across a common rigid coax line. This has eliminated the problems associated with the older corporate feed system using semi-flexible solid dielectric low-power cables.

Shunting elements every one wavelength across a transmission line makes impedance matching simple. Bandwidth is limited by the VSWR of the individual elements and the use of an internal transformer.

With more than about 7 bays, the first three of the above antennas have a more difficult task being matched and there is undesirable beam squint, since the elevation beam angle changes with frequency deviation by the transmitter. Antennas with more than 7 bays are fed from or near the center, thus dividing the phase change in one-half and effectively eliminated the beam squint. Center feeding also simplifies the VSWR matching.

A means for tuning out reactance after the antennas have been installed on the tower is also common with all the antennas. Located at the input to the antenna, the VSWR tuner consists of adjustable location dielectric or metal slugs on the inner conductor of the main coax line. Several fixed-position variable capacitors, spaced ⅛ wavelength along the main feeder near the antenna input are also used on some sidemounted antennas to adjust the VSWR to very small values.

Another variety of antenna has curved radiating elements around a circumference whose diameter is determined by the number of element arms. Each radiator consists of two, three, or four such circular arms, depending on the model. Each element is fed through a shunt arrangement, and then shunted across the vertical rigid feed coaxial line.

Wideband panel antennas are becoming popular where high buildings, favorable mountain sites or high towers are available. Several firms make wideband panel antennas. Some have very wideband VSWR features in each radiator. Others with not so broad VSWR, use phase impedance compensation similar to the European scheme, which uses 90° phase quadrature impedance compensation.

Phase quadrature compensation makes it possible to cover the entire 88 MHz to 108 MHz band with a VSWR under 1.1:1 while maintaining excellent elevation, and azimuth patterns, together with very good axial ratios. Power ratings up to several hundred kilowatts are offered so that many FM stations can be diplexed into one such antenna.

Only the wideband community FM antenna design now uses a corporate feed system, while the others are shunt fed from a common rigid coax line. This corporate feed system, using air dielectric semi-flexible line at the lower power levels, is very successful. It splits the input power to many different dipoles at the correct amplitude and phase.

Standard Sidemount Antennas

Standard sidemount antennas come in a variety of shapes and forms. They are currently used in the majority of applications. Their chief advantages are low cost, easy installation, availability of high gains, and low tower constraints. They are available in linear polarized configurations (H-pol or V-pol) or circularly polarized (CP).

Most sidemounts are comprised of a series of radiating elements, or bays, which are fed via a rigid innerbay feed line. The most typical feed lines used are 1⅝ in. O.D. for applications with less than 10 kW antenna input power, and 3⅛ in. line for up to 40 kW. Most antenna elements come in high and low power versions. These antennas are mounted directly to the side of a tower or pole. Leg and face mounts are typical on tower structures.

Some manufacturers with test ranges offer sidemount antennas with custom directional patterns. The pattern shaping is accomplished by optimizing its mounting and adding parasitic reflectors which are on the order of ½ wavelength. Repeated range tests have shown that the sidemount antennas have largely distorted patterns due to feed lines, mounting structures, and other conductive media in the antenna aperture.

Sidemount antennas are inherently narrow banded. The bandwidth of a single element rarely exceeds 1 MHz. Although diplexing two stations on a single sidemount is occasionally done, the spread between stations must be small (a few MHz), and compensation tuning (such as long stubs must be used). In addition, none of these antennas are symmetrical, and each type has uncontrolled radiation from booms and feed lines in the aperture. This distortion deteriorates the antennas axial ratio and circularity.

Series-Fed V-Dipole Antennas

This antenna has similar bandwidth to its shunt fed counterpart, but the array is typically intentionally tuned high in frequency. The combination of this tuning scheme, and the internal protection of its feed allow this antenna to be somewhat resistant to light icing.

This model is larger in size and heavier than other types of sidemount antennas. Care should be taken in determining tower constraints. The antenna is typically field tuned for an optimized match. Careful placement of ceramic slugs can produce a good VSWR over the stations useful bandwidth.

Ring Radiators

There are several antennas that are simple adaptations of ring radiators and were designed and manufactured in the 1950s and 1960s for horizontal polarization. By adding vertical stubs to the ends of the radiator or twisting the ring, elliptical polarization (of sorts) is achieved.

Both the ring and the ring stub suffer from temperature variations which tend to change the spacing between the ring openings and thus the electrical capacitance and resonant frequency. The ring stub and the twisted ring are not really circularly polarized because the axial ratio varies considerably with azimuth. At best they may be said to be elliptically polarized.

Over the years the design has improved by adding a second horizontal ring and improving the feed. Reducing bay spacing reduces high axial side lobes. The antenna has very good circularity in free space, but like other types of sidemount antennas, it is strongly affected by its support structure and feed line.

The radiation patterns are strongly affected by the tower mounting environment. Being of relatively high Q design, they are more susceptible to detuning because of icing. Radomes and electrical deicers are available to overcome this problem. While the icing problems may be overcome, pattern optimization is not offered for these antennas.

Ring-Stub Antennas

The H-pol radiation from these antennas comes from the ring portion whose plane is parallel with the earth. There is a minor lobe from each radiator, which is strengthened with vertical stacking for additional power gain. This nadir-zenith lobe is the result of 360° stacking on the rigid coax feed line. It reduces the gain and presents a lobe at the tower base which is detrimental to low level audio equipment and personnel located in a building at the base of the tower.

In order to keep the cost down, like the twisted ring antenna, the ring-stub is manufactured in several radiator-to-radiator spacings across the FM band. This results in some minor beam tilt up or down depending on the frequency. Most higher priced slanted dipole and helix antennas are spaced exactly 360° and are usually tested to assure this spacing during production.

Shunt Fed Slanted Dipole Antennas

The slanted dipole antenna in its present configuration was developed and patented in 1970.[16] It consists of 2 half-wave dipoles bent 90°, slanted and fed inphase.

The slant angle is critical as it is the factor which determines the ratio of vertically and horizontally polarized radiated power. The phase point center is at the feed insulator on the dipole support arm as shown in Figure 4.12-9. When fed through a vertical support pole on which the antenna was mounted during initial development tests, the axial ratio varied less than 1 dB.

The commercial adaption uses a horizontal boom containing a step transformer. This boom supports two half-wave dipoles in which the included angle is 90°. The two sets of dipoles are rotated at 22.5° from the horizontal plane. Two opposite arms of the dipoles are delta matched to provide a 50 Ω impedance at the radiator input flange. All four dipole arm lengths may be adjusted to resonance by mechanical adjustment of the end fittings. Shunt feeding, when properly adjusted, provides equal currents in all four arms resulting in excellent azimuth circularity.

Short Helix Antennas

A relatively recent asymmetrical radiator is the four-arm shunt fed helix. By using four dipoles, curved so that their circumference is about one wavelength, a CP antenna is produced.[17] Each dipole is about ½ wavelength and is shunt fed. These are supported on a four arm structure, one end of which is tied to the supporting structure. The dipoles overlap so that the current flow around the circumference is circular. The four feed arms are connected in shunt and the feed impedance is quite low, but may be brought up to useful values with an internal step transformer.

Figure 4.12-9. Three bay non-symmetrical FM antenna mounted on the tower leg. The guy cables are insulated fiber glass rods near the tower legs.

The CP quality of the four-arm side-fire short helix is good. Three and two arm models are also available, but their axial ratio is not as good as the four arm. Pattern circularity is ±1 dB for the four arm, together with an axial ratio of about 3 dB.

These radiators are stacked about one wavelength apart on a rigid coax feed line to obtain the necessary power gain. Like other asymmetrical FM antennas its patterns are strongly affected by the supporting structure. See "Pattern Optimization" in this chapter for the need and methods to circularize the azimuth pattern.

Electrical deicers using the stainless steel dipole arms as one half of the heating circuit are available. Heat is created by passing a large current at low voltage through each arm from voltage dropping transformers placed at each bay level. Plastic radomes are also available to keep snow and ice off the sensitive VSWR parts of the antenna.

Twisted Ring Antennas

This type consists of one or more rings, which have been partially twisted so that the open ends of the ring are about 10 in. (25 cm) apart. One semi-circular arm of the ring is fed with a small loop or by a direct tap on that arm. A number of these rings are fed in the same manner as the ring stubs, and have the same zenith-nadir lobe problem.

The mechanical twist is not the same when viewed in all the azimuth directions. Therefore the current is not the same, with the end result that in some directions there is much more elliptical radiation than in others.

These antennas are very simple and relatively inexpensive for single frequency use, but have some serious operational limitations for CP operation. They do not have the same signal penetrating effect as the slant dipole, short helix, or the flat panel antenna type of CP antennas.

Short Helix—Multi-Arm Antennas

The number of arms may be increased to four instead of the two in the slanted dipole variety. To provide CP, the arms are curved to form a 1 wavelength circumference. These short multi-arm helices are also stacked in the conventional manner, like the others in this series for power gains as desired. This design uses 2 γ feed straps to feed all the elements in phase. This antenna is shunt fed, and is arrayed and mounted similarly to the slanted vee dipole antenna.

The azimuth pattern of all these non-symmetrical antennas is affected by the supporting steel structure. With pattern optimization, the pattern can be made quite omnidirectional. (See Pattern Optimization in this chapter.)

Series Fed Antennas

A similar arrangement of arms supported by a T arrangement may be series fed. That is, part of the outer end is insulated from the rest of the dipole and fed across the insulated break. To allow for adequate power handling capacity and to increase the VSWR bandwidth, 3 in. (75 mm) diameter tubing is used.

The antenna has an VSWR bandwidth of about 1%, so it makes an excellent single channel FM antenna. The antennas are usually mounted on the side of a supporting tower or pole, and stacked vertically to achieve required power gain.

This antenna has greater wind loading than the shunt fed version due to its larger element diameters necessary to achieve useable VSWR bandwidth. It presents considerable large amounts of ac power for electrical deicing. Plastic radomes also present additional wind loading.

Flat Panel Antennas

Panel antennas for CP FM broadcasting are relatively new in the Western Hemisphere, although H-pol and V-pol have been used in Europe since the mid-1950s. This antenna was developed in Europe to provide a wide bandwidth for several collocated government stations without the need to change antennas when a new channel was added or the operating channels were changed from time to time.

Panels are from 7 to 8 ft (2,100 to 2,450 mm) square in the flat configuration. In the cavity style they are about 8 ft (2450 mm) in diameter and about 3 ft (1,000 mm) deep.

A heavy metal frame is often used over which large diameter wire mesh has been welded. The wire mesh screen openings vary from 4 to 12 in. (100 mm to 300 mm). Electrically they are considered nearly solid metal. These openings produce relatively low wind loads. The entire flat frame or cavity is strong enough to support a man on its mesh openings. Some manufacturers hot dip galvanize their steel after fabrication; others use stainless steel construction.

For FM use, two crossed dipoles are used as the illuminating source for each panel or cavity. Each dipole is fed in phase quadrature, that is one dipole receives its peak current 90° after the other, to produce CP. A typical set of electrical and mechanical specifications for a CP 8-bay cavity community antenna is shown in Table 4.12-6.

Flat panel antennas are typically sidemounted on large face size towers. The screen panels greatly reduce interaction and distortion between the antenna and tower. The panels are directional, thereby requiring 3 or 4 panels to be mounted around the tower to achieve acceptable azimuthal circularity.

These antennas are usually branch fed, and often the array's top and bottom halves are fed separately. This allows operation of either half of the antenna separately when it is necessary for maintenance or repairs. Circular polarization is achieved on each panel by feeding two perpendicular dipoles 90° out-of-phase. This phase offset helps this antenna achieve usable bandwidths on the order of 10 MHz.

By pulling the dipole back on its feed support arms, the arrowhead shaped dipoles control both V-pol and H-pol azimuth patterns. Rotating the dipoles 45° with the earth-ground reference improves the polarization ratios even further.

Round dipoles made of tubing as large as 6⅛ in. (155 mm) in diameter are used along with a single line quadrature feed. This combined arrangement makes an excellent wideband CP panel to cover the entire FM band. Power splitters, dividers, and cables, along with a number of these panels, completes the antenna.

Even on large face towers, circularity in the H-pol can be quite good, on the order of ±2 dB. On standard

Table 4.12-6

Typical measured community antenna performance

Operational frequency range	88 to 108 MHz
Safe RMS input power rating	200 kW
Power gain ratio, each polarization	4.4 (6.43 dB)
Maximum VSWR any frequency between 88–108 MHz	1.1:1
Elevation pattern beam tilt	−0.5°
Polarization	Right hand circular
Axial ratio	Better than 2 dB
Azimuth circularity Vpol or Hpol	Better than ±2 dB
Antenna dead weight, less than	7,000 Lbs (3,183 kgs)
Active wind load, RS-222-C 50/53 PSF	8,000 Lbs (3,636 kgs)
Antenna input flanges, two, size	6-1/8 inch
Number of bays (stacks)	Eight
Radiator type	Circularly Polarized Cavity

configurations, the V-pol pattern is quite different. As a result, the axial ratio of this antenna ranges from good at some azimuth headings to rather poor at others. This is because the azimuth pattern of a H-pol dipole is like a figure eight, or cosine function, while the pattern for a V-pol dipole is not directional in its azimuth plane. Therefore, each polarization will react quite differently when mounted in front of a panel.

Dipoles on these panels are often mounted at 45° referenced to the ground. This has no effect on the axial ratio or pattern performance, it instead is done for tuning considerations to compensate for mutual coupling.

Variations to this design have reduced the differences between the patterns of the polarizations. These techniques are effective for applications requiring only a few MHz of bandwidth. One method optimizes the angle of the dipole bend as well as its distance to the panel. This design requires three panels to be mounted around a tower. Axial ratio and pattern circularity are improved at the cost of system bandwidth.

Another method uses four dipoles forming a square shape in front of the panel. By adjusting the spacing between the dipoles, the beamwidth of a panel can be controlled. Over a small bandwidth, the pattern performance is greatly improved. It is necessary to mount four panels around a tower for a circular pattern. A large amount of panel interaction and leakage are severe design limitations.

For projects that require wider bandwidth, skew mounting is often used. This physical configuration allows the panels to be fed in mod 1 (0°, 90°, 180°, 270° phase for 4 around) which can increase the bandwidth of the system at the input. Although skew mounting deteriorates pattern performance, the increase in bandwidth extends its applications.

Cavity Backed Panel Antennas

The use of a cavity screen instead of a flat panel has greatly improved axial ratios. The cavity acts as a resonator with little leakage towards the tower. The shape of the azimuth pattern in each plane becomes both controllable and symmetrical. System bandwidth is improved over the flat screen design. By adjusting the diameter of the cavity structure, beam widths can be altered to meet specific requirements. Mounting three cavities around a tower gives good pattern circularity. Axial ratios usually range from good to excellent.

The cavity antenna uses the reflective properties of the flat screen panel. In the cavity however, the illuminating dipoles are flat instead of round and all four arms are parallel to the plane of the cavity. Like the flat panel with its round dipole supporting balun, the cavity also holds its flat dipoles with a double coaxial balun.

The dipoles in the cavity get their wide VSWR bandwidth through the sleeve dipole principle.[18] Capacity is provided by a metallic ring close to all four dipole arms placed between them and the back of the cavity. Circulating surface currents flow on the dipole arms, which result in evenly radiated patterns in all polarization planes. The bandwidth of a single cavity can cover the full 20 MHz band with a VSWR better than 1.1:1. Therefore it is not necessary to skew mount these antennas for bandwidth considerations.

This antenna has the advantage over some other designs of greater VSWR bandwidth. It is considered closer to state-of-the-art due to better elevation and azimuth pattern control of both planes of polarizations by the shape of the cavity.

Cavities and flat panels can be modeled using a computer. Factors such as tower size and orientation, as well as the phase and skew of the elements, can be modeled to determine optimum mounting and feeding. This is useful in projects which require a directional pattern. A station should take pattern constraints and desires to an antenna manufacturer to find out what is feasible.

Crossed Dipole Theory

Common to the flat panel and the cavity is the operation of the dipoles which generate CP. The dipoles are fed currents in phase quadrature, through a coaxially balanced balun, which provides equal currents to all four arms of the two dipoles. They excite the entire cavity or flat panel with a rotating RF field in a plane parallel to the dipoles. The RF field is thus CP and may be ideally represented by a rotating vector of constant magnitude revolving one revolution per wavelength of propagation distance. It is right hand polarized as the field rotation is clockwise as viewed from behind the screen, looking toward the direction of propagation, if the phasing between the two crossed dipoles is properly made.

Radiation patterns, associated beamwidth, and directivity are determined to a large extent by the size of the cavity or flat panel. The geometry of the dipole has less effect than the reflector size. The size and shape of the dipole controls the antenna impedance and the VSWR. The screen panel, be it flat or a cavity, fulfills the following five important electrical functions:

- Isolates the radiating elements from the tower or the mounting structure, and reduces mutual coupling
- Provides sharper beamwidth and more gain than achievable with the dipoles alone
- Furnishes pattern control so that the beamwidth is nearly equal for both horizontal and vertical plane polarization
- With an effective balun feed system, the crossed dipole radiated pattern phase is very uniform as the amplitude changes normally with azimuth
- Computer aided designs are easily achieved in production for various width towers because the pattern is simply pure electrical geometry.

Antenna Element Spacing and Downward Radiation

Most FM antennas have elements that are spaced one wavelength apart (9 to 11 ft) for reasons such as gain considerations, mutual coupling effects and ease of feed design. There are cases, however, which require a different element spacing. High levels of downward radiation is the most common reason, although considerations such as aperture constraints and beam shaping also utilize nonwavelength spacing.

Radio frequency radiation (RFR) safety levels must be considered in nearly all site locations. Power radiated in the lowest sidelobe can cause a variety of problems, of which human exposure levels are most critical. See Chapter 9.4, *Non-Ionizing Radiation,* for further information.

When antenna elements are arrayed, the resulting elevation pattern contains lobes and nulls. The furthest sidelobe from the horizon typically peaks between 70° and 90° below the horizon for full wave spacing. This lobe occurs since the physical path results in no phase cancellation in that direction, and thus each elements downward radiation is additive. Shortening the spacing changes the difference in the elements physical path length, and results in some phase cancellation.

Half wave spacing, for example, greatly suppresses the levels of the side lobes, while increasing the width of the main beam. Despite the lack of power in the side lobes, the extra width of the main beam causes the pattern to be less directive. Thus, this exchange results in an overall gain reduction on the order of a third. Spacing the elements 0.8 wavelengths apart improves sidelobe suppression and the gain of the antenna is not greatly affected.

Short spaced antennas are fed either by a shunt or branch feed system. For half-wave spaced antennas, a shunt line delivers each element 180° out-of-phase with the next element. This phase distribution problem can be overcome by flipping every other element upside down, thus inducing a 180° phase shift in the feed. Other spacings, such as 0.8 wavelengths, require a branch feed, which can deliver equally phased signals to each element independent of spacing.

Problems With Sidemounted Antennas

Single station FM antennas are typically sidemounted on a pole or tower. Unlike panel antennas, the support structure greatly effects or distorts the radiation pattern. The resultant pattern may have large peaks and nulls that can result in coverage and reception problems.

In addition, the V-pol and H-pol patterns react quite differently to these distortions. Due to the geometric complexities of the CP radiating elements and tower structure, computer modeling exists to accurately predict pattern effects is a difficult proposition. Therefore, the use of test ranges are required to determine how an antenna behaves when mounted on a tower section similar to the one on which the antenna will eventually be used.

For nondirectional stations, a test range can determine the proper mounting of an antenna to achieve an acceptable circularity. Depending on the tower size, the depths of nulls can be greater than 10 dB. An optimized mounting configuration can make the nulls less significant and oriented in areas where service to the primary coverage area is not hurt. Parasitic reflectors are often used to improve the circularity of nondirectional antennas.

When the top spot on a tower or structure is available, pole mounting is often preferred. A pole provides a stable and symmetrical support structure which has low interaction with the horizontally polarized component. In combination with the feed line, the pole typically induces a null in the V-pol pattern, directly opposite of the elements. Proper orientation of the element can reduce the effects of pattern distortion.

Mounting an antenna on the side of a tower can produce unpredictable results. The position of the peaks and nulls vary greatly from the orientation of the elements. As the face size of the tower increases, the distorting effects magnify. To compensate, many stations use smaller sections of tower at the top, where they plan to install the FM antenna. Eighteen-inch and smaller face towers tend to produce good results. With careful planning, the use of a 24 in. or larger face tower can also be successful.

Note that the patterns of each polarization react differently, and thus axial ratios can be quite poor.

PATTERN OPTIMIZATION

Single-station FM antennas are usually sidemounted on a pole or tower. This is economical and it frees the tower top for other possible uses. Unfortunately the pole or tower tends to distort the radiation pattern, seriously affecting station coverage in some directions.[19]

This problem can be serious if the FM antenna has been randomly attached to a support tower. FM antenna makers do not manufacture and sell towers. A few have made supporting poles on which the FM antenna has been affixed, adjusted and pattern tested. TV antenna makers, on the other hand, usually build the antenna as a complete self-supporting structure to be mounted on top of a support. They are usually not faced with this sidemounting problem. The logical but more expensive solution would be to make the FM antenna a self-supporting structure just like TV antennas.

Improper FM antenna sidemount installation on a tower can cause serious pattern problems. Measured patterns have indicated that, in some cases, the maximum radiation can actually be in the opposite direction from the desired direction.[20]

Need To Optimize

It is not wise to gamble with an FM station's antenna coverage. Nulls may be toward important service areas. Nulls as low as 1% of the RMS power have been measured with towers varying in width from 18 to 120 in. (0.5 m to 3 m).

Another problem is that with nulls come lobes. Lobes as great as 9.8 dB over RMS have been found. When used without pattern optimization, this lobe would produce an ERP in a given direction nearly ten times the FCC licensed value.

Translating this to a 50 kW ERP station there would be radiation in some directions of only 0.5 kW and others with 477 kW. This is a maximum to minimum ratio of 29.8 dB, and clearly not acceptable.

With CP came additional problems as the H-pol and the V-pol ratios are not always the same and vary moderately in any given azimuth. This ratio can be as great as 15 dB and must also be addressed in order to resolve the horizontal plane circularity problem. The axial ratio could be degraded causing the V-pol radiation in certain directions to be much stronger than the H-pol. This violates FCC's requirement that with CP, the V-pol must not be stronger than the H-pol component.

Section 73.316 of the FCC Rules covers FM antennas but does not specifically address this problem of azimuth circularity. In fact the FCC assumes that FM nondirectional broadcast antennas have perfectly circular horizontal radiation patterns.[21] In actual practice, they seldom do.

In order to produce a horizontal plane pattern which even approaches a circle requires considerable work by the firm making the antenna. Since it is nearly impossible to produce a circular pattern with a non-symmetrical sidemounted antenna, the term and technique, *optimization* (to do the best possible) is in common usage now.

Theory of Optimization

Figure 4.12-10 indicates how energy from the horizontal loop representing H-pol is intercepted by a pole and reradiated. Similarly, in Figure 4.12-11 energy from the vertical dipole is intercepted and reradiated as V-pol.

In the first case, the pole diameter is small in wavelength in the direction of the electric field, thus, scattering is minimal and not much H-pol radiation can be expected. However when the V-pol dipole excites the pole, a large amount of energy is intercepted (Is) and

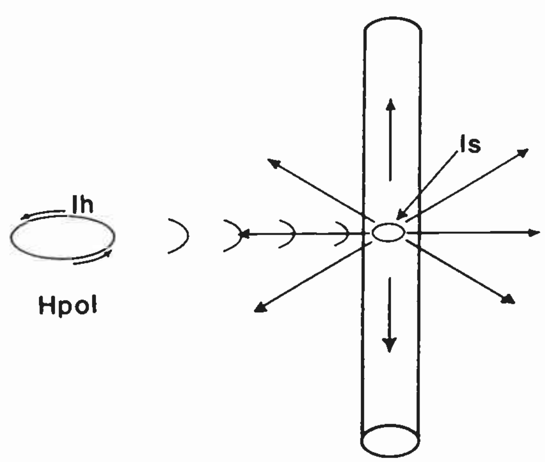

Figure 4.12-10. The effects of supporting steel towers or poles on one side of a non-symmetrical antenna are shown as horizontally polarized currents Ih flow on supporting members as Is and reradiate in all directions.

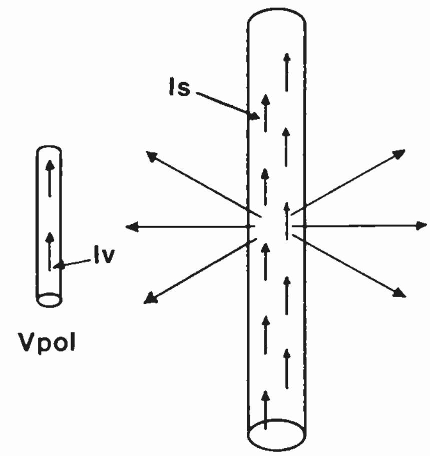

Figure 4.12-11. Vertically polarized current Iv flow over the supporting structure members as Is and reradiate in all directions.

reradiated because the large dimension of the pole (length) is parallel to the electric field. A similar effect is produced by the vertical transmission line which is common to the antenna itself, (IV in Figure 4.12-11). The result is appreciable distortion of the vertically polarized azimuth pattern.

Figure 4.12-12 shows the resulting H-pol and the V-pol patterns. The pole and/or vertical coaxial line have transformed the V-pol pattern from circular to a cardioid, while the H-pol pattern remains essentially omnidirectional. The null of the cardioid can be more than 7 dB down from the RMS value. This phenomenon is well known, and as a compromise, broadcasters generally install the antenna on the side of the tower support structure facing the main service area. There are many exceptions to this, as some measured patterns

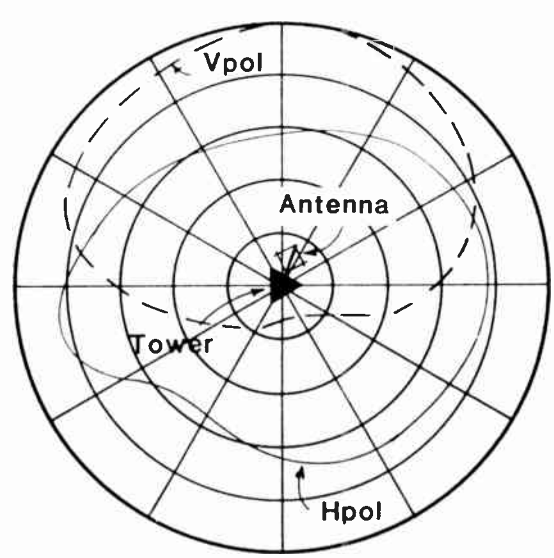

Figure 4.12-12. Combined results of H-pol and V-pol reradiation distort both patterns, producing more than 17 dB variation. This poor Cpol pattern should be pattern optimized to smooth out the azimuth pattern.

on triangular towers of standard construction have shown.

In Figure 4.12-12 the V-pol is much stronger than the H-pol in the favored direction. In the opposite direction, there is little V-pol. The power ratio of H-pol to V-pol is 16 times. This makes for a very poor CP antenna in some directions.

Tower and poles under about 2 ft (0.6 m) in cross section will exhibit the same effects on the antenna patterns, as in Figure 4.12-12. Towers greater than this size obviously will increase the complexity of scattering effects. Three or four tower legs, the horizontal and diagonal cross members, transmission lines, ladders, tower lighting, and deicer conduits, all will be excited by the vertical and horizontal currents from the radiators. All these surfaces will reradiate and affect the horizontal plan patterns.

In contrast to the simplicity of the antenna on the side of a pole, the tower supported antenna may be mounted on the face, or on a corner, at or between horizontal cross members, or tilted at various angles compared to the tower—all multiplying the complex factors affecting the patterns.

Optimization Methods

The most popular technique to achieve the desired pattern is through the use of Yagi antenna principles, wherein parasitic elements are placed in the field of the radiator to modify its radiation pattern. For example, a shortened dipole (director) placed in close proximity to a radiator reinforces radiation in the forward direction, and suppresses the signal in the opposite direction. If the parasitic element is longer than the radiator (reflector), the effect is reversed. The signal is suppressed on the side of the parasitic element and reinforced in the direction of the radiator.

Similarly, parasitic elements can be used with FM antennas mounted on the sides of towers or poles to produce pattern changes. As discussed here, both directors and reflectors may be used. Both are frequency sensitive. The effects of the supporting structure are also frequency sensitive.

Therefore, an arrangement of parasitic elements for a given FM frequency will not necessarily be the same for another, nor will the pattern be the same for a given arrangement, if it is moved up or down the tower by as much as 1.5 ft (0.5 m).

The resulting patterns cannot be predicted. There are many factors which affect the horizontal plan pattern. Only by actual antenna pattern range testing can the patterns be adjusted and properly measured. Therefore the cost for doing this is high, since it is time consuming, and requires qualified antenna technicians and the use of an antenna range. In addition, the final parasitic arrangement must be permanently fabricated and installed. However, the results are well worth it.

Pattern Service

There are two basic types of pattern service furnished by several antenna manufacturers in the United States. FM antennas may be adjusted for the best omnidirectional pattern possible or they may be adjusted to proven minimum ERP values in particular azimuth directions. The minimum required values, plotted on a polar chart by the broadcasters may be combined with the tower orientation. Using the customer's make and model tower, two or more bays of the antenna are fabricated, installed on a section of the tower, and put on the test range. Adjustments are made such as leg chosen, distance from the leg, and the orientation of the antenna with respect to that leg. Parasitic elements are then used to further improve and shape the pattern, so that the minimum ERP values will be achieved in the customers service area as given with the order on the polar plot.

For example, a Class A station may wish that a minimum of 3 kW be radiated in a pie from 90° to 120° and the remainder of the azimuth be no less than 1.5 kW. This would then require the antenna technicians to achieve a pattern without any field voltages less than 70% and that the vectors between 90° and 120° to be 100%. This sort of work has been done by many antenna manufacturers. See Figures 4.12-13A and 4.12-13B for a typical before and after optimized pattern.

Various methods have been used to optimize FM antenna azimuth patterns. Some firms use models at twice the operating frequency. Others use theoretical methods, backed up by experimental proof. The final optimized antenna is match marked on the tower sections so that it will be assembled exactly as it was made and tested at the fabricator's plant, and tested on the antenna range.

A complete set of installation prints must be provided so that the antenna is assembled exactly as tested, with all the correct locations, and angles of all the parasitic elements.

WIDEBAND COMMUNITY AND MULTI-USER ANTENNAS

The most significant developments in FM antennas have come in broadband designs. Flat panels, cavities, helicals, and a sidemount design have given broadcasters a range of choices to fit their application. Factors such as pattern requirements, tower constraints, and system budget can narrow the options.

In order for an antenna to be useful throughout the 20 MHz FM band, its operation must be the same on any frequency. The VSWR on 89 MHz for example, must be just as good as on 108 MHz. The CP azimuth pattern should remain the same on one end of the band as the other, as must the axial ratio. This is a much more rigorous requirement than placed on the single-channel slanted dipole or the ring stub.

In the wideband antennas, several factors go together in order to meet these severe requirements:

- Basic wideband dipole radiators
- Screen-panel pattern control
- Quadrature phase distribution

By using these three principle parameters in a wideband antenna the radiation pattern, VSWR, and the

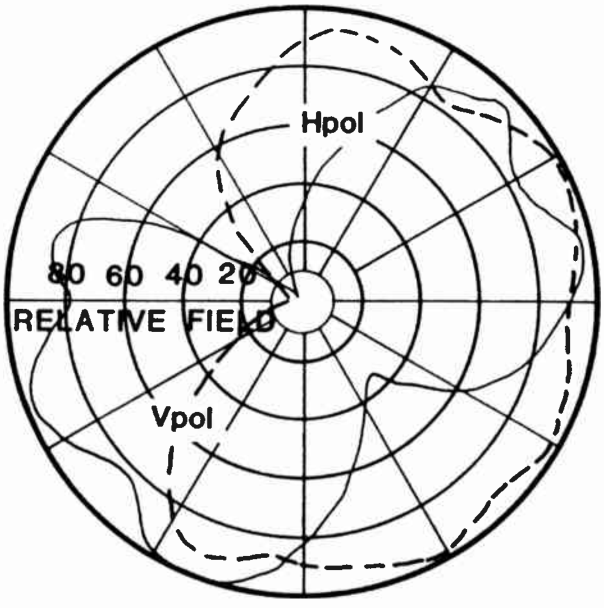

Figure 4.12-13(a). Measured non-symmetrical C-pol pattern of tower side mounted antenna. V-pol variation is ±15 dB, while H-pol is ±12 dB. The axial ratio was 24 dB. Antenna patterns are very poor.

gain can be nearly the same on any channel within the FM band.

Several methods are used to make the VSWR of the crossed dipoles as good as possible. The dipoles are usually fed with a folded balun or the split-tube type balun.[22] This improves the impedance match, phase as well as amplitude linearity of the resulting azimuth pattern.

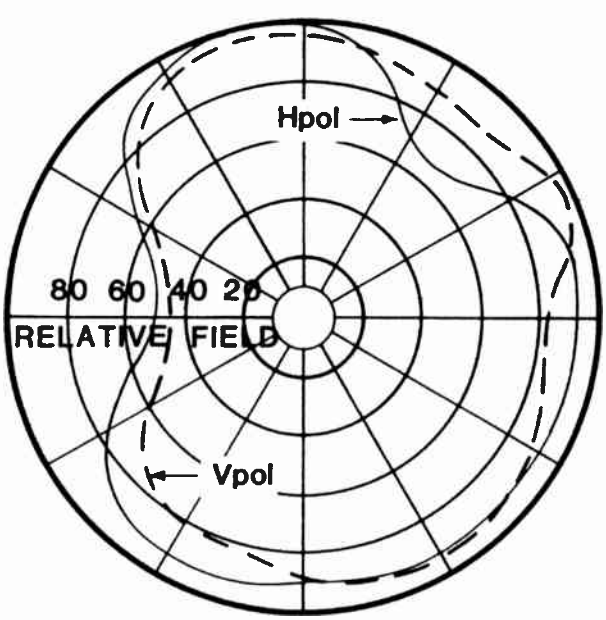

Figure 4.12-13(b). Same antenna as 22A but much improved after pattern optimization. H-pol variation is ±3 dB and V-pol is ±3.4 dB. Axial ratio is quite acceptable at 2.9 dB.

The length to diameter (or width) ratio is usually about three. This not only reduces the Q but also increases the voltage flash over levels. The low Q also increases the bandwidth by decreasing the rate of reactance change with frequency.

A natural factor aiding the VSWR problem is the fact that in order to obtain CP from two crossed dipoles, there must be a phase quadrature of the two currents feeding the crossed dipole. The two reflections, as a result of VSWR, return back to the phasing device 180° out-of-phase with each other. Being the same amplitude, they cancel.

All of the above factors, plus two or three more levels of quadrature reflection cancellations, bring the overall system input at the antenna to under 1.08:1 across the band. This cancellation technique eliminates the need for electrical deicers or plastic radomes, as the VSWR is not affected by moderate ice coatings. However radomes may be necessary with flat panels, to physically protect some radiators from falling ice.

These and other factors all contribute to make the panel-cavity antenna the best possible for either single channel or community antenna use.

Top Mount Antennas

There are a few broadband designs which require top mounting on a pole. The first design incorporates a series of dipoles which are mounted on a pole. Each dipole is branch fed individually. By rotating the mounting scheme, circular patterns can be achieved. The rather small radius between dipoles keeps nulls from crossover points to an acceptable level. Large bandwidths and good patterns have been measured on this system. The considerable amount of feed cables that run through the aperture, however, can cause problems if not properly RF grounded or shielded. Line damage, failure, and pattern distortion are possible results.

Spiral (or normal mode helical) antennas are now being used for FM applications. This traveling-wave-type antenna has bandwidth on the order of 15% to 20%. Fed from the top, a series of wires are wrapped around the conductive pole over an aperture of 2 to 3 wavelengths. The pitch angle of the wire wrap controls the pattern characteristics. Pattern circularities of ±1 over a 20 MHz band have been measured. Axial ratios better than 2 dB are considered typical. The feed system is enclosed by stainless steel feed cans which eliminates pattern distortion by the feed system, a common fault of other top mounts. In icing regions, heating elements inside the radiating wires stabilize its performance.

Multi-Channel Sidemount

Another broadband FM broadcasting antenna is the sidemount. This design incorporates dual baluns, which insure a balanced and symmetric current excitation. This balance eliminates spurious radiation from currents on booms, feed lines, and other nearby conductors. The feed arms are of the skewed vee dipole configuration. Excellent circularities and axial ratios have been measured in free space. Interaction with feed lines and support structure still distort the pattern, though to a lesser extent.

A single FM element has been measured to have a bandwidth of 5.5 MHz with a VSWR of 1.1:1. This bandwidth does not limit the spread of two combined stations. By centering the band edges, the antenna can tune two stations over 8 MHz apart with a VSWR of 1.1:1 over each channel. This comes at a cost of poor performance at center frequencies, thus three stations over 8 MHz is not achievable. As a sidemount, this antenna has substantially reduced costs and tower constraints over a panel type.

Community Antenna Economics

The community antenna fits best in multiple station service. This allows sharing costs so all parties benefit from a superior antenna that each station independently could not economically justify.[23]

If enough planning is done in advance, it may be possible to install all the FM stations of one community on one tower, at considerable savings to all users. Some preclusions are lack of adequate mileage separations, the existence of excellent facilities, and FAA tower height limitations.

The break-even point appears to be with four stations. When five stations are involved, there is perhaps a 20% reduction in cost to each of them when compared to the costs of putting up their own individual single channel antenna and tower at the same height.

One of the first large-scale community antenna projects in the U.S. was the Senior Road Tower.

In 1984, a group of Houston, Texas broadcasters formed the Senior Road Tower Group, and installed a 2,049 ft (625 m) tower supporting a 12-bay community FM antenna system, with its HAAT at 2,000 ft (610 m).[24] This height permitted the maximum service allowed.

Two runs of 8³⁄₁₆ in. (208 mm) diameter coaxial lines are used to feed the antenna in such a manner that power in both the lines causes right hand CP from the antenna for nine FM stations.

The nine stations use one diplexer each, all of which are housed in one 2,400 square foot (223 square meters) room. The 10 port modular diplexer has a total power handling capability of 350 kW. The insertion loss for each station is 0.80 dB (17% loss). The isolation between the various transmitters meets FCC spurious emission (intermodulation) requirements.

All the diplexers are monitored at a central operating rack which indicates each diplexer's forward, reflected, and rejected power. This permits trouble shooting in an orderly and rapid manner. Electrically operated coaxial switching permits each station to be connected to the dummy load for individual testing. Air conditioning and chilled water are used to remove heat produced during operation.

This community FM antenna project demonstrates the technical feasibility for a large system with nine FM users. The technology is available, the difficulty is in bringing broadcasters together to start, plan, fund and complete such a large undertaking.

Technical Advantages

Besides the financial advantages cited under the economics heading, there may be the competitive advantage of protecting the channel classification and using the same height antenna as the competitor. Other advantages include its emergency upper-lower half feature for transmission line or antenna half backup. The flat VSWR curve is highly useful for SCA and stereo operation. Stations sharing this type antenna will all experience less intermodulation interference than if they had separate antennas, but closely placed.

STATION DIPLEXING

Diplexers are passive devices used to combine the power of two or more stations and feed the combined power to a common transmission line and/or a common transmitting antenna. This system of utilizing one well-sited, high-quality antenna has become popular, convenient and economical.

Wideband panel antennas, although expensive for use by one station, are cost-effective for two or more stations. These antennas maintain their omnidirectional horizontal plane patterns and VSWR throughout the FM broadcasting band from 88 to 108 MHz. Thus, they make the ideal antenna for multi-station diplexing.

Diplexer Economics

Diplexers permit several stations to be combined into a single master antenna. New channels at any power level may be combined in any order by connecting another diplexer in tandem to the previous unit. The first channel may be fed into a wideband antenna without a diplexer. When two stations are to be combined, the first diplexer is put into service. When the third station is added to the system, a second diplexer is required and so forth. Figure 4.12-14 shows this arrangement.

Each diplexer contains a pass through broadband input port and an injected frequency port. Nearly all uncombined diplexer power and other undesired products are absorbed by a dummy load connected to the fourth port. The third port goes to the antenna or to the next diplexer's broadband input port.

The combining of two different stations must be done without degradation to station. The important factors are amplitude, group delay, VSWR bandwidth, isolation, and insertion loss. Insertion loss is a continuing cost item as it consumes RF power that is generated by the transmitter at considerable expense. Table 4.12-7 shows the measured performance of a typical three-diplexer installation.

Constant Impedance Type Diplexers

The constant impedance type takes its name from an operating characteristic of one of its components,

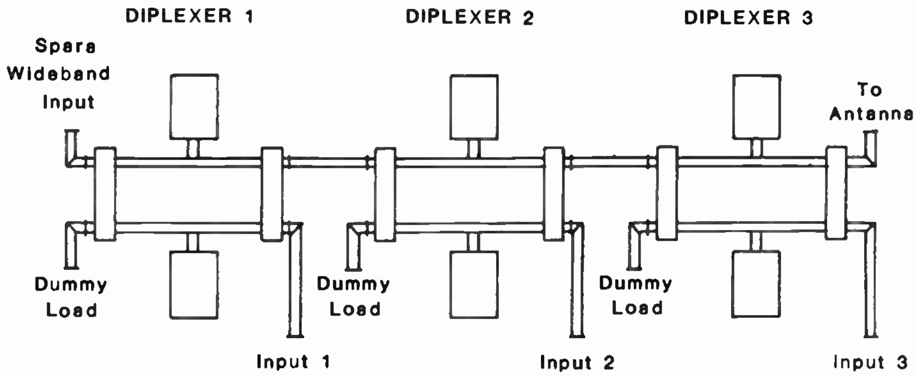

Figure 4.12-14. Three diplexers connected to provide combining facilities for three different stations for one community antenna. Note spare emergency wideband input port.

Table 4.12-7
Typical measured diplexer performance
(Three channels into one antenna)

Channel frequency	93.5 MHz	99.3 MHz	100.5 MHz
Input VSWR, plus minus 250 kHz	1.1:1	1.04:1	1.04:1
Isolation: From 93.5	—	−80 dB	−80 dB
From 99.3	−59 dB	–	−50 dB
From 100.5	−80 dB	−50 dB	–
From broad band port	−56 dB	−44 dB	−39 dB
Amplitude Response:			
Carrier plus minus 250 kHz	0.15 dB	0.25 dB	0.35 dB
Group Delay, in nanoseconds:			
Carrier plus minus 250 kHz	25	27	38
Insertion Loss, carrier	0.23 dB	0.24 dB	0.23 dB

the constant impedance of the broadband 3 dB hybrid. All of this type use two hybrids and cavities. Because of the use of hybrids, the constant impedance hybrid diplexer is sometimes called a *hybrid combiner*.

An efficient diplexer is not a complicated device, as it consists of two basic components, the two hybrids and two cavities. Coax is used to interconnect the components. Hybrids and cavities either have coaxial flange connections or are directly coupled. Some units are pressurized to keep moisture from tarnishing the cavities which may be silver plated or polished copper, in order to attain high Q.

A terminating load, rated at one-half the highest transmitter power being diplexed in that unit is connected to the reject port. In the event of failure of one or both cavities, half of the power will appear in this load before thermal and other sensors normally turn the affected transmitter off.

The hybrid, sometimes called a *3 dB coupler,* is a four-port device. When power is fed into one port, it appears split 50% between two other ports, thus the name 3 dB coupler. Another very useful feature is that the two split powers are 90° apart in their phase relationship. The fourth port is isolated from the input port typically by 26 to 40 dB. If two of these hybrids are connected back to back, nearly all the power entering the first input port will appear in one of the output ports, and a second port will be isolated.

In TV use, a single hybrid is quite useful in feeding a turnstile batwing antenna, which requires split input power with a phase quadrature displacement. The old square quarter wave TV hybrid diplexers are similar in operation, but they are limited bandwidth devices and not suitable for wide-band use in FM community antenna diplexing.

FM diplexer hybrids are capable of extremely high power. They are usually made of large coaxial components with quarter wavelength coupling bars. Their large physical size and low Q greatly reduces power loss which rarely exceeds 0.05 dB (1.1%) (see Figure 4.12-15).

Many constant impedance diplexers use only reject cavities. Each diplexer contains a broadband input port and an injected frequency port. Nearly all uncombined diplexer power and other undesired products are absorbed by a dummy load connected to the fourth port. The third port goes to the antenna or next diplexer's broadband input port.

A band reject diplexer is shown in Figure 4.12-16. The signal from TX-1 splits equally in hybrid H-1. It

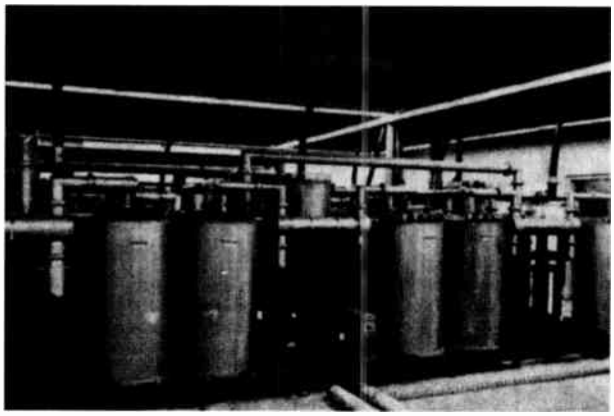

Figure 4.12-15. This Senior Road, Houston, Texas ten-port diplexing system, combines nine FM stations into one community antenna. It is capable of 350 kW total input power. (Courtesy Harris Corp.)

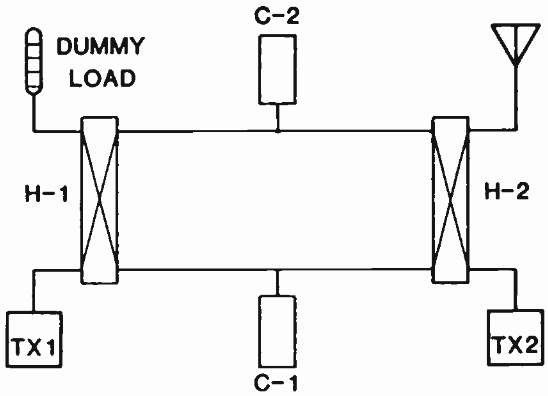

Figure 4.12-16. Basic constant impedance diplexer. See text for explanation of component functions.

passes by the cavities (C-1 and C-2) which are tuned to TX-2 frequency. The two signals of TX-1 combine in the antenna output port of hybrid H-2 since the two inputs to H-2 are equal in amplitude, but 90° out-of-phase, due to the action of hybrid H-1.

The signal from TX-2 splits equally in hybrid H-2 and are 90° out-of-phase with each other. Cavities C-1 and C-2 are tuned to the TX-2 frequency and present a short circuit to it. So the signal is nearly 100% reflected back to the inputs to H-2. These signals are 90° out-of-phase so they combine only in the antenna port of H-2 and go out to the antenna.

TX-1 frequency is not critical and can be any frequency within the FM band, as long as it is removed from the cavity frequencies by at least 1.0 MHz. However, it will work with some makes of reject diplexers when the separation is a minimum of 800 kHz.

The cavities tuned to TX-2 are not critical in their spacing from hybrid H-2. Because of the nature of the two hybrids, the VSWR remains low and is not affected by temperature variations. The isolation also remains high under these conditions.

Another advantage of the constant impedance notch diplexer is that any beat frequency or intermod product generated in the transmitter TX-2 will be absorbed in the dummy load since only TX-2 will be reflected. This is due to the frequency selectivity of C-1 and C-2.

When more than two transmitters are to be combined, the additional diplexers are merely added in series as shown in Figure 4.12-14. Additional diplexers do not affect the performance of the rest of the system, and can be added at a later time if the need arises. Because of their simplicity, constant impedance diplexers are virtually maintenance free.

Branched Starpoint Diplexers

This type does not use hybrids. Each transmitter feeds into a set of branching filters. In each set there is a bandpass cavity tuned to pass the operating frequency and at least one reject cavity tuned to the frequency of the adjacent channel to sharpen the skirt selectivity. If more than two frequencies are being combined, the middle frequencies have reject filters for both their adjacent frequencies.

All the filter sections connect to one common junction, or starpoint, which is the combiner's output. Coaxial cable lengths between each diplexer and the starpoint must be a defined electrical length for proper filtering action and low VSWR. This type of diplexer does not use an absorption load, as the small amount of rejected power is consumed by the rejected frequency transmitter and the antenna.

There is no broadband input, so adding channels requires that balanced modules be added on the output. If there is a failure of one branch, it will usually not take the others out of operation. Since there is no broadband port, the affected frequency cannot be switched as would be done with a hybrid diplexer system. However, the transmitter from the failed branch may be operated into one half of the antenna, while the output of the combiner, containing the unaffected channels feeds the other half, for an ERP reduction of 3 dB.

The principal advantages of a branched system are in space and price. There are fewer components—no dummy loads, no hybrids, and fewer cavities. They are frequently fan cooled, thus permitting the use of smaller cavities. This is all at the price of flexibility and, in some cases, performance.

Cavity Construction

In order for diplexers to work, a frequency selective electrical short circuit is required to be placed between the two hybrids. This is provided by high Q cavities.

During World War II, low-pass and high-pass filters were developed for VHF communications and radar. The need for microwave receivers with greater selectivity led to the development of magnetically coupled, quarter-wavelength long cavities. Improvements since the 1940s have made cavities with excellent loaded Qs and extremely low insertion loss.

Temperature stability improvement is the result of using invar steel, and the high Q results from silver plating and polishing the inside of the cavities. Cavity size for FM use varies due to the resonance mode selected by the design. Round cavities as small as 20 in. (508 mm) in diameter and 30 in. (760 mm) long have been used. Square types as long as 60 in. (1524 mm) using wave-guide modes have been used. Generally speaking, the larger the cavity, the smaller the RF loss through the cavity.

A very high loaded Q is necessary for a frequency spacing of 800 kHz, which is the closest frequency assignment in any specific community. Practical Q values vary from 1,000 to 12,000.

The power dissipated in heat will expand critical parts of the cavity, detuning it if the heat is not efficiently removed. Air blowers, cooling fins, or simple black paint can be used, depending on the amount of heat to be removed.

The cavities contribute most of the loss found in a diplexer. A diplexer with its two cavities tuned to the first possible channel 800 kHz away could have an efficiency of about 95% (0.25 dB loss). Efficiency goes up as the spacing between the passband and the reject frequency increases so that at 1.6 MHz it could be 96% and at 2.3 MHz, about 97%.

An extremely high Q would be excellent on the operating frequency but would not be useful on the FM sidebands. Using more cavities and stagger tuning them increases costs but does not completely solve the efficiency problem.

FM ANTENNA INSTALLATION ON AM TOWERS

The current trend is to locate FM transmitters in places where the best service may be rendered to the most listeners. This usually permits the maximum possible height to be used. Sometimes however, it may be economical and convenient to install the FM antenna on a tower used for AM broadcasting. If the steel AM tower is not base insulated but is grounded and shunt fed, the FM coaxial line may be connected to the tower, without any further problems.

Transformer Isolation

If the AM tower is insulated at the base, an isolation transformer may be used to couple the FM power across the base insulator without introducing objectionable mismatch into the FM antenna feed line. An isolation transformer is especially desirable for feeding high impedance AM radiators or AM radiators which are part of an AM directional antenna system which might be adversely affected by a quarter-wave isolation system.

These transformers have two tightly coupled RF coils which are resonant at the FM operating frequency. An air gap is provided for the AM power to pass through the two resonant loops. The capacity is quite low, resulting in a very high capacitive reactance placed across the tower base insulator.

Figure 4.12-17 shows the internal basic construction of a typical isolation transformer. The insulation for AM under the top of the box may be high density polyethylene, teflon, or fiberglass. The metal top provides a rain shield as well as protection from dust, mud, or snow.

The use of these isolation transformers permits the AM tower to operate undisturbed by the presence of the FM antenna. It also allows the FM coaxial line to be connected in the usual manner, except for the placement of the isolation transformer. These have internal gas blocks and permit the passage of dry air pressure through the transformer via a plastic tube.

In addition to lower cost, the isolation transformer method has another advantage in directional AM tower use. It does not distort the AM radiator current distribution which may adversely affect the AM radiation pattern.

Quarter-Wavelength Isolation

A less popular and older method is to use the technique of quarter-wavelength transmission lines. Simply stated, the opposite end of a shorted quarter-wavelength line has high impedance. This high impedance is placed across the AM tower base and may be successfully used to provide the necessary isolation. It is more difficult to physically accomplish this as the tower should be at least one quarter-wavelength high, and the FM antenna coax line must be insulated all the way down the tower. In practice the insulated part may be as short as 75° of line, as the line hangers and distributed capacity of the line tend to electrically increase the physically shorter line. For best results, the FM line should be placed within the tower body.

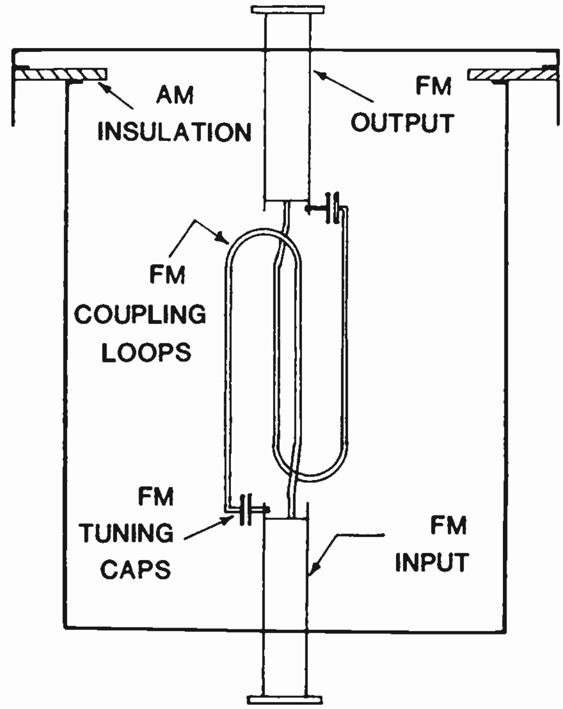

Figure 4.12-17. Typical AM-FM tower isolation transformer, used to decouple FM transmission line on a series fed AM tower.

Guy Cable Considerations

The presence of continuous steel guy cables going through the FM antenna level on a steel supporting tower was studied by Jampro Antenna Company in 1968. It was found that guy cables had an effect of less than 0.6 dB in the azimuth pattern of a H-pol antenna. On V-pol the maximum variation was 1.8 dB on the azimuth pattern. The strongest effect is on CP where the azimuth pattern change was as great as 3.4 dB. The elevation pattern was also affected since the first and second nulls were filled as much as 4 dB.

In addition to pattern anomalies, the steel cables reradiate near the ground. This may cause RF feedback problems in some high power installations with low level audio equipment located in a building near the base of the tower.

Strong currents may be induced when the steel guys are in the immediate vicinity of the radiators. If that guy passes close to the side of the radiator, the field on that particular side of the antenna element will induce currents in the guy wire. The radiator currents can become unbalanced and the impedance of the element is disturbed, changing its VSWR and radiation pattern.

Because of these effects, it is common practice to break-up the guys using insulators, fiberglass rods, or plastic guy cable, within 10 ft (3 m) of the antenna radiators.

When a CP antenna is side-mounted on a guyed tower, the vertically polarized field will have an appreciable component parallel to the guy wire in its aperture and will induce currents in the wire. If the guys are continuous, a progressive wave traveling toward the ground will result, and will radiate most of its energy before reaching the ground. The energy will be radiated in cones concentric with the wire. A small amount of the V-pol power will thus be bled off.

Porcelain Insulators

If the FM antenna is side-mounted on an AM tower, which usually will have metal guys and porcelain break-up insulators, those insulators will probably be spaced several FM wavelengths apart. The induced currents will form standing waves on the sections between insulators and radiate multilobed patterns into space at many angles from the wire axis. If the sections between insulators happen to be of a resonant FM wavelength however, currents in the guy wires and their radiated fields will be considerable.[22] A single isolated piece of guy wire with its ends insulated can only resonate in multiples of one half wavelength, so this spacing of insulators must be avoided. In fact, with the capacitive end loading of the insulators, the resonant length of wire will be somewhat less than one half-wave, so ⅜ wavelengths should also be avoided. A quarter-wavelength is much better, but this would be quite expensive as it requires insulators every 30 in. (762 mm).

Alternatively, the guys through the FM antenna aperture on the tower could be replaced with plastic cable, which is transparent to RF energy.[25]

Figure 4.12-18. A roll of plastic guy cable with eye and jaw end connectors in place. Diameter strength is equal to EHS steel stranded guying cable. (Courtesy Phillystran, Philadelphia Resins Corp.)

Nonconductive Guys

In order to eliminate FM pattern distortion, any guy cable going through the antenna level should be of non-conducting material. Plastic fiberglass (GRP) insulating rods as well as flexible plastic rope covered with a PVC plastic jacket can be used. The black jacket prevents deterioration due to ultra violet sunlight radiation, which may be injurious to the plastic strands of the rope. Plastic rope has been successfully used for more than 25 years.

The idea is to remove metallic RF conducting steel guy cables from within the antenna aperture. The rest of the guy may be of steel construction. The length of the steel guy from its attachment point near the antenna to a point well below the antenna is simply replaced with an equal length of fiberglass rods, or plastic rope.

Plastic rope is available in continuous lengths of up to 1,000 ft (304 m) and kits are available for installing the end fittings. The cable is quite flexible as the Figure 4.12-18 shows a 225 ft (69 m) length coiled up with its end fittings installed at the factory.

The cable may be purchased in strengths exceeding similar diameter steel guy cable. These strengths are shown in Table 4.12-8 for corresponding size of com-

Table 4.12-8

monly used extra high strength (EHS) steel guy wire. Sizes smaller and larger than shown in the table are available.

INSTALLATION PROCEDURES

If the installation is not properly planned and carried out, there may be unwarranted delay and cost associated with putting the FM antenna on its support tower. The following suggestions are offered to avoid unnecessary delays and expenditures.

Planning The Installation

Because of the extremely high cost of rigging services, it is essential to carefully plan the installation. Make sure that all parts are on hand.

The installation of the antenna should be planned by a technically qualified person who must supply accurate tower construction information to the antenna manufacturer. If this information contains errors, these will be carried through the design and fabrication of mounting hardware, and finally show up in the field to plague the installing crew, wasting time and money at every stage of the process.

The station should consider hiring a tower rigging firm that is financially qualified and mechanically well equipped to do the work. A written contract should exist between the station and rigging firm, with a fixed price. The rigging contractor should be licensed as a contractor in your state, and should post a completion bond. He should also supply an insurance policy holding the station harmless, and making the station and its personnel co-insured. Only in this manner will the broadcaster be protected in the event of injury or property damage.

The riggers should be knowledgeable about antennas and coax line, and should inspect the tower and check out the mounting design of the brackets before the full rigging crew arrives.

If any factors are discovered which appear to negate the installation design, contact the factory immediately. Particular attention should be paid to the following:

- Fit of mounting brackets to tower member
- Freedom from interference of the mounts with gussets, leg flanges, guys, and their attachment points, tower face members, and obstruction lights
- Compatibility of transmission line and antenna input coax terminals
- Location of transmission line run relative to antenna input terminals
- Use of fiberglass guys on the tower in the region occupied by the FM antenna (refer to the AM Guying section in this chapter)
- Availability of proper voltage, current, and cable size for deicers if required
- Adequacy of tower to carry the windload placed upon it by the antenna, particularly where radomes are used. This radome/antenna load should be checked by a competent structural engineer, as all antenna installations should be checked. This is usually required by the company carrying insurance on the tower.

Receiving And Unpacking

The boxes are usually numbered and the total number is indicated on each box; contact the shipper if not all boxes are delivered, or if equipment is received damaged. Do not store the material outdoors, boxed or otherwise.

As soon as the antenna is received, open and examine for shipping damages so that any necessary claims may be filed with the shipping company immediately. Check the material against the parts list and installation drawing.

The box with the installation drawing and instructions is usually marked. Open it first, so that the balance of the items may be easily identified and counted. Contact the factory immediately if any material appears to be missing or is damaged during transportation.

Do not call the riggers until all antenna and coaxial line at the site. Otherwise, unnecessary delays and costs may result.

Installation Tips

Broadcast antenna manufacturers furnish detailed installation procedures with their products. These instructions should be closely followed by the rigger. Together they will ensure a perfect installation saving time and money.

The following items are specifically called to the attention of the broadcast engineer (in addition to all those stated before) to permit proper installation and good performance for many years.

- Follow manufacturer's instructions. See that the riggers also read these instructions
- Do not leave antenna parts where rain or moisture can enter. Store indoors and keep units capped as received
- Do not allow dirt or other foreign matter to enter any coaxial part
- Protect all antenna parts from physical damage and abuse
- Hoist antenna members carefully, with a tag line to prevent damage by striking against the tower
- Install on the tower as indicated by the manufacturer's instructions, remembering that bay number 1 is the uppermost top unit
- Riggers should lubricate O-rings with a small amount of silicone grease before mating flanges
- The full complement of flange bolts must be used and they should be as tight as possible
- Tuners or individual element devices, if used, should be adjusted only after the entire antenna and tower installation has been completed
- Rigid transmission lines should be properly installed with two hangers per 20 ft (6 m) length, and with the inner conductor retaining pin on the top of each section

- If semi-flexible cable such as Heliax or Wellflex is used, it should be firmly tied down at least every 5 ft (1.5 m) for 3 in. (76 mm) line, and every 3 ft (1 m) for 1⅝-in. (43 mm) coax line. The line manufacturer's hangers should be used. The line should not be attached to the tower using wrap-lock straps
- After physical installation has been completed in accordance with the manufacturer's recommendations, the main transmission line should be pressurized with dry air through a dehydrator, air pump, or by using dry nitrogen gas. (See the Air Pressurization section in this chapter for more information.)
- Dry air or gas pressure should be maintained at all times. Most antenna warranties are not valid unless this is done. It is the riggers responsibility to make certain that the entire coax and antenna holds air pressure
- The antenna system should be checked by a qualified rigger every time the obstruction lights are replaced, or if lights are not used, at least once a year. The rigger should look for vibration and storm damage, loose or broken coax hangers, and signs of arcing across exposed insulators. A dry rag soaked in 91% isopropyl or other solvent alcohol or equal should be used to wipe clean all exposed insulators in each antenna element. (Do not use carbon tetrachloride!)

STRUCTURAL CONSIDERATIONS

Most FM antennas in the western hemisphere are installed on the sides of a steel tower, between 18 and 60 in. (45 to 152 cm) wide. The antenna and its transmission line together with all mounting brackets introduce wind loading, in addition to their dead weight. The live wind loading is a result of the amount of physical surface presented to the wind. It is sometimes called the *wind catch area*. This consists of either flat or round antenna members, coaxial lines, mounting brackets, and hardware, all represented as surfaces which are exposed to the wind.

The dead weight of the antenna system is fixed and is always present on the tower. The live load is a variable, depending on the wind velocity, and is added to the dead load for the total amount present.

The standard wind load starts with an assumed wind velocity of 87 mph (139 m), which will produce a push of 35 lbs per square foot. (170.8 kgs/sq.m) With lesser wind speeds the wind push is less, and more with higher velocities. Various building codes determine the rated winds to be considered in the design of the tower system. While most of the United States has a 35 lb per square foot minimum rating, some parts of the country have higher requirements due to higher wind velocities. Some insurance companies may require even higher safe wind ratings.

ANTENNA POLE MOUNTING

Nonsymmetrical antennas may also be installed on a round pole, made of various diameters of steel pipe. Several antenna manufacturers supply these as a complete system and will optimize the horizontal plane pattern. The advantage of pole mounting on top of a tower or building is that the pattern may be more easily contoured. This provides more signal in the service area since the antenna orientation is not limited by a fixed triangle formed by a guyed tower.

TRANSMISSION LINE SYSTEMS

Two types of coaxial transmission lines may be used to feed FM antennas. One uses rigid coaxial line sections, each 20 ft (6.09 m) long and requires elbows, flanges, spring hangers and other devices.

The other has a semi-flexible coaxial line which is available in either air or foam dielectric, with fixed hangers. Semi-flexible cable is available on a spool whose diameter depends on the line size. EIA end flanges mate to the antenna flanges as well as other RF equipment. A typical semi-flexible coaxial transmission line layout is shown in Figure 4.12-19.

A supply of dry air should be used with all air dielectric transmission line. Its purpose is to keep out moisture, which may find its way into the line. Dry air keeps the moisture from covering the internal plastic insulation, and thus the potential for arcing is greatly reduced. It also keeps the internal copper from corroding. Copper which has been exposed to moisture will turn dark brown and oxidize after time. Rigid as well as semi-flexible line in the 3 and 3⅛ EIA size which had not been pressurized have been measured with increased attenuation of nearly 4 dB per 100 ft (30.4 m)

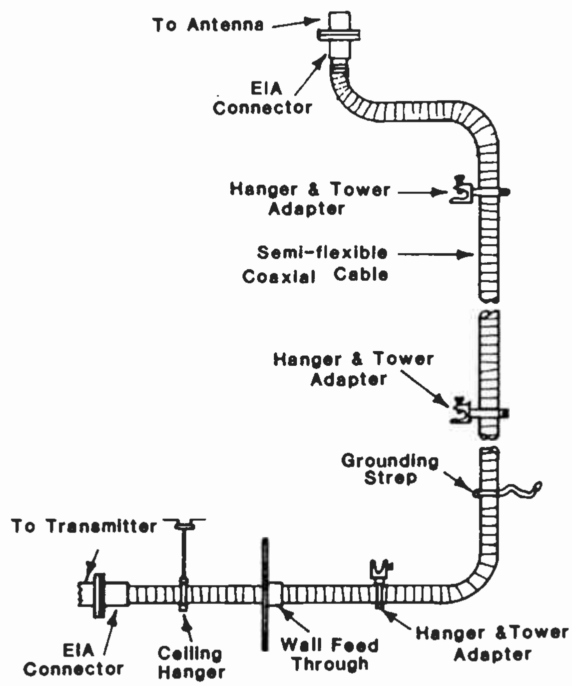

Figure 4.12-19. Typical semi-flexible coaxial cable installation on a tower. Number of various pieces of hardware depend on length and the diameter of the cable.

Table 4.12-9
Coaxial transmission line (Characteristics At 1000 MHz)

Line Type & Number	Nominal EIA Size	Attenuation in dB	100 Ft Eff. %	Safe FM Power-kW

-Rigid-				
1213-1	1-5/8	.191	95.7	10.0
1313-1	3-1/8	.096	97.8	40.0
1413-1	4-3/8	.070	98.4	81.0
1613-1	6-1/8	.050	98.8	161.0

at 100 MHz. This is a power loss of 60%. (See the section on Air Pressurization on how this may be accomplished.)

Popular types and sizes of coaxial cable transmission line are shown in Table 4.12-9. The most popular are the semi-flexible air cables.

The safe power ratings shown in Table 4.12-9 are for a perfect VSWR of 1.0:1. It is considered good engineering practice to derate this by dividing the power in kilowatts by the expected VSWR. For example three inch Heliax rated at 36.8 kW at 100 MHz and divided by 1.1 derates it to 33.45 kW. Other increases and decreases of coaxial cable ratings may be found in the catalogs of most manufacturers of transmission lines.

Ratings are for a VSWR of 1.0:1; ambient temperature of 75°F (24°C) with one atmosphere of dry air pressure. Rigid line is rated at 122°F (50°C). The LDF and HJ series are manufactured by Andrew Corp. of Orland Park, Illinois while the rigid line is by Shively Labs., of Howell Labs. Inc. Bridgton, Maine.

AIR PRESSURIZATION

If the antenna is operated without positive pressure of dry air or nitrogen, the manufacturer will not assume responsibility for failure under power. Moisture or even the accumulation of water within the coaxial transmission line is a very serious matter. Its presence causes the VSWR to rise. When a sufficient amount of moisture is present, arcing will take place burning the line or antenna radiating elements. High humidity or moisture will cause the inside of the coaxial transmission line to corrode over time, thereby increasing the line loss. For this and other reasons, the entire antenna system must be dry air pressurized.

After the antenna is installed and the transmission line connected, the system is purged with dry gas or dry air to remove trapped moisture before RF power is applied. A manually opened or pressure actuated purge valve is installed in nearly all FM antennas made by American firms. When the gas pressure is raised to 10 psig (0.68 atmospheres), the automatic pressure relief valve (if the antenna has one) will open up letting moist air out. The complete system purge requires a considerable volume of dry gas.

Before expending this amount, it is good practice to perform a quick check for major leaks. The system pressure is raised to a point below the relief valve setting, such as 8 psig (0.48 atmospheres) the source of supply shut off. A pressure gauge should be installed on the antenna side of the shut-off valve. The pressure, when corrected for temperature, should not fall to less than half its initial value in a 24-hour period.

If the pressure loss is more than this, the system should be checked with a leak detector, or soap suds, to locate the leak. A pinched or missing O-ring is the most common cause for large leaks.

Once the system is known to hold pressure, it should be purged with dry air or gas. Either must be dry enough to have a dew-point well below the coldest temperature expected to be encountered. When using nitrogen, it should be of the oil-dried type, to remove nearly all the moisture from the gas.

Five to eight psig (0.34 to 0.48 atmospheres) should be maintained in the system at all times to ensure that no moisture will be able to enter. Very small leaks will pull in moisture, if the pressure is lower than suggested above, when the transmitter is turned off nightly. This is due to the pumping action due to expanded dry air/gas pressure cooling down, and contracting below the outside air pressure, during cold ambient temperatures.

PROTECTION FROM ICING

High Q antennas are subject to increased VSWR ratios as well as pattern distortion, with light to moderate coatings of ice. Low Q antennas such as the panel type are usually not affected in this manner. Where climatic conditions cause sufficient ice or in some cases snow to affect the antenna's performance, there are two remedies. The radiating element may be covered with a plastic cover, or, it may be electrically heated to melt or prevent the formation of ice on its sensitive surfaces.

Electrical Heaters

By far the more popular method of deicing is to order electrical heaters at the time the antenna is ordered. Electrical deicing equipment is supplied as an option and is factory installed. Kits are furnished for interbay connections, but the broadcaster must supply power from the building to the center of large arrays, or the bottom element on smaller antennas. Local electrical codes of course must be followed.

While a thermostat may be used with small total deicer wattages, a power relay operated by such a device is required and furnished with most electrical deicer kits by the antenna supplier. Due to high power costs, a sophisticated deicer control, which operates when both temperature and humidity conditions produce sleet or icing, is often required.

Most deicers use a resistance heating element which is inserted inside the antenna radiator arms. One manufacturer, however, uses a different method, dropping the 230/240 volts to a few volts with a transformer located at each bay level. The low voltage is passed through the ice sensitive arms of the radiator and connected to the far ends by a heavy teflon coated wire. The current return is by the stainless steel antenna element, whose ohmic resistance is sufficient to produce enough power heat loss to melt or keep the ice off. This method is becoming obsolete as the transformers are expensive and heating costs are rising, as hourly electrical rates go up. The voltage dropping transformers are not as efficient as direct heaters.

A word of caution when selecting a FM antenna with electrical heaters. Some deicers use 1 kW of power for each bay as previously described and increase the wind loading by 225%. Others have a switchable power option feature using 125/500 W per element, with only a 15% increase in windloading, when compared to an antenna without electrical deicers. The continuing cost of electrical deicers is a consideration of the operational cost of the station and should not be overlooked.

Automatic deicers are those with a thermostat for mounting near the antenna for accurate temperature sensing of the actual ambient temperature. The temperature zone of +20°F to +35° (−7°C to +2°C) is generally the most likely icing range, depending on humidity conditions. Deicers should be turned on at +35°F, prior to ice formation, because it is better to prevent icing than to remove it once it is formed. Power should be turned off when the temperature goes below +20°F since ice does not usually form below this temperature. Figure 4.12-20 shows electrical deicers being wired.

Figure 4.12-20. Rigger finishing electrical tie in box for deicers. Looped stainless steel heaters were factory installed in the four arms, plus one in the feed support boom.

Radomes

A radome is a protective dielectric housing for an antenna radiating element. Its function is to protect the antenna not only from ice, but snow and physical damage due to ice dropping from above. Radomes also protect the radiating element from environmental corrosive atmospheres.

The primary purpose of using radomes on FM antennas is to prevent the VSWR from rising with the formation of ice, if the site and height causes icing to occur during the winter months. Ice formation detunes high Q radiators, increases the VSWR, and causes vertical plane pattern changes. Figure 4.12-21 shows a typical radome enclosing a radiator.

Ice may form on the radome but does not particularly affect the operation of the radiator if that ice is kept at least 0.05 wavelengths from the sensitive portions of the antenna element.

Radomes are particularly desirable in heavy icing environments where deicers are not adequate even with very high heat density. They are also useful in protecting antenna elements from falling ice when they are so exposed.

Radomes are cost effective with single channel high Q antennas where electrical deicer heating power costs are expensive. The deicer power cost is a continuing one, while radomes are a one time capital investment, which may be depreciated over time.

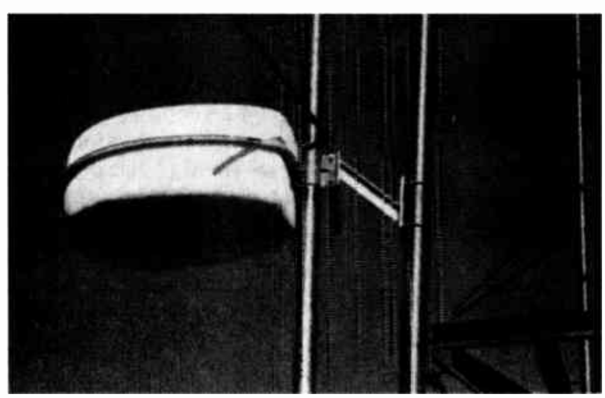

Figure 4.12-21. Radome over radiating element. Transparent to RF, it keeps ice from detuning high Q radiator.

Radomes are generally composed of low-loss dielectrics with low values of dielectric constants and loss tangents. Laminated fiberglass, using glass cloth reinforcements, has a constant of about 4.1 and a loss tangent of about 0.15. Water absorption by the radome increases its dielectric constant and loss tangent. Materials which do not easily absorb water or those treated with a protective gel coat are often used to shed water and prevent the adhesion of ice.

Good radome designs take into consideration operating temperature, a relative humidity of 100%, safe wind pressures, ice, hail, snow loads, rain adhesion, wind and supporting tower vibration, fire retardant plastic, and the ability to safely withstand air contaminants over the useful life of the antenna. All these factors increase the cost, but are necessary for long, useful life. Radome shapes are dictated by the form of the radiating element in most instances.

In all cases radomes are supplied by the antenna manufacturer, and usually supplied in two pieces which are bolted together with stainless steel fasteners.

LIGHTNING

Because FM towers are usually located on high ground, hilltops, or high buildings, they require lightning protection since they are likely recipients of lightning strikes. The type of damage that can be caused by lightning to a FM tower varies. Smaller coaxial lines will usually melt; larger coax (1⅝, 3⅛) will also melt in some cases, and others will conduct the heavy current into the transmitter building to do damage there.

The FM antenna itself may heat, arc, melt, and otherwise be damaged. Holes in the outer conductor, burns, and melting at flanges are common. Teflon or polyethylene insulation will burn, depositing a film of carbon, causing further damage if RF from the transmitter continues after the strike.

Protection of the FM antenna system may be provided to some degree, by taking several precautions. The top of the tower should have a lightning rod, about 1 ft (0.3 m) higher than the uppermost obstruction light part. The FM antenna itself should be firmly grounded to the tower. If the coaxial cable is buried between the tower and the transmitter building, it must be at least six ft away from any tower base grounding system copper wire or strip.[26]

A ground system should be located immediately around the base of the tower. This should have a direct current loss of less than 10 Ω to earth ground. This low resistance may be obtained by using ground wires buried in the soil. Six radials spaced 60° if possible, buried as deep in the soil as possible and running out up to 150 ft (46 m) each, should provide a suitable ground of less than 10 Ω, even if the soil is shallow or rocky.[26]

Guyed tower anchors should also be grounded. This is covered in the chapter on *Design, Erection, and Maintenance of Antenna Structures*. It is important to install the proper number of ground rods and/or copper wire radials in order to obtain a connection to earth ground of less than 10 Ω. In any event these ground rods or radial wires must be tied together with number AWG 4 or larger copper wire, or copper strap 2 in. (5 cm) minimum width. This is to provide for thousands of amperes of current flow for less than one second in the event of a direct lightning hit.

If the FM antenna is located on an AM insulated base tower, then the spark gap should be set at the lowest point providing protection for the highest AM modulation peak voltage.

Another way to protect the FM transmission line isolator (if one is used), as well as the tower and FM antenna, is to use a RF choke across the insulated tower base. This tends to reduce the static build-up voltages due to passing thunderstorm clouds, snow, hail, or dust storms. Arcovers due to these sources usually do not cause damage, but may trip the FM transmitter reflectometer since they will create a current flow through the reflectometer circuitry.

If the base insulated tower supporting the FM antenna is located in an area of regular thunderstorms, another way to protect both antennas from lightning is to ground the AM tower at the base, and shunt feed it. Several excellent methods exist. The folded unipole method not only grounds the tower for lightning purposes, but improves the VSWR bandwidth, so necessary for AM stereo. (See Chapter 4.8, *AM Antenna Systems*, for several suggested methods.)

FM SCA MULTIPLEXING

With a 92 kHz subcarrier and 110% modulation, intermodulation products may be created due to mixing of the various subcarriers with their own harmonics within nonlinear devices. One such nonlinear device can be the antenna system.

Antenna linearity is determined by its VSWR response curve versus frequency. Phase delay in the antenna system is also important. In the past, with 67 kHz being the highest SCA frequency, the ±100 kHz bandwidth was considered sufficient. Now with a 92 kHz subcarrier and 110% deviation (82.5 kHz), the minimum bandwidth is ±130 kHz under 1.1:1 VSWR.[27] (See VSWR Bandwidth in this chapter for more specific requirements and recommendations.)

Tests have shown that 92 kHz is the frequency of choice for a new aural SCA service after 67 kHz.[28] The 92 kHz subcarrier produces lower intermodulation product levels and less interference to the main channel stereo service than 67 kHz.[29] It may be successfully operated in addition to stereo and existing SCA services.

Other nonlinearities in the exciter, and transmitter, plus multipath reception, receiver misalignment, and user mistuning are contributions to the received intermodulation distortion of the baseband signals. In addition these products can cause small levels of audible swishing beat notes in some types of FM receivers.

SPURIOUS FREQUENCIES

Interference to other stations within the FM broadcast band as well as to other services outside the band can be caused by RF intermodulation product energy developed between two or more FM broadcast transmitters. It may be due to coupling through a diplexer or coupling between two antennas. This phenomenon has been well documented.[12]

Detailed information on the susceptibility of various types of transmitters to interference from other collocated transmitters has not been thoroughly investigated. A method has been devised by which the mixing loss between two transmitters can be accurately characterized.

When RF energy from two or more transmitters is combined, new spectral components are produced by mixing the fundamental and the second harmonic of each of them. The dominant intermod product generated by each transmitter is at twice the transmitter's frequency. For example, 101.1 and 102.7 transmitters would produce two intermod signals appearing on 99.5 and 104.3 MHz.

Second harmonic traps or low-pass harmonic filters in the transmission line of either transmitter prior to the diplexer have little effect on the generation of intermod products. This is because the harmonic content of the interfering signal entering the transmitter output circuit has much less effect on intermod generation than the harmonic content within the nonlinear device itself. The resulting intermod falls within the passband of the low-pass filters and outside the reject band of the second harmonic traps, so these devices offer no attenuation to intermod products.

Even the perfect diplexer by its very nature will reflect some of the undesired energy back to each transmitter, generating intermod products. The key to this problem is to keep that undesired power level as low as possible using proper transmitter output circuitry and tight diplexer specifications. Diplexed transmitter installations should be routinely checked for the presence of excessive intermod products.

HARMONIC FILTERS

FCC Rules Section 73.317(d) calls for the harmonics of FM transmitters to be up to 80 dB or more below the transmitter output. This requirement is usually met by using a low-pass filter which passes the station carrier frequency power but attenuates its harmonics.

The transmitter provides some harmonic attenuation of course, and is usually 25 to 38 dB for single ended amplifiers. The worst case harmonic is the third. Harmonic filters by several firms provide a minimum of 50 dB for harmonics from the second through the tenth. Adding the transmitter attenuation to that of the filter normally provides more than the required level.

The high level of rejection is made possible by using high-impedance (inductance) and low-impedance (capacity) coaxial sections for m-derived three to five section filters, with half-pi end sections. Harmonic filters are commonly made in three production schedules. One firm actually adjusts them to the customers operating frequency, so that there are no attenuation gaps in the higher harmonics. They are not tunable outside the factory as the insertion loss, and attenuation along with pass band VSWR are closely related. It requires sophisticated knowledge and equipment to properly adjust.

The insertion loss in the pass band varies from 0.05 to 0.08 dB while the rejection from the second through the tenth harmonic is from 50 to 60 dB, depending on the number of internal filter midsections. The VSWR in the pass band varies from 1.05 to 1.1:1. Harmonic rejection is due to the very high VSWR on the harmonic frequencies which may be as high as 15 to 1. This rejected power is passed back to the transmitter amplifier.

Harmonic filters are available in straight rigid coaxial line sections and may sometimes be pressurized. Power capacity varies from 10 kW for 1⅝ EIA line size to 50 kW for the 6⅛.

ACCESSORY ANTENNA SYSTEM EQUIPMENT

Several other devices are associated with the antenna system. The dry air pressurization of coaxial transmission line was discussed under that heading in this chapter.

Reflectometers

The reflectometer is a device for detecting the ratio of power flow from the transmitter to the antenna (forward) and the rejected power back from the antenna (reverse). A short coaxial line section about 12 in. (305 mm) contains diode detectors, coupling loops and terminations to produce DC current, which drives a suitable VSWR meter.

Reflectometers are wide band devices and therefore must be placed AFTER the harmonic filter. Putting them between the transmitter and the filter causes them to read the rejected harmonic power along with the reflected, thus giving an erroneous reading.

Dummy Loads

A very useful test device in an antenna system is the terminating load. At least one is needed when two amplifiers are combined and fed to the antenna, or when a number of diplexers are used in a community antenna arrangement. Dummy loads are available in several power levels up to 50 kW or more and are cooled by air or water.

RF Switches

Often used with a dummy load, coaxial line switches are available to provide electrical or manual switching of transmitter power to diplexers, antennas, standby transmitters, etc. They typically are not pressurized.

4.13
FM COMBINING SYSTEMS

ROBERT A. SURETTE
SHIVELY LABS, BRIDGTON, ME

INTRODUCTION

Transmitting several frequencies from a single broadband antenna system requires the use of a combining system, or combiner, composed of RF filters and an interconnecting transmission line. In general, a combiner can be categorized as one of three types: *runout*, *branched* (star point) or *balanced* (constant-impedance). Any of these types may employ band-reject (notch) or band-pass filters. This chapter discusses the use of filters and other components in FM combiners.

Applications

For years, the FM channel was relatively simple, with only the main channel audio (L + R and L − R) and a stereo pilot. In the mid-1980s, the 67 kHz (Subsidiary Communications Authorization (SCA) became more widely used, then the 93 kHz SCA followed. The 1990s brought Digital Audio Broadcast (DAB).

Each of these developments has widened bandwidths. Updated technologies have been needed to provide the required amount of isolation from other frequencies, while passing a wider bandwidth within each FM channel.

Why Combiners Are Used

As populations migrate to the suburbs, it has become more desirable to construct large broadcasting facilities which can reach these heavily populated areas from more central locations. Of course, these prime locations have become more valuable, so it makes sense to use each to its fullest potential. This can best be done by sharing a transmitter site and a common antenna among several users. To accomplish this, the broadcast industry uses combiners of various types and sizes. For example, in San Francisco (Mt. Sutro), Toronto (CN Tower), Montreal (Mt. Royal), New York City (Empire State Building), and Chicago (John Hancock Building), huge towers or towers on skyscrapers have been used to consolidate as many broadcasting facilities as possible, including VHF-TV, UHF-TV, FM and land mobile communications services. This approach has proven very effective, not only in using real estate economically, but spreading the tower costs over many users. In fact, the CN tower carries virtually all the services in the Toronto area. These installations, of course, employ combining systems to prevent interference among services.

Group ownership of FM stations in a market has led to a proliferation of combined stations. And with the implementation of DTV systems, FM stations are being forced off existing TV towers, making it even more imperative that they share tower space, and increasing the demand for combined systems.

FCC Isolation Requirements

Why not just merge two or more signals in a tee and send them to a common antenna? Because unless they are stopped by some means, the signals will backfeed into each other's transmitters, where spurious intermodulation products (spurs) will be generated within the final amplifier stages of the transmitters, depending on the spacing of the stations. These spurs will then be transmitted up to the antenna and broadcast, causing interference to other FM stations, TV Channel 6 and the aviation band—so care must be taken to prevent them. To keep a transmitter from generating spurs, it must be isolated from unwanted signals by at least 40 dB. Therefore, the basic design criterion for a combiner is to provide 40 dB of isolation, plus a 6 to 10 dB safety margin. The closer the spacing of the frequencies between transmitters, the more filtering is required to attain the 46 to 50 dB of isolation. The farther the spacing, the less filtering is required.

FCC Rule 73.317(d) specifies that spurs more than 600 kHz removed from the carrier be attenuated 80 dB or (43 + $\log_{10}$ (power in watts), whichever is the lesser attenuation) below the carrier frequency.

Modern FM band-pass combiners yield a total isolation of 75 to 80 dB, and when added to transmitter losses of 13 dB, ensure that the 80 dB FCC spur rule is not just met but exceeded.

History of FM Combiners

Dr. Andrew Alford designed several of the early combiner systems in the United States. A major installation was a multichannel system on the Empire State Building in the mid-1950s. This system used pairs of quadrature hybrids with a phase delaying cavity in one leg of each hybrid pair. In the 1960s (for the John Hancock Building in Chicago) Dr. Alford designed a runout combiner system, again using quadrature hybrids. However, the phase matching was accomplished with coaxial runout lines instead of cavities, to combine 10 stations into one broadband antenna. Both of these early combiners have since been replaced by balanced bandpass systems.

In the 1970s, RCA built a three-station runout combiner with the antenna on top of the tallest building (then) in downtown Miami. Unfortunately, a few years later, an even taller building was built across the street! This system was then abandoned and the stations moved to a modern high powered, expandable balanced combiner system, using band pass filtering and, for the first time, group delay equalization modules, in the mid 1980s.

The same purpose has been accomplished in other ways. The Sears Building in Chicago carries a multistation antenna system where, instead of a combining system with a common feed, each station feeds a single-level panel antenna. The antennas are mounted closely together on the tower, well within each other's zone of interaction, so to prevent interference from the others, each transmitter feeds through a three-cavity band-pass filter. To help reduce the interactions, antennas whose frequencies are close-spaced were physically separated as far apart as possible.

In other parts of the world, notably Europe, higher population density and government ownership of broadcasting have led to much earlier adoption of combiner technology, although at relatively low power levels. Many large combined sites have existed for years, such as at the Eiffel Tower and various BBC facilities in Britain.

COMPONENTS OF COMBINERS

Tee or Star-Point Junctions

A *tee junction*, shown in Figure 4.13-1, is a coaxial component that provides for two RF signals to flow into a common path; a *star-point junction* is a tee with more than two input paths. This basic coaxial component is one of the building blocks of a branched combiner.

Resistive Loads

Resistive loads, often called *dummy* loads, are used in many applications and can be manufactured in many sizes and impedances depending on the requirements. In a dummy load, incoming power is absorbed and converted to heat. The heat must then be dissipated to the surrounding air, so the power rating of a dummy load is determined by the size of the resistor and the amount of heat that can be dissipated before the resistor overheats and fails. If enough resistors can be chained together with enough cooling, they can dissipate almost an unlimited amount of RF energy. Most coaxial systems use either 50 or 75 Ω dummy loads, depending on the base impedance of the system.

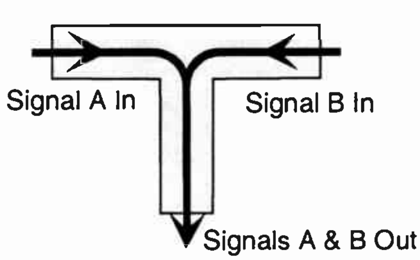

Figure 4.13-1. Tee junction schematic.

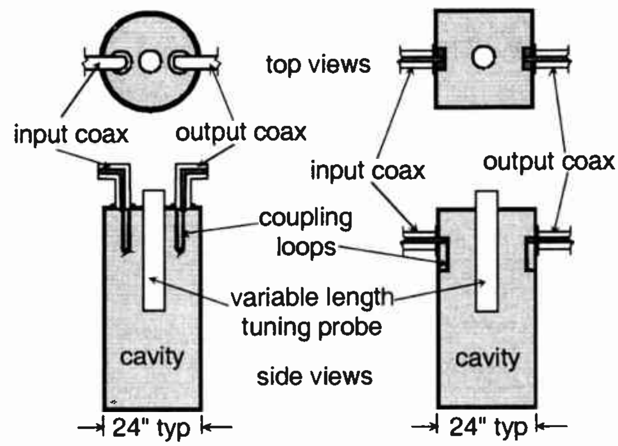

Figure 4.13-2. Band-pass cavity filter designs.

Filters

Filters sort RF frequencies, attenuating some while allowing others to pass readily. Depending on the design, a filter may either *attenuate* (band-reject type) or *pass* (band-pass type) a narrow bandwidth.

The performance of a filter can be expressed in several ways. Common methods include plots of transfer efficiency (frequency response and insertion loss), impedance (Smith Chart) or VSWR, and phase delay (group delay), all as a function of frequency.

Band-Pass Cavity Filters

Figure 4.13-2 shows the basic mechanical configuration of a band-pass cavity filter. When RF energy is applied to the input coupling loop, the loop inductively couples the energy into the cavity. Energy is transferred through the cavity and inductively coupled to the output coupling loop.

The resonant frequency of the cavity is tuned by adjusting the length of the tuning probe. The transfer of energy is maximized at the resonant frequency. Therefore, a filter of one or more identical cavities can be used to attenuate frequencies other than the resonant frequency.

Frequency Response

Energy transfer through a band-pass filter is highest, or least attenuated, at the resonant frequency, and drops off at frequencies above and below that frequency. This *frequency response* is the fundamental property that enables a filter to sort frequencies.

If it were possible to design an ideal filter, its frequency response plot would be as shown in Figure 4.13-3. Response would be flat within the pass band, with a vertical roll-off at the edges of that band.

Curve A of Figure 4.13-4 shows the frequency response of a real-world single-cavity band-pass filter. Note that the energy transfer is highest at the resonant frequency (f_0). The curve is not perfectly flat within the pass band, and drops off gradually away from f_0.

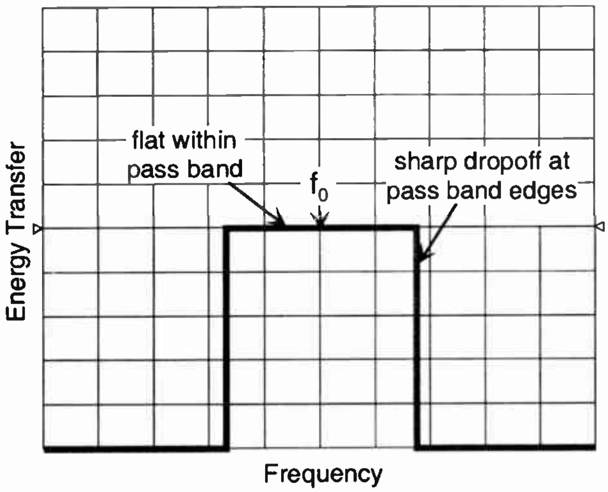

Figure 4.13-3. Frequency response for ideal filter.

Insertion Loss

Even at the resonant frequency, energy transfer is not perfect; some energy is lost along the way. The efficiency of a filter at the resonant frequency is expressed (inversely) as *insertion loss;* that is, the loss of energy at that frequency. For a cavity filter, the lost energy is converted to heat and dissipated in the metal surfaces of the cavity. A cavity that is larger in size is more efficient, in that it will provide a lower insertion loss at the resonant frequency with comparable frequency response. Adjustment of the coupling loops also affects insertion loss (curve B of Figure 4.13-4 shows the effects of coupling loop adjustment).

Our theoretical ideal filter would show no insertion loss in the pass band.

Group Delay

The signal takes a finite amount of time to pass through the cavity, and just as more energy is lost, so is more time taken at non-resonant frequencies. Figure 4.13-5 is a plot of time versus frequency and shows that as the frequency changes further away from f_0, the signal takes more time to pass through the cavity. This is termed *group delay difference,* or group delay. Excessive group delay within the pass band results in signal distortion.

An ideal filter would have no group delay difference; that is, the curve would be a horizontal line, at least across the pass band.

Today's complex broadcast signals use the full channel bandwidth, so it is important to limit group delay. Modern group delay equalization devices compensate for this type of distortion.

A group delay equalizer consists of a *hybrid* and two open-ended band-pass filters, which selectively delay the carrier frequency relative to the sidebands (Figure 4.13-6).

When a group delay equalizer is cascaded with a band-pass filter module, it results in minimal group delay across the pass band, as shown in Figure 4.13-7.

In FM, a group delay equalizer can be installed either at the combiner input, using high-power components, or between the transmitter's exciter and the intermediate power amplifier (IPA), using similar low-power components.

Impedance

Current flow in any RF circuit must overcome resistance, capacitive reactance and inductive reactance. The vector sum of these is termed *impedance.* Because this is a complex function, it may only be fully represented on a complex diagram known as a *Smith Chart.* A full discussion of Smith Charts is beyond the scope of this

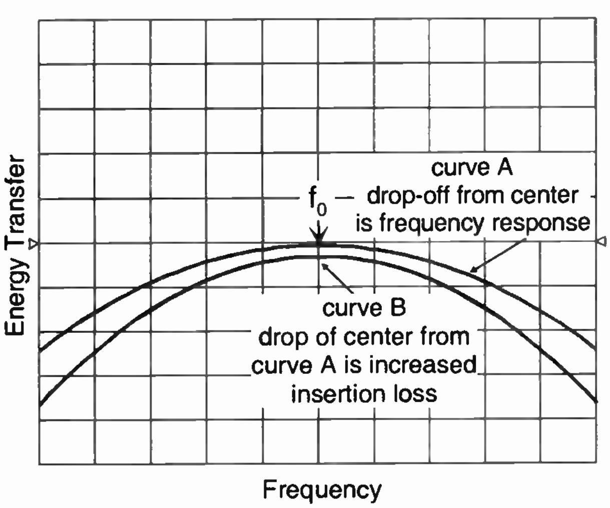

Figure 4.13-4. Frequency response and insertion loss, single-cavity band-pass filter.

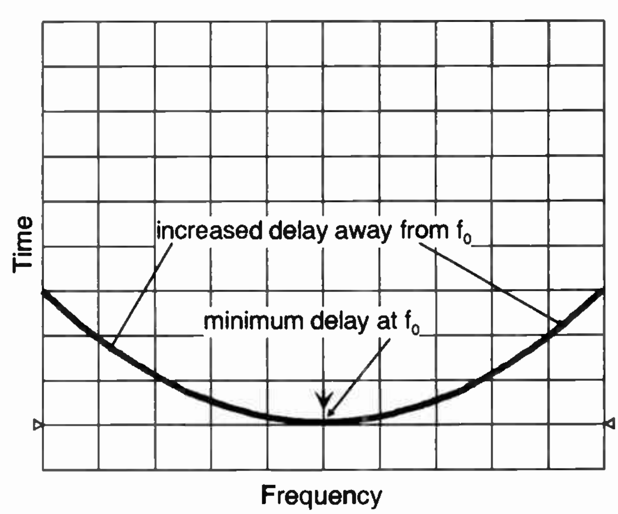

Figure 4.13-5. Group delay for band-pass filter.

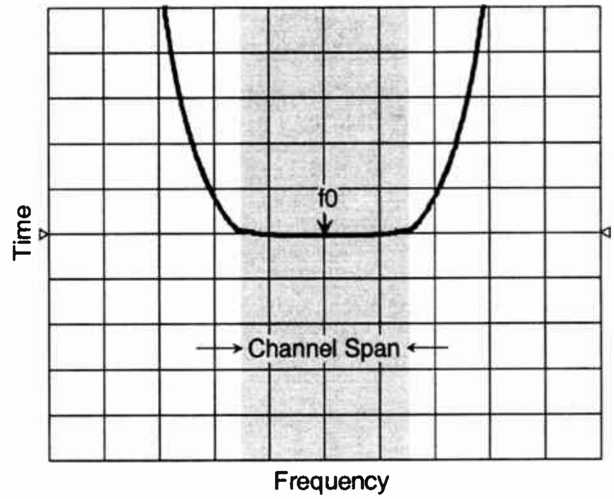

Figure 4.13-7. Group delay curve for a band-pass filter balanced combiner with group delay equalizer.

chapter,[1] but explanation of a few basic features will aid in the understanding of filter performance and tuning.

Figure 4.13-8 shows a Smith Chart. The center horizontal axis (A) represents a state of pure resistance. In a properly tuned system, this state exists at f_0, the resonant frequency, where the inductive and capacitive components cancel each other out. The center point on line A represents the resistive value characteristic of the system being considered (typically 50 or 75 Ω). To the left, the resistive value decreases, approaching a short circuit (0 Ω); to the right, it increases, approaching an open circuit (∞ Ω).

The region above the horizontal axis represents a state when the vector sum of the circuit is inductive in nature. Conversely, below the axis, the circuit is capacitive. Any point on the chart may be expressed as R ± jX, where "R" is the resistive component, "j" is a constant and "X" represents the magnitude of the net inductive or capacitive component of the circuit.

An ideal filter (assuming a 50 Ω system) would be plotted as a dot at the center of the chart, representing a pure 50 Ω resistance throughout the pass band.

Figure 4.13-9 shows the Smith chart for an optimally-tuned single-cavity band-pass filter (50 Ω characteristic image dome). At the resonant frequency f_0, the impedance is pure resistance and 50 Ω at chart center. If the frequency is changed away from f_0, the inductive and capacitive components grow, forming a vertical arc.

The small circles (beads) on the curve indicate the pass band. Usually, a range of ±150 kHz is considered an acceptable pass band for an FM filter system.

[1] *See* Carron, Wilfred N. *Antenna Impedance Matching.* American Radio Relay League (ARRL), Newington, CT, 1989, *or* Besser, Les. *The Smith Chart and Its Applications.* Besser Associates, Los Altos, CA, 1992.

An ideal cavity filter would have a 50 Ω impedance (unity VSWR), no insertion loss, no group delay, and flat frequency response within the pass band. As Figures 4.13-4, 4.13-5 and 4.13-9 show, actual cavities do not meet these ideals. Reaching the aforementioned characteristics is a goal, within the limits of practicality, of filter system design.

If circles were drawn around the center point, each would be a locus of points of equal VSWR; for example, circle B in Figure 4.13-8 represents a VSWR of 1.1: 1. Points within the circle then represent conditions of VSWR less than 1.1:1.

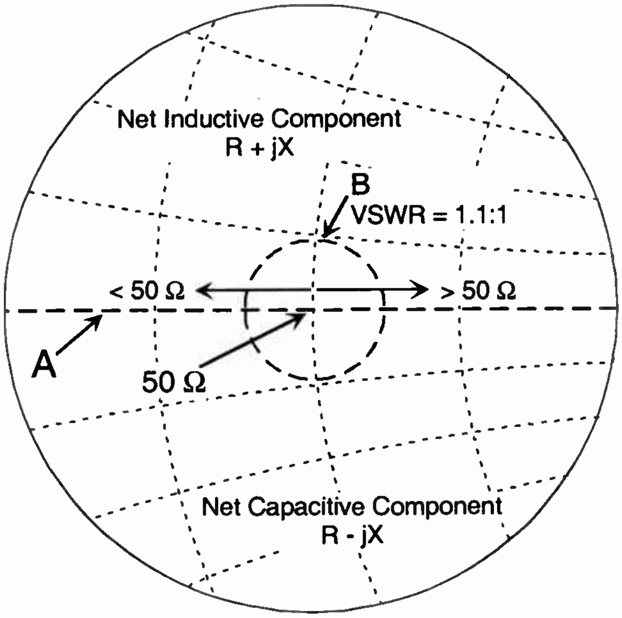

Figure 4.13-8. Smith Chart components.

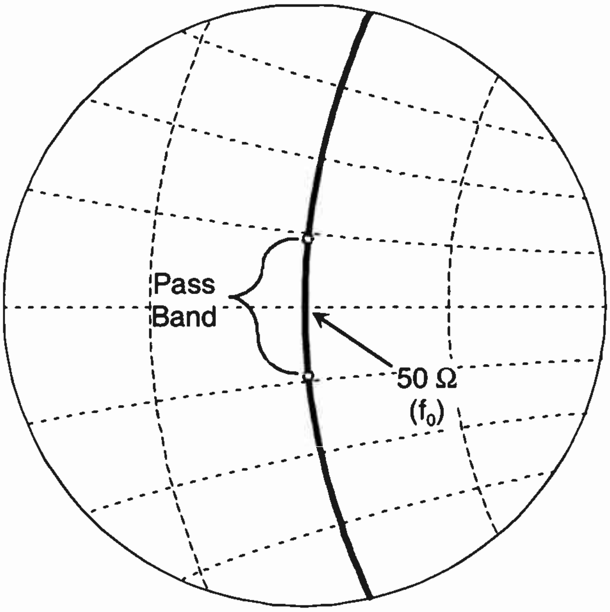

Figure 4.13-9. Smith Chart for a single-cavity band-pass filter.

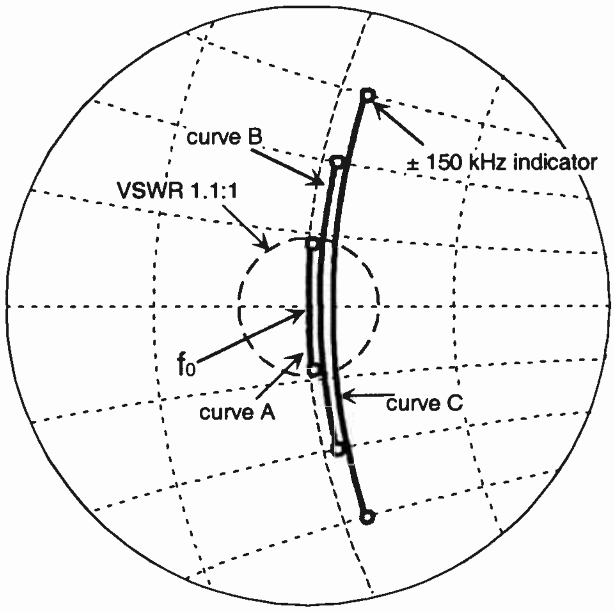

Figure 4.13-10. Impedance diagram, single-cavity band-pass filter, showing effects of loop adjustment.

Single Band-Pass Cavity

The physical size of the cavity is established for the purpose of power handling. The placement, size and rotation of the coupling loops are then chosen to provide coupling which will optimize the cavity performance for a given application.

In Figure 4.13-4 while the center of curve B has dropped below curve A, the outer edges have dropped even more. Although there is increased insertion loss at f_0, there is gained increased *isolation* away from f_0. This is often a favorable trade-off.

Figure 4.13-10 is an impedance diagram showing the same process. Curve A (truncated for emphasis) is an optimally tuned cavity. The curve passes through the center of the chart ($R = 50\ \Omega$), and the entire 150 kHz pass band (between the beads) is within the circle representing VSWR = 1.1:1.

As the coupling is adjusted to achieve increased isolation, (curve B) and still more isolation (curve C), the center of the curve moves into the $R > 50$ area to the right of chart center. In addition, the beads representing ± 150 kHz move outward, well outside the 1.1:1 VSWR area. The trade-off between increased isolation and decreased transfer efficiency can be easily seen.

Generally, a filter system is considered adequate if it provides a VSWR of 1.1:1 over a frequency range of ± 150 kHz. This is termed the bandwidth of the filter system. In most cases, a single band-pass cavity will not yield this much bandwidth. To increase the isolation and improve bandwidth, a second cavity may be cascaded with the first, as shown in Figure 4.13-11.

When two identical cavities are coupled 1/4-wave apart, the impedances superimpose themselves as shown in Figure 4.13-12. Note that Figure 4.13-12 shows two Smith Charts superimposed 180° apart. The beads representing the bandwidth fall on a VSWR circle of about 1.3:1.

When their impedances are added together mathematically, due to phase cancellation, the bandwidth improves to about 1.1:1 VSWR as shown in Figure 4.13-13.

Curve A of Figure 4.13-14 shows the frequency response of the two-cavity filter.

When still more isolation is required, more cavities can be added. Curves B and C of Figure 4.13-14 show the frequency responses of a three-cavity system and a four-cavity system, respectively. As more cavities are added, the curve becomes squarer—flatter across the pass band, with a sharper roll-off; that is, it starts to approach our ideal filter, shown in Figure 4.13-3.

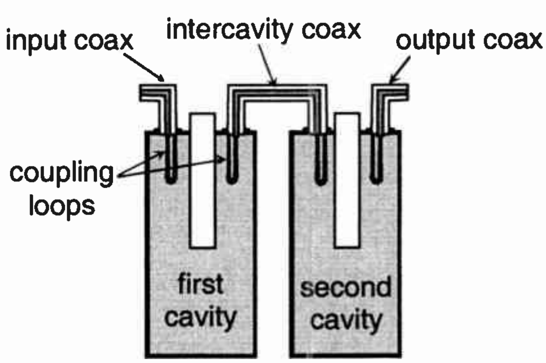

Figure 4.13-11. Loop-coupled cavities.

Figure 4.13-15 shows Smith Charts for a three-cavity system and a four-cavity system. Note that the beads indicating the ±150 kHz points are well within the 1.1:1 VSWR circle.

Tuning Considerations

It is important to remember that filters should always be designed for best real-world *overall* performance. A little performance may have to be sacrificed in one parameter to improve performance in another.

As cavities are added, frequency response is improved—but at the cost of increasing group delay. In a four-cavity system, the group delay curve becomes so steep it is unacceptable (Figure 4.13-16).

Therefore, tuning can be modified to decrease group delay to an acceptable level, as shown in Figure 4.13-17.

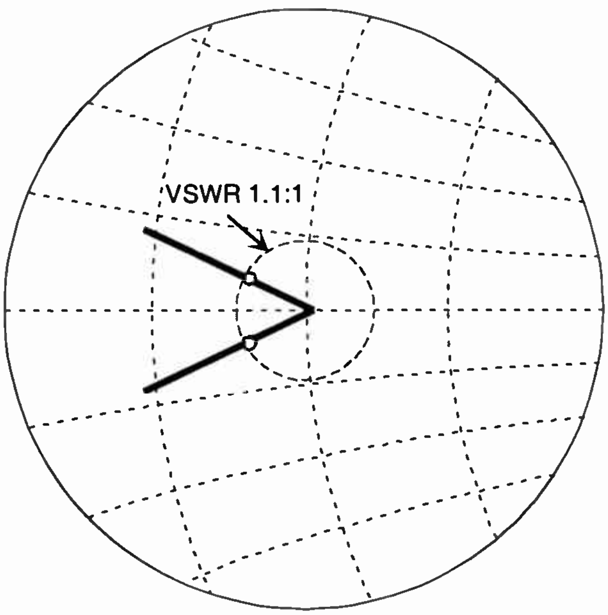

Figure 4.13-13. Impedance diagram, two-cavity band-pass filter.

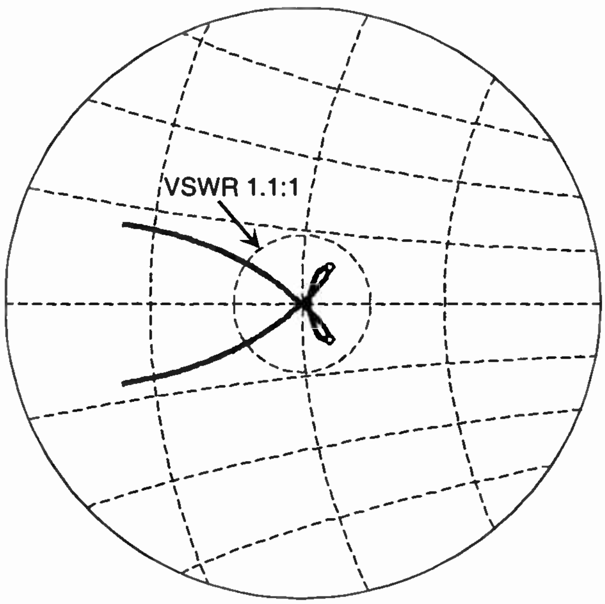

Figure 4.13-15(a). Impedance diagram, three-cavity band-pass filters.

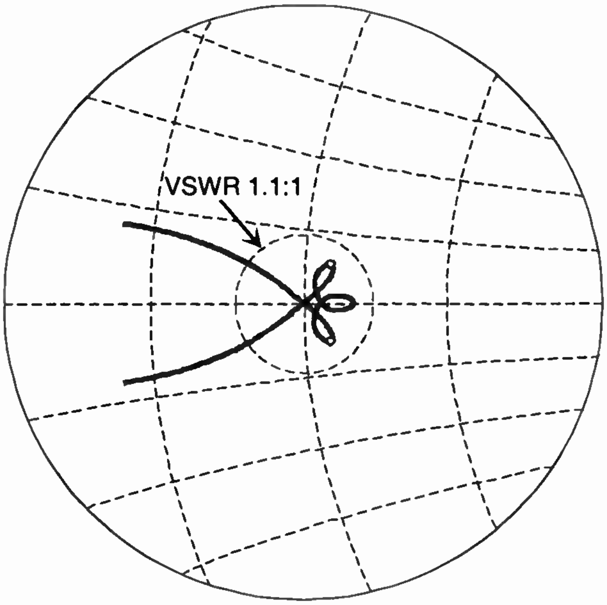

Figure 4.13-15(b). Impedance diagram, four-cavity band-pass filters.

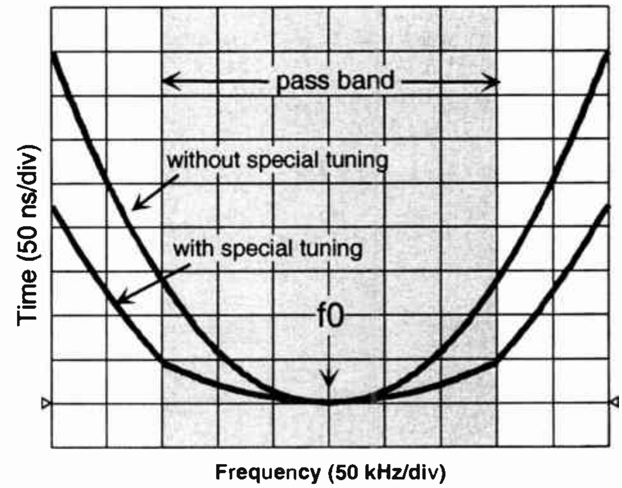

Figure 4.13-17. Group delay comparison, four-cavity band-pass filter, tuned to reduce group delay versus not specially tuned.

This adds some minor distortion to the frequency response (Figure 4.13-18) and considerable distortion to the impedance diagram, as shown in Figure 4.13-19.

Although none of the individual parameters is optimized by itself, the overall performance of the filter is optimized and acceptable. A four-cavity band-pass filter is usually as large a filter system as is needed for most high isolation applications.

Mechanical Constraints

In order to obtain the optimum mathematical cancellation show in Figure 4.13-12 and 4.13-13, the cavities must be spaced at 1/4 wavelength. As the frequency increases, the electrical wavelength decreases—therefore the physical length of the intercavity coax must be shortened. At the higher frequencies of the FM band, the large cavities used for high power applications are difficult to link together, because the cavities themselves approach 1/4 electrical wavelength. As a result, when the intercavity coax is added, the electrical spacing is longer than 1/4 wavelength. In this case, the coupling loops must be manipulated to compensate for the extra length, so that the impedance bandwidth of the cavities is maintained.

Iris-Coupled Cavities

The spacing problem can be prevented by building the cavities contiguous to each other and coupling

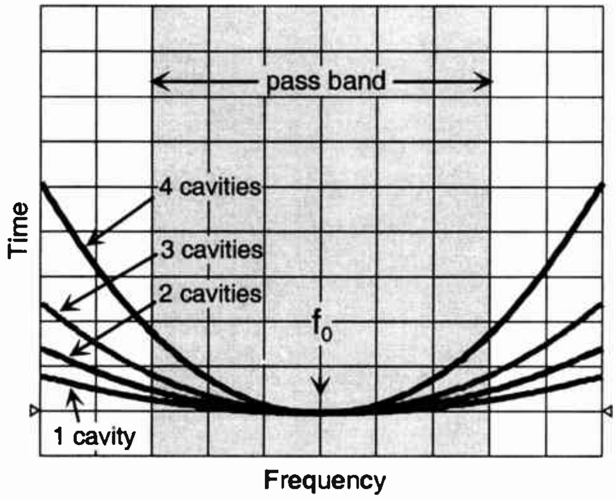

Figure 4.13-16. Group delay comparison, one through four-cavity band-pass filters.

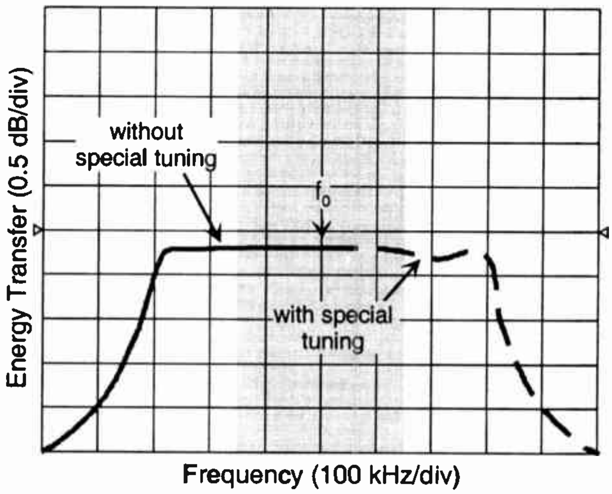

Figure 4.13-18. Frequency response comparison, four-cavity band-pass filter, tuned to reduce group delay versus not specially tuned.

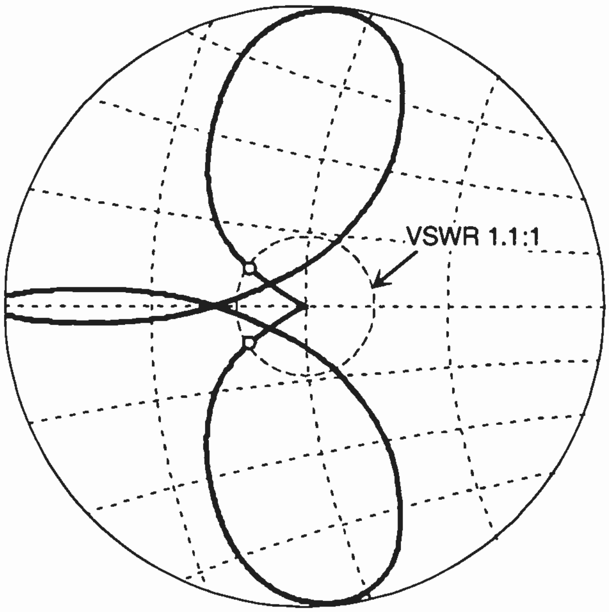

Figure 4.13-19. Impedance diagram, four-cavity band-pass filter tuned to reduce group delay.

them through an iris or slot in the wall between them, as shown in Figures 4.13-20 and 4.13-21. The electrical 1/4 wavelength spacing is maintained by the coupled fields between the cavities.

Band-Reject or Notch Filters

There are several ways to design a notch filter (Figure 4.13-22), but they all accomplish the same purpose. In one form, a notch filter is like a band-pass cavity, but with only an input coupling loop. The cavity is mounted off the transmission line by means of a matched tee. Other designs employ some form of capacitive coupling into the cavity and away from the main transmission line.

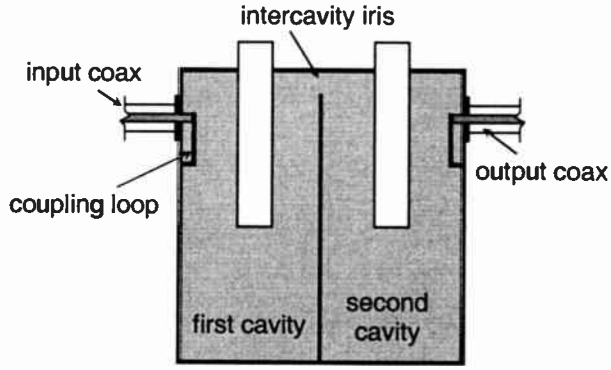

Figure 4.13-20. Iris coupled cavities.

Instead of passing the RF energy *through* the cavity, a notch filter provides a path which *removes* the tuned frequency from the system, allowing other frequencies to pass with minimum loss. Compare the response curve of a single-cavity notch filter, Figure 4.13-23, to that of a single band-pass cavity (see Figure 4.13-4, curve A). The impedance plots of the two filters are basically the same (Figure 4.13-9). When a single notch cavity is used, an impedance matching network is added to the filter to improve the impedance bandwidth.

Multiple Notch Cavities

When more isolation is needed, two notch cavities are coupled in sequence, and if 1/4-wave spacing is used, the impedance bandwidth is basically the same as for a two-cavity band-pass filter (Figure 4.13-11).

When two notch filters are used in sequence, the resonant frequencies of the cavities may be identical, yielding a response curve with a very deep narrowband notch, as shown in Figure 4.13-24, or they may intentionally be staggered, to give a broader notch response, as shown in Figure 4.13-25.

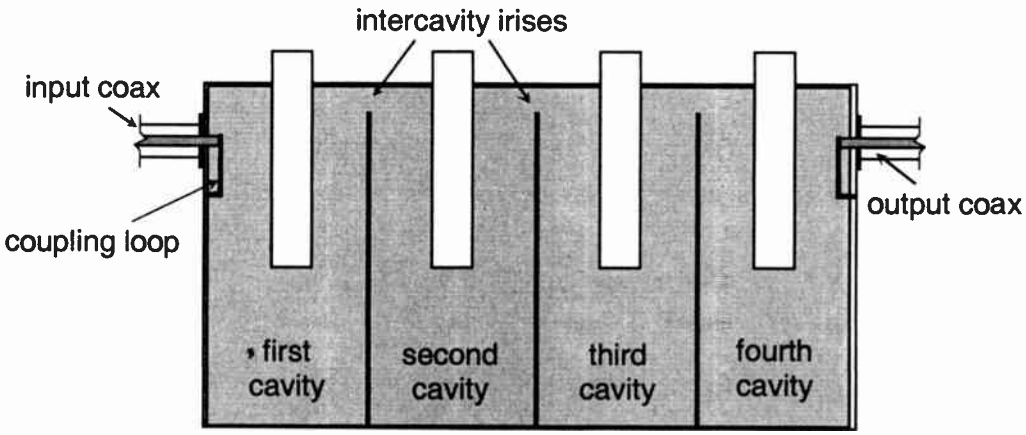

Figure 4.13-21. Four-cavity iris coupled filter.

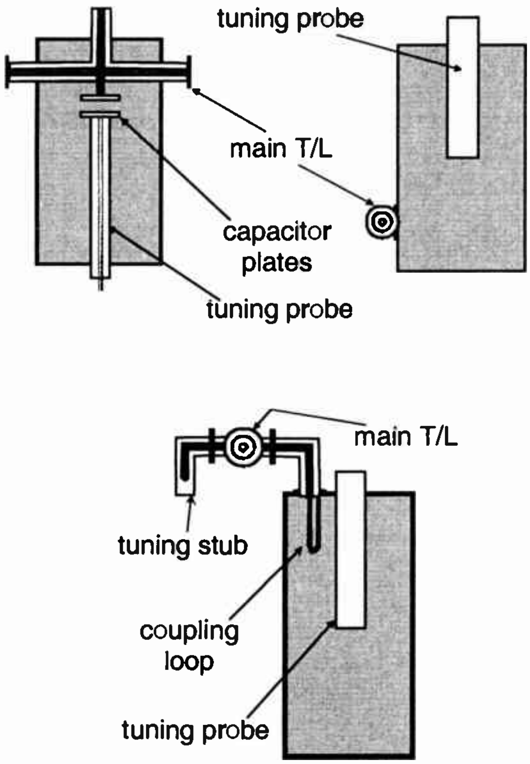

Figure 4.13-22. A variety of band-reject filter styles.

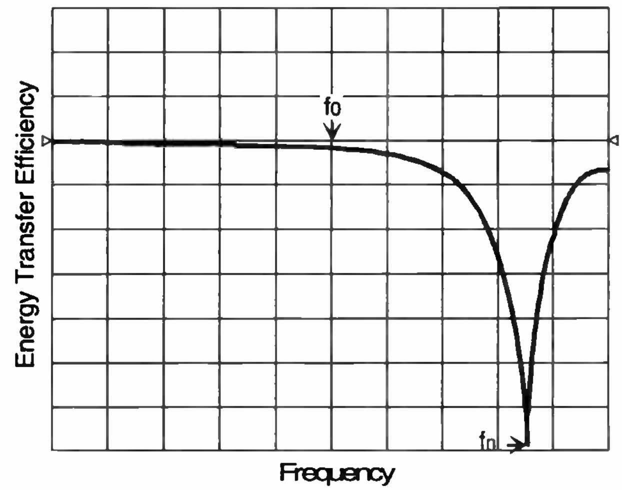

Figure 4.13-24. Frequency response, two-cavity band-reject filter with identical resonant frequencies.

Notch Cavity Group Delay

The group delay plot for a notch cavity is quite different from that of a band-pass cavity (see Figure 4.13-26). However, it is likewise damaging to signal quality.

No practical device has been marketed to equalize the group delay of a notch cavity system. This has not been a major issue, since at about the same time that group delay was recognized as an issue mid-1980s the industry was turning towards band-pass filtering anyway.

Modern Choices

Modern combiner systems are all based on band-pass filters, with limited use of reject cavities to enhance isolation of specific frequencies, for the following reasons:

- Broader response profile. Modern combiner systems must be as broad band as a filter system can be. From the previous illustrations above, it is obvious that the band-pass filter gives a broader band response across the pass band. Furthermore, group

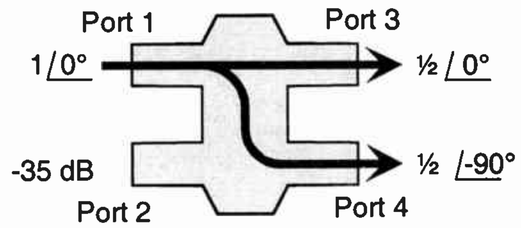

Figure 4.13-27. Hybrid used as a signal splitter.

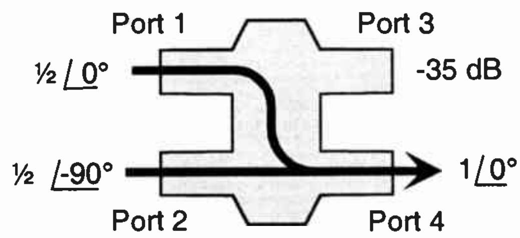

Figure 4.13-28. Hybrid used as a signal combiner.

delay equalization is feasible only for band-pass filtering.

- Expandable site. Because of its ability to attenuate all frequencies except its own, a site with band-pass filtering is easier to expand to include more stations than is a notch filtered site. In a notch-filtered site, if a new station were added, a new notch filter would have to be added to *each* of the existing stations, making their existing notch filter systems even more narrow band and complex.
- Round-trip attenuation. In a band-pass combiner, if enough energy gets by the filter to generate a spur in the transmitter, the spur must then go back through the filter to get to the antenna, and is therefore attenuated a second time. With a notch cavity, if a spur is generated, the notch filter, not tuned for the spur frequency, will not attenuate the spur, and the signal is more likely to violate FCC rules.

Hybrids

A *quadrature hybrid* is a complex broadband device that has the ability to operate in various modes either singly or simultaneously. The detailed electrical explanation of a hybrid is beyond the scope of this chapter.[2] Hybrids are discussed here only with regards to combining systems.

Figures 4.13-27 and 4.13-28 show a typical hybrid. In Figure 4.13-27, the hybrid is acting as a power and phase splitter. When an RF signal is applied to port 1, the hybrid splits the signal, and the phase of port 4's output is delayed with respect to port 3's output by 90°. Port 2 is called the *isolated port* and is usually terminated with a 50 Ω resistive load equal to the characteristic impedance of the device (usually 50 or 75 Ω).

Use of a hybrid in reverse, for combining, is shown in Figure 4.13-28. If two equal RF signals, with the proper phasing, are introduced at ports 1 and 2, the combined signal exits the hybrid through port 4. If the phase of the two input signals is reversed, the signal will exit the hybrid through port 3. Again the isolated port is usually terminated with a matched resistive load.

The hybrid's third mode of operation is called the *reflected mode* and is shown in Figure 4.13-29. When two identical devices with high impedance, such as band-pass filters tuned to another frequency, or band-reject filters tuned to the incoming frequency, are attached to ports 3 and 4 of the hybrid, the signal entering at port 1 is reflected and exits the hybrid through port 2. The characteristics of this third mode make the hybrid useful in conjunction with other hybrids and cavities in filter systems.

Two hybrids can be connected together to form a *hybrid ring*. As shown in Figure 4.13-30, when an RF signal is applied to port 1, the energy flows diagonally across and exits port 4 with very little loss; ports 2 and 3 are isolated by a factor of 35 dB. If the two

Figure 4.13-30. Hybrid ring, showing low-loss diagonal energy flow.

hybrids are tuned for a specific frequency this isolation can be optimized to 40 dB.

The multiple operational modes of the quadrature hybrid make it the backbone of the runout and balanced combiners.

TYPES OF COMBINERS

In the early days of FM combining systems, the easiest way known to combine two frequencies was to use a hybrid ring where one leg contained an extended path equaling an even multiple of both signals' wavelengths. This was accomplished by adding a long length of coaxial transmission line (the runout) between the two hybrids to connect two of the internal ports, as shown in Figure 4.13-31, while the other two internal ports were directly connected. The transmitter-to-transmitter isolation for this combining system depends on the accuracy of the runout line length and the tuning of the hybrid ring.

In a two-station system, this is fairly straightforward. For example, to combine 92.5 and 94.5 MHz, the runout line is approximately 450 feet long.

But for each additional station, an additional combining stage and another long length of transmission line are necessary. The line length for each stage is calculated from the new frequency and the center frequency of the preceding stage. Disadvantage of this method include:

- The runout lines tend to be hundreds of feet long and are difficult to store and protect
- Since each combining stage is tuned to the center output frequency of the previous combining stage, optimization is lost at each stage
- This type of combiner is narrowband, because it is line-length dependent

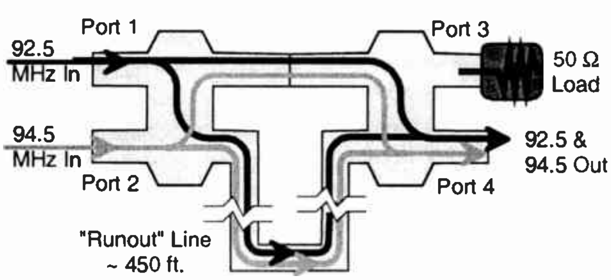

Figure 4.13-31. Runout combiner schematic.

- The isolation is not high enough for today's transmitters. Therefore, filters have had to be added on the transmitter side of the combiner to retrofit existing systems.

A variation of the FM runout combiner used a filter in place of the long runout line to provide the same electrical delay as the transmission line. However, this modification did not substantially improve the electrical performance of the runout combiner, and additional filters have also been retrofitted to these systems.

Runout combiners have almost all been either retrofitted or replaced by more modern combining systems.

Branched or Star Point Combiners

A branched combiner is a simple combination of a tee junction and the required number of filters to ensure a sufficient amount of isolation. For example, an FM branched combiner containing a three-cavity band-pass filter in series with a two-cavity band-reject filter may be used to provide the high quality isolation required for two close spaced (0.8 MHz apart) frequencies (see Figure 4.13-33).

A five-cavity filter system is tuned for one of the channels in a two-station branched combiner, and forms one leg of the combiner. The second leg is a similar combination of filters tuned for the other frequency, and its response plot resembles a mirror image of Figure 4.13-32. The basic schematic, shows the combiner configuration (see Figure 4.13-33).

TX1 and TX2 are the signals from transmitters 1 and 2 as they enter the combiner. The length of the coaxial line between each set of filters and the tee junction is adjusted to provide a very high impedance (approaching an open circuit) to the other frequency, so that the power flow of each signal is through its own filter, out of the tee junction, and up to the antenna.

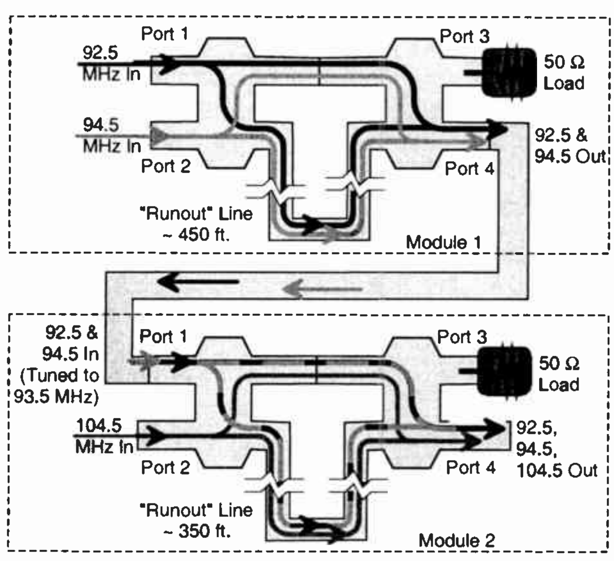

Figure 4.13-32. 3-station runout combiner combining 92.5 MHz, 94.5 MHz and 104.5 MHz.

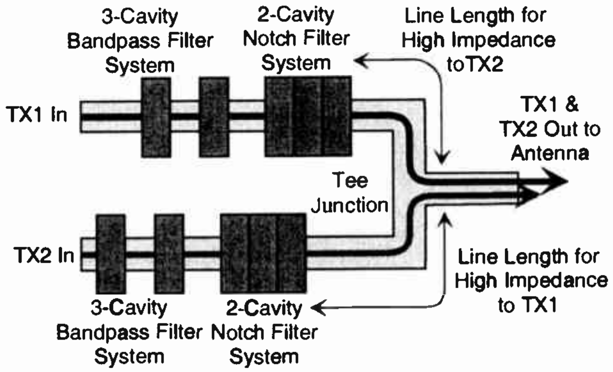

Figure 4.13-33. Branched combiner schematic.

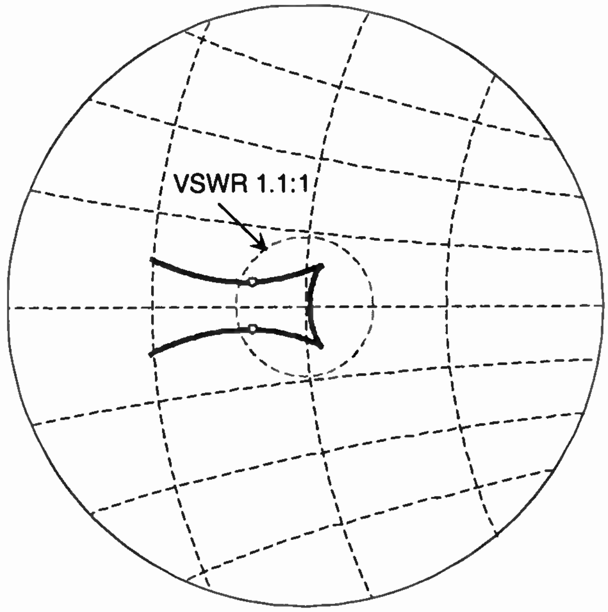

Figure 4.13-35. Impedance diagram, three-cavity band-pass filter and two-cavity band reject filter in series.

Refer again to Figure 4.13-14, curve B (response curve for a three-cavity band-pass filter) and Figure 4.13-25 (response curve for a two-cavity staggered-frequency band-reject filter). When these filters are used in combination, the resulting response from this five cavity system curve is shown in Figure 4.13-34.

Note that the insertion loss for the pass frequency f_1 is only about 0.25 dB and the isolation at the reject frequency f_2 is greater than 50 dB across the channel.

The impedance plot is likewise the combination of impedance plots for the same filter combination (see Figure 4.13-35).

Limitations

A branched combiner is very efficient for a two-station installation, and has been used for as many as four stations, but a tee junction for more stations than that starts to become impractically large, and adjusting the lengths of interconnecting coax becomes more complex. Also, a simple branched combiner cannot be expanded later to include more stations, although it can be expanded by integrating it with balanced combiner modules. To combine more than four stations, a balanced combiner becomes more practical and cost effective.

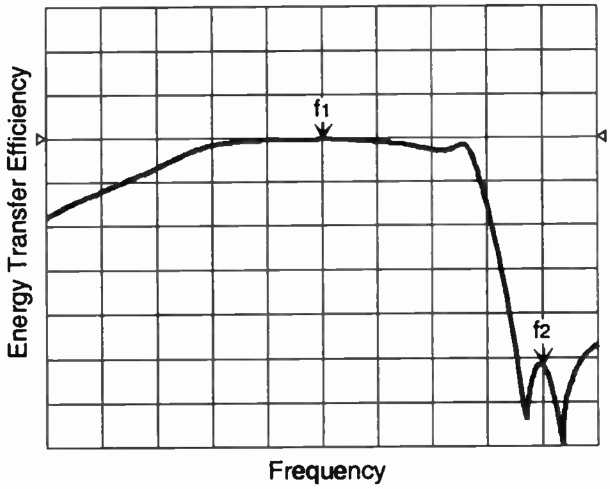

Figure 4.13-34. Frequency response, three-cavity band-pass filter and two-cavity band-reject filter in series.

Balanced Combiners

The balanced combiner, like the runout combiner, is based on a hybrid ring. Each leg of the ring contains an identical set of either band-pass or band-reject filters. Most of the original balanced combiners used notch filters.

Notch Filter Balanced Combiners

In the notch filter balanced combiner (Figure 4.13-36), both notch filters within the hybrid ring are tuned to reflect TX1's frequency, which enters the combiner (black arrows) at port 1. That signal is reflected by the filters, and exits at port 2, utilizing the reflected mode of hybrid operation as shown in Figure 4.13-29.

TX2 (gray arrows) enters the broadband input port of the module, port 3, passing through in the diagonal

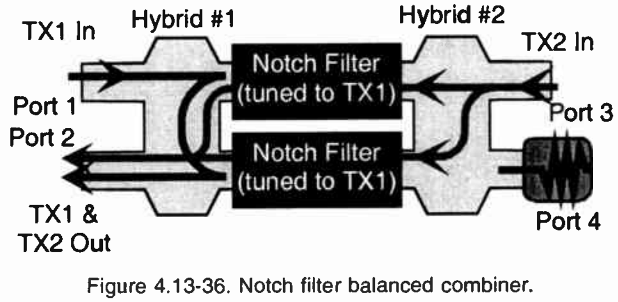

Figure 4.13-36. Notch filter balanced combiner.

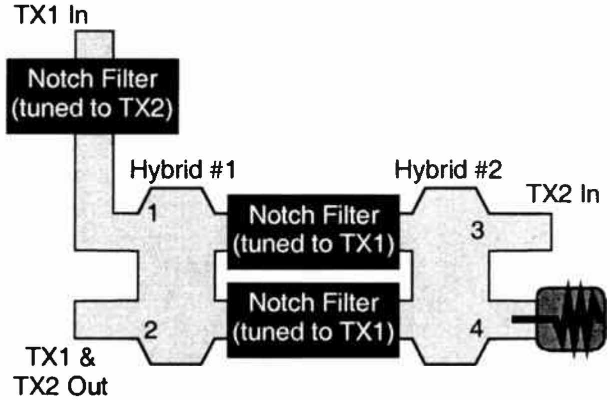

Figure 4.13-37. Balanced combiner with additional filter at TX1 input.

mode shown previously in Figure 4.13-30, with minimal loss in the reject cavities.

The isolation of transmitter 2 from frequency TX1 is the sum of the hybrid ring isolation of 35 dB and the isolation of the notch cavities, which can approach 35 to 40 dB. However, the isolation of transmitter 1 from frequency TX2 is only that of the hybrid ring about 35 dB. Therefore, additional filtering tuned to TX2 is required to ensure that no spurs are generated within transmitter 1. This added filter is shown in Figure 4.13-37.

More modules must be added as the number of stations entering the system is increased. Figure 4.13-37 shows a three-station, two-module combiner. Note the filter in the TX1 input line, as previously described, Module 1's output becomes the input at module 2's port 1. Since both TX1 and TX2 are entering module 2 at port 1, the filter at the TX3 input at module 2's port 3 must now reject both frequencies TX1 and TX2. This can be done with two reject filters, as shown.

External Band-Pass Filtering

A better way to reject multiple unwanted frequencies, of course, is to use a band-pass filter tuned to the desired frequency. For example, in Figure 4.13-38, instead of two notch filters at the input of TX3, use a single band-pass filter, tuned to frequency TX3.

A further extension of this pattern is shown in Figure 4.13-39, showing a five-station, four-module combiner. In this example, each input filter is a band-pass filter tuned to the frequency of that input. If reject filters were to be used at the various inputs, each input would have to filter *all* the frequencies previously introduced. Therefore, port 3 of module 2 would have to contain two notch filters; port 1 of module 3, three filters; and port 3 of module 4, four filters. This proliferation is avoided by the use of external band-pass filters.

Emergency Input Port

In some cases, instead of having a station located at port 3 of module 1, that port is terminated in a 50 Ω load and can be used as an emergency input for any station in the system. Providing an extra port in this way allows a damaged module to be bypassed. Because of the nature of that particular port, as long as the input filter at port 1 of module 1 is a band-pass filter, no further input filtering is necessary.

Limitations of Notch Filter Balanced Combiners

A problem with using notch filters within the hybrid rings is that if the two filters in any one module are

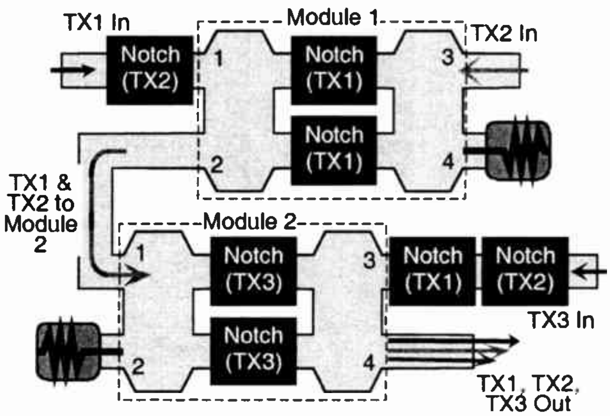

Figure 4.13-38. Three-station, two-module notch-filter balanced combiner.

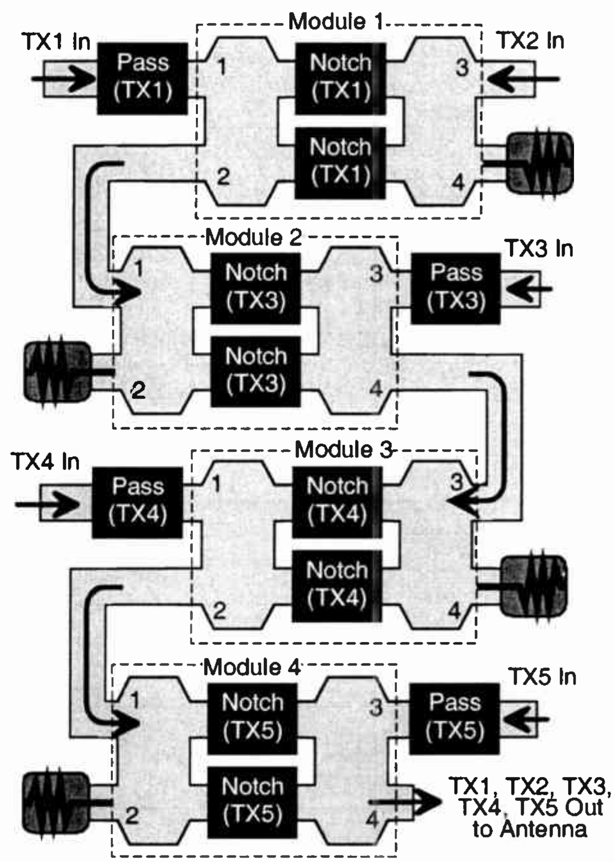

Figure 4.13-39. Five-station, four-module notch filter balanced combiner with band-pass filters at the inputs.

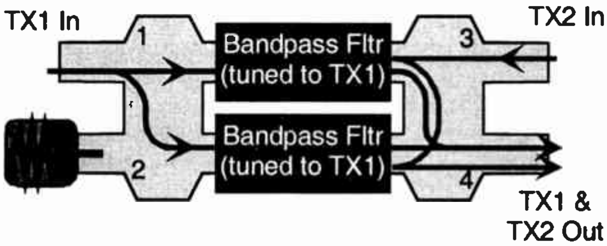

Figure 4.13-40. Band-pass filter balanced combiner.

not identically tuned, an imbalance occurs within the hybrid ring, reducing the isolation to a point where a spur can be generated within a transmitter. Once a spur has been generated, there are no filters within the system to reject that spur, since the notch filters in the system filters are tuned only to the signal center frequencies and not the potential spur frequencies. Therefore, the spur is broadcast.

A second disadvantage of using internal notch filters is that since each module in turn has to conduct the accumulated power of all the previous modules, for a high powered system each module must be larger than the previous one, and the power rating of the system is limited by the size of the final module.

Third, notch filter combiners are impractically narrowband in nature for today's wide channels, especially when the frequencies combined are close spaced.

Because of these limitations of notch filter systems, they are seldom used. Modern FM combiners use band-pass filters.

Band-Pass Filter Balanced Combiners

In a band-pass balanced combiner system, band-pass filters are used within the hybrid ring. The basic system layout is similar to that of a notch combiner.

The power flow is shown in Figure 4.13-40 (compare to Figure 4.13-36). In the notch system, the filters reflected signal TX1 entering port 1. In the band-pass system TX1 also enters port 1, but passes through the hybrid ring's band-pass filters and out port 4, while signal TX2, entering at port 3, is reflected by the filters and exits at port 4.

The isolation of transmitter 1 from frequency TX2 is the sum of the hybrid ring isolation (35 dB) and the isolation of the band-pass filter (about 25 dB).

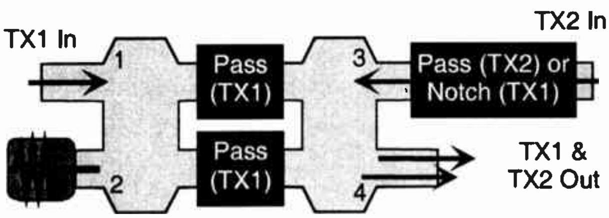

Figure 4.13-41. Band-pass filter balanced combiner with added filter at TX2 input.

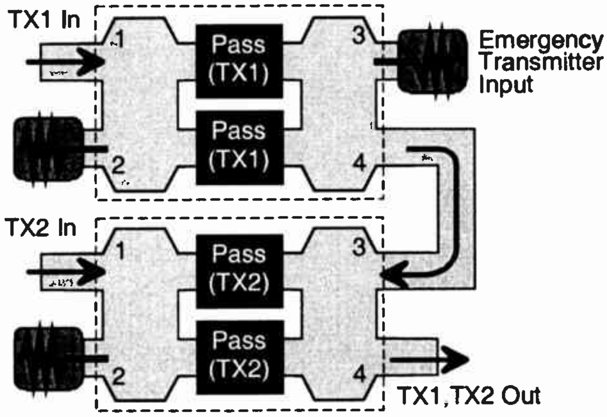

Figure 4.13-42. Two-station, two-module band-pass filter balance combiner.

However, the isolation of transmitter 2 from frequency TX1 is only the hybrid ring isolation of about 35 dB. Therefore, an additional filter must be added between transmitter 2 and its input port (Figure 4.13-41).

Alternatively, a second module may be added to port 4 of module 1, and port 3 terminated in 50 Ω

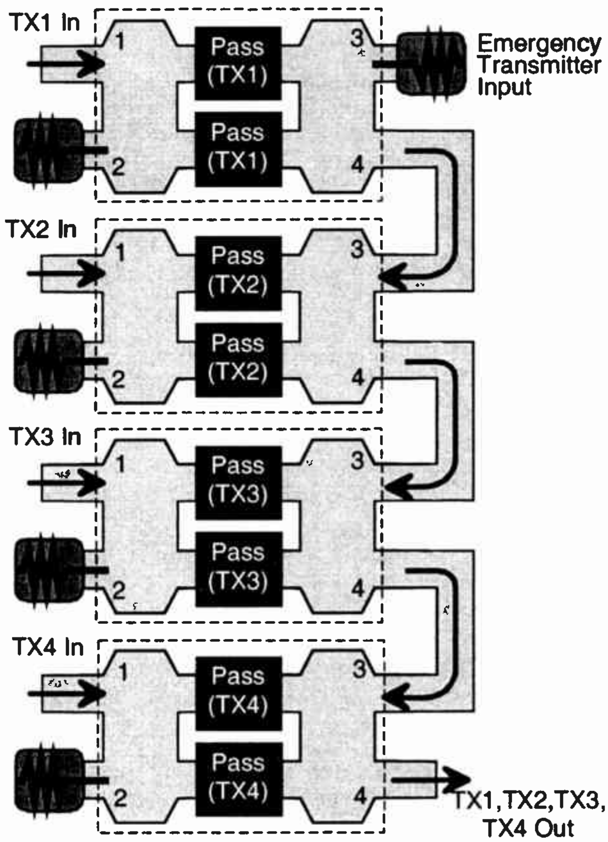

Figure 4.13-43. Four-station, four-module band-pass filter balanced combiner.

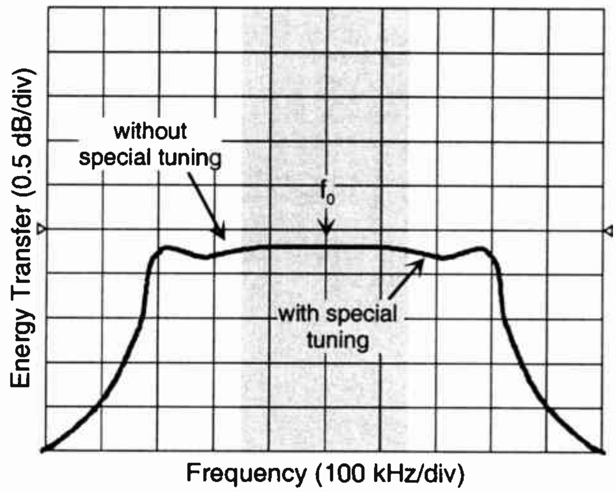

Figure 4.13-44. Frequency response for one station of four-station, four-module combiner.

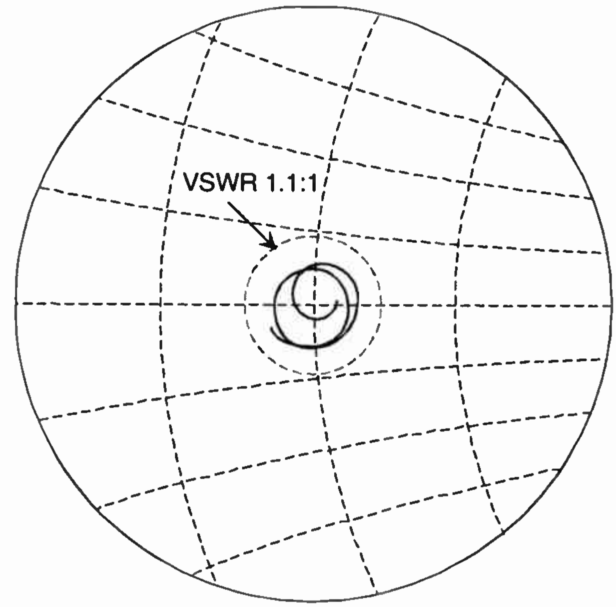

Figure 4.13-46. Impedance diagram for one station of four-station, four-module combiner.

(and available as an emergency input port). Signal TX2 is then introduced at port 1 of module 2 as show in Figure 4.13-42.

No input filter is necessary now for TX2, because it is isolated by the bandpass filters in Module 2. The energy seen at Port 4 of Module 2 is now the combination of TX1 and TX2.

A multiple-station band-pass balanced combiner is an extension of the latter configuration, where each frequency has its own module (see Figure 4.13-43).

In a band-pass system the accumulated power entering each module flows only through the output hybrid, so the power handling capacity of the system is limited only by the size of the output hybrids and interconnecting transmission line, not the entire module.

The frequency response, the group delay, and the impedance diagram for this combiner are shown in Figures 4.13-44, 4.13-45 and 4.13-46, respectively.

Group Delay Effects

When two stations are 1.2 MHz apart or closer, the band-pass filter will not provide quite enough isolation, allowing a small amount of signal interaction. This affects the group delay curve of the module which is furthest from the antenna, as shown in Figure 4.13-47.

This phase distortion can be compensated for by adding a group delay equalizer (see Figure 4.13-48).

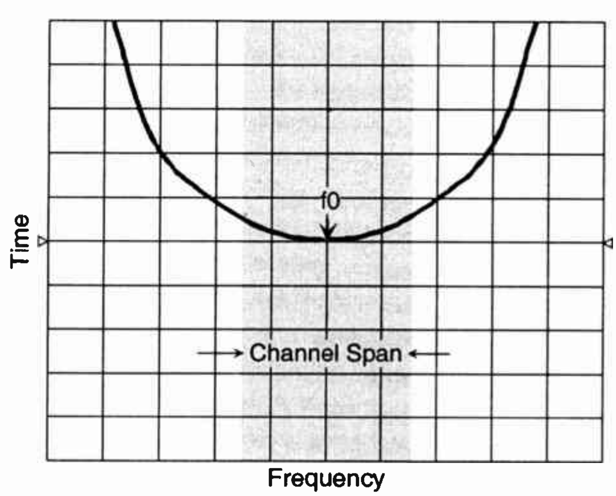

Figure 4.13-45. Group delay for one station of four-station, four-module combiner.

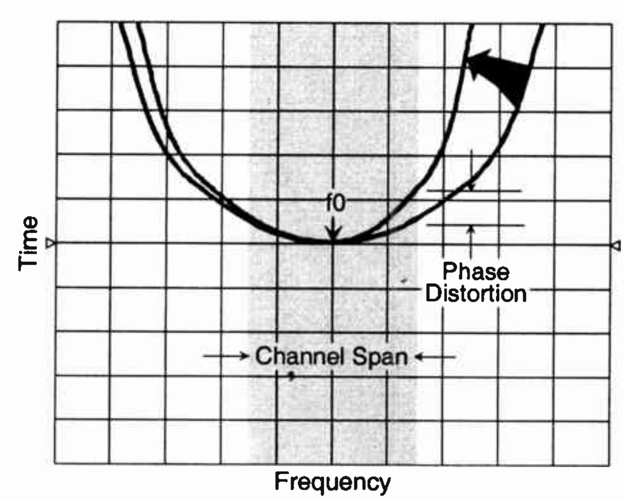

Figure 4.13-47. Group delay diagram showing phase distortion in module farthest from the antenna.

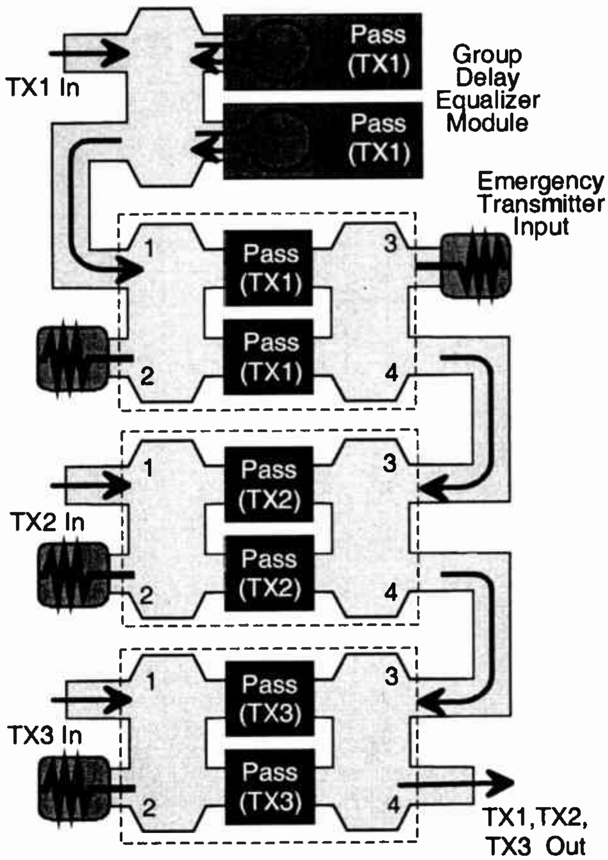

Figure 4.13-48. Band-pass filter balanced combiner with group delay equalizer.

CONCLUSION

Combiners are required when it is necessary to transmit multiple signals from a single antenna. Without proper combining, signals will interact in each other's transmitters, producing intermodulation and spurious products. This section discusses the use of combiners in FM broadcasting. Several fundamental designs and many different components and configurations are described, including some that are now obsolete and are presented mainly for historical interest.

The various types of combiners have their own advantages and disadvantages. The system designer must be aware of each so that he can select the appropriate filter system or systems for his own application.

4.14
FM TRANSLATORS AND BOOSTERS

CHIP MORGAN
CMBE, INC., EL DORADO HILLS, CA

INTRODUCTION

Translators and boosters are very interesting from a technical perspective. Although they appear to be easy to design and simple to build, they can actually be more critical than higher-powered stations. In fact, since the signal is local and likely to receive or cause interference, design and optimization methods for these low power systems can make the difference between a successful operation and a failure.

It is a mistake to think that a translator or booster cannot perform as well (within its intended coverage area) as a "full powered" station. There are many low power facilities around the world that provide excellent full-time service to communities every day.

Modern technology provides engineers with the interesting design challenges including synchronized systems, complex three-dimensional directional systems to fill in specific areas, and local systems located in tunnels, buildings or temporary gathering places such as stadiums. These techniques also have application for fill-in service for satellite delivered services as well as terrestrial digital broadcasting.

This chapter does not discuss Federal Communications Commission (FCC) Rules on translators and boosters, since this information is readily available from the FCC. Rather it provides the reader with some ideas and concepts about the successful design and implementation of such a facility.

Definitions

Generally, FM translators and boosters are low powered facilities used to "fill in" the coverage of an FM radio station. Due to the nature of the current FCC Rules regarding service areas of primary stations, it is common for service area contours to extend over areas that actually have terrain shielding from the main signal. If a translator or booster is used to add signal in these shadowed areas, the broadcaster better serves the public within the licensed service area of the station.

FM Translator

A translator is a radio frequency (RF) device that retransmits an FM signal within a specific broadcast band. It alters none of the signal's characteristics except frequency, and its main purpose is to extend or fill in the coverage of a transmitted signal. It typically receives a signal, changes its carrier frequency and then rebroadcasts the signal at substantially higher levels of radiated energy. A translator is essentially a repeater. Listeners within the coverage area of the translator receive primary station programming on *a different frequency from the primary station*. Thus, the station signal is *translated* in that area.

FM Booster

A booster is a RF device that retransmits an FM signal within a specific broadcast band. It alters none of the signal's characteristics including frequency, and its main purpose is to extend or fill in the coverage of a broadcast station. A booster operates on the same frequency as the primary signal and rebroadcasts it at substantially higher levels of radiated energy. A booster is also sometimes called an iso-frequency transmitter. A booster must be located inside the 60 dBuV/m contour of the station it boosts and cannot degrade the original service of the primary station. Listeners receive the programming from the primary station on *the same frequency as the primary station*. Thus, the station signal is *boosted* in that area.

GENERAL DESIGN GUIDELINES

The following tips and points should be considered when designing a translator or booster. Some of these items are simple common sense; others require computer system analysis to compare options and identify predicted results. These guidelines also apply to high-powered systems. In most cases, low powered systems have very stringent requirements due to specific signal challenges. Because the field is quite complex, having a complete understanding of all the technical issues before designing a system will minimize problems. For example, propagation and signal analysis is a career unto itself, but understanding the basics will help you identify potential problems in the initial design of a system. For best results, use the services of a professional who designs translator and/or booster systems regularly.

Initial Needs Analysis

When a low powered station (especially a booster) is being considered to help solve coverage problems in specific local areas, the potential owner should determine the answers to several questions:

- Is there an area with high potential revenues within the service area of the primary station that does not receive signal from the main transmitter?

- Is there sufficient terrain shielding to allow a booster to work technically?
- Does the capital investment required justify the potential improvement to signal problems?
- Do all parties completely understand that when a booster is used, there will be a zone of interference around the booster signal?

If the needs analysis proves value in proceeding, the first step is understanding the process of choosing a location and a system to achieve the goals. Note that the location process outlined below assumes that the reader is familiar with current FCC Rules.

Site Selection

Site selection is the first step in designing a system. The details of the site determine many other design criteria, so an overall review of the impact of any potential site must be quite exhaustive. Choosing the best site for a transmission system is often a series of compromises. Strike a balance between economic, environmental and performance issues of the particular site under review. In addition to these restrictions, the site must satisfy all regulatory, practical and engineering requirements. It must also be accessible during and after construction and in varying weathering conditions (excessive winds, erosion, snow, heat and water).

The primary technical consideration of site selection is the performance of the transmission system located there. Computer analysis should be performed to predict the performance at all intended receiving locations, to predict the interference generated to other operators from the proposed site and to demonstrate the relative quality of any particular site in terms of others being considered. In addition to the performance of the transmitter(s) located at the proposed site, receiving capability of the primary signal must be possible. This may mean satellite reception, microwave link reception or off-air reception of the modulating signal.

When using off-air rebroadcast, site selection is very critical. For example, if a booster receives its primary signal from a receiver tuned to the primary FM transmitter, the booster's transmitted signal generally ranges from 90–110 dB stronger than the intended input signal. If feedback contamination is to be limited to less than 30 dB, the transmitting antennas and receiving antennas must have between 120–140 dB of isolation. Most boosters use other methods of signal delivery, and this is less of an issue in modern systems.

Location of Antenna in Relation to Population

Locate the transmitting antenna site as close to the target population as possible. Building penetration and received signal strength decrease rapidly as distance between transmitter and receiver increases. RF energy diminishes with the square of the distance. If the transmitter site is too distant from the target population, system design becomes much more critical and difficult.

Height of Antenna above Population

More antenna height usually means better coverage. However, excessive antenna height leads to unnecessary interference, increased construction and operating costs and decreased reliability. Specify an antenna height just high enough for adequate Fresnel ellipsoid clearance to the target area but not much higher.

Fresnel Ellipsoid Clearance of Signal into Target Market

The antenna signal is not a narrow ray of energy like a laser beam. The signal is a noncoherent three-dimensional beam that gets wider as it leaves the transmitting antenna, just like the beam from a spotlight. For maximum received signal strength, all the energy in the Fresnel ellipsoid must pass from the transmitter to the receiver with no obstacles affecting the path of transmission. The receiving antenna works exactly opposite from the transmitting antenna. It gathers energy from a three-dimensional area and narrows it down to the location of the receiver, just like a telescope gathers light from a wide area and focuses it on a small area. At the midpoint of the transmission/reception path, the signal beam is its widest. Therefore, even if you can see the population you want to serve from the transmitter site, the broadcast signal may not be able to reach it due to obstructions below the line-of-sight path.

The area of best signal coverage is within the areas receiving the entire Fresnel ellipsoid. These areas can extend beyond visible line-of-sight due to the refraction of electromagnetic waves in the atmosphere. Use a path clearance of at least 0.6 Fresnel zone to avoid excessive diffraction loss due to path obstructions. Path clearances above 1.3 Fresnel zones can yield multipath propagation and nulls in received levels (see Figure 4.14-1).

SYSTEM DESIGN

The strategy of frequency or channel selection for low power systems, particularly translators, is an art form of itself. According to one common theory, the output frequency of a translator should be as close to the input as possible and ideally an adjacent channel. The reality is that practical and technical issues may preclude this possibility. The majority of quality equipment should be able to operate well on adjacent channels, but there are other more complex issues. For example, operation of a translator on an adjacent frequency usually causes interference to the main station. If the translator is located in the center of a large population, it could actually cause more harm than good.

On the other hand, there is no limit to the frequency separation. Somewhere between the two extremes lies the solution. If maximum quality is the design goal, use at least 2 MHz separation for an FM translator so that filters and traditional engineering solutions can be used in case of installation difficulties.

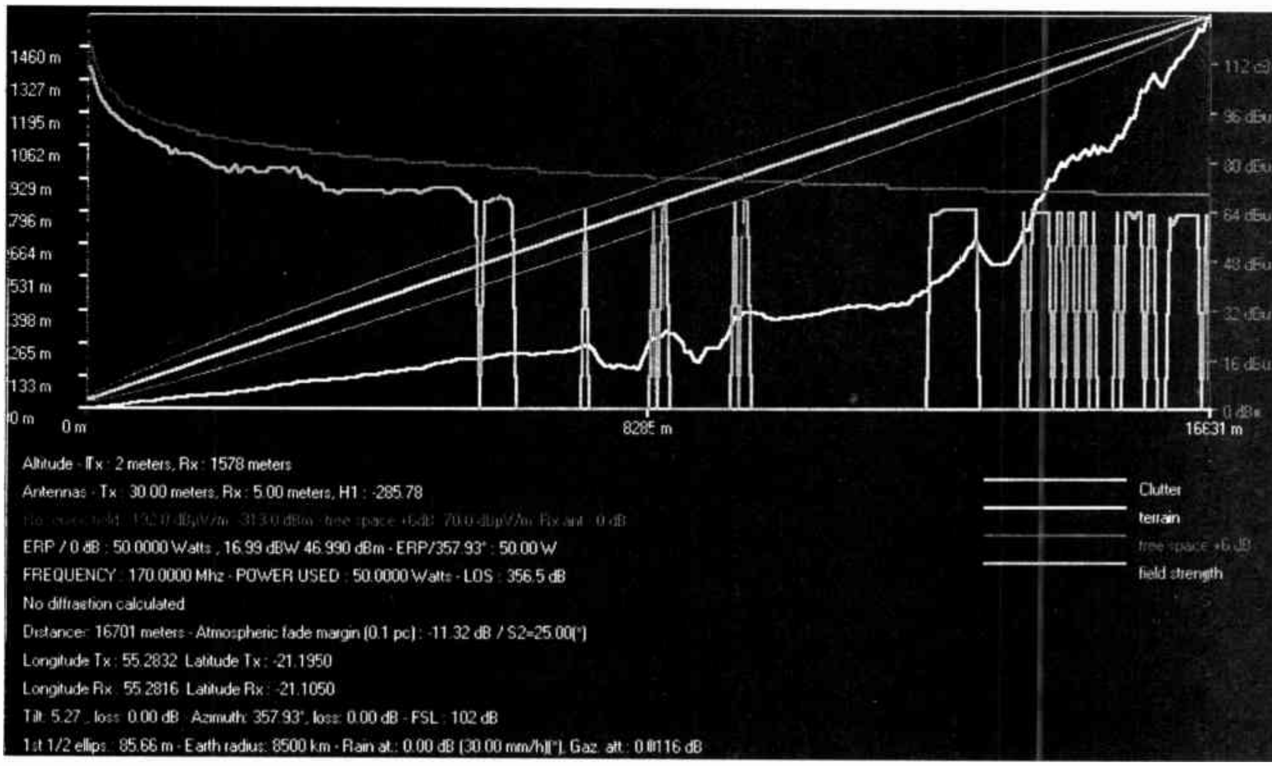

Figure 4.14-1. Fresnel ellipsoid.

Antennas

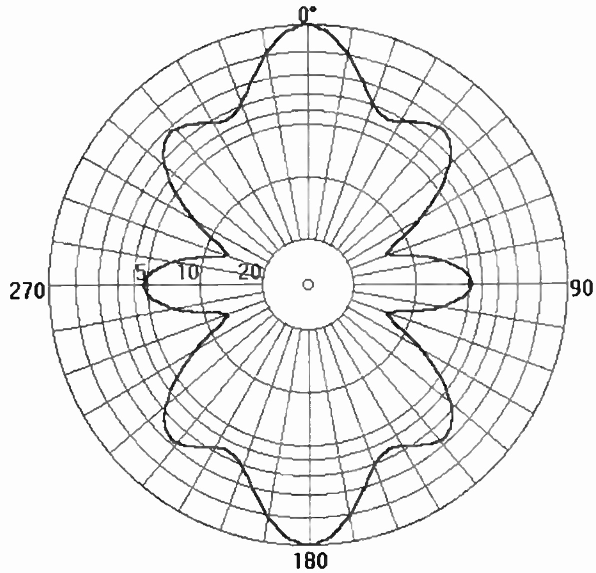
Deciding what kind of antenna to use is a very important aspect of the system. Some system designers mistakenly believe that running a high power transmitter and a low gain antenna is the best course of action in all circumstances. Others believe that a high gain antenna and a low powered transmitter are best. In reality, the best system is designed with specific understanding of the target area and uses the appropriate combination of antenna design and transmitter power to achieve the best three-dimensional pattern beam for the desired performance.

High gain antennas have small vertical beam width that can cause poor reception spots in the minor lobes due to the nulls in the radiation pattern. Since the major lobe provides the most gain to the detriment of areas near the antenna, signals in distant areas will likely be excellent but at the expense of local signal. Sometimes, however, this is an intended effect when lightly populated areas are near the antenna.

If it is necessary to have coverage in both local and distant areas, choose an antenna location high enough to provide adequate illumination of the target area and an antenna configuration that will be the best compromise. A high signal level and a signal path with no obstructions between the transmission site and the receiving sites are required for consistent service to the intended audience. If local coverage is of paramount importance, use a high gain antenna with a moderate degree of beam tilt, or lower power and an omnidirectional antenna. This will make the best use of radiated power and reduce interference. Under all circumstances, analyze the effect the new system will have on co-channel and adjacent channel stations, including the primary station. Antenna pattern control equals better system performance, less co-channel and adjacent channel interference and better spectrum utilization. Early engineers used to say a dime spent on the antenna is worth a dollar spent on the radio, and this holds true even today.

Elevation Pattern of the Antenna

There is often population below the height of a transmitting antenna—especially if it is on a tall tower or hill. The elevation pattern of the antenna identifies the amount of signal radiated toward the horizon as well as the amount radiated above and below the horizon. The elevation pattern below the horizontal plane is critical in transmission systems design because most of the target audience is usually below the horizon. Conversely, a receiving antenna often receives from a location above its horizontal plane, so the elevation pattern above the horizon is important. The number, spacing and type of elements in the antenna array typically control the elevation pattern of an antenna. Elevation pattern gain and beam tilt will not completely solve a problem caused by insufficient Fresnel ellipsoid clearance *shadowing*. If a site has poor performance due to radio shadowing, no amount of manipulation of the antenna system will make a substantial improve-



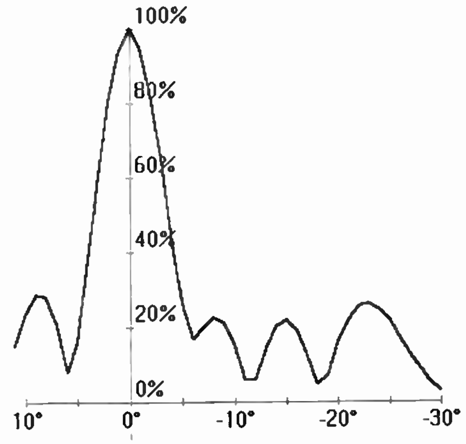


Figure 4.14-2. Elevation pattern.

ment over a properly designed and operating antenna system. Some operators are willing to pay for minor improvements, especially in major markets, but a better use of finances is to carefully analyze a potential site before building it. Examine every proposed system with care to accurately determine the magnitude of the potential problem areas (see Figure 4.14-2).

Antenna Stacking

Antenna stacking increases gain of an antenna array. Stacking which can be either vertical or horizontal applies in transmission and reception and can be helpful in solving certain reception difficulties.

Vertical antenna stacking influences vertical beam width and is effective in amplifying the gain of the array. Horizontal stacking narrows the array's beam width from side to side. If the antennas are in phase, this method adds 3 dB to antenna gain for every doubling of the stack. (A single yagi antenna has a horizontal acceptance angle of approximately 30° between the 3 dB down points off its front). Note that horizontal beam width decreases considerably, and vertical beam width remains unaffected.

A variation in stacking resolves certain interference and reception difficulties. There are a myriad ways to make use of this technique, including offset antenna arrangements, which allow phase reinforcement off the front of the array and phase cancellation off its rear. As an example, set the space from one antenna boom to another so that it will cancel an unwanted signal from a specific forward direction. Install the antennas with the center of each spaced so the unwanted signal is out of phase at the connection between the two antennas, the interfering signals will cancel each other at the combined output (see Figure 4.14-3).

Interference from Adjacent and Co-channel Stations

Consider the potential of interference in the design of a facility. Unless the station is located in an area with very few signals, certain portions of the service area will receive interference from other nearby or more powerful transmitters. This can come from stations as far as three channels above or below the operating channel. Most complaints of poor performance are a result of interference, due to poor signal from the intended transmitter in an area of excessive signal from an interferor or jammer (see Figure 4.14-4).

Translator and Booster Equipment

Once the design is complete selecting equipment for a translator or booster is quite simple. There is a wide choice of equipment available in a range of prices. Of course, the trick is to get the lowest cost equipment while maintaining the desired quality and reliability. To avoid costly mistake use an experienced engineer to assist in equipment choices.

Transmitting Antennas

There are a number of factors to consider when building the antenna system for a low power operation. Careful attention to materials selection is key. A poor quality antenna will adversely affect the best system. For omnidirectional usage, use low power versions of the standard higher-powered transmitting antennas. (They are available in horizontal, vertical and elliptically polarized models.) The relationship between the tower and the radiating elements is essential. The best designs are custom-tuned for the specific situation. Pattern measurements should be performed on an antenna test range, and results of the measurements

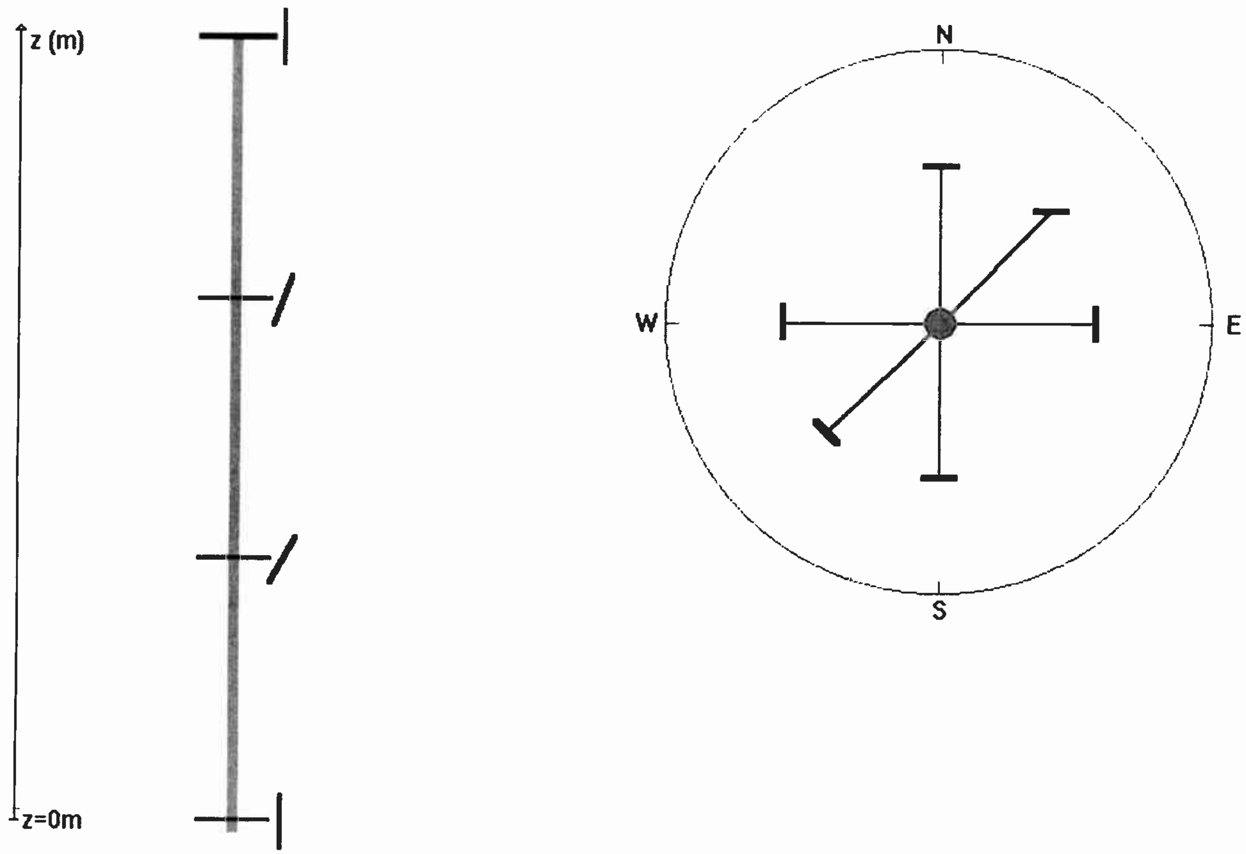

Figure 4.14-3. Antenna stacking.

should be input into a computer generated predictive system to measure the impact of the antenna pattern on the coverage of the system.

When building the antenna system, make sure that antenna and tower manufacturers and the station owners are kept abreast of any possible problem areas such as wind resistance, the antenna's post-installation directivity patterns and mounting procedures.

Receiving Antennas for Retransmission

The input signal's delivery to the transmitter is an essential factor in overall system design when retransmitting a signal. A poor quality input signal affects in the entire operation of the system.

A simple antenna on a nearby tower is sometimes sufficient for off-air reception. More often, more intricate measures are necessary. Sometimes increasing antenna gain or narrowing the pattern of the arrangement is an option. A number of methods can resolve retransmission reception difficulties, including signal filtering to minimize out-of-band products, antenna-mounted pre-amplification to increase signal levels and horizontal and vertical antenna stacking techniques to increase antenna gain and directivity.

The majority of difficulties related to the input signal have to do with weak input signal strength, measured in microvolts on the receiver front panel. Depending on the manufacturer, equipment specifications usually specify that 200–1000 microvolts will result in a good output signal, but those numbers are reflective of equipment capabilities only.

Practical limits at a site tend to be much higher for several reasons. Depending on local conditions, weak signals can result in fades. Upward of 1000–3000 microvolts is usual, but even this level of signal can have problems during a fade. Carefully monitoring of proposed sites helps avoid the problem. The level of RF noise near a receiving antenna can also influence input. Noise levels can be higher than the signal strength of the desired signal. Subsequent filtering or antenna location can help resolve the issue.

In many cases, one must take special measures to ensure that reception and retransmission signals stay clean. A weak signal with poor signal-to-noise ratio (S/N) is generally the problem. The system's receiving section must contain a superior signal conditioning system, pre-amp and receiving antenna to maximize clarity.

Transmitters

Transmitters provide the RF power for the antenna. Proper design of a low power facility includes selection

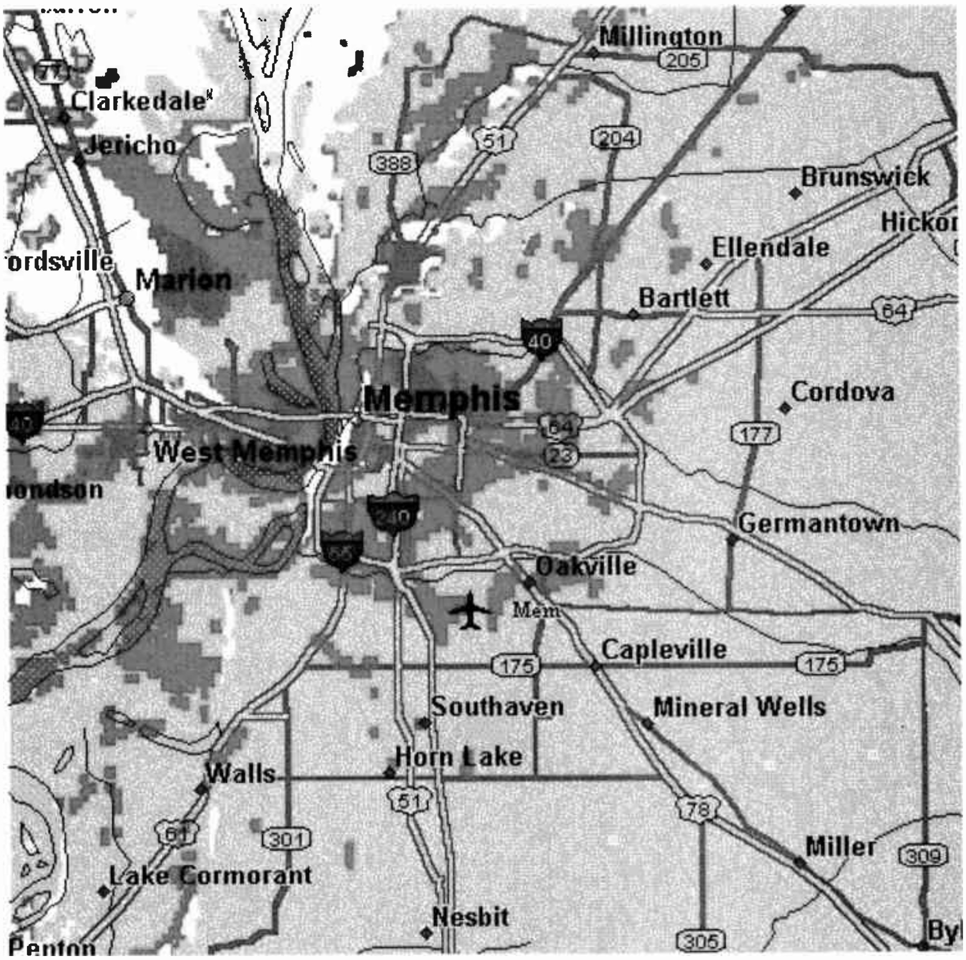

Figure 4.14-4. Interference.

of the appropriate transmitter for the job. A primary consideration is adequate power in order to achieve desired effective radiated power. The gain of the antenna(s) and the length of the transmission line(s) affect this power level requirement as do the available electrical power and the cooling system available at the transmission site. Generally, low power facilities do not need more complex electrical power systems, such as three-phase power or high-voltage power systems. As in any design, the transmitter should be well designed, easy to maintain and able to provide diagnostic information about its status and condition. Low power FM transmitters are usually either a standard FM exciter with low-pass filter or an exciter with a power amplifier. Many of the translators or boosters are solid-state; others operate with vacuum tubes. In a translator or rebroadcast application, several systems are available as complete solutions with built-in receivers and audio processors. In most cases, the transmitter is simple to install and operate.

Transmission Lines

Transmission lines play a major role in the design of a translator or booster. They provide the connection between the antennas and the equipment—whether transmitters or receivers. Detailed engineering data are available to allow the user to accurately calculate and compensate for feedline losses. Use the best cable in low power applications to maximize the power delivered from the transmitter to the antenna or from the antenna to the receiver. The antenna can only radiate the power it receives.

Avoid using a foam type dielectric cable unless it has a rigid outer conductor. Foam dielectric is flexible and has no need for pressurization, but extended exposure to high temperatures can result in migration of center conductors and impedance variations. In some cases, rigid outer conductor foam dielectric cable may be more cost efficient than air-dielectric lines if it is installed carefully without sharp bends or kinks. Keep in mind that air-dielectric cable or some alternate means of delivering nitrogen gas or dry air must be provided if the antenna requires pressurization.

An air-dielectric transmission line has a spiral-wound spacer that runs along its length to hold the center conductor in place. It is harder to handle and install than foam because it is so stiff, but it is much sturdier. Air-dielectric lines have diameters ranging from 1/2–5 in. (1.3–12.7 cm), but the most common sizes for low power operations are 7/8 and 1-5/8 in. (2.2–4.1 cm.)

Here are some important points to remember about coaxial cabling: The coaxial cable and connector quality are just as important as the quality of the system components. All it takes is one bad connector to make a system worthless. Use a semi rigid line for optimum performance. Never use braided cables. Since shield movement can cause noise in systems, secure all flexible cables to keep them safe from strain and unnecessary motion. Become familiar with the dielectric material, as connectors are the weakest link in every coaxial cable system. Avoid nylon connectors—they can absorb moisture as well as high-frequency RF energy. Only buy superior quality connectors from a company with a respected name. Polystyrene and Teflon are excellent choices. Avoid permanently installed adapters. Adapter construction is a compromise providing greater loss and inferior stability than using the correct cable terminations. It can introduce high Voltage Standing Wave Ratio (VSWR) into the system, thereby deteriorating overall performance and decreasing isolation. Above all else, pay attention to manufacturer's instructions. Just about any good quality connector works well if properly installed and protected from cable motion.

Towers

The supporting structure for a low power antenna may be very short or it can be 500 meters tall. Tower design details are beyond the scope of this chapter, but it is important for the translator or booster designer to be aware of various aspects of tower use. Towers are expensive, dangerous and have a tremendous impact on the surrounding environment. Delays in construction can last for years if proper planning and coordination do not occur. In the initial design phase, using of only the best quality tower can help avoid many devastating problems in the end. The loss of a tower can cause more time off the air than the loss of any other major component, it can cause severe damage as well. Pay proper attention to the tower supporting any broadcast antenna. While purchasing the best tower money can buy sounds like an expensive proposition, it is nothing compared to the cost of two towers plus any damage resulting from failure.

Receiving Pre-Amplifiers

Many manufacturers produce tower-mounted preamps with gains ranging from 10 dB to more than 60 dB. Since the received signal may experience increased noise and loss as it travels from the cable to the receiver, mount the pre-amp as close to the antenna as possible. A high quality amplifier should have no effect on signal reception except to increase amplitude to conquer cable and/or system losses as well as render the signal useful. A pre-amp with greater gain does not necessarily mean better performance than one with a smaller gain. The reason is that high gain pre-amps become more subject to overload as signal input increases. Select a pre-amp so that installation and input signal requirements are compatible. Overloading during input will result in distortion that can never be "cleaned up" afterwards. Moreover, if a pre-amp experiences a poor S/N at the input, an equal or slightly worse S/N will be on the output.

Receiver Filtering

There are many ways to implement filtering. In early gain stages of receiving equipment, tuning is broader, and a strong first or adjacent second signal may overload the input or mix in the receiver. Increased sharpness of input tuning can result in an increase in system noise.

Traps or band-pass filters at the input or at the tower may help in certain situations. Usually, a band-pass filter attenuates everything but the desired signal, and a trap may attenuate a specific signal causing interference.

Transmitter Filtering

Band-pass cavities are commonly used to reduce a transmitter's sideband noise. They pass the desired signal with a minimum of loss while sharply attenuating those frequencies that lie above and below the pass-band. Notch cavities have a response curve that is the reverse of a band-pass filter—they possess the same general configuration. Some people call a notch cavity a trap filter or a reject due to its ability to pass the desired frequency while it suppresses the rest. *Pass rejects* (sometimes called *pass notch*) cavities are a combination of the two other cavities. When the interfering frequency is extremely close to the undesired frequency, a *pass reject* is used.

Combiners

Wireless communications usage increases every day. Tower or system space is becoming more difficult to arrange due to environmental pressures, lack of real estate and costs. Transmission sites are becoming crowded. These trends are resulting in a greater need to mix two or more transmitters into one antenna. Combiners do a number of good things at the same time. They filter potential interference and intermodulation, provide isolation between transmitters and allow two or more transmitters to be mixed into one coax run and antenna. Although combiners themselves are relatively, the cost savings to tower sites operators are high.

Cavity combiners are generally manufactured from intercabled band-pass cavities. The isolation is the result of the cavity's resonant response curve. Sometimes, pass reject cavities provide for closer frequency spacing or greater isolation. Advantages of cavity combiners include flexible configuration, cost efficiency and low insertion loss. Negative features include large size, reduced channel capacity and possible redesign of a combiner when frequencies are changed or added. Use a combiner when the frequency spacing between channels is extremely wide. The minimum spacing for the FM band is usually about 1 MHz.

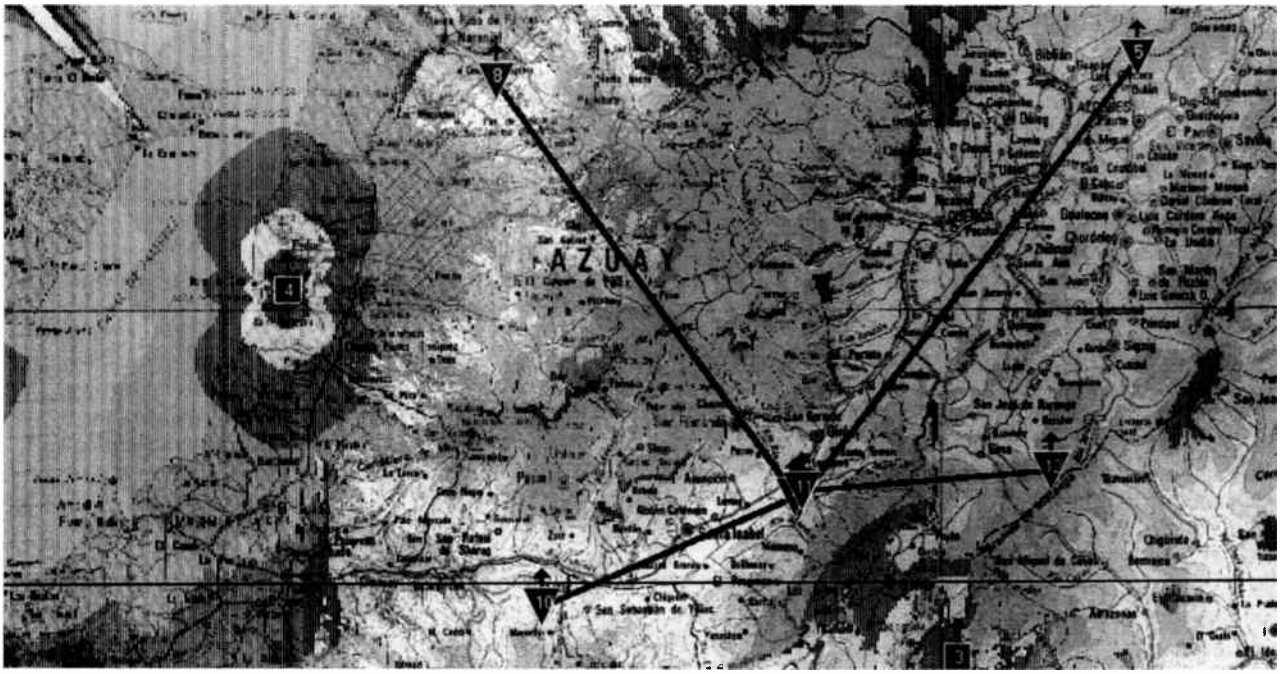

Figure 4.14-5. System coverage.

INSTALLATION AND TROUBLESHOOTING

Every transmitter site has potential for problems. While it is impossible to anticipate every conceivable difficulty, proper foresight and planning can help avoid the likelihood of many disasters.

Tuning and Installing the Antenna

A transmitting antenna is just as sensitive to its immediate environment as a receiving antenna. If you have ever adjusted a rabbit ear antenna on a TV set or the rod antenna on a boombox, you understand the concept. A very small change in the antenna orientation or environment has a drastic effect on its performance. Install the antenna and tune it properly from the beginning, and the facility will perform as predicted. The supporting structure, the antenna design and the way the antenna is mounted all affect the quality of the signal. After installation, the system should be swept with a network analyzer; the coverage should be measured and documented to verify proper installation and for use as a baseline for future review of possible system problems (see Figure 4.14-5).

Adjacent Channel Interference

Adjacent channel interference can be exasperating because the adjacent channel can sound weak and yet be powerful enough to create distortion in the desired signal. When modulation components overlap on adjacent channels, mixing occurs, resulting in out-of-band product generation. The problem can be fixed through special intermediate filters or external filters on the receive antenna.

Condition of Antenna System

Most transmitters have a test meter that indicates if the antenna has failed to the point that it can harm the transmitter. However, there is typically no accurate test equipment available at a transmission facility to qualitatively indicate how well the transmitter or antenna is performing. Most antenna complaints are very subjective. (You just can't "get" the station as you used to. It does not sound right any more, etc.) The only accurate way to tell if an antenna is working correctly is to test it with appropriate test equipment used by antenna manufacturers and consultants. A network analyzer can measure return loss and impedance as well as many other fine details of the antenna system (see Figure 4.14-6).

Quality of Modulation

A commonly overlooked cause of signal problems is poor source material. In this case, no amount of improvement to the antenna or transmission system will correct the problem. Translators and boosters cannot improve the quality of signal they receive. Some systems are implemented with signals from primary stations as much as 100 miles (160 km) away, usually when the elevation is high at the transmit and receive points and low through the transmission path. In such cases, it is important to monitor the received signal for a good length of time using recording equipment, since signal quality can be intermittent.

Spurious Emissions

When there are several stations located at one transmitter site receiving interference, there may be har-

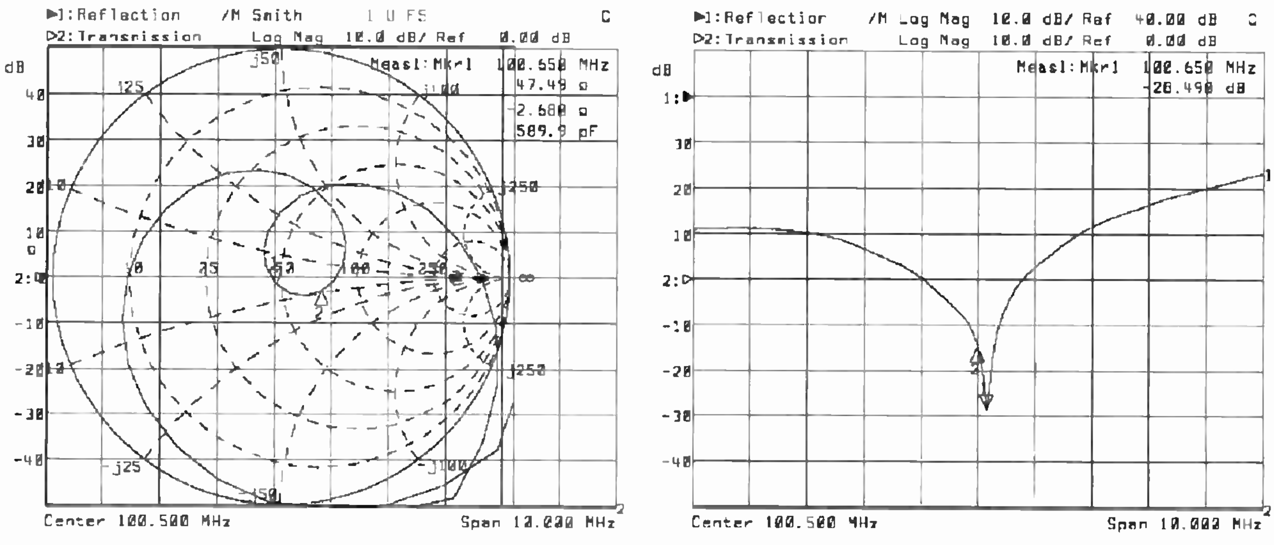

Figure 4.14-6. Network analyzer sweep.

monic mixes between the other stations that fall on or near your frequency. Sometimes these harmonics originate within the transmitters involved in the mix. If the spurious harmonic signals are above a certain threshold, they may be in violation of governmental rules. The existence of this type of interference is verified by using a spectrum analyzer at the towers of the offending stations. The source of this kind of interference can only be verified by connecting the test equipment to the various transmitters involved.

Most complaints are about interference to nearby television receivers. Installing a filter at the output of the TV receive antenna might help. If a filter does not work and the antennas are properly spaced, cabinet radiation or power line feedthrough is the likely culprit.

Serious performance issues can arise when a high-powered nearby FM station's output energy mixes with that of the translator. This is a common problem. Tubes and output transistors are not linear and thus tend to operate as mixers, producing spurious signals that interfere with sensitive receiving equipment. Because the problem goes away when the transmitter is shut off, inexperienced technicians tend to blame the transmitter. The truth is, all transmitters react this way under the same conditions. The goal is to keep external signals from the final RF stage of the transmitter. Installing an isolator in the output transmission line is a cost efficient way to solve the problem. A second option is to employ a high "Q" cavity in the output, which bypasses the transmitter output and rejects the offending signal.

Re-Radiation

Spurious emissions are not necessarily transmitter related. Towers and other metallic objects can re-radiate signals and cause nonlinear distortion resulting in spurious emission. Use a spectrum analyzer to examine the output channel. If the measured signal is clean at the output of all involved transmitters, re-radiated spurs may be the cause. These problems are very difficult to isolate and correct because they are often intermittent. Sometimes introducing mechanical vibrations can help identify trouble locations, but this kind of problem usually takes much time and patience to resolve.

Receiver Induced Third Order Harmonic Interference

When a receiver is near other transmitters, even if the desired station has a strong local signal, the receiver will overload or "be blanketed" by the relatively higher signal levels of the jamming transmitter. The selectivity (ability to reject strong local interference) of the receiver determines its susceptibility to this kind of interference. In either case, harmonic mixes occur within the receiver itself, causing the desired signal to be jammed. This situation is *receiver-induced third-order harmonic interference.* There is no easy cure for this problem except replacing the receiver with a better-designed unit.

Front-End Overload

Front end overload is the result of brute power RF transmissions in the surrounding area. It is entirely possible to have a translator operating on 300 microvolts, for example and a 100 kW station 1 km (.6 miles) away. Front-end overload occurs when the translator tries in vain to accommodate the lower level input signal while being hit by the much stronger signal. Filtering on the input line is the best way to solve the problem before the signals mix in the first place. If the site lacks a strong enough input signal to overcome the insertion loss of a selective filter, consider using special pre-amps designed just for that purpose. Relocating or redesigning the input antenna structure is another viable option. Other methods include raising the receive antenna, adding or stacking receive antennas and relocating receive antennas (or perhaps the entire site). Of course, these methods work for professional fixed receive sites. Vehicles or consumer receivers often have no simple cure.

Feedback

If, after translator installation is complete and the power is turned on, there is nothing but hash and noise, you are probably experiencing feedback. This is because any low power system conveys undesirable products as well as the desired modulation. These products possess a wide bandwidth, which is usually several megahertz from the main carrier frequency. Generated products are comprised of the energy caused by the random motion of electrons (Johnson noise) and sideband components from the desired modulation. Generally, the undesirable products are quite weak, so they cannot be observed on a spectrum analyzer without suppressing the main carrier. Regardless of whether the undesirable products are modulation components or noise, some of these undesirable products will be in phase between the input and the output of the translator or booster. Translator output power is usually in the millions of microvolts while the input signal is just a few hundred microvolts. Poor translator performance is the result of spacing the antennas a few meters apart because the relatively high-powered output puts too much strain on the receive section. A distance of at least 15 vertical meters (49.2 vertical ft) is recommended. To ascertain whether antenna separation is the problem, replace the transmit antenna with a dummy load. Solve the problem with good antenna and frequency separation, usually at least 1 MHz between input and output.

Filters

Providing a filter at the transmitters output can solve many problems. The purpose of the filter is to subdue those undesirable products that fall on a receiver's input channel, but execution is more difficult than it sounds. Note that the quality factor "Q" denotes how lossy the filter will be in operation.

If a translator operates at 100.1 MHz, it would need a filter to prevent undesirable products from falling on the input channel at, for example, 102.1 MHz. Two MHz is the separation factor, so to make sure that no products from the output fall on the input, the bandwidth cannot be more than 1 MHz. $Q = 100.1/1 = 100.1$. This is the minimum value. To have a filter with a low insertion loss and a minimum of energy loss, the Q for every element inside the filter has to be 100 times the minimum, or 10,000 times. However, the realization of such a Q factor necessitates the use of costly cavity type filters.

It is much more cost efficient to use Q factors of around 800 for the filter elements. The filter uses a combination of two techniques: band-stop and band-pass. The band-stop section is a slot about 300 kHz wide, adjusted to the input channel frequency.

The band-pass section passes carrier frequency and useful modulation data. This low loss device adds more selectivity to optimize the system's performance and it can also decrease the radiation of out-of-band signals. A good example would be between an antenna and transmitter combiner, where the filter's job is to overpower any harmonics originating in the ferrite isolators and reduce any broad band transmitter noise so that receive sensitivity remains intact. Energy from the translator output that falls on the input frequency is attenuated by approximately 50 dB. Using an example of 5 microvolts worth of undesirable products falling on the input after passing through the filter, the magnitude is reduced by 50 dB (.0158 microvolts the $s/n = 10/.0158 = 632 = 56$ dB).

AM AND FM FIELD STRENGTH MEASUREMENTS

**DONALD EVERIST, P.E., COHEN, DIPPELL AND EVERIST, P.C.
WASHINGTON, DC**

AM FIELD STRENGTH MEASUREMENTS

INTRODUCTION

Properly conducted field strength measurements can provide valuable insight on the performance of a broadcast transmission facility. Because of the differing characteristics of AM-band and FM-band propagation, the procedures used for taking AM measurements differ from those used for FM measurements. This chapter will explain both procedures.

AM Field strength measurements are central to establishing and maintaining a directional array. They are performed to determine antenna radiation efficiency and propagation path characteristics. The Requirements for U.S. Broadcasters are given in Table 4.15-1.

Proof-of-Performance

An AM directional antenna is composed of at least two or more radiating elements. The amplitude and phase relations of RF energy fed to each element and the physical spacing between each element produces a predicted directional pattern shape. Each directional pattern is designed and constructed for a specific application, to provide the optimum service to the desired area while providing adequate protection for other co-channel and adjacent-channel stations.

The *proof-of-performance* is used to establish the initial operation of the directional pattern at the time of licensing. It is a condition imposed by the FCC before licensing can occur and is used to update the performance of the antenna system at such times as may be necessary or may be directed by the FCC. It is also used as a reference for subsequent partial proof-of-performance.

Reference Proof-of-Performance

A reference proof is the latest complete proof-of-performance accepted by the FCC, and is the proof to which partial proof measurements must be referenced. The *reference proof-of-performance* specifies, for each monitoring point, the point number, the distance in miles from the transmitter site, the radial and the point location. Section 73.151 of the FCC Rules defines the general field strength measurement requirements to be made on the construction permit and non-construction permit radials for the reference proof.

A reference proof defines the nulls, suppression and major radiation areas of the directional pattern. A reference proof-of-performance requires the taking of non-directional and directional measurements along each radial under similar environmental conditions. While each proof has its own requirements, in general, non-directional measurements begin (as specified by the FCC Rules, Section 73.186) at a distance of five times the height of the non-directional antenna. They are to be made at approximately equal sets of intervals such that, as a goal, 15 to 20 measurements are established within the first 3 km (two miles), eight to ten measurements within the next 7 km, (miles two through six) and 14 measurements to extend to a distance of 24 to 32 km from the transmitter site (miles 6 through 15 to 20). Directional measurements are to be made under similar environmental conditions beginning at ten times the widest spacing between the elements of the antenna system. The instantaneous changing of patterns from non-directional to directional at either a prearranged time or by two-way communications can be beneficial. This technique permits the acquisition of the measurement data in the minimum amount of time and permits the continuous measurement observation without moving the field strength instrument. The accumulation of measurement data whereby both the non-directional and directional measurements are made at a given point at the same time will eliminate relocation and time differences.

Measuring Instrument to Be Used

When field strength measurements are made in support of the partial or reference proof-of-performance, a portable instrument made solely for this purpose and of known accuracy is utilized.

For directional antenna systems, the taking of a proof-of-performance and the availability of the measurement instrument are conditions of the construction permit.

The authorization granted is subject to the following conditions:

> A complete non-directional proof-of-performance, in addition to a complete proof on the directional antenna system shall be submitted before program tests are authorized. The non-directional and directional field strength measurements must be made under similar environmental conditions.

Authorization to Use an AM Directional Antenna System

The directional antenna system requires FCC approval before its operation can commence. Unlike non-directional operations, directional operations cannot be instituted upon a notice and a promise of a subsequent submission to the FCC to fulfill license requirements. The FCC program test authority indicates that the FCC is in essential agreement that the antenna system is in compliance with the FCC Rules and indicates that the permittee has met their basic obligations and authorizes that operation can commence as described in its licensed application. However, specific requests by the Commission may accompany the program test authority and those requests must be satisfied before the FCC will issue a license. The FCC requires a 30 day set of measurements for each directional operation after submission of the proof-of-performance and receipt of the program test authority from the FCC. This request for the data will accompany the issuance of the antenna parameter data and has language similar to the following:

> Program test should be conducted with the directional antenna system adjusted in accordance with the enclosed corrected specifications pending further action on the license application. It is requested that you check the values of field strength at each of the monitoring points at least once weekly during the next 30 days and submit this information in tabulated form to the Commission together with the following meter readings extracted from the transmitter log at the time the monitoring points are checked: (1) common point current, (2) base currents and their calculated ratios, (3) antenna monitor sample current ratios, (4) phase indications, (5) final amplifier voltage, and (6) current.

Partial Proof

Section 73.154 of the FCC Rules governs the taking of a *partial proof-of-performance* as presently required by the FCC Rules. A partial proof must be done, for example, when there is a change of directional operating parameters; when changes are made above the base insulator of the antenna (such as the addition or alteration of an FM antenna or transmission line mounted on the tower), when there is an increase of an existing monitor point license value, or when changes in the environment of the array dictate the necessity of demonstrating compliance with the station's instrument of authorization.

The partial proof-of-performance measurements are to be made at the same locations as specified in the reference proof, but measurements do not have to be taken at all locations. The partial proof-of-performance must contain a minimum of ten measurements at points along each of the radials defined in the reference proof. The partial proof must contain an arithmetic or logarithmic analysis of the measurement data so obtained. It must be demonstrate that the antenna system is operating within its instrument of authorization. Generally speaking, the measurements should be made at an interval of 3 to 16 km (two to ten miles). A statement that the impedance of the common point has been measured and is unchanged from the licensed value prior to the making of the measurements should be provided. A change in common point impedance at the operating frequency requires an appropriate submission to the FCC and is to be requested using FCC Form 302.

The partial proof-of-performance in those areas where ground conductivity is not constant should be made under similar environmental conditions as the reference proof. More accurate information can be obtained when the directional partial proof-of-performance is based upon current non-directional measurements.

General Requirements for Measurements

All measurements should be made during daylight hours in the absence of interference. Special temporary authority may be required prior to the commencement of measurements for a new station. For established stations, the FCC Rules permit considerable flexibility in operation during periods of making field intensity measurements on the antenna system.

FCC policy has been that the measurement observation to be recorded and utilized as a basis of analysis of the inverse distance radiation is that observed with the field set oriented towards the station. The field set maximum indication can have an orientation away from the transmitting source. This phenomenon can be affected by many factors, particularly the depth of a null. Other factors vary from local effects surrounding or adjacent to the measuring point, non-uniform conditions inherent in the propagation path and the position of the monitoring point in region where there is a sharp change in the pattern.

A record must be kept of the measurement data including the point number and description, field strength observation, date and time, pattern under investigation, name of the individual taking the measurements, general weather conditions, and the field strength instrument and date of last calibration. A sample form is provided in Figure 4.15-1 for tabulating the field measurement data.

Monitoring Points

An important, initial step in setting up a directional antenna is the selection of *monitor points* along the

radials specified in the construction permit. These points must be reachable in inclement weather and free of possible reradiation objects such as underground pipes and overhead wires. Schoolyards, churches and cemeteries often provide useful locations since the surrounding area is usually clear.

Prior to submission to the FCC, data should be taken at proposed monitoring points over a period of time until the accuracy and stability of measurements can be established. Readings must be in the direction of the station. This can be established by using a U.S. Geological Survey topographic map or by switching the antenna array to the non-directional mode (if available). See Chapter 1.7 *Broadcast Related Organizations and Information* for information on obtaining USGS maps.

Once the directional array has been adjusted and its performance documented, one of the often overlooked items is the monitoring of the area for new construction. Vertical structure construction or new construction authorized by governmental authorities is often very difficult to detect in the advanced stage of planning. New power line construction and construction of other communication structures can act as reradiators if located sufficiently close to the array. Such reradiated energy can affect the pattern so as to reduce interference protection to other stations.

Graphical Analysis

The inverse distance field or attenuated field intensity at a reference distance (1 km) is that radiation predicted if the earth were to behave as a perfect conductor. As the wave energy travels away from the antenna, this energy reduces in value. The value of the radiated field is reduced by the inverse proportion to the distance from the antenna. For example, if the value of the unattenuated field at 1 km is 100 mV/m, its value at 2 km will be one-half that value or 50 mV/m, and at 10 km, its value will be one-tenth or 10 mV/m.

After the distance from the transmitting antenna to each of the measuring points has been determined and tabulated opposite to the observed field strength values, a measured field strength can be plotted on log-log graph paper. The ordinate is expressed in mV/m and the abscissa is expressed in distance. The FCC, in its conversion to metric, redetermined the frequency curves.

There are 20 frequency charts that encompass the frequencies from 540 kHz to 1700 kHz. The uppermost portion of each chart contains conductivity curves normalized for 100 mV/m at one kilometer from 0.1 km to 50 km and the bottom portion contains the same conductivity curves for distances from 10 km to 5,000 km. (The chart for 670 kHz is shown in Figure 14.5-2.)

For the logarithmic coordinate system, (log-log graph paper) the inverse distance line plots as a straight line. Each of the curves is drawn for the case of an inverse distance field of 100 mV/m at 1 km, and its use is not limited to that value. If an inverse distance field is 200 mV/m (twice the reference value) or 50 mV/m (one-half the reference number) or some other value at 1 km, and if all points on the curve are multiplied by that ratio, this would be the equivalent of moving the curve by that amount on logarithmic coordinate paper. This is the basis by which measurements are analyzed and the appropriate graph for the frequency involved is made by matching the abscissa of the data with that of the FCC graph. By sliding the ordinate information data vertically, the best fit is obtained. By this method, both the unattenuated field at 1 km and the conductivity value along the radial path have been determined. The use of a light table or window or TV set tuned to an unused channel will serve as a backlight for visual analysis of the data.

An individual attempting to analyze measurement data for the first time or not having benefit of supervision can find this is a frustrating experience. One approach is to take log-log graph paper for the appropriate frequency (either the regular or expanded scale) and plot the measurement point values normalized to 100 mV/km. For example, if the non-directional 0.25 kW operation is expected to possess an RMS field at 1 km of 91 mV/m 70° (0.194 of a wavelength) electrical height tower with a normal ground system, see Figure 8, Section 73.190 of the FCC Rules), it has a field 91/100 less than the FCC log-log conductivity graph. Therefore, multiply all values (divide all values if the expected field is greater than 100 mV/m) of the measurement data by the ratio of 100/91 to normalize this data to 100 mV/m. Plot the normalized data. The plotted values can be viewed in relation to the conductivity values if the assumption of the inverse distance field is correct. If the normalized data appears to be over the inverse distance line then the radiation value is higher than assumed and conversely if the normalized data appears abnormally low, the assumed radiation value selected is too high.

This approach can be useful when the non-directional measurements out to 3 km in the various directions have been taken and a quick evaluation of the conductivity values/radiation efficiency around the site is desired. It also will help to assess whether or not the non-directional radiation pattern is being influenced by other adjacent towers in the directional antenna system.

Authorizations

Special temporary authority (STA) will be generally required with any operation which has not received prior authorization from the Federal Communications Commission. Section 73.1635 of the FCC Rules provides that STA be requested in writing (an original and two copies) to the FCC. The authorization request should delineate the station frequency, location, a complete description of the proposed operation and the necessity of the STA. The letter should indicate the capacity of the requesting individual and their contact information so that the FCC can request additional information informally, if required.

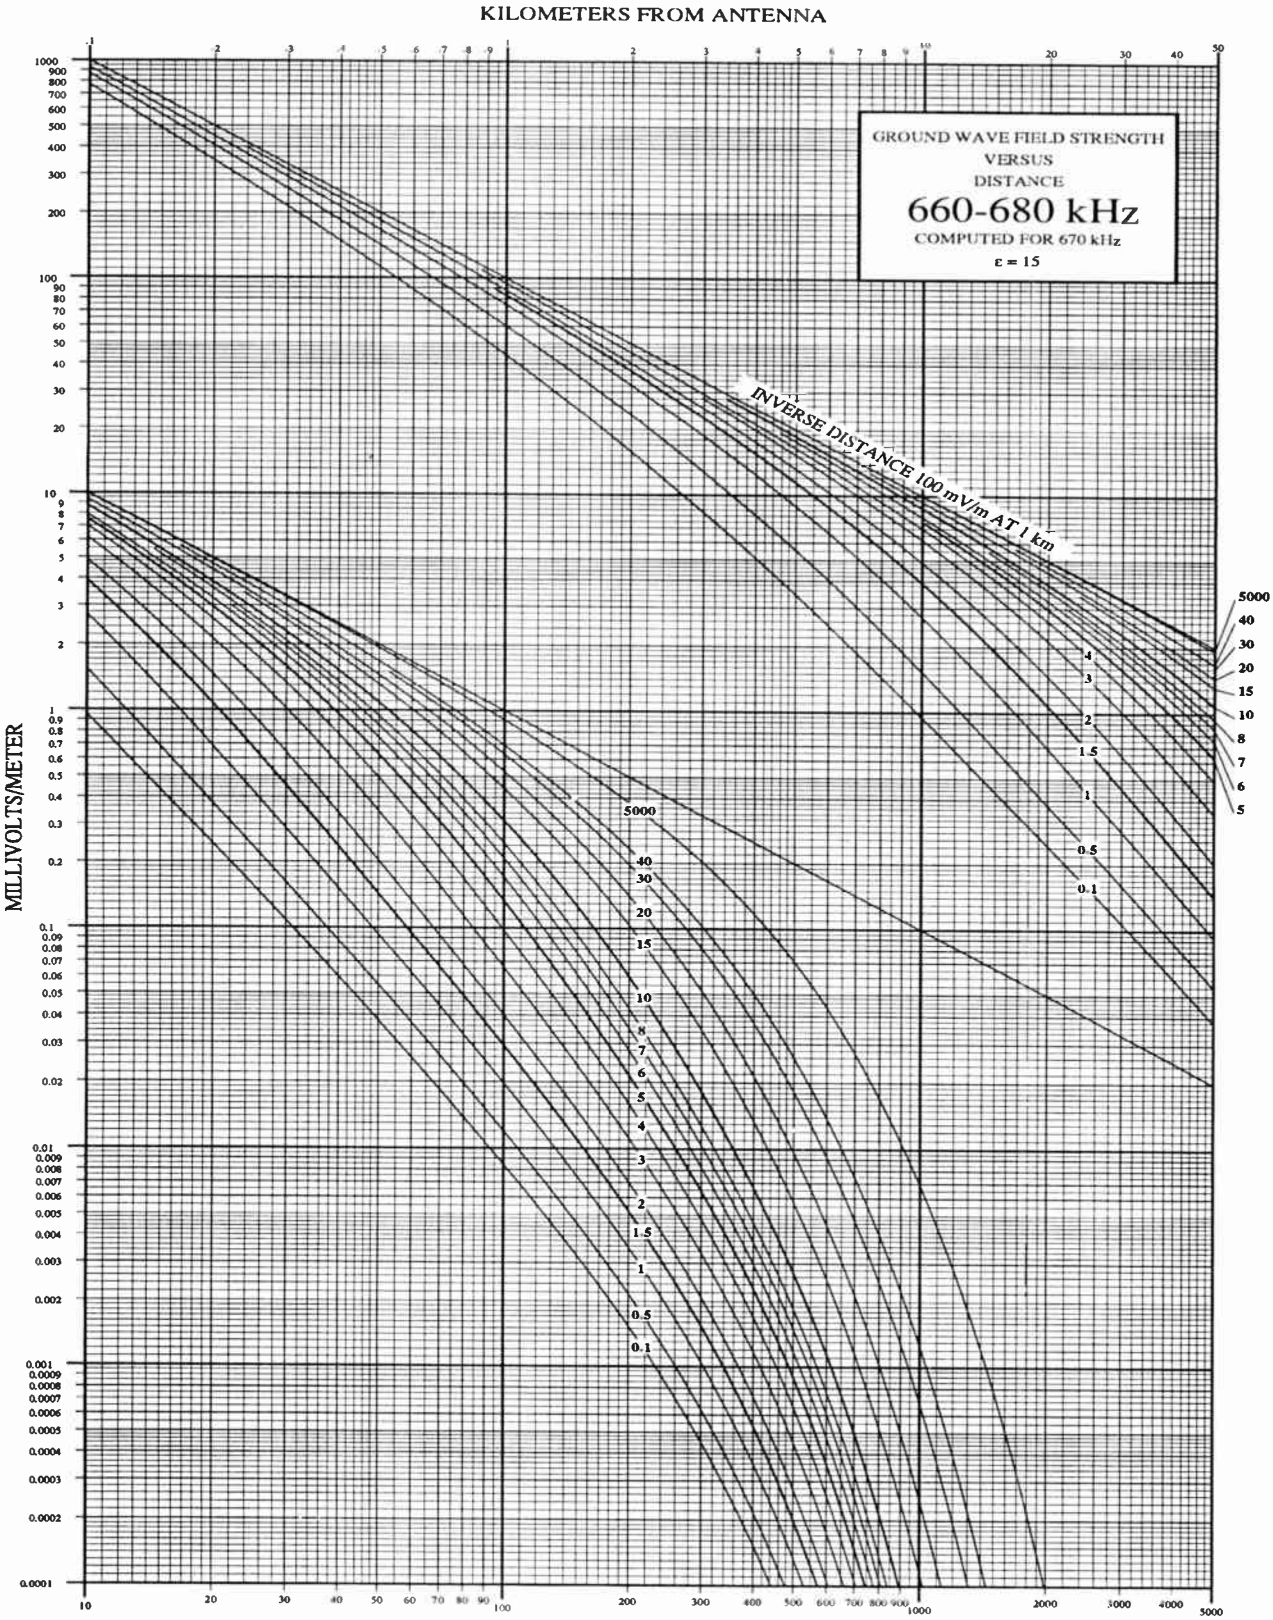
For licensed operations, the FCC Rules provide that non-directional power has been authorized for a proof-of-performance during daytime-only. A station with a single, or more than one, directional pattern for day and night, etc., can utilize non-directional power set forth in the latest proof-of-performance without further authorization from the FCC. However, this privilege is permitted only for the purpose of field strength measurements. In addition, the FCC permits without further authorization the nighttime pattern being operated during daytime hours when field intensity measurements are being taken.

Antenna Monitor System Approval

For each authorization for a new station, details of the antenna monitor system components and installation must be contained in the proof-of-performance in order to obtain the necessary recognition from the FCC that the antenna monitor system conforms to the FCC Rules. An antenna monitor system description accompanying a partial proof must be sent, for prompt consideration, in a separate submission. During construction or revision of the monitoring system, STA for variance of parameters may be required for existing stations. This authority can be obtained by submitting a request (original and two copies) to the FCC. The purpose of the request as well as its duration should be provided. For specific situations, reference should be made to Section 73.68 of the Rules; however, with the revision in Docket 85-90, the FCC is less specific as to the detail of sample-system construction. The FCC indicates as a matter of policy that the methods outlined in the Rules as modified by MM Docket 83-16 would receive continued FCC acceptance. Other less conventional methods may be subject to rigorous scrutiny including observations over a period of time and a partial proof-of-performance. For convenience, Section 73.68 of the FCC Rules is provided as an appendix to this chapter prior to alteration by Docket 85-90.

FCC License Application

The FCC license application is FCC Form 302. Each proof-of-performance must include the information requested in Form 302. It must comply with the provisions and intent of the FCC Rules including Section 73.186 regarding the number of measurement radials, number of non-directional and directional measurements made along each radial, mathematical or graphi-



KILOMETERS FROM ANTENNA
GRAPH 5

4.15-2. Groundwave field strength versus distance frequency curve.

cal analysis, if utilized, plot of the field versus distance measurements on semi-log or log-log graph paper and reproduction of the quadrangle maps (or other maps as required) showing the radials along which measurements were made and locations used in making each of these measurements. Section 73.186 also dictates form and substance concerning the submission of non-directional antenna resistance data as well as the common point impedance measurements with the required graphical plots.

Furthermore, descriptions of the monitoring points complete with the monitor-point photographs and a route diagram as specified by the construction permit must be supplied (see Section 73.158). The station must also comply with other provisions of the construction permit.

A diagram of the RF feed system as constructed (including the phasor, transmission lines, and the tower matching networks) is to be provided. A plot of the inverse distance field at 1 km for the non-directional as well as each directional mode is to be supplied based upon the interpretation of the measured data. The directional pattern must not exceed the authorized pattern in any direction and must have the requisite RMS. In certain situations for new stations or revisions of existing facilities requiring a new reference proof-of-performance, the FCC will permit an adjustment of directional power which can be effected at the time of the license application.

For each directional operation, the parameters as indicated by the antenna monitor for both loop and phase (including sign) as well as the base currents and the ratios are to be furnished. Each field strength instrument and its type number, make and model, and date of the last calibration should be listed. If more than one instrument is utilized, a comparison of the accuracy observed for each instrument should be made.

License

The FCC license provides, among other things, the licensee name, term of the license, station location, main studio location (if not at the transmitter or within the boundaries of the principal community contour) remote control location, transmitter location and its coordinates, type of antenna and ground system (if non-directional) frequency, nominal power, hours of operation and any special conditions. For stations using a directional antenna system, the second page will provide a description of the directional antenna system, the spacing, orientation, and height of the towers and a description of the ground system. Also provided are the theoretical and operating specifications determined from the most recent partial or full proof-of-performance. The description of the monitor points and the maximum limits of the field strength that the points must not exceed are contained on the following pages(s).

Changes and modifications of any of these items require appropriate notification to and approval by the FCC. When receiving a new license, it should be inspected for correctness by comparison with the license application. The operating parameters must be maintained in accordance with Section 73.62 of the FCC Rules. The directional parameters must be maintained with indicated relative amplitude of the antenna base currents and antenna monitor currents within 5% of the values specified in the license, unless other tolerances are specified. In addition, the directional antenna relative phase angles must be maintained within 3° of the values specified in the license unless other tolerances are required.

Monitor-point values must be maintained within the values specified in the license. An increase in an existing monitor point value can only be accomplished by submission of a partial proof-of-performance to the FCC. A change in monitor point location requires submission of a photograph, route diagram, description of the new monitor point and a minimum of ten measurements including the newly-designated monitor point between two and ten miles as shown in the latest reference proof. This information is to be submitted to the FCC.

FM FIELD STRENGTH MEASUREMENTS

FM field strength measurements performed for general determinations of service area require prior planning including safety considerations, study of the topography of the propagation path, proper field strength measurement equipment, documentation and analysis tools.

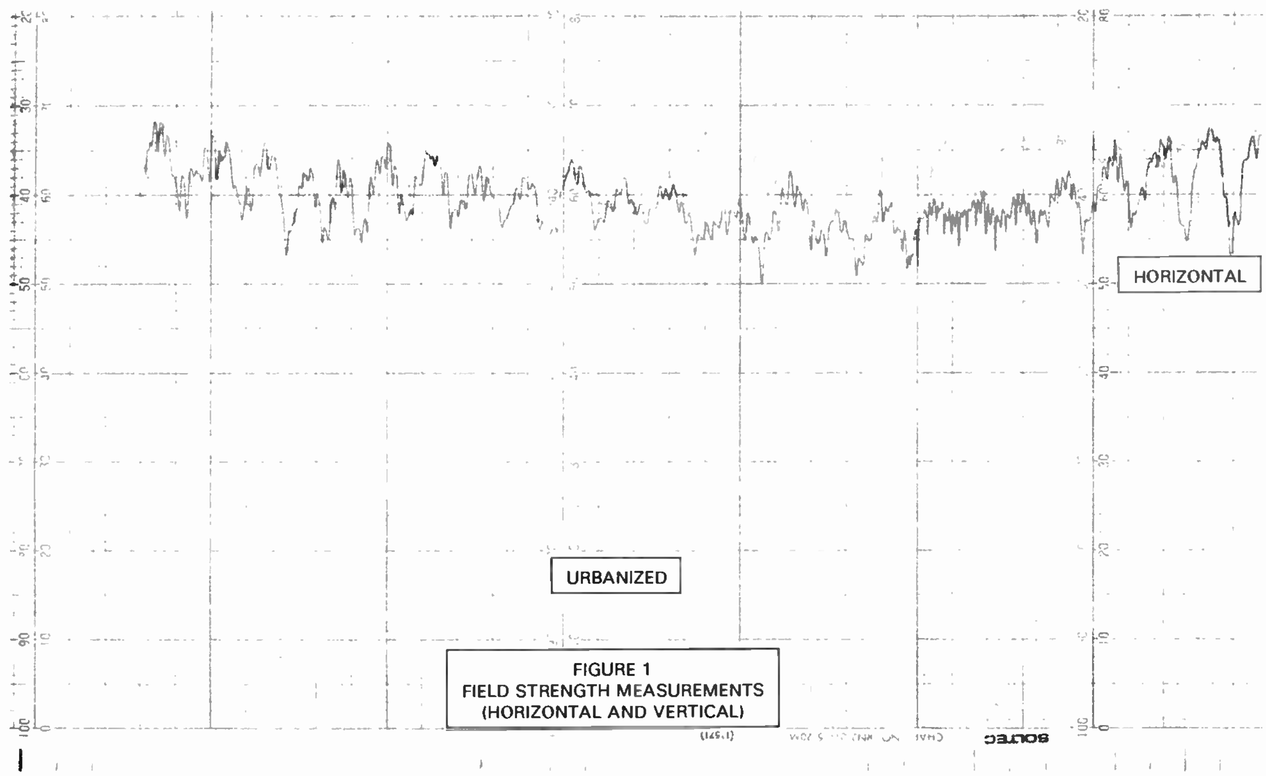
Field Measurements and the FCC Rules

In Section 73.314 of its Rules, the Federal Communications Commission outlines what is required when submitting FM field strength measurements in support of applications. The Commission addresses two methods of measurement—radial and grid. Either of these methods, when properly performed, can be a valuable investigative tool and can yield valuable information about a station's service area on a selective and/or overall basis.

The field measurement data for the station can be helpful, for example, in verifying a site's propagation characteristics to an important service area[1] and in determining an antenna's horizontal and vertical performance characteristic.[2] Performing proper field measurements can be a daunting task since the FM signal level can vary dramatically over a short distance particularly if the measurements are taken with the antenna located close to the ground. The FCC propagation curves F(50,50) and F(50,10) are referenced to a height of 9 meters (30 feet). Figures 4.15-3 through

[1] Alternatively, properly conducted field strength measurements can help define an underserved area. Field strength measurements can provide important information if supplemental service via a booster or translator is being considered.

[2] Field strength measurements can also be made to determine radio frequency levels and spurious emissions.



PERFORMED WITH POTOMAC INSTRUMENT MODEL FIM-71 METER
WITH MANUFACTURER'S SUPPLIED CABLE AND CALIBRATED ANTENNA AT 9.1 METERS

4.15-3. Field strength measurements (horizontal and vertical) urbanized terrain.

4.15-5 provide an example of consecutive horizontal and vertical data recorded at 9 meters in generally urbanized, hilly and flat terrain. While this measurement data is reasonably well behaved, it does provide insight as to the degree of difficulty in attempting to gather reliable and meaningful data under varying propagation paths.[3]

The Commission's Rules provide guidance for the taking of field strength measurements. Briefly, these are:

- field strength measurements are to be taken with an antenna height of 9 meters (30 feet) above ground
- field strength measurement data are to be continuously recorded (graphically and digital) over a path segment of specified length of at least 30 meters (100 feet)
- field strength measurements are to be performed with an antenna and field meter designed to accurately measure the FM signal
- the manufacturer's calibrated antenna is to be oriented for the maximum signal. Each field strength measurement point is to be made in an area which is representative of the area and free of overhead obstructions
- documentation should include the use of a GPS receiver for coordinates, or marking the location on the latest USGS quadrangle plus the date and the time, and the description of the point including topography height and the type of vegetation, buildings, obstacles, weather, etc.
- analysis of the field strength data must be based on the median value of measured signal if it is to be referenced to the FCC F(50,50) propagation curve.

Planning

To minimize time and effort, the purpose for taking the measurements must be determined prior to taking the first measurements. If the inquiry is to be an examination of an aging antenna's radiation performance, this may require field strength measurements to be taken in the eight cardinal directions. Field strength measurements to characterize antenna radiation performance could require the use of a reference antenna with known gain characteristics and effective radiated power (ERP). Also another antenna on the same tower as the antenna under test and whose radiation performance is known, can be used. This could be a top

[3] Measurements were performed with a specially designed vehicle that uses a method in which the chart recorder is dependent on the distance traveled. This permits field strength measurements to be repeated.

mounted FM or VHF television antenna. The mathematical relationship between the desired FM signal and the signal from the reference antenna can be determined and results compared with those anticipated. In any measurement program, measurement points located in clear and unobstructed areas are required. The number of measurements along each radial should be sufficient to establish the antenna's performance in a particular direction.

To investigate an area in which reception difficulties (low signal, multipath or interference) are being experienced will require organization of all factors pertinent to the inquiry. These service area concerns or locations, where possible, should be compiled by zip code and address. Also, additional information such as whether the complaint is from a stationary or mobile receiver, at what time frame and other particular factors must be documented so that they are available when performing the measurements.

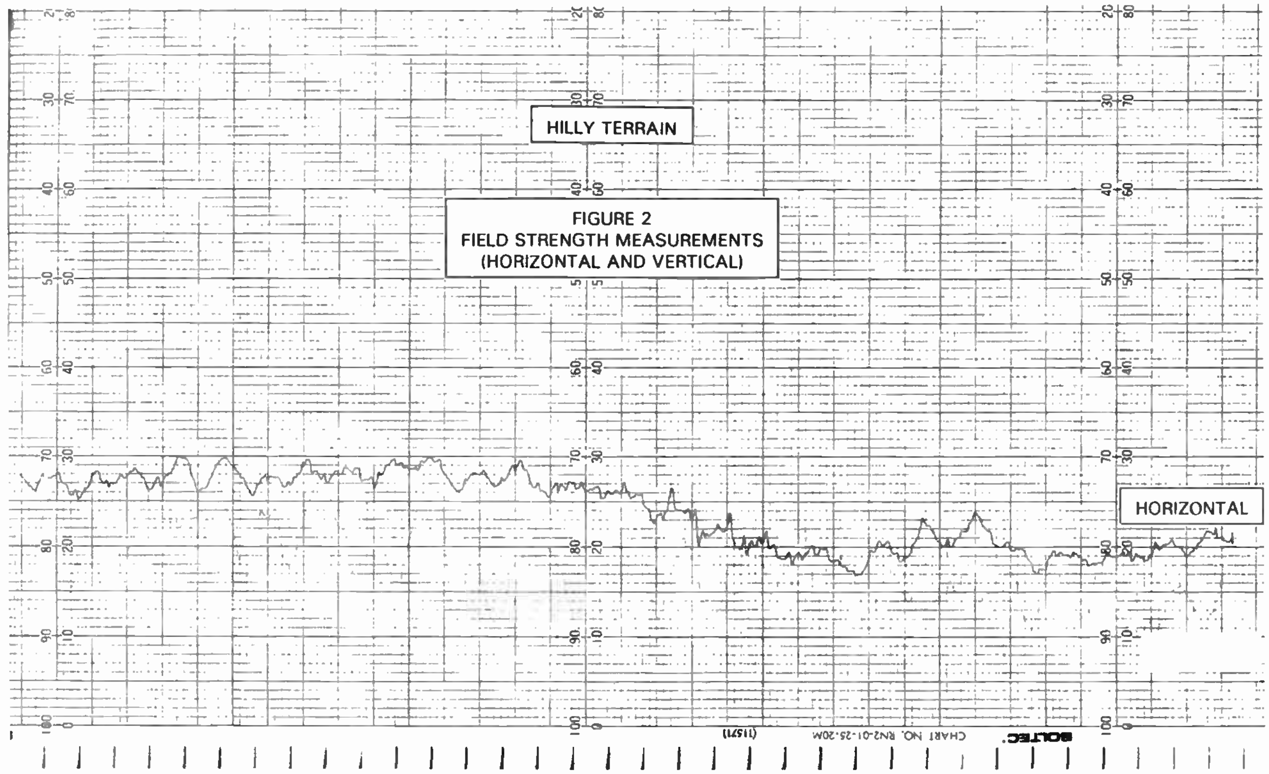
When sufficient information is available to warrant further investigation, several approaches may be used. Initial physical investigation could be performed by documenting the area of concern by using several types of good quality receivers. The results of this initial investigation could be augmented by manually plotting profile information or by using one of a variety of computer profile programs to ascertain the nature of the propagation path.

From this preliminary examination, if the cause of the service deficiency is not apparent, expansion of the study by making field strength measurements may be warranted. The preliminary examination, prior to measurements, must yield sufficient information to give focus to the nature of the further investigation. In essence, complaints by advertisers and the listening public must be verified before taking any measurements.

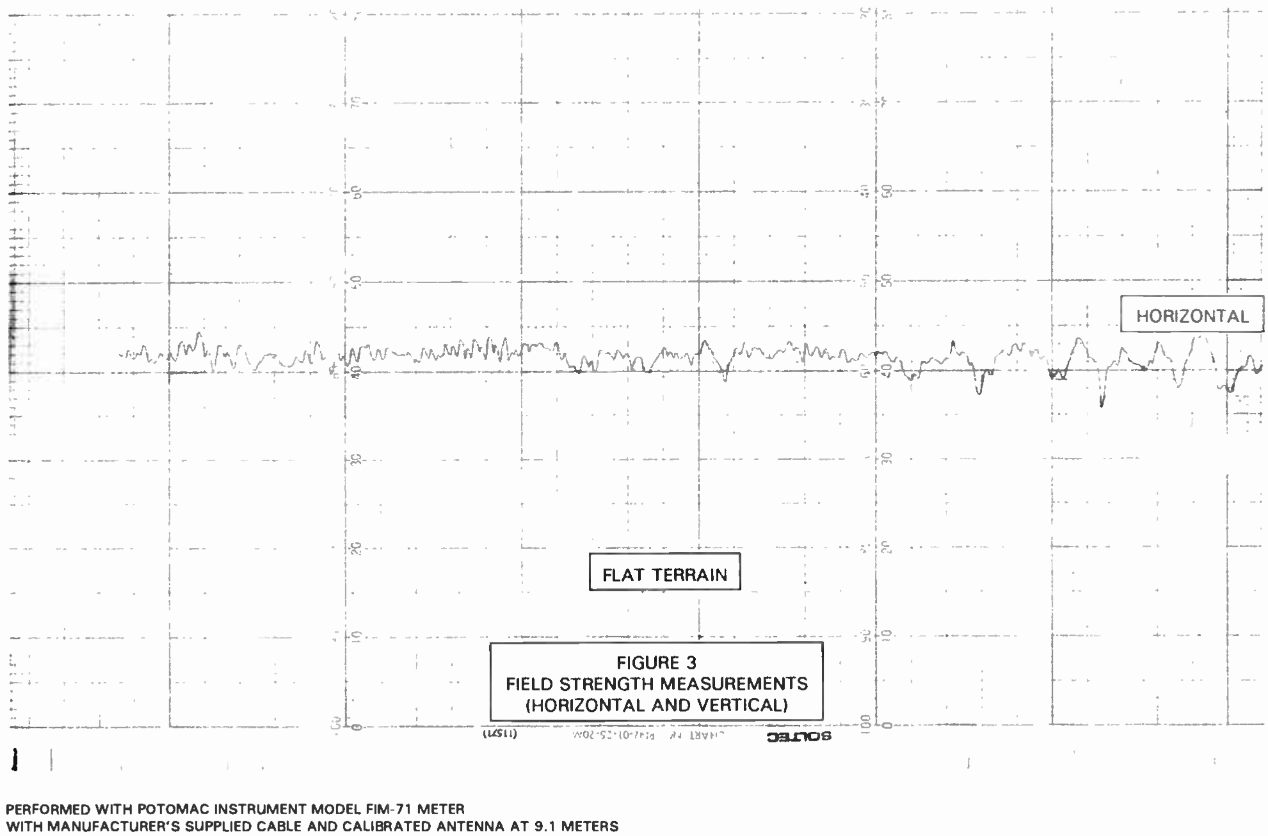
Data Analysis

Data analysis can be performed manually or through the use of computer software. Analysis techniques should be configured to adapt to the measurement program. Mathematical or graphical analysis may be appropriate.

Figure 4.15-6 shows the Commission's F(50,50) propagation chart (from Section 73.333, Figure 1 of the Rules). This chart describes the FM signal levels versus distance at a particular average terrain value. The average terrain value is determined by an evaluation of the terrain from 3 to 16 radial km from the antenna location (see Section 73.313 of the Rules). The curves can be used to extract a set of data to be



4.15-4. Field strength measurements (horizontal and vertical) hilly terrain.



4.15-5. Field strength measurements (horizontal and vertical) flat terrain.

compared to the measurement data. For example, along a particular radial, a value can be determined which best describes the terrain in which the measurements will be performed. The second piece of information is the appropriate ERP in that direction in dB (for example 50 kW = 17 dBk, 100 kW = 20 dBk, etc.). Next, a distance needs to be selected. From these steps, using the F(50,50) propagation chart, a new curve can be generated from a set of values that characterizes propagation path in terms of predicted signal level. These steps are performed for arbitrary distances such as 1 km, 5 km, 10 km, etc. There are illustrations on Figure 4.15-6 which show that, for a 50 kW ERP at a height above average terrain of 100 meters, the predicted signal level at 10 km is 87.5 dBu and for 20 km is 75.4 dBu. This data can be used at specific distances to provide a comparison to the measurement values. Alternatively, a set of points can be developed such that a curve can be plotted if a graphical approach is desired.

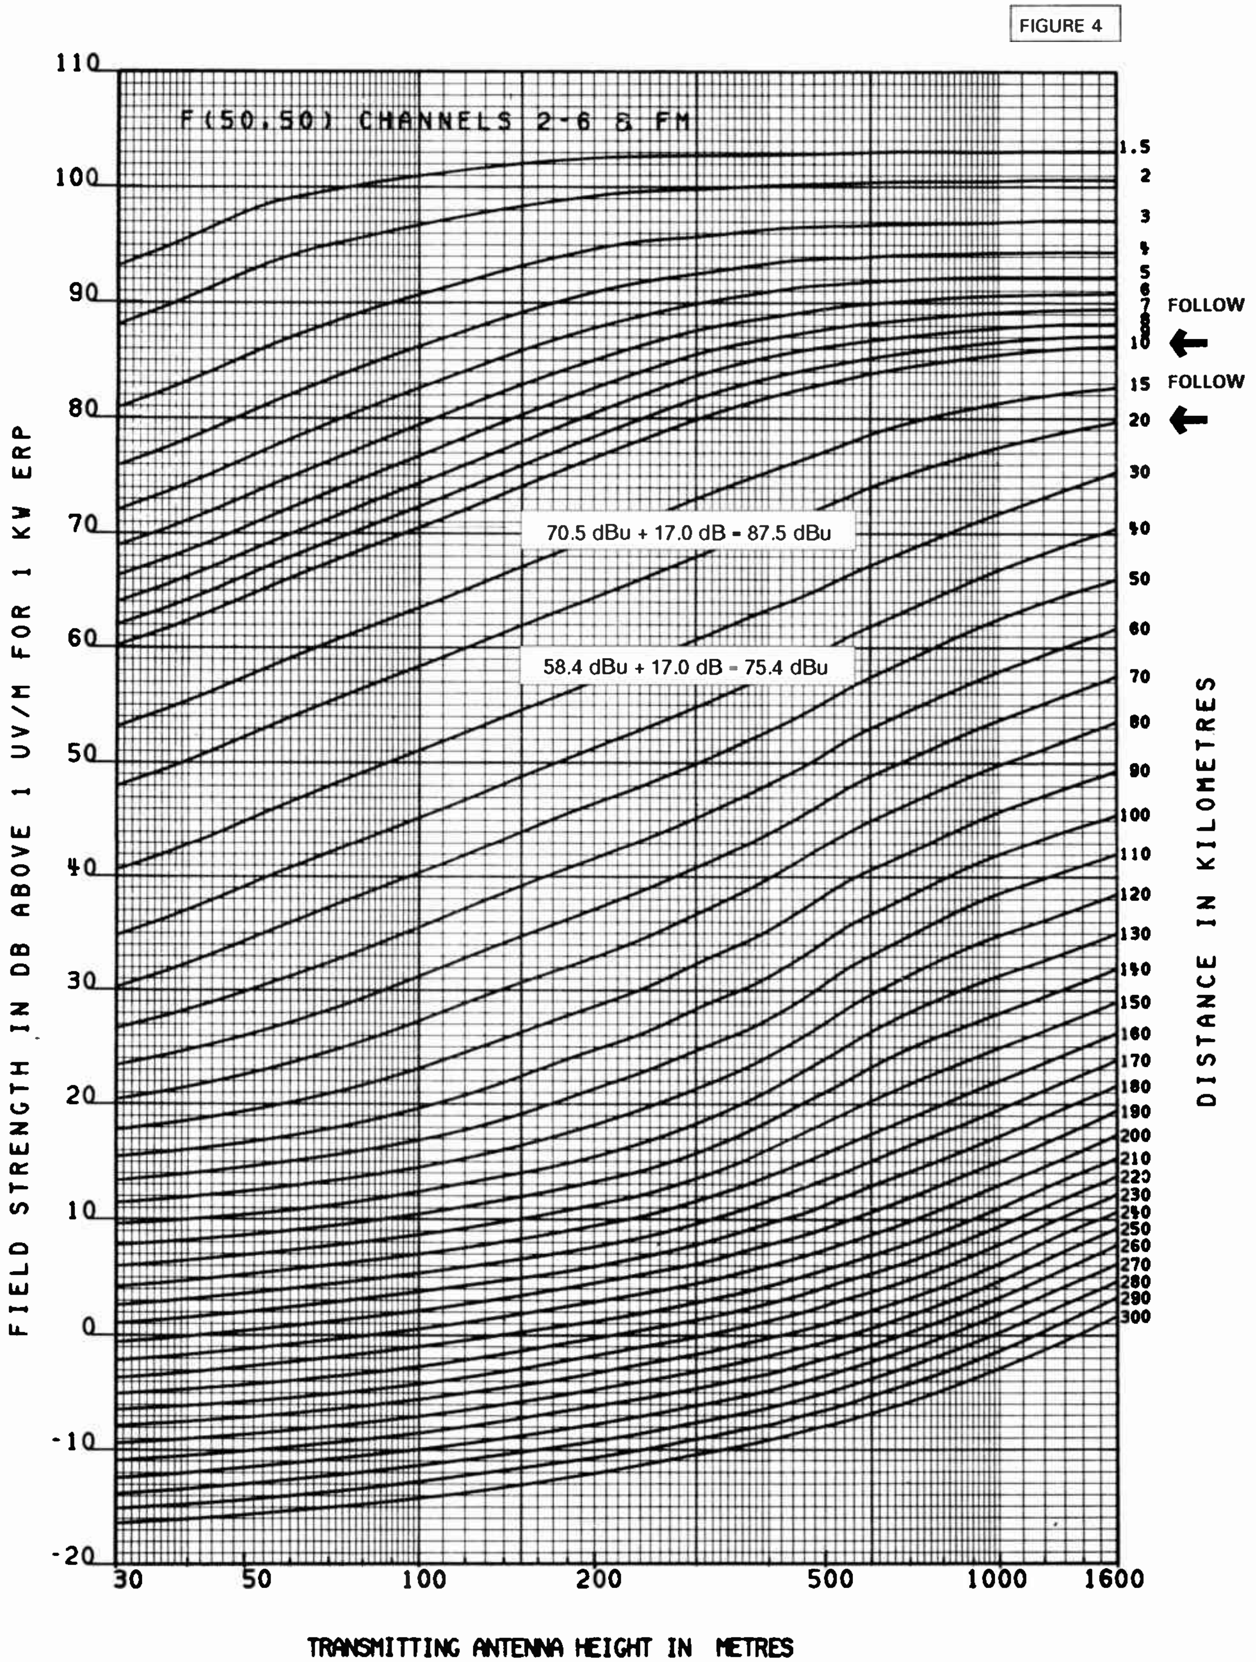
Safety

Performing measurements requires that all safety considerations be made, including every facet of the measurement program. This includes proper mounting of all measurement equipment, raising and lowering of the calibrated antenna, point selection methodology and ensuring that there are no overhead obstructions and navigating the measurement vehicle in traffic.[4] Measurements of this type must never be taken at nighttime. In addition, if field strength measurements are going to be performed for extended periods, then appropriate rest intervals should be implemented so that operator vigilance can be maintained.

Field Measurements

Horizontal and vertical measurements performed at 3.0 meters (10 feet) can be constructive in documenting difficult reception areas. This technique is used to gather general reception information so that other measures of study can be implemented as warranted. For more difficult situations, enhanced measurement techniques using a receive antenna height of 9.1 meters (30 feet) should be used. It is to be emphasized that for a meaningful measurement program, appropriate planning, details of the transmission equipment, measurement equipment geographic maps and analysis tools are required.[5] In low signal reception areas, but close to where other higher powered transmitters are

[4] This office has continuously maintained a measurement vehicle for over 50 years. In the 1950's this office had a partner killed when the antenna inadvertently encountered a power line.



4.15-6. The FCC F(50,50) propagation chart.

located, it may be necessary to employ a filter or a pad at the input of the measurement instrument. This is to minimize the receiver overload in the measurement instrument. It is imperative that a shielded line be used with good quality connectors. In low signal reception areas where intervening terrain may be a factor, an elevation profile study using 4/3 earth radius of the transmission path using 7.5 minute USGS geological quadrangles may be appropriate. For initial studies, profile radials using 4/3 earth radius generated by a computer database may be sufficient. However, the computer generated profile data should be confirmed in critical areas by the use of current USGS maps. By plotting the center of radiation of the transmitting antenna above mean sea level and carefully drawing a straight line to each reception area under scrutiny may give insight if terrain is a factor. From this study buildings or other manmade obstacles can be added. If a clear propagation path is evident, then examination of the transmitting antenna and its placement should be made.

Transmitting Antenna

A well known phenomena occurs when an FM transmitting antenna is side-mounted on a wide-faced tower.[6] Interaction by the FM signal with the tower members will modify the FM antenna radiation pattern. This can be confirmed by making a number of radial measurements at clear and unobstructed points. If this condition occurs, the horizontal and vertical signal behavior will typically be modified differently. The reason is the effect of the individual tower members upon the horizontal or vertical radiated signal is a function of the tower member dimension, position, and its physical relationship to the radiating element.

Field Measurement Configuration

The configuration of vehicle-mounted measurement equipment can be adjusted depending upon the vehicle. It is essential to have all measurement equipment appropriately mounted in a stable configuration and secured. For all measurement programs including those using non-dedicated vehicles, good documentation of the measurement configuration and the equipment is required so that the measurement program can be reestablished at a later date and time.

A simplified method of making spot measurements is provided in Figure 4.15-7. For example, vehicles with a hinge mounted rear tire support can be modified to permit four uniform height measurements at a single vehicle location. Also provided is a sample chart (Figure 4.15-8) which can serve as a guide for documentation.

CONCLUSION

Field strength measurements are a valuable tool for broadcasters who want to determine exactly how their transmission systems are performing, and how their coverage is being affected by such things as their towers, propagation path and other nearby signals. In the case of AM stations, these measurements are generally required as a condition of license. For FM, they are usually an optional tool available to the broadcaster. In either case, understanding the basic procedures for taking these measurements is a necessity for broadcasters performing their own measurements, and for broadcasters who will be hiring an expert to perform the measurements.

APPENDIX A

FCC Policy Statement Entitled, *Criteria for Approval of Sample Systems for Directional AM Broadcast Stations,* Dated December 9,1985

On October 31, 1985, the Commission adopted a *Report and Order in MM Docket 85-90* concerning the antenna sampling systems and proof-of-performance for directional AM broadcast stations. The new rules are based upon performance standards in terms of accuracy and stability rather than upon construction specifications. This Notice clarifies the information required for directional AM sampling system approval under the new provisions of Section 73.68(a) of the Rules. As before, stations constructing new antenna systems pursuant to a construction permit must obtain approval of their sample system by informal request to the FCC in Washington, D.C.

To obtain antenna system approval, applicants may follow either of the procedures set forth in Paragraphs A or B below:

A. Demonstrate that the system complies with the provisions of Section 73.68(a) of the Rules in effect prior to January 1, 1986.
B. Demonstrate stability of operation by submission of the following information:
   1. A detailed and complete description of the antenna monitoring system installation.
   2. Field strength readings taken on a monthly basis at each of the monitoring points specified in the instrument of authorization for a one year period prior to the date of the application.
   3. The following readings taken daily for each directional pattern used during the 30 day period prior to the filing of the application:
      a. Common point current
      b. Base currents and their calculated ratios
      c. Antenna monitor sample current ratios

[5] It is recommended that a field meter of known accuracy with a manufacturer supplied calibrated antenna be used. The antenna dipole length is to be set to distance indicated by the instrument manufacturer's instructions. Data acquisition can be made using a chart recorder or digital storage device.

[6] Typically, pattern modification can occur when the tower face is greater than three feet and/or the antenna operation is in the presence of other antennas or guy wire.

Additional sampling system components and configurations found by the Commission to be accurate and stable over a wide range of environmental and operational conditions will be acceptable under Paragraph A above and announced periodically via FCC Public Notice.

Section 5: Video Production Facilities

Introduction by Andy Butler, PBS, Alexandria, VA

The average broadcast station consumes more than 8,000 hours of programming a year. As location is the key to success in real estate, content is the driving force in broadcasting. The ability to create audience pleasing material is in large part what distinguishes broadcasters from pure content haulers like telephone and many cable companies. This ability has never been more important. It is the key to maintaining broadcasting's competitive edge in the battle for eyeballs. The importance of quality content will continue to grow as DTV provides even more opportunities for innovation in content packaging and cross media delivery.

Providing the facilities that support competitive creative efforts is a key task for broadcast engineers. Creating the right combination of tools to effectively support all of the production processes requires a great deal of knowledge in a wide variety of fields. These areas range from mundane, but critical support items, like intercom systems to advanced theoretical topics including photometry and video compression.

In the following section a diverse group of industry experts share their expertise. We begin with a comprehensive overview of facility planning by David Carr. Jerry Whitaker continues with a look at the physics and physiology underlying visual imaging. Peter Gloeggler moves us from the theoretical to the practical with a survey of the options for capturing and manipulating video images. Jay Kuca details the challenges in routing and switching the signal after it's captured while Joe Grega surveys options for storing video.

A key component of effective video usage is efficient storage. Advanced compression techniques combined with the latest recording technology and disc based storage systems are offering flexible, cost effective alternatives to traditional tape based alternatives. Peter Symes, Steve Epstein and Jerry Whitaker bring us the latest in technique and technology.

The production process begins with an idea. Turning that idea into compelling visual images often requires intense manipulation of the captured content. Jeff Mazur looks at some of the latest tools for creating special effects.

Infrastructure is not as flashy as the latest production gadget but a weak support system can destroy the best creative effort. John Weigand and Brad Dick tackle the gritty details of communications, automation and control, while Robert Beach scans the horizon for the latest update on weather radar for TV.

Part of the magic of broadcasting is its universal appeal. Making that magic easily accessible to everyone is a key goal for the industry. Amnon Saloman takes a comprehensive look at closed captioning and other enhanced services.

Creating and capturing compelling images is an art. The medium that stores those images can have a profound impact on their effectiveness. Film has played a major role in television for many years and is still the preferred palette for many video artists. It is also the most universal medium for international program exchange. With all of its strengths, using film effectively on television is a challenge. Richard Bauer looks at the legacy and the limitations.

Program production is expensive. To remain competitive broadcasters constantly seek ways to do more with less. Camera robotics has become an important tool in the quest for efficiency but they also offer quality benefits and expand creative possibilities. Robert Murch explores the efficiencies and the creative bonuses.

Images are reflected light. Lighting paints the canvas of the TV image. The right lighting reinforces and strengthens the message while poor lighting distracts the eye and garbles the communication. Bill Marshall goes beyond the glare for a thorough look at the art of illuminating the image.

The best video production is practiced inside studio walls but the events that are the most compelling content rarely occur in a production studio. From the earliest days, broadcasters have been forced to go out in the field for the best programming. Ned Soseman and Carl Bentz are veterans of the remote production battlefield. They have some invaluable suggestions to make sure you get the content you want without sacrificing your health or your sanity.

Television is entering a new age. One of my favorite colleagues has an insatiable appetite for knowledge and a stubborn determination to understand technology at its very basic levels. After spending a couple of years reading, asking questions and probing he summed things up by noting that "DTV is Different . . . its REALLY Different." David Leathers appreciates that difference and offers us a look ahead with some production considerations for DTV.

5.1
PLANNING A VIDEO PRODUCTION CENTER

DAVID CARR
KHOU-TV HOUSTON, TX
AND MALCOLM M. BURLESON

INTRODUCTION

This chapter contains information that may be used as a guide for general planning and cost estimating of facilities. It is beyond the scope of this chapter to describe all of the many details that go into the design of a facility. Rather, it is intended here to provide hints and reminders of some of the more important considerations that should be addressed.

Before planning the budget for such a project, goals must be set. Why is this project being undertaken? Do we want to provide additional space and if so in what areas? Are we planning on taking on production projects? What kind and what magnitude of production sessions are we envisioning? Do we want to convert our studio operations to robotics? An overall agreement on goals must be reached at before any planning and budgeting can be done.

There are many factors that go into determining the initial planning budget, as well as accounting for the final cost figures when the project is completed. The cost per square foot varies greatly depending on what area is being constructed. The cost of studio or technical space is much greater than that of office space. Advance planning combined with close project coordination and continuous oversight by the owner's representative will result in a well-built, cost-effective facility, constructed on time.

Give the construction or refurbishment of the facility the same study that would be given to a major equipment purchase. Research the facility needs, available architects and contractors. Review local codes, construction specification criteria and cost accounting methods. Hire additional personnel to cover for staff that will be occupied overseeing design and construction.

Construction of broadcast and production facilities is not the same as simple office construction. They require special attention to elements such as control rooms, special acoustic and air conditioning treatment and special technical services not normally found in routine construction. Special consideration must also be given to the backup power generators and other redundant systems to be installed. Years of experience have taught the lesson that numerous large and small broadcast facility projects all have one major thing in common: the need to plan ahead and to watch every detail, or else the barrage of changes will undermine the budget and completion date.

GENERAL PLANNING CONSIDERATIONS

The early planning of a broadcast facility involves factors such as: consideration of the market to be served, site selection, studio requirements, nature of programming, expected hours of operation and available capital.

First and foremost decide whether the studio and transmitter are to be combined under one roof or established in separate locations. Wherever practical, it is more economical to combine the studio and transmitter. While the initial equipment requirements may be less, more importantly, the day-to-day operating expenses are substantially lower. With the plant all under one roof significant savings in heating, air conditioning, building maintenance, travel time and personnel can be realized. When a combined operation is not practical, the second best approach is to place the transmitter and other facilities in a separate building and operate the equipment by remote control from the studio. With a good remote control system, a transmitter site can be selected that provides the best coverage and the studio can then be placed in the most convenient location for business and production. The building requirements at the transmitter can be kept to a minimum, with space only for the transmitting and support equipment, a small work area and the heating and air conditioning system.

Building Codes

Virtually any construction or alteration of a building is likely to be covered by one or more codes. In addition to general building codes, there are electrical, mechanical, plumbing and other specialized codes. The building at a separate transmitter site is likely to be subject to fewer building code restrictions, because it is away from heavily populated areas and fewer personnel are involved in its operation. While various national associations have proposed model codes, individual state and local jurisdictions adopt whatever codes, with variations, they find appropriate. Reputable architects, contractors and subcontractors are familiar with local codes affecting their area as they apply to a specific construction job.

Zoning Regulations

Zoning is another consideration that is dependent on the local jurisdiction and can have a significant impact on selecting a studio location, appearance of construction, access to the facility and placement and size of towers and antennas (microwave and satellite). While it is sometimes possible to have zoning requirements changed to suit a particular construction requirement, this should not be counted upon when considering a new site. However, if a site is particularly desirable, an advance team can be employed to:

- Investigate the zoning regulations
- Determine whether they are enforced
- Consider the attitude of potential neighbors to having the proposed facility constructed nearby
- Propose solutions to the problems the zoning regulations are likely to cause.

If the planned construction is for an expansion of an existing facility, a careful review of local zoning regulations is essential. It may be necessary to increase parking if there is a staff increase. Construction that was grandfathered in the past may be required to meet new requirements if a modification is made.

PLANNING FOR NEW AND RENOVATED FACILITIES

The first step in planning a new facility or renovating an existing one is to develop an outline of requirements that will form the basis upon which future decisions are made. Such an outline for broadcast facility planning might be developed as follows:

Site Selection

- Select a site that provides adequate space, not only for immediate building needs but any expansion anticipated
- Provide adequate space, open areas and parking for employees, guests, and studio audience (if under consideration), and a reasonable surrounding landscape environment, if possible
- Access for delivery trucks and a generous loading area with a loading dock is essential if shipments over 100 lbs are expected on a regular basis. The additional cost for deliveries and the occasional rental of a forklift will be paid for in the first year of dock use
- Accessibility to major (and preferably less congested) roads for mobile units, audience and the general convenience of employees will save time and reduce frustration
- Space for a tower for line-of-sight and electronic news gathering (ENG) microwave and communications antennas will be needed either on the site or on the building itself
- Zoning regulations will affect use of towers, antennas, appearance of construction and facility identification or advertising signs
- Consider a space for a helicopter landing pad on the roof or adjacent to the building for possible use for news and traffic reporting
- Consider various environmental elements such as noise from nearby airports and highways, weather to high winds or snow accumulations and of course, susceptibility to flooding or high water
- Take into account the special technical requirements that broadcast and production facilities have, such as installation of satellite antennas, access for remote vans, microwave paths, telco connections and alternate or standby power.

Building Planning

It is essential to pay particular attention to efficient personnel traffic flow and the relationship of studios, administrative offices, technical areas, craft shops, storage and building utilities, such as power, heating, air-conditioning.

The design, layout and space arrangements of a new facility should include means for easy coordination between such operational functions as programming, operations, and engineering; between on-air talent, dressing rooms and studios; and between newsrooms and their mobile units. Examples include:

- Entrance arrangements for employees, guests, VIPs and audience
- Relationship of studios to loading areas
- Relationship of parking areas to employee and audience entrances
- Storage spaces—area, rooms, closets, nooks and corners
- Physical security inside to discourage unwanted entry and passage throughout the facility
- Controlled access areas for staff
- Outside security to discourage theft and vandalism to the building and employee and visitors cars and outside technical facilities (satellite antennas).

Budget Development Checklist

The following checklist is designed for estimating the scope and cost of station construction.

Preliminary

- Land
- Land tests
- Site clearing and preparation
- Architect and engineering fees
- Permits (zoning & building)
- Special consulting fees (decoration, landscaping, communications)
- Local zoning and building codes

General Construction

- Architectural
- Electrical
- Mechanical
- Heating and plumbing
- Special in-house cabling (TV, telephone, computer, PA)
- Communications (microwave, two-way radios, satellite)

Interior Finish

- Wall covering (fabric or paint)

- Floor covering
- Special studio treatment

Furniture and Fixtures

- Decorative office furniture
- Standard office furniture
- Office area built-ins
- Working area counters, cabinets and built-ins
- Studio fixtures
- Draperies
- Artwork

Telephone System

- Broadcast line facilities
- TWX and facsimile (FAX)
- System configuration
- Office intercom system
- Number of private lines
- System: owned or leased
- Backup arrangements (very important)

Computer Systems

- Administrative
- Technical
- Production
- Backup arrangements (very important).

Security Arrangements

- Control of public (entrances and exits)
- Control of all points of entry (including employees)
- Closed circuit TV systems, security tours
- Controlled access doors and gates
- Separation of 9:00–5:00 areas from 24-hr. areas
- Night lighting and emergency power
- Surveillance of ENG and satellite news gathering (SNG) units and parking areas

Miscellaneous Items (Often Overlooked)

- Copier or printer outlet (may require special power hookup and ventilation)
- Special ventilation for odor producing areas (artwork, craft shops)
- Building maintenance equipment closets
- Drinking fountains and vending machine areas (power hookups)
- Space for air-conditioning subdistribution boxes, fans
- Special waste water treatment for film darkroom processing (local codes)
- Cable access to roof for various communications systems
- Provisions for microwave and satellite antenna mounts
- Power, communications, signal lines to SNG, ENG unit areas
- Use of walls for built-in filing cabinets

Building Construction: General

Here are some of the major elements regarding building construction that should be considered:

- **Official Contact.** Restrict contact with the contractor to only those staff or employees given the authority to speak for the company and authorize changes. Route all official communications with the contractor through one individual, if possible
- **Change Orders.** Any changes in the design must be kept to a minimum if the budget is to be maintained. Changes in design are expensive and time consuming. Virtually any suggestion offered to the contractor by the facility staff will be considered a change by the contractor if change authority is not specifically designated. The extra time spent in careful planning in advance of construction will more than pay for itself with fewer change orders. Coordinate any changes with all departments for a possible overlooked error. Make sure the contractor obtains written approval on all change orders and that the station understands the amount of additional cost involved. Several dozen relatively small change orders can result in many thousands of dollars of budget overruns with very little to show for the changes
- **Document the Construction.** Take pictures of all new construction areas at various stages in construction. Alert the architect that as-built drawings are to be provided. In some cases there is added cost, but advance notice will keep the cost down and the accuracy of the drawings will make future changes easier and less costly
- **Structural.** The selection of the main structural system will take into account local conditions, codes, availability of materials, flexibility for future changes, special loading conditions and spans, degree of fire resistance and effect on fire insurance rates. A careful study of local fire code requirements will result in designing a facility that meets the codes and avoids costly retrofit later (doors, fire control systems, ventilation)
- **Partitions.** Plan the layout of the interior of the building to provide sound isolation in the studio and control room areas, yet enough flexibility for ease of removal or relocation or some of the walls and partitions in office and general purpose areas. In general, the walls needed for good sound isolation will be more permanent than those for offices and other areas. It is generally better to make rooms larger in the initial planning and construction stages and subdivide them later (after construction is completed) if necessary
- **Ceilings.** Ceiling spaces contain virtually all utility services: sprinkler system, heating ducts, water, sewer, power for lights (and more recently outlet power), communications (computer, signaling, security, production video and audio), conduits and wire trays. A high degree of accessibility is required to the ceiling spaces as well as good acoustical quality and ease of cleaning. Attention paid to the ceilings during the design phase will result in easier and less costly access to the space later
- **Wall Materials.** Greater durability is needed in technical and production areas, due to the mounting of various equipment to the walls as well as frequent

moving of equipment and supplies. Install wall guards or rails along all corridors and rooms in which equipment will be transported
- **Floors and Floor Materials.** Most office buildings have concrete floors. Avoid placing any conduit in concrete floors in order to reduce installation costs and increase flexibility later. Different floor types and coverings are needed in different areas. Get the best available that is durable yet will reduce traffic sounds and vibration. It will be costly and disruptive to replace it in the future. Use carpeting in areas where footfalls and dolly wheels are likely to transmit sound to a nearby studio, control room or edit booth. When using carpet remember that it tends to build up a static charge that can damage equipment. There are some grades of carpet that will build up less of a charge under certain temperature and relative humidity ranges. Consider the pros and cons of using raised computer floors in control rooms, videotape and other electronic areas. Computer floors are expensive, require constant maintenance and are difficult and dangerous to work with when installing cables. However, they are an ideal duct for ventilating cool air into the bottoms of racks and consoles. They may be more convenient to use in an area devoted exclusively to computer facilities and may be selectively employed in technical areas. Computer floors look better than overhead cable trays but trays are easier to wire and rewire
- **Studio Floors.** Floors for studios have altogether different requirements. Concrete slab floors are typically covered with either a rubberized surface (higher maintenance) or close fitting tile (lower maintenance, but subject to potholes). Slab floors for TV studios must be extremely level if smooth camera movement is expected. If robotics operations are being considered, a self leveling epoxy floor may be installed. It seems to outlast the other floor surfaces under the rigorous operations of robotics. Robotics tend to be harder on the floor because the pedestals go to the same positions time and again.

Studio floors are often isolated from the building structural members in order to reduce sound transfer. Consider this approach, which is expensive, only if the studio will be relatively close to interior (air conditioning, craft shops) or exterior (aircraft or highway) sound sources, or if a higher degree of sound isolation is required. Floors are more difficult than walls or ceilings to acoustically isolate from building vibration and noise transfer.

Footfalls in corridors will be heard in adjacent studios and control rooms if the studio floor is not isolated or the corridor floor is not carpeted or acoustically treated.

- **Studio Ceilings.** If the ceiling of the studio is directly under a roof, consider what acoustic and thermal isolation may be needed if the site is near an airport, subject to heavy rains, snow or hail or hot sunny days. If a helipad is on the roof low frequency noise isolation will be required
- **Tape Vaults.** Give special consideration to this area that contains the station's major programming resources. Use fireproof construction and limit ventilation to no more than that necessary for proper temperature and humidity control. Install instruments to measure the temperature and humidity. Control access to the vault and keep logs of tape movement
- **Sound Locks.** Sound locks are small vestibules to provide sound isolation between noisy places (such as corridors, newsrooms, offices and control rooms) and studios. The sound lock, when properly used, effectively allows entry or exit from a studio during a broadcast or recording session. Sound locks can have several doors and serve more than one control room or studio. The space used by a sound lock is not entirely wasted. The space above the ceiling can be used for the ballasts for fluorescent lights used in the studio or control rooms
- **Sound Lock Doors.** These special doors must be carefully designed and properly installed. In addition to their superior acoustic performance, sound lock doors must have:

  A. A double glass window with rubber mounting to allow a view of who might be using the sound lock to avoid opening both doors at the same time.
  B. All sound lock doors must open outward from the sound lock so that when a slight vacuum is created it more firmly seals the other doors
  C. The outer door of the sound lock must have a latch and optional lock
  D. The inner studio door must have no latch, that would cause an audible click in the studio, but handles must be provided.

- **Windows.** The main product of a broadcast or recording facility is the sound material generated in its studios. Windows can be strategically placed in studios and control rooms to allow clients to view the activities, for visual communications between the areas, for tours to see the operation without disruption and for employees to see who is working in the studios without having to enter or use the sound lock. The additional expense for properly designed and installed windows will be well worth the effort in the long run. Adding windows after facility construction or renovation is completed is even more expensive because the operation will be disrupted during construction, the studio or control room may have to be rearranged to accommodate the new window and conduits and support members in the wall of interest may have to be moved, modified or removed altogether.

If after construction the window is not needed, it is a simple matter to cover it or add drapes to limit the times when it is appropriate for use.

Also consider that an external window will allow light into a television studio making it more difficult to maintain the desired color temperature due to the sun's constantly changing intensity.

Engineering: General

- **Main Power Service.** A new physical facility will require a new main power service and metering to be constructed by the power company, that may pass the cost on to the customer. An addition to an existing facility may require some construction for the additional power capacity. Research the costs with the power company well in advance of construction in order to reach a cost compromise. After all, studios are good electrical customers. Consider an alternate service entrance to reduce the construction on the main service and provide a partial backup in event of a main service failure. Examine the path the main service takes from the substation. Consult neighbors for indications and frequency of power problems. It is not usual for a second service to be installed if convenient. That is, if one is within a block or so of the studio. However, it may be expensive to have it brought in when it is to be rarely used. It may be better to spend the money upgrading or hardening the main service
- **Power Substations.** Consider separate unit substations for air conditioning and electric heating and other major motor loads (such as elevators), general illumination, studio production lighting and technical facilities. However, arrange for a common metering system to keep the per unit usage costs low
- **Lighting in General.** Use fluorescent lights providing about 100 ft candles in all personnel working areas. Use dimmer controlled incandescent lights in control rooms and other technical areas during production activity and to provide ambiance. Include fluorescent lights in the same areas for installation, maintenance, and cleaning
- **Air Conditioning.** Studios require high volume, low velocity air ducts for sound control. They also require a backup system. If two air handlers are used per studio, one as a main and one as a backup, they will take up valuable space and be quite costly. If you have two studios and are considering a tridundant system, that is three air handlers to serve two studios, the third air handler to backup either of the other two, you will have to provide air ducts that in essence connect both studio together. While this is more economical than the previous option, the acoustics of both studios will be compromised. A third option however is available. Have a specially designed air handler built for each studio. Each of these air handlers should have two coils and two drive motors within the housing. Only one coil and motor is used at a time, but in case of failure a simple switch will change over to the other coil and motor. This is much less expensive and requires less floor space than the first option and will not compromise the acoustics of the studios. Consider a separate system or standby component or cross-connecting arrangement for control rooms and editing suites. Install a separate air purging exhaust system for TV studios
- **Energy Savings Systems.** Novel energy savings techniques should be considered but only with a thorough understanding of the consequences of a system outage
- **Miscellaneous Systems.** Telephone, public address, security's tour, door security, closed circuit TV and fire alarm.

Electrical

The following sample specifications for the electrical system of a television station are based on the *National Electrical Code*, and are intended to show how such specifications may be tailored. Elements may be adapted to other applications, such as facility upgrading as well as radio station construction.

All state and local electrical, fire and safety codes are to be observed.

Area Classification

All electrical installations, materials, and equipment shall comply with the classification *General Purpose* except for hazardous areas that shall be designed for Class I, Group D, explosion-proof conditions. (There are normally no hazardous areas in a broadcast facility.)

Incoming Power Service and Metering

Incoming power service should be high voltage (4.16 kV or 13.8 kV) due to high load requirements. Standby partial or full incoming service shall be provided (if practical) with automatic transfer when normal service fails. One primary metering point shall be provided to obtain best possible utility rates.

Primary Distribution

Distribution within the complex may be high voltage (4.16 kV or 13.2 kV) from a primary switchgear to unit substations located as close as possible to the center of the loads served.

Separate unit substations shall be provided for different type loads, as follows:

- A secondary 120/208 V system to handle equipment and motor loads and a 277 V system for all fluorescent lighting
- A secondary 120/208 V system to handle receptacle, incandescent lighting and small equipment loads
- A secondary 120/208 V system to handle studio production lighting only
- A secondary 120/208 V system to handle technical TV loads only

Each unit substation shall include components as follows:

- Primary compartment with high voltage (HV) fused load break switch
- Open dry-type transformer with a delta HV primary and 120/208 V or 277/480 V, three-phase, four-wire secondary with best possible sound rating of transformer
- Voltmeters and ammeters provided for each phase
- A main secondary air circuit breaker
- Molded case feeder circuit breakers and spares

Secondary Distribution

Power shall be extended from unit substations with cable and conduit to automatic circuit breaker panels and motor control centers.

Motor control centers shall be Class I, Type B, with combination magnetic, full-voltage starting, circuit-breaker-type motor starters or circuit breakers only for 480 V, three-phase operation. Each starter shall have three thermal overloads. Power panels shall be designed for 480 V, three-phase, three-wire service. Panels shall be of the dead-front type with automatic circuit breakers of ampere rating as required.

Panels for receptacle and incandescent lighting loads shall be designed for 120/208 V, three-phase, four-wire service. Panels shall be of the dead-front type with automatic circuit breakers of ampere rating as required. Ground fault detector breakers shall be installed as required by codes.

Lighting panels shall be designed for 277/480 V, three-phase, four-wire service. Panels shall be of the dead-front type with 20 A automatic branch circuit breakers. Panels shall be similar to Westinghouse Type NH1B-4.

Conduit

Conduit shall be rigid steel, asphaltum painted when installed in concrete slabs, below grade and outdoors above grade.

Rigid aluminum conduit shall be used for exposed installation in mechanical equipment rooms, damp locations and locations where exposed to mechanical damage.

Rigid aluminum or steel conduit shall be used for all feeder and subfeeder runs. Steel EMT conduit with compression weather tight fittings shall be used for all other branch circuit wiring indoors and above grade.

Wire

HV cable shall be single conductor crosslinked polyethylene insulated and shielded. Building wire shall be Type THW rated at 600 V, 75° C. No. 12 AWG and smaller shall be solid copper. No. 8 AWG and larger shall be stranded. Fixture wire shall be Type AF, 300 V insulation. Minimum wire size shall be No. 12 AWG, except No. 14 AWG for control wires. Maximum wire size shall be 500 MCM.

Grounding

Electrical grounding shall be provided in accordance with the *National Electric Code*. Equipment enclosures, electrical service, transformer neutrals, outdoor lighting standards and cable shielding shall be grounded.

Insulated bushings and double lock nuts shall be provided at all panel boards and pull boxes in feeder runs and pull boxes shall be bonded through with bare copper wire.

A separate technical equipment ground system shall be provided as required. This technical ground system will help to isolate the non-technical electrical noise from the more critical technical system. The key to this technical ground system is to keep all technical racks and equipment from coming into contact with earth ground. The resistance between the earth and technical ground must be continually monitored during installation. The technical ground should be attached to earth ground at one point and only one point.

An uninterruptable power supply (UPS) may be used to power as much of the technical equipment as possible. This will reduce the time necessary to reboot the software based systems in the plant. If you can afford to put all of the technical equipment on a UPS and you have an auxiliary power generator, you will not lose power during the 15–20 seconds that it takes the generator to take over the load.

Switches, Wiring Devices, Wall Plates and Special Enclosures

Single pole switches shall be 20 A, 120/277 V, ac, quiet type. Duplex receptacles shall be 20 A, 125 V, 2 pole plus U-slot ground. Special outlets to be provided as required.

All wall plates for switch, receptacle, telephone and computer outlets shall be 0.06 in. stainless steel.

Telephone System

Two incoming underground services are required, one for technical use and one for business and office use.

The equipment room for the technical service shall be located close to master control and there shall be a cable-tray tie between the telco equipment room and master control.

The business and office system shall be complete, consisting of conduits from equipment room outlying telephone closets and interconnecting panels and then to the various outlets as required. All installations shall be in accordance with the requirements of the local telephone company.

Interconnecting panels shall be steel with plywood backboard with full opening door, latch, cylinder lock and trim. Each telephone closet shall be furnished with plywood backboard for the installation of distribution equipment. Conduits from the equipment rooms to each destination shall be 3/4 in. minimum.

Telephone and computer outlets shall be 4 in. square with bushed aluminum cover plates.

At least two separately fused ac power circuits from the emergency power distribution system shall be provided in each telephone terminal room.

Modern telephone systems are digital or multiplexed systems often requiring no more than two pair between instrument and telephone panel. To save substantial time and money in the future it is recommended that three or four pair be pulled into each office as a home-run to the panel. This will help to serve the needs of future communications services.

Public Address System

A complete public address (PA) system consisting of amplifiers, loudspeakers and microphones; shall be provided. In some cases this function can be accomplished with the telephone system.

Loudspeakers shall be located in corridors and other strategic locations. System shall be zoned as required.

Fire Alarm System

New codes have made fire alarm and control systems extremely complicated. The system must operate reliably. While it is expensive to evacuate a television facility, stations have been known to burn to the ground. False alarms can be kept to a minimum with knowledge of the system and operational procedures. Fire drills must be held annually and may be planned in advance to reduce the disruption to the operation.

The fire alarm system shall be closed circuit zoned, consisting of control cabinet, gongs, manual stations and automatic fire and smoke detectors. Manual stations shall be provided at each stairway on each floor and at all ground level exterior doors.

Automatic thermal or smoke detectors shall be provided in all areas except where sprinkler heads are installed. Each sprinkler alarm valve shall indicate on the fire alarm panel zone annunciator as a separate zone when activated.

A detailed instruction tour of the system shall be provided by the vendor. A fire suppressant system is to be installed in the master control and videotape areas. One practice dump shall be provided under supervision of the station and witnessed by the fire marshall.

Local codes may require that the building be protected by a water sprinkler system. If you are required to use such a system in the technical area, use a dry pipe system. If you are not required by code to use water you might consider using water in the non-technical parts of the building and a gas system in the technical areas. Remember, however that while the gas system produces less damage to the equipment it simply suffocates the fire but does not cool the area as does water. This means that the fire can start again once the gas action ceases.

Provide hand fire extinguishers at exit doors, in corridors and as required in shop and craft areas and as required by local codes.

Cable Trays and Signal Conduits

A system of cable trays and signal conduits originating from master control shall be provided to studio control rooms, studios, microwave rooms, electronic maintenance shop and computer centers.

In addition, a separate cable tray for microwave waveguide shall be provided from the antenna site to areas where the microwave receivers are located (news room or master control).

Special insulation (Teflon) must be used for all signal cables located in an air plenum and not enclosed in conduit. The purpose of this regulation is to keep a fire from traveling from one part of the building to another by way of a burning cable. Because of the substantial extra cost for this cable, serious consideration should be given to running extra cable ducts between technical and production areas, and areas that might be used in the future as well as conduits to most other locations in the facility.

Studio Production Lighting System

Unit substation and dimmer board shall be located as close as possible to studio served.

Unit substation shall include the following:

- Electrically operated main circuit breaker to permit remote control from studio floor
- Transformer with 6-1/2% taps, three above and three below rated primary voltage, to compensate for secondary voltage variations

Other work shall be as follows:

- Wireway with wiring from load side of dimmers to studio floor patch panel
- Studio grid wireways with load wiring to studio patch panel
- Control wiring from studio control console to dimmer board

In sizing a unit, substations serving dimmer boards, a 50% demand factor may be applied to connect dimmer load.

An *on-air* studio warning light system shall be provided as required. Install *on-air* or *in-use* lights beside (not above) doors to specified control rooms, edit booths and studios. Install *on-air* lights above windows to studios. Install *on-air* beacons in noisy scene construction, storage and staging areas.

Security

The following security systems shall be provided:

- Supervision of all exterior doors on ground level, with the control cabinet in the guard's room
- Closed circuit TV cameras at key positions, with monitors in the guard's room
- Manual nonwired security's tour stations located throughout complex
- Electrically operated gates to control automobile traffic
- Controlled access doors and gates to main office and technical facilities.

Emergency Systems

Power for the emergency system shall be provided with a water-cooled diesel generator set with generator output configuration to be 277/480 V, three-phase, four-wire. The installation shall include (but not be limited to) accessories such as automatic transfer switch, output switchboard, battery starting set, oil storage tank, fuel pump, mufflers and vibration isolators.

Generator set shall automatically sense power failure or 80% under-voltage, start engine, attain and maintain speed and transfer designated emergency load. A manual override of start and transfer of load controls shall be provided.

Provide local transformer with primary delta 480 V, three-phase and secondary 120/208 V loads on emergency supply. Install rechargeable battery operated lights in control rooms, studios, corridors, rest rooms and other areas without windows but which are used by the public or extensively used by employees.

Loads on emergency supply shall include auxiliary lights in the generator room, stairway lights, exit signs, selected corridor lights, telephone and PA systems, selected technical lighting and heating, ventilating and air conditioning loads required for transmission of limited live news programs, network and taped programs. Do not connect the rechargeable battery operated emergency lights to the emergency lighting circuit as they will go out when the emergency power comes on.

Broadcasters should plan for more than mere evacuation procedures. Broadcasters should also plan what must be taken with evacuating staff if the alarm is more than just precautionary. That is, determine what steps should be to ensure the continuation of programming. Decide which documents, logs, tapes, data files and other information should be taken out by staff or immediately stored in fire-proof files (for later retrieval) to protect the business and programming operations of the facility.

Lighting—277 V Fluorescent, 120 V Incandescent

Lighting fixtures shall be completely installed with all required outlet boxes and accessories. Lighting levels shall be in accordance with IES recommendations, with minimum 100 ft candles in working areas.

Fluorescent fixtures shall be used for general illumination. Fixtures shall be with 40 W RS lamps and HP factor ballast, with best sound rating. Fluorescent fixture types shall be as follows:

- Recessed with acrylic lens diffuser to be used in areas with hung ceiling
- Surface or pendant mounted with wrap-around acrylic lens diffuser to be used in stairs and other selected areas with exposed ceiling
- Industrial RLM with porcelain reflectors to be used in mechanical equipment rooms, storage rooms, etc.
- Executive offices and conference rooms shall be provided with dimmer-controlled incandescent lighting using recessed fixtures in addition to fluorescent fixtures for maintenance and cleaning.

Selected walls and art work shall be illuminated with recessed ceiling-mounted incandescent wall-washing fixtures.

Make-up room mirrors shall be illuminated with special bracket wall-mounted fluorescent fixtures. Dressing room mirrors shall be illuminated with special wall-mounted strips with incandescent bare lamps. (Consider the use of special color temperature lights for the dressing room and make-up areas so that the colors applied in make-up will appear the same under the studio lights.)

Outside Lighting

Outside lighting shall include illumination of audience concourses, entrances, parking lots, signs, building exteriors, planters and the like, and shall be installed in accordance with IES recommendations.

Miscellaneous

Outlets for wall-mounted clocks operating on 120 V shall be provided in designated areas. A clock system for use with the master clock in master control, studios, and news areas shall be provided as required. Local office intercommunication systems shall be provided as required. An audio-visual system shall be provided for all conference rooms.

Mechanical

Television studios require special consideration in solving the many problems entailed in the mechanical design due to the high-lighting capacity, noise criteria, air distribution and entrances. Radio broadcasting facilities require many of the same considerations, but some of the problems may not be as severe.

Grounding Systems

A technical ground system is one that grounds all technical equipment and contacts earth ground only at one point. To achieve this care must be taken while installing the technical plant. Equipment racks should not come in contact with earth ground. Teflon spacers may be used to provide such an isolation. Care must also be taken to ensure that the racks do not come in contact with earth ground by way of the ceiling grid. Great care must be taken to ensure that no violation takes place during and after construction.

In some instances it may be necessary to install some racks on earth ground. In those cases you will need to isolate all the inputs and outputs to all the equipment mounted in those racks. An example of such equipment is an earth station controller. It is very difficult and expensive to isolate the controller from the motors on the satellite antenna. It is easier to let the controller remain on earth ground and isolate the inputs and outputs to the antenna system.

Air Conditioning Design Criteria—General

The optimum summer and winter design conditions to be maintained by the air conditioning system is 73° F dry bulb and 50% relative humidity for office and general use areas. However, these conditions may need to be varied depending upon the side of building, whether there are windows, geographic location and in craft and technical areas where temperatures may need to be lower and humidity more closely controlled.

Air Conditioning Loads

Studio and production lighting for television constitute the major portion of the heat gain and can exceed 75% of the total cooling load requirement. The unit lighting load requirement in the production area of the studio can equal 50–60 W per square foot of floor area and in many cases this load can occur in any part of the studio since the production area and audience accommodations usually are flexible.

The studio air conditioning system should be separate from the rest of the building so that it can be turned off or down during nonproduction times. Transmission and solar heat gains are minimal since the exterior walls of television studios are well insulated and windowless for lighting and acoustic reasons.

Another contribution to the cooling load results from occupancy heat gain and the fresh air load. The fresh air requirement should be based on either 15 CFM per person, or the equivalent of one air change of fresh air per minute, whichever is greater. Fresh air quantities must conform with all code requirements.

Methods of Air Distribution and Noise Control

Proper air distribution and air movement in broadcasting studios are of critical importance. Systems should be designed so that within a zone of up to 12 ft above the floor, an air movement of 25 ft per minute (fpm) is not exceeded. Air velocities exceeding the 25 fpm cause drafts and movement of performer's hair and clothing, and stage props that are often built of light materials such as thin canvas and plywood.

The air supply should be introduced at a level above the movable lighting grid system to prevent interference with closely spaced lighting system batten strips. Low-level return grilles located at the perimeter of the studio, in principle, would be desirable. However, due to the nature of studio operation, the grille uses valuable wall space and could be blocked off by the cyclorama curtains or by studio props, that would result in an ineffective return air system. It could also be a possible source of noise generation. Locating the return air outlets at a level above the air supply will tend to relieve the neutral zone before it can heat the ceiling and radiate heat downward. Proper location of return air grilles and maintaining low velocities will reduce the problem of air system short circuiting.

Sound power levels (SPL) and noise criteria (NC) ratings for studios are of utmost importance and unless proper consideration is given to this problem, will result in an acoustically unpleasant studio. Noise level should be within a range of NC 20 to NC 25, so as not to interfere with studio performance, particularly during scenes where there is no conversation and no background sound effects. Duct velocities should be designed for approximately 400 fpm within 10 ft of diffuser or register opening, 525 fpm within 10–30 ft from opening, 700 fpm within 30–50 ft of opening, and 800 fpm within 70–90 ft of opening.

All air ducts (supply and return) should be acoustically lined for sound attenuation and the sound power level of all outlets should be carefully checked to ensure that it does not exceed the decibel rating at the end of the duct run, otherwise it will become additive (logarithmic) and negate a portion of the acoustically treated duct.

All exposed pipes should be insulated and all air ducts should be externally insulated to eliminate reflected sound in studios. Where ducts and pipes pass through walls or floor, the openings should be sealed with acoustical sound-deadening material. Ducts and piping should be suspended from vibration isolators. Where ducts and pipes pass through studio walls, flexible pipe and flexible duct connections of appropriate size should be provided to reduce the transfer of acoustic energy into the studio.

Any hole, pipe or conduit that is not properly treated will allow the transmission of sound into the studio and effectively defeat the other expensive sound isolation measures that have been incorporated. Remember this when making modifications to studio facilities after construction is completed.

Mechanical equipment should be located remotely from the studio to eliminate transmission of sound and vibration. All equipment should be properly supported from vibration isolators. Sound traps for sound attenuation and flexible duct connections to prevent transmission of vibration should be provided for all air handling apparatus.

Hire an acoustic consultant to make measurements of the installed studio air-conditioning system in order to insure the system meets design requirements.

Type of System and Control

Each studio should be served by its own air handling apparatus and should consist of supply and return fans, filters, heating and cooling coils, sound traps and a purge exhaust system.

The arrangement and selection of the component parts of the air conditioning system are highly dependent upon the economics, space conditions and geographical location of the project. Special air flow schemes should also be considered. For example, an *economizer* cycle utilizing 100% fresh air during moderate seasons, or a fixed percentage fresh air system can be used. Preheating coils and reheaters may be required depending upon the percentage of fresh air used, the geographical location and the outside humidity. Heating coils can be steam or hot water coils. Cooling coils should be chilled water coils.

In areas where freezing outside temperatures are experienced, special arrangements must be incorporated to prevent possible freeze-up of preheating coils and chilled water coils. Reheaters are often used in individual areas that have less heat buildup than a larger nearby area.

A separate purge exhaust system should be provided to permit the studio to be evacuated during periods when it is not in use. During the purge operation, the system should provide 100% outside air without attempting to maintain studio design conditions. Where an economizer type cycle is provided, purging of the area can be accomplished by resetting controls to 100% outside air.

The control system should be arranged to control studio temperature, and where facilities are provided for audience participation, additional humidity control should be provided.

The installation of a supervisory data center provides operational supervision of the system and normally includes some remote controls for resetting of space temperatures and humidity, starting and stopping of air handling system, read-out of other pertinent air and water temperatures and alarm indication.

A digital control system should be provided that will allow you to completely monitor and control the system. Water temperature, air temperature, valve position, water flow, fan motors, thermostat settings, room temperature, etc., can all be monitored. The range of individual thermostats can be set at the central monitoring station. Filter conditions can also be determined. Alarm monitoring can also help prevent catastrophic events.

Standby Operation

Master control rooms, videotape rooms, editing rooms and the newsroom generally operate on a 24-hour basis, and an air conditioning failure cannot be tolerated for more than a few minutes. A separate air handling system should be employed to serve various combinations or these areas with provisions for standby equipment or cross-connection in the event primary equipment fails. This can be accomplished by interconnecting the ducts and appropriate dampers, with another air handling system serving a noncritical area in the building such as office areas, thereby permitting the technical areas and newsroom to be satisfied during an emergency period. Another desirable feature to be incorporated in the system is provision for handling 100% fresh air in the event refrigeration equipment becomes inoperative.

Multiple refrigeration units and boilers should be provided so that in the event a single unit becomes inoperative, partial operation can maintain conditions in critical areas.

In the event of an electrical power failure, an emergency generator should start automatically to maintain operation of the boilers, heating pump and air handling system serving the master control room and videotape room.

STUDIO ACOUSTICS[1]

When a microphone is opened in a studio, it is expected to pick up only the voice of the on-air talent. But the microphone also picks up building rumble, office noise, air conditioning noise and unwanted reflections from the room walls. The resulting broadcast signal can sound hollow, dull or boomy instead of bright and clean. Poor acoustics can diminish intelligibility and invite listener fatigue. A studio with good acoustic design and treatment is easy to mic and sounds good without the need for extensive audio processing. The sound from a studio with poor acoustics cannot be fixed with electronic processing.

Creating the ideal studio acoustic environment is often an expensive undertaking. It requires the expertise of an acoustical consultant working in cooperation with the architect, both of whom must be familiar with broadcast and recording studio construction. Studio designers often find it necessary to recommend types of construction that are several times more costly to execute than standard office construction. However, the additional expense will result in studios and control rooms that will be well isolated from intrusive noise and vibrations, and will project a clean and crisp on-air signal from live talent, free of unwanted resonances and echoes.

Estimating Costs

When planning new studios, significant cost reductions can be realized by selecting a site which is removed from street, rail and air traffic and manufacturing equipment. Within the building, keep the studios away from noise generating sources such as pumps and air conditioning equipment. Be sure to consider ceiling height, as large HVAC ducts are required to keep air flow noise at a minimum. If insufficient space exists for the installation of the large insulated ducts, expensive alternatives to solve the acoustic problems will be required.

When initially sketching a studio floor plan, remember that studio walls occupy space and should not be drawn as single lines. All partitions have some thickness that will take up floor space. It is not uncommon for some acoustic partitions employing internal air spaces to exceed a 16 in. thickness. If space is not a premium, such constructions are generally more economical than thinner partitions with similar transmission characteristics. Absorptive surface treatments can easily add an additional 4–6 in. to each side of the wall profile.

The control of the transmission and reverberation of sound are two acoustics disciplines which apply to broadcast studio and control room environments. They are independently designed and require completely different methods and materials in creating studios suitable for broadcast and recording. It is important that each be understood, since confusion between the two can aggravate an existing problem.

Controlling Sound Transmission

Sound transmission occurs when a source of sound is carried from one area to another. The vehicle of transmission may be a direct path, a flanking path around an object or a path carrying vibration. The most economical and practical means of limiting the transmission of noise usually requires the control or reduction of it at or near the source. Disturbances with low frequency components are the most difficult and expensive to contain. Completely enclosing the noise source in a highly absorptive room, and isolating its vibrations from the building structure, will limit the ability of noise to intrude upon other areas.

It is often cheaper to isolate the sound at the source than to isolate several rooms from the building structure. For example, if footfalls on a cement floor adjacent to or above the studio are causing problems, try carpeting those areas before attempting to increase the transmission loss of the studio construction. Where treatment at the source is not practical, the most effective way of isolating an area against noise intrusion is to employ *floating construction*. With floating construction as shown in Figure 5.1-1, the noise sensitive

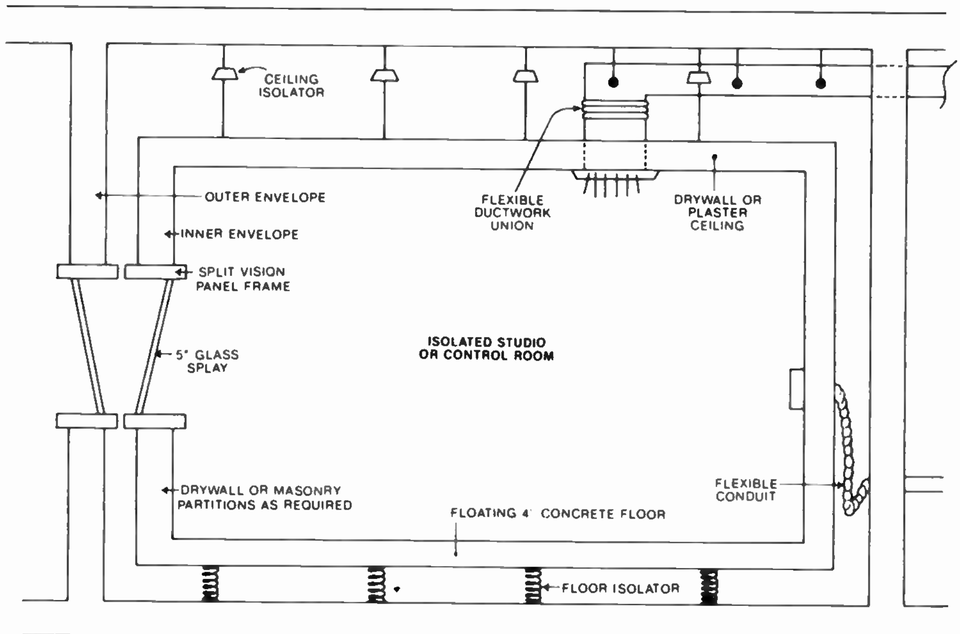

Figure 5.1-1. Floating construction schematic showing mechanical isolation between inner and outer rooms.

area is actually a room built within a room. The important aspect of this type of construction is that mechanical contact between the inner room and outer room is kept to a minimum, with the construction of both rooms creating as complete and uninterrupted an envelope as possible. This is most commonly achieved by resilient floor supports and suspending the ceiling of the inner room on springs or neoprene isolators, hence the term *floating*.

Floating studios in radio stations generally are simpler because the inner and outer walls have fewer connections between them. Television studios, however, have ceilings that are significantly higher and resilient sway brace connections between the inner and outer walls may be required to stiffen the construction and prevent buckling. Television and recording studios often have a variety of utilities provided in the studio, such as electrical lighting and water connections, in addition to the audio circuits that must be isolated. In addition, there are more windows and doors in television studios that must receive special attention.

Depending on the intensity and proximity of the noise source, and the degree of residual noise that can be tolerated, some or all of the aspects of floating construction can be employed in designing a broadcast studio or control room. The resiliently isolated floor and ceiling is necessary to prevent structure-borne sound and vibration from entering the interior space. The double walls with the resulting air cavity between them are actually more effective than a single partition of the same mass. In order to preserve this advantage, no service such as air conditioning ducts, plumbing, or electrical conduit should be allowed to make a solid mechanical contact between the outer and inner rooms. The use of flexible connections within the cavities is extremely important.

When spring or neoprene isolators are employed for vibration isolation, the effectiveness of the isolator is measured by its nominal deflection, the relation of its natural period to that of the disturbing vibration and the stiffness of the structure supporting it. Therefore, isolators with the proper characteristics must be specified. Isolators that are too lightly loaded will provide little isolation, while isolators that are too compliant may cause instability, or bottom out. If the isolation system exhibits a natural resonance equal to the disturbing frequency, the transmission of the disturbing frequency can actually be amplified.

One often overlooked source of vibration that may induce unwanted disturbances into adjacent areas is the control room monitor speaker system. Suspending the loudspeaker enclosure from the wall or ceiling on a resilient mounting will significantly reduce the structure-borne transmission of sound from the monitor.

Acoustic Materials

The materials used for the reduction of sound transmission in walls, ceilings, and floors are typically heavy, dense and thick. Factors to be considered when designing a barrier for maximum transmission loss include the stiffness, resonance, mass, isolation, cost and construction details of a partition. Typical acoustic partitions may be composed of brick or masonry block, poured concrete, lead, multiple layers of gypsum board supported by metal studs or a combination of these materials. Regardless of the materials used, the most efficient barriers employ an integral airspace or cavities filled with a damping material such as fiberglass bats.

Isolation at the lower frequencies is more difficult and expensive and usually requires stiffer, thicker and heavier construction than that needed for higher frequencies.

The single most important aspect in the construction of acoustical barriers is sealing. Regardless of the materials used, the fit of the individual components with each other and the existing structure must be tight. All joints should be filled and sealed with a resilient, nonhardening caulk. The smallest openings can have serious consequences, and render otherwise expensive construction no better than a far cheaper counterpart.

Table 5.1-1 shows how the sound insulation value (R value) of a hypothetical partition at some mid frequency, is reduced due to acoustic leakage through various size openings. Example: Partition with R value = 60 dB

Controlling Reverberation Time

Separate and distinct from sound and vibration isolation, is that part of acoustics which governs how a room sounds when a sound originates in it. This is almost entirely a function of the room size, proportion and the ability of its contents to reflect, diffuse or absorb sound of differing frequencies. To complicate matters, all these parameters interact with each other in determining the reverberation characteristic of a room.

The major measurable acoustic characteristics are a combination of:

- The time that it takes a sound to decay 60 dB within a room, once the source of that sound is terminated (T60)
- How T60 differs with frequency
- How uniform the decay rate is
- The ratio of early and late reflections
- The natural room resonances (modes).

Room tuning is both an art and a science, and research continues to more fully understand the process. While divergent philosophies are often involved, most consultants agree on the following guidelines for broadcast and recording studios:

- The smaller and more symmetrical a room, the more noticeable its undesirable resonances. This is why many television announce booths sound more like stuffy little phone booths
- Avoid exceptionally long and narrow proportions, square rooms, rooms with concave walls and rooms with a ceiling height equal to the height or width. Splayed walls and ceilings are dramatic, but necessary only as opposing surfaces that cannot be covered with mid and high frequency absorptive material, such as large vision panels and glass doors.

Table 5.1-1

Reduction in the sound insulation (R) of a partition due to acoustic leakage through various size openings.

Size of Opening	Resultant R
0.0%	60 dB
0.1%	30 dB
1.0%	20 dB
10.0%	10 dB
50.0%	3 dB

Controlling the T60 of a room yields the most dramatic results. A medium size radio studio with a T60 of approximately 0.3–0.4 seconds from 100 Hz to 6 kHz will yield a pleasant acoustic environment.

Unlike the massive solids that are used for acoustic isolation, the most common absorptive materials are light and porous. The most common materials that are commercially available for absorbing sound are carpeting, acoustic tile ceilings and fiberglass or polyurethane foam wall panels. The difficulty in using these materials in broadcast studios is that they provide only mid and high frequency absorption.

The exclusive and excessive use of these materials can cause a studio to become boomy, by having a long T60 at low frequencies in proportion to the short T60 at the higher frequencies which these materials absorb.

An acoustic consultant can specify the design of resonant slot, hole and panel absorbers, as well as extra thick mineral fiber materials to absorb low frequency sound. Boominess can also be decreased by adding a thick fiberglass blanket above a lay-in tile ceiling and by using commercial absorptive materials in their thickest available form. Applying 3 or 4 ft widths of these materials with 2 or 3 ft spacings between them may also help balance the T60 of low and high frequencies. However, to avoid reflective echoes, no hard untreated surface should ever oppose another, either parallel or at an acute angle to it.

In combination control rooms (*combo* studios), often used in radio stations, mechanical equipment such as cartridge tape machines and reel-to-reel tape decks should be surrounded with as much absorptive material as practical. This will help absorb some of their mechanical sounds that might otherwise be reflected toward the host's microphone. Also, avoid placing the console microphone position too close to a vision panel. Whether omnidirectional or cardioid, any conventional microphone requires a free field behind it. A reflective surface behind the microphone such as a window or script panel will color the sound it picks up from the front.

Large television studios may derive as much of their acoustic characteristic from their sets and backdrops as from any materials purposely installed for acoustic purposes. However, because any portion of a studio wall may be exposed at one time or another, it's a good idea to cover the walls with absorptive mineral bats. The bats should be protected by a wire mesh, to keep them from disintegrating when props and sets are stored up against them.

The ceiling, above the lighting grid, should also be heavily absorptive, especially since large portions of the floor will remain reflective. It is important to keep the T60 of the television studio quite low to minimize the transmission of camera and crew noises, and to permit greater distances between talent and microphone without an off-mike quality. Hard, concave, acoustically reflective sets must be avoided, since any combination of these shapes tends to reflect unwanted sound toward the talent microphones in front of them.

The most reliable rule of thumb in acoustics is that treating low frequency problems is always more difficult and expensive than mid and high frequency work. If the budget is tight, always assign top priority to sound transmission considerations. Once the facility is built, little can be done to make up for economies made in the basic construction, while considerably more flexibility for improving interior room acoustics will remain.

Sound Locks

Once the design of the partitions has been decided, an entrance with the same sound insulation characteristic will be needed. There are few practical doors commercially available which meet or exceed the R values of the most common partitions used in broadcasting. Therefore, a sound lock entrance scheme is often required, that will attenuate sound through two doors and an intervening air space.

The sound lock is a small vestibule between the studio and a hallway or other room that provides access to the studio as shown in Figure 5.1-2. By entirely covering the walls of the sound lock between the studio and external doors with absorptive material, the efficiency of the sound lock will increase, decreasing the effect of opening one door. The use of a sound lock not only reduces the insulation requirement for each door, but also provides passage in and out of the studio or control room without exposing it to the full noise and disturbance of an adjoining area. Doors with good acoustic characteristics are available either in metal or wood, both of which feature a sound retardant core.

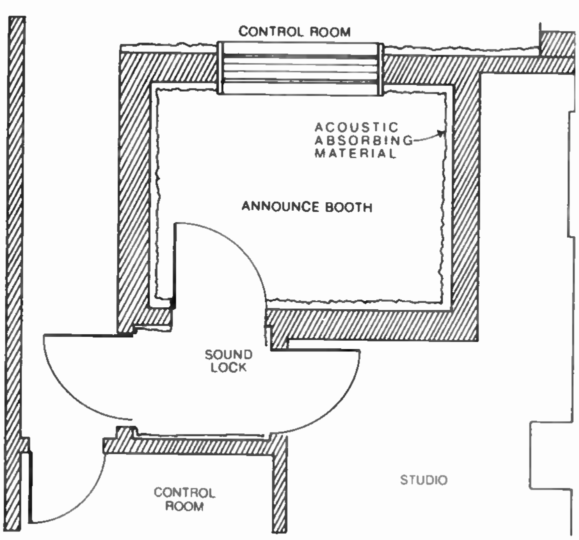

Figure 5.1-2. Soundlock entry to a small announce booth.

Like the partition requirements, the sound lock door must seal tightly within its frame. Lack of a good seal wastes whatever investment is made to procure a good sound rated door. Commercially available compression and/or magnetic type seals are recommended at the head and jambs of the door, while a mechanical drop seal and step saddle should be employed at its threshold. Some expensive prehung doors feature integral seals and can lift hinges that actually lower the entire door into place tightly against the threshold saddle when it is closed. The greatest advantage of these doors is that they never have to be pushed shut to make a good seal all around the door. All other types require an oversize door check (pneumatic or hydraulic closer) and a latch to properly compress the seals when the door is closed.

Windows

Studio windows require special consideration. In order to match the transmission loss characteristic of the partition surrounding it, a studio window must be double glazed. The two panes of glass should be of different thicknesses to minimize the coincidence of each pane's deficiencies. The glass should be mounted in a resilient neoprene or felt lined channel and caulked tight. Some provision should be made for removing either piece of glass for replacement or cleaning. The glass should be mounted with a 5° outward splay at the top to reduce acoustic and visual reflections.

Where a high degree of isolation is required, acoustic laminated glass should be employed. Each pane of this glass consists of alternating layers of plastic and glass and it is lighter, less resonant, and a better acoustical barrier than standard plate glass.

Welded hollow metal frames are preferred over wood for both doors and windows for their stability. However, the void within them should be packed with either a cement-like or mineral fiber filler. It is important that the frames not connect the vertical partition sections in floating room or double wall construction.

Modular Rooms

In large cities where the cost of construction labor is high, small studios, announce booths and control rooms may be economically built from modular components. The modular rooms are constructed from 4 in. thick, prefabricated hollow steel panels. A modular room usually includes a self-supporting ceiling and an integral floor. The entire room is assembled on rails that can be isolated with springs or neoprene from the building structure. Most companies offering modular rooms also include double and triple partitions, doors, windows, conduit, ventilation ducts and a performance guarantee as available options. Because modular rooms can be disassembled and relocated, they are not usually considered leasehold improvements and may offer certain financial benefits in addition to being somewhat portable.

ACOUSTICS SUMMARY

Regardless of the design, the installation contractor must be familiar with the stringent requirements of acoustic construction. The efforts of the general construction, electrical and mechanical trades must be coordinated by the architect both in the design and execution of the studio project to assure that no conflicts compromise the acoustic plan. The job should be inspected during construction by the acoustical consultant, to check for potential leakage paths brought about by existing field conditions, and conformance to acoustical details. If the station or studio is to be situated in an office building, or other shared location, consider that other tenants may be annoyed by high-level monitoring, tape rewind noises and other sounds peculiar to broadcasters. Therefore, during the design phase, if the acoustic consultant recommends protection for adjacent building tenants, the extra effort will result in happier neighbors.

ESTIMATING FACILITY COSTS

Estimating the cost of a broadcast or production facility is a complicated process. In addition to the technical equipment costs, that can be easily estimated, there is the cost of the physical facility construction or renovation that varies according to:

- The area or location in which the facility is to be built or renovated
- The quality of materials and level of attention to detail
- The time allowed for construction and time of year of construction
- The employment of energy saving techniques for long term savings
- Whether an architect, consultant or station staff will be supervising the entire project.

The costs of construction continue to increase. Materials and labor must be examined carefully by competent architects and construction engineers for the specific structure and area involved, if there is to be any accuracy in budgeting the project.

A major factor contributing to cost overrun on projects is inadequate initial plans and the resultant change orders during construction. Therefore, the owner should provide a supervisor to be directly involved in the project on a daily basis. While it is not necessary for the supervisor to be a construction expert, it behooves management to select someone who is skilled in project management, has a general understanding of the project and the time to devote to it.

Standardized Construction Specifications

Most contractors employ standardized methods for estimating costs of construction and breakout costs in a standardized manner. An example of a standardized list of the different construction areas, disciplines and trades is the *Masterformat* published by Construction Specifications Institute. All construction is divided into numbered 16 super-categories and each super-category is subdivided into more specific construction type and third and fourth levels of specifications. For example, a contractor would refer to Section 16780 for Television Systems (Broadcast Video Systems), under the sub-head of 16700 for Communications, under Division 16 which is Electrical.

Another example of the use of the standardized codes would be for the major heading of 15 for Heating, Ventilating and Air Conditioning system under which are sub-headings (or products) including 15550—Heat Generation, 15680—Water Chillers, 15750—Heat Transfer, and 15850—Air Handling.

When working with competitive bidding on the project the standardized code numbers provide the means for comparing the costs for a given kind of work.

CONSTRUCTION EXAMPLES

The following two examples illustrate construction costs for television facilities in large cities. The costs shown should be increased by some amount to reflect the increase in construction costs since these projects took place. In each of the cases, a general contractor was retained and coordination was handled by station staff engineering personnel. Electrical costs include power to all equipment, but not wages paid to station staff technicians who installed the broadcast equipment.

Example A. New Studio Facility

For this addition to the studio facility there were four basic requirements that had to be met (see Figures 5.1-3 and 5.1-4):

- Provide Television Station offices
- Provide expansion for the News Department
- Provide two studios and ancillary facilities capable of producing local newscasts as well as increased local station production
- Provide technical facilities that would meet future needs.

KHOU-TV, the Houston CBS affiliate underwent an expansion and remodeling project from August, 1993 until July, 1995. The 24,000 sq. ft addition and the remodel of the existing 36,000 sq. ft facility took two years to plan and two years to build.

Part of the project included the expansion 912 sq. ft. to one of our studios. An exterior wall had to be removed to allow for the increased studio space. Also included in this portion of the expansion was the acoustical applications as well as the installation of the self-leveling epoxy floor.

The asbestos found in the existing facility was abated as part of this project. The costs listed below are in addition to the cost of equipment. The technical support and equipment installation totaled $1,250,000, while the equipment purchased was $3,817,150. If this amount seems high, keep in mind that this analog facility was converted into the country's first all digital television station.

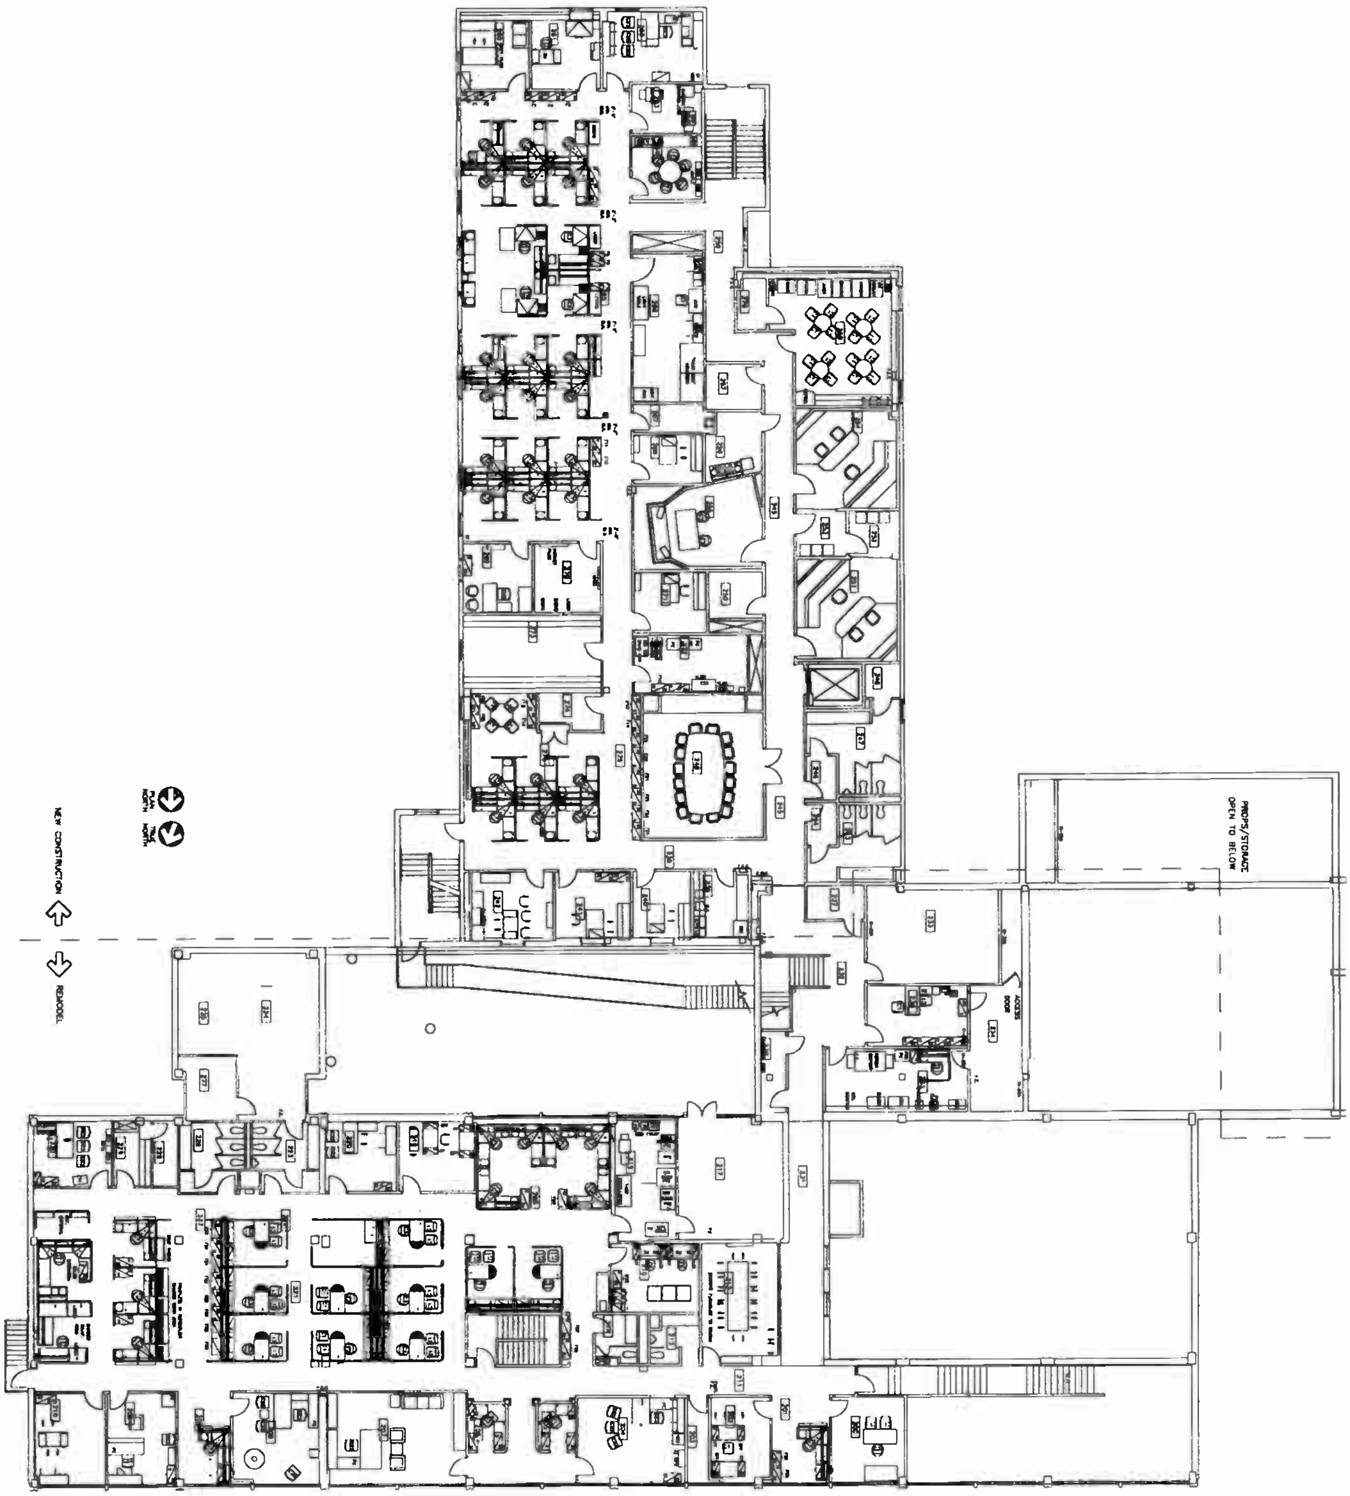

Figure 5.1-3. KHOU studio facility second floor.

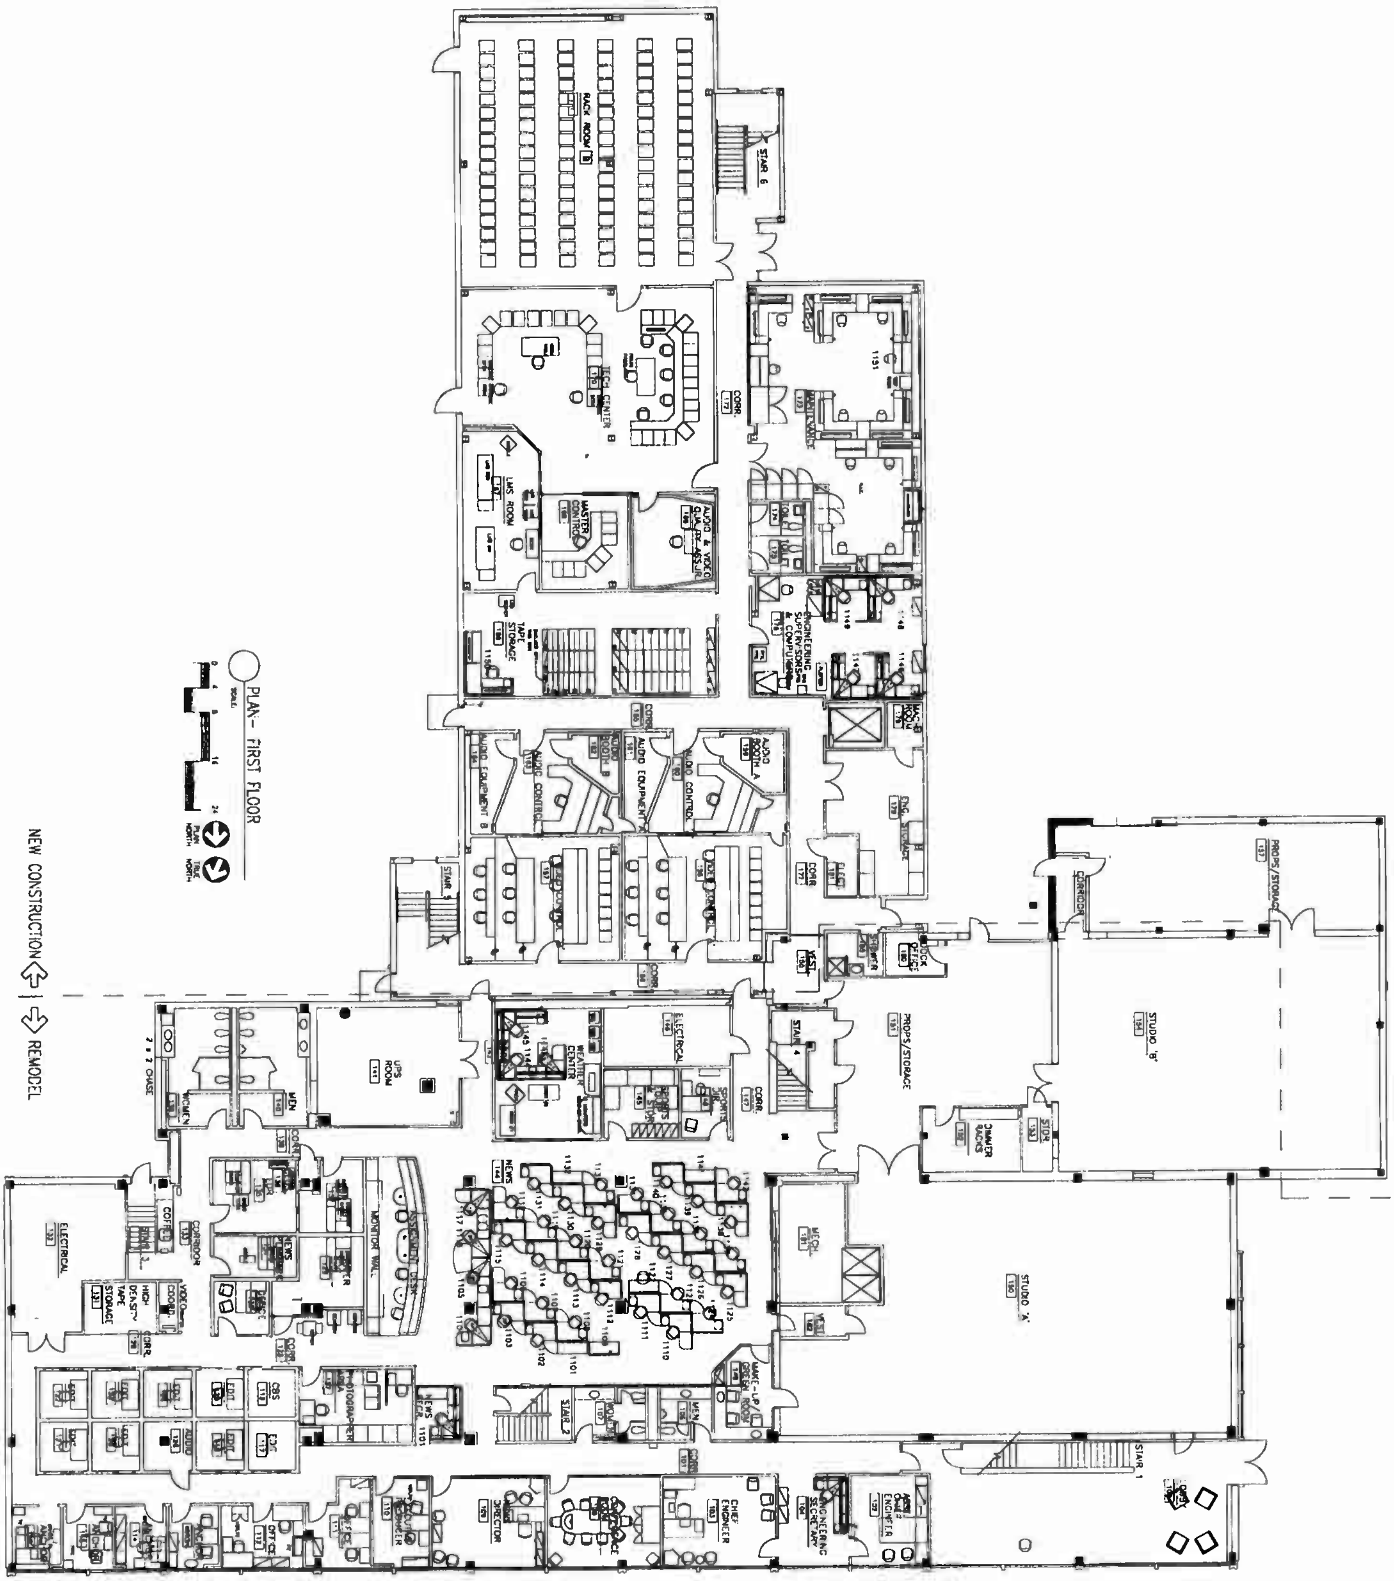

Figure 5.1-4. KHOU studio facility first floor.

Example A. Cost for New Building and Renovation of Existing Building and Expansion of Studio

Activity	Cost	Per Sq. Ft.
Land Acquisition	$ 108,500	
Site Survey & Site Work	$ 115,000	
Architectural Fees	$ 639,700	
Construction of New Space	3,328,600	$139.00
Renovation of Existing Space	2,373,300	66.00
Asbestos Abatement	212,700	
Furniture	601,500	
Contingency	174,500	
Studio Expansion	503,400	552.00
Auxiliary Power Generator	214,300	

Example B. Transmitter Building

In this example a transmitter site is to be relocated from downtown Houston to a site outside of town and a new transmitter building and towers are to be constructed (see Figures 5.1-5 and 5.1-6). The following goals were set:

- Relocate from downtown site which was being surrounded by buildings taller than the existing transmitting antenna
- Locate in same general area as the existing Houston TV stations
- Permit an antenna height of 2,000 ft AMSL
- Provide a Principal City Coverage over the same area as the old transmitter site.

A site was found that met FAA approval for a 2,000 ft AMSL antenna height. Two towers were to be constructed 100 ft apart. The foundation design included both towers and the transmitter building. The transmitter and antenna were selected to provide the best compromise between minimizing primary power consumption and providing 5 MW radiated power.

Example B Cost for New Transmitter Building—2,300 Sq. Ft.

Activity	Cost	Per Sq. Ft.
Structural	$29,000	$12.72
General Construction	$77,000	33.77
Decoration	$ 6,000	2.63
Heating & Ventilating	$15,000	6.59
Electrical (including Auxiliary generator, pad and roof)	$67,898	29.78
Plumbing	$10,000	4.39
Architect, Elect. & Mech. Engineering	$14,730	6.46
Special Woodwork & Built-Ins	$ 4,000	1.75
		$98.09

Typical Construction Cost Ranges

Activity	Cost Per Sq. Ft.
New Studios and Offices (new structure)	$82 to $138
Conversion for Studios & Offices (in existing structure)	$40 to $65
Transmitter Building (new structure)	$61 to $98

When divided into separate elements the breakout is as follows:

Activity	Cost Per Sq. Ft.
Demolition and Site Work	$1.80 to $3.00
Structural	$9 to $14
General Construction	$18 to $50
Heating, Ventilating and Air Conditioning	$9 to $16
Electrical	$5.40 to $18.00
Plumbing	$1.35 to $4.00
Architect and Engineering Fees	$2.25 to $7.00
Special Acoustical	$2.70 to $5.00
Woodwork and Built-Ins	$1.08 to $3.00
Office Furniture	$2.70 to $7.00
Decoration	$3.60 to $7.00

Electronic equipment installation and wiring is not covered by any of the previous estimates. A good

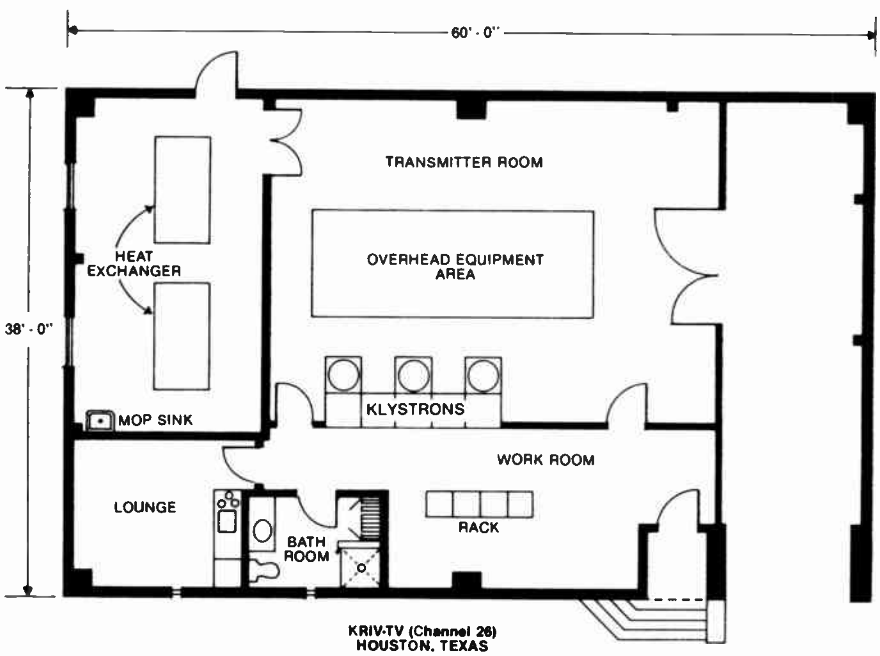

Figure 5.1-5. Transmitter building.

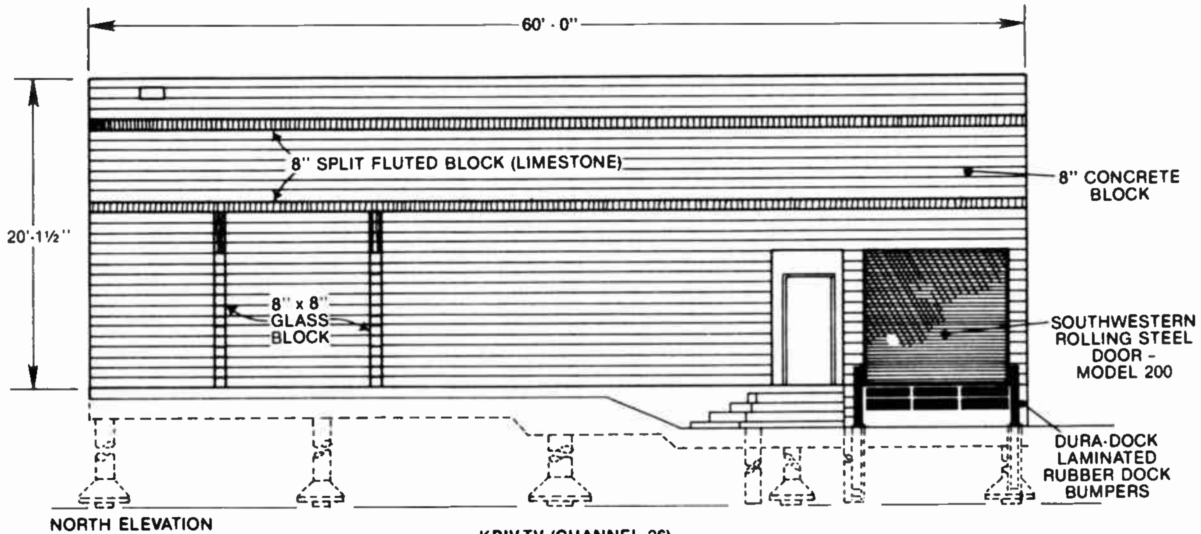

Figure 5.1-6. Transmitter building.

general rule is to allow 15–25% for this in addition to basic equipment cost. Variations are due to location, personnel and working rules.

CONCLUSION

The construction or renovation of a broadcast or recording facility is a major undertaking. Only the briefest explanations of the various elements and concerns were provided in this chapter. It behooves station management to become intimately involved in the construction details or to have a knowledgeable employee or consultant supervise the work. Advance planning and coordination with all departments and personnel will help design the best facility and smooth the construction and the transition to the new facility.

5.2
PRINCIPLES OF LIGHT, VISION, AND PHOTOMETRY

BY JERRY WHITAKER
EDITOR-IN-CHIEF

INTRODUCTION

Vision results from stimulation of the eye by light and consequent interaction through connecting nerves with the brain.[1] In physical terms, light constitutes a small section in the range of electromagnetic radiation, extending in wavelength from about 400 to 700 nanometers (nm) or billionths (10^{-9}) of a m. (See Figure 5.2-1.)

Under ideal conditions, the human visual system can detect:

- Wavelength differences of 1 millimicron (10 Å, 1 Angstrom unit = 10^{-10} cm)
- Intensity differences of as little as 1%
- Forms subtending an angle at the eye of 1 arc minute, and often smaller objects

Although the range of human vision is small compared with the total energy spectrum, human discrimination—the ability to detect differences in intensity or quality—is excellent.

Sources of Illumination

Light reaching an observer usually has been reflected from some object. The original source of such energy typically is radiation from molecules or atoms resulting from internal (atomic) changes. The exact type of emission is determined by:

- The manner in which the atoms or molecules are supplied with energy to replace that which they radiate
- The physical state of the substance, whether solid, liquid, or gaseous

The most common source of radiant energy is the thermal excitation of atoms in the solid or gaseous state.

The Spectrum

When a beam of light traveling in air falls upon a glass surface at an angle, it is *refracted* or bent. The amount of refraction depends upon the wavelength, its variation with wavelength being known as *dispersion.* Similarly when the beam, traveling in glass, emerges into air, it is refracted (with dispersion). A glass prism provides a refracting system of this type. Because different wavelengths are refracted by different amounts, an incident white beam is split up into several beams corresponding to the many wavelengths contained in the composite white beam—thus is obtained the spectrum.

If a spectrum is allowed to fall upon a narrow slit arranged parallel to the edge of the prism, a narrow band of wavelengths passes through the slit. Obviously, the narrower the slit, the narrower the band of wavelengths or the sharper the spectral line. Also, more dispersion in the prism will cause a wider spectrum to be produced, and a narrower spectral line will be obtained for a given slit width.

It should be noted that purples are not included in the list of spectral colors. The purples belong to a special class of colors; they can be produced by mixing the light from two spectral lines, one in the red end of the spectrum, the other in the blue end. Purple (magenta is a more scientific name) is therefore referred to as a *nonspectral color.*

A plot of the power distribution of a source of light is indicative of the watts radiated at each wavelength per nanometer of wavelength. It is usual to refer to such a graph as an *energy distribution curve.*

Individual narrow bands of wavelengths of light are seen as strongly colored elements. Increasingly broader bandwidths retain the appearance of color, but with decreasing purity, as if white light had been added to them. A very broad band extending generally throughout the visible spectrum is perceived as white light. Many white light sources are of this type, such as the familiar tungsten-filament electric light bulb (see Figure 5.2-2). Daylight also has a broad band of radiation, as illustrated in Figure 5.2-3. The energy distributions shown in Figures 5.2-2 and 5.2-3 are quite different and, if the corresponding sets of radiation were seen side by side, would be different in appearance. Either one, particularly if seen alone, however, would represent a very acceptable white. A sensation of white light can also be induced by light sources that do not have a uniform energy distribution. Among these is fluorescent lighting, which exhibits sharp peaks of energy through the visible spectrum. Similarly, the light from a monochrome (black-and-white) video cathode ray tube is not uniform within the visible spectrum, generally exhibiting peaks in the yellow and blue regions of the spectrum; yet it appears as an acceptable white (see Figure 5.2-4).

MONOCHROME AND COLOR VISION

The color sensation associated with a light stimulus can be described in terms of three characteristics:

- Hue
- Saturation
- Brightness

The spectrum contains most of the principal hues: red, orange, yellow, green, blue and violet. Additional hues are obtained from mixtures of red and blue light—these constitute the purple colors. *Saturation* pertains to the strength of the hue. Spectrum colors are highly saturated. White and grays have no hue and, therefore, have zero saturation. Pastel colors are of low or intermediate saturation. *Brightness* pertains to the intensity of the stimulation. If a stimulus has high intensity, regardless of its hue, it is said to be bright.

The psychophysical analogs of hue, saturation, and brightness are:

- Dominant wavelength
- Excitation purity
- Luminance

This principle is illustrated in Table 5.2-1.

By means of definitions and standard response functions, which have received international acceptance through the International Commission on Illumination (CIE), the dominant wavelength, purity, and luminance of any stimulus of known spectral energy distribution may be determined by simple computations. Although roughly analogous to their psychophysical counterparts, the psychological attributes of hue, saturation, and brightness pertain to observer responses to light stimuli and are not subject to calculation. These sensation characteristics as applied to any given stimulus depend in part on other visual stimuli in the field of view and upon the immediately preceding stimulations.

Color sensations arise directly from the action of light on the eye. They are normally associated, however, with objects in the field of view from which the light comes. The objects themselves are therefore said to have color. *Object colors* may be described in terms of their hues and saturations, as is the case for light stimuli. The intensity aspect is usually referred to in terms of lightness, rather than brightness. The psychophysical analogs of lightness are *luminous reflectance* for reflecting objects and *luminous transmittance* for transmitting objects.

At low levels of illumination, objects may differ from one another in their lightness appearances but give rise to no sensation of hue or saturation. All objects appear to be of different shades of gray. Vision at low levels of illumination is called *scotopic vision,* as distinct from *photopic vision,* which takes place at higher levels of illumination. Table 5.2-2 compares the luminosity values for photopic and scotopic vision.

Only the rods of the retina are involved in scotopic vision; the cones play no part. As the fovea centralis is free of rods, scotopic vision takes place outside the fovea. Visual acuity of scotopic vision is low compared with photopic vision.

At high levels of illumination, where cone vision predominates, all vision is color vision. Reproducing systems such as black-and-white photography and monochrome video, however, cannot reproduce all three types of characteristics of colored objects. All images belong to the series of grays, differing only in their relative brightness.

The relative brightness of the reproduced image of any object depends primarily upon the luminance of the object as seen by the photographic or video camera. Depending upon the camera pickup element or the film, however, the dominant wavelength and purity of the light may also be of consequence. Most films and video pickup elements exhibit uniform sensitivity throughout the visible spectrum and, consequently,

marked distortions in luminance as a function of dominant wavelength and purity are not encountered. Their spectral sensitivities seldom conform exactly to that of the human observer, however, so that some brightness distortions do exist.

Visual Requirements for Video

The objective in any type of visual reproduction system is to present to the viewer a combination of visual stimuli that can be readily interpreted as representing or having close association with a real viewing situation. It is by no means necessary that the light stimuli from the original scene be duplicated. There are certain characteristics in the reproduced image, however, that are necessary and others that are highly desirable. Only a general qualitative discussion of such characteristics will be given here.

In monochrome video, images of objects are distinguished from one another and from their backgrounds as a result of luminance differences. In order that detail in the picture be visible and that objects have clear, sharp edges, it is necessary that the video system be capable of rapid transitions from areas of one luminance level to another. This degree of resolution need not match that possible in the eye itself, but too low an effective resolution results in pictures with a fuzzy appearance and lacking fineness of detail.

Luminance range and the transfer characteristic associated with luminance reproduction are likewise of importance in monochrome video. Objects seen as white usually have minimum reflectances of approximately 80%. Black objects have reflectances of approximately 4%. This gives a luminance ratio of 20/1 in the range from white to black. To obtain the total luminance range in a scene, the reflectance range must be multiplied by the illumination range. In outdoor scenes, the illumination ratio between full sunlight and shadow may be as high as 100/1. The full luminance ranges involved with objects in such scenes cannot be reproduced in normal video reproduction equipment. Video systems must be capable of handling illumination ratios of at least 2, however, and ratios as high as 4 or 5 are desirable. This implies a luminance range on the output of the system of at least 40/1, with possible upper limits as high as 80/1 or 100/1.

Monochrome video transmits only luminance information, and the relative luminances of the images should correspond at least roughly to the relative luminances of the original objects. Red objects, for example, should not be reproduced markedly darker than objects of other hues but of the same luminance. Exact luminance reproduction, however, is by no means a necessity. Considerable distortion as a function of hue is acceptable in many applications. Luminance reproduction is probably of primary consequence only if detail in some hues becomes lost.

Images in monochrome video are transmitted one point, or small area, at a time. The complete picture image is repeatedly scanned at frequent intervals. If the frequency of scan is not sufficiently high, the picture appears to flicker. At frequencies above a *critical frequency* no flicker is apparent. The critical frequency changes as a function of luminance, being higher for higher luminance. The basic requirement for monochrome video is that the *field frequency* (the rate at which images are presented) be above the critical frequency for the highest image luminances.

Images of objects in color video are distinguished from one another by luminance differences or by differences in hue or saturation. Exact reproduction in the image of the original scene differences is not necessary or even attainable. Nevertheless, some reasonable correspondence must prevail because the luminance gradation requirements for color are essentially the same as those for monochrome video.

Luminous Considerations in Visual Response

Vision is considered in terms of physical, psychophysical and psychological quantities. The primary stimulus for vision is radiant energy. The study of this radiant energy in its various manifestations, including the effects on it of reflecting, refracting, and absorbing materials, is a study in physics. The response part of the visual process embodies the sensations and perceptions of seeing. Sensing and perceiving are mental operations and therefore belong to the field of psychology. Evaluation of radiant-energy stimuli in terms of the observer responses they evoke is within the realm of psychophysics. Because observer response sensations can be described only in terms of other sensations, psychophysical specifications of stimuli are made according to sensation equalities or differences.

Photometric Measurements

Evaluation of a radiant energy stimulus in terms of its brightness producing capacity is a photometric measurement. An instrument for making such measurements is called a *photometer.* In visual photometers, which must be used in obtaining basic photometric measurements, the two stimuli to be compared are normally directed into small adjacent parts of a viewing field. The stimulus to be evaluated is presented in the *test field;* the stimulus against which it is compared is presented in the *comparison field.* For most high-precision measurements the total size of the combined test and comparison fields is kept small, subtending about 2° at the eye. The area outside these fields is called the *surround.* Although the surround does not enter directly into the measurements, it has adaptation effects on the retina and thus affects the appearances of the test and comparison fields. It also influences the precision of measurement.

Luminosity Curve

A *luminosity curve* is a plot indicative of the relative brightnesses of spectrum colors of different wavelength or frequency. To a normal observer, the brightest part of a spectrum consisting of equal amounts of radiant flux per unit wavelength interval is at about 555 nm. Luminosity curves are therefore commonly normalized to have a value of *unity* at 555 nm. If, at some other wavelength, twice as much radiant flux as at 555 nm is required to obtain brightness equality with radiant flux at 555 nm, the luminosity at this wavelength is 0.5. The luminosity at any wavelength λ is, therefore, defined as the ratio P_{555}/P_{λ}, where P_{λ} denotes the amount of radiant flux at the wavelength λ, which is equal in brightness to a radiant flux of P_{555}.

The luminosity function that has been accepted as standard for photopic vision is given in Figure 5.2-5. Tabulated values at 10 nm intervals are given in Table 5.2-2. This function was agreed upon by the CIE in 1924. It is based upon considerable experimental work that was conducted over a number of years. Chief reliance in arriving at this function was based on the step-by-step equality-of-brightness method. Flicker photometry provided additional data.

In the scotopic range of intensities, the luminosity function is somewhat different from that of the photopic range. The two curves are compared in Figure 5.2-6. The two curves are similar in shape, but there is a shift for the scotopic curve of about 40 nm to the shorter wavelengths.

Measurements of luminosity in the scotopic range are usually made by the *threshold-of-vision* method. A single stimulus in a dark surround is used. The stimulus is presented to the observer at each of a number of different intensities, ranging from well below the threshold to intensities sufficiently high to be definitely visible. Determinations are made of the amount of energy, at each chosen wavelength, that is reported visible by the observer a certain percentage of the time, such as 50%. The reciprocal of this amount of energy determines the relative luminosity at the given wavelength. The wavelength plot is normalized to have a maximum value of 1.00 to give the scotopic luminosity function.

In the intensity region between scotopic and photopic vision, called the *Purkinje* or *mesopic region*, the measured luminosity function takes on sets of values intermediate between those obtained for scotopic and photopic vision. Relative luminosities of colors within the mesopic region will therefore vary, depending upon the particular intensity level at which the viewing takes place. Reds tend to become darker in approaching scotopic levels; greens and blues tend to become relatively lighter.

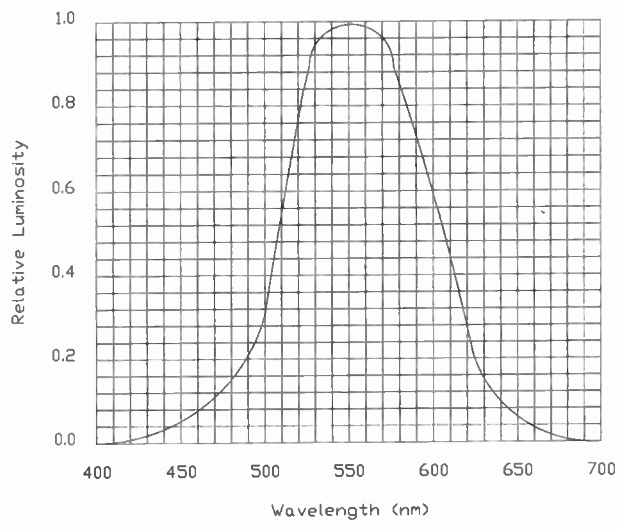

Figure 5.2-5. The photopic luminosity function.[7]

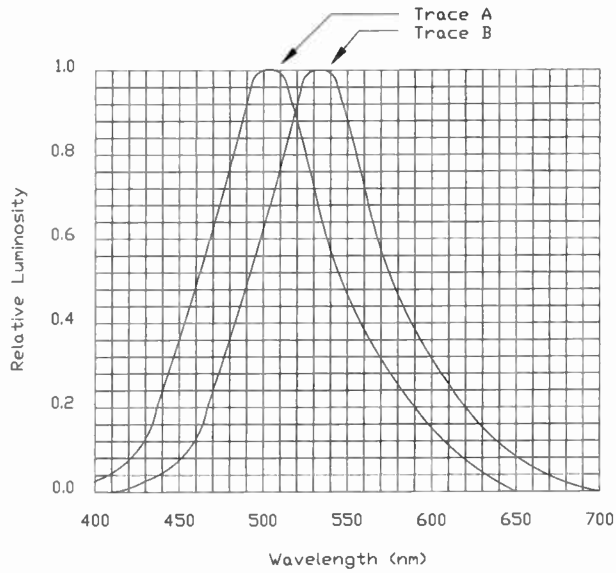

Figure 5.2-6. Scotopic luminosity function (trace *A*) as compared with photopic luminosity function (trace *B*).[7]

Luminance

Brightness is a term used to describe one of the characteristics of appearance of a source of radiant flux or of an object from which radiant flux is being reflected or transmitted. Brightness specifications of two or more sources of radiant flux should be indicative of their actual relative appearances. These appearances will depend in large part upon the viewing conditions, including the state of adaptation of the observer's eye.

Luminance, as indicated previously, is a psychophysical analog of brightness. It is subject to physical determination, independent of particular viewing and adaptation conditions. Because it is an analog of brightness, however, it is defined in such a way as to relate as closely as possible to brightness.

The luminosity function is the best established measure of the relative brightnesses of different spectral stimuli. In evaluating the luminance of a source of radiant flux consisting of many wavelengths of light, the amounts of radiant flux at the different wavelengths are weighted by the luminosity function, which converts radiant flux to luminous flux. As used in photometry, the term *luminance* is applied only to extended sources of light, not to point sources. For a given amount (and quality) of radiant flux reaching the eye, brightness will vary inversely with the effective area of the source.

Luminance is described in terms of luminous flux per unit projected area of the source. The greater the concentration of flux in the angle of view of a source, the brighter it appears. Luminance is therefore expressed in terms of amounts of flux per unit solid angle or *steradian*.

In considering the relative luminances of various objects of a scene to be captured and reproduced by a video system, it is convenient to normalize the luminance values so that the *white* in the region of principal illumination has a relative luminance value of 1.00. The relative luminance of any other object then becomes the ratio of its luminance to that of the white. This white is an object of highly diffusing surface with high and uniform reflectance throughout the visible spectrum. For purposes of computation, it may be idealized to have 100% reflectance and perfect diffusion.

Perception of Fine Detail

Detail is seen in an image because of brightness differences between small adjacent areas in a monochrome display or because of brightness, hue, or saturation differences in a color display. Visibility of detail in a picture is important because it determines the extent to which small or distant objects of a scene are visible, and because of its relationship to the *sharpness* appearance of the edges of objects.

Picture definition is probably the most acceptable term for describing the general characteristic of crispness, sharpness, or image-detail visibility in a picture. Picture definition depends upon characteristics of the eye, such as visual acuity, and upon a variety of characteristics of the picture-image medium, including its resolving power, luminance range, contrast, and image edge gradients.

Visual acuity may be measured in terms of the visual angle subtended by the smallest detail in an object that is visible. The *Landolt ring* is one type of test object frequently employed. The ring, which has a segment cut from it, is shown in any one of four orientations, with the opening at the top or bottom or on the right or left side. The observer identifies the location of this opening. The visual angle subtended by the opening that can be properly located 50% of the time is a measure of visual acuity.

Test object illuminance, contrast between the test object and its background, time of viewing, and other factors greatly affect visual acuity measurements. Up to a visual distance of about 20 ft (6 m) acuity is partially a function of distance, because of changes in shape of the eye lens in focusing. Beyond 20 ft it remains relatively constant. Visual acuity is highest for foveal vision, dropping off rapidly for retinal areas outside the fovea.

A black line on a light background is visible if it has a visual angle no greater than 0.5 s. This is not, however, a true measure of visual acuity. For visual acuity tests of the type described, normal vision, corresponding to a Snellen 20/20 rating, represents an angular discrimination of about 1 min. Separations between adjacent cones in the fovea and resolving power limitations of the eye lens give theoretical visual acuity values of about this same magnitude.

The extent to which a picture medium, such as a photographic or a video system, can reproduce fine detail is expressed in terms of *resolving power* or *resolution*. Resolution is a measure of the distance between two fine lines in the reproduced image that are visually distinct. The image is examined under the best possible conditions of viewing, including magnification.

Two types of test charts are commonly employed in determining resolving power, either a wedge of radial lines or groups of parallel lines at different pitches for each group. For either type of chart, the spaces between pairs of lines usually are made equal to the line widths. Figure 5.2-7 shows a test signal electronically generated by a video measuring test set.

Resolution in photography is usually expressed as the maximum number of lines (counting only the black ones or only the white ones) per millimeter that can be distinguished from one another. Measured values of resolving power depend upon a number of factors in addition to the photographic material itself. The most important of these typically are:

- Density differences between the black and the white lines of the test chart photographed
- Sharpness of focus of the test-chart image during exposure
- Contrast to which the photographic image is developed
- Composition of the developer

Sharpness of focus depends upon the general quality of the focusing lens, image and object distances from the lens, and the part of the projected field in which the image lies. In determining the resolving power of a photographic negative or positive material, a test chart is generally employed that has a high density difference, such as 3.0, between the black-and-white lines. A high quality lens is used, the projected field is limited and focusing is critically adjusted. Under these conditions, ordinary black-and-white photographic materials generally have resolving powers in the range of 30 to 200 line-pairs per mm. Special photographic materials are available with resolving powers greater than 1000 line-pairs per mm.

Resolution in a video system is expressed in terms of the maximum number of lines, counting both black and white, that are discernible in viewing a test chart. The value of horizontal (vertical lines) or vertical (horizontal lines) resolution is the number of lines equal to the vertical dimension of the raster. Vertical resolution in a well adjusted system equals the number of scanning lines, roughly 500 in conventional television. In normal broadcasting and reception practice, however, typical values of vertical resolution range from 350 to 400 lines. The theoretical limiting value for horizontal resolution (R_H) in a 525 line, 30 Hz frame rate system is given by:

$$R_H = \frac{2 \times 0.75 \times \Delta f}{30 \times 525}$$

$$R_H = 0.954 \times 10^{-4} \times \Delta f$$

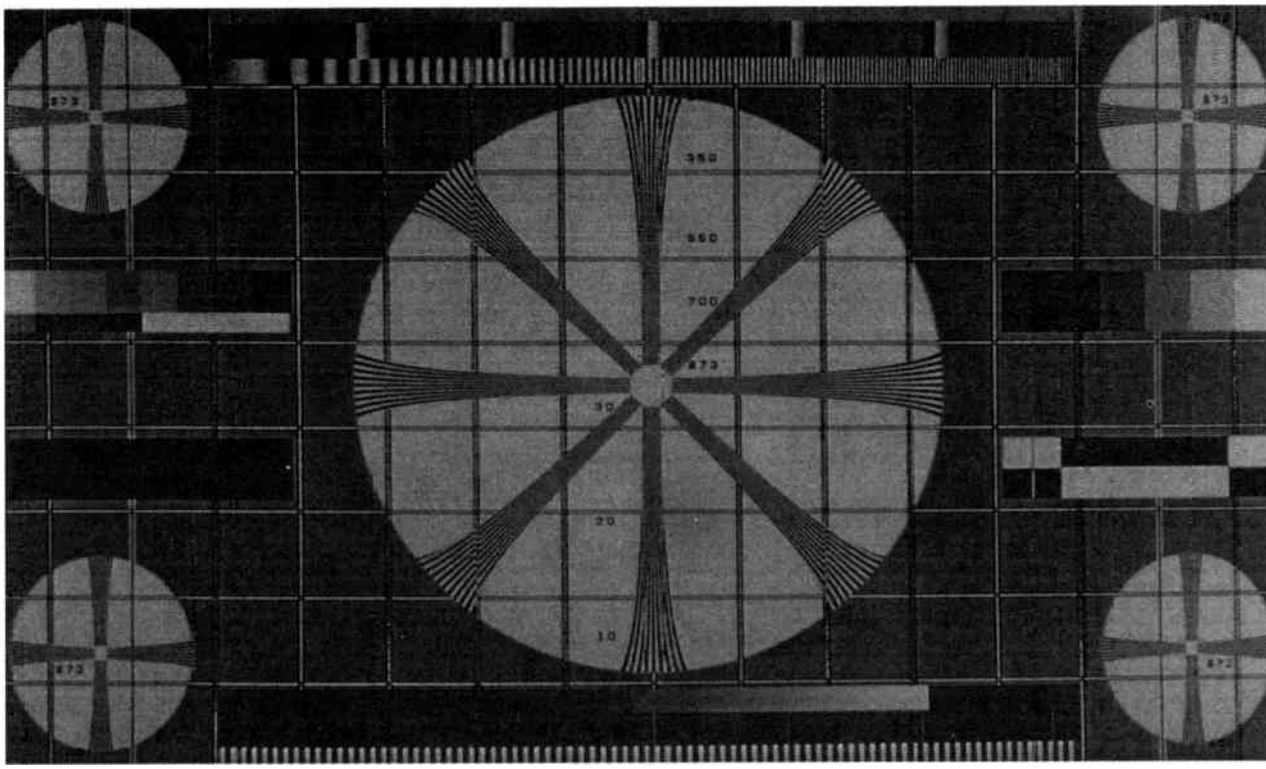

Figure 5.2-7. Test chart for high definition television applications produced by a signal waveform generator. The electronically produced pattern is used to check resolution, geometry, bandwidth, and color reproduction. (*Courtesy of Tektronix.*)

Where:

Δf = the available bandwidth frequency in Hz

The constants 30 and 525 represent the frame and line frequencies, respectively in the conventional United States television system. A factor of 2 is introduced because in one complete cycle both a black and a white line are obtainable. The factor 0.75 is necessary because of the receiver aspect ratio—the picture height is ¾ of the picture width. There is an additional reduction of about 15% (not included in the equation) in the theoretical value because of horizontal blanking time during which retrace takes place. A bandwidth of 4.25 MHz—typically that of the conventional terrestrial television system—thus makes possible a maximum resolution of about 345 lines.

Sharpness

The appearance evaluation of a picture image in terms of the edge characteristics of objects is called *sharpness.* The more clearly defined the line that separates dark areas from lighter ones, the greater the sharpness of the picture. Sharpness is, naturally, related to the transient curve in the image across an edge. The average gradient and the total density difference appear to be the most important characteristics. No physical measure has been devised, however, that in all cases will predict the sharpness (appearance) of an image.

Picture resolution and sharpness are to some extent interrelated but they are by no means perfectly correlated. Pictures ranked according to resolution measures may be rated somewhat differently on the basis of sharpness. Both resolution and sharpness are related to the more general characteristic of picture definition. For pictures in which, under particular viewing conditions, effective resolution is limited by the visual acuity of the eye rather than by picture resolution, sharpness is probably a good indication of picture definition. If visual acuity is not the limiting factor, however, picture definition depends to an appreciable extent on both resolution and sharpness.

HUMAN VISUAL SYSTEM

The human visual system (HVS) is powerful and exceeds the performance of artificial visual systems in almost all areas of comparison. Researchers have, therefore, studied the HVS extensively to ascertain the most efficient and effective methods of communicating information to the eye. An important component of this work has been the development of models of how humans see in an effort to improve image processing systems.

A Model for Image Quality

The classic approach to image quality assessment involves the presentation to a group of test subjects visual test material for evaluation and rating. The test material may include side-by-side display comparisons, or a variety of perception threshold presentations. One common visual comparison technique is called the *pair-comparison* method. A number of observers are asked to view a specified number of images at two or more distances. At each distance, the subjects are asked to rank the order of the images in terms of overall quality, clearness, and personal preference.

An image acquisition, storage, transmission and display system need not present more visual information to the viewer than the viewer can process. For this reason, image quality assessment is an important element in the development of any new video system. For example, in the development of a video compressing algorithm, the designer needs to know at what compression point impairments are visible to the average viewer.

Evaluation by human subjects, while an important part of this process, is also expensive and time consuming. Numerous efforts have been made to reduce the human visual system and its interaction with a display device to one or more mathematical models. (Some of this research is cited in [1–5].) The benefits of this research to design engineers is obvious: more timely feedback on new product offerings. In the development of advanced imaging systems, it is important to evaluate the visual performance of the system well in advance of the expensive fabrication process. Image capture and display design software, therefore, is valuable. Because image quality is the primary goal in many systems, tools that permit the engineer to analyze and emulate the captured and/or displayed image assist in the design process. Such tools provide early feedback on new display techniques and permit a wider range of prospective products to be evaluated.

After the system or algorithm has successfully passed the minimum criteria established by the model, it can be subjected to human evaluation. The model simulation requires the selection of many interrelated parameters. A series of experiments is typically conducted to improve the model to more closely approximate human visual perception.

HVS as it Affects Digital Video

A video compression system reduces the volume of data by exploiting spatial and temporal redundancies and by eliminating the data that cannot be displayed suitably by the associated display or imaging devices. [8] The main objective of compression is to retain as little data as possible to reproduce the original images without causing unacceptable distortion of the image. A compression system consists of the following components:

- *Digitization, sampling and segmentation.* Steps that convert analog signals on a specified grid of picture elements into digital representations, then divide the video input—first into frames, then into blocks.
- *Redundancy reduction.* The decorrelation of data into fewer useful data bits using certain invertible transformation techniques.
- *Entropy reduction.* The representation of digital data using fewer bits by dropping less significant information. This component causes distortion and it is the main contributor in *lossy* compression.
- *Entropy coding.* The assignment of code words (bit strings) of shorter length to more likely image symbols and code words of longer length to less likely symbols. This minimizes the average number of bits needed to code an image.

Key terms important to the understanding of this topic include the following:

- *Motion compensation:* The coding of video segments with consideration to their displacements in successive frames.
- *Spatial correlation:* The correlation of elements within a still image or a video frame for the purpose of bit-rate reduction.
- *Spectral correlation:* The correlation of different color components of image elements for the purpose of bit-rate reduction.
- *Temporal correlation:* The correlation between successive frames of a video file for the purpose of bit rate reduction.
- *Quantization compression:* The dropping of the less significant bits of image values to achieve higher compression.
- *Intraframe coding:* The encoding of a video frame by exploiting spatial redundancy within the frame.
- *Interframe coding:* The encoding of a frame by predicting its elements from elements of the previous frame.

The removal of spatial and temporal redundancies that exist in natural video imagery is essentially a lossless process. Given the correct techniques, an exact replica of the image can be reproduced at the viewing end of the system. Such lossless techniques are important for medical imaging applications and other demanding uses. These methods, however, usually realize only about a 2:1 compression efficiency. For video, a much higher compression ratio is required. Exploiting the inherent limitations of the human visual system can result in compression ratios of 50:1 or higher. These limitations include the following:

- Limited luminance response and very limited color response
- Reduced sensitivity to noise in high frequency components, such as at the edges of objects
- Reduced sensitivity to noise in brighter areas of the image

The goal of compression, then, is to discard all information in the image that is not absolutely necessary from the standpoint of what the HVS is capable of resolving. Such a system can be described as *psychovisually lossless.* Understanding the HVS, then, is fundamental to the development of advanced compression technologies that have made possible the ATSC digital television system.

DEFINING TERMS

Brightness. A term used to describe one of the characteristics of appearance of a source of radiant flux or of an object from which radiant flux is being reflected or transmitted.

Critical frequency. The rate of picture presentation, as in a video system or motion picture display, above which the presented image ceases to give the appearance of flickering. The critical frequency changes as a function of luminance, being higher for higher luminance.

Dispersion. The variation of refraction as a function of wavelength.

Energy distribution curve. A plot of the power distribution of a source of light giving the energy radiated at each wavelength per nanometer of wavelength.

Field frequency. The rate at which images in an electronic imaging system are presented. In conventional terrestrial television (NTSC), two fields are presented each second to make up one *frame* (a complete picture).

Refraction. The bending of light as it passes from one medium to another, such as from air to glass, at an angle.

Resolution. The extent to which an imaging system, such as a photographic or a video system, can reproduce fine detail.

Sharpness. The appearance evaluation of a picture image in terms of the edge characteristics of objects contained therein. The more clearly defined the lines separating dark areas from light ones, the greater the sharpness of the picture.

FOR FURTHER INFORMATION

The International Society for Optical Engineering (SPIE) (Bellingham, Washington) offers a number of publications examining the characteristics of the human visual system. The organization also conducts technical seminars on various topics relating to optics and the application of optical technologies.

5.3
VIDEO PICKUP DEVICES AND SYSTEMS

PETER GLOEGGLER
SONY CORPORATION, PARK RIDGE, NJ

INTRODUCTION

Color television, color printing and color photography all share the *tristimulus* concept of reproducing a colored image. In each of these systems, a combination of basic colors is used to create the wide spectrum of colors each of these mediums is capable of producing. Figure 5.3-1 shows a plot of the three NTSC color primaries on the CIE chromaticity diagram. The full range of colors contained within the red, green and blue (RGB) triangle on this diagram can be reproduced by the NTSC color television system. In its most basic form, all of the color television systems currently in use separate the incoming light into three separate images, corresponding to the red, green and blue spectra of the original scene.

Solid-state imagers are most commonly used to convert the three optical images into three electrical video signals that correspond to these images. These signals are then transmitted to another location or to the home for display. The signals are frequently combined into a single analog composite signal, using NTSC, *Phase Alternation Line* (PAL) or *Sequential Couleur Avec Memoire* (SECAM) encoding before transmission. At the receiver (or monitor), these composite signals are separated again into the red, green, and blue components and applied to a color display device, most commonly a *cathode ray tube* (CRT).

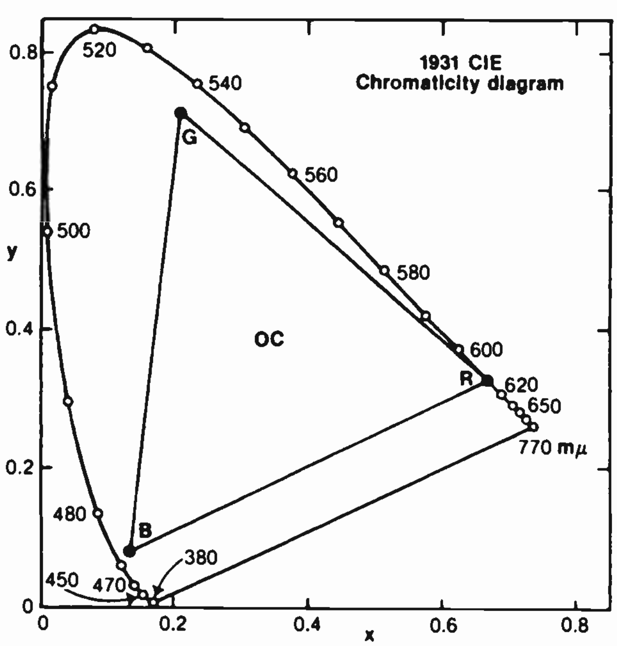

Figure 5.3-1. CIE chromaticity diagram showing the NTSC color primaries. *(Courtesy of Wiley Publishing.)*

In the United States, the existing composite analog transmission to the home using the NTSC encoding format will be supplemented and eventually replaced by the new component digital transmission system (the three color components are transmitted separately) as recommended by the Advanced Television Standards Committee (ATSC). With the FCC's acceptance of this recommendation, the migration to digital television is underway in the United States. Unlike NTSC, where a single picture format is mandated, the new standard for digital television describes a family of acceptable picture formats. (See Table 3 of the ATSC Document A/53 for a listing of the permissible transmission formats.)

In the case of the CRT, an array of red, green and blue phosphors on the screen are excited by electron beams corresponding to the red, green and blue signals to create the final color image.

THE CAMERA SYSTEM

Television became a practical reality with the invention of two electronic devices that use an electron beam in a vacuum envelope to overcome the limitations of the electromechanical devices used in earlier experiments with television. Both devices use an electron beam, albeit to opposite purposes. The first device, the CRT, uses an electron beam to scan a phosphor layer that emits light in direct proportion to the intensity of the electron beam striking it. Because the intensity of the electron beam can—in turn—be controlled by an electrical signal applied to the CRT, this electrical signal can be used to create an optical image.

The second device, the *image pickup tube,* also uses an electron beam. However, in this case, the electron beam scans an image focused on the photosensitive layer of the tube and produces an electrical signal that is proportional to the optical image. The image pickup tube and its solid-state successor, the *charge coupled device* (CCD) imager, constitute the heart of the television camera.

The video camera is only the starting point in bringing a television image to the viewer, but it is one of the most exciting and challenging parts of the system. Creating a modern video camera requires the latest

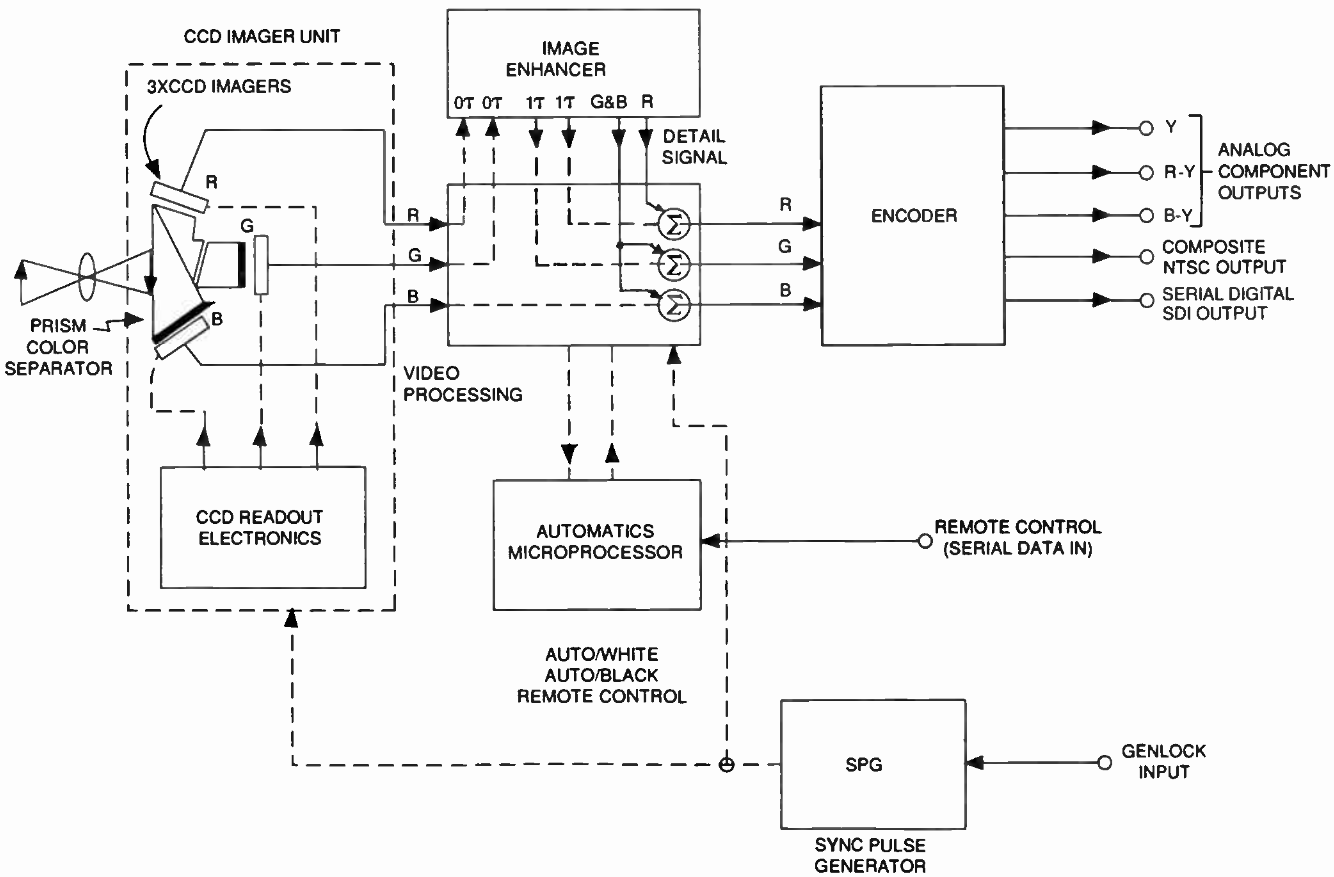

Figure 5.3-2. Basic block diagram of a video camera.

technology from a wide variety of disciplines: optics, integrated circuit technology, microprocessor control and manufacturing technology.

Video cameras, from the largest units used in the studio, to small cameras used for *electronic news gathering* (ENG), share many common elements (see Figure 5.3-2). Cameras, typically contain these major parts:

- A lens to capture the scene
- Color separation optics to separate the incoming light into three primary color images: a red, green and blue image
- Three pickup devices that convert the red, green and blue images into three electrical signals, the RGB video signals
- Video processing circuitry that performs a variety of processing steps to:
  correct for errors in the lens and optical system, correct for the color temperature of the scene illumination, compress the dynamic range, increase the apparent sharpness of the image through the use of image enhancement techniques, and introduce gamma pre-correction
- Encoding system—circuitry that encodes the basic RGB signals created by the camera into analog component, analog composite or digital signals appropriate for recording or distribution
- Timing signal generator—circuitry that produces the waveforms necessary for the internal operation of the camera
- Power supply—circuitry that generates the voltages required to operate the various parts of the camera.

Camera System Details

To illustrate the complex processes that occur in a video camera, we will follow the rays of light entering the lens, conversion of the light to an electrical signal and the processing of the signal to the final output signal delivered by the camera.

The Optical System

The optical system of the camera is used to form a precise image of the original scene on the surface of the imaging devices. The optical system consists of:

- A lens to capture the image
- Optical filters to condition the image
- The color separation system to split the incoming light into the three primary color components.

Clearly, the quality of the optical system is critical to the performance of the overall camera. In the world of optics, there is usually a close correlation between cost and performance. It is not surprising, therefore, to find a somewhat lower level of performance in the optical system of lower cost cameras and lenses.

Brief descriptions of the optical components used in a camera are given here. For further information, see references 1 and 3.

The Lens

With the exception of the highest levels of program production, where fixed focal length (*prime lenses*) are sometimes used, the *zoom lens* is the universal lens used with virtually all television cameras. Zoom lenses are available at a wide range of prices and performance levels, up to and including performance levels required for use with high-definition television (HDTV) systems.

At first look, the requirements for a lens intended for use with a TV camera appear to be quite similar to lenses intended for use with a film camera, and indeed, film lenses are routinely used with black and white and single imager color video cameras. Unfortunately, lenses appropriate for a high quality video work differ in one critical parameter from lenses designed for film cameras. The *back focal distance* (the distance from the end of the lens to the plane where the image is formed) is increased significantly compared to film lenses to allow the insertion of the prism type color separation system between the lens and the imagers. For this reason, it is not possible to use the immense installed base of high quality film lenses directly with a professional (prism color separation) color video camera. A sophisticated optical adapter is necessary to use film lenses directly. Such *relay optic* adapters are available and are typically used with extreme wide angle and extreme telephoto film lenses for shooting requirements that cannot be achieved with available video zoom lenses.

With the FCC's acceptance of a new digital broadcast system in 1997, a new factor has been added to the television picture. Broadcasting in a widescreen 16:9 aspect ratio as compared to the current 4:3 ratio of NTSC transmission will be permitted on this digital channel. Video cameras are now being made available with imagers capable of producing a wide aspect ratio image. The decision has been made that the image diagonal dimension for cameras that produce 16:9 aspect ratio pictures and cameras that produce the current 4:3 pictures shall be the same. This means that a 16:9 camera can use the same lens that is used with a 4:3 aspect ratio camera. On the other hand the 16:9 aspect ratio and the higher picture quality that can be delivered to the home by the new new digital broadcast system, mandates the use of the higher quality offerings of lens suppliers to fully support these new picture quality levels (for more details on lens parameters see Appendix B).

Optical Filters

Several optical filters are used to achieve the high level of performance found in a modern camera:

- Color correction and neutral density filters
- Infrared filter
- Quarter wavelength filter
- Anti-aliasing filter.

Color Correction and Neutral Density Filters

The human eye adapts to changes in the characteristics of the surrounding illumination. Thus, after a short period of adaptation, the color of an object will be perceived by the eye as the same in daylight or in incandescent illumination. Cameras, whether they are film or electronic, do not adapt to the illumination, and so the color of an object will differ with the color temperature of the illuminant if appropriate adjustments are not made in the camera. Color cameras are designed to operate with lighting of a nominal color temperature, most commonly 3,200° K—the lighting provided by standard halogen studio lights. (See Appendix C for a more detailed discussion of the concept of color temperature.)

However, the camera must have the ability to operate properly with various other illumination sources. A combination of optical color correction filters and electrical adjustments of the relative gain of the camera's red, green and blue processing channels are used to reproduce the object correctly under different illumination. Outdoor scenes challenge the camera with a wide range of illumination, rich in reds early in the day and late in the afternoon, and dominated by blue at midday. In terms of color temperature, the video camera must be able to achieve white balance for illumination with a color temperature of less than 3,000° K for warm incandescent lighting, to color temperatures as high as 10,000° K on a bright, wintry day outdoors. Outdoor illumination is frequently much brighter than indoor lighting, and for this reason a neutral density filter is commonly used in conjunction with a daylight correction filter to keep the lens iris at the most favorable portion of its operating range.

Color cameras commonly include a four position filter wheel that allows convenient selection of the most appropriate combination of neutral density and color correction filters for a given scene illumination. Although many cameras have the ability to electronically achieve white balance even when an incorrect filter is used, the signal-to-noise (S/N) and the ability to handle pictures with very high contrast will be impaired.

Infrared Filter

The response of a CCD imager extends beyond the visible range to include the near infrared region. To avoid incorrect color reproduction from the unwanted response of the CCD or pickup tube imager to infrared light (wavelengths below the visible spectrum), video cameras normally include an infrared filter in the optical path to limit the response of the camera to the visible spectrum.

Quarter Wavelength Filter

The dichroic coatings used in the prism type color separation system respond differently to light of different polarization. To avoid a change in colorimetry with a change in polarization in the scene, a quarter wavelength filter is introduced before the prism in high performance cameras. The quarter wavelength filter alters the plane polarization of the incoming light to circular polarization. Lower cost cameras may not include this filter due to its high cost.

Anti-Aliasing Filter

A filter relatively new to the design of video cameras, the anti-aliasing filter has the difficult task of removing the extremely fine picture detail that can produce objectionable aliasing in a solid-state imager but have relatively little affect on picture detail within the resolving power of the imager. The quality of this filter is the key element that controls the compromise between useful resolving power and curtailment of the aliasing phenomenon in the imager.

Different from the smooth homogeneous imaging layer used in the pickup tube, the CCD solid-state imager uses an orthogonal, two-dimensional array of separate discrete sensors. Each sensor element develops a charge that is directly proportional to the light level impinging on this specific sensor element. The CCD array is, therefore, a collection of discrete electronic samples of the original optical image. Recognizing the CCD imager as a sampled data system, it becomes clear that the Nyquist sampling theorem applies. That is, errors will result when an input is sampled at a rate that is less than twice the highest frequency in the input. Here, the frequencies are spatial rather than termporal, but the results are the spatial equivalent.

To avoid the aliasing phenomenon in the electrical output of the imager, an optical low-pass filter must be added to the camera to remove fine image detail above the spatial Nyquist limit. The optical low-pass filter is similar in design to a multielement *star filter*, and one of the signatures of this optical filter—found in almost all CCD cameras—is the star filter-like rays emanating from a strong highlight. Two-axis optical low-pass filters are most frequently used in industrial grade CCD cameras, while three-axis filters are normally provided in broadcast grade cameras, because aliasing tends to be much lower with the more complex three-axis filter.

The Color Separation System

A color camera requires an optical system that separates the incoming image into its three component colors. The type and quality of the color separation system used determines not only the faithfulness with which the camera reproduces colors, but also determines the physical arrangement of the imagers and thereby the mechanical design of the camera.

Current color cameras use one of the following designs:

- A single imager camera with color separation achieved by color filters positioned over the individual pixel
- Two imager camera, with one imager for luminance and the other for color reproduction
- Three imager camera, with prism type optics for color separation.

Sensitivity and the ability to accurately reproduce colors, particularly when luminance values are close to black or peak white, are compromised in the two imager cameras. Resolution, sensitivity and color reproduction near black and peak white luminance values are compromised in the one imager camera. For this reason, applications of one and two imager cameras tend to be limited to consumer and industrial applications, while prism type cameras are usually the choice for broadcast and program production.

For single and two imager type cameras, two different methods of color separation are available: *the RGB Primary Color Separation System* and complementary type color separation system. The RGB primary color system uses red, green and blue optical filters in front of the CCD devices. The *complementary type* color separation system uses yellow, cyan and magenta optical filters in front of the CCDs.

The *prism type color separation system* has become the dominant technique for high-end cameras by virtue of its compactness and overall performance (see Table 5.3-1). (An illustration of the three types of color separation systems and a more detailed description of the prism type system is provided in Appendix 1, *Color Separation Systems.*)

Imaging Devices

The imaging device is the transducer that converts the optical image into an electrical analog of the image. Cameras used in television broadcasting are almost entirely color cameras and use one, two or three imaging devices.

Image Diagonal

Image size is one of the more important factors that determine the overall performance of a camera. High performance cameras suitable for broadcast and production commonly use 2/3 in. or 1/2 in. format CCD imagers. The 2/3 in. image format has established itself as the optimum compromise between camera size, weight and performance. Limitations on minimum line width and other limitations of integrated circuit technology make it difficult to shrink the size of the imager and maintain the same level of performance. For a given type of CCD imager, 2/3 in. format cameras, therefore, tend to offer a higher level of performance than cameras using 1/2 in. imagers. In addition, a theoretical analysis indicates that the design requirements for the lens and the optical system become more severe as the image diagonal is reduced.

Sensitivity is one more specification of the camera that is strongly related to image diagonal. The prism color separation system has a basic limitation on the rate of convergence of the light rays that pass through it (the rate of convergence is limited to $f/1.4$ in the commonly used *three-piece* prism system) and as a result, it is possible to use a lens with almost twice the light gathering power (larger objective diameter)

Table 5.3-1
Relative performance of color separation systems
(Performance in a camera using 2/3 in., f/5.6, 768 pixel CCDs).

Color Separation System	Number of Imagers Required	Resolution	Sensitivity at 2000 Lux (Full Output)	Color Fidelity	Cost
Three Imager Cameras: Prism Type	3	Good, −700 TVL	Good, −f/5.6	Good	High
Two Imager Cameras: Luma/Chroma Type	2	Good, −560 TVL	Fair, −f/4.0	Fair*	Medium
Single Imager Cameras: Color Stripe: RGB Primary	1	Poor, −330 TVL	Poor, −f/2.8	Fair*	Low
Color Stripe: Complementary	1	Fair, −330 TVL	Fair, −f/4.0	Poor*	Low
Mosaic Type: Primary Color	1	Fair, −440 TVL	Poor, −f/2.8	Fair*	Low
Mosaic Type: Complementary	1	Fair, −440 TVL	Fair, −f/4.0?	Poor*	Low

* The color stripe/mosaic method of color separation tends to be ineffective for very dark colors (luminance <5 IRE) and very bright colors (luminance >95 IRE).

with a 2/3 in. format camera as compared to a 1/2 in. format camera. As a negative, the cost of the imagers and the overall size of the camera tends to increase when CCDs with larger image diagonal are used. It is not surprising to find that 2/3 in. imagers are the choice for the highest cost cameras, while 1/2 in. imagers predominate among the lower cost cameras offered by manufacturers.

The Camera Pickup Tube

In 1970, Willard Boll and George Smith of the Bell Labs announced the discovery of the CCD and with this development, the dream of a solid-state imager for use in a television camera took a big step toward reality. After almost 30 years of development, the CCD imager is displacing the pickup tube in virtually all cameras. This chapter, therefore, concentrates on the details of the new solid-state imagers and limits the discussion of cameras using pickup tubes.

The pickup tube was one of the key inventions that made the television system possible. In the pickup tube, the optical image focused on the photosensitive layer is scanned by an electron beam and an electrical signal directly proportional to the optical image is provided at the output of the device.

In a series of steps, the early pickup tubes evolved from the *Image Iconoscope*, demonstrated by Zworykin in 1933 and frequently described as the most important invention in the development of television cameras, to the *Image Orthicon, Vidicon*, and finally to the *Plumbicon*® and *Saticon*® pickup tubes. Refined over a period of many years, the Plumbicon and Saticon achieved a level of performance that allowed these two devices to reign as the unchallenged imagers for high performance cameras for a period of approximately 20 years. Of the two devices, the Plumbicon is considered to have somewhat more desirable characteristics overall. Short- and long-term image retention, in particular, tend to be better and, for this reason, the Plumbicon became the most commonly used imager in broadcast cameras. Saticons were easier to manufacture than Plumbicons and as a result were more commonly found in lower cost cameras.

The CCD Solid-State Imager

Ever since the introduction of the first professional CCD camera by RCA in 1983, the imagination of the broadcaster has been sparked by the concept of a new kind of camera, one that would eliminate the intensive care and maintenance required to sustain the performance of a pickup tube camera.

Another three years would pass before the dream would become at least a partial reality. In 1986, a new solid-state camera, the Sony BVP-5 camera was introduced with a docking videotape recorder (VTR) for ENG use. The BVP-5 went on to become the first CCD camera with widespread use in a broadcast environment.

Gone was the notion of the perfect camera; the considerable benefits of the solid-state imager were tempered by a whole new array of terms to describe the imperfections and foibles of these new devices. The terms frame transfer, interline transfer, frame interline transfer, pixels, aliasing, vertical smear, fixed pattern noise, spatial offset and many others entered the technical vocabulary and needed to be understood to decipher the competing claims of this new technology.

It is useful to compare the capability of these devices against the well known characteristics of the Plumbicon and Saticon pickup tubes, as a frame of reference. The advantages of CCD imagers compared to pickup tubes include the following:

- Cameras using solid-state imagers are smaller, lighter and consume less power than cameras of comparable performance using pick up tubes
- CCD imagers do not change characteristics or wear out with use

- CCD cameras are not damaged by strong highlights or high ambient temperatures
- Short- and long-term image burn-in and *comet tailing,* objectionable in pickup tubes, are more easily avoided
- CCD camera resolution and registration accuracy are uniform over the whole screen, compared to significant fall-off in certain areas with pickup tubes
- No centering or registration adjustments are required with CCD cameras
- A whole new concept, the *electronic shutter* to reduce blur in fast motion is possible with the CCD imager
- *Dynamic resolution,* (resolution with the subject or the camera in motion) is significantly better with the CCD imager than with the pickup tube.

The disadvantages of CCD imagers compared to pickup tubes include the following:

- *Aliasing,* caused by the limited number of discrete picture elements in the CCD, can cause objectionable artifacts with the presence of very fine details in the picture
- Diagonal lines have a stepping effect because of the limited number of picture elements in the CCD
- The dark noise of one picture element may differ slightly from the noise level of the next pixel, resulting in an objectionable phenomenon called *fixed pattern noise* when gain boost is used
- Registration of the imagers is fixed in a CCD camera. Longitudinal and lateral chromatic aberrations in the lens optical system are much more difficult to correct in CCD cameras
- The *vertical smear* phenomenon, a line from top to bottom when an excessive highlight is encountered, is only totally eliminated in the frame transfer type CCD imager
- *Dynamic picture distortion* is an artifact that introduces a bowing effect in a vertical structure as the camera is panned quickly.

The Basics of the CCD Imager

For all the wonders promised by this new solid-state era, it must be remembered that the CCD is, first and foremost, an analog device, just like the pickup tube. It, thus, possesses a wide range of analog characteristics, some labeled with the same familiar terms used to describe the characteristics of pickup tubes, others labeled with terminology specific to this new technology.

The CCD is radically different in concept from its photoconductive counterparts. In place of the amorphous layer in the pickup tube that is scanned by an electron beam, the CCD consists of a large number of discrete picture elements (pixels) arranged in an orthogonal, two-dimensional array. Each pixel accumulates an electronic charge directly proportional to the unique light level stimulating it. The CCD array, then, is a large collection of discrete electronic samples of the optical image.

Unlike the smooth, continuous output of the pickup tube as it is scanned by the electron beam, the output signal of the CCD imager is a series of discrete samples, generated as the information contained in the array is read, pixel by pixel. The resulting output signal of the CCD imager is very much like the analog output signal of a pickup tube if it were sampled at a corresponding rate.

Similarly, the CCD behaves as other sampled data systems. For example, the Nyquist sampling theorem mandates that the input to a sampled data system must be bandwidth limited at one half the sampling frequency to avoid aliasing errors in the sampled data. The nature of the aliasing experienced with a solid state imager and the need for an anti-aliasing filter may be analyzed on this basis.

In the solid-state imager, the sampling takes place in the optical domain, and for that reason, the bandwidth limitation prescribed by the Nyquist theorem must also take place in the optical domain. This requires use of an optical filter that will attenuate the high frequency energy impinging on the imager that can cause aliasing, without attenuating the useful in-band frequencies. Difficult trade-offs must be considered in the design of this filter. A more effective optical filter reduces aliasing, but also reduces the ability to reproduce fine detail in the picture.

Figure 5.3-3 shows the theoretical output of a CCD imager that has the form of Sin X/X, the response of the optical prefilter to reduce aliasing and the typical response of a Plumbicon pickup tube for comparison.

The Nyquist theorem now also makes it clear that an increase in the number of pixels in the imager is equivalent to an increase in the sampling frequency in a sampled data system. An increase in the resolution of the overall system is thereby possible.

The concept of sampling also explains the number of horizontal elements in current CCDs, which feature 768 horizontal pixels. A quick calculation shows that this number of 768 samples per active horizontal line corresponds to four samples per color subcarrier cycle, better known as $4f_{sc}$ sampling:

$$4 \times f_{sc} = 4 \times 3.579545 \text{ MHz} = 14.318 \text{ MHz}$$

and

$$14.318 \times 10^{6} \frac{\text{samples}}{\text{sec}} \times 53.6 \times 10^{-6} \frac{\text{sec}}{\text{activeline}} = 768 \frac{\text{samples}}{\text{line}}$$

Increasing the number of pixels in the CCD imager has the potential to increase the resolution and to lower the aliasing phenomenon. However, technical difficulties arise when the sampling frequency is not a multiple of the subcarrier frequency. For this reason, the commonly used 420,000 pixel CCD with 768 horizontal pixels is now being replaced with a higher resolution 520,000 pixel CCD with 960 horizontal pixel and an 18 MHz clock, effectively providing 5 samples per subcarrier cycle.

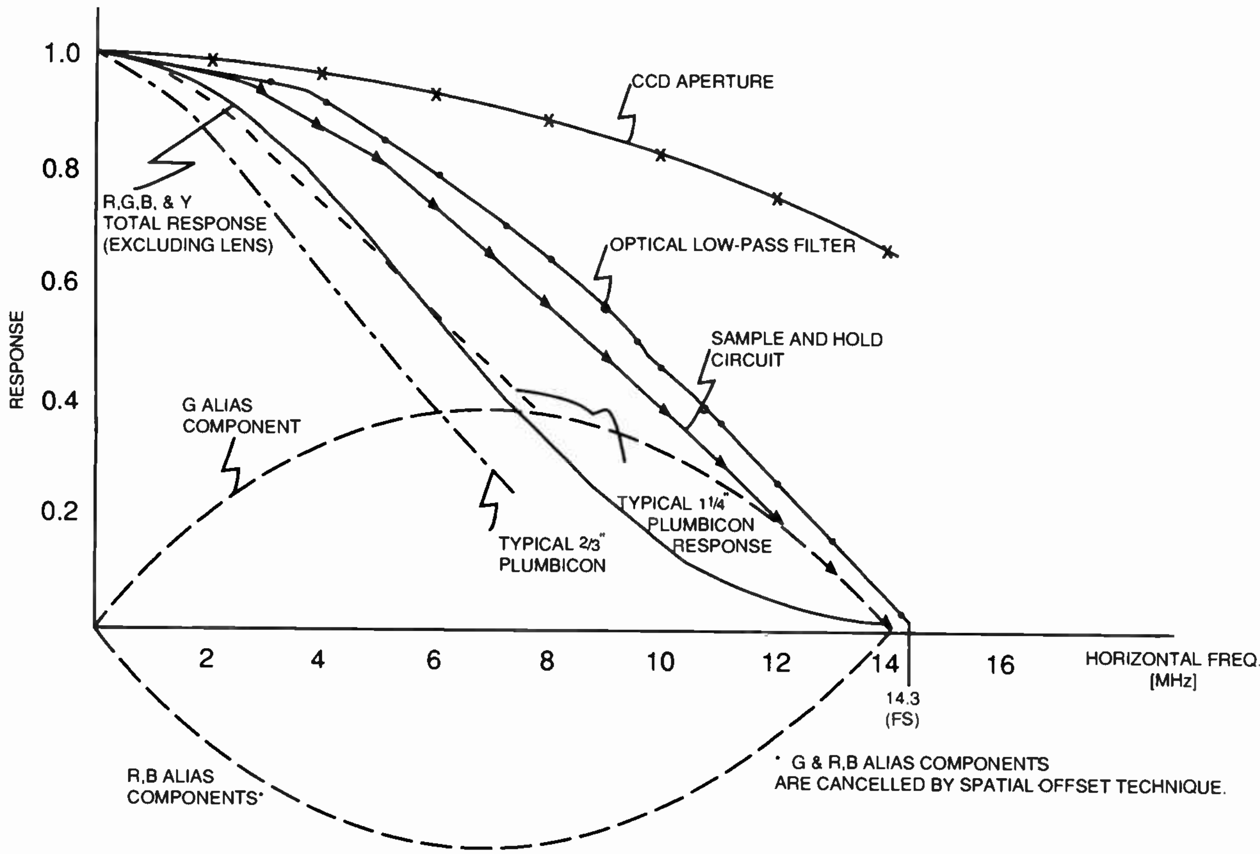

Figure 5.3-3. Typical MTF of a 3-chip CCD camera compared with the typical responses of Plumbicon tubes. Alias components in the G and the R and B signals cancel each other as a result of spatial offset.

The method for transforming the samples from the CCD also affect performance.

Frame Transfer CCD

The *frame transfer CCD* array has two separate sections: an array of imaging cells to capture the image, and an equally large array of cells carefully protected from light to store the image. A means of transferring the charges from the imaging section to the storage sections is also needed.

The basic diagram of such a device is shown in Figure 5.3-4. During the active field period, the cells of the imaging sensor array accumulate charges representative of the optical image focused on it. The information in the sensor array is shifted to the lower storage array at high speed during the next vertical interval. The now empty imager array will be charged with the succeeding image during the next active field period while, at the same time, picture information in the storage section is read to create the camera output signal.

An important characteristic of the *frame transfer* CCD (FT CCD) is its optical efficiency. Each picture element is large and virtually contiguous with the next element to capture virtually all of the incoming light.

The FT CCD also offers an efficient mechanism to transfer the charges from the imaging section to the storage section. The imaging elements function both as imagers and as effective shift registers to transfer the contents of the imager section into the storage section.

The weakness in the basic FT imager is the contamination that can result as the charges are shifted from the imaging array to the storage array. The sensors are

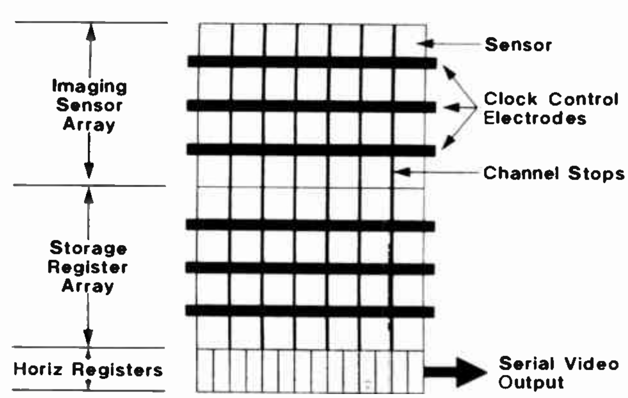

Figure 5.3-4. Frame transfer CCD structure.

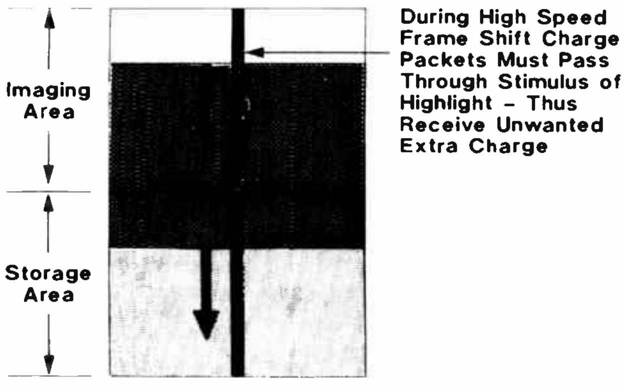

Figure 5.3-5. Mechanism of vertical smear in the frame transfer CCD.

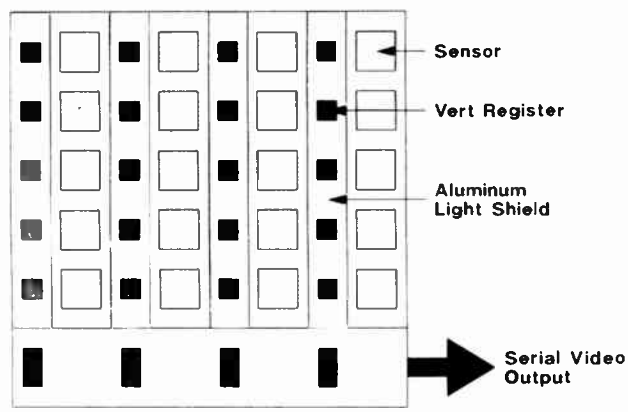

Figure 5.3-7. Structure of the interline CCD.

still being stimulated by the continuously impinging optical image during the short time the content of the imager section is transferred to the storage section. Erroneous signals at levels approximately 50 dB below normal signal level may result, levels clearly not acceptable in a professional camera. The name vertical smear has been applied to describe this phenomenon (see Figure 5.3-5).

A mechanical shutter interposed between the lens and the prism provides a solution to this problem. The shutter is synchronized with the vertical blanking interval to totally block the incoming light during the transfer process and thereby avoid the contamination that can otherwise occur (see Figure 5.3-6). The use of a FT CCD imager with a mechanical shutter form a viable imaging system for a broadcast camera. The FT CCD was introduced to the broadcast industry by RCA in 1983 and continues to be used in current broadcast cameras.

Interline-Transfer (IT) CCD

A completely different approach to the problem of moving the charge packets from the imaging array to the storage array is taken in the *interline transfer* (IT CCD). Storage elements protected from light are located next to each of the imaging elements. A simplified structure of the IT CCD is shown in Figure 5.3-7.

During the active field period, the sensor array again accumulates charges proportional to the image focused on it. However, during the next vertical interval, these charges are quickly transferred to the adjacent light protected storage elements, called the *interline storage register*. During the succeeding active field, the now empty sensor array charges with the next image, while the previous image is read from the interline storage register to become the video output of the camera. Comparing the IT CCD to the FT CCD imager, note that a part of optical sensing area had to be sacrificed in the IT CCD to make room for the interline storage

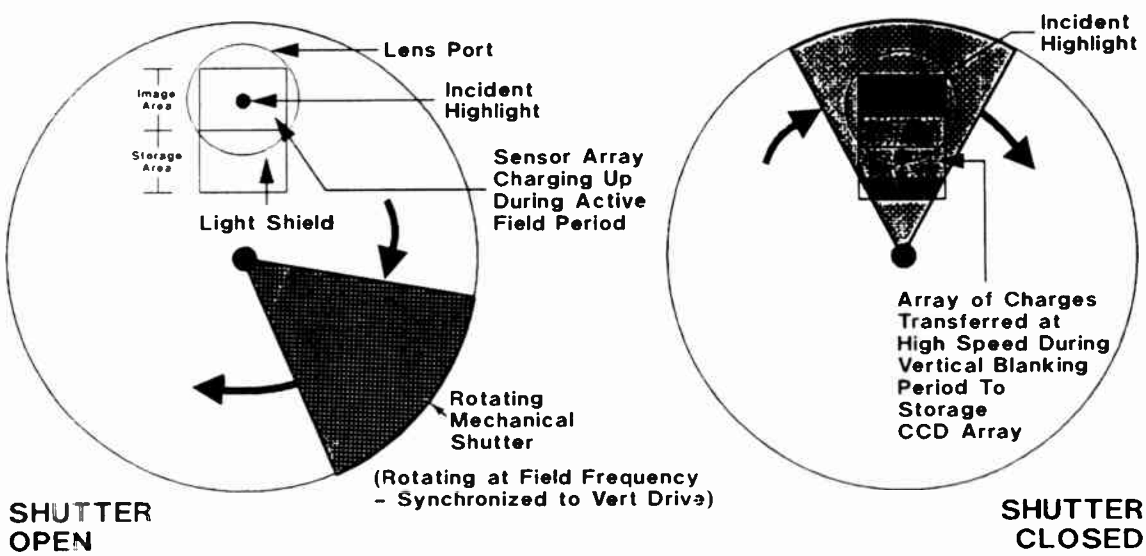

Figure 5.3-6. Removal of vertical smear in the frame-transfer CCD by means of a rotating mechanical shutter.

registers. This reduces sensitivity, which can, however, be recovered by other means. The use of the separate interline storage register now makes it possible to transfer the charge packets out of the sensor array without worrying about incident light directly contaminating these charges; but there is still one more problem to contend with: the intense highlight. When an intense highlight, such as the filament of a car headlight, is focused on the sensing element of the imager, a small amount of this light is reflected within the CCD and will be able to add charges to the immediately adjacent interline storage register. This means the vertical smear phenomenon is still present, albeit at a much lower level than the FT CCD, approximately 105 dB below normal output (see Figure 5.3-8). A vertical streak appears above and below the object or light source. A typical example of where this effect would be observed is when the headlights of an oncoming car are shot with a CCD camera at night. The smear is caused by direct leakage of the incoming light into the vertical storage register (path *A*) or via electrons generated through the photoelectric effect (path *B*) into the vertical storage register. While not perfect, the IT imager achieves the long sought goal of a true solid-state imager with performance suitable for many broadcast applications.

Note that there is currently no industry agreement on a method of measurement for the vertical smear CCD artifact. The method used by some manufacturers uses a square highlight at the center of the screen with an area equal to 10% of the active picture area. Based on the threshold of 2 IRE units as the level below which an artifact is not considered objectionable in the active picture area, a CCD camera with 85 dB smear rejection can be exposed to a highlight about 5-1/2 *f*-stops above 100 IRE units of video before the 2 IRE unit smear level is reached.

Frame Interline Transfer (FIT) CCD Imager

The FIT imager combines the best features of the IT and FT structure and virtually eliminates the vertical smear phenomenon. It is, however, a more complex and hence more expensive semiconductor. Figure 5.3-9 illustrates the basic structure of a FIT type CCD.

In the FIT CCD, the charge packets from the sensor elements are first transferred to the interline storage register, and while still within the vertical interval, these charges are quickly transferred to a frame storage array totally protected from light. Because the charges are present in the interline register only for a very short time, the amount of contamination from an intense highlight is extremely small. In the FIT structure, the vertical smear phenomenon has been suppressed to an insignificant level of 140 dB or more below the main signal level.

Spatial Offsetting

Different from the FT type CCD imager that has almost contiguous sensing elements, the presence of the interline storage register in the IT and FIT type CCDs, reduces the area available to the active sensor element to a fraction of the overall pixel area. A reduced sensing area carries the penalty of reduced sensitivity, but allows the use of *spatial offsetting,* an extremely powerful method to increase the effective luminance resolution of the camera. When spatial offsetting is used, the red and blue CCDs are each bonded to their respective optical ports with extreme precision such that they are physically displaced by one-half pixel distance horizontally from the green CCD (see Figure 5.3-10).

Spatial offsetting does not increase the resolution of the individual red, green and blue channels, but spatial offsetting significantly increases the effective number of samples in the luminance channel and thereby increases the effective resolution of this signal. An example of the benefit derived from using spatial offsetting techniques is as follows:

A camera using three 768 pixel imagers that are co-sited (no spatial offset) achieves a limiting luminance resolution of 560 TV lines. When spatial offsetting is used in a camera using three 768 pixel imagers, a limiting resolution of 700 TV lines is achieved for the luminance (Y) channel. A black triangle on a white

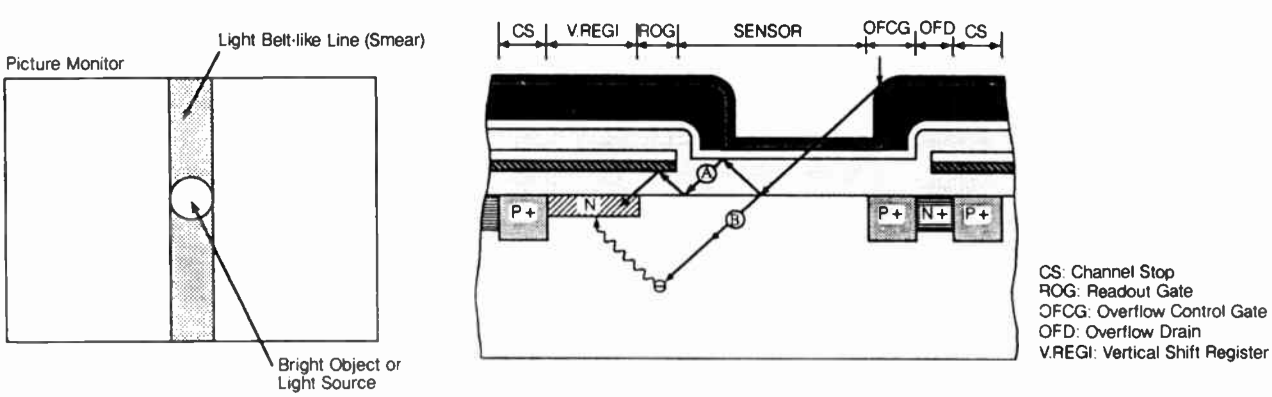

Figure 5.3-8. Vertical smear in an interline transfer CCD. This characteristic of CCD cameras is observed when a very bright object appears in the scene.

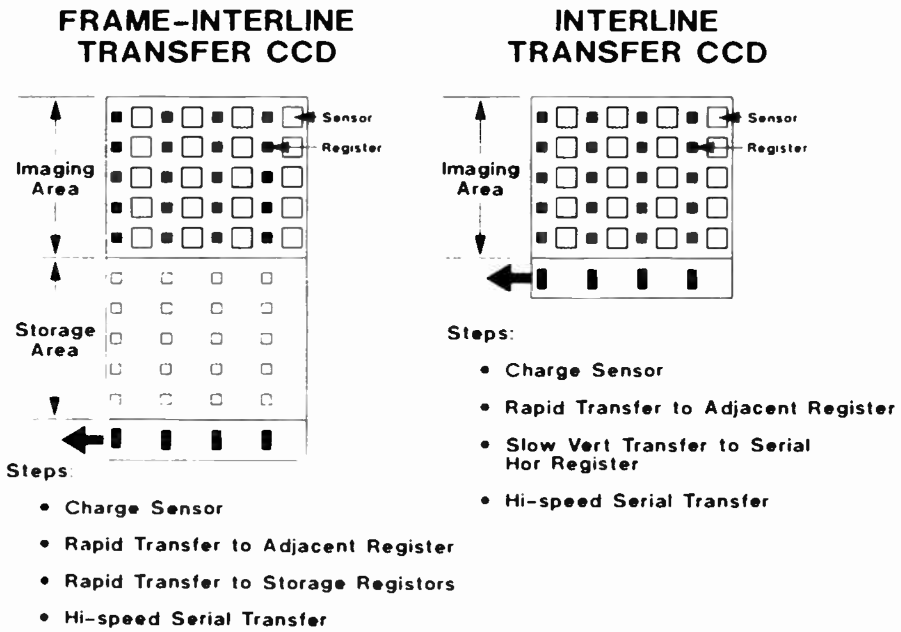

Figure 5.3-9. Steps in the transfer of pixel data for FIT and IT CCDs.

background is used to illustrate the effectiveness of spatial offsetting to enhance the effective resolution of the luminance channel. In Figure 5.3-11, the resulting image projected on the green imager is shown in close-up (a) the corresponding image projected on the red and blue imagers are shown in (b). The quantities of charges corresponding to the input signal stored in the individual sensors of each CCD can be found in the waveforms labeled 1-7. Thus, the output of the green CCD can be visualized as shown in (a) and the outputs of the red and blue CCDs can be visualized as shown in (b). The luminance signal is derived by linear summing of the red, green and blue signals and is shown in illustration (c). The diagonal line in the original scene is reproduced with relatively coarse steps in the individual red, green and blue channels, whereas the diagonal is reproduced with much finer steps in the luminance output, a clear indication of the enhancement in resolution that occurs in the luminance channel when spatial offsetting is used.

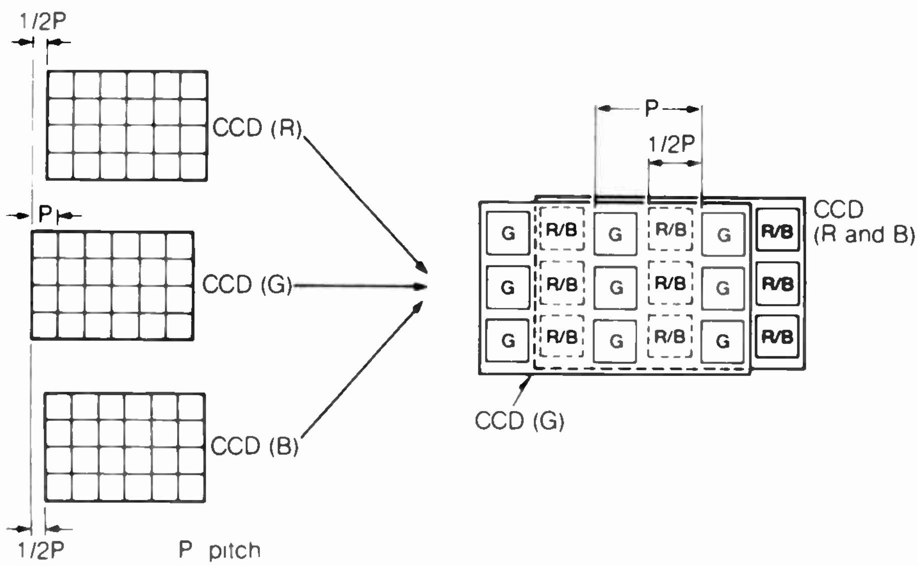

Figure 5.3-10. Spatial offsetting used in CCD cameras.

On Chip Lens Array (OCL)

A relatively new word in the vocabulary of CCD terms, the *on chip lens* (OCL) construction, represents a major advance in CCD technology. Sensitivity of 2/3 in. IT and FIT CCD cameras is increased from $f/5.6$ to a remarkable $f/8.0$ at 2000 lux. This represents a threefold improvement in sensitivity compared to a 2/3 in. Plumbicon imager rated at $f/4.5$ and a fourfold increase in sensitivity compared to a camera equipped with Saticons rated $f/4.0$ at 2000 lux.

In an IT and FIT CCD imager, the area assigned to one pixel must be shared by the active sensor, the adjacent interline storage register and the necessary interconnect wiring. As a result a significant part of the incoming light falls on an area of the pixel that does not contribute to accumulation of charge. With the OCL construction, the sensitivity of IT and FIT CCDs is dramatically increased by carefully positioning an array of microscopic lenses, one lens per pixel, over the imager to gather light over a much larger area and focusing it onto the photosensitive area of the pixel (see Figure 5.3-12). By recovering light previously lost, almost one f-stop improvement in sensitivity is achieved. In addition to an increase in sensitivity, the OCL construction also reduces the amount of oblique rays that cause smear in a CCD and thereby dramatically improves the highlight handling capability of the imager. A slight increase in the diffusion of light is the only negative characteristic of the OCL construction and is far outweighed by the positive benefits.

Camera Signal Processing

The output signal from the camera imagers requires extensive processing to produce the video output of a camera. Different from VTRs, where digital recording was implemented long ago to overcome the noise and nonlinearities of the recording tape, analog signal processing has been implemented in cameras to a level of perfection that is to this day the standard of excellence for a digital implementation. Only progress in semiconductor technology and the recent development of

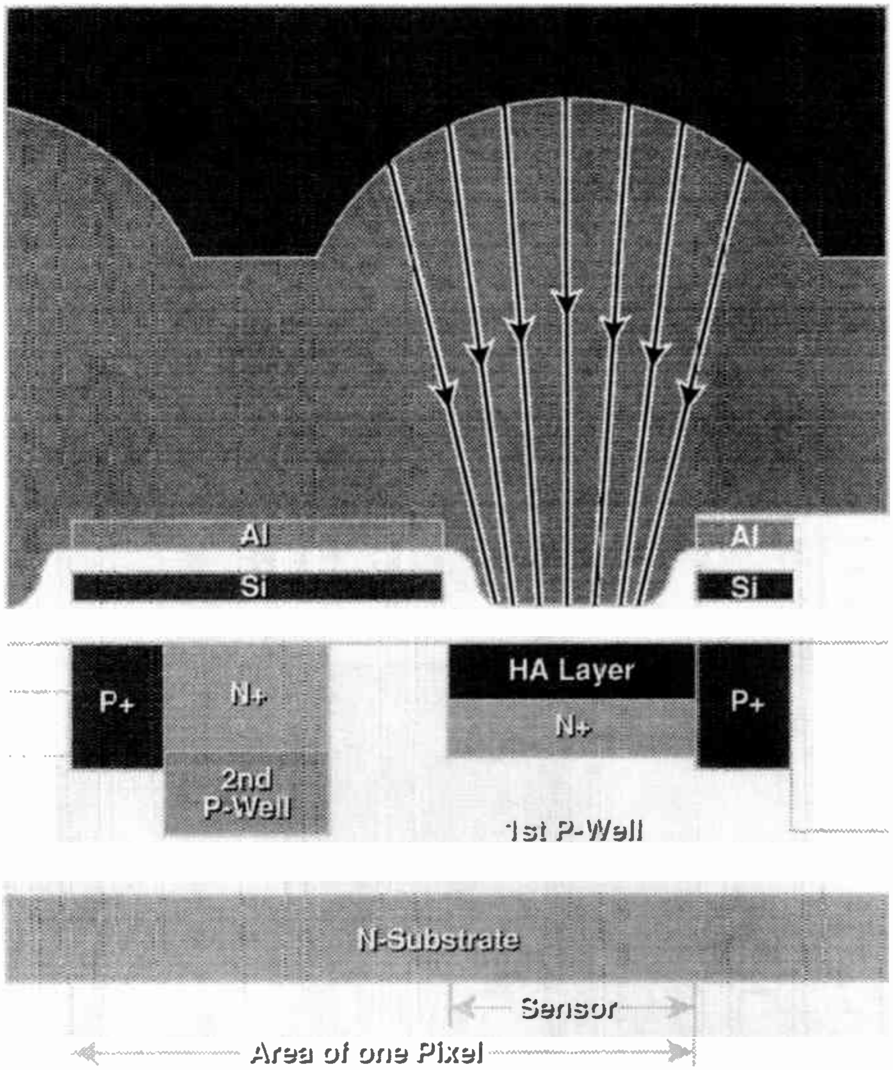

Figure 5.3-12. On chip lens construction. The lens collects light that would otherwise fall on insensitive areas and concentrates it onto the imaging part of the pixel. *(Courtesy of Sony.)*

12 bit analog-to-digital (A/D) converters allows digital signal processing (DSP) cameras to equal and exceed the performance of the best analog signal processing (ASP) cameras. Although it has been difficult to equal and exceed the picture quality of ASP with DSP, DSP provides significant operational benefits. The transition to DSP that started in 1994 will be complete in a few years.

The basic block diagram of an analog signal processing camera is shown in Figure 5.3-13(a). The corresponding block diagram of a digital signal processing camera is shown in Figure 5.3-13(b). Note that the digital processing duplicates the processing steps of the analog processing albeit in the digital domain. This section will elaborate on the analog signal processing followed by some special considerations applicable to a digital signal processing camera.

Analog Signal Processing Camera

The camera processing circuitry has four major functions:

- Adapt to the normal variations in the scene illumination and content
- Correct for unavoidable errors in the lens and optical system
- Correct for the limited dynamic range and other limitations of the video recorder, transmission system and display devices
- Introduce intentional preemphasis, such as gamma correction, to correct for a known nonlinearity in the cathode ray tube.

The camera processing stages implement these specific tasks:

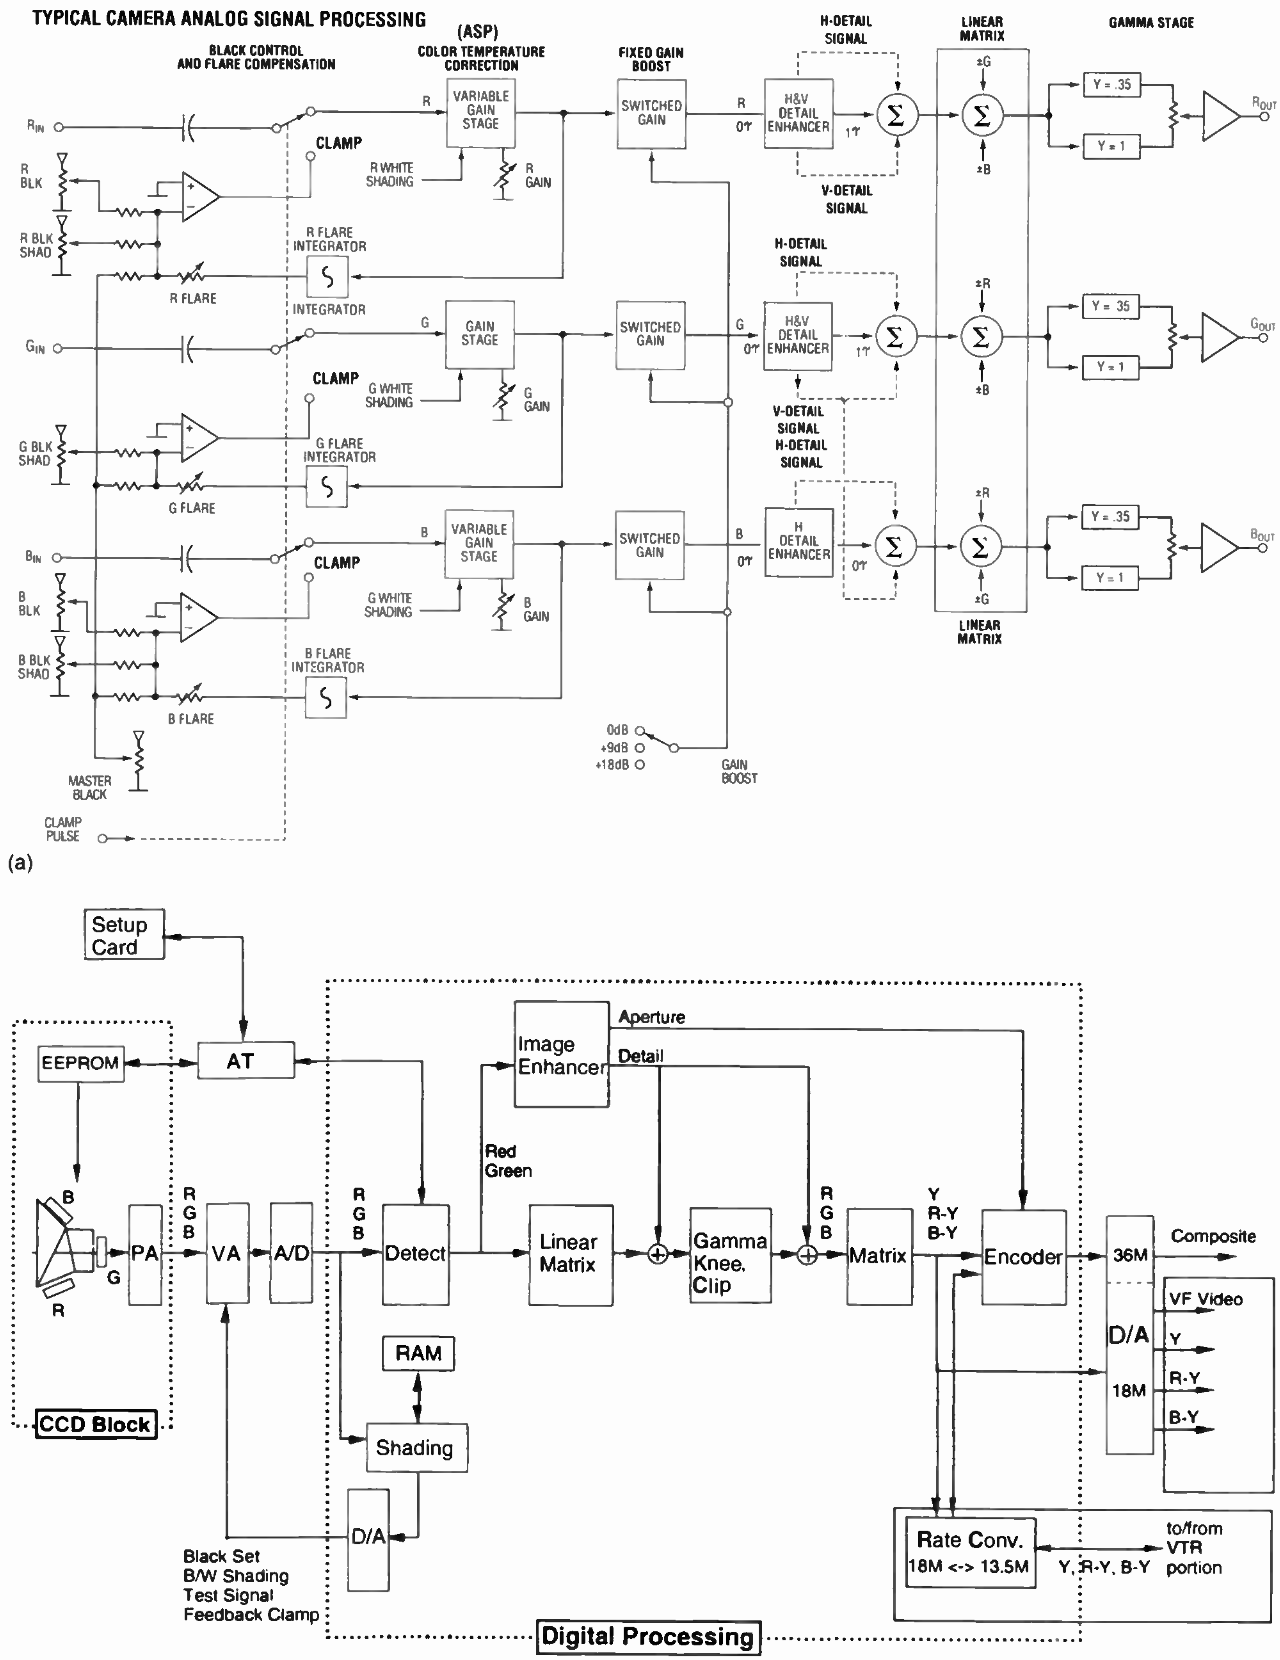

Figure 5.3-13. Camera signal processing system: (a) analog system, (b) digital system.

- **Black level/auto black set circuitry.** The residual signal level from a CCD imager corresponds to the absence of all light or pure black. This *black current*, which is a consequence of the electron mobility (a quantity common to all semiconductor devices), increases with increasing temperature. For this reason, a small section of the CCD imager is masked to protect it from light. The black current reference is determined from masked pixels and used to maintain accurately a constant camera black level with variations in temperature. The overall camera black level can be adjusted using the master black control. The individual red-black level and blue-black level controls can be used for manual black balance or the *auto black* circuit, normally provided in the camera, can be used to set the camera black balance automatically.
- **Shading.** Shading correction circuitry compensates for errors in the lens, color separation optics and imaging devices. Both black and white shading correction controls are normally provided in a professional camera. One example of a shading error is the nonuniform light transmission of a lens. Light transmission of a lens tends to be strongest at the center and falls off towards the edges. White shading (parabolic) can be used to reduce this error significantly.
- **Flare Correction.** The flare correction circuitry provides an approximate correction for the scattering of peripheral rays in the various parts of the optical system. When flare occurs, a small amount of light is scattered into areas of the picture that should be totally devoid of light, resulting in a general rise of the picture black level. The amount of scattered light (rise in black level), tends to increase as the overall amount of light in the scene increases. In the flare correction circuit, an integrator is used to measure the total amount of light in the scene, as an indication of the amount of scattered light. A portion of this integral is then introduced into the camera black level circuits to restore black areas of the picture back to true black (capped level black).
- **Auto White and Color Temperature Correction.** This circuitry is used to correct for the natural color temperature variations of the scene. The red and blue processing channels are equipped with a voltage controlled gain stage that makes it possible to adjust the camera white balance using the red and blue gain controls. An *auto white* circuit, which establishes a white balance automatically, is normally also provided in the camera.
- **Gain Boost.** This circuitry increases the effective sensitivity of the camera, at the expense of creating a noisier picture, by introducing at least three fixed electronic gain steps, typically totaling +9 dB or +18 dB, into the processing circuitry.
- **Linear Matrix.** The primary function of the linear matrix is to correct for deficiencies in the color separation process. The spectral characteristics of the optical system do not provide negative lobes prescribed by the ideal spectral characteristics for the color separation process. A matrix with negative and positive coefficients is used in the signal processing stages to correct for the missing lobes (see Figure 5.3-14).

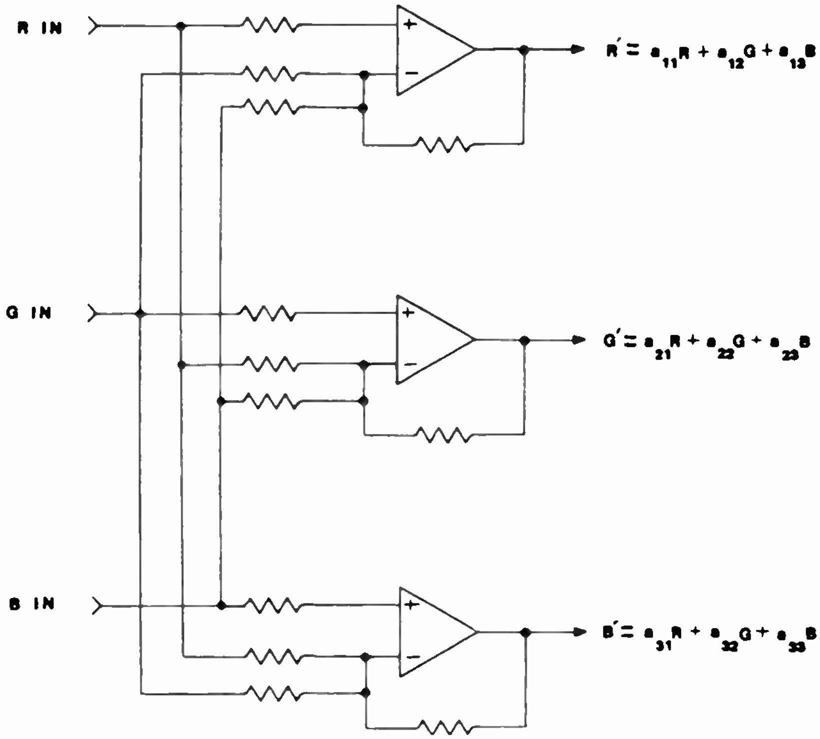

Figure 5.3-14. Basic diagram for the linear matrix circuit.

If an adjustable linear matrix instead of a fixed matrix is provided in the camera, it is possible to match the colorimetry of two dissimilar cameras by judicious adjustment of this matrix.

- **Image Enhancement (Contour Correction or Detail Correction.** This circuitry increases the subjective crispness of the television picture. A detail signal is used to outline transitions in the image, resulting in an apparent increase in the crispness of the picture. A similar outlining of transitions does not occur in film. The closest parallel is in graphic arts, where the apparent crispness of a graphic is increased by outlining the transitions of text or drawings to make them stand out. The dramatic improvement in subjective picture quality achieved by the detail correction circuit is clearly shown by turning the circuit on and off in a working camera. High end cameras generate enhancement for both horizontal and vertical transitions, and this type of image enhancer is called a *two line* enhancer. To provide enhancement for both horizontal and vertical edges, it is necessary to delay the signal from the imager for two full horizontal line periods. Extensive circuitry, including two expensive glass delay lines, is required and hence the designation *two line* enhancer. Less costly cameras frequently provide enhancement for the horizontal transitions only. This type of enhancer is typically called a *one-line enhancer* because it avoids the high cost of the horizontal delay lines.

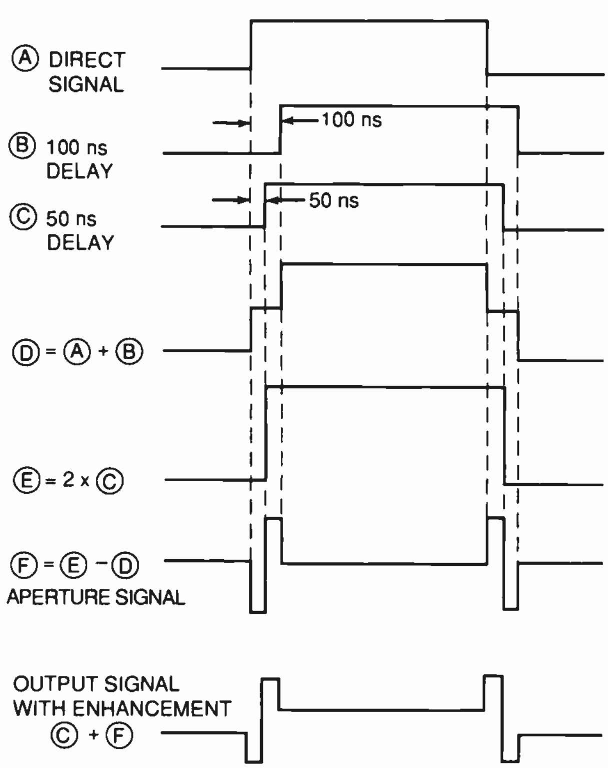

Figure 5.3-15. Generation of the horizontal enhancement signal.

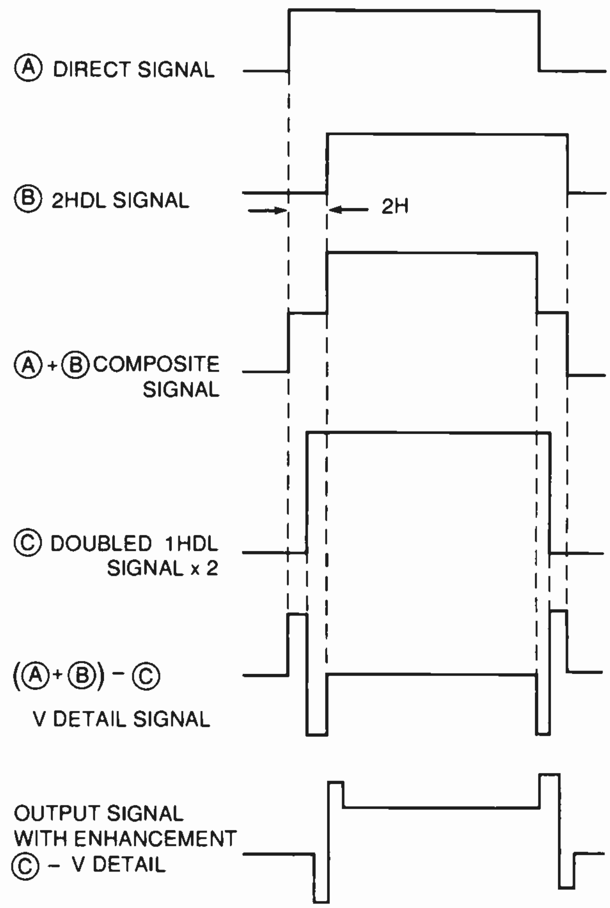

Figure 5.3-16. Generation of the vertical enhancement signal.

The detail circuit generates the detail signal, and it is one of the most complex circuits in the camera (see Figures 5.3-15 and 5.3-16).

- **Gamma Correction.** This circuit precorrects for the nonlinearity of the CRT used in a TV set or monitor by boosting the signals near black and compressing the signal in the white part of the picture, the exact inverse of the nonlinearity of the CRT. The overall result of applying a signal with gamma correction to a CRT is a faithful reproduction of the gray scale in the original scene, as illustrated in Figure 5.3-17.
- **Automatic Knee, Knee and White Clip.** Outdoor scenes routinely encompass contrast ratios as high as 1000:1. One of the most difficult tasks of the video camera is to capture the important content of the scene, while compressing the unimportant details to fit into the limited 40:1 contrast range from camera to the home TV set that is supported by the overall conventional television system.

Significant progress has been made in the ability of the video camera to handle the large dynamic range of outdoor scenes. The hard white clip at 105 IRE implemented in early cameras resulted in a loss of

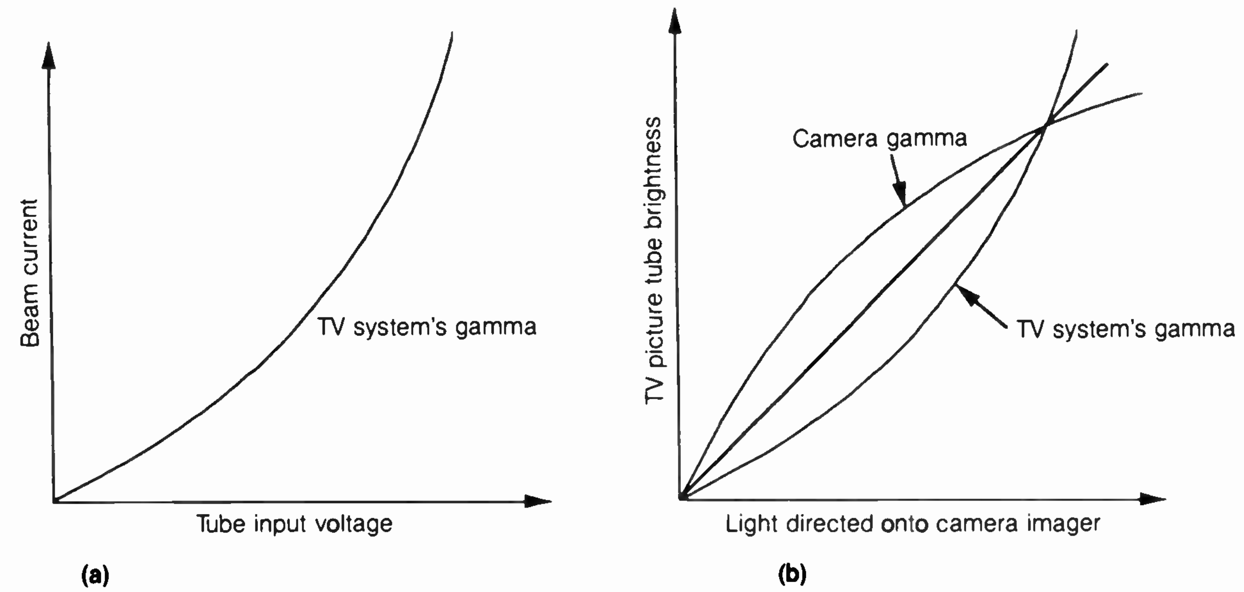

Figure 5.3-17. Gamma correction process: (a) CRT gamma, (b) gamma correction.

significant picture information in the highlight areas. The next advance in handling was the *knee circuit:* a soft bend or knee introduced, while the hard knee was moved up to about 108 IRE. At least one additional *f*-stop of highlight detail was compressed in the range from 96 to 108 IRE. The most recent advance in camera highlight handling is the *automatic knee* circuit, also called *dynamic contrast control* (DCC) or *dynamic knee* (see Figure 5.3-18). With this circuit, the onset of the soft knee is progressively shifted as low as 85 IRE with the existence of strong highlights. The equivalent of up to 600 IRE of picture information in the highlight area is now compressed in the range from 85 to 108 IRE of video (the range of video that can be recorded by a VTR, transmitted and reproduced by a display device).

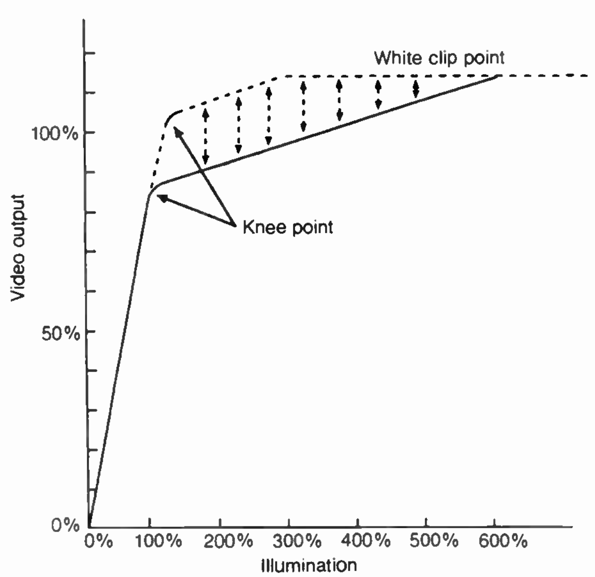

Figure 5.3-18. Auto-knee dynamic contrast control.

Auto Iris and Zebra Circuits. In a production environment, significant time and effort are expended to adjust the lighting and iris opening for the desired artistic effect. Manual adjustment of the iris with the support of a waveform and picture monitor is most commonly used in this application. The *auto iris* circuit in combination with the *zebra* indication are the tools provided by the camera for ENG and field production, where it is not practical to use a waveform monitor and picture monitor. The basic auto iris circuit evaluates the video level, compares this level to a reference (typically called the *auto iris set point*), and then sends a correction signal to the lens to open or close the iris as appropriate to achieve proper exposure. Various designs and degrees of sophistication are used to improve the performance of the auto iris circuit in difficult lighting situations. The method used to evaluate the video level is the key to improved performance. Some of the improvements to the basic auto iris circuit are:

- **Peak/average picture evaluation.** The peak level of the video signal is detected by one circuit, the average video level is detected by a second circuit, and a mix of the two circuits (peak/average adjustment) is then used for improved iris control.
- **Weighting and masking.** Commonly used to improve the performance of an auto iris circuit. Because most of the important action takes place at the central part of the picture, correct exposure at the center is most important. Without weighting or masking, a bright light source at the periphery of the picture, such as the sky, may cause the iris to close and provide improper exposure at the center. When

bright highlights at the edges of the picture are excluded from the picture evaluation by masking, or the video level at the center of the picture is weighted more heavily than video at the periphery, performance of the auto iris circuit with difficult scene content is significantly improved.

Despite the various refinements in picture evaluation, the resulting auto iris setting is not satisfactory with some difficult scenes. The zebra circuit can then be of significant help in finding the proper manual iris setting by superimposing diagonal stripes on bright areas in the viewfinder image. There are two common operating modes for the camera zebra circuit. In one mode, it is adjusted to identify in the viewfinder all video at the 60 to 70 IRE level (proper exposure for facial features). The other operating mode of the zebra circuit is to identify all video that is at 100 IRE and above (all video that is going into the white clippers). In the latter mode, the iris is adjusted until the brightest part of the scene that still carries useful information is just below the threshold of the characteristic diagonal zebra stripes.

- **Encoder.** For some applications of a video camera, the *component* video signals in the form of R/G/B or Y/R − Y/B − Y are used directly. For other applications, it is desirable to encode the red, green and blue signals generated by the camera into a *composite* color signal. In the United States the camera signals are normally encoded to the NTSC standard.

The encoder used in a high performance video camera differs from other commonly used encoders in having exceptionally wideband luminance response, reaching as high as 10 MHz. Figure 5.3-19 shows a simplified block diagram of an encoder.

The RGB output of the camera processing system is applied to the luminance or Y matrix and the I and Q color matrixes. The equations of these three matrixes are:

$$Y = 0.30R + 0.59G + 0.11B$$

$$I = 0.60R - 0.28G - 0.32B$$

$$Q = 0.21R - 0.52G + 0.31B$$

The I and Q signals are processed by 1.2 Mhz and 0.6 MHz lowpass filters respectively. The Q filter introduces a delay of about 750 ns, which introduces delay into both signals. The I signal filtering is less severe and

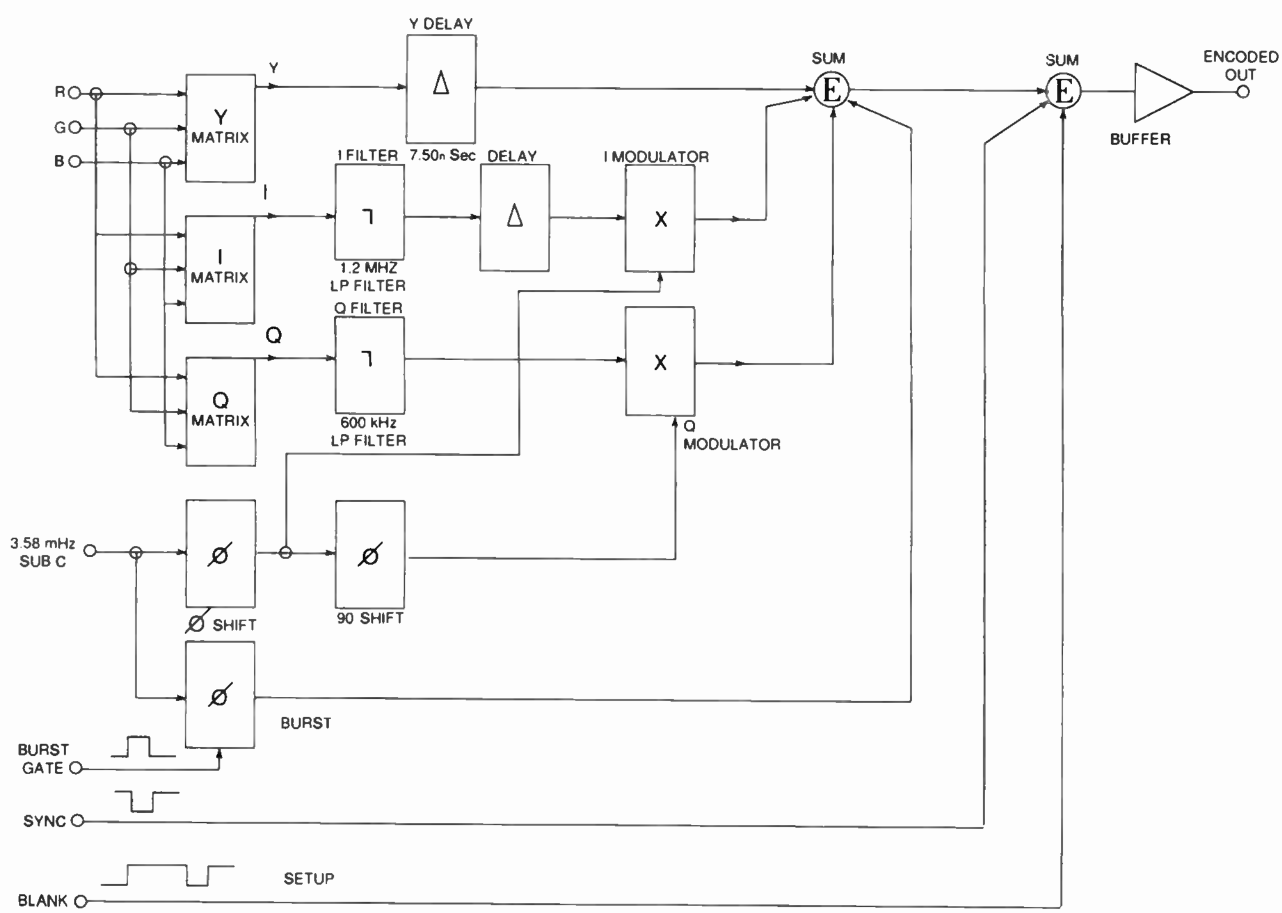

Figure 5.3-19. Simplified block diagram of an NTSC encoder.

has correspondingly less delay. An additional delay or a special filter design is used to equalize the delay of the I and Q channels. The bandwidth-limited I and Q signals are then applied to the I and Q modulators, where the I and Q information modulates two 3.58 MHz subcarriers in quadrature (phase shifted by 90°). The output of the Y matrix is delayed by about 750 ns to match the inherent delay in the I and Q chroma channels. The output of the I and Q modulators, the 3.58 MHz burst, sync and setup are added to the Y signal to create the composite NTSC output.

Normally, a color bar generator is included in the encoder to aid in system setup. The typical output waveform of an NTSC encoder is shown in Figure 5.3-20 (for a color bar signal). The phase relationship of the I and Q axis vs. burst is shown in Figure 5.3-21.

- **Sync/Timing Generator.** This is the master timing system that provides the various timing waveforms required by the camera, in accordance with the television standard used. In the United States broadcast cameras are normally designed so that the output signal meets the requirements of the Electronic Industries Association recommended standard RS-170M.

The timing waveforms required by the camera circuits are normally derived by digital countdown from a crystal oscillator operating at four times subcarrier frequency ($4f_{sc}$) or 14.3 MHz. A temperature-compensated crystal oscillator is used to maintain the strict frequency requirements of the RS-170M Standard when the camera is used in a self contained mode. For multicamera operation, it is necessary to synchronize the cameras. For this purpose, the camera sync/timing generator is provided with genlock capability. The sync/timing generator has the ability to phase lock to an external composite video signal applied to the camera genlock input.

- **Power Supply.** The power supply voltages required to operate a solid-state camera are quite low, and

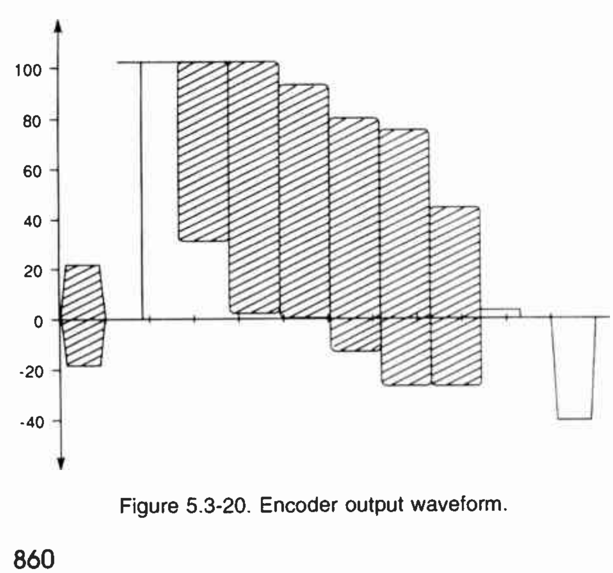

Figure 5.3-20. Encoder output waveform.

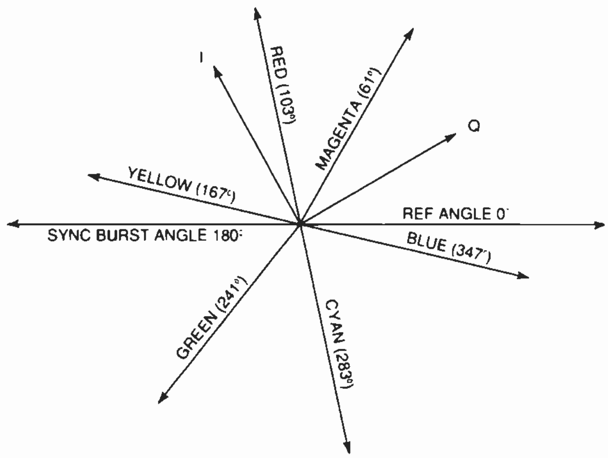

Figure 5.3-21. Subcarrier phase relationship in the NTSC encoder.

only normal precautions need to be observed when working on the inside of a CCD camera. The accelerating voltages used in the camera viewfinder are the exception, of course. Tube cameras, on the other hand, require substantial accelerating voltages, and appropriate precautions should be observed when working on any viewfinder or a tube type camera.

Virtually all modern cameras use a switching type regulator that converts the incoming voltage to the various potentials required by the camera. The universally accepted power supply range for portable cameras is 10.8 to 17.4 Vdc. By the nature of a switching type regulator, the camera presents a constant power load to a battery or an external power source.

Digital Signal Processing Camera

Digital video processing was first introduced into videotape recording, where the benefits were most dramatic and cost effective. In most portable applications digital processing was either too expensive for the benefits it provided. As a result, a mix of digital and analog equipment represented the most cost effective system configuration. With time, the performance of digital circuits has improved dramatically, while costs have been reduced. It is increasingly cost effective to use digital circuitry in virtually all production equipment, including cameras.

The standard imager for cameras is currently the CCD, a thoroughly analog device despite the fact that the information from the imager is read out in discrete packets. The dynamic range of a CCD (or a pickup tube) is quite large. It is not uncommon for the early processing stages of an analog camera to faithfully process signals as high as 600% video. Digital processing with an inordinate high number of bits per sample (greater than 12 bit A/D) is required to handle this large dynamic range while retaining the ability to resolve fine shades of luminance difference. In addition, although the camera is required to process highlights up to 600% of video, it is only necessary to compress these large highlights to a more reasonable range. An analog pre-knee circuit has been found to execute this function quite efficiently so that it is possible to limit the digital signal processing circuitry to a dynamic range of 226%. Until the current analog imagers are displaced by true digital imagers, studio and portable cameras will remain hybrid analog/digital devices. Figure 5.3-22 illustrates the analog pre-knee with 10 bit linear A/D bit assignment.

The benefits of digital signal processing for video cameras include the following:

- **High stability and reliability.** However careful its design, the circuitry in analog cameras is inevitably subject to drifting that requires manual correction. Subsequent readjustments are then subject to operator interpretation, and so the actual setup of a camera at any one time is difficult to define. With digital processing, parameters are held in a digital memory and stay constant for long periods of time (potentiometers, the least reliable component of cameras, are reduced from about 150 for analog processing to less than 6 for cameras with digital processing). As a result, the need for operator adjustment is dramatically reduced. A further advantage of digital processing is that it is much easier to implement digital circuits in ICs and LSIs than analog circuits, allowing the size and weight of cameras to be reduced.
- **Precise alignment.** The accuracy of a camera setup can be defined with great precision by digital processing. Moreover, variations between cameras, which are difficult to avoid with analog processing cameras, can be reduced to a minimum with digital processing by simply choosing the same setup parameters.
- **Flexible signal processing and parameter setting.** A significant advantage of digital signal processing is that it can provide very flexible operation. Many camera parameters can be controlled and each setting can be controlled over a wide range of values. It has been well known that different camera adjustments can dramatically improve the ability of the device to capture difficult scene material. With analog cameras, such custom adjustment is difficult and time consuming to implement as well as to restore. With digital processing cameras, control adjustments can be manipulated quickly and easily, stored and then recalled with great accuracy. Convenient menus are provided to manipulate the digital parameters and some cameras are now equipped with miniature memory cards that allow preset camera adjustments to be executed almost instantaneously by the simple expedient of reading the setup card.
- **Improved reliability.** One of the most important concerns of the broadcaster is the reliability of equipment. This is considerably improved with digital processing. In digital cameras, all the processing parameters can be completely and precisely defined at the design stage and almost all the potentiometers of analog cameras are replaced by semiconductor memories. Consequently, the digital cameras show precise and stable performance regardless of environmental conditions such as temperature, humidity, shock and vibration.

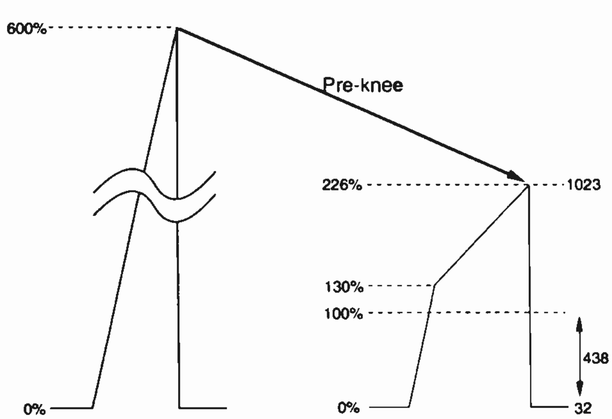

Figure 5.3-22. Pre-knee and 10 bit linear A/D bit assignment.

Interlaced and Progressive Scan Cameras

Starting in the mid 1970s, solid-state CCD imagers began to take the place of pickup tubes in video cameras. And more recently, advances in high capacity, low cost memory storage, have made it possible for cameras generate various types of output signals to suit different applications.

The most promising of these new camera output capabilities is *progressive scan.* Progressive scan images capture amazing clarity, without the motion double exposure, or flicker that is seen in still-frame images derived from conventional cameras that use interlaced scanning. The clear, flicker-free image quality provided by progressive scan cameras offers dramatic benefits for anyone who wants to view a still frame of a moving scene, use the captured video as the base line signal for extensive manipulation by a computer, analyze details of the image or print out a hard copy of the video frame.

To understand the creation of interlaced scanning it is best to look in time at the operation of the pickup tube and the cathode ray picture tube.

In the video camera, an electron beam is used to scan the visual image. In the television monitor, the picture tube uses an electron beam to scan the phosphor layer deposited on the inside of the front surface, thereby creating a faithful reproduction of the image captured by the camera.

To create the television image, the electron beam starts at the upper left-hand comer of the pickup tube scanning pattern, or raster, and moves from left to right. When the scan reaches the right-hand edge of the picture, the beam retraces quickly back to the left edge and drops down to the next scan line in the raster. This process is repeated until the complete picture has been scanned.

The picture information that results from this scanning process is transmitted to the TV monitor, where an electron beam in the picture tube is synchronized to trace out the same scan pattern that was used to scan the original image in the pickup tube. When the electron beam hits the phosphors on the front of the picture tube, a light output proportional to the intensity of the beam is generated.

Engineers quickly discovered that, if the pickup tube and the CRT are scanned progressively, line by line, the light output of the phosphors at the top of the picture tube had already started to fade by the time the scanning beam reached the phosphors on the bottom of the tube. As a result, progressive scanning can exhibit objectionable flicker unless the number of complete pictures scanned each second (*refresh rate*) is quite high.

Increasing the refresh rate overcomes the flicker problem and improves the ability of the system to portray motion more accurately, but a higher number of complete scans, or frames, requires a higher transmission bandwidth.

To reduce flicker and reproduce smooth motion, and at the same time minimize the amount of bandwidth required, the creators of television developed a strategy called *interlaced scanning*. In the NTSC interlaced scanning system, the TV camera takes 60 independent pictures (or samples) of the scene per second—but only half of the full 525 scan lines are transmitted for each picture that is captured. This nominal 262.5 line sample is called a *field*, and contains half of the original picture information. The two successive fields are respectively called the *odd field* and the *even field*. When combined in the CRT, the two fields create one complete picture or *frame*.

Interlaced scanning eliminates flicker and reduces the amount of transmission bandwidth required to achieve smooth motion compared to progressive scanning, but the ability to extract a clear, flicker-free still-frame from the video signal is significantly impaired compared to a video system that uses progressive scanning at the same frame rate.

The new digital transmission system adopted by the FCC allows both interlaced and progressively scanned images to be transmitted.

The High-Definition Camera

The performance of the current NTSC television system using 525 scan lines is limited. Although the new digital transmission standard that conveys three separate color signals will improve the picture quality to the home, a dramatic improvement in television quality is observed when the number of scan lines is increased to a thousand scan lines and more. Although the technical requirements to produce such a high definition camera are quite severe, the actual design of the HD camera is essentially identical to the standard-definition camera described previously.

BASIC CAMERA PERFORMANCE VERIFICATION

With tube type cameras, it was almost mandatory to fine tune the camera before a major shoot to achieve optimum performance. The intrinsic stability of the CCD imager and the stability of the circuitry used in current CCD cameras now make it possible to operate the camera for several months without internal readjustment. Physical damage to the camera or lens, in use or transport, is probably the most frequent cause for a loss of performance in a current CCD camera. With careful handling, the probability of malfunction is very small. It is nevertheless prudent to schedule a quick checkout of the camera before the start of a major shoot, when the high cost of talent and other aspects of the production are considered.

The following items are appropriate for inclusion in such a quick checkout procedure. If the test results show a significant deviation from the manufacturers specifications or from the data previously obtained for the same test, a more thorough examination of the camera, as prescribed in the camera service manual, is then indicated. Several basic tests with expected data are also described. Adjustments appropriate to a CCD cameras are also described.

Visual Inspection And Mechanical Check

Visually inspect the camera and lens for any evidence of physical damage as a clue to the possibility of more serious internal damage. Carefully operate the lens adjustments—manual and servo zoom, focus and manual iris. If there is evidence of binding or a rough spot in any of these adjustments, physical damage that may affect the optical performance of the lens must be suspected. Inspect the front and rear lens elements, clean if necessary using pure alcohol and soft, lint-free wipes. Fingerprints in particular should be removed as quickly as possible to avoid harm to the optical coating of the lens elements. Note that the lens manufacturers generally discourage the use of silicon-impregnated wipes for cleaning high quality optics.

Confirmation Of The Camera Encoder

A properly adjusted encoder is particularly useful since it provides a convenient window to look inside the camera and confirm proper operation of the remaining circuitry. Encoder setup is particularly easy to confirm because the color bar generator, normally provided in a professional camera, provides a convenient self test of the encoder. To confirm proper operation of the camera encoder:

- Apply the camera (encoder) output signal to a waveform monitor (WFM), vectorscope and picture monitor (a high resolution black and white monitor with 800 television lines (TVL) or higher resolution is recommended)
- Terminate the WFM, vectorscope and picture monitor using a discrete 75 Ω termination. The preferred tolerance for this termination is ±0.1% and no greater than ±1%. Internal terminations should not be used unless they have been tested and, if necessary replaced with terminations within the recommended tolerance
- Select the color bar mode on the camera. Confirm on the vectorscope that the burst and I and Q vectors

are of the correct phase and amplitude. Confirm that all of the color bar vectors fall within the tolerance boxes on the vector scope.

If all of the above vectors are within tolerance, correct operation and adjustment of the encoder is confirmed.

Confirmation of Auto Black

To confirm proper operation:

- Activate the auto black circuitry of the camera
- Confirm that the lens caps during this adjustment. Confirm the character display in the viewfinder indicates the auto black adjustment has been successfully executed
- Select the 0 dB, +9 dB, and +18 dB gain settings in sequence and confirm the black level adjustment is correct for all three gain settings. This is most easily confirmed with the vectorscope; the output signal should be a dot at the center of the display with no shift in position as gain is switched. The only change should be an increase in noise at the higher gain settings.

Lens Back-Focus

This adjustment trims the lens to the specific optical dimensions of the camera. Whenever a new lens is put on a camera, it is necessary to make this adjustment. Some lenses use a screwdriver lock, while others use a knurled knob to lock the lens back-focus adjustment in place. Accidental misadjustment in use has been known to occur, and it is therefore recommended to confirm this adjustment. To adjust the lens back-focus:

- Locate a Siemens Star Chart (Figure 5.3-23) at least 10 ft from the camera. Place the chart in a location with low lighting such that the lens iris is wide open
- Using the high resolution picture monitor: 1) adjust the lens zoom for full close-up and adjust for best focus using the focus ring on the front of the lens, 2) and adjust the zoom for maximum wide angle position and adjust for optimum focus using the lens back-focus adjustment. Repeat both steps several times
- Securely lock the lens back-focus adjustment in place
- Confirm the lens stays in focus over the full zoom range.

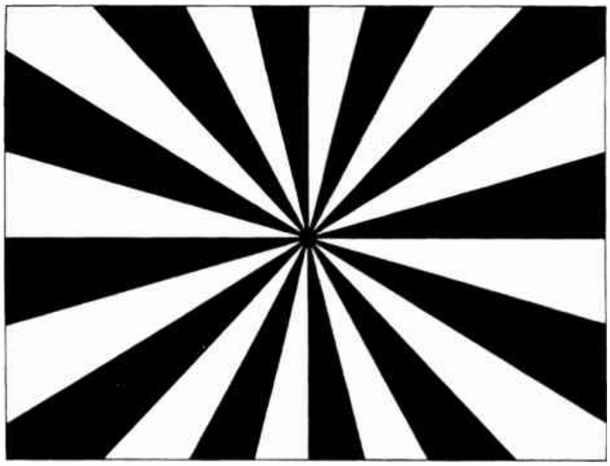

Figure 5.3-23. Siemans star chart.

Black Shading

To confirm black shading:

- Cap the lens. Raise the master black level to about 10–12 IRE to avoid any clipping
- Using the waveform monitor in the vertical display mode, then in the horizontal display mode, if the black level is a thin horizontal line, there is no black shading in any of the three color components
- Restore the black level to its proper position.

Detail Circuit

Using the 11-step gray scale chart, confirm the amplitude of the detail signal as required for the application. A stronger detail signal is typically required for a lower performance recorder and less for a higher performance recorder.

Optional Tests

If the camera system is capable of resolving fine detail close to the limiting resolution specified by the manufacturer, there is a strong assurance that the lens, camera optics and overall camera signal processing are working correctly.

Use a suitable chart with resolution wedges or a chart with a multiburst pattern and confirm that the overall resolution of the camera system is close to the manufacturers specification (see Figures 5.3-24 and 5.3-25).

White Shading

To confirm white shading:

- Set up a uniformly lit white test chart
- Using the waveform monitor, open the lens to obtain about 70 IRE units of video (confirm the iris is in the range of $f/4.0$ to $f/5.6$, adjust the lighting if necessary), confirm there is a minimum of vertical, then horizontal, shading
- Adjust as necessary using the camera horizontal and vertical white shading controls.

Flare

The camera flare correction circuitry provides an approximate correction for flare or scattering of peripheral rays in the various parts of the optical system. To confirm the adjustment of the flare correction circuit:

- Frame an 11-step gray scale chart that includes a very low reflectance strip of black velvet added to the chart
- Adjust the iris from fully closed until the white chip is at 100 IRE units of video. The flare compensation circuitry is adjusted correctly if there is almost no

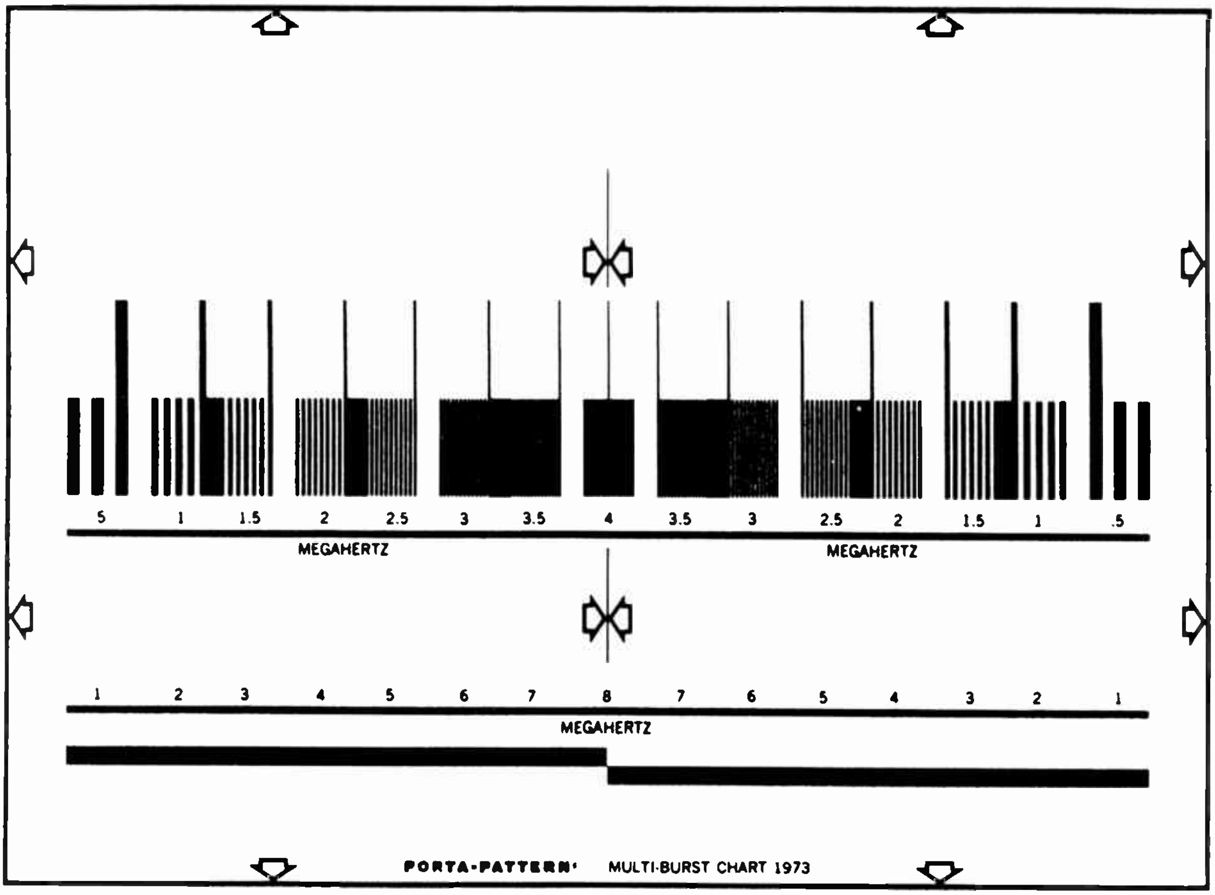

Figure 5.3-24. Multiburst chart (10 MHz).

rise in the black level of the velvet strip as the white level is increased to 100 IRE units and only a small rise in the black level, with no change in hue, when the iris is opened one more f-stop beyond the 100 IRE units point

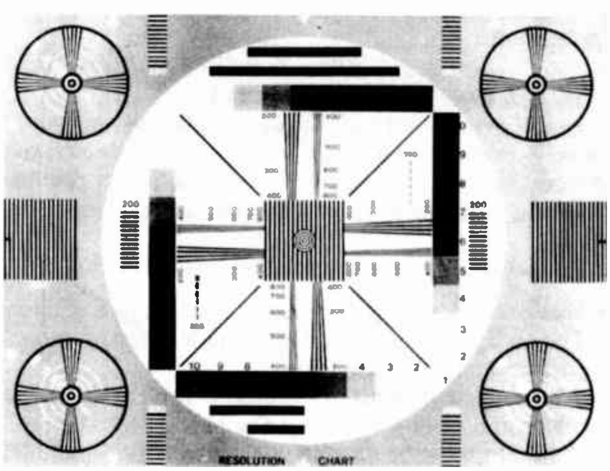

Figure 5.3-25. Resolution wedge chart.

- Adjust the R, G and B flare controls as defined in the camera service manual if the flare correction is not adjusted correctly.

Linear Matrix

When it is necessary to use two dissimilar cameras models in a multicamera shoot, and either of the two models provides an adjustable linear matrix, it is possible to use the variable matrix to obtain a better colorimetry match between cameras. Specific matrix parameters and adjustments (if any) will be found in the camera service manuals.

CAMERA SELECTION

This section is intended to give some practical guidelines as to the types of camera to consider for a given application.

Studio/Remote Applications

Triax cameras have now almost completely replaced cameras using multiconductor cable for studio and field acquisition. The small size, ruggedness and low cost of triax cable, plus the ease of repair, provide a strong advantage over cameras using multiconductor cable. As analog cameras are being replaced by full digital cameras, the bandwidth provided by triax cable is no longer adequate and triax cable will be slowly replaced by camera systems using fiber optic cables.

A *studio camera* system is the system of choice when:

- There can be no compromise in picture quality. The ability to use large studio lenses with superior optical performance is a key factor
- A teleprompter is required for coaching the talent and both power and the signals for the teleprompter must be carried in the camera triax cable
- Extended zoom capability (well above the 18× zoom ratio normally provided and the 32× zoom ratio provided by the largest portable lenses) is required, which can only be achieved with studio lenses
- The look and feel of a large camera head is desired

A *portable camera* is indicated when:

- Mobility and handheld operation is important
- The *reach* (zoom ratio and maximum focal length) of available ENG style lenses is adequate
- The lighter weight of the portable camera head is critical, such as with robotic pedestals
- Teleprompter and multiple channels of intercom are not mandatory, or use of additional cables for teleprompter use is not objectionable.

Electronic Field Production (EFP)

Field production has seen a gradual change from the use of a self-contained camera and a separate VTR to the use of a portable camera that is capable of accepting a dockable VTR creating a two-piece camcorder. With the camcorder, creative freedom is enhanced significantly by the ability to shoot on a tripod or shoulder, as desired. The dockable camera can also be configured with a suitable adapter and operated with a camera control unit (CCU) for convenient remote operation of the camera system.

The one-piece camcorder, that integrates the camera and recorder in one unit, is now becoming the camcorder of choice for field production use due to its outstanding ease of use and high performance. Frequently used in conjunction with a handheld remote control unit, the one-piece camcorder now combines convenience with artistic control.

Electronic News Gathering (ENG)

For the ENG camera operator, weight, size and ease of use are the critical issues, particularly with the trend to reduce ENG crew size. The one-piece camcorder optimizes size, weight and balance to provide the most ergonomic camera for ENG use. For these reasons, the one-piece camcorder is now the virtual standard camera for ENG use.

Camera Specifications

A TV camera performs the complex task of creating an electronic image of a real scene, ranging from scenes with extreme highlights—scenes with large dynamic range that must be compressed to fit within the capability of the TV system—to scenes with marginal illumination. Defining the performance of a camera in a complete but concise set of specifications may be impossible, but camera manufacturers need to provide more complete specifications than are currently provided. It is not unusual to find a low cost camera with virtually the same published specifications as a camera costing significantly more. Actual day-to-day performance, on the other hand, will probably show the more expensive camera to be far superior in handling difficult lighting situations. For this reason the published camera specifications are no more than a basic guide for which cameras to consider for actual evaluation.

It is no longer necessary to limit the choice of camera to the one with the best picture quality since virtually all current professional CCD cameras make high quality images. Such factors as ease of use, cost and operational features can now frequently be the deciding factors in choosing one camera over another for a specific application.

In an actual camera evaluation, it is typically not necessary to spend a great deal of effort to confirm the specifications provided by the manufacturer. Instead it is recommended to expose the camera or cameras considered for purchase to the most difficult shooting situations that they are likely to be exposed to in the intended application(s), and then make the final choice based on the overall advantages of one camera over the others.

APPENDIX A: COLOR SEPARATION SYSTEMS

A color camera contains an optical system that separates the incoming light into its three component colors. Currently, there are three types of color cameras in descending order of performance:

- The *three imager* design with prism type color separation
- The *two imager* design with a beam splitter and color stripe color separation for the chrominance imager
- The *single imager* design using alternate optical filters over the individual pixels of the imager to achieve color separation.

Dichroic mirrors have also been used for color separation in some portable and studio cameras.[2] The dichroic mirror system is not used in current cameras because there is significant loss of light as compared with the prism system.

The prism type color separation system has become the dominant system for use in broadcast cameras and will be described in more detail.

Color Separation System for Three Imager Color Cameras

In front of the prism, several color correction and neutral density filters are mounted on a filter wheel to

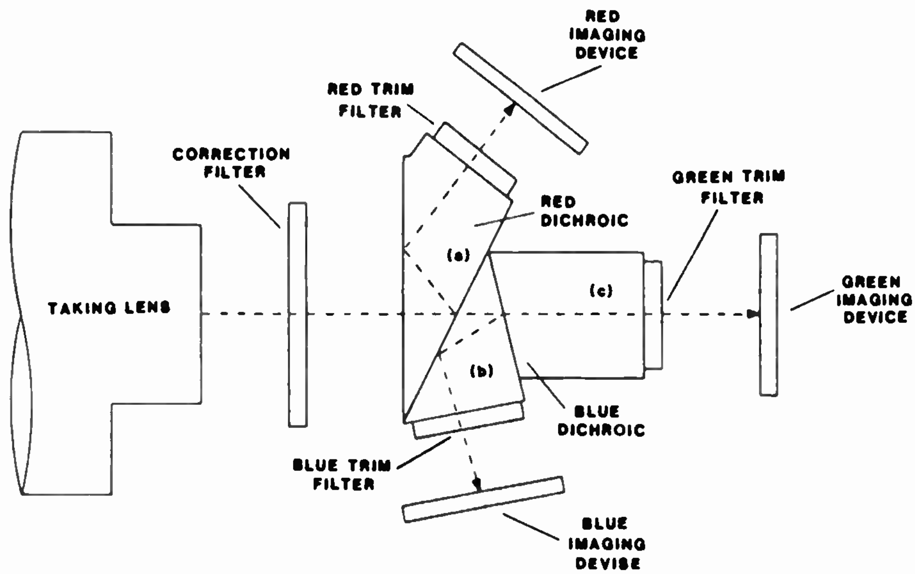

Figure 5.3-A-1. The three imager prism-type color separation system.

provide large-scale compensation levels for the color temperature and intensity of the incoming light. The infrared filter, quarter wavelength filter and anti-aliasing filter described earlier are also located here. The beam-splitting prism system makes use of selective reflection at dichroic layer surfaces to separate the incoming light into the red, green and blue color components. Total reflection, at untreated surfaces, is also used within the prism system (see Figure 5.3-A-1.

A dichroic layer is formed by vacuum evaporation of 10 to 20 layers with alternating high and low refractive indices. Proper choice of the material and thicknesses can give the dichroic layer the property of reflecting only one color and passing other colors.

The spectral characteristics of the prism are the determining factor in the quality of color reproduction achieved by the camera. The trimming filters on the output of the prism are used to shape the rising and falling edges of the spectral characteristics to improve the reproduction of neutral colors. Figure 5.3-A-2 shows an example of the spectral characteristics of a complete prism type color separation system. The color-selective characteristic of the blue-reflecting and red-reflecting dichroic coatings divert the blue and red components of the image to the respective blue and red imagers. The remaining component, green, passes straight through to the green imager. The imagers themselves have no special color characteristics. The spectral characteristics of the complete optical system are called the *taking characteristics* of the camera. The ideal taking characteristics are shown in Figure 5.3-A-3. Note that the ideal taking characteristics include negative lobes, shown dotted in the Figure. The optical system cannot generate the required negative lobes (cannot subtract light); however, subtraction of the video signals is possible in the camera processing stages. One of the functions of the linear matrix circuitry is to correct for the missing negative lobes in the optical system.

Color Separation System For Two Imager Color Cameras

The incoming light is applied to a partially silvered mirror (or prism surface) to divert half the incoming light. The straight-through portion goes to the luminance (Y) CCD imager. The reflected portion goes to the chrominance channel CCD imager (see Figure 5.3-A-4) Color separation is achieved on the chrominance imager by the use of alternate red and blue optical filters on the pixels of the CCD. The luminance resolution of the two imager system is high. Color

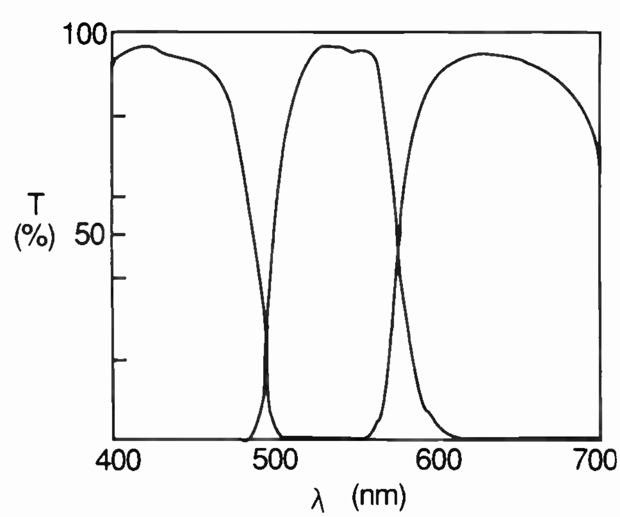

Figure 5.3-A-2. Spectral characteristics of an entire color separation system.

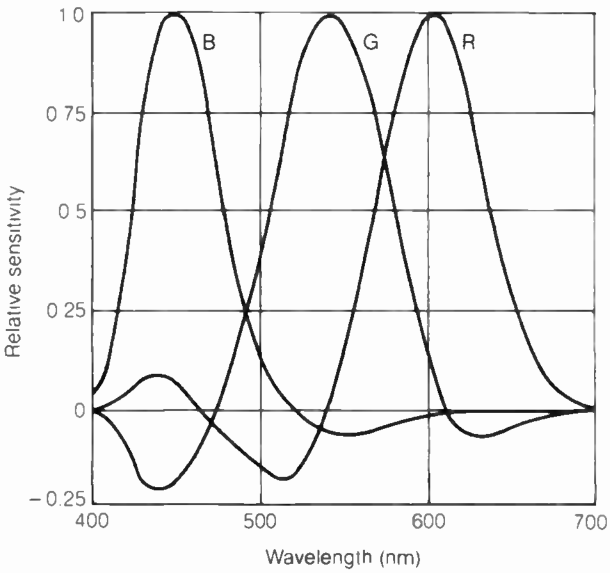

Figure 5.3-A-3. Ideal taking characteristics. *(Courtesy of Wiley Publishing.)*

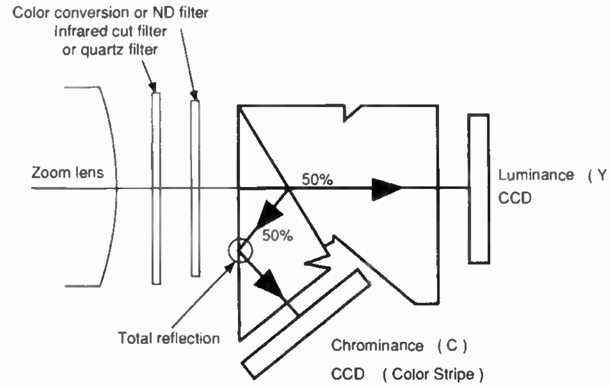

Figure 5.3-A-4 Two imager color separation system.

performance is only a little better than the one imager system.

Color Separation System For Single Imager Color Cameras

In the classic single imager camera, the red, green and blue optical filters are deposited on the surface of the CCD in a mosaic or stripe filter pattern (see Figure 5.3-A-5). The relative merits of the mosaic vs. stripe filter are given in Table 5.3-A-1. In some cases an alternate pattern of color filters is used to achieve a different combination of characteristics.

Table 5.3-A-1

Relative Performance of a mosaic vs. stripe filter.

Mosaic Filter	Stripe Filter
Higher cost	Lower cost
Higher H resolution	Lower H resolution
Higher sensitivity	Lower sensitivity
Complementary color filter	Primary color filters
Poorer colorimetry	Better colorimetry

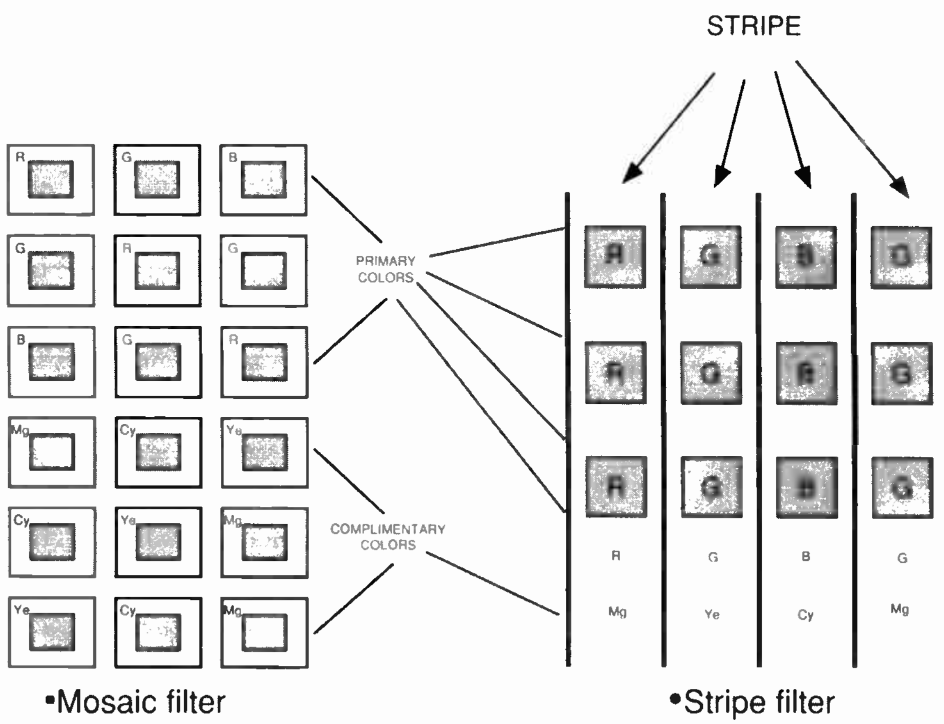

Figure 5.3-A-5. Single imager color separation system.

APPENDIX B: LENS CHARACTERISTICS

A zoom lens is typically used with a television camera. The zoom lens has the following characteristics:

- The focal length can be continuously varied over a wide range. The action of varying the focal length is called *zooming*
- The image position does not change as the lens is zoomed (focal length of the lens is changed). The ratio of the maximum focal length divided by the minimum focal length is called the *zoom ratio.*

A common type of zoom lens is illustrated in Figure 5.3-B-1. In this type of lens, a lens group (the *variator*) moves along the optical axis to vary the focal length, while another lens group (the *compensator*) is moving in a complementary manner to maintain the image in the same plane. Precisely machined cams are used to effect the complex movement of the variator and compensator elements.

Focal Length

If parallel rays of light pass through a (convex) lens, they will converge to one point on the optical axis, the *focal point* of the lens. The *focal length* of a lens is the distance from the center of the lens to the focal point. Practical camera lenses consist of several convex and concave lenses grouped together to minimize aberrations, however, this combination of lenses functions essentially the same as a single convex lens of negligible thickness (and no aberrations) also called a *thin lens* (see Figure 5.3-B-2). The focal length of a *complex lens* is then the distance from the center of this equivalent thin lens to the focal point (see Figure 5.3-B-3). The focal length is the most fundamental parameter of a lens and directly defines the angle of view of the lens.

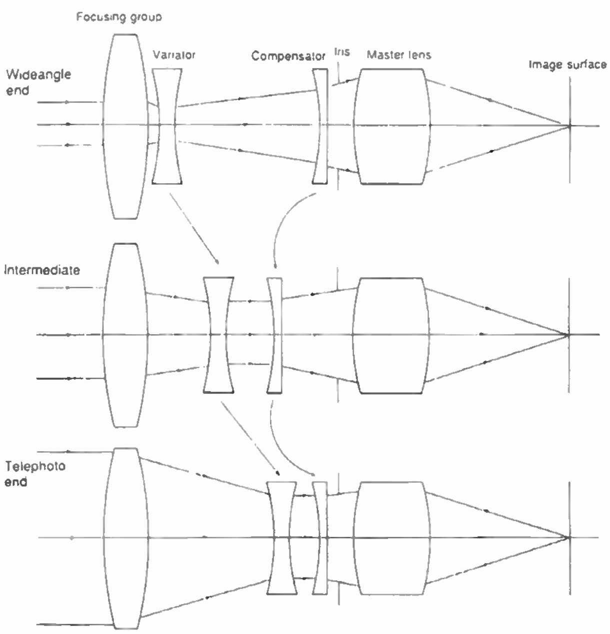

Figure 5.3-B-1. Common type of zoom lens.

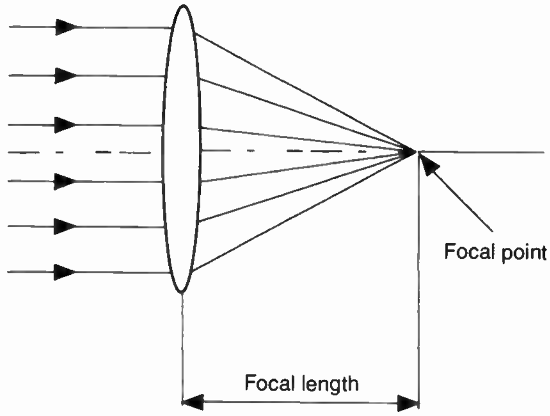

Figure 5.3-B-2. Focal length of a single or thin lens.

Angle of View

The angle of view of a lens is directly related to the image size and the focal length, as shown in Figure 5.3-B-4. Currently, the standard television systems have an aspect ratio of 4 units horizontal to 3 units vertical (4:3); therefore, the angle of view is greater in the horizontal than the vertical direction.

Field of View

The field of view is the size of an object that fills the image format (see Figure 5.3-B-5). Expressed mathematically,

$$y = 2l \tan \frac{w}{2} \quad \text{or} \quad y = y' \frac{l}{f}$$

where:

y = object dimension
l = object distance
w = angle of view
y' = image size
f = focal length

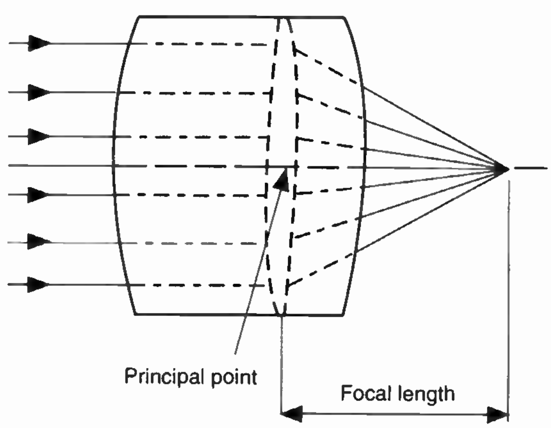

Figure 5.3-B-3. Focal length of a compound lens.

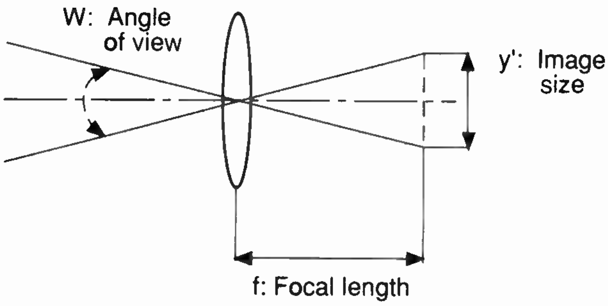

Angle of view: $w = 2 \tan^{-1} \frac{y'}{2f}$

Figure 5.3-B-4. Calculating the angle of view.

For example, if the object being viewed is 1,000 ft away and the lens has a vertical angle of view of 2°, then

Vertical field of view = 2 × 1000 × tan (2°/2)

Vertical field of view = 35 ft

Horizontal field of view
 − 35 × 4/3 (aspect ratio) = 46. 7 ft

Relative Aperture (*f*-number or *f*-stop)

This parameter characterizes the speed or light gathering power of the lens. The relative aperture is defined as f-number = f/D, where f = the focal length and D = the effective aperture diameter. A lens providing a smaller f-number is more sensitive than another lens that has a higher f-number at maximum aperture. The f-number selected is also closely related to the depth of field, where minimum depth of field corresponds to the lens at maximum aperture. For example, the typical sensitivity of a CCD type camera is 2000 lux (− 186 footcandles) at $f/8.0$ for a full output signal (see Table 5.3-B-1).

Depth of Field and Depth of Focus

Depth of field is defined as the difference between the maximum and minimum distances to a subject

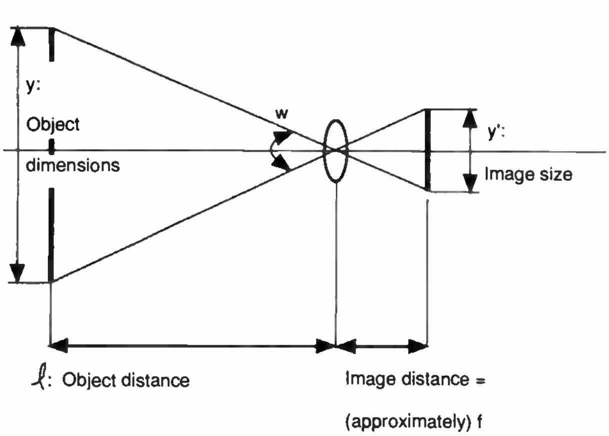

Figure 5.3-B-5. Field of view.

Table 5.3-B-1
Relationship Between f/number and Illumination Sensitivity

f/number	Illumination Sensitivity
f/8.0	2,000 lux
f/5.6	1,000 lux
f/4	500 lux
f/2.8	250 lux
f/2.0	125 lux
f/1.4	62. 5 lux

such that the image is within an allowable amount of blurring (see Figure 5.3-B-6). The human eye cannot detect blurring below the *circle of confusion* (the permissible circle of confusion becomes smaller as the resolving power of the system is increased). Correspondingly, the distance the image plane can be moved within the allowable circle of confusion is defined as the depth of focus. In CCD cameras, the CCD imagers are precisely fixed to the color separation prism and it becomes critical that the optical system be compensated such that the R, G and B images are well within the depth of focus, a difficult requirement that is now imposed on lenses intended to be used with CCDs.

The smaller the f-number of a lens, the shallower the depth of focus and therefore the smaller the depth of field. In other words, the depth of field can be controlled by adjusting the iris (aperture) of the lens in conjunction with a suitable ND filter to provide correct exposure. The depth of field characteristically becomes greater both as the focal length of the lens becomes shorter, and as the distance between the lens and the subject becomes longer (see Figure 5.3-B-6).

Ramping

Ramping or f-drop is the term applied to the drop in sensitivity (increased f-number) typically experienced in a zoom lens at the upper end of its focal length range. It is common for lens manufacturers to allow a certain amount of ramping in portable lenses to reduce the size and weight of a zoom lens. Studio lenses, however, frequently employ a large enough focusing group to avoid the ramping effect.

When the ramping effect is present in a lens, the iris must be readjusted to maintain full video level at the extreme zoom positions. In the example of Figure 5.3-B-7, the lens has a relative aperture of $f/1.6$ through a zoom range of 12 mm to 120 mm, but ramps down to $f/2.8$ at its maximum focal length of 180 mm.

Modulation Transfer Function (MTF)

MTF defines the resolution capability of a lens. MTF is typically measured by using a black-to-white sine wave pattern. The peak-to-peak amplitude of a low frequency sine wave (0.5 MHz) is used as the 100% reference; the peak-to-peak amplitude for other frequencies defines the MTF of the lens for those frequencies. Most lenses exhibit their best MTF when operated in the middle of their aperture range. For example, a

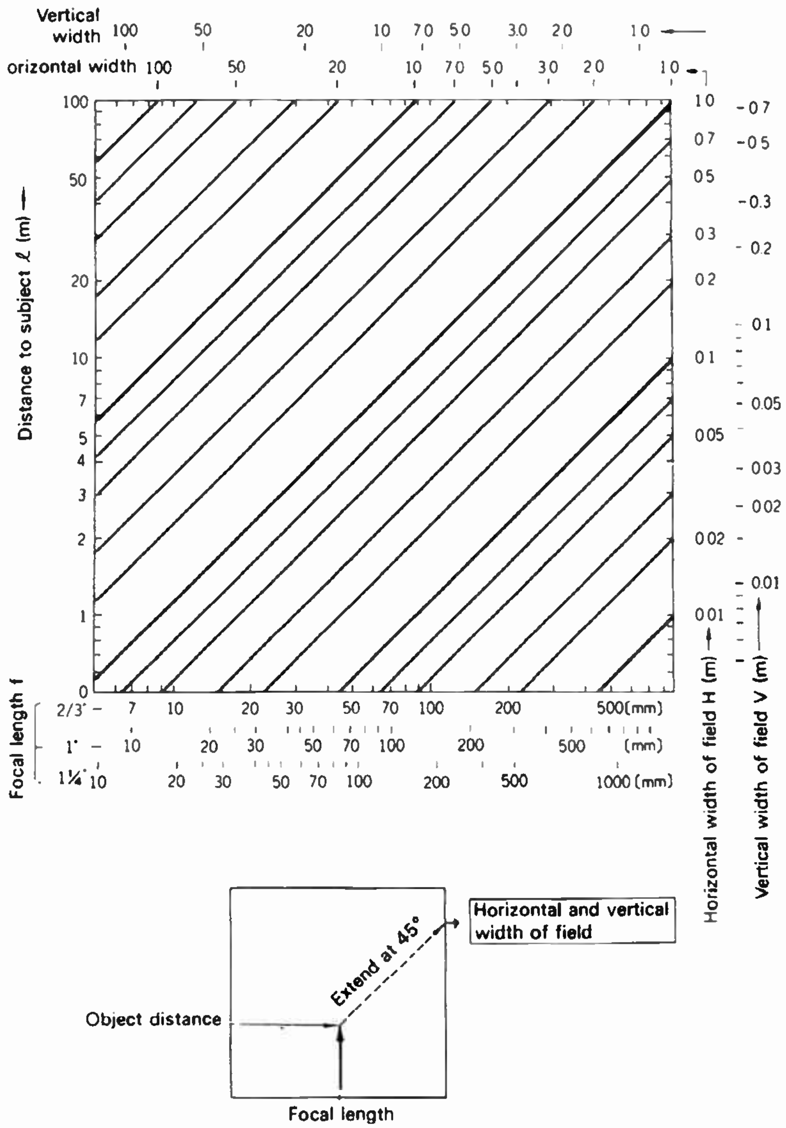

Figure 5.3-B-6. Depth of focus and depth of field.

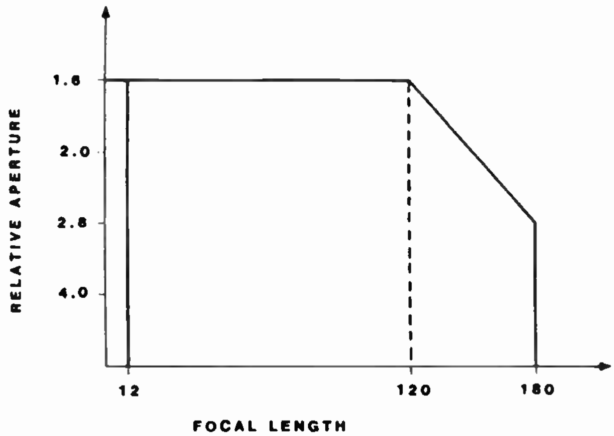

Figure 5.3-B-7. Lens ramping.

lens with an aperture range of $f/1.6$ to $f/16$ will probably gives its best MTF at about $f/4.0$. If the lens is further stopped down towards $f/16$, some small reduction in modulation depth may result because of the light being refracted as it passes through such a small aperture. However, as the lens is opened towards its maximum aperture of $f/1.6$, a more severe loss of modulation depth is likely to occur as the spherical aberrations become more significant.

In addition, the MTF of the lens tends to be best at the center of the picture and fall off toward the edges of the picture. Figure 5.3-B-8 illustrates the MTF characteristics of a typical zoom lens. Note that the MTF becomes worse as the iris is opened. This difference is more exaggerated in the corners, which illustrates the importance of considering the f-stop when evaluating the performance of a lens.

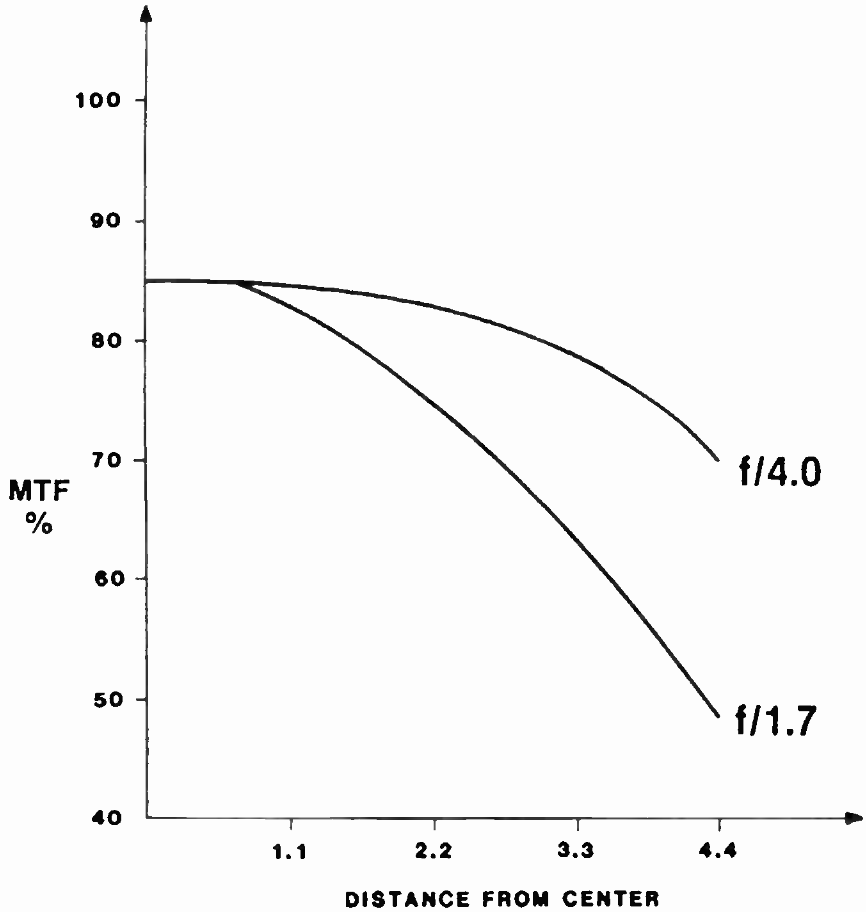

Figure 5.3-B-8. Typical MTF characteristics for 2/3 in. lens (average for all focal lengths).

Uniformity of Field (Vignetting)

Uniformity of field is a measure of the response to a white field over the full picture area. The typical uniformity of field characteristic of a zoom lens is shown in Figure 5.3-B-9, which illustrates that the response is usually greatest in the center and least in the corners. The nonuniformity in the corners becomes more pronounced at wide aperture settings and varies with focal length. High quality video cameras frequently contain a white shading circuit that increases

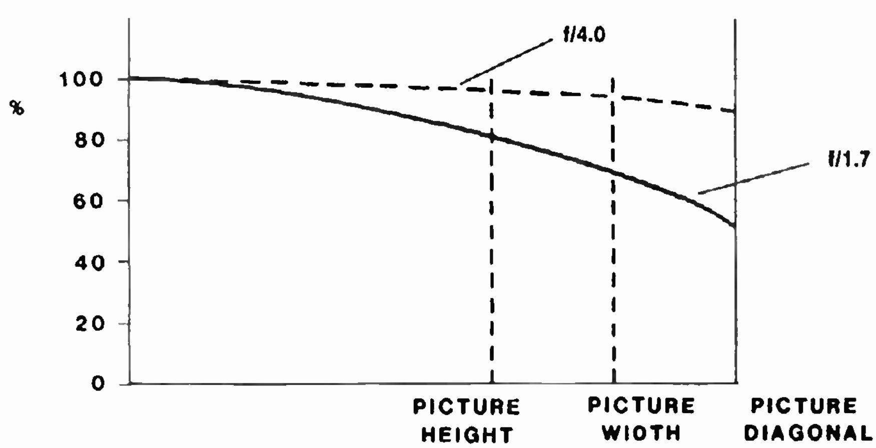

Figure 5.3-B-9. Uniformity of field.

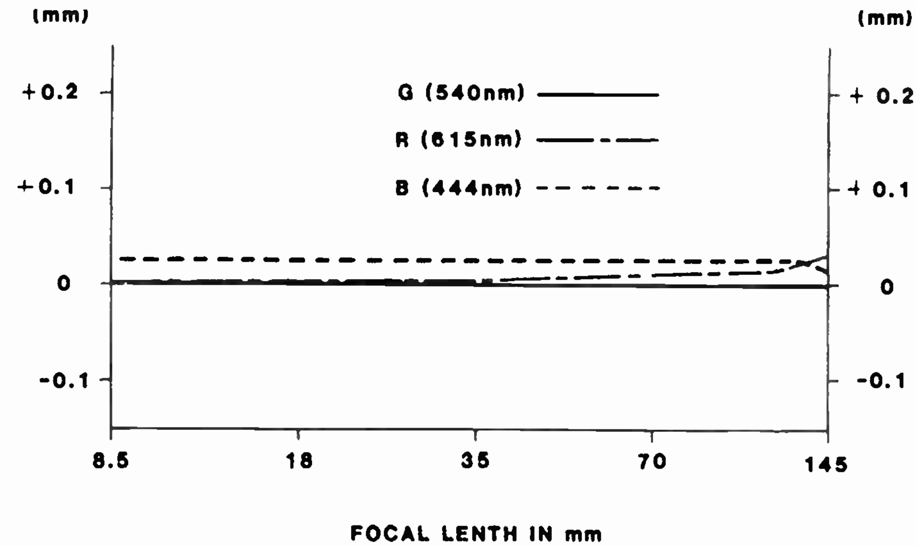

Figure 5.3-B-10. Longitudinal chromatic aberration.

gain toward the edges and provides first-order correction for this effect.

Longitudinal Chromatic Aberrations and Lateral Chromatic Aberrations

The refraction of optical glass varies with the wavelength of the light. This causes the lens to form different images for different colors (see Figure 5.3-B-10). Chromatic aberration is classified in two types:

- **Longitudinal chromatic aberration.** The position of the image plane varies according to color
- **Lateral chromatic aberration.** The size of the image on a given image plane changes according to color.

Although the lens designer makes a great effort to achieve consistency, the focal length of a zoom lens tends to vary slightly with color throughout its zoom range. This means that there will be some small differences between color channels, in both focus and image size, as the zoom is operated.

Geometric Distortion

All lenses exhibit some degree of geometric distortion, a symmetrical error (shown in Figure 5.3-B-11) affecting the red, green and blue images equally. In the case of the zoom lens, the distortion varies with the focal length such that the negative (*barrel*) distortion occurs at short focal lengths and positive (*pincushion*) distortion occurs at long focal lengths. For camera

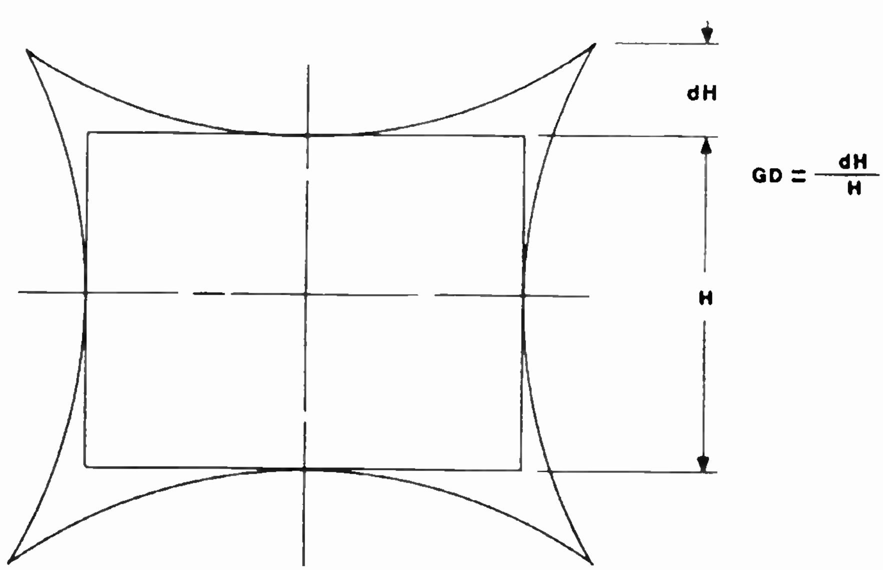

Figure 5.3-B-11. Geometric distortion.

measurements and adjustment, it is advisable to use the middle of the zoom range where this error is minimized.

Minimum Object Distance (MOD)

MOD is the closest focusing distance of a lens. Wide angle lenses generally have the shortest MOD and telephoto lenses the longest. When a lens is chosen for a specific application, it is critical to insure that the MOD is adequate.

APPENDIX C: COLOR TEMPERATURE

The illumination from an incandescent lighting fixture is frequently described as a warm source of light by cinematographers, and indeed, when analyzed with a spectra device that measures the relative intensity of the color components, red wavelengths described as a warm color, predominate. Daylight illumination on the other hand is frequently described as being cool and the same spectral analysis shows blue wavelengths, usually described as a cool color, to predominate. The concept of color temperature makes it possible to describe the character of the illumination in a much more precise manner than these vague descriptions. The concept of color temperature also makes it possible to easily determine the proper color correction filters to use with a specific source of illumination.

Color temperature is defined as the visible spectrum emitted by a black body that has been heated to specific temperature in degrees Kelvin. The color of an illuminant is determined only by its temperature and is almost the same for all substances at a given temperature. For example a quartz halogen studio light is said to have a color temperature of 3,200°, because the visible spectrum of the studio light closely resembles the spectrum emitted by a black body heated to 3,200° K. Daylight is said to have a nominal color temperature of 5,600°,

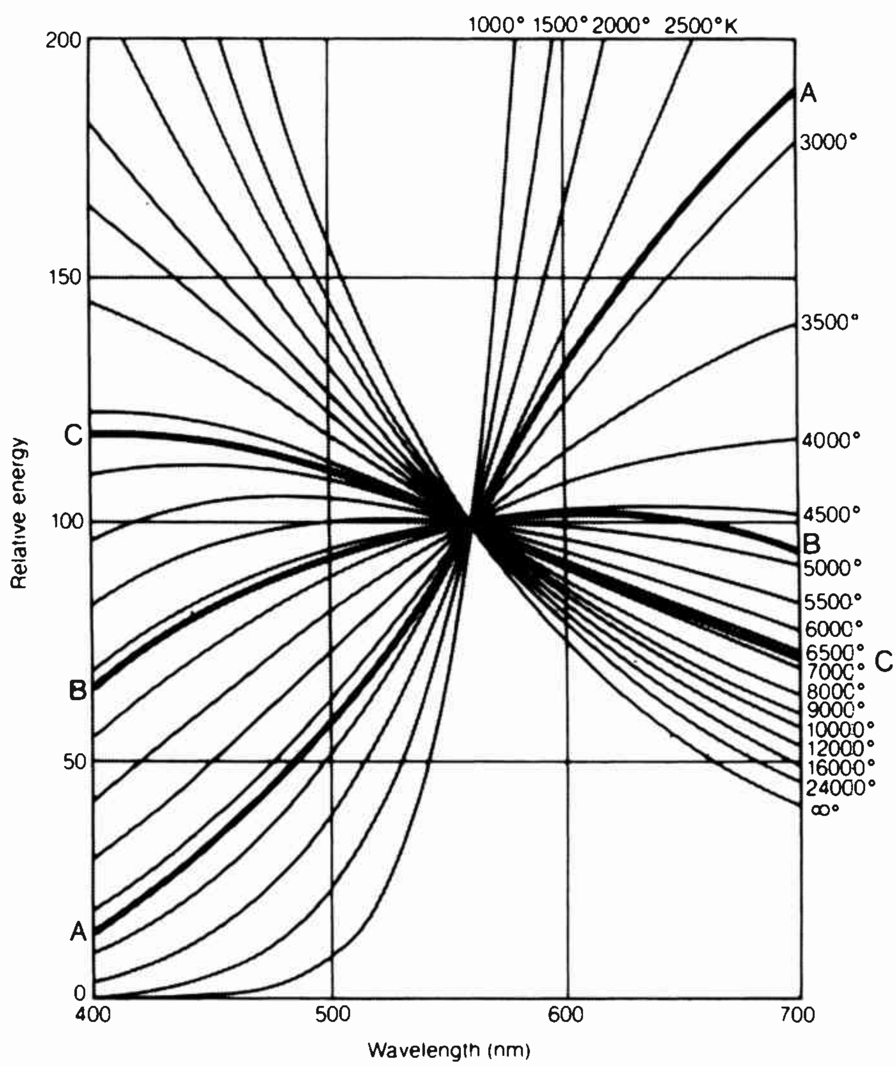

Figure 5.3-C-1. Spectral distribution at each color temperature.

because its spectrum provides a close match to the spectrum of a black body heated to a temperature of 5,600° K.

The light emitted by a black body that has been heated, is a smooth, continuous spectrum that covers the complete visible spectrum. Lighting sources such as metal vapor lights and fluorescent lights typically have a discontinuous spectrum of strong spectral lines. Nevertheless, a color temperature designation is frequently assigned to such sources, to give an overall indication of the character of the light as perceived by the eye. These lighting sources, frequently used in stadiums and arenas because of their efficiency, must be used with great caution to achieve acceptable color reproduction with a color television system.

The relative energy vs. wavelength at various color temperatures is given in Figure 5.3-C-1. For example, consider an illuminant of approximately 2,900° K (curve A). The magnitude of the long wavelengths which correspond to red (600–700 nm wavelength) are large, while the magnitude of the short wavelengths corresponding to blue (400–500 nm wavelength) are very small. This relationship reverses for high color temperatures.

APPENDIX D:11-STEP GRAY SCALE

An 11-step gray scale chart is highly recommended for use in adjusting a camera. The 11-step chart incorporates a true gamma of 0.45, as well as a 40:1 contrast ratio. It is highly recommended not to use the traditional EIA 9-step logarithmic gray scale chart for camera verification and adjustment for the following reasons:

- All the instruction manuals provided with current cameras provide waveforms and voltages appropriate for an 11-step chart. It is extremely difficult to relate these waveforms and voltages to a 9-step chart.
- The EIA chart uses logarithmic steps that do not mathematically fit the gamma curve of the camera
- The 9-step chart covers only a 20:1 contrast ratio, inadequate to test a modern video camera that is capable of at least a 40:1 contrast ratio.

5.4 VIDEO SIGNAL SWITCHING, TIMING AND DISTRIBUTION

JAY KUCA
GRAHAM-PATTEN SYSTEMS, GRASS VALLEY, CA

INTRODUCTION

Evolutionary changes in video equipment technology have had a dramatic impact on the design of video systems. Not that long ago, composite analog systems were the norm. Today, however, the typical facility is a hybrid of composite and component, analog and digital systems.

Engineers and technicians working in this mixed format environment must be aware of the system design considerations that are unique to each format. They must also have a clear understanding of the implications of converting between formats. There are four basic video signal formats which are currently in use in professional video installations: composite analog (NTSC), component analog (RGB or Y, P_r,P_b), composite digital (4fsc), and component digital (Rec. 601).

Most of the infrastructure which is in place in television stations today is composite analog. This is because NTSC has been in existence longer than the other formats and a substantial amount of composite analog equipment is still in service. It is also due to the fact that the current terrestrial delivery system is NTSC based.

Newly acquired equipment is more likely to be digital than analog. As the balance of analog versus digital equipment in a facility shifts more toward digital, conversion of the facility's routing and distribution systems will become more attractive. This will be accelerated by the conversion of the terrestrial delivery system to digital.

NTSC and digital television (DTV) are likely to coexist for many years to come. Throughout the transition, it is important that technical staff maintain proficiency in both analog and digital technology.

NTSC SYSTEMS

In 1953, the National Television Systems Committee (NTSC) recommended a set of color television standards to the Federal Communications Commission (FCC). The FCC adopted the standards and color television transmissions commenced shortly thereafter.

These color standards were based on the monochrome standards developed by the NTSC in the early 1940's. In fact, a key requirement of the color standard was that the transmitted signal be compatible with existing monochrome receivers. This was accomplished by retaining all of the characteristics of the monochrome signal and adding color information through the use of a quadrature modulated subcarrier added to the monochrome signal.

The subcarrier frequency was carefully chosen to fit within the channel bandwidth to minimize its visibility on the screens of monochrome receivers and interference with the 4.5 MHz sound carrier used in transmission. The actual frequency which was selected is 3.579545 MHz ± 10Hz. It is commonly referred to as 3.58 MHz.

NTSC Video Signal Characteristics

Figure 5.4-1 is an oscillogram of a typical video signal. The peak to peak amplitude of the signal is 1 V peak to peak or 140 IRE units. This is the standard level for signal distribution in all professional television facilities. The signal is comprised of +100 IRE units (714 mV) of picture and −40 IRE units (286 mV) of sync.

Even though video is an ac signal, proper operation of most equipment depends upon a fixed dc component. By convention, blanking (0 IRE) is assumed to be at ground (0 VDC). This reference is lost, of course, in portions of the system which are ac coupled, but when the signal is clamped or dc restored, standard practice dictates re-establishing blanking at ground.

The bandwidth of a studio quality NTSC video system is determined primarily by the state of the art and economic factors. And while it can be argued that the transmission system cuts off any information above 4.2 MHz, it is good engineering practice to strive for response which is flat to 8 to 10 MHz in the studio.

Timing integrity is ensured through the use of a *master sync pulse generator*. In nearly all installations, timing for all signals in the plant is derived from this single reference. In most cases, the master sync generator is driven from a high stability crystal oscillator. Occasionally, a *precision rubidium* or *cesium reference oscillator* is used. (Figure 5.4-2 illustrates the relationships between the horizontal, vertical and color timing signals.)

Interconnection Conventions

All analog composite studio equipment is designed to be interconnected with coaxial cable with a nominal characteristic impedance of 75 U. In the simplest case, a point-to-point connection between two pieces of equipment, a continuous length of cable is driven from a 75 Ω source and terminated in a 75 Ω load (see Figure 5.4-3).

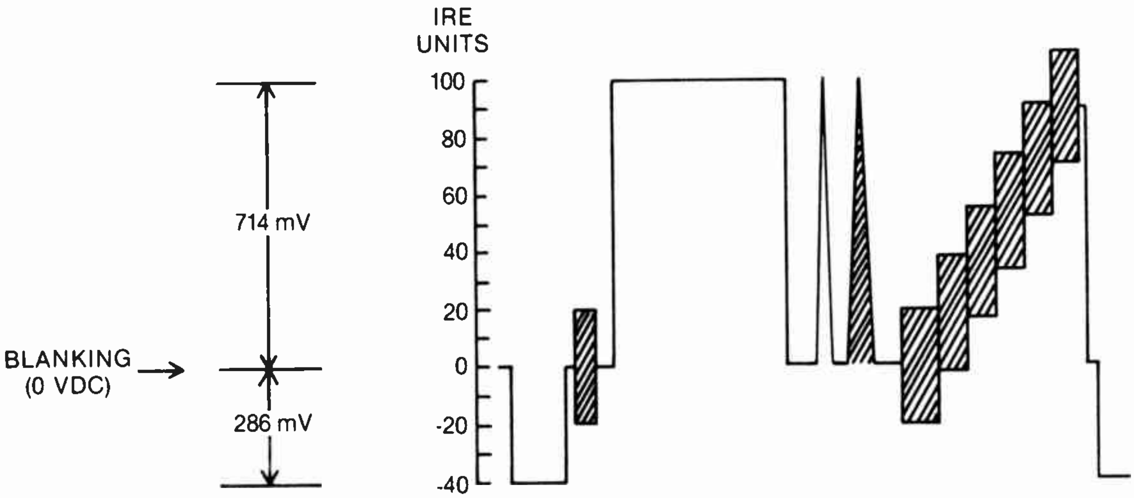

Figure 5.4-1. Oscillogram of a typical video signal.

Two possible approaches exist when it is necessary to distribute the signal from a single source to more than one destination. The first is entirely passive in nature: one end of the cable is driven from the 75 Ω source and, instead of terminating the far end in a 75 Ω load, a *loop through* connection is made to the first piece of equipment. The loop through is carried on to the next piece of equipment, and so on. A 75 Ω termination is placed on the loop through connection on the last piece of equipment. This approach, shown in Figure 5.4-4, will work well provided the loop through inputs are properly designed and the cable lengths are kept short. The number of loop throughs should also be kept as small as possible to prevent frequency response errors and, in severe cases, signal reflections.

Terminations should be made using *non-inductive precision resistors.* An ideal termination should present a purely resistive load of exactly 75 Ω. Any reactive components will cause frequency response errors. Errors in the value of the resistive component will cause errors in signal levels. Terminations made with 0.1% tolerance metal film resistors are recommended.

Whenever possible, video signals should be distributed using an active device such as a *distribution amplifier or routing switcher.* This effectively results in the equipment being interconnected in the point-to-point manner previously described.

Nearly all modern equipment uses BNC connectors for video input and output connections. Some older equipment still in service may use UHF (PL-259/SO-239) connectors. Occasionally, space limitations dictate the use of a subminiature connector such as a BSM series. However, the BNC is by far the most common connector in use.

A wide variety of cable types are available which are suitable for high quality video interconnect. One popular type is Belden 8281, a double shielded 75 Ω precision coaxial cable designed specifically for video use. 8281 provides a good balance between loss and physical size. Its double shielding helps reduce the likelihood of stray signal pickup.

Where space limitations, increased flexibility, or other factors require the use of a smaller diameter cable than 8281, an RG/59 type cable is the usual choice. In choosing such a cable, make certain it has a solid copper center conductor and braided copper shield. There are many RG/59 type cables on the market with copper clad inner conductors and foil shields. These are designed for RF applications such as CATV and are not suitable for use in baseband video systems.

Distribution Amplifiers

The distribution amplifier or (DA) is the most elementary building block in a video system. Its primary function is to allow a single 75 Ω video source to feed multiple 75 Ω loads with no apparent loss. Quite often, other functions such as cable equalization are included in the DA's circuitry.

Even though DA functions and designs vary, it is quite easy to construct a generalized model. As shown in Figure 5.4-5, the typical DA consists of an input amplifier followed by a conditioning stage (gain, equalization, delay, etc.), followed by an output amplifier.

The input amplifier is generally designed with a rather high input impedance (several tens of kilohms). This allows the driving signal to be looped through the input with minimal loading effects. Quite often, a complex network is used at the input connection to cancel out any reactive components which might affect the loop through. The input stage may be either single ended or differential, the latter being more common on high quality DA's.

A differential input stage can be very useful in combating one of the most serious problems encountered in unbalanced signal transmission—common mode hum and noise. In larger facilities, common mode hum due to ground loops may run as high as several volts. Even in small plants with excellent ground systems it is

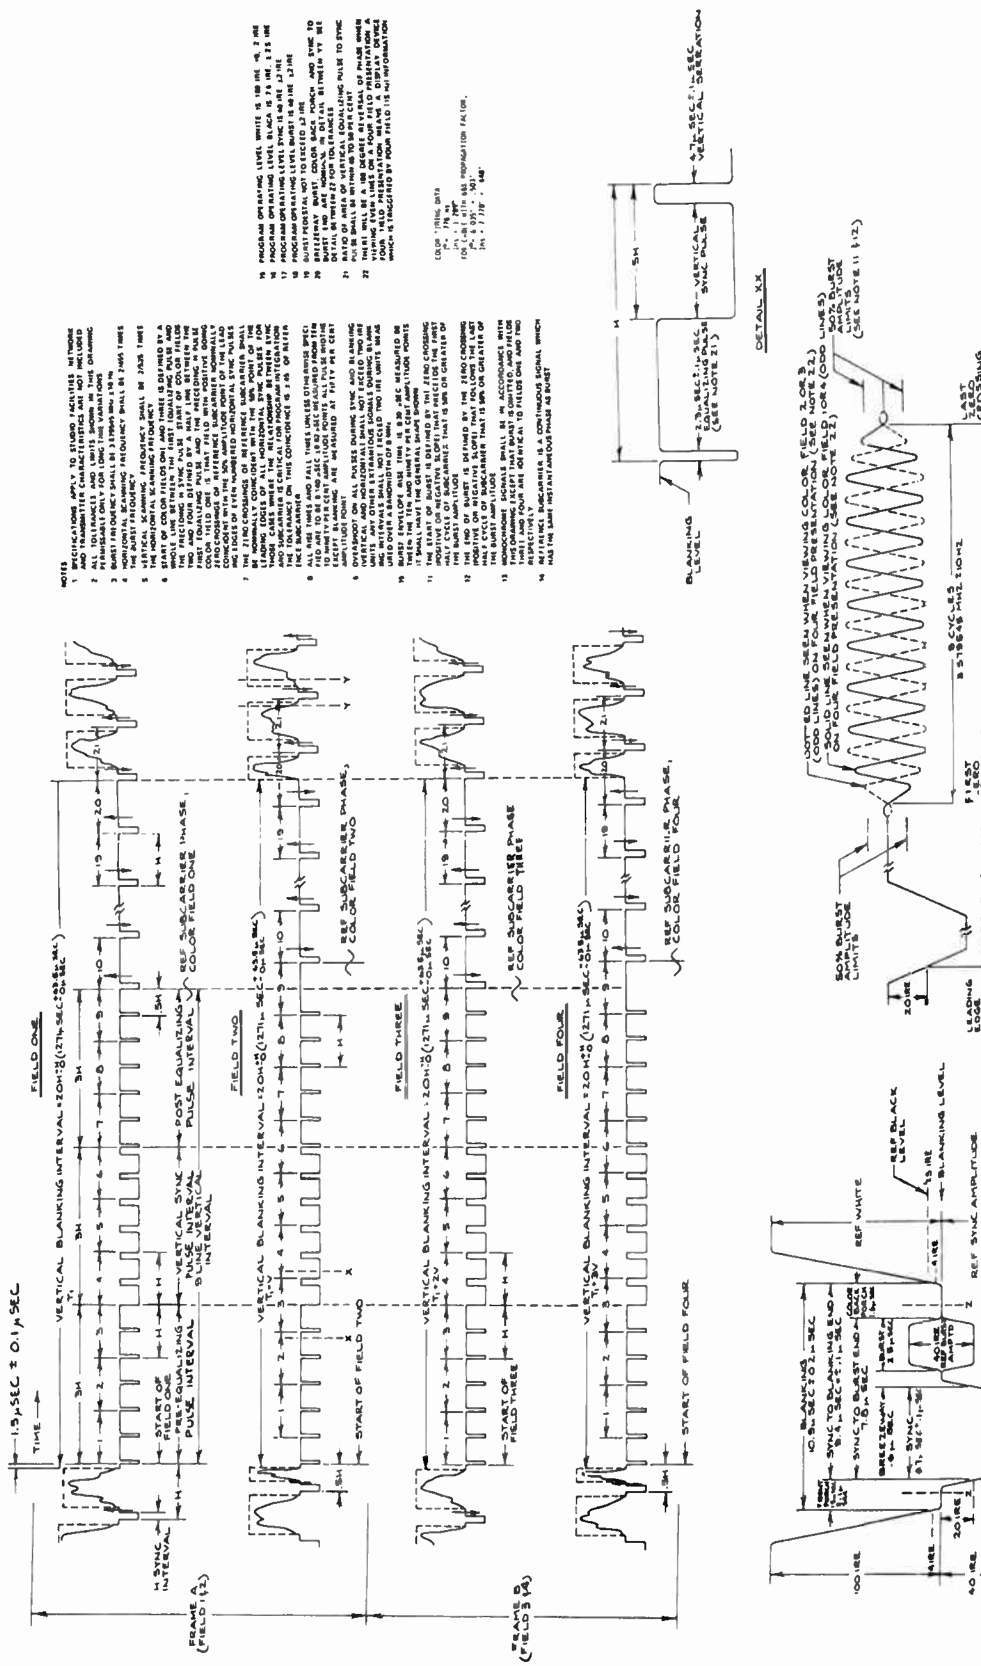

Figure 5.4-2. NTSC timing parameters. An updated version of the EIA Tentative Standard RS-170A. *(Courtesy of the Grass Valley Group)*

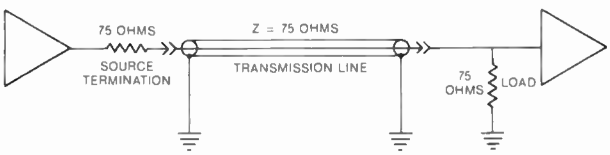

Figure 5.4-3. Point-to-point video connection.

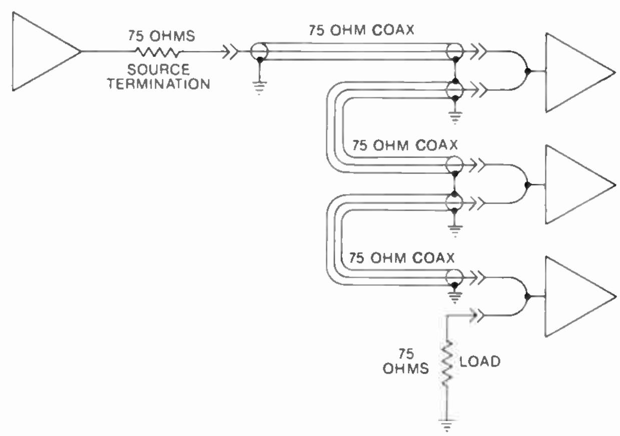

Figure 5.4-4. Loop through video connection.

possible to have several tens of millivolts of difference in ground potential between different pieces of equipment. A differential amplifier will cancel any common mode signals while amplifying the (desired) differential mode signal. Common mode rejection ratios (CMRR) of 50 to 60 dB are typical of most modern differential input DA's.

The conditioning stage may be a *wideband gain stage*, *active equalizer stage*, or *delay amplifier*, depending upon what additional function the DA performs. If distribution is the only function, the conditioning stage may be omitted.

The *output stage* is an amplifier with very low output impedance. It is followed by source termination resistors which ensure that the cable recognizes 75 Ω at the sending end as well as the load end. High output to output isolation is ensured by the low impedance of the output stage.

Cable equalization is often required in video systems. This is due to losses increasing with frequency in coaxial cable. Belden 8281 has approximately 0.8dB of loss per 100 ft at 10 MHz. Since runs of 100 ft or more are not uncommon in most facilities, achieving flat system response makes equalization of these losses necessary. The approach taken by most manufacturers is to construct an equalizer network with a response that closely approximates the inverse of the cable loss curve. When this equalization is applied to the cable/DA system, the result is flat overall response.

Cable equalizers must be designed for a specific type and length of cable. When a variable equalization control is provided, it usually serves to adjust the amount of equalization applied. Because cable loss is a complex function, the equalization curve is only correct for one cable length. Slight response errors will be noted at other length settings.

Cable losses should always be equalized at the load end of the cable. The reason for this is simple: if a flat signal is applied to the input of the amplifier, the high frequency boost of the equalizer stage will be added to the signal and the output stage will have to track these larger than normal amplitude high frequencies. In cases where the amount of equalization is more than a few dB, the output stage will be unable to deliver the necessary current into its low impedance load. If, however, the DA is located at the load end of the cable, the cable losses have attenuated the high frequencies at the input of the amplifier. The high frequency boost of the equalizer stage restores the flat response characteristic to the signal, and the output amplifier does not have to deal with larger than normal swings at high frequencies.

Another function which is often required in video systems is *clamping*. Clamping is used primarily to reduce low frequency hum and tilt but may also be used to restore the dc component of a video signal which has passed through one or more ac coupled devices. Clamps operate on a line-by-line basis and, as such, are fast acting. They can be triggered by noise impulses and should therefore not be used on noisy signals.

Direct current restoration may be used in lieu of clamping to reduce the dc signal bounce due to multiple

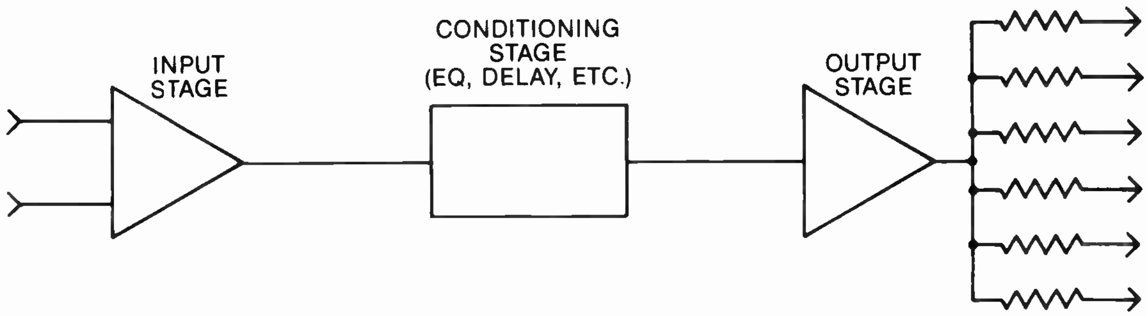

Figure 5.4-5. Simplified block diagram of a video DA.

ac couplings. Because of the slow time constants employed in dc restorers, they are not affected by noise; but by the same token, they are not useful in eliminating hum and tilt.

Delay DA's are often used in place of coaxial cable or other passive delay elements. Delays of up to a microsecond or more are possible on modules no larger than a conventional DA. Many delay DA's include circuits to compensate for delay line response errors which produce better results than a passive delay line and DA in combination. Some delay DA's also include other functions such as cable equalization.

Distribution Amplifier Selection

As a signal traverses a typical path through a typical system, it may pass through ten or more DA's. Therefore, the performance of a single amplifier must be, for many parameters, an order of magnitude better than the system specification. Table 5.4-1 lists the performance specifications of a representative unit.

Selecting the right DA for a particular application involves determining the desired level of performance and the features and functions required. Since most manufacturers offer a range of models which all fit into the same mounting tray, it is wise to look at the sum total of all requirements and then choose the manufacturer who can best accommodate those requirements.

DA's fall into the *install it and forget it* category—low maintenance and long service are important factors. When selecting distribution amplifiers, consider the quality of the components which the manufacturer has used. Will they hold up for ten or fifteen years? Is the design a conservative one, or are devices being run at their limits? Thermal stress will not only lead to equipment failure, it will cause drift as well.

Pulse and Subcarrier Distribution Amplifiers

Black is by far the most commonly used signal for equipment synchronization. However, separate pulses and subcarrier are still used as timing references in some systems. *Pulses* (sync, blanking, H drive, V drive) are generally distributed as 2 to 4 V negative going signals. Subcarrier is generally distributed as a 1 to 2 V peak-to-peak signal.

Table 5.4-1
Typical video DA performance specifications

Frequency Response	+/− 0.025 dB to 5 MHz, −0.2 dB at 10 MHz
Differential Phase	<0.1°
Differential; Gain	<0.1%
T-Pulse to Bar	<1.0%
Tilt	<0.5%
Chrominance/Luminance Delay	< 10ns
Hum and Noise	>70 dB below 1 V p-p
Common Mode Rejection	>60 dB
Input Return Loss	>40 dB to 5 MHz
Output Return Loss	>40 dB to 5 MHz
Output Isolation	>40 dB to 5 MHz

Most video DA's will not accommodate signals larger than 2 volts peak-to-peak. So, while most video DA's would be suitable for subcarrier distribution, the typical video DA will not handle full amplitude pulses. DA's designed specifically for pulse distribution are optimized for large negative signal swings. They will not function well, if at all, as video amplifiers.

There are two general categories of pulse DA's—regenerative and linear. Regenerative DA's include circuitry for pulse regeneration, typically edge detectors driving one-shots. Timing of the one-shots is usually adjustable, allowing the relative delay of the amplifier to be varied. Delays of up to several microseconds are common. Due to the inherent delay of the pulse regeneration circuitry, these amplifiers always exhibit some value of minimum delay.

Regenerative subcarrier DA's are also available. These amplifiers generally feature adjustable circuits to shift the phase of the subcarrier. The adjustment range is usually slightly more than 360.

When pulses and subcarrier are distributed through regenerative DA's, there is a good chance that the subcarrier to horizontal (SC/H) phase will not be maintained throughout the system. This is because it is possible to adjust sync and subcarrier timing independently. For this reason, linear (non-regenerative) pulse and subcarrier DA's should be used in SC/H phased installations. Specially designed linear pulse DA's are available and most high quality video DA's can be used as linear subcarrier DA's.

Video Signal Switching

Analog video signals can be switched using a variety of methods. Simple monitor selectors may be nothing more than passive mechanical switches. In some cases, electromechanical devices such as relays are employed. Most modern switching systems employ solid state switching devices.

Figure 5.4-6 is a simplified block diagram of a video switching system. Input amplifiers buffer the input signals and provide drive to the switching elements (crosspoints). The crosspoints are bussed in horizontal

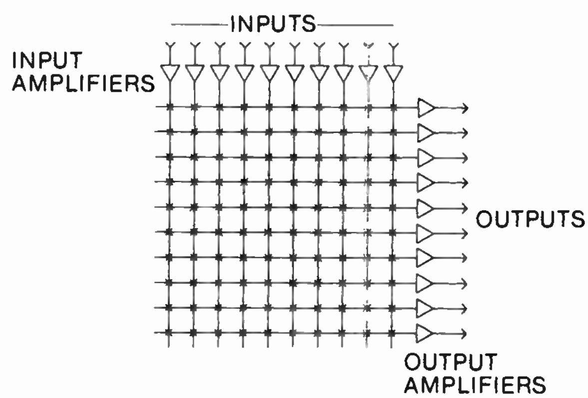

Figure 5.4-6. Simplified block diagram of a video switching system.

rows (output buses) to an output amplifier. If the switcher has more than one output bus, the buffered input signals are bussed in vertical columns (input buses) which run across the output rows.

Not shown in the block diagram is the crosspoint control logic. In single bus switchers with ten inputs or less, control is generally accomplished using a single wire per crosspoint. In single bus switchers with more than ten inputs, an encoding scheme such as BCD is generally used to reduce the number of wires required. Larger multiple bus switchers generally use some sort of serial control scheme.

Single Bus Switchers

Single bus switchers run the gamut from simple to elegant. For noncritical applications such as picture monitor input selection, a mechanical switcher may be adequate. Most mechanical designs are entirely passive; that is, they have no input or output amplifiers. As such, they have terminating inputs and require dedicated (non-loop through) input feeds.

A slightly more sophisticated design adds an output amplifier only. Switching is still done using mechanical switches, but the bus is made high impedance to allow looping inputs. This approach makes it possible to stack units to provide an economical multiple input/ multiple output configuration. In terms of performance, this type of switcher is no better than the passive type. If the input loop throughs are not compensated, its performance may actually be worse.

Any single bus switcher that is in a program path should be designed more along the lines of Figure 5.4-6. In other words, it should have input buffer amplifiers, solid state crosspoints and an output amplifier. If it is being used for live switching, the buffer amplifiers should clamp or dc restore the input signals to provide bounce free switching. To minimize disturbances in the output signal when switching between synchronous inputs, the design should provide vertical interval switching. If the unit is used in an actual program loop, the design should permit servicing with minimum disruption; that is, all active circuitry should be mounted on plug-in printed circuit boards.

Single bus switchers can be combined to make multiple bus switchers, but in most cases the result will cost more and lack the flexibility and performance of a true multiple bus design.

Multiple Bus Switching Systems

There are two basic architectures for multiple bus switching systems. One is *output oriented switcher* in which the circuitry for each bus is physically separate from the circuitry associated with other buses in the system. The other is a *matrix switcher* in which the circuitry for multiple output buses is packaged together.

Output oriented switchers occupy more rack space and are more expensive than comparable matrix switchers because it requires more duplication of circuitry and more interconnect. The chief advantage of an output oriented switcher over a matrix switcher is that circuit cards can be removed from an output oriented switcher without disturbing multiple signal paths. This is an important consideration in large facilities such as network switching centers.

Matrix architected switchers are physically more compact and less expensive than comparable output oriented switchers. They offer several other advantages as well: reduced power consumption, slightly higher reliability due to fewer mechanical interconnections and shorter signal path. Matrix switchers are generally designed around a relatively small square or rectangular building block, making input and output expansion in bite sized increments relatively simple.

Input signal distribution in both types of switchers can be handled using either looping techniques or distribution amplifiers. The cost objectives of most matrix designs suggests the use of looping while the large physical size of the output oriented switcher makes the distribution amplifier approach almost a necessity.

As is the case with single bus switchers, if live switches are made on a multiple bus switcher, the input signals must be clamped or dc restored to ensure transient free switching. This signal conditioning may be done externally, but better overall performance will result if it is done in the switching system. The reason for this is that a common precision dc reference can be used for all inputs if the clamping or dc restoration is done inside the system.

Switch timing is also important if glitches are to be avoided. Most multiple bus switching systems have a sync input which is used as a reference for a master trigger pulse generator. The trigger is set to occur during the vertical interval, thus ensuring glitch free switching between synchronous sources.

Timing scatter is an important parameter for any switching system that will be used in a studio environment. It is the measure of the delay difference between paths in the switcher. In a system which uses looping techniques to distribute the input signals, there will be a fixed amount of delay between output bus groups. But on a given bus, there should be very little path length difference from input-to-input: less than plus or minus 1 of subcarrier is a typical figure. In a system that uses DA's to distribute the input signals, it should be possible to achieve the same timing accuracy from any input to any output. Representative performance specifications that should be expected of a modern routing switcher are listed in Table 5.4-2.

With respect to the use of routing switchers in video facilities, two basic schools of thought prevail: a single large switcher as a master grid, or a network of smaller switchers distributed throughout the facility. With the master grid approach, one large switching system is used with all switched sources in the plant appearing as inputs. This provides maximum flexibility, but at considerable expense. If all sources are not needed at all destinations, many of the crosspoints in the system will not be utilized.

In the distributed approach, the plant is subdivided into functional areas (studios, master control, transmis-

Table 5.4-2
Typical video switching system performance specifications

Frequency Response	±0.1 dB to 5 MHz, −0.5 dB at 8 MHz
Differential Phase	<0.1°
Differential Gain	<0.1%
2 T-Pulse to Bar	<0.25%
Tilt	<0.5%
Crosstalk	>60 dB to 5 MHz
Hum and Noise	>70 dB below 1 V p-p
Input Return Loss	>40 dB to 5 MHz
Output Return Loss	>40 dB to 5 MHz
Switching Transients	<30 mV
Timing Scatter	±1° maximum, input to input on any bus

sion, central machine room, news editing, etc.) and a small switching system placed in each area. Each system has only those area sources it requires plus a few master sources common to the other areas (color black, bars, etc.) Tie lines between matrices provide connectivity between functional areas.

The distributed approach can be considerably more cost effective than the master grid approach. However, careful consideration must be given to overall system design and tie line management. A sufficient number of tie lines must be provided to accommodate worst case connectivity needs, otherwise, system users might experience busy signals, an unacceptable condition in most broadcast facilities. And in all but the smallest, simplest systems, tie line management should be relegated to a computer. In the final analysis, the complexity and potential limitations of a distributed system with tie lines must be weighed against the higher cost of a large master grid system.

Switching System Control

Microprocessor based control systems have enhanced the operational capabilities of multiple bus routing switchers. Microprocessor control makes it possible to select sources using their familiar names (BLACK, BARS, or VTR 5) instead of input numbers. Many systems allow the naming of destinations (STL, UPLINK, or VTR 12) and levels (VIDEO, AUDIO 1, AUDIO 2, or KEY) as well. Some systems provide advanced control features like salvo switching, privileged access, and virtual matrix mapping.

These enhanced capabilities add considerable complexity to the control system. To minimize downtime due to control system failures, it is advisable that any routing switcher in an online environment be equipped with dual control computers with a fail-safe changeover system.

Video Signal Timing

Timing requirements stem from the fact that a video signal is a serial stream of analog information which is used to electronically reconstruct a picture. Horizontal timing information is used to trace out each line of the picture on the face of a display tube in exact synchronism with the camera tube beam which scanned the original scene. Vertical timing information is used to signal the end of each still picture in the frame-by-frame reconstruction process. Color timing information in the form of a brief burst of subcarrier each line is used to ensure that the color at each point on the screen is accurately reproduced.

Timing in the television studio is the responsibility of a ubiquitous black box called a *sync generator.* In the early days, a monochrome sync generator filled a 6 ft equipment rack. Today, color units which are several orders of magnitude more accurate and stable can be packaged on a single printed circuit card.

The size and complexity of the early generators prompted the master generator approach to plant timing. Since it would have been impractical to include a sync generator with each source, a set of signals was defined that would provide the information necessary to generate and process a television picture. The responsibility for generating these signals fell to the master sync generator. These signals were then distributed to each piece of equipment requiring them. They included sync and blanking (used mainly in video circuits) and horizontal and vertical drives (used to drive the sweep circuits in cameras).

The introduction of color meant that a 3.58 MHz subcarrier had to be generated by the same master generator and distributed throughout the plant. In addition, another pulse called a burst flag was needed to gate the color burst. Six separate signals, just to keep everything locked to the same timing reference.

The advent of solid state devices led to a dramatic reduction in the size of the master sync generator. At the same time, integrated circuit logic made it possible to easily derive horizontal and vertical drives and burst flag from sync. Before long, timing input requirements dwindled to sync, blanking and subcarrier on most equipment.

The capabilities of large scale integrated circuit (LSI) technology has made it possible to reduce most of the circuitry required for pulse generation to a single chip. For this reason, most modern equipment has its own sync generator built in. In addition to making stand-alone operation possible, this reduces the input timing reference requirements to a single wire reference such as color black.

Figure 5.4-7 is a simplified functional block diagram of a sync generator. A precision oscillator is used to

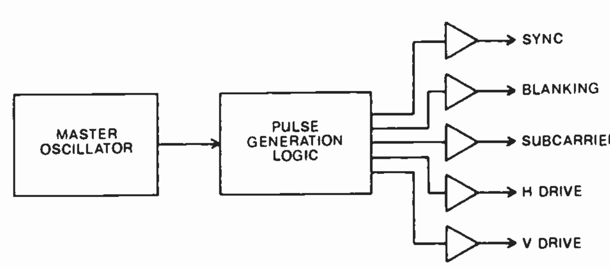

Figure 5.4-7. Simplified block diagram of a basic sync generator.

drive a set of complex logic which generates all of the required timing signals. Buffer amplifiers convert the logic levels to the required 4 V negative going pulses and 2 V peak-to-peak subcarrier.

The FCC requires that subcarrier frequency be maintained within 5 Hz of 3.579545 MHz. Therefore, an ovenized or temperature compensated crystal oscillator is generally employed.

Most modern sync generators utilize a single LSI integrated circuit as the heart of the pulse generation logic. Numerous off the shelf and custom parts exist which have 90% or more of the logic required. External parts are often needed to provide additional features such as variable pulse widths.

All IC logic families produce pulses with very fast rise times. So, in addition to providing the proper impedance and voltage levels, the output buffer stages often include shaping or filtering circuits to control the rise times of the output pulses. Controlled rise times help to ensure the reliable and predictable operation of pulse detection and regeneration circuits in the equipment being driven by the sync generator.

Genlock

A considerable amount of additional circuitry is required to enable a sync generator to lock to a composite video signal such as color black. Figure 5.4-8 shows the basic functional blocks: an input amplifier, subcarrier regenerator, sync separator and video presence detector.

The input locking signal may contain common mode hum or noise which could upset the operation of the circuits which follow. For this reason, a differential input amplifier is generally used, followed by a clamp. Since the locking signal may not always be present, the genlock circuitry usually includes a video presence detector. The output of this detector is a logic level signal which tells the sync generator whether to select the *free run* or *locked* mode of operation.

The buffered and clamped input signal is low pass filtered and then fed to a sync separator which outputs sync and burst gate. The burst gate, along with high pass filtered video, is used to regenerate the 3.58 MHz subcarrier present on the input locking signal. The separated sync and subcarrier drive phase locked loops in the generator. Adjustments of these locking circuits permit the generator phase to be varied with respect to the phase of the input signal.

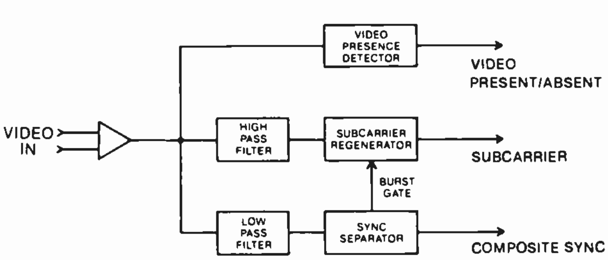

Figure 5.4-8. Simplified block diagram of basic sync generator genlock circuits.

The generator may be genlocked to the input signal in one of two basic ways: by independent locking of sync and subcarrier or dependent locking of these two signal components. With the independent method, the generator's sync and subcarrier locking circuits are continuously referenced to the input signal's sync and subcarrier. With the dependent method, lock is initiated in the same manner as the independent method. But once full genlock is achieved, the input signal's subcarrier is used as a reference for both loops.

An independent locking generator will track the SC/H phase of the input signal. It will also lock to a non-standard color signal (one in which the subcarrier and sync are not phase locked at all). A dependent locking generator will maintain correctly SC/H phased outputs regardless of the SC/H phase of the input signal. It will also lock more reliably to signals with occasional noise hits or with sync-only timebase error.

The once common practice of genlocking the station's master generator to a non-synchronous source such as network has given way to the use of frame synchronizers. However, genlocking is still used in master/slave sync systems where individual sources or groups of sources are driven off slave generators which are locked to the plant's master generator. And, as was previously mentioned, many of today's cameras and VTR's contain their own sync generators which are locked to an external color black reference.

As a result, it is not uncommon to find situations where three or more sync generators are cascaded. This makes it very important that the first generator in the line (usually the plant's master generator) has very good timebase stability. It is equally important that all slave generators exhibit very low jitter. A figure of 5ns or less is typical for timebase stability, while 2ns or less is a reasonable jitter spec.

Where genlocking to an outside source such as network is done on a regular basis, a feature called protected genlock is highly desirable. With protected genlock, the local generator may be locked to an outside source using the independent locking method. Any horizontal timing jumps on the locking signal will not disturb the generator; it will remain frequency locked to the locking signal's subcarrier. If the input signal disappears or reverts to monochrome, the protected genlock logic will instruct the generator to make a smooth switch to the free run mode.

Studio Timing Concepts

In the early days of color, the system designer's attention was focused on the importance of color timing. While timing errors as large as 100 ns could be tolerated in monochrome systems, color systems demanded accuracy two orders of magnitude better. The vectorscope took its place alongside the waveform monitor as an indispensable measurement tool.

As monochrome systems were converted to color, these new timing tolerances had to be addressed. The required degree of precision was not difficult to attain if reasonable care was exercised.

Unfortunately, the importance of the relationship between sync and subcarrier timing, or SC/H phase, were not fully appreciated at the time. It wasn't until the advent of color videotape recording and editing that these issues came to light.

When the NTSC color system was devised, the frequency of the color subcarrier was chosen to be an odd multiple of half the line scanning frequency. This was done so that the subcarrier peaks would occur in alternating positions on adjacent scan lines, thus minimizing the visibility of the subcarrier on monochrome receivers.

The multiplier which was finally chosen was 455/2, or 227.5; this is also the number of cycles of subcarrier per scan line. Since there are 525 lines per frame, there are 227.5 times 525 or 119437.5 cycles of subcarrier per frame. The extra half-cycle of subcarrier means that it takes two frames (or four fields) for the color sequence to repeat.

When a video tape is edited, the machine must ensure that the continuity of this sequence is preserved. If it is not, there will be a noticeable horizontal shift in the picture at the edit point. Many machines incorporate *color framers* to prevent this from occurring. They operate by matching the color framing of the signal recorded on the tape with that of the house reference.

Reliable operation of these color framers is dependent upon the maintenance of consistent SC/H phase throughout the plant. Furthermore, when tapes that were recorded in another facility are edited, the SC/H phase of the off tape signal must match the local plant's SC/H phase. For this reason, an industry wide standard has been established which defines correct (zero) SC/H phase as the coincidence of the 50% point on the leading edge of horizontal sync and the zero crossing of subcarrier (see Figure 5.4-2). Establishing and maintaining correct SC/H phase begins with having a means to measure it. Many modern waveform monitors provide this capability as illustrated in Figure 5.4-9.

Maintaining SC/H phase depends upon careful selection of equipment and periodic measurements of actual performance. Sync generators with low SC/H phase drift are key elements in any SC/H phased plant. It is equally important to avoid system design techniques which might lead to SC/H phase problems (such as the use of regenerative pulse or subcarrier distribution amplifiers). SC/H phase should be checked as routinely as video levels or color phase.

Video Timing Tools

Numerous approaches to plant timing exist, but they all fall into one of two general categories: adjusting the relative phase of the source timing reference or delaying the source video. In general, it is always better to move the timing signal around because even the best video delay systems introduce a certain amount of signal distortion. Obviously, video delay is not a viable solution where a source must be advanced in time with respect to other sources.

Video delay lines are often used when a single source must feed different timing points. This is quite often the case in a system where a source must appear as a direct input to a studio production switcher, but the same source may be selected on a routing switcher which, in turn, feeds the production switcher (see Figure 5.4-10).

In general, it is better to use a delay DA than a passive delay line/video DA combination, because a properly designed delay DA will include circuits which compensate for response errors in the delay elements. Where passive delays are used, they should be of the highest possible quality and the shortest electrical length required to get the job done.

Other devices which can be useful in plant timing are regenerative pulse and subcarrier DA's. They should be applied with caution, however, since they can create system SC/H phasing problems.

Guide to Plant Timing

At first glance, timing a television plant may appear a formidable task. Like anything else, though, the task can be whittled down to size through a systematic method comprised of analysis, synthesis and execution.

Analysis entails the careful examination of the timing requirements in each individual operating area of the plant. This information, along with a clear understanding of the capabilities of the equipment, can be used to synthesize a plan for overall plant timing.

The demands placed on most plants are constantly changing and ever increasing today's special setup may be the standard setup tomorrow. It is important to realize, therefore, that the plan which has been put together so carefully may change. If this happens, it

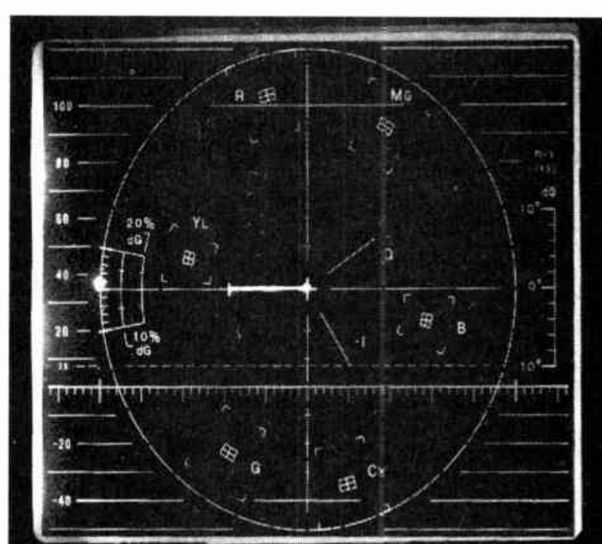

Figure 5.4-9. SC/H phase measurement on the Tektronix model 1750 waveform and vector monitor shows the relation between the burst phase vector and the "sync dot" as either an absolute value or relative to an external reference. Phase may be read out from the graticule or by adjusting and reading calibrated controls. *(Courtesy Tektronix, Inc.)*

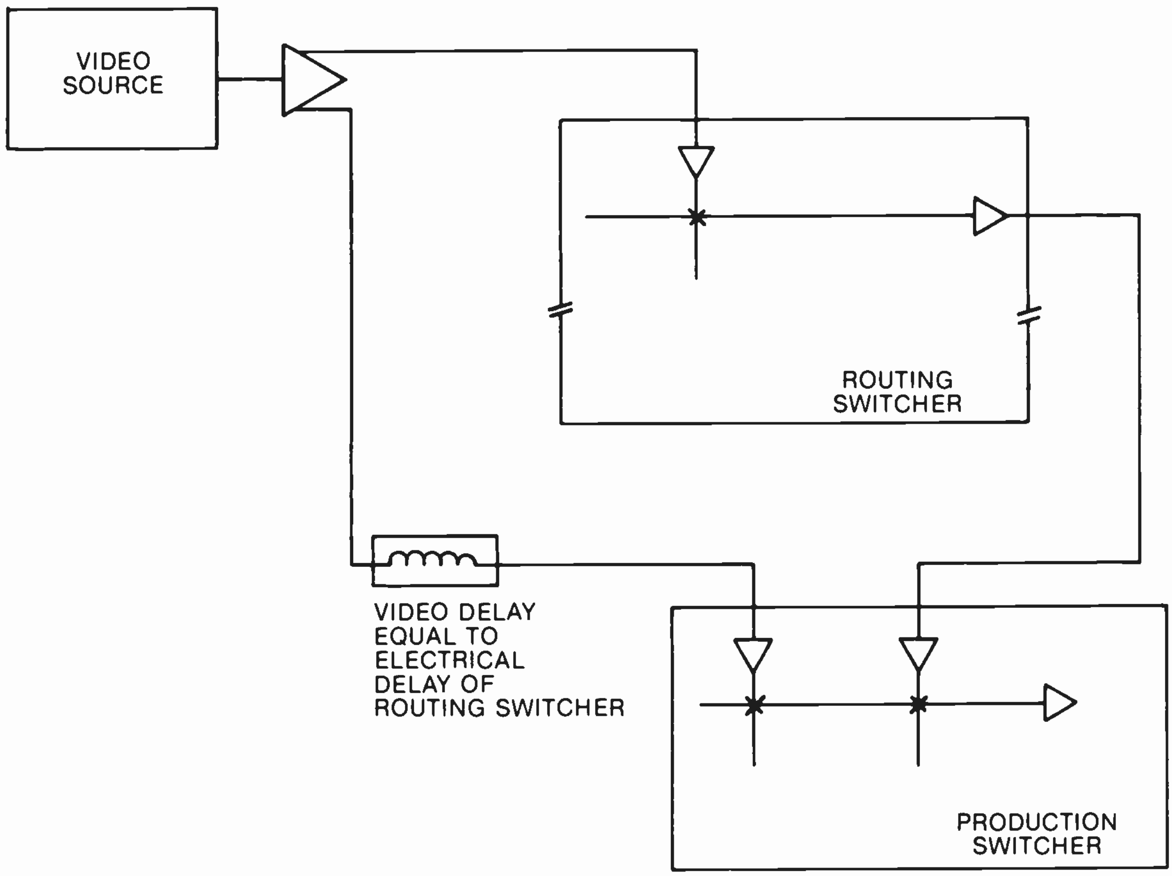

Figure 5.4-10. Timing a single video source to two different timing points.

may be necessary to add or replace equipment or perhaps even alter the system design.

Studio Timing

The studio (or edit suite) is an excellent place to begin a discussion on system timing, since it is the place where proper source-to-source timing relationships is most important. This is due to the fact that the studio is the primary area of the plant where multiple sources are combined. If visible picture jumps and/or color shifts are to be avoided when making mix, wipe or key transitions, all studio sources must be carefully timed.

Timing the inputs to a studio switcher is a very simple, straightforward process:

1. Identify those sources which do not have timing adjustments or whose timing can only be adjusted over a limited range. These will more than likely include the black and background generators in the production switcher itself and may also include test signal generators character generators, and older studio cameras.
2. Using delay DA's or delay lines, match the timing of all of the sources identified in item 1 to the latest in the group of fixed sources. Designate one of these sources as the reference source for setting the timing of all of the adjustable sources. Note that if there is only one fixed source, it should be used as the reference source.
3. Adjust the timing of each of the adjustable sources to match the timing of the reference source.

All timing adjustments should be made by selecting each source, in turn, on the production switcher. An externally referenced waveform monitor and vectorscope connected to the output of the production switcher provide the necessary monitoring capability. Timebase and/or gain magnification should be used on the test instruments to ensure the accuracy of timing adjustments.

The output SC/H phase may change when timing adjustments are made. If the plant is to be SC/H phased, it is imperative that this parameter be checked whenever source timing is adjusted. For equipment that uses separate pulses and subcarrier for timing, care should be taken to maintain a consistent phase relationship between the input sync and subcarrier once the output SC/H phase of the source is established.

If the plant is equipped with multiple studios, the procedures outlined previously should be repeated in each studio. On those sources which feed more than one studio, extreme care should be taken to ensure that cable lengths are made equal. If this is not done, it will be impossible to achieve proper timing in all locations.

Timing in Master Control

For all intents and purposes, master control is just another studio and can therefore be timed using the previously mentioned procedure.

One timing problem which is fairly common in master control is that of studio delay. It generally shows up as a slight timing disturbance when the master control operator switches from a given program source to that same program source through a studio switcher (a common occurrence going into or coming out of a live program such as news). An easy solution to the problem is to resynchronize the output of each studio (see the *Cascading Studios* section of this chapter).

Timing Through an Assignment Switcher

If routing switcher buses are used as input preselectors for a studio switcher, the propagation delay through the routing switcher must be taken into account when timing the plant. This is usually accomplished by setting up both direct and delayed paths for any sources which feed a production switcher both directly and through a routing switcher (see Figure 5.4-10).

In plants where the routing switcher is used for source assignment, it is a good idea to designate the output of the routing switcher as the zero timing point for the plant. If this is done, a bus on the switcher can be designated the plant *quality control point*—one location (with one set of accurately calibrated test instruments) where the signal levels and timing relationships of all sources in the plan can be observed and compared. The generalized timing procedure for studio switchers can be used to time sources into the plant routing switcher.

Cascading Studios

Occasionally, it may be necessary in some plants to cascade studios. In order to preserve overall system timing, the delay through each studio must be taken into account. One approach to keeping everything in time is to time all sources into the first studio *early* by an amount equal to the studio delay. However, if more than two studios are involved and timing into a routing switcher and/or master control are a factor, alteration of source timing may not be practical.

A far better approach is to resynchronize the output of each studio using a frame synchronizer. The timing of each studio can then be set to match that of all other sources in the plant.

A word of caution is in order, however: since nearly a frame of video delay is required to resynchronize a source which is only 100 ns or so *late*, the video from the studio when passed through a frame synchronizer will be out of sync with the audio by approximately 33 ms. While this amount of time difference might not easily be perceived by most individuals, the cumulative effects of several passes probably would be. Therefore, it is a good idea to insert an audio delay line in the program output from the studio.

COMPONENT ANALOG VIDEO (CAV) SYSTEMS

It was once a safe assumption that all video signals throughout a broadcast facility were 1 V p-p standard NTSC signals. However, the widespread use of component analog VTR's in broadcast applications represents a potential challenge to this assumption.

One in. type C and 3/4-in. U-matic VTR's record an NTSC signal on the tape. Half-inch broadcast machines (Betacam, Betacam SP, and MII) record a component analog video (CAV) signal on the tape. These machines have NTSC inputs and outputs and are designed to drop into an NTSC environment, but CAV inputs and outputs are also available.

The chief advantage afforded by this equipment is very high picture quality in a compact, cassette based format. First generation quality comparable to that of 1-in. is possible. The quality of successive generations is good and can be improved considerably if dubbing (and any attendant picture manipulation or processing) is done in the component domain.

In order to extract the most quality from these new tape formats, it is best to avoid repeated conversions to and from the NTSC domain. This can be accomplished quite easily, even in an existing all NTSC plant, by creating CAV *islands*.

CAV camera/recorder units are used extensively in electronic news gathering (ENG) and electronic field production applications (EFP). They are lightweight, relatively low cost, and produce very high quality pictures. Source material recorded in the field is nearly always edited before being used on air. Often, digital effects, captions, and other graphics are added to the finished product. This makes the ENG/EFP edit suite a good model for a CAV island.

The rules of good system design outlined earlier in this chapter apply generally to component systems. There are a few differences, all related to the nature of the component signal itself. NTSC is a one wire system; CAV is a three wire system. All color television signals originate in component form, usually as RGB. The NTSC system was developed to allow these color components to be transmitted over a single transmission channel. And since a single wire is more convenient to deal with than three, NTSC has been the distribution standard as well as the transmission standard. In small islands, the inconvenience of three wires versus one wire is a small price to pay for the enhanced picture quality that CAV offers.

In designing a CAV island, the choice must be made as to which component set the island will be designed around: RGB or Y, R-Y, B-Y. There are pros and cons associated with both, but most system designers lean toward Y, R-Y, B-Y. This is because the Y signal provides a convenient feed for monochrome preview monitors and because the + in. CAV recorders utilize the Y, R-Y, B-Y component set.

In the Y, R-Y, B-Y component set, the Y channel carries the luminance information. The Y channel signal is nominally 1 V p-p and looks very much like a conventional NTSC signal, except that it is monochrome and therefore contains no subcarrier or burst. The other two channels (the color difference channels) contain the color information. They are quite different in appearance from a conventional video signal. First, they do not contain sync. Second, they are bipolar signals with a nominal level of plus/minus 350 mV.

CAV Signal Distribution

When distributing CAV signals, a number of their unique characteristics should be considered. Since they are monochrome signals, overall source timing is not as critical as with NTSC. Therefore, rather than being concerned with timing accuracy to within a nanosecond, the system designer can think in terms of ten or more nanoseconds. Interchannel timing should be maintained as tightly as possible in order to prevent picture impairments due to differences in luma/color timing. Also, the bipolar characteristics of the color difference signals must be preserved throughout the system. Blanking level must be maintained as close to 0 VDC as possible. Since the color difference signals do not contain sync, clamps or dc restorers cannot be used. Instead, it is best to use straight dc coupling. Many DA's and switching systems offer this capability, usually by setting straps or jumpers. Further, interchannel gains should be closely matched and maintained as tightly as possible. Interchannel gain errors or dc shifts will result in color errors in the final picture. These errors can be avoided through careful setup and maintenance of system levels and the selection of distribution and switching equipment with good gain and dc level stability.

Interformat Conversion

Regardless of which component set is selected for the design of the island, some interformat conversion will undoubtedly be required. For example, assume that a CAV edit suite is designed around the Y, R-Y, B-Y component set. Integrating an RGB character generator into such a system will require interformat conversion from RGB to Y, R-Y, B-Y. This is a relatively simple process which can be accomplished using a variety of commercially available products.

In some instances, conversion in the other direction, from Y, R-Y, B-Y to RGB, might also be required. Fortunately, this is also a relatively simple process.

Conversion between the CAV and NTSC environments may also be a consideration. In a CAV edit suite, for example, it may be necessary to import or export NTSC signals. This can be accomplished quite easily by means of the tape medium. But if real time ingoing and outgoing NTSC feeds are anticipated, decoding and encoding equipment will be required. Commercially available NTSC decoders and encoders span a wide price and capability range. In choosing among the alternatives, the system designer must carefully evaluate the level of performance required.

There are basically two types of decoders: *notch filter* and *comb filter*. Notch filter decoders are relatively inexpensive and are fairly good at removing residual subcarrier from the luminance information. The basic characteristics of a notch filter do cause some loss of horizontal resolution in the luminance channel. Comb filter decoders are more expensive but provide excellent suppression of residual subcarrier. Luminance horizontal resolution is not usually affected, but apparent vertical resolution can be impaired, especially in areas of the picture where there are sharp horizontal transitions.

A third type of decoder, the so-called *adaptive comb filter decoder*, combines the best characteristics of both types of filters. Adaptive decoders contain circuitry which dynamically selects the most appropriate filter characteristic, notch or comb, based on picture content. As might be expected, adaptive decoders are relatively expensive.

A similar range of choices exists with respect to NTSC encoders. Inexpensive units employ simple filters, while more expensive units employ more complex filtering techniques. The quality of the encoded picture varies directly with the cost of the box.

Other CAV System Considerations

Unfortunately, there is not a universal standard for CAV. One area of considerable variability is the precise signal levels for the Y, R-Y, B-Y component set. At the time of this writing, there are three standards: SMPTE/EBU, Betacam, and MII. The differences between these standards are relatively small and fall within the adjustment range of all affected equipment within the CAV system.

Timing within a CAV island is relatively straightforward. If the island is to be timed into a large plant, there are certain things which must be taken into account. Chief among these is decoder delay. A simple notch filter decoder will have an electrical length of several hundred nanoseconds. An adaptive decoder may be as long as several horizontal lines. If decoded feeds are to be in time with sources local to the island, the entire timing reference for the island must be delayed (with respect to plant zero time) by an amount equal to the decoder delay. This can be accomplished quite easily through the use of a dedicated sync generator for the island. This generator would be locked to plant sync and adjusted to provide the correct amount of delay.

If the output of a CAV island is to be timed into the plant, the island sync generator could be adjusted to advance the timing within the island by an amount equal to the delay through the encoder placed on the output of the island. If the island is to be fully timed into the plant—on both the input and output side—the island output would have to be re-synchronized using a frame synchronizer.

Test and monitoring in the component domain requires specialized equipment. Conventional NTSC equipment is not suitable. Manufacturers offer a range of equipment specifically tailored to CAV applications.

Figure 5.4-11 depicts a representative CAV edit suite and illustrates some of the concepts covered in the text.

DIGITAL SYSTEMS

Digital video equipment has been around for many years. Electronic character generators, first introduced in 1970, were among the first devices to use digital technology. The first video product to employ digital circuits for signal processing was the timebase corrector, introduced in 1974. The first digital frame synchronizer followed in 1975, and the first digital video effects system in 1976.

This equipment used digital technology for one of two reasons: the superiority of a digital solution over analog (TBC's), or the inherent impracticality of an analog solution (frame synchronizers). All of these early devices were intended to be used in an analog environment and therefore had no digital I/O.

As the variety of commercially available digital video equipment increased, so did the interest in digitally interconnected video systems. The push for digital I/O shifted into high gear in the mid 1980's with the impending availability of the digital videotape recorder (DVTR). In 1987, when the first commercially available digital recorder was introduced, many manufacturers had already incorporated digital I/O into their products.

Digital Video Standards

The majority of digital video equipment available today is equipped with both analog and digital I/O. Digital interconnectability has been made possible by a set of internationally agreed upon standards, many of which have been prompted by the standardization of digital video recording formats.

Digital video equipment exists for both component and composite systems. The first digital video recording format, the so-called D1 format, records a component signal on the tape. Most high quality digital video effects and electronic graphics systems employ component processing. Therefore, if these devices are equipped with digital I/O, it is likely to be component digital I/O. Component signals which have been recorded digitally suffer virtually no degradation from generational losses or encoding/decoding artifacts. This is why component digital is the format of choice for critical graphics work or high end post production.

The high cost of D1 VTR's have made them prohibitively expensive for use in many applications. For example, program and spot playback in broadcast facilities. The need for a more economical digital videotape format prompted the development of two composite digital formats, D2 and D3.

Since then, a number of additional digital video recording formats have been introduced, and all are component formats. They include D5, D6, DCT, Digital Betacam, DVC Pro, and Digital-S.

Interconnection Conventions

Initially, parallel interconnect was the only method available to the digital video system designer. The SMPTE 125M and 244M standards specify a method which uses a separate pair of wires for each data bit and a separate clock. The connector called out in these standards is a 25 pin "D' connector. SMPTE 125M is the standard for component equipment and systems. SMPTE 244M is applicable to composite equipment and systems.

There are numerous drawbacks to the parallel interconnect method. First, the cable is considerably more expensive than coax, both in terms of the cost of the raw cable and the cost of applying connectors to it. Second, the cable and connectors are more bulky than coax. Finally, the distance over which parallel data can be reliably sent is limited to 100 meters maximum.

For these reasons, the vast majority of digital video equipment available today is equipped with serial I/O. SMPTE 259M specifies the mechanical and electrical characteristics of this interface as well as the formatting of the serial data stream. The connector called out in the standard is the familiar BNC. The data rate for serialized composite digital signals (525/60 NTSC standard) is 143 Mbits/sec. The data rate for component digital is 270 Mbits/sec.

Integrating older equipment with parallel I/O into a serial digital system may be accomplished using external conversion devices. Standalone serializers and deserializers are available from a number of different manufacturers.

Standard high quality video cable such as Belden 8281 may be used for serial digital interconnects. Cable manufacturers have begun to introduce cable types that are designed specifically for serial digital video. Belden 1505A is one example of such a cable. Because of the high data rates involved, a low loss double shielded cable is recommended. Runs of up to 300 meters are possible with low loss cable.

Serial digital interconnect cables should be terminated in high quality 75 Ω BNC connectors. For many years, it has been a common practice to use 50 Ω BNC connectors in analog systems. Depending upon its design, a 75 Ω female BNC connector may be damaged when mated with a 50 Ω male BNC. This is due to the larger pin diameter on the 50 Ω connector. Therefore, when existing analog system cabling is used to interconnect serial digital equipment, 50 Ω connectors should be replaced with 75 Ω connectors.

When distributing serial digital signals, plan on using a distribution amplifier. Because of the high data rates, passive loop throughs are not possible on serial digital equipment. Some equipment may have active loop throughs, but this is the exception rather than the rule.

Impairments in Serial Digital Systems

Digital video signals are more robust than analog signals and are therefore less susceptible to hum, noise,

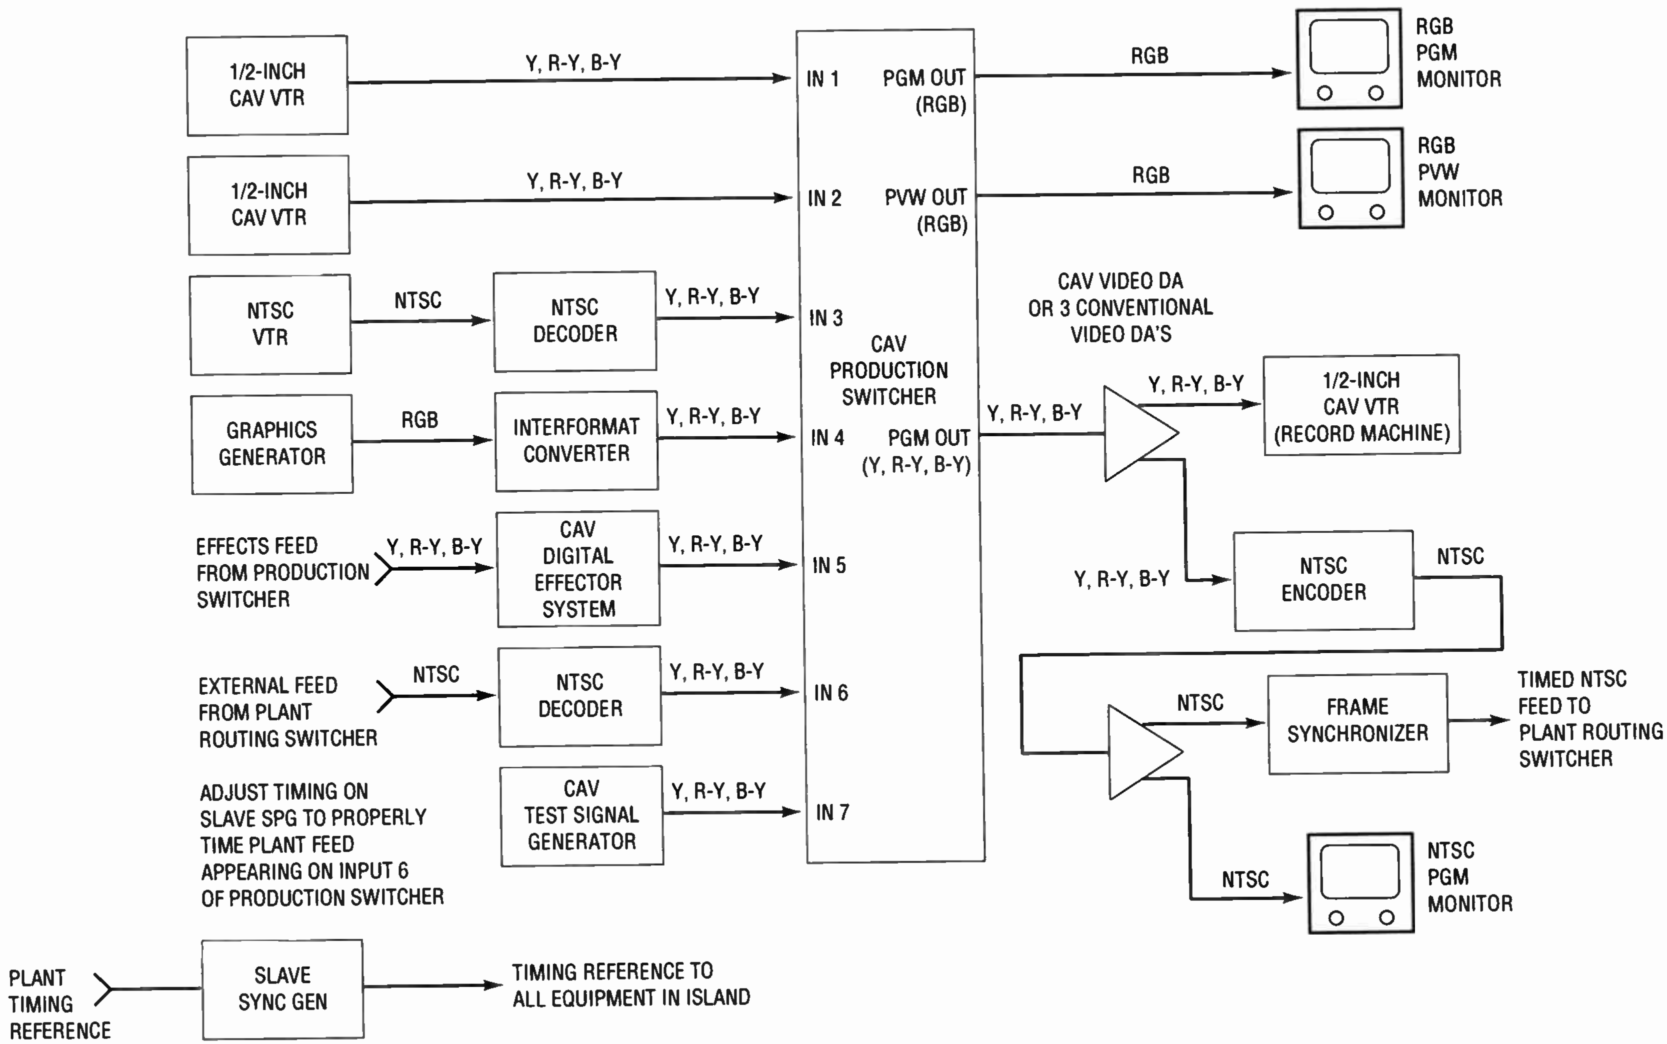

Figure 5.4-11. A typical CAV *island* within an NTSC plant.

crosstalk and other such impairments. Gain variations, frequency response errors and drift are analog problems which disappear in the digital environment.

Cable equalization is still required, but it is of a much different sort than that required in analog systems. Analog cable equalizers must be designed to ensure flat response from nearly dc to 8 or 10 MHz. There is very little low frequency information in a serial digital signal, so the cable equalizer can be designed to compensate primarily for high frequency losses. Flatness of frequency response is not important. And since the data stream can be (and usually is) regenerated, gain adjustments are not necessary. In practice, in a properly designed digital system, all cable equalization and gain adjustments are automatic.

One problem which may occur in serial digital systems which is unique to the digital domain is *clock jitter*. The serial digital signal contains an embedded clock signal which must be extracted to recover the data. As the signal passes through various devices in the system, the data stream may be subjected to repeated regeneration. This has the potential of adding significant jitter to the signal, making clock recovery difficult if not impossible. The solution to this problem is to deserialize the signal then reserialize the parallel data using a stable clock.

Figure 5.4-12 illustrates how jitter affects the serial digital signal. The waveforms show the characteristic eye pattern that is associated with a self clocking serial data stream. The waveform on the left is of a clean, jitter free signal. The eye pattern is well defined. The waveform on the right is of a signal with a moderate amount of jitter. The eye pattern is less defined and the horizontal opening in the eye pattern is closed.

Serial Digital Distribution Amplifiers

A variety of different types of distribution amplifiers are available for serial digital systems. Even the simplest models, designed primarily for use as fan-out amplifiers, have automatic cable equalization. This is because all of the commercially available serial digital receiver IC's have this function built in.

Simple fan-out DA's should be used in applications where reclocking is not required or desired, that is, where the input signal is relatively jitter free. Typical applications would include output fan-out on a VTR, character generator, test signal generator or other source device.

Reclocking DA's should be used in applications where the input signal has jitter in excess of the maximum allowed by SMPTE 259M, 500 ps peak-to-peak. Typically, this would be the case in portions of the signal path that are farthest downstream from the signal source.

There is a phenomenon in digital systems called the *cliff effect*. The term refers to the fact that digital signals do not gradually degrade the way analog signals do. Instead, they suddenly and abruptly fall off the edge of the cliff. One way of monitoring the integrity of a digital signal and to avoid the cliff effect is to measure the bit error rate at various points along the signal path. *Error detection and handling* (EDH) is a method for monitoring and reporting errors in digital systems. It is documented in detail in SMPTE RP-165.

EDH uses hardware to calculate a checksum which is inserted in the auxiliary data space of the serial digital signal. When an EDH coded bit stream traverses a signal path, EDH-enabled hardware can be used to monitor the signal for transmission errors and flag them when they are detected. Serial digital DA's with EDH capability are available from several manufacturers.

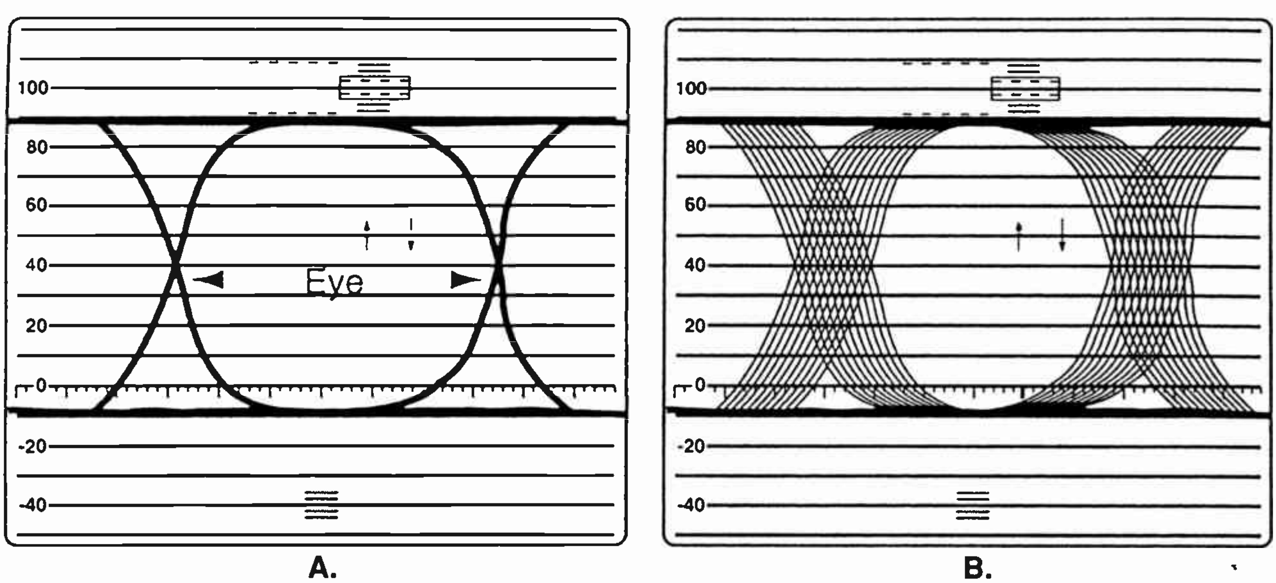

Figure 5.4-12. Eye pattern displays of a serial digital signal, without jitter (left) and with jitter (right). *(Courtesy of the Grass Valley Group)*

Another variety of special purpose DA's of interest to the systems designer is the serial digital DA with analog monitor outputs. Many of the larger color monitors used for program or preset monitors in a control room are available with serial digital inputs. However, most of the smaller monochrome monitors used for source preview monitors have only analog inputs. Using a separate digital to analog converter is one solution to this problem, but it is an expensive one. A far more economical alternative is to use the aforementioned specialty DA whenever an analog monitor feed is required.

Serial Digital Switching Systems

Serial digital video is nothing more than very high speed data. Routing switchers designed to handle serial digital video employ technologies and design philosophies that are radically different from those employed in analog switchers. Switching elements are typically 16x16 (or larger) high speed monolithic crosspoint arrays. Multibus routing switchers are therefore nearly always matrix oriented designs.

Serial digital designs are more compact than comparable analog systems. This is partly due to the density of the digital crosspoint technology, but is also due to the fact that crosstalk in a digital matrix is not as serious a design consideration as it is in an analog matrix. Therefore, digital systems can be packaged more densely.

Important factors to consider when selecting a serial digital routing switcher include: maximum data rate required, discrete data rates supported, expandability, compatibility with other types of matrices (digital audio, analog video, and analog audio) and control system capability.

In an all 4fsc facility, the maximum data rate required is 143 Mbits/sec. However, since 4fsc equipment is not likely to play a significant role in the future of broadcast television, new installations should be built to accommodate the higher bit rates required for component digital signals: at least 270 Mbits/sec, and preferably 360 Mbits/sec.

Many digital routing switchers contain reclocking circuits which are bit rate dependent. Therefore, it important to ensure that any new system can accommodate all standard bit rates up to the maximum rate supported.

The expandability of a routing system should always be given careful consideration. In addition to knowing what the maximum matrix size is, system designers must understand how the system is architected and what will be needed to expand it. In many systems, input fan-out amplifiers, secondary switching matrices, and considerable cabling are needed when expanding beyond a certain size. It is best to have knowledge of these requirements when the initial installation is done, so that they can be planned in advance.

Another important factor to consider is compatibility with other types of matrices. In a transitional, hybrid analog/digital facility, it is often a requirement that the central routing system be capable of handling analog video and audio as well as digital video and audio. Not all matrices need be purchased from the same manufacturer, since many companies provide protocol translators to interface their systems with those from other manufacturers.

The possibility exists in a serial digital routing system to route multiple channels of digital audio along with the video. This technique, commonly referred to as *embedded audio*, is described in detail in SMPTE 272M. Basically, digital audio is formatted into the serial digital video stream during the vertical blanking interval. Embedded audio can provide significant cost savings over separate audio, provided there are enough sources and destinations in the facility which have embedders and disembedders built in. If external devices have to be used to perform these functions, their cost can easily offset any savings in the routing and distribution system.

Timing Considerations

Precise timing is a necessity in analog video systems, particularly where multiple signals arrive at a single point where they will be combined—for example at the input of a production switcher. This is typically not a requirement in digital systems. Most digital switchers and video effects devices have an input timing window with in which all signals are expected to fall. Manual, and in some cases automatic, adjustment is provided to precisely time the signal for the internal processes which the device performs.

Digital signal processing involves longer time delays than analog. As an example, a large analog production switcher has an input to output delay of 500-600 ns. In comparison, its digital equivalent has a delay of a line (63.5 μsec) or more. In order to deal with delays of this magnitude, the systems designer will need correspondingly longer delay lines.

Digital video effects devices typically exhibit throughput delays of either a field or a frame. Delays of this magnitude can create lip sync problems with companion audio, not unlike that which broadcasters experienced with the advent of the frame synchronizer. The system designer should take care to ensure that companion audio signals be delayed to match any video signals which are subjected to very long processing delays. Fortunately, delays of several lines up to a frame or more can be implemented cost effectively in the digital domain.

Generally speaking, plant timing in a digital facility (or in a hybrid analog/digital facility) can be approached in the same manner as described earlier in this chapter for an analog facility. Key points to remember:

1. Establish correct source timing at the zero timing point of each studio or island. This is usually the program bus of a production switcher.
2. Establish a zero timing point for the whole facility. This is usually a reference test bus on the master routing switcher.
3. Time the outputs of all studios and islands into the master routing switcher. This usually involves adjusting the phase of the slave sync generators in the studios/islands.

4. Time studio or island sources that appear as direct inputs on the master routing switcher. This usually involves adjusting delay lines which compensate for the delay through the studio/island.
5. Use frame synchronizers to time external non-synchronous sources and studio reentries.
6. Insert lumped delays in any audio circuits as needed to maintain proper lip sync.

ADVANCED TELEVISION

In 1982, the Advanced Television Systems Committee (ATSC) was formed to develop standards for an advanced television system for deployment in the United States. At the time, analog HDTV was being tested on an experimental basis in Japan, and Europe was engaged in the development of its own analog HDTV system. See Chapter 1.11, *DTV Standard*, for more history of the process.

The U.S. DTV Standard

In December of 1996 the FCC adopted essentially all the ATSC standards for digital television. The new standard supports both high definition television (HDTV) and standard definition television (SDTV) in a variety of different scanning formats. The standard also supports multichannel surround sound and data broadcasting. At the time of this writing, there is considerable debate about how broadcasters will choose to program this new service. Two basic options exist: a single HDTV program or multiple SDTV programs for each DTV channel. The most likely scenario is that there will be a combination of both.

DTV System Issues

Uncompressed high definition video requires approximately 1.5 Gbits/sec of bandwidth. Networks and stations that opt to produce and distribute HDTV programs will be faced with many technical challenges. Even though several manufacturers have built or plan to build digital HDTV cameras and VTR's, very little switching and distribution equipment exists outside the laboratory.

The situation is entirely different with respect to SDTV. Existing 270 or 360 Mbit/sec switching and distribution equipment will easily handle digital SDTV. This same infrastructure could be used to distribute compressed HDTV signals within a facility. A compression ratio of approximately 4 to 1 would provide sufficient bit rate reduction while minimizing the effects of cascaded compression codecs.

The transmission bit rate specified in the DTV standard is approximately 19 Mbits/sec. To fit a single HDTV or multiple SDTV programs into this bandwidth requires a high degree of compression, approximately 75 to 1. It will not be possible to decompress such a signal and recompress it without serious picture degradation. Therefore, new techniques will be required to perform simple operations such as video mixing and keying when dealing with highly compressed bitstreams.

Switching compressed MPEG-2 bitstreams is also a nontrivial task. The MPEG-2 compression scheme utilizes I, P, and B frames to achieve a high degrees of bit rate reduction. I frames are complete descriptions of a scene, but P and B frames contain only changes since the last I frame. The sequence of I, P and B frames generated by an MPEG-2 encoder changes dynamically with scene content. Therefore, it is not possible to perform a deterministic switch between two MPEG streams. The two streams must be spliced according to a complex set of rules regarding the frame sequences of both.

Solutions will be developed for many of these system problems as the DTV build out progresses.

5.5
MAGNETIC AND OPTICAL RECORDING MEDIA

JOE GREGA
QUANTEGY, INC., PEACHTREE CITY, GA

INTRODUCTION

Recording media has been in existence since magnetic wire recording was invented by Valdemar Poulsen in 1898. The idea of recording on media has resulted in continual evolution of magnetic tape and the introduction of magnetooptical and optical recording media and systems. Historically, data storage requirements have doubled every year and this trend is expected to continue. The next step in the evolution of recording media may be a few years away; it may be charged particle technology using specifically focused ion beams, blue laser optical tape or some other type of new technology.

This chapter focuses on the primary or most common formats of magnetic or optical recording media. The technology or principles of the media types reviewed will cover the majority of the recording media formats that are not reviewed. The most significant trend affecting the entire recording media business has been the storage of more information in less space (packing density). This trend is expected to continue regardless of the media used. Recording technology companies are on a never satisfied quest to increase storage densities, in smaller form factors, and to increase read, write and retrieval speeds.

When selecting a media for an application there are many options and many criteria to consider. Table 5.5-1 provides a basic comparison of a several different types of media.

Brief History of Magnetic Recording

The recording systems of today are based upon the pioneering work of a number of individuals and companies. Some of the more prominent include the following:

- 1888 Principle of magnetic recording discovered by Oberlin Smith
- 1898 Magnetic wire recording invented by Valdemar Poulsen
- 1912 Lee DeForest invented the vacuum tube
- 1927 ac bias discovered
- 1931 Blattnerphone steel band recorder used by the BBC
- 1935 I.G. Farben (BASF) makes tape with iron oxide powder on a plastic film AEG-Telefunken develops the Magnetophone tape recorder
- 1946 The German Magnetophone is demonstrated in the U.S. by Jack Mullin of AMPEX
- 1948 First U.S. audio tape recorder is introduced by AMPEX model 200
  First U.S. magnetic tape is introduced by 3M and Audio Devices
- 1951 Stereo tape recorder, Magnecord (1250) introduced
- 1956 November 30, first broadcast of a videotaped recording, Douglas Edwards and the News.
  The computer hard disc is introduced
- 1958 Color videotape recorder is introduced
- 1963 Philips introduces the audio cassette
- 1975 SONY Betamax is the first successful consumer videotape recorder
- 1981 Camcorder is introduced
- 1984 The audio CD is introduced
- 1986 DAT audio format introduced
- 1992 Audio Data mini disc format is introduced
- 1994 Recordable CD format is introduced
- 1996 Digital versitile disc is introduced

OPTICAL RECORDING MEDIA

The use of optical media has become more widespread since the consumer introduction of the audio CD in 1984. While magnetic tape is still the most popular or commonly used form of removable recording media, its ability to increase packing density appears more limited than optical media and its future, therefore, is limited.

Optical recording media reads and writes information by different means. Reflectivity and Keer effect are the basics underlying principles of optical media. ROM type media is read as the pickup reads the intensity of the reflected laser beam as it is changed by the pit and land surfaces. The signal received from the disc depends on both changes in reflectivity and the polarization angle of the reflected light (Kerr effect). Chemical and physical changes in the dye layer result in changes in reflectivity contrast.

Optical Recording System Description

An optical media system is composed of the following basic components:

- Media drive mechanism—powers the laser, supplies the error correction code, controls the optical head and disc media motor. It also consists of the electron-

ics that amplifies the signal and the performs signal processing.

- Optical (send/receive) head consists of the laser light source, an optical system to focus the laser and a detector to convert the returning light to an electronic signal. Figure 5.5-1 shows the basic components of the optical head.
- Optical media. There are three basic types of optical media, CD-ROM, WORM and erasable.
- Computer system and interface—provides data from numerous sources and controls basic computer functions.
- The amount of data that can be stored on a given disc depends on the computer system and optical drive system.

Optical Recording Media

It is necessary to discuss optical media by a number of defining terms, such as form factor, functionality, and capacity; for example a 130 mm 2.6 GB magneto-optical disc. To more completely describe an optical disc, the following five items should be specified:

- **Form factor.** Describes the physical dimensions of the disc itself and does not include the cartridge dimensions. Common sizes of discs are 3.5 in. (90 mm), 4.72 in. (120 mm), and 5.25 in. (130 mm).
- **Functionality of disc.** ROM = read only—cannot write or erase. WORM = write once read many—can write once and read but not erase. Rewritable = can write, read, and erase many times.
- **Read/write methodology.** Embossed, organic dye, ablative, phase change, magnetooptical.

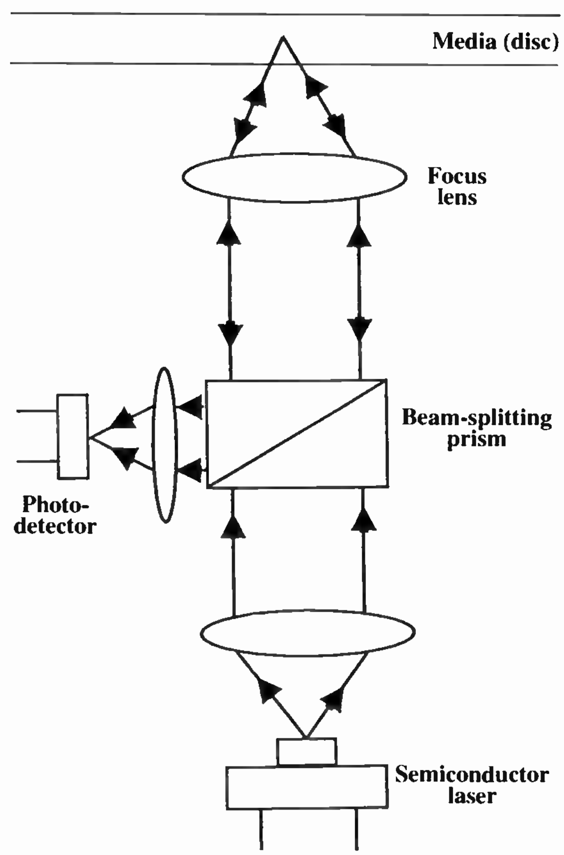

Figure 5.5-1. The basic components of the optical head.

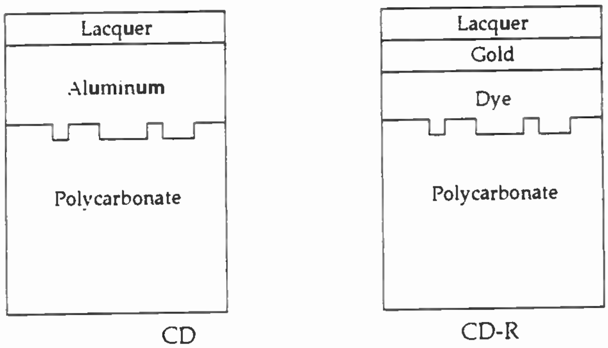

Figure 5.5-2. The basic differences between a typical CD-ROM disc and a CD-R (recordable) WORM disc.

- **Format.** Usually defined at three levels: 1) low level allows the drive to recognize the disc through physical sector layout; 2) defect management and embossed track and sectors; 3) high level formatting provides application-specific formatting.
- **Capacity.** Specified by total storage capacity and sector size, for example, 2.6 GB at 1024 bytes per sector for data application discs, and by recording time in minutes for audio and video discs.

Optical Disc Functionality

ROM devices cannot be rewritten or erased. Laser disc, prerecorded audio CD, computer software CD, prerecorded Mini Disc, and prerecorded DVD discs are examples of this type of media. ROM media consists of a series of pits of varying length that are formed as the polycarbonate substrate disc is molded. Once a CD-ROM disc has been molded the data cannot be altered. A thin reflective film is coated onto the pit surface of the substrate. When light is focused on the pit, it is scattered by edges of the pit. Light reflected from the area between (the land) the pits are scattered very little. The difference between the non-scattered and scattered light is sufficient to be read by the detector. Figure 5.5-2 shows the basic differences between a typical CD-ROM disc and a CD-R (recordable) WORM disc.

WORM discs are best known as the CD-R format, which has become popular for computer storage applications. They are ideal for distributing large amounts of information. The newest technology addition to this group is the DVD-R. WORM discs have a special reflective layer which is melted by the laser to form a pit or hole in the reflective layer. During the forming of the pit or hole the laser is operating in a high power mode. Chemical and physical changes in the dye layer result in changes in reflectivity contrast. The reflectivity difference between the hole or pit and the reflective surface is read by the detector. Figure 5.5-3 illustrates the read and write technology of an Ablative WORM disc.

WREM (write-read-erase memory) is also called erasable or rewritable. Data can be written, erased, rewritten and erased as many times as desired. Magnetooptical media is one form of WREM media that has become popular in recording systems because it can be erased and rewritten over one million times. Examples of rewritable discs are 3.5″ MO, 5.25″ MO, Mini Disc Data, and DVD-RW discs.

Rewritable optical discs can be written on and erased just like floppy discs. Rewritable MO discs are ideal for a variety of uses, ranging from personal computing to video applications such as short-form segment storage.

Magnetooptical Media

The MO disc has a number of layers stamped into its surface during manufacture. In MO technology, magnetic and optical principles work together to enable hundreds of megabytes of data to be stored over many decades without data loss. The Magnetooptical recording process is based on two principles: 1) a magnetic materials coercivity (its resistance to changing magnetic orientation) drops when heated, and 2) laser light polarization is rotated when exposed to a mag-

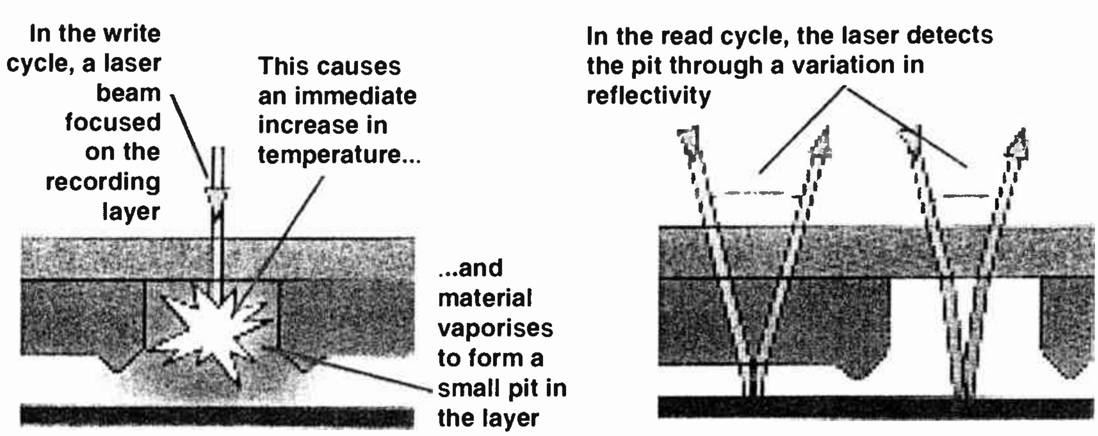

Figure 5.5-3. Read and write technology of an Ablative WORM disc.

netic field. The signal received from the MO disc depends on both changes in reflectivity and the polar Kerr rotation. High data storage is achieved because each data spot is identified by the narrow wavelength of laser beam. At the focus of the beam the local temperature of each spot increases to 200° C, and its coercivity drops from 8,000 Oe to less than 200 Oe. At such a reduced coercivity level, it requires the influence of only a low intensity magnetic field to alter the magnetic polarity of each spot. The information to be stored on the disc is coded by the sequence of north and south polarities, each representing a binary state of "0" or "1."

Figure 5.5-4 shows the basic differences between ROM, WREM, and MO discs. During MO recording, data is written onto the disc when a laser beam is focused to a spot (1 μ) on the spinning disc. The laser heats the magnetic material to the Curie point temperature, the threshold at which its coercivity drops. A magnetic head on the opposite side of the disc is driven by the digital signal to be recorded. The spot heated by the laser takes on the magnetic orientation given by the head. The laser beam in MO does not encode the magnetic material, it only heats the medium to make it more easily magnetized. A switchable electromagnet is used to record the data as either "1s" or "0s." In conventional MO drives, the laser is pulsed while the magnetic bias field, which determines the magnetization of the recording layer, is held constant (see Figure 5.5-5).

During playback, a lower power laser beam is reflected from the spinning disc where it is exposed to the magnetic fields on the recorded disc. These magnetic fields rotate the laser beam's polarization (Keer effect). The reflected beam can be of two alternating polarizations as a result of the north-south or south-north recorded magnetic fields. A polarizing beam splitter directs the two polarizations to photodetectors.

Separate erase and verification passes are usually required before re-recording can be done on a previously recorded MO. Technology to allow direct overwrite has been developed using a few different meth-

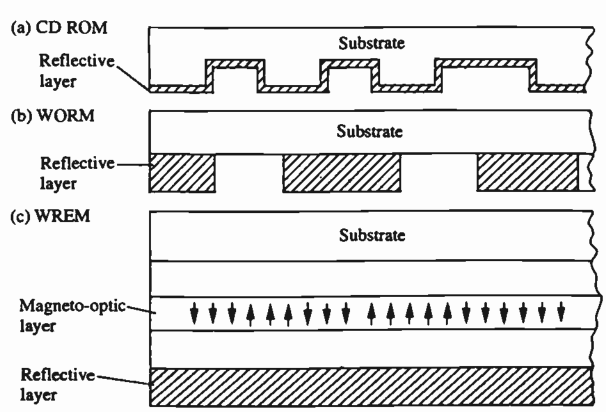

Figure 5.5-4. The differences between ROM, WREM, and MO discs.

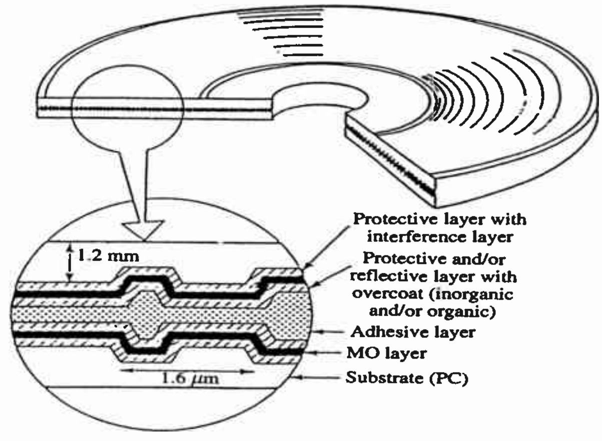

Figure 5.5-5. The conventional MO drive.

ods. MO discs are usually formatted for three distinct purposes. Embossed track and sector formatting and defect management area (DMA)/bad sector formatting are performed at the factory before the disc is shipped. System specific formatting is performed on the actual hardware to be used. Storage capacity of optical media is a function of track pitch, laser beam wavelength, objective lens numerical aperture, data encoding technique, data storage linear density and data storage user area.

There are two types of MO disc compatibility: drive compatibility and logical format compatibility. As long as the device driver and formatting software are recommended by the drive manufacturer there should be no compatibility issue. Optical jukeboxes (or autochangers) utilize a robotic device to insert and remove the optical media from an optical device. Optical jukeboxes are typically used with MO drives and provide as much as 79 Gb of near-line storage per unit. These devices are finding acceptance in most of the standard MO application environments.

Mini Disc

The Mini Disc (MD) is a 2.5 in. optical disc that stores 74 minutes of digital audio. It has a frequency response of 5 Hz to 20 kHz, a dynamic range of 105 dB, and a sampling rate of 44.1 kHz. Mini Disc is not CD compatible as it employs data compression. The MD format uses two types of media: ROM media for prerecorded software and audio and magnetooptical disc for recordable blank discs. The magnetooptical drive is similar to other drives already in use with the added capability of direct overwriting, previously recorded data can be erased and new data written at the same time. To ensure compatibility between discs and players, recordable discs are manufactured with grooves. These grooves guides the writing and reading laser within a spiral track that is 1.1 microns wide. These grooves contain a wobble to create addresses in 13.3 ms intervals (see Figure 5.5-6).

The MD was introduced in 1982 and was targeted at the analog audiocassette and the digital compact

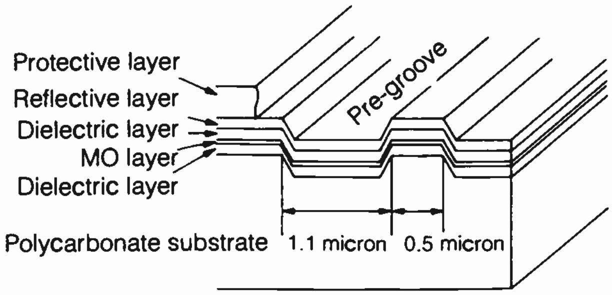

Figure 5.5-6. The Mini Disc.

cassette (DCC). The MD is a consumer product that has the potential of completely refocusing retail music business. It offers the best of features of cassettes and CDs—high sound quality, random access, durability, portability, convenience, shock resistance, and recordability. Professional 4 track systems offer 16 bit audio, MIDI time-code and 37 minutes of recording time of four track mode.

The Mini Disc is also available in a data version for use with the newly developed MD Data Drive format, appropriately called MD Data Disc—with a capacity of 140 MB, a transfer rate of 1.2 Mbps and an average seek time of 300 ms. The MD Data Disc is specifically formatted for data recording and cannot be used for audio recording.

Digital Versatile Disc (DVD)

The Digital Versatile Disc is the latest entrant into recording disc technology. This format actually represents a family of discs using the DVD format and performing different functions.

A DVD-ROM disc is constructed in the same basic way as any ROM disc. The technology of the head and disc has improved and thereby increased the capacity of the data that is stored on the disc. The DVD-ROM format has a capacity of 4.7 GB per side. The DVD-ROM disc is being used for video and software distribution and an audio DVD will soon be available. DVD-R or DVD-RW (rewritable) writers and discs are beginning to appear in the marketplace.

The DVD-R disc is a write once media and depending on the type of data recorded may be capable of being played back on DVD-ROM players. In its initial version, the DVD-R disc will be capable of recording 3.95 GB per side, or six times the capacity of a CD-R disc. Data can be written at 11.08 Mbps, or nine times a CD-R's 1X speed. The write technology employed is similar to that used by CD-R except that the data can be written at a higher speed and the recording density is much higher. To achieve the six times increase in density two components of the recording hardware were changed. The wavelength of the laser was changed to red laser with a wavelength of 635 nm. In the case of CD-R the laser is infrared with a wavelength of 780 nm. The numerical aperture of the lens was improved to 0.5 from 0.6. These changes allow a DVD-R disc to record marks as small as 0.44 um as compared to 0.834 um for CD-R. The recording action happens by momentary exposure of the recording layer to a high power laser (approx. 10 mw) beam that is tightly focused onto the surface. The heated dye polymer layer and is permanently altered so that microscopic marks are formed in the pregroove. The light intensity of the recording laser is tuned to a wavelength of light that is not effected by exposure to ambient light or playback lasers. Playback occurs when a low power laser, of approximately the same wavelength, is focused onto the disc. Figure 5.5-7 shows the basic footprint of the DVD-R.

MAGNETIC RECORDING TAPE

Magnetic tape has been used for over 50 years as a recording media. Since its introduction magnetic tape has evolved in many aspects and diverged into many different types of tape. Particulate iron oxide coating has been the backbone of the magnetic recording industry for most of these 50 years. As recording technology has evolved the magnetic tape has had to evolve to increase its packing density. The ability of magnetic tape to increase in information packing density has been possible through improvements in magnetic particle and recording head technology. Smaller sized magnetic particles and more consistently sized (narrow distribution) particles in combination with improved formulation chemistry and processing procedures have aided the ease of manufacture of these smaller particles. Initial development to improve packing density was focused on increasing the magnetic coercivity of the oxide itself, by increasing the amount of magnetic oxide in the coating and by changing the type of magnetic material. The magnetic portion of a typical particle is approximately 50 volume percent. The actual magnetic part of a typical magnetic coating may be as low as 31 volume percent. Pure iron (metal particle) began to appear in the industry in the mid-eighties. These particles are pyrophoric by nature (they spontaneously burn on exposure to air) so the outermost layer are treated (coated) by the manufacturer. The resultant particle is 74 volume percent magnetic in a coating that contains 45 volume percent magnetic material.

The orientation of magnetic particles greatly determines the recording properties of magnetic tape. Developments in coating and processing technology to improve the orientation have contributed to increases in packing density. The direction of magnetization in a standard iron oxide particle is parallel to its long axis. The more uniform the orientation, the more discrete the transitions are on playback, giving better signal-to-noise properties. As coercivity continues to increase, particle size continues to fall. Today's metal particles are considerably smaller and have much less surface area (a major factor in determining the amount of binder used in a formulation). Smaller particles obviously mean that a greater number of individual parti-

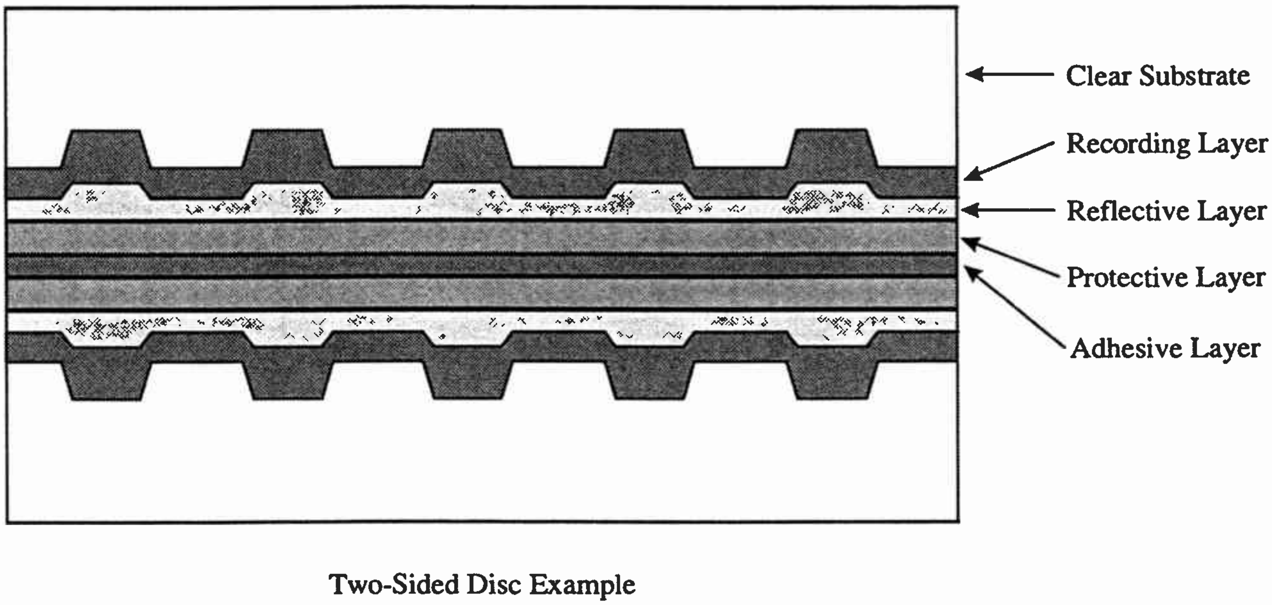

Figure 5.5-7. The basic footprint of the DVD-R.

cles can be located within a given area. This fact, along with the higher coercivity and retentivity, allows a much greater packing density rate, that is, a greater amount of information to be stored in a given area. More uniform particle shapes and sizes and better dispersant or milling technology has also contributed to packing density increases. Figure 5.5-8 shows the increases achieved in some of the more recently introduced videotape formats.

Recording Format Trends

In the development of newer tape recording formats there are four major trends: digital, component, cassette and compactness. While digital recording has been standard in the data field, it is a major trend in

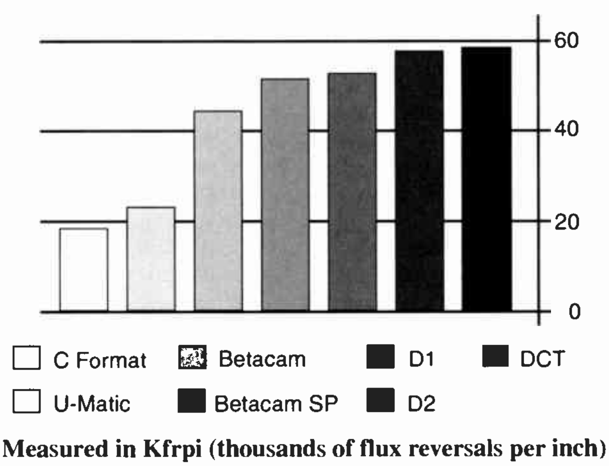

Figure 5.5-8. A comparison of packing density in videotape formats.

the video and audiotape marketplace. The movement is away from the traditional analog recording and toward digital recording formats. Most of the more recent tape based format introductions have been digital recording formats. This is clearly a desirable trend as far as the quality of the audio and video to the marketplace.

Another format trend, specifically in the videotape marketplace, is the movement away from composite recording systems toward component recording. Component recordings are generally of a higher picture quality than composite recordings. Composite signal systems record one signal onto the tape, whereas component signal systems record three—a luminance signal and two chrominance signals. As a result, component systems must record more information onto the tape surface within a given physical space.

The third major format trend is the movement from reels toward cassettes. Most new magnetic tape formats introduced in the last ten years have been cassette based.

The fourth major trend is compactness. Newer formats are becoming progressively smaller, both in terms of the cassette size and the track widths recorded onto tape. As cassettes become increasingly smaller, the complexity of their design keeps increasing, both in the physical number of component parts contained within them, and, the interaction of these component parts. Recent format introductions such as DVCPRO, Digital S, and Betacam SX all continue these trends.

Physical Attributes Trends

Figure 5.5-9 shows the changes in the physical width of videotape formats over time. The earliest format, quadruplex was 2 in. wide, whereas, the newer digital formats have seemingly settled on ½ in. and 19 mm

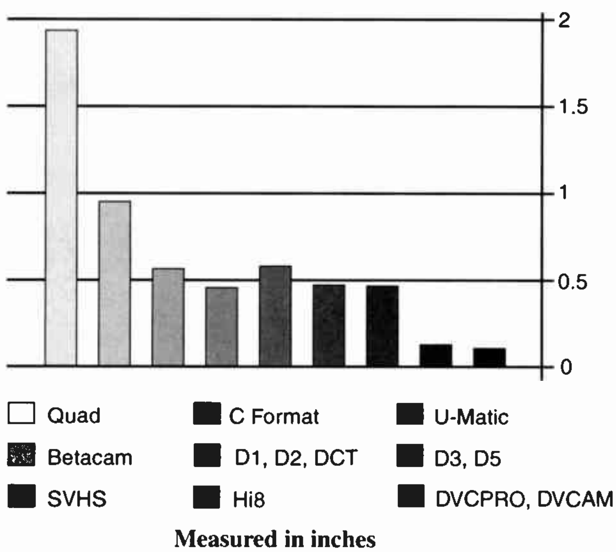

Figure 5.5-9. A comparison of the physical width of various videotape formats.

as the most desirable width. Even narrower widths have been introduced in the professional market.

Figure 5.5-10 shows the changes in the physical thickness of the various formats over time. Newer formats are becoming increasingly thinner. This also represents a series of challenges to the tape manufacturer. With the reduction of the thickness of magnetic coatings, different coating methods have been required for magnetic media manufacturers.

An additional factor that is effecting coating thickness is the trend to digital formats which use very high frequencies in recording. The use of very high frequencies requires only the uppermost portion of the tape surface to be highly magnetic. As the lower portion is unused for recording its purpose is to add some tensile properties that additional thickness brings to the tape. Applying relatively thick coatings in digital is an unnecessary practice and raises the cost of manufacture. Consequently, coating thickness becomes thinner as the trend toward digital formats continues.

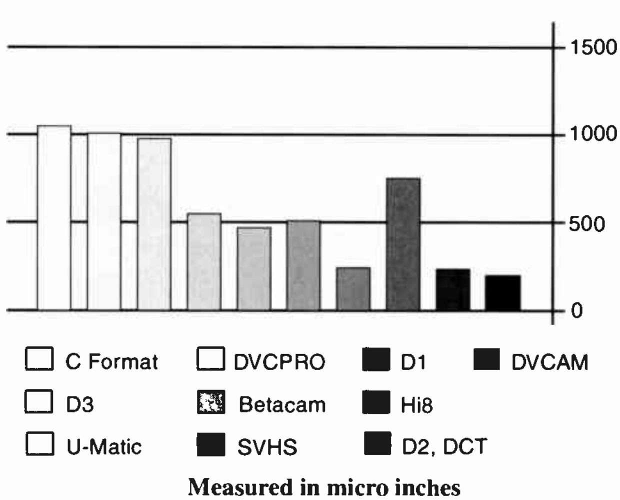

Figure 5.5-10. A comparison of the physical thickness of various videotape formats.

THE MANUFACTURE OF MAGNETIC TAPE

The manufacture of magnetic recording tape is a complex process involving a wide variety of sciences and manufacturing disciplines. The manufacturing process is essentially linear in concept. One step of the process follows its predecessor and cannot be started until its predecessor is complete. The manufacturing process, varies slightly from manufacturer to manufacturer, depending on the physical plant equipment and preferences. Consequently, the description of the process that follows is a lower level, basic or generic process. It provides an overview of the manufacturing process, not an in depth discussion on any or all steps. The following flow diagram represents a basic magnetic tape manufacturing process (see Figure 5.5-11). One element that is not shown is that of time. The entire coating of one batch or mix may take one week, depending on the amount of time required for milling, heat curing and final finished goods assembly.

Formulation Components

Magnetic tape is typically made up of three parts or layers: backcoat, magnetic coating, and base film. The formulation of any magnetic layer contains several components. Each component is chosen for how well it performs its specific function and its synergy within the entire formulation. Although the types of components may differ from one formulation to another, essentially all magnetic recording tape coatings contain most or all of the following components. The final formulation in its wet, coating state has a consistency similar to that of fingernail polish.

Magnetic Media (Pigment)

The type of magnetic material used during the evolution of magnetic recording tape has changed dramatically. Early audiotape products used ferric oxide (FeO_2) with coercivities in the 300–350 Oe range. In search of higher packing density capabilities tape manufacturers have moved toward high energy particles such as gamma ferric oxide, cobalt doped gamma ferric oxide, metal particles, and cobalt nickel for metal evaporative tape. The trend is clearly toward magnetic materials exhibiting high coercivities (1500–2500 Oe) and high retentivity performance. Generally, magnetic particles can be described as acicular in shape (similar to a sewing needle). The smaller the size of the metal particle, the larger the quantity of the particle that can be packed into a given surface area on the tape. This allows much higher data packing densities. The first magnetic recording tape, in 1935, used magnetite (Ferroso-oxide Fe_3O_4), which proved to highly unstable. The magnetic material used has evolved to gamma

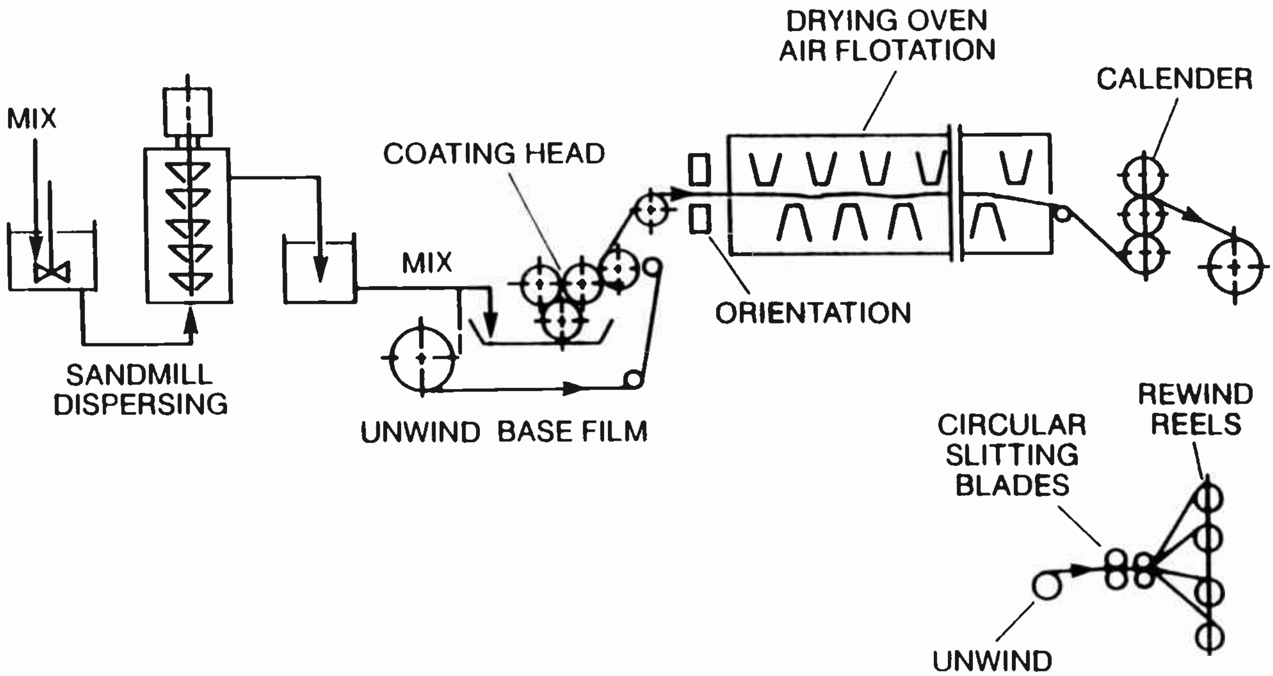

Figure 5.5-11. Schematic of mix preparation, tape coating and processing.

ferric oxide, chromium dioxide, and magnetic particles. Figure 5.5-12 is a representation of the crystal structure of a gamma ferric oxide and metal particle to show the difference in the density of the iron atom versus the oxygen atom. A typical gamma ferric oxide particle is 25 to 35 μ in. in length and about 7 to 12 μ in. in width. For comparison, a cigarette smoke particle is about 25 μ in. in diameter.

Binder

The binders used in the formulation can be likened to paste as they provide the cross linking necessary to keep all of the ingredients together (cohesion) and to ensure the coating does not shed or flake off the base film (adhesion). Binders also add considerably to the stiffness of the finished tape product. Stiffness is required so that the tape wraps the helical scanner and transport assemblies properly and adequate head-to-tape contact is maintained.

The term binder is a generic term covering a wide range of synthetic polymeric material such as polyurethane, elastomers, and vinyl chloride. A recent trend is toward the use of a functionalized binder system. This type of binder system more effectively provides the cross-linking necessary to achieve both thinness and durability as compared with more traditional non-functionalized binder systems. Functionalized binder systems allow the formulation to use less solvent and dispersant, thus simplifying the formulation chemistry.

Plasticizer

The design geometry of modern tape transports results in tape to guide wrap angles of greater than 90°. This is particularly true in most helical scan (head angle across the tape surface) transports. Because of these guiding requirements, some of the forces placed on the tape are in a plane other than vertical. This type of physical requirement places different demands on a tape product than in the past. There is a clear need for the tape to be flexible, yet have relatively high coating modulus. Plasticizers typically perform this function. Without plasticizers, tape would be somewhat brittle and unable to survive the high physical demands and speeds of a modern tape transport. While equipment manufacturers design their transports to place the minimum possible physical requirements on the tape, their priority in design is in the more critical footprint and system performance areas.

Head Cleaning Agent

Typically, head cleaning agents are added to formulations. Usually, in the form of an alumina particle of a specific size. The purpose of these particles is to ensure the heads of the machine remain clean. In addition, these cleaning agents keep the remaining portions of the tape path free from dirt and contamination.

There are a number of questions pertaining to head life and transport maintenance that are raised when discussing the amount of head cleaning agent. Regarding head life, it is frequently stated that the alumina added to a tape formulation is responsible for premature head deterioration. This is not necessarily the case. The amount of head cleaning agent added is extremely important. If too much alumina is added certainly the abrasivity of the tape is higher and head life deterioration becomes an issue. If too little alumina is added

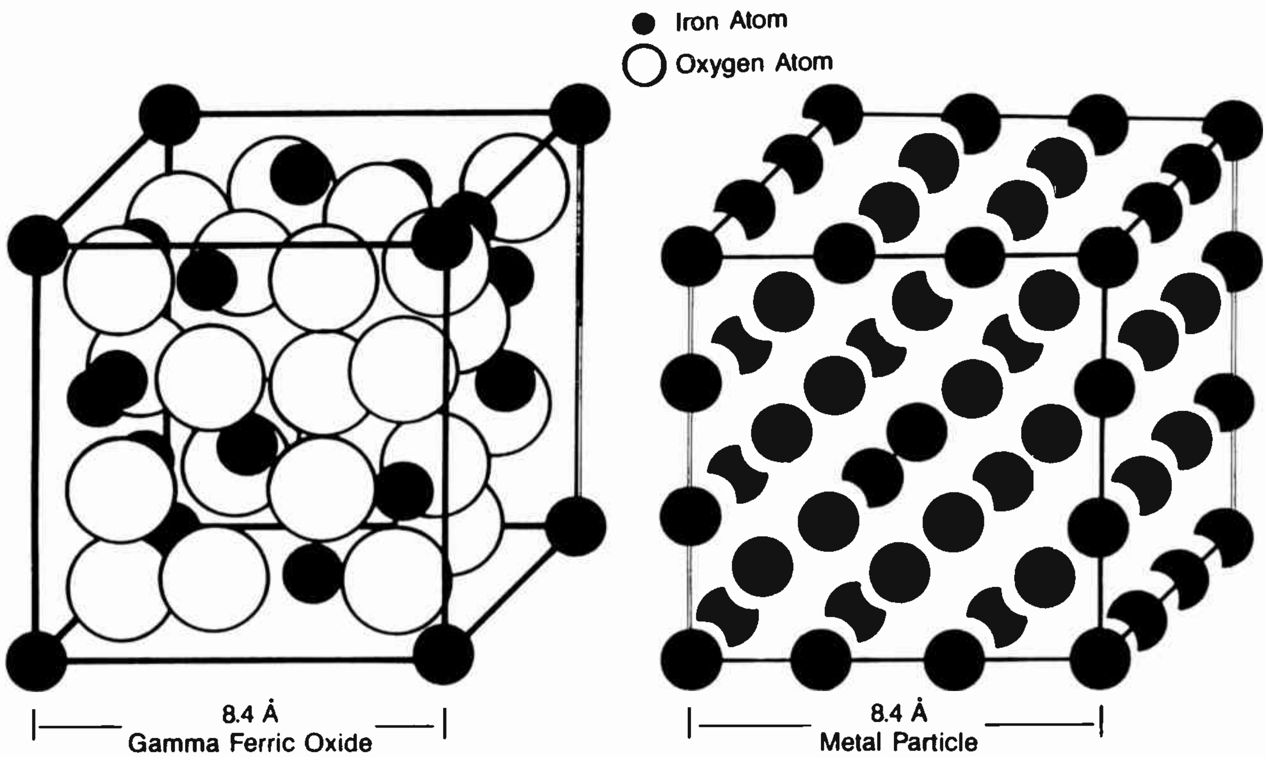

Figure 5.5-12. Crystal structures for metal iron and iron oxide.

the tape may not be able to keep the transport clean enough to ensure good head-to-tape contact and a poor quality recording results. There are many other factors that contribute to the actual abrasivity of a given tape. The type of particles, binder systems and other formulation ingredients all play a role in determining a particular tape's abrasivity.

The head cleaning agents added to a tape's formulation are not a substitute for good engineering practices in the form of routine cleaning and transport maintenance. Routine cleaning and alignment checking are part of any good preventative maintenance regime and will help to reduce the incidence of dropouts and machine induced physical damage.

Solvents

All of the mix ingredients are added together to form a slurry and part of the formulation will include some solvents. These are used to dissolve other mix chemicals such as binders during the milling process. The solvent system must maintain solubles in solution and not disturb the pigment solution. In addition, these solvents add to the formulation's rheological properties and effect the manner in which the finished mix flows. This directly impacts the manner in which the particular formulation performs on the coating line. While the solvents are needed during the mixing and coating of the formulation they are not required in the final state of the magnetic tape. The solvent laden air can be collected during the drying phase of manufacture and routed to a solvent recovery system. Here the solvents are recovered using a distillation process. This is an environmentally friendly process and can typically yield solvents of a purer quality than those originally purchased from suppliers and therefore reusable in another coating mix.

Dispersants

Because of their magnetic nature, particles tend to clump together in their raw form. This situation is not desirable as it would tend to result in some areas on the tape surface highly saturated with particles, whereas other areas may be entirely void of magnetic material. Dispersants are added to the formulation to aid in dispersing the particles evenly throughout the mix. The dispersion process is completed in mix preparation and can be achieved through a variety of methods. These methods are discussed in the subsequent section on mix preparations.

Fungicides

Fungus growth on the surface of tape may occur and is almost entirely confined to storage or operating environments with very high humidity. Fungicides are added to the mix formulation to help prevent fungus growth. Despite manufacturers' best efforts, poor storage environments are commonplace.

Antistatic Agents

One of the causes of dropouts (the momentary loss of head-to-tape intimacy) is static electricity buildup.

The buildup causes dust and dirt particles to attach themselves to the tape surface and cause a lack of head-to-tape intimacy. Antistatic agents are, therefore, added to tape formulation, particularly backcoat formulations. Carbon black is a common antistatic agent that is used for this purpose.

Mix Preparation

Once all of the formulation ingredients have been combined, it is necessary to mill or disperse the slurry so that two conditions are met. First, the magnetic particles, and other mix ingredients, must be thoroughly dispersed throughout the slurry. Second, all ingredients must be dissolved so that no particles larger than a given size remain. This is achieved in a milling process, which can be performed in a variety of ways. A typical milling cycle maybe from 72 to 96 hours and depends on the chemistry of the formulation. It is normal to filter the mix after milling. Filtering will remove unwanted materials such as foreign particles, (broken pieces of the milling media which were introduced during that process). At the end of the milling process, the slurry is ready for coating.

Ball or Pebble Mills

Ball mills are the oldest of the milling technologies. The ball mill is a horizontally oriented cylindrical rotating vessel into which the formulation is poured. The vessel is than rotated for a predetermined amount of time. The time is determined during the formulation development process. Inside the vessel is the milling media. In this case the media can either be steel balls or smooth pebbles. The media in the mill acts on the formulation ingredients causing them to be fully dispersed throughout the slurry.

Sand Mills

Sand mills are a more recent technology and operate on a flow system rather than the static batch system of the ball mills. Sand mills are actually banks of milling vessels vertically oriented. The sand mills themselves do not rotate, rather, the mix is pumped through each vessel from bottom to top. As the mix is pumped through the vessel it must pass through a series of rotating discs and milling media. The media in this case is typically zirconium silicate. The number of vessels through which the mix must pass is determined during the formulation development process.

High Solids Mixers

The most recent advances in milling technology are high solids mixers, the most common, double planetary mixers, can be likened to an industrial dough mixer in a bakery. High solids mixers can operate in either a batch mode, like balls mills, or a continuous flow mode, like sand mills. As the name implies, this type of technology requires a much more viscous mix than do ball or sand mills. Consequently, this technology provides an efficient and effective milling procedure. High energy kneaders are becoming very common for the high coercivity formulation of magnetic particle tape. This type of mixer is similar to a plastic injection molding screw drive. A number of passes is usually required through the kneader and the mix is very dense and paste-like compared to traditional mixes. This kneaded mix is then converted to a more traditional slurry consistency before coating.

Base Film

When magnetic tape was first coated it was constructed on kraft paper backing. This was later replaced with a more resilient cellulose acetate and then with today's range of polyester base films or backings. The current polyester base film includes Polyethylene Terephthalate (PET), Polyethelene Naphthalate (PEN) and Polyaramide type films.

Polyester type base film can be produced in a variety of widths, lengths, thicknesses, surface smoothness and tensile properties. Different magnetic recording systems call for magnetic tape products with different physical and tensile properties. The base film is electrically inert and provides no electrical or magnetic function. Base films are becoming thinner with newer tape formats. This presents a unique challenge to the tape manufacturer. It is essential that tensile properties are maintained despite the move toward thinner films. Base film derives a lot of its stiffness from its thickness. Obviously, the thinner the film, the less stiff the magnetic tape may be. Base film manufacturers are developing newer products to meet the changing requirements of the magnetic tape recording system. PEN and polyaramide base films are the next generation of films expected to someday take over from standard PET films. As a general rule of thumb, both PEN and polyaramide films provide greater tensile strength than PET film of the same thickness.

Magnetic Coating

Coating can be achieved by using a variety of coating technologies. As the requirements for higher magnetic tape has increased over the years, the coating technology to produce these newer tapes has been the result of this necessity. Older tape was thicker (base film and magnetic coat), coated at slower speeds and was relatively easier to coat. The coating technology to produce the thinner and smoother generation of metal particle tapes are more technologically complicated. However, each coating technology is valuable in that it does produce the desirable tape product to meet the requirements of its respective recording system.

Knife Coating

Knife coating is probably the oldest type of coating method employed in the manufacture of magnetic tape. As Figure 5.5-13 shows, the coating mix (wet) is fed onto the base film and then past the knife blade. The blade height (with respect to the base film) determines how much mix is left on the film. Knife coating is particularly good for relatively thick coatings such as those found on professional audio mastering tapes. This method is not the most accurate and is best for coating thickness above 400 μ in.

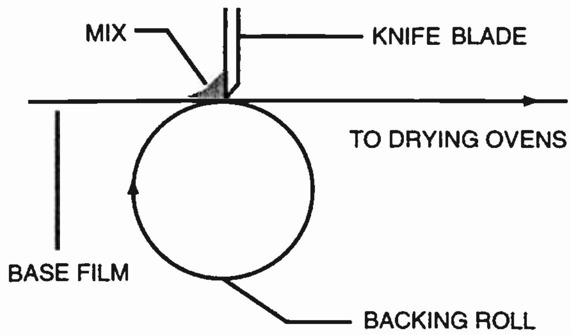

Figure 5.5-13. Application of knife coating.

Reverse Roll Coating

Reverse roll coating is more complex than knife coating and, consequently, is capable of coating much thinner coatings. As shown in Figure 5.5-14, in the reverse roll coating method, the mix is picked up from a mix pan by the pickup roll and transferred to the applicator roll. A metering roll than meters the amount of mix on the applicator roll. The amount of mix remaining on the applicator roll is determined by the distance between the two rolls. The mix is then transferred to the base film from the applicator roll. The applicator roll is turning in the reverse direction or against the motion of the base film, hence the name. Reverse roll coating was the mainstay of the tape industry for many years and is still in common use today. Reverse roll coating is better suited to thinner coatings (above 200 μ in.) such as those found on some older professional videotape formats process.

Gravure Coating

Gravure coating was adapted to the tape industry from the printing industry. It is the most accurate means of coating thin thickness where tight tolerance control is required. The gravure roll is pitted with cells, small grooves or cuts of given width or diameter and depth. The diameter and depth of the cell, as well as the viscosity of the mix, together determine how much mix is retained by the gravure roll and thereby deposited onto the base film. Gravure coating is an ideal method for very thin coatings such as consumer VHS and the backcoat coating found on most professional videotapes (see Figure 5.5-15).

Metal Evaporation Process

The process or coating technique of depositing a metal layer onto a flexible substrate through evaporation of a metal in a vacuum is referred to as metal evaporation (ME) coating. This process was developed to increase packing density, or meet the need to be able to record more and more data on the tape. Therefore, make the tape thinner and hotter (or more magnetic).

One means of increasing the volumetric packing density of magnetic tape is to make the magnetic layer thinner while preserving or increasing its magnetic capabilities. A means of achieving these seemingly contradictory objectives is to deposit a continuous pure metal film onto the base film, instead of using the typical dispersed particulate coating. In the introduction to this section the actual volume of magnetic oxide in typical coatings was reviewed. The most direct way to maximize the magnetic volume of the recording layer is to remove all non-magnetic components (oxygen) of the particle itself and by removing binding and resin matrix from the formulation. The ideal magnetic recording medium is achievable through this physical deposition of magnetic material on the base film through metal evaporation. The technique of depositing a metal on a flexible base film is based on the evaporation of a metal in a vacuum. As pressure is increased (vacuum increases) liquids evaporate more rapidly and at a lower temperature. A vacuum chamber used for metal evaporation onto a base film consists of the following components (see Figure 5.5-16):

- Transport system for unwinding and rewinding the base film

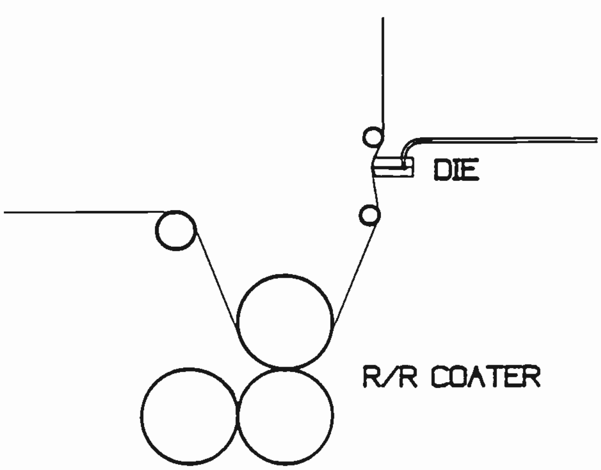

Figure 5.5-14. Application of reverse roll coating.

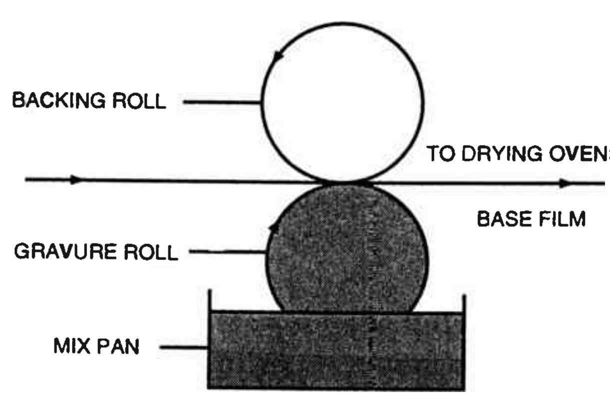

Figure 5.5-15. Application of gravure coating.

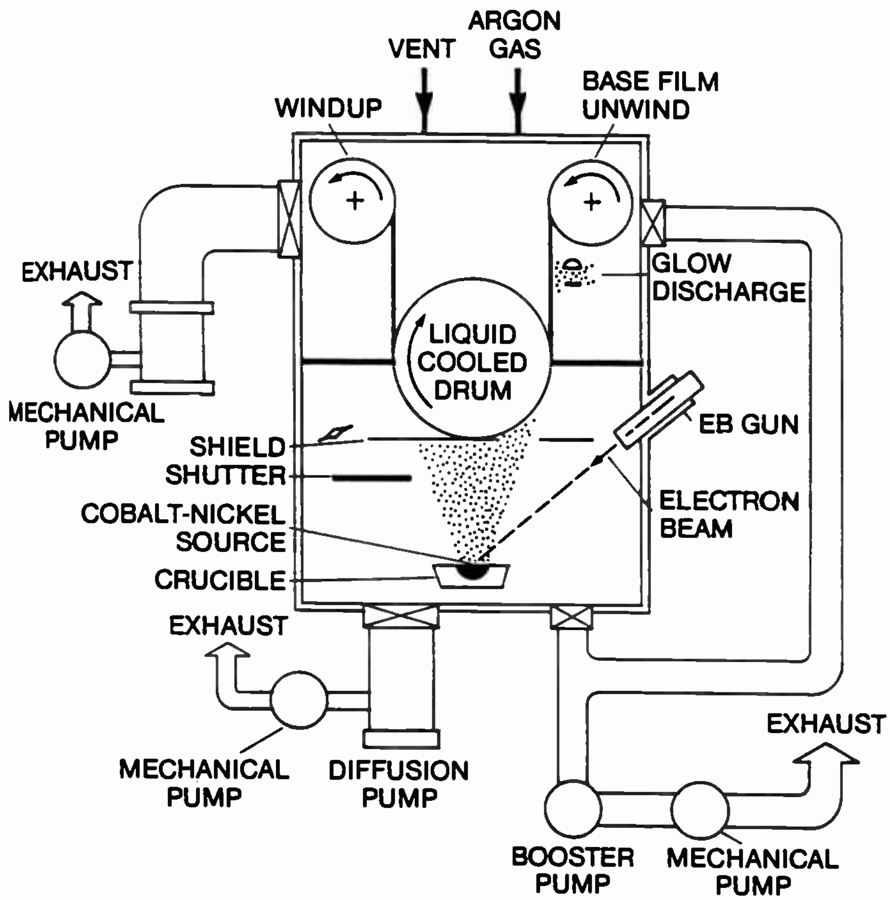

Figure 5.5-16. The vacuum deposition process.

- A high temperature crucible that can hold molten metal after it has been heated either by resistance or with an electron beam gun
- An internally chilled cooling drum around which the base film is wrapped to remove the heat from the condensing metal
- A vacuum pump to quickly remove the air and water vapor from the vacuum chamber

The magnetic coating thickness of a metal evaporated tape is typically 1 μ or 4 μ in. This is more than 20 times thinner than the metal particle layer of D-2 tape. This practically means that the entire thickness of the tape is basically that of the base film being used. The advanced magnetic properties of metal evaporated tape have allowed equipment manufacturers to significantly increase packing densities.

Slot Die Coating

As shown in Figure 5.5-17, slot die coating uses a coating head that has a slot cut into it. The geometry of this slot and its position relative to the base film determines the parameters of the coating surface. Slot die coating is one of the newest of coating technologies and is typically used for the thinnest and most critical of coatings. The slot die head usually has one slot but is capable of two or three slots which results in multiple and different layers being applied to the base film. These can be applied wet on wet or wet on dry.

Orientation

After leaving the coating area, the web, as it is now called, passes through the orientation process. This process physically moves the individual particles into a specific direction. The direction desired is always identical to the direction of head travel across the tape or as near to this direction as possible. In the case of the original videotape format quadruplex, developed by AMPEX in 1956, the head traveled in a lateral or transverse, direction. The particles in quad tape were therefore oriented in the lateral or transverse direction.

Drying, Solvent Evaporation, and Recovery

As noted previously, the mix formulation contains a number of different solvents. These solvents are undesirable in a finished tape and are therefore removed during the drying process by heating and causing evaporation. After leaving the orientation stage,

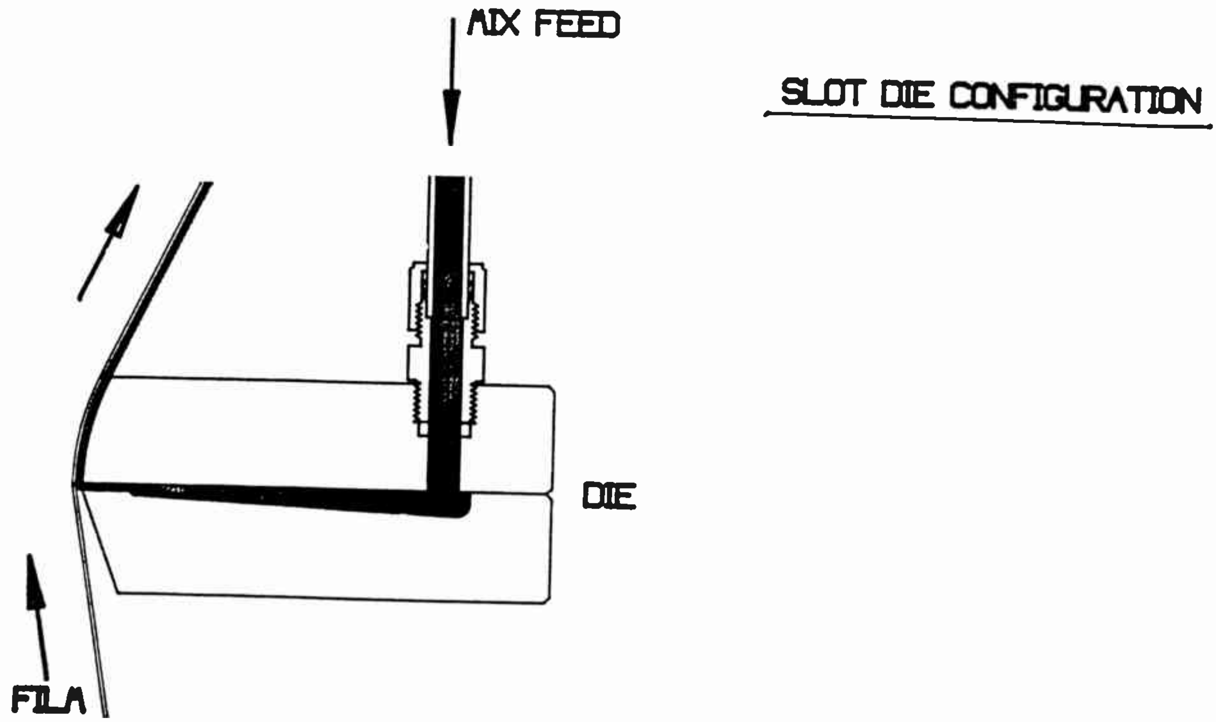

Figure 5.5-17. Slot die coating.

the coated web passes through an oven with a series of different temperature zones. The temperature of each zone is usually matched to the evaporation temperature of one of the solvents being used. Within the ovens, the web typically travels over a series of air plenums, which suspend the tape on a cushion of hot air. This prevents the tape from touching any of the surfaces inside the oven, which would damage the coated surface.

The oven air is gathered in the process and is sent to the solvent recovery unit. This is a relatively simple process whereby the air is passed through a vessel containing activated charcoal. The charcoal absorbs the evaporated solvent and the air is passed into the atmosphere. The charcoal is then flushed with steam and the solvents recovered as part of a distillation process.

Calendering

After passing through the ovens, the coated web then passes through a series of calenders. The coating layer is usually done at a thickness a few times more than actually desired in the finished product. This is to compensate for shrinkage during the drying and calendering processes. The calendering process is a smoothing or surface finishing process that is accomplished by heat and pressure. Calendering may either be performed inline, that is, in a continuous process, or offline, which involves a separate set of calender stacks to those found on the coating line itself.

A calender stack consists of two rolls located side by side. The meeting point of the two rolls is called a nip. One of the rolls provides pressure and the other heat. The calendering process can be roughly likened to ironing of clothing. During the process, which usually consists of a number of nips, the tape surface is smoothed and compressed. The smoother tape surface tends to give higher electrical outputs than rougher ones and better signal to noise ratio.

Take Up

If the calendering process is performed inline, the last task in the coating line is to wind the coated and calendered web onto a web core ready for the slitting process. This station acts in the very same manner as the take up reel on a reel-to-reel recorder.

Slitting

A 26 in. or 3 meter wide jumbo roll of tape in roll form is useless to anybody. It must be slit and packaged into a usable form. Slitting takes the jumbo roll and cuts it into strands of the appropriate width for the given format. Each strand is then wound onto a hub. This is commonly referred to as a pancake. All slitters operate in a similar manner. The web passes through a series of blades, known as arbors. There are two major parts to the arbor. The first is the male cutting blade, which is typically positioned above the web surface. The second is the female or guides, which are typically positioned below the surface.

The male and female portions of the arbor operate together to form the slitting process. Edge weave and edge quality are all critical factors that must be tightly controlled during this process. Today's thinner magnetic tape formats are becoming more demanding on the integrity of the magnetic surface. As well as the tape surface itself, edge quality becomes a major issue. Defects in edge quality are greatly magnified in smaller formats, which depend on every mechanical component of the recording process being within a very small tolerance range in guiding and tracking.

Curing

A process that is required for most crosslinked binder systems of metal particle formulation tape is heat curing. The heat curing can occur at different phases of the manufacturing process, before the back coat is applied or after the entire product has been coated. Heat curing can be done on full webs or on slit pancakes. It is usually done at a temperature cycle and for a period of time determined to be optimum for that specific formulation. The heat curing phase can take a few hours or for a few days.

Post Conditioning

Also referred to as burnishing, the post conditioning phase is used to condition the edges and to clean the tape after it has been slit to pancakes for the specific format. The burnisher is typically similar to a tape transport and can consist of different type of cleaning and wiping materials. The number of burnishing sections, the type of blade or device used in each and the tape tension can be adjusted for the particular formulation.

Assembly

The final task in the magnetic tape manufacturing process is to load and assemble the cassettes or to add flanges to hubs. In cassette format products, manufacturers have a choice between spool loading and in-cassette loading. Spool loading is a process where the spools are wound with the correct amount of tape prior to being placed into the unfinished cassettes. The cassette is then assembled around the spools. In-cassette loading assembles the cassette first, and then winds the footage into the cassette by cutting and splicing the leader material from outside of the cassette. Large scale assembly of cassettes and their component parts is largely achieved using relatively simple robotics and industrial controls. Typically, assembly lines have several stations where a certain task is performed: placing a guide, placing a break lever, inserting and driving screws into final position, etc. The use of robotics helps to improve consistency of product and lower the overall cost of manufacture. The assembled cassette or flanged open reel, is then placed in the appropriate unit container, labeled, and placed in the shipping carton and ready for sale.

KEY TERMS

Ablative. A method of optical recording where holes are made in the optical media. Also referred to as pit forming. A laser actually burns a hole into the film layer. Data is read by reflectivity contrast (WORM)

Birefringence. The property of a material which causes incident light waves of different polarization to be refracted differently by the material.

Coercivity. A measurement of the magnetic characteristics of a given particle. Coercivity refers to the amount of magnetic energy required to bring a saturated magnetic particle to a zero or demagnetized, state.

Curie point (or Curie temperature). The temperature at or above which the coercivity of magnetic material decreases substantially, permitting a change in orientation by a weaker magnetic field.

Embossed. Data written marks are molded into the substrate. Data is read by reflectivity contrast (ROM).

Kerr effect. The phase change exhibited by certain substances when exposed to a magnetic field, due to rotation of the plane of polarization of light reflected from them.

Laser. A device that uses the natural oscillations of atoms to amplify or generate electromagnetic waves into an intense beam of coherent optical radiation. (Acronym for light amplification of stimulated emission of radiation.)

Phase change (PC). An amorphous coating in which individual spots on the disc are changed by laser irradiation from a crystalline state, which reflects light, to a non-crystalline state, which absorbs light. Data is read by reflectivity (WORM or Rewritable).

Reflectance (reflectivity). The ratio of the incident light to the reflected light measured at normal incidence on the disc at a specified wavelength, through the protective layer, if any.

5.6 VIDEO COMPRESSION SYSTEMS

PETER SYMES
TEKTRONIX, GRASS VALLEY PRODUCTS, GRASS VALLEY, CA

This article is based on material extracted and adapted from the book Video Compression *by Peter Symes and published by McGraw-Hill (ISBN 0-07-063344-4), by permission of the publisher.*

INTRODUCTION

Compression is the science of reducing the amount of data used to convey information. This article examines a wide range of techniques—some simple, some very complex—and how these techniques may be applied to video. Compression relies on the fact that information, by its very nature, is not random but exhibits order and patterning. If this order and patterning is extracted, the information can often be transmitted using less data than would be needed for the original. The original, or a close approximation to it, can then be reconstructed at the receiving point.

It may be tempting for the television engineer to conclude that compression is a subject for experts, but good engineers understand in principle what is happening in each of the major components of a system, even if they could not design that component. Compression will exist at some point in virtually all television systems and its performance is affected, sometimes dramatically, by characteristics of the video signal including any prior compression history. An understanding of compression principles will help video engineers to understand the processes that are being applied to their images. Only in this way can they protect quality and diagnose problems.

There are several families of compression techniques, fundamentally different in their approach to the problem—so different in fact that often they can be used sequentially to good advantage. Sophisticated compression systems use one or more techniques from each family to achieve the greatest possible reduction in data. The JPEG and MPEG standards are the most important today; many systems already installed use JPEG or its derivatives, new systems will mostly be based upon MPEG-2.

One important categorization of compression systems is the degree of *symmetry* or *asymmetry*. For applications such as video conferencing where there are similar numbers of transmitters and receivers, there is no particular advantage if the decoder is less expensive than the encoder. For other applications such as broadcast a very small number of encoders generate signals that will be sent to a large number of decoders. Such systems can be asymmetric; the decoder must be as inexpensive as practicable, but the encoder can be very complex if this improves efficiency.

INFORMATION AND DATA

Information exists in many forms—written text, the spoken word, music, still pictures, and moving pictures are just a few examples. Whatever the type of information, we can represent it by electrical signals or data to transmit, or store it.

The more complex the information, the more data is needed to represent it. Plain text can be represented by eight bits per character, or about 20 kb for a page. CD quality music requires nearly 1500 kb for each second, and full motion 525-line component video needs over 200 Mb for each second.

In order to transmit a given amount of data, a certain data bandwidth (measured in bits per second) is used for the time necessary to transmit all the bits. In the real world, there is always some restriction on the available bandwidth. For example, if the transmission is sent over regular telephone lines using modems it is difficult to achieve more than 33.6 kb/s (kilobits per second). This is fast compared to the 300 b/s modems of a few years ago, but even at 33.6 kb/s it would take two hours to transmit a single second of high quality video.

Sometimes it is a practical restriction like the use of a modem that sets the requirements for compression. It is possible to send high quality uncompressed audio data over a modem, but each second of audio would take about 50 seconds to transmit. The data would have to be received gradually and stored away; then the resulting file could be played at the correct rate to hear the sound. However, it may be important to transmit sound so that we can listen to it as it arrives in "real time." Quality reduction would help, but even telephone speech quality needs a data rate substantially higher than a high-speed modem can provide. To send real-time audio over a modem link, the data has to be compressed.

Another example of this type of requirement is the digital television system developed for North America. When the study was started in 1987, few thought it would be possible to transmit high definition television (characterized by the 1125-line system) over a single 6 MHz channel as used for today's 525-line television. When digital techniques were considered, the problem looked even worse, as the high definition signal represented over 1 Gb/s of data. In the end, two teams of engineers combined to produce the answer; the transmission engineers designed a system to reliably deliver nearly 20 Mb/s over a 6 MHz channel, and the compression engineers achieved data reduction of about sixty to one, while maintaining excellent picture quality.

Sometimes the motive for compression is purely financial. Bandwidth costs money—compression reduces the cost of transmission. A satellite link with a data bandwidth of 40 Mb/s will earn more money if it can carry ten television channels instead of just one.

Transmission and storage of information may seem to be very different problems, but when considering the quantity of data, the economics are the same. Just as there is a cost for each bit transmitted, there is a cost for each bit stored in memory, disk or tape. If less data is used, both transmission and storage will be cheaper. There are some differences in how compressed data is best structured, but otherwise everything said about compression applies equally to transmission or storage.

Signal Conditioning

It is extremely important to ensure that the signal or data stream to be compressed represents the information that must be transmitted, and *only* that information. If there is additional information it will require bits to transmit, and result in fewer bits being available for the necessary information. Surplus information is irrelevant because the intended recipients can make no use of it.

Surplus information can take many forms. It can be information in the original signal or data stream that exceeds the capabilities of the receiving device. For example, there is no point in transmitting more resolution than the receiving device can use.

Another form of surplus information is artifacts—features or elements of the input that are not truly part of the information. Noise is the most obvious example. Noise is by nature random or nearly so and this makes it essentially incompressible.

Many other types of artifacts exist, ranging from filter ringing to film scratches. Some may seem trivial, but in the field of compression they can be very important. Compression relies on order and self-consistency in a signal, and artifacts damage or destroy this order.

This statement is just one aspect of a more general rule. Compression systems are designed for particular tasks and make use of assumptions about the nature of the data being compressed.

Video is generally an environment where images are sampled according to the limitations of the *Nyquist Theorem*. The theorem can be expressed as:

> *To ensure that a signal can be recovered from a series of samples, the sampling frequency must be more than double the highest frequency in the signal.*

The frequency transforms widely used in video compression, particularly the *Discrete Cosine Transform,* depend for their action on the fact that the information is band limited, and that sampling was performed according to Nyquist. If these rules are broken the transform does not perform as expected, and the compression system will fail.

Correctly used, signal conditioning can provide remarkable increases in efficiency at minimal cost. Equipment available today incorporates many different types of filters targeted at different types of artifact. The benefit of appropriate conditioning is twofold. Because the artifacts are unwanted, there is a clear advantage in avoiding the use of bits to transmit them. Moreover, because the artifacts do not belong they generally break the rules or assumptions of the compression system. For this reason artifacts do not compress well and use a disproportionately high number of bits to transmit.

Lossless Compression

Some compression techniques are truly lossless. In other words, when data is compressed, the process can be reversed (decompression) and the original data can be retrieved. Lossless compression works by removing *redundant* information—information that, if removed, can be recreated from the remaining data.

In one sense this is the ideal form of compression—there is no cost to using it other than the cost of the compression and decompression processes. Unfortunately, lossless compression has two significant disadvantages. Typically, lossless compression offers only relatively small compression ratios, so used alone it often does not meet the economic needs. Also, the compression ratio is very dependent on the input data. Used alone, lossless compression cannot guarantee a constant output data rate such as might be required for a transmission channel.

For some applications lossless is the only type of compression that can be used. If a binary file such as a computer program is to be transmitted, receiving an approximation to the original is of no use. The program will only run if replicated exactly. Fortunately, many computer files have a high degree of order and patterning, so lossless compression techniques do yield very useful results. Compression programs like the well-known PKZIP use a combination of lossless techniques, and are particularly effective on graphic image files.

One advantage of lossless compression is it can be applied to any data stream. Most video compression schemes use lossy techniques to achieve large degrees of compression. Lossless techniques are then applied to the resulting data stream to reduce the data rate even further.

The simplest form of lossless compression is *run-length encoding*. Many data streams contain long runs of a single value. For example, a graphics file will typically contain values for each pixel, ordered line by line. A red object will likely be represented by several long runs of the value red. With appropriate coding it can use much less data to say *Red 23 times* instead of "R R R R R R R R R R R R R R R R R R R R R R R." This is run length encoding—the code represents the length of the run of a certain value. As this chapter will describe, various tricks are used in video compression to make the data suitable for run length encoding.

A more sophisticated type of lossless compression is *entropy encoding,* also know as *variable length encoding*. This is usually the last step in compression. Where run length encoding relies on adjacent values being the same, entropy encoding looks at the overall frequency of specific values, wherever they are located. The implementation of entropy encoding is quite complex, but the principle is easy to understand.

If the data is represented by bytes (groups of 8 bits), each byte can have any *value* between 0 and 255. When the data is transmitted a *symbol* is used to represent each possible value. A sequence of *symbols* is transmitted then until all the *values* have been sent.

The simplest way to code the data is to send the bytes themselves—each symbol is the same as the value it represents. This is so obvious that there is a tendency not to think of anything else, and do not distinguish between the value and the symbol; but it does not have to be like this. As long as both the transmitting and receiving points know and apply the same set of rules, any set of 256 unique symbols can be used to represent the 256 possible values. This is not very helpful without an added factor—provided there is a set of rules that lets the recipient know when one symbol ends and another begins, *not all the symbols need to be the same length.*

This is the essence of entropy encoding. It compresses the data by using short symbols to represent values that occur frequently, and longer symbols to represent the values that occur less frequently. Unless the input data is very close to random in its distribution of values, this technique means that total data used for the symbols will be less than the total of the original values.

Optimization of entropy encoding is complex, but the basic idea is neither difficult nor new. Consider two ways of coding the alphabet. Anyone who has spent much time with computers has come across the ASCII encoding system. In ASCII, letters are represented by a particular set of eight bits, or one byte. It does not matter what the *value* (letter), the *symbol* is eight bits long. A much earlier method of encoding the alphabet was invented by Samuel Morse in 1838. The *Morse Code* is a simple but useful example of an entropy coding system.

The Morse code uses combinations of dots and dashes as symbols to represent letters. A dash is three times as long as a dot; each dot or dash within a symbol is separated by one dot length; each symbol is separated by one dash length. Morse designed his code to transmit English language text. To maximize the speed of transmission he looked at the frequency with which the various letters of the alphabet appear in typical text. The letter "e" is the most common letter in English, so Morse assigned the shortest possible symbol—one dot (actually four dots in length because of the inter-symbol space). The next most common letter "t" received the next shortest symbol, one dash. At the other extreme, an infrequent letter like "y" receives three dashes and a dot, a symbol four times as long as that used for "e," as shown in Figure 5.6-1.

The Morse Code also illustrates one of the problems of entropy encoding. For transmission to be successful, obviously both the transmitter and the receiver must use the same mapping of symbols to values. The relationship between values and symbols is known as the *code table.* But the most efficient mapping can only be determined when the frequency of values is known. The code table for Morse is derived from the frequency of letters in English text. This code would not be efficient to send Polish language text, where the letters "c" "y" and "z" are used much more frequently than in English because those letters have long symbols. This is probably not a major concern when transmitting a few lines of Polish in the middle of many pages of English, but it would be advisable to change the code table before transmitting a large volume of Polish text. In order to do this rules must be established at the transmitter and receiver to allow for different code tables. However if the code tables are changed, the new table must be transmitted and that means transmitting a considerable amount of additional data!

There is no perfect solution to this, and the best compromise depends on the application. Some coding schemes use only one code table. This may not always be the most efficient table, but the coding system does not carry any of the overhead necessary to change tables. Other systems have a small number of fixed code tables, known to both transmitter and receiver. The encoder can examine the data to be transmitted, and select the most efficient code table. The only overhead is the provision of a message that tells the receiver to use, say, "table number three." Still other schemes allow for the transmission of custom code tables whenever the characteristics of the data change substantially.

In 1952 Huffman demonstrated a method for deriving an efficient set of (variable length) symbols for a data source with known statistics. This method is widely used today, and entropy coding is frequently referred to as Huffman coding.

Figure 5.6-1. Morse Code provides a simple example of variable length encoding.

Lossy Compression

As mentioned in the previous section, lossless compression would be an ideal answer, except that it rarely provides large degrees of compression, and it cannot be used alone to guarantee a fixed bit rate. Lossless compression is an important part of the tool kit, but on its own it does not provide a solution to many practical problems. To put digital audio over a modem link, or high definition television through a 6 MHz channel, some loss from the compression system must be tolerated—what comes out will not be exactly the same as what went in. This is the field of lossy compression. Ideally lossy compression, like signal conditioning, removes *irrelevant* information. Some information is truly irrelevant in that the intended recipient cannot perceive that it is missing. There is also information that is close to irrelevant, where the quality loss is small compared to the data savings.

The objective of lossy compression is simple—maximum benefit (compression ratio, or bit rate reduction) at minimum cost (the loss in quality). However, the realization of this objective is not simple. A very large number of parameters have to be chosen for any given implementation, and many of these parameters must be varied according to the dynamic characteristics of the data. Even with a simple measure of the resulting quality (or lack of it), optimizing such a large number of variables is a very complex task.

Unfortunately there is as yet no simple measure that can be applied to the quality of a compression system, particularly for video. The only measure that really matters is the subjective effect as perceived by a viewer, and this is a very complex function. If compression loss were confined to one characteristic of a picture, it would be relatively simple to derive a way of measuring this characteristic objectively. Subjective tests could be performed on a representative sample of viewers to arrive at a calibrated relationship between this characteristic and subjective quality. Unfortunately, compression loss results in not one but many changes to the characteristics of the picture; each of these has a complex, non-linear relationship to subjective quality and they interact with each other.

Compression loss in images involves two main components: things that should be in the picture, but are lost; and things that are added to the picture (artifacts) that should not be there. Expected areas of a compression-related loss include spatial resolution (luminance and color, probably to different degrees) and shadow and highlight detail. Where extreme compression is needed for applications like video conferencing, or the Internet, temporal resolution would also be sacrificed. Artifacts that might be added include blocking, *mosquito noise* on edges, quantization noise, stepping of gray scales, patterning, ringing, etc. As a further complication, in the presence of a loss, the addition of small amounts of artifact such as noise or ringing may actually improve the subjective quality of the picture.

Even within standardized compression schemes such as MPEG, the tuning of a system to yield the maximum quality-per-bit is a black art involving models of the human psychovisual system that are closely guarded commercial secrets. Evaluation of the effect of parameter changes is very complex for the reasons discussed above.

Quantization

For lossy compression, information in some form has to be discarded, and quantization is the tool used most frequently. Quantization determines the precision with which values are represented. As previously mentioned, information needs to be represented with sufficient precision, but it is important not to transmit unnecessary information. Properly applied, quantization can ensure that the information transmitted or stored has just enough precision for the intended application. Quantization is also used to reduce information beyond this point, knowing that impairments will be introduced. Part of the job of a compression system is to ensure that the data is arranged so that the information discarded by quantization has the minimum possible subjective effect on the delivered image.

The simplest form of quantizer is the *scalar quantizer*, and the most common implementation is the *uniform scalar quantizer*. It operates on a one-dimensional variable such as intensity and corresponds to a staircase function with equal spacing of the steps. A continuum of input values is divided into a number of ranges of equal size. Figure 5.6-2 shows a range of input values from 0 to 255, divided by a uniform scalar quantizer into eight equal regions. There are 256 possible input values, but only eight possible output symbols.

As the individual input values are processed by the quantizer, they are compared with *decision values* representing the steps of the staircase. Any input value between the first two decision levels will be assigned the first output symbol, and so on.

The other parameter that has to be considered is the *reconstruction value*. When the quantizer shown in Figure 5.6-2 is applied there are only eight possible output values, each of these can be represented by a three bit code, or a value between zero and seven, as

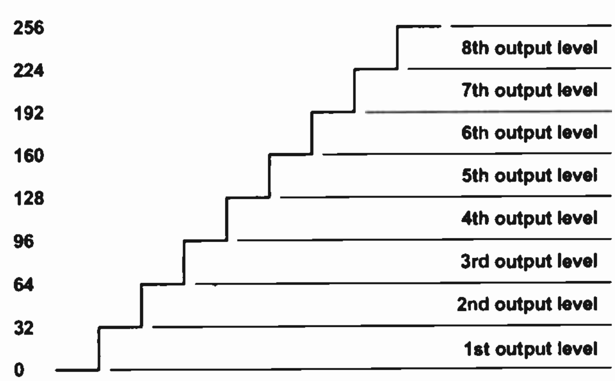

Figure 5.6-2. Uniform scalar quantizer.

Table 5.6-1
Choice of reconstruction value, and its effect on mean square error.

Input Range	Output Code	Reconstruction Value	MSE	Reconstruction Value	MSE
0–31	000	00000000 (0)		00010000 (16)	
32–63	001	00100000 (32)		00110000 (48)	
64–95	010	01000000 (64)		01010000 (80)	
96–127	011	01100000 (96)	325.5	01110000 (112)	85.5
128–159	100	10000000 (128)		10010000 (144)	
160–191	101	10100000 (160)		10110000 (176)	
192–223	110	11000000 (192)		11010000 (208)	
224–255	111	11100000 (224)		11110000 (240)	

shown in Table 5.6-1. When using the quantized data, it is no use applying intensity values zero to seven—these are all almost black. To get back to an approximation of the original range of input values, the quantized levels need to be a single value in the range 0 to 255. Adding five zeros to each three-bit symbol, would make all of the output values less than the input values but all of the errors would be in the same direction.

It is reasonably intuitive that if the input values are evenly distributed, a reconstruction value at the center of each step is likely to give smaller overall errors. This is illustrated in Table 5.6-1 where the overall error is expressed as a *mean square error* (MSE).

The most obvious application of quantization is to directly reduce the precision of the intensity values of the image. The necessary precision depends upon the application. Too few bits will produce a *paint-by-numbers* effect because the boundaries between adjacent values will be clearly visible. Assuming all the quantization steps are equally visible, the eye can detect intensity differences of about 1%. To avoid visible boundaries the quantization step should be smaller than 1%, preferably by a factor of about two to one. To achieve a contrast ratio in a displayed image of 100:1 (about the best that can be achieved in a movie theater) the 256 values offered by 8-bit quantization should be adequate. For applications with lower contrast ratio, such as the printed page, a coarser quantization such as 6 bits may be sufficient.

Data Manipulation

Earlier the two most common methods of lossless compression, run-length encoding and variable length encoding were described. Reducing the amount of information by the use of quantization has also been covered. These techniques may all be used directly on image data, but far greater efficiency may be obtained if the form of the data is manipulated to take maximum advantage of the techniques. Two manipulation techniques commonly used in compression systems are *prediction* and *transformation*.

Predictive coding relies on the fact that continuous tone images have a high degree of correlation between the values of nearby pixels. In other words, gradual shading is more common than abrupt changes in intensity. Various prediction schemes may be used; the simplest is just to use the preceding pixel according to the scanning system used. The technique predicts or guesses each pixel value according to a known rule, then transmits just the error between predicted and actual values. At the receiving end, the decoder uses the same rule to make the same prediction, and uses the transmitted error value to obtain the correct value.

The range of possible errors is actually twice as large as range of intensity values, so initially this may not appear to be a good technique to use in compression. The secret lies in the statistical distribution of values. Intensity values in a typical image are scattered fairly randomly across all or most permissible values. However, if a good predictor is chosen most of the error values will be small—low values will be much more common than high values. This distribution is well suited to variable length encoding. In practice a typical continuous-tone image may be transmitted losslessly with about half the number of bits per pixel. If the error signal is quantized, then variable length encoded, an image may be transmitted to any desired quality level with fewer bits than would be needed for the same quality using direct quantization.

Predictive encoding is used in the lossless mode of JPEG, and is used in most compression schemes to compress sequences of correlated values such as dc coefficients and motion vectors.

Another powerful means of data manipulation is the *transform,* and the transform most commonly used in today's compression systems is the *discrete cosine transform* (DCT). DCT takes a block of (typically) 8 × 8 pixel intensity values and transforms these into an 8 × 8 block of DCT coefficients, representing a range of horizontal, vertical, and diagonal spatial frequencies within the original block. The DCT transform can represent any 8 × 8 block of pixel values by an appropriate mix of the 64 basis patterns shown in Figure 5.6-3. The appropriate mix is the 8 × 8 array of DCT coefficients. The process is reversible given sufficient arithmetic precision, but this requires 11 bit DCT coefficients to represent 8 bit intensity values. Again, the first step has increased the amount of data.

The benefit of DCT comes from a remarkable correspondence with the sensitivity of the human psychovisual system. When a continuous tone image is transformed by DCT, most of the energy is represented by a few high value coefficients. Many of the coefficients will be close to zero, and if these coefficients are forced to zero the effect on the reconstructed image to a human observer is negligible. Furthermore, it is found that the higher frequency coefficients may be very coarsely quantized with only small effects on the quality of the reconstructed image. The following description of JPEG will show how quantized DCT coefficients may be manipulated to make them well suited for run length encoding and variable length encoding.

JPEG

The Photographic Experts Group of the International Standards Organization began work on a data compres-

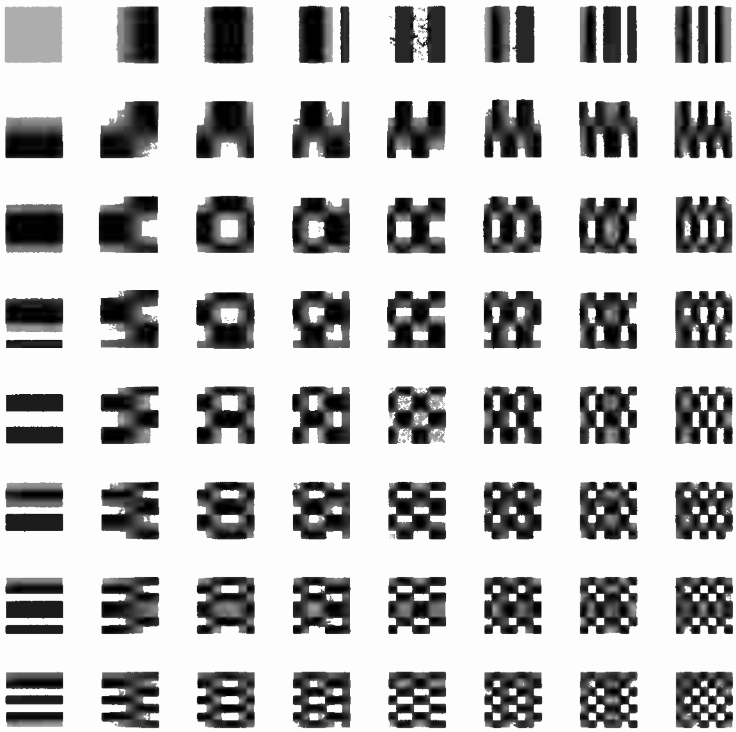

Figure 5.6-3. The DCT basis functions.

sion standard for color images as early as 1982. This effort was joined in 1986 by a study group from CCITT (now ITU-T) and became the Joint Photographic Experts Group (JPEG). In 1987 ISO and the International Electrotechnical Commission (IEC) formed a Joint Technical Committee for information technology, and JPEG continued to operate under this committee. Eventually the JPEG Standard was published both as an ISO International Standard and as a CCITT Recommendation.

At an early stage it was decided that the core JPEG compression would address monochrome images, and that compression would be applied separately to the various components of a color image. Given an 8 bit per pixel monochrome image, the original targets were to provide *recognizable* pictures at 0.25 bits per pixel, *excellent* quality at 1.0 bits per pixel, and images *indistinguishable* from the original at 4.0 bits per pixel. As the work proceeded the committee aggressively pushed performance requirements and the targets were revised several times. Final testing was performed against targets of 0.083 (recognizable), 0.75 (excellent), and 2.25 (indistinguishable) bits per pixel, and an addition level of 0.25 bits per pixel was added for *useful* quality images.

Many compression schemes were tested, but eventually DCT was chosen as the core technology for JPEG. DCT provided the best pictures at low bit rates, and is relatively easy to implement with fast algorithms that can be built into hardware.

This chapter covers JPEG only superficially, as it relates to the various tools already discussed. Because JPEG uses tools such as DCT, it is intended for applications that obey the assumptions made by these tools. It is intended for the compression of continuous tone images, *photographic* or *real-world* images as they have been characterized in this chapter; images that do not conform to these constraints can suffer badly. Specifically, JPEG is not designed for binary (black/white) images, nor is it well suited to discontinuous images such as limited color palette images (GIF images).

JPEG is a very extensive standard offering a large number of options for both lossless and lossy compression. This chapter addresses only the best known JPEG implementation—*Baseline JPEG*. This method uses DCT compression of 8 × 8 blocks of pixels, followed by quantization of the DCT coefficients, and entropy encoding of the result.

Baseline JPEG requires that an image be coded as 8 bit values. Compression is specified in terms of one value per pixel; color images are encoded and handled as (usually) three sets of data input. The JPEG Standard is color blind, in that there is no specification of how the color encoding is performed. The data sets may be *R, G, & B*, or some form of luminance plus color difference encoding, or any other coding appropriate to the application.

The most common coding used with JPEG is luminance plus C_B and C_R. C_B and C_R are derived from *(B-Y)* and *(R-Y)* respectively by scaling and shifting so that the full gamut for permissible *RGB* values can also be represented by 8 bit values. Level 128 represents the zero color difference. Usually, the C_B and C_R signals are filtered to half the spatial bandwidth of the luminance signal, so that each may be represented by only one quarter of the samples of the luminance (half the sampling rate horizontally and half vertically).

The first step in JPEG encoding is to divide the data into its different components, for example, Y, C_B, and C_R. Although the compressed data derived from the components may be interleaved for transmission (reducing the need for buffering at both ends), JPEG processes the various components quite independently. If the color components are bandwidth reduced, the effect is merely that the coder operates on a smaller picture. For example, a Y, C_B, C_R 4:2:2 picture might be processed as one 720 × 480 image (luminance) and two 360 × 480 images (CB and C_R). A simplified block diagram of both encoder and decoder for a single image is shown in Figure 5.6-4.

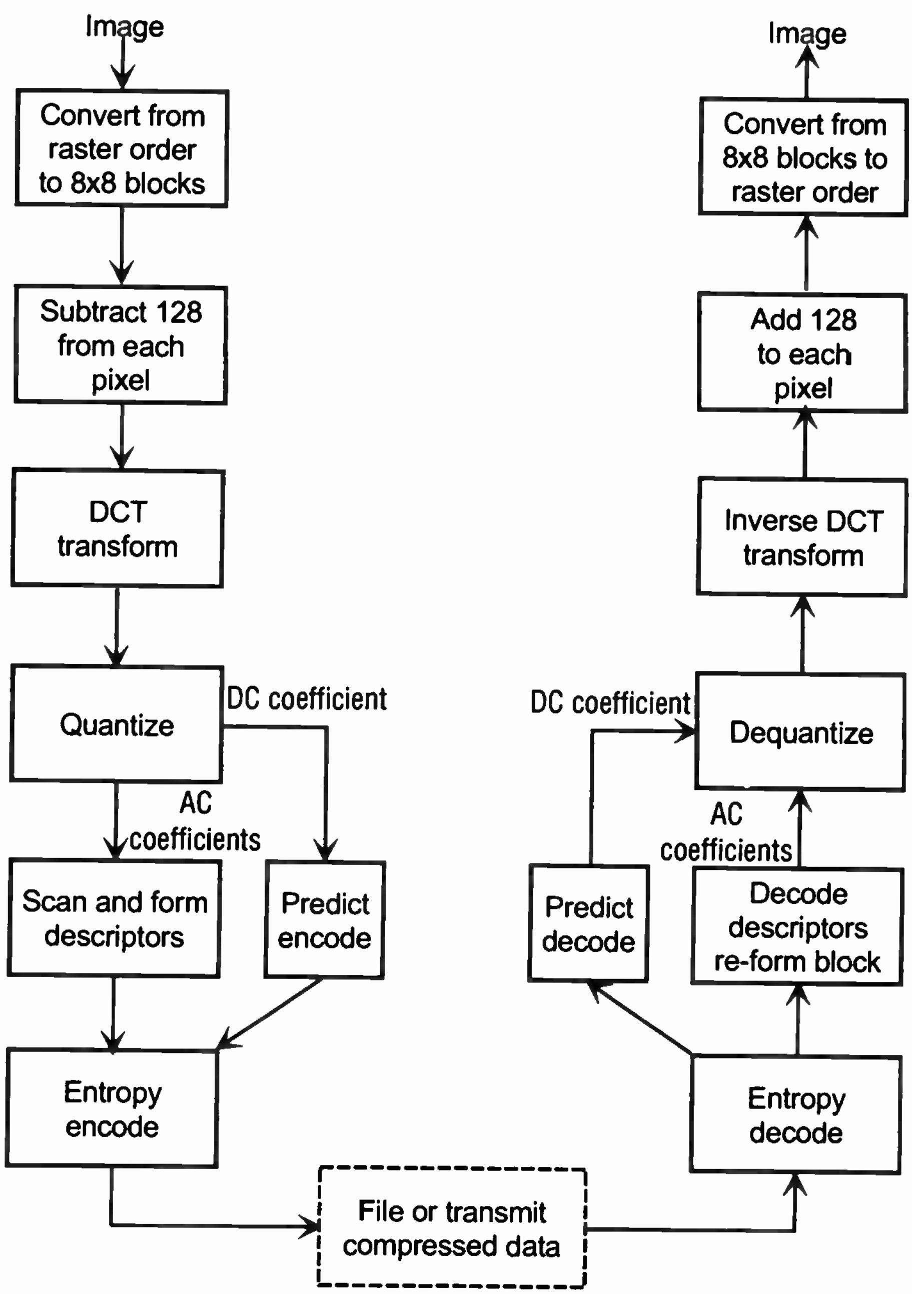

Figure 5.6-4. JPEG encode and decode.

Each component (and from now on we shall consider only one) is divided into 8 × 8 blocks, the value 128 is subtracted from each pixel, and each block is DCT transformed. The Forward DCT equation as used by JPEG is:

$$F(u, v) = \frac{1}{4} C_u C_v \sum_{x=0}^{7} \sum_{y=0}^{7} f(x, y) \cos \left(\frac{(2x + 1)\mu\pi}{16}\right) \cos \left(\frac{(2y + 1)\nu\pi}{16}\right)$$

where:

$$C_u = C_v = \frac{1}{\sqrt{2}} \textit{ for } u, v = 0,$$

$$C_u = C_v = 1 \textit{ otherwise}$$

This formula is not as daunting as it may appear, but it does involve a large number of calculations. $F(u, v)$ is the 8 × 8 array of DCT coefficients; $f(x, y)$ is the 8 × 8 array of pixel values. A single DCT coefficient (at location u, v) is calculated by summing the contribution from each of the 64 pixels (at locations x, y). This process is repeated 64 times to form the complete array of DCT coefficients. With pixel values, $f(x, y)$ in the normal range of 0–255, this equation yields ac coefficients in the range −1023 to +1023, and these may each be represented by a an 11 bit signed integer. The dc coefficient, however, would be in the range 0–2040, and this would require higher precision in the hardware or software performing the DCT transform. To avoid this discrepancy, the value 128 is subtracted from every pixel value prior to the DCT transform. This subtraction has no effect on the ac coefficients generated, but shifts the dc coefficient into the same range, so that all coefficients may be represented by 11 bit signed integers.

The next step is *quantization*. JPEG quantization is a sophisticated process that can effectively use a different quantizer for each coefficient in the 8 × 8 array. Higher spatial frequencies are quantized more coarsely than low frequencies. This process is one of the most significant to the power of JPEG.

The quantized dc coefficient (top left) is separated from the ac coefficients, and the sequence of dc coefficients (one from each block of pixels) is predictively encoded, and then entropy encoded (see Figure 5.6-4).

The quantized ac coefficients from a block are scanned in a diagonal pattern. With typical images this technique yields long runs of zeros, making the output very suitable for run length encoding (another example of manipulating the data to make best use of the available tools). The zero runs, and the remaining non-zero DCT coefficients are grouped to form *descriptors*, units that are particularly suited to entropy encoding. These descriptors are in turn encoded by an entropy encoder (usually a Huffman encoder) according to their frequency of occurrence. Finally, the resulting data stream is combined with various markers to indicate data types and boundaries; these markers also serve to aid re-synchronization at the receiver in the event of data errors.

Figure 5.6-5. Before (top) and after (bottom) JPEG compression. The lower image has been compressed by about 22:1.

At the receiver, the data stream is parsed to separate the different types of data. The entropy encoded data from each pixel block is decoded into descriptors which, together with the known descriptor definitions, allows the block of ac DCT coefficients to be re-assembled. Separately, the stream of data representing the dc coefficients is decoded first by the entropy decoder, then by the predictive decoder, and the appropriate dc coefficient is associated with each group of ac coefficients.

The next step is known as de-quantization. This is a misnomer as the process does *not* undo the effects of quantization. It does replace each quantized coefficient with the appropriate reconstruction value, taking into account the quantizer used for each individual coefficient.

All the coefficients of the block are now back in the correct range, and the inverse DCT transform is applied to generate a block of received pixel values. These are re-ordered into the correct scan or file format, along with any other color components, and the process is complete.

Figure 5.6-5 shows examples of fairly aggressive JPEG compression on the image known as *Boats*. The compression ratio is about 22:1, corresponding to about 0.36 bits per pixel.

On the one hand, it is easy to see the results of compression. There is loss of detail and very evident blocking artifacts in the sky. This large compression ratio is chosen to make the effects easily visible in the book. Nevertheless, the results are not all that bad. When the book is held at arm's length, the compression errors are not very evident.

In the enlarged views in Figure 5.6-6 the mechanism of JPEG can be seen clearly. The small blocks are pixels grouped into blocks of 8 × 8. It is easy to see that some blocks were coded with the DC coefficient only—they appear completely flat. In other blocks pat-

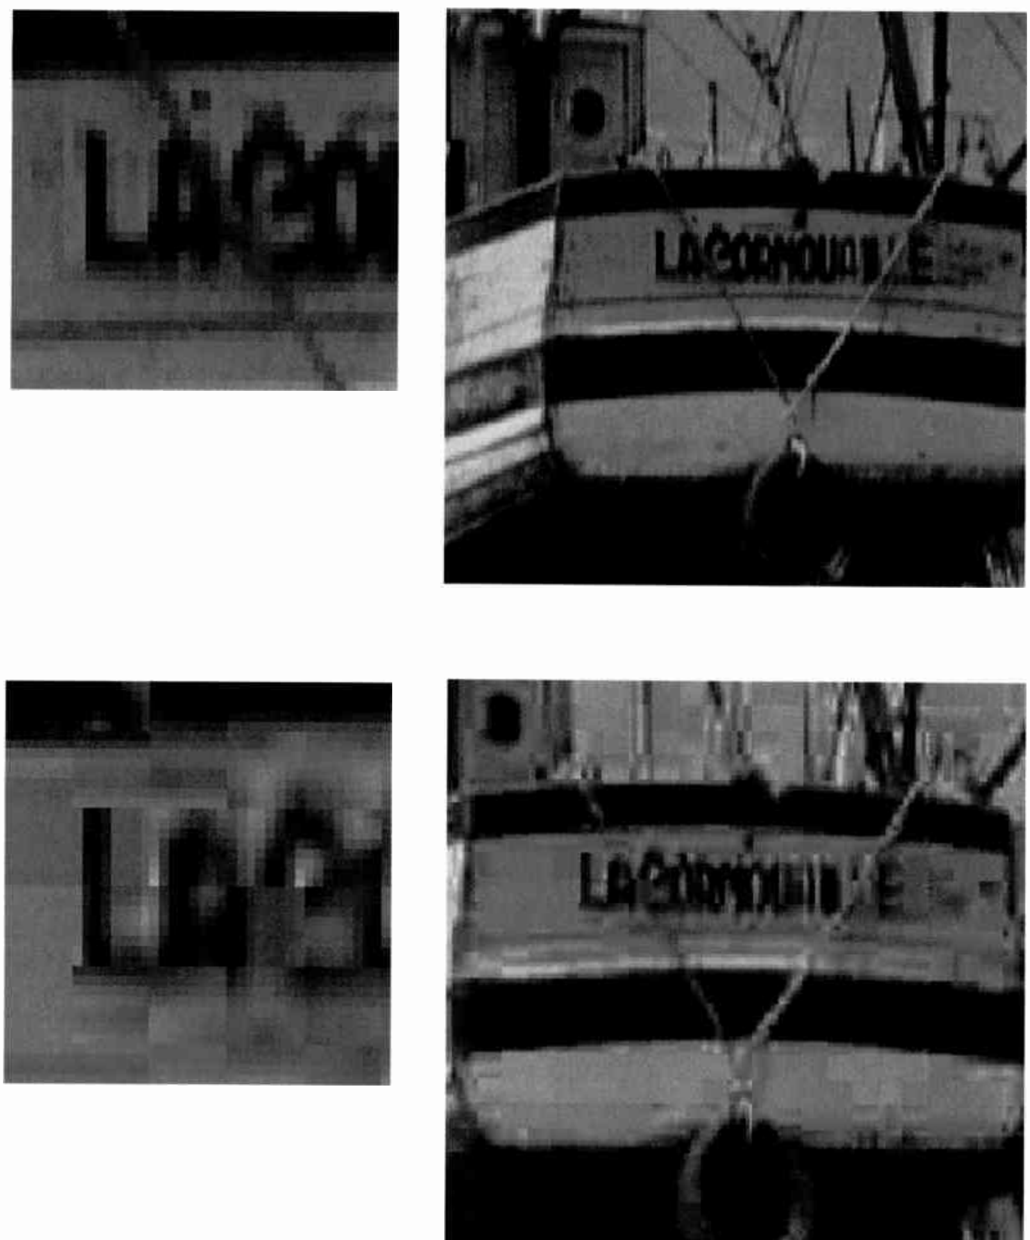

Figure 5.6-6. Enlarged detail from the images of Figure 5.6-5.

terns resembling the low order basis functions are clearly visible.

The previous description addresses the fundamentals of baseline JPEG. The standard includes many optional extensions, but these are beyond the scope of this chapter. The extension most important to television engineers is Motion JPEG. This is not part of the standard but, prior to the arrival of MPEG, it was the most powerful tool for compressing motion sequences. The concept is simple—each frame of an image sequence is coded as a JPEG image, and the frames are transmitted or stored sequentially. This is the basis of most non-linear editors, and most compressed video disk stores, today.

Unfortunately, because Motion JPEG is not properly standardized, virtually every implementation is proprietary and different. Usually image exchange must be performed by decoding in one equipment and re-coding in another. This is inefficient, but it is reality today. In most applications motion JPEG will be replaced by MPEG in the near future, and compressed interchange should be possible.

Motion Compensation

JPEG uses the concept of spatial correlation within a continuous tone to compress the image data. JPEG compression can be applied to a sequence of images, compressing each individually, with the technique known as Motion JPEG. In Motion JPEG, it is clear that the compression efficiency is a function of each individual image, and of that only. Each image in the sequence is compressed according to the same rules; it makes no difference whether the images are totally unrelated, similar in content, or even identical. Motion JPEG takes no advantage of any correlation between successive images.

However, it is easy to see that there should be considerable benefit available here. A sequence of images representing a moving scene is a set of temporal samples. In a typical scene there will be a great deal of similarity between nearby images of the same sequence. In other words, it should be possible to predict one from the other with some degree of success. As in the spatial domain, a compression system can use this property to separate and eliminate redundant data. The analysis of an image sequence to make predictions is called *motion estimation,* and the process of using these predictions to construct images is known as *motion compensation.*

The technique used is to find blocks of pixels, usually 16 × 16, that are identical or very similar in two images. First, one image is encoded by a spatial technique such as JPEG and transmitted to the decoder where it is decoded and displayed. This image will be stored at both the encoder and decoder, and will become the reference image. The second image is examined one block of pixels at a time. The motion estimator searches the reference image for a pixel block that is identical, or very similar to, the block being coded. Depending on the result of this search, various coding methods are available.

If an identical block is found in the same location (the picture at this location is unchanged), the block can be *skipped;* one simple code will instruct the decoder to use the block from the same location in the reference image. If an identical block is found in a different location, the decoder will have to be told where to find the block in the reference image. In this case a *motion vector* is transmitted, a two-dimensional value representing the horizontal and vertical offsets of the block found by the motion estimator.

The motion estimator may not find an identical block; instead it will return the motion vector pointing to the most similar block it was able to find. In this case, the encoder will subtract this block from the block being encoder to arrive at a block of residual values. This block of residuals may be spatially encoded and transmitted with the motion vector.

Static backgrounds and moving backgrounds provide a simple visualization of how motion vectors may be used to identify correlation between images in a sequence. However, it is evident that there is nothing special about the background—this technique can be used on any part of the image provided to find the same object, or part of an object, in two images of the sequence. The simplest technique, *block matching,* is to treat each image block separately, and search for an identical or similar block in the reference image.

The difficult part is finding the matching block due to the lack of adequate temporal sampling. If the temporal sampling obeyed Nyquist, tracking an object from one sample to the next would be a very easy task. Nyquist sampling implies the simplest possible path that connects an array of samples. It has already been established that the temporal sampling rate of any common imaging system is much less than that required by Nyquist rate. This fact leads to a simple conclusion—the position of an object in one image of the sequence provides no clue where it will be in the next.

Full search block matching tests every possible block within a defined search range against the block it is desired to match. The technique is accurate and exhaustive—if there is a match within the search range, this technique will find it. It is, however, computationally demanding.

MPEG

The Moving Pictures Experts' Group (MPEG), like JPEG, is a committee formed under the Joint Technical Committee of ISO and IEC. The MPEG-1 goal was to record video and stereo 48 kHz audio on a CD at the standard CD data rate of about 1.5 Mb/s. For this reason MPEG-1 is confined to a maximum image size of 352 × 288 for 50 Hz systems, and 352 × 240 for 60 Hz systems. This format, in its two variants, is known as *common intermediate format* (CIF), and is the image size used by many non-broadcast quality compression systems. Note that MPEG-1 has no tools for interlaced video.

MPEG-1 was "frozen" (subsequent changes were editorial only) in 1991. In the same year the MPEG-2 process was started, eventually becoming a standard in 1995. The initial goals were simple: to accommodate broadcast quality (standard definition) video and to accommodate interlace. In many ways, MPEG-2 represents the coming of age of MPEG. The greater flexibility of MPEG-2, combined with the increased availability of large scale integrated circuits, meant that MPEG-2 could be applied to a vast number of applications.

MPEG-1 is vastly more complex than JPEG, both in specification and implementation. Nevertheless, it is fair to look at MPEG-1 and characterize it as "slightly modified JPEG plus temporal compression and rate control." There are improvements on JPEG, but the changes are minor and based upon experience of an excellent system. This was not a given—at the beginning of MPEG many alternative spatial compression algorithms were tried, but the JPEG approach proved still to be superior. Similarly, MPEG-2 is based very heavily on MPEG-1. It is a measure of the quality of the work performed by these committees that each standard provided a solid basis for extension to the next.

MPEG-2 provides for coding of larger images and for interlaced video. It also adds layered coding schemes and a system layer, permitting multiple program streams (each with video(s), audio(s), and auxiliary services) to be carried in a single bitstream. The most fundamental addition, however, is a system of *profiles* and *layers*. MPEG-1 defined a single level of service; any MPEG-1 compliant decoder is required to decode any MPEG-1 bitstream. MPEG-2 permits such a wide variety of compression tools, and such a wide range of permissible bit rates, that the MPEG-1 approach is impractical. The set of permissible compression tools is defined by the profile, and the limits on picture size and rate, and bit rate, are defined by the level. Table 5.6-2 shows a few of the parameters that are constrained by particular profiles and levels. A particular use is defined by both sets of constraints, usually expressed as *profile@level*. The best known implementation is *Main Profile at Main Level*, usually abbreviated as *MP@ML*.

Some profiles of MPEG-2 permit encoding of 4:2:2 or 4:4:4 representations. The 4:2:2 profiles was added at the request of the professional television community, mainly for use in studios. Main profile met all the requirements for tools for this application, but supports only 4:2:0 coding. The 4:2:2 profile is defined by MPEG at Main Level, but its extension to High Level is being standardized by SMPTE for lightly compressed high definition signals in for studio applications, and for high definition program contribution and distribution links.

Perhaps the success of MPEG-2 is best highlighted by the demise of MPEG-3. This exercise was started with the objective of providing a compression system suitable for high definition television. It was soon abandoned when it became apparent that the versatility of MPEG-2 embraced this application with ease.

Table 5.6-2
The most common Profiles and Levels for MPEG-2.

Level	Profile: Simple	Main	4:2:2
High		1920H 1152V 60 Hz	1920H 1152V 60 Hz
High 1440		1440H 1152V 60 Hz	
Main	720H 576V 30 Hz	720H 576V 30 Hz	720H 512V/608V 30 Hz
Low		352H 288V 30 Hz	

Table entries represent maximum values.

MPEG-2 is, of course, the basis for the ATSC Standard for Digital Television now being implemented for both standard and high definition transmissions in the United States and other countries. The ATSC Standard employs MPEG-2 at *Main Profile at High Level (MP@HL)*.

It is worth noting the MPEG philosophy of standardization. MPEG describes various tools that may be used to perform compression, and gives some examples of how these might be implemented. The standard defines the syntax of a compliant bitstream and the ways in which a decoder must interpret valid bitstreams (those that conform to the defined syntax).

The really important thing here is the omission. MPEG does *not* define the encoder. A valid encoder is any device, implemented in hardware and/or software that produces a syntactically correct bitstream, resulting in the desired output if the bitstream is fed to a compliant decoder. This is a powerful approach, as no restrictions (other than intellectual property rights) apply to techniques or technologies used in the encoder. Any process, any algorithm, may be used in the encoder provided the output can eventually be expressed by some combination of the permitted syntactical elements. Given this, no matter what advances are made in encoder technology, any compliant decoder will produce the correct output.

MPEG-1 and MPEG-2 differ from JPEG in two major aspects. The first big difference is that both permit temporal compression as well as spatial compression. The second difference follows from this—temporal compression requires three-dimensional analysis of the image sequence, and all known methods of such analysis are computationally much more demanding than two-dimensional analysis. Motion estimation is the way we approach three-dimensional analysis today and practical implementations are limited by available computational resources. MPEG-1 and MPEG-2 are both designed as asymmetric systems; the complexity of the encoder is very much higher than that of the decoder. They are, therefore, best suited to applications where a small number of encoders are used to create bitstreams that will be used by a much larger number of decoders. Broadcasting in any form and large distribution CD-ROMs, are obviously appropriate applications.

The top level definition in MPEG is the *sequence* of pictures. A sequence is of arbitrary length and can represent a video clip, a complete program item, or a concatenation of programs.

Within the sequence, the next lower definition is the *group of pictures (GOP)*. The GOP is a very important concept in MPEG. A typical MPEG bitstream consists of a repeating GOP structure. In the simplest form of encoding, without temporal compression, the GOP can be a single picture, but in typical MPEG applications the GOP will be a comprised of pictures coded in three different ways, and arranged in a repetitive structure most commonly between 10 and 30 pictures long.

Below the GOP, the next step in the hierarchy is the *picture*, or *frame*, and one important point must be made. MPEG-1 includes no concept of interlace; every picture or frame contains all the lines that make up a complete image in the sequence. This is not the same as saying that MPEG-1 cannot encode interlace. The two fields of an interlaced frame can be combined as one frame, but MPEG-1 makes no concession to this practice. There are no special tools for interlace, and no means of avoiding the coding inefficiencies that may result from interlace (in an interlaced system the frame will consist of lines that were captured at different times). MPEG-2 offers a number of tools for coding interlaced pictures, and the combination is extremely efficient.

Continuing down the hierarchy are the *slice* and the *macroblock*. A macroblock contains all the information required for an area of the picture representing 16 × 16 luminance pixels. Macroblocks are numbered in scan order (top left to bottom right). In MPEG-1, a slice is any number of sequential macroblocks; MPEG-2 restricts this to a single horizontal row, or less, of macroblocks. The chief significance of the slice is that it is encoded without any reference to any other slice; this means that if data is lost or corrupted decoding and recovery can usually commence at the beginning of the next slice.

The prefix *intra* means *inside* or *within*, and an *intra frame* or *I-frame* is a frame that is encoded using only information from within that frame. In other words, a frame that is encoded spatially with no information from any other frame—no temporal compression. Coding of an I-frame is similar, but not identical, to coding of an image in JPEG, or of a single frame in motion JPEG.

Non-intra frames use information from outside the current frame; from frames that have already been encoded. With non-intra frames motion compensated information, as described in the previous section will be used for a macroblock where this results in less data than directly (intra) coding the macroblock.

There are two types of non-intra frames, *predicted frames (P-frames)* and *bidirectional frames* or *(B-frames)*. These will be described with reference to the series of images shown in Figure 5.6-7.

The first image *X* shows a background, a tree and a car. The third image *Z* shows the same scene somewhat later. The camera has panned to the right, causing all static objects to move left within the frame, but the car has moved to the right, and now obscures part of the tree. The second image *Y* shows a point in time somewhere between *X* and *Z*.

Image *X* will be encoded as an I-frame (it is spatially encoded without reference to any data outside that frame). When the frame has been processed, the encoded data is sent to the decoder where it is decoded and the reconstructed image stored in memory. At the same time, the encoded data is decoded at the encoder to provide a reconstructed version of *X* identical with that stored at the decoder. This is the reference picture.

Image *Z* will be encoded as a *P-frame*. For each macroblock in *Z* the encoder will search for a matching macroblock in the reference picture. The objective is to find a motion vector that links the macroblock to an identical or very similar macroblock in the reference. As described in the previous section, residuals will have to be considered if the macroblocks are not identical.

Assuming that the motion detector is good, and has an adequate search range, we should be able to encode a large proportion of image *Z* with respect to *X*. Notable exceptions are the area behind the car in *X*, and the strip of image at the right-hand side of *Z* that was revealed by the camera pan—this information just did not exist in picture *X*.

This gives a clue as to how to improve the efficiency of temporal encoding. In the image sequence shown *X* is the earliest in time, followed by *Y*, followed by *Z*. The coding of *Z* has been described, but as yet the encoding of *Y* has not been discussed. Suppose picture *Y* is stored away until after *Z* is encoded. Both *X* and *Z* can be used as reference frames while encoding *Y*. In this idealized case it should be easy to find a motion vector for almost every macroblock in *Y*. This type of encoding is known as *bidirectional encoding*, and frame *Y* is said to have been encoded as a *B-frame*.

A typical MPEG GOP is shown in Figure 5.6-8. The pictures are now categorized in a slightly different way. I-frames and P-frames are called *anchor frames*, because they will be used as references when coding other frames using motion compensation. B-frames, however, are not anchor frames, as they are never used as a reference.

The GOP shown starts with an I-frame. Clearly, it is essential to *code* an I-frame first to start the sequence; if no previous information has been received there is no possible reference for motion estimation. It is possible to have a number of B-frames precede the I-frame provided these are encoded and transmitted after the I-frame. The first P-frame is coded using the previous I-frame as a reference for temporal encoding. Each subsequent P-frame uses the previous P-frame as its reference. (This shows an important point: errors in P-frames can propagate as the P-frame becomes the reference for other frames.) B-frames are coded using the previous anchor (I or P) frame as a reference for forward prediction, and the following I or P frame for

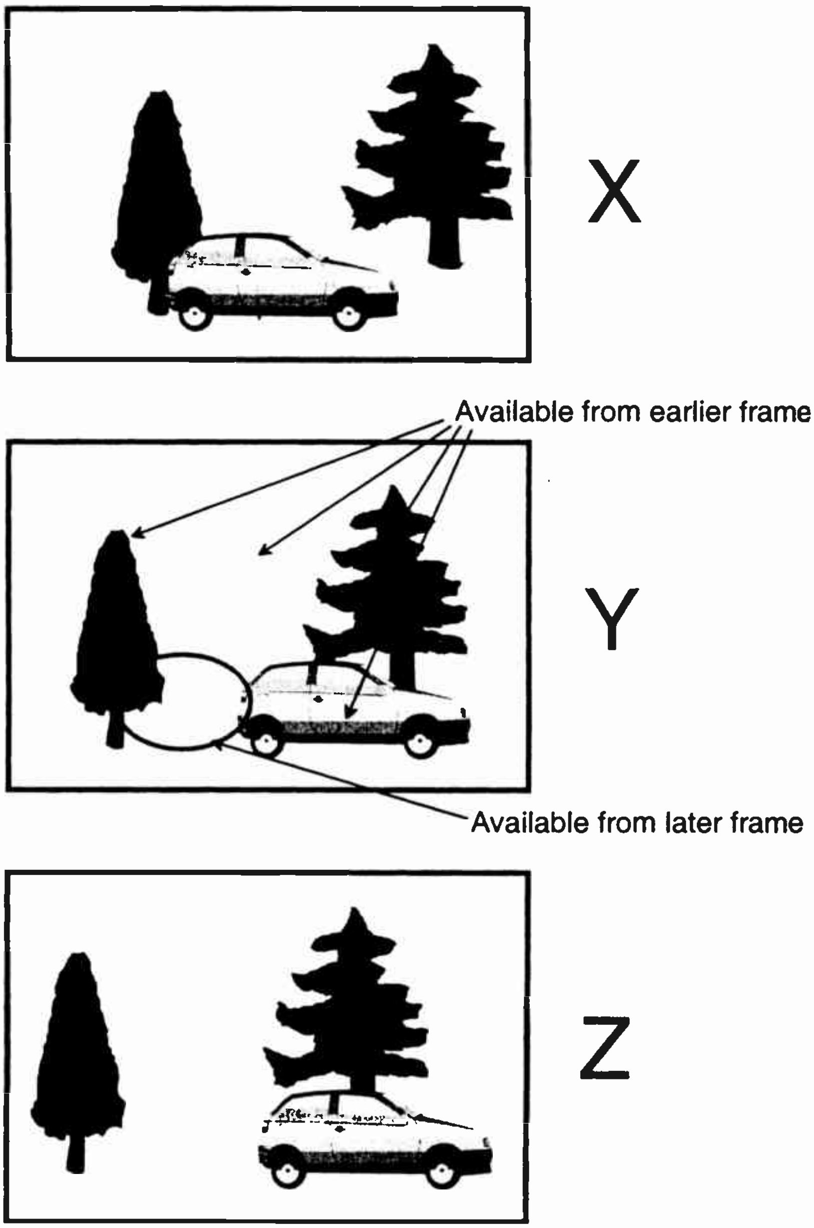

Figure 5.6-7. Bi-directional motion estimation.

backward prediction. B-frames are never used as a reference for prediction.

In a *closed GOP*, as shown in Figure 5.6-8, all predictions take place within the group of pictures. Many MPEG practitioners prefer this approach, but there are examples of *open GOP* structures (I-B-I-B-I). Such structures can be quite efficient, but there is no point at which the bitstream can be separated, every frame boundary has predictions that cross it.

Note that B-frames can only be decoded if both the preceding and succeeding anchor frames have been sent to the decoder. Figure 5.6-8 shows the GOP in *display order*, but to enable decoding the frames are actually transmitted in a different order, as shown in Figure 5.6-9. It is important to note that this re-ordering, essential when B-frames are used, adds substantially to the delay of the system.

It can be seen from the preceding discussion that the coding decisions for a macroblock depend upon the type of frame. However, before considering this, we need to look at the structure of a macroblock and the various possible ways of coding it.

MPEG-1 and MPEG-2 Main Profile use Y, C_B, C_R coding and a 4:2:0 structure of color information. This means that the luminance is coded every pixel, but the color difference information is filtered to half the luminance resolution, both horizontally and vertically. Therefore, an image area represented by a block of

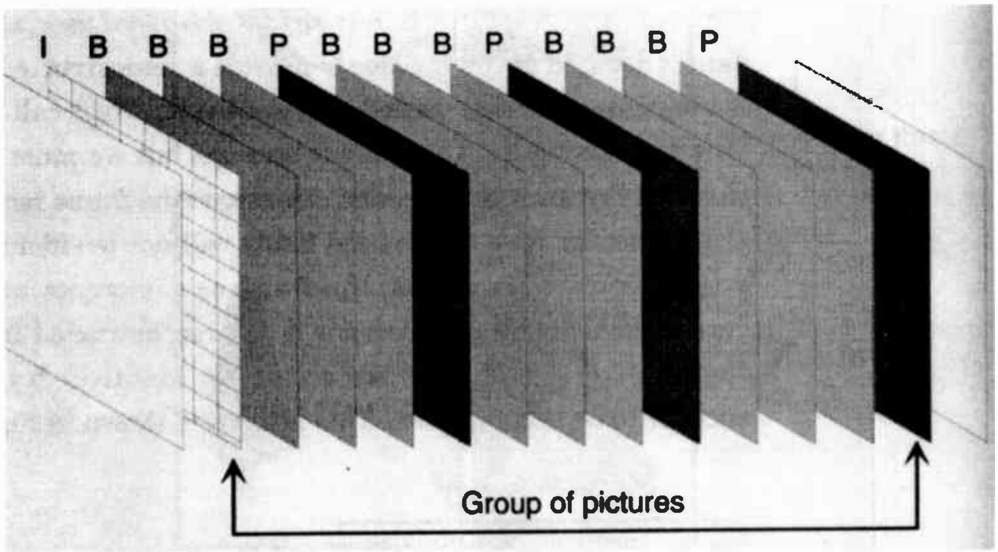

Figure 5.6-8. A typical group of pictures in display order.

luminance pixels 16 × 16 requires only 8 × 8 for C_B, and 8 × 8 for C_R. When using 8 × 8 blocks for all DCT coding, the macroblock consists of four blocks of luminance samples and one block each of C_B and C_R samples. (Note that 4:2:0 coding is not identical in MPEG-1 and MPEG-2; the location of the C_B and C_R pixels is defined differently.)

When a macroblock is intra coded, the procedure for each block of samples is almost exactly the same as described for JPEG but there are a few significant differences. Unlike JPEG, MPEG does define default quantization tables, one is used for intra coding, the other used to code any residuals when inter coding. Either or both quantization tables may be changed by specifying new tables in the sequence header, otherwise the decoder will assume the defaults.

MPEG scales the quantization by means of a *quantization scale factor*, sometimes known as *M-Quant*.

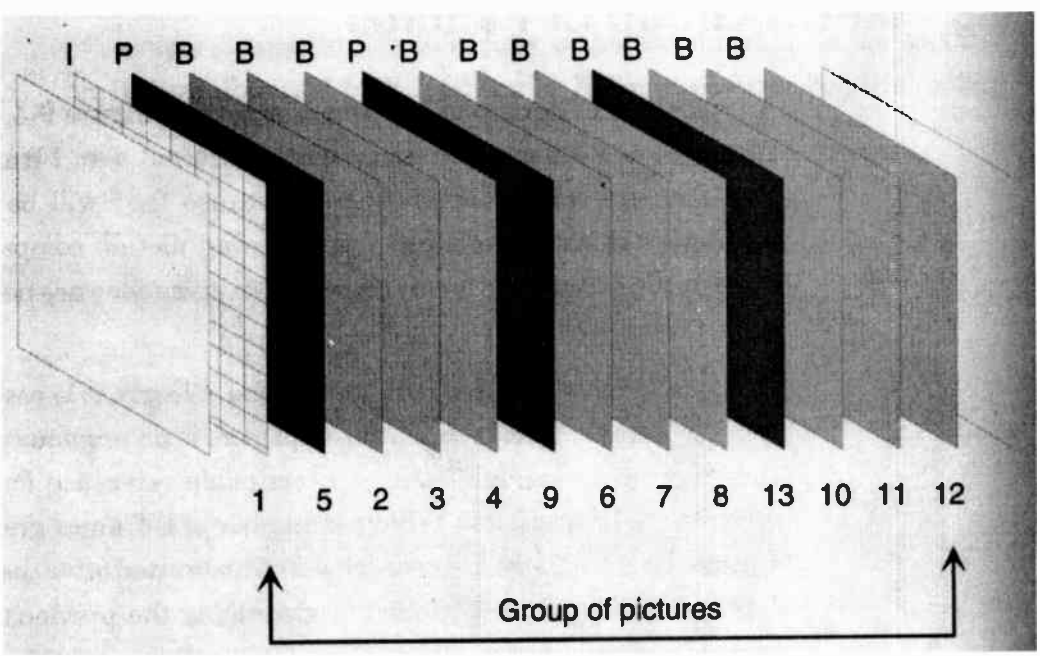

Figure 5.6-9. The same group of pictures as shown in Figure 5.6-8, but pictured in coding (and transmission) order. The numbers below the frames represent display order.

This value is set explicitly for every slice, but may be changed at the macroblock level if required. Each macroblock is assumed to use the same value as the preceding one, unless a new value is set in the macroblock header. M-Quant values range from 1 to 31. The ac coefficients are quantized by multiplying by eight, then dividing by the appropriate value from the quantization table, and by M-Quant. An M-Quant value of one will decrease the severity of quantization by a factor of eight (higher quality); a value of 31 will increase the severity by a factor of four (approximately), yielding lower picture quality.

As in JPEG, the dc coefficients are extracted and coded predictively. The ac coefficients are quantized as previously discussed, then scanned and variable length encoded almost exactly as described for JPEG.

In a P or B-frame, it may be necessary to intra-code a macroblock just as with an I-frame. If there is not a reasonable match in the motion estimator, or if the best match requires transmission of substantial residuals, it will revert to intra-coding of that macroblock. In MPEG, only the luminance samples are used in motion estimation, but the resulting motion vector is used in coding both luminance and color difference blocks.

When the motion estimator has found the best match, each block within the macroblock will be treated separately. Each block being encoded will be subtracted (pixel-by-pixel) from the corresponding block in the matching macroblock, leaving an array of error values. This block of error values (residuals) will be encoded by DCT transform and quantization as in intra-coding, except that a flat inter-quantization matrix is used. This process is applied to the six blocks that make up the macroblock (four luminance plus two color difference). If the motion estimation is good, some blocks will likely produce small residuals that quantize to zero throughout, and these blocks do not need to be encoded at all and can be skipped. When all blocks have been either encoded or skipped, a code is chosen to represent the pattern of blocks that have actually been encoded. If no blocks need encoding, the entire macroblock may be skipped.

Motion vectors also need to be coded. For the first macroblock in a slice, the motion vectors must be sent in full. For the rest of the slice, the vectors are predictively coded; in other words the vectors are assumed to be the same as for the preceding macroblock and differential values are sent for correction if required. Both motion vectors and differentials are variable length encoded.

When encoding a P-frame, there is a choice of coding methods. If it has been determined that the entire macroblock can be skipped, the decision is easy, simply write a *skip* code into the macroblock header and proceed to the next macroblock. Otherwise, total the number of bits that will be required to transmit the motion vectors, the code showing which blocks of residuals have been encoded, and the coded residuals, and compare this total with the number of bits required to transmit the macroblock intra-coded. If the motion compensated coding uses fewer bits, that is what is transmitted. Otherwise the macroblock is marked as intra-coded and that data is transmitted. (In this case, the next macroblock assumes a value of zero for the preceding motion vectors when predictively encoding its motion vectors.)

When encoding a macroblock in a B-frame, there are a few more calculations to perform. As with a P-frame, the number of bits for intra-coding is calculated, and the number for inter-coding with forward prediction. Because this is a bidirectionally encoded frame, two more operations are performed.

The motion estimator will also find a backwards prediction, and the encoder must go through exactly the same process as previously described to determine a total number of bits for inter-coding with backward prediction.

Finally, the encoder may assess a fourth method of encoding that is allowed for bidirectionally encoded macroblocks, interpolated prediction. For regular motion prediction, the macroblock is used at the end of the motion vector as a predictor. This is then subtracted from the macroblock being coded. In interpolated prediction the mean (on a pixel-by-pixel basis) of the macroblock at the end of the forward motion vector and the macroblock at the end of the backward motion vector are considered. This mean is used as the predictor. It is subtracted from the macroblock being encoded to form the residuals. So, if "C" is the current macroblock, "F" is at the end of the forward motion vector, "B" is at the end of the backward vector, and "R" is the macroblock of residuals:

$$R_{i,j} = C_{i,j} - \left(\frac{F_{i,j} + B_{i,j}}{2}\right)$$

where i and j range from 0 to 15 to cover all 256 samples.

Note that this is an unweighted average, irrespective of the position of the B-frame with respect to the surrounding anchor frames. The mechanism is, apparently, useful when encoding noisy pictures.

Any one of the inter-codings may allow the macroblock to be skipped, although in this case we need to specify which of the prediction modes provided that condition. Otherwise, the bit totals for the three prediction modes are compared. If the best of these needs fewer bits than intra-coding then that mode is used, otherwise the intra-coding is transmitted.

Perhaps the most difficult concept associated with MPEG is rate control. Consider the GOP structure. Even if there were no issue in distributing bits throughout a picture, the different coding methods create a problem in rate control. Intra-coding is necessary, otherwise there is no place to start when creating video in the decoder. Obviously inter-coding must be more efficient, or compression system designers would not go to the enormous difficulty and expense of implementing it. A P-frame will typically use fewer bits than an I-frame, and a B-frame should use fewer still. This means that over a transmission system that uses a constant or nearly constant bit rate, I-frames will take longer to transmit than P-frames, which will take longer than B-frames. However, at the encoder the unencoded frames are arriving regularly every 1/30 of a second, and the decoder must send a frame to the display every 1/30 of a second. In turn, this means that the delay from encoder input to decoder output must be constant. This can only be achieved with a buffer at each end.

Actually, the situation is far more complex than this. A good MPEG encoder has to apportion bits according to the image type, the overall complexity of each image, and the differing complexities within each image. It would be reasonable to expect a formidable array of tools to help control bit allocation. In fact, there is one tool—the quantization scale factor, or M-Quant. Everything else will minimize the number of bits for each macroblock for a given M-Quant, but nothing else provides any type of control as to where the bits are used.

The encoder produces a variable rate stream of bits that go into a buffer. The buffer is emptied by a constant transmission rate. If the encoder produces bits too slowly, the buffer will empty, and there will be nothing to transmit. If the rate from the encoder is too high the buffer will overflow and data will be lost. To try to stay within these two bounds the control system must feed a measure of buffer fullness to the magic box called the rate controller, which responds by varying the quantization scale factor, affecting quantization of the DCT coefficients of blocks that have not yet been coded!

In the real world delivery of useful program material requires audio as well as video, and may require additional data streams such as captioning. Clearly it is not a good idea to send all the video, then start the audio, so the bitstreams need to be *multiplexed* together. In some situations it may be desirable to send several different programs, each with its associated video, audio, etc. in the same bitstream. Because continuous information (such as audio) is being transmitted in a discontinuous manner (packets), there is a need for timing and control to ensure that all the inputs can be re-assembled correctly. All of these issues are handled by the MPEG systems layer that defines two types of bitstream, the *program stream* and the *transport stream*. Program streams are best suited to variable rate, low error, applications such as CD replay. Transport streams are intended mainly for fixed rate applications, and use short, fixed length, packets of data that are very suitable for forward error correction. This is the stream type used by the ATSC Digital Television Standard.

OTHER COMPRESSION SYSTEMS

JPEG and MPEG together represent most of the television broadcast applications of compression today. In particular, MPEG-2 is used in DVD, and in the ATSC Digital Television Standard. This section mentions briefly some of the other systems suitable for video.

The DV compression standard has become very popular, particularly for news applications. The system was designed to be very economical so as to be suitable for consumer applications; the same chip performs compression and decompression. DV is an intra-field system using the DCT transform, followed by quantization and lossless compression. Incoming data is shuffled to distribute complex blocks evenly, and there is a mechanism that allows left-over bits to be used by more complex blocks.

Basic DV encodes a 4:1:1 color space with approximately 5:1 compression to give a 25 Mb/s bitstream. A professional varient uses two chips and encodes 4:2:2 yielding a 50 Mb/s bitstream. In this mode the compression ratio is only 3.3:1, and the system is very close to transparent.

SX compression is an implementation of MPEG 4:2:2@ML using an open GOP with an I-B-I-B structure and a bit rate of about 18 Mb/s. The open GOP structure makes insert editing complex.

Wavelets have been used in some television applications. Some suggest that wavelets are well suited to low bite rate applications, but to date DCT has proved superior for near-transparent broadcast applications.

Finally, a word about MPEG-4. Initially intended just to address very low bit rate applications, the work has expanded to cover a wide range of bit rates, and a system permitting separate transmission of picture elements that may be composited in the decoder. It is likely that this system will have a major effect on computer applications using internet communications. However, the large number of decoders now being deployed into the consumer market suggests that MPEG-2 will dominate this market for some time to come.

5.7
VIDEO RECORDING PRINCIPLES

STEVE EPSTEIN
BROADCAST ENGINEERING AND *VIDEO SYSTEMS* MAGAZINES
OVERLAND PARK, KS

INTRODUCTION

Before the invention of the videotape recorder (VTR), film provided television's only video storage method. Images (and sound) were recorded using standard film equipment, either in the studio or on location. Specialized projectors and television cameras were used to convert filmed images into video. Images were also recorded onto film directly off special, high quality television monitors for later playback. Devices such as these, called *kinescopes*, were used to time shift network feeds to the west coast. Unfortunately, exposed film had to be developed before it could be used, adding considerable time to the procedure. Film could be used for recording only once, and the networks required a considerable amount of film to time shift an entire day's broadcast. By 1954, American TV operations used more raw film than all of the Hollywood studios combined. A rerecordable medium that allowed for immediate playback was needed. As it turned out, that medium was videotape.

Immediately prior to the 1956 NAB convention, on April 14, Ampex introduced the first practical VTR to a meeting of CBS station executives. Later that year, on November 30, the VTR was first used on-air for the CBS airing of *Douglas Edwards and the News*. In the forty years since, the VTR has gone from technological breakthrough to commodity.

Within the broadcast and professional community, the VTR remains a resounding success, but in this age of computer based systems, hard disk drives, developed and used throughout the computer industry are finding popularity as video recording devices. In addition to computer based hard drive systems, specialized disk recorders are also finding use. Although many of these video disk recorders (VDRs) record digital bits, a handful are analog devices. For the most part, this chapter examines professional video recording systems, however, some information relative to popular consumer devices is also included.

FUNDAMENTALS

Nearly all video recording today is done using magnetic media, either tape or disk. Some optical or magnetooptical devices are also used; many in specialized applications including archive libraries, kiosks and short form programming such as CD-ROM or DVD (Digital Versatile Disk) applications. DVD is just becoming available at the time of this writing, and its level of acceptance into the marketplace (both consumer and professional) remains to be seen. DVD offers considerable longer play times than CD-ROM, especially on the larger disk sizes.

For any video recording method, some fundamental design choices must be made. The first is whether the recording is to be analog or digital. For analog recordings, there are bandwidth issues to be decided, whereas for digital, the choice is the number of bits to record. Most popular recording systems use 8 bits. The second choice is whether to record composite or component video. Early recorders were composite, while much of today's equipment records the video components individually. One additional choice is whether to record on tape or disk. Videotape, in terms of dollars per minute is by far the most cost effective, however, videotape machines can be expensive, both to purchase and maintain. Disk drives require only minimal maintenance, but typically do not provide the long record times offered by tape. Unlike videotape, if a disk drive fails, the media cannot be easily moved to another machine. Another consideration of disk storage is the type of accessibility. Some of this is dependant on the VDR chosen, but it boils down to whether the video is stored, handled and output as video, or if it is dealt with in terms of a computer file. A few recorders can handle either method gracefully. Both systems have their merits. The advantages and disadvantages many times come down to the intended application within the facility.

Several criteria can be used to categorize videotape machines. These include:

- *Physical tape size:* Tape widths range from 1/4″ (6.35mm) up to 2″, Lengths, rather than being expressed in terms of feet or inches, are expressed in minutes or hours, with 2–3 hours being the typical maximum
- *Tape style:* These include open reel and cassette. In the professional arena, only the 2″ and 1″ formats were open reel machines, all others have used cassettes. Today's machines are almost exclusively cassette based
- *Scanning method:* Transverse and helical scan are the only successful types. The 2″ quadruplex format utilizes transverse scanning, all others have been helical scan (see Figure 5.7-1)
- *Recording format:* Formats include composite (direct-color), Y/C (color-under) and component (Y,

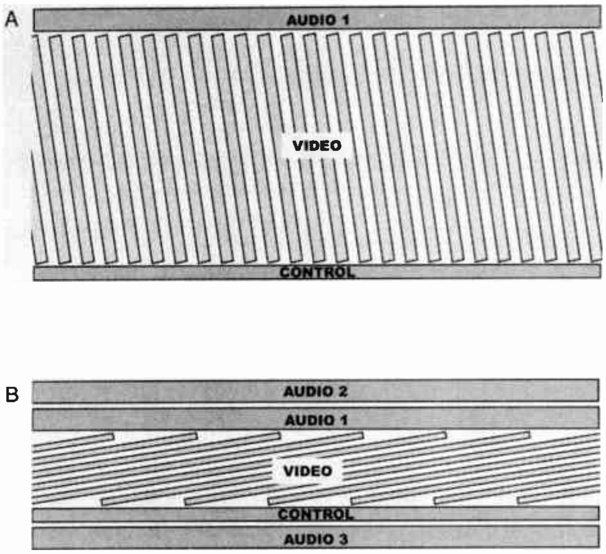

Figure 5.7-1. Scanning system used for videotape recording, (a) transverse scan, (b) helical scan.

R-Y, B-Y) methods in both analog and digital designs
- *Input/output connections:* Most machines provide input and output connections for analog composite video and two channels of balanced audio. Some machines provide analog component video I/O. In addition, some machines provide for up to four analog and/or digital balanced audio connections. S-video (separate luminance and chrominance on a single 4-pin mini-DIN connector) and dubbing connections are common on many of todays VTRs. Digital video, either component or composite is available on nearly all of the VTRs designed to record video digitally.

Video disk recorders have similar criteria including:

- *Maximum record time:* This is based on the amount of storage within the device. Some devices can be expanded through the use of external drives. Storage time may be for video and two audio channels, or for video only
- *Compression requirements:* Compression may or may not be required depending on internal bandwidth issues. Some units may have selectable compression rates, but require all clips played in a sequence to be compressed to the same level. Other units may offer the ability to playback various compression levels randomly
- *I/O connections:* Units may have video I/O, LAN connections, or disk drive connections such as SCSI. Some units provide all of these and more. VDRs may be video only, or offer video and audio recording. Some units are capable of handling multiple I/O streams simultaneously
- *Redundancy/backup:* Magnetically recorded media typically cannot be separated from the complete drive assembly, therefore, some level of redundancy (RAID) or backup mechanism may be required for critical applications
- *Random access:* One of the primary features of VDRs is their ability to randomly access clips. Not all drives are created equally. A few units can truly play any frame after any other frame, however, some require sequences to be prerendered for real time playback.

The basics of today's VTRs are similar to the machines produced in the mid 60's. The 2″ VTRs are relatively straightforward and easy to understand, and having a basic knowledge of these formats makes it much simpler to grasp the concepts behind the newer machines. Because of this, many of the descriptions are based on the 2″ machines.

VTR basic building blocks include:

- *Transport and related control systems.* The transport is an electromechanical assembly that provides a precise path through which the tape moves. Also included are the various motors and guides used to move and position the tape. Magnetic tape transports require mechanical alignments to be maintained precisely. Tape must be capable of moving at any speed and in the forward or reverse directions without experiencing any edge damage. This is especially true in editing machines. Control of the early VTRs was accomplished using simple relay circuits; today's units rely heavily on microprocessor based systems
- *Servos.* Used to control the head drum assembly, capstan and in many units, the reel motors
- *Video and audio circuitry.* Basic video circuits consist of input, modulator, demodulator and output stages. Some newer machines include bit rate reduction (compression) circuitry as well as A/D, D/A convertors and/or composite to component encoder/decoders. Audio in most VTRs is comparable to professional audio recorders
- In many cases, additional circuitry for editing or other special functions such as dynamic tracking.

Tape Transport and Control

Fundamental to any videotape machine is the mechanical transport assembly. The transport provides the mechanical interface between the machine's electronics and the information recorded on the tape. Depending on the format, the transport will include the loading mechanism and reel hubs, tape guides and sensors, the drum assembly and the capstan. Recording/playback heads include the erase head, audio heads, a control track head and the various video heads within the drum assembly. Additionally, the transports of professional editing machines typically include time code heads, audio confidence playback heads, audio-only erase heads and flying erase heads mounted in the drum assembly. Flying erase heads are used during insert edits and at the beginning of assemble edits, until sufficient time has passed to allow the full track head to begin erasing the tape (if necessary).

Constant torque motors linked to the reel hubs prevent slack tape and minimize tape stretch caused by excessive tension. Brakes are engaged when tape is stopped to prevent spillage. On many units, the brakes are also used to slow the tape during movement, however, more sophisticated machines rely on eddy currents within the motors to provide gentler tape deceleration.

Precision rotating and fixed guides are used to route the tape around, over and through the various assemblies of the transport. Some machines also make use of air (either pressure or vacuum) to position, handle or buffer the tape. The 2" machines used a vacuum guide to control and position the tape at the head drum assembly. Several formats have used vacuum capstans to precisely control tape movement without a pinch roller. Pressurized air escaping through small holes in fixed guide assemblies provides an *air bearing* reducing both tape and guide wear. Loading and unloading of tape transports has also been accomplished quickly and accurately using air pressure, vacuum or both.

Head drum assemblies contain one or more video heads. For professional level recording, relative tip to tape movement is typically on the order of 1,000 ips (inches per second). A capstan/pinch roller combination or a vacuum capstan is used to precisely control tape movement. A tracking control is used to electronically change the mechanical timing relationship between control track pulses and the recorded video tracks. Non-standard recordings may have these pulses delayed or advanced with reference to the video tracks. Either way, the RF signal recovered from the tape is less than ideal, as the head is not centered on the recorded tracks. Proper adjustment of the tracking control centers the heads on the recorded tracks and allows maximum RF to be recovered from the tape.

Control circuitry provides the proper signals to the various motors involved. Early control systems were rather primitive when compared to today's machines, which rely almost exclusively on microprocessor based control systems. Relays or transistor drivers provide the necessary power to the motor. Modes include what has become the standard transport controls: Stop, Play, Record, Fast Forward and Rewind. Most professional machines have forward and reverse search modes which combine viewable pictures with rapid tape movement. Dynamic tracking, provides a playback mode in which the tape moves at a non-standard rate. Fields (2 per frame) are skipped or dropped as necessary. A ready mode on some machines provides a means to get the head drum assembly up to speed without rolling tape, allowing for shorter preroll times. In addition, an electronics to electronics (E–E) mode provides a path from the input circuitry to the output circuitry during stop mode.

Additional control circuitry is required based on the transport type. Open reel machines typically have tape in path detectors that consist of either spring loaded tension arms or optical sensors. Few provisions are made for threading other than brake release switches. Newer machines detect near end of tape based on reel pack diameters and can be instructed not to cross into the near end of tape zones, preventing accidental unthreading at tape ends. Machines capable of this type of detection generally offer an *unload* mode in which the tape is unloaded at a slow speed. Head drums can be damaged by wrinkled tape ends being pulled through at high speed. Ragged tape ends should be cut off, and tape ends should lay flat on the takeup and supply reels of open reel machines, reducing the possibility of damage to the video head assemblies.

Moving from the open reel to the cassette machines, early cassette transports were of the *top load* variety. Cassettes were inserted into a bin which was lowered into the deck. Most newer studio units are *front loaders* and like today's home units will take the tape from the operator once inserted. Many portable units designed for field use are of the push to load variety. Elevators of some type are required on nearly all videocassette formats, because tape must be removed from the shell and threaded through the transport mechanically. To accomplish this, guides must be behind the tape to pull it out of the shell. The elevator moves the cassette above the guides. Once the tape is past the guides, the cassette is lowered, positioning the tape between the guides and the transport. A door assembly is used to protect the videotape from contamination when the cassette is out of the machine. Many newer cassette formats have a clamshell door assembly that protects both sides of the 1nbtape. Reel locks, located inside of some cassettes, prevent the hub assemblies from rotating when the cassette is out of the machine. A pin assembly located in the transport disengages the brakes as the elevator positions the cassette within the transport.

Servo System

VTR servos include those used for the capstan and drum. *Capstan servos* are responsible for tape movement during most modes that provide viewable pictures. Drive oscillators typically have a wide range to provide the tape speeds required. Error correction signals are provided through a feedback loop that includes the control track head. The capstan servo must position the tape such that recorded tracks are physically located where they can be read by properly positioned video heads. The *drum servo* positions the drum assembly containing the video playback head such that it can properly playback the signal recorded on tape. Nearly all professional units allow the capstan and drum servos to be referenced and locked to external sync. Once a transport is locked to external sync, it is relatively easy to lock two transports for editing purposes. *Reel servos* are used in many newer VTRs, but some, especially small format machines, rely on constant torque motors. Felt clutches or brake bands on the reel tables provide takeup and holdback tension. Some high-end machines tie the reel servos to the motion of the capstan, assuming if the capstan is stationary, the tape is not moving. *Capstan motion*, along with pulse generators located in the reel tables can be used to calculate tape pack diameters precisely. These calculations, along with tape tension detectors provide sufficient information to gently and precisely handle tape in a manner that allows nearly instantaneous high speed acceleration and deceleration.

Video Signal Path

The electronic components used in VTRs as well as the actual circuitry have evolved considerably over the last 40 years. However, the basic building blocks are comparable. There are numerous variations depending on the format and actual recorded signal. Consider the task of recording a composite signal. On the record side, 1V pp composite video goes into an input amplifier and sync separator. Sync pulses are routed to the servos so the transport mechanisms can be properly phased and standard recordings can be made. Once the tape is in motion and the servos are locked, a record lockout circuit verifies that the tape can be recorded on. The erase heads are energized, erasing any previous recordings and preparing the tape for the new one. The video signal is sent through a preemphasis circuit and frequency modulated. Rotary transformers complete the circuit to the record amplifier and record heads. Many machines provide inputs and output connections at the record amplifiers and playback preamplifiers. In this manner, the modulated RF signal can be dubbed from one machine to another without having to be demodulated to baseband and then remodulated for the duplicate recording (dub).

Upon playback, the capstan and drum servos position the tape such that the reproduce heads are properly aligned with the recorded tracks. Relative movement of the tape and head assemblies causes an induced current in the heads proportional to the recorded information on the tape. Preamplifiers located close to the video heads, typically within the spinning drum, are used to increase signal levels, thereby minimizing noise. Once amplified, the reproduced signal is equalized to produce flat frequency response. Rotary transformers provide a signal path from the spinning heads to the stationary transport. A limiting amplifier and demodulator complete the playback signal path. Because the recorded signal is frequency modulated, amplitude variations in the reproduced signal do not affect the reproduced signal. Passing the signal through a limiting amp provides the demodulator with a constant level signal. In the demodulator, the carrier frequency is removed from the signal, and only baseband video remains. The baseband video is put through a deemphasis circuit to remove the frequency distortions which were added to improve the recording process. Finally, an output amplifier is used to set the signal level and provide sufficient power to drive the unit's outputs (see Figure 5.7-2).

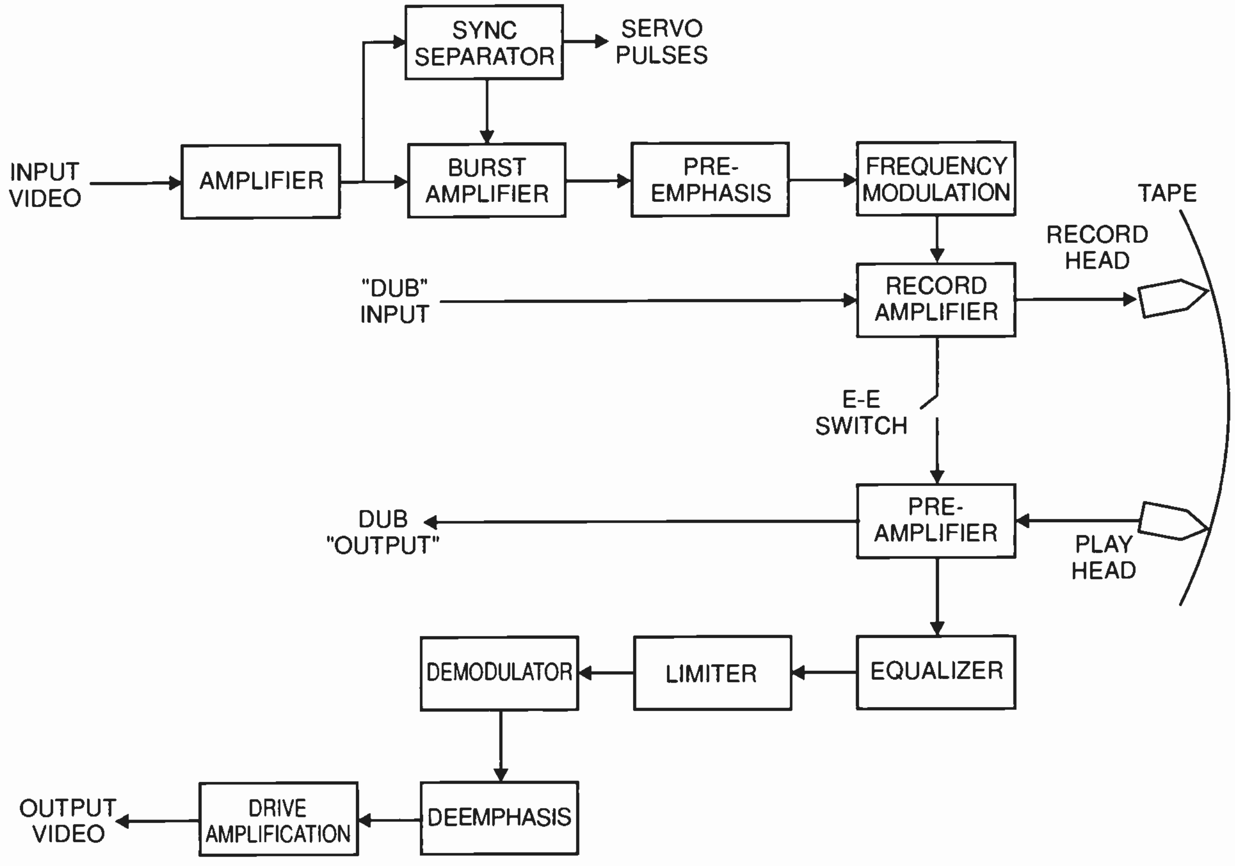

Figure 5.7-2. Block diagram of the video record and reproduce circuits used in a typical videotape machine. (Adapted from *NAB Engineering Handbook, Eighth Edition p. 880*)

Generally, the output amplifiers are considered the final stage in the playback circuitry. However, due to time base errors caused by both the playback and record processes, additional circuitry is required to stabilize and correct the signal to meet the requirements of RS-170(A). Time base correctors (TBCs) have become so common place that today complete units are available as plug-in cards for personal computers. Many videotape machines, typically those of the color-under variety, require minimal stabilizer circuitry to provide output signals suitable for display on a color monitor or television. Although these machines provide viewable pictures, a TBC is recommended if the video output is to be used for anything other than viewing.

Dropouts are fairly common on video recordings, and are caused by either airborne particulates or small sections of tape with poor response. Particulates that end up between the head and tape during record will prevent RF from being recorded, thus causing a permanent loss of signal. During the playback process, particulates will cause random and generally non-repeatable dropouts. Tape response problems are caused either by physical damage or a lack of oxide. Manufacturing techniques have improved considerably over the years and high quality tape is readily available. Today, airborne particulates are the primary cause of dropouts not caused by physical damage. Maintaining a clean environment is the best way to reduce dropouts of this nature. In analog recordings, dropout compensation is typically accomplished by repeating previous lines whenever a loss of RF occurs. For digital recordings, error correction and concealment techniques are used to prevent noticeable signal loss.

For the most part, the previous description applies to the composite recording process used in the 1″ type-C format. The 2″ quads used similar circuits, however, the video signal was segmented. Four separate heads were used to record and playback the video signal. For color-under recordings, including the 3/4″ U-matic, S-VHS and Hi8 formats, two parallel circuit paths are used, one for luminance and the other for chrominance. These units typically provide composite and Y/C inputs and outputs. Many decks also provide dubbing connections. Although the distribution of separate Y/C signals throughout a facility may be considered *component distribution*, the color-under recording process is not considered a component format. In the color-under process, composite input signals are fed through a low pass filter, limiting high frequency luminance components to approximately 3 MHz and separating the luminance signal from the chrominance signal. The chrominance subcarrier is bandpass limited to provide a 0.5 MHz wide double sideband signal. This signal is amplitude modulated onto a carrier near 650 kHz, which is added to the FM luminance carrier for recording on tape. The recording spectrum is shown in Figure 5.7-3.

At present, all color-under systems are helical scan machines. Normally two heads are used to record the combined signals, one for each field. Typically the tape wraps 180° around the head, allowing the heads

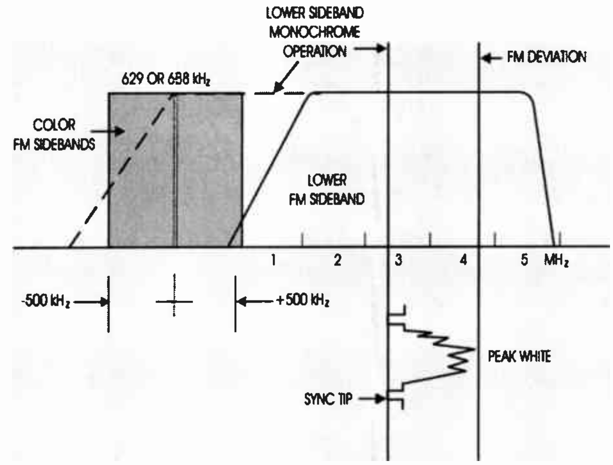

Figure 5.7-3. The recording spectrum used by video tape machines that use the color-under recording process. The AM chrominance subcarrier is added to the FM luminance carrier and recorded on tape. Part of the lower sideband of the FM luminance signal is removed to allow for the chrominance signal. (Source: Benson and Whitaker, *Television Audio Handbook p. 7.7*)

to be switched by a symmetrical square wave locked to incoming vertical sync or, during playback, generated by the control track signal. One advantage of the color-under process is that time base errors in the color signal are kept to a minimum, allowing the output signal to be displayed on a monitor or television with little or no correction circuitry. Disadvantages include high chroma noise and limited chroma and luminance resolution. Many of the smaller formats improve tape packing density by eliminating the guard bands between recorded tracks. This is accomplished by angling the head gap relative to the recorded track. Rather than being perpendicular to the track, the gap is up to ±15° from perpendicular. One head is angled one direction from perpendicular, and the other head is angled the other way. Because of this, guard bands are not needed as the off-axis response of adjacent tracks is minimized.

Like the color-under formats, the component formats separate luminance and chrominance. However, these formats take an additional step and separate the chrominance into two color difference signals, R-Y and B-Y. The two primary formats using this recording process are M-II from Panasonic and Sony Betacam (SP). These two formats are similar but not interchangeable. Although the same component signals are used for input and output (Y, R-Y and B-Y), signal levels are different. Care must be taken to adjust I/O levels when decks based on these different formats are interconnected. Most decks provide composite and component inputs and outputs as well as dubbing connectors. These units provide reasonably high quality encoders and decoders for composite to component signal conversion. Three parallel signal paths exist, the luminance path typically has a 4.2–4.5 MHz bandwidth, while the paths used for the color difference signals have only a 1.5 MHz bandwidth each. On these machines, one head records the FM luminance signal on a single track per field. A second track, recorded by a second head, contains the chrominance signal as well as FM audio. The chrominance signal is a compressed time division multiplexed (CTDM) signal in which the analog R-Y and B-Y components are time compressed and then multiplexed into a single signal. Delaying the B-Y signal approximately one-half of a field allows the R-Y information to be recorded first, followed by the B-Y. FM audio is placed at the beginning of the track, before the color difference information. Upon playback, timing differences between the three component video signals are removed, and the components are time base corrected separately. The component signals are output at specified signal levels and also fed to an encoder. The encoder combines the signals to provide a composite output that can be used if desired.

One additional twist in many of the newer VTR formats is the use of compression or bit-rate reduction. Two formats, Ampex DCT and Sony's Digital Betacam perform a discrete cosine transform (DCT) on the video signal, reducing the number of bits required to approximately half. The DCT process is lossless, however, subsequent quantization can result in data being discarded permanently. Professional formats based on the consumer DV format such as Sony's DVCAM, Panasonic's DVCPRO and JVC's Digital-S (which uses a dual DV codec), as well as Sony's Betacam SX perform lossy compression on the video signal. The compression ratios used are minimal, and the resultant pictures are quite good, due in part to the fact they are recorded as digital rather than analog signals.

Audio Signal Path

The audio circuitry in videotape machines is comparable to the circuitry in professional audio recorders. One notable exception is a notch or filter around 15.7 kHz, the video horizontal frequency. Depending on whether the unit is intended for broadcast, industrial or consumer use, this is handled differently. One of the simplest methods is to simply roll off the audio response somewhere above 12 kHz such that the response at 15.7 kHz is relatively low. Other systems employ tighter notches specifically at the 15.7 kHz frequency. Many high quality professional units employ significant measures to prevent the 15.7 kHz from affecting the audio circuitry.

Most professional VTRs have balanced inputs and outputs referenced to +4 dBm. Most machines have at least two audio channels, while some have as many as four longitudinal channels. In addition, many offer up to two channels of pulse code modulated (PCM) or FM audio recording, however, on many units, these channels cannot be independently edited.

Quickly reviewing the audio record process, audio enters the machine, and once set at the proper level, is mixed with the bias current. The bias current is an ultrasonic (60 kHz to 200 kHz) low-distortion sine wave. Once the bias and audio signals are mixed, the output is fed to an equalization circuit for preemphasis. The signal is then recorded on tape. Upon playback, a deemphasis circuit restores the original frequency characteristics. Amplifiers then provide the required output from the machine. Most units provide E–E circuitry for monitoring the input signal(s) when the unit is in the stop mode.

ANALOG VIDEOTAPE FORMATS

The first successful videotape format was the 2″ quadruplex. Since then more than 30 videotape formats have been introduced. Only a few have been commercially successful in the professional arena. New tape formats, as well as older formats that remain in widespread use are covered here. For additional specifics, readers are referred to service information provided by the manufacturers.

3/4″ U-matic VCRs

The U-matic format is based on 3/4″ tape contained within a hard plastic shell (cassette). Two shell sizes are available, a large shell (which contains approximately 63 minutes of videotape) and a smaller shell (which can hold up to 23 minutes). A small slot in the bottom of the shells serves as a guide for insertion into machine elevator assemblies. When correctly aligned, the cassette lands on a set of fixed alignment pins within the transport. Loading mechanisms pull the tape from the cassette and wrap it around the drum assembly.

Reel tables are typically driven by direct drive motors or clutch and gear assemblies driven by a single motor. In most of today's machines, pulse generators within the reel tables provide feedback to control circuits. Lamps and optical pickups determine the beginning or end of tape. A clear leader at one end and clear leader with an opaque stripe at the other end provide feedback to ensure that sufficient tape is on each reel for the loading process. When either clear leader is encountered, tape movement is reversed, thereby ensuring that the remaining tape is not accidentally pulled from the hub assembly.

Within the transport assembly, when viewed from the front and above, the supply reel is on the right. Tape leaves the cassette shell and moves through several heads and guides. These typically include a full track erase head and one moveable guide (slanted) used to pull the tape from the cassette during threading. The tape rounds the slanted guide and begins its descent down the helix. In most U-matics the helix is a shelf machined into the lower drum assembly. The tape wraps the head drum assembly 180°. On the back side of the drum assembly the tape leaves the slanted guide but continues its descent, passing over the audio and control track (CTL) head and then to the capstan/pinch roller. The tape rounds a guide after the capstan, reversing its direction and beginning its ascent to the height of the take-up reel table.

At this writing, Sony is the only manufacturer still making 3/4″ machines. Today's machines offer improved performance (SP mode) and sophisticated machine control. Optional internal TBCs are available with outboard controls. Serial (RS-232, -422) and parallel remote control of all machine functions is common.

1″ Type C

1″ Type-C is an industry workhorse that remains in widespread use. Despite its popularity, use of type-C is declining. The format solved a major problem of the 2″ Quads—the use of multiple heads (4) during the active picture area. Differential response from the four heads caused a problem referred to as *banding*. The type-C format provides a single head that records one television field per scan. During playback there are no head switches and therefore no banding. The type-C format uses frequency modulation to record the entire composite video signal on each track. In addition to helically scanned video tracks, an area of the tape is set aside for optional helically scanned sync tracks. Longitudinal tracks include a control track and three audio tracks. Many type-C machines provide time code generators and readers for use with Audio 3. Vertical Interval Time Code (VITC) is also available.

The type-C format is an open reel, helical scan format. Servos include the head drum, capstan, reel motors and the video head itself. The type-C machines were the first to employ tracking servos to position the video playback head. Known by several names including Ampex's Automatic Scan Tracking (AST), RCA's SuperTrack and Sony's Dynamic Tracking, these servos used the off-tape RF envelope to determine the location of the tape's video track. Envelope tracking servos simplified machine operation, and allowed for tape playback without the need for control track information. Because of this, tapes could be played back at variable speeds. Depending on head flexibility, playback speed could range from −1X to +3X normal playback speed.

Betacam and M-II

The BetacamSP and M-II formats are highly successful refinements of earlier formats. M-II from Panasonic was an outgrowth of the less than successful M format. BetacamSP is an improved version of the Betacam format. Both M-II and BetacamSP require the use of metal particle tape. Both formats offer several advantages including ease of use, high quality component analog recordings, up to four channels of audio (2 longitudinal and 2 FM), and quality multi-generation editing. Most of these decks have built in TBCs standard, and several offer variable speed dynamic tracking. Camcorders and dockable recorders are available for field acquisition. Because of their portability and convenience, these formats are used in a wide variety of professional, semi-professional and broadcast applications. Two cassette sizes are available, and each shell type uses a different hub location. Because of this, models that accommodate both cassette shells must be capable of moving the reel tables. Depending on make and model one or both of the reel tables are moved to accommodate the different hub locations.

S-VHS & Hi-8

Both the S-VHS and Hi-8 formats are color-under, helical-scan formats designed for the high end consumer markets that have been adopted for professional use. Both offer backward compatibility, in that they can play and in many instances record tapes in the earlier mode (VHS and 8mm). Both Hi8 and S-VHS offer features for the professional market, including full editing capabilities, time code and dynamic tracking. JVC recently introduced a new innovation to the S-VHS format, control track time code. Rather than tying up an audio track for time code, the information is placed in the control track, and tapes can be *post-striped.* Post-striping allows time code to be properly added to the original recording, after the record process has been completed. Tapes can be shot in the field using a standard camcorder without time code, and post-striped in a studio deck. TBCs are available with Y/C inputs and outputs. Hi8 machines along with several other formats have added S-video connectors to the available I/O connectors.

DIGITAL VCR FORMATS

Digital recording formats have been replacing analog formats for the last 10–15 years. Although analog machines are still manufactured, no new analog formats have been introduced for nearly 10 years. Digital video formats (both tape and disk) have even found their way into the consumer video markets. In 1995, announcements concerning digital video decks for home use were made by several companies, followed by the DVD in 1997. Recording digital video is quite similar to recording digital data. Many of the differences between today's digital recorders parallel the differences found in the analog formats, and boil down to bandwidth and signal type.

D-1

The first digital videotape machines appeared in the mid-80's and were designated D-1. These component digital recorders were manufactured by Ampex and Sony and use 19 mm oxide tape and three different cassette shell sizes. The L-size can record 76 minutes of CCIR-601 video. The M-size can record 34 minutes and the S-size only 11 minutes. Video components are digitized and recorded using 8 bits and without compression. D-1, despite its age, remains the top of the line digital recording standard and is used throughout the post-production industry for multi-generational editing.

D-2

This composite digital format uses 19 mm metal tape, with machines originally available from Sony and Ampex. Three shell sizes are available, containing maximums of 208, 94 and 32 minutes of tape. Sampling structure is based on 4Fsc and the decks have widespread usage in composite facilities. A series of data recorders are based on these machines. Like D-1, 8 bits are recorded without using compression.

D-3

In 1990, Panasonic introduced the D-3 composite recording format which combined the small size of M-II and Betacam with the advantages of digital recording. D-3 uses 1/2 in. metal particle tape and provides for two cassette sizes, the small cassettes hold a maximum of 125 minutes of tape and the large hold up to four hours of tape.

DCT

The Ampex DCT component recorder uses 19 mm tapes in specially designed shells. The shells come in three sizes with maximum tape lengths the same as for D-2. A parallel product, DST, is a data storage unit based on the same technology. The units are similar, with the most obvious difference being the I/O modules. A mild 2:1 DCT compression is used but is essentially lossless. Ampex claims that error correction is used rather than error concealment, making the deck robust enough for data applications, and allowing perfect duplicates to be made from a master tape.

D-5

Panasonic's D-5 is a component recorder based on the D-3 transport and is backward compatible with D-3. An 18 MHz sample rate is included with the deck for making recordings of 16:9 aspect ratio material. Panasonic has made an adapter available that allows D-5 recorders to record the 1.2 Gb/s HDTV signal. D-5 decks record digital video at full data rates without compression, however, 4:1 compression is used for HDTV recordings.

Digital Betacam

Digital Betacam, from Sony, is a component format that uses 1/2 in. tapes along with a 2:1 DCT compression. These decks are capable of 10 bit component recordings, and some models are backward compatible with analog Betacam SP.

Betacam SX

Betacam SX provides 8 bit recordings on 1/2 in. tape, using approximately 10:1 compression. The MPEG 4:2:2 Studio Profile is used, as it provides for improved editability. Some of the Betacam SX decks include hard disk drives which allow a single machine to be used as an editor. The data rate used for Betacam SX recording is approximately 18 Mb/s.

Professional Derivatives of the Consumer DV Format

The consumer DV specification defines a recording and compression scheme based on 6.35 mm (1/4 in.) metal evaporated tape, the DV codec and a recording track pitch of 10 μm. No linear tracks are supported, as everything (video audio and data) is recorded digitally by the rotating heads in the scanner assembly. The signal structure used in the DV format is 4:1:1, 8 bit recording, and when combined with a compression ratio of 5:1 and the necessary data and error correction, produces a data rate of 25 Mb/s. Three professional recording formats have been derived from the DV Standard, Panasonic's DVCPRO, Sony's DVCAM and JVC's Digital-S.

Panasonic's DVCPRO uses 1/4 in. tapes and a 5:1 compression scheme. Transports are comparable in size to the half-height 5.25″ disk drive form factor. Consumer DV tapes can be played in the DVCPRO transports as can tapes produced on the Sony DVCAM format. DVCPRO requires metal particle tape because of two longitudinal tracks, a cue track and a control track, both designed to improve editing performance. DVCPRO recordings use a track pitch of 18 μm. A 4:2:2 version of DVCPRO, DVCPRO 50 is now available. A 100 Mb/s version of the format has been announced which will be capable of recording compressed HD signals.

DVCAM from Sony uses 1/4 in. metal evaporated tapes and a track pitch of 15 μm. No longitudinal tracks are recorded, however, a small IC within the shell is used to record cue points and other information to simplify the editing process. At present, DVCAM decks can playback DV consumer tapes, but not DVCPRO tapes.

Digital-S, from JVC uses 1/2 in. tape, and a dual DV codec to produce 4:2:2 recordings on an S-VHS compatible transport. Digital-S uses a compression ratio of 3.3:1 and some models can playback analog S-VHS tapes. Digital-S recorders at 50 Mb/s and a 100 Mb/s version has been announced.

HD Recorders

As professional video moves into the realm of High Definition (HD), recorders will be needed for these signals. Several recorders have already been implemented for HD. UniHi is an analog format that uses 1/2 in. metal tape to record 1125/60 signals. The UniHi luminance channel is limited to 20 MHz and the chroma difference channels are 7 MHz each. UniHi provides 4 channels of 16 bit digital audio. Sony's HDD-1000 is an open-reel 1″ digital machine that records a full bandwidth (30 MHz) HDTV signal. A tape speed of just over 30 ips is required to make uncompressed recordings of the 1.2 Gb/s signal. D-6, introduced by BTS/Toshiba also records full bit rate HDTV and uses the 19 mm D-1 cassette.

Compressed HD recordings are possible with a modified version of the D-5 format from Panasonic which uses 4:1 compression to record the HD signal at 300 Mb/s on 1/2 in. tape. HDCAM, from Sony is a HD camcorder and a companion studio editor that records what amounts to a 3:1:1 HD recording on 1/2 in. metal particle tape. Other HD recorders are available from JVC at both a consumer and industrial level.

VTR ACCESSORIES & OPTIONS

VTRs are used for storage and editing. However to be truly functional, the basic VTR requires some additional features. Although many models are available with all the bells and whistles, not all are. What follows is a list of some of the things that may not be included in all decks, but may be helpful—or necessary—in some applications.

Dynamic Tracking

Dynamic tracking was developed during the late 70's and first implemented on the type-C format. Since then it has found its way into the majority of helical scan formats. The concept is simple, however, the implementation is quite complex. Starting with the simplest example, if a non-standard tape is played back on a machine that is properly aligned, the playback tracking must be adjusted to center the playback head on the recorded track. With dynamic tracking, rather than adjusting the tracking control, the head is dithered (moved up and down) slightly, increasing and decreasing the RF envelope as the head moves toward and away from the center of the recorded track. By offsetting the head, based on the location of the increased RF envelope, the process can be used to consistently locate and center the head on the recorded track. A servo loop, using tip position and RF envelope amplitude, coupled with a dither signal (~450 Hz) can be used to locate the recorded tracks and follow them precisely.

To accomplish dynamic tracking, the head is mounted on a bimorphic strip (see Figure 5.7-4). The strip deflects when a sufficient voltage is applied (up to 400 V). Along one side of the strip, a sense strip is mounted. The sense strip provides feedback information to the servos. Use of the sense strip is less common today, as sufficient information can be obtained directly from the RF envelope. Bimorphic strips composed of a single element cause zenith errors. To reduce these errors, the bimorph is split near the end and the polarity is reversed (as is the sense strip, if used), causing the bimorphic distortion to become somewhat "S" shaped (see Figure 5.7-5).

Dynamic tracking can also be used to produce quality pictures at speeds other than normal play speed. For a standard head, recovering the recorded information becomes more difficult as the tape speed changes, due to the apparent change in track pitch. Dynamic tracking systems can handle these apparent changes in track pitch easily. Depending on flexibility, many dynamic tracking systems can playback stable, noise-free pictures at speeds ranging from −1X to +3X normal play speed. Some systems are capable of this range in a single continuous ramp, while others have discrete speeds stored in lookup tables. In addition to following the recorded track, the dynamic tracking servo must determine the appropriate times to jump or repeat tracks. In stop mode a single field is repeated constantly. At half normal speed each field must be repeated once. At 2X normal play speed, only every other field is played. At speeds other than normal play, the control track is not used nor is it required on most units.

Dynamic tracking adds to the work required from the TBC. Fields are reproduced from the tape as needed,

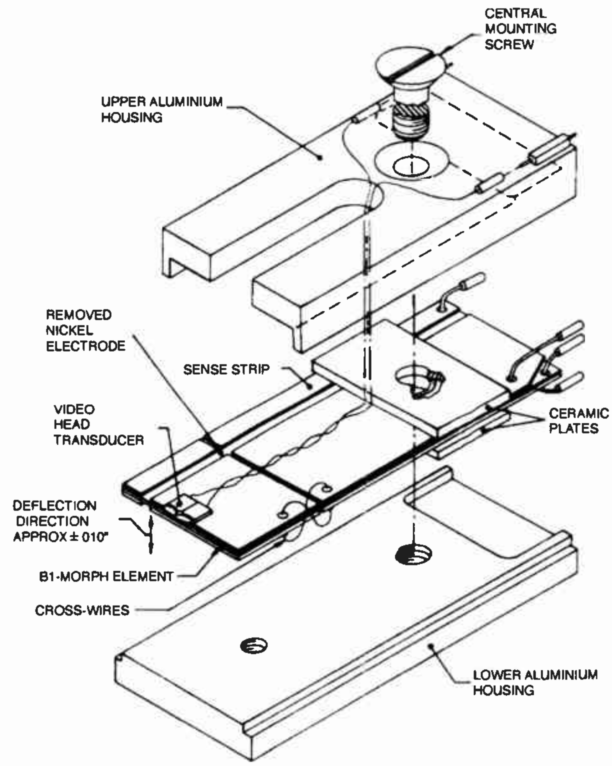

Figure 5.7-4. The Ampex AST dynamic tracking head used in 1" type-C machines. Similar units are common in many of today's professional and semi-professional helical scan machines.

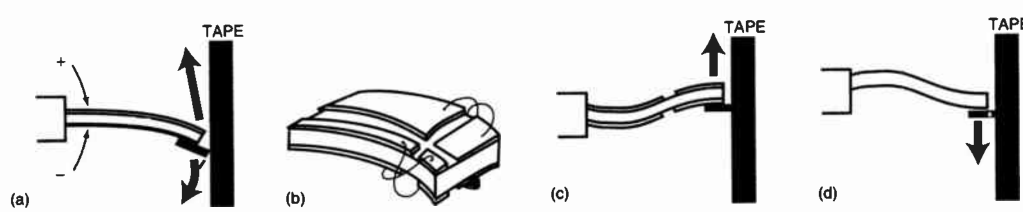

Figure 5.7-5. Video head deflection of dynamic tracking systems is accomplished by applying a voltage to the bimorphic strip the head is mounted on. If a single strip is used, (a) the deflection causes a zenith error. By adding an additional bimorphic segment (plus the sense strip), (b) the head deflection becomes a more "S" shaped (c & d) resulting in reduced zenith errors.

however, they generally do not agree with the sequence required for output. For instance, when playing at half speed, even or odd fields are played back to back and must be combined with a sync signal that includes both even and odd fields. Because of this, for every other field, the lines that make up the picture must be displaced by a single line. As the picture is displaced up and down it results in a phenomenon known as *field hop*. At half speed field hop is not noticeable, however, at speeds within 5% of play speed, as well as others, it can become objectionable.

Time Base Correction

Time base correction is required to make all analog tape machines meet RS-170(A) specifications. For digital machines, this can be accomplished using buffers and error correction routines. Time base errors are caused by several factors including tape stretch, temperature induced expansion and contraction of the tape binder, and by minute distortions and ripples of the tape surface caused by head impacts. Off-tape horizontal sync pulses and color burst phase are typically used to determine the amount of error in the signal. Today's TBCs employ various amounts of memory, the most common being 16 horizontal lines for a time base corrector and an entire field or frame for frame synchronizers with time base correction capability. Vertical sync, typically advanced by an amount equal to half the buffer (8 lines) is fed from the TBC to the tape machine, to allow time to process the signal. Frame synchronizers, because of their increased memory, simply delay the signal to align the incoming video signal with the reference sync. A frame synchronizer will not do TBC and a TBC will not do frame synchronization, however, the circuitry involved is similar and many times both units are found in a single package. Many of these single unit packages will automatically switch to whatever mode is required, based on the input signal.

Today's digital TBC/frame synchronizers are simple, rather elegant, solutions to what used to be a very difficult problem. In these units, the video information is converted to digital by sampling at a frequency normally three or four times the subcarrier frequency (3.58 MHz). Once the picture information is in a digital form, it is clocked into memory based on the incoming (off-tape) horizontal sync pulses. Later the information is clocked out of memory using the reference sync pulses. In this manner, TBC simply happens. The amount of information stored in memory shrinks and expands as necessary. Ideally, memory remains 50% full at all times. An error occurs if the read and write circuits attempt to access the same location simultaneously. This can happen both when the memory is empty and when it is full. Special effects such as slow motion can tax the system, and machines that use these effects generally require TBCs with larger memory buffers.

Field hop was discussed earlier and was addressed in the *Zeus* series of TBCs from Ampex. The problem of field hop occurs because the interlaced NTSC system requires two fields vertically displaced by a single horizontal line. If, during slow-motion playback, an even field was output on an odd field, the picture would be shifted vertically one line. Later when the field sequence returned to normal, the picture shifts in the opposite direction. If these shifts occur within a few seconds of each other, the picture appears to hop up and down. The Zeus system addresses this by displacing all fields by one-half of a line during dynamic tracking sequences. This way the picture can be held stable vertically.

Time Code

Several versions of time code exist, but the one most commonly associated with videotape machines is SMPTE time code (described in ANSI standard V98-12). Originally longitudinal time code (LTC) was recorded on an address track if available, or an audio track. The problem with all longitudinal recordings is the increased difficulty reading them as the tape speed drops. Since the primary use of time code is for editing, it is very important to accurately locate cue points. Precisely parking the tape for preroll becomes very difficult, as the nearer the machine is to the cue point, the slower the tape moves. One method is to simply count control track pulses if time code becomes unreadable. Unfortunately, control track is also a longitudinal recording. Vertical interval time code (VITC) addresses this problem. VITC is recorded on one or two horizontal lines in the vertical interval and is readable as the tape slows, because the video head remains in motion. Machines with dynamic tracking are helpful when reading VITC at slow speeds, but are not required. The proper line in the vertical interval is decoded and provides time code information at slow tape speeds.

When both VITC and LTC are recorded on a tape, the tape can be searched and cued quickly and efficiently. Machine detection circuitry normally uses VITC at speeds below ½X play speed. At speeds above 2X play speed, LTC is used. LTC can be read at speeds well over 25X play speed. Between ½X and 2X play speed, either VITC or LTC can be used, but most machines default to LTC. It is important that both LTC and VITC agree. Although it should be impossible to record two different time codes, it seems to be a common problem. A breakdown of the time code bit structure is shown in Figure 5.7-6.

MAINTENANCE

Today's tape machines are highly reliable units. The biggest problems are mechanical, and are generally caused by the accumulation of dirt on the mechanical transport assemblies. Units should be cleaned regularly with lint-free cloths and non-residue producing solvents, taking care not to bend or in any way damage or distort the various guides. Pinch rollers should be inspected as they will distort with age and use. Video head assemblies should be cleaned carefully as the tips are fragile. A good method is to hold the cloth against the drum and rotate the drum slowly in its normal

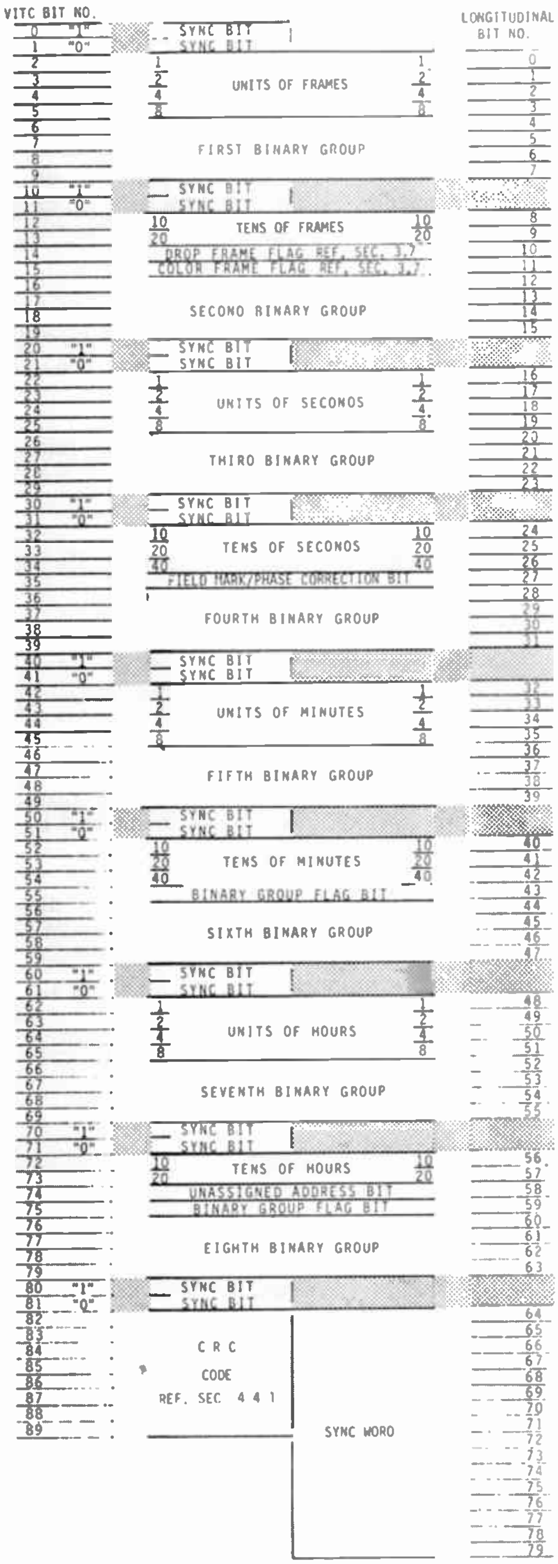

Figure 5.7-6. Bit structure of SMPTE time code, 80 bits are used for longitudinal time code, 90 bits are used for VITC. Although they are part of the standard, the user bits have received only limited use to date. (Source: *NAB Engineering Handbook, Eighth Edition, p. 921*)

direction of travel, leaving the cloth stationary. Mechanical assemblies in the tape path should be carefully inspected for wear as well as scratches or nicks that could damage the tape. Any parts showing excessive wear should be replaced. Occasional checks should be made to verify the unit is on standard. This is accomplished using an alignment tape. Before any attempt is made to service a tape machine, consult the manufacturer for recommended procedures, as significant damage can result if done improperly.

When aligning most types of recording equipment, the procedure is to playback a recording that is known to be on standard. In the case of VTRs, these recordings are in the form of alignment tapes. Tapes are typically produced on *golden machines* that are verified to be on standard through various methods which include precision mechanical devices. Once recorded, alignment tapes are considered usable for approximately 100 passes, at which time they should be replaced. Generally, by that time, the tapes have been stretched and/or damaged to an extent that the recordings are no longer standard. Various sections of the tape are used to verify proper operation of different portions of the videotape machine. Although, it is possible to copy an alignment tape, the new recording is only as good as the machine that was used to record it.

Normally, each tape contains an interchange section, a video section and an audio section. Cue tones, time code and other signals used within the format are also recorded on the tape. This allows the various mechanical and electronic sections to be properly aligned. The interchange section is used to verify proper mechanical alignment of the transport and servos. Video and audio sections provide test signals for setting the proper playback levels and equalization. Once a machine is setup for proper playback of the alignment tape, a recording is made and checked to see if it plays back properly. Any problems found at this stage are due to errors in the record section, which can then be adjusted so that recordings made on the machine will play back properly on any unit that is on standard.

DISK RECORDERS

Analog recorders using disk technology were first introduced in the '70s. The units were physically large and bulky, while the available recording time was very small. Applications included slow-motion playback for sports. Today, a variety of units are available. Most are based on magnetic recording technology, while some use optical methods or a combination of the two. Some disk recorders using optical technology are rewriteable, however, most optical methods are of the write-once variety. Although some older magnetic units provided removable media, the media within nearly all of today's magnetic drives designed for video use is non-removable. Most optical based drive systems are removable. The primary advantage of disk technology is the ability to randomly access individual frames—almost instantly. Videotape requires the tape to be shuttled—in a linear fashion—to the desired frame or clip. Depending on the clip's location, and the speed of the transport, the time required can be considerable. Video disk recorders are widely used in editing environments and for applications such as news and master control that make repeated use of short video and audio clips.

Most of today's video disk recorders are based on hard drive technology developed for the computer industry. To obtain the necessary storage capacity and throughput, many individual drives are combined and function as a single unit. Most systems make some use of compression, which reduces both bandwidth and storage requirements. Although hard drives require little maintenance and have MTBFs quoted over 50,000 hours, their failure can be disastrous. Therefore, many systems provide some type of redundancy. A common redundancy scheme is RAID (redundant array of inexpensive drives). Various RAID levels are defined, and include:

- RAID 0—a combination of multiple drives that has no redundancy.
- RAID 1—disk mirroring, where two or more drives are configured such that redundant drives are mirrored. All data is stored on each of the drives.
- RAID 2—uses additional error correction systems and is not widely implemented.
- RAID 3—uses one additional drive for parity information.
- RAID 4—is similar to RAID 3, but redistributes the information to better accommodate multiple simultaneous reads.
- RAID 5—uses one additional drive, but distributes parity information across all drives.

RAID 3 and RAID 5 are the levels most used for video applications. In both, the loss of a single drive will not result in any data loss, however, the loss of a second drive before the first drive is rebuilt results in a complete loss of any data not yet rebuilt.

As disk recorders for video mature, many are finding their way into server applications. In these applications, video is stored on drives and accessed using techniques and systems comparable to computer file servers. (See Chapter 5.8 *Video Server Storage Systems* for more information on servers and disk based systems. Other disk based recorders are being used as direct replacements for VTRs. In these applications, the disk recorders emulate many, if not all, of the functions commonly found in tape machines. A few of these units are bridging the computer and video worlds. These units can act like VTRs as well as being addressable as network drives. This allows users to move information easily between computer-based systems to traditional video systems. Not all video disk recorders are designed to record audio, some units are video only. When considering video disk systems, items such as the use of compression, image quality, storage capacity and interface requirements need to be carefully reviewed.

CONCLUSION

Videotape recording has come a long way since its introduction. Decks have gained considerable functionality and provide many of the essential tools for broadcast and professional applications. Although the days of the VTR are far from numbered, disk recorders are providing many of the VTRs capabilities alongside a new generation of computer based non-linear production technology. Tape will likely remain a viable acquisition technology for years to come, as disk acquisition is still in its infancy. Analog formats are also likely to remain in use for many years (consider how long 2″ survived), however, the majority of new recordings will be made using digital decks or onto disk recorders. As VTRs move from the center of the editing process, to devices used only at the beginning and end of the process, the wear and tear will be reduced, extending the lifetime of these machines. Later, as server technology improves, VTR use is likely to decline further. VTRs will be needed for many years for archive playback. Regardless, of how antiquated videotape becomes, tape recording technology will be necessary. Servers and computer systems require regular backup, and tape remains the most cost effective large scale storage available.

Although some have said they have purchased their last VTR, they remain the most cost effective and reliable storage method for most video programming longer than a few minutes. However, as the size of the transports is reduced, the amount of maintenance possible within the average facility will also be reduced. Electronic components are getting smaller, as are the parts counts on the circuit boards. More and more, small format transports are likely to become disposable, or not user serviceable, reducing the cost effectiveness of in-house repair. Tape is likely to see a resurgence over the next few years for HD recording, but that may be short lived. With minimal compression, today's computer disk drives are capable of handing video efficiently. If Moore's law holds, drive technology is likely to be capable of handling HD recording by the year 2000 or shortly thereafter.

KEY TERMS

Color-under recording. A recording process that adds an AM chrominance subcarrier centered near 650 kHz to an FM luminance carrier for recording on tape. This process is used for some professional formats and most consumer formats.

Control track (CTL). One of several longitudinal tracks laid down during the recording process. Information from the CTL is used to position the tape for proper playback. In many ways, the control track is the electronic equivalent of sprocket holes in film.

Dithering. The process of moving the video head perpendicular to the recorded track. An oscillator provides a 450 Hz signal to the head assembly to move it in such a way as to locate the recorded track precisely.

Under servo control, the head can deflect a precise distance and remain centered on the track even at speeds other than normal play speed.

Drum assembly. The drum assembly in helical scan machines typically consists of an upper and lower drum. The upper drum contains the head and preamp assemblies. The lower drum consists of the reference edge guide (helix), rotary transformers and the servo motor used to rotate and position the video heads. The lower drum also contains a pulse and/or frequency generator that provides rotational velocity and position information to the drum servo.

Helical scan. A recording method in which the tape is wrapped around a rotating drum in the shape of a helix. Various methods exist which vary drum diameter, number of recording heads, wrap angle and direction of tape travel (either the same or opposite direction as drum rotation).

LTC. Longitudinal Time Code

Quads. Video tape machines that used 2″ tape and the transverse scan recording method pioneered by the Ampex Mark IV in 1956. The format was referred to as *quadruplex* because four heads, mounted 90° apart on a drum assembly, were used to record the video signal on tape.

Time code. A system of numbering the individual frames of a video recording. Valid time code numbers run from zero to 23:59:59:29, a 24-hour clock. Time code can be generated as an audio signal and recorded longitudinally (LTC) on audio tracks, or can be inserted into video on a single horizontal line of the vertical interval (VITC). Many small format recorders insert two identical lines of time code due to the possibility of a dropout making a single line unusable.

Transverse scan. A recording method in which the recorded track is perpendicular to the direction of tape travel.

VITC. Vertical Interval Time Code

5.8
VIDEO SERVER STORAGE SYSTEMS

JERRY WHITAKER
EDITOR-IN-CHIEF

INTRODUCTION

Video servers, with their unique set of features and functions, have reshaped the way program segments are stored and played to air. These systems have emerged from the realm of limited use, special purpose devices to mainstream video production. Among the many attributes of video servers are:

- They permit material from a single storage source to be used simultaneously by multiple users
- Provide a migration path to the all-digital facility that is not necessarily format limited
- Result in a reduction in lost or misplaced materials
- Reduction in the size and space requirements relative to a tape environment
- Complete computer-control capabilities
- Near instant access and playback of video segments

The end result of these attributes is an environment where multiple applications and/or services can be generated from a single system. This reduces the amount of playback equipment required, reduces tape consumption and generally permits more efficient use of human resources.

Architecture

The basic video server architecture consists of three elements:[1]

- A multiple hard disk drive system capable of fast and simultaneous data access, with sufficient capacity and redundancy for the contemplated application. A disk array controller manages data distribution and communications between all drives
- Fast data communication interfaces between disk drives and networks. Several approaches can be used to perform fast data transfer such as very fast CPUs, multiple CPUs and buses, and routing switchers. Interfaces may also include data compression encoding and decoding
- An operating system capable of handling multiple digital audio and/or video data streams in any combination of record and playback modes, while ensuring correct file management and easy access

The design and performance of the server involves trade-offs between the quality of compressed signals, storage capacity, data speed, play time, number of channels, access speed and reliability. Table 5.8-1 shows the storage space requirements for different audio and video signals.

All video servers have in common a large storage capacity and multiple channel capability; differences involve the basic architecture and performance targets, because different systems may be designed to meet specific requirements. The most common application groups for broadcasting include the following:

- **Transmission.** High compression ratios can be used for server-to-air applications, typically commercial and short-length program replay. The resulting bit rates and number of channels are usually low, therefore, with relatively low bandwidth requirements
- **Data cache.** A caching system is basically a temporary random access disk buffer. It is commonly used in conjunction with tape library systems in on-air applications. Caches are well suited to commercial on-air insertion applications where elements are repeated several times a day and last moment changes occur frequently. Bandwidth and channel requirements are usually not critical
- **News.** For most news materials, moderate overall quality levels are acceptable. Video compression is used to reduce the data file size and increase the transfer rate. Multiple access to multiple segments must be possible and a moderate bandwidth is necessary. Guaranteed availability of output ports might be required for direct on-air programming of news materials
- **Production.** Wide bandwidth must be provided to meet simultaneous transfer demands for large uncompressed video files with real-time and random access capabilities. In a production facility, a server stores all compressed or uncompressed audio and

Table 5.8-1
Storage space requirements for audio and video data signals.

Media Signals	Specifications	Data Rate
Voice-grade audio	1 ch; 8 bit @ 8 kHz	64 kbps
MPEG audio Layer 2	1 ch; 16 bit @ 48 kHz	128 kbps
MPEG audio Layer 3	1 ch; 16 bit @ 48 kHz	64 kbps
AC-3	5.1 ch; 16 bit @ 48 kHz	384 kbps
CD	2 ch; 16 bit @ 44.1 kHz	1.4 Mbps
AES/EBU	2 ch; 24 bit @ 48 kHz	3.07 Mbps
MPEG-1 (video)	352 × 288, 30 fps, 8 bit	1.5 Mbps
MPEG-2 (MP@ML)	720 × 576, 30 fps, 8 bit	15 Mbps, max.
MPEG-2 (4:2:2 P@ML)	720 × 608, 30 fps, 8 bit	50 Mbps, max.
ITU-R Rec. 601	720 × 480, 30 fps, 8 bit	216 Mbps
HDTV	1920 × 1080, 30 fps, 8 bit	995 Mbps

Table 5.8-2
Production and broadcast server bandwidth requirements for 4:2:2 video signals.

Production Applications	Bandwidth Mbps	Sample Resolution	Compression Ratio
High-end post-production	270	10	1
Typical post-production	90	10	2.3:1
Low-end post-production	25–50	8	6.6:1–3.3:1
News (compressed data)	18–25	8	9:1–6.6:1
HDTV broadcast	20	8	10:1–50:1
Good-quality SDTV broadcast	8	8	20:1
Medium-quality SDTV broadcast	3	8	55:1
Low-quality SDTV broadcast	1.5	8	110:1

video data files for use in post-production and distribution. The server is central to the production operation and, thus, determines the overall performance of the facility. Table 5.8-2 lists production server bandwidth requirements for 4:2:2 video signals
- **Video on demand (VOD).** This server application must deliver a large number of channels, each of relatively low video quality, such as MPEG-1 (1.5 Mbps). A high overall bandwidth may be required to satisfy all demands. Short access times are necessary for VOD, whereas long access times permit *near-VOD* (NVOD) only.

Video servers have redefined many of the common applications of videotape recorders (VTR). The VTR is being displaced in direct-to-air uses, complex post-production and desktop editing. As new VTR formats evolve, they will increasingly be aimed at acquisition and long-form storage applications. Table 5.8-3 lists the digital tape formats in common usage.

Table 5.8-3
Digital video tape formats.[3]

Format Designation	Format Description
D1	A format for digital video tape recording conforming to the ITU-R Rec. 601 (4:2:2) standard using 8 bit sampling. The tape is 19 mm wide and allows up to 94 minutes to be recorded on a cassette.
D2	The VTR standard for digital composite (encoded) NTSC or PAL signals. D2 uses 19 mm tape and records up to 208 minutes on a single cassette. Neither cassettes nor recording formats are compatible with D1. D2 has often been used as a direct replacement for 1 in. analog (Type C) VTRs.
D3	A VTR standard using 1/2 in. tape cassettes for recording digitized composite (encoded) NTSC or PAL signals sampled at 8 bits. Cassettes are available ranging from 50–245 minutes.
D4	There is no D4 designation; most DVTR formats were developed in Japan where "4" is regarded as an unlucky number.
D5	A VTR formal using the same cassette as D3 but recording component signals sampled to ITU-R Rec. 601 at 10 bit resolution. With internal decoding, D5 VTRs can play back D3 tapes and provide component video outputs.
D6	A helical-scan digital tape format that uses a l9 mm cassette to record uncompressed HDTV material at 1.88 Gbps. D6 accepts both the European 1250/50 interlaced format and the SMPTE 260M version of the 1125/60 interlaced format, which uses 1035 active lines.
D7	The designation assigned to the DVCRPO recording format.

Figure 5.8-1. Simple application of a video server in a one in, many out configuration.

Among the technical frontiers for video servers is the ability to transfer files at faster than real-time. Such features place considerable demands on the bandwidth and throughput of the system; however, they provide many operational benefits, such as accelerated nonlinear editing and reduced program load-up times.

Video Server Design

A number of operational scenarios can be implemented with a video server system. The simplest involves multiple streams of one or two video inputs, as illustrated in Figure 5.8-1. All the material is stored within the server and plays out to multiple channels as required.

In Figure 5.8-2, the basic system is expanded to allow for some material, particularly long form programs, to be held in an external storage area or device (most likely on tape) and loaded into the server on an as-needed basis to coexist with the short-form (typically commercial) library that is stored in the server. The server then manages the entire play-out process to one or more outputs.

In Figure 5.8-3, a large-scale system is depicted typical of a newsroom environment. Feeds are received into the system through a triage station permitting rough editing of material (*keep or discard*). The selected material is then stored in a feed server, which is accessible for viewing or by editors for story composition. Completed program elements are forwarded to the on-air server, which stores them and plays-out as needed. Also shown in the Figure is a *clip server*, a low resolution companion server that delivers video to multiple desktop viewing and editing systems.

Video servers are often constructed from off-the-shelf computer components by integrating the basic hardware and software. This approach promotes a migration path for future growth in several ways, including:

- Utilization of standardized components
- Enhanced ability to expand or alter the system
- Ability to upgrade system core capabilities with new software releases

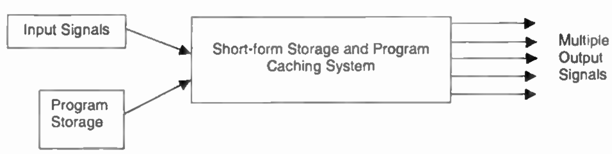

Figure 5.8-2. A server system expanded to utilize long-form program storage.

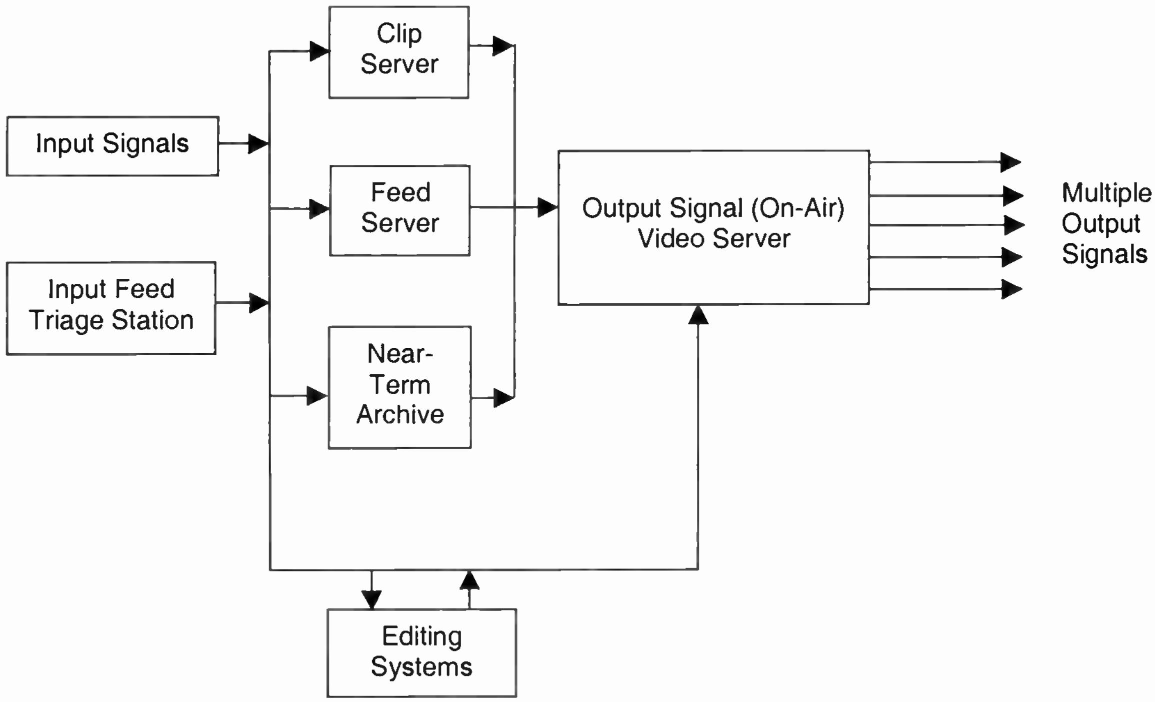

Figure 5.8-3. A server system designed for editing-intensive applications involving a variety of program inputs and distribution requirements.

By utilizing standard components, the research and development cost are spread across a large market, providing faster and more cost-effective advancement. For example, all disk drives adhere to a similar footprint, respond to a similar set of commands, mount in a similar manner and so forth. This makes it easy to take advantage of improvements in specific technologies.

Archiving Considerations

As a conventional tape library grows, a two-sided challenge unfolds. First, operators must identify and archive the contents of the tape. Next, they must be able to find the tape. Servers inherently must maintain a database of the materials within their contents and manage the recall of that material on demand. In addition, because the server brings basic data storage concepts into play, more use is being made of asset management software that permits identification and location of all materials and their contents, regardless of the storage medium.

Tape, however, remains an exceptionally robust and inexpensive medium for field acquisition. It also is economical for many long-form materials and for archiving. Tape and servers can work together to provide a performance and economic model that offers maximum benefit to the user. As illustrated in Figure 5.8-4, raw footage is acquired on tape. The tape material is loaded into the editors for composition and the finished programs are forwarded to a server, where it is held for play-out.

Despite the many benefits of server systems, there are a few drawbacks. Catastrophic failure is first among them. Tape, as a medium, is not susceptible to catastrophic failure (generally speaking). Disk drives can—and do—crash. However, advancements in drive technology have greatly increased the mean time between failure for disk drives. *Redundant array of independent disks (RAID)* schemes provides built-in backup, particularly when linked with hot spare drives and hot-swappable components such as power supplies. With these additions, the risk of total failure of a server system is quite low.

VIDEO SERVER STORAGE SYSTEMS

Because of the fundamental impact that storage technology has on any video server, it is important to understand the various RAID configurations commonly in use. The typical solution to providing access to many gigabytes of data to users fast and reliably has been to assemble a number of drives together in a *gang* or array of disks. Simple RAID subsystems are basically a group of up to five or six disk drives assembled in a cabinet that are all connected to a single controller board. The RAID controller orchestrates read and write activities in the same way a controller for a single disk drive does, and treats the array as if it were—in fact—a single or *virtual* drive. RAID management software, which resides in the host system, provides the means to control the data being stored on the RAID subsystem.

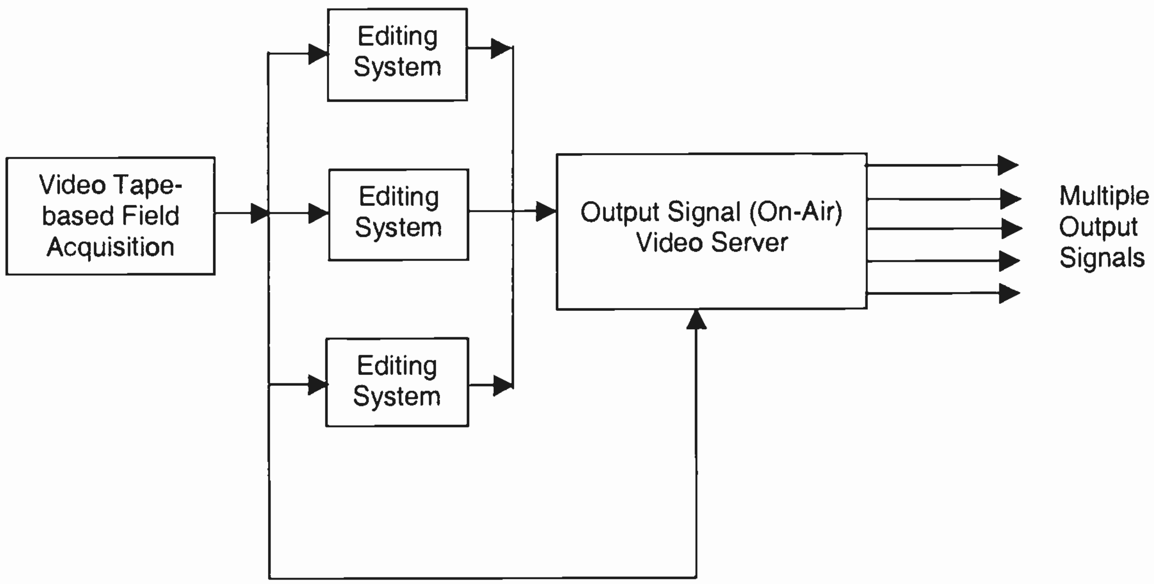

Figure 5.8-4. A video tape-to-server environment with editing capabilities.

Despite its multi-drive configuration, the individual disk drives of a RAID subsystem remain hidden from the user; the subsystem itself is the virtual drive, though it can be as large as 1,000 Gbytes or more. The phantom virtual drive is created at a lower level within the host operating system through the RAID management software. Not only does the software set up the system to address the RAID unit as if it were a single drive, it allows the subsystem to be configured in ways that best suit the general needs of the host system.

RAID subsystems can be optimized for performance, highest capacity, fault tolerance, or a combination of these attributes. Different *RAID levels* have been defined and standardized in accordance with these general optimization parameters. There are six such standardized RAID levels, called RAID 0, 1, 2, 3, 4 and 5. The use of a particular level depends upon the performance, redundancy, and other attributes required by the host system.

The RAID controller board is the hardware element that serves as the backbone for the array of disks; it not only relays the input/output (I/O) commands to specific drives in the array, but provides the physical link to each of the independent drives so they may easily be removed or replaced. The controller also serves to monitor the integrity of each drive in the array to anticipate the need to move data should it be placed in jeopardy by a faulty or failing disk drive (a feature known as *fault tolerance*).

Basic Drive Technology

Small computer system interface (SCSI) hard disk drives are the foundation of any RAID system. The drives use various numbers of magnetic coated disks that rotate at 5,400, 7,200, or 10,000 RPM.[2] Each disk has two recording surfaces. The disks are logically divided into concentric circles (*tracks*). A set of tracks at a given position on the disks is known as a *cylinder.* The number of cylinders is the same as the number of tracks across the disks. Tracks are then divided into varying numbers of *sectors.* The number of sectors varies according to the position of the track located on the disk. This technology is known as *zone bit recording* (ZBR).

Data is written to one track of a given surface at a time. If more space is needed, a head switch takes place and the data is then written to the next surface. Head switches continue down the cylinder until the last track in the cylinder is filled. If additional space is needed, the heads are stepped to a new cylinder and the process of head switching and track stepping continues until the file is completed. Using ZBR, the outside tracks contain more sectors than the inside tracks because there is more physical space on the outside tracks. The transfer rate is greater from the outside as well because a greater amount of data is available from a single rotation of the disks. The first partition created uses the outside tracks and moves to inside tracks as the drive or drives are fully partitioned.

SCSI is a general purpose interface. In its basic configuration, a maximum of eight devices can be connected to a single bus. SCSI specifies a cabling standard, a protocol for sending and receiving commands and the format for those commands. SCSI is intended as a device-independent interface so the host computer requires no details about the peripherals that it controls.

As the SCSI Standard has evolved, various levels have been produced, the most common being:

- Standard SCSI, with a 5 MBps transfer rate
- Fast SCSI, with a 10 MBps transfer rate

- Ultra SCSI, with a 20 MBps transfer rate
- Ultra SCSI-2, with a 40 MBps transfer rate

For each of these schemes, there is the 8 bit normal or so-called narrow bus (1 byte per transfer) or the 16 bit wide bus (2 bytes per transfer). Therefore, for example, Ultra SCSI-2 is designed to transfer data at a maximum rate of 80 MBps. Actual continuous rates achieved from the disk drive will be considerably less, however.

RAID Levels

The RAID 0 through 5 Standards offer users a host of configuration options.[3] These options permit the arrays to be tailored to their application environments, for broadcast purposes a video server. Each of the various configurations focus on maximizing the abilities of an array in one or more of the following areas:

- Capacity
- Data availability
- Performance
- Fault tolerance

RAID Level 0

An array configured to RAID Level 0 is an array optimized for performance, but at the expense of fault tolerance or data integrity.[3] RAID Level 0 is achieved through a method known as *striping*. The collection of drives (*virtual drive*) in a RAID Level 0 array has data laid down in such a way that it is organized in stripes across the multiple drives. A typical array can contain any number of stripes, usually in multiples of the number of drives present in the array. As an example, a four-drive array configured with 12 stripes (four stripes of designated *space* per drive). Stripes 0, 1, 2 and 3 would be located on corresponding hard drives 0, 1, 2 and 3. Stripe 4, however, appears on a segment of drive 0 in a different location than Stripe 0; Stripes 5 through 7 appear accordingly on drives 1, 2, and 3. The remaining four stripes are allocated in the same even fashion across the same drives such that data would be organized in the manner depicted in Figure 5.8-5. Practically any number of stripes can be created on a given RAID subsystem for any number of drives. Two hundred stripes on two disk drives are just as feasible as 50 stripes across 50 hard drives. Most RAID subsystems, however, tend to have between three and 10 stripes.

The reason RAID 0 is a performance-enhancing configuration is that striping enables the array to access data from multiple drives at the same time. In other words, because the data is spread out across a number of drives in the array, it can be accessed faster because it is not bottled up on a single drive. This is especially beneficial for retrieving a very large file, because it can be spread out effectively across multiple drives and accessed as if it were the size of any of the fragments it is organized into on the data stripes. By any measure of comparison, video files qualify as very large files.

The downside to the RAID Level 0 configuration is that it sacrifices fault tolerance, raising the risk of data loss because no room is made available to store redundant information. If one of the drives in the RAID 0 fails for any reason, there is no way of retrieving the lost data, as can be done in other RAID implementations.

RAID Level 1

The RAID Level 1 configuration employs *disk mirroring* to ensure data reliability or a high degree of *fault tolerance*.[3] RAID 1 also enhances read performance, but the improved performance and fault tolerance come at the expense of available capacity in the drives used. In a RAID Level 1 scheme, the RAID

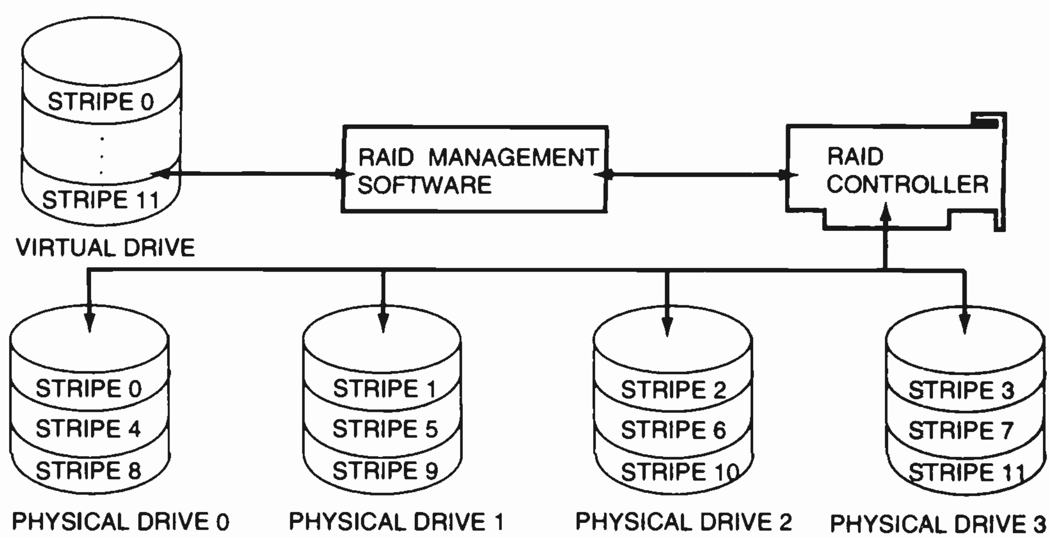

Figure 5.8-5. In a RAID Level 0 configuration, a virtual drive is comprised of several stripes of information. Each consecutive stripe is located on the next drive in the chain, evenly distributed over the number of drives in the array.[3]

management software instructs the subsystem's controller to store data redundantly across a number of the drives (*mirrored set*) in the array. In other words, the same data is copied and stored on different disks to ensure that, should a drive fail, the data is available somewhere else within the array. In fact, all but one of the drives in a mirrored set could fail and the data stored to the RAID 1 subsystem would remain intact. A RAID Level 1 configuration can consist of multiple mirrored sets, whereby each mirrored set can be a different capacity. Usually, the drives making up a mirrored set are of the same capacity. If drives within a mirrored set are of different capacities, the capacity of a mirrored set within the RAID 1 subsystem is limited to the capacity of the smallest-capacity drive in the set, hence the sacrifice of available capacity across multiple drives.

The read performance gain can be realized if the redundant data is distributed evenly on all of the drives of a mirrored set within the subsystem. The number of read requests and total wait state times both drop significantly; inversely proportional to the number of hard drives in the RAID, in fact. To illustrate, suppose three read requests are made to the RAID Level 1 subsystem (see Figure 5.8-6). The first request looks for data in the first block of the virtual drive; the second request goes to block 0 and the third seeks from block 2. The host-resident RAID management software can assign each read request to an individual drive. Each request is then sent to the various drives, and now—rather than having to handle the flow of each data stream one at a time—the controller can send three data streams almost simultaneously, which in turn reduces system overhead.

RAID Level 2

RAID Level 2, rarely used in video applications, is another means of ensuring that data is protected in the event drives in the subsystem incur problems or otherwise fail.[3] This level builds fault tolerance around *Hamming error correction code* (ECC), which is often used in modems and solid-state memory devices as a means of maintaining data integrity. ECC tabulates the numerical values of data stored on specific blocks in the virtual drive using a formula that yields a checksum. The checksum is then appended to the end of the data block for verification of data integrity when needed.

As data is read back from the drive, ECC tabulations are again computed, and specific data block checksums are read and compared against the most recent tabulations. If the numbers match, the data is intact; if there is a discrepancy, the lost data can be recalculated using the first or earlier checksum as a reference.

This form of ECC is actually different from the ECC technologies employed within the drives themselves. The topological formats for storing data in a RAID Level 2 array is somewhat limited, compared to the capabilities of other RAID implementations, which is why it is not commonly used in commercial applications.

RAID Level 3

This RAID level is essentially an adaptation of RAID Level 0 that sacrifices some capacity, for the same number of drives, but achieves a high level of data integrity or fault tolerance.[3] It takes advantage of RAID Level 0 data striping methods, except that data is striped across all but one of the drives in the array. This drive is used to store parity information for maintenance of data integrity across all drives in the subsystem. The parity drive itself is divided into stripes, and each parity drive stripe is used to store parity information for the corresponding data stripes dispersed throughout the array. This method achieves high data transfer performance by reading from or writing to all of the drives in parallel or simultaneously, but retains the means to reconstruct data if a given drive fails, maintaining data integrity for the system. This concept is illustrated in Figure 5.8-7. RAID Level 3 is an excellent configuration for moving very large sequential files, such as video, in a timely manner.

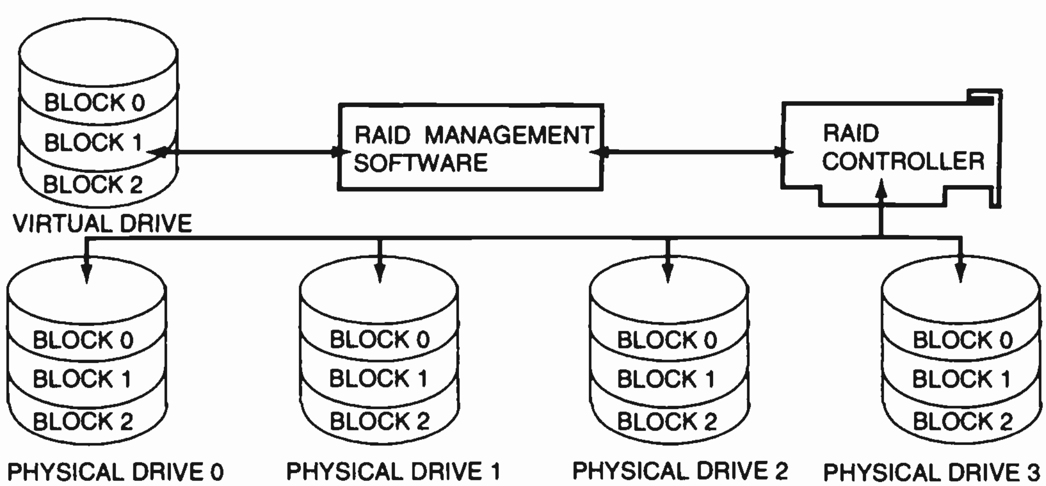

Figure 5.8-6. A RAID Level 1 subsystem.[3]

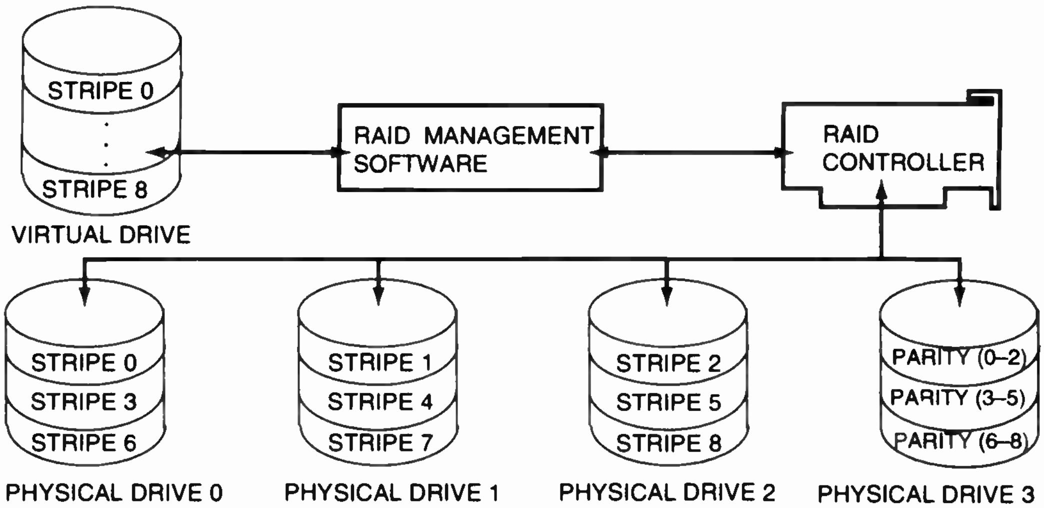

Figure 5.8-7. A RAID Level 3 configuration.[3]

The stripes of parity information stored on the dedicated drive are calculated using the *Exclusive OR* function. By using Exclusive OR with a series of data stripes in the RAID, any lost data can be recovered. Should a drive in the array fail, the missing information can be determined in a manner similar to solving for a single variable in an equation.

RAID Level 4

This level of RAID is similar in concept to RAID Level 3, but emphasizes performance for particular applications (database files versus large sequential files).[3] Another difference between the two is that RAID Level 4 has a larger stripe depth, usually of two blocks, which allows the RAID management software to operate the disks more independently than RAID Level 3 (which controls the disks in unison). This essentially replaces the high data throughput capability of RAID Level 3 with faster data access in read-intensive applications (see Figure 5.8-8).

A shortcoming of RAID level 4 is rooted in an inherent bottleneck on the parity drive. As data is written to the array, the parity encoding scheme tends to be more tedious in write activities than with other RAID topologies. This more or less relegates RAID Level 4 to read-intensive applications with little need for similar write performance. As a consequence, like Level 2, Level 4 does not see much common use in commercial applications.

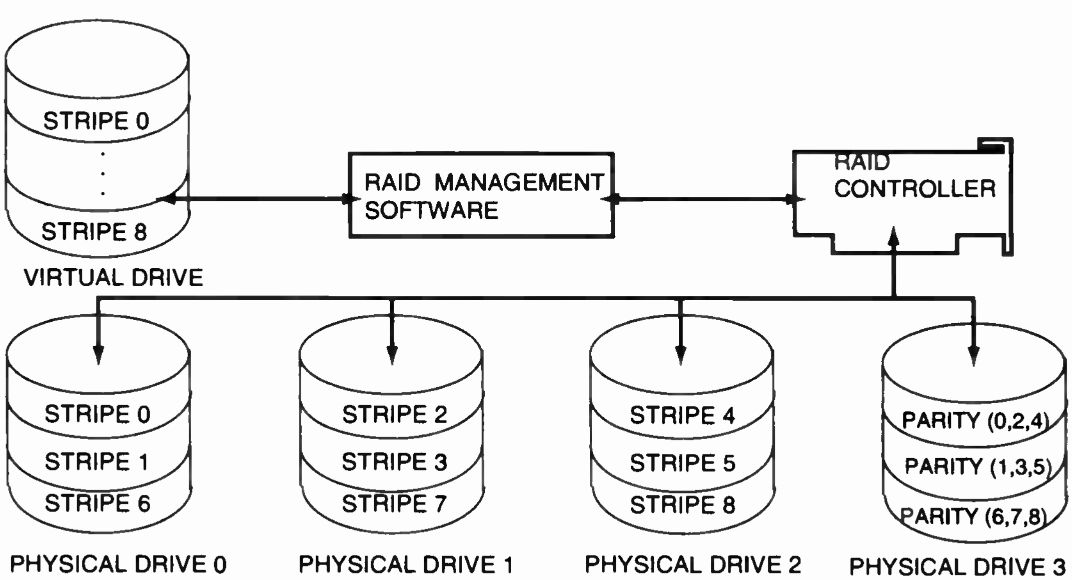

Figure 5.8-8. RAID Level 4.[3]

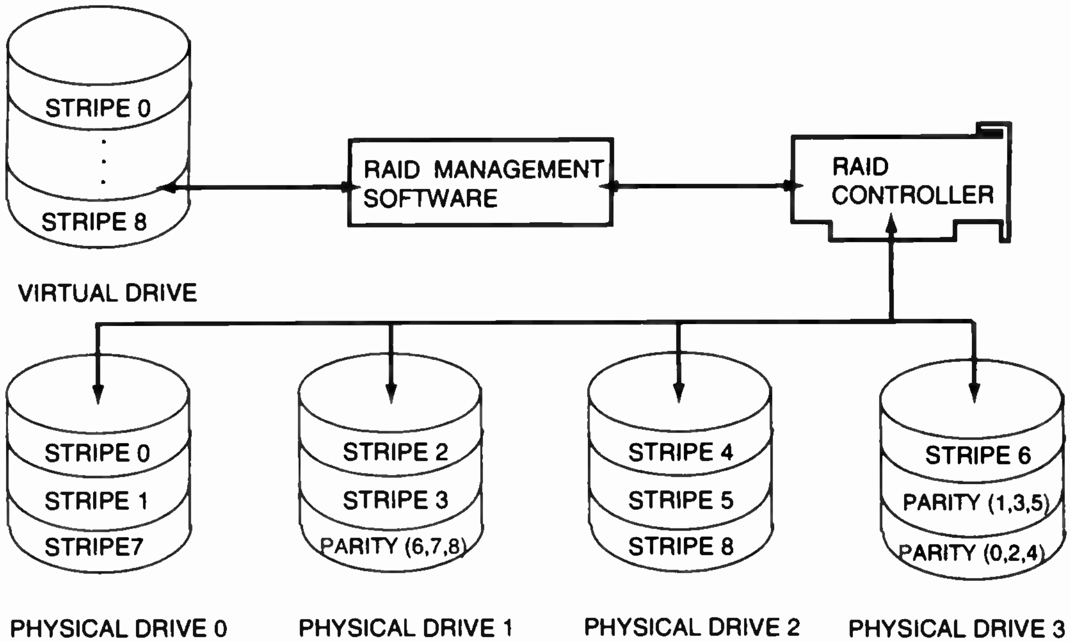

Figure 5.8-9. RAID Level 5 configuration.

RAID Level 5

Level 5 is the last of the common RAID levels in general use, and is probably the most frequently implemented.[3] RAID Level 5 minimizes the write bottlenecks of RAID Level 4 by distributing parity stripes over a series of hard drives. In so doing, it provides relief to the concentration of write activity on a single drive, which in turn enhances overall system performance (see Figure 5.8-9).

The way RAID Level 5 reduces parity write bottlenecks is relatively simple. Instead of allowing any one drive in the array to assume the risk of a bottleneck, all of the drives in the array assume write activity responsibilities. This distribution eliminates the concentration on a single drive, improving overall subsystem throughput. The RAID Level 5 parity encoding scheme is the same as Levels 3 and 4, and maintains the system's ability to recover lost data should a single drive fail. This recovery capability is possible as long as no parity stripe on an individual drive stores the information of a data stripe on the same drive. In other words, the parity information for any data stripe must always be located on a drive other than the one on which the data resides.

Other RAID Levels

Other, less common, RAID levels have been developed as custom solutions by independent vendors, including:

- RAID Level 6, which emphasizes ultra high data integrity
- RAID Level 10, which focuses on high I/O performance and very high data integrity
- RAID Level 53, which combines RAID Level 0 and 3 for uniform read and write performance.

Perhaps the greatest advantage of RAID technology is the sheer number of possible adaptations available to users and systems designers. RAID offers the ability to customize an array subsystem to the requirements of its environment and the applications demanded of it. These attributes make RAID systems an integral element in applications requiring mass storage of video signals, such as video servers. Table 5.8-4 lists the relative attributes of the various RAID implementations.

Table 5.8-4
Summary of RAID level properties.

RAID Level	Capacity	Data Availability	Data Throughput	Data Integrity
0	High	Read/Write High	High I/O Transfer Rate	
1		Read/Write High		Mirrored
2	High		High I/O Transfer Rate	ECC
3	High		High I/O Transfer Rate	Parity
4	High	Read High		Parity
5	High	Read/Write High		Parity
6		Read/Write High		Double Parity
10		Read/Write High	High I/O Transfer Rate	Mirrored
53			High I/O Transfer Rate	Parity

Digital Media Applications

Speed and storage capacity are particularly important to digital media applications (those applications that record or play audio and/or video data).[3,4] One minute of uncompressed CD-quality audio requires over 4.5 MB of storage. That is over 150 times the storage required to hold most word processing documents. The typical data rate requirement for a single channel of uncompressed digitally encoded audio is 76 KBps.

For digital video, the capacity requirements jump exponentially. A single frame of 70 mm film, if stored in uncompressed format, requires 40 MB of disk storage. Video is typically compressed to increase the amount of information that can be stored on the disk and to reduce the high data rate requirements. The data rate varies depending upon the video compression techniques used (JPEG, MPEG or other proprietary schemes) and the desired quality of the stored video image. One minute of broadcast quality video using JPEG compression requires at least 120 MB of storage. The data rate can vary from 150 KBps for MPEG compression, up to 27 MBps for full frame, uncompressed, interlaced video.

Simply put, the higher the video resolution the more space and higher data rate it requires. Where a 4 GB capacity drive might have been big enough for a mid-quality video production, higher quality video may require 9 GB of storage for a given segment.

Storing audio and video information on disk drives is a logical step on the digital media road because it provides instant access to stored data. However, not all disk storage is created equal. Optimizing disk drives for digital media requires more than just high capacity and fast data rates. Data processing applications read and write small chunks of data stored more or less randomly around the disk. Consequently, conventional disk drives have been optimized for small block, random data transfers. Yet, while contemporary data processing disk drives deliver data to traditional applications quickly, they usually have difficulties satisfying the requirements for real-time audio and video applications. Because of the nature of audio and video playback, digital media applications require that data be delivered on time, at the required rate, with no delay. Any delay in the delivery of data from the disk will cause noticeable interruption in the playback, resulting in audio breaks and/or missing video frames.

The linear nature of sound and video playback dictates that these files must be organized contiguously on the disk in much the same way as they are on tape. With tape, the media containing the information travels past the read head at the velocity required to present the sound and images at a real-time speed. In this case, the next word, musical note or video frame always resides adjacent to the current sound or picture. It is the sequential linearity of tape that ideally suits it for these purely playback applications. When the application demands manipulation or editing of the audio or video information, the utility of linear tape storage methods quickly become dubious and cumbersome.

For video servers and non-linear audio and video production systems, a storage device is required that can instantly access any video frame, sound or word and record or playback with the same-or better-measured precision as tape. This is a type of storage for which standard data processing disk drives were not designed. Figure 5.8-10 charts the speed and smoothness of a disk's throughput by graphing worst case data access over time. The performance of the tested drive is indicated by the broken line. The straight, solid line above the X axis indicates the slowest acceptable access time to deliver video data. Every time the disk drive data response time exceeds this value, the video playback will experience dropouts or lost frames, which result in visual and/or audible discontinuities in the playback.

Previously, data interruptions were solved by adding large memory buffers in the host system to hold several frames of data while the disk performed the requisite housekeeping chores. Although host memory buffers cannot be completely eliminated, their size and subsequent cost can be significantly reduced by minimizing the time the disk spends attending to certain housekeeping functions. A disk drive optimized for continuous recording and playback will maintain a virtually constant data rate to ensure that every picture and every sound is recorded and played back without any evident errors. The broken line in Figure 5.8-11 illustrates the performance of a drive optimized for audio/video applications.

Different manufacturers approach the challenges of designing drives optimized for audio/video applications in different ways. One design achieves the desired relatively flat data rate performance by changing the way disk drives work. By designing disk storage with the requirements of digital media in mind—including the development of new on-disk caching schemes optimized for the file characteristics of audio and video applications and the implementation of *intelligent housekeeping* techniques to hide necessary tasks in the background—the overall performance is improved considerably.

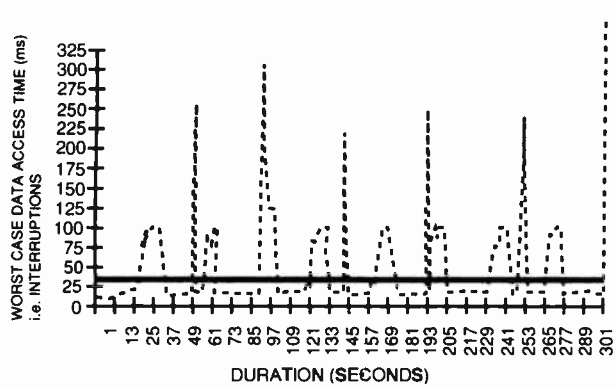

Figure 5.8-10. Disk drive data access as a function of play time for a conventional hard drive. Host demand rate = 4.0 MBps.[3]

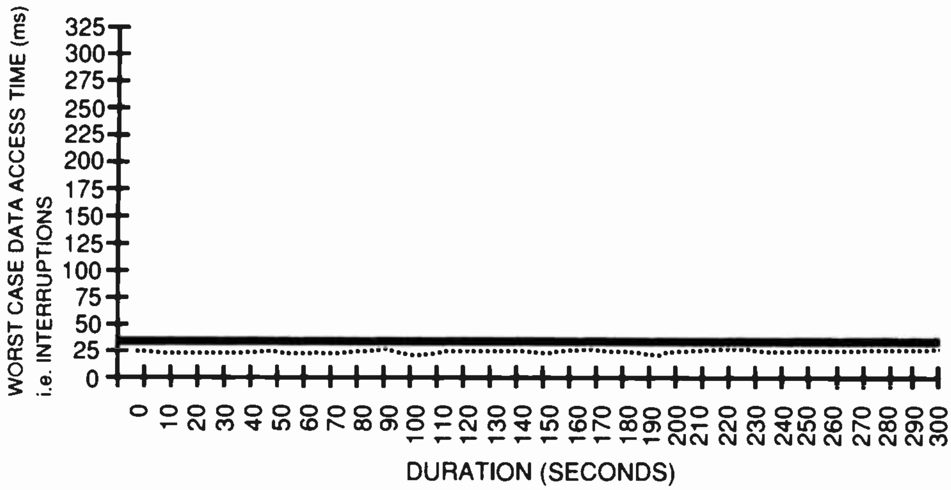

Figure 5.8-11. Disk drive data access as a function of play time for a hard drive optimized for A/V applications. Host demand rate = 4.0 MBps.[3]

Optimizing Digital Media Disk Performance

Although the error recovery methods used in conventional disk drives are adequate to keep disks operating within desired parameters, they are not optimized for speed.[3,4] To maintain the disk drive at its optimum operating range, or to correct errors, some additional issues are important. Issues that can interrupt the flow of data include the following:

- **Error recovery procedure overhead.** The error recovery procedure within most conventional disk drives is very robust and thorough. However, it is a major contributor to data flow interruptions due to soft data errors. For example, the time required for a worst case recovery from a correctable data error can often exceed 750 ms. Most digital media applications cannot tolerate a delay of this magnitude without a disruption in the audio or video playback. One solution to this situation is to implement sophisticated and exceptionally reliable means of error correction that maintains data integrity while rapidly completing housekeeping and recovery tasks. The time required to perform error recovery procedures can, in most cases, be held to 10 ms or less
- **Hardware ECC on the fly.** By adding a dedicated hardware correction engine, hardware-implemented error correcting code can be implemented *on the fly*. In other words, a soft read error can—in most cases—be corrected by a dedicated hardware correction engine. This operation is done within a few hundred microseconds, without incurring the overhead of waiting a full rotation in order to read the same data again. The more conventional approach uses a software error correcting code technique which is many times slower than the hardware ECC approach
- **Rotational retries.** If hardware ECC is not present in the drive or is unsuccessful in properly recovering the data, the next step in the error recovery process is to simply retry the operation. This approach, however, is not optimized for speed. When a disk tries to re-read data it could not retrieve on the first pass, at least one revolution is lost. The ECC on the fly techniques can usually recover soft read errors without extra disk revolutions.
- **Thermal calibration (T-Cal).** Thermal calibration is a periodic (every 10 min) housekeeping function that is necessary for disk drives incorporating have a dedicated servo system. Dedicated servo designs are commonly used by many disk drive manufacturers. The T-Cal operation calibrates the servo system to ensure that the disk heads remain precisely over the data tracks by compensating for temperature changes during normal operations. The T-Cal operation, depending upon the exact design, can require hundreds of milliseconds to complete. During all or at least part of this process, the drive will not be responsive to data requests. This is one of the major causes of dropped video frames and interrupted audio during playback of digital media. Drives optimized for audio/video applications can employ a hybrid servo system, which combines the best features of both dedicated and embedded servo system designs and eliminates the requirement for periodic T-Cal operations. Through clever design, it is possible to eliminate T-Cal operations, not simply defer them
- **Data head degaussing.** During the normal course of disk operation, the data heads accumulate a slight magnetic orientation. This residual magnetism can adversely affect operation. To prevent this condition, the drive must degauss each head. Because head degaussing involves at least one head seek plus some rotational latency, this activity can cost more than 40 ms and will interrupt the flow of data from the disk. Refined degaussing schemes minimize head seeking and rotational latency.

By combining the aforementioned techniques, it is possible to significantly improve the overall sustain-able throughput of disk drives so that they can reliably be used for demanding audio/video applications.

Thermal Calibration

It is worthwhile to explore the issue of T-Cal in greater detail. To understand the need for thermal calibration, the physics of disk drives must be examined.[5] All metals expand and contract to a certain degree under varying temperatures. The same is true with disk drive parts, including platters and the actuator arms that read the data. As a drive spins, the components heat up and expand. Although the size variance may at first seem minimal, it is potentially rather significant as tracks are spaced closer together on disk drives. Soon, the actuator arm may have moved over one or more tracks from its original course.

Initially, drives circumvented this problem by delaying read/write operations long enough to recalibrate the location of the actuator arm over the platter. This would take a few milliseconds, and would be unnoticeable in standard applications. With A/V projects, however, a pause lasting several milliseconds results in skipped frames and lost audio output.

Several approaches have been developed to solve this problem. One involves the repositioning of the heads. Normally, all heads of a disk drive would recalibrate at the same time, bringing a complete stop to the data flow. To minimize the duration of data flow interruptions, newer drives reposition one head at a time. Further, the drive can complete a thermal calibration by taking advantage of its onboard cache. A segment of data is read ahead of time and stored in the drive buffer. When that data is requested from the computer, the drive dumps it from the cache back to the system. While the buffer is being read, the actuator arms take the opportunity to recalibrate.

SCSI and Fibre Channel (FC)

Although not specifically a function of disk drive technology, new variations of SCSI and *fibre channel arbitrated-loop* (FC-AL) are important in the broad view of storage technology because of their impact on data transfer rates.[3] For this reason, they will be examined briefly here.

Since its inception in the early 1980s, SCSI has evolved to become a widely accepted and successful disk drive interface.[6] Despite its venerability, however, parallel SCSI still has its drawbacks, including cable distance limitations, a confusing mix of variants to the bus (*Fast, Fast&Wide, Differential, Ultra,* and so on) and a ceiling on the number of peripherals it can support. SCSI throughput performance has also reached a point where disk drive capacities and data rates are likely to render current SCSI variants as bottlenecks in future systems built around fast new microprocessors. These and other limitations of SCSI are creating demand for a better solution to the high-performance I/O needs of the computer systems market, FC-AL is one solution. FC-AL is a subset of the box-to-box standard created by original members of the Fibre Channel Association, Hewlett Packard, IBM and Sun Microsystems. Like its Fibre Channel superset, FC-AL is an industry standard interface endorsed by the American National Standards Institute (ANSI). Fibre Channel is usually thought of as a system-to-system or system-to-subsystem interconnection standard that uses optical cable in a point-to-point or switch configuration. This is what it was originally designed to do, in fact, HIPPI and the Internet Protocol were among the protocols defined for it. One of the goals in the development of the Fibre Channel interface was to improve or eliminate SCSI shortcomings, particularly in the areas of connectivity, performance and physical robustness.

In 1991, the Fibre Channel box-to-box interconnect standard was enhanced to include support for copper (nonoptical) media and multidrop configurations, both of which enable the low-cost connection of many devices to a host port. FC-AL made it possible for Fibre Channel to be used as a direct-disk-attachment interface (SCSI-3 has been defined as the disk interface protocol, specifically SCSI-FCP). The implications of that capability are enormous in terms of the cost savings and ease with which users will be able to migrate to standard systems with performance capabilities heretofore only found in expensive proprietary systems at the workstation or mainframe level.

The basic features of Fibre Channel are listed in Table 5.8-5. The interface features of FC-AL are given in Table 5.8-6.

FC-AL Topology

As shown in Figure 5.8-12, the FC-AL interface is a loop topology, not a bus in the conventional sense like SCSI.[3] It can have any combination of hosts and peripherals, up to a loop maximum of 126 devices. Table 5.8-5 summarizes the basic features of FC-AL.

Table 5.8-5
Fibre Channel features and capabilities.

Parameter	Range of Capabilities
Line rate	266, 531, or 1062.5 Mbps
Data transfer rate (maximum)	640–720 Mbps # 1062.5 line rate
Frame size	2112 byte payload
Protocol	SCSI, IP, ATM, SDI, HIPPI, 802.3, 802.5
Topology	Loop, switch
Data integrity	10E-12 BER
Distance	Local and campus; up to 10 km

Table 5.8-6
Basic parameters of FC-AL.[3]

Parameter	Range of Capabilities
Number of devices	126
Data rate	100 MBps (1.062 GHz using an 8B/10B code)
Cable distance	30 m between each device using copper (longer, with other cabling options)
Cable types	Backplane, twinaxial, coaxial, optical
Fault tolerance	Dual porting, hot plugging

Using a connector based on the 80-pin parallel SCSI *single connector attachment* (SCA), Fibre Channel disk drives attach directly to a backplane. This not only eliminates cable congestion, it makes hot drive insertions practical and simplifies mechanical designs. Fewer cables and components translate to lower-cost systems and higher reliability.

Figure 5.8-13 shows the use of a backplane with dual-ported drives and dual loops. This would be typical of a disk array subsystem with hot-plug capability. The drives are attached directly to the backplane for both signal and power; there are no other connections. No jumpers, terminators or switches need be set on the drive. An FC-AL drive can be simply plugged into the backplane, and the Fibre Channel controller determines the drive address from either the relative position on the backplane or the drive's unique IEEE Fibre Channel address (all Fibre Channel interface devices have a worldwide unique address). The backplane and drives can be located in the same cabinet as the rest of a computer system, or connected as the separate units shown in Figure 5.8-13. Each of the loops in this system would be capable of transferring data at 100 MBps. Note that the two systems are on different loops for redundancy. Both computers could just as easily be on both loops for full fault tolerance, or share a single loop for the sake of economy.

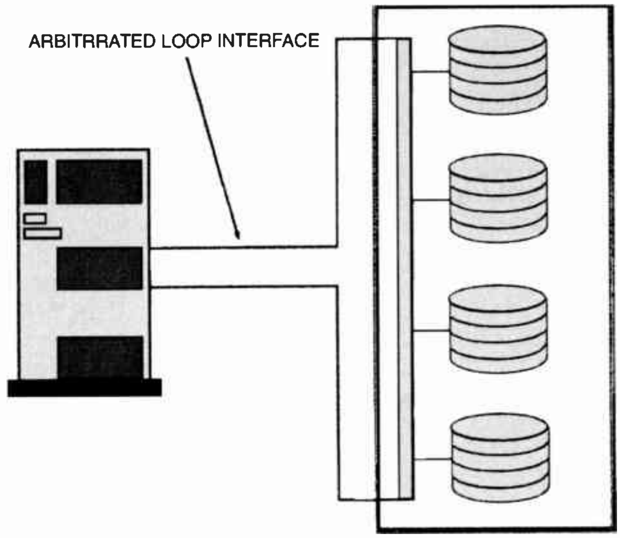

Figure 5.8-12. Basic topology of FC-AL.[3]

Connectivity Considerations

Applications such as video and image processing have pushed the demand for huge increases in disk capacity per system.[3] In some cases, the capacity requirements for these types of applications are such that it is difficult to configure a sufficient number of SCSI

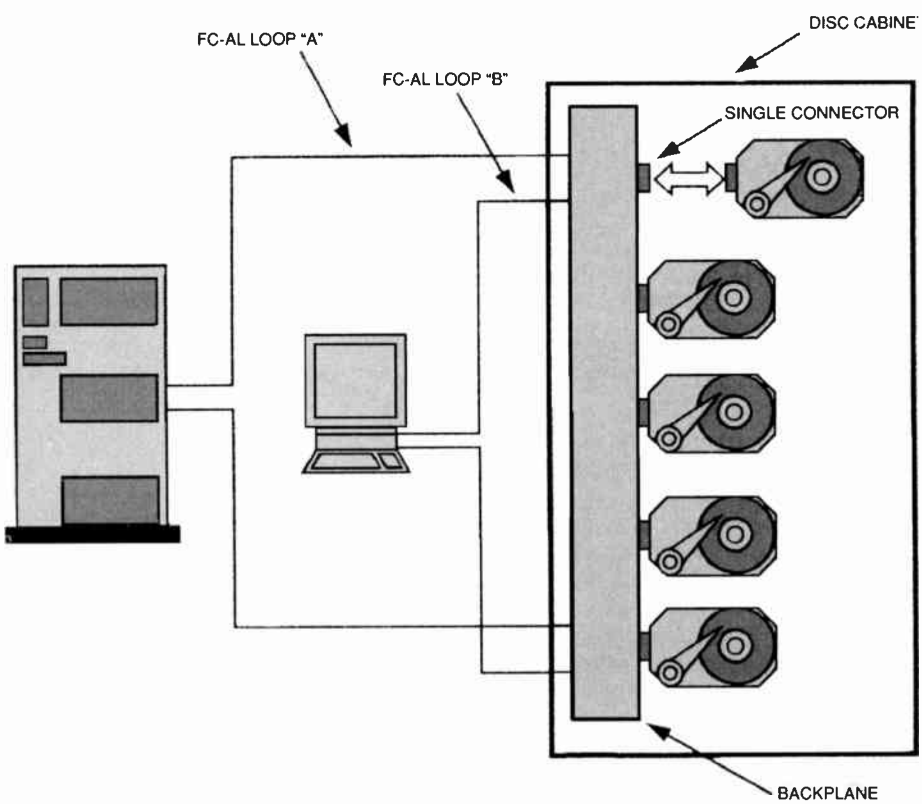

Figure 5.8-13. An array of disk drives in a dual loop FC-AL system.[3]

buses on a system so that enough drive addresses are available to attach the necessary disk storage. Moreover, simply increasing the addressability of SCSI—making it possible to have more than 15 devices per wide SCSI bus, for example—would not be a solution, because more bus bandwidth is needed to support the additional drives. Besides, protocol overhead is already excessive. FC-AL can address up to 126 devices, but practical usage is another matter. A loop can practically support about 60 drives in a UNIX (with 8 KB I/Os) environment, as an example. With a 9 GB FC-AL interface disk drive, a loop of 50 drives would make more than 450 GB available on a single FC-AL host adapter. This makes it possible for any workstation or system with a Fibre Channel port to become an incredibly large file server. When the cost of a single host adapter is compared to the many channels and controllers that a mainframe would employ to attach the equivalent capacity, the economics of Fibre Channel attached-disk storage become obvious.

Bandwidth

A Fibre Channel loop, as stated previously, supports data rates up to 100 MBps in single-port applications and up to 200 MBps in dual-port configurations.[3] Applications such as digital video data storage and retrieval, computer modeling and image processing are growing in popularity and demanding ever increasing improvements to disk data transfer performance. Moreover, file servers are increasingly looked upon as replacements for mainframe computers. In order to fulfill that promise, they will need to deliver higher transaction rates to provide a mainframe level of service.

Magnetic disk drive areal densities are known to be increasing at about 60% per year in production products. Because the number of bits per inch—one of the two components of disk areal density—is increasing at about 30% per year, the data rate performance increases proportionately. In addition, drive spindle speeds (or spin rates) have more than doubled over the last five years, and any spin rate improvements will also directly contribute to improved data rate performance.

Remote Online Storage

Because the FC-AL interface is part of, and fully compatible with the Fibre Channel Standard, optical cabling can be used in any portion of a subsystem (with the exception that optical signals, of course, cannot be used on a backplane).[3] This makes it possible to have a disk subsystem a significant distance from the computer system to which it is attached. For example, using single-mode fibre optics, online disk storage could be as far as 10 km away from its host. As illustrated in Figure 5.8-14, the computer system on the left could have disks within the system connected via a Fibre Channel loop. That loop can be extended by using an electronic-to-optic signal adapter and lengths of fibre optic cable. On the same loop running the internal disks, remote disks would appear to the system to be directly attached exactly like the local disks, even though they might be five miles away. This can be an advantage in many ways, including the shadowing the local disks in the event a disaster destroys the on-site data banks. That capability, in particular, offers an attractive means for having a remote and secure online copy of critical data that could be used to continue operations should anything happen to the facility housing the primary computer system.

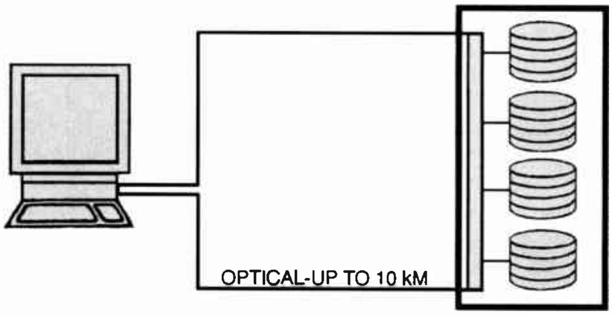

Figure 5.8-14. The use of optical interconnection for long-distance FC-AL service.[3]

Array Implementations

Array controllers have traditionally been designed with multiple SCSI interfaces for drive attachment.[3] This enables the controller to supply data and I/O rates equal to several times those achievable from a single interface. This is sometimes referred to as an *orthogonal array*, because the disks comprising the arrays elements, are across, or orthogonal to, the SCSI controllers. The decision to design a specific number of drive interfaces into a given controller forces on the customer the parity amortization, granularity and controller cost associated with that decision. This limits the customer's choices for configuring the optimal combination of economy—that is, maximizing the *granularity*, or number of data drives per parity drive, the total capacity per array and overall performance. In the example shown in Figure 5.8-15, the array has six rows, amortizes the parity data over five data drives, and often requires adding six drives each time any increase in capacity is required. With Fibre Channel, it is possible to configure an array along a single interface instead of across many (see Figure 5.8-16). Because the drives constituting the array unit are organized along an interface, it is sometimes described as a *longitudinal array*. While a single loop makes a perfectly legitimate array configuration, the diagram shows an optional second loop and controller for fault tolerance.

Some of the more important benefits from using FC as the basis of a longitudinal array include:

- A system designer has the flexibility to decide the economy of the array. It can utilize 5, 8, 18 or 24 data drives per parity drive, with no additional controller cost
- The granularity is on a drive-by-drive basis—the system designer is not required to add a whole row

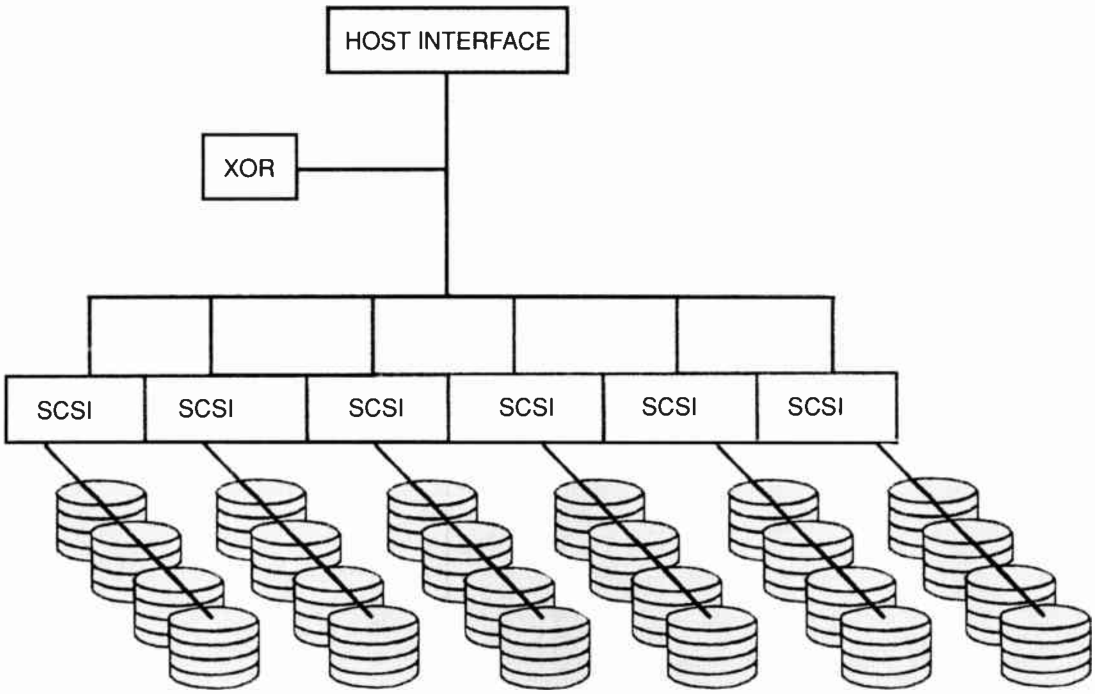

Figure 5.8-15. A conventional SCSI orthogonal array.[3]

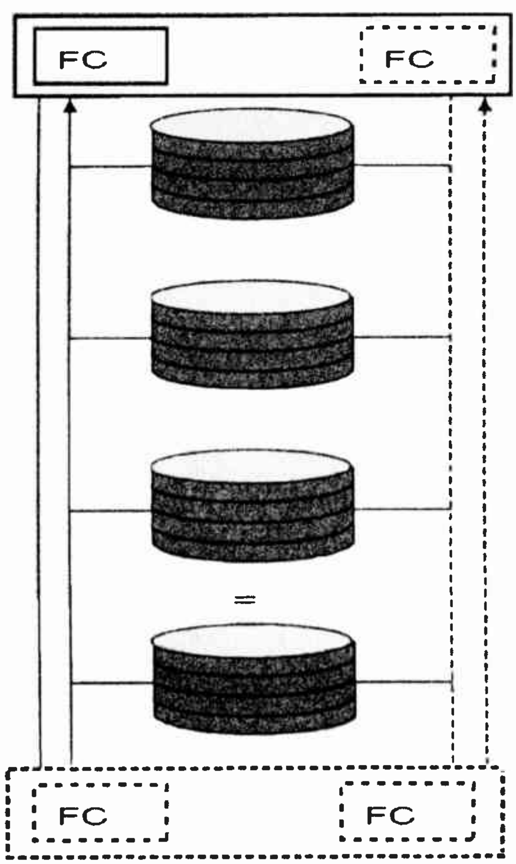

Figure 5.8-16. A Fibre Channel longitudinal array.[3]

of drives as on a traditional array. The capacity of a subsystem can be increased on a drive-by-drive increment basis

- The cost of the array over conventional array implementations is smaller. Because the FC-AL controller has been significantly simplified, it is less expensive than a multiple drive interface version
- A designer can add controllers and spread drives across them as more performance is needed (but only add drives if extra capacity is desired). The designer can scale performance and cost per megabyte to best suit a particular application.

Networking Considerations

Because Fibre Channel is a generic, standard interface, it has multiple uses and supports many different protocols, such as SCSI, IPI-3, Internet Protocol and asynchronous transfer mode (ATM).[3] All of these can run on the same FC facility, which means that an investment in a FC adapter for a disk array may also bring high performance networking and vice versa.

While relatively new to the scene, *network-attached storage* offers intriguing possibilities and Fibre Channel makes it architecturally practical. Figure 5.8-17 shows an FC network, including a file server with an arbitrated loop of drives. Because the disk interface is the same as the network interface, there is no reason the disks could not be put directly on the network, as with the two drives depicted in the upper left section of the loop. The systems could be communicating with each other using IP protocol and with the disks using some variation of SCSI over the same facility. All the

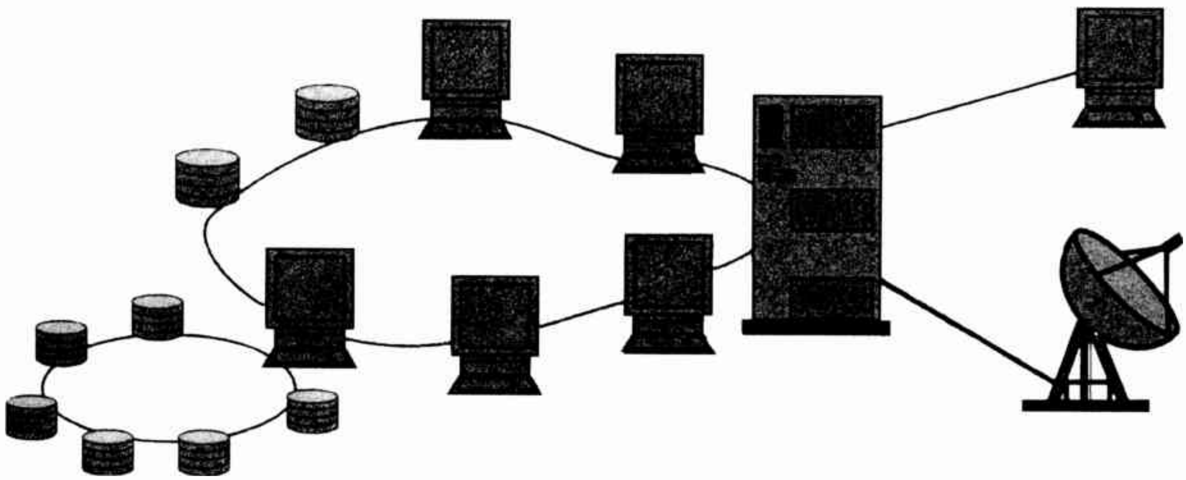

Figure 5.8-17. The concept of network-attached-storage.[3]

systems in the network could access that data at Fibre Channel speeds. This might be especially attractive in a video server application where the data could be sent directly from the drive to a cable head end or satellite dish at speeds much higher than could be achieved if routed through a file server.

Server-Based Video Editing

Video editing is mostly a cutting and pasting process, and as such, it lends itself to synergistic applications involving the video server.[6] The digital recorder enabled users to re-record the same video several times with minimal generation loss. Digital recording also offered the ability to read-before-write. With tape, this required judicious care, because the underlying video track was erased by the subsequent one. Disk based systems, either optical or magnetic hard disk drive designs, also offer this capability, but allow nondestructive read-out.

Server based editing resembles digital disk based editing, except that files from one user can be instantly available to another. Facilities need only to endure the time penalty of transfer and digitizing (as necessary) the input source material once. Thereafter, all potential users can access the material simultaneously. For example, assume an important piece for the five o'clock news is being produced in edit room "A." Via the server, the producer in edit room "B" can start putting together the same story for the six o'clock news, accessing the same digitized elements.

Not every facility puts out back-to-back newscasts. Many that do, reuse stories with minimal updating. There are, however, a number of facilities that not only produce multiple newscasts, but provide separate news programming to cable channels or that sell news to other stations. If Internet broadcasting increases in importance, it may begin to consume editing resources as well. With this many hands fighting for a field tape, conflict is inevitable. A unique economic advantage of the server based facility is that a multitude of users can cherry pick off the main storage system, without disrupting the work flow of other operation.

CONCLUSION

The video industry has become accustomed to an ever increasing number of tape formats, each targeting a particular market segment. Disk storage of video has been an effective refuge from such format wars. This is not to say that video disk stores do not vary greatly—they do. The only standardization is their interface: SCSI, SCSI-1, SCSI Wide, Fiber Channel, IDE and so on. Because video disk interchange is not a major requirement today, there is no specific need to define the internal format. With no standards of measurement except the ultimate performance of the system to fall back upon, it is important to carefully examine the system architecture to be certain that it addresses the requirements for performance and reliability for a given application. Clearly, all video servers are not created equal.

The utilization of server systems opens considerable opportunities for video production. The ability to operate multiple channels, provide multiple, simultaneous access, reduce the space required per task and better track program materials is helping to define the video production center of the future.

5.9 VIDEO SPECIAL EFFECTS SYSTEMS

JEFF MAZUR, ABC INC.
HOLLYWOOD, CA

INTRODUCTION

Special visual effects is one of the fastest growing fields in entertainment production. The proliferation of music videos, commercials and even video games has created an insatiable need for newer and better effects. Once used only for truly special effects, or impossible shots (*Bewitched* style magic or sci-fi environments such as outer space) they are now routinely used to make subtle changes to brand names, lighting and to create realistic scenes such as the drifting feather in the movie *Forest Gump*. Although more prevalent in large budget motion pictures, most of these effects are now being performed digitally in a high resolution video environment. Therefore, the techniques described here apply equally well to standard and high definition television as well as to digital film effects equipment.

There are many techniques that go into the making of special effects, from mechanical (wires) and chemical (pyrotechnics) to motion control, camera tracking and virtual sets. Some of these effects are created in *real time*, during original camera shooting. Other visual effects such as 2D and 3D computer generated images (CGI) and digital effects are added later during post-production. This chapter focuses primarily on the use of digital video effects (DVE) devices and compositing systems.

History

The history of digital video effects dates back to the early days of television when the only effect that could be performed was superimposition (mixing two video feeds) similar to making a double exposure on film. Normally used to add graphics or credit rolls to a live video feed, the video mixer was simply dissolved halfway between two cameras. Although the effect was crude—and lowered the brightness level from each camera—it was possible to create composite images of ghosts, giants, etc. For this to work, one subject had to be shot against a black background to avoid spoiling the other image.

Later, video switchers developed the ability to actively switch between two cameras thus creating a wipe. With the advent of the videotape recorder (VTR) and careful planning, it became possible to wipe between a live camera and tape playback, allowing one actor to play against herself, much like the traditional optical effect used in film.

Analog Effects

A *keyer* enables the switching between two video sources. The switching signal is derived from a video source rather than a fixed pattern generator. An internal key typically uses the luminance level of the video to create the switch; this is practical for superimposing black-and-white graphics or text.

For effects work, the next advance took place with the introduction of the *chroma keyer*. A chroma keyer generates a key signal based upon the color of objects in the scene. Thus an actor posed in front of a strongly lit blue or green screen can be isolated from that picture and placed over, or into, a completely different scene from another camera.

For more than 20 years, this was about the extent of the effects that could be performed on video signals. In the early 1970's however, a revolution was taking place in the field of electronics. In the broadcast arena, it began with the digital time base corrector (TBC). By storing a small portion of the video signal in random access memory (RAM), a digital TBC could eliminate jitter from the raw output of a VTR. As memory capacities grew, it was soon feasible to hold an entire frame of video in RAM, thus creating the *frame store*. At this point, many inventive engineers realized the potential this had for creating digital video effects.

DIGITAL VIDEO EFFECTS SYSTEMS

The techniques of sampling, digitizing, RAM storage and conversion from digital to analog video were honed on the TBC and frame store. With an entire frame of memory, video could be stored into RAM at one rate and read out at another. This is the basic operation of the frame store—allowing asynchronous video signals to be combined without the need for genlock. In this scenario, the digitized video samples from the incoming signal are stored more or less sequentially into the RAM buffer. They are also read out sequentially although the offset between the read and write addresses will change depending upon the difference in frequency and phase of the incoming video versus the station reference.

However, it should be obvious that there is no restriction on how the video samples can be retrieved

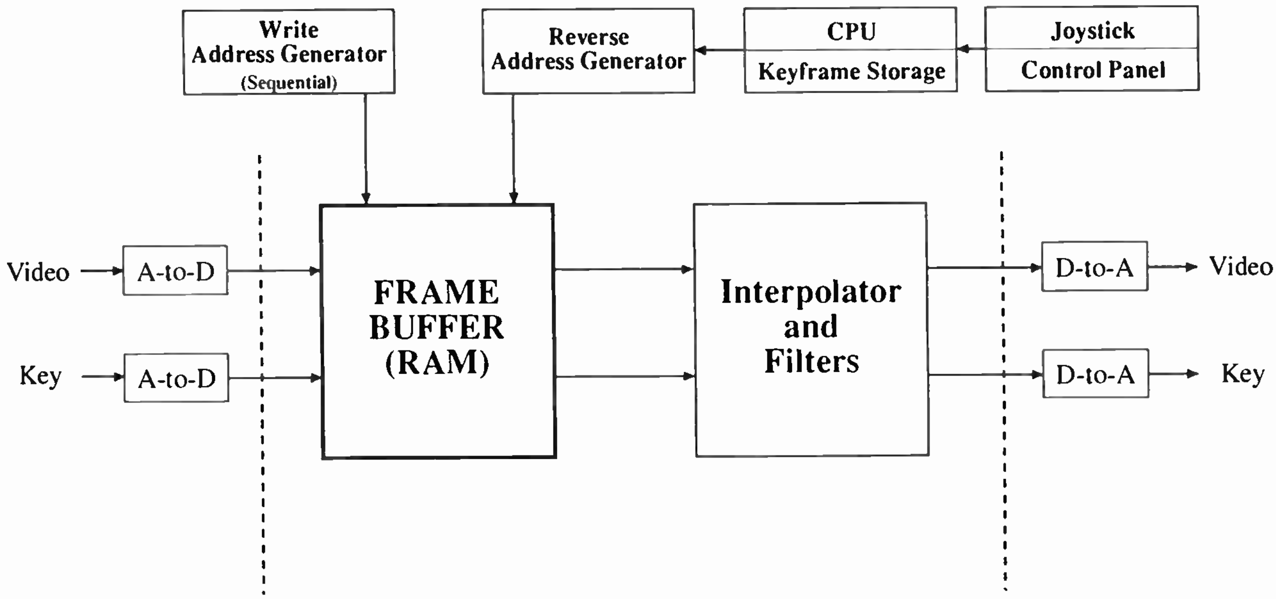

Figure 5.9-1. Block diagram of a typical standalone DVE device. Most effects are created by the Reverse Address Generator (RAG), under control of the CPU.

from memory. For example, start with the assumption that each digital sample represents one pixel of video.[1] If the read addressing is then altered so that the video pixels are read out from RAM in reverse order, there would then be an upside-down and mirror image picture coming out of the framestore (a digital video effect).

When trying to define the various effects capabilities of a DVE, it is helpful to think in terms of source and destination spaces. Imagine the original video signal which is fed into the DVE as represented by a flat piece of paper; that would represent the two dimensional source space. Since the output is also a video signal that might be displayed on a monitor, it too can be represented by the two dimensional face of the monitor screen; this is the destination space. The relationship between these two spaces can be altered in various ways within the DVE including separation into an imaginary third dimension going into the screen. These operations are usually performed using a 3-axis joystick.

Figure 5.9-1 shows the basic block diagram of a typical DVE. First, all analog video and/or key signals are digitized by an A/D converter. The video samples are written directly into the frame buffer. The Reverse Address Generator (RAG) then determines how these video samples will be read out. The RAG is controlled by a CPU which calculates the sequences necessary to give the desired effect. The output from memory is passed through an interpolator and one or more filters to create the final digital output frame. If necessary, the output is converted back to analog. This process continues for each frame of video passing through the DVE; thus the CPU must be fast enough to calculate the RAG sequences in real time.

Translation

The simplest effect that can be performed involves *translation*, or movement in the horizontal and/or vertical direction. It easy to see that these effects can be accomplished by altering the sequence in which the stored pixels are read out. If the sequence itself is then manipulated in real time, it's possible to have the DVE smoothly move the picture left or right, up or down. When trying to read out past the edges of the source space, the DVE will usually substitute black or a fixed background color.

Interpolation

The previous examples did not alter the original video samples. They were simply read out in a different order. Almost all effects however will require some manipulation of the stored samples to create the pixels in the output image. This is the job of an *interpolator*. For each output pixel, the interpolator examines the surrounding pixels stored in memory. Then using a precisely weighted average, it calculates (or interpolates) what the final output pixel should be.

Because the NTSC video signal is an interlaced format, finding an adjacent pixel is somewhat ambiguous, at least in the vertical direction. For example, consider what would be called the pixel directly above. If the pixel from the previous line (within the same field) is used, then this ignores half of the vertical resolution contained in the other field. Looking further back into memory to the previous field, gives the true

[1] In reality, the luma and chroma data from each pixel are stored and processed separately through different sections of the DVE.

pixel which is on the line directly above. This restores the full vertical resolution but introduces another potential problem—motion artifacts. If the pixel in question represents a part of the scene that is in motion, then looking back at the previous field represents what the pixel looked like 1/60 of a second ago.

In a nutshell, if the video stream is processed as fields, then half of the vertical resolution is given up but fluid motion is retained; with frame processing, full resolution is retained at the expense of possible jittery motion or *judder*. For this reason, the frame mode is usually used only for still, high resolution images such as computer generated graphics. For most other video sources which contain any amount of movement, the field mode will usually produce better results. If the motion is great enough, it will mask much of the loss of resolution.

Many interpolators also have an *adaptive* mode which can select the optimum processing for each pixel of the video image. By comparing every pixel with its counterpart in the previous frame, the interpolator can determine whether there is motion occurring in that particular spot on the screen. If motion is detected, then that pixel is processed using field interpolation. If not in motion, then frame interpolation is used for that pixel. Although the motion detector is sometimes fooled, this mode usually produces excellent results.

Rotation and Size Manipulation

Although slightly more complicated, rotation of an image is accomplished in a way similar to translation. The read addresses are calculated using standard polar to Cartesian coordinate transforms. The center, or axis, about which an image is rotated can also be easily altered.

Size manipulation is likewise performed by mathematical operations. Shrinking a picture involves tossing away information (a one-quarter size image can be created by eliminating every other pixel and line). But to blow an image up greater than full size requires more information than is available in the original video signal. Thus the interpolator is relied upon to create the missing pixels. At best, the image will appear slightly fuzzy and at large magnifications the loss of resolution may not be acceptable.

Digital Optical Effects

If the computer generating the read addressing is fast enough, then more complicated functions can be performed. Generally referred to as *warps*, these effects look like page turns, rolls, ripples, or wrapping the video onto a solid object such as a sphere.

It is also quite an easy trick to manipulate the pixel size to give a mosaic look, add multiple images on the screen, or add video effects such as a drop shadow or glow around an image. To further enhance the illusion that a video image has been moved through three dimensional space, a DVE can add perspective size and defocus to the video or even bounce an imaginary light source off of the source video plane.

Latest Computer Effects

Going even further, computerized alteration of the video can produce morphs (changing one image into another), distort (painting the video on a sheet of rubber and then deforming it) and painterly effects (changing the video to look like an oil painting, for example). Because of the mathematical processing necessary to produce these effects, they currently (1998) cannot be created in real time. Thus they probably will not be found on a dedicated DVE device such as those used for live broadcasts.

For effects work done in post-production, non-real time compositing workstations with built-in DVE functions are used to create such effects. Although processing times vary, a typical workstation can render frames somewhere between several frames per second to several seconds per frame.

Recursive Effects

Other interesting effects can be generated by feeding all or part of the processed video back through the DVE. Much like pointing a camera at its video monitor to produce video feedback, the DVE can recycle its output video to provide recursive functions. The most popular uses for this mode are to create decays or trails from moving parts of the image.

Key Channel

Although the primary function of a DVE is to manipulate the video coming into it, most DVEs also keep track of the original source rectangle or an external input key through a separate *key channel*. This channel undergoes all of the transformations along with the video so that it can be used to key the output from the DVE onto another video signal. The key channel can also be used to create a drop shadow of the processed video onto the background.

Motion Keyframing

Sometimes a DVE is used to simply perform a single, stationary effect onto an incoming video stream. The real power of the DVE however comes with its ability to alter its effect over time. A simple effect for example, might be to move a shrunken source image from offscreen left, through the target space and then completely offscreen to the right. It would also be necessary to specify the length of time that this move should take place.

To set up such an effect, *keyframes* are created where absolute parameters are to be entered. In this case, it would be necessary to specify the picture size parameter and then create a starting and ending keyframe. These keyframes would then be set to the beginning and ending x-coordinates respectively. The DVE will then calculate the x-coordinate for all of the other frames of the effect—this is called *in-betweening*. Most DVEs have a timeline display that shows the location of each keyframe within the total length of the complete effect.

Types of Motion

Adding the fourth dimension of time to the DVE also allows manipulation within this new dimension.

(a) (b) (c) (d)

Figure 5.9-2. Various motion paths that can be applied to an effect. In all of these figures, the same eight frame video clip is moved from left to right across the screen (an integrate function has been applied to show all eight frames in the same figure). In a), a *linear* motion gives rise to equidistant spacing and thus constant velocity; in b), the effect is given an s-linear motion which starts off slower, accelerates through the move and then decelerates at the end; by varying TCB values, many other motion paths are possible such as c), constant acceleration or d), deceleration in the middle of the effect.

The simplest type of motion between keyframes is *linear motion*, where each frame moves the same fraction of the difference between the keyframes. Thus the video moves with constant velocity, in a rather mechanical fashion. Another type of motion is *S-linear*, which adds a small amount of acceleration at the start of the move and deceleration at the end. This usually gives a more natural feel to the motion. Other variations such as smooth or curve motions also try to mimic more closely the movement of actual objects in nature. Very specific motion paths, such as that of a bouncing ball, may require many keyframes or finer control over the motion parameters.

One scheme for setting precise control over keyframe motion is the use of *motion vectors*. Three parameters—tension, continuity and bias—determine how the video moves into and out of each keyframe. Figure 5.9-2 shows the effects of various motion types on a simple video clip which is moved across the screen.

For the ultimate in motion keyframing, some systems present a graph for each parameter that changes. The curve representing how the parameter changes from one keyframe to the next can then be manipulated to give the exact motion desired.

COMPOSITING

While some visual effects can be added during production (and indeed, *must* be for a live broadcast) most effects work today is done during post-production. Here, at a much more leisurely pace, the full force of the post-production tools can be focused on perfecting each effects shot. Many devices and techniques can be combined to achieve the desired look. In most cases, the final effect will come together in a compositing suite where all of the various elements are combined. A typical effects shot might consist of 5 to 10 layers: an original background plate with one or more keyed in elements, plus shadow passes, reflections, highlights or glints and possibly a CGI or hand animated element.

In its simplest form, *compositing* involves the layering, or keying, of one video image over another. This multiple image is then recorded off to tape or disk where it can be recalled later as the background image for the next layer. Thus an entire image or video clip is built up one layer at a time. In a linear compositing suite, clips would be laid off to a component digital VTR or digital disk recorder (DDR).

Today however, falling prices and increased capacities have made dedicated compositing workstations much more popular. A complete edit suite can now be built into a single box with non-linear editing, keying and digital video effects all being controlled by a single operator. The increased efficiency and ease of operation now make them the logical choice for most effects compositing.

With early compositing suites, changing something on the first or second *bed* in a 30 layer composite was very time consuming. It could take almost as long to rebuild the composite just to make a small change to one of the first layers. It was like peeling off the layers of an onion to make a change inside and then carefully reassembling the pieces back together. Modern compositing workstations now allow the operator to work with many layers concurrently, making changes to any layer at will. Other features, such as the ability to marry a matte channel to a video clip, can drastically improve the efficiency of a compositing system.

When compositing, there are basically two ways in which video sources can be combined: *mixing* or *keying*. Mixing can be performed in either an additive or non-additive fashion. Keying—also referred to as matting—can be performed using one of the existing sources as a key signal (internal key) or using a third, separate source for the key signal or matte.

Additive versus Non-Additive Mixing

When mixing two video signals, the usual operation is to add a portion of each signal such that the total percentages add up to 100. This is referred to as an *additive* mix. This duplicates the function of the dissolve lever on a switcher. Inside the switcher or compositing computer, the mix is performed by mathematically adding the two signals in this fashion:

$$V_o = M * V_1 + (100 - M) * V_2$$

where V_o is the video output signal from the mixer, V_1 and V_2 are the video sources and M is the mixing percentage.

For certain operations however, it may be desirable to combine the signals in such a way that the output video represents the level from the video source with the higher luminance. This is called a *non-additive* mix and can be used, for example, to combine mattes from multiple objects to make a single combination matte. Another common use is to add one or more garbage mattes to eliminate areas where the camera shoots past the area of interest. Mathematically, the non-additive mix can be expressed as:

$$V_o = V_1 \quad \text{where } V_1 \geq V_2$$
$$V_o = V_2 \quad \text{where } V_1 < V_2$$

Figure 5.9-3 shows the difference between an additive and non-additive mix using two *hicon* (high contrast, 0-100 IRE) matte signals.

Keying

As previously mentioned, keying involves the combination of two video sources by selectively switching between them. A separate, monochrome key signal is used to determine when to switch. A simple keyer switches between the two sources based on the level of the key signal in relation to key level and/or clip controls. The key signal can be derived from either the overall brightness level (luminance key) or from the color hue information (chroma key), or possibly a combination of both.

The output from a keyer can be expressed mathematically by the formula:

$$V_o = V_f \quad \text{for } K \geq K_{th}$$
$$V_o = V_b \quad \text{for } K < K_{th}$$

where V_f and V_b are the foreground and background video signals respectively, K is the key signal level and K_{th} is the key threshold level set by the operator.

The previous statement describes the operation of a hard clip keyer which switches instantaneously between video sources. Such a switch often creates undesirable artifacts which are visible in the output video. To reduce this problem, most keyers can set two thresholds over which a linear dissolve between signals is produced. This is often referred to as *softening* the key. However, the most precise control can be achieved by using a linear key.

The linear keyer, with its full range of transparency has allowed much more natural and pleasing composit-

Figure 5.9-3. Additive vs. non-additive mixing. The two hicons shown in a) and b) are combined in c), a 50% additive mix and d), a 100% non-additive mix.

ing of images. With a linear keyer, the key signal is used to effectively dissolve between the two video sources. Where the key signal is zero, or black, the foreground image will be totally transparent and thus does not show through over the background. Where the key is 100 units, or white, the foreground image becomes completely opaque and thus covers up the background. In between, as the key signal takes on other values, the foreground becomes as opaque as the absolute value of the key signal and the background shows through accordingly. This is expressed mathematically as:

$$V_o = K' * V_f + (1 - K') * V_b$$

where the key signal K is normalized to vary between 0 and 1 ($K' = K/100$).

One of the great advantages of a linear keyer is that it can maintain the proper levels of anti-aliased images (especially graphics) when creating the composite.

Chroma Key

In a chroma keyer, the key signal is extracted from the foreground video source. Thus the quality of the key will depend upon the video source as well as the chroma keyer's ability to discern colors. For a live production, the RGB outputs from a camera would be used; for later use in post-production, the blue (or green) screen shoot must be recorded. Although it is possible to pull a key from composite video, this should only be done as a last resort. All blue screen source work should be shot on 35 mm film and/or recorded directly onto a component VTR such as D1, D5, DCT, or DigiBeta. This will preserve the greatest bandwidth of the color signals and eliminate artifacts that cannot be removed from the NTSC composite signal.

Most chroma keyers work in the RGB domain. Thus, the foreground video signal must first be transformed into an RGB signal. The keyer will then analyze the individual red, green and blue levels and isolate a small range of color values to represent the key signal. It can take a lot of patience to set up the keyer properly, especially if there are other production or lighting problems. A bad key is quite noticeable; there may be parts of the foreground subject that start to disappear, or often there will be a blue halo around the keyed subject.

Edge effects around the key are the number one giveaway that a chroma key has been used. Unfortunately, even if everything is set up correctly, there may still be a colored halo around the foreground subject. Most often, this is caused by blue light from the backing material reflecting back onto the subject. It can also be caused by reflections or flares within the camera or camera lens itself. To reduce these effects, many keyers have the ability to *hue suppress* the foreground image before keying it over the background. Hue suppression selectively eliminates the backing color from the foreground image. At worst, any remaining halo would be monochrome and would blend into the background more naturally.

For the ultimate in chroma keying, an additive mixing process can be used. First the foreground image (against the colored screen) is processed to produce both a matte signal and a hue suppressed foreground image (against black). Then the two signals are combined in a fully additive mix according to the equation:

$$V_o = V_f' + (1 - K) * V_b$$

where V_f' is the preprocessed (hue suppressed) foreground signal.

Note that there is no attenuation of the foreground video, other than removal of the backing color. With this technique, very high quality keys can be achieved despite the usual problem areas such as fine details (wisps of hair) and transparent objects such as glass. Even reflections from shiny surfaces and shadows cast onto the backing wall can be recreated in the final composite.

Effective Chroma Keying

Since many effects rely upon chroma keying, it is worth discussing the various parameters that go into making a believable composite. Blue (or green) screen effects can basically be divided into two categories, depending upon whether the foreground and background cameras move or not. Early chroma keys were mostly performed with locked down camera shots. Since the purpose of the chroma key is to place a new object into an existing background scene, there could be no relative motion between the two without destroying the illusion. Later advancements with motion control rigs, motion tracking and virtual set technologies have allowed moving chroma keys to be created. Since most people are used to seeing such effects shots as stationary, these new effects seem even more believable.

Whether stationary or moving, there are many tricks that can be used to make a successful chroma key. First, there are some decisions which need to be made during pre-production. This would include the choice of backing color and the type of keying required. Knowledge of the keyer to be used for compositing and whether the original shoot will be captured on film or video will aid in the effect's planning.

Backing Color

Although technically a chroma key can be pulled from any solid background color, blue and green screens are used almost exclusively. In many cases, the choice between the two is very subtle and may be dictated solely on the availability of a suitable stage. When given the option however, there are several factors to consider. The most common concern is with colors that are to be used in the foreground scene. Conventional wisdom implies that there shouldn't be any strong blues on a subject that is to be shot against a blue screen. This is especially true with older keyers that are not very selective (the notorious background peeking through a spot of blue on a subject's tie, for example). Modern keyers however are much more accurate and flexible and this is not such a great problem today.

When shooting live actors, a green screen is often preferred. This is due to the fact that any green spill on the subject is much less objectionable than blue. Again however, most modern keyers offer some degree of hue suppression which can greatly reduce this problem. The higher resolution and lower noise of a camera's green channel also favor the use of green screens. Other factors such as the effect of detail correcting circuits in video cameras should also be considered.

Linear and Shadow Keyers

Depending upon the effect required, it is important to choose the appropriate type of chroma keyer. A simple keyer can be used when the subject simply needs to be isolated from the backing and inserted into the composite image. This is often the case when the composite is not meant to be realistic (when the subject will be flown around in the composite using a DVE).

When shooting a live chroma key where the foreground subject contains translucent objects such as glass or smoke, a linear keyer must be used to preserve the illusion. Otherwise, the object simply disappears or worse yet, shows the backing color behind it. A linear chroma keyer reduces the level of the background scene according to the level of the backing color as seen through the translucent object. This makes the composite much more realistic.

Another way to add realism to live chroma keys is to let the foreground subject cast shadows onto the backing (or other keyed out objects in the foreground). Like translucent objects, a linear keyer will recognize the reduced level of the backing color and darken the background video accordingly. This creates a very real illusion of the subject casting shadows into the background scene.

When the chroma key compositing is to be performed later in post-production, keep in mind that most compositing workstations have relatively simple keyers. Fortunately however, there are numerous tricks that can be used to enhance these effects. For example, it may not be possible to pull shadows directly from the foreground video. To get the same result, it may be necessary to create a separate shadow matte, possibly requiring the use of rotoscope. Another trick—although somewhat of a cheat—is to take the shadowless matte and pass it through a DVE to lay it down in the proper perspective; when mixed with the original matte signal, the very effective illusion of a shadow can be obtained.

Once again, the foremost goal when compositing with a chroma key is to reduce any edge effects. This may take a careful balance between all of the keyer and hue suppression controls. Another technique for improving chroma keys in post-production is to add a slight blur to the matte signal. Even better, some devices have the ability to add or subtract one or more pixels around the edge of a matte signal. Such a grow (or shrink) function can be very effective in creating the perfect composite.

Matching Foreground and Background

After edge effects, nothing spoils a chroma key shot more than mismatched foregrounds and backgrounds. The single most important consideration in matching both foreground and background scenes is *lighting*. Obviously the intensity and direction of key lighting in both scenes should be similar. Color temperature and atmospherics should also be matched whenever possible. For example, when the background scene is an outdoor shot on a sunny day, it might be best to shoot the foreground blue screen outdoors as well under similar lighting conditions (pay close attention to shadows).

Other camera parameters such as depth of field may also have subtle effects on the composite image. If the foreground subject is to be placed well in front of the background scene, consider shooting the background with the camera focused onto the area where the foreground subject will later be placed. If this is not possible, the background may be defocused later during compositing to give a similar effect. Once again, pay attention to the details.

Another quality which must be matched between foreground and background is *colorimetry*. Since each scene might be shot with a different camera, lighting setup, film/video setup, etc., it will be necessary to color correct each scene so that they match. Sky colors, skin tones and shadows are usually first to be tweaked. Color correction capabilities vary widely from system to system, but they are very important in creating that seamless composite.

Film Versus Video

Film shoots introduce several other factors to consider. Most importantly, when making the telecine transfer of either background and/or blue screen film to video, a pin-registered gate must be used to eliminate film weave. *Film grain* is another quality which must be matched if the foreground and background scenes are to appear as if they are parts of the same scene.

Motion Considerations

When the effect calls for a moving chroma key, there are even more details to watch out for. Even though a tracking keyer or motion control rig will be used to keep the foreground image in the right place with respect to the background, optical parameters such as perspective and motion blur must also be considered. This is especially true when either the foreground or background scene is shot with miniatures. In this case, camera height and distance to subject should be scaled accordingly.

When an object is moving fast enough so that it would not appear sharply defined in a single frame, there should be some degree of blurring in the direction of travel. Many video cameras have a high enough shutter speed to mask this effect. When called for in the composite, or if the foreground is moved around with a DVE, it may be desirable to add a degree of motion blur electronically to enhance the effect.

Other Effects

Full featured compositing systems will also have the ability to process video clips in various ways. This might include the ability to de-interlace/re-interlace or cine compress/expand a clip. The first function creates two frames from each original frame—one for each field. The latter is used to remove or replace the 3-2 pulldown used in a telecine to convert 24 fps film to 30 fps video. Both of these functions can be useful for rotoscope.

It is also possible to stretch a video clip to make it fill any given time period. Much like an interpolator, the output frames are calculated from the input clip by mixing adjacent frames in proportion to their proximity to the desired time slice. This is often used to add extra speed to a fast scene or to present something in slow motion. There is a limit however to how much a clip can be slowed down. Just as the DVE loses resolution when blowing up an image, a slowed down clip may look strange if the added dissolves between frames become noticeable. If very clean slow motion is required, then the original footage must be shot at a higher than normal frame rate (either high speed film or super slo-mo video).

Motion Tracking

Another useful tool for creating special effects is *motion tracking*. This can be used to composite a new image onto an existing object in a scene that is moving or in a scene where the camera moves. The computer uses a high contrast edge or point to track the movement over a series of frames. This *motion data* can then be used to stabilize the image. This is an effective way to remove film weave from non-pin registered film transfers or to eliminate hand held camera shaking. This process can even be repeated a second or third time to remove any residual motion.

The motion data can also be applied to another image which is to be keyed into the original scene. By tracking the motion of the background scene, the new keyed in foreground element appears to blend into that picture. When done correctly, the tracking motion reinforces the illusion and makes for a great effect; it only takes a small amount of mistracking (wandering) however to give the effect away.

Motion tracking with one point only lets a key follow horizontal and vertical movements. If the object being tracked rotates or changes size, then the keyed in video must be adjusted accordingly. This can be accomplished using *corner pinning* and *four-point tracking*. With corner pinning, a roughly rectangular area is defined on both the tracked background object and the insert video element. The computer then uses its built-in DVE to match the perspective of the insert video by pinning its corner points onto the corresponding points in the background image. If four-point tracking is then applied to independently and simultaneously track all four corner points, the result can be quite spectacular. This technique is often used to track images onto a sign or video screen on the set.

Rotoscoping

Shooting an object or person against a blue screen makes it very easy to generate a matte for the object. This matte can then be used to composite the image over a different background. However, it is not always possible to have the subject shot blue screen. Sometimes, it is necessary to generate a matte for one object within a busy picture. In such a case, present computer tools are usually unable to perform this separation. It then becomes necessary for a human artist to painstakingly create the matte on a frame by frame basis. This is called *rotoscoping*. While mostly used for generating a traveling matte, roto can also be used for other effects such as wire removal and adding hand drawn objects such as sparks, pixie dust or laser beams.

Virtual Sets and Ad Replacement

One technology that appears to hold the most promise for the future of video special effects is that of *virtual sets*. A virtual set is basically a CGI background scene created entirely within a high speed supercomputer. Foreground subjects are then shot blue screen and chroma keyed into the virtual background. The real trick is to then have the CGI background automatically track movements by the foreground camera in real time. Here is where the supercomputer comes in—it must calculate the position and field of view of the real foreground camera and then render a complete frame of the background scene at the proper perspective. And, of course, it must do this at 60 fields per second.

Current computer technology limits the complexity of the background which can be rendered in real time. Thus, early virtual sets were somewhat surreal. But with sufficient computing power, it will be possible to create truly photorealistic imagery (current computers require on the order of minutes—perhaps even hours, for HDTV or film—to create just one such frame).

Creating a virtual set requires two basic components: *camera tracking* and *real time rendering* of a 3D graphic database. Camera tracking—including position, height, pan and tilt angles, lens focal length and even focus—is derived either by position sensors or via pattern recognition. The former method involves the physical attachment of various devices to the camera to relay pertinent data to the render computer. These devices must be calibrated in advance to give the computer a starting frame of reference.

Pattern recognition offers an alternate technique for gathering the camera parameters. With this system, the blue screen is crosshatched with various sized lines. These lines are painted in the same hue, but slightly darker than the regular background. The colors are close enough to be completely keyed out together, but different enough that they can be detected. The camera parameters can then be extracted by analyzing the camera's video signal. By detecting the presence of and the relative relationship between, various lines of the crosshatch pattern, the computer can determine all of the needed parameters. Even the fuzziness of the lines can be used to determine the relative focus needed to render the background correctly.

The camera tracking technology of virtual sets was first used for advertisement replacement during sporting events. It is now quite possible that a banner or logo seen in the stands (or even on the field, court, rink, etc.) of a televised sporting event might not actually be visible to a spectator at the same event. And pattern recognition can also be used to create other interesting effects (tracking the motion of a single player or other object in a live sports production).

The use of virtual sets is currently limited to special news shows, some sci-fi and a few children's programs. As the technology improves however, it may see wider use. If for no other reason, the potential for reducing set construction and storage costs make it fiscally appealing. Several networks have given considerable thought towards its use in producing soap operas, for example. However, one major stumbling block still remains—it requires a different kind of acting to play a scene inside a virtual set. Gone are the traditional walls—and in some cases even the props—that an actor must interact with.

Some believe that the next great visual effect will be the use of *virtual actors* (dead actors brought back to life or new, totally computer generated actors). Currently, live actors wearing body suits with motion sensors can be used to animate CGI characters. Higher resolution however is needed to capture slight nuances such as facial expressions. In the future it may be possible to eliminate the actor altogether and have a realistic character completely controlled by computer.

VIDEO TO COMPUTER INTERFACES

The power and low cost of personal computers has not gone unnoticed by video professionals. Some of the most exciting and lucrative fields of software development are in the area of video creation and processing. Many tasks that are traditionally performed on dedicated video production equipment or 3D supercomputers can now be executed on low cost PCs.[2] Of course, it may take much longer to perform the same task on a PC, but often this is well worth the tradeoff of much lower equipment costs. And as PCs get faster and more powerful every year, the gap between them and dedicated equipment continues to narrow. With the addition of one or more specialized plug-in boards (or an external video processing unit), this gap can even be eliminated; indeed, many new video production tools are now based on, or *driven by*, PCs. With the advent of digital television (DTV), this approach will undoubtedly be used even more.

[2] The use of the term personal computer PC here is not platform specific.

Video Format Conversions

To process video in a computer requires some manipulation of the video signal. Analog composite or component video must obviously be digitized; composite signals must also be decoded into RGB or YUV components. Even component digital video signals may require YC_bC_r to RGB color space conversion and/or pixel aspect ratio correction. For compressed video systems, conversion to an M-JPEG, MPEG-2, or similar bitstream must also be accomplished. And these processes will likely need to be reversed when bringing the video back out of the computer realm.

To understand all of the conversions necessary, it is helpful to examine each of the standards currently in use. Broadcast engineers should be familiar with the NTSC composite, RGB analog and perhaps the ITU-601 digital video standards.[3] Inside computers, video is most likely to be represented by 24 bit RGB values. An optional 8 bit alpha channel is sometimes added to ease keying (besides, computers handle 32 bit values more efficiently than 24 bit). (The NTSC composite video format is described in detail in Chapter 1.9, *NTSC Standard*). The RGB analog format utilizes three separate monochrome video circuits to convey the complete video signal.[4] Sync and setup are optional on each signal and obviously there is no color burst. If sync is not present on any of the RGB signals, it must be carried as a fourth signal and the format is referred to as RGBS. Since this adds to the complexity of the overall system, most equipment is designed to add/extract sync from the green channel, otherwise known as *sync on green*. Sync may also be added to the red and blue channels to prevent discrepancies in the way the three channels are processed; however, this sync is never used.

Component digital (ITU-601) is based upon YC_bC_r component signals.[5] These are derived from the standard, gamma corrected R′G′B′ signals according to the following equations:

$$Y = 0.257R' + 0.504G' + 0.098B' + 16$$
$$C_b = -0.148R' - 0.291G' + 0.439B' + 128$$
$$C_r = 0.439R' - 0.368G' - 0.071B' + 128$$

By definition, the Y signal has a range of 16-235 and the C_b/C_r signals have a range of 16-240 (assuming 8 bit resolution). This leaves some digital headroom for over- and under-shoots of the video signal. Even so, much of the YC_bC_r color space is outside of the standard RGB gamut, as shown in Figure 5.9-4. This is a result of restricting the RGB values to a range of 0 to 255.

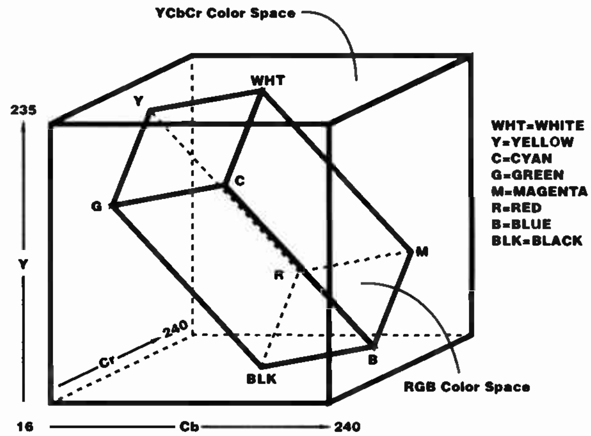

Figure 5.9-4. Comparison between the YC_bC_r and RGB color spaces. Note that about one-half of the YC_bC_r values are outside of the RGB gamut.

To make matters worse, some RGB combinations translate into illegal colors when encoded to NTSC composite (mostly due to excessive chroma levels). For this reason, it is imperative to check levels on all signals brought in from YC_bC_r space (from a digital paint system). Any objects created on the computer should be drawn using an NTSC legal palette. Compositing programs should have an NTSC filter function to ensure that their rendered output is within spec.

Picture Resolution and Pixel Aspect Ratio Conversions

Picture resolution (both horizontal and vertical) and pixel aspect ratio must also be considered when interfacing video signals with a computer. This is most likely to be an issue when dealing with ITU-601 signals. The ITU-601 standard specifies a horizontal resolution of 720 pixels by 486 lines.[6] Given the 4 × 3 (or 1.33) aspect ratio of NTSC, this effectively makes each pixel rectangular. Computer graphics adapters however, almost exclusively use square pixels. Since the number of lines already matches the number of active lines of video in 525 NTSC, it remains a logical choice. Therefore, to give a true 1.33 aspect ratio using square pixels, there would have to be 648 pixels per line. To convert between 720 × 486 and 648 × 486 requires that the pixels be squeezed horizontally by 10% (multiplied by 0.9).[7] The 648 × 486 resolution

[3] Formerly CCIR 601, now completely specified as ITU-R BT. 601-4 (1994) *Encoding Parameters of Digital Television for Studios*.

[4] RGB may alternately be denoted as GBR.

[5] YC_bC_r is the correct terminology for this luminance (Y), R-Y (C_r) and B-Y (C_b) component format. This is sometimes incorrectly referred to as YUV (which also is related to the unscaled and offset signals upon which YC_bC_r are derived).

[6] Technically the standard allows for 487 active lines in NTSC. When dividing the 525 lines per frame into two fields, the standard does not allow half-lines. Thus an extra line is added to field one. Whether this line is used for active video is somewhat debatable, but the majority of ITU-601 devices appear to specify an image size of 720 × 486.

[7] Again, there remains some debate over the exact pixel aspect ratio. While ultimately this remains a function of the specific display device, some calculations prefer to eliminate a few horizontal pixels which get blanked, or are used for the transitions into and out of blanking. It is common to see the number of "active" pixels per line set at 711, which translates into a pixel aspect ratio of 0.911.

is often further scaled down to 640 × 480. Although this is somewhat easier for the computer to handle, it does not allow enough active vertical lines to create a legal (as defined by the FCC) signal. Despite this however, many 640 × 480 images are still being broadcast today.

When the final result is to be laid off to film, the computer must render a higher resolution image. Typically, film images will be handled at *4K resolution* which implies 4096 pixels per line. Since film aspect ratios vary considerably, this could represent a frame size between 4096 × 1870 (70 mm @ 2.19:1) to 4096 × 2990 (35 mm @ 1.37:1). At 24 bits per pixel, that translates into a file size of 22–35 MB per frame. This compares to approximately 1 MB for a single frame of 720 × 486 video.

Interfacing Video with Computer Workstations

For offline quality editing, composite video will probably suffice. Even online editing is possible thanks to faster computers and hard drives which allow for lower compression ratios. Special effects and compositing however, are usually done in an uncompressed, component video domain. For most television work, this will be based on the ITU-601 Standard.

Images created solely within the computer however can be rendered to any resolution. Higher resolutions of course, will require corresponding increases in rendering time. For this reason, long video clips (or short, film resolution scenes) can require rendering overnight. While this may make good use of computing time, it also carries the danger that something will go wrong which halts the process. Or, after seeing the final render, there may be a problem that requires making a change. In either case, another long render may be required. For those working under tight deadlines, this can be disastrous.

Composite video work can be digitized and laid back out in real time. Film resolution jobs, on the other hand, will usually be laid off from the computer to some form of digital tape (Exabyte™), or possibly transferred directly over a network to the digital film recorder. Most video work however, is done by transferring component video in and out of the computer. This can be accomplished in one of three ways: using *analog component video, digital component video* or via *data transfer.*

Analog component video usually requires an add-on video card that feeds RGB (or YC_rC_b, Betacam™, etc.) to the computer. This card performs sampling, digitizing, and possibly color space conversion on the input side. For output, it must perform D/A conversion and filtering. Make sure that the card is set up correctly for the type of component signals to be used (whether setup is present or not on RGB signals). Also be careful when feeding the analog output from a computer into other ITU-601 devices. Images created on the computer often have risetimes exceeding the standard NTSC bandwidth. When these signals are fed into a digital device, they can cause ringing on sharp edges. Some computers also have built-in S-video ports; while certainly better than standard composite, they are still not as clean as full component video.

Feeding component digital to the computer requires a very high end video card. Serial digital video (SDI, per ANSI/SMPTE 259M) most likely will be color space converted between YC_bC_r and RGB. The levels may also be scaled to match the computer ($Y=16$ black would scale to $Y=0$, or $R=G=B=0$; $Y=235$ white becomes $Y=R=G=B=255$). Color bandwidth is expanded from 4:2:2 to the computer's equivalent of 4:4:4 sampling. Although these operations are mostly transparent, beware of illegal colors and optional filters that can cause slight variations in color. This could make the processed frames stand out if they are edited back into the original clip. The best advice is to work in YC_bC_r space whenever possible.

As with most UNIX-based 3D workstations, video frames can also be passed as data files. These files can either be written to a standard data tape format or transferred over a network to another digital device. Quite often, the other device is a DDR. In this case, the video is rendered and transferred to the DDR one frame at a time. When this process is complete, the entire clip can then be played back in real time on the DDR.

Video Editing/Compositing Programs

Once video has been digitized and stored within the computer, it is up to a software program to perform whatever manipulation is required. This could be as simple as cuts-only editing or as complicated as full multi-layer compositing with DVE moves, morphs, motion tracking, etc. Most programs offer an intuitive *user interface*, often representing clips as reels of video frames (like filmstrips) and using menus and buttons to operate on these clips. One of the main advantages of general purpose PCs is their ability to run several different programs on the same hardware. Therefore it is possible to capture a video clip with one program, send the video to a standalone morphing program and finally composite the morph using yet another piece of software.

Video editing programs are most likely to use compression techniques to store the lengthy video clips used in long form production. High end systems will use the least compression (approximately 2:1) for online work. With additional hardware, it is possible to process two video streams simultaneously, allowing dissolves and simple effects to be created in real time. These programs also handle multiple channels of digital audio at the same time.

For effects work, 2D and 3D animation programs are often used in conjunction with compositing software. These programs tend to work with higher quality, uncompressed video. As such, they do not operate in real time. Although this type of work generally deals with short video clips, even a few seconds of complicated compositing can take an hour or more to render.

KEY TERMS

CGI. Computer Generated Images. Still pictures or complete motion video created solely within a computer (i.e. without a camera).

Compositing. The layering of multiple video elements to create a montage of motion video.

DVE. Digital Video Effects creator. May be a standalone unit, combined with a switcher or part of an integrated video workstation.

Field dominance. The specification of which field (one or two) is to denote the start of a new frame. Most facilities adopt the standard of field one dominance. Incorrect field dominance can result in juddery motion and flicker frames at edit points.

Fill. The foreground video signal which is keyed over a background using a matte.

Hicon. High contrast matte. A monochrome key signal ranging from black (making the fill totally transparent) to white (making the fill totally opaque).

In-betweening. Creating those frames in between keyframes of an effect.

Interpolation. Calculating the value of a pixel based upon its surrounding pixels. Also used to describe the creation of frames when altering the speed of a clip.

ITU-601. Formerly CCIR-601, the standard for component digital video. Specifies a resolution of 720 × 486 (NTSC), 4:2:2 sampling (chrominance sampling at one-half that of luminance) and 8- or 10-bit signaling. Also the format used internally by many digital video devices, most notably the D1 VTR (See endnote 3 for full title to ITU-601).

Matte. Also referred to as a key, is the signal used to determine which parts of the foreground and background images appear in the final composite. (Also used to describe to the keying process itself.)

Keyframe. A specific frame of an effect where certain parameters are specified.

Rotoscoping. The frame by frame hand drawing of a video clip. The drawing may be used to create a moving matte or to add special hand drawn effects to a clip.

STATION AUTOMATION AND NETWORKING

JOHN D. WEIGAND
KSWB-TV SAN DIEGO, CA

INTRODUCTION

When looking at an overview of automation for television stations, the network computer system and the various departments within the infrastructure of the station must be considered. Each department must be carefully reviewed in order to create a well running, efficient station-wide system. Engineering, traffic, programming, accounting, promotion, sales and news each have unique and specific needs that must be met, and the automation process must integrate computer hardware and software used within the various departments in order to create a station wide computer system network (see Figure 5.10-1).

Network Architectures

The basic computer system within a station requires a local area network (LAN). The LAN most frequently used today is the 10Base-T system. The station with foresight will use hardware allowing for future expansion to a 100Base-T system. This is because as more departments are added to the network and more data is required through the LAN, the LAN slows down. The faster the system is, the greater is the amount of information that can be sent upon it. The 10Base-T system allows information to travel at 10 Mbps, while the 100Base-T system moves at 100 Mbps. If the station can afford to build a 100Base-T system to begin with, it will be better off in the long run. However, building a 100Base-T system is far more expensive than building a 10 base-T system and is, in most instances, not a cost effective alternative with which to begin.

A compromise between these two alternatives is to install hubs and group lower volume users on the same hubs, while placing higher volume users on faster hubs. The hubs can then be connected though a multiport switch. This will save money on a short term basis and still keep data moving through the LAN system quickly.

How can a station plan for future expansion to a 100Base-T system? Any network interface cards installed should be a 10/100Base-T interface that will work at either a 10Base-T speed or a 100Base-T speed. All wiring used should be category five wire that will support operation of a 100Base-T system. In this manner, the foundation will be laid for moving to a 100Base-T system in the future.

When building a new computer network within a station, or when upgrading an existing network, planning should include switched networks in order to reduce system latency. Multicast and automated push technology, and accompanying increased traffic, will bog down the network. Figure 5.10-2 shows a typical stacked hub network where all ports share on a 10

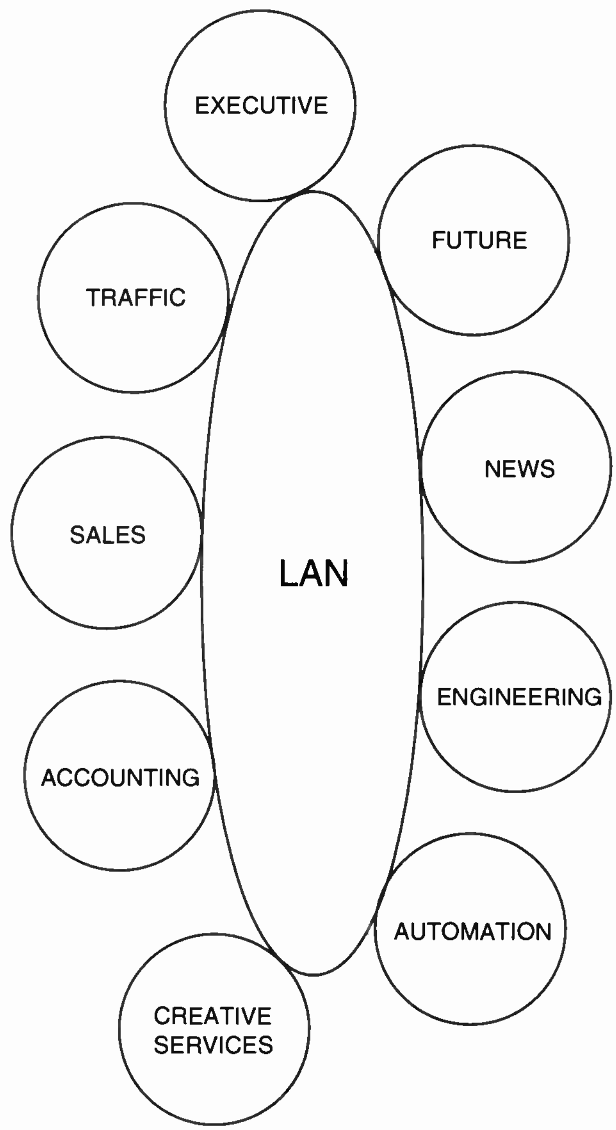

Figure 5.10-1. The elements involved in a television station automation system.

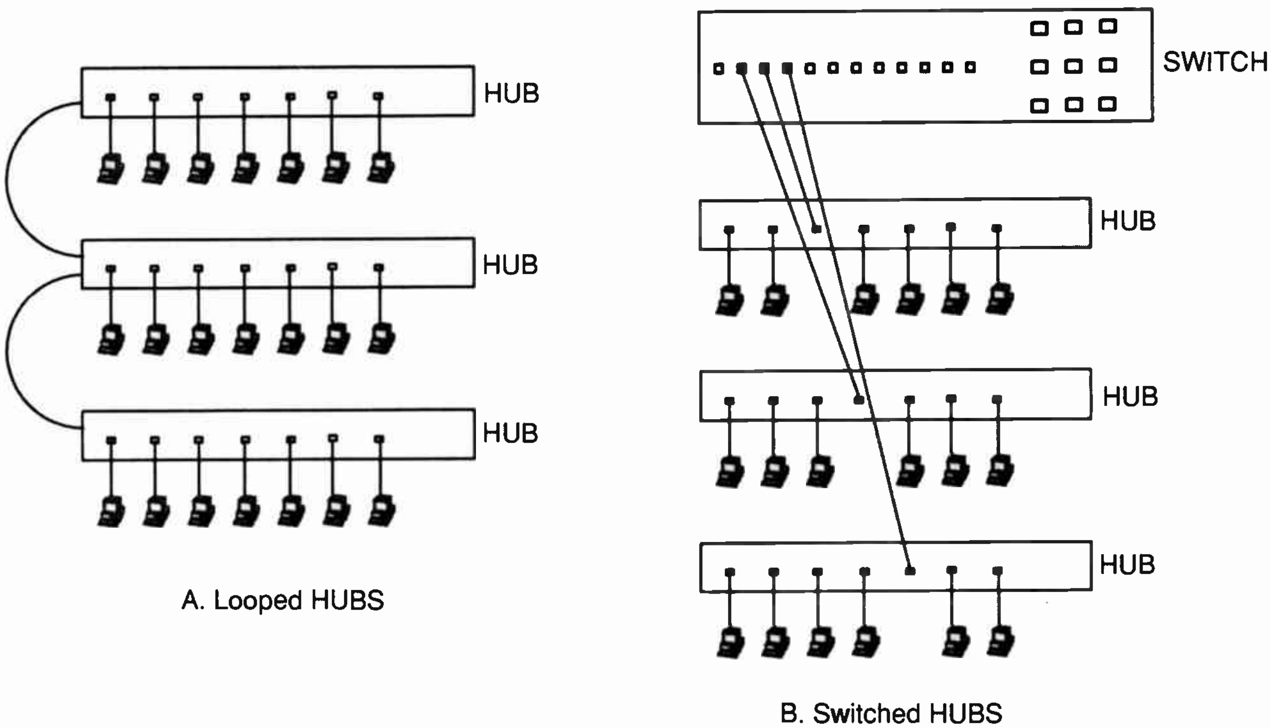

Figure 5.10-2. Network hub configurations: (*a*) looped hub, (*b*) switched hub.

Base-T system (10 Mbps). Adding a switch where each hub sits at a separate switched port reduces *latency* of the system. Latency is the slowing down of the network and it must be avoided whenever possible and practical. The intelligent choice for a computer system within a television station is, therefore, the switched system that avoids latency within the network.

In the past, servers have been connected through a hub to the backbone, or LAN, where traffic is divided by network components such as bridges, routers and switches. These components create *firewalls* between sub LANs, filtering out unwanted traffic. However, from the hub to the backbone, these servers share the 10 Mbps connection up to the backbone. This results in a number of servers working through the same restricting element, as illustrated in Figure 5.10-3. In order to increase the bandwidth, each server should be connected to a switch having multiple switched connections to the backbone, shown in Figure 5.10-4. Each server will then have 10 Mbps *dedicated bandwidth* (each server has a separate a connection to the backbone). If there are three servers, there should be three connections to the backbone, and so on. This increases speed of the network as well as its overall efficiency.

In the network architecture, there should be a grouping of users by *commonality*. This means that traffic, accounting, general office, programming, sales, promotion and engineering should ideally be placed on a separate hub, and from there each group or hub should be connected through a switched port. Such an approach will reduce the latency of the network.

The IEEE Standards P802.1P and P802.1Q prioritize the class of service and quality of service within a network by addressing the issue of separate cueing of time critical frames in bridges, in order to cut down

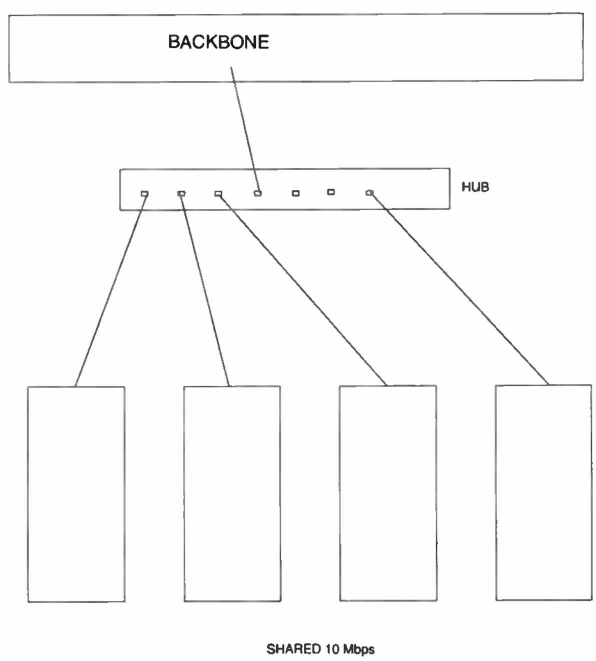

Figure 5.10-3. Network choke point caused by a single connection from the server hub to the backbone.

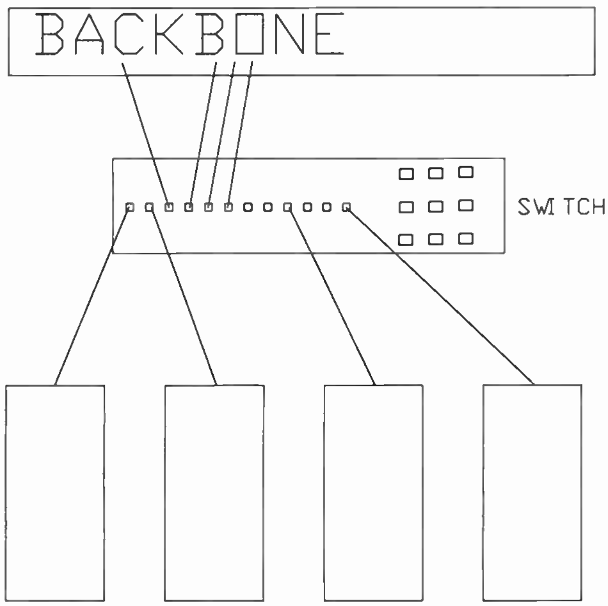

Figure 5.10-4. Multiple switched connections to the backbone, which provides each server with 10 Mbps dedicated bandwidth.

on the latency imposed by the handling of large data blocks. This will allow dynamic configuration and distribution mechanisms to work in such a manner that *general attribution recognition protocol* (GARP) can be used to reconfigure video LANs (VLANs) and propagate information databases.

Push technology allows each user to receive automated transmissions that are broadcast to the entire network. A problem often occurs with push technology and the standard unswitched 10baseT network because they can cause the network to bog down as it sends the information to each user. This problem is avoided simply by moving to a switched network and utilizing the attributes of P802.1P and P802.1Q.

With everything that is being sent over today's networks—video conferencing, stock quotations, Internet research information and the like-television station planners must carefully consider growth options needed for the future of the facility. They may do this by researching and keeping abreast of present and future developments in this important area of technology.

TELEVISION EQUIPMENT AUTOMATION

The standards for television equipment automation include Esbus, RS232 and RS422. A great deal of the television equipment available—VTRs, servers, satellite receivers, satellite controllers, switchers, routers, character generators and related hardware—adhere to these standards. When manufacturers design equipment, they choose which standards they will use. Most of the equipment available is set for RS422. However, it should be noted that RS232 equipment can be converted to the RS422 Standard and vice versa. Esbus is a higher form of remote control and is the SMPTE preferred protocol for RS232 and RS422 bidirectional inputs and outputs.

Protocols are tables of commands and status reports that videotape machine manufacturers develop for their products so that outside devices, such as remote control units or editing units, can tell what is happening. Protocols complement the remote control capabilities of the machine and tell the remote control system the status of the machine. In the past, some manufacturers of tape machines were reluctant to share protocols with competitive manufacturers of units used in conjunction with their tape machines, which made planning difficult. However, that is not the case today. Automation tables are commonly published on computer software within the automation system. The information is readily available when performing the initial set up of the equipment-run software, making planning easier.

Automation within Departments

Automation in the engineering department means controlling satellites, VTRs, servers, switchers, routers, character generators and archiving of commercial and promotional material.

Satellites can be automated by interfacing the antenna controller and the satellite receiver to the automation system. This enables the user to program timed rotation of the antenna for a specific satellite and polarity, either vertical or horizontal. The satellite receiver also is controlled to select the transponder and audio subcarrier channels. The video and audio may be directed to a recording device through control of the router. For example, if the user is utilizing a tape machine, the automation system would confirm there is a tape machine and that a tape is ready before beginning to record.

VTRs can be controlled through automation or manual control. In an automated system time code is read off of the videotape by the VTR. The automation program uses the time code read from the tape to determine exactly when to switch the VTRs output to the program channel. Clearly, in this situation, the automation system needs to know or at least needs to calculate the time code reading at the exact point on the tape where the program begins.

Automation control servers through RS422 ports, and read the timecode on the servers to find specific pieces of video (or audio).

Automated master control switchers receive the information they need to control cross-point switch closures at scheduled times from the traffic/automation system via the LAN or *sneaker net* (manually transferred data). The same can be true for all automated routing switchers.

Character generators are also controlled though RS422 control ports and in this manner they can be used to automate control character output consisting of station identification, transparent branding (bugs) and other information.

Software written for automation can include data that enables a copy of commercial or promotional material to be stored in an archive, generally a digital storage tape.

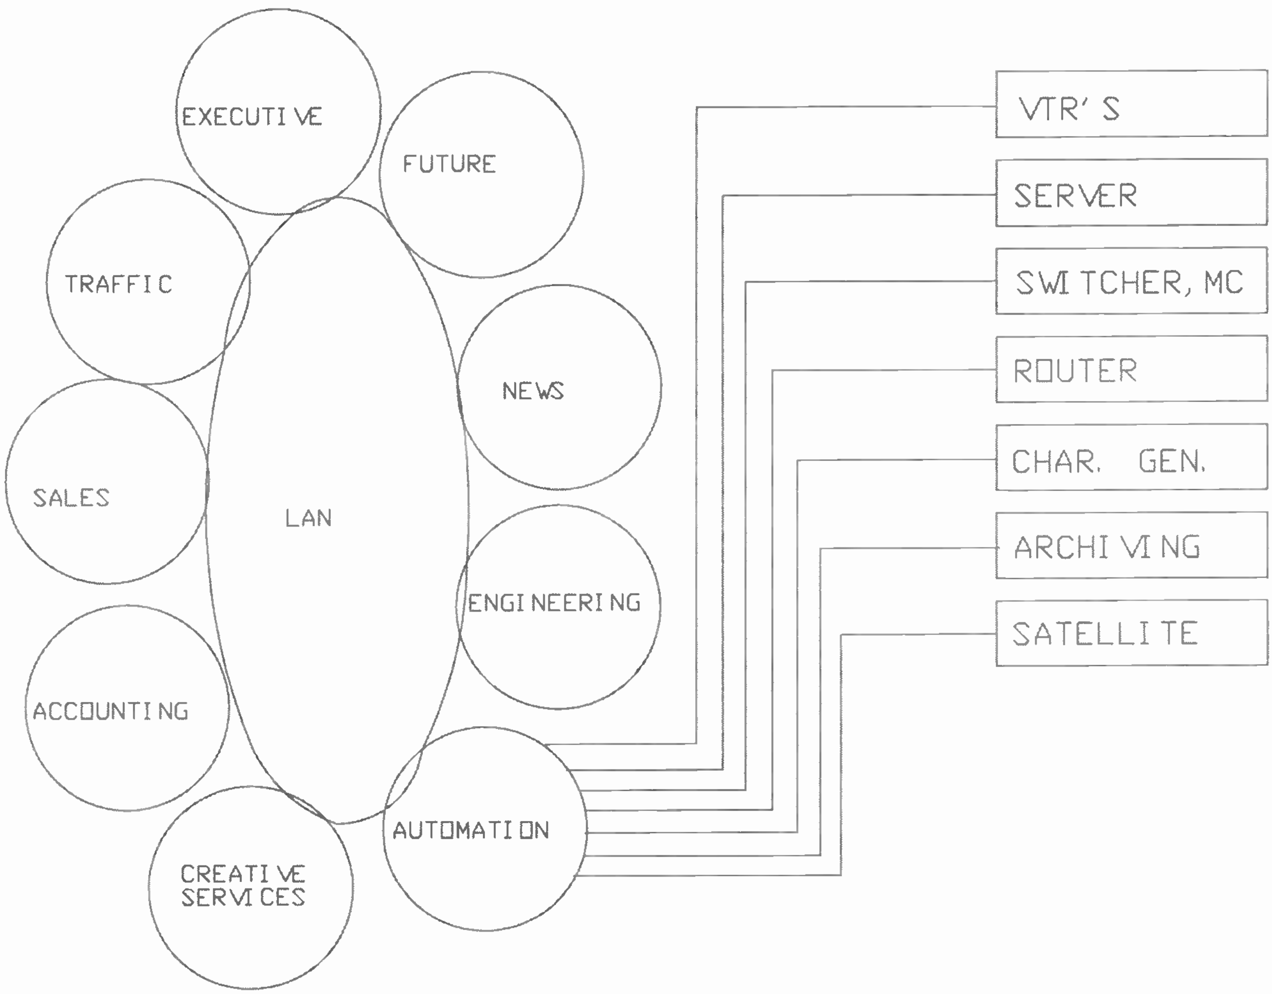

Figure 5.10-5. Integration of a television station automation system with various facility functions, equipment and departments.

All of the broadcast equipment discussed in this section is directly controlled through a single automation computer, as illustrated in Figure 5.10-5.

The traffic department can use contracts from sales for commercial playback scheduling. It can schedule program content received from the programming department and create an entire program for the broadcast day. The accounting department can reconcile the program log. The promotions department can create promotional materials to run on air. Clients can be invoiced from the program log for commercials that have actually run on-air. This multitasking can be done through a building-wide network. All departments are connected on the same LAN, but through different switch ports and servers. The computer use is then interfaced with the broadcast equipment systems. While it would be useful to do programming of broadcast equipment directly though the LAN, at this time some manufacturers recommend the sneaker net. Using the recommended sneaker net means the user hand carries the daily log down to the engineering department on a floppy disk. This disk is installed in the dedicated equipment computer, rather than launching the information through the LAN. The reason for this approach is usually the fear that the program log might become corrupted at some point in the LAN-to-broadcast equipment chain. Log corrections on the day of the log are done from a traffic workstation sent through the LAN to the automation system, which converts the file, makes the corrections and notifies the master control operator of the change on the screen.

In order for traffic functions to work efficiently with the automation system, there must be a 24 hour log. The traffic log should be able to use six digit numbers. The lowest order digits (in the ones and tens places) should be reserved for the cut number of each segment. This way, it is easier to keep track of the client's multiset cuts. Also, for promotional material, there can be a two week rotator based on week "A" and week "B." This will give a seven day time frame to input the "B" week while the "A" week is still running. This facilitates technical operations interfacing with the traffic and promotions departments, permitting easy updating of the various schedules.

The creative services departments can move nonlinear and computer graphics through the LAN to other departments, or from work station to work station for nonreal-time processes over the 10Base-T Ethernet LAN or 100Base-T hub on a switched port of the LAN.

The sales department can schedule air time for a sale and easily access the LAN to see where time is available. At sales sites, the marketing representatives can call into the station network, access traffic, and immediately see what time is available for sale. This facilitates immediate sale of the time slot. At the same time, the market representative of the station can communicate with traffic regarding the sale and electronically enter the contract into the accounting traffic system, which all resides on one common LAN.

Networking and Automating the Newsroom

The network system for the newsroom should be both *modular* and *scaleable*. At this writing, newsroom automation and network systems are in a major transition. An example layout of a typical newsroom of the near future can be seen in Figure 5.10-6. In this newsroom, news stories are gathered though satellite and recorded on a server in real-time. Stories are gathered on a field unit (recorded on a camera VTR storing information digitally on the camera hard drive), which can be played back at four times real-time and then fed to the studio server, either physically or by microwave relay. An abbreviated version of the stored stories is fed into a clip server. The clip server feeds the various work stations for the writer, producer or editor for writing and editing the news to be aired. At any one of the work stations, both writing and editing may be done simultaneously. This means the camera person can bring in the camera and edit and write the story alone, or let a writer/producer edit the story as it is written. Thus, the jobs within the newsroom of the future are likely to be redefined. Instant editing and writing of a breaking story as it is fed by satellite or microwave through the server to one or more of the work stations is one reasonable scenario. At any one of the work stations, a newsperson can write the story for the TelePrompTer, indicate and signal the character generator to type keyed characters on air and make an edit decision list. Video can be fed from the server out to a nonlinear edit suite, where A-B edits can be made. Presently, in most newsrooms, video has to be played from videotape machine A and videotape machine B and recorded on videotape machine C in an A-B edit room. With new technology, the process can all be done on one machine, a nonlinear editor.

With camera robotic capabilities in the news studio, the individual writing the story to be read on air is further able to direct camera shots required by first inputting the shots and chromakey positions into the robotics computer and then assigning shot numbers. From this point, the robotics computer can be linked to the newsroom computer. When a story is written at the newsroom computer, the robotic system shots can be programmed by entering the appropriate shot number. The two computers are linked on a LAN, bridged or switched through one of the network hubs.

Stories can be sent from the server to air, and simultaneously archived on digital tape as data within their respective archive machines. The servers and the archive machine are connected by a Fibre Channel, as illustrated in Figure 5.10-6. From this point, scripts, graphics, video and audio information can be sent to a web publisher. This data will be converted into *hypertext markup language* (HTML) and sent to the station's web page.

Management Considerations

Automation can reduce the cost of operating broadcast station facilities, making more effective use of personnel and time. Operating costs can be reduced, showing a healthier bottom line. Instead of each department working solo within the broadcast station, the various departments will begin working together, forming a new cohesive bond as they share equipment resources. The facility investment will be protected by keeping up with the latest technologies available. Income relative to expenditures will be maximized.

The engineering department must begin the automation process with careful planning and evaluation of system needs. Planning needs to include the physical elements required to automate the station, the workflow procedures currently in place and the work patterns of the personnel involved. A traffic system, for example, must be developed with a synergy to engineering, programming and marketing.

While you may be building a new plant and making it digital, keep in mind the current and future requirements of DTV, bring a whole new set of standards and will pose an entire new set of rules to be considered.

DIGITAL VIDEO INTERFACE AND NETWORKING[1]

Parallel connection of digital video equipment is practical only for relatively small installations. There is, then, a clear need to transmit data over a single coaxial or fiber line.[1] To reliably move large amounts of data from one location to another, it is necessary to modify the serial signal prior to transmission to ensure that there are sufficient edges (data transitions) for reliable clock recovery, to minimize the low frequency content of the transmitted signal, and to spread the transmitted energy spectrum so that radio frequency emission problems are minimized.

In the early 1980s, a serial interface for ITU-R Rec. 601 signals was recommended by the EBU. This interface used 8/9 block coding and resulted in a bit rate of 243 Mbps. The interface did not support 10 bit

[1] This section was contributed by Jerry C. Whitaker, editor-in-chief.

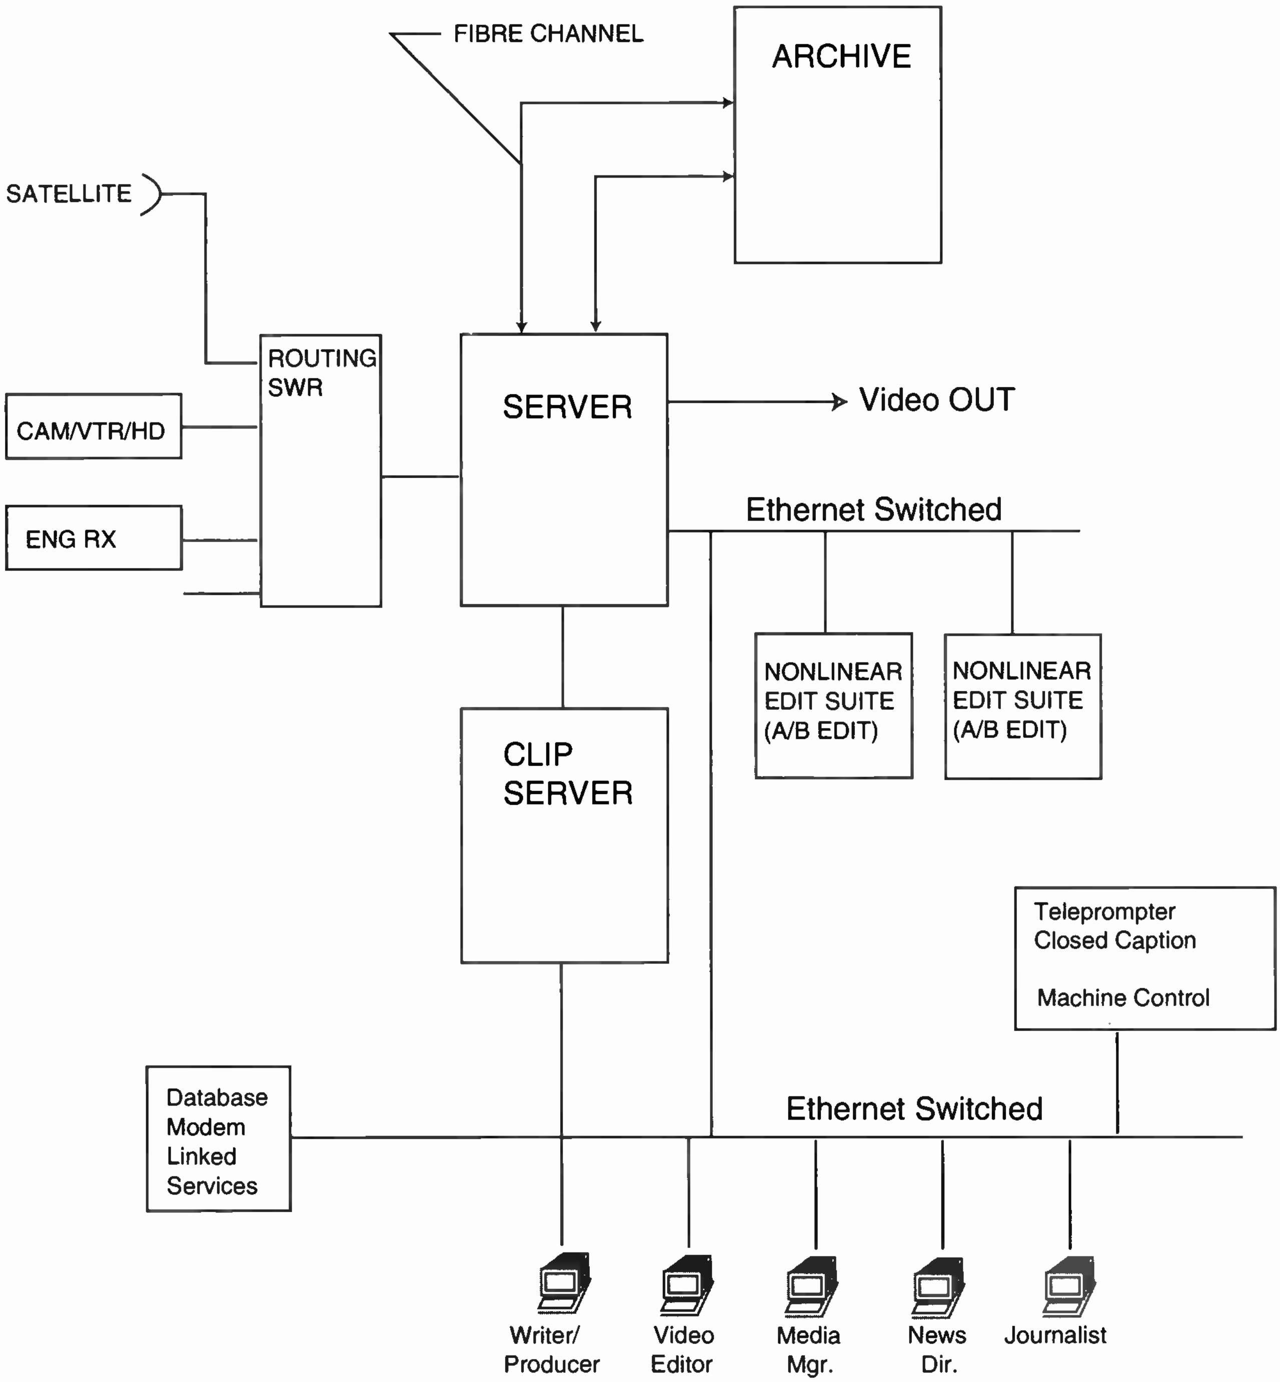

Figure 5.10-6. A full featured newsroom server system.

precision signals, and there were some difficulties in producing reliable, cost effective integrated circuits for the protocol. The block coding-based interface was abandoned and replaced by an interface with a channel coding scheme that utilized scrambling and conversion to *non return to zero inverted (NRZI)*. This serial interface was standardized as SMPTE 259M and EBU Tech. 3267, and is defined for both component and composite conventional video signals, including embedded digital audio.

From this beginning, a number of complementary techniques have been developed to efficiently move digital video information from one location to another. Some of the systems—such as SMPTE 259M—are intended for intra-facility applications, while others—such as *asynchronous transfer mode* (ATM)—are intended for inter-facility applications. The challenge today lies in utilizing and then interfacing the various systems.

Serial Digital Interface

Conceptually, the serial digital interface (SDI) is much like a carrier system for studio applications. Baseband audio and video signals are digitized and combined on the serial digital carrier. (SDI is not strictly a carrier system in that it is a baseband digital signal, not a signal modulated on a carrier wave.) The bit rate (carrier frequency) is determined by the clock rate of the digital data which is 270 Mbps for the ITU-R Rec. 601 component digital. The widescreen (16 × 9) component system defined in SMPTE 267 will produce a bit rate of 360 Mbps. This serial interface may be used with normal video coaxial cable or fiber optic cable, with the appropriate interface adapters.

Following serialization of the video information, the data stream is scrambled by a mathematical algorithm and encoded. At the receiver, an inverse algorithm is used in the deserializer to recover the data. In the serial digital transmission system, the clock is contained in the data, as opposed to the parallel system where there is a separate clock line. By scrambling the data, an abundance of transitions is assured, which is required for reliable clock recovery.

Figure 5.10-7 shows the SDI bitstream for 270 Mbps and 360 Mbps operation. The EAV and SAV elements of the bitstream are reserved word sequences that indicate the start and end of a video line, respectively. For the 270 Mbps case, each line contains 1440 10 bit 4:2:2 video samples. The horizontal interval (HANC) contains ancillary data, error detection and control, embedded audio and other information.

The *serial digital transport interface* (SDTI) is a SMPTE Standard that uses the current SMPTE-259M serial interface link as a carrier for other types of data. It is seen as a valuable component in the distribution of both SDTV and HDTV signals within a television plant. SDTI allows reuse of conventional SDI equipment and wiring to carry compressed video signals. The resulting data stream looks like serial video and, therefore, works with 270 or 360 Mbps SDI. SDTI can, in fact, be used for any compressed video format. Furthermore, it allows faster than real-time data transfer between devices in SDI.

Referring to Figure 5.10-7, in the SDTI case, the active line is the *user data payload.* This payload carries packetized compressed video samples, which are subdivided into blocks of information. In compressed video transport applications, the blocks are fixed in size and carry MPEG-2 transport packets. Header blocks in the SDTI stream contain addressing and other information required for processing of the data blocks. Table 5.10-1 lists the payload capacity of SDTI as a function of format.

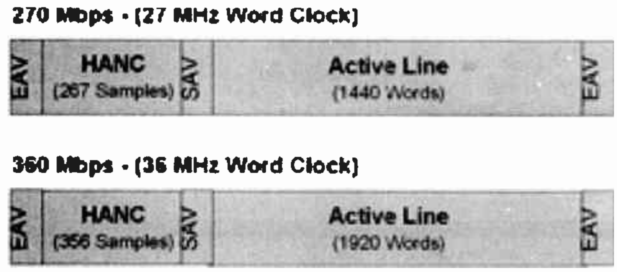

Figure 5.10-7. The basic SDI bitstream. *(Courtesy of Leitch.)*

High-Definition Serial Digital Interface

Based upon the experience gained from the application of digital technology to the 525/625 broadcast and production environments, it is evident that wide acceptance of new professional video equipment takes place only after an efficient means of interconnection is available.[2] For studios today, the means of interconnection is typically SDI. In an effort to address the facility infrastructure requirements of HDTV, SMPTE and Broadcasting Technology Association (BTA) (Japan) developed a standard for digital serial transmission of studio HDTV signals.

The overall transmission rate for transporting a digital studio HDTV signal (1125-line, 2:1 interlace, with 10 bit component sampling) is approximately 1.5 Gbps. The active payload is on the order of 1.2 Gbps (for 1035/1080 active lines). The transmission of video signals at these bit rates represents a far more difficult technical challenge than serial distribution at 270 Mbps used for conventional television signals.

The introduction of the SDI for conventional video in 1986 (SMPTE 259M) was well received by the television industry and has become the backbone of digital audio/video networking for broadcast and post production installations around the world. SDI is ideally suited to the task of transporting uncompressed component/composite digital video and multichannel audio signals over a single coaxial cable. To emulate the same level of operational usability and system integration of conventional television equipment in the HDTV world, the implementation of a *high-definition serial digital interface* (HD-SDI) system—based on an extension of SMPTE 259M—was essential.

Work on the HD-SDI system began in 1992 under the auspices of SMPTE and BTA. The end result of these efforts was the BTA document BTA S-004 (May 1995), followed closely by SMPTE 292M (July 1995), both with similar technical content.

Table 5.10-1
Payload Capacity.

Format	Serial Data Rate	Payload Per Line	Approximate Maximum Transport Payload
SDI, SMPTE-259, Level C	270 Mbps	1440 10 bit words	225 Mbps
SDI, SMPTE-259, Level D	360 Mbps	1920 10 bit words	300 Mbps

The source formats of SMPTE 292M adhere to those signal characteristics specified in SMPTE 260M and 274M. In particular, the field frequencies of 59.94 Hz and 60.00 Hz, and active line numbers of 1035/1080 are used by HD-SDI. Table 5.10-2 lists the basic parameters of the input source formats.

Network Contribution Options for DTV

The form in which material is delivered to broadcast affiliates is a point of some interest and concern as stations plan their DTV plant. The simplest approach has the station taking a broadcast-ready, 19.4 Mbps ATSC data stream from the network. This feed, however, is basically acceptable for pass-through functions only because of the compression already taken on the signal. For applications requiring some form of manipulation of the incoming signal, a higher bitstream rate is required. Options include the following:

- 45 Mbps over satellite or telco fiber links
- 68 Mbps from satellite systems using the latest in modem technology

There are also several potential negative implications of a higher bitstream, including:

- It requires one satellite transponder per signal
- Requires a contribution-grade encoder/decoder
- If some affiliates simply pass-through, they will still require a 19.4 Mbps bitstream
- Concatenation artifacts may arise from different compression systems.

Mezzanine Level Distribution

Mezzanine level distribution is a likely solution to plant infrastructure issues. Under this scenario, video signals are compressed from 1.5 Gbps down to 200–300 Mbps using *higher level* MPEG-2 (higher level = less compression). SDTI is used as a carrier for the resulting compressed stream. This permits the continued use of the existing SDI plant infrastructure, which may consist of:

- Routers
- Digital-to-analog converters (DA)s
- Cabling
- DVTRs and servers (In this application, they must provide >200 Mbps raw data rate for playback and record).

In an ideal arrangement, new DTV devices would support mezzanine I/O. The data rate could vary from one device to the next, as it is assumed that encoders would support a variety of rates and be user-configurable. The higher the data rate, the better the quality of the compressed bit stream. The maximum data rate will be established based on the lowest of the following two parameters:

- The SDI router and available DAs (270 or 360 Mbps)
- The uncompressed *(bit bucket)* capability of the recorders being used

Mezzanine encoding/decoding is attractive because it is much less severe in terms of compression than 19.4 Mbps. Figure 5.10-8 illustrates one possible mezzanine implementation.

Audio Issues

The process of distributing digital audio through a video facility by multiplexing it into the digital video steam is not particularly new. Implementation roadblocks slowed acceptance at first, as considerations relating to the video signal were sorted out. SMPTE refers to this audio signal multiplexing process as *embedded audio.* AES-formatted digital audio signals are carried in the ancillary data space of serial digital video signals. This capability permits routing of video and accompanying multichannel audio through a single cable and through a single level of a routing switcher.

The benefits of this capability are obvious: it eliminates multiple cables, tandem audio/video routers and audio-to-video timing considerations when switching. Embedded audio holds particular advantages for a facility (or portions of a facility) that route or pass signals through without modifying the content. In other words, for strictly audio-follow-video applications such as uplink, STL and network feeds.

It is fair to note that timing considerations when using embedded audio do not disappear, they merely change form. The encoding/decoding process introduces delay into the audio element, just as it does

Table 5.10-2
Referenced Source Format Parameters.[2]

Reference Document	SMPTE 260M	ANSI/SMPTE 274M	ANSI/SMPTE 274M
Parallel word rate (each channel Y, C_R/C_B)	74.25 Mwords/s	74.25 Mwords/s	74.25/1.001 Mwords/s
Lines per frame	1125	1125	1125
Words per active line (each channel Y, C_R/C_B)	1920	1920	1920
Total active lines	1035	1080	1080
Words per total line (each channel Y, C_R/C_B)	2200	2200	2200
Frame rate	30 Hz	30 Hz	30/1.001 Hz
Fields per frame	2	2	2
Total data rate	1.485 Gbps	1.485 Gbps	1.485/1.001 Gbps
Field 1 EAV V = 1	Line 1121	Line 1124	Line 1124
Field 1 EAV V = 0	Line 41	Line 21	Line 21
Field 2 EAV V = 1	Line 558	Line 561	Line 561
Field 2 EAV V = 0	Line 603	Line 584	Line 584
EAV F = 0	Line 1	Line 1	Line 1
EAV F = 1	Line 564	Line 564	Line 564

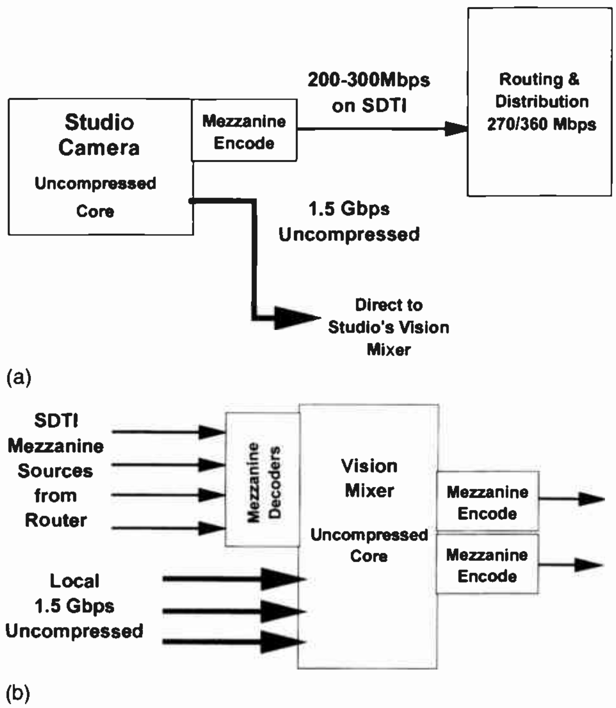

Figure 5.10-8. One possible studio implementation scenario for mezzanine level compression: (*a*) camera system, (*b*) vision mixer. *(Courtesy of Leitch.)*

with the video signal. For greatest flexibility, the serial digital system must be capable of delaying either the video or the audio to maintain synchronization between the two. These elements may necessitate additional expense and complexity, which must be balanced against the cost of additional audio levels in the routing matrix and a separate level of audio wiring within the facility.

Despite its intrinsic benefits, embedded audio rapidly loses its appeal in facilities where breakaway switching is required. When either the video or audio of a combined datastream must be changed, the two signals must again be separated. Time delay compensation must be provided for the delays introduced by this demultiplexer/multiplexer stage. The cost of the encoding/decoding hardware is, of course, also a consideration. Given these necessary tools, the desired changes can be made to the audio and/or video signal, after which the video and audio are recombined and sent on their way.

It is obvious that embedded audio is not usually practical in a post-production environment, except for intra-facility tie-line feeds and, perhaps, machine room switching systems.

Inside AES/EBU

Most professional digital audio devices employ an output protocol developed jointly by the Audio Engineering Society (AES) and the European Broadcasting Union (EBU). This serial digital transmission format, known as AES/EBU, has seen several incarnations. The basic format was agreed to in 1985, and soon thereafter, equipment began showing up built to the standard, known at the time as AES3-1985. Subsequent revision in 1992 led to the standard in use today, AES3-1992. Figure 5.10-9 shows the basic framing structure of AES3-1992.

The AES/EBS format transmits and receives left and right channel information using a data rate that corresponds exactly to the source sampling frequency. One *frame* consists of two *subframes*, labeled A (left channel) and B (right channel), each consisting of 32 bits of information. Each subframe, in turn, contains data for one audio channel. The first four bits are used for synchronization and for preamble identification. The next 4 bits are for auxiliary data. The next 20 bits carry audio data, with the Most Significant Bit (MSB) transmitted last; for 16 bit audio, 4 of the bits are set to zero. The last four bits form a control field consisting of:

- *Validity bit* (V), which indicates if the previous audio sample is error-free
- *User bit* (U), left uncommitted for a variety of user-related applications
- *Channel status bit* (C), which is used to form a data block. For each channel, one block is formed from the channel status bit contained in 192 successive frames
- *Parity bit* (P), which provides even parity for each subframe

Two interconnection methods are used for AES/EBU audio:

- Twisted pair cable with a characteristic impedance of 110 Ω and terminated with XLR connectors (balanced). This is the basic mode specified by AES3-1992
- Seventy-five ohm coaxial cable terminated with BNC connectors (unbalanced). This mode is the result of recent work between AES and SMPTE to accommodate the needs and available hardware of video users.

Interconnection between these two modes is possible with either passive or transformer-coupled matching networks.

Sampling rate

The AES/EBU specification is capable of supporting sampling rate frequencies ranging from approximately 25—54 kHz. Most equipment, however, will only operate at a given, specific sampling rate. Several standard rates have evolved over time; the most common being:

- 32 kHz, used sparingly in broadcasting, with the exception of certain satellite distribution networks
- 44.1 kHz, the standard for the compact disc audio system
- 48 kHz, the professional standard used by most broadcasters for original recording and transmission

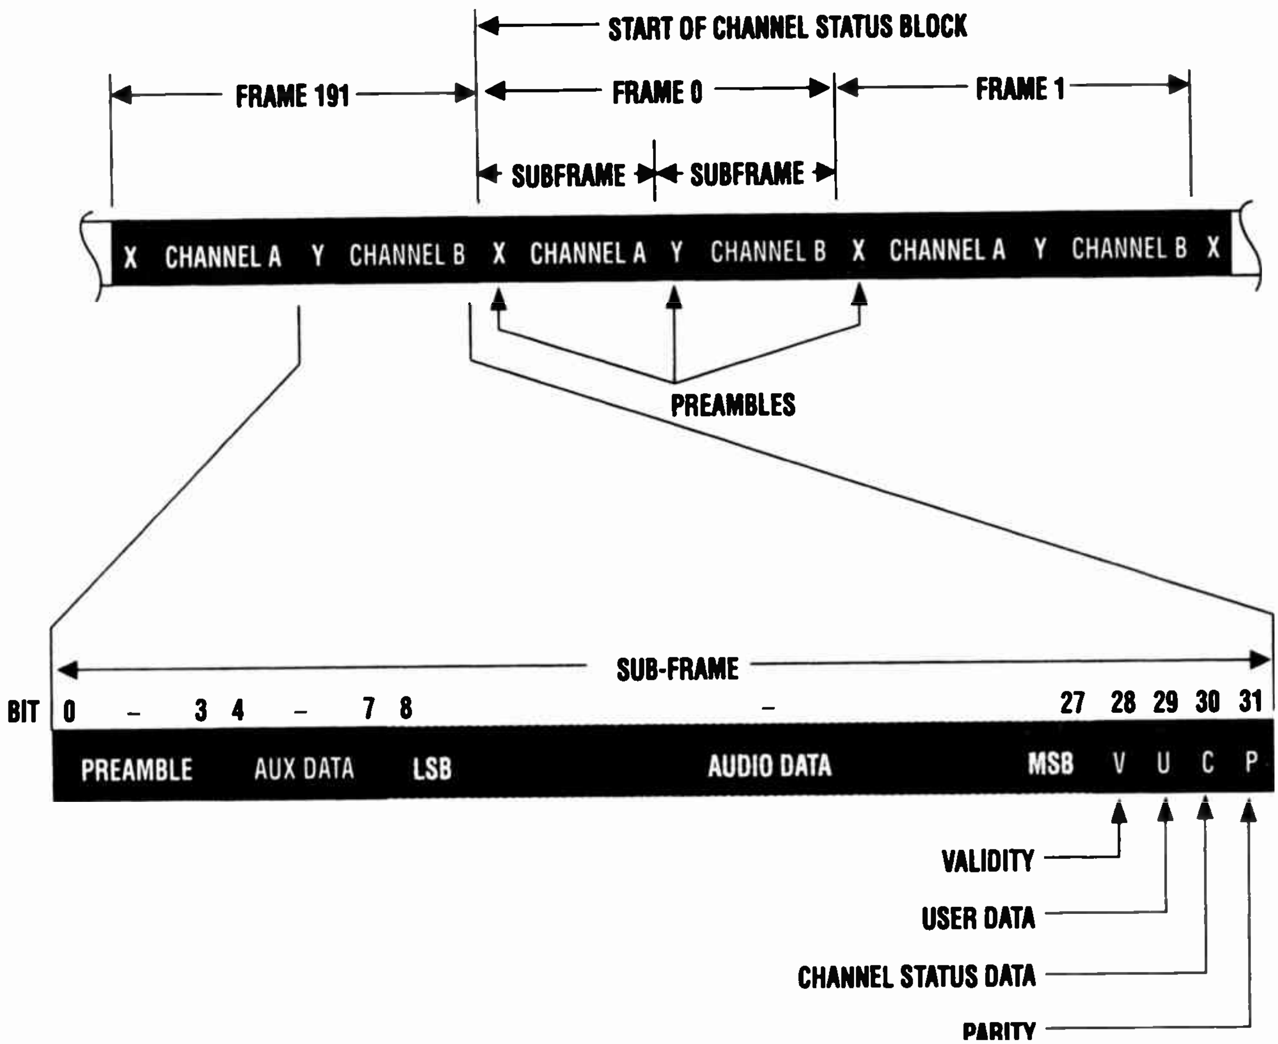

Figure 5.10-9. The structure of frames and subframes for the AES/EBU digital audio standard. (*Source:* AES3-1992.)

Although professional digital video equipment almost always uses a 48 kHz sampling rate for audio, TV stations and post-production facilities often use some quantity of CD-originated material in the production process, requiring them to deal with 44.1 kHz audio as well. Such situations require the use of a sampling rate converter to avoid unnecessary analog-to-digital (A/D) and digital-to-analog (D/A) conversions. It should be noted, however, that although the rate conversion process operates in the digital domain, it is not completely transparent and can have an audible impact on the signal.

Sampling rate synchronization is a related issue for application of the AES/EBU protocol. Audio and video digital devices have their sampling rates determined by an internal oscillator/clock. This leads, predictably, to sampling rate variations between machines operating at the same nominal sampling rate. For example, consider two digital audio tape (DAT) machines running with 48 kHz sampling rates and sitting side-by-side playing out material. It is possible—and perhaps likely—that the machines will drift with respect to a fixed 48.0 kHz reference; they will tend to periodically drift in and out of synchronization. Such a loss of synchronization between devices can cause audible artifacts, typically pops and clicks when switching or otherwise processing the signals. The worst case scenario is that the destination device will not recognize the incoming audio datastream. The result—dead air.

The obvious solution is to lock all of the audio equipment to a common reference, like the video gear. Most current technology digital video equipment derives its video and audio clocks and sample rates from the same oscillator or timebase. This being the case, the audio sampling rates should remain fixed and stable so long as the video equipment is referenced to a common source (either sync or composite black burst). There are, however, problems with extending this genlock philosophy to the rest of the facility, including:

- Most digital audio gear will not accept a video signal as a reference. The reference input (if provided) on digital audio equipment is typically an AES/EBU port or a *word clock* signal from another digital audio device. (A word clock is a square wave signal at the sampling frequency used to synchronize digital audio devices.)
- Video equipment will not typically accept any of the audio reference signals for its video reference.

As you might suspect, the relative phase of the sample clocks is also important for proper operation of an AES/EBU based digital audio system. The term isochronous is used to describe the locked but not phased condition; synchronous, on the other hand, describes two or more signals with coincident timing reference points. In order for an audio switch or mix to be clean and free of pops or other degradation, it must be made at the AES frame boundary, with the source and the destination devices having coincident frame boundaries and identical sampling frequencies. *Frame discontinuities* are the most common cause of pops and clicks in a digital audio system, and accurate timing between signals is the easiest way to eliminate them.

Asynchronous Transfer Mode

Asynchronous transfer mode (ATM) is a technology based on high speed packet switching. It is an ideal protocol for supporting professional video/audio and other complex multimedia applications. ATM is capable of data rates of up to 622 Mbps.

At the present time, ATM is primarily directed at telecommunications applications. Inter-facility video transfers over ATM are typically rather expensive and complex at this writing. Despite these current limitations, there is a great deal of interest in ATM technology for video and great promise for the future.

The Basics

ATM was developed in the early 1980s by Bell Labs as a backbone switching and transportation protocol. It is a high speed, integrated multiplexing and switching technology that transmits information using fixed length cells in a connection oriented manner. Physical interfaces for the *user network interface* (UNI) of 155.52 Mbps and 622.08 Mbps provide integrated support for high speed information transfers and various communications modes, such as circuit and packet modes, and constant, variable or burst bit rate communications.

These capabilities lead to four basic types of service classes of interest to video users:[3]

- *Constant bit rate* (CBR) which emulates a leased line service, with fixed network delay
- *Variable bit rate* (VBR) which allows for bursts of data up to a pre-defined *peak cell rate*
- *Available bit rate* (ABR) capacity is negotiated with the network to fill capacity gaps
- *Unspecified bit rate* (UBR) provides unnegotiated use of available network capacity.

These tiers of service are designed to maximize the traffic capabilities of the network. As illustrated in Figure 5.10-10, the CBR data streams are fixed and constant with time. The VBR and ABR systems vary as shown. The bandwidth of the UBR class of service is a function of whatever network capacity is left over after all other users have claimed their stake to the bandwidth. Not surprisingly, CBR is usually the most expensive class of service and UBR is the least expensive.

One of the reasons ATM is attractive for video applications is that the transport of video and audio fits nicely into the established ATM service classes. For example, consider the following applications:

- Real-time video, which demands real-time transmission for scene capture, storage, processing and relay, fits well into the CBR service class
- Non-real-time video, such as recording and editing from servers, distributing edited masters and other operations that can be considered essentially off-line, can use the ABR service
- Machine control and file transfer, such as sending still clips from one facility to another, find the VBR service attractive.

ATM is growing and maturing rapidly. It has already been implemented in many industries, deployed by customers who anticipate such advantages as:

- Enabling high bandwidth applications including desktop video, digital libraries and real-time image transfer
- Coexistence of different types of traffic on a single network platform to reduce both the transport and operations costs
- Long term network scalability and architectural stability.

In addition, ATM has been used in both local and wide area networks. It can support a variety of high layer protocols and will cope with future network speeds of gigabits per second.

The Cell Structure

It is worthwhile to explore the ATM channel format in some detail because its features are key to the usefulness of ATM for video. ATM channels are represented by a set of fixed-size cells and are identified

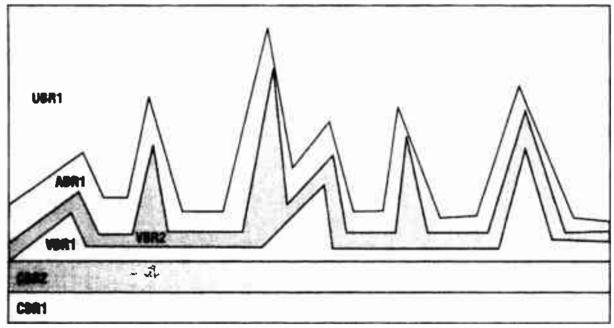

Figure 5.10-10. The typical packing of an inter-nodal ATM trunk.[3]

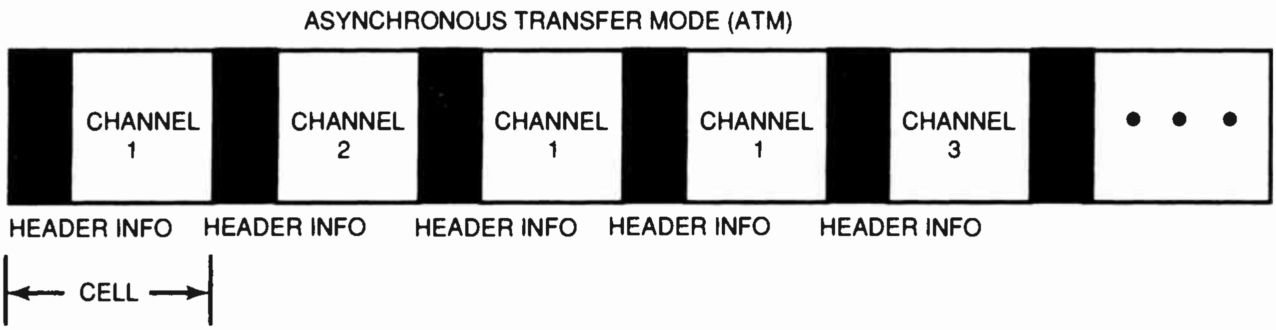

Figure 5.10-11. The ATM cell format.[4]

through the channel indicator in the *cell header*.[4] The ATM cell has two basic parts: the header (5 bytes) and the payload (48 bytes). This structure is shown in Figure 5.10-11. ATM switching is performed on a cell-by-cell basis, based on the routing information contained in the cell header.

Because the main function of the ATM layer is to provide fast multiplexing and routing for data transfer based on information included in the header, this element of the protocol includes information not only for routing but also fields to indicate the type of information contained in the cell payload. Other data is included in the header to perform the following support functions:

- Assist in controlling the flow of traffic at the UNI
- Establish priority for the cell
- Facilitate header error control and cell delineation functions.

One key feature of ATM is that the cells can be independently labeled and transmitted on demand. This allows facility bandwidth to be allocated as needed, without the fixed hierarchical channel rates required by other network protocols. The connections supported are either permanent or semipermanent, and do not require call control, real-time bandwidth management and processing capabilities; hence, the flexibility of ATM for video/multimedia applications.

Using ATM for broadcasting

Although ATM has been around for some years, it is still in its infancy with regard to video applications in general, and television broadcasting in particular. Generally speaking, ATM begins to look attractive today from a cost standpoint for point-to-point service over 50 miles in distance or for multiple site connectivity.

When additional network capacity and video interface systems are available and are more cost effective, it is quite reasonable to consider building a *virtual studio* where production elements can be physically separated and interconnected via ATM. This concept is illustrated in Figure 5.10-12. Note that feeds from the remote camera crew and studio are routed to a production suite, which also has access to an asset database. The finished product is then transported to the broadcast facility, where it is transmitted to viewers. Each of these five sites could be separated by many blocks or many hundreds of miles.

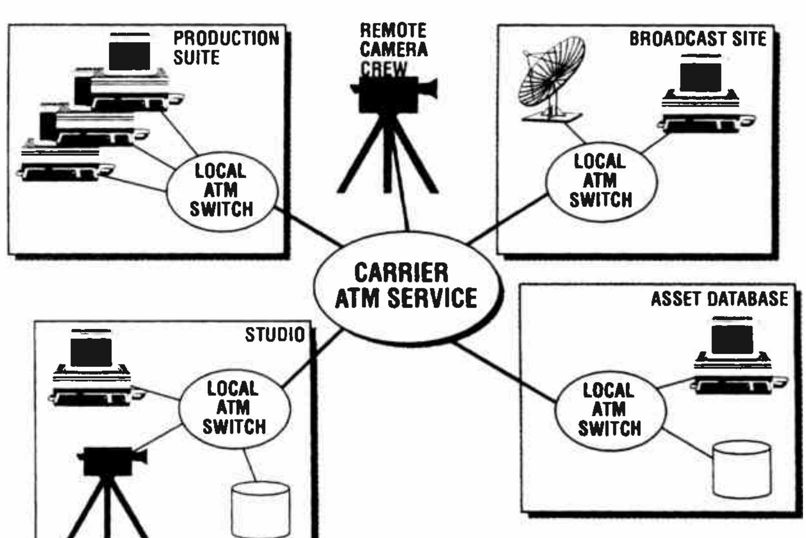

Figure 5.10-12. The concept of a virtual studio via ATM.[3]

INTERCOM AND IFB SYSTEMS

BRADLEY DICK
***BROADCAST ENGINEERING* MAGAZINE, OVERLAND PARK, KS**

INTRODUCTION

Intercoms. Everyone has used them, and probably without thinking about it. Put on the headset or press the button for instant communication. In today's complex and fast paced broadcast world, the need for rapid, reliable and flexible communications has never been greater. Fortunately, the available intercom equipment is capable of meeting almost any need that might arise. Unfortunately, the lowly intercom system is frequently left out of budgets or is grossly under funded. The key to the proper purchase, installation and use of intercom equipment begins with a thorough understanding of the equipment basics.

The historical background of intercoms, as far as broadcast is concerned, lies primarily in television. The early radio stations had less need for intercoms because of the ability to use hand signals. In television, it was seldom possible for the camera operator to see the director, let alone take visual hand cues. In fact, it was the need for TV directors to be able to communicate with camera and floor personnel that brought about the first broadcast intercom systems as we know them today.

From a usage standpoint, there are two basic kinds of intercom systems: point-to-point (matrix) and conference line. These names stem from *how* the communications take place; either in a point-to-point, (private line) manner or on a conference (also called party line, or PL) where everyone hears everything. To further confuse matters, digital technology has resulted in a new classification for intercoms, although they do the same thing. From an overall design standpoint, these new digital systems are sometimes are referred to as distributed crosspoint and centralized crosspoint systems. And if that is not enough confusion, the term digital system may only refer to digital control or the system may be fully digital control and audio. Related communications systems called *IFB* and *ISO* are often included in any intercom discussion.

SYSTEM ARCHITECTURE

Point-to-point or *matrix systems* allows communication with a selected person or area. The communication travels from one point to another point. No other people or locations receive that communication. These types of intercoms provide complete privacy between stations and may also provide custom programming capability from a central computer or terminal. With many systems, groups or *virtual party lines* can be created to provide great flexibility.

Matrix systems require 4-wire interconnection (although a 2-wire matrix is possible). Such systems are well suited to post production operations where the system configuration remains relatively constant. In a 4-wire topology, talk and listen signals to and from each station are carried on separate paths. These paths may be wires, RF, digital links or fiber optic paths. Matrix systems usually allow stations to selectively call other stations and there is generally a tally indication at the receiving point showing who is calling.

Historically, point-to-point or matrix system consisted of a centralized card frame and signal routing equipment controlled from remote stations. Today, distribution technology affords more versatile equipment arrangements. The audio signal paths are typically analog and simplex.

Each station in a matrix system typically interconnects via a 4-pair cable. Two pair of conductors are used for audio receive and listen for both the main and remote station and one or two pair of conductors are used for data (typically RS-422). Some of the newest digital matrix intercom systems operate on a single coax cable.

The system allows a station to route its voice to one or more other stations. Normally, point-to-point systems require direct (home run) cabling from each station to the central rack. In this system, the speaker decides who hears the communication. The listener normally has no control over who is received at the individual stations.

Some advantages of 4-wire matrix systems include: simple interfacing to other devices, no hybrid null problems, selective calling to all stations, call tally and privacy. Disadvantages of the 4-wire topology used to include all the multipair cabling required. Modern matrix systems, however, eliminate most of these problems.

The second type of intercom system is the conference line system. Also known as party line (PL) systems. These are the simplest form of intercom system, typically used for teamwork activities like remote productions. Anyone connected to the intercom line hears all of the communication that takes place. When someone speaks, everyone hears it. Live studios and outside broadcast activities are best served by PL systems.

PL intercoms are generally 2-wire systems. Talk and listen audio is carried on the same pairs. Power may be carried on the audio pair or separate conductors. A party line intercom can also be implemented with 4-wire techniques, but it is much simpler and less expensive to do so with the 2-wire technique.

In a PL system, all operators share a common channel or number of channels. The only privacy is what may be provided by multiple channels or a camera isolation subsystem. Some signaling can be provided, but usually not to the extent that every operator can selectively signal another operator.

The conference line (PL) system is sometimes called a *distributed amplifier or distributed crosspoint system.* This means that each station is equipped with all of the required electronics for both receiving and transmitting audio and call signals. Conference line systems require minimal centralized rack equipment, which typically consists of the system''s power supplies and passive assignment switching in multichannel systems.

Conference line systems allow groups of stations to communicate in real time, full duplex fashion. Multichannel conference systems allow users access to several different channels, determining who they talk and listen to. Keep in mind that with the conference line system all stations on a particular loop hear everything on that loop. Normally, there are no private communications such as point-to-point systems provide, although multiple *channels* may be provided. (Note, channels and stations are not the same thing, see Key Terms at the end of this chapter.)

Advantages of 2-wire PL systems are: simple wiring, easy expansion for additional stations, less complex central equipment, low cost per station and simple operation, which is important for team activities like remotes. Of prime importance, 2-wire PL systems can be quickly and easily reconfigured, which is especially important for remote trucks and mobile venues.

There may be a size limitation for 2-wire PL systems, especially in terms of ease of installation. Once you go above a five or six station system, the matrix solution may become more viable—and easier to use.

Some disadvantages of 2-wire PL systems are their reliance on hybrids and the difficulty in interfacing them to other (often incompatible) 2-wire systems, lack of selective calling and limited privacy. Figure 5.11-1 shows a typical single channel conference line system.

It may seem that point-to-point and conference line systems are mutually exclusive. In fact, it is not uncommon to find a combination of both systems. The more sophisticated point-to-point and conference line systems currently available usually have the ability to integrate both types of communications functions within one system. This usually means that multiple channels are available. Stations can be assigned to different channels for communication, but communication between channels is minimal.

(Table 5.11-1 summarizes the relative merits of the various architectures.)

Number of Wires

As discussed earlier, intercom systems are also sometimes classified by the number of wires required for the audio path, not including any conductors for dc power. If it takes two wires to carry the audio, it is called a 2-wire system. If it takes 4 wires to carry the audio, it is then called a 4-wire system. There are also references to 3-wire systems.

With a 2-wire system, full duplex communications can generally take place on one pair of wires. This means that conversation travels in both directions on the same pair of wires. Some 2-wire systems run balanced intercom audio, others run unbalanced audio. Also, some intercoms put the dc operating voltage on the same two wires. Others require one or more additional wires for dc power or use a local power supply. An example of a 2-wire system combining both audio and dc power on a single pair is the telephone.

In a 4-wire system, one pair of wires is used for each simplex (one direction) path of communication. Therefore, two pairs a transmit pair and a receive pair (four wires) are required for the complete two-way communication link. Generally, 4-wire systems require a local dc power source or additional conductors for dc power, plus the interconnect.

Defining 3-wire systems is confusing, as there are several different ways 3-wire can be interpreted. It can refer to equipment and systems that interconnect using standard 2-conductor shielded microphone cable terminated in 3-pin XLR type connectors, regardless of how many conductors are required for the audio path. (Two conductors plus the shield equates to three wires.) The equipment of most manufacturers of conference line intercom systems interconnects via this standard microphone cable. But different systems use the microphone cable in different ways.

One technique places one channel of unbalanced intercom audio between one conductor and shield and dc operating power between the other conductor and shield. (Because this type of system normally requires all three conductors to operate, it is sometimes referred to as a 3-wire system.) This is the easiest conference line system to switch and route.

A second design provides two channels of unbalanced intercom audio, one channel between each conductor and shield, and combines the dc operating power with one of the intercom audio channels (see Figure 5.11-2). Since this type of system actually only requires two conductors to operate, it is sometimes referred to as a 2-wire system, despite that it interconnects with 3-conductor cable.

A third design provides one channel of balanced intercom audio between the two inner conductors with the dc operating power phantomed between the shield and the inner conductors. If two conductors are used, this would only be a one channel system. (Again, because this type of system actually requires all three conductors to operate, it is sometimes referred to as a 3-wire system. Only one manufacturer uses this method.)

Three-wire can also refer to the tip, ring, sleeve (TRS) plug or jack typically used on the old carbon

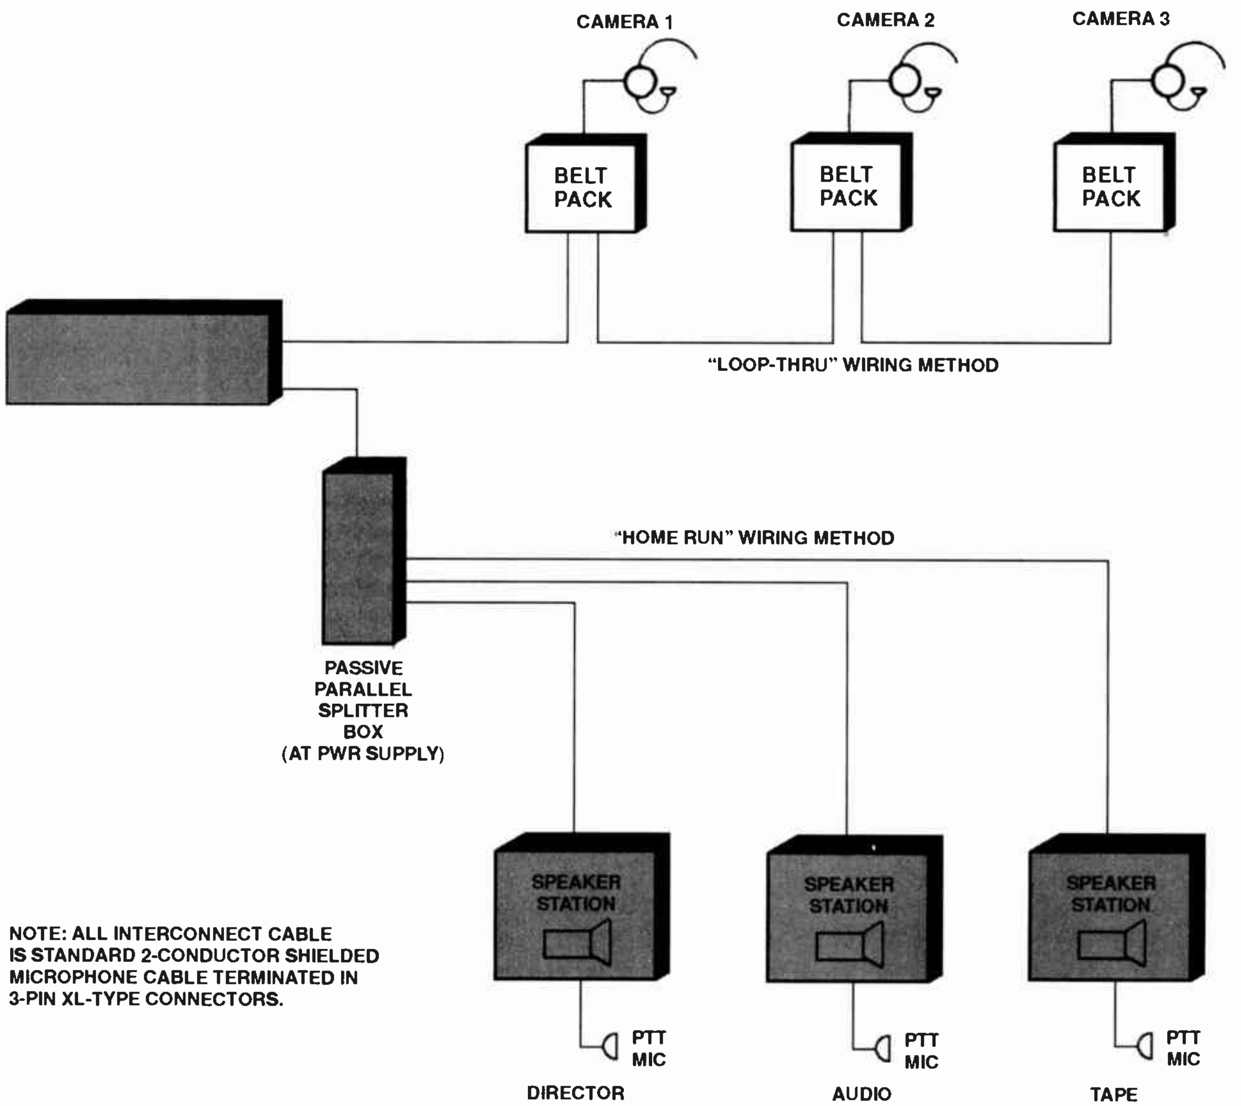

Figure 5.11-1. A simple 6-station single-channel conference line intercom system. (Courtesy *Broadcast Engineering*). Note: All interconnection cable is standard 2-conductor shielded microphone cable terminated in 3-pin XLR-type connectors

mic type headsets. This is essentially a 4-wire circuit with one side of the headphone circuit and one side of the microphone circuit tied together in common, making it a 3-wire system. (Note: Any headset is inherently a 4-wire device, two wires in the receive circuit going to the earphone and two wires in the send or transmit circuit coming from the microphone.)

The Need for Interfaces and Power

Regardless of what's happening at the central switching matrix, certain things must still happen at the business end of the intercom. Intercom stations are powered in two ways. Rack or wall mounted (fixed) stations can be powered from available ac by way of external dc supplies. These stations can then communicate via dry lines carrying audio only. Beltpack stations, on the other hand, are powered via wet communications lines, carrying 24VDC to 32VDC and audio. Some fixed stations can also take power from a wet line.

However supplied, the power is used to drive several necessary functions. With the low impedance headsets in use today, intercom stations must provide a headphone amplifier with volume control, switching circuits for microphone and channel selection, call light power and switching, and a preamp for the headset microphone and sidetone amplifier usually with screwdriver-adjustable gain control.

It is important to remember that not all intercom makers get power to their beltpack in the same way, even though they all use the same standard low impedance microphone cable and XLR connectors. A case in point is the difference between the 2-wire schemes

Table 5.11-1
Comparison of 2 and 4-Wire Systems

2-wire (party line, conference) system advantages:	2-wire (party line, conference) system disadvantages:	4-wire (matrix, point-to-point) system advantages:	4-wire (matrix, point-to-point) system disadvantages:
Simple wiring.	Reliance on hybrids.	Simple interfacing to other equipment systems.	Requires lots of central equipment (rack space).
Easy to install and expand with additional stations.	Difficult to interface to other manufacturers' 2-wire systems.	No hybrid null problems.	May require more time to install and requires more wiring.
Little central equipment required.	Difficult to implement selective calling.	Easy to interface to audio systems.	May be more expensive than other solutions.
Low cost per station.	Limited privacy capability.	Customer programming capability.	May be difficult to expand, expansion often require the addition of blocks of stations, rather than individual stations.
Generally less expensive than matrix (4-wire) systems.		Selective calling capability.	Analog systems require significantly more wiring than conference line systems, but digital technology can reduce this.
Offers a wide variety of stations and user features.		Tally usually provided.	Control panels may be larger and cumbersome to operate, especially if the system has a large number of stations.
Best choice for remote production units.			Offers limited flexibility, especially for mobile applications.
Simple operation for team type activities.			Generally used for large, in-plant applications.
			Provides instant, unblockable communications to selected points.
			Inappropriate for field use.

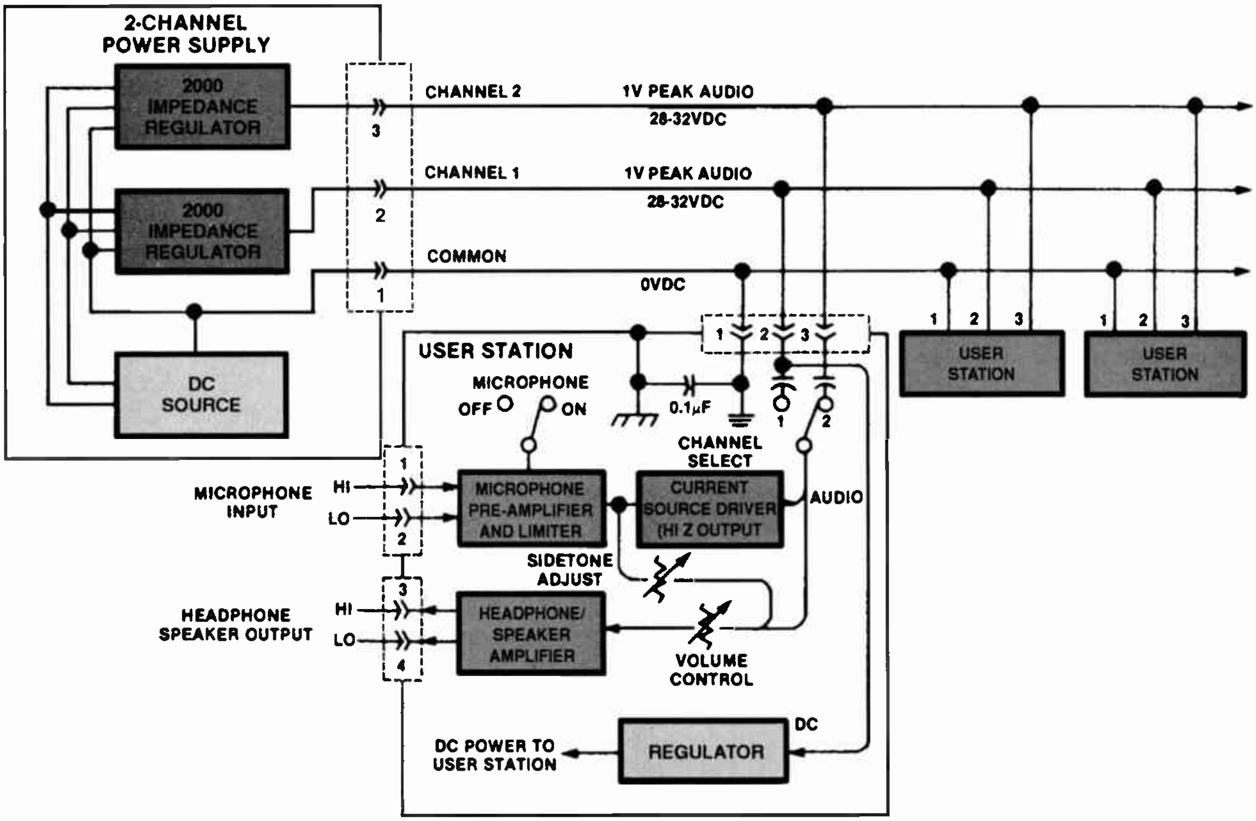

Figure 5.11-2. A 2-wire intercom system can provide two channels of communication on a single standard microphone cable. In this example, the dc power for the system carried along with the channel one intercom audio. (Courtesy *Broadcast Engineering*)

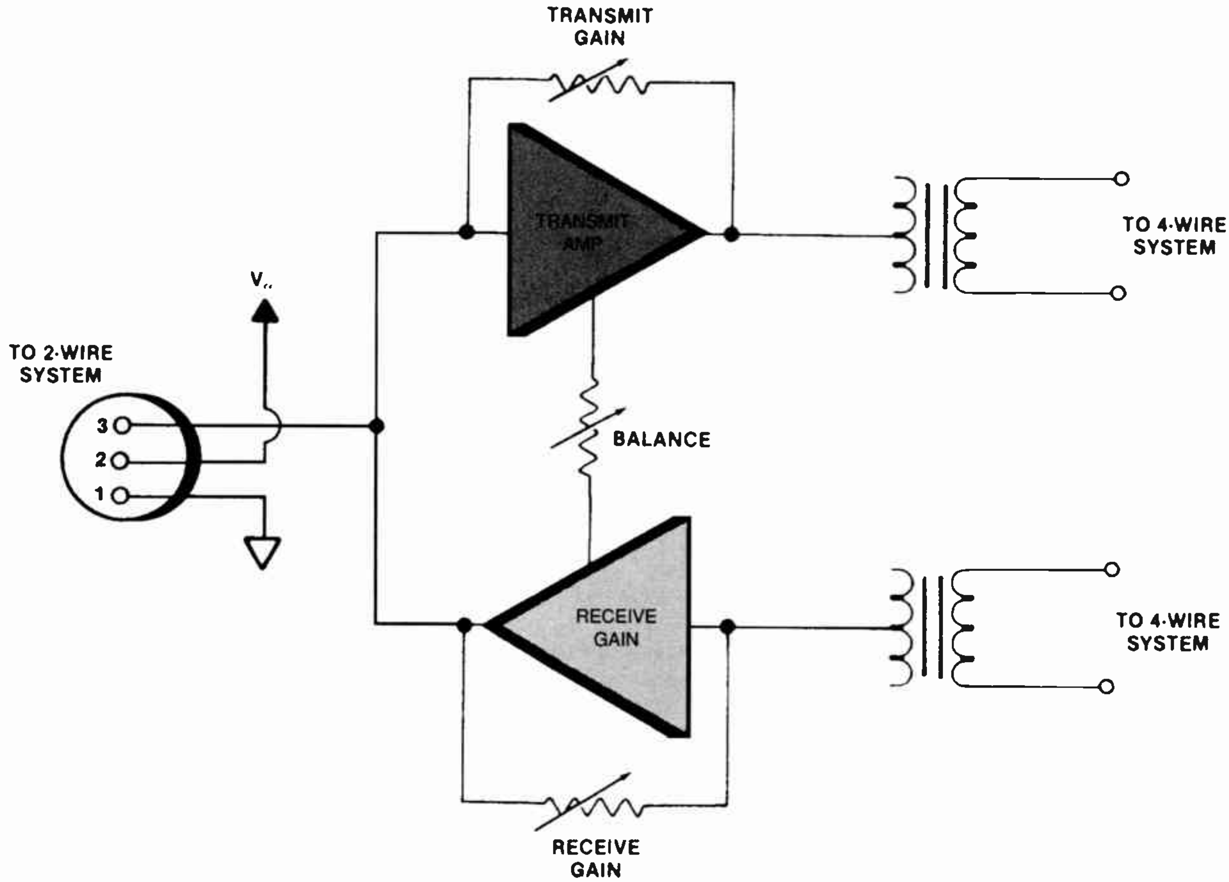

Figure 5.11-3. Connecting a 4-wire intercom signal to a 2-wire intercom system is easy if a standard 4-wire to 2-wire interface box is used. The box provides all of the necessary impedance and level correction. (Courtesy *Broadcast Engineering*)

used by Clear-Com and Telex. Clear-Com uses pin one for ground, with operating voltage on pin two and audio on pin three. Telex uses a method similar to microphone phantom powering, using pin one for ground and pins two and three for both balanced audio and simplex power. Figure 5.11-3 illustrates how to interconnect a 2-wire intercom to a 4-wire intercom.

Call lights on these systems also operate differently. RTS/Telex systems use a 20 kHz tone while Clear-Com uses a dc voltage for signal activation. These methods are not compatible, and if there is ever a situation where a remote truck with one system pulls up to a venue equipped with the other, an interface will be needed. Fortunately, such adapters and interfaces abound. Almost every manufacturer makes an adapter for its gear to plug and play with most other makers' equipment. Any well-equipped remote truck should have such a universal interface, which is typically packaged as a rack mount unit.

These interfaces generally provide bidirectional, 2 channel communication between the hosts system's and the foreign system's 2 channel lines. The interface usually can be powered by either wet lines or via local dc. The lines on each side of the interface are assigned just as if they were beltpacks and each side of the interface can be powered by the wet line powering scheme to which it its native. These units are versatile and provide the necessary impedance, level matching, pin conversion and call signal translation. This is certainly an improvement over the lighting director having to wear two headsets(one to the light crew and one to the TV truck.

Finally, some 2-wire base stations use different connections for single channel beltpacks versus 2 channel beltpacks. If single channel beltpacks are mixed up with 2 channel connectors, the whole system can be loaded down. This is usually revealed by a sudden drop in reception level at every station. Beltpacks on these stations are usually color coded to differentiate between single channel and 2 channel units. It pays to also color code the corresponding intercom connections on the studio truck breakout panel because the single and dual channel units once again use the same type of cable and 3-pin XLR connectors.

Camera Systems

Camera intercom systems create the biggest problems with interfacing and providing quality audio signals. Today's production environments often require lots of headsets be coupled onto the camera line. However, simply tacking additional headsets onto the camera intercom line will not work. Typical camera intercoms provide very little audio power to the headset. This level is frequently insufficient to drive some headsets, especially if the ambient noise at the camera's location high, such as a live sporting event. The solution may be to use an external beltpack intercom station, which typically can provide up to 2 W of audio power, more than enough to overpower any ambient noise.

Unfortunately, multiple standards seem to be common with camera intercom systems. Furthermore, manufacturers are not consistent with intercom design within their own products. It is not uncommon to find that a single line of cameras from one manufacturer has completely different intercom systems. Therefore, providing good communications sometimes means modifying the camera intercom. Four basic approaches can be taken to improve the camera's intercom.

The first is to completely ignore the intercom. A separate cable can be tagged along the camera cable and coupled to beltpacks and headsets. This approach has the advantage of providing communications that are equally as good as the rest of the plant"s intercom system. This also has the advantage of guaranteeing compatibility between intercom stations. The disadvantage is that another cable along has to be run along with the camera cable and separate beltpacks and headsets must be provided.

A second method of dealing with the camera intercom also requires that separate wiring be used for the intercom. If the camera operates on multicore cable, the conductors normally used for intercom and program audio in this cable can be used for the external intercom. This modification involves bypassing the internal camera intercom totally, and bringing the circuit out of the camera head for connection to an external beltpack. While it does eliminate adding a separate cable to the camera, it means modifying both the camera and the Communications Control Unit (CCU).

Unfortunately, this option will not work with triax cable. Also, crosstalk and noise between the video and intercom circuits can sometimes become a problem if the conductors used for the intercom have insufficient shielding. For instance, using the camera's ground can result in horizontal sync buzz in the intercom. Try for a separate ground path here whenever possible.

The third method would be to completely remove the camera's internal intercom. In this case, the camera's intercom circuits are replaced with a standard intercom card from the same manufacturer as the external system. This method has the advantage of providing good audio quality and compatibility with the remainder of the facility's intercom. Also, this approach works with both multiconductor and triax cabled cameras. One disadvantage is that not all cameras have sufficient space for the additional circuit card. It also requires that all cameras be modified. An unmodified camera may not work with the modified intercom system.

The fourth method of modifying a camera intercom system is the easiest, but perhaps the least desirable. In this case, an interface device is placed between the existing camera intercom and the facility intercom. For optimum results, each camera should be interfaced individually rather than collectively. The interface box, essentially an active 2-wire to 2-, 3- or 4-wire hybrid, provides the necessary conversion of line and levels. Because there may be a significant difference in levels between the camera and control point, optimum results are not always possible. There is a limit to the amount of level correction and isolation that can be provided with the interfaces. This approach has the advantage that no modifications are required to the camera or its CCU. The disadvantage is that the audio levels and quality are limited by the original camera circuits. The interface box cannot always make up for poor levels from the camera.

Wireless Intercoms

Generally, there are three types of wireless intercom systems. The first provides a one-way, listen-only feature for the remote stations, typically an interrupted feedback or foldback (IFB). In this system, the master transmitter is tied to the intercom line. All communications on the intercom line are relayed to all of the wireless receivers. This type of one-way intercom is typically used for people who need to know what is going on, but do not need to talk back.

The second is a two-way system. In this configuration, the base unit and the field units can both talk and listen to each other. The two-way wireless intercom system can be further broken down into three sub types. The first is a simplex, 1 frequency system, as shown in Figure 5.11-4a. All stations talk and listen on the same frequency (F1). Everyone uses a push-to-talk (PTT) switch so users cannot listen and talk at the same time. If the system is tied to a conference line, it must be turned off before any field units can talk back to the base or other units. In this configuration, even a 6 station wireless system requires only one frequency.

It is also possible with several intercom systems to incorporate a two-way transmitter (Land Mobile-type) into the communications link. An interface is used to connect the two-way transceiver to the intercom system. Signalling from the intercom link can then be used to activate the transmitter. This technique is especially useful in situations where broadcast sites are located so far apart from each other that wired interconnection is not convenient or cost prohibitive. If repeaters are a part of the two-way system, even wider intercom range operation can be obtained.

The second type of two-way intercom system is a partial full duplex, 2-frequency system (see (Figure 5.11-4b). The units still use a PTT switch. The base station is tied to the conference line and is always transmitting to the remote units (F1). The remote units can then hear all of the communications on the conference line. All field units talk back to the base on the same frequency (F2) so only one unit can talk at once. This approach requires only two frequencies, no matter how many stations are involved.

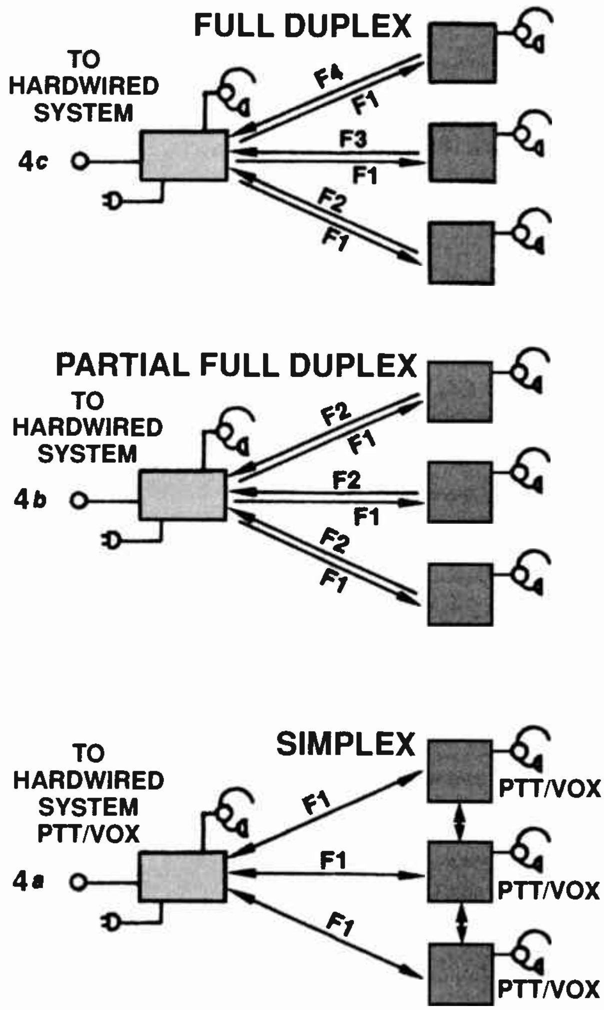

Figure 5.11-4. Wireless intercoms provide complete portability for the user. A full duplex system, shown in 4c, requires one frequency for each remote station, plus one frequency for the base station. (Courtesy *Broadcast Engineering*)

The third, type of two-way wireless intercom is more complex, but also much more flexible. It is also more costly. In this full duplex design (Figure 5.11-4c), everyone receives on the same frequency (F1), as described previously. However, each of the field units transmits back to the base on different frequencies (F2, F3, etc.). In this configuration, any number of remote units can listen and talk at the same time. A system with six remote units requires seven frequencies. This design is really a wireless version of a wired conference line intercom and no PTT switches are required. In a high quality system of this type, a wireless remote headset is virtually indistinguishable from a wired headset.

Virtually all wireless units will interface with wired systems either by themselves or through interface boxes. However, take care to not connect wireless intercom transmitters directly to an IFB system using wet lines. The powering on these lines can damage the transmitter. Instead, buffer the feed to the wireless transmitter using hard-wired IFB talent beltpack that outputs only audio on a dry line.

RF base units are usually generic in that they can operate with a hard wired system from the same manufacturer or they can be internally dip switch programmed to work with other intercoms. All generally offer a real panel loop-through just like hard wired beltpacks. Many models have two antennas on the base and two on each beltpack. This does not imply any type of spatial diversity as in wireless microphone systems rather, one antenna is used for transmission and the other for reception. Diversity reception in not commonly found on wireless intercoms.

Because intercom beltpacks not subject to the same size constraints as wireless microphones, they typically operate on a RF output power of 50 mw, or about five times the RF power output of many wireless mics. These systems have traditionally used the VHF band, but as with wireless microphones, many users are moving to the UHF band because of overcrowding and interface at VHF frequencies.

Wireless base station front panels generally include all the necessary connections: headset indicator light for continuous base transmit and a light to denote reception of each beltpacks' RF carrier.

The advantage of the wireless system is the mobility it provides users. The potential disadvantages include limited range, the possibility of interference and dropouts. Proper frequency coordination at the site in which the system will be used is extremely important. Failure to do so could result in a complete communications failure if a stronger RF signal appears in the area during the broadcast or taping. With the advent of DTV, frequency coordination is even more critical.

New digital solutions to the wireless intercom have recently appeared. One provides the option of up to two channels of frequency agile operation in either the VHF or UHF band. Another model provides the ability to switch between two channels of transmit and two channels of receive on each unit.

For private applications, like major league sports, an encrypted version is available. Communication takes place like on other wireless units, but the audio is digitally encrypted. Providing more than 64,000 different settings, eavesdropping is effectively eliminated.

An example football system might include: two channels of offense duplex communication (offense 1 and offense 2), one channel for defense and one channel for special teams. Connecting the system into four channels of a traditional wired intercom channels would provide extremely versatile operation. The head coach, using the two channels of his intercom, could switch between channel A (offense 1) and channel B (the defensive coaches). The offensive coaches have two channels, split among their three coaches. The defensive coaches area all connected to one channel and do not communicate with any other channels, but can still talk to the head coach. The special teams coach uses one channel and does not communicate with other coaches.

An encrypted wireless UHF intercom system can cost about 10 times what a wired system will cost. An non-encrypted VHF system will cost about five times that of a wired system.

SIGNALING

As mentioned previously, signaling is an important aspect of intercom capability. In a conference line intercom, signaling is normally referred to as a call or signal. Signaling provides a means (usually visual) to attract the attention of a person who is not wearing a headset or has turned off the loudspeaker. In a conference line system all stations in a given channel of communication will be signaled at once. It is generally not possible to signal individual users in the conference line system. Although signaling is usually a visual indication, it can be made audible for special situations.

Signaling is accomplished by applying either a high frequency tone or a dc signal to the audio pair. When using audio instead of dc for the trigger, the tone passes through any interfaces that may be in the line. However, dc signaling is less complicated and usually costs less. Recall from before that signaling can be used to activate a two-way transceiver for longer distance communications.

Signaling simply to get someone's attention has limited application in teleproduction. It is more often used in theater work or industrial applications. There are, however, many unique applications for signaling in teleproductions that extend beyond the mere calling of someone to the station.

Signaling functions of the intercom can also be used for remote control purposes. For example, in a small ENG or SNG truck, the call light signaling circuit can be wired to turn on the two-way radio through a relay, operating in a PTT mode. When the signaling is activated, the talent and engineers know that the studio is hearing the conference line audio because all of the signal lights are illuminated.

Another use for signaling is for push-to-talk-and-listen features. One system allows the signal circuit to be tied to the microphone circuit of a remote station. As an example, a director presses the push-to-talk button to address the tape room. In this case, the videotape operator does not have to press a switch to respond to the director. The signaling circuit at the remote station automatically turns on the microphone in the tape room, allowing hands-free communications from the tape operator. The signaling circuits can also be used to override a volume control on a paging speaker or in conjunction with IFB audio.

Conference line systems that provide signaling as a standard feature can be thought of as providing a free remote control capability. The applications for signaling/remote control functions are limited only by the engineer's imagination.

Program interrupt and ISO

Although not strictly a two-way intercom, IFB is often an integral part of a facility's intercom system. Also called program interrupt, or PI, director interrupt, director cue, IFB is used to cue both on and off air talent.

The talent end of the IFB system usually takes one of two forms. A subminiature in- or over-the-ear earset is often used in news and field report situations. Sportscasters often use dual earmuffs, one of which has the IFB channel.

The program audio is fed to the talent, usually through an in-the-ear earphone. Then, the program audio can be interrupted or attenuated by an operator (usually by the director or producer) to give verbal cues to the talent. This allows the talent to continue to talk, while at the same time listening for directions on future actions. IFB systems can be quite extensive involving multiple program inputs and links to off premise locations. Their heaviest use is in sports and news operations.

There is a less well known application for IFB in non-broadcast uses. In this application, the talent wears a small receiver tuned to the base station frequency. The audio output of the receiver is connected to an inductive loop antenna worn around the talent's neck. Finally, an ultraminiature receiver/earphone is worn in the talent's ear. The receiver/earphone is so small that it cannot be seen by the camera or audience and picks up its signal from the loop antenna. With this equipment, the talent can receive instructions from a director or lip-sync to an audio track. Stunt people often use this type of arrangement to coordinate their work on complex scenes.

Most IFB systems contain more than one channel (typically four or more) and allow selective communication to individual talent without disturbing others. Systems typically provide tally signals when there is more than one control point. In some systems, the program audio is cut off for the duration of the announcement or cue.

Other designs merely duck the program audio under the announcement. This latter approach adds a confidence factor for the talent in that they can still hear the program signal during the cues, but at a reduced level. IFB systems are available either as stand-alone systems or as an integral part of an intercom system.

An *ISO*, which means *station isolate* is like IFB, but the communication between the caller and destination can be two-way and private. A typical application would be for studio or remote camera intercoms where all operators are normally talking on a common party line. However, each camera intercom station can be interrupted, usually by the TD or director, and private communication take place. The communication removes any IFB audio and any other stations for a clean, private feed between the two points. This feature is typically available in the new matrix type intercoms.

REASONS TO UPGRADE A SYSTEM

There are a lot of reasons to upgrade to a newer intercom technology. Sometimes it is simply because the number of users has grown beyond the system's capabilities. Other times, additional functionality is needed. In general, there are some often heard reasons for installing a better intercom system.

- Client driven. Sometimes a complicated show requires more operators with additional user stations. Or, as the hours of operation within your facility expand, scheduling/equipment use eliminates the time sharing that was once possible with the existing system.
- Having to interface with other new equipment. New cameras will not interface with the current intercom system. As the industry races ahead, fueled by new technology, some otherwise acceptable systems will have to change to accommodate the newer hardware.
- The current system is too small and can not be expanded due to manufacturing limitations. Even if the inevitable end of the useful life of a system has come, do not trash it. Some of the older items can probably be reused and interfaced or updated to work with the new technology.
- The time and effort spent reconfiguring the current system to meet the needs of regularly schedule events is too great.
- Finally, as engineering becomes more of a freelance task, especially in maintenance engineering, a facility may need to streamline its functionality. Reliability is the name of the game with intercoms. A system that has all the necessary functions all the time is more reliable and consistent than one that is built as the needs arise.

Planning Your New System

Planning for a new intercom system should center on a careful step-by-step analysis of the station's (or truck's) communication needs. Purchasing an intercom is similar to buying a computer. First decide what the operational requirements are going to be to consider the hardware.

It is easy to underestimate the time and effort it takes to design an intercom system because the subtleties and requirements of the various features and systems are difficult to identify. An intercom system is a foundational element in a broadcast facility and if the proper choice is not made early on, other decisions get more confusing. Start early in the overall project with a decision so that other equipment choices will be less complicated.

Probably the most important knowledge the system specifier must have is an accurate understanding of the operational routine of the facility. This is hard to come by in a new facility or in a facility that is moving to new quarters. It is slightly less daunting to upgrade a current system because the work habits and operational routines are easily identified.

A facility-wide intercom system, be it an SNG truck, news control room, production facility or a network master control, is typically a combination of multiple types of intercom systems, some tied together, some stand-alone. While in theory an intercom system is either a PL or matrix design, the final configuration will usually encompass elements of both identities.

For instance, the ability to talk to on-air talent may be a completely separate intercom system from the one used by engineering to setup a remote truck incoming feed. Likewise, the master control operator might have a microphone on the console that simply pages to a speaker in the tape machine room. Again, the key is to thoroughly understand the needs of the facility.

Intercoms can be as simple as two people in different rooms communicating, such as a video editor and a tape operator, or as complicated as a NASA mission control room with users located all over the world and beyond. As an intercom system grows in size, so does the need for focused attention from the engineering department.

Digital Solutions

No look at intercoms would be complete without a discussion about digital intercoms. The term *digital system* and *digitally controlled system* are used interchangeably today. The key point is that digitally controlled or digitally based does not necessarily mean that the signals between stations are digital. It may mean that the central switching matrix and audio processing is digital. Although several current intercoms feature a digital switching matrix or internal digital audio processing, there are only a few on the market that actually send digital audio signals to the user stations. Various digital implementations are available from Clear-Com, Drake and RTS/Telex. These digital systems also support both new digital rack mount stations as well as the traditional analog stations (see Figure 5.11-5). All beltpack and earpiece stations on these systems still operate in the analog domain.

These new digital systems allow remote key panels to be located almost anywhere. Using dark fiber, coax or even an ISDN line, it is possible to install an intercom control panel in one city and have complete communication capability to another location thousands of miles away.

Note that both digitally controlled and fully digital systems have interfaces that provide the conventional 2-wire analog lines to beltpacks, but not all beltpack wiring schemes are compatible—even though they all use standard microphone cable and XLR connectors. This is an area where operator knowledge is critical. Beltpacks are not interchangeable and using the wrong type can load down the system or even cause damage.

One feature that totally digital systems have yet to implement is the ability to daisy-chain stations like current analog systems allow. Daisy-chaining stations, even on today's analog systems, is not the best approach anyway because it can add noise and make failures harder to diagnose and fix. Although daisy-chaining is convenient when running cable around a large event, the main reason the tradition developed was the small number of output channels that intercom systems offered in the early days. Today's newer intercoms effectively eliminate the need for daisy-chaining because most of their digital switching matrixes can deliver 128 × 128 crosspoints and are often expandable to 512 × 512 or larger.

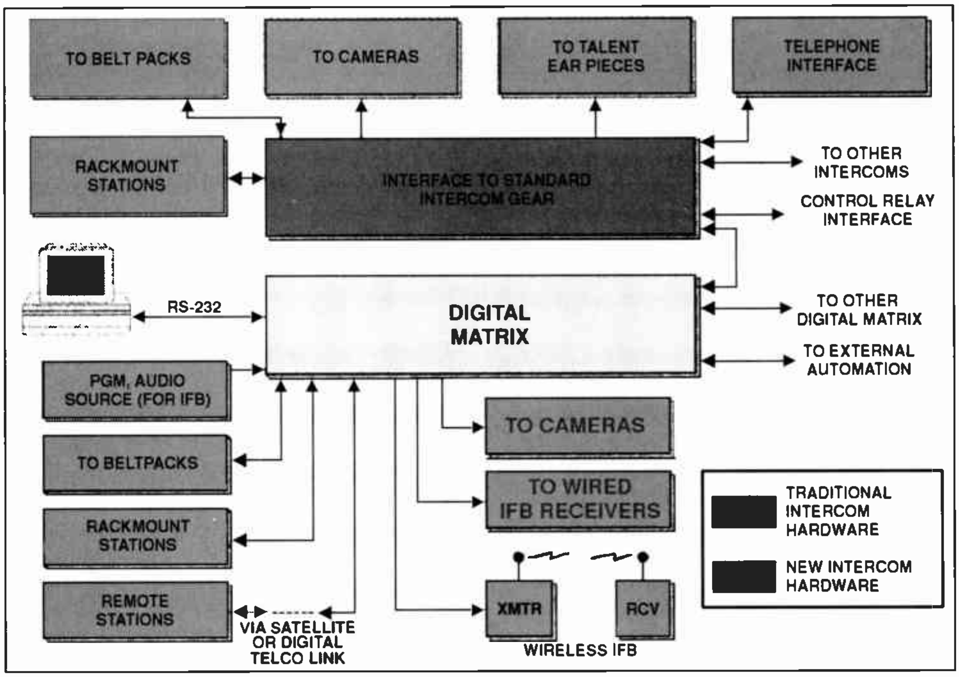

Figure 5.11-5. Block diagram of a fully featured current intercom system incorporating traditional equipment and new digital systems. Note the analog interface provided to adapt to existing hardware. (Courtesy *Broadcast Engineering*)

As digital hardware costs continue to fall, expect the trend to digital audio distribution to continue, especially in the case of large central crosspoint systems. The major advantage of taking digital audio all the way through the system is the elimination of induced electrical hum and noise. This can be appreciated by anyone who has ever had to run intercom lines around a pile of lighting cables and SCR dimmers.

Finally, digital does not necessarily mean serial digital (coax) installation. Depending on the application, being able to interconnect the stations with runs of coax may offer a lot of advantages. Check with the manufacturer regarding their definition of digital.

System Administrator

Intercom systems are supposed to just work, like an elevator, or the water faucet in the kitchen. They are supporting structures that allow the real work to happen more efficiently. As important as intercoms are to most people, it would be short sighted to minimize the attention that is required for them to become something that just works. When discussing the station's needs with manufacturers, identifying the stations engineering manpower resources do not specify a system that is so sophisticated or complicated that it becomes a maintenance or administration burden.

If the station's needs are very sophisticated, especially if there is computer software programming involved, consider assigning one person to the task of administration. It is almost impossible to maintain a large or complex system if more than one person can make fundamental changes to the software. This person typically need not be electronics expert, but rather more like a computer network manager. Maintaining proper filenames, backup files, entering the changes in a timely manner, and communicating in written form the profile of the system to the users are the most important tasks for the administrator. If the administrator is not a member of the regular engineering staff, be sure he works closely with the engineering department so there is some personnel redundancy.

Another point to remember is that unlike hardware based systems, a software based centralized architecture intercom depends on the integrity of the software that defines its nature. Do whatever it takes to assure that the software is what it needs to be.

Cost-basis Analysis

The cost structure of the two systems, distributed crosspoint and centralized crosspoint, typically means that a centralized crosspoint architecture is more appropriate for a large facility, while the distributed architecture approach may be more cost effective for a smaller facility. The single most expensive component in the centralized architecture approach is the frame containing the crosspoint circuitry. In this design, the individual stations are typically half to one third the price of an equivalently sophisticated distributed architecture user station. So, if the system needs to be big, it gets very expensive to implement a distributed architecture system. Conversely, If the system is small, it may be difficult to amortize the expense of the frame across only a few stations.

For example, a facility that buys 50 distributed crosspoint stations costing $6,000 each will spend $300,000 and have limited circuits. That same facility using a centralized architecture approach will spend $100,000 on a frame and $100,000 on stations at $2,000 each for the same total of $200,000. In this example, for less money the facility gets additional versatility and an expansion path that is only $2,000 per station.

Obviously, not all systems are this big and the numbers can greatly vary. It would be just as unwise to spend $50,000 on a frame to connect eight $2,000 stations together. In this case, it would be better to spend $48,000 on eight $6,000 stations.

These two architectures are not the only choices. There are some that combine features of each, however, the industry trend is to focus on either great versatility and with it low fault tolerance and focused attention, or a limited, highly tolerant more consistent system.

Consider the Supplier

There are some manufactures that only produce one type of architecture while others make all types. Most large intercom systems, like those in a full size production truck or a large studio/news control room, use both distributed and centralized crosspoint systems. A large centralized crosspoint frame with 2-wire beltpacks interfaced with 2-wire to 4-wire converters is a common application over all systems. In addition, it is not uncommon for the 2-wire and 4-wire components to come from different manufactures because each is considered better at one technology than the other for a specified system.

Do not be intimidated by the complexity and versatility offered in today's intercom systems. One important goal may be to simply emulate the 2-wire system that the station's operators are most familiar with. Build from this common point, adding the features and future options later.

Intercom systems do not get much notice—until they fail. So, when all is said and done, if the new intercom system meets the operator's needs and does so reliably, it has been a successful endeavor.

KEY TERMS

Administrator. The person that maintains the functional integrity of a system.

Call. Feature allowing user to get the attention of someone at a remote or main station, typically through a light or tone.

Conference line. Also known as party line, everyone hears all communication (see 2-wire system).

Control data. An electronic information signal that allows an action at one location to effect the function of a device at another location. Some systems embed the control data into a digital audio data stream form one point to another.

Crosspoint. A switch in an audio signal path from one point to another that is opened or closed at the request of the user.

Crosspoint control. The method by which the user requests a crosspoint be opened or closed.

Channel. Most commonly refers to a 2-wire path with multiple users on the same wire.

Dry pair. A telephone line or any other conductive cable of two wires that can carry audio but no voltage.

Duplex. The ability to both talk and listen at the same time.

Two-wire (2-wire). A user station connection scheme where by the talk and listen for a particular user are on the same wire pair. Each pair of wires can consist of ground/common and a single conductor or in a balanced configuration, a positive and a negative conductor. Usually found in a distributed crosspoint architecture

Four-wire (4-wire). A user station connection scheme where by the talk and listen audio for a particular user are on two different wires. Usually a balanced audio pair is used for the talk out and a separate pair for the listen input. Signals can be carried in an unbalanced wire set while still being referred to as 4-wire. This technique is most commonly found in centralized crosspoint architectures.

ISO. Also called isolated feed. Typically a private feed to an important station on the intercom system.

Listen signal. The signal that emanates from a speaker, earphone or headset earpiece.

Matrix. A device that switches inputs to various outputs or channels. A matrix intercom is usually point-to-point, 4-wire product (see 4-wire system).

PL. Short for party line. Any one channel having multiple stations connected to it.

Point-to-Point. Often refers to a type of intercom system, as opposed to a party line type of intercom. Point-to-point communication occurs between one person/station to a single other person/station (see 4-wire system and matrix).

Port. An audio input and output pair with dedicated real world connections. Works with a 4-wire scheme.

Program input. An audio source, typically on-air or studio audio, fed to an input channel on the intercom station for monitoring by stations.

Side tone. The audio heard in a headset when a user speaks-their own voice.

Station. A device, either rack mount or portable, consisting at a minimum of a microphone connector/ preamplifier with an off/on switch, and a speaker with an amplifier/volume control. May also include serial data stream, and multiple listen/talk circuits.

Talk signal. The post-microphone preamplified signal that will be heard by other people.

2-wire system. A communications system in which the talk and listen signals to and from each station travel on the same path. Also called party line, PL, conference line or interphone.

4-wire system. A communications system where the talk and listen signals to and from each station travel on different paths (wires). Also known as matrix, squawk, point-to-point, talkback or intercom.

User. A person that talks or listens at their discretion to other individuals utilizing the intercom system.

Wet pair. A telephone line or any other conductive cable of 2 wires that carries DC voltage to power remote stations.

5.12
WEATHER RADAR SYSTEMS

ROBERT BEACH
KAVOURAS, INC., BURNSVILLE, MN

INTRODUCTION

Radar was invented in the 1930s and has been widely used for air traffic surveillance and control. Beginning in the late 1940s, it was determined that radar could also be useful for detecting and measuring precipitation. Since then radar has become the preferred technology for detecting and tracking severe weather. More recently, Doppler capability has been added to many weather radar systems to permit measuring the wind velocity associated with the precipitation.

At this writing, the U.S. National Weather Service (NWS) was in the final stages of upgrading the U.S. National Weather Radar network to WSR-88D (NEXRAD) radar systems. WSR-88D is a sophisticated fully coherent Doppler weather radar with true 3D volume scanning and processing capability.

Also at this writing, the U.S. Federal Aviation Administration (FAA) was installing Terminal Doppler Weather Radar (TDWR) systems at selected airports in the U.S. TDWR is also a sophisticated, fully coherent Doppler radar system whose primary function is to detect low level wind shear in the approach and departure flight path of an airport runway. Low level wind shear has proven to be extremely hazardous to aircraft during takeoff and landing.

BASIC RADAR THEORY

The term *radar* is an acronym for *RA*dio *D*etection *A*nd *R*anging. There is no magic; radar is nothing more than a very special way of using radio signals.

The basic principle of radar is simple; transmit a pulse of radio signal, form that pulse into a very precisely focused beam and listen for reflections that bounce back from any targets the beam happens to come in contact with. For a weather radar, the desired target is precipitation: rain drops, hail stones, snow flakes, etc. The larger and/or more numerous the precipitation particles, the stronger the reflection.

The reflections are typically displayed on a plan position indicator (PPI) display as colored areas where the color represents the strength of the reflected signal. The PPI display is essentially a map with the radar at its center. Thus, intensity of precipitation, in a given geographical location within the radar's range, can be estimated quickly.

A radar with Doppler capability also measures the speed at which the precipitation is moving. Moving precipitation implies wind, thus a Doppler radar can also estimate wind velocities. In a PPI Doppler velocity display, the wind velocity is displayed with the color indicating the wind velocity in each geographical location.

In addition to forming the transmitted signal into a very precisely focused beam, the radar antenna also aims that beam into the area of interest in the atmosphere. Typically, radar antennas will be set to scan the atmosphere at the rate of 2 or 3 revolutions per minute. If the radar beam were visible, it would look very much like the beam of light from a lighthouse sweeping around through the atmosphere.

Wavelength

There is a very narrow range of radio wavelengths that are useful for weather radar. If the wavelength is too long, there are no useful reflections from precipitation. If the wavelength is too short, the signal is absorbed rather than reflected by intense precipitation. The range of useful wavelengths is between 3 and 10 cm.

Table 5.12-1
Wavelength frequencies used for weather radar.

Wavelength Frequency	Band	Typical Radar	Comments
10 cm (3 GHz)	S	National Weather Service WSR-88D (NEXRAD)	Good penetration of torrential rainstorms, but requires very high power and a very large antenna.
5 cm (6 GHz)	C	FAA TDWR, and most commercially available weather radars	Reasonable trade-off of operating characteristics, works well with modest antenna size.
3 cm (10 GHz)	X	On-board aircraft weather radar systems	Small antenna compatible with aircraft space limitations, but absorption of signal by intense precipitation can produce misleading images.

Locating the Reflection

Radar systems locate the target with respect to the radar antenna (the direction and distance from the radar antenna to the target). The distance is typically referred to as the *range*.

Direction

The radar signal processor monitors the azimuth position of the antenna as the antenna rotates. Thus, the direction of transmitted and received pulses, and consequently the direction to each target is known.

Range

The range (distance) from the radar antenna to the target is determined by measuring the length of time that elapses between transmitting the pulse and receiving the reflection. Because the propagation velocity of the signal is a known constant, the distance from the radar antenna to the target can be accurately calculated.

Many radar systems use *range bins* to determine the range of target reflections. The radar's range is divided into some number (typically somewhere between 100 and 1024) of *bins* of equal size. Each bin has a time associated with it that corresponds to a distance from the radar antenna. The receiver's signal is sampled at each range bin time, and the strength of the signal at that time is stored in that bin. The resulting array of data represents the target reflectivity versus distance along the radar beam.

Pulse Rate and Range

All the reflections of interest should get back to the radar before the next pulse is transmitted. Therefore the pulse rate and the radar's maximum range are related. The pulse rate, in pulses per second, is often referred to as the PRF (pulse repetition frequency).

That relationship is expressed by the following formula:

$$R_{max} = \frac{c}{2(\text{PRF})} \tag{1}$$

Where:

R_{max} = Maximum unambiguous range
c = Speed of light (typically 300,000 km/sec)
PRF = Pulse repetition frequency (pulses per second)

For example, the maximum unambiguous range at a PRF of 1,000 pulses/sec is:

$$R_{max} = \frac{300{,}000}{2(1{,}000)} = 150\text{ km}$$

From this relationship it is clear that longer ranges require lower PRF's.

If a reflection from a previous pulse returns to the radar after the next pulse has been transmitted, it is frequently referred to as a *second trip echo* and the range at which it is displayed is said to be *folded*. The term *unambiguous range* means the range at which all reflections are first trip echoes with no range folding. In the above example, with the radar set to a pulse rate for 150 km range, a target located at 200 km range producing a very strong reflection might appear to be at 50 km range. Range folding can be confirmed by setting the radar to its longest range and observing the data for one or more scans. Targets producing strong reflections which appear to move out to the longer range are almost certainly folded when they appear at shorter ranges.

Reflection Strength

The strength of the reflected signal is proportional to the number and size of precipitation particles within the radar beam, and to the type of precipitation: rain, snow, hail, etc. The reflection strength is also proportional to certain parameters in the radar system: transmitter power, pulse width, etc.

Typically, the weather radar's signal processor categorizes the strength of the reflected signal into one of 16 levels. Each level is displayed in a different color. Therefore, it is easy to look at a display and quickly determine the strength of the reflection in any given location. Typically the weakest reflections are shown in light blue, with a spectrum of colors up to bright red for the most intense reflections. For meteorological purposes, these levels are usually measured in units of "Z". Z is the radar reflectivity factor for precipitation.

Z is usually displayed as decibels of Z. This is done because going from the weakest to the strongest Z routinely covers six or seven orders of magnitude of signal strength. The decibel scale provides a convenient way of expressing such a wide variation. The standard reference for Z is the signal reflected by precipitation with a single 1 mm drop of rain per cubic meter of space.

A signal strength of +10 dBZ means the reflected signal is 10 times stronger than the signal reflected by the 1 mm drop/m^3 standard. +20 dBZ is 100 times stronger, etc. A −10 dBZ signal is 10 times weaker than the standard, etc. A 0 dBZ signal is equal to the standard. Figure 5.12-1 provides a comparison of the sensitivity versus range of a typical commercial weather radar with the sensitivity of both the TDWR and WSR-88D radars.

The actual amount of power reflected back from precipitation to the radar can be calculated using the *Probert-Jones* equation. In practice, the radar set measures the power reflected back (P_r, the received signal) and solves the Probert-Jones equation for the Z value that caused that reflection. The precipitation intensity is then estimated from that Z value.

$$P_r = \frac{P_t G^2 \theta^2 H \pi^3 K^2 L Z}{1024(\ln 2)\lambda^2 R^2} \tag{2}$$

Where:

- P_r Reflected signal power received at the radar antenna
- P_t Transmitted power—fixed by transmitter design
- G Antenna gain—fixed by antenna design
- θ Antenna beamwidth—fixed by antenna design
- H Pulse width—limited to certain values by transmitter design
- K^2 Physical constant—typically 0.93 for rain or 0.197 for ice
- L Loss factors—determined by radar installation and atmospheric factors
- Z Target reflectivity—determined by the type and intensity of precipitation

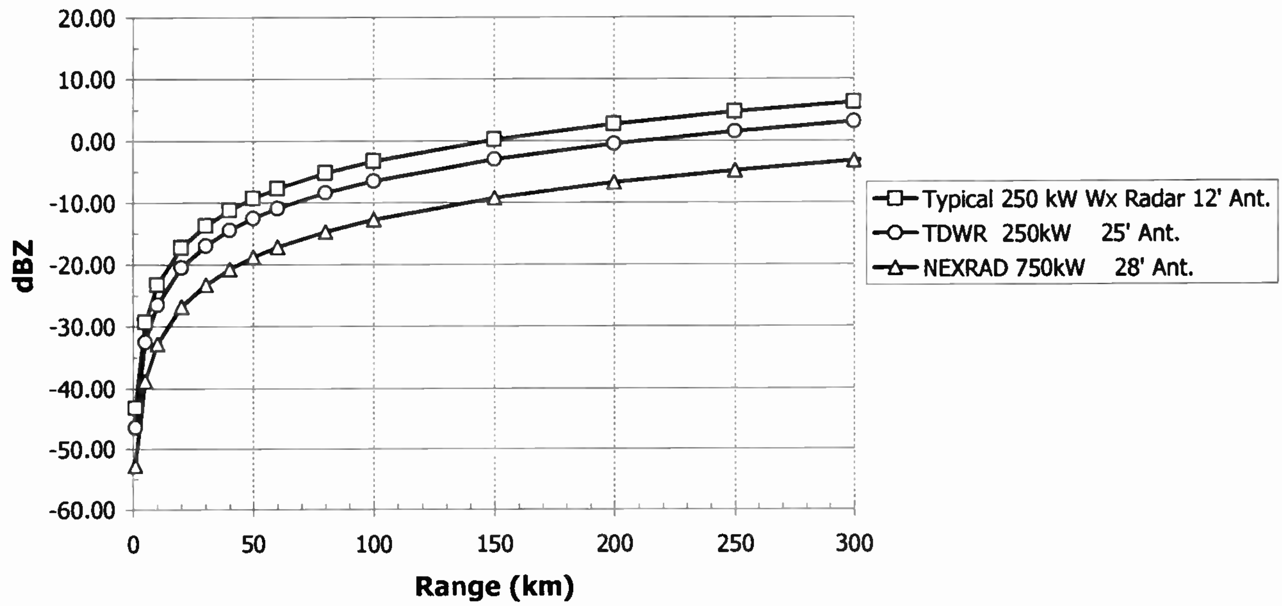

Figure 5.12-1. Sensitivity versus range.

λ Transmitter wavelength—fixed by transmitter design
R Range—distance from radar antenna to target

To be strictly accurate in calculating the reflected power, rain drops would have to be perfectly spherical. Since rain drops are not perfectly spherical, there is a small difference between the theoretical and actual results. This difference is accounted for in the empirical nature of the value of Z.

Pulse Width and Resolution

Weather radar systems typically transmit pulses with widths in the range of 1 μsec to 5 μsec. Some systems are capable of narrower and/or wider pulses.

The advantage of a wider pulse is that more signal power is reflected from the target, therefore it is easier to see weak targets with wider pulses. Doubling the pulse width is equivalent to doubling the transmitter's peak power. This is expressed by the "H" term in the numerator of the Probert-Jones equation.

The advantage of a narrower pulse is the ability to see the separation between closely spaced targets. To be separately distinguishable, targets must be separated by more than 1/2 the pulse length. As an example, the propagation velocity of a radio signal is approximately 1,000 ft/μsec. 1 μsec pulse will be approximately 1,000 ft from front edge to the back edge in the direction of its travel. Therefore, with a 1 μsec pulse, multiple targets that are separated by less than approximately 500 ft will appear on the radar display as one single target.

For many meteorological situations, targets of interest are frequently several miles wide and several miles apart. In this situation, the ability to use wider pulses to see weak targets may be more important than the ability to distinguish between several closely spaced targets.

Doppler Effect

The *Doppler effect* is named after Christian Johann Doppler, an Austrian physicist. Doppler became interested in why the sound of a train whistle seemed to change to a lower pitch as the train passed by where he was standing. He determined that, by measuring the change in pitch, it would be possible to accurately calculate the speed of the train. This principle applies to radio waves as well as sound waves. One of the more familiar examples of the Doppler effect is a police radar used to measure the speed of vehicles.

A Doppler weather radar measures the speed of the target as well as the target's location and reflectivity. The speed of the target (precipitation) implies a wind velocity.

The wavelength of the reflected radar signal is slightly compressed ahead of a target or slightly stretched behind a target, that is moving. The radar will measure either a slightly shorter or slightly longer wavelength reflection, depending on whether the target (precipitation) is moving towards or away from the radar antenna. After the reflection is received, the radar's signal processor compares the wavelength of the reflected signal to the wavelength of the transmitted signal. The velocity of the target is calculated from the difference in wavelengths.

Because the Doppler wavelength shift is very small, obtaining accurate Doppler velocity data requires a radar system with a high degree of frequency and phase stability. If the frequency or phase of the transmitted signal changes, even a little bit, during a pulse, there is no way for the signal processor to determine if the

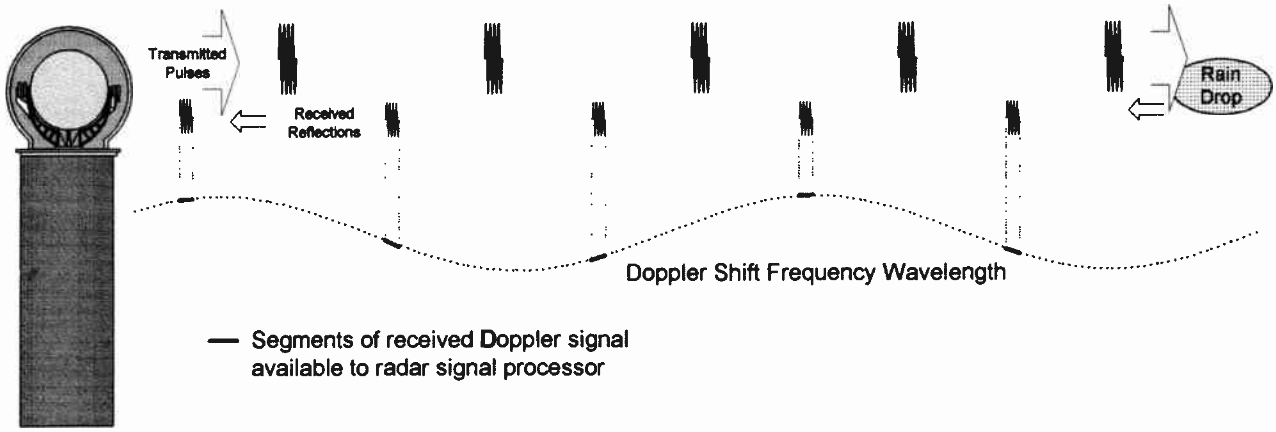

Figure 5.12-2. Doppler shift sampling technique.

difference it is measuring is due to real velocity of the target or to changes in the transmitted pulse.

Figure 5.12-2 illustrates the manner in which the radar signal pulses, in effect, sample the Doppler shift wavelength. The Nyquist data sampling principle requires that there must be a minimum of two samples per wavelength for the samples to accurately measure the wavelength. As a result, the maximum Doppler velocity any pulsed radar can measure is a function of the PRF (Nyquist principle) and the wavelength (Doppler principle). This is expressed by the following formula:

$$V_{max} = \frac{PRF\lambda}{4} \qquad (3)$$

Where:

V_{max} = maximum unambiguous velocity
PRF = pulse repetition frequency (pulses per second)
λ = transmitted wavelength (0.0535 m for C-band, 5600 MHz)

For example, for a C-band radar with a PRF of 1000, V_{max} is:

$$V_{max} = \frac{(1000)(0.0535)}{4} = 13.375 \text{ m/sec} \left(\approx 30 \frac{\text{mi}}{\text{hr}}\right)$$

Many radar systems provide velocity unfolding capability. These techniques often use staggered pulse rates and a processing algorithm which can multiply the maximum velocity that can be measured by a factor of 2. Some radars also offer a 3 times velocity unfolding capability.

From this relationship, it is evident that higher velocities require high pulse rates.

Maximum Unambiguous Range and Maximum Unambiguous Velocity

In a pulsed Doppler radar, the PRF, the maximum unambiguous velocity and maximum unambiguous range are interrelated. The graph in Figure 5.12-3 expresses that relationship for a C-band radar. Measuring high velocities requires a high pulse rate. Measuring long ranges requires a low pulse rate. Therefore there is a trade-off between the maximum velocity and the maximum range. This situation is sometimes referred to as the Doppler dilemma. The end result is that, at any given range, there is one unique PRF that will provide the maximum velocity measurement capability at that range.

Coherence

To obtain Doppler velocity data, the frequency and phase of the reflected pulses that are received must be compared to the frequency and phase of the transmitted pulse.

There are two challenges in making this comparison:

- The Doppler frequency shift is very small, so this comparison requires a high degree of stability and accuracy to get reliable velocity data. A great deal of precision is required in the radar's transmitter and signal processing circuits.
- The received pulse arrives back at the radar long after the transmitted pulse has ended. Therefore, it is impossible to make a direct comparison between the transmitted and received pulses.

There are two commonly used ways of making an indirect comparison between the transmitted and received pulses:

- A *coherent-on-receive* radar typically uses a *magnetron tube* in the transmitter. The magnetron is a power oscillator which starts up, transmits a pulse and then shuts down. This cycle is repeated for each pulse. Thus each pulse can have a slightly different frequency, depending on magnetron voltage, current, temperature, magnetic field, etc. The phase of each pulse from a magnetron is random.

  Circuits, typically called stable local oscillator (STALO) and coherent oscillator (COHO), sample and remember the frequency and phase of the magnetron's last pulse. The output of the COHO is used

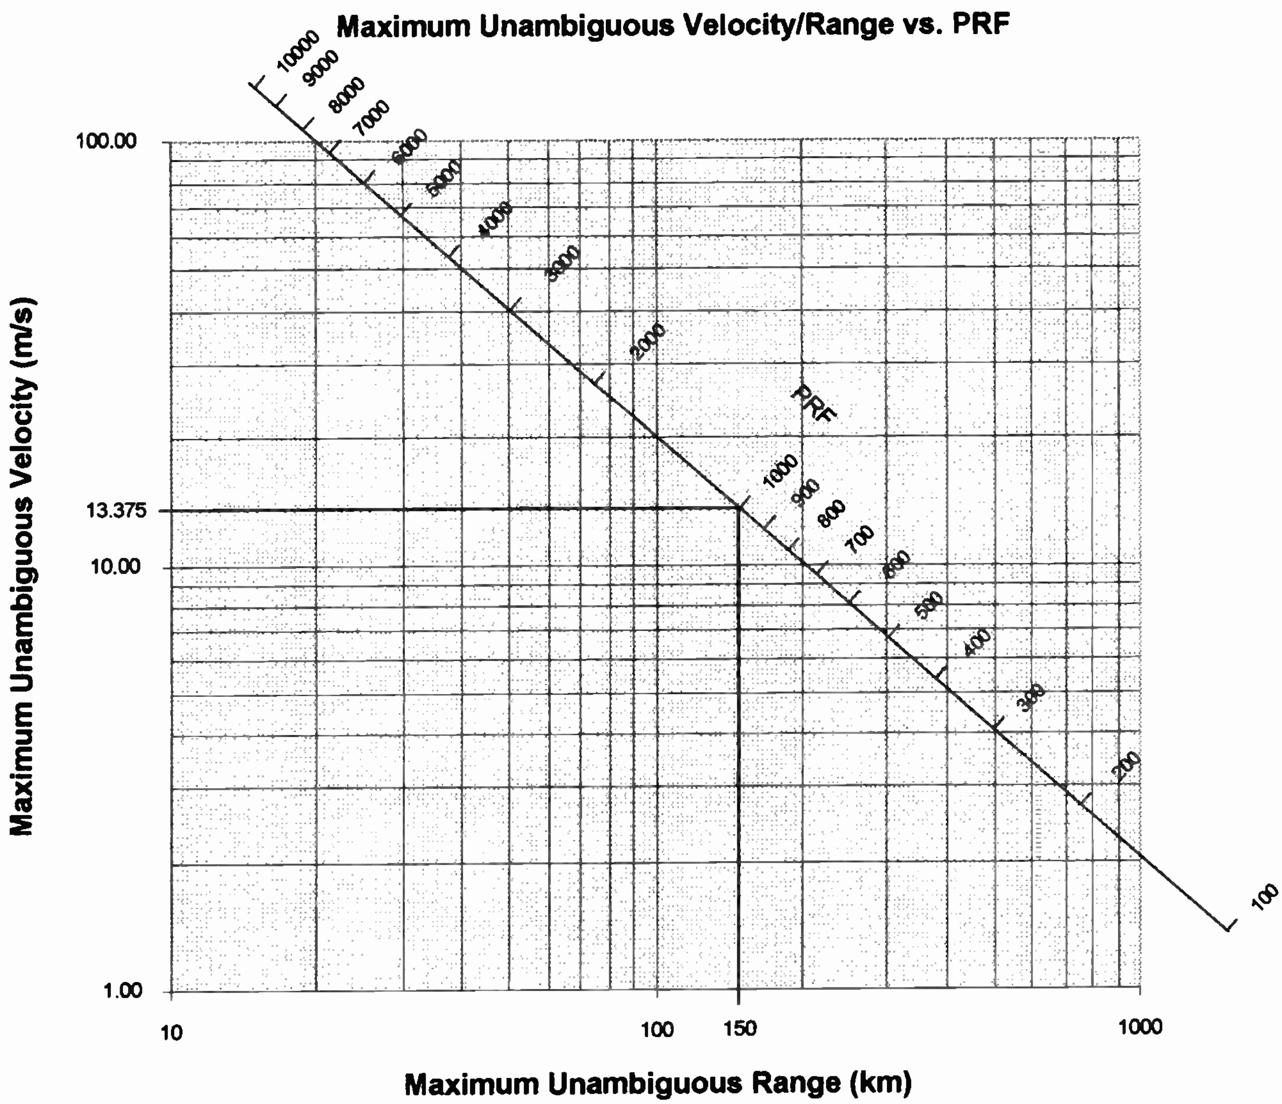

Figure 5.12-3. C-Band Doppler weather radar PRF vs. range and velocity.

as the reference for Doppler processing of the received pulses.

Many commercially available weather radar systems are coherent-on-receive. As a result of the small variations between pulses, these systems are typically limited to around 30 dB of ground clutter suppression by clutter filters.

- A *fully coherent* radar has a precision oscillator which operates continuously. This oscillator serves as the source of a master reference signal for all circuits in the radar.

The transmitter is a true amplifier which typically uses a klystron tube, traveling wave tube (TWT) or solid-state device(s). Each transmitted pulse is a small portion of the reference signal that is amplified, thus the frequency and phase of transmitted pulses are accurately known and are consistent from pulse to pulse.

The signal processor uses the precision oscillator as the reference for determining Doppler shift in the received pulses. As result of the phase locked consistency of all signals, fully coherent radars can typically achieve around 50 dB of ground clutter suppression from clutter filters.

WSR-88D, TDWR, nearly all research radars and a few commercially available weather radar systems are fully coherent.

BASIC RADAR METEOROLOGY

Radar meteorology is a science in itself. The information presented here contains only the most basic concepts. The bibliography at the end of the chapter provides references to far more detailed and comprehensive information.

Reflectivity and Precipitation Intensity

Interpreting the meaning of radar reflectivity displays requires meteorological knowledge plus experience with local conditions. As an extreme example of local conditions, there are places where, at sunset, large numbers of bats leaving their daytime roosts may appear on the radar as a strong gust front line.

The amount of signal reflected is determined by the number, size and type (rain, snow, hail, ice crystals, etc.) of precipitation. Light snow is a very weak reflector of radar signals, hailstones that are wet on the outer surface are very strong reflectors, and liquid raindrops are somewhere in between depending on the size of the drops. Research has shown that precipitation reflects horizontally polarized signals best. Nearly all weather radar systems in use today have antennas which transmit horizontally polarized signals.

With current technology, the radar can only measure the total reflection. Thus estimating the actual amount of precipitation from only a radar image becomes a classic case of one equation with three unknowns.

There is a significant amount of research currently being done to determine how get more precipitation information using a radar system. Most of that research is focused on radar with dual polarization capability, that is a radar that can transmit pulses that alternate between horizontal and vertical polarization. The differences between the horizontal and vertically polarized reflections are analyzed to extract more information about the precipitation. Differential reflectivity (ZDR) has been demonstrated to have a high probability of being able to accurately differentiate between hail and other types of precipitation. Research suggests that ZDR, in conjunction with linear depolarization ratio (LDR), differential phase shift (KDP) and other parameters will ultimately be able to provide much improved precipitation data.

The reflectivity of raindrops is approximately proportional to the diameter of the drop raised to the 6th power, while the volume of water in the drop is approximately proportional to the diameter of the drop raised to the 3rd power. Thus the relationship between reflectivity and actual water content of a raindrop is highly non-linear. The reflectivity is also proportional to the number of drops; twice as many drops reflect twice as much signal. Since neither the drop size nor the number drops can be readily determined, calculating the actual water content of precipitation from radar reflectivity data alone is at best an estimate.

One commonly used method of estimating rainfall rate from radar images is to use the formula:

$$Z = aR^b \qquad (4)$$

Where:

Z = radar reflectivity factor of the precipitation
R = rain rate in mm/hr
a = an empirically determined constant
b = an empirically determined constant

It should be emphasized that this formula provides only an estimate of precipitation. Over the years there have been a large number of experimental data sets collected to attempt to refine the values of a and b in this relationship. Table 5.12-2 provides rainfall rates in inches/hour for various commonly used Z-R relationships:

Table 5.12-2

Radar rainfall precipitation estimates—inches/hour.

DBZ	$300R^{1.4}$ Stratiform and convective rainfall	$200R^{1.6}$ Stratiform rainfall	$486R^{1.37}$ Convective rainfall (reduces hail effect)
20	0.02	0.03	0.01
30	0.09	0.12	0.07
40	0.48	0.47	0.36
50	2.5	1.9	1.9
60	12.9	8.1	10.3
70	67.0	34.1	55.4

Many radar systems allow the operator to enter values for a and b and display reflectivity directly as estimated rain rates. Some radar systems also provide a capability to total the estimated rainfall over a period of time.

As a point of reference, for a number of years the NWS used the values given in Table 5.12-3 to correlate display color, estimated rain rate and reflectivity dBZ:

Table 5.12-3

Display system color definitions.

DVIP Level	Rain rate (in/hr)	Reflectivity (dBZ)
1- lt. green	0.1	0–30
2-dk. green	0.25	30–41
3-yellow	0.5	41–46
4-orange	1.25	46–50
5-red	2.5	50–57
6-dk. red	4.0	57 or more

It should be cautioned that these relationships only provide estimates of the water content based on radar reflectivity. In any given storm, the actual water content may vary significantly from the values indicated by the formulas and data shown here.

Reflection Shape

The shape of the area of precipitation is also significant. For example:

- If a line of precipitation begins to bulge out, the bulge (or bow echo) may indicate the presence of strong winds, possibly the outflow from a downburst
- A hook shaped echo may indicate the presence of a tornado
- A long thin line ahead of an area of precipitation may indicate a gust front.

Non-Meteorological Reflections

Weather radar systems from time to time will also display reflections from non-meteorological targets such as dust, insects, birds and even bat migrations. Correct interpretation of these factors is usually a matter of local experience.

Velocity

A Doppler radar measures the velocity of the precipitation's movement. That velocity implies a wind blowing the precipitation. Thus, a Doppler radar can measure wind velocity. The velocity the radar measures is either directly toward or directly away from the radar antenna. This is called *radial velocity*. For winds blowing at an angle to the radar beam, the velocity measured by the radar will be the vector component of velocity along the centerline of the radar beam.

In the wind velocity display, velocity is usually indicated by color. Typically winds blowing toward the radar antenna are shown in shades of blue and green while winds blowing away from the radar antenna are shown in shades of orange and red. Each color indicates a range of velocities, typically the darker/brighter the color, the higher the velocity.

Velocity measurement capability has dramatically improved the accuracy of tornado warnings. Research has shown that most tornadoes are produced by mesocyclones (rotating thunderstorms). The Doppler velocity measurements can usually identify the rotation within a storm cell many minutes before a tornado actually forms. This rotation is typically identified by winds within a storm cell blowing in opposite directions in close proximity to each other.

The velocity measurement capability can also detect winds associated with low level wind shear. Low level wind shear has been determined to be extremely hazardous to aircraft during takeoff and landing. Some Doppler radar systems can be programmed to automatically detect the patterns of storm related wind shear, and produce an alarm when those wind shear patterns are detected.

Spectrum Width

Spectrum width is the difference between the maximum and minimum wind velocities in close proximity to each other. If the wind were perfectly uniform, all velocity measurements in the same area would be identical and the spectrum width would be zero. In essence, spectrum width is a measure of turbulence in the atmosphere.

Many radar operators will use the spectrum width display to locate areas where development of severe weather is most likely. Areas of high spectrum width are also of interest to pilots, as areas of turbulence to be avoided.

Beam Width and Beam Altitude

There are several factors related to the antenna beam width and altitude:

- Radar theory requires that, for accurate measurement of precipitation intensity, the precipitation must completely fill the pulse volume of the radar beam, that is the height, width and length of the volume of space the transmitted pulse occupies. For many meteorological purposes, precipitation areas more than 3 km (1.86 mi) wide are of most interest. To assure beam filling, and therefore accurate measurement of precipitation, the radar beam should be no more than 3 km wide in the areas of greatest interest.
- As a result of the earth's curvature, the altitude of the radar beam increases with distance from the radar antenna. Most precipitation occurs at relatively low altitudes, typically below 10,000 ft, and nearly always below 20,000 ft. At very long distances, the radar beam is too high to provide any meaningful data.

  A useful rule of thumb is that, with the antenna elevation set at the normal $+0.5°$ tilt, the beam will rise approximately 1,000 ft for every 10 mi of range.

The diagram in Figure 5.12-4 indicates the beam width and altitude for a radar with 1° beam width (C-band with a 14 ft antenna at $+0.5°$ elevation angle). Figure 5.12-5 illustrates the altitude of the beam centerline as a function of range at various antenna elevation angles.

The diagram in Figure 5.12-6 illustrates two situations in which the radar can be misleading as a result of beam altitude. The first shows virga (streaks of water drops or ice particles which evaporate before reaching the ground) which the radar detects. However, no rain actually reaches the ground, even though it is displayed on the radar. The second situation, which is typical at longer ranges, shows the radar beam well above precipitation. Thus that precipitation will reach the ground, but will not appear on the radar.

Ground Clutter

Ground clutter is one of the largest single problems for a weather radar. It often masks real precipitation. For a radar covering a metropolitan area, the ground clutter is likely to be worst in the area where radar data is of most interest (directly over the metropolitan area).

Unfortunately, some of the transmitted pulse is radiated by the antenna at angles away from the main beam. These are called *side lobes*. Figure 5.12-7(a) illustrates how these side lobes cause reflections from buildings, trees, vehicles, etc.—these reflections are referred to as ground clutter. Figure 5.12-7(b) illustrates how reduced side lobe energy avoids much ground clutter. The antenna's first side lobe is usually the primary cause of ground clutter.

Stationary ground clutter from buildings, terrain, etc. can be filtered out either by using a *clutter map* to subtract known clutter sources from an image, or by using *clutter filters* in a Doppler radar. The effectiveness of Doppler ground clutter filtering is heavily dependent on the stability of the radar transmitter.

Filtering moving clutter caused by vehicles, sea surface waves, etc. is an extremely difficult problem. If moving clutter is expected to be a problem in a given location, selecting a radar antenna with the lowest possible side lobe energy is likely to be the most effective way to suppress that clutter.

Anomalous Propagation

Anomalous propagation (AP) is caused by atmospheric effects bending the radar beam downwards so

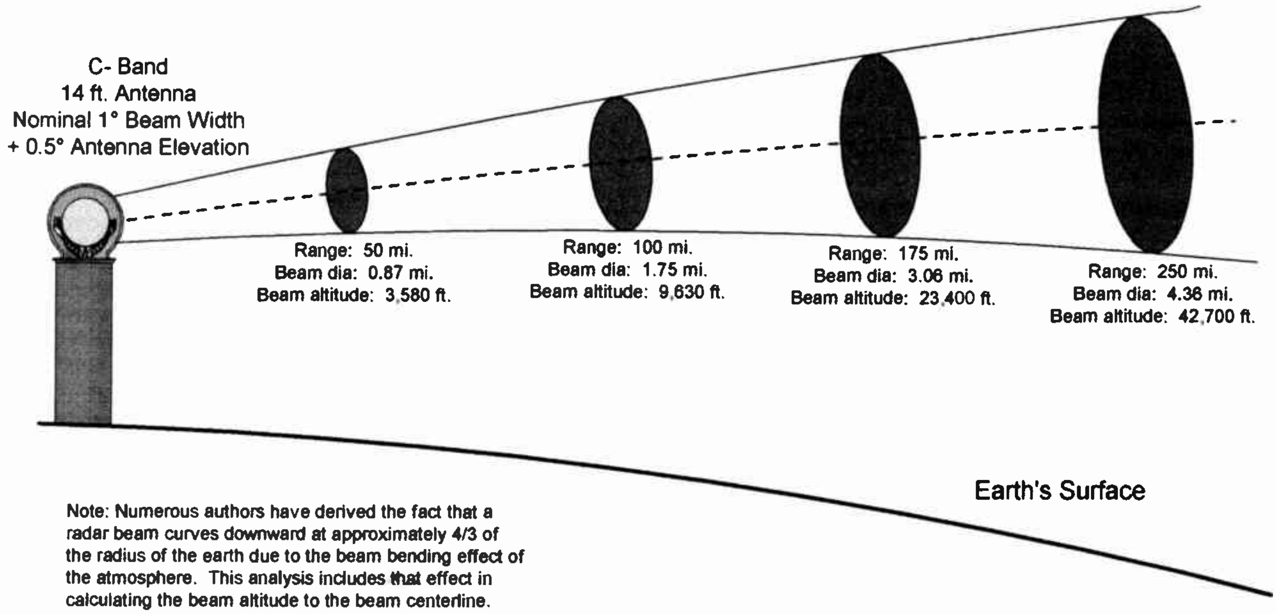

Figure 5.12-4. Radar beam size and altitude vs. range.

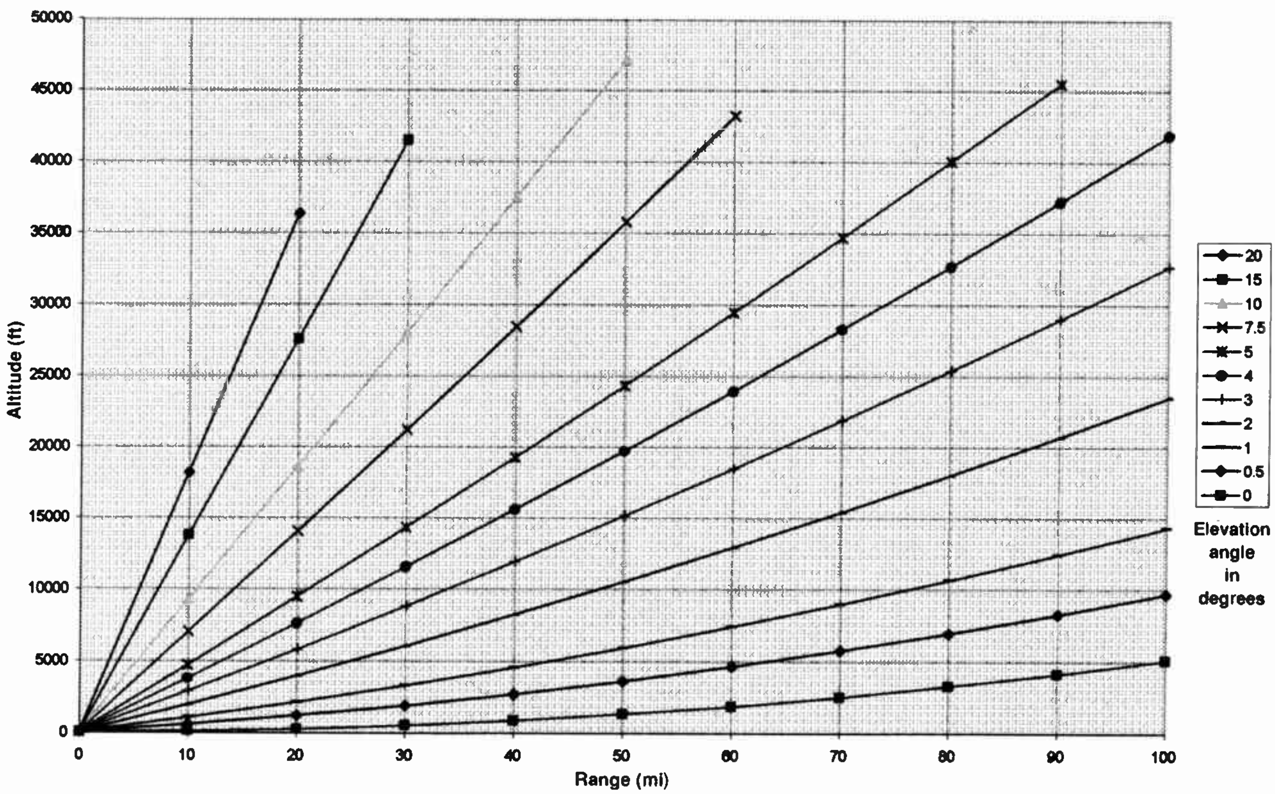

Figure 5.12-5. Beam altitude vs. range at various antenna elevation angles.

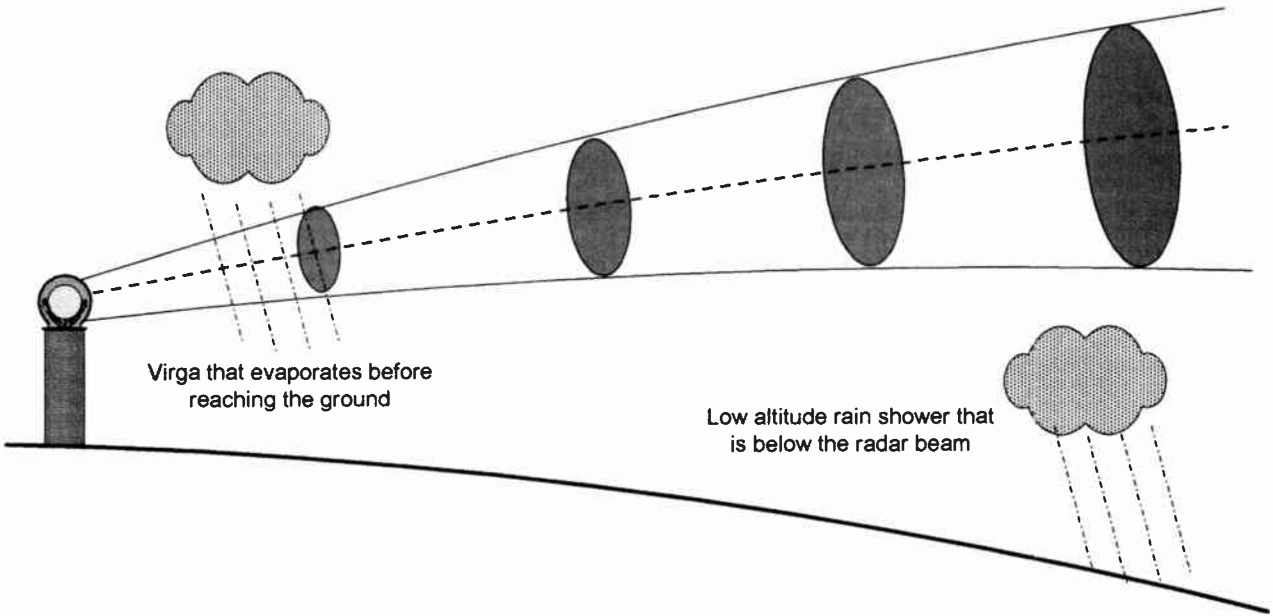

Figure 5.12-6. Rain detection considerations.

far that it actually hits the ground. The reflections travel back via the same path so that the image displayed is actually the ground. This is illustrated in Figure 5.12-8.

AP is typically a very low altitude situation caused by the radar beam passing through a thermal inversion layer. Raising the antenna elevation angle from the normal 0.5° to 1.0° or even 1.5° (getting the beam above the inversion layer) may help to identify AP. If raising the elevation angle causes a reflection area to move away from the radar or disappear entirely, that reflection is likely to be AP.

RADAR SYSTEM COMPONENTS

The *antenna* is a critical element in the overall performance of a weather radar system. The antenna performs two functions: forming the transmitted pulse into a very narrow beam and aiming that beam in the desired direction. If a weather radar beam were visible, it would look very much like the beam of light from a lighthouse, a very powerful, narrowly focused beam sweeping around through the atmosphere.

Weather radar antennas are almost universally parabolic. The one exception is small *slot array antennas,* sometimes referred to as pizza pan antennas. For most weather radar purposes, the performance of a properly designed slot array antenna is equivalent to a parabolic antenna of the same diameter.

For a weather radar, the general premise is that the narrower the beam the better. However, basic physics requires a progressively larger antenna to obtain a progressively narrower beam. The costs of a radar antenna, radome, tower, etc. increase dramatically for larger antenna sizes.

Figure 5.12-4 illustrates the relationship between range, beam width and beam altitude. From this data, it is apparent that a weather radar antenna with an angular beam width of approximately 1° will provide

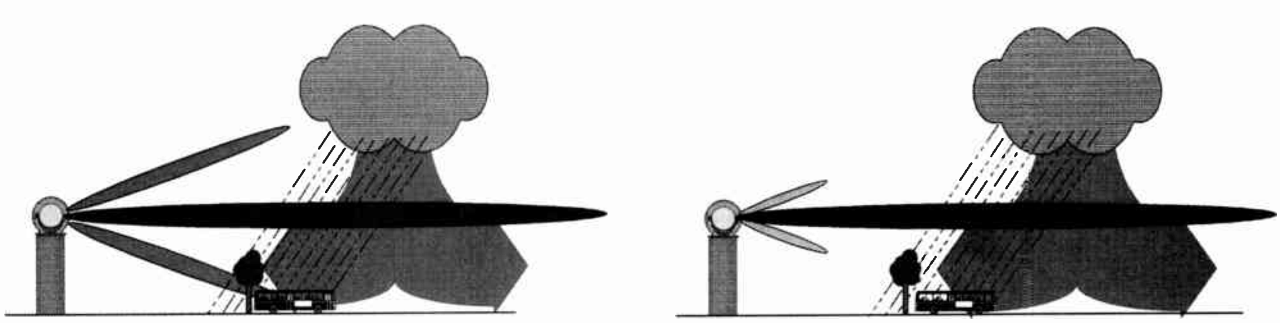

Figure 5.12-7. The effects of sidelobes on radar performance (a) large sidelobes, (b) small sidelobes.

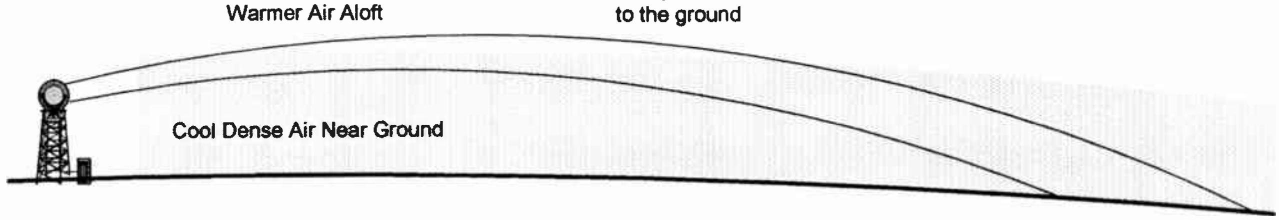

Figure 5.12-8. Radar beam super-refracted down to the ground.

a beam width of less than 3 km at ranges and altitudes that are often of the most meteorological value.

Side lobes are caused by a combination of basic physics, plus very small imperfections in the shape of the antenna, plus the waveguide, support struts and feedhorn being located in front of the antenna reflector where they are in the main beam.

Side lobe suppression is typically measured as decibels of side lobe signal strength, with the center of the main beam as the reference. This is typically quoted as the one-way value. The actual signal path is a round trip (transmitted signal out, and received signal in). The round trip attenuation is double the normally quoted value. Center feed parabolic antennas typically achieve side lobe suppression in the range of −25 dBc (25 dB down from the carrier) to −30 dBc one way. (The larger the negative number, the greater the attenuation.) Precision antennas with an offset feed arrangement have been reported to have side lobe suppression of −40 dBc or better one way.

Pedestal

The weather radar antenna is typically mounted on a device called a *pedestal*. The job of the pedestal is to accurately turn and elevate the antenna to aim the antenna's beam in the desired direction.

Typically the pedestal can turn the antenna continuously a full 360° either clockwise or counter-clockwise in the azimuth direction at a specified rate. The elevation (up and down) angle is often limited by drive mechanics to something like −2° to +60°, with horizontal being the 0° reference. This creates a situation where the area directly above the radar cannot be scanned. This area is sometimes referred to as the *cone of silence*. Since most weather occurs at lower altitudes, (at lower antenna elevation angles) the cone of silence is not a very significant limitation in most weather radar installations.

The pedestal sends both the azimuth and elevation angles to the radar processor. Frequently ±0.1° (1/10 of the antenna's beam width) is specified as the required accuracy for the antenna position and position measurement. Improving the pedestal's angular accuracy can be done, but the cost increases dramatically, and typically does not significantly improve the meteorological quality or usefulness of the data.

Most radar systems permit adjusting the speed at which the antenna turns. Turning the antenna faster provides more frequent updates for data at a given location. However, it also puts greater demands on the radar signal processor (one revolution's data must be processed in less time). If the antenna rate is too high, the accuracy of the Doppler velocity data is reduced. Typical scan rates are often in the range of 2 or 3 revolutions per minute. Many antennas are capable going as fast as 5 or 6 rpm.

Many older designs of radar antenna pedestals use dc motors, which require periodic replacement of motor brushes, to drive the antenna. Newer designs often use brushless motors. Because the pedestal is typically on top of a tower where it is not readily accessible, changing the brushes can be a significant undertaking.

Transmitter

A radar transmitter typically has three major functional areas: the high voltage power supply, modulator, and RF power output stage. In a Doppler radar, stability of the transmitter is particularly important because of the small changes that the Doppler shift produces in the reflected signal. If the transmitter causes small changes in the signal, it is impossible to separate those changes from the Doppler shift changes.

When evaluating radars, there is a tendency to place heavy emphasis on the peak power, with more being better. Peak power is only one factor. A radar having more a capable signal processor and an antenna with better side lobe attenuation may outperform the more powerful radar in many situations.

High Voltage Power Supply

The high voltage power supply typically produces a dc voltage somewhere between 10,000–75,000 V depending on the design of the particular radar. Peak pulse currents, at those voltages, may be 20 amps or more. While the peak power is very high, the average power is typically quite low, often not much over 100 W.

The high voltage must be well regulated and stable for the best accuracy of data. If the transmitted power, which is a function of the high voltage, varies the reflected power will also vary giving erroneous reflectivity readings. Variations in voltage may also affect the transmitted frequency and/or phase during a pulse, particularly with a magnetron transmitter. This variation in frequency will in turn appear as a Doppler shift in the reflected signal, giving erroneous Doppler velocity data.

Modulator

The job of the modulator is to form the high voltage into pulses of the proper duration and pulse repetition rate (PRF) to drive the RF power output stage. Many radars use a pulse forming network to do this. The pulse forming network typically uses some combination of capacitors and/or inductors to store energy such that a high energy pulse is available at the right time.

Pulse forming networks are typically designed around a particular pulse width and PRF. This factor limits a radar system that is based on pulse forming networks to a very narrow range of choices of pulse width and PRF.

Some research radars and a few commercially available radars use dc switch type modulators. A dc switch type modulator does not have the timing restrictions of a pulse forming network. Therefore a radar based on a dc switch type modulator typically allows the selection of pulse widths and PRFs over a wide range that is limited only by the duty cycle of the components involved.

Many older radars use Thyratron tubes to conduct the pulse from the pulse forming network to the RF power output stage. Newer designs often use solid state devices which tend to be much more reliable than Thyratrons.

RF Power Output Stage

There are two categories of RF power output stages: coherent on receive radars typically use magnetron tubes, and fully coherent radars which use a true amplifier that is often based on a klystron tube. Some commercially available fully coherent radars also use traveling wave tubes (TWT's) or solid state devices.

A magnetron can be described as a power oscillator. Every time a pulse arrives from the modulator, the magnetron starts up, begins to oscillate, produces a pulse at the RF frequency and power level and shuts down. This sequence is repeated for every pulse.

A magnetron operates by causing a beam of electrons to sweep around the interior of a cylindrical cavity. That cavity typically has a series of slots around the outer surface of the cylinder. The number of slots and the speed at which the beam sweeps around determine the operating frequency. The beam speed is determined by a combination of the physical geometry of the tube and slots, voltage, current, magnetic field strength and the load on the magnetron's output. As a result, the frequency of oscillation for the magnetron is likely to be slightly different for each pulse. The phase of each pulse is random.

Coaxial magnetrons have an additional cavity that couples the slot output to the waveguide output. This additional cavity tends to isolate the beam from output loads and make the operation of the tube more stable and less affected by changes in load.

A fully coherent radar has a master oscillator which is always running. The RF power output stage amplifies that signal during the pulse from the modulator. Thus the frequency and phase of each pulse is very stable, accurately known and essentially identical to every other pulse.

Klystron's and TWT's are both linear electron beam tubes. In both, the input signal is injected into the tube and the beam energy is used to amplify the input signal. The frequency and phase of the output signal is determined by input signal and is largely independent of the tube and circuit parameters in the RF power output stage.

Receiver

The reflections returning to the radar antenna are extremely weak. Therefore the receiver must be very sensitive and have a very low noise level such that weak signals can be detected and are not masked by noise. In addition, the receiver must be able to receive a very strong reflection from a nearby target without overloading. Meeting both objectives is a very challenging engineering problem.

Receiver sensitivity is typically referred to as minimum detectable signal (MDS) and is measured in dBm. Commercially available radar systems typically have an MDS in the range of −108 to −115 dBm (−115 is more sensitive than −108). A few systems have an MDS of −120 or better.

Dynamic range, the difference between the weakest and strongest signal the receiver can handle without overloading, is typically at least 90 dB. A few currently available systems can exceed 100 dB. In many systems, this dynamic range is achieved by using an intermediate frequency (IF) amplifier with logarithmic rather than linear response.

Unfortunately, the logarithmic amplifier alters the phase of the received signal, thus its output is not coherent and will not provide accurate Doppler data. Therefore, many Doppler radar systems include both a linear and a logarithmic IF amplifier. The log channel is used for reflectivity data and the linear channel is used by the Doppler signal processor.

Classical radar theory indicates that the IF bandwidth is related to the transmitted pulse width. Narrower pulses require wider IF bandwidths. Some radar systems automatically adjust the IF bandwidth when different pulse widths are selected.

Signal Processor

Most radar systems today use digital signal processors. The received signal is analog, so it must be converted to digital format by using an analog/digital (A/D) converter. In many radar systems the A/D converter has 12 bits of precision. The A/D process is critical in the overall performance of the radar system. The conversion process introduces noise and is subject to a number of factors which may reduce the quality of the signal.

The signal processor typically performs several functions:

- Performing $1/R^2$ compensation—Radio signals propagate according to the inverse square law, that is the signal has 1/4 the strength at twice the distance. If this were not compensated for, precipitation would always appear to be weaker at greater distances. The compensation causes precipitation of a given intensity to be displayed at the correct intensity regardless of its range
- Doppler velocity processing—The signal processor compares the frequency and phase of the signal in each range bin with the frequency and phase of the transmitted pulse and computes the radial velocity from that difference
- Spectrum width processing—The signal processor computes the difference between the maximum and minimum velocity within the same range bin
- Clutter filtering—In a Doppler radar, a ground clutter filter assumes that targets with zero or near-zero velocity are buildings, smokestacks, etc., and suppresses those reflections.

If the radar is to produce true real time images, the signal processor must have the capacity to process all the data immediately as the antenna scans. Processing capacities of 500 million instructions per second (MIPS) or more are readily available.

Radar Data Product Generator and Volume Scanning

The signal processing referred to in the previous section applies to data from the radar at a single antenna elevation angle. Many state-of-the-art radars have the ability to perform true 3-D volume scans. This is typically accomplished by taking successive scans of one revolution each with the antenna at successively higher elevation angles and repeating the sequence from the ground up.

In many radar systems the volume scan data is processed by a separate workstation. That workstation will generate many different radar image products from the volume scan data. A few typical volume scan products are:

- CAPPI—constant altitude plan position indicator, a horizontal slice through the atmosphere at an arbitrarily specified altitude
- VIL—vertically integrated liquid, the integrated value of the total amount of liquid in the atmosphere above a specified point on the ground
- XSECT—cross-section, a vertical slice through the atmosphere above a line between two arbitrarily located points on the ground
- VAD—velocity azimuth display, a display of a time series of wind velocity versus direction and altitude parameters.

A number of other volume scan products have been devised for various purposes. Radar manufacturers can provide details of the products their particular equipment supports.

Display

The basic images a Doppler weather radar system displays are reflectivity, velocity and spectrum width. Some systems provide both raw and filtered reflectivity. The operator controls which image is displayed.

The reflectivity, velocity and spectrum width displays are typically shown with specific colors representing calibrated data values. Thus precipitation intensity, wind velocity and atmospheric turbulence at a given location can be quickly estimated.

The basic radar display contains a great deal of information, but is typically not very useful by itself because the location of the data is not clear. Adding a map overlay to the radar image is one of the most common display graphic functions. A map permits users to quickly identify areas of precipitation, velocity, etc. with respect to known locations on the ground.

Many radars provide the ability to blink selected colors in a display. This makes it easy for users to identify areas of particular interest. Some radars provide the ability to generate additional graphic overlays that can be created by the user for specific purposes.

If a radar is to be used for live on-air presentations, it should have the ability to produce broadcast quality genlocked video output. For on-air presentations, having a radar system with a powerful graphics processor is a significant advantage. That graphics processor can be used for the creation of sophisticated weather products which have the look the station desires.

Uninterruptible Power System

Severe weather is one of the most frequent causes of power failures. Having an uninterruptible power system (UPS) for all radar equipment is good insurance against having the radar go dead.

A typical UPS system will have both a battery supply and an engine driven generator. The installation is typically designed such that the batteries will keep the minimum essential items running for a few minutes until the engine starts and can take the full load.

Some jurisdictions have special building codes that apply when large arrays of batteries are used inside of a building. The general concern is that, under certain conditions, most commonly available types of batteries produce hydrogen gas. In a small enclosed area, such as a radar transmitter building, that hydrogen can accumulate to an explosive concentration very quickly. If not covered by specific building codes, the UPS batteries should be in an area that is well ventilated, with that ventilation going directly to the outside and not connected to the rest of the building's ventilation system. In addition, the amount of electrical equipment in the battery room should be minimized and equipment in the battery room should be explosion proof.

LOCATION OF RADAR SYSTEM

There are many factors that affect the choice of the ideal location for a weather radar system and its antenna. However, the practical reality is, in many cases, only a certain location is available and that is where the radar must be placed. In these cases, effective use of the radar requires understanding the limitations imposed by the specified location.

Define Coverage

What is the primary objective of the weather radar?

- To provide severe weather warnings for a metropolitan area?
- To provide rainfall data for a particular watershed?
- To detect potential aviation hazards?
- To provide scientific data for a specific application?

Determining the nature of coverage to be provided and the primary area of interest for that coverage is required.

Selection Factors

If providing warnings of approaching severe weather is one of the objectives, more advance warning time is usually desirable. That dictates locating the radar system between the area to be protected and the usual direction of approach of severe weather. In many locations in the U.S., severe weather approaches from a generally westerly direction, therefore the radar in those locations should ideally be to the west of the area to be protected. Placing the radar elsewhere would typically reduce the warning time.

The radar beam from the antenna should have a clear view of the area to be protected. Locations where buildings, hills, etc., block or obstruct that view should be avoided. Trees also can block the view and trees grow. One common practice is to place the radar antenna on a tower that is tall enough so that it will still be comfortably above the tops of the trees after 20 years of growth.

EMC Considerations

The radar must be in an area that is free from interference on its operating frequency. Other radar systems are a common source of interference. Interference includes both other sources interfering with the radar's operation and the radar interfering with other equipment.

Non-RF sources can also be significant. For example, normal corona leakage from very high voltage power lines near the radar may raise the background noise level to the point that very weak radar reflections will be masked.

Site Access

The radar site location should have access 24 hours per day, 12 months per year. Selecting a site that is known to be periodically inaccessible as a result of snowfall, flooding, etc., is not recommended.

Radar to Control Location Data Link

In many situations the radar system must be placed in a location different from the location where the radar data is needed. In many broadcast situations, the radar system may be located at the transmitter site and the radar data and control must be at the studio.

Weather radar systems produce large volumes of data. Having real time coverage means getting that data from the radar to the studio in real time. That requires high bandwidth data circuits. It is not uncommon for a real time radar installation to require a T1 (1.544 Mbps) data circuit between the radar and the data/control location.

The availability and cost of high speed data circuits, or a private microwave or satellite link, between the radar site and the studio is a factor that should be considered in the site selection process.

Installation Planning

Planning the installation of a weather radar system involves a great many details. A checklist of items that may be helpful in the planning process is provided at the end of this chapter.

Lightning Protection

Lightning is one of the most frequent and costly causes of damage to weather radar systems. Systems from different manufacturers vary in their resistance to lightning strikes. However, nearly any radar installation will benefit from lightning protection which includes a grounding system suitable for the purpose.

Operating Frequency

An integral part of the plan should be the process of determining an operating frequency for the radar. That process is usually easier if an existing radar is being replaced. If the radar is new, a determination of a clear frequency must be made. Some radar manufacturers will require that the operating frequency be specified very early in the order process.

FCC

The radar system includes a transmitter which requires an FCC license to operate in the U.S. just as any other transmitter.

FAA

A tower for the radar antenna may be subject to FAA regulations, and require registration as an aviation hazard, based on its height.

Local Permits

Construction of a radar tower is likely to require local permits, variances and/or zoning changes.

SAFETY ISSUES

Radars are complex and powerful systems. Personnel who will operate and maintain a radar system should be trained in the safety aspects of the radar's operation as well as in the operational details of the radar.

Microwave Hazards

The effect of microwave radiation on the body has been the subject of a great deal of study. Of the potential hazards investigated to date, the heating effect on tissue is the only one that has produced general agreement and is readily replicated under controlled scientific conditions. The joint ANSI/IEEE *Standard for Safety Levels with Respect to Human Exposure to Radio Frequency Electromagnetic Fields, 3 kHz to 300 GHz* C95.1-1991 and the *FCC OET Bulletin 65* are based on tissue heating effects.

The location of the radar beam with respect to areas where people live and work must be considered. The radar antenna should be located such that no persons are within the area where the maximum permissible exposure (MPE) limits are exceeded. The MPE limit typically results in a minimum safe distance in front of the radar antenna given the transmitter power, antenna gain, frequency and duty cycle.

Electrical Hazards

The high voltage, high energy circuits in most radar transmitters present an extreme hazard to personnel. Because of the high voltage, normal skin resistance is ineffective at limiting current. Due to the circuits ability to deliver large quantities of energy very quickly, often in the sub-microsecond range, large amounts of energy will be conducted before even the fastest protective devices can operate.

Only personnel who are thoroughly trained should be permitted to work on a radar transmitter. Even then, strict safety procedures must be observed at all times. There may not be a second chance.

Mechanical Hazards

The motors that move the antenna are powerful and are typically geared down to provide the massive amounts of torque necessary to move a heavy antenna with precise accuracy. Typically the antenna is in a location out of sight of the circuits that control its movement. The antenna is also typically in a very confined space inside a radome. The end result is that personnel near the antenna have a high risk of being injured or crushed if the antenna moves unexpectedly.

Again, only personnel who are thoroughly trained should be permitted to work on the radar system, and strict safety procedures must be observed at all times.

X-Ray Hazards

Some radar transmitter tubes may produce X-rays in certain operating modes. The radar transmitter should not be operated if any X-ray shields provided by the manufacturer have been removed.

Weather Radar Site Checklist Site

1. **Area To Be Covered:** (Population centers, watershed area, airport, etc. prioritized in order of importance. A map with coverage areas outlined is helpful.)

2. **Type Of Coverage To Be Provided:** (Prioritized in order of importance)
   - General purpose meteorological data/forecasting
   - Severe weather detection/tracking
   - Rainfall measurement for hydrology application
   - Aviation safety hazard detection
   - Other ______________________________

3. **Antenna Site Location:** Lat. ______________ Long. ________ (Provide a brief description of location from known reference points if lat/long are not available)

4. **Radar Beam Obstructions:** (type, direction, approx. distance, consider coverage priorities)

5. **Access To Site:** (road, trail, cross-country, etc., special vehicles, equipment required? Is access subject to being cut off (snow, floods, etc.)?)

6. **EMC Factors:** (other radars, radio transmitters/receivers, etc. that may be interference problem and their location, also consider radar beam safety, i.e., personnel that may be exposed to beam during normal operation)

7. **Tower Height:** (radar must see over tops of trees and buildings, may be restricted by proximity to airport)

8. **Soil Conditions At Tower Site:** (sand, clay, rock, etc., soil test data available?)

9. **Electrical Service To Radar Site:**
   - Voltage, frequency, single or 3 phase: ______
   - Reliability of source: (voltage surges, sags, interruptions, etc., seasonal problems)
   - Number And Duration Of Interruptions In The Past 12 Months
     - Less than 1 second ________
     - 1 second to 5 minutes ________
     - More than 5 minutes ________

10. **Uninterruptible Power System (UPS):**
    - Battery Capacity: _____________ Watts/VA ______ Minutes
    - Generator Capacity: ___________ Watts/V/A ______ Hours fuel capacity
    - Testing/Maintenance Schedule Established:
    - Items powered by UPS
      - Radar Xmtr/Rcvr
      - Antenna Pedestal
      - Radar Data Comm.
      - Radar Workstation
      - Tower Warning Lights
      - Radar Air Conditioning
      - Security System
      - Other ___________________________

11. **Data Communications**

    Data communications capability will be required to get radar image data and control information back and forth between the radar and analysis locations.
    - Telcom service:

      Nearest connection point ______________________________

      Type of service ______________________
      (analog, ISDN, T1, E1, etc.)

      Data rate required/available ______________________________

      Interface required to connect to service ______________________________
    - Private microwave:

      Single hop or multi-hop ______________________________

      Obstructions in path ______________________________

      Multi-hop tower site locations ______________________________

      Rain fade potential ______________________________

      Radio interference ______________________________

      Data rates required/available ______________________________

      Interface required to connect to microwave ______________________________
    - Private fiber optic:

      Right-of-way for cable route ______________________________

      Interface required to connect to fiber optic ______________________________
    - Satellite data link:

      Antenna locations ______________________________

      Antenna look angles ______________________________

      Type of service required (SCPC, TDMA, etc.) ______________________________

      Data rates required/available ______________________________

      License requirements, restrictions ______________________________

      Rain fade potential ______________________________

12. Tower Grounding:
- Required ground resistance ______________ ohms
- Type of grounding system required:

13. Schedule:

5.13
CLOSED CAPTIONING AND EXTENDED SERVICES

AMNON M. SALOMON
GERALD FREDA
FALLS CHURCH, VA

INTRODUCTION

Closed captioning is the depiction of the audio portion of a television program as text displayed on a television screen with the aid of a decoder that may be internal or external to a television receiver. Closed, as opposed to open, captioning means that the captions do not normally appear as part of the broadcast television picture. The viewer must have the proper equipment and must select the captioning mode. Closed captioned programs are compatible with other programs in that the addition of the captioning signal does not interfere with the regular audio or video signals. Digital data to create captions are transmitted with the television program on line 21 in the vertical blanking interval (VBI).

Open captioning refers to captions that are transmitted as part of the picture rather than as a separate signal. Such captions are visible to all viewers (English subtitles in a foreign-language film.)

Captioned TV enables viewers to read the dialogue and narration of programs. The technique provides access to the entertainment, educational, and informational benefits of television for viewers who are hearing impaired. Other audiences can use captioning as well, including people learning English as a second language.

The captions produced by the closed captioning system generally appear in the lower portion of the television screen. The size of the characters varies in proportion to the size of the television screen. On a 19 in. screen, for example, they are about 1/2 in. high. The captions are easily visible—typically white letters against a black background—and usually do not obstruct essential parts of the picture (see Figure 5.13-1).

Closed captioning may be added in real time to a live program or it may be added later as part of post production or distribution. It may be done in-house or by a captioning service.

A Brief History of Closed Captioning

Closed captioned television technology was developed by the Public Broadcasting Service (PBS) during the period 1973–1979 with funding support from the Federal Government (Department of Health, Education and Welfare). Field test transmissions were conducted on all aspects of caption generation, encoding, decoding and display features of the service. PBS and others provided captioning services for several years after approval of the system by the FCC in 1976.

Figure 5.13-1. Digital closed caption data on video line 21 are processed by a decoder and displayed as text across the lower portion of the picture. (Courtesy of ABC News and the National Captioning Institute).

The closed captioning service was launched in March 1980 by the newly created National Captioning Institute (NCI), in cooperation with the ABC, NBC, and PBS networks, with 16 hours per week of captioned programming. The first consumer product containing the decoding feature, called *TeleCaption*®, was sold by Sears, Roebuck and Co.

The original target audience for captioning included hearing impaired people (about 20 million). The market has since expanded to include people learning English as a second language and those learning to read, especially students with reading disabilities.

FCC STANDARD

The line 21 captioning data signal is protected from interference from any other VBI service, test signal or spillover from active video under FCC Rules and Regulations, Section 73.682(a)(22), adopted in 1976. These rules also established the transmission standards for captioning and list the uses of the data channel.

Following are excerpts from rules associated with the Television Decoder Circuitry Act of 1990 that amended Part 15 of the FCC Rules (Radio Frequency Devices, which relate to television receivers).

Television Decoder Circuitry Act of 1990

The U.S. Congress passed the *Television Decoder Circuitry Act of 1990* (Pub. L. 101-431, 104 Stat. 960 (1990)). This act required that, effective July 1, 1993, all television receivers with picture screens 13 in. or greater must be equipped to display closed-captioned television transmission.

Excerpts from FCC Report and Order

General Docket 91-1*: In the Matter of Amendment of Part 15 of the Commission's rules to implement the Provisions of the Television Decoder Circuitry Act of 1990.* The Order was adopted April 12, 1991 and released to the public on April 15, 1991. The Order became effective July 1, 1993.

The Order amends Part 15 of the FCC's Rules. A new section 15.119 was added to read as follows:

Section 15.119 Closed Caption Decoder Requirements for Television Receivers.

(a) *Effective Date.* Effective July 1, 1993, all TV broadcast receivers with picture screens 13 inches or larger in diameter shipped in interstate commerce, manufactured, assembled, or imported from any foreign country into the United States shall comply with the provisions of this section.

(b) *Transmission Format.* Closed caption information is transmitted on line 21 of field 1 of the vertical blanking interval of television signals, in accordance with Section 73.682(a)(22) of this Chapter.

(c) *Operating Modes.* The television receiver will employ customer-selectable modes of *TV* and *Caption*. A third mode of operation, *Text*, may be included on an optional basis. The Caption and Text Modes may contain data in either of two operating channels, referred to in this document as C1 and C2. The television receiver must decode both C1 and C2 captioning, and must display the captioning for whichever channel the user selects. The TV Mode of operation allows the video to be viewed in its original form. The Caption and Text Modes define one or more areas (called "boxes") on the screen within which caption or text characters are displayed. . . .

(d) *Screen Format.* The display area for captioning and text shall fall within the SAFE TITLE AREA as defined by SMPTE Recommended Practice #27.3—1989. This display area will be further divided into 15 character rows of equal height and 32 columns of equal width, to provide accurate placement of text on the screen. Vertically, the display area begins on line 43 and is 195 lines high, ending on line 237 on an interlaced display. All captioning and text shall fall within these established columns and rows. The characters must be displayed clearly separated from the video over which they are placed. In addition, the user must have the capability to select a black background over which the captioned letters are displayed.

(l) *Compatibility with Cable Security Systems.* Certain cable television security techniques, such as signal encryption and copy protection, can alter the television signal so that some methods of finding line 21 will not work. In particular, counting of lines or timing from the start of the vertical blanking interval may cause problems. Caption decoding circuitry must function properly when receiving signals from any cable security system that was designed and marketed prior to April 5, 1991. Further information concerning such systems is available from the National Cable Television Association, Inc., Washington, DC, and from the Electronic Industries Association, Washington, DC.

(m) *Labeling and Consumer Information Requirements.* The box or other package in which the individual television receiver is to be marketed shall carry a statement in a prominent location, visible to the buyer before purchase, which reads as follows:

This television receiver provides display of television closed captioning in accordance with Section 15.119 of the FCC rules.

Receivers that do not support color attributes or text mode, as well as receivers that display only uppercase characters . . . must include with the statement, and in the owner's manual, language indicating that those features are not supported.

The complete text of the FCC *Report and Order* may be obtained from the U.S. Government Printing Office. The text was also published in the *Federal Register* Vol. 56, No. 114, p.27200. The FCC Rules & Regulations are contained in the *Code of Federal Regulations*, Part 47, Telecommunications. See Chapter 1.7, *Broadcast Standards* and *Recommended Practices*, for information on contacting the U.S. Government Printing Office and other organizations mentioned in this chapter.

Update Since Passage of Decoder Circuitry Act

Since the passage of the decoder circuitry act, several additions have been ruled by the FCC. These additions are documented with other technical details in a document titled *Recommended Practice for Line 21 Data Services* (EIA 608). This document can be obtained from the Electronic Industries Association, Engineering Department. A modest charge will be assessed for this document by Global Engineering Documents.

The regulation and use of line 21 for captioning has been expanded to include both fields. Additional features have been added to deal with additional languages. Within Field 2 is a capacity to deliver additional captioning services (C3, C4, T3, T4) in addition to extended data services (XDS). XDS includes but is not limited to content advisory (V-chip), Time of Day and source of transmission.

In June 1997, the next generation of closed captioning was adopted. This new standard (EIA708) will enable improved closed captioning to exist within digital television (including High Definition Television) while continuing to provide a method of delivering captions to analog sets via EIA608. The next generation caption system provides but is not limited to an improved appearance for captions, greater capability to provide multiple languages for a single program and greater user control (ability to select character size). The new standard was developed by an industry group made up of caption service providers, receiver manufacturers and encoder manufacturers.

Display Format

The line 21 captioning system has two independent channels, C1 and C2, each of which contains a captioning subchannel and a text subchannel. Caption data for most programming are carried in channel one, leaving channel two available for other applications such as caption data for another language. The captioning channel can operate in either of two different modes, *pop-on* and *roll-up*. Within each of these modes, *paint-on* can also be used.

The pop-on mode is used when the captions are prerecorded. Captions are loaded in advance of the time they are to appear and are displayed on command. While the caption in the first memory is displayed, a second memory may be loaded with the next caption for display upon the next command, and soon, alternately loading and displaying memories.

The roll-up mode is used for real time captioning. From one to four rows at the bottom of the screen display the real time captions with the text moving from bottom row upwards to the top-most of the 4 rows after which the text is erased. The roll-up mode distinguishes the captions as being real time.

The paint-on mode is currently used within the text service. The text is displayed as it is received from left to right beginning at the top of the screen and working down to row 15 after which the text scrolls up.

Captions and text may have any of several attributes in addition to block monochrome characters. Attributes include upper and lower case, six different colors, italics (or slanted text), underline, and flash. Attributes are determined by the editor at the time of encoding the captions and text.

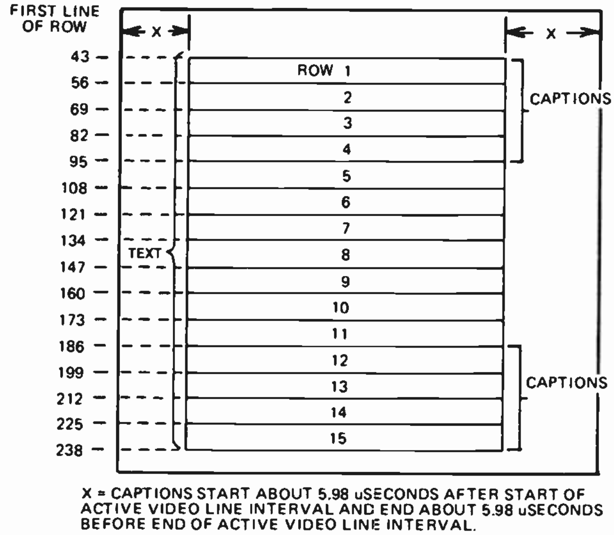

Figure 5.13-2. Caption row positions.

The caption display on the television screen consists of 15 rows with up to 32 characters per row as shown in Figure 5.13-2. A switch in the decoder permits the viewer to select captions or text. In the captioning mode, a maximum of four rows is used onto which each caption pops-on when prerecorded captions are received and rolls-up when the captions are live. The four rows can appear anywhere on the 15 displayable rows which occupy most of the screen area.

The first row starts at line 43 in each field. Each row occupies 13 lines of a field scan or 26 lines of the 525 lines. When the decoder is in the text mode the screen is nearly covered by the 15 rows of text, which scroll upward.

Each row of characters is displayed within a black surround box to enhance the readability against the normal video background. The box extends one character position to the left of the initial character in each row and one character to the right of each row. Partial or segmented rows also conform to this black box surround.

CAPTION DATA ENCODERS

Encoding is the process of inserting the caption data into the VBI of the television signal. The data contains the caption text in addition to positional instructions and display attributes (color and italics). The encoder is placed in the video path of the program to be captioned. There are two versions of the line 21 VBI encoder *smart encoder* and *simple encoder*.

Smart Encoder

The smart encoder is used to insert caption data into line 21 of fields 1 or 2 of the VBI. The smart encoder receives data through an RS-232 serial data port or via telephone line from an internal modem. Through the use of the smart encoder, locally produced caption and text services may be added to an already closed-captioned video program or if noncaption text is contained on line 21 (see block diagram of smart encoder in Figure 5.13-3). If captions are present on the incoming program, noncaption text may be interleaved into the gaps between the captions by the smart encoder.

Smart encoders are used in the process of creating real time captions, live display captions and captions from newsroom computers (prompters).

Simple Encoder

The simple encoder generates the line 21 data signal, to be inserted on a video signal, from caption data received at the RS-232 serial input. This encoder is used mainly for offline or prerecorded captions. The simple encoder cannot add captions to a video signal already containing line 21 data.

To create the line 21 caption signal, after the editor has produced the captions and they are stored in the computer, the videotape with program video and time code information is fed through the simple encoder (see block diagram of simple encoder in Figure 5.13-4). The time code information is used by the encoder to trigger the transfer of data (captions) from the captioning computer. The special software in the computer processes the data and matches each caption

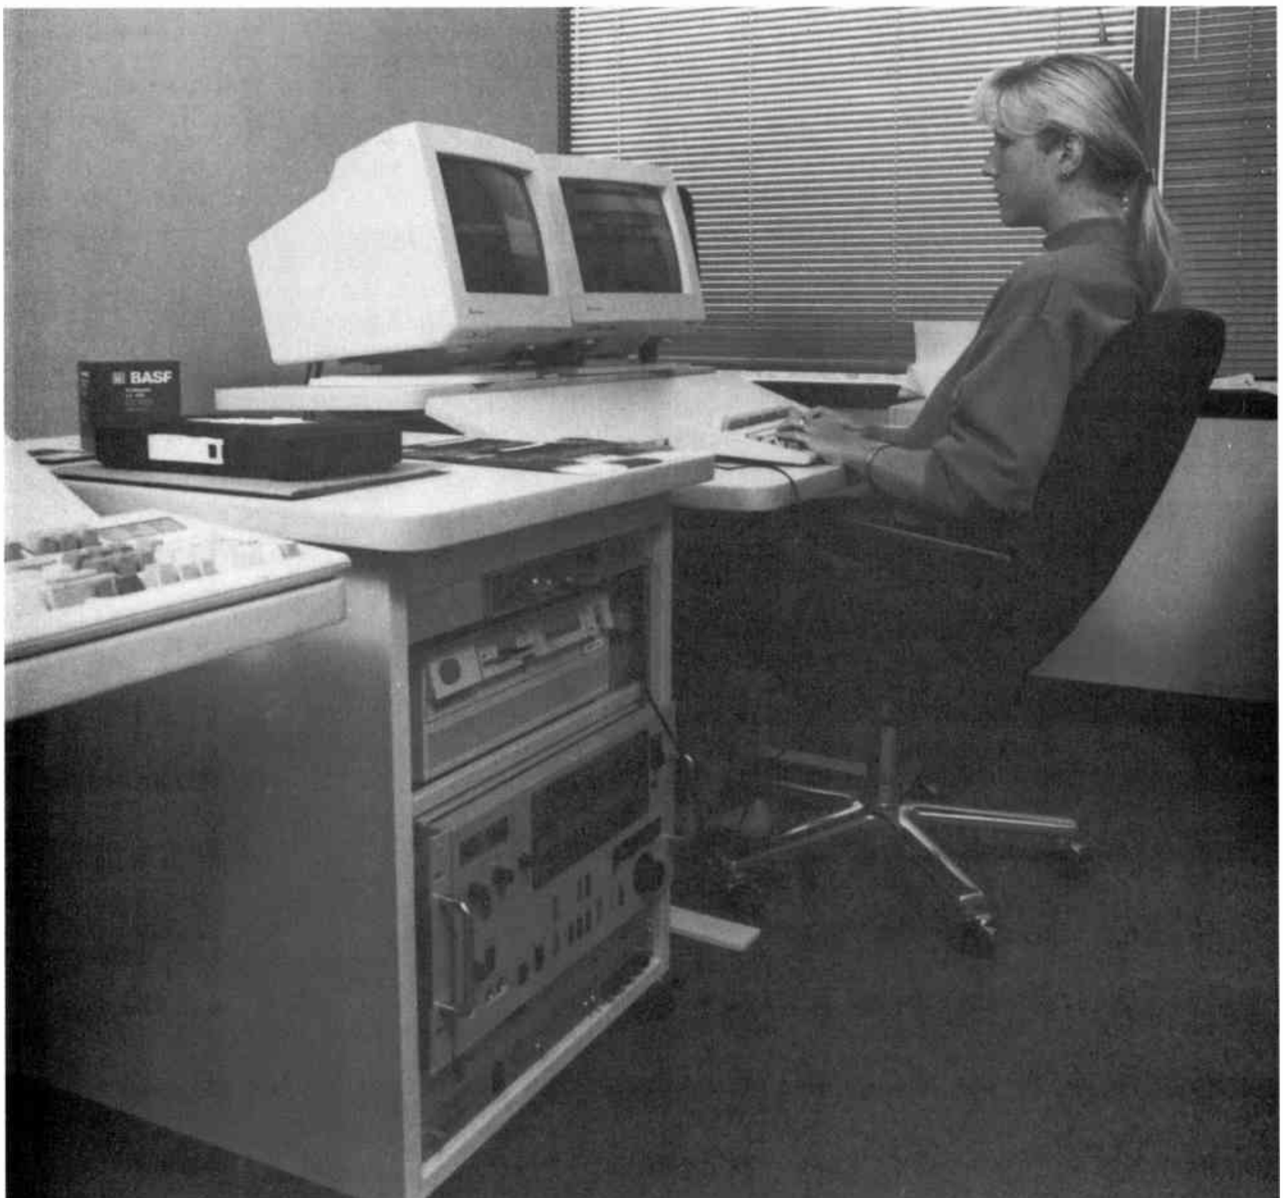

Figure 5.13-3. Captioning prerecorded materials is done by an editor working at a standard computer keyboard. (Courtesy of National Captioning Institute.)

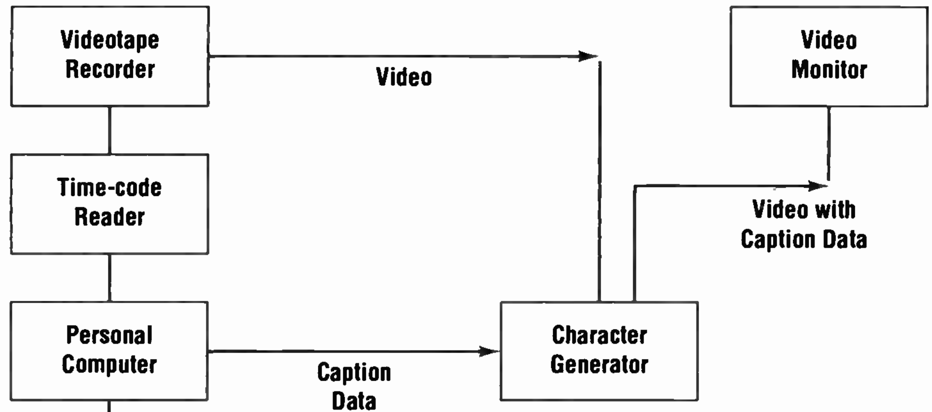
Figure 5.13-4. Off-line captioning system. Caption creation.



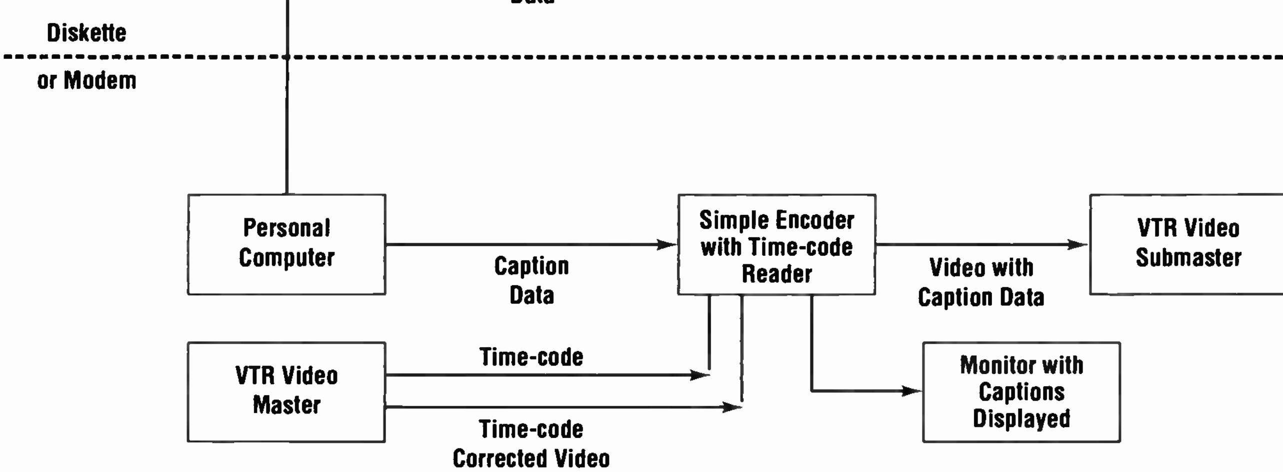


Figure 5.13-5. Off-line captioning system. Caption encoding.

to the appropriate time code. A microprocessor in the encoder processes the RS-232 data and encodes two characters of caption data onto each field 1 of line 21 of the program video. The output of the encoder may then be recorded on a second videotape recorder for playback at a later time.

Digital Encoders

In 1996, encoder manufacturers produced a new line of encoders to deal with analog and digital broadcasts.

METHODS OF CREATING CAPTION DATA

Several techniques are employed to create caption data based on whether the broadcast is live or prerecorded. There are also variations within the live and prerecorded captioning technologies.

Prerecorded Captioning

Prerecorded captioning (offline or nonlive captioning) involves the preparation of closed captions for programs that have been recorded prior to their telecast. The captions are also created in advance, and a closed captioned videotape version of the program is made. There are several steps in this process.

A captioning facility receives a time coded videotape copy of a program master. A caption editor reviews each scene, listens to the spoken words, and types the captions using a standard keyboard on a personal computer (PC) (see Figure 5.13-3). Several quality control checks are performed, including spelling, grammar, syntax, timing, and screen positioning of the captions. The captions are then stored with their corresponding time codes on a diskette. Figure 5.13-4 shows a block diagram of a captioning facility.

The recorded program and data from the diskette are then merged, using the time codes to trigger the captions, to produce a closed captioned submaster videotape recording, with the captions encoded on line 21 (see Figure 5.13-5). The encoded version of the program is returned to the producer and is used when the program is aired.

Captions which are produced in advance are displayed on a caption equipped receiver as pop-on captions, each one complete and timed to coincide with the spoken dialogue on the screen.

The equipment necessary for creating prerecorded or offline captions includes:

- PC with caption creation software
- Video monitor
- Audio monitor
- Character generator
- Time code reader
- Videotape player
- Simple caption encoder
- Videotape recorder

Using this equipment, the caption editor can view the program, listen to the audio, enter the captions along with the appropriate timing and placement information and review the program as it would appear through a decoder. It takes approximately 20–25 staff hours to caption one hour of television programming.

Live Captioning

Live captioning involves the addition of caption data to the television signal at the time of a live transmission or broadcast. Examples of live captioned programming include news programs, sporting events, news conferences and special bulletins or reports. There are three versions of live captioning.

Real Time Captions

For *real time captions*, a specially trained caption editor listens to the audio of a live television program and, using a stenotype machine similar to the ones used by court reporters, keys in words using a special shorthand code corresponding to syllables or phonetic codes (see Figure 5.13-6). Instead of keying in individual letters, groups of keys can be pressed down simultaneously. Each group of keys, a stroke, produces different phonetics. Using this kind of machine saves time, since a word such as *institute* may be keyed in using just three strokes (one for each syllable) rather than nine (one for each letter).

With a stenotype machine, the real time caption editor can key in up to 260 words per minute. The phonetic codes are translated into English words by the captioning computer which has been programmed with the phonetic codes and caption editor dictionary (see Figure 5.13-7). From the computer, the words and caption control codes are sent via a data circuit to

Figure 5.13-6. Real-time captioning is done by an operator using a stenotype keyboard similar to those used by court reporters (Courtesy of National Captioning Institute).

Figure 5.13-7. Live captioning system. Caption creation.

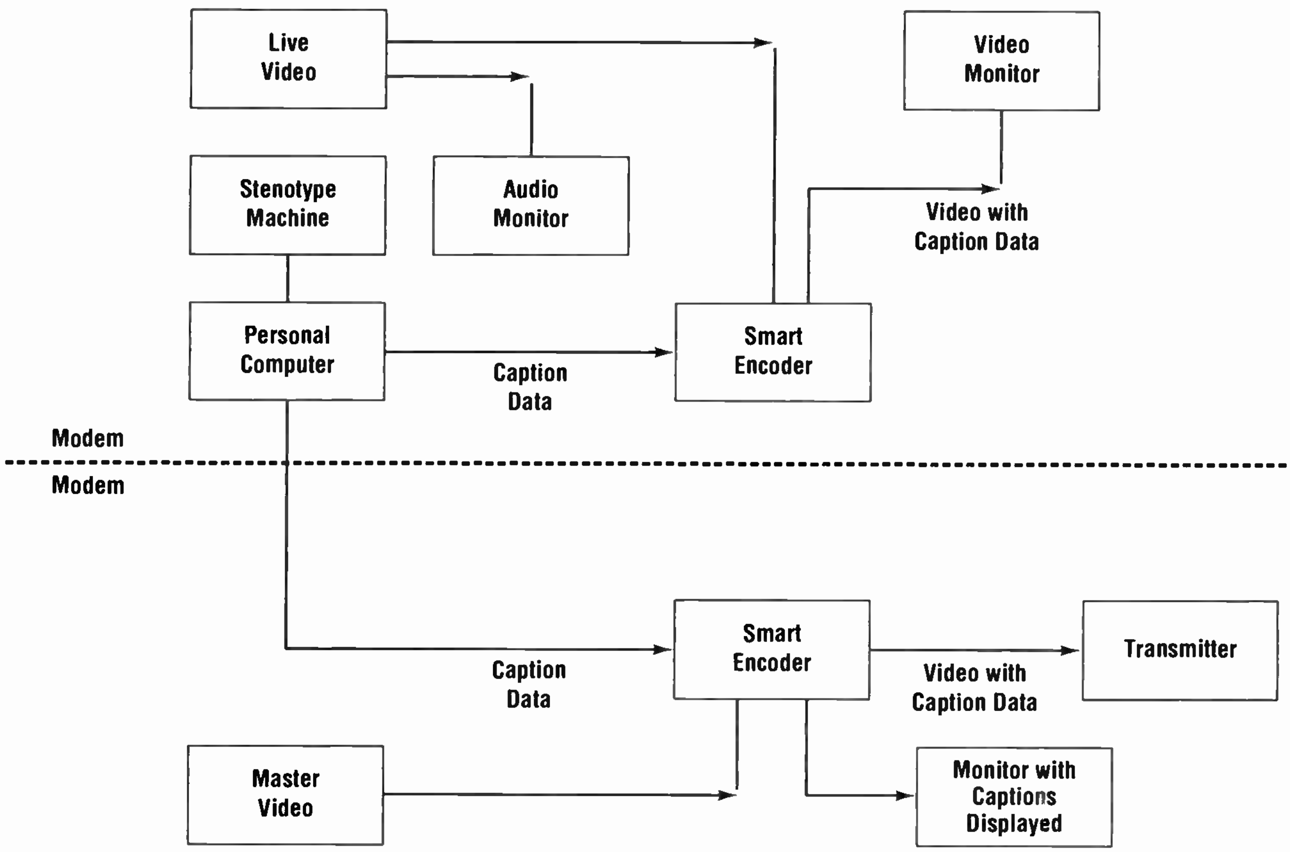

Figure 5.13-8. Live captioning system. Caption encoding.

a caption encoder where they are encoded into the television signal on line 21 as real time, or roll-up captions (see Figure 5.13-8). A television receiver with a decoder then displays these words as part of a continuous multi-line (1 to 4 lines) scroll (caption) at the lower portion of the television screen. It takes up to three seconds from the time a word is spoken to the time it appears on the screen as a caption.

Newscasters often speak faster than the captions can appear on the TV screen and may occur faster than the viewer can read. To keep up with what is being said, and to control the display rate, the real time caption editor must, at times, edit words or delete phrases. The real time caption editor must also realize that the computer dictionary may not contain a particular spoken word, and substitute a different word, one the computer will understand and at the same time convey the meaning to the caption viewer. Alternatively, if the computer does not have the word, the captions are transmitted as phonetically spelled out.

The equipment needed for creating and monitoring real time captions includes:

- Special stenotype machine
- Personal computer with translation software
- Video monitor
- Audio monitor
- Smart caption encoder
- Live video program signal on which line 21 will be encoded with the captioning signal

The real time captioning equipment need not be located where the live program is taking place. It is only necessary for the caption editor to hear and see the live program material (even over-the-air) and, using the stenotype machine, enter the captions into the captioning computer. The computer transmits the data through a modem to the caption encoder which must be placed in the program line of the live video signal to be captioned. Thus, any live program may be captioned as long as the caption editor has access to the live program audio signal and a caption encoder is in the live program circuit. Of course, it is desirable to be able to see the results of the captioning process and the same over-the-air signal can be used for the monitor.

For real time captioning of programs which may not be broadcast at the time of captioning or for which an over-the-air signal is not available, a microwave feed of the encoded signal may be used as the program monitor.

Because of the investment required for a captioning

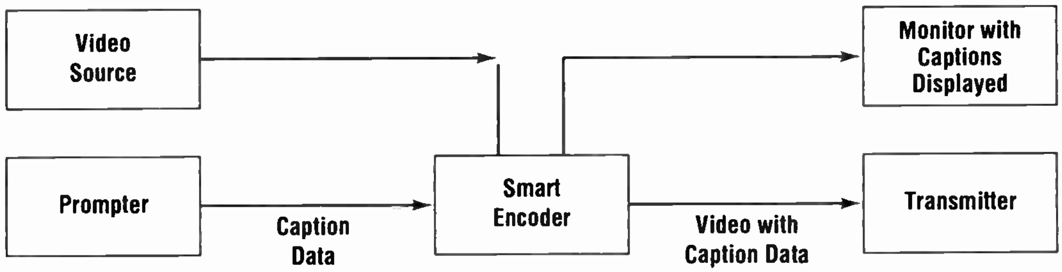

Figure 5.13-9. Captioning in an electronic newsroom.

facility and the high level of skill needed by the real time caption editor, stations and production facilities may find it more practical to employ the services of a captioning agency where captioning equipment and personnel are more readily available and the cost is based on an hourly basis.

Live Display Captions

Live display captioning is used when an accurate script is available in advance of a televised live event such as a speech or newscast. The scripted words are converted to captions by an editor and stored on a computer disk. When the live event is televised, the editor manually calls (triggers) each caption from the disk which is then processed by the computer and transmits the data to a caption encoder. The editor transmits a display command when each caption is to be displayed. With live display captioning, the words are timed to appear on the television receiver as they are being spoken. If last minute changes are made in the script it may be necessary to switch to real time captioning.

Newsroom Computer Captions

The third method of live captioning is the generation of captions through the use of newsroom computer equipment. Many television newsrooms convert news stories from their word processors into data for use on a prompting machine for the news reporter to read while on-the-air. At the same time the reporter reads the script from the prompter, the computer controlling the prompter passes the data through a serial interface to a caption encoder, through which the live program signal passes, that inserts the captions into line 21 of the video signal (see Figure 5.13-9). The result is the scroll or roll-up display on the viewer's screen.

There are some dangers in this process. It is not as automatic as might be assumed. Some newsrooms add cues to the prompting text designed for the on-air personnel, some of which might be inappropriate to appear as captions. Program breaks or changes of scene may require changes in the prompting operation that could interrupt the captioning process. Also, it is desirable for the operators and program producers to have an off-air monitor to insure the integrity of the captioning process. Finally, it may be necessary for an operator to signal the captioning encoder to add captions at the beginning of the local program and to revert to the pass through mode at the end.

The equipment needed for electronic newsroom captioning includes:

- Prompting system with data output
- Captioning software for the prompting system
- Smart caption encoder

Automated Live Encoding

When production schedules are tight, an alternate means of producing a captioned submaster is available. *Automatic live caption encoding* makes use of the same caption creation techniques used in prerecorded captioning, but a different method is used to trigger the data into line 21 of the television signal. Figure 5.13-10 shows a block diagram of the system. In this case, the captioned data are loaded into the PC and the internal clock within the PC is used to trigger the captions as opposed to using time-code from the program videotape. A manual trigger is used to start the transmission of data between the PC and the smart encoder.

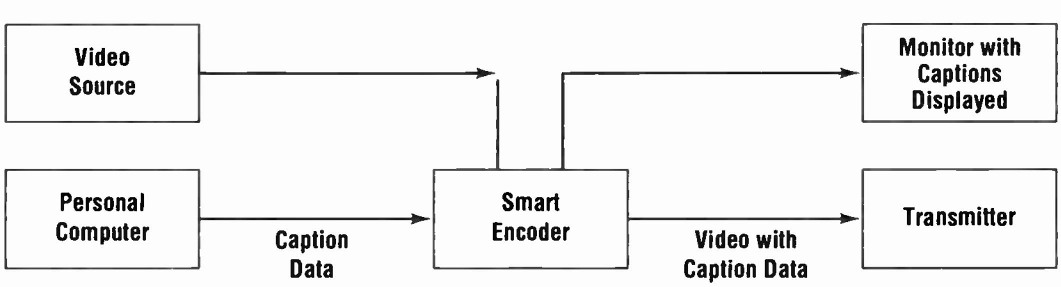

Figure 5.13-10. Block diagram of an automatic live encoding system.

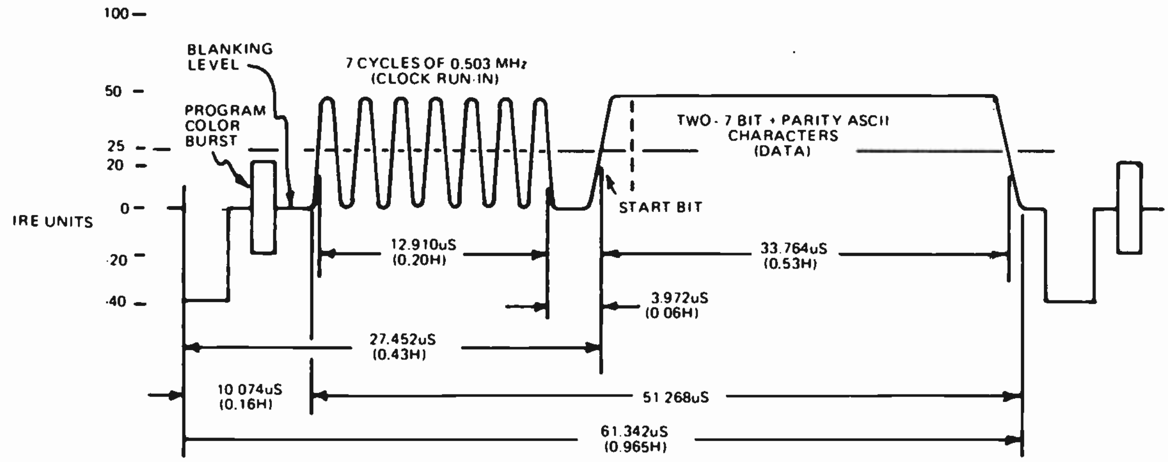

Figure 5.13-11. Line 21 field 1 data signal format.

The display of automatic live caption encoding on the television receiver is the pop-up display mode, the same as used for prerecorded captions.

Text Service

Information transmitted as part of the text service is usually independent of the program with which it is transmitted. Captions do not use all the available data capacity of the line 21 captioning system, and the additional capacity may be used to transmit nonprogram related information to the television viewer. Such text may consist of program notes, news, weather, sports, farm and financial reports and other information. Unlike the captions, the text service appears as full screen rolling text (without pictures) on the television screen.

The text service is accessed in the decoder by a switch that selects either captioning or text. There are two text channels for each field. Field 1 includes T1 and T2. Field 2 provides T3 and T4.

The data rate of the text service is quite low compared to the data rates of various teletext services that have been proposed for use in the United States and is in widespread use in Europe. The text may pause occasionally when the higher priority captions are being transmitted.

The equipment necessary for creation of a line 21 text service includes:

- a personal computer with appropriate text generation software
- an information source
- a smart encoder along with appropriate monitors

The text service can, under certain conditions, operate completely unattended if desired.

DATA TRANSMISSION FORMAT

Captions associated with a television program are transmitted as an encoded composite data signal during line 21 on field 1 of the standard NTSC video signal shown in Figure 5.13-11. The signal consists of a clock run-in signal, a start bit, and 16 bits of data corresponding to two bytes of 8 bits each (7 bit ASCII code plus one parity bit). Therefore, transmission of actual data is 16 bits every 1/30 of a second or 480 bps. The data stream also contains encoded information (control codes) which provides the instructions for formatting and changing the attributes of the characters to be displayed.

The clock run-in consists of a seven-cycle sinusoidal burst which is frequency and phase locked to the caption data clock. The frequency of 32 f_H (0.503496 MHz $= 32 \times 15{,}734.26$ Hz), which is twice that of the data clock, provides synchronization for the decoder clock. The clock run-in signal is followed by the equivalent of two data bits at logical zero level, then a logical one start bit. The last two cycles of the clock run-in, the two logical zero bits, and the logical one start bit constitute an 8 bit frame code signifying the start of data as shown in Figure 5.13-12.

The 7 bit ASCII transmitted data are coded in a nonreturn-to-zero (NRZ) format. An 8th bit is added to each character to provide odd parity for error detection.

The sequence of identification, control, and character code transmission is shown in Figure 5.13-13 and 5.13-14. Each caption transmission is preceded by a preamble code, which consists of a nonprinting character followed by a printing character to form a row address and display color code. Both characters of all control codes are transmitted within the same field of line 21 and twice in succession to ensure correct reception of control information. A transmitted caption may be interrupted by a mid-caption control code between two words in order to change display attributes such as color or italics. At the completion of a caption transmission, an end of caption control code is sent.

The first character of a control code is a nonprinting ASCII character (0000000 through 0011111). Codes 0000000 through 0010000 are not used. This is followed by a printing character (0100000 through

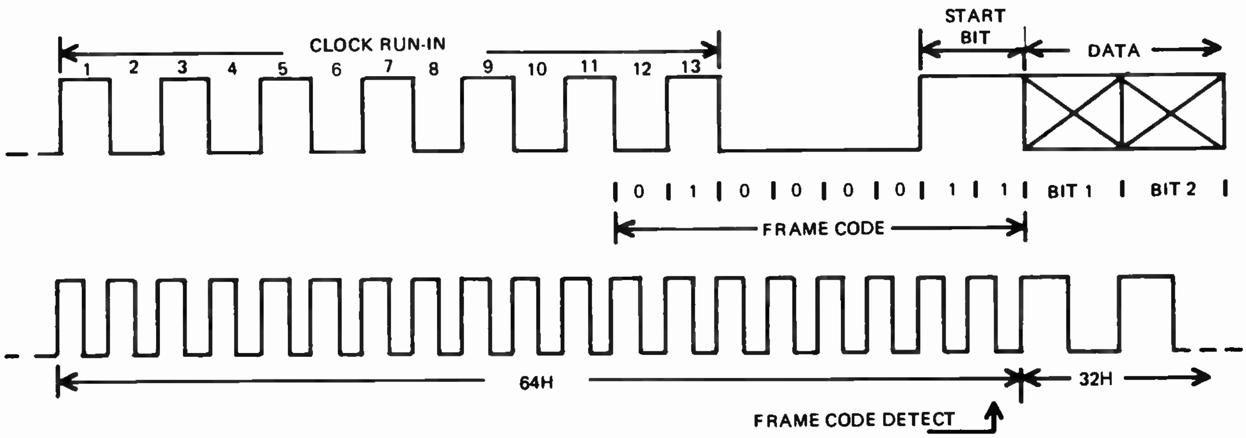

Figure 5.13-12. Line 21 data.

1111110). All characters that are received after a set of valid control codes are interpreted and loaded into the decoder memory as printing characters. Character codes with bad parity result in an all ones code being written into memory; this causes display of a white box (the delete symbol) in place of the desired character which, of course, was in error.

The data rate is 480 bps (8 bits per byte including parity). At an average of 5 bytes or letters per word, a maximum word rate of 12 words per second or 720 words per minute could be achieved. In practice, the word rate is somewhat less than this, about 600 per minute, due to the time required for transmission of control codes. Because most speech is much slower than this, there is adequate time for a second captioning channel and a text service.

LINE 21 TECHNICAL ADVISORY

Special precautions must be undertaken to ensure the continuous and correct passage of the line 21 signal throughout the facility. Unless a station is actively involved in producing captioned program materials, the line 21 signals may not normally be monitored at a television facility to the same extent as the video and audio signals. With the passage of the *Decoder Circuitry Act*, millions of caption receivers will be in use within a few years. Therefore, it is prudent for stations to install captioning monitoring facilities and to routinely check the path of the line 21 signal.

The captioning data signal is contained in the NTSC television signal VBI on line 21, field 1 (field 2 is not normally used for captioning but could be used for

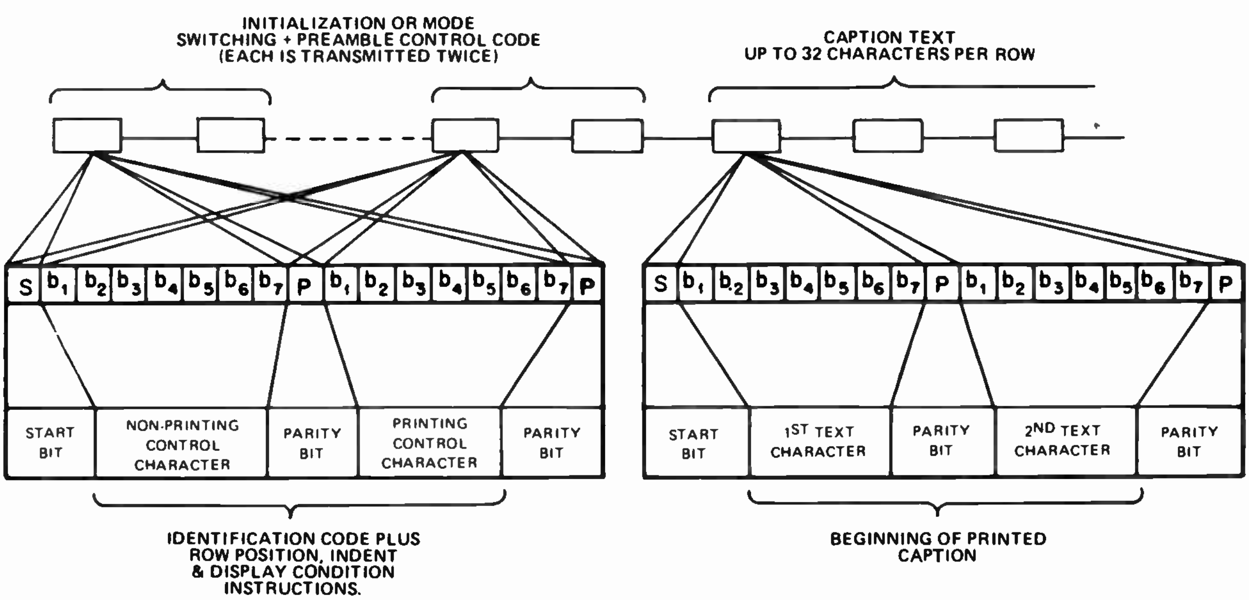

Figure 5.13-13. Caption row preamble format.

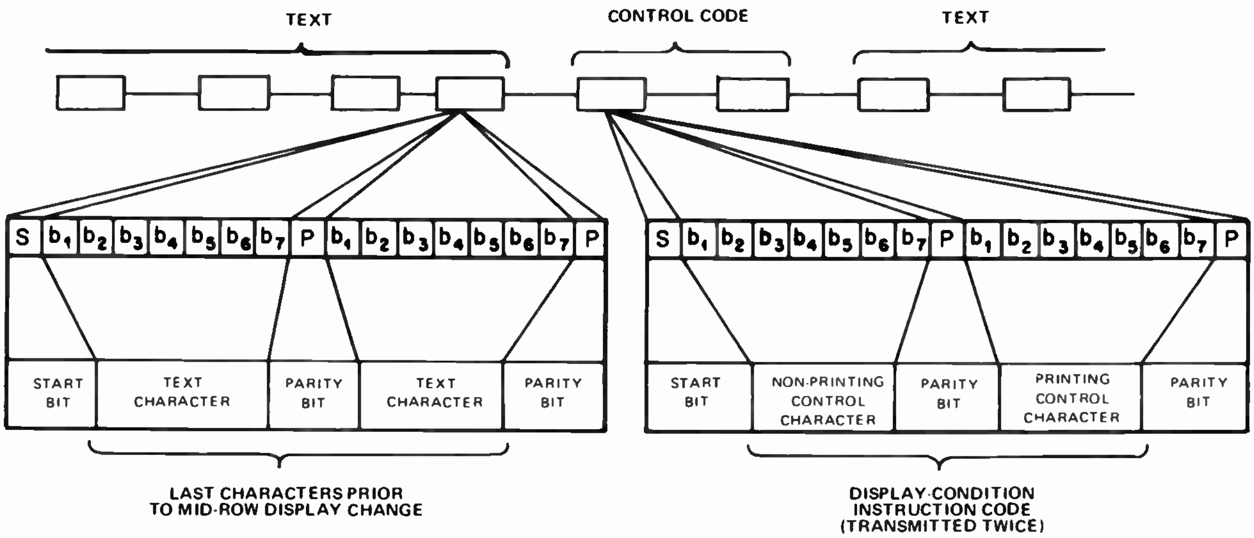

Figure 5.13-14. Mid-caption display. Condition change format.

text and signalling data). Unless the caption data signal is transmitted intact and on line 21, field 1, a viewer's decoding circuitry will not operate properly.

The captioning signal waveform is detailed in Section 73.682(a)(22) and Figure 17 of Section 73.699 of Part 73, Subpart E of the FCC Rules and Regulations and conforms to the standard television synchronizing waveform for color transmission given in Figure 5.13-6 of Section 73.699.

The captioning data signal is a part of the television program, compared to vertical interval test signals which are not. Regular observation and monitoring is essential in order to verify the presence and proper location of the data signal. Equipment throughout a video facility should be routinely checked and, if necessary, adjusted to pass the line 21, caption data signal.

Maintenance personnel as well as control room operators should be made aware of the importance of the line 21 signal and adjust all applicable equipment accordingly.

The following video processing equipment may adversely affect the line 21 signal:

- **Video processing amplifiers.** Certain types may delete the line 21 signal, move it to another line, exchange the fields or partially blank the signal.
- **Time base correctors (TBC).** Some may blank the line 21 signal or advance or delay line 21 by a field or a line.
- **Videotape machines.** Certain types contain a TBC which may blank or move line 21.
- **Video switchers or digital store devices.** May blank or move the line 21 signal.
- **Frame store or frame synchronizers.** May blank or distort the line 21 signal.
- **VITS generators or inserters.** Should be checked to determine if they are programmed to pass the line 21 signal correctly.
- **Digital effects generators.** May delete or distort the line 21 data signal.

A waveform monitor with line select capability is required to view the line 21 caption data to determine that it is on the correct line and field. For example, a Tektronix 1480 series; VM 700A, 1700 Series, 1780R, or Hewlett-Packard equivalent with line selector will easily locate and display the signal.

The line 21, field 1 data signal may be partially, but inadvertently, blanked. This can occur when the active video line is advanced or delayed relative to horizontal sync. The decoding system is more tolerant of this problem when the data signal is early and causes part of the clock run-in sinusoidal burst to be blanked. On the other hand, if the data signal is delayed relative to horizontal sync, loss of the last data bit (parity bit) may occur producing decoding errors which in turn will cause the characters to be displayed as white boxes. In an extreme case, too many errors will cause the decoder to disable all closed captioning functions.

Some video processing amplifiers have sensitive vertical phase blanking and horizontal blanking controls. These may also adversely affect the line 21 signal.

Video processing amplifiers are frequently used in the following configurations:

- Output of a satellite receiver
- Input or output of an intercity relay link (ICR)
- Input or output of a studio-to-transmitter link (STL)
- Input to a transmitter
- Input to a videotape machine
- Output of a studio or master control switcher
- Remote truck video processor
- Utility proc amp (equipment racks)
- Maintenance shop test equipment

All signal paths, backup transmitters and their VITS generators and processing amplifiers, and tape-delayed broadcast installations should also be routinely checked to insure passage of the line 21 signal.

It is important to note that if the overall signal level is allowed to drop substantially below the normal 50 IRE level, captions could become garbled.

Special Cautionary Notes

Locally Originated Captioning

Programs and commercials prior to, during, and after locally originated captioned programs may also be closed captioned. Therefore, the local smart encoder must be disabled, preventing pass-through, until the completion of a network telecast. The encoder must be enabled immediately following the locally captioned program to avoid stripping line 21 data from network programs which follow and pass through the caption data.

Newsroom Computers

Newsroom computer captioning typically uses the smart encoder in a newswire/real time mode. When this mode is invoked, incoming line 21 data are automatically turned off, preventing any previously recorded caption information from being passed through and displayed. The newswire/real time mode must be properly exited at the conclusion of local live captioning by issuing an *end of message* command to restore or enable the line 21 data.

Other systems may use the smart encoder pass-through mode rather than the newswire/real time mode. Pass-through offers more complete control of encoder and decoder functions. In this mode, incoming line 21 data can be specifically turned off and must be specifically turned back on (enabled) to allow line 21 caption information passing through the smart encoder to be displayed. The encoder must be specifically issued an enable command to turn on line 21.

A smart encoder reset command will always return the encoder to the default enabled condition but will delete any user stored articles, such as text channel information.

Network Origination/Local Origination

If a local station uses the master control routing switcher for signal distribution during a program originating from the network and then switches to local origination and a studio controller prior to the end of the network feed, the line 21 signal should be checked to insure its integrity.

Using Captioned Excerpts

Excerpts of programs, received or recorded off-air or from external satellite or network feeds, for use in other programming, may contain line 21 closed captions. In these cases, the captions should be stripped if the excerpted material audio will be edited or replaced because the captions may no longer be germane. A time base corrector or video processing amplifier can be used to remove or move the caption data signal from line 21.

Broadcast Decoder

In addition to consumer models, a professional broadcast type decoder is available for stations to use to monitor the line 21 data signal on the network, videotape machines, or the broadcast signal. The broadcast model accepts a standard video signal with captioning data on line 21 and produces a video output with the captioning data decoded and, using an internal character generator, displays the data as open captions on a standard video monitor.

Many stations have also installed Telecommunication Devices for the Deaf (TDD) in order to communicate with the hearing impaired television viewers.

Emergency Messages

Broadcasters which elect to transmit emergency messages are required to provide a readable version of the aural emergency message in order to inform hearing impaired viewers of impending weather or other emergencies (see Section 73.1250(h) of the FCC Rules). One means of doing this is to insert a moving line of words (crawl) with the message across the lower portion of the screen. If a program, over which the message is superimposed, is captioned the lower portion of the viewer's screen may be covered with the captions and the emergency message may become obscured or unreadable. Therefore, procedures should be established to stop or interrupt the captions or text transmission during the emergency message or to incorporate the message into the captions or text material.

Passage Through Other Distribution Systems

The line 21 captioning signal was designed to be robust and able to withstand a significant amount of degradation before errors appear in the text. The low data rate and placement of the signal at the very beginning of the active portion video of the signal contributes to this robustness. As a direct result, the captioning data signal will easily pass through:

- Master antenna (MATV) systems
- Community antenna (CATV) systems
- Satellite circuits and receivers
- Translators, multipoint distribution systems (MDS) and multichannel multipoint distribution systems (MMDS)
- Set-top converters (RF and baseband)
- Consumer video cassette recorders (VCR)

Most set-top receiving converters have outputs on channel 2, 3, or 4. A stand alone captioning decoder can be inserted between virtually any converter and any television receiver with little degradation to picture and sound quality.

5.14
FILM FOR TELEVISION

RICHARD W. BAUER
CONSULTANT, ROCHESTER, NY

INTRODUCTION

Until the development of the quadraplex videotape recorder in the 1950's, film was the only medium for recording television productions. Film was the primary distribution medium for the delivery of syndicated television programs to the local broadcaster for many years. It was used for news gathering and broadcast and local TV stations maintained large film libraries. The major network broadcast centers used *kinescope* recording systems and even some local stations had film processing facilities. The use of kinescope recorders to record TV images on film, broadcast telecines and videofilm news gathering are now of mostly historical interest. Direct broadcast of film is not common practice today but film still retains its important place in the origination of broadcast images.

To many broadcast engineers, the use of film in the broadcast studio is almost unheard of today. In the U.S., most film chains have been removed from the local facility. Film libraries, film projectors and film processing equipment are no longer in use. Although the presence of film and film related equipment is not obvious in the local TV studio, the images produced on film are still very important to the broadcaster and telecines are still in use at the network broadcast centers and in some of the larger facilities elsewhere.

The close relationship between film and television goes back than 50 years and it continues to grow as new films and new electronics continue to be developed. The motion picture industry supplied feature films for TV programs as well as camera people, craftsmen and technicians and this close association still exists today. In the early growth years of television broadcasting, the use of film for kinescope recordings allowed for the broadcast of programs on both coasts, for delayed broadcasting and for the distribution of programming worldwide. For example, programs originating in New York were kinescoped and the film was immediately flown to the other cities or other broadcast centers for broadcast. The electronic/photographic systems used produced poor quality images and, because of the very rushed nature of the work along with poor processing control and film handling techniques, a less than desirable end product was produced. The quality level of the various components of the system (CRT, film, film processing equipment, personnel) was not conducive to providing the image quality seen in the movie theaters or on TV from live broadcasts. This, however, was the only means of providing images for delayed broadcast and distribution. Now quadraplex recorders, trinoscopes and broadcast telecines are of more historical interest rather than day to day operations. The local broadcaster no longer needs to maintain a film library, broadcast telecine or other film related peripherals.

The use of film for kinescope recordings caused many broadcast people to denigrate film and its fuzzy, grainy image. These feelings were well founded as far as the finished *kine* was concerned but the criticisms were somewhat misdirected at only the film. Film manufacturers made film for the motion picture industry, not for the fledgling TV industry. However, as TV grew the film and television engineers worked closely to develop systems that would utilize the best components from both industries to provide the high broadcast image quality enjoyed today. Films were specifically designed for TV and reproducing equipment was specifically designed for film.

When TV was just converting to color broadcasting, color motion picture film was ready and produced the color programs. However, news coverage was still restricted to black and white images from the video news cameras. The Eastman Kodak Company developed a color reversal, high speed news film with integral magnetic track for single system sound and image recording. This system was the basis of much expanded, rapid news coverage on the local and national level and flourished until the development of portable color recording video cameras and tape recorders.

Since those early years, the films have been improved for speed, grain, sharpness and contrast, all of which make the reproduction of film images on television better. Also of high importance are the developments in flying-spot and charge coupled device (CCD) telecines, automatic color correction and the digital revolution now in progress. With the development of high definition television (HDTV) film will continue to provide the quality images as it meets or exceeds the high line resolution and it provides a standardized format that can be used with any system chosen.

In the U.S. and internationally, film remains the preferred medium for the origination of television programs and commercials. Motion picture film in 35mm width, four-perforation pull-down, and 24 fps projection is the worldwide standard. It can be projected or transferred via telecine to any videotape format or line scan. Film has maintained its role as the primary production medium for prime time television programming. The percentage of prime time programs originated on film has remained fairly constant, above 80%, for nearly 40 years. With the many improvements in telecines, electronic editing, auto-color correction and digital tape recording, many of the programs are directly transferred from the camera negative film and post-produced on videotape. Many national commercials are also shot on film then post-produced in the same way.

Film and television are an inseparable combination that continues to grow and prosper. As film characteristics are improved for TV, the electronics are challenged to reproduce the improved quality, thus leading to the development of the next generation of high-quality systems. Then the cycle starts all over again. It is this relationship that has greatly contributed to the success and popularity of modern day television.

FILM CHARACTERISTICS

Color motion picture film has three photosensitive layers, sensitized to red, green and blue light. Exposure and processing produce cyan, magenta and yellow dye images in these layers which, when projected on a large screen or scanned in a telecine, produce the color pictures. Although the 16mm width was the most common format for distribution of television programs for many years, 35mm is currently the most used format but *super 35* and *super 16* are also utilized.

Film (35mm) is the main format for large screen projection in theaters *and* is also used for the production of prime-time television programs. This format is used extensively in the post-production houses and for the production of television commercials. Film continues to be improved for speed, grain and sharpness by the manufacturers. Eastman Kodak Company estimates another 10× improvement is still possible with silver halide technology. The quality of film images, versatility of production techniques and worldwide standardization keep 35mm film an important and valuable tool for the production of images for television broadcast. New versions of both flying-spot type and CCD film scanners continue to be developed for direct broadcast or transfer of film to video. Television film scanners have interchangeable optical blocks enabling either 16mm or 35mm format to be reproduced in telecine equipment.

Professional motion pictures, most prime-time television programs and television commercials are originated on color negative film. From these originals, prints can be made for broadcast and distribution on either 35mm or 16mm formats. Duplicate negatives can be made and large numbers of prints prepared for theatrical release. Telecines are capable of scanning either color positives or color negatives. A program originated on color negative can be transferred directly to tape, edited electronically and then broadcast. The same negative can be edited and either broadcast from film or a transferred tape. There are many choices available when the program or commercial is originated on motion picture film.

To display motion pictures on large screens in the theater, the projector advances the film one frame at a time and a rotating shutter cuts off the light while the film is being moved. A *claw* or *Geneva mechanism* advances the film by engaging perforations along the edges. Film 35mm wide has perforations on both edges, but the 16mm material used to make prints has perforations on one edge only; the space on the other edge is taken up by the sound track.

In camera tube telecines, the film advances intermittently one frame at a time by means of the perforations just as in theater projectors. But in film scanners, the film is moved continuously and the perforations are used only to drive a sprocket that generates framing pulses.

The film sound track may be either optical or magnetic, although magnetic striped film is rarely used today. Telecine projectors and film scanners usually have interchangeable optical/magnetic sound playback heads. In the playback of an optical sound track, the lens imaging the exciter lamp filament at the film plane must be sharply focused on the emulsion side. Usually an adjustment is provided for this purpose, as the emulsion side in 16mm prints may be either towards the lens (preferred position) or towards the light source.

The standard motion picture frame rate worldwide is 24 fps for both 35mm and 16mm formats, although 25 fps is often used for 50 Hz TV systems like PAL. The 35mm format has 16 frames per foot so at 24 fps, the rate of film movement in a projector or scanner is 90 feet per minute (fpm). With 40 frames per foot in 16mm format, the film passes through a projector or scanner at 36 fpm.

The super formats, super 16 and super 35, provide larger picture areas by using the sound track area for picture, with double system sound on another media.

When motion picture prints made for theatrical projections were a primary source of program materials for broadcasting, significant quality losses occurred. This was due to the inability of the television system to transmit the range of gray scale value needed to create acceptable pictures on motion picture screens. Committees of the Society of Motion Picture and Television Engineers (SMPTE) addressed this problem and published a report recommending the light density range in films for television be limited by adjustments in staging and lighting, rather than in the making of color prints. In this way, prints could be produced with a range of density values that the television system, at that time, could reproduce.

For creative and practical reasons, it was not always possible to adhere to the recommended lighting ratio of 2:1; nor to the recommended 60% reflectivity of the lightest scene element. Market requirements that made necessary the production of motion pictures for both purposes (theater projection and television display) have since changed, but at the time were extremely important.

The problem was addressed by the Eastman Kodak Company with the development of a low contrast print film. This film was designed with reduced upper scale contrast compared with the print film for projection on theater screens. The transfer characteristic of the low contrast print film was, of necessity, a compromise among several considerations. The contrast had to be as low as possible for good telecine performance, yet high enough to provide acceptable screen images in direct projection in review rooms. Also, the color saturation had to be high enough to maintain a chroma gain at a fairly low level. When a film with a contrast range of 160:1 is being squeezed into the television system, the shadow areas in the pictures are compressed and much of the shadow detail is lost. Some improvement was achieved electronically through the use of black stretch circuitry in the telecine. Further improvement was made by using low contrast print film for the television prints.

Some modifications were made in various films and in lighting techniques but these compromises were not the whole answer. New films have been completely designed specifically for television program production and much better image quality results. Today movies are produced especially for television, so the films, lighting, sets and actions are all optimized for video transmission. With the new design telecines and films, compromises are no longer required. Optimum image reproduction can be obtained for large screen theatrical release, television broadcast and videotape release.

There have been and continue to be significant cooperative research and development programs among the telecine manufacturers and film manufacturers. Continued improvements in all elements of the film system, from the negative through the intermediates to the final print, contributed to major quality improvements in the broadcast of film on television. The design of circuitry to allow the use of negative working films for either transfer or broadcast also led to major quality improvements as well as economic gains for the use of film in television.

Film for Television

Many programs are still originating on film though most broadcasters today do not see the film itself, but rather a videotape transfer. Nearly 80% of the prime-time programming on U.S. television originates on film, whether the program is a dramatic or comedy series, made-for-television movie, or theatrical motion picture. A large percentage of commercials also originate on film but are transferred to tape for distribution and broadcast.

There are many reasons why film remains the medium of choice for origination. One of the main reasons is an undefined phenomenon called *film look*. This characteristic has defied quantification by performance parameters but continues to be a major consideration. Another advantage of film origination is the standard format worldwide. Programs originated on film today can be readily syndicated for distribution in today's 525 or 625 line standards or any of tomorrow's HDTV systems.

With today's family of color negative films, the cinematographer has the flexibility to choose high speed emulsions or slower, finer grain emulsions simply by changing the camera magazine. A comparison of film characteristics and video camera characteristics indicates that film still has the advantage for sensitivity and speed, tone scale reproduction and resolution.

Recently, the Eastman Kodak Company designed a film specifically for television production. Its speed rating is EI 640 for tungsten balanced light sources. This film has some unique features that allow the capture of more information in the origination negative that can be subsequently scanned and manipulated to give the final image qualities desired. The film has three features that take advantage of a telecine's controls: lift, gamma and gain. First, the film has a low contrast capture which by definition is a very long latitude film (~ 10–12 stops). The low contrast capture also allows outstanding highlight handling capability. Second, the film was designed to match the spectral response of modern telecines, which enables the telecine to see the red, green and blue color records neutrally. Third, the *toe*, or region of the film which captures shadow detail was optimized to be controlled by the gamma control. This allows better control of the amount of shadow detail and fleshtone contrast. Much better independence of control between the lift, gamma and gain is also achieved with this specially designed television production film. This film offers all of the benefits of conventional theatrical films, but with a design cooptimized for making the production of television programming faster and more efficient.

Motion picture film offers significant advantages as a medium for the production of TV programming, while videotape offers advantages for the handling and broadcasting. Films transferred to videotape can be broadcast and handled many times without losses due to dirt and scratches that may occur with repeated handling of film.

The Broadcast Telecine

Traditionally, telecines were used for the transfer and direct broadcast of syndicated television programs and feature films. Only print films were transferred, and generally without supervision with no scene-to-scene color correction other than that provided by automatic gain or automatic black level circuitry. Today all types of films—negative, intermediate or print in black and white or color—are routinely transferred to video.

The original broadcast telecines evolved from television camera technology combined with motion picture projectors. During the 1970's, flying spot and CCD telecines were developed for broadcast use. Now in the United States, telecines are rarely used for on-air broadcast, but some broadcast facilities maintain a telecine to transfer print film from their libraries to videotape for local broadcast.

The Transfer Telecine

The transfer telecine is used to transfer feature films to videotape masters for subsequent duplication to videocassettes and videodisc formats as well as for broadcast. Flying spot and CCD telecines are used by film-to-tape transfer houses in this market. A skilled colorist provides scene-to-scene color correction, using programmable color correction controls. The transfer telecine is designed to accommodate negative film, print film, low contrast print film, duplicate negative or interpositive film. Some television programs are edited on film and transferred to videotape in a similar manner with scene-to-scene color correction.

The Production Telecine

The production telecine is used in the production of television programs and commercials. Post production facilities use flying spot and CCD production telecines. Selected camera shots (*circle takes*) are transferred from the camera negative film to videotape with a colorist providing scene-to-scene color correction.

Commercials may be edited directly (online), but television programs are typically edited offline. Dubs are made to videodisc or videocassette formats for offline editing. The edit decision list (EDL) generated in the offline edit session is then used to assemble a finished videotape master in an online editing session.

For internationally syndicated television programs, a PAL master is made. Video standards conversion from the NTSC master has proven inadequate, due to compromised spatial resolution and motion judder. The preferred approach is to cut the negative film to a cut list generated from the EDL that was produced in the offline edit session. The cut negative film is then transferred directly to a PAL master with scene-to-scene color correction. The recently introduced machine-readable edge numbers (Key-kode™) are expected to facilitate the process of negative cutting.

TELECINE DESIGN

The basic function of a telecine is to convert an optical image on motion picture film to a television signal. This conversion involves an optoelectronic transducer and a scanning operation. The resulting video signal must be color matrixed, gamma corrected and frame rate converted.

There are two basic telecine designs that are commercially available: cathode ray tube flying spot scanner (FSS) and CCD line array. An experimental laser telecine for HDTV has also been demonstrated by NAC.

A third design which was actually the original system used was the *photoconductive telecine*. This design involves the combination of a synchronized motion picture projector with a television camera. As the design evolved, specialized video signal processing circuitry was developed to improve the image quality of the transferred or broadcast images. The photoconductive (camera tube) telecine is no longer manufactured and probably only a few still exist. It was the first system and it was manufactured by a large number of companies worldwide, but with the development of the flying-spot and the CCD line array systems the photoconductive system could not compete for quality of the reproduced images nor with the ease of operation and maintenance.

Figure 5.14-1 illustrates the major components of a generic telecine design. These components include:

- film transport
- illumination system
- projection lens
- scanning system
- video signal processing

Implementation of these basic components depends on the telecine technology and design.

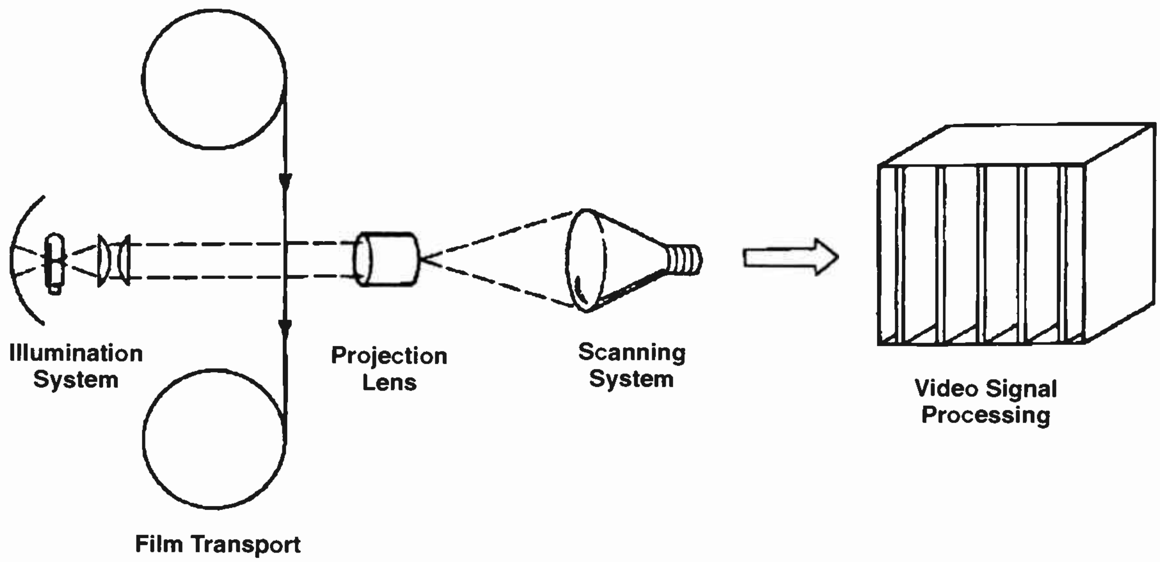

Figure 5.14-1. Generic telecine components.

CRT Flying Spot Scanner

The CRT FSS produces the video signal by scanning the film images with a very small spot of light and collecting the light transmitted through the film with a *photomultiplier tube* (PMT). A high intensity CRT is scanned by an unblanked electron beam.

The CRT FSS was developed by Rank Cintel and originally designed for 25 fps film transfer to 25 fps European television standards (PAL and SECAM). Early attempts at 30 fps NTSC designs involved a complicated *jump-scan* approach, controlling the scan to implement both interlace and 3:2 frame rate conversion. The development of the *Digiscan* frame store, which permitted the film frame to be progressively scanned and then interlaced, and frame rate converted by controlling the output (read) rate, made the FSS design practical for NTSC.

One of the fundamental innovations of the FSS design was the development of a continuous motion, capstan driven film transport. The velocity of the film is monitored by a shaft encoder on a free-running timing sprocket that tracks the film perforations, and the timing pulses are used to control the capstan velocity via a servo loop. This transport has proven to be gentle enough to handle negative and intermediate film stocks in addition to print film.

One of the fundamental challenges in the CRT FSS design is the selection of a high intensity, short persistence phosphor with a broad spectral energy distribution for scanning color film dyes. The typical phosphor has little blue output, limiting the signal-to-noise ratio of the blue record of transfers from negative film, as negative film contains yellow masking couplers (0.90D).

The basic block diagram for a CRT FSS is shown in Figure 5.14-2. The scanning spot is divided into three color channels by a dichroic beam splitter where each signal is picked up by a PMT. The signal from each PMT is buffered by the head amplifier and applied to the afterglow correction circuitry. Afterglow correction is a high pass filtering operation that compensates for the persistence (afterglow) of the phosphor.

The next step is shading correction, which compensates for uneven illumination, optical losses and uneven tube sensitivity. Here, shading correction compensates for nonuniformity of the CRT and lens system.

The video signal processing is implemented in four steps: (1) log amp, (2) color masking, (3) variable gamma and (4) expo amp. Color masking and gamma correction are implemented on logarithmic signals and the resulting signal is exponentiated for display. The color masking operation is implemented by a resistor bridge matrix, with selectable options for different film stocks. Electronic color masking compensates for the unwanted absorption, or crosstalk between the film dye records and the spectral response of the telecine.

The variable gamma function is implemented as a gain adjustment on the log signal. Black level (or lift) correction is applied by controlling the reference pulse to the log amp, and white level (gain) correction is applied at the expo amp.

A digital frame store is used to provide both interlace conversion and frame rate conversion (24 fps to 30 fps). This is accomplished by independent control of the input (write) clocks and the output (read) clocks. Aperture correction is also implemented digitally.

Recent advances in CRT flying spot scanners include an all digital video signal processing channel. Also of note is the development of a pin registered gate for image compositing and the development of an electronic pin registration (EPR) system for real time steadiness correction. In modern telecine equipment practically all of the analog signal processing has been replaced with digital signal processing. This has improved the reliability and the creative flexibility.

The primary advantage of the CRT FSS is the scan flexibility—zoom, pan and anamorphic expansion are

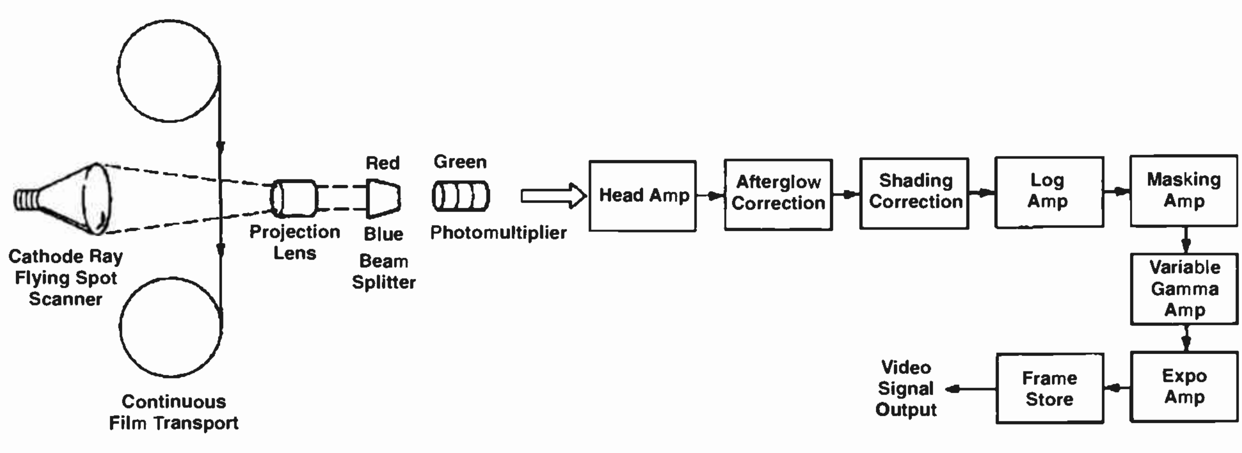

Figure 5.14-2. Block diagram of cathode ray tube flying spot scanner.

easily implemented by changing the scanning raster. The continuous motion transport handles film gently, making the transfer of camera negative film viable. Also, the lag and color misregistration artifacts of photo conductive telecines are eliminated.

The limitation of the CRT design is primarily the short life (2,000 to 5,000 hours) of the tube before it must be replaced due to phosphor burn or spot size deterioration. While not a real problem with NTSC or PAL transfer, prototype CRT HDTV telecines exhibit limited sharpness and signal-to-noise performance (particularly when scanning negative film).

CCD Line Array

The CCD line array telecine was first introduced in the early 1980's. As its name implies, the heart of the system is a CCD line array imager which converts the optical image to a video signal by transferring the charge accumulated in each photosite of the line array through a charge coupled output register. CCD telecines are manufactured by Philips BTS and are used in production and broadcast applications. The CCD telecine design also utilizes the digital frame store and continuous motion transport first implemented in the CRT FSS.

The illumination system is a high energy, blue rich tungsten halogen lamp, which is important in achieving high signal-to-noise performance when transferring orange masked color negative films.

Sensor clocks are generated to control the integration time of each line and the pixel readout rate. The commonly used CCD element photosensor has dual channel readout with alternate samples interleaved.

Pattern correction removes any stripe patterns resulting from photosite sensitivity variations and output shift register mismatches.

The video signal processing in a CCD telecine is much the same as that of the CRT FSS telecine described earlier. A basic block diagram is illustrated in Figure 5.14-3.

Film-to-Video Transfer

Most programs or features which originate on motion picture film will be transferred to a video format. In addition to cinema theater release, a feature film may be released for distribution to airlines, television broadcasters and home video retailers. Programs and commercials which originate on film, such as documentaries, prime-time comedies and dramas, are transferred to video as part of the post production process.
