Film continues as an origination source for television for a variety of reasons. Feature films are a tremendous and popular resource of program material for broadcasters. Film creates images with the unique film look due to the inherent way in which motion picture film captures and records image records. Film is a worldwide standard and archival medium which continues as a significant image source for the television program production.

Telecine equipment makes the job of transferring film to video fast and efficient. Telecine equipment also provides the opportunity for creativity as the operator has the option to interact with the telecine controls to change image characteristics such as color, contrast, sharpness, zoom, and crop.

For the conversion of feature films, a telecine converts the film signal to the proper video signal and aspect ratio. Often feature film releases are shot in wide aspect ratios such as 2.1. The standard definition 525 and 625 video standards requires an image with an aspect ratio of 1.33. A telecine will produce an image with an aspect ratio of 1.33 (or 1.78 for wide screen or HDTV) from the film image record. This can be accomplished by *pan and scan* or *letterboxing*. During pan and scan a full resolution, smaller aspect ratio image is extracted from the larger aspect ratio film image. During letterboxing, a lower resolution, wide aspect ratio image is placed in the 1.33 aspect ratio video image. Black bars are added to the top and bottom of the image.

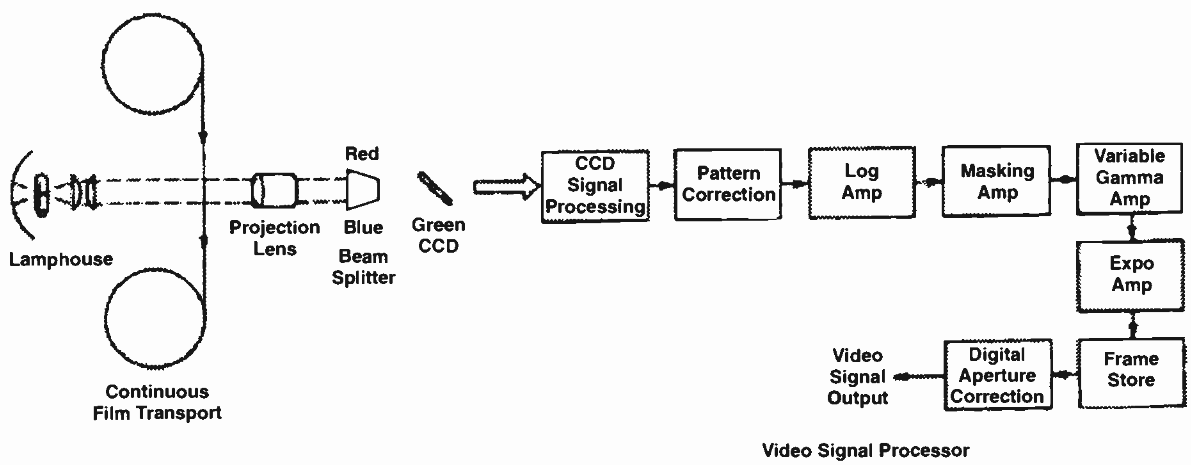

Figure 5.14-3. Block diagram of CCD line array telecine.

Telecine manufacturers make a variety of optical and transport gates to accommodate the film-to-video transfer of the various image formats which can be captured on 8, 16, 35 and 70mm film formats. Telecines handle the various film types such as original camera negative, reversal, black and white, intermediate and print film types by automatic alterations to the optical configuration and electronic signal processing.

For a given television program, the actual film material which will be transferred to video will depend on actual client preferences, requirements and material availability. Most motion picture film productions are captured on a camera negative material as this film material gives the cinematographer the greatest latitude in terms of capturing details and highlights and is the master version for making additional film duplicates. Some applications may require origination on reversal film, a film that produces an optical positive directly, without subsequent printing.

The film-to-video transfer may also be made from one of the subsequent film versions which originate from the camera negative, either intermediate film or print. Subsequent film generations exhibit different image quality features as the photographic process alters the characteristics of the image records. In order to optimize quality, the trend in film-to-video transfer has been to transfer from the original negative or from a film generation as close as possible to the original negative film.

Certain telecine machines also react differently to various film types. Some telecine equipment cannot handle the wide density range contained on print film. Eastman Kodak has produced a special low contrast print film for this application to reduce the adverse effects of print film transfer on these limited dynamic range telecines.

Telecine machines are very flexible in the types of video output obtainable. Practically all telecine machines can output both 525 and 625 video standards. Telecines output the variety of standard definition formats and are rapidly advancing to include high definition video images and digital computer data formats such as DXP and TIFF.

Programmable Color Correction

Telecines are controlled by programmable color correction devices. With these devices, the controls on a telecine can be programmed on scene by scene or frame by frame basis. With a programmable color correction unit, the telecine can be programmed to compensate for film differences contained within a roll or create special effects such as color enhancement, day for night, rotation, zoom, pan, noise reduction and sharpness enhancement.

Programmable color correctors can perform primary and secondary color corrections. Primary control refers to lift, gamma and gain controls which control the blacks, midscale and whites of an image respectively. Primaries also allow for red, green and blue interactions in the black, midscale and white portions of the image. Primaries are used to make overall color adjustments to the film transfer for the purpose of matching various elements or creating a color effect.

Secondary color correction refers to additional, precise manipulations. For example, a specific shade of red in a particular region of the image may be altered. Primary controls on a color corrector can be applied to both the signal processing within the telecine and the video processor of the color correction unit. Secondary controls are applied to the video processor of the color correction unit and usually cannot affect the internal workings of the telecine.

Programmable color correctors provide a multitude of other options for image manipulation such as processing of key and luminance channels. These devices control telecines and a variety of video recording tape machines and disk arrays.

MONITOR SETUP

The color picture monitor is the subjective reference for all film-to-video transfers. Although a video waveform monitor and vectorscope provide some objective signal levels, the color picture monitor is the basis for the artistic judgments of the colorist and the acceptance of the finished product by his client. Program interchange between facilities and consistent quality can only be assured by high standards for color picture monitor performance, alignment and viewing conditions.

The SMPTE Working Group on Professional/Studio Monitors (T14.28) has worked to develop recommended practices and standards for color picture monitors. These include:

- *Recommended Practice for Critical Viewing Conditions of Color Television Pictures (RP 166-1995)*
- *Recommended Practice for Alignment of Professional Television/Studio Color Picture Monitors (RP 167-1995)*

Performance

Performance criteria for color picture monitors identified in the SMPTE standard include the following specifications:

- White point = 35 ft L
- Color temperature = D65
- Colorimetry = SMPTE "C" phosphors
- Contrast ratio $\geq$ 50:1
- Gamma = 2.2 + 0.4/−0.0
- Luminance nonuniformity $\leq$ 25%
- Color purity $\leq 6\Delta$ E* CIELUV units
- Resolution $\geq$ 500 TV lines per picture height (without aperture correction)

Aperture correction should be switchable. Underscan capability is a must in order to see the full active video raster. Long and short-term stability requirements are also specified in the SMPTE standard.

Alignment

A color picture monitor can be aligned with a test signal generator and a color analyzer (*tristimulus device*). The required test signals will be indicated in the following discussion of alignment procedures.

- *Scan size* is adjusted in underscan mode so that all four corners of the raster are visible. Overscan mode should involve no more than 5%.
- *Geometry, linearity* and *aspect ratio* are adjusted using the crosshatch test signal, turning on only the green beam, and adjusting pin-cushion and scan-linearity controls for visual alignment with a linearity overlay (ball chart) over the CRT face.
- *Convergence* is adjusted with the crosshatch signal with all three beams on. The manufacturer's recommended adjustment sequence should be followed.
- If *aperture correction* is used, the amount should be set to make the apparent brightness of the 2T $\sin^2$-pulse match that of the bar in the *pulse-and-bar* signal. Alternatively, the multiburst signal can be used to match the apparent contrast of the 4.2 MHz burst to that of the 3 MHz burst.
- SMPTE color bars are used to set *chrominance amplitude* and *phase* for the decoder, viewing the blue channel only. The left blue bar is the reference bar and its brightness is not affected by the chroma or phase controls. The phase control affects the brightness of the inner two bars. The recommended adjustment sequence is to first adjust the chroma control and then the phase control so that all bars are of equal brightness (matching).
- A 100 IRE window signal is used to set *color temperature* and *reference white*. First a visual comparator is used to adjust the RGB gain controls for a visual match to D65 color temperature. A photometer is used to set the contrast control for a reference white level of 35 ± 3 ft.L.
- *Gray scale tracking* is set using an unmodulated stairstep signal and adjusting the RGB screen controls to produce visual neutrals in the darker steps. As the screen controls and gain controls interact, this requires an iterative approach.
- The last step is to use the Picture Line-Up Generator (PLUGE) signal to set the *brightness* control so the darker patch just merges with the reference black level, but the brighter patch is clearly distinguishable at the normal viewing distance. The PLUGE signal of the SMPTE color bars can be used.

Viewing Conditions

The recommended viewing distance for the telecine colorist is four to six picture heights. The monitor surround should be a neutral gray illuminated by D65 lighting in order to permit unbiased color judgments. A graded illumination is recommended to minimize fatigue, with a peak luminance of less than 3.5 ft.L (10% of reference white). A surround area of at least eight times the area of the color monitor is required. This can be obtained either by lighting a rear wall behind the monitor or by placing the monitor in a rear illuminated panel.

All room lighting should be filtered to D65 color temperature and directed so that there are no spurious reflections from the monitor face.

Telecine Exposure Calibration (TEC) Film

With the increased use of computer based editing systems, video dailies are replacing film dailies to a great extent. Processed negative is sent directly to the telecine transfer facility. Depending on post production needs, video dailies may not provide accurate feedback for directors of photography (DP). Without film dailies, there is no laboratory report with its list of printing lights to tell the DP whether the exposures are satisfactory before shooting the next setup. A telecine exposure calibration (TEC) film enables the colorist to calibrate the telecine and provide the DP with transfer points (TP), similar to the printing lights traditionally provided by laboratories.

The problem was how to calibrate an extremely complex device, such that it would give the same meaningful exposure data, no matter which telecine was used, which facility house was using it or where it was located. The solution, a TEC film is a strip of EASTMAN EXR color negative film, exposed and processed to precisely known densities. This film calibrates the telecine, turning it into a rather expensive color analyzer and densitometer, at least for exposure evaluation. The cinematographer must photograph an 18% gray card, such as the gray card plus. The telecine engineer (or colorist) uses TEC to setup the telecine to a position where the controls are centered and the saturation is at an appropriate level. Using only the primary controls, the operator calibrates each channel of the telecine to the RGB values provided with the TEC film.

The settings are stored in memory to be recalled when exposures on client film are evaluated. The film image of the gray card is read with the setting stored in memory from when the telecine was calibrated according to TEC film. Using a waveform monitor, the colorist reads the RGB voltages or IRE values from the gray portion of the card shot in the scene. Using the appropriate look-up table, the red, green and blue measurements are converted to TP.

Some telecine equipment manufacturers have developed systems to work along with TEC film for automated readout of transfer points. Real time readings as well as computer logging are now available.

The TP Table is used to convert the measured IRE values into transfer points. (There is a separate table for each Kodak Motion Picture film.) A separate set of tables for voltage is also provided. The table has a range of −3 to +3 stops of exposure, which corresponds to approximately 42 TP, where about 7 TP equal one stop in exposure.

TP are related to printer points, but are not equivalent. Each processing laboratory has its own normal printer points. TP are equivalent worldwide if the TEC film is used properly. However, in use, a change of one TP is equivalent to one printer point. The exposure position is quantified removing ambiguous terms such as a little light or a bit heavy which different people can describe to similar conditions. The basis of the exposure reporting is similar to the well accepted printer points used for many years. The TEC system provided a worldwide telecine standard for exposure determination.

SOUND

In the film projectors used in camera type telecines, the sound reproducer is located just below the picture gate. An optical system focuses a slit of light from an exciter lamp onto the film. Usually this lens is adjustable to accommodate films with the emulsion side either towards the light source of the projector or towards the lens. This is necessary only for 16mm format sound; 35mm is always in the same position with the emulsion towards the light.

A system of damping rollers smoothes out the movement of the film over the sound scanning drum following the intermittent frame-by-frame movement of the film in the picture gate. The sound in the film track is located 26 frames ahead (in the direction of film travel) of the corresponding picture frame for 16mm film, and 21 frames ahead for 35mm.

Variations in the light transmitting properties of the sound track modulate the light beam as it passes through the film. The light falls on a photoreceptor, generating an output which, after suitable amplification, becomes the audio signal. The optical system in the sound reproducer must be sharply focused on the emulsion side of the film, where the sound track is located, for best high frequency response. This is a critical adjustment because the focal length of the lens is quite short; a change of only 1/1,000 in. can cause noticeable high frequency loss. For 16mm, the lens usually has only two positions: the back or the front of the film. On 35mm reproducers, the lens is fixed after factory setup.

If the intensity of the scanning beam across the width of the sound track is not uniform, the reproduced sound may be distorted or low in level. Lack of uniformity is usually caused by dirt accumulating in the slit of the optical system. Incorrect positioning of the exciter lamp filament will also adversely affect sound quality. Films that are scratch free and clean will also produce better sound quality.

Continuous film motion in flying spot and CCD type scanners makes sound reproduction much easier, since there is no need for a system of damping rollers at the sound drum as in intermittent projectors used in camera type telecines.

CCD telecines and flying spot telecines scan optical and magnetic sound tracks directly at the capstan. A roller is mounted between the capstan and the picture gate to obtain the necessary picture/sound separation for 16mm and 35mm films.

Many 16mm films in circulation have magnetic sound tracks consisting of a stripe of iron oxide coated on the side of the film facing the projector lamp. The playback head is located 28 frames ahead of the corresponding picture frame. Projectors for television service usually have selectable optical and magnetic sound playback devices.

The azimuth of the magnetic playback head must be properly aligned. Ideally, the gap in the head should be positioned at exactly 90 in the direction of film movement. An incorrect azimuth setting results in loss of high frequency output, as does separation in the head-to-film contact. Periodic cleaning is essential to remove buildup of oxide that prevents good contact.

Today, most film is transferred to videotape for broadcast and it is easier to control the cleanliness, alignment and pristine condition of the telecines' optical systems for both picture and sound in the transfer house.

In post-production and high quality film-to-video transfer operations, 35mm color negative film is the preferred format, instead of making prints from the negatives. The sound is supplied on a separate high quality magnetic film that can be synchronized with the pictures. This way, the best television picture and sound can be obtained for broadcast or for mastering videocassettes for the home VCR market.

Significant quality improvements have been made in recent years in the sound amplifiers and speaker systems of home television sets. Better frequency response, signal-to-noise ratio, and even stereo sound now requires the transmission of clean, quality sound signals. This is possible whether the sound is transferred from film or tape, and if the usual precautions for dirt free, scratch free operations are followed.

FILM HANDLING, CLEANING, STORAGE

In the normal operation of a TV station, it is not easy to ensure that all films are spotlessly clean and free from physical defects. The methods of film handling adopted by station personnel and the degree of tolerance for image imperfections that broadcasters allow sometimes aggravate these conditions. Motion picture film will stand a considerable amount of abuse, but scratches and abrasions can permanently damage a film.

Films can be scratched in any piece of equipment where it is drawn over metal or plastic surfaces. A tiny burr in the gate of a telecine projector can put a scratch on the film from one end to the other. Constant attention is needed to make sure that imperfections are not being caused by faulty or dirty equipment. In this respect, film and tape handling requirements on their respective reproducers are very similar for cleanliness and meticulous maintenance of the mechanical parts.

Abrasions are usually caused by careless handling, such as excessive or erratic rewinding speed. Another very common cause of abrasions is the tightening of a loose wound roll by pulling on the end of the film causing the convolutions to rub on each other. A particularly bad practice is to start winding at high speed and then allowing the film reels to coast. The film should be rewound at constant low tension, sufficient to wind a tight roll without slipping.

With a little practice, the probable cause of a film scratch can be identified by noting the nature of the damage. A straight, uninterrupted scratch parallel to the film edges is most likely caused in a machine where the film moves continuously such as an FSS or CCD telecine. Camera tube telecine projector scratches may show some discontinuities caused by the intermittent action of the claw and gate mechanism. Wave scratches are usually caused by careless cleaning practices.

Torn or damaged perforations are usually caused by faulty projectors or damaged sprockets. Damaged perforations likely will give rise to unsteadiness in the television pictures. (Kodak Publication H-23, *The Book of Film Care* is an authoritative guide on all aspects of film handling, pages 51–83).

Film Cleaning

When film and slides are reproduced in the television system, any particles of dust and dirt as well as scratches and abrasions on the film surfaces are visible in the transmitted images. Electronic enhancement of the images invariably enhance the picture defects as well.

The large network centers rarely broadcast a scratched or dirty film, but local stations often have no choice as they may receive prints that have been used many times. Few stations seem to have the time to clean every film prior to telecast and replacements for defective prints are seldom available.

The preparation of film programs for on-air release or transfer to videotape usually involves much handling and rewinding, often at a high rate of speed. If the film's reels are bent or damaged, the film base and emulsion may be scraped off the edges of the film and trapped in the convolutions of the wound roll.

Static charges on the film surface, generated by high speed handling, can cause the particles of film support, film emulsion or other airborne dust particles to cling to the film surface. Smoking in film handling areas should be forbidden, as ashes and smoke residues can be deposited on floors, work surfaces and eventually on the films. Personnel traffic should be restricted in film cleaning and handling areas as dust and dirt particles emanate from clothing, shoes and even hair. It is not necessary to create an antiseptically clean area to handle film, but clean room practices and common sense can prevent problems in film transfers or transmission.

Cleaning films to remove dust and dirt particles is neither difficult nor time consuming. There are several methods that have been in use for many years. The oldest, simplest and most economical method is the use of *plush pads* and a cleaning fluid. In this method the film is placed on a rewinder and a plush pad is moistened with a cleaning solution, such as pure isopropyl alcohol. The pad is folded over the film strand and the film is slowly pulled through the moist pad and wound on a takeup reel. A fresh section of pad should be used for every few hundred feet of film, depending on the amount of dirt being removed. Care must be taken to keep the pad moist but not so wet that the film strand is wet when wound. If the film surfaces are wet as the roll is being wound up, drying marks may appear on the film surfaces. Cleaning pads can be made from pieces of plush velvet, 12 x 16 in. in size, folded over once and sewn around the sides with the edge turned inward. This is to prevent any plush strands from getting onto the film. These pads may be obtained from photographic supply stores.

Solvent film cleaning machines are available to provide excellent cleaning, proper film handling and high volume. These machines are available from several manufacturers and can be sized for various capacities. Both the ultrasonic cleaners and the plush pad cleaning technique utilize organic solvents. These solvents were especially selected to remove fingerprint grease, wax pencil, and other markings found on film. When used according to the manufacturer's recommendations, properly stored and used with adequate ventilation, they are reasonably safe. New controls for use, storage and disposal of solvents and solvent vapors have made these methods of cleaning more expensive and less desirable.

Film Splicing

Many different methods can be used to prepare films for on-air release or transfer to videotape. For example, a film program and all the short commercials, promos, etc, to fill a full half-hour broadcast period can be spliced together into a single, complete roll ready to run in a telecine projector or scanner.

Another method is to splice together all the commercials and promos on one reel, with short sections of leader between these items, and run the reel on one telecine projector or scanner while the main program is running on another. A complete on-air program or a videotape transfer can be produced by switching from one projector or scanner to the other. Still another method is to transfer the film program and all the commercials, promos, etc, to videotape and package a complete program by electronic editing.

Whatever method is used in a station, some film splicing will always be needed. Each of the splices should be considered as a potential hazard in the telecasting of a program or in its transfer to tape. If a splice comes apart in the telecine, operating schedules will be disrupted, with accompanying losses of time and money and potential damage to the film.

Splicing film is not a difficult or complicated procedure. Good splices that will stand up to normal handling and repeated projections, running backwards or forwards if necessary, can be made in two different ways: either by joining with cement or by applying transparent adhesive tape to the two sections of film at the joint. (See Kodak Publication H-23, *The Book of Film Care*, pages 60–67.)

Cement Splices

Triacetate base films may be spliced using either cement (solvent) splices, or using transparent splicing tape. Polyester (Estar) base films may be spliced with either splicing tape or an ultrasonic (thermal fusion) splicer.

When a cement splice is being made, the ends of the two pieces of film to be joined are overlapped in the splice area and the emulsion is removed from the lower section of film.

Then a little splicing cement is applied to the scraped area, and the base side of the other piece of film is placed over it and pressure is applied until the cement dries.

Film cement is a solvent capable of dissolving the film base. Usually films are spliced in a small hand-operated machine, which has two hinged platens, registering pins to accurately position the two film ends by the perforations, a scraper for removing the emulsion in a narrow strip in the splice area, a knife to cut off the two ends neatly and a hinged pressure block to hold the two ends in contact after the cement has been applied. The film cement is stored in a small bottle, with a tiny brush to apply the cement sparingly in a narrow area of the film at the splice. A good splice has sufficient strength after about 20 seconds to be removed from the splicer and wound up on a reel. Cement (solvent) splicers will *not* work with polyester (Estar) film base.

Tape Slices

Tape splices are easier to make, are less likely to come apart or break during projection than cement splices, and can be made on any film base. The tape used for making splices is clear, with an adhesive backing. Many different types of film splicing tape are available.

Tape splicing machines, readily available, make application of the tape and finishing of the splice very easy. An important advantage of tape splices in a television station is that no frames are lost when two films are being joined together. The film ends are simply butted in the space between frames and the splicing tape applied. Another advantage is that tape splices can be taken apart easily later on, with no damage to the film frames, by simply peeling off the tape.

Storage

Store processed film according to the recommendations in standard ANSI IT9.11-1992. SMPTE Recommended Practice RP 131-1994 also contains recommendations for proper film storage. For short-term *active* storage and projection (telecine rooms and transfer facilities), room temperature of 20 to 25 degrees Celsius (68 to 77°F) at 50 to 60% relative humidity is recommended. Avoid prolonged unconditioned storage at high temperatures or excessive humidity. For medium-term storage, store at 10°C (50°F) or lower, at a relative humidity of 20 to 30%. For extended-term storage (for preservation of material having permanent value), store at 2°C (36°F) or lower, at a relative humidity of 20 to 30%. Enclosed long-term storage (sealed cans) will benefit by the use of Molecular Sieves in the storage container. Molecular Sieves are available from FPC, 6677 Santa Monica Boulevard, Hollywood, CA 90038, Telephone (213) 468-5774.

Additional information on the proper storage and handling of processed film is contained in Kodak publication H-23, *The Book of Film Care*.

FILM AND THE FUTURE

HDTV has been under development for nearly three decades, and although worldwide standards are stil evolving, there is general agreement that HDTV will occur in the near future. HDTV has been used for limited program production in a few studios, and Japan began broadcasting an HDTV signal (MUSE) in 1989. However, there is still significant disagreement over which signal formats are the best choices for production, distribution, and broadcasting.

Film has been, and continues to be, the worldwide standard for the origination and display of theatrical entertainment programs. For over 40 years, it has been the preferred medium for the origination of prime-time television programs.

There have been several studies made of the film and HDTV mediums for video program productions. The performance parameters compared were sensitivity and speed, gray scale transfer functions, contrast range, MTF and limiting resolution, noise and granularity, color reproduction and artifacts. The results of one of the more recent studies was presented in a SMPTE paper by G. Kennel, L. DeMarsh, and J. Norris entitled *A Comparison of Color Negative Films and HDTV Cameras for Television Program Production*. The conclusion reached was that 35mm motion picture film offers significant advantages as a medium for the production of HDTV programming, even if a single HDTV standard is chosen. Sensitivity, scene contrast range, practical and artistic flexibility, speed and worldwide standardization are all advantages of film origination for HDTV.

Film-Video Interface Definitions

The definitions on page 12 are not intended as literal television or motion picture definitions, but are meant to afford a mutual understanding of terms.

APPENDIX A: STANDARDS

The Society of Motion Picutre and Television Engineers (SMPTE) provides continuous development and updating of standards, Recommended Practices (RP), and Engineering Guidelines (EG) for film and television. A complete listing may be obtained from SMPTE.

SMPTE

5.15 TELEVISION CAMERA ROBOTICS

ROBERT S. MURCH
RICHARD D. SLENKER, JR.
FOX TELEVISON STATIONS, WASHINGTON, DC

BRUCE LEVY
AND EDMUND A. WILLIAMS

INTRODUCTION

With the application of high speed microprocessors and improvements in servomechanisms, robotic camera systems are now available at an affordable cost and level of sophistication which rival the performance of a competent human camera operator in certain production situations. Performance and reliability have reached a point that a television station or production facility must seriously consider whether the use of camera robots can be an operational as well as financial asset to the facility.

Servomechanisms have been used in industrial settings for many years, from assembling automobiles to assisting in brain surgery. Their precision is well-known and the technology well-developed. It is only recently that robotics has been coupled to studio cameras in order to reduce operator costs, improve shot repeatability and reduce errors. While camera robotics may not be a replacement for camera operators in fast-moving or dramatic productions where a high degree of operator flexibility and creativity is required, they are ideally suited for many less demanding productions.

News programs and productions requiring exact repetition of shots, such as commercials, are perfect applications for camera robotics. Moreover, most productions such as news and talk shows are scripted to a degree where use of camera robots can add to the quality of the presentation due to the smoothness and repeatability of shots.

CONSIDERATIONS FOR USING CAMERA ROBOTICS

An important reason for considering camera robotics is the potential for labor cost savings. Other, operational considerations include the following:

- Repeatability of shots
- Scheduling
- Smooth execution of complex camera work
- Placing cameras in dangerous or normally inaccessible to human operators (point of view cameras)
- Reliability and durability

Labor Costs

The cost of camera robotics varies for different manufacturers and different options. Consider the return on investment of a three camera robotic system that costs $200,000 to purchase and install, for illustrative purposes, and is depreciated over five years. Simply depreciated, the cost of the equipment is approximately $40,000 per year. If the system is operated by an existing video operator and if the station is employing three camera operators at a salary of $500 per week for each operator (or $26,000 per year, per operator) for a total of $78,000 per year, the equipment will pay for itself in about two and one-half years.

Looking at cost trade-offs another way, there is a savings of $78,000 per year in salaries (exclusive of benefits) less the $40,000 cost of capital for the equipment for a net savings of $38,000 per year. The return on investment is further improved with each additional shift of usage plus any savings of employee benefits.

Another payback calculation example: Assume three camera robot systems are purchased at $100,000 each for a total of $300,000. At 10% simple interest and a three year payment plan with equal monthly payments, each payment is $10,833 or $130,000 per year.

Further assume that a station or production facility has 6 full-time camera operators in two shifts at an average of $26,000 each plus 25% overhead for a total of $32,500 each or $195,000 per year. If four of the six operators are replaced (two from each shift) at $32,500 per year each, the savings is $130,000 per year or break-even for the first three years. One camera operator remains on each shift as the robot operator or to be on call for special production shots.

If salary or benefits is higher than those shown above or if the purchase or lease plan is longer than three years, actual cash savings can be realized immediately. A detailed analysis of the station production requirements versus the cost of staff and the costs associated with leasing or purchasing camera robots must be performed before initiating an investigation into replacing skilled studio personnel.

The increase in workload on the maintenance staff to care for the robots, including lubrication, adjustment, repair, testing, software checks and electronic service, must be factored into the decision to use robotics. However, the incremental increase can be expected to be relatively small.

The increase in additional production planning effort may add an extra few percent to the production costs.

This is due to the time needed to setup, rehearse and store the positional information for each shot. However, once done for a given production, less time will be needed for future editions of the same program.

Scheduling

Camera robotics provide a high degree of scheduling flexibility as they are available 24 hours a day and are unaffected by holidays, vacation, illness or overtime.

Repeatability of Shots

Camera robot systems have a degree of precision that provides highly accurate repeatability of all programmed camera shots and camera moves. Once a difficult shot is programmed, the system will execute the shot on-air exactly the same way it did in rehearsal. This factor is important when repeating scenes or to avoid accidentally shooting offset, thus saving countless re-takes or on-air mistakes. Camera robot systems also are designed to accommodate last moment changes and execute them with the same degree of accuracy as pre-programmed shots. From the program director's perspective, the repeatability of shots, and the ability to quickly accommodate last minute changes, provide an additional level of confidence that the production will occur as planned in rehearsal.

The servos that perform the movements of camera robots are able to position the pan-tilt head within 0.1°. The pedestal (dolly and trucking movements) will return to the same place in the studio to within a fraction of an inch and maintain the aim to within 0.1° using the tape guidance system or other guidance techniques. Slightly less accuracy can be obtained when the pedestal is operating in a free mode, that is off the tape or unable to obtain a reference. In any event, the accuracy is equal to or greater than what most human operators could produce.

Movement rates of the pan-tilt heads and pedestals are generally slower than what human operators can perform. This is due to the mechanical effort of the servo needed to move the heavy camera, prompter and pedestal and the desire to keep movements slow enough to prevent injury to someone in the way of the movement.

Studio productions may require dozens of different camera positions and up to 100 different shots by multiple cameras with varying angles, zoom positions and framing differences. Camera robot systems have provisions to store hundreds of shots in memory (for longer, more complex productions or multiple shows) and can interface with zoom lenses, iris controls, camera control units, lighting systems and virtually any other computer controlled studio facilities with external data ports (see section on interfacing).

Smooth Execution of Complex Camera Work

Full featured camera robots will execute virtually all the standard moves of similarly equipped manual cameras including:

- Pan
- Tilt
- Zoom
- Focus
- Dolly (in and out)
- Trucking (left, right)
- Arc (curve left and right)
- Pedestal (up, down)

Each movement can be made at different and varying speeds and have gentle starts and stops.

The manner in which the transition from one shot to another occurs may be critical in some production operations. Some robotics systems allow shots to be linked together along with varying speeds of transition.

Camera robot systems allow an operator to control several cameras at the same time. For more artistic, creative productions a director can plan a number of different, complex, simultaneous camera moves and program them into the system to occur in a particular sequence. When these moves are recalled, they will be replayed exactly as rehearsed, every time they are recalled. For productions which require repetitive shots, such as news programs, this ability relieves the boredom human operators suffer and the subsequent potential for error.

Some robot control systems will also link the zoom lens focal length and focus controls to the camera movements so that as desired objects within the field of view change distance, the focus will track as well, much as a human operator would do. However, it should be noted that, if the mechanical system of the zoom lens is operating unevenly (sticky), the robotics system cannot correct such a defect.

Another caution is that robots will only perform the tasks that have been given to them, exactly as given. If a scene that is changed after rehearsal, a human operator can make an instant and creative decision on adjusting shots while the robot cannot automatically make the on-air adjustment.

Compared with productions with human operators, more advanced planning may be required on the part of production personnel in setting the shots and entering them in the robot's memory. For example, the robot will not automatically focus the lens on a scene but will follow orders to change focus only if the operator programmed it to do so in advance.

Operation of Cameras Located in Inaccessible Places

Advances in robot technology and the use of the smaller, high quality color television cameras make it possible to obtain shots from places and angles never previously thought achievable. Camera robots allow great flexibility for that special point-of-view shots that give the audience fascinating and informative views. Examples of these locations include studio ceilings, on racecars, roofs of sports stadiums, tight spots along parade routes and masts of microwave trucks.

Reliability and Durability

The reliability of any system is dependent upon the reliability of the individual components and subcomponents that make up the system. In the case of camera robotics, the principal components are the servomechanisms and the computer control systems. Servos, by their very nature, are very reliable and if operated at less than their rated loads, will last indefinitely. However, in order to achieve a high level of reliability, a regular program of inspection, cleaning, lubrication and preventative maintenance must be instituted for the mechanical parts of the robot system.

Servos are designed to withstand a certain amount of physical abuse. Some servos have built-in clutches on motors or gear trains to prevent stalling or stripping of the gears. Others can be stalled without burnout. Most will provide an indication of inability to react to commands, such as when an obstruction prevents a pan-tilt head or pedestal from moving to the desired position.

Servomechanisms are designed to operate in relatively hostile environments such as the high heat and humidity of summer and in cold winter conditions. They are, therefore, suitable for use in locations that human operators would find uncomfortable. The range of conditions in which the servos can safely operate is likely to exceed the conditions acceptable for the camera itself.

The computer systems of most camera robots use PC components. The normal lifetime of most of these parts is approximately several years. Little maintenance is required other than the usual routine inspection and cleaning. However, if mechanical memory devices are used (hard and floppy disk drives), an occasional check should be made of the disks using standard software available for this task.

Because most camera robots are likely to be operated 16 to 20 hours a day, and may in fact be left on 24 hours a day, the disk drives are the most likely parts of the computer to fail. A backup drive or computer is recommended to help bridge the time when such a failure occurs.

INSTALLING CAMERA ROBOTICS

The major installation issues to be addressed are:

- The impact installing robots will have on the staff
- Potential locations for camera robots
- Smoothness of the studio floor
- Location of the robot controls.

Personnel Considerations

The installation of camera robots can result in more effective uses of production personnel. How management deals with the staff, who may believe that robots will replace human operators, may determine the level of success of the installation more than any other factor. Depending upon individual situations it may be possible for reassignment or attrition to help adjust staffing arrangements.

In addition to the changes in the technical and production staff due to the installation of robots, other departments in the station must also be directly involved in the project.

The use of camera robots will affect how a production is designed and executed. All production personnel, including producers, directors and other production managers throughout the facility must be aware of the advantages and the limitations of using robots. Initially, this awareness could begin with the Engineering Director providing information about robots and how they can improve production and reduce production costs. Later, after the staff has become used to the idea of using robots, production staff can be trained on how best to use the camera robots. After the initial introduction of the robotic system, it is essential for engineering and production departments to work jointly to develop daily standard operating procedures for the new robots.

Potential Locations for Camera Robots

While the studio is the obvious first choice for using robotic cameras, it is by no means the only location. Newsrooms are popular sites for robots where the camera is not required to be as full featured as in the studio. Newsroom cameras may not need to be mobile and simpler robots (equipped only with pan, tilt, zoom and limited side-to-side travel) may be all that is required. In any event, when considering installation of camera robots, carefully study how the camera will used. Consult with other stations that have installed robots and review the performance limitations of the system under consideration to insure that it meets the needs of the facility. While it is relatively easy to have an operator move a camera to a more suitable location, moving the robot may not be possible without considerable time and expense.

Camera robots also can serve to relieve operator boredom in production situations where a camera must be left in place for long periods and used only occasionally. Examples include parade routes, city councils or other public forums, racetracks, elections and telethons. All that is needed for control is a data circuit between the control point and the robot. The operator at the control position can observe the response of the robot by the action shown on the monitor for that camera.

Robots come in a wide variety of configurations and cost ranges. Some of the simplest devices are the older, yet still desirable, pan-tilt mounts. At the next level are those with memory for different shots and variable speed, followed by those with capability for movement along one or more axes. The full featured robot adds elevation to the other movements and some have scissor type mounts (or cranes) to extend the elevation range at both upper and lower extremes.

Studio Floors

Camera robots weigh several hundred pounds. Occasionally, they and may be required to execute shots while in motion. Thus, the surface of the studio floor is extremely important to the on-air look the cameras will produce. One of the best studio floors is built of concrete with a smooth epoxy paint covering that, together, provide a degree of levelness of less than

1/8 in. height variation for every 12 linear ft. Many studio floors have a concrete base but have been covered with tiles that may not be entirely suitable for the weight of robots or may be chipped and require replacement.

Another possible and popular location for camera robots is the station newsroom. Many newsrooms have computer style raised deck flooring that must be evaluated for suitability. The manufacturer should be consulted to insure that the floor will be suitable for the robots.

Control Point

An important part of installing camera robots is deciding where to locate the control point of the system. Possibilities include the studio, production control room, camera control position or a dedicated control room. An advantage of having the robot controls at the camera video control position is that the video operator can combine this function with that of the robot controls.

One approach is to have the camera control or video operator also assume the duties to control the robots, either from a studio control room or a dedicated video control room. Some installations locate the robot operator on the studio floor. In some instances the control position is elevated. This has the advantage of giving the operator direct view of all camera movements.

Some systems have cable length limits between the camera control heads, the robot control panels and the rack mounted control processing and memory storage units. Such restrictions may limit the operation for placement of control panels or rack systems.

CAMERA ROBOT NAVIGATION SCHEMES

Camera robots use sophisticated computer techniques and servomechanism technology to provide the quickness, smoothness and repeatability required to be effective. In addition to robot systems the pedestals are manually moved to a location by a person on the studio floor, camera robot pedestals that can automatically move about the studio are also available. A variety of schemes are used by the different manufacturers for the system to know where each pedestal is located. The sophistication of these navigation systems is such that most systems will not allow cameras to run into each other. As discussed in the following section on Safety, there are mechanisms on the camera pedestals, such as proximity and sonar detectors, to protect the cameras if they encounter an object.

Studio camera robots must have some means for determining their position in the studio and with respect to other robots. There are several different approaches to determining how the robots move about the studio which include mechanical tracks, tape tracks, targets, and wall mounted bar coded signs. Of paramount concern is safety to both studio personnel and other robots and facilities (monitors, set pieces, microphone and lighting stands) within the range of the robots.

New studio procedures must be developed and established when employing camera robots. Camera robots depend upon reference marks which cannot be covered or damaged. The robots also may move without apparent warning during setup, rehearsal and on-air production. Camera robots do not have peripheral vision! Therefore, a new awareness of studio activities is required of all production personnel. Moreover, the damage a robot can cause to monitors, lenses and other studio equipment may cost more than the operator that was replaced.

There are several methods and associated technology that are employed for controlling the position and keeping track of camera robots.

Mechanical Track System

The oldest and most limited method is the X-Y rail system which requires the construction of wooden or metal tracks or rails on the studio floor on which the robots travel. This system was adopted from the camera dolly systems used in motion picture studios. While the technique provides extremely smooth and repeatable shots, substantial work is required to move or reconfigure the tracks if the studio set is changed or if a different perspective is desired. A simple track system may be ideal for use in the newsroom or dedicated news studio where limited movement is all that is needed.

While movement of the robots is limited by the rail system, it is important that a sufficient number of proximity and contact sensors be included to prevent cameras from colliding, cables becoming cut or damaged or personnel being injured by the moving equipment.

Tape Track System

This basic navigation system uses a metal foil tape placed on the studio floor that functions as a track for the pedestal to follow. Some robot control systems allow the pedestal to move away from the tape for short distances. The robot then relies on counting wheel revolutions (tachometer pulses) to compute its position. Disadvantages to this system are the need to change the tape whenever there is a change in set placement or damage to the tape caused by moving heavy objects over it.

The Target System

The tape track technique can be expanded and simplified by having a home target on the studio floor. Each camera robot uses its target to establish a reference just before a production and is then free to roam the studio floor. Of course, the further the robot moves from the target the greater the accumulated error will be, especially after changing positions several times during a production. Just as the tape track must be protected from damage, the target must also be protected yet made available to the robot whenever it is necessary to re-establish its reference.

Bar-Coded Signs

Another robot navigation approach is to attach bar code signs on one wall of the studio. Each camera robot pedestal then uses a laser in the pedestal base to scan the bar codes on the wall. By knowing the location of the bar code cards, the system can calculate the location of the pedestal. While this technique employs substantial computer programming power, accidentally blocking the view of the signs can render the robot blind to finding the reference. The operator will be signaled when this happens, but the carefully designed production may be adversely affected as a result.

Each of these navigation schemes has its advantages and disadvantages. When selecting a camera robotic system, the user should evaluate each scheme to decide which one is best for the facility in which the robots will be working. An evolutionary approach may be employed in which initially a system would be installed with manually positioned pedestals that would later be upgraded to full mobility, perhaps one camera at a time, for economic reasons.

SAFETY

Safety is an extremely important matter with robotics cameras. The cameras must not run into people, the set, or each other! Several methods are employed by different manufacturers to provide various levels of safety.

- Limits: Virtually all robotics servos are current or torque limited. This means that if, for example, the camera pans left and the lens pushes into a floor monitor, the servo will sense the obstruction and stop movement in that direction. In some systems the servos will back up a little. This limiting action can apply to any of the several directions of movement of the robot. Moving pedestals may have additional safety features. For example, infrared sensors or microswitches on the base of the pedestal will sense any obstruction and stop the pedestal movement.
- Observation: One way of observing the movements of the camera robots is to install a ceiling mounted camera that takes a wide shot of the studio. The output of this camera can be displayed on a monitor in the camera robotics control area.
- Signs: The installation of large and bright signs on the sides of the camera robots and the studio doors and walls will serve to remind production personnel that the cameras move by themselves and without warning.

WARNING!
KEEP CLEAR!
CAMERA ROBOT MAY MOVE
WITHOUT WARNING!

- Cables: Making sure that the cameras do not get tangled in their own cables is both a safety as well as an operational consideration. Problems of this nature can be alleviated by careful planning of camera movement. The camera cable and the robotics control cable can be sleeved in a nylon webbing. This webbing combined with low skirts on the camera, will minimize cable management problems.

OPERATING CONTROL SYSTEMS

Three of the most common types of controls for robotics cameras include: joysticks, data tablets, and touch screens. Most control systems can operate several cameras (four to eight) at once. The software in most control systems is designed to prevent the operator from requesting the cameras to do something that cannot be done (move to the other side of the studio in 5 seconds); is dangerous (move to the same location as another camera); change position while on-the-air (unless the operator over-rides the warning); or exceed a built-in limit or range.

Joysticks

This popular and relatively simple method provides simple direct control over the camera movement. Typically, one camera is selected at a time for direct control in the system. Using the joystick, the operator sets up the shot to the director's satisfaction. The rate of movement is also established. The shot is then stored as a number or an alphanumeric designator in the computer memory. The shot can later be recalled during rehearsal or broadcast using that number or alphanumeric.

Data Tablets

These devices are similar to those used on some video graphics generators. The operator can draw a studio layout on the tablet, indicate the positions of the camera and then teach the system the desired camera shots. Shots can then be recalled by touching a specific area on the tablet. For example, touching the tablet at a location representing the front of the sports desk could move a camera to a wide shot of the sports desk. Touching the tablet at a point behind the desk could cause the camera to go to an effects shot. In addition to positional information the system also stores zoom lens settings and pan-tilt positions.

Touch Screens

Similar to other touch screen controlled devices, such as graphics generators, computers and test equipment, this control system allows the operator to set and recall camera cues by the touch of a finger on a screen. Typically, these systems use menu driven color touch screens. On some systems on-air tally indication can be provided on-screen that are driven by the tally signals from the switcher. This feature reduces the chances for error by the operator accidentally moving an on-air camera to its next shot.

Options

When the primary usage of a camera robot system is the presentation of news, two other newly developed operations may be of interest: *auto focus* and *auto framing*. Auto focus works on the same principle as an auto focus consumer film camera. The time delay between the transmission and reflected reception of a high frequency sound is used to determine distance that sets the zoom lens focal length. An override control is needed with this option because auto focus may be fooled into focussing on a large foreground object rather than the intended subject.

Auto framing is an option that uses sophisticated comparison technology to adjust the framing of a shot when a moving subject is involved. A predetermined shot is programmed into a video frame store. The system continuously compares the stored shot to the live shot and automatically pans or tilts the camera as required to keep the object and stored frame coincident. A news talent who is prone to body movement on the air can be kept properly framed automatically.

Limits

Most systems, regardless of the type of control, can control multiple camera moves simultaneously. Some systems can also warn of impossible shots. For example, giving a command to move a camera from one end of the studio to the other in three seconds will cause some systems to display a warning message. Using camera robotic systems simultaneously to move multiple cameras, however, can result in added finesse to productions since more complicated moves can be smoothly executed on a consistent basis.

Backup Systems

Because the entire studio operation may be contingent upon the proper operation of the camera robots, it is essential that backup power and computer arrangements be made. In event of an electrical circuit outage that could take the robot controls down, some kind of uninterruptible power supply (UPS) on the computer control system (not the robot mechanisms) to bridge the gap between outage and restoration of line power should be considered.

During installation of the robot system some of the power supplies for zoom and other functions on the camera may be replaced with power from the robot system. To avoid a complete failure of the camera if the robot fails, the original power supplies could be left in place for manual reconnection if needed. This arrangement may also aid maintenance of the system.

The computer control itself is also a source of single-point failure that can take out the entire system. A backup computer would reduce the time to restore operation if the main computer had to be repaired. Of course, a means for switching to a manual control panel could also help solve this problem.

Backup systems become more important if the camera robot controls are interfaced with other studio facilities. More than just a camera position is at stake if a control system failure should occur.

INTERFACE WITH OTHER SYSTEMS

Camera robot systems have varying levels of interface capability. Some provide for extra extension panels (pushbuttons, keyboards, joysticks) to be used for addressing external devices or systems but tied to the robot control system. The cues and control signal can be initiated as part of the shot list for the cameras. Some of the possible options are described below.

Some caution is needed when considering the interconnection of multiple devices employing microprocessors. The interfacing software must be developed, rigorously rehearsed, and carefully documented to avoid one system causing problems with another. The knowledge of how the systems interact must be shared with others so that when problems occur, personnel are available to solve them quickly. Few situations are more exasperating than when it is impossible to accomplish a function because the computer is down or a bug has been encountered in the software.

Camera Control Unit

Many robot control systems provide an interface with the camera control unit (CCU) such as iris, pedestal or blanking or black level, color balance, and other controls) if the CCU has a serial data port that can be accessed.

Switcher Automation Systems

The robot controls can be interfaced with some production video switcher and effects systems (if an external serial data port is available) that can, give instructions to the switcher upon selection of a camera move or activate a camera movement upon selection of the camera by the switcher. The result is simultaneous selection and start of movement by the camera.

Lighting Systems

The interface of studio lighting control systems with the robot control system provides the ability to cue lighting sequences along with the activation of camera moves. The camera control could be used to provide a trigger to the lighting system to initiate a lighting change sequence or merely to turn on or off the lights for a set about to be used on camera or a set that no longer is needed. Again, a serial data port is needed on the lighting control system for the interface.

Audio Control Systems

Just as audio-follow-video (AFV) interconnection systems are common in many television stations to switch microphones along with camera takes, similar interconnect arrangements can be made with robot control systems. However, the use of a more intelligent controller than that in the switcher provides the ability to control the audio with more finesse. For example, in situations where a complex video switcher and effects system does not provide reliable tally or AFV signals, the robot controller may provide the ability to turn on a microphone slightly in advance of a camera take to that on-air talent and turn it off some time after the camera is off the talent (to avoid clipping dialogue).

Newsroom Facilities

An interface with electronic newsroom facilities and the robot controller provides the ability to cue prompters, turn on microphones and lights, and activate tallies and other signals. Cues in the prompting text can be used to switch cameras or select pre-programmed shots.

Data Modems

Because the robot control is a computer, virtually any device that can be connected to a modem can be controlled in some fashion. Thus, it becomes possible to control a camera or some other device at some remote location via telephone lines or other data link. For example, cameras and other devices can be controlled via modems at satellite news bureaus or other remote sites.

OPERATIONAL CONSIDERATIONS

Frequently camera robots are used daily for scripted or fairly predictable shows such as newscasts or talk shows. Occasionally it may be desired to use camera robots for telethons or other more complex or spontaneous productions that would be difficult to do with robotics control. On these occasions it may be desirable to have camera operators. Some camera robot systems have switches that allow the robotics to release control of the camera pan head and the pedestal and thus allow for almost instant manual operation. This feature (also called *backdrive*) can also be used as a manual backup in the event of failure of the robotics system. Another advantage of having this feature is to mix manned and unmanned cameras to suit the needs of the production.

Some robots will allow a switch to manual control, memorize the new position, and, after returning to remote control, adapt to the new position and continue with the shot sequence. In other words, on some systems, remote and local control may be mixed at any time.

Operator Training

The operation of robotics camera systems is fairly straightforward. Therefore, training can usually be accomplished in a few sessions with a good instructor. After the operator is familiar with the system, it is important that directors and others involved in studio production agree on a uniform set of commands for robotics camera operation. Rehearsals before the first live session can also be helpful. As with other operating positions in a station, one primary and several backup camera robot operators should be trained for this essential position.

Maintenance

Camera robot systems are generally considered to be reliable and require little routine maintenance other than the general cleaning, lubrication, routine testing, and periodic software and electrical checks that any electromechanical device in daily use would require. Support from manufacturers varies, however, and the availability of parts and service must be resolved at time of purchase. Good documentation on mechanical components, electrical systems, and computer software will help insure fast repairs and fullest use of the system's capabilities.

Some robot controllers use standard personal computer (PC) hardware plus specialized keyboards, tablets, or touch screens to help keep maintenance simple and straightforward.

SUMMARY

Camera robotic systems can be a cost-effective investment for a broadcast television station or production facility. The level of sophistication in computer control and servomechanisms has reached the point where camera robots can provide respectable performance in certain production situations. In addition to the cost savings in operators there is the potential for linking the robots to other automation systems to integrate programming activities. However, consideration of the use of robots must be made based on evaluating the capabilities of the technology that can improve operational efficiencies without causing any degradation of production values.

Careful planning, both of people and equipment, selection of a manufacturer, proper installation, a good maintenance program and a control system with the degree of sophistication that meets the needs of the station can result in an effective, efficient and cost-saving installation.

5.16
LIGHTING FOR TELEVISION

BILL MARSHALL
CARIBINER INTERNATIONAL, INC., NEW YORK, NY

INTRODUCTION

The role of the television lighting director has been transformed due to the continuing development of more sensitive television cameras. The position is now more commonly referred to as the lighting designer, and has become an essential part of the creative team in television production. Lighting techniques in television have become as deliberate and carefully crafted as in film production. Many of the compromises of real time multicamera production are no longer necessary due to lower light level requirements, sophisticated control systems and enhanced editing capabilities. Despite the advances in technology, the lighting designer must remain aware that the home receiver, with its limited range of contrast (30:1 approximate), continues to be the weakest element of the television system.

Television is a two dimensional medium and therefore lighting of the subject is critical to the suggestion of three dimensional forms. Even the impressive resolution of high definition television can only replicate an image as it is revealed by light and shadow. Good lighting will both model the form of the subject and its surrounding and maintain its relative balance of intensity to the rest of the image. Lighting design can be most accurately defined as *constructive* use of controlled light for a predetermined objective.

A major portion of the shots used in television are close-ups; therefore, lighting of faces is the single most important task even though modern robotic lights are often used as a major background element. The standard techniques for modeling faces with light as used in still photography were simply a modern adaptation of the same approach used by portrait painters for centuries.

The basic arrangement of lights for television lighting is commonly referred to as the *two-* or *three-point system*. The first element or *point* is the *key light* which is the principal illumination of the subject's face. It is placed on an axis or slightly to one side of the camera and generally at an elevation of about 30° above the horizontal line between the subject's face and the camera lens. The elevation should be adjusted relative to the particular structural elements of each subject's face (such as length of nose or depth of eyes relative to the brow). The location in practical terms will obviously be determined by where or how the fixture can be supported. In studio work, this means the key light is very often suspended much lower than the general grid height to gain precise positioning.

The second point or component of this lighting approach is *backlight*. Located above and to the rear of the subject, the backlight creates a glow on the hair and a highlight on shoulders separating the subject from the background. The combination of a camera mounted key light and stand mounted backlight is the most prevalent arrangement used in electronic news gathering (ENG) and electronic field production (EFP). Ironically, the sole use of the camera mounted key light often creates a somewhat less than ideal picture, but has come to have direct association with realism.

The third element of the classic three-point lighting system is *fill light*. A single key light can often provide modeling that is too severe in the absence of other ambient light sources. Fill light generally softens and blends the back and key light accents while maintaining their purpose to highlight and separate the form.

While a setup such as described here is relatively easy with one camera and one subject, the reality of television production is that there is generally more than one camera and multiple subjects. To light an actual production, the lighting director will expand the basics of the three-point system to cover all the subjects and for all the camera angles. This often requires clever fixture arrangements wherein the function of a fixture has multiple uses. For example, in a typical two person interview, the lighting design might be arranged such that one subject's key is simultaneously serving as the other subject's backlight.

Simultaneous with careful positioning of light fixtures for modeling, the lighting director must also carefully consider the control of the shadow the light sources will create. Microphone boom shadows can be difficult to control. For each camera angle, the key light and backlight relationship must continue as well as control of the shadow they create. Control of boom shadows can require careful coordination between the boom operator, the director, lighting director and scenic designer; however, the use of wireless mics have greatly simplified this issue. Other common shadow problems, which are generally within the lighting director's control, are elongated nose and chin shadows which occur from improperly positioned key or backlight fixtures.

It should be noted that projected shadows, shapes or patterns can be some of the most powerful techniques available to a lighting director in suggesting time, place, mood or even pure background decoration. The character and quality of light is often more apparent from the shadows it casts. Shadows can be hard, soft, transparent, or even a different color than the apparent source. Because shadows are so important, major lighting arrangements should be carefully planned and drawn to scale. Section views in scale will help to predetermine where the shadows will fall, if there will be any scenic conflicts and most of all, this preplanning will save a tremendous amount of time in the studio or on location.

Once the lighting of the faces is established, the lighting director plans the background lighting. While a TV program can occur in almost any conceivable background, the lighting of faces continues to determine the relative brightness of the backgrounds. The reflective value of a face ranges between 28 to 41% while a white wall can be 96% reflective. A lighting director must therefore be very careful to use lighting to maintain a proper balance since the viewers' attention will be naturally drawn to the brightest spot of a television picture. Lighting intensity along with scenic element selection is critical to controlling the viewers' focus.

The cyclorama (cyc) is a generic background found only in studio lighting. A cyc can easily be over lit and then in contrast over power and appear to darken the skin tones. Projection of light patterns on the cyclorama is often an inexpensive way to create a setting with light, but again, the patterns which decorate a long shot should not appear undesirable or too bright relative to natural skin tones in the close-ups. Elaborate scenic treatment may require all types of built-in specialty lighting and a whole assortment of fixtures for each unique requirement.

LIGHTING LEVELS

There is no one proper level of light, except as required to allow a particular camera to make a good picture under specific conditions. The level required will vary by camera type, lens, type of action, quality of teleprompter glass, existing ambient lighting conditions and other purely aesthetic considerations. The lighting director must control the relative balance of the lighting for every given situation whether it is in brilliant sunlight or in a dark dramatic stage setting. There are often situations where the natural conditions greatly exceed the limited 30:1 contrast range of the television broadcast receiver. Therefore, it is also the lighting designer's responsibility to lead the director and design team away from these difficult conditions.

As with any camera lens system, the amount of light required is a direct relationship between the pickup medium, lens aperture and depth of field desired. Long focal length lenses used in sports events have smaller apertures by design. Since the fast moving action demands a high depth of field, the lighting level must therefore be high enough to satisfy this combination of factors. Conversely, the exact same camera in a dimly lit studio close-up may require a fraction of the illumination level of the sporting event. Good picture quality and proper level can only be determined through the lens of the video camera.

There are many devices available to the lighting director to control the levels of illumination including a wide variety of television studio and location lights. The distance between the fixture and the subject will directly affect intensity. Intensity can also be controlled by scrim, which is actually a wire screen inserted in front of the lamp. The greater the density of screening, the more the light level is reduced. Actually, any medium placed in front of a fixture will reduce its output to a predetermined degree. A wide variety of available sheet diffusion materials will reduce intensity and reshape the pattern and quality of the light. Diffusion materials soften the light and shadows produced. Even colored filters reduce light output relative to the coefficient of transmission of the particular color. For example, a blue filter passes very little light while a yellow-green filter will reduce the output light level very little. The most precise and convenient level control of incandescent lighting is dimming. Compact portable dimmers are also used outside a studio or theatrical environment, but do not necessarily eliminate mechanical means of level control. While dimming does change the color temperature of the lamp, it can still be used effectively.

COLOR TEMPERATURE

For accurate color rendition, the television system must operate within a consistent range of *color temperature*. Color temperature is measured in degrees Kelvin (°K) and varies dramatically from type of artificial light to time of day and atmospheric conditions of daylight. A television camera must be white balanced for the same lighting conditions as the scene will be shot. Segments shot separately which are to be seamlessly edited together must be shot under consistent color temperature light for accurate color rendition between segments. In our daily routine, the eyes experience the effects of different color temperatures while the brain interpolates color rendition. Recalibration of the camera for varying lighting conditions has somewhat the same effect yet it is often important to retain some of the original lighting color and character. The television system is actually quite flexible, permitting color temperature swings of ±300°K without major effect to visible color rendition.

Exterior windows generally present the greatest color temperature problem because exterior daylight is a tremendously different color temperature and is extremely bright relative to the artificial interior lighting. Large sheet filters which correct both color temperature and intensity are available for this purpose; however, if the window area is extremely large and daylight dominates the scene, it is generally easier to work with high color temperature light sources rather than incandescent.

LIGHTING FIXTURES

A designer's choice of lighting equipment differs considerably between the studio and on location. On location, equipment is chosen for its light weight and efficiency. The lighting designer on location must cope with varying natural light conditions from full sunlight to little or no light. Studios conversely are designed and equipped to give the lighting designer absolute control over all aspects of lighting: intensity, color and placement.

Location Lighting

Since lighting design is deliberate control of light for a desired effect, good lighting design may not even require the use of any fixtures at all. In many daylight situations, a lighting director may choose to simply use reflectors and scrims to achieve the desired effect. Movement of the sun is predictable so the survey of the site must be made at the same time of day of the event shoot in order to select workable camera positions and to determine the proper equipment. The sun as a key source is very harsh and requires intense fill light for the talent. Reflectors are very effective for this purpose. They require no electrical power, but must be attended by a person at all times to keep them oriented correctly to the moving sun. Lightweight folding reflectors are convenient to pack and setup but do not present the necessary hard, stable surface needed to provide a smooth field of light. The heavy solid panels are less convenient but are stable. Another way the harsh light of the sun can be controlled in intensity is by using large silks or nets to soften or to shadow the talent. Nets and silks under 6 ft × 6 ft attached to frames are called *butterflies* up to 20 ft × 20 ft are called *overheads*. Wind is an obvious factor in the decision to use these tools.

For smaller remotes, the lighting director's selection of fixtures is often governed by weight and portability relative to lumen output. There is a tremendous variety of extremely ingenuous and lightweight fixtures available. These generally are packaged in kits with a full assortment of stands and grip hardware to accommodate any situation which may occur while on location (see Figure 5.16-1). Many of these kits are designed to incorporate dichroic filters to match the 3200°K incandescent lighting to the 5600°K daylight. This filter reduces the light output quite noticeably.

For larger location work involving daylight conditions HMI® lighting has become the standard of both the film and television industries. HMI® is a registered trademark of OSRAM, although it is often used (or misused) in referring to lamps of other manufacturers. The name refers to the basic elements, which are combined in the lamp's quartz envelope to create the unique color temperature: "H" for mercury (Hg), "M" for the various metal halide rare earths, and "I" for the halogen iodine and bromine.

The highly efficient ballasted arc source lamps come in a wide variety of sizes from 200 to 20,000 W. They provide about 80+ lumens-per-watt at 5500°K (which is 4 times the output of incandescent light). HMI® lighting is often the best solution for interior situations with tremendous window exposure. As in any exterior situation, the lighting director must carefully monitor the changing color temperatures of daylight and remember that the light of a clear sky late afternoon is quite a different color and character than mid-morning when the sky was overcast. Figure 5.16-2 shows a typical HMI® device.

Figure 5.16-1. For remote lighting, compact kits which contain a large assortment of fixtures, stands, reflectors and grip hardware are available. *(Courtesy of Lowel-Light Manufacturing, Inc.)*

Often a lighting director has to shoot in situations where the existing lighting is a low ceiling covered with fluorescent fixtures and they must be used because they characterize the space. Common architectural fluorescent light does not provide a full spectrum light and the most common type cool white is very short of red energy. While it is possible to color correct each fluorescent lamp using a minus green color correction gel it is often impractical. By color balancing the camera under a representative mix of the fluorescent and the 3200°K talent's lights acceptable skin tone can be produced while the background may still appear greenish. Today, there are a wide variety of fluorescent lamps available and some offer quite a high color rendering index. In fact, a line of fluorescent studio fixtures that utilize compact fluorescent lamps have

Figure 5.16-2. HMI lamps are most often used in fresnel lens housings and are available in a wide variety of sizes. The associated lamp ballast is a separate unit from the lamp housing. *(Courtesy of Arriflex Corporation.)*

become quite popular. They are very energy efficient and are an excellent choice under certain conditions.

Exteriors at night for TV require great simplicity to look real. Large HMI's® are very useful because one large source can supply the basic illumination for a very wide area. Within an exterior scene there are always elements supposedly lit by artificial sources either seen or imagined. With the camera balanced for 3200°, quartz lights can be used for the people areas while the overall HMI's® at 5500° will seem very blue. If the HMI® light is too blue, it can be corrected slightly until it seems to be the proper gray-blue of moonlight. Using smaller HMI's as back and rim light will further enhance the moonlight effect. In attempting to provide realism, lighting must suggest the correct mood. Lighting is essential in creating the feeling or mood the production team envisions.

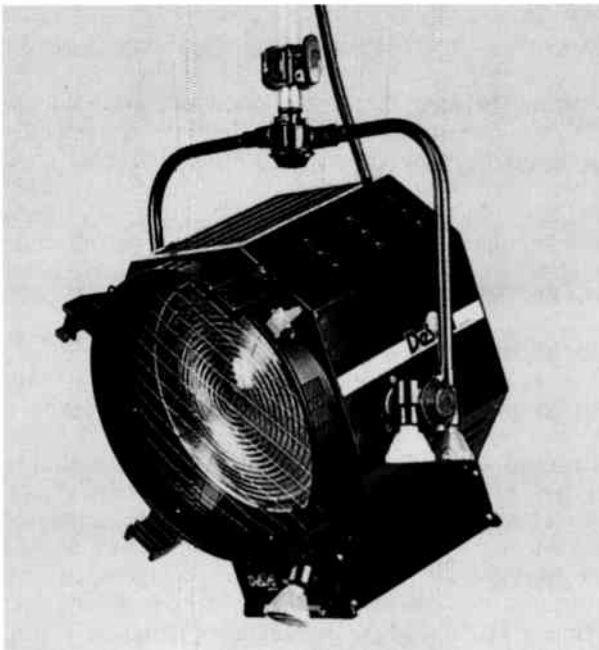

Figure 5.16-3. Studio quality fresnel spotlights are much more durable and have superior optical systems compared to more inexpensive theatrical units. *(Courtesy of DeSisti Lighting)*

Studio Lighting

In a studio the television lighting director has the greatest control over lighting quality. A TV studio is by definition an idealized environment for production of television programming.

In a well equipped studio the television lighting director has quite a variety of lighting fixtures or luminaries available to accomplish the basic objectives of TV lighting: separation, modeling, accent, illumination and directing viewer attention (see Figure 5.16-3). This variety of fixtures and the various qualities of light which they produce have been developed to enhance the efficiency of studio operation. The careful manipulation of light quality by external diffusers, cutters, reflectors, etc., for each shot is still not as common in video production as film but has increased greatly. A complement of fixtures with given characteristics plus the mechanical light control techniques of the film industry provide a television lighting designer with a versatile palette of choices to design the lighting.

Spot Lighting—Fresnels

In a studio, the most common and useful fixture is the *fresnel lens spotlight* (see Figure 5.16-4). The lighting from a fresnel is very controllable and has a smooth even field. By a simple adjustment of the position of the lamp, the fixture will produce either a narrow spot or wide flood beam of light. Equipped with barndoors, this beam can be further shaped to virtually any pattern. Slots in front of the lens allow color, diffusion media or screens for intensity control to be slipped in place. A complement of single and double thickness. and half and full frame screens

Figure 5.16-4. Studio quality fresnel spotlights must offer good quality long leaf barndoors as an essential accessory. *(Courtesy of Strand.)*

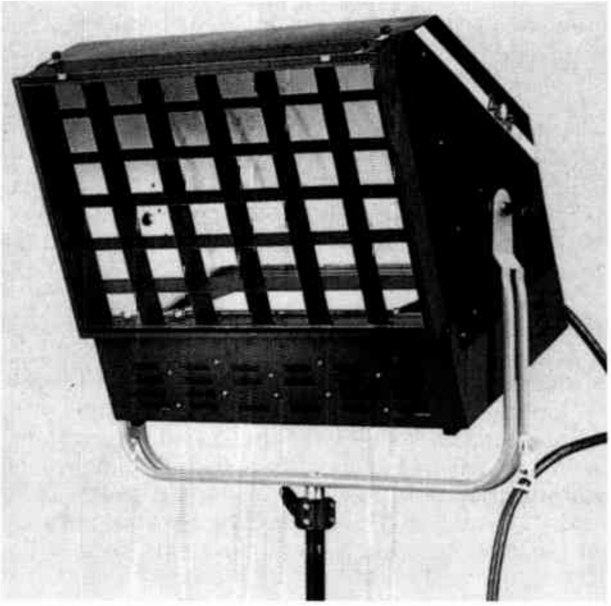

Figure 5.16-5. Spotlights fitted with eggcrate louvers offer controlled smooth even lighting.

should be provided for all fresnels even when dimmers are available.

For most 14 ft to 18 ft high grid studios the 6 in., 8 in. and 10 in. in wattages from 500 to 2,000 are the most common units. In smaller studios or tight applications smaller fixtures are often employed. These units enclose the same wattage lamps in small housings. A number of people prefer these baby size units for their easier handling and somewhat different optical characteristics. As noted previously, the higher the grid, the higher the required wattage fixtures. Therefore, in higher studios, the standard complement of fixtures might be 5,000 and 2,000 W units or even up to 10,000 W. Conversely, fresnel lens units are also available in sizes down to a 2 in. lens with a 100 W lamp.

In selecting a line of fresnels the studio lighting designers must carefully weigh both the optical and mechanical features including:

- *Stability.* Poorly made fixtures will not focus properly once they are hot
- *Balance.* Fixtures should also be well balanced, even with barndoors to remain in focus
- *Accessories.* The manufacturer should also provide a complete line of suitable accessories including barndoor, with leaves that are long enough, screen sets, diffusion frames and stand mounting hardware.

Soft Lighting—Softlights

The softlights are another common studio fixture (see Figures 5.16-5 and 5.16-6). They provide a controllable diffuse base or fill light. In this fixture the light sources are totally concealed and the light is

Figure 5.16-6. Softlights produce a very diffuse source and have switches to select as many lamps as necessary. *(Courtesy of Mole-Richardson.)*

reflected in an indirect manner. These units are not particularly energy efficient, but are unequaled in providing a shadow free light, which can be controlled with eggcrate attachments. They are available in a variety of sizes. Large 4,000–8,000 W units are pretty unwieldy for many applications, but the smaller units in the 1,000 to 2,000 W range are becoming very popular as fill lights, because they are easy on the talent's eyes. With lower light level requirements softlights have become the preferred broad baselight source.

Area Lighting

Scoop floodlights were once very commonly used in studios to build up high levels of base light that is no longer required. Scoops are used invariably with diffusion media, so it is essential that a diffusion frame is ordered. While the majority of lighting can be done with fresnels and some type of diffuse source, there are a vast variety of fixtures which each produce a different quality of light for special applications. For a harder rectangular field of fill light, a broad can be used. It is very similar to a scoop in concept, except its housing/reflector creates a somewhat less diffuse light. It is always used with diffusion media. These fixtures are now most commonly limited to lighting backgrounds.

Other Fixtures

Probably, the most efficient incandescent fixture used in television lighting is the *Par unit* (see Figure 5.16-7). The lamp contains both the reflector and the

Figure 5.16-7. The source 4 Par provides similar output as standard Par 64, at a lower wattage. It has interchangeable lenses for a variety of beam spreads.

Figure 5.16-8. The source 4 ellipsoidal produces extremely sharp pattern for many interesting effects.

lens, which is available in 5 different beam spreads. While limited to very large studios and remotes, the Par is an inexpensive and powerful tool for the lighting director. A new variation of this fixture has been recently developed which provides a similar quality and quantity of light with a lower wattage lamp. It has the added convenience of interchangeable glass spread lens, which match the different lenses of standard Par lamps.

The *ellipsoidal reflector* spotlight is a unique effect light in a studio (see Figure 5.16-8). The optical system of this unit allows the beam of light to be hard or soft-edged and the projected pattern of the beam can be precisely shaped by internal shutters. It is most commonly used to project patterns on the cyclorama. The modern ellipsoidal spotlights with dicroic reflectors and sophisticated optics offer very bright clear projections of patterns, which can be made from photographic half tone-etched metal or lithographed glass slides. These sophisticated patterns are available in a variety of standard and custom designs. Ellipsoidal spots come in a variety of beam spreads but the wide-angle short-throw sizes are most useful in small and medium studios.

Robotic Fixtures

Robotic fixtures have become common place in in theatrical and television lighting. These lights fall into two categories. The first group can position its light by means of a motorized yoke which therefore requires a sturdy mounting position that does not sway from the inertia of the moving unit. The second group utilizes a motorized mirror that reflects the output beam of light into the correct position. Within these two mechanical solutions there are *wash* lights with a soft-edge beam of light and *hard* lights, which project a very defined beam of light and can project all types of patterns. These lights are primarily used for concert lighting and theatrical productions where movement of the lights and changing colors provide dramatic effects. These lights are used for face lighting only when they present the only practical alternative because of the useful remote focus capabilities.

Fluorescent Fixtures

Fluorescent fixtures have become quite popular in many studio installations. Utilizing the improved color temperature of compact fluorescent lamps, several manufacturers have developed a variety of useful fixtures. These systems offer some very compelling features such as low energy consumption, with minimal heat production. They are excellent soft or fill light but are somewhat limited in throw distances. Fluorescents are most commonly employed in news and other continuously on air forms of production to take advantage of their energy efficiency. Fluorescents are an excellent tool for the lighting director and can be effectively used in conjunction with standard incandescent fixtures.

Accessories

There are a number of accessories, which make positioning light fixtures more versatile. Despite the expenses and care expended on planning the grid system, it cannot satisfy every fixture mounting requirement; every studio must have some fixtures on *rolling floor stands*. In addition, many types of *clamps* and general grip equipment are available for special mounting situations.

One of the key accessories in the lighting system are *extension rods* either *straight* or *telescopic*. This device allows fixtures to be hung at a lower level than on the fixed grid. For example, a key light at a 30° angle (elevation) above the talent could be moved much closer to the talent and provide more light if it were hung lower. Counter-balanced devices such as pantographs and spring load telescoping hangers are not recommended because they cannot locked in place.

The *Century stand* has endless applications around the studio. It can grasp all types of material such as flags, cutters, cookies and support reflectors (see Figure 5.16-9). *Century* stand use is limited only by the lighting designer's imagination. No matter how many are available, they will all be put to good use.

Ultimately, the proper quantity of fixtures, accessories and other components of a lighting system for a studio of a given size can vary widely according to the requirements of a specific situation. For example, a studio with a fixed grid and a tight production schedule will function more efficiently with a heavy saturation of fixtures. With a large quantity of fixtures, major relocation of all the units is somewhat minimized. When sophisticated motorized grid systems are available, the ease of relocating fixtures will reduce the total quantity of fixtures for the same size studio. The choice of either of these two approaches is also dramatically affected by labor costs within a particular facility. Too often the expense of a few extra fixtures is not significant compared to the additional time and labor required to fully utilize a minimal complement of equipment or the cost of elaborate rigging. Final discussions on equipment purchase require a careful analysis of a station's specific production requirements in coordination with all the financial ramifications of various approaches.

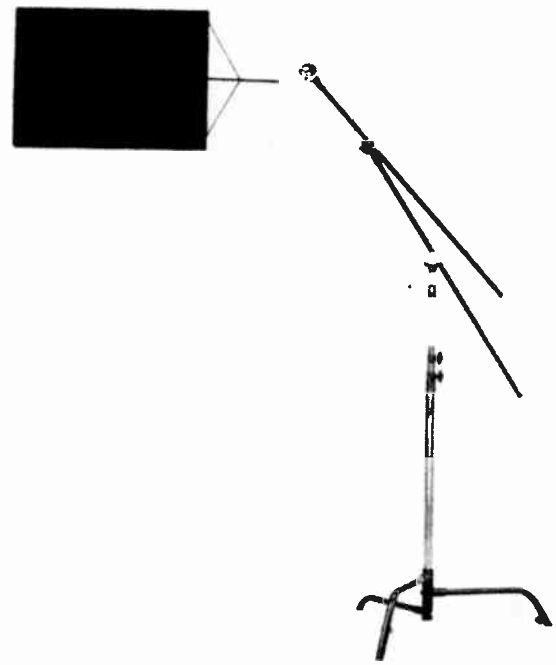

Figure 5.16-9. The three level legs allow the "C" stand to fold flat for storage. The head can grasp numerous flags, cutters, cookies, etc.

It should be evident from the previous general discussion of lighting problems that the close cooperation between the lighting designer and the video shader is absolutely essential. The video shader is in control of a marvelously versatile picture machine whose limits are stretchable in the name of art. Great television pictures are the result of careful teamwork by the lighting designer and the video shader.

STUDIO DESIGN

In designing a television studio, the lighting system is a major consideration as it is so closely interrelated to the physical size and shape of the room. While the television industry has seen tremendous technological improvements throughout its evolution, the basic phys-

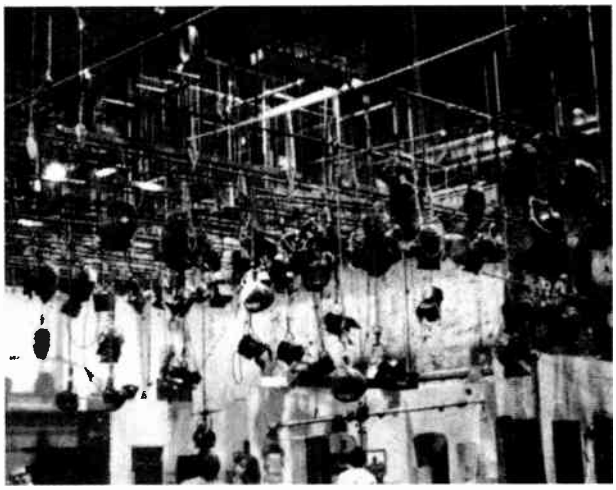

Figure 5.16-10. This large fixed grid studio illustrates the relationship of the various aspects of the studio lighting system. *(Courtesy of WPBT.)*

ics of light and its ability to describe three dimensional form cannot change. Consequently, many older studios have upgraded virtually every piece of broadcast equipment, while the basic components of an older, well designed lighting system still function extremely well.

Studio Size

Ideally, a studio provides the optimum environment for any type of production. In practice however, studios of various sizes tend to function best for particular types of production. The typical broadcast plant requires several sizes of studios to most effectively service its programming schedule. Typically, a small studio (1,200 sq. ft) is dedicated to news, interviews and public affairs; while 2,400 sq. ft is the most common size of small production studio. For general production, a studio of 5,000 sq. ft or more will offer fewer limitations. The size of the studio must be carefully determined by existing and future programming requirements, keeping in mind that the larger the studio, the fewer limitations. These are important decisions, since the lighting system must be planned relative to the size and specific requirements of the studio as shown in Figure 5.16-10.

Studio Height

When determining the height of a new studio, the lighting suspension system must be given careful consideration. The grid height for small and medium size studios is a function of the current fixed TV aspect ratio 4:3 and the normal wide-angle zoom lens. Most zoom lenses can cover approximately a +45° field. By calculating the actual width of this maximum horizontal dimension, the height of the grid can be determined by applying the aspect ratio (see Figure 5.16-11). Keep in mind that the studio lighting fixtures will hang approximately two feet below the suspension structure. In addition, a normal studio pedestal and cameraperson will prevent the lens from getting closer than approximately five ft in from a wall or any other obstruction, further reducing the maximum coverage of the lens. This method describes the theoretical maximum picture possible and the height the fixtures need to be mounted to stay out of the picture. However, television is primarily a close-up medium, and limitations in grid height can be overcome by various camera angles and special fixture mounting systems. High definition television will bring about a new, more rectangular aspect ratio (16:9) in the near future, which could actually reduce the theoretical studio height requirement.

Suspension Systems

The suspension system for the studio lighting is also a critical factor in determining studio height. All types of lighting suspension systems are commonly referred to as the *grid*. In its simplest form the system consists of a series of pipes suspended below the studio ceiling,

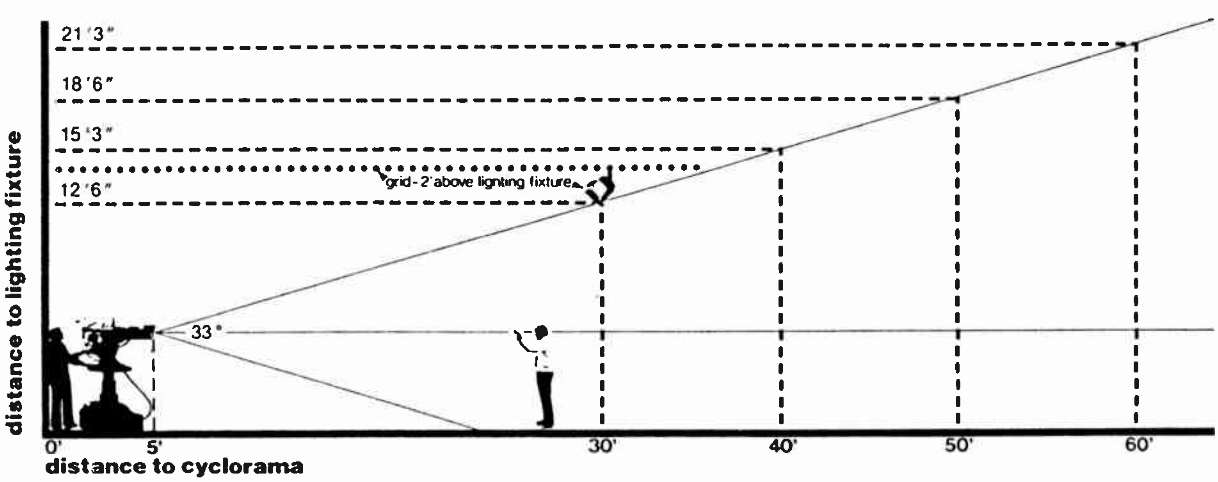

Figure 5.16-11. This drawing illustrates how the vertical aspect of a camera lens at eye level determines the height of a studio grid.

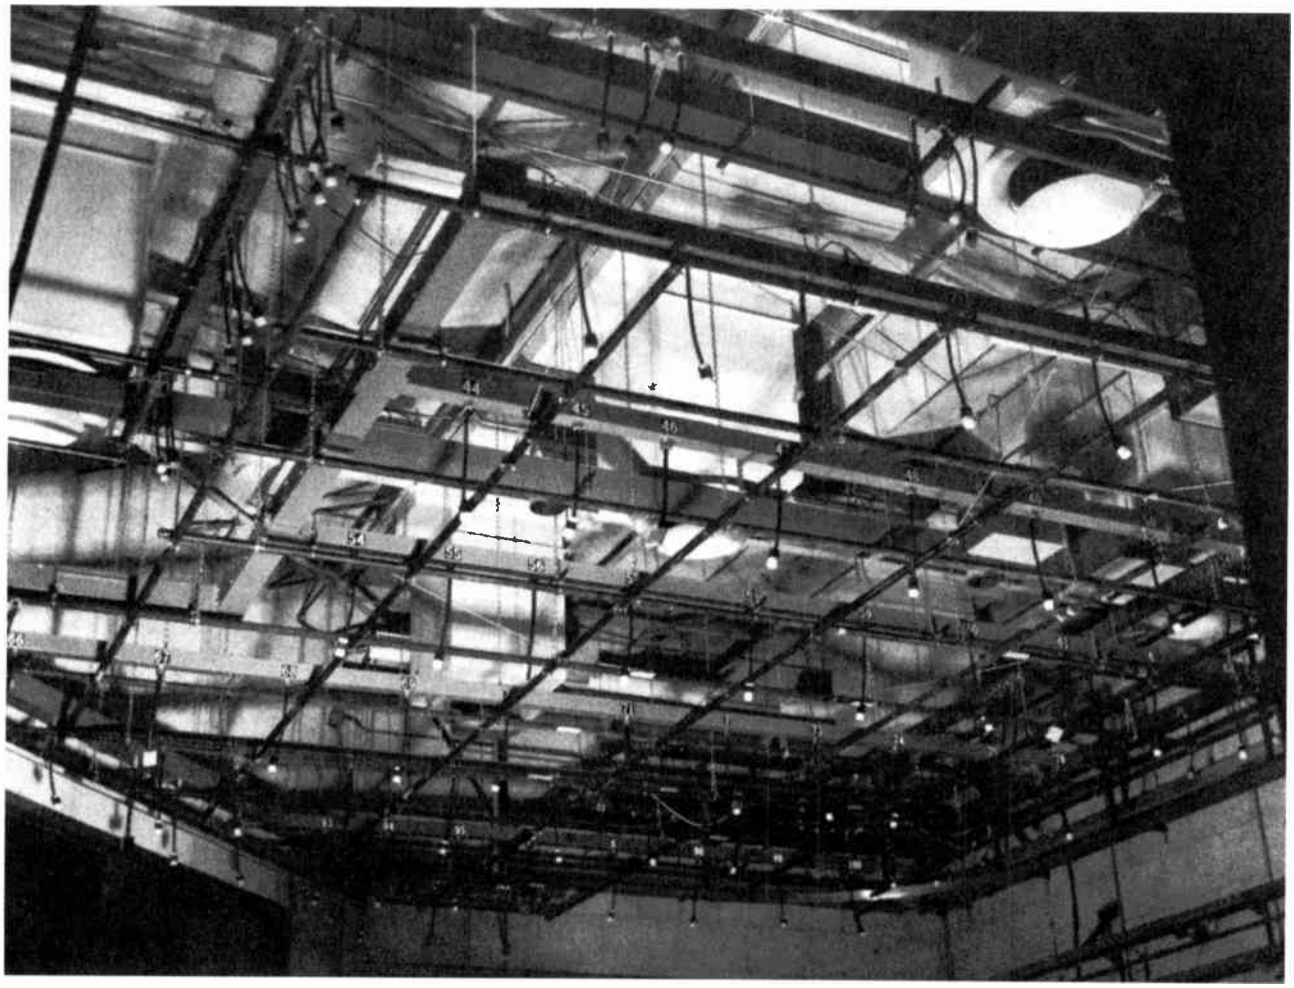

Figure 5.16-12. This fixed grid studio employs two levels to create a higher apparent background. Multiple pigtail outlets are positioned for cyc lighting units. *(Courtesy of WFAA-Dallas.)*

in a regular pattern. A grid must allow lighting fixtures to be hung anywhere over the entire studio. Actually the grid can consist of several different types or combination suspension system.

Fixed Grid

A *fixed grid* is the most common and least expensive system of suspending lighting fixtures (see Figure 5.16-12). The pipes are generally laid out on a perpendicular 4 ft × 4 ft spacing, which provides adequate flexibility in hanging positions. A common fixed grid height is 14 ft because it offers a good compromise between easy ladder reach and adequate clearance for wide shots. A fixed grid that is much higher than 14 ft increases the amount of labor needed to install and adjust fixtures. For a large multipurpose studio, a fixed grid could be a limitation, but the availability of a wide variety of self powered manlifts has allowed reasonable access to higher fixed grids. Bi-level fixed grids have been utilized to create a higher apparent background without additional cost and to keep the major portion of the grid at a reasonable height. To solve this problem more efficiently, several other systems have been developed.

Catwalks

Catwalks are generally also hung at a fixed level. Catwalks provide a measure of increased efficiency over a fixed grid but they are considerably more expensive. Catwalks allow studio electricians to work on lighting at the same time carpenters are handling the scenery. This can be an important time savings on a tight production schedule. Catwalks are usually arranged to create a fixed grid utilizing handrails in conjunction with an extension rod on each fixture. Catwalks when hung too low create the same height limitation as a fixed grid, but generally catwalks are employed at heights greater than would be reasonable for a fixed grid. Unfortunately, catwalks do not eliminate actually getting on a ladder to adjust the fine focus of each fixture. Catwalks primarily save time in setup and strike and offer the crews a safe work platform above the studio. In recent practice their high cost has prevented many installations.

Most studio fixture manufacturers offer developed pole-operated yokes for their units. Each fixture has a socket, which can be reached by a pole crank to adjust each of the basic functions, pan, tilt and spot-flood. There is a reasonable limit to how long a pole can be easily manipulated, but this feature considerably enhances fixed, high level grid systems. It is not possible to focus studio fixtures by this method as quickly or efficiently as by hand, but this system does provide a means of focusing otherwise unreachable units blocked by scenery and is seriously worth considering for any type of grid system.

Battens

The larger and therefore higher a studio that is required, the more complex the studio lighting suspension system becomes. In very large studios, a basic theatrical staging factor—"flyout clearance"—in addition to the TV aspect ratio, determines the grid height. Just as in a theatre stagehouse, flying scenery is a common requirement in larger scale TV production. Flown scenery commonly requires a minimum grid height of 40 ft. To raise and lower the scenic units and the lighting fixtures, a regular pattern of long battens or pipes run across the width of the studio. These battens run up and down on steel cables and are manually balanced by cast iron weights. These counterweighted battens solve the height problems but add additional work in rebalancing the counterweight arbors every time fixtures are added or removed from the batten. Counterweight rigging mounted along the studio wall encroaches on valuable floor space. Figure 5.16-13 compares the various approaches to the grid plan.

Winches

To solve the negative aspects of counterweight systems, many installations use electric winches to raise and lower the battens. These winches can be operated by sophisticated control systems which will allow the batten to be lowered for service or adjustment and then returned to an exact preset trim or level. The motors will easily lift any variable load within its designed capacity.

Many variations on the motorized batten system have been developed. In order to increase flexibility the battens have become shorter. This increases the number of motors required and the cost.

Modular Grids—Self Hoisting

To take advantage of the convenience and power of electric winches without excessive cost, a number of modular grid or short batten systems have been installed. These modules are essentially small pipe grid sections, which can be raised and lowered. Grids offer a flexibility similar to battens, but since they cover a larger area fewer motors are required. Both grids and modular short battens are designed to be self-hoisting. These systems greatly simplify structural requirements

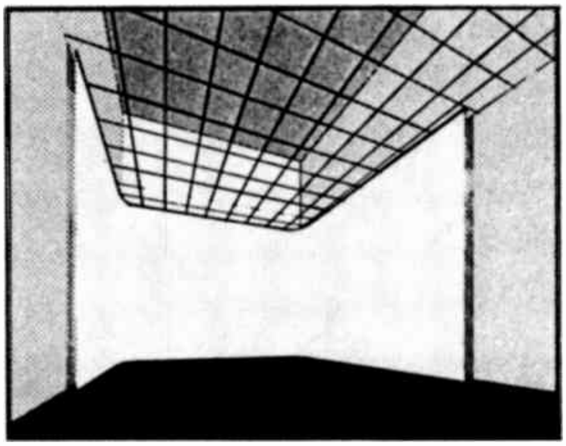

Figure 5.16-13(a). Fixed grid plan.

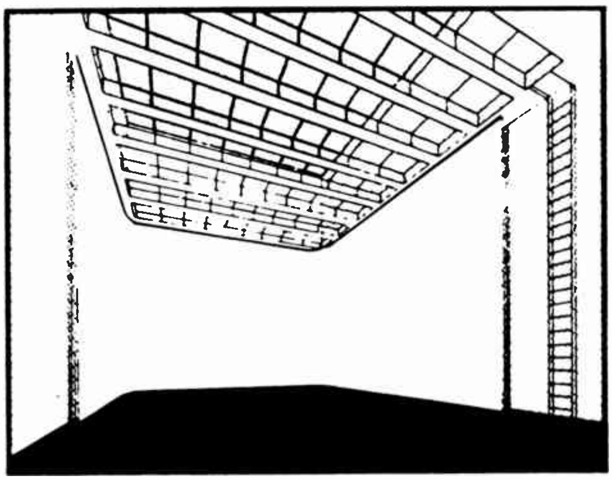

Figure 5.16-13(b). Catwalk grid plan.

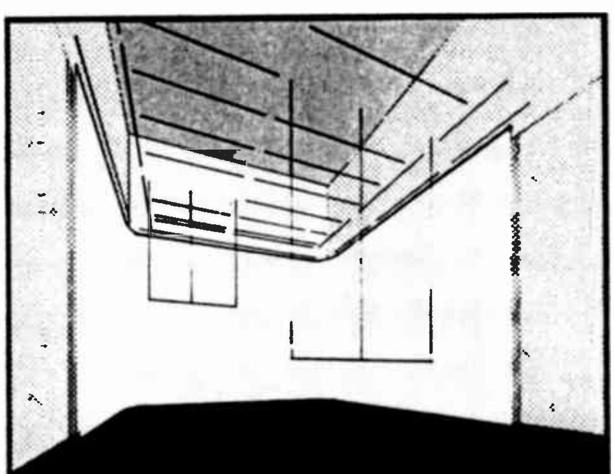

Figure 5.16-13(c). Batten plan.

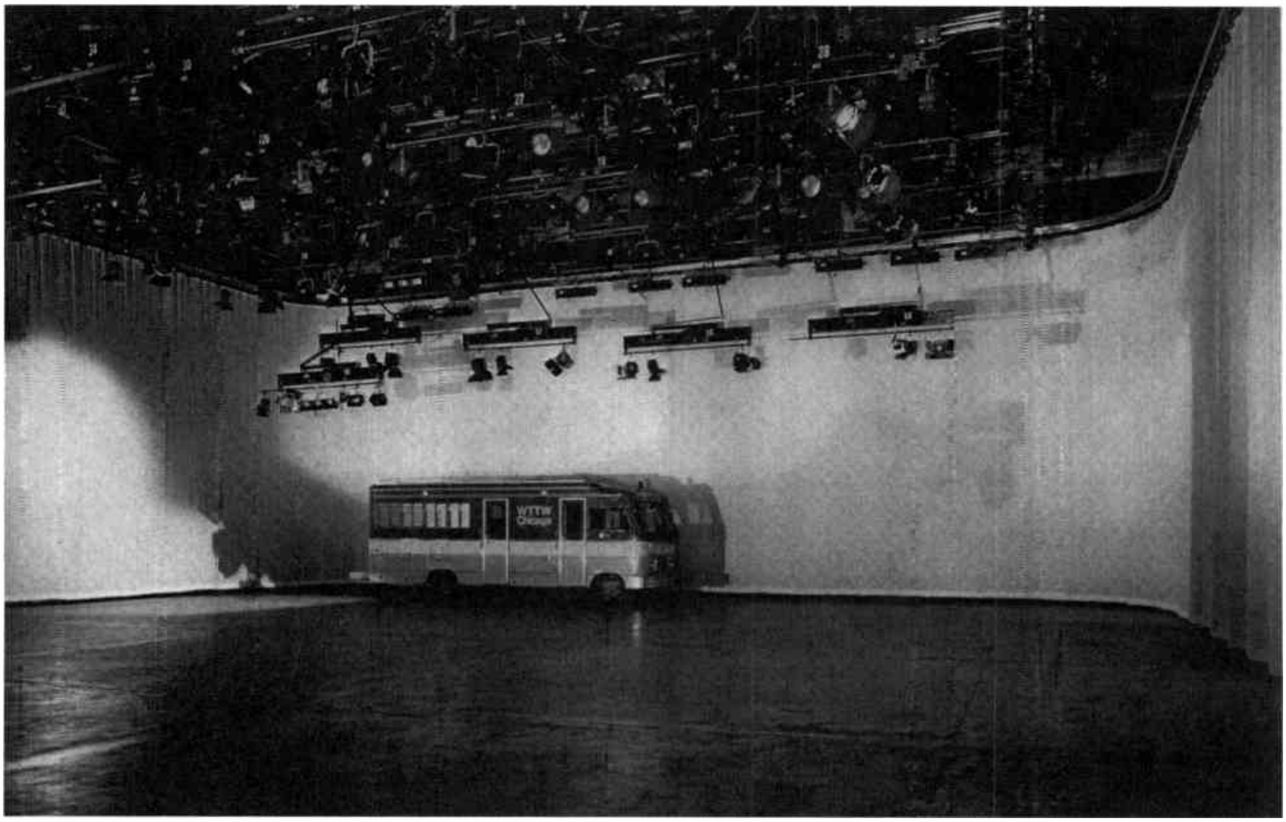

Figure 5.16-14. Self-hoisting batten are an effective suspension solution for large high grid studios *(Courtesy De Sisti Lighting.)*

of the studio, and the overhead structure remains clear of motors or steel hoisting cables (see Figures 5.16-14–5.16-18).

In studios which have either counterweighted or motorized battens a full walk-over grid should cover the entire studio. This grid-iron usually is made of steel grating or channels, as in a theatre stagehouse, and provides the support for the adjustable rigging. This walk-over grid provides easy access for any overhead suspension task any production may require.

In developing a fully integrated grid system, it is essential to coordinate all the building's structural, electrical and mechanical systems in relationship to each other and the grid. Whereas, in normal construction many of the mechanical elements in a ceiling are placed where convenient, it cannot be over-emphasized that improperly planned or installed ductwork and conduit runs can be a hindrance to production.

CYCLORAMA

Designing the cyclorama is integral in planning the studio lighting and grid systems. The grid or suspension system must provide a mounting position for the cyc lights located at the proper relationship to the cyc. Also, the total area of cyclorama will affect the calculation of the studio power service.

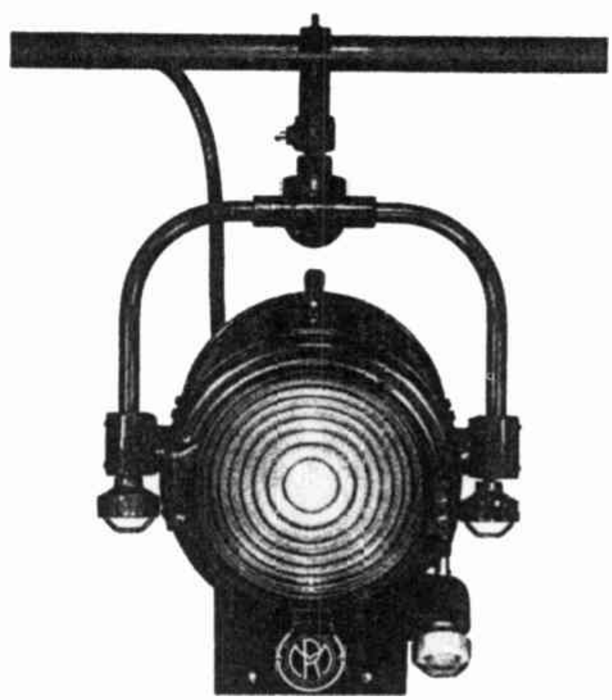

Figure 5.16-15. By inserting a long crank into the adjustment cups, this pole operated fixture can be panned, tilted or spot/flood focused from the floor. *(Courtesy of Mode-Richardson.)*

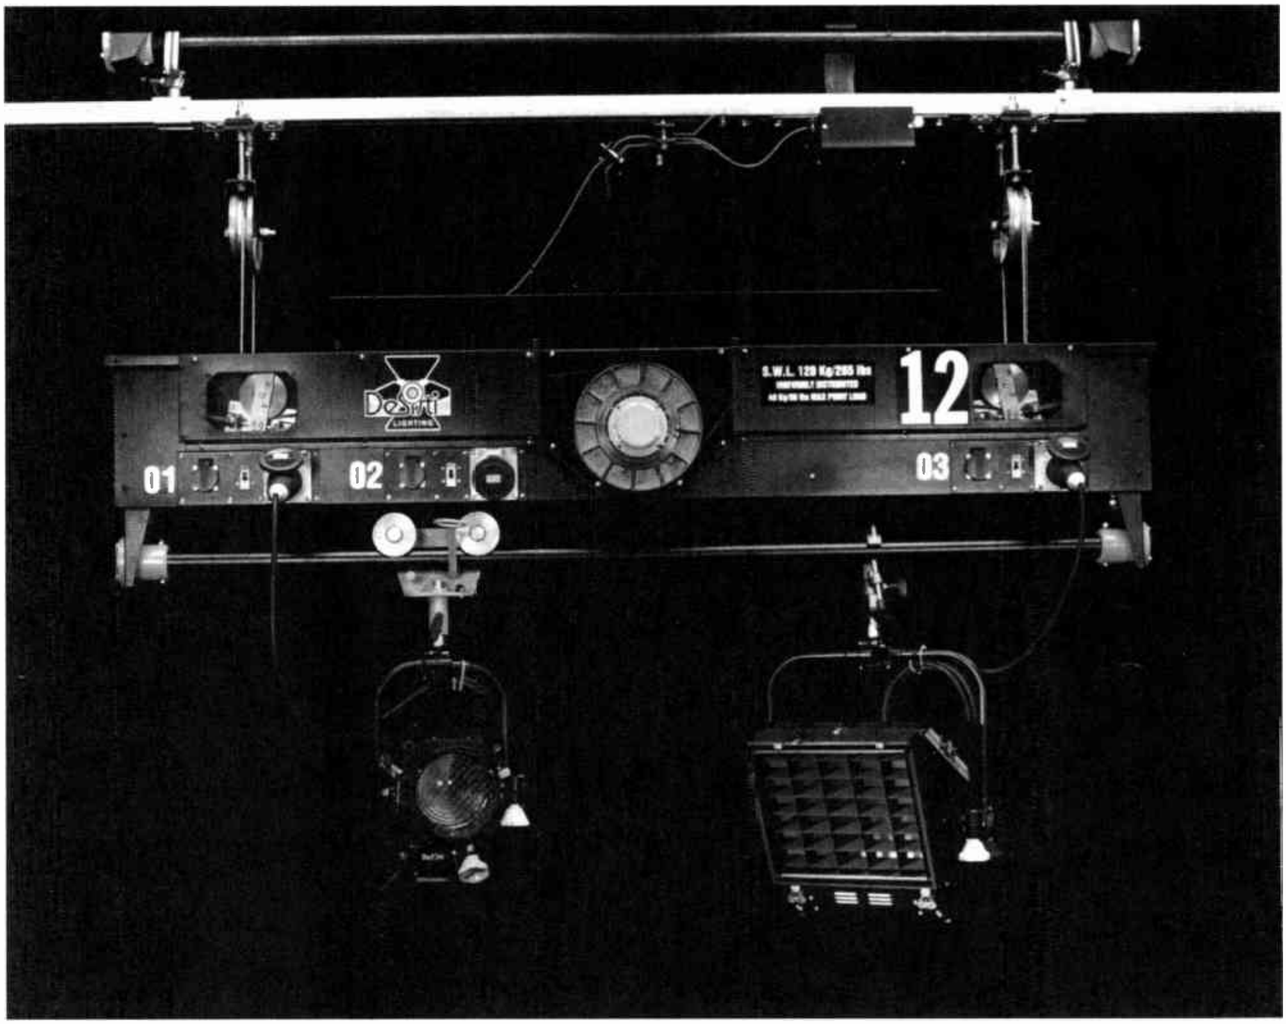

Figure 5.16-16. Manufactured self-hoisting battens are quick to install and efficient to use. *(Courtesy DeSisti Lighting.)*

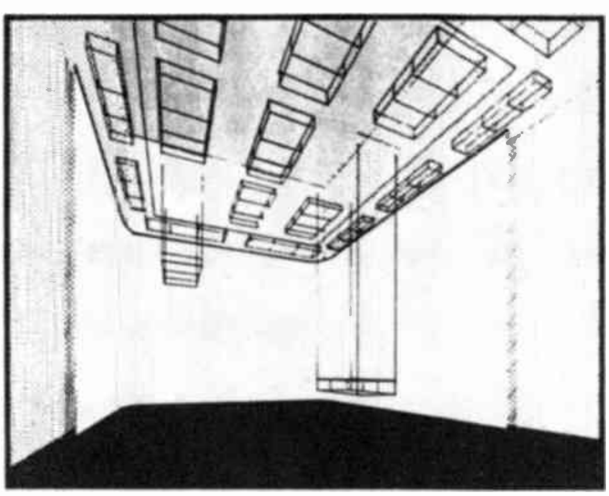

Figure 5.16-17. Modular grid plan.

Hard Cyc

Small studios often incorporate *hard* cycloramas which are smooth plastered surfaces that actually blend flush into the floor. They provide the ideal infinity effect which draperies cannot equally simulate. Hard cycloramas can be easily painted any color as needed and are especially effective for certain chroma-key techniques that can be spoiled by even the most invisible seams. Hard cycloramas are generally limited to small studios since their hard surface area invariably creates acoustical problems.

Cyc Pit

In very large studios a *cyc pit* is a compromise solution for creating the infinity effect (see Figure 5.16-19). The pit contains and conceals the bottom cyclorama lighting, which is essential for a tall cyc and the bottom of the drapery. When it is shot from the proper angle the pit will simulate a background without a horizon.

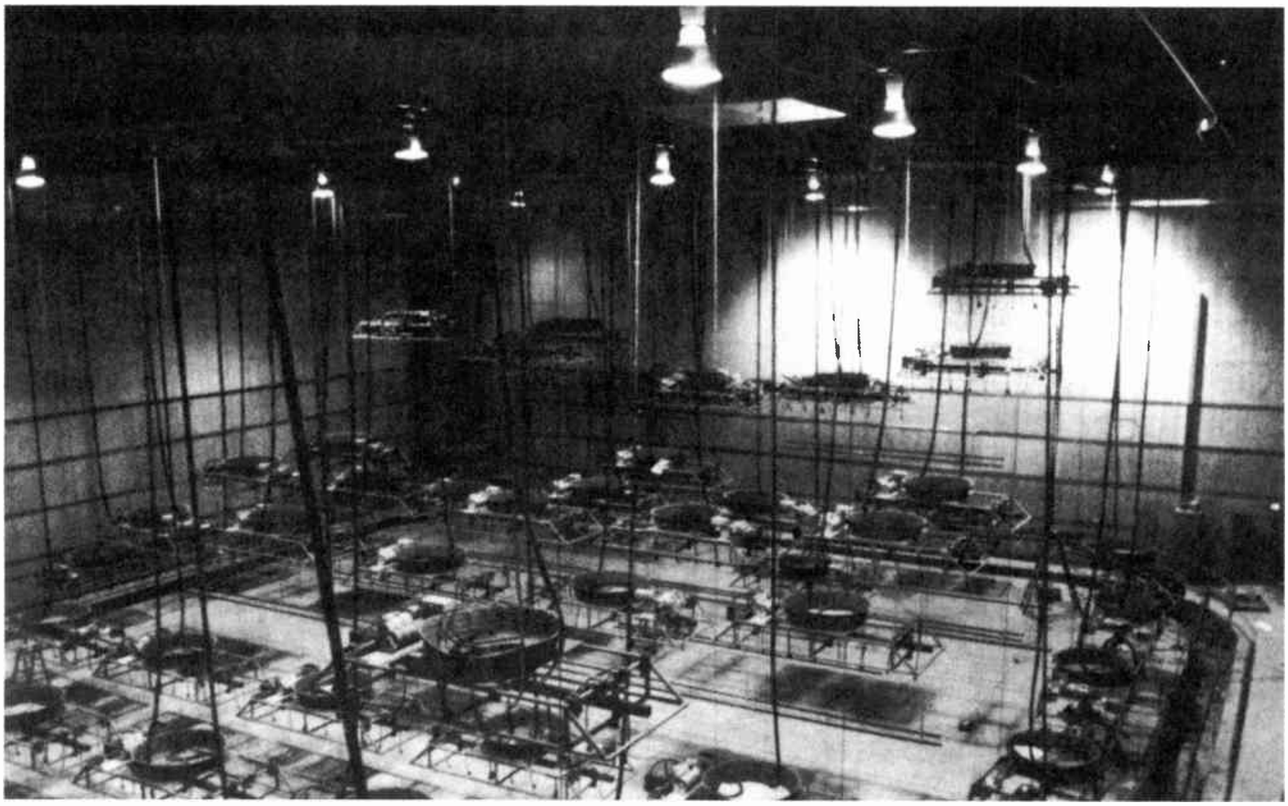

Figure 5.16-18. Modular self-hoisting grids allow variable height suspension of fixtures in a regular pattern through the studio. The round tubs serve as cable collectors for lighting and winch power. *(Courtesy Dallas Communications Complex.)*

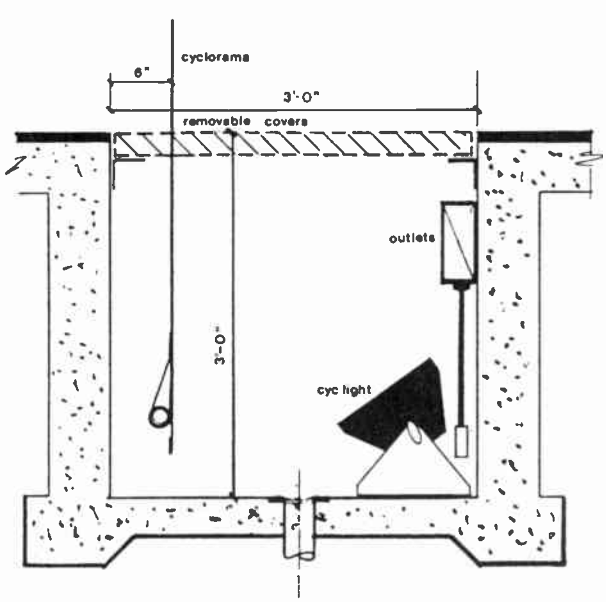

Figure 5.16-19. Cyc Pit: Section view through a typical cyclorama pit.

For most studios, a *drapery cyclorama* is the most convenient solution. This seamless drapery is hung on carriers which roll along a track and allow the cyc to be positioned anywhere around the perimeter of the studio (see Figure 5.16-20). Two parallel tracks permit another type of background to be pulled in front of the stretched cyc. Switches on the track system allow the draperies to be easily transferred to the front or rear tracks. *Leno* or *filled scrim* is the most common drapery material, although seamless muslin is an inexpensive alternate material. Translucent plastic rear-projection screen type material is also a popular material because it can be lit from either the front or the rear.

In large studios where experienced lighting directors are available, true white cycloramas are used to achieve greater color intensity on the cyc. However, in smaller studios, where the talent occasionally must work close to the background or where limited control equipment is available a 60% TV white cyc should be used for better control of contrast.

Drapery cycloramas are generally furnished with jack chain weights. Removable pipe weights bent to match the shape of the track should also be provided to create a wrinkle-free background. One of the most common errors in cyclorama design is an insufficiently large radius at the corners of cyc. No matter what material the cyc is made of, the larger the radius the easier it is to light evenly and accomplish the desired effect.

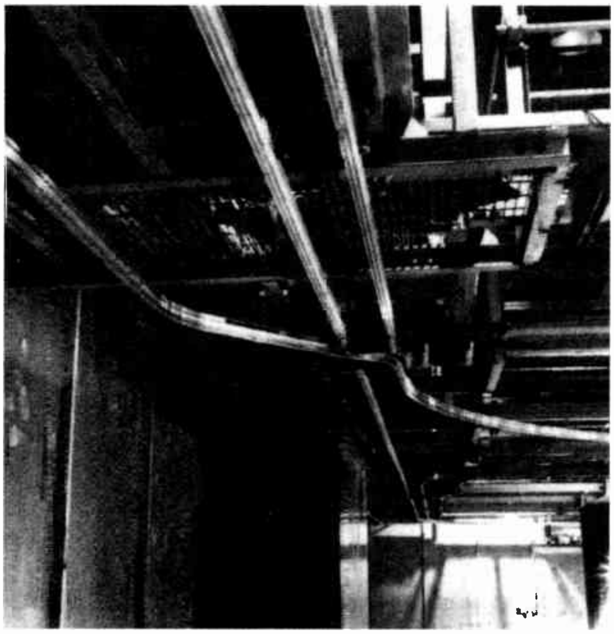

Figure 5.16-20. Cycloramas and draperies can be shifted to various track configurations by utilizing transfer switches. (CBS-NY) *(Courtesy of Peter Albrecht Corporation.)*

Cyclorama Lighting

Generally the arrangement of doors into the studio will define the most functional area for the cyc to be normally positioned. In the basic design of the grid or suspension system the type of cyc lighting system should be predetermined, and the proper hanging system provided accordingly.

There are several types of cyclorama lighting fixtures—striplights and a type of widespread fixture commonly know as *Far Cycs* (see Figure 5.16-21). Striplights are continuous rows of quartz halogen, MR-16, or Par lamps, which for an 18 ft high cyclorama should be mounted 5 to 6 ft from the cyc, while

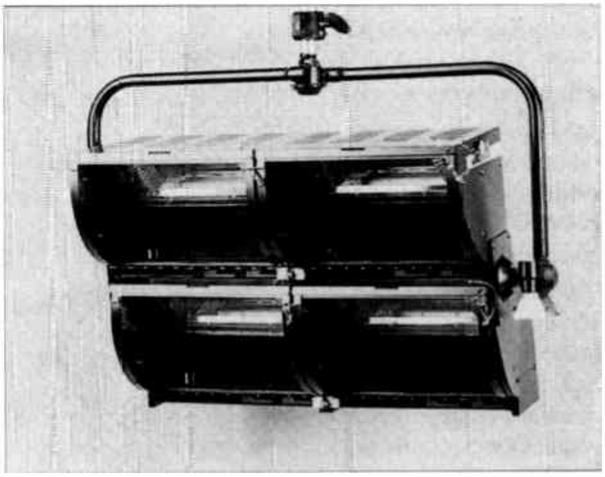

Figure 5.16-21. Four unit Far Cyc fixtures are very effective in lighting tall cycloramas. *(Courtesy Desisti.)*

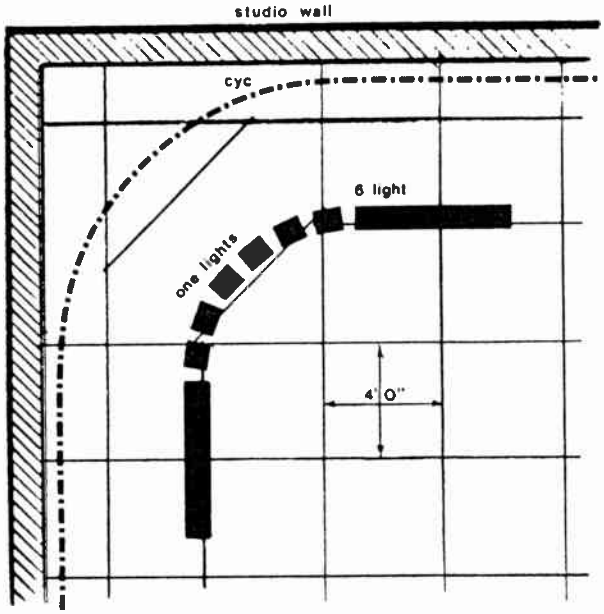

Figure 5.16-22. Cyc Light Layout: Typical arrangement of strip cyc lights relative to the cyc curve.

the far cyc units should be mounted 7 to 8 ft from the cyc (see Figure 5.16-22). Another type of fixture is referred to by its brand name *Pallas*. It is a version of a striplight that is made up of individual cells which can be placed to match any curve or straight surface. The entire suspension system should be designed around these dimensions. Far cycs generally will light the cyc as evenly as striplights, with less wattage. Because far cycs are mounted a greater distance from the cyc, they force the talent further away from the background. Generally, striplights should be limited to three colors, otherwise the separation between alternately colored lamps is too great to provide even coverage.

ARCHITECTURAL CRITERIA

Electrical

With the basic studio size determined and the net production area (NPA) defined by the cyclorama, it is possible to determine the power requirements for any given studio. The power requirements for studio lighting are a direct function of area and the required level of illumination. This power requirement remains consistent regardless of the grid height. For a lower grid, a greater quantity of smaller wattage fixtures are used, while a higher grid will require fewer fixtures of increased wattage. In either case, the total watts per square foot will remain roughly the same.

An average of 55 W per square foot of NPA has been proven in production to provide sufficient power for any normal television lighting requirement. This method of calculating the studio load will provide sufficient power for virtually any situation. This is generally more power than is actually required for the average studio with today's state-of-the-art equipment, but it allows for over-lighting by novices and higher levels necessary for special situations. It also provides sufficient power for an average cyclorama as well as lighting the entire studio as required for audience participation. Very tall cycloramas which may required double rows of fixtures at the top, bottom or both, cyc lights should be calculated as an additional power requirement based on the wattage per lineal foot of cyclorama according to the lighting system chosen.

This calculated power service describes a real maximum probable load, and the feeders must be able to supply this full amount of power. Only certain limited productions will ever require this full amount. Also, note that for dimmer-per-circuit systems, the dimming capacity will be far greater than this calculated power service. The full dimming capacity need not be fully serviced, since the larger number of dimmers is a matter of convenience, and should never be fully loaded beyond the maximum probable load.

Air Conditioning (HVAC)

Because the maximum lighting load seldom occurs, it is unnecessary to use that maximum load as the basis for the air conditioning capacity. Production practice has shown that a diversity of 60% can be applied to the maximum load and still provide sufficient capacity for full period shooting. Of course any other heat generating devices and the population of the studio should be included in the air conditioning calculations. A properly designed HVAC system will require very large ducts to meet stringent acoustical requirements. These large ducts can often interfere with a grid system and should be closely coordinated.

Determining Studio Power and HVAC Requirements

1. Net Production Area (NPA) =
   NPA = Actual studio area in sq. ft minus area behind cyc and other areas unusable for production.
2. Approximate Number of Studio Lighting Outlets Required:
   $$\frac{\text{NPA}}{\text{16–18 sq. ft}} = \text{Number of outlets required (dimmer-per-circuit).}$$
   NOTE: Actual number of outlets determined by specific layout.
   NOTE: Breakdown of 20 A circuits and 50 A circuits varies by grid height.
3. Studio Lighting Load:
   NPA sq. ft × 55 W = Total W
4. Studio Lighting Power Service:
   $$\frac{\text{Total Watts}}{\text{120 V}} = \text{Total W}$$
   $$\frac{\text{Total Amps}}{3} = \text{Power Service 3 phase/4 wire 120/208 V}$$
   NOTE: Round off to the next larger standard panel size.
5. Studio Lighting Heat Load for HVAC:
   Studio lighting load (kW) x 60% (Diversity) = Heat Load for HVAC
   Design (kW)
6. Dimmer Room Heat Load for HVAC:
   HVAC Heat Load (Item 5 above) × 5% = Dimmer Room Heat Load

Electrical Distribution

For a studio to be totally flexible, lighting equipment power must be distributed uniformly throughout the studio. At the grid level, power is commonly distributed through prewired plugging strips. These strips are mounted directly to the grid, catwalks or fly in and out on battens or moveable grid sections (see Figure 5.16-23).

Each circuit terminates in the studio in a pigtail/outlet. There are two types of connectors in common use—*stage pin connectors* and *twist lock*. Stage pin connectors are less expensive and more common in rental equipment. If you envision renting additional fixtures on occasion, this may be an important consideration. In addition, the cost savings of stage pin connectors recur with each fixture and cable purchase. Twist lock connectors have a positive locking feature. The final choice should be based on your specific requirements.

The number of circuits and their capacities is also related to studio size. The actual number of circuits of based initially on the square footage (approx. one outlet every 18 sq. ft NPA) and then altered as necessary to conform to the particular grid system and the cyclorama layout. Dedicated circuits for the cyclorama are often overlooked. The cyc lights consume a large number of circuits and once they are hung in place they will seldom, if ever, be moved. Because of the rather wide spacing of the cyc units it is sometimes more efficient to feed these lights from individual grid

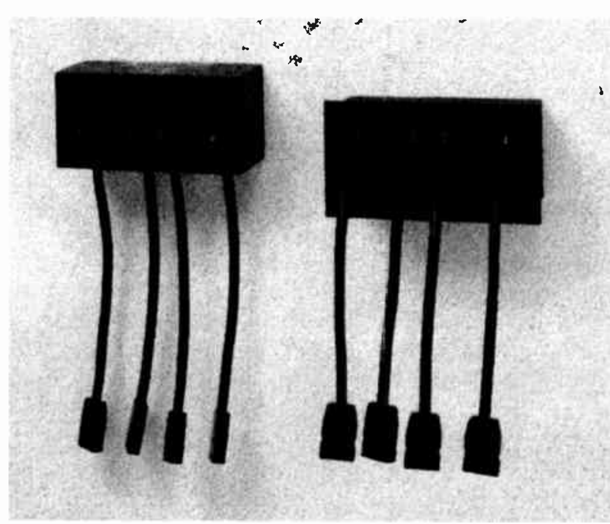

Figure 5.16-23. Wall mounted outlet boxes are generally located around the perimeter of the studio. *(Courtesy of ETC.)*

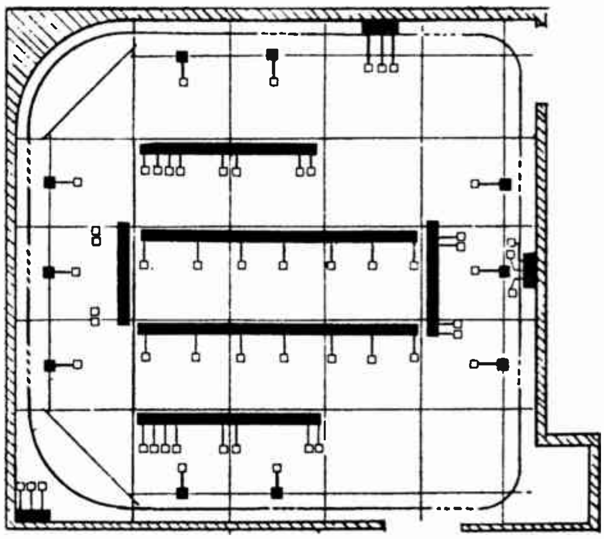

Figure 5.16-24. Typical studio distribution plan for a small industrial studio.

mounted junction boxes rather than a plugging strip. Also, when using far cyc lights it is often convenient to double up the outlets to take full advantage of the 20 A capacity of the dimmers.

Additional circuits should be located around the perimeter of the studio at grid level (see Figure 5.16-24). This is a natural backlight position for a set facing away from the wall. Properly located circuits save considerable time in running jumper cables.

At 30 in. above floor level, around the perimeter of the studio wall, mounted outlet boxes should be provided. Generally, the governing factor for their placement is relative to a layout of floor mounted cyc strips. Otherwise these outlets are used for miscellaneous lights on floor stands and practical fixtures on the set.

For most studios the vast majority of circuits will be rated 20 A. The larger the studio, the greater the quantity of 50 A circuits. In a medium size studio (3,500–5,000 sq. ft), 50 A circuits are generally located in a regular pattern throughout the center area of the grid and slightly more frequently around the perimeter backlight position. In larger and higher studios the density of 50 A circuits must be increased, although the overall outlet density should not be significantly decreased. On adjustable height grids, a full complement of both 20 A and 50 A outlets should be provided for using the appropriate fixtures for the varying heights. Large studios (10,000+ sq. ft) with high grids must be furnished with 100 A circuits.

Lighting Control

The importance of a dimming and control system cannot be underestimated. Dimmers allow easy control of numerous fixtures, balancing and recording of levels and the blending of colors. A dimmer system frees the lighting director of the unnecessary burden of calculating and controlling the loads through more labor intensive mechanical methods. Electronic dimming and control allows the execution of complex lighting cues, which are a very effective production element.

Most studios today are outfitted on a basis of one dimmer-per-circuit. In this type of system every circuit terminates in its own dimmer, with the integral circuit breaker protecting both the dimmer and the circuit. The dimmer-per-circuit system gives the lighting director individual control of each individual fixture, or group of fixtures plugged into that circuit. Normally, the studio is outfitted with 20 A and 50 A dimmers.

Dimmer Bank

The individual dimmer units generally plug into electronic equipment racks to form the dimmer bank (see Figure 5.16-25). This modular system also allows quick plug-in substitution of faulty dimmer modules. Depending on the manufacturer, up to 96 individual 2.4 kW dimmer modules can fit into a single rack. Most modern studio quality electronic dimmers utilize silicon controlled rectifiers (SCR) although a few have used MOSFET (see Figure 5.16-26 and 5.16-27). These units are very reliable and are universally available in 2.4 kW, 6.0 kW, and 12.0 kW (20 A, 50 A, 100 A @ 120 V) ratings. Only dimmers which have sufficient filtering to prevent unwanted RF interference and excessive filament vibration should be considered for use in television studios. Toroidal chokes are uti-

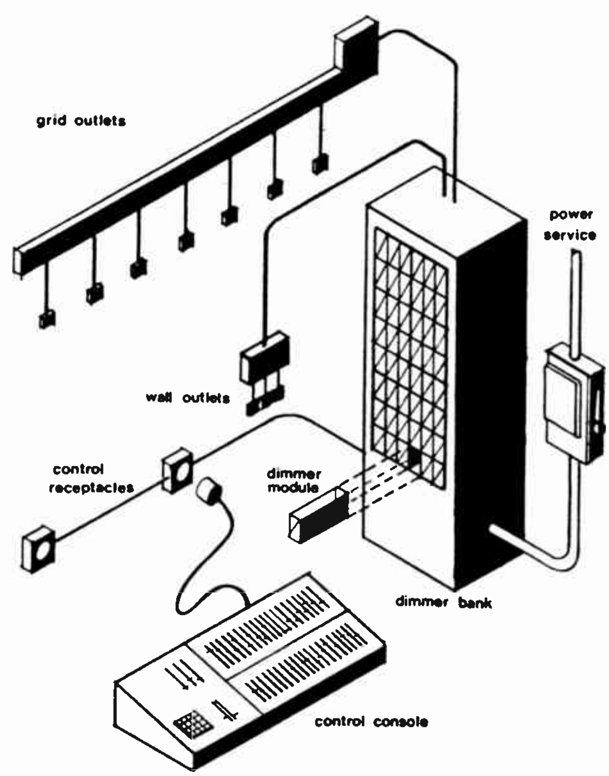

Figure 5.16-25. Dimmer system riser diagram; indicating the basic components of the dimmer system.

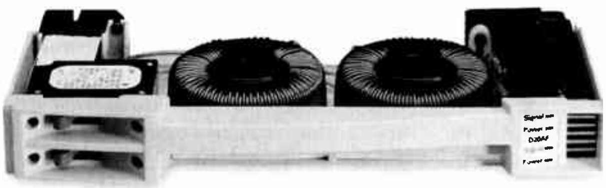

Figure 5.16-26. Tray mounted dual dimmer modules allow high density and quick replacement. *(Courtesy of ETC.)*

lized to control the rise time of the dimmer and the associated electrical noise.

The location of the dimmer bank is an essential part of the initial studio space planning. The dimmer room should be centrally located to minimize the length of all the circuit homeruns to avoid voltage drop and excessive installation cost. This room should be sized to allow sufficient space for required conduit radii, access to the feeder lugs and adequate front clearance as specified by the local code.

Virtually all SCR dimmers are approximately 3 to 5% inefficient. Therefore, they could create heat equal to 5% of the energized lighting load. Since the maximum lighting load is an infrequent occurrence the dimmer room cooling should more reasonably be based on 5% of the diversified load on which the studio HVAC is based.

Control Consoles

In electronic dimming systems, each dimmer circuit represents a channel. Each dimmer channel can be programmed to retain a particular dimmer level setting. A group of preset levels is called a *scene*. While manual control panels with two scenes are sufficient for small productions, even a relatively simple production could require many more. The physical size of manual multiscene control panels is cumbersome.

Even the most modest control consoles offer enough control channel for individual settings of every dimmer although it is possible to electronically patch dimmer circuits to smaller number of control channels. Although the simplest systems physically resemble a standard manual two scene preset system, they have virtually all the capabilities of the largest systems systems. Each slider can represent any channel, group of channels or act as a submaster, rather than a hardwired individual dimmer. The specific number of control channels is a matter of the physical electronic design of the console. Obviously, more channels afford greater control within a single scene.

In a dimmer-per-circuit system it is not unusual for a medium size studio to have in excess of 200 dimmers. To control this large quantity of channels it is possible to patch the dimmers into to control channels. The patching function allows any dimmer to be controlled by any channel. For example the blue cyc lights load may require 12 separate dimmers. By patching them into the same channel they will operate together in perfect unison. All this patching occurs within the console and does not require any cord, plugs, or diode pins. For small to medium size studios, consoles with over 100 miniature potentiometers in 2 or 3 presets are available to provide the operational convenience and simplicity of manual systems.

After patching the dimmers to channels and setting the desired levels, the entire preset can be stored in a memory by assigning a memory number. This preset can then be recalled by keying the appropriate number or operating the slider to which the preset has been assigned. This type of system is very economical and is suitable for most small and medium studio situations.

For studios which encounter more complex production requirements there are a number of systems which resemble a personal computer with specialized keypad and controls with much greater capabilities (see Figures 5.16-28 and 5.16-29). One type of system which is common to several manufacturers utilizes a single or double color CRT or flat panel to display various functions. In operation, the screen displays the channel numbers and below each channel is a two digit number for the intensity. At the bottom of this field of numbers is the *cue sheet* which displays various operational functions such as cue numbers, fade times, etc. The most complex systems employ dual displays to actively display more information. These systems offer many features and can even tell whether the lamp is burned out from a console readout.

The control panel on this type of computer control generally has a series of submaster sliders, X, Y faders, numerical keypad and a function keypad and some tactile type of encoder for easily altering fade times and intensities.

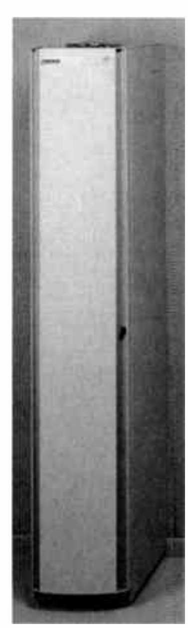

Figure 5.16-27. Dimmer systems are packaged in extremely compact rack configurations for every size studio.

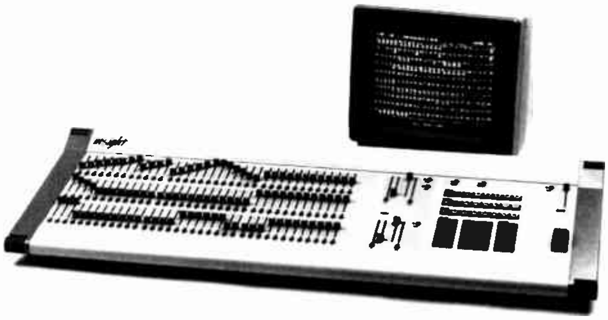

Figure 5.16-28. For medium size studios, memory consoles offer both manual and memory control. *(Courtesy of ETC.)*

Computerized lighting systems store their memory on one of several types of removable storage media for reuse. This permits a complete copy of all the settings in memory. In addition most larger systems are available with varying degrees of internal backup memory systems and can be networked to interconnect various types of remote controls and peripherals. The operational software is permanently stored in ROM within the machine.

Most computer lighting control systems were originally designed for the legitimate theater where the easy daily repetition of very complex multipart cues is the primary goal. Some manufacturers have modified their programming to be more sympathetic to television's somewhat less predictable demands. In selecting a system with this caliber of sophistication, the lighting director must carefully determine which features are really necessary.

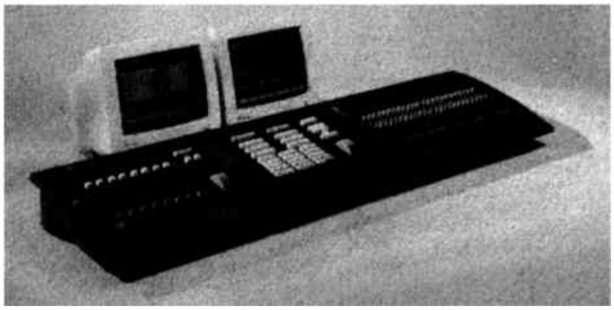

Figure 5.16-29. The most sophisticated consoles utilize dual CRT displays and can control very large quantities of dimmers with equal number of discrete channels.

Computerized lighting systems have greatly simplified the installation of the control wiring. While analog systems required at least one wire for every dimmer, these computerized systems use standard computer network wiring. An advantage to this simplified cabling is that the console can be easily relocated to any of the plug-in stations. In addition, when the main computer is located outside the studio, a small focus remote the size of a handheld calculator can be used in the studio to activate fixtures as necessary for focusing or other simple operations. The technology of computer networking is now used on lighting control systems to add greater flexibility and multiple control locations. This allows the console to be located in the most convenient position for a particular phase of the production. It also allows several studios to share a more sophisticated system as required, since the largest systems can plug into the same control wiring as the smallest.

Computerized control has made sophisticated remotely controlled fixtures possible. Most consoles now have the ability to control moving lights as well as the dimmer system from a single console. A single console can be used to program and record the intensity, position, speed of movement, iris, internal pattern selection, color mixing, pattern rotation as well as soft or hard beam patterns. The console records and replays all these functions as desired by each cue programmed.

THE PLANNING PROCESS

Most television production professionals have the opportunity to be involved in planning a new studio maybe once or twice in their entire careers. Even years of experience in studio production are not necessarily the best preparation for coordinating studio requirements into a construction process. Often, a new studio provides an opportunity to acquire a complement of equipment, which is more sophisticated than the existing staff's level of experience. In this situation, an experienced lighting designer should be consulted in preparation of the equipment requirements and evaluating the quantities required. While manufacturers are sometimes helpful in this area, they are still primarily interested in selling their product, and no single manufacturer offers a full line of suitable equipment in every area. By working with a consultant, you can share their experience in the planning and design of the lighting system for your studio.

5.17
REMOTE VIDEO PRODUCTION

NED SOSEMAN
KCTV, MEREDITH BROADCAST GROUP AND
CARL BENTZ
INTERTEC PUBLISHING, OVERLAND PARK, KS

INTRODUCTION

Television brought the dimension of pictures by radio into our lives. Yet, over the years, technology has achieved technical successes almost as important as was the mere existence of early telecasts. Once bound to a studio by sheer size of equipment, TV production is now almost at home in the field. Going remote is more than just buying battery-powered equipment, however. This overview of field production will examine some of the aspects that impact the development of outside broadcast capabilities.

WHAT IS FIELD PRODUCTION?

Producing television at remote locations is like piloting a jet fighter aircraft. Both are filled with elements of the unknown, danger and excitement, and both conclude with a distinct sense of accomplishment or disaster. Both depend on sophisticated skills, equipment and support and both must prepare for the eventuality that anything that can go wrong probably will.

The secret to technically successful remote video production is to rehearse and prepare for the worst. Like fighter pilots, experienced producers have learned that practice and standardized procedures are the keys to consistently successful completion of the mission at hand.[1]

Safety First

While Chapter 9.5: *Electrical Shock* reviews electrical safety issues thoroughly, no discussion of remote video production would be complete without emphasizing the fact that electricity kills. Too many people have been killed by electricity during remote video productions.[2]

The prevailing cause of remote production deaths is overhead power lines. An ENG vehicle's 40 to 50 ft pneumatic microwave antenna mast can easily contact overhead power lines. The first rule in remote video production is "look up before raising the mast!" and look around for other potential electrical hazards, including standing water, before doing anything else. No deadline is worth death.

Follow local electrical codes. Regularly inspect all electrical connectors and cables for physical damage and loose connections. Keep splice type connections dry by wrapping connectors as well as a few inches of cable on each end with plastic film then sealing the film with gaffer's tape. Electrical problems can be catastrophic, and there is always the chance that a fire marshal might want to inspect the location.

A host of other dangers, from falling objects to fires, also lurks in the field. A camera might crash to the ground if the tripod legs are not properly set. A forklift might run over a cable and short or break it. Wind might blow a hot unsecured light tripod into dry brush and start a fire. If it could possibly happen, change or fix it. Avoiding potential danger (and legal difficulties) is the top priority for everyone involved in remote production.

Production Categories and Styles

Video production work performed beyond the confines of four studio walls is considered remote or field video production. The emergence of portable video cameras and VTRs has produced two categories of remote video production: electronic field production (EFP) and electronic news gathering (ENG).

As the ENG name implies, this is the *shoot it as it happens category*. Typically, crews are minimal, retakes are few and time constraints are tight. It is usually the default category for fast or late breaking daily news stories.

The ENG category is defined by the lack of control a production crew has over the subject in the frame. As a result, ENG equipment must be adaptable to function in a variety of climatic, shooting and lighting situations, and able to do so with battery power. Typically, an ENG production system is operated by a one person crew.

Remote production outside the fast news lane is known as EFP. This category is characterized by control. EFP shoots are better planned and as near studio-quality as possible. For instance, major outside broadcast tractor trailer rigs with multiple cameras and sophisticated live audio and video switching facilities would define one end of the EFP spectrum. At the other end would be a high quality single camera, a lav mic and an artificially well lit scene. In general, the

[2] Bell, Mark, "Truck Safety Remains an Issue" *TV Broadcast Magazine*, Miller Freeman P.S.N. Inc, New York, pp 52, 54. March 1996.

difference between ENG and EFP is time, money and control.

The ENG category has spawned its own shooting style, characterized by a live or reality feel, which, of course may not be either. This shooting style is achieved with a single camera, hand held or mechanically supported and minimal or harsh lighting augmentation. While it is possible to shoot ENG style with multiple cameras, or even ENG style during an EFP shoot, the ENG category should not be confused with ENG style.

Whether using the most sophisticated multi-camera production trailer, an ENG van or a camcorder in the back seat of your personal auto, the discipline of video production remains the same. Only the scale changes.

PLANNING THE SHOOT

Many well worn stories have been spun describing scenarios where a project with more than one leader resulted in problems. Similarly, successful video productions (in the field or studio) can have only one person in charge. All members of the crew must understand and follow the direction of the person in charge. Typically, that person is either the producer or director.

The producer is responsible for the entire production. Typically, producers visualize, secure financing and organize the production. The producer approves the scripts and helps create the storyboards. Some producers like to direct, most use a contract or use a staff director to execute the plan. At the point where a director is brought into a production project, the director becomes the boss—in charge of fulfilling the vision of the producer. Electronic equipment and production crew responsibilities are usually delegated to a technical director (TD) or engineer-in-charge (EIC).

Before the first frame of video is shot, the producer must define the scope of the project on paper. Typically, the first documents created are the budget and the production schedule.[3]

Budgets, financial and time, govern the options of any producer. Outside of the studio walls, everything becomes more difficult and expensive to control. Items taken for granted in a studio environment, such as parking, restroom facilities and telephone communication must be identified and included in the production plan.

Does the production call for helicopter shots of thousands of extras on horseback galloping across the desert, for intimate ENG style reality shots inside a moving Miata, or both? Does the production call for overseas travel or is the shoot across the street? Regardless of the size of the production, the planning process remains the same. The size and budget controls the scope.

If production crews work for more than a few hours, the cast and crew get hungry. To avoid wasting time, many producers opt to cater food to the location. Good catered food raises morale and keeps the cast and crew on location. Ample drinking water and cups are also necessary to keep crews focused.

The producer and director must also develop contingency plans for potential problems, such as bad weather and equipment failures, before the production begins.

Once these questions have been answered, and talent has been secured, the producer generates the working production schedule. The schedule is a timeline that lists the stages and steps of the production process from the first day of preparation until the project is completed in post.

Choosing Locations

Using the production schedule, the producer can identify the crew and logistic requirements. A one person crew may be adequate to shoot some field video or pick up sound effects. Other scenes may require grips, boom mic operators, audio recordists, camera operators, cable pullers, focus pullers and others. The budget usually dictates crew size.[4]

If the production venue is out of town, the producer is also responsible for securing travel arrangements and accommodations for the cast and crew. Of course, before any arrangements are made, the producer must scout the location. Scouting includes shopping for crew accommodations as well as performing a thorough aural and visual check of the actual shooting locations.

Every field shooting location is unique. In addition, the technical aspects of virtually every shooting location change with the passage of time. Thus, the site that worked well last year may not work so well this year. Similarly, the site that seemed perfect when it was checked at 11 a.m. may have a different level of acceptability at evening rush hour. Check the site at a time similar to the hours the shoot will occur.

There is much more to a location than its visual attributes. The level of ambient noise may be too high or may change at different times during the day. There may also be sources of natural or man-made noise, such as a waterfall or portable power generator, that must be avoided. If noise cannot be avoided, then audio fix up work, such as sweetening and dialog replacement must be planned and budgeted for post.

Depending on the scope of the production, local shore power sources may or may not be a consideration. While using shore power may seem convenient, most standard wall outlet circuits will not support the power professional video production gear consumes. Often, in cases where quartz lighting is used, a portable generator may be the best source of adequate power. If shore power is the only choice, identify the location of the circuit breaker box, find the specific breaker on the circuit used and verify the current rating of that circuit breaker before doing anything else. A total

[3] Dellaria, David, "The Ten-Minute Miracle", *Videography Magazine*, Miller Freeman P.S.N. Inc, New York, Volume 21, Number 5, pp 68–70, 72, 74, May 1996.

[4] Ibid.

circuit load exceeding 65% of the circuit breaker's current rating is virtually guaranteed to cause the breaker to trip over time.

When possible, it is best to use separate circuits for electronics and lights. Some lights may have a tendency to generate noise spikes on the ac power line and some electronic equipment may tend to be susceptible to such spikes. Quartz lights, when powered over time, tend to heat and trip circuit breakers operating near their maximum capacity. Keeping the lights on a separate circuit will keep lighting and electronic problems separate.

If renting a generator is an option, rent a unit that can supply at least double the total load the production equipment will draw. Shop for a well maintained generator. Inquire about the condition of the generator and ask to see its maintenance log. Do not rely on a generator that is nearly due for scheduled maintenance or one that has no maintenance record. If the budget permits, rent a backup generator.

Bringing fixed frequency two-way radios and wireless mics to remote locations can also be treacherous. Unless you are operating in your home city, other people may be using your frequencies. Check with the local SBE frequency coordinator to ensure your production will not be plagued by interference and that you will not be interfering with anyone else. Frequency agile RF equipment helps avoid interference problems.

With the location identified and scouted, and production schedule in place, personnel requirements would be the next element to address. Working together, the technical director and producer or director must identify all positions to be filled and develop a crew assignment schedule. Typically, crews are scheduled to report to the location at least 30–60 minutes before the shoot begins, not including extra hours or days for setup, checkout and teardown.

Equipment

The next planning step is to develop a list of production equipment requirements. A physical checklist is the best method to identify every possible item that might be used in any shoot. Working backwards, the technical director can use the checklist to determine what gear is not necessary. What is left is what is needed.

Remote production equipment can be categorized in four equally significant groups: Video, audio, lighting and communication. (A fifth category, microwave, is usually reserved for ENG work.) Among the categories, communication has gained notoriety as the most important and most likely to fail. Unfortunately, because of its behind-the-scenes invisibility, it is also most likely to be ignored—until failure brings an entire production to a grinding halt.

Modern communication systems are the backbone of the production. The larger the crew or venue, the more critical communications become. Communications include telephones, two-way radios and crew intercom systems.

Before embarking on any remote production verify that all necessary communications equipment, wires and headsets are on hand and in good working order. Further details on communication systems are covered later in this chapter.

Typically, the producer chooses the videotape or film format that will be used. From that point, equipment selections are a function of budget and inventory. (Video and audio equipment choices are too myriad to fit within the scope of this chapter.)

It is also the responsibility of the producer or technical director to secure the necessary equipment and an adequate supply of recording stock. If rental equipment or for hire services are involved, the further in advance plans can be made and equipment reserved, the better. If considering renting, establish a credit line with any rental facility. Few rental facilities can process a credit application on short notice.

Camera Support

Most studio cameras are tethered to an unwieldy supporting pedestal. The primary benefit of ENG and EFP is that cameras and recorders are mobile. More recently, lipstick style cameras can provide even more unique mobility and point-of-view options. For standard ENG and EFP cameras and camcorders, jibs, dollies, cranes, Tyler™ mounts, Steadicams™, helicopters and blimps are but a few of the many devices available to support a camera.[5]

Typically, the director determines camera angles. While a standard tripod and fluid head may be seem practical in most situations, directors should consider the options and advantages other support systems may offer.

Audio Concerns

Two common audio problems are dead mics and hum. Thanks to the popularity of the condenser mic, dead mic batteries have become a risk, particularly if batteries remain in mics for long periods of time. At best, replace the batteries before a production begins. At the least, thoroughly check the operation of all mics and always have extra mic batteries on hand. (See Chapter 3.3: *Microphones* for details on microphone selection and techniques.)

Hum can be a more difficult problem to resolve. In addition to the potential for ground loops, the production in the field introduces many variables into the audio and ac wiring equation not found in studios. Grounding problems are most likely. Check all audio circuits for hum and use extreme care to ensure that there is no ac leakage to the audio grounding system.

Not all field locations are ideal for all types of mics. Lav mics are popular for field work because they are virtually invisible, and they automatically follow the speaker. They also tend to eliminate background noise due to their close proximity to the body. However,

[5] Avgerakis, George, "You Want Me to Shoot Where?" *Videography Magazine*, Miller Freeman P.S.N. Inc, New York, Volume 20 Number 6, pp 40–42, 44–46, 112 June 1995.

according to some audio experts, lavs tend to muffle the sound as compared to a boom mic. Most experts agree that mics mounted on booms are preferable because they sound better and they can be controlled.[6]

Wind is another common source of problems on location. A good baffle or windsock will reduce or eliminate wind noise. Windsocks are made from a variety of materials. Typically fur works best, and thicker fur works better.

Lighting

The element of control separates ENG from EFP. In EFP, the ability to manipulate the lights, camera and action is the source of creative control. Lighting is an art and well beyond the scope of this chapter. See Chapter 5.17: *Lighting for Television* for more information on lighting.

The Remote Bag

Most people who work in remote production for any length of time build a remote bag. A typical remote bag contains a variety of disaster averting tools and useful gadgets.

Items found in many remote bags can range from gaffer's tape and permanent ink markers to volt-ohm-meters and portable test generators. The bag usually also includes various audio and video cable adapters, bullets and turn arounds that can come in handy.

Typically, people who shoot ENG rely on their remote bags for quick access to supplies that may be difficult or impossible to find on location.

The use of three-way to two-way electrical outlet adapters is not recommended. These adapters, commonly called suicide plugs did not gain the nickname by accident.

Other items include extra audio and video cables, chewing gum, work gloves and pre-packaged wet hand wipe towels.

Shooting Styles

ENG has evolved into a shooting style, characterized by less-than-perfect framing and heavy use of ambient light. It tends to evoke a sense of immediacy and importance. For single camera productions, style is limited to moving the camera to change the angle. The change may be live or edited in later, such as the addition of cutaway shots.

Far more popular, when possible, are multiple camera shoots. The video outputs of multiple cameras can be synchronized and switched live on a production switcher for live feeds. Alternatively, cameras can be synchronized with time code and edited together in post. With proper planning, either method can yield equal results.[7]

A newer shooting style is evolving as digital video editing gains momentum. People are learning that there are special considerations when shooting for non-linear postproduction. One common misconception is that non-linear editing does not require offline editing. In fact, digitizing video from field videotapes is a real time process (or 4× speed with some digital tape formats). Also, the limited capacity of most hard drives and disk arrays will not allow much space for unused clips.

People shooting for non-linear editing are finding that accurate time code logging during the shoot can save a great deal of time in post. See Chapter 5.9: *Video Editing Systems* for more details on shooting for the non-linear edit.

The Day of the Shoot

Whether the shoot is an emergency call to the scene of a breaking news event or a project that is well planned in advance, the basic procedure is the same: Get out the checklist.

With checklists developed for all categories of equipment, video, audio, lights and communication, inventory all items necessary for the shoot. Verify every item, regardless of size, including all cables and connectors. Using the lists, there is no excuse to ever show up for a shoot without all the pieces to make the shoot work.

For most EFP projects, setup may take a few hours or a few days, depending on the scope of the project. Take care to leave enough time for the crew to setup, including allowing time for potential repairs.

Be sure all crew members know their call times. It is best to provide each crew member with a personalized memo, complete with call times, maps and any other information that the crew should be aware of.

Upon arrival on the scene, check for electrical and other hazards first. Then, follow the plan.

SPECIFYING A REMOTE PRODUCTION VEHICLE

The market for remote production vehicles (RPVs) is a limited one, which forces the cost of such a vehicle to be high. Errors in specifying the vehicle can prove very expensive. Avoiding buyer's remorse, endless criticism, inconvenience, and potential trouble, the best approach to shopping for a production vehicle means asking the right questions; because unlike other TV plant projects, RPVs cannot be planned for expansion. Once a basic chassis is ordered, a number of aspects of the RPV become fixed.

Levels of Production

There are several levels of production requirements that will determine the overall scope and subsequent price tag of the project. On-site commercial videotaping requires the least from an RPV; live professional sports coverage can stretch the capabilities of the best equipped system. A good deal of the complexity of a vehicle is reduced if the vehicle is used only for remote

---

[6] Grotticelli, Michael, "Location Audio: Boom or Bust", *TV Broadcast Magazine*, Miller Freeman P.S.N. Inc, New York, pp 28, 62. May 1996.

[7] Reizner, Dick, "Be Prepared" *AV Video Magazine*, Montage Publishing, Inc., White Plains, NY, Volume 16, Number 12, pp 102, 104, 106–108, 110–111, December 1994.

videotaping. Such an operation leaves all editing, graphics insertion, effects system, audio sweetening, and other post production tasks in the studio. When the vehicle becomes the source of finished productions for live telecasting, the complexity and cost increase considerably because of the extra equipment and personnel requirements.

Single-Unit Vehicles

Once the RPV use is identified, an initial budget can be developed and the search for a vehicle type started. The single unit vehicle (with cab and box on a common chassis) is more maneuverable, easier to drive and park, and far less expensive than a tractor trailer system. For many stations, the step beyond the typical ENG vehicle is a cutaway van chassis with a cube-shaped box attached to the frame directly behind the driver. The height of the box offers adequate headroom and is commonly about 14 ft long with a 7 ft width. Approximately 100 square feet of useable area is available for work and storage space.

Single unit vehicles have drawbacks. One is a 29 ft maximum box length and resulting storage space limitations. Because of the drive shaft connecting the engine to the rear driving wheels, the under the truck storage is reduced. Belly box storage depth is usually limited to about a three feet, which prohibits its use for long tripods, light kits, cables, and bulkier items.

It may be instructive to contact a local truck dealer for the cost of unmodified vehicles of various sizes. The addition of two or three cameras, one or two VTRs, control equipment, an on-board generator, and possibly a microwave mast and transmitter electronics quickly raise the price. On the plus side, this unit will function well as a backup ENG vehicle when it is not involved in other field production assignments.

For somewhat more room, consider a stretch van, recreational, ambulance type vehicle or straight truck, each of which may be outfitted as a very serviceable RPV for two- to four-camera productions with on-board graphics. A straight truck, with a 29 ft box provides approximately 200 square ft of deck space. Systems based on straight trucks are often used for multicamera sports events, with four cameras, slow motion VTRs, graphics and a variety of sources. As a rule, they do not include a generator or microwave mast. If shore (on-site) power is not available, a generator can be rented locally.

The weight load and its distribution in the vehicle may require attention. A large concentration of weight over or behind the rear axle may create problems in steering. Ideally, the greatest concentration of weight should be fairly far forward. However, if the weight between the front and rear axles is too great, a tandem axle may be needed to relieve some of the strain. Such an axle must be ordered before the vehicle is constructed.

RPV builders may include a tag along axle behind or a pusher axle in front of the original rear drive axle. The tag along is particularly useful in stabilizing the vehicle, but does nothing in regard to weight distributions. A pusher axle improves load distribution and adds stability, while also reducing chassis flex. Modifications to the suspension may include heavier springs and shock absorbers, as well as electrical or hydraulic stabilizers.

The vehicle chassis size is directly related to the number of cameras the unit will be expected to handle. For a complex unit such as a complete 40 ft semi-network type vehicle including multiple cameras, switching and distribution equipment, recorders, titling and effects packages, expect a multimillion dollar price tag.

Interior Designs

The layout of an RPV interior does not provide for a great deal of flexibility. It would be wise to examine some existing vehicles to see what types of layouts might fit the expected requirements. It may also be a worthwhile investment in time to construct an actual-size cardboard mockup of an RPV interior, including control panels, rack layouts, and monitors. Such a mockup is an inexpensive engineering tool to get feedback from the staff and management before holes are drilled and wires are cut. In working with actual-size models, the staff will get a better feel of the proposed environment. Correcting a mistake in cardboard is much easier and less expensive than fixing an error in sheet metal and angle iron in the real vehicle. Combined with a logical, documented analysis of needs and wants, the mockup will help to prepare the purchase order.

While not as realistic as the life-size approach, miniature cardboard models can be used to check the fit of equipment into a floor plan. How well this works depends upon the accuracy with which the models are scaled. Computer assisted design (CAD) software offers another method by which various arrangements can be checked for proper fit. The basic floor plan is laid out in one layer of the drawing, a second drawing layer is used to locate racks and control equipment. If each element of the proposed design is created as a separate object, it is a relatively easy procedure to manipulate the positioning of the individual objects.

If an error in judgment or a lack of organized input to the builder results in alterations that must be made to the finished RPV, the minimum cost of the changes will be nearly threefold compared to the cost of doing it right the first time.

Equipment and people working in an enclosed area operate more reliably with a comfortable environment. When the truck is parked in an asphalt lot outside the stadium on a hot Sunday afternoon, heat buildup inside the vehicle can be considerable. Proper insulation and an air conditioning system designed for the heat load will keep the staff and the equipment at their best performance level. Formulas are available in texts and handbooks on heating and air conditioning for calculating the optimum capacity for an air conditioning system, given the wattage rating of the equipment, the number of people that will be in the area, insulation rating, outside temperature, and other factors.

MAKING IT MOBILE

In the case of the large production van, some arrangement must be considered to transport the vehicle from place to place. The cost of leasing a semitractor varies with the length of the lease period, with long term contracts being more economical. The lease plan usually includes normal and emergency maintenance and repairs, licensing, and taxes required for the tractor.

To purchase a semitractor, plan on a price tag over \$100,000 for a new unit. A serviceable, used tractor will probably carry a cost about half that of the new one, depending upon age and condition. Remember to add the weight of the trailer and all equipment and supplies when specifying the size and load capability of the tractor. If the vehicle will be used over a wide area, considerations may include a tractor with sleeping berth for long haul trips. Keep in mind, however, that reliability is a key. If the production system is to be in position at a specified time on a given date, it must be there!

An additional expense in the operation of a semitractor is the driver. Reliability and experience are very important. Requirements for drivers of network vehicles include a spotless driving record and experience with all types of driving conditions in all four seasons and in all areas of the country. Because the driver is in charge of a multimillion dollar package of equipment, a very professional attitude toward the job is important.

The Department of Transportation also has requirements for drivers of vehicles with a gross vehicular weight of more than 10,000 pounds. DOT regulations involve a record of duty status report to be kept by the driver. (The records to be kept may be found in DOT regulation Title 49 CFR, Section 395.8.) Requests by DOT inspectors to inspect the record could result in substantial monetary fines and a forced out-of-service period for a driver if rules have been violated. In some areas, additional local requirements more strict than those of the Federal Government will also apply. The driver must know all such rules for areas where the truck will travel and must meet medical physical requirements specified by the DOT.

Alternatives: To Lease or Buy

If there are uncertainties about the field production activities or the amount of expected use is limited, leasing presents a practical alternative. With a leased vehicle, production concepts can be checked out. Feasibility of remote activities for the station can be proven. Then, if the station later determines that the purchase of a vehicle is the proper step, valuable experience will have been gained toward specifying the purchase.

If the station owns its vehicle, it is responsible for continuing equipment maintenance, vehicle upkeep, and financing. Any time the system is out of service, it is a financial liability, so the need to keep all parts operating is essential. Under a leasing program, most major maintenance is handled by the leasing organization. The availability of maintenance facilities and the maintenance program offered should be important criteria in the selection of a leasing company.

The cost of leasing will vary with the equipment package desired, the size of the system, and with the area of the country. Many of the plans arrive at a total from a per item equipment schedule. The agreement can be written to include a complete operating crew for the required number of hours per day.

The purchase of a turnkey production truck is expensive, even for the simple ENG super van configuration. If the purpose is strictly ENG, perhaps a four-wheeled vehicle would provide the solution. With some protective storage for the camera, recorder and other essentials, and a microwave system, there should still be enough room for a camera operator, microwave technician and the reporter. Such a project might be easily handled by members of the engineering staff.

As the size of the vehicle increases, so does the complexity of the installation and the significance of the decision whether to do it yourself or buy a turnkey system. Outside manufacturers usually build trucks following a general design that reflects their experience and user feedback. Input from experienced station personnel will be valuable for whomever builds the vehicle and helps to determine a configuration that maximizes the vehicle's benefit, usefulness, and practicality, while remaining satisfying to the buyer.

If the plans include live remotes, the production vehicle will probably require microwave equipment to feed signals back to the studio. In addition, some plan should be made for two-way communications for cueing purposes. Fortunately, there is a range of choices, including cellular telephones, subcarrier transmissions, and mobile radio. As the distance between the remote site and the station increases, the communications selections could include a channel on the microwave system or even a connection through a mobile satellite facility. Another approach to get the program back to the station could use an established common carrier network.

In most large metropolitan areas today, the use of RF communications channels, particularly in the microwave bands, also means dealing with problems of interference. An extensive frequency coordination program has been instituted by the Society of Broadcast Engineers. Chapter 1.5: *Frequency Coordination* provides an in depth discussion of the problems and procedures of frequency coordination.

Lease Out: An Aid to Financing

The status of owning a vehicle and the convenience of not having to arrange for a production truck every time one is needed are plus factors. If the station's production schedule does not keep the system constantly in use, then it could be leased to others as a means to help in financing the purchase. Planning for this arrangement should include answering some additional questions.

1. Will the equipment complement make the truck desirable to others?

2. Given the station's planned uses of the vehicle, what is the likelihood that the station might need the vehicle when someone else is using it?
3. Will the vehicle need a staff when on lease out assignments? Depending upon the experience of the lessee, it may be advisable for the owner-lessor to provide some experienced staff to help ensure safe and effective operation.
4. How much effort would be required of the station's staff to prepare the vehicle for use by others and how much effort would be required to service and test the systems when the vehicle is returned?

PLANNING THE EQUIPMENT PACKAGE

Shopping for remote production equipment is as critical as buying for the studio. The right purchase includes several specific criteria:

- Quality
- Reliability
- Operational Simplicity
- Maintainability
- Compatibility with other equipment used by the station
- Price

Often equipment suppliers make special package offers, which provide significant cost savings over the purchase of individual items. While a program of getting bids on equipment packages takes time and may involve a good deal of paperwork, the process can result in a price tag that will allow an extra or two to be included.

The following sections include points to consider in various equipment areas. Most of the comments are directed toward portability. If a facility has already had experience with field production equipment, that experience will no doubt be a primary factor in future equipment purchases. Past experience could also be a reason to use an entirely different line of thinking. Applications of the decision spreadsheet can prove quite useful in this stage of system planning.

Acquisition Equipment

If the station is already active in ENG, has a major investment in the equipment of a single format, and has experienced good results with that equipment, then the purchases for additional field production units should stay with the same format. Where several systems are in use, the greater the similarity among the cameras and recorders, the easier it will be for operators to switch from one system to another, as the need arises. The more familiar an operator is with the equipment, the greater the effort the operator can put toward visual concerns. The performance advantage of a new format may be outweighed by such practical operational concerns.

An initial evaluation of equipment, based on published specifications, is another opportunity to use a spreadsheet approach to compare information about different models. List the models as column heads, let the rows be the more important specifications. Numbers can be filled in from manufacturers' literature. Table 5.17-1 is an example of items of interest for cameras.

Field Cameras

Selection of a portable camera for ENG has been simplified by improvements in charge coupled device (CCD) technology.

Two areas are left open for discussion: the type of output and the lens. Many of the current generation of cameras are designed to mate with a series of adapters. The adapter determines the output signal format: composite with multicore, coax, triax, or fiber optic cable; luminance and color components; Y/C components; and adaptations for docking recorders.

The trend in lens designs meets the special characteristic of CCD cameras. Because CCDs are cemented to the beam splitting prism and cannot be moved individually for fine focus, as was the case with tubes, the lens system must be optimized to compensate for chromatic aberration. While an uncompensated error may be visible as a slight fringing of color, lenses designed for CCDs bring all three color images into focus at the same plane.

Lens length may be partially based on a matter of personal choice and partially on the type of event to be covered. Lenses with a greater zoom ratio permit greater flexibility in camera location for coverage of some events, but one characteristic of long lenses should be kept in mind: the longer the lens focal length, the more pronounced are even minor movements. As lens focal length increases, the need for a more stable support than the operator' shoulder may be required.

Table 5.17-1
Spreadsheet to Compare NTSC Cameras.

Attribute	Model 1	Model 2	Model 3
CCD type & pixel array			
Sensitivity & max.sens.			
Resolution depth of modulation S/N Ratio			
Output format			
Adaptors: NTSC composite RGB<R>Y/R-Y/B-Y R/C(S-VHS)			
Cables: Multicore, Triaxial Coaxial, Fiber optic			
Docking VTR			
Control units: RCU, LCU, CCU Multicamera CU			
Camera Head Weight			

Another factor in camera selection may be of importance particularly to camera operators who rove through crowds or shoot video at sports activities. Several special shapes of the camera package are designed for better operator vision. Standard camera designs create a blind spot to the right of the operator. A more ergonomic design reduces the height of the camera body in such a way that the operator can see toward the right while shooting. Although the appearance may seem odd at first, many operators come to appreciate the design feature after they are acquainted with it.

Operators should be aware of the relative levels of illumination in which they are shooting. Most CCD cameras can produce usable images to quite low levels. The use of a shutter with CCDs has become common place to avoid smearing in the pictures as a result of highlights or difficult contrast conditions. Integral neutral density filtering and an automatic iris are important in coping with widely differing or rapidly changing levels of light. For reference, Table 5.17-2 notes several common lighting conditions and the relative light levels that may be encountered:

Nearly all portable cameras include two or more levels of color correction filters to assist in color balancing for various light sources. These filters, along with color balance memories, can be used to produce realistic color in the output pictures.

Field Recording

Field recording formats include analog component and digital formats. Making a choice among these presents a real challenge, because all of the professional systems perform quite well. Beyond the problem of compatibility with existing equipment, consider how the product will be used.

ENG cameras typically provide for microphones to be mounted directly on the camera body with a connector tied into a program audio circuit. The purpose of the video acquisition will decide the type of microphone pattern to be used. For shoots that involve general audio coverage, an omnidirectional or general cardioid pattern will serve nicely. If it is necessary to pickup only specific talent on the audio track, a shotgun unidirectional instrument will prove a better choice. This feature can avoid the problems of microphone cables at the remote site. Many instances will still require the talent to use a handheld microphone for best vocal pickups. With a miniaturized wireless microphone receiver attached to the camera, a wireless handheld or body pack microphone solves the cable problem. Wireless operation does have the drawback of possible interference from external sources.

When multiple microphones are used, a need for some audio mixing capability exists. If the portable recorder includes multiple audio channels, mixing may be deferred until post production. Much more freedom and creativity is available during post production work when separate audio tracks are recorded.

Table 5.17-2
Light levels of Common Lighting Conditions.

Full sun	100,000 lux
Overcast at noon	10,000 lux
Interior by wind	1,000 lux
Interior work area	100 lux
Full moonlight	0.2 lux

Cables and Links

More a concern for EFP and OB projects is the question of getting the signal back to the truck. For cameras that operate on the various types of cables, the choice must be made between multicore, coax, triax and fiber cables. Fiber optic options permit the greatest distance between the camera and the production vehicle of the four types. If distances are greater than those suggested for a single fiber optic cable run, relay units are available to double the length. During the construction of some stadium facilities, the needs for television are often included in the design. Cabling may be permanently installed to various locations in the stadium, reducing the setup time required for the TV crew.

Cableless cameras may be outfitted with a miniature microwave system to beam the output to the central production center. These systems may include a tracking antenna, which permits a return channel for communications between the truck and the operator. If the line-of-sight path is blocked, a relay becomes necessary. Such a relay in an open stadium setting might use an antenna (and electronics) held aloft by a balloon attached to the upper, outer wall of the stadium. The relay unit remains relatively fixed positioned with respect to the truck parked outside the stadium, while the tracking system in the camera unit keeps the primary transmitted energy aimed at the relay antenna.

GETTING BACK TO HEADQUARTERS

Live remotes bring together every complexity of the television broadcast industry. Not only must the remote truck operate perfectly, so must the program link from the remote originating site to the base station. Technology has produced a variety of methods for transporting the program signal back to the station. Options include wired connections (via telephone company facilities), microwave video radio (ENG), and satellite relays. The distance between the production site and the station can be a deciding factor in the transmission choice.

Terrestrial Microwave

If the site is local, for example, the most expedient link between the two locations is probably by microwave, especially if line-of-site operation is possible. If obstacles to a direct line path exist, perhaps the use of a reflector can redirect the signal around the obstacle. Microwave system design is detailed in Chapter 6.1: *Microwave and STL Systems.*

Although microwave frequencies may already be assigned in a metropolitan area, a check on frequency coordination is advisable to make certain that interference can be avoided. Often cooperation between stations is needed to ensure interference-free operation for special events. A case in point is the renowned July Fourth celebration in Boston, during which a live performance of the Boston Pops Orchestra is telecast nationwide by PBS. In addition to the site-to-station channels, local site microwave between boats, helicopters, nearby buildings, and the production truck are in use. Because of a limited number of frequencies, the production is made possible only through cooperation between the various local stations in frequency coordination and equipment sharing. Coordination activities for such scheduled events typically begin months in advance.

As distances between the remote site and base facilities increase, microwave by common carrier services becomes practical. Demands for more communications channels have lead to the use of digital transmissions to accommodate multiplexing as well as bandwidth reduction through data compression. Several services are now offered using the technology of digital transmissions.

Satellite Backhaul

Program relays by satellite permits the remote site to be almost anywhere in the world. Many of the relay and backhaul services available by satellite also involve digital signal carriage with data compression to help deal with the amount of traffic that must be transmitted at all times. Depending upon the destination for the signal, the satellite system may be the more practical route to be used. In larger urban areas, occasional use satellite time can probably be obtained on short notice and is competitively in price with fiber.

For remote operation, the development of smaller Ku-band terminals and antennas offers several advantages. The size of a C-band antenna was too large to easily include an uplink antenna as a part of a remote production vehicle. As a result, such C-band equipment was often taken along to the remote location on a separate vehicle. Ku-band uplink equipment can actually be mounted on a production vehicle and immediately deployed upon arrival of the truck at the site. An option provides the convenience of almost completely automatic satellite antenna alignment through the GPS navigation system. The engineer needs only to key into the control computer both the geographical coordinates of the site and the satellite through which the relay will pass. Within minutes the system is setup and operational.

Fly-away C-band and Ku-band equipment is available with folding dishes in the two meter diameter range. Electronics, antenna, and mount can fit into a half dozen or so suitcases that can be checked as airline luggage. Equipment manufacturers and the operators of satellites and commercial teleports can provide technical and cost information on which to base planning decisions for the use of such facilities. With the growth of switched fiber networks, the available combinations of satellite, fiber, and terrestrial microwave links offer almost unlimited possibilities for live remote production anywhere in the world.

COMMUNICATIONS

Keeping in touch with the remote production crew is one of the secrets of a successful production session. Even for a simple ENG assignment, where only a camera operator is dispatched to gather local color for a special closing segment, communications between the operator and the station should not be forgotten. It may be necessary to direct the operator to another assignment before returning to the station or the operator may require assistance from the station before returning. As the production project becomes more involved, communications becomes even more important. When ENG goes live, cues to the technical staff and talent are as crucial as those to a remote team located halfway around the world.

Options now available for keeping in touch with mobilized members of the staff are widely varied. Cellular telephones and two-way radio provide convenient bidirectional links between the control room and the remote van over a wide area of operation. Both require licensing. Cellular telephones can also be used to transmit data between two points, including facsimile type data transmissions. Just as facsimile messages have become popular throughout modern business, the remote copier capability is particularly valuable in sending graphic type material that would require much more complex equipment for handling.

When the remote production crew leaves the area served by the TV station, two-way communication with the station can be carried along with program signals by microwave or satellite through an order wire subchannel of the existing connection. The roaming feature of cellular telephones can keep a remote crew in almost constant contact from most areas of the United States and Canada. Undoubtedly this will expand to a worldwide connection, as satellites play a greater role in linking terrestrial communications facilities.

Communications among the staff at the remote site may mean another challenge for engineering. Operators of wired cameras remain in touch through the intercom circuit available with all cameras. Roving, nonwired camera operators are generally equipped with two-way radios or wireless intercom equipment. In a facility such as a stadium, where similar communications are required on a frequent basis, numerous wired systems may be permanently installed and staff members are required only to be plugged into the network.

These are only a few of the equipment areas that must be carefully considered before the purchase order for a remote production vehicle and equipment package can be finalized. You will also need to consider video switchers, audio mixers, on-board audio and video recording equipment, signal distribution and monitoring products. No less important to the comfort and efficiency of the operations staff are such concerns as the furnishings in the vehicle.

KEY TERMS

Cutaway. A particular type of scene, usually shot after the fact, to be edited in later. The scene is either a person talking (usually a shot of the back of the head), or a person listening (usually physically responding to what the other person is saying). Cutaways are used as a video source to cover the edits of incongruous scenes.

Shore power. A source of electricity other than a portable generator. Typically, shore power is electrical service from the local electric utility.

5.18
PRODUCTION CONSIDERATIONS FOR DTV

DAVID LEATHERS
DIGITAL MEDIA LAB, CULVER CITY, CA

INTRODUCTION

At this writing, any discussion of the production realities of digital television (DTV) is a bit like shooting at a moving target. The only certainty is that it will be a rapidly changing environment that will present both opportunities and problems that have not yet been anticipated.

What forms DTV's implementation will take is still a matter of great speculation. The various political, market, technical and creative forces that will shape DTV's future are still evolving. The standards and uses that will eventually emerge will not be defined until broadcasters, manufacturers and content creators have gained real experience in the use of the medium. However, it is reasonable to assume that there will be a fairly wide range of approaches, both initially, and as more technological resources are introduced.

PROLIFERATION OF FORMATS

In the earlier conceptual stages, DTV was thought of primarily as a delivery system for a digital form of high definition television (HDTV). However, as DTV moves from the theoretical to the practical, it is clear that high bandwidth HDTV represents only one use of the technology. There are currently 18 video format standards that have been adopted for DTV transmission at greater than SMPTE 259M resolution. However, the use of DTV as a high definition medium has not been mandated by the FCC. In addition to HDTV broadcasting, broadcasters are free to use the digital spectrum for multicasting multiple channels of standard definition video, lower resolution video, interactive programming, internet downloads or other digital forms to be determined. Consequently, the range of possibilities for content has expanded dramatically beyond high bandwidth HDTV.

Production models used in other entertainment areas, such as electronic games, the internet, DVD and video CDs and visual effects production, are useful in predicting the directions that DTV may take and the consequent production requirements and considerations. Each of these industries is highly responsive to rapid changes in their respective technological and market environments. Also, the costs and capabilities of production systems change rapidly, creating a volatile arena for technicians, producers and artists.

The net result is, in addition to all the other considerations that go into developing production properties, producers will have to consider a far wider range of production and distribution formats than ever before.

HDTV PRODUCTION

Forms of high resolution television have been displayed at NAB conventions for nearly a decade. In that time, the specifications have changed and multiple formats and standards have evolved. HDTV production equipment is just now becoming readily available, yet production in the HDTV domain has been limited to date.

There are several reasons for this. Since, until now, the equipment itself has been produced in small numbers, the cost-per-unit has remained high. Since, there is no installed base of display equipment, those productions that have been done in HDTV have had limited exhibition possibilities or have been converted to other formats.

Until more equipment exists, it is likely that most feature entertainment productions will be produced on film.

However, film cannot be produced live. The need for live HDTV content will begin to drive the need for pervasive affordable HDTV production systems. Accurate predictions of how long this will take are impossible at this time.

Film Production and Media Assets

In today's distribution environment, feature films are usually shot in 35 mm film. After the film is distributed theatrically, using 35 mm prints, it is usually telecined to standard NTSC, PAL and/or other video standards and distributed on broadcast quality digital and/or analog tape for broadcast, satellite and cable delivery. It is subsequently duplicated to VHS tape for distribution in the home video rental and other consumer markets. Other forms of video entertainment and information, which are not intended for film release, are often produced on video. The exception is when productions, intended for television or video, are shot in film, in anticipation of a possible future re-release in a higher resolution format. This is a method employed to protect the future value of unique and/or valuable content, or media assets.

35 mm film specifications exceed the resolution and contrast of all forms of HDTV by a significant margin. For this reason, major television productions, as well as feature films, have been shot in film for many years. It is still the best way to ensure that the material shot

in the present, will retain its full media asset value in the foreseeable future. Once the media assets are in this high resolution form, they can be telecined and down converted to whatever lower resolution format is required for delivery at that time. As delivery systems improve, the original media assets can be copied into better formats, retaining their original value.

Predictable Production Resources

There are other inertial factors that will likely keep high end production in the film domain for some time to come. 35 mm production equipment and experienced crews are widely available. Production techniques are well developed and understood. Production schedules and costs are generally predictable.

Also, in the last decade, the visual effects industry has developed many ways to work with film originated imagery in the digital domain. This makes it possible to create almost any imaginable visual effect at film resolutions that exceed today's specifications for HDTV. When it does become practical to produce feature entertainment in HDTV, the visual effects components will already be in place.

Visual Effects and Electronic Production

With the release of Pixar's *Toy Story* in 1996, audiences saw the first feature film that was produced completely in the digital domain. Similar end-to-end computer generated production of HDTV content is therefore possible. Since the beginning of production for *Toy Story*, which reportedly took five years to produce, advances in hardware and software have reduced the cost and production time required to levels that are feasible for television production. In fact, many of the facilities that were once dedicated to film visual effects production are now also involved in the production of graphics, animation and visual effects for lower resolution media, such as television and electronic games, in addition to their high resolution film activities.

The primary tools of visual effects production are computer hardware and software. As the toolset has evolved away from dedicated hardware systems (black boxes) and towards open computer platform based systems, visual effects production has reached a point where it is essentially resolution independent. Once again, the resolution requirements for digital film production exceed the requirements of all anticipated HDTV formats. This means that essentially all available production tools and techniques in use today for film visual effects production, are, or will be available for HDTV production, regardless of the resolution or aspect ratio.

Live HDTV Broadcasting

The major disadvantage to both film production and computer based production is that they can not be done in real-time. Television style production of live events is unique to the video domain. HDTV production systems will have to be used for HDTV presentations of live events.

The engine that will drive the development of HDTV production systems will most likely be this need for live broadcasting. Sports production is likely to play a large role in this development. Major sporting events are frequent enough and have the budgets to push the technical envelope in live production. Olympic competitions have already served as some of the first ventures in HDTV production.

HDTV Formats, Progressive Scan and 16:9 Aspect Ratios

While video professionals have been evaluating HDTV technology and picture quality using studio quality equipment and monitors for years, the quality of the initial consumer installed base of HD capable home viewing equipment will be subject to significant trade-offs in picture quality in deference to price.

While, tests continue, there is widespread *speculation* that the differences in the aspect ratio between 4:3 displays and 16:9 displays and the differences between interlaced and non-interlaced (progressive scan) displays are far more dramatic than the effects of increased pixel density.

The Computer Environment

As the shift to DTV takes place, perhaps the largest consideration affecting those involved in production, will be the central position that computers will take in the entire process, from preproduction through delivery to the home.

Digital videotape formats and serial digital systems in production environments have improved on the traditional production process but have not fundamentally changed the production process. Digital tape machines and switchers are used in much the same way as their analog predecessors and are used together in systems with the older analog equipment.

DTV's demand for both compression and interactivity will drive more of the production process into the computer domain. This will fundamentally change the production process. The great strides being made in the production capabilities of computer systems in the last few years are indicators of a process that will be greatly accelerated by the implementation of DTV. For evidence of this, consider the current role of online nonlinear editing systems and computer based graphics production in television production and compare this to their roles and capabilities of only a few years ago.

While these roles have increased dramatically, they have still remained a part of a process with the purpose of putting standard resolution, linear programming on the air. The demands of DTV production will require the flexibility of more computer-centric systems to accommodate the wider range of output demands. These include multiple streams of video, compressed or uncompressed, at varying resolutions and aspect ratios, multiple streams of compressed digital audio, computer graphics and animation and interactive programming at the minimum. The integration of data services, interactivity and more advanced forms of video will further centralize the role of computers.

Software and Computer Programming

It follows that this greater reliance on computers in the production process will create a need to understand computers and computer programming. A look at today's visual effects and interactive gaming industries offers some insights into the role that software and computer programming will play in DTV production.

In the visual effects industry, film effects are generated using a variety of software packages in multiplatform production environments. Typically, a process will call for more than one software program to be used. Also, the interoperability between these software packages is not adequate for the producer's purpose and custom software must be developed to solve the incompatibility. Therefore, most visual effects facilities support a software development department to work with artists and solve production problems. It is reasonable to assume that this type of approach will be necessary for the leaders in DTV production. Like visual effects producers, DTV producers will be pushing the technical envelope, as well as the creative envelope. The only way to do this in a computer production environment is to have available skills to solve problems and offer solutions that involve custom computer programming solutions.

This will create high demand in production environments for computer programming skills and for producers, technicians and others involved in the creative process to understand the role of software in the overall production process.

Interactivity

While questions associated with HDTV, and multicasting are important, of at least equal importance are the questions posed by the interactive aspects of DTV. In terms of how DTV is used, interactivity may play a larger role in the future orientation of consumers to television than HDTV or the proliferation of programming choices offered by multicasting.

While the production of linear programming is familiar territory to film, television and video producers, broadcasters and distributors, the development of interactive programming and the interactive infrastructure that will become possible with DTV is new and largely unfamiliar.

Programming interactivity is inherently custom work. There is no standard for interactivity. This is because, in an interactive experience, the design and implementation of the interactivity is fundamental to the creative concept.

Interactivity must be programmed into a production, one step at a time. It is a labor intensive activity that requires specific training and skills.

As with other creative computer processes, such as graphics, animation and visual effects production, the more innovative the implementation, the greater the demand for custom programming. While it is possible to create interactive presentations, using off-the-shelf tools, the most dynamic results are achieved using custom programming techniques.

Interactive programming will be addressed differently by individual DTV producers and broadcasters. While some may perceive demand for a lot of interactive programming in their market and get involved in the production of programming to meet that demand, others will not pursue it as a staple, in part due to the costs and skills required for production. However, even those stations that do not broadcast interactive programming, may need to transmit data that can be used by the receiver to create interactive menus and navigation systems that allow the user to select their services.

Interactivity and Multiple Simultaneous Cameras

One of the ideas for the use of interactivity in DTV is the delivery of multiple camera angles to the viewer along with the viewer's ability to select between them. The viewer would see small proxies of several angles along the side or bottom of his screen, and flip between them to display his choice on the main screen area.

From the production standpoint, this means that multiple cameras have to be framed, focused and online at any point in time. In film style production done offline, this means that there will be more cameras shooting simultaneously, or more retakes from more angles. In live production, this means that camera operators will have less time to hunt for shots and frame and focus and will have to be live more of the time. In a large sports production, where there are a dozen or more cameras, directors will have to be sure that a minimum number of those cameras are online and providing usable angles at any point in time. The possibility of this kind of coverage is exciting from the viewing standpoint and undoubtedly will be tried as technology permits.

What this kind of interactivity means to the line producer, whether live or not, is that more source material will be required to fill the same amount of linear time.

Immersive Video

A future consideration, that admittedly is in the early stages of development, but has very important possibilities in the future of DTV is *immersive video.* Immersive video is the use of input from multiple cameras surrounding an area to produce a videographically generated 3D database of that area that is live and changes in real-time.

Once the 3D database is created (in real-time), an interactive viewer will be able to navigate the 3D environment using a virtual camera controlled by a joystick or similar device. Users will be able to walk through the video environment, just as video gamers can walk through the 3D environments in today's 3D computer generated game environments. For instance, the sports viewer will be able to watch their favorite game from a virtual camera position anywhere on the field.

CHARACTERISTICS OF THE VIDEO SIGNAL[1]

HDTV has improved on earlier techniques primarily by calling more fully upon the resources of human vision.[2] The primary objective of HDTV has been to enlarge the visual field occupied by the video image. This has called for larger, wider pictures that are intended to be viewed more closely than conventional video. To satisfy the viewer at this closer inspection, the HDTV image must possess proportionately finer detail and sharpness of outlines.

Critical Implications for the Viewer and Program Producer

In its search for a "new viewing experience," NHK conducted an extensive psychophysical research program in the early 1970s. A large number of attributes were studied. Non-technical people were exposed to a wide variety of electronic images, whose many parameters were then varied over a wide range. A definition of those imaging parameters was being sought, the aggregate of which would satisfy the average viewer that the television image portrayal produced an emotional stimulation similar to that of large screen film cinema experience.

Central to this effort was the pivotal fact that the image portrayed would be large—considerably larger than current NTSC television receivers. Some of the key definitions being sought by NHK were precisely how large, how wide, how much resolution and the optimum viewing distance of this new video image.

A substantial body of research gathered over the years has established that the average U.S. consumer views the television receiver from a distance of approximately seven picture heights. This translates to perhaps a 27 in. NTSC screen viewed from a distance of about 10 ft. At this viewing distance most of the NTSC artifacts are invisible, with perhaps the exception of cross color. Certainly the scanning lines are invisible. The luminance resolution is satisfactory on camera close-ups. A facial close-up on a modern, high performance 525-line NTSC receiver, viewed from a distance of 10 ft, is quite a realistic and pleasing portrayal. But the system quickly fails on many counts when dealing with more complex scene content.

Wide angle shots (such as jersey numbers on football players) represent one simple and familiar example. Television camera shooting, however, has long adapted to this inherent restriction of 525 NTSC—as witnessed by the continuous zooming-in for close-ups on most sporting events. The camera operator accommodates for the technical shortcomings of the conventional TV system and delivers an image that meets the capabilities of NTSC, PAL, and SECAM quite reasonably. There is however, a penalty, as illustrated in Figure 5.18-1. The average home viewer is presented with a very narrow angle of view—on the order of 10°. The video image has been rendered clean of many inherent disturbances by the 10 ft viewing distance, and made adequate in resolution by the action of the camera operator; but in the process the scene has become a small window. The now acceptable TV image pales in comparison with the sometimes awesome visual stimulation of the cinema. The primary limitation of conventional TV systems is, therefore, one of image size. A direct consequence is further limitation of image content; the angle of view is constantly constricted by the need to provide adequate resolution. There is significant, necessary and unseen intervention by the TV program director in the establishment of the image content that can be passed on to the home viewer with acceptable resolution.

Compared to the 525-line NTSC signal (or the marginally better PAL and SECAM systems), the Grand Alliance DTV system and the North American HDTV studio standard (SMPTE 240M) and its digital representation (SMPTE 274M) offer a vast increase in total information contained within the visual image. If all this information is portrayed on an appropriate HDTV studio monitor (currently available in 13, 19, 28, 38 in diagonal sizes) the dramatic technical superiority of HDTV over conventional technology can easily be seen. The additional visual information, coupled with

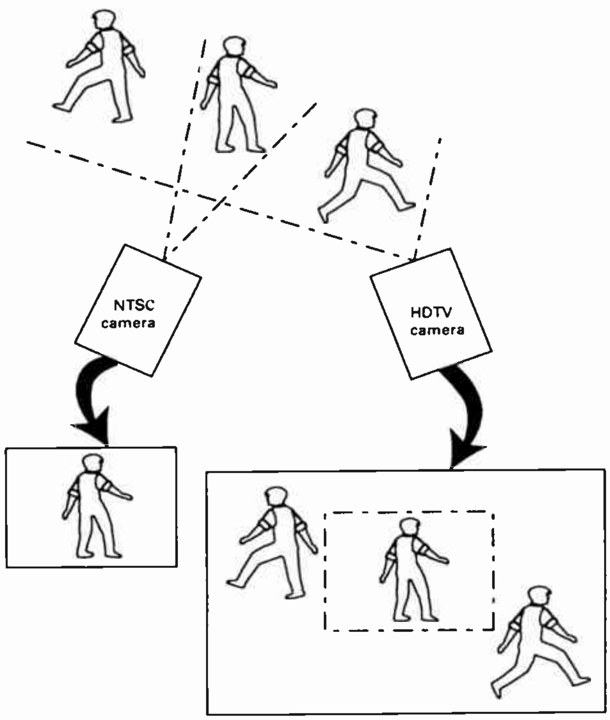

Figure 5.18-1. An illustration of the differences in the scene capture capabilities of conventional video and HDTV.[2]

[1] Whitaker, Jerry, *DTV The Revolution in Electronic Imaging*, McGraw-Hill, 1998, pp. 45-50.

[2] Thorpe, Laurence, J., "Applying High DefinitionTelevision," *Television Engineering Handbook*, rev.ed. K.B. Benson and J.C. Whitaker (eds.), McGraw-Hill, New York, p.23.4, 1991.

the elimination of composite video artifacts, portrays an image almost totally free (subjectively) of visible distortions, even when viewed at a close distance.

On a direct-view CRT monitor, HDTV displays a technically superb picture. The *information density* is high; the picture has a startling clarity. However, when viewed from a distance of approximately seven picture heights, it is virtually indistinguishable from a good NTSC portrayal. The wider aspect ratio is the most dramatic change in the viewing experience at normal viewing distances.

Image Size

If HDTV is to find a home for the consumer, it will find it in the living room. If consumers are to retain the average viewing distance of 10 ft, then the minimum image size required for an HDTV screen for the average definition of a totally new viewing experience is about a 75 in. diagonal. This represents an image area considerably in excess of present large 27 in. NTSC (and PAL/SECAM) television receivers. In fact, as indicated in Figure 5.18-2, the viewing geometry translates into a viewing angle close to 30°, and a distance of only three picture heights between the viewer and the HDTV screen. Compare this with the viewing angle for conventional systems at 10°, as shown in Figure 5.18-3.

HDTV Image Content

There is more to the enhanced viewing experience than merely elevating picture size. Unfortunately, this fundamental premise has been ignored in some audience surveys. The larger, artifact-free, imaging capability of HDTV allows a new image portrayal that capitalizes on the attributes of the larger screen. As mentioned previously, as long as the camera operator appropriately fills the 525 (or 625) scanning system, the resulting image (from a resolution viewpoint) is actually quite satisfactory on conventional systems. If, however, the same scene is shot with an 1125/60 HDTV camera, for example, and the angle of view of the lens is adjusted to portray the same resolution (in the picture center) as the 525 camera when capturing a close-up of an individual ball player on its 525 screen,

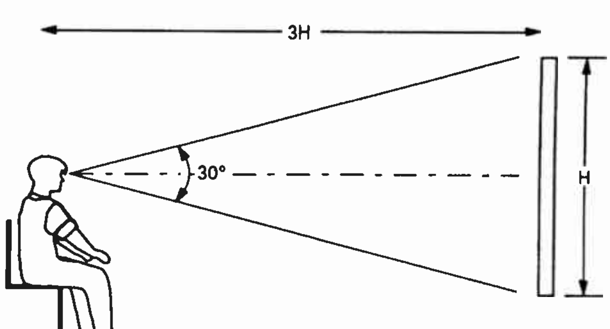

Figure 5.18-2. Viewing angle as a function of screen distance for HDTV.[2]

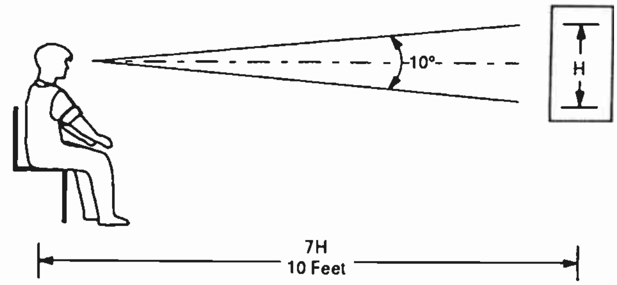

Figure 5.18-3. Viewing angle as a function of screen distance for conventional video systems.[2]

a vital difference between the two pictures emerges: the larger HDTV image contains considerably more information, as illustrated in Figure 5.18-1.

The HDTV picture shows more of the ball field—more players, more of the total action. The HDTV image is, thus, radically different than that of the NTSC portrayal. The individual players are portrayed with the same resolution on the retina—at the same viewing distance—but a totally different viewing experience is provided for the consumer. The essence of HDTV imaging is this greater sensation of reality.

The real dramatic impact of HDTV on the consumer will be realized only when two key ingredients are included:

- Presentation of an image size of approximately 75 in. diagonal (minimum)
- Presentation of image content that capitalizes on new camera freedom in formatting larger, wider, and more true to life angles of view.

Format Development

Established procedures in the program production community provide for the 4:3 aspect ratio of video productions and motion-picture films shot specifically for video distribution. This format convention has—by and large—been adopted by the computer industry for desktop computer systems.

In the staging of motion-picture films intended for theatrical distribution, generally no provision is made for the limitations of conventional video displays. Instead, the full screen, in wide aspect ratios—such as CinemaScope—is used by directors for maximum dramatic and sensory impact. Consequently, cropping of essential information may be encountered more often than not on the video screen. This problem is particularly acute in wide-screen features where cropping of the sides of the film frame is necessary in producing a print for video transmission. This objective is met in one of the following ways:

- *Letter-box* transmission with blank areas above and below the wide screen frame. Audiences in North

[3] Benson, K.B. and D.G. Fink., *HDTV: Advanced Television for the 1990s*, McGraw-Hill, New York. 1990.

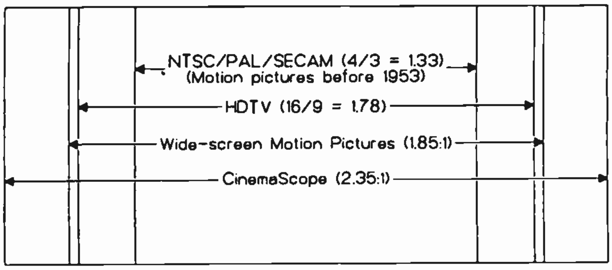

Figure 5.18-4. Comparison of the aspect ratios of television and motion pictures.[3]

America and Japan have generally not accepted this presentation format, primarily because of the reduced size of the picture images and the aesthetic distraction of the blank screen areas
- Printing the full frame height and crop equal portions of the left and right sides to provide a 4:3 aspect ratio. This process frequently is less than ideal because, depending upon the scene, important visual elements may be eliminated
- Programming the horizontal placement of a 4:3 aperture to follow the essential picture information (*pan and scan*). This process is used in producing a print or in making a film-to-tape transfer for video viewing. Editorial judgment is required to determine the scanning cues for horizontal positioning and, if panning is used, the rate of horizontal movement. This is an expensive and laborious procedure and, at best, compromises the artistic judgments made by the director and the cinematographer in staging and shooting, and by the film editor in post production.

These considerations are also of importance to the computer industry, which currently has keen interest in multimedia technology.

One of the reasons for moving to a 16:9 format is to take advantage of consumer acceptance of the 16:9 aspect ratio commonly found in motion picture films. Actually, however, motion pictures are produced in several formats, including:

- 4:3 (1.33)
- 2.35, used for 35 mm anamorphic CinemaScope film
- 2.2 in a 70 mm format

Still, however, the 16:9 aspect ratio is commonly supported by the motion picture industry. Figure 5.18-4 illustrates some of the more common aspect ratios.

CONCLUSIONS

DTV opens the doors to all kinds of new possibilities in programming formats for producers. This will be both a blessing and a curse.

The range of possibilities is so vast that producers will have more choices to make. Delivery format decisions will have to be considered at a fundamental level along with content. New skills will be required in the production process and producers will have to draw talent form the areas of visual effects production, internet programming, electronic games and computer software.

Funding projects will take on new dimensions. The great proliferation of potential channels, created thorough multicasting, will generate a need for more programming. At the same time, this proliferation of channels will dilute the audience, necessitating smaller production budgets for many projects.

As stated at the beginning of this chapter, how the implementation of DTV actually evolves will depend on a vast number of forces and interests. Producers need to increase their knowledge of as many of these areas as they can in order to be able to respond to the challenges that lie ahead and to take advantage of the many wonderful new capabilities that the technology will deliver.

Section 6: Television Transmission Facilities

Introduction by: Donald Wilkinson, Fisher Broadcasting, Seattle, WA

This is a time of remarkable changes in the television broadcasting industry. Many new players are competing with traditional broadcasters for the attention of the viewers. The quality of the picture that you transmit can easily make the difference between an enjoyable experience and driving the viewer away. With the conversion to digital television, even more care must be taken to preserve the integrity of your RF transmission path. Failure to do so can reduce your coverage area as surely as if you reduced power.

In this section, NAB has assembled a group of experts in television transmission facilities to address some of the issues facing broadcast engineers today. Much of the information contained herein will be very useful, especially for those of us being exposed to UHF transmitters for the first time. The chapters include a wide range of valuable information that will assist you in keeping your transmission facility operating properly. Subjects covered include microwave and fiber transmission, transmitters, combiners and diplexers, waveguide, antennas, measurements and satellite systems.

The section begins with the *Microwave and STL Systems* chapter, wherein Ernest M. Hickin and James H. Rooney III discuss the importance of microwave transmission and studio-to-transmitter links with regards to the broadcast engineer's responsibilities.

Gerald W. Collins and Robert J. Plonka discuss the relevant technology and provide the information needed for selection, installation, operation and maintenance of TV transmitters in today's environment in their *Television Transmitters* chapter.

Multichannel television sound is a generic term for the process of adding subcarriers to the aural carrier of an NTSC television station. In his *Multichannel Television Sound* chapter, Edmund A. Williams delves into the technical intricacies behind the generic term.

"Changes in telecommunications markets and technologies are challenging TV broadcasters to broaden the definition of their business and address new market opportunities." Neil Mitchell and NAB Staffer Kelly T. Williams explain how datacasting allows TV broadcasters to expand their business in *Television Data Broadcasting* chapter.

To help television broadcasters meet their compliance goals, John E. Leonard Jr. examines the regulatory requirement changes to Part 73 of the FCC's Rules and Regulations in the *Transmission System Control and Monitoring* chapter.

A waveguide is much more than a structure that guides electromagnetic waves. In his *Waveguide* chapter, *Handbook* Editor-in-Chief Jerry Whitaker discusses the several types of waveguides and its advantages over coax.

William Decormier's *Diplexers, Combiners and Filters* chapter reminds broadcasters that in order to optimize the performance of a station's transmission system, they must first understand and optimize the components upon which the system is built.

Thomas J. Vaughan's instructive *Antennas for Television Broadcasting* chapter begins with FCC considerations followed by a review of antenna design considerations as they relate to these demands and a review of specific applications. The chapter concludes with a look at current broadcast antennas and antenna systems.

Joseph W. Stielper and Ann Gallagher's *Television Field Strength Measurement (54–806 MHz)* chapter discusses planning a program of television broadcast field strength measurements and the analysis of the resulting data. FM broadcasters will find this chapter useful as well.

Signal transmission using fiber optic technology is the focus of C. Robert (Bob) Paulson's chapter on *Fiber Optic Transmission Systems for Broadcasting.*

As satellite technology for communications becomes more developed and in widespread use throughout the world, broadcasters will need to consider its possible impact on the industry. James H. Cook, Jr. provides an in-depth look at this technology in their *Satellite Earth Stations and Systems* chapter.

In the *Low Power Television* chapter, Robert M. Unetich discusses low power television/translators operating on conventional TV channels and multichannel multipoint distribution service/instructional television fixed service operating in the 2500–2690 MHz band.

In his *Cable Television Systems* chapter, Walt Cicora provides a historial perspective on cable television and offers readers an opportunity to get a better understanding of the technology that supplies video to households.

MICROWAVE RADIO COMMUNICATIONS, CHELMSFORD, MA

INTRODUCTION

Microwave transmission is an integral part of the broadcast engineer's operations responsibilities. The studio-to-transmitter link (STL) using frequency modulation (FM) has been the backbone of the industry for decades. Equipment design allows for essentially transparent, full color analog video transmission, as well as subcarriers capable of full FM stereo audio bandwidth and multiple voice and remote control functions. Similar technology is used for satellite earth stations (TVRO) which require backhaul links, for electronic news gathering (ENG), field production and regional news networks.

The major change new to this, the *9th Edition of the NAB Engineering Handbook*, has been the advent of digital video transmission, which requires an understanding of the advantages and the problems, associated with a variety of new modulation methods.

In most cases, microwave equipment suppliers are prepared to support broadcast engineers in their design needs. For path profiling, surveying and the prediction of path performance the engineer can undertake much of the work, or these services are available from the suppliers or from consultants. The availability of contour data for much of the USA now permits much of the initial study to be simulated by computer programs. The following discussions are presented to aid broadcast engineers in their own understanding of this technology.

PATH PERFORMANCE

Free space path loss for any electromagnetic wave arises from the spreading of the wavefront radiating from the source, like ripples on a pond. The loss increases by 6 dB (4:1 in power) every time the range doubles once outside the near field of the antenna. Since a 1:2 increase in range leads to a 2^2:1 reduction in power this relationship is generally referred to as the *inverse square law.*

Free space path loss (L), which is independent of ground or atmospheric effects, is given by:

$$L(\text{dB}) = 36.6 + 20 \log F(\text{MHz}) + 20 \log D(\text{miles})$$

or

$$L(\text{dB}) = 32.45 + 20 \log F(\text{MHz}) + 20 \log D(\text{km})$$

This is the loss between isotropic antennas (theoretical antennas which radiate or receive equally in all directions). The gain (G) of a microwave antenna is then expressed in dBi (gain relative to an isotropic antenna). For a parabolic reflector antenna, diameter d (ft), with an efficiency of 55% (which is typical of all but the smallest antennas), gain is given by:

$$G(\text{dBi}) = 20 \log d(\text{ft}) \times 20 \log F(\text{MHz}) - 52.6$$

Strictly speaking, an antenna being a passive device cannot possess power gain. The value G is the amount by which the radiation in a desired direction has been increased by redirecting energy, which would have been radiated in unwanted directions by an isotropic antenna. It should be noted that below 1 GHz it is usual to express gain relative to a dipole where 0 dBd = 2.2 dBi; thus the gain of a VHF or UHF TV transmitting antenna is most likely to be quoted in dBd.

The ratio of received power to transmitted power between two correctly aligned antennas of gains $G1$ and $G2$, when D miles apart, will be given by:

$$\frac{\text{Pr}}{\text{Pt}} = +G1 - 36.6 - 20 \log F - 20 \log D + G2 \text{ (units of dB)}$$

This number will be negative; the numerical value (i.e., absolute value) is referred to as *path loss.*

As examples, if the antennas are 6 ft diameter and the path is 30 miles long then:

at 2 GHz:

$$\frac{\text{Pr}}{\text{Pt}} = +28.5 - 36.6 - 66.0 - 29.5 + 28.5$$
$$= -75.1 \text{ or path loss} = 75.1 \text{ dB}$$

at 7 GHz:

$$\frac{\text{Pr}}{\text{Pt}} = +39.8 - 36.6 - 76.9 - 29.5 + 39.8$$
$$= -63.4 \text{ or path loss} = 63.4 \text{ dB}$$

Similarly, if the antennas are 2 ft diameter and the path is 8 miles long then:

at 23 GHz:

$$\frac{\text{Pr}}{\text{Pt}} = +40.7 - 36.6 - 87.2 - 18.1 + 40.7$$
$$= -60.5 \text{ or path loss} = 60.5 \text{ dB}$$

Note that in these equations doubling the frequency increases the total antenna gain by 12 dB (2 × 6) while the path loss increases by only 6 dB. This means that lower frequency systems require larger antennas or more power, or both, for a given received carrier level.

Other Sources of Path Loss

The free space loss is easily calculated and antenna manufacturers issue slide rules from which that loss and the antenna gain, can be read. However, atmospheric and other conditions will cause the loss to vary with time and these effects must be considered when planning a link.

Multipath (wanted signal arriving by other than the direct path) can be caused by reflections from water, hills, buildings or atmospheric discontinuities. Depending on the time delay these can add to or cancel the direct path signal, causing increases of up to 6 dB or reductions of more than 50 dB. The longer the delay, for a given magnitude, the more serious the effect as the path loss becomes increasingly frequency selective. By altering the ratio of the carrier to the sidebands in an FM system the effective deviation and therefore the level of the demodulated signal, can be raised. In a digital system, the delayed signals introduce intersymbol interference. Thus, multipath will introduce distortion into either system.

Delayed signals can also be generated within the system by reflections from discontinuities at branching devices, flanges in the feeder, at the antenna connector or by the antenna itself; these sources are very important, especially in the case of digital systems.

Atmospheric Bending of the signal due to abnormal changes in temperature and/or humidity with height can cause loss of signal due to diversion from the desired direction. This effect is discussed under the *K factor*.

Rainfall and to a lesser extent snow and ice, can attenuate the signal; this effect increases with frequency and is the over-riding factor at 18 GHz and above.

To offset these effects a system is designed to give a more than adequate signal level at the receiver under the free space loss condition (which is the norm to be expected for at least 90% of the time). The excess of signal over the minimum required for satisfactory service is called the ***fade margin***. Typical fade margins are in the range 26 to 46 dB and ideally will be larger for higher frequencies, longer paths and over water or similar difficult situations.

The choice of fade margin may involve compromises, for example when the need to use existing towers or masts may limit the size of antenna. It should also be influenced by the environment, being more necessary in humid, flat country and less necessary in dry, mountainous regions.

Outages: Multipath

Outage time is the time out of service due to propagation effects—it is usually given in minutes per month or per year. Availability, expressed as a percentage of a year or a month, is (525,960 − outage time) × 100 when the outage time is given as minutes/year, or (43,830 − outage time) × 100 when given in minutes/month. Both expressions are in frequent use.

An estimated time can be derived from an accepted formula which assumes that the path has adequate clearance for the area and is based on frequency, path length, fade margin and two empirical factors related to terrain roughness (the rougher the terrain the better as this tends to keep the atmosphere unstable) and to humidity (where the lower the humidity the better as moisture enhances atmospheric effects).

The formula, derived by Barnett & Vigants from the average of many Bell System paths, is:

$$t = a \times b \times 2.5 \times 10^{-6} \times f \times D^3 \times 10^{(-10/F)}$$

where

- t = time out of service as a fraction; in this case availability = $(1 - t) \times 100\%$
- a = {4 for very smooth terrain; 1 for average terrain with some roughness; 0.25 for mountainous, very rough or very dry areas}
- b = {0.5 for Gulf coast or similar low-lying, humid areas; 0.25 for normal interior, temperate or northern areas 0.125 for mountainous or very dry areas.}
- f = frequency in GHz
- D = path length in miles
- F = fade margin in dB

This formula can be useful in predicting performance for links where D is between 10 and 40 miles and for fade margins between 25 and 55 dB.

Outages: Rainfall

Attenuation due to rainfall is not covered by the B & V formula, which was derived from 4 GHz data where rain effects are negligible. Rainfall becomes of increasing importance at frequencies above 10–12 GHz and in higher rainfall areas. Note that it is the peak rainfall rather than the annual average, expressed in inches or mm/hour, which is important; while a day-long drizzle and a short thundershower may deposit the same volume of water it is the latter which will cause an outage.

To calculate probable outages due to rainfall a five-step procedure is used.

1. The fade margin is divided by the path length in kilometers (miles × 1.6).
2. By reference to Figure 6.1-1, from ITU-R (formerly CCIR) Report 721-2, the average rainfall rate (in mm/hr) along the whole path which would just cause a loss equal to the fade margin can be read by laying a rule from the right-hand scales through the center scale to the left-hand scale (note that this number is different for vertical and horizontal polarizations).

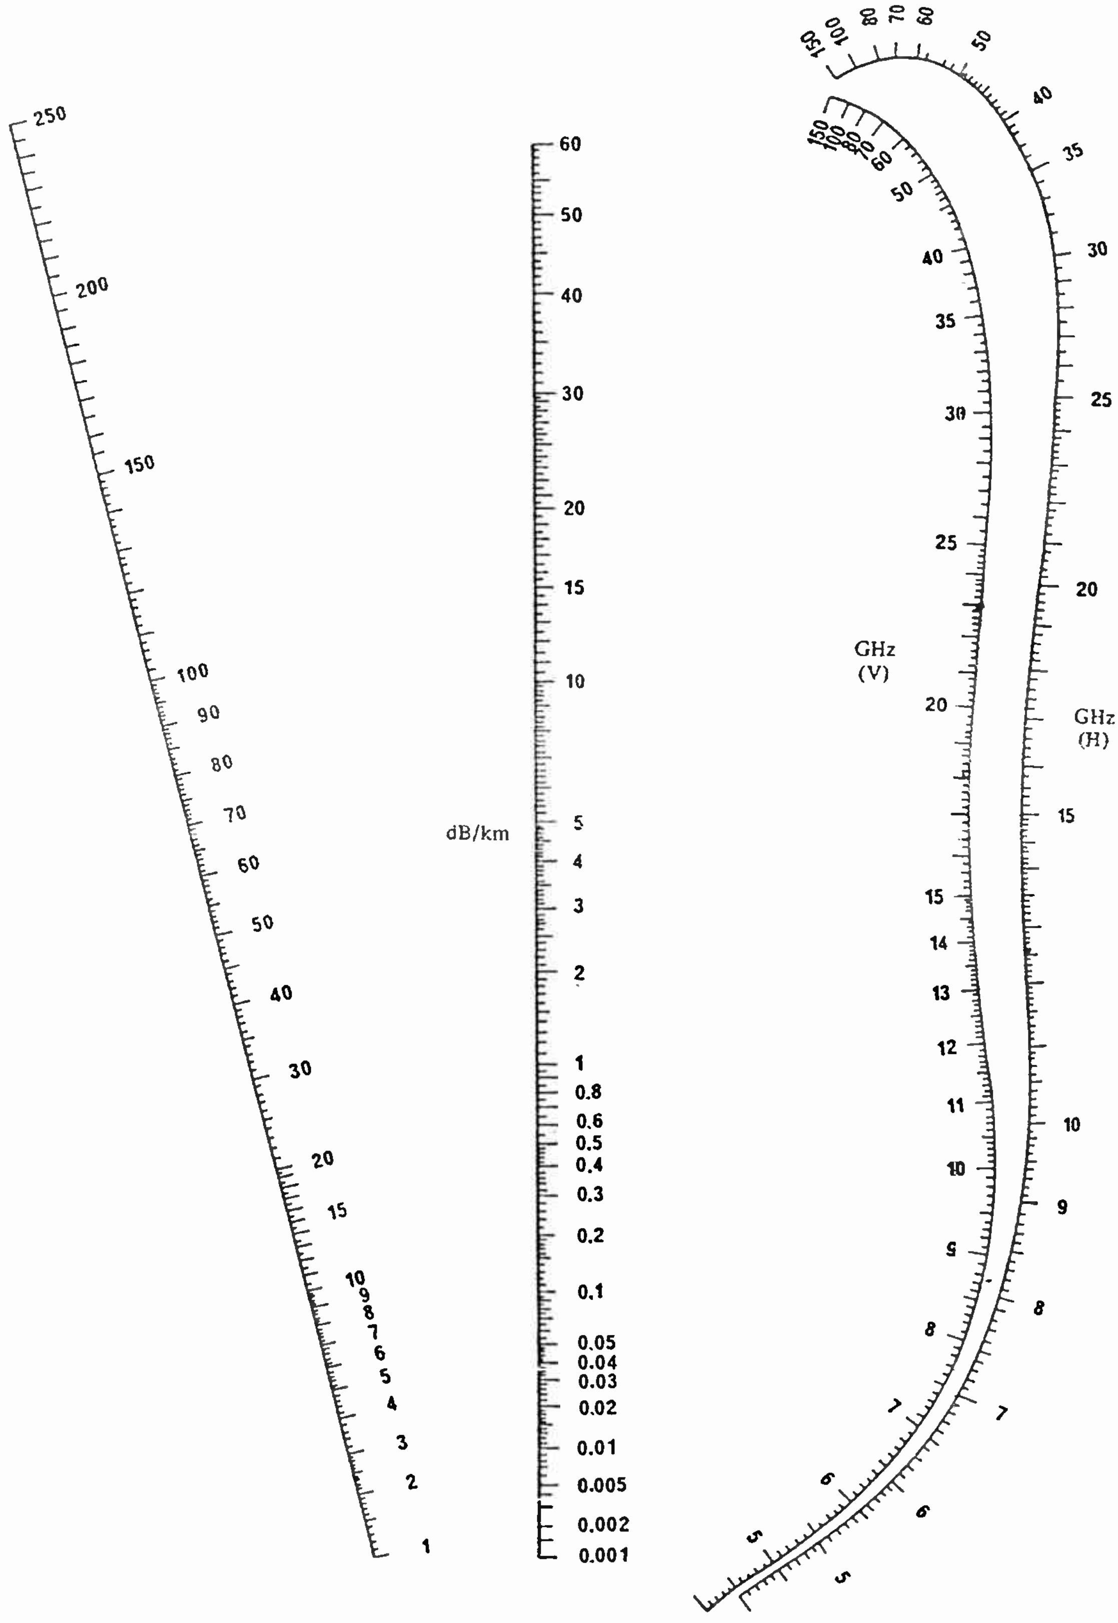

Figure 6.1-1. Specific attenuation due to rain. (H): horizontal polarization, (V): vertical polarization. *(From CCIR Report 721-2)*

3. By reference to Figure 6.1-2, from Barsis & Samson, find the point corresponding to that average and to the path length in question. Read the ratio number at the left and use it to divide the average rainfall rate to get the point rainfall.
4. By reference to Figure 6.1-3 note the rainfall zone in which the link is to be established.
5. Finally, read the outage time by reference to Table 6.1-1.

For longer paths at 13 or 15 GHz and for all paths at 18 GHz and above, the rainfall outage predominates and multipath effects as derived from the B & V formula can usually be ignored.

K Factor

The pressure and hence the density of the atmosphere surrounding the earth varies with height, getting less as the height increases and the weight of the air above decreases.

As a result the dielectric constant also decreases with height and this has a prismatic effect causing microwaves (and light waves) to bend towards the earth. Under normal conditions, the bending is less than the curvature of the earth but nonetheless micro-

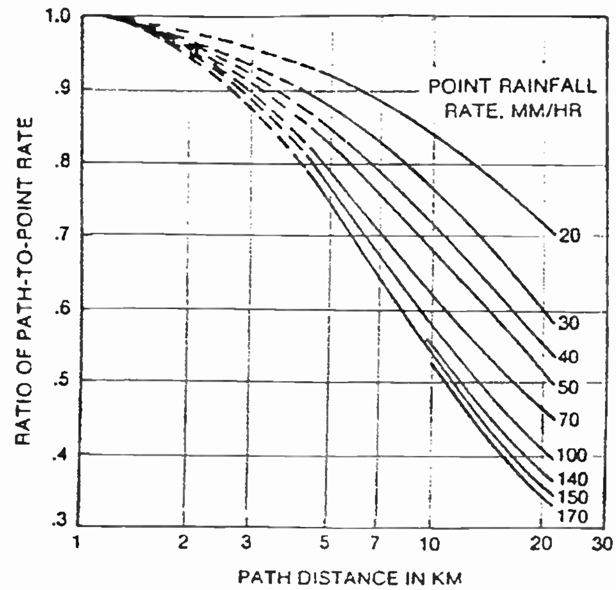

Figure 6.1-2. Path average-to-surface point rainfall rate as a function of path length. *(From Barsis & Samson, IEEE Transactions on Communications, April, 1976)*

(From Crane, IEEE Transactions on Communications, Sept, 1980)

waves will go further than simple geometry would suggest. A convenient way to allow for this when drawing profiles is to increase the radius of the earth until the microwaves appear to be travelling in straight lines.

The ratio of this effective earth's radius to the true earth's radius is called k and its value is approximately 4/3 or 1.33 for over 90% of the time in most parts of the world. However, there are times when "k" can be anything from infinity to as low as 0.45. When "k" is equal to infinity, the earth appears to be flat; it is a condition where mirages are seen and radar echoes are received from hundreds of miles away. It is an embarrassment as interference between systems is increased—fortunately, it is relatively rare. Values of "k" between 1 and 0.45 can occur for a few percent of the hours in a year and it is necessary to allow for this if a reliable link is to be established. Figure 6.1-4 is a map of the continental United States showing contours of equal minimum k-factor; this is based on refractive index measurements made by the Central Radio Propagation Laboratory.

Clearance Requirements

Figure 6.1-5 shows the manner in which the microwave signal is attenuated when the path is close to an obstruction. Clearance is stated as a fraction of the *first Fresnel zone (FZC)*, a function of frequency.

FZC (feet) is given by:

$$\mathrm{FZC} = 2280(d(D - d)/fD)^{1/2}$$

Where

f = frequency (MHz)
D = path length (miles)
d = distance to the obstruction from either end of the path.

Figure 6.1-5 illustrates that the attenuation with a clearance of 0.6 FZC is equal to the free space attenuation. However, as noted earlier, k-factor variations will mean that more than this clearance will have to be built in to allow for values less than 4/3 and a typical design parameter is to plan for 0.3 FZC for the lowest value of "k" expected on the path, as derived from Figure 6.1-4. While such a clearance will introduce 2 to 8 dB of loss, this is well within the fade margin of a well designed link.

Path Profiles

Sites for microwave link terminals are likely to be studios, earth stations or TV transmitters, all of which are predetermined. Choice of sites for repeaters, if they are necessary, may be constrained by availability and access. Since the access road is often the most costly part of a site, it can prove more economic to avoid the highest point and use a taller mast close to a road.

To see if any combination of sites is viable and to determine the antenna heights required at each end of the path, it will be necessary to construct a profile. This can be done with the aid of USGS 7.5 or 7.5 × 15 minute topographical maps. Now that the entire country has been surveyed to 3 arc-seconds and this

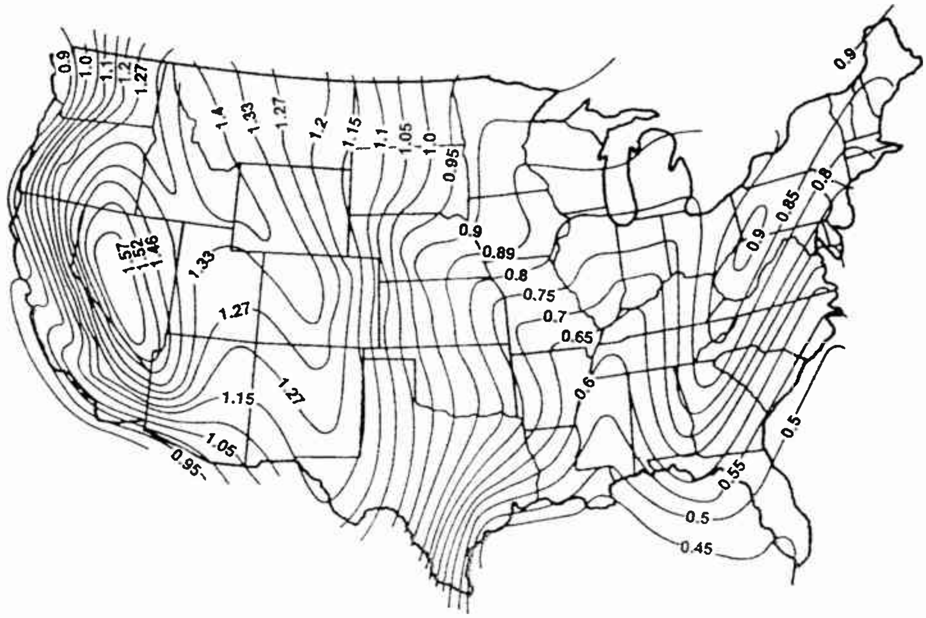

Figure 6.1-4. Estimated minimum K-factor for the continental United States.

topographical data is available on disc, there are programs which will draw the profile given the coordinates of the terminals. The programs are expensive but consultants (and some manufacturers) have them and the work can be subcontracted economically. Whichever route is chosen, some on-site examination of the path is almost always necessary to ensure that tree heights are correct, and that there have been no new buildings added on the path since the maps were compiled or the data entered.

If the work is to be done in house the profile can be drawn on simple squared paper or on special *k*-

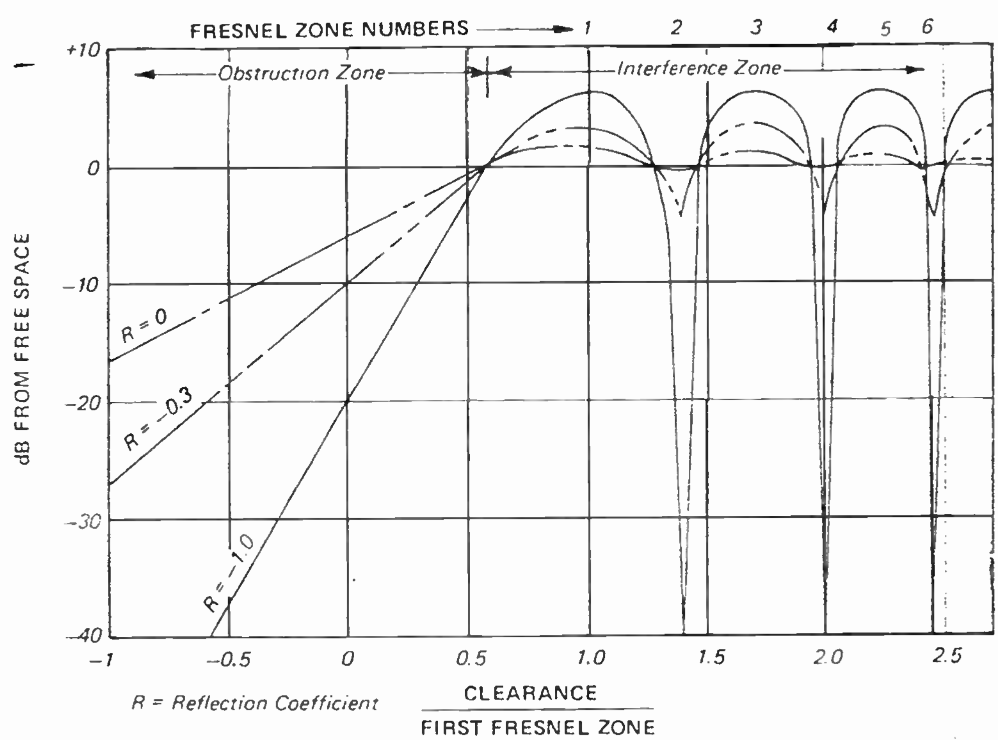

Figure 6.1-5. Attenuation vs path clearance for various types of obstruction.

factor paper (usually prepared for $k = 4/3$). Squared paper has the double advantage of easy availability and that any convenient scale can be chosen for the x and y axes; k-factor paper has the advantage that potential obstructions are more obvious and the effects of path length on necessary clearance stands out. Whichever paper is used the first step is to draw a straight line on the map between the sites. Then plot the contour heights on the paper every half mile where the ground is low, more often near high spots. It is usually clear where the dominant obstruction is going to be. Since the topographical map shows only ground level, the height of trees or buildings must be added in the region of any obstruction; this requires a site visit unless the terrain is well known.

Having established the level of the obstructions (ground level plus any trees or buildings) on the path an allowance (additional clearance) must be added to take care of the minimum clearance (0.6 FZC is recommended) and lower than normal values of the k-factor, using the following formula:

If using squared paper then add to each obstruction:

0.6 FZC + $d(D - d)/2$ (feet) (minimum clearance factor)

0.3 FZC + $d(D - d)\ 3k/2$ (feet) (low k-factor value)

If using 4/3 paper then add to each obstruction:

0.6 FZC (feet) (minimum clearance factor)

0.3 FZC + $d(D - d)\ 3k/4$ (feet) (low k-factor value)

where D is path length in miles, d is the distance of the obstruction from either end of the path and "k" is taken from Figure 6.1-4.

Then a straight line drawn through the highest points (usually (2) except on short paths or at lower frequencies) will pass through the minimum antenna heights at the terminals. If there are problems in mounting the antenna at one end at the height indicated then the line can be adjusted to the reduced height at that end, at the expense of increasing it at the other end. If most obstructions are near one end of the path it may be more economic to raise the antenna at that end and save a greater amount at the far end.

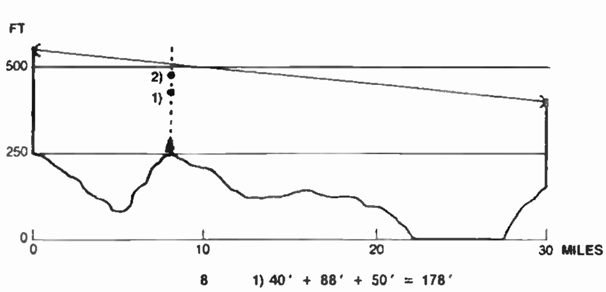

Figure 6.1-6. Example of profile plotted on squared paper, with required clearances for (1) 0.6 first Fresnel zone when K = 4/3, (2) 0.3 first Fresnel zone when K = 2/3 (50-ft tree allowance)

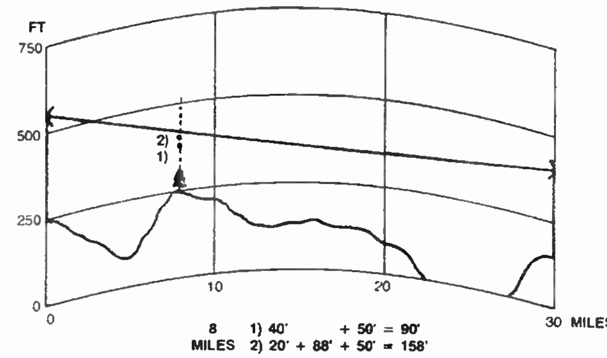

Figure 6.1-7. The profile of Fig. 6.1-9 plotted on k = 4/3 paper; (1) and (2) marked as on that figure.

Figures 6.1-6 and 6.1-7 show examples of the same profile plotted on squared and 4/3 papers and the final selection of antenna heights. The worst k-factor assumed was 2/3 shown as (2) on each profile at the main obstruction point at 8 miles.

ANTENNA SYSTEMS

Several different types of antenna can be used in a microwave TV link system. Omnidirectional antennas with vertical or circular polarization are frequently used for portable systems on moving vehicles and helicopters. Dipoles or discs, often in fiberglass covers, are used at 2 GHz for ENG either singly or in pairs; polarization can be switched to horizontal, vertical, right or left circular polarization to reduce path reflections. For STL's, intercity and community receiver antenna systems (CARS), the parabolic reflector type antenna is by far the most common. (See EIA/TIA Standard 195A for mechanical and electrical specifications.) A transmission calculation worksheet is given in Figure 6.1-8.

Isotropic

As previously noted the isotropic antenna is a hypothetical antenna used as a reference against which the gain of practical microwave antennae can be measured. Gain is the given in dBi, gain relative to an isotropic antenna. The isotropic antenna has a radiation pattern which is a perfect sphere. Other antennas are designed to enhance their radiation in a given direction at the expense of all other directions; this has the double advantage of increased sensitivity in the desired direction and reduced pickup of unwanted signals from other directions.

Parabolic

The parabolic reflector antenna comprises a feed at the focus of a parabolic reflector; the focus may be in the aperture plane of the reflector, for minimum sidelobes, or more usually in front of the aperture, to give maximum gain. The feed may be a dipole with a subreflector at frequencies up to 2.5 GHz; it can be fed by foam filled coaxial cable to avoid the need

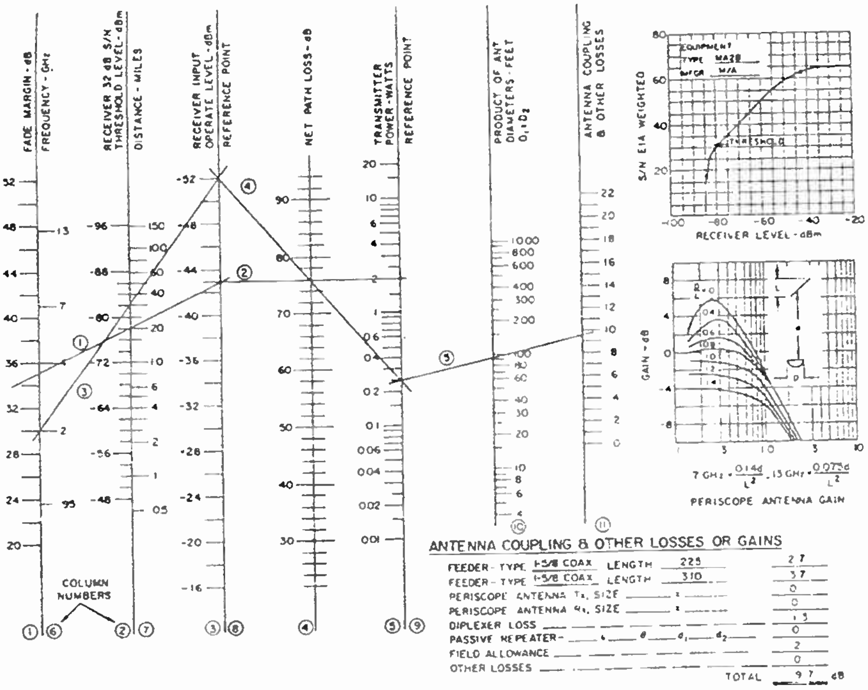

Figure 6.1-8. Transmission calculation worksheet.

for dry air pressurization. At higher frequencies, it is invariably a small horn fed by waveguide. The feed is designed to concentrate radiation onto the reflector with as little spillover as possible; a compromise has to be made between maximum gain and minimum spillover depending on the application. When minimum sidelobe radiation is critical (high performance antennas), a cylindrical metal shroud is fitted to the reflector extending beyond the focal plane; this may have absorbing material attached to the inner surface.

At frequencies up to 2.5 GHz the parabolic reflector of an antenna can be built up from closely spaced rods which must all be parallel to the polarization of the feed; this construction gives some relief from wind load. Above 2.5 GHz the reflector is solid but may be metal, metalized fiberglass or other reflecting material. Dual cross polarized feeds, with isolation in the 25 to 33 dB range, can be used to increase the number of signals sharing the antenna. Dual band antennas (for example, 7 GHz and 13 GHz) can also be built, each band having one polarization. Since the mast or tower is a costly item, these types offer reduced wind loading for multichannel systems.

The gain of a parabolic reflector antenna is given by:

$$G(\text{dBi}) = 10 \log 5.5(Df)^2$$

and the half power beam width (the total included angle between the points at which the gain has fallen by 3 dB) is given by:

$$\text{BW (degrees)} = 68.7/(Df)$$

where D = parabolic reflector diameter (ft) and f = frequency (GHz). Note that the half power beamwidth is a guide to the torsional rigidity required of the antenna mounting (including the mast or tower); in practice any movement should not exceed one quarter the above value to ensure minimum effect.

The voltage standing wave ratio (VSWR, expressed as a ratio to 1) or return loss (given in dB), which results from mismatch between the feed and free space, varies with antenna size and design. A standard antenna of 4 ft diameter or more may have a 1.10 VSWR (26 dB) while a high performance antenna would have a 1.06 (30.7 dB) to 1.04 (34.2 dB) figure.

Digital radio links, being more sensitive to reflections in the transmission path, are likely to require high performance or low VSWR antennas.

Radomes

Radomes can be fitted to parabolic antennas, the design depending upon the antenna construction. In addition to giving weather protection, the radome tends to reduce wind loading and torsional instability caused by the aerofoil effect of the reflector surface. For standard antennas, the radome is usually convex in shape and made of fiberglass, which may have imbedded heating elements. High performance antennas with shrouds have plane covers of Teglar or Hypalon stretched across the aperture; because these flex in windy conditions they tend to shed ice deposits and are not heated.

Other Radiation Patterns

Fixed point-to-point links, for STL applications as an example, use directional antennas to reduce power requirements, unwanted reflected signals and interference to and from other users of the frequency band. However, for portable links as used for ENG and other field applications wide-angle antennas may be needed. For links from motorcycles or cars to helicopters, hemispherical radiation patterns are used. Hand held cameras can have antennas with omnidirectional radiation in the horizontal plane. Manufacturers of portable equipment provide special antennas for differing applications.

Antenna Feeders

Microwave equipment is connected to the antenna with coaxial cable or waveguide. Cable is used below about 3 GHz and may be foam filled or with air dielectric and minimal plastic support. The copper outer is typically corrugated with a protective outer coating. Waveguide can be rigid, with rectangular or circular cross section, but as with coaxial cable is generally made of corrugated elliptical copper with a protective outer coating. The corrugations both strengthen the feeder and make it bendable. However, both cable and waveguide can be kinked if not installed with care and bending jigs are strongly recommended. Both Andrew Corporation and Cablewave Systems provide a wealth of information on feeders, connectors and all the accessories needed for installation in their catalogs.

When waveguide or air-dielectric cable is being used, it must be maintained at a positive pressure (0.5–5.0 lb/in^2) above atmospheric with dry air or nitrogen. Compressor/dehydrator units to supply this dry air can be fully automatic (where the desiccant is dried out periodically by the unit) or semi-automatic (where the desiccant must be periodically dried out or replaced by an operator). To avoid rapid cycling of the compressor the volume of air in the system should not be less than 1.5 cubic feet: this can be achieved in small systems by fitting a regulating tank.

Connectors for both cable and waveguide need careful fitting to avoid leakage of air and ingress of moisture. The mismatch introduced by a connector can be reduced by the use of tuned connectors, which have provision for canceling reflections.

Passive Repeaters

When two terminals are less than 10–15 miles apart, but the direct path is blocked by an obstruction, it may be possible to employ a passive repeater (a microwave mirror) to bypass the obstruction. The passive design is dependent upon the included angle between to two sections of the path at the repeater site. If the angle is less than about 120° a single flat panel can be used as the reflector—typical sizes at 7 or 13 GHz are from 8′ × 10′ to 20′ × 32′. Even larger ones can be used at 7 GHz while special smaller ones with a carefully controlled surface are available for 18 and 23 GHz.

For angles greater than about 120°, an arrangement of two closely spaced flat reflectors, or two parabolic antennas back-to-back with a short section of wave guide between them, can be used. In the latter case, a low noise amplifier can be fitted in the waveguide to improve performance. Care must be taken to prevent overloading of the amplifier if the repeater is near one terminal of the system.

Figure 6.1-9 is a nomogram with which the transmission loss through a passive repeater (relative to the direct free space loss) can be read. It will be clear that the loss is significantly less at higher frequencies and passive repeaters are seldom used below 4 GHz. Because the passive repeater requires no power, and little maintenance, its use should not be overlooked when designing microwave systems. (For more information

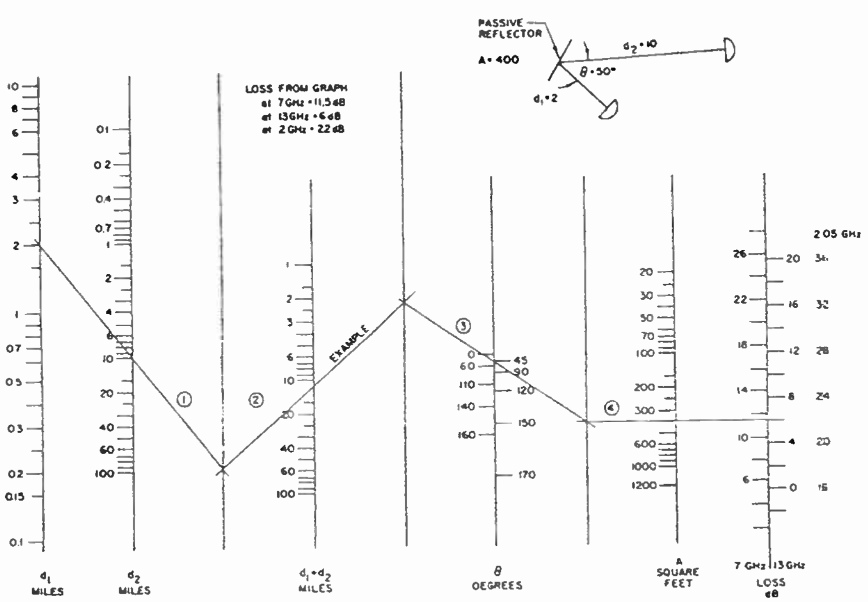

Figure 6.1-9. Passive repeater loss relative to direct transmission distance $D_1 + D_2$.

see *Passive Repeater Engineering* by the Microflect Company.)

RADIO EQUIPMENT

There are two generic terrestrial line-of-sight microwave transmission techniques in use today, analog systems typically using FM and digital systems typically using phase-shift keying (PSK) and quadrature analog modulation (QAM, typical 16-QAM to 512-QAM). Historically, transmission of video and audio signals over the last 50 years has been almost exclusively carried out using frequency modulation of the microwave carrier by an analog signal (the exact waveform to be broadcast rather than a sampled and coded version of that waveform from which the original can be regenerated at the end terminal as is the case in digital systems).

Since the television transmitter itself has used that analog signal, it has been a logical arrangement. Now that the studio equipment increasingly generates a digital output and the new standards for digital television are firmly set on a digital format, a new look at link design is required. Audio information also has usually been frequency modulated onto subcarriers, above the video, although digital modulation of the sync pulse is widely used in Europe and digital modulation of subcarriers is increasing. With DTV, the audio is built into the digital data stream.

The microwave transmitter and receiver may still comprise similar units, but whereas there is but one set of FM parameters set out in ITU-R recommendations (making interconnection of different manufacturers equipment simple, even at RF), common digital parameters have yet to be accepted. Because the bulk of equipment in service is still using FM, these systems are covered in detail in the next section. The section which follows deals with the various modulation techniques, (analog and digital).

Analog FM Systems

Two types of transmitter are in common use, *directly modulated* RF and *heterodyne*. In the former the analog signal is applied directly to the RF source to vary its frequency; in the latter the analog signal is used to frequency modulate an intermediate frequency (invariably 70 MHz) which is then transposed to the final radio frequency.

The advantage of the directly modulated RF system is simplicity. Since the modulation is applied to the RF source, no RF amplification is needed whether that source is an oscillator at the final frequency or a lower frequency source followed by one or more multipliers. Also, in multihop systems, since the carrier is generated afresh at each repeater, there is no build up of carrier-frequency error. The disadvantage only shows up in multihop systems where multiple remodulations can lead to level instabilities and bounce; after about three repeaters it is desirable to fit a level clamp.

The advantages of the heterodyne system lie in the multihop case. Once the modulation process has been accomplished at the initial transmitter the deviation (and hence the baseband level after demodulation) will not change; other sources of noise and distortion associated with the modulator occur only once in a system of any length. The disadvantages are that to ensure that a carrier frequency error does not build up over a multihop system, very stable oscillators, or an AFC system, are required. As the transmitter involves a mixing process, the power level is low and considerable RF amplification is needed. These factors lead to higher costs. The heterodyne repeater is the system of choice for longer microwave systems.

Directly-Modulated Transmitters

A basic transmitter of this type is shown in Figure 6.1-10. It comprises a video amplifier (with preemphasis), an oscillator, which can be frequency, modulated, a crystal referenced AFC loop and the options of a power amplifier and/or multiplier to deliver the required power and frequency. Various other optional items are available to extend the usefulness of the transmitter; these include audio subcarrier modulators, pilot generator, hot-standby protection switch, and off-air monitor, while portable equipment may have multi-RF channel switching. In a fixed link, the output will have a channel filter and provision to combine the signal with other transmitters and/or receivers sharing the same antenna and feeder.

The baseband amplifier will be broadband (10 MHz or so) to ensure linearity and permit multiple subcarriers above the video signal. Preemphasis is used to improve the signal-to-noise ratio and reduce the effects of the dc component of the video signal. Combining circuits are used to inject the audio subcarriers as well as a pilot and the engineer's order wire.

The transistorized voltage controlled oscillator typically runs at 2 GHz where high power is readily available. The output may be sufficient to use directly—more often, a 10 dB amplifier is used. To generate frequencies in the 6–8 GHz band, the 2 GHz signal is amplified and then multiplied by 3 or 4 times (the deviation of the primary oscillator being reduced to allow for this; for 13 GHz a further doubler is used). The power amplifier comprises one or more broad band stages to provide 8 to 10 W at 2 GHz, enabling 1–2 W at 7 GHz and 0.5–1 W at 13 GHz to be generated using varactor diodes.

The phase locked AFC uses a microwave IC divider which samples the output of the 2 GHz oscillator and compares the phase of the divided signal with a crystal oscillator; this is a simple and reliable method. Portable equipment, which may have to operate on any channel in the band, may use multiple crystals or more likely a frequency synthesizer as the reference in the AFC circuit. Since other circuits are broadband, no tuning is necessary when the reference is switched to another channel.

Because both fixed and portable equipment is likely to have to operate in the vicinity of high powered TV transmitters careful, filtering of power lines and baseband inputs is necessary.

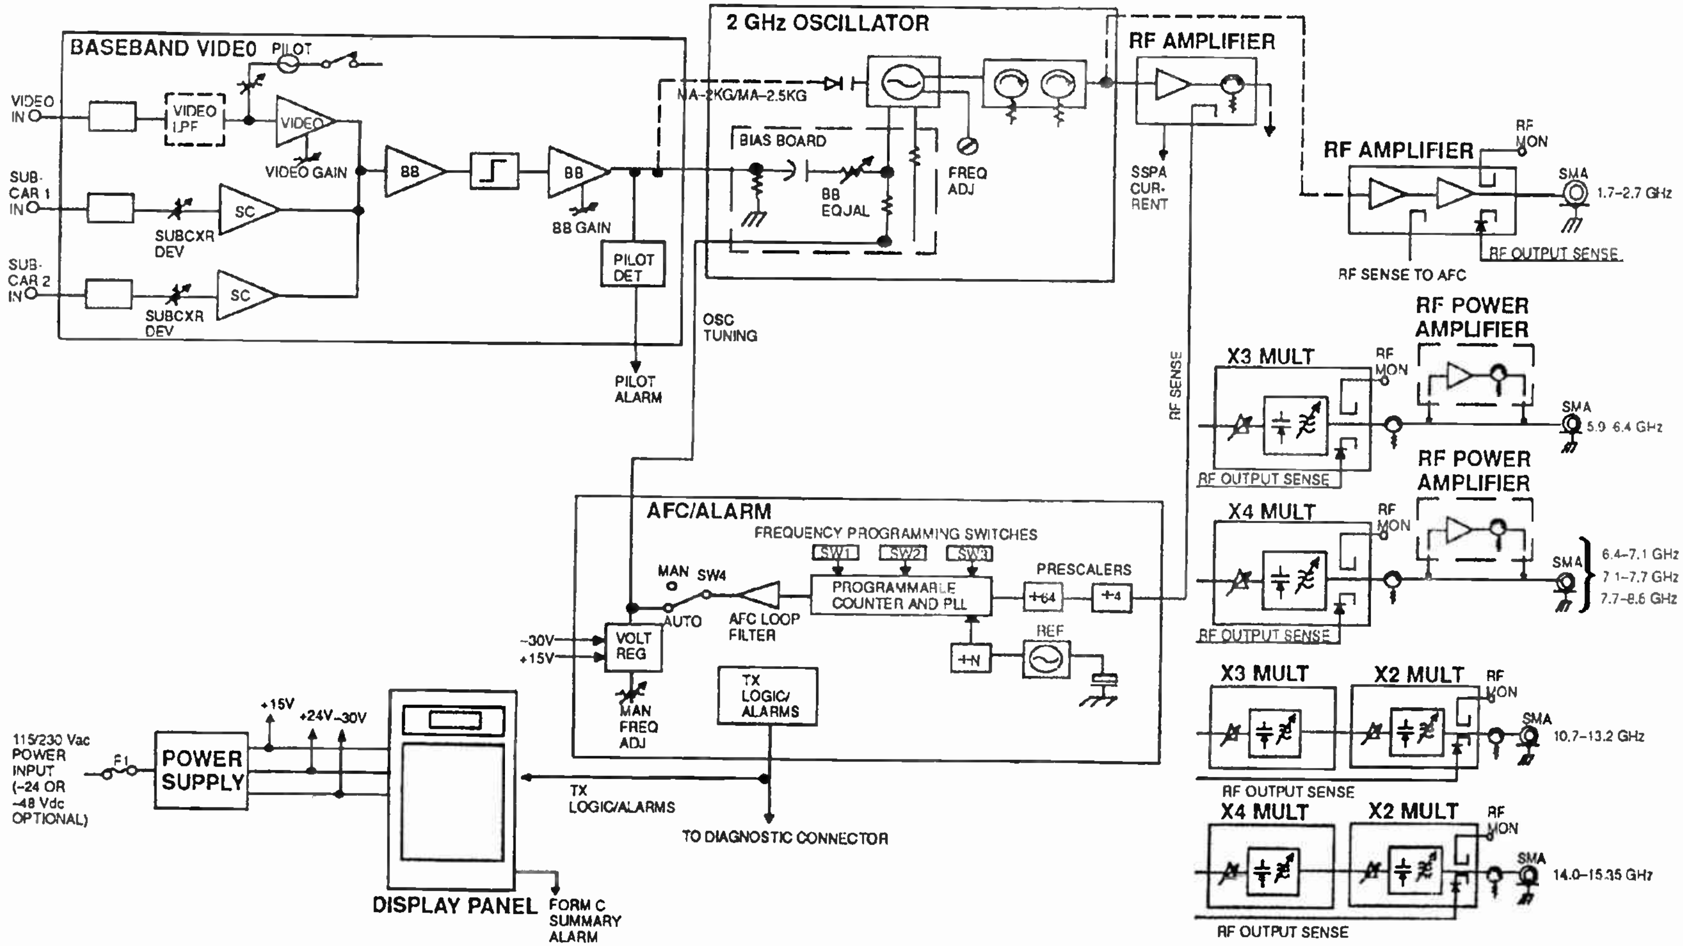

Figure 6.1-10. Directly-modulated transmitter—Functional block diagram.

Heterodyne Transmitters

A typical heterodyne transmitter block diagram is shown in Figure 6.1-11. It comprises an IF amplifier and a microwave source both of which feed an upconverting mixer. One sideband, usually the upper one, is selected by a filter or by the use of an image rejecting mixer. The mixer output, at a level around 0 dBm, is then amplified by 30 to 40 dB to provide the transmitter output. At a terminal the modulation is applied to a 70 MHz frequency modulator which produces a constant voltage at a frequency proportional to the applied voltage; the deviation sensitivity is such that a 1 V peak-to-peak signal produces a deviation of 8 MHz peak-to-peak. The modulator has a baseband amplifier with provision for the injection of subcarriers identical to those feeding the oscillator of the directly modulated transmitter. At a repeater, the 70 MHz output from the receiver is used instead of that from the modulator. To maintain transmitter output in the event of a failure of the incoming IF signal the IF amplifier is preceded by a monitor which triggers a locally generated 70 MHz carrier *(carrier reinsertion)*; this is important as the RF output is not being regenerated at each transmitter but is an amplified version of the original input to the system.

Note that in Figure 6.1-11 the local oscillator has provision for modulation; this is an important feature which permits the injection of a single sideband suppressed carrier (SSB-SC) signal with order wire or supervisory signals even though the through signal has not been demodulated. Since this follows the carrier reinsertion feature, alarms generated at a repeater will still be sent out even if the preceding receiver output has failed.

Receivers

The same basic receiver design is used with both directly modulated and heterodyne transmitters. Figure 6.1-12 is a block diagram of a typical receiver. In fixed (STL) equipment the RF input is invariably via a channel filter; this facilitates multiplexing with other receivers or transmitters, suppresses local oscillator radiation and eliminates any response at the image frequency (140 MHz above or below the received signal). In Figure 6.1-12, the input is amplified at RF in a low-noise amplifier (LNA) before the image rejecting mixer. Following the mixer is an IF amplifier, a filter equalizer which provides a flat passband with high adjacent channel rejection and a further high gain amplifier with automatic gain control (AGC). This latter feature ensures a constant level of 70 MHz at the receiver output despite level changes of 50 to 60 dB *(dynamic range)* in the received carrier level (RCL).

In the heterodyne repeater one IF output is used to drive the following transmitter via the carrier reinsert unit; another output may be used to drive a demodulator for the SSB-SC orderwire and supervisory channel or for monitoring.

The local oscillator may be a Gunn or dielectric resonance (DRO) type oscillator. In the remodulating case a stability of 0.005% is sufficient as any errors are not passed on to the following transmitter. In the heterodyne case frequency errors will add up and either a stability of 0.001% or better, or an AFC circuit which will ensure a 70 MHz output, are necessary. Figure 6.1-12 shows the latter arrangement.

Optimum receiver noise performance is achieved when the minimum necessary bandwidth is used. This is typically 20–25 MHz between the 3 dB points for TV with up to four audio subcarriers and a service channel. For portable equipment, with one or at most two audio subcarriers, channel allocations may require an IF bandwidth of 12.5 MHz. Recently, some major educational networks have been established with 4.2 MHz video bandwidth and a single subcarrier at 4.5 MHz, using a 10 MHz IF bandwidth; by reducing the peak deviation the quality can be maintained close to broadcast standards. In all cases, the characteristics of the filter equalizer must be carefully controlled for good phase and amplitude linearity.

The main IF amplifier follows the filter and provides 50–65 dB of gain. Since the input microwave level can vary between −20 and −85 dBm, while the output must remain substantially constant at about +5 dBm, an automatic gain control (AGC) must be incorporated in the main IF amplifier. When very large variations are expected, as in portable applications where path lengths can be very short, the AGC action may be extended to the LNA; this can prevent overloading of the mixer. The receiver should have multiple IF outputs available to allow for repeaters where the signal may be required to go in more than one direction as well as feeding a demodulator; for preference these outputs should be available squelched or unsquelched.

The demodulator comprises a limiter, discriminator, deemphasis and a baseband amplifier. The limiter is an essential part of an FM receiver in that it removes AM before the discriminator; threshold performance is significantly affected by limiter design. The discriminator demodulates the FM signal back to AM. In a TV system the discriminator must be linear over a wide bandwidth about the 70 MHz IF, at least ± for video and more when multiple subcarriers are being carried. Any non-linearities will produce distortion and noise by generating intermodulation products.

Finally the deemphasis network and baseband amplifier restore the baseband response and ensure the required 1 V peak-peak level of the video signal. The video output will require a lowpass filter to remove the sub-carriers; typically 35–40 dB is used.

Subcarriers

In addition to carrying the video traffic, a microwave link can carry other information above the video portion of the baseband. As the NTSC video bandwidth does not extend above 4.5 MHz, the region above this, after allowing a guard band, is available for other traffic. Four different uses are made of this region: one or more audio program subcarriers; an engineering order wire; supervisory signals (alarms and controls) and a continuity pilot. All these generally deviate the carrier at 20–26 dB below the 4 MHz video peak.

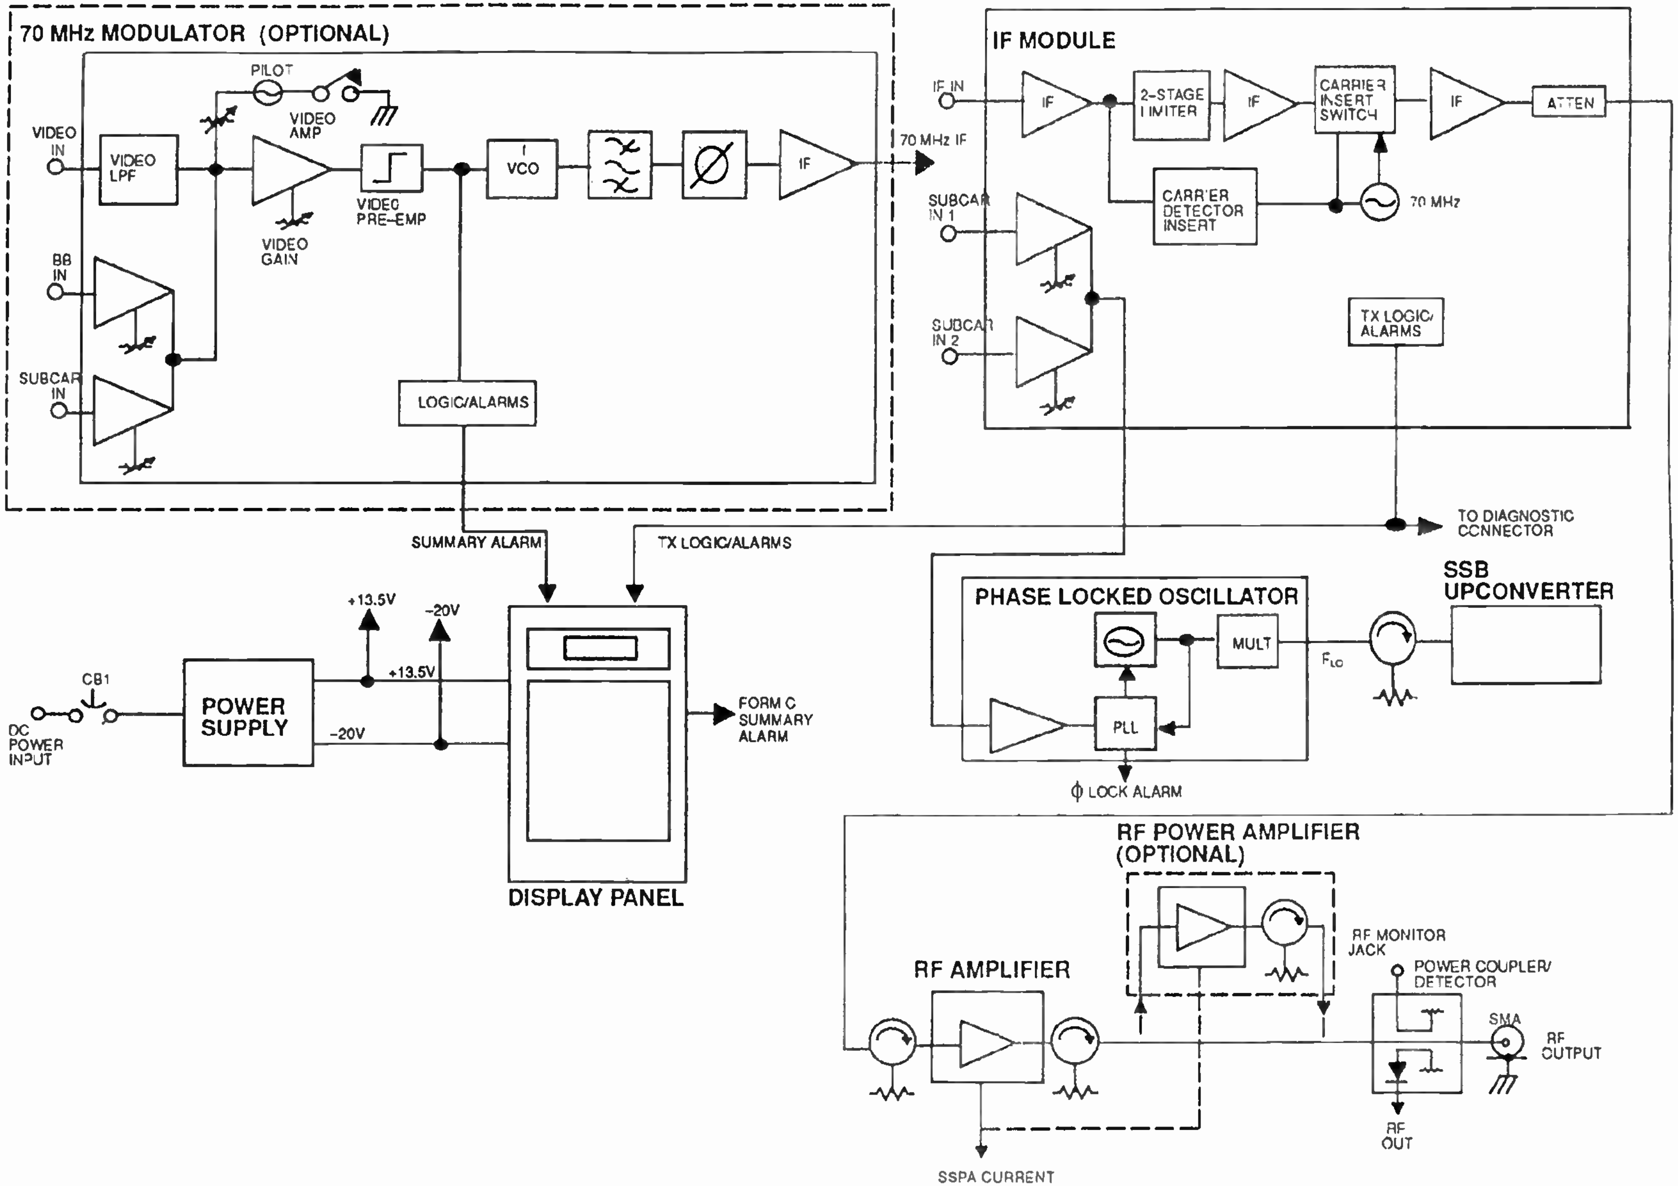

Figure 6.1-11. Heterodyne transmitter—Functional block diagram.

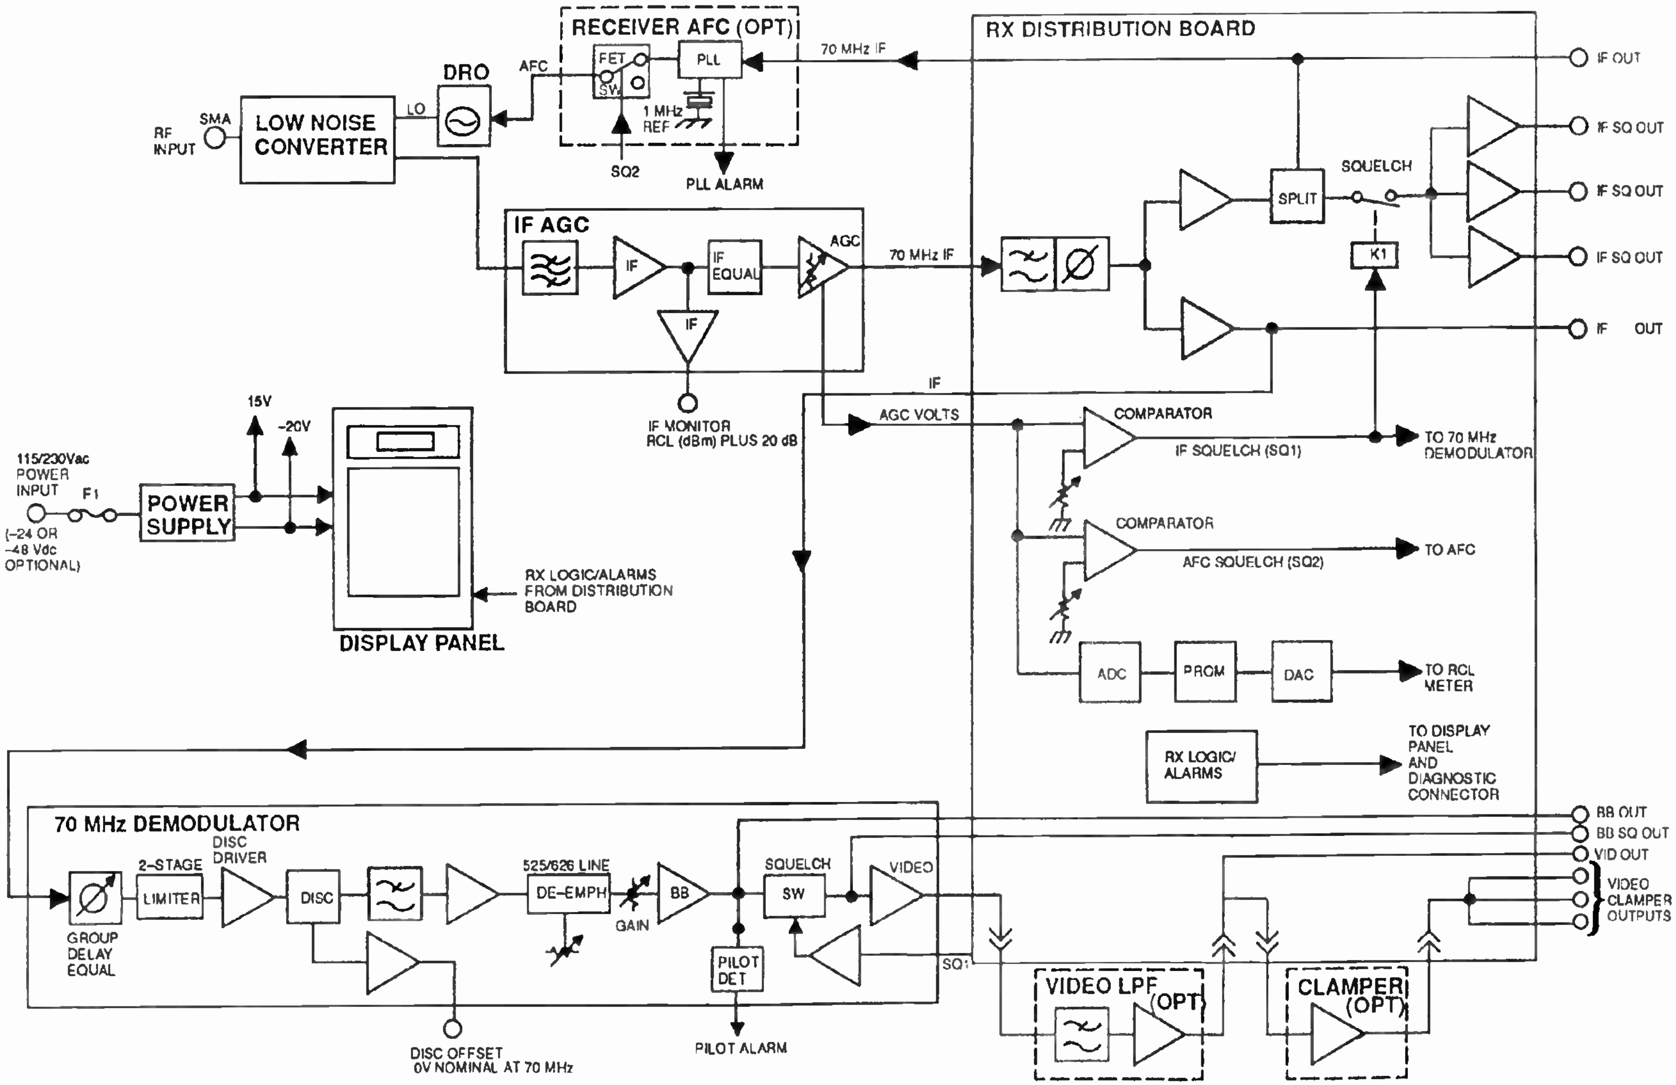

Figure 6.1-12. Receiver—Functional block diagram.

FM audio subcarriers are generally deviated at 75 kHz peak at 1 kHz; to improve the signal-to-noise ratio the audio signal is preemphasized. Maximum audio bandwidth is 15 kHz, giving an information bandwidth using Carson's rule of 180 kHz. To allow for filtering a minimum subcarrier spacing of 500 kHz is used, with increasing separation at higher frequencies to avoid beats between subcarriers falling into other channels. Typically, a 15.7 kHz trap filter is fitted to reduce the effects of intermodulation with the sync pulses.

Up to four FM subcarriers are used with NTSC STL links, at 6.2, 6.8, 7.5 and 8.3 MHz (with 4.83 and 5.2 MHz being used with ENG systems where the RF bandwidth is restricted). PAL and SECAM systems with 5.5 or 6.0 MHz video bandwidth use 7.020, 7.5, 8.065 and 8.59 MHz. These can carry stereo left and right and second language and FM transmitter feeds to co-sited transmitters. An encoded stereo signal (left plus right, left minus right, second audio channel and pro channel) can be carried on a single subcarrier, permitting the encoder to be in the studio; this requires a special modulator and demodulator.

Program audio equipment may be supplied as a separate unit or packaged in with the radio terminals. In the FM case the transmit end comprises a baseband amplifier with level setting controls to permit the recommended deviation to be achieved with inputs from 0 to + 18 dBm, a preemphasis network and a frequency modulated oscillator. The receive end comprises a filter followed by either a subcarrier amplifier or a mixer and IF amplifier, limiter/discriminator, deemphasis network and baseband amplifier with level setting capability similar to that at the transmit end. Unlike the video case there is no universally accepted audio interface level; the impedance is invariably 600 Ω balanced at the transmit end and the same, or a low impedance, at the receive end.

Often a SSB-SC AM signal is carried above the audios, at 8.59 or 8.85 MHz (for example). By using a suppressed carrier, information can be inserted at repeater stations without carrier beats. In a typical SSB-SC system the bandwidth can be up to 108 kHz, with 0.3–4.0 being used for an omnibus engineer's order wire, 4–12 kHz for supervisory and control signals and 12–108 kHz for up to 24 ITU-T (formerly CCITT) telephone channels.

In addition, a continuity pilot at the ITU-R recommended frequencies of 8.5 or 9.023 MHz is also used; this is essential if a protected system is to be provided. In the broadcast bands, only hot standby protection is permitted. In this system two transmitters on a single frequency run continuously with an RF monitor controlling a changeover switch to ensure a working transmitter is connected to the antenna. Similarly, two receivers are coupled to the antenna with a splitting network; a baseband switch controlled by the pilot ensures continuity.

Power Supplies

Microwave equipment requires voltages in the 5 to 30 VDC range. These can come from 60 Hz ac or from battery banks, usually − 24 or − 48 VDC.

Figure 6.1-13 is a block diagram of a typical power supply system. Alternate current units comprise a transformer and rectifiers to obtain the unregulated operating voltages. Various types of transistor regulator are used to keep the operating voltages within a narrow range. Direct current units, when used, are chopper types to reduce the transformer size and improve efficiency. Good designs tend to employ protection circuits on both input and outputs to guard against overloads due to lightning surges and accidental short circuits.

Digital Systems

With the advent of digital video, microwave transmission links will remain an integral part of the broadcast engineer's operation responsibilities. However, the existing FM radio infrastructure currently in service will not be capable of supporting the digital modulation needed for digital video transmission.

The STL will remain the industry backbone. During the analog to digital transition period, the STL in some cases will be required to carry a HDTV signal and a digitized NTSC signal. The simultaneous transmission

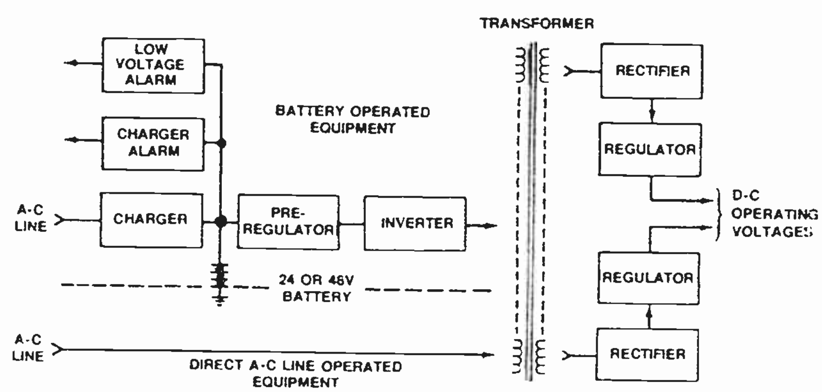

Figure 6.1-13. Power supply—Functional block diagram.

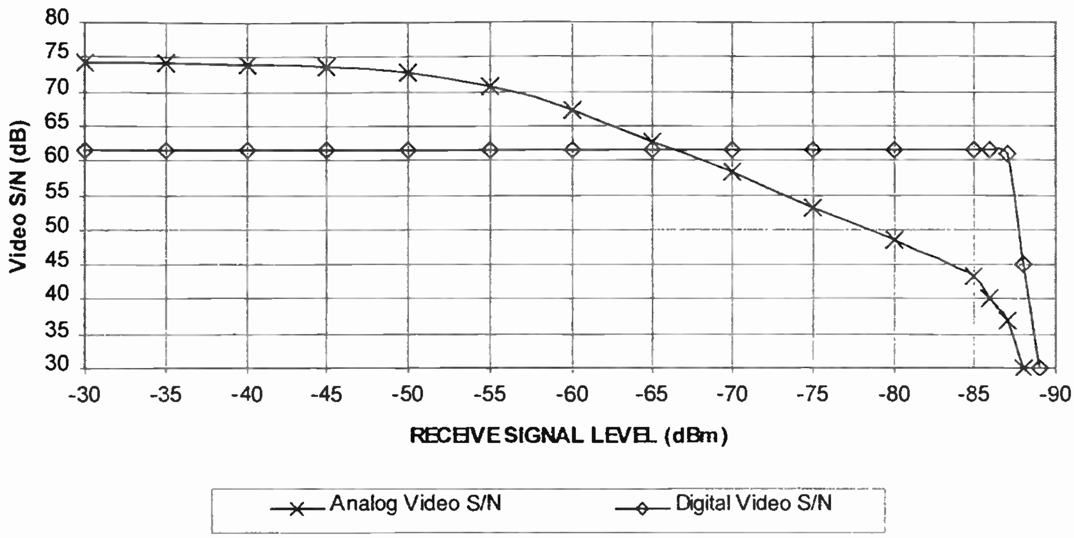

Figure 6.1-14. Typical Analog Video S/N vs. Digiral Video S/N.

of both signals is made possible by the emergence of MPEG-2 (Moving Picture Experts Group) technology and time division multiplexing.

In a properly designed digital video microwave link, the major advantage to be had over the analog link is that the video signal-to-noise (S/N) ratio is constant over the microwave receiver's operating range. This inherent digital feature provides constant picture quality over the radio receiver's dynamic range. Figure 6.1-14 shows the S/N comparison between an FM analog and 16-QAM DS3 radio system. The digital S/N is limited by the analog-to-digital (A/D) converters employed in the video encoding system and not the received signal level (as in the analog case), as illustrated by the figure. The rule of thumb is 6 dB of S/N for every bit used in the A/D. For the digital system show in Figure 6.1-14, the video encoder employs a 10 bit A/D.

In the coming years, there will be a great temptation to replace analog radios with digital radios in many of the existing links around the country. However, simply replacing an analog radio with a digital radio will not always provide the performance shown in Figure 6.1-15. It is the responsibility of the broadcast engineer to insure the path will meet acceptable availability criteria. Fortunately, the broadcast engineer will not be alone during this transition period. Radio manufacturers and consultants are available to analyze existing links and to determine what changes are necessary to provide reliable performance. If the broadcast engineer is so inclined, there are many software analysis programs available to aid in link design.

Modulation Techniques

The FM system is one in which the frequency of the carrier is caused to vary in accordance with some

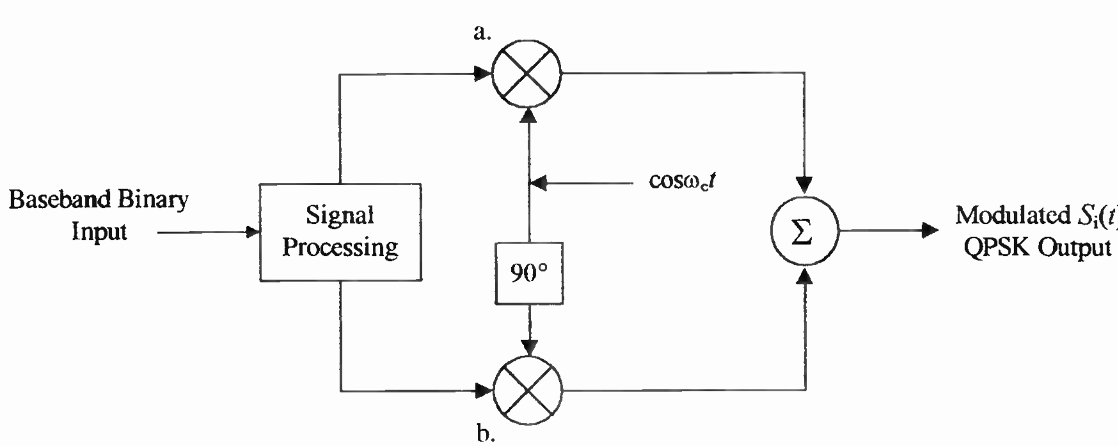

Figure 6.1-15. Simplified block diagram of QPSK modulator.

specified information carrying signal. For the simple case of a sinusoidal modulating signal at frequency f_m, the corresponding frequency modulated signed is given by $f(t)$ where:

$$f(t) = a \cos \omega_m t$$

where, "a" is the fixed amplitude of the modulated signal, and $\omega_m(\omega_m = 2\pi f_m)$ is the rate of modulation of the modulating signal.

Simply stated, there is a fixed amplitude sine wave of varying angular frequency ω_m. In the FM system all of the information is encoded as a function of the continuously varying angular frequency ω_m.

In digital systems, the amplitude, frequency and phase properties of the RF are quantized by the modulating signal. Digital implies a fixed set of discrete values. A digital radio waveform, then, can assume one of a discrete set of amplitude levels, frequencies or phases as a result of the modulating signal.

Frequency shift keying (FSK) consists of shifting the frequency of a sinusoidal carrier from a mark frequency (corresponding to a binary 1) to a space frequency (corresponding to a binary 0). This can be expressed as:

$$f_{c1}(t) = a \cos \omega_1 t$$

$$f_{c0}(t) = a \cos \omega_2 t$$

where "a" is the fixed amplitude of the modulated signal, a binary one corresponds to frequency f_1 and a binary zero to frequency f_2. An alternative representation of an FSK waveform consists of letting $f_1 = f_c - \Delta f$ and $f_2 = f_c + \Delta f$. The two frequencies then differ by $2\Delta f$ hertz and thus we can write:

$$f_c(t) = a \cos(\omega_c \pm \Delta\omega)t$$

(where $\Delta w = 2\Pi\Delta f$)

The frequency then deviates $\pm\Delta f$ about f_c. Δf is commonly called the *frequency deviation.*

Phase shift keying (PSK) consists of shifting the phase of a sinusoidal carrier 180° with a unipolar binary signal. This can be expressed as:

$$f_c(t) = \pm\cos \omega_c t$$

Here a binary one in the baseband binary stream corresponds to positive polarity and a binary zero to negative polarity. This modulation is commonly called *binary phase shift keying* (BPSK).

For BPSK, the values of 0° and 180° are typically used. These values are used to maximize (or to separate) the decision distance. There is no reason why 45° cannot be assigned as the binary 1 and 225° as the binary zero, as long as the distance between the two states is maximized.

Continuing along this line, instead of using two phase states, four can be used, each separated by 90°. The binary values to each of the four phase states can now be assigned as: 0° = 0, 1; 90° = 0, 0; 180° = 1, 1 and 270° = 1, 0. This type of multisymbol signaling is commonly called *quaternary phase shift keying* (QPSK) modulation or 4-PSK modulation. It can be expressed as follows:

$$S_i(t) = a_i \cos \omega_c t + b_i \sin \omega_c t$$

A simplified block diagram of a QPSK modulator is shown in Figure 6.1-16.

It is useful to represent the signal of $S_i(t)$ in a two-dimensional diagram locating the various points (a_i, b_i). The horizontal axis corresponding to the location of a_i is called the *inphase axis.* The vertical axis, along which b_i is located, is called the *quadrature axis.* The four signals of $S_i(t)$ assigned above then appear as shown in Figure 6.1-16. The points are said to represent a signal constellation, or as it is sometimes called, a *signal state diagram.*

More general types of multisymbol signaling schemes may be generated by letting a_i and b_i take on multiple values themselves. The resultant signals are called *quadrature amplitude modulation* (QAM) signals. These signals may be interpreted as having multilevel amplitude modulation applied independently on each of the quadrature carriers. A simplified block diagram of a QAM modulator is shown in Figure 6.1-17. The output of such a modulator can be expressed as:

$$S_i(t) = r_i \cos (\omega_c t + \theta_i)$$

where the amplitude r_i and the phase angle θ_i are given by the appropriate combinations of (a_i, b_i).

The signal constellations for a 4-, 16- and 64-QAM modulation is shown in Figure 6.1-18.

After careful examination of the PSK and QAM signal constellations one begins to appreciate the complexity required in a modem that can resolve the amplitude and phase information in multisymbol signaling schemes. One has to be more impressed with the modem that can resolve this information when the digital radio system is subject to external noise factors. To get a feel of how different digital modulations compare in the presence of thermal noise we can look at the bit energy to noise density ratio:

$$E_b/N_o$$

where, E_b is the energy per bit and N_o is the single sided noise spectral density. E_b/N_o can be expressed

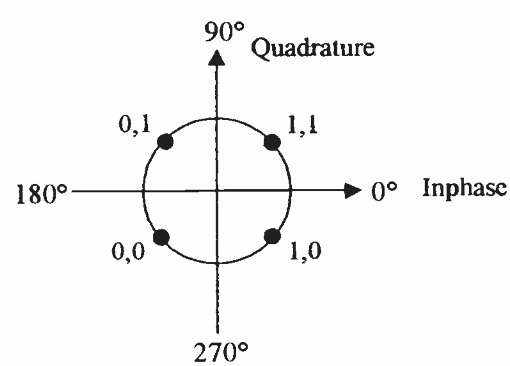

Figure 6.1-16. QPSK signal constellation.

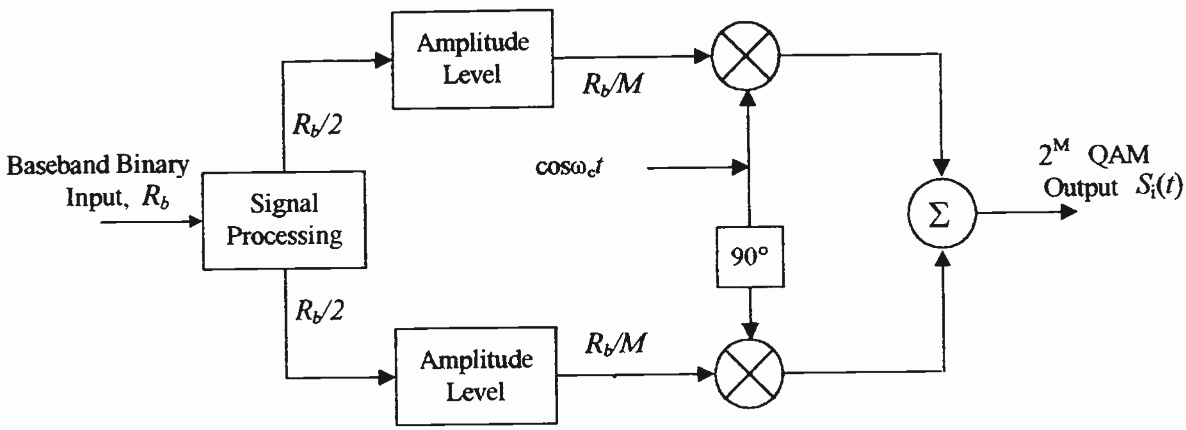

Figure 6.1-17. Simplified block diagram of a QAM modulator.

as the ratio of receive signal level (RSL) to the bit rate; in terms of log arithmetic, this can be written as:

$$E_b = \text{RSL}_{\text{dBm}} - 10\log(\text{bit rate})$$

The single sided noise spectral density of a perfect receiver in a 1 Hz bandwidth with a noise figure (NF) can be expressed as:

$$N_o = -174\text{ dBm} + \text{NF}_{\text{dB}}$$

The expression for the bit energy to noise density ratio is:

$$E_b/N_o = (\text{RSL}_{\text{dBm}} - 10\log(\text{bit rate})) - (-174\text{ dBm} + \text{NF}_{\text{dB}})$$

$$E_b/N_o = \text{RSL}_{\text{dBm}} - 10\log(\text{bit rate}) + 174\text{ dBm} - \text{NF}_{\text{dB}}$$

The above expression shows that as RSL increases so does the E_b/N_o. In other words, the greater that E_b/N_o needs to be, the less sensitive the receiver will be. This will be an important factor when determining the type of modulation to employ when converting existing analog links to digital.

Table 6.1-2 shows the E_b/N_o ratios based on a bit error rate (BER) of 10^{-6} for some common digital modulation formats and their bandwidth efficiencies based on the Nyquist bandwidth[1] (bandwidth numerically equal to the bit rate).

The parameters listed in Table 6.1-2 are idealistic because the only source of errors is due to thermal noise in the receiver. No modulation implementation loss is considered.

With the information given in Table 6.1-2 and from the E_b/N_o equation above, the receiver threshold for a T3 (45 Mbps) 16-QAM radio system with a radio noise figure of 4 dB can be calculated.

If we solve the E_b/N_o equation for $\text{RSL}_{(\text{min dBm})}$ we have the expression:

$$\text{RSL}_{(\text{min dBm})} = E_b/N_o + 10\log(\text{bit rate}) - 174\text{ dBm} + \text{NF}_{\text{dB}}$$

$$\text{RSL}_{(\text{min dBm})} = 17.0\text{ dB} + 10\log(44.736 \times 10^6) - 174\text{ dBm} + 4\text{ dB}$$

$$\text{RSL}_{(\text{min dBm})} = -76.5\text{ dB}$$

For a 64 QAM system the $\text{RSL}_{(\text{min dBm})} = -71.0$ dBm
For a 256 QAM system the $\text{RSL}_{(\text{min dBm})} = -65.7$ dBm

The example clearly shows that for higher order modulation schemes a greater E_b/N_o is required to enable the demodulator to extract the phase and amplitude information from the modulated signal. This inherent digital radio feature also causes the system gain to decrease as the modulation complexity increases. The previous example limits the distance between the transmitter and receiver as a function of the modulation scheme.

As a means to increase system gain, modem designers employ error correcting codes (or forward error correction (FEC)) to help improve performance. Error correcting coding usually requires redundancy (increasing the bit rate) and therefore, poses a contradictory requirement to obtaining maximum spectral efficiency. There is no set standard for the amount of FEC a manufacturer will employ in a given modem. During the modem design phase, trade-offs are made concerning BER performance, dispersive fade margin, spectral efficiency and cost.

For the applications being discussed in this chapter, satellite modems require more FEC than terrestrial modems to improve the system performance at threshold. Satellite links cover great distances and thermal noise becomes the dominant impairment. The composite bit rate at the output of a satellite modulator can be as much as 50% higher than the data rate into the modulator and as much as 10 dB of coding gain can be realized.

[1] The Nyquist bandwidth, in this context, represents the minimum theoretical bandwidth required to transmit the modulated signal if a brick wall filter were used in the modulation process. As a practical matter, the actual bandwidth required is always greater than this.

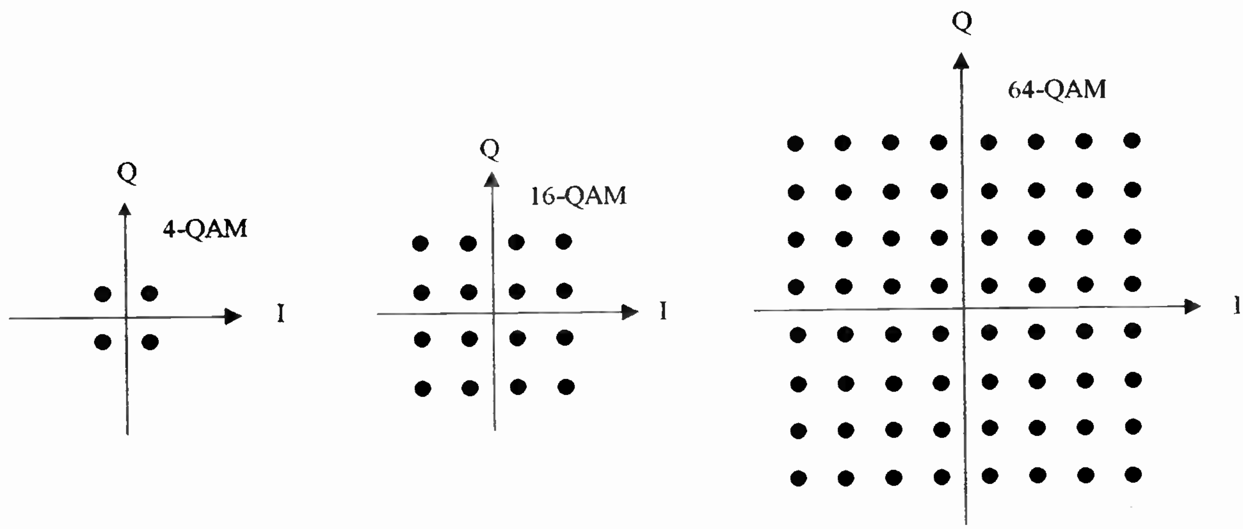

Figure 6.1-18. Signal constellations for a 4-, 16-, and 64-QAM.

A well designed terrestrial digital link is not fighting thermal noise as its major impairment. A modem designed for terrestrial use has to operate in a more hostile dispersive environment than the vacuum of space. The terrestrial modem designer has to balance coding gain, dispersive fade margin, spectral efficiency and cost. Terrestrial modems typically employ 5 to 15% of error correction redundancy. Table 6.1-3 shows the effect that 6.7 % of error correction redundancy has on QAM modulation (compare these values with the corresponding values shown in Table 6.1-2).

Again, FEC is not a cure-all for digital radio performance. The amount of error correction redundancy is up to the discretion of the modem designer and is just one of many factors that needs to be optimized during the modem design.

Transmitter

The transmitter in the digital radio link is the device that upconverts the modulated signal, amplifies it and then delivers it to the antenna system for transmission into free space. A simplified block diagram of a digital radio transmitter is shown in Figure 6.1-19.

As shown in Figure 6.1-19, an IF signal is first generated by the modulation portion of the system. The IF frequency is typically 70 or 140 MHz. This

Table 6.1-2
Basic Modulation Schemes

System	Variants	E_b/N_o (dB)	S/N (dB)	Nyquist Bandwidth
FSK	2-state FSK with discriminator detection	13.4	13.4	B

	512-QAM with coherent detection	28.9	35.5	B/9

Table 6.1-3
QAM modulation schemes with FEC added.

System	Variants	E_b/N_o (dB)	S/N (dB)	Nyquist Bandwidth
QAM	16-QAM with coherent detection	13.9	17.6	B/4 x (1 + .067)
	32-QAM with coherent detection	15.6	20.6	B/5 x (1 + .067)
	64-QAM with coherent detection	19.4	23.8	B/6 x (1 + .067)
	128-QAM with coherent detection	21.1	26.7	B/7 x (1 + .067)
	256-QAM with coherent detection	24.7	29.8	B/8 x (1 + .067)
	512-QAM with coherent detection	25.8	32.4	B/9 x (1 + .067)

signal is then upconverted by an image reject mixer. This translation of the modulated IF signal up to the RF carrier frequency is made by a mixing operation or multiplication between two frequencies. The result of this mixing operation is a summation of frequency components that can be expressed as:

$$nF_{LO} \pm mF_{IF}$$

where $n = 1, 2, 3, \ldots$ and $m = 1, 2, 3, \ldots$.

The frequencies that are of most concern for the case when $n = m = 1$, or:

$$F_{LO} + F_{(IF)}$$

and

$$F_{LO} - F_{(IF)}$$

The desired frequency for transmission is:

$$F_c = F_{co} + F_{(IF)}$$

$F_{LO} - F_{(IF)}$ is the difference frequency, which is commonly called the *image frequency*. The image frequency is typically suppressed 20 to 25 dB by the image rejection properties of the mixer.

In addition to the sum and difference frequencies, there will be some LO leakage present at the output port of the mixer. The LO leakage is attenuated approximately 20 dB by the mixer's LO to RF isolation. Some digital transmitter designs may employ a bandpass filter to remove the image and LO leakage signals.

The local oscillator that drives the mixer in a digital radio is a high stability, low phase noise frequency source. The low phase noise LO is required when implementing multisymbol modulation. Phase noise (or short-term instability, or jitter) is seen near the carrier and causes degradation of BER. As can be seen in the signal constellation diagrams shown in Figure 6.1-18, LO phase noise causes the constellation points to jitter about. If the LO in the transmitter and receiver were an ideal frequency source the constellation points would not move at all. The more phase noise the LO induces onto the modulated IF signal, the more difficult signal recovery becomes. Figure 6.1-20 shows the empirically derived phase noise requirements for QPSK, 16-QAM and 64-QAM modulation. Notice that as the modulation complexity increases the LO phase noise needs to decrease.

Continuing the journey through the transmitter, the signal out of the frequency translating mixer is input into a linear operating amplifier (typically solid-state). A linear operating amplifier is one that is operating below its 1 dB gain compression point. The 1 dB gain compression (called G_{1dB}) is defined as the power gain where the amplifier's non-linearity reduces the power gain by 1 dB over the small signal linear power gain. That is,

$$G_{1dB}(\text{dB}) = G_o(\text{dB}) - 1$$

where G_o(dB) is the small signal linear power gain in decibels. Since the power gain is defined as

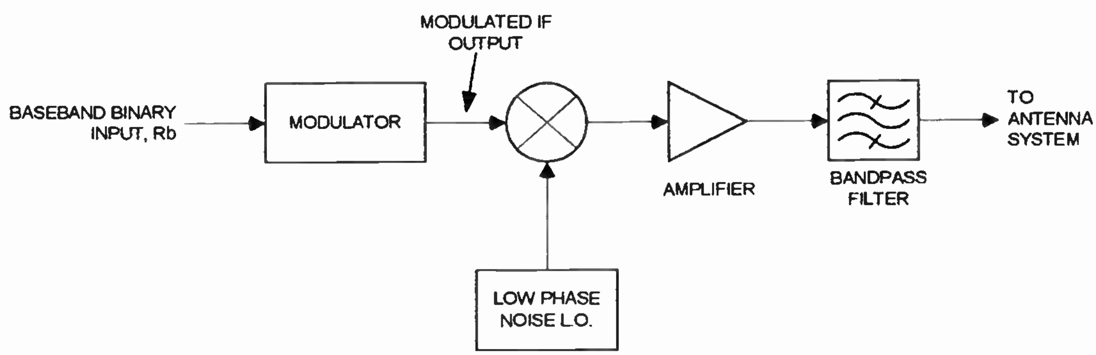

Figure 6.1-19. Simplified block diagram of a digital transmitter.

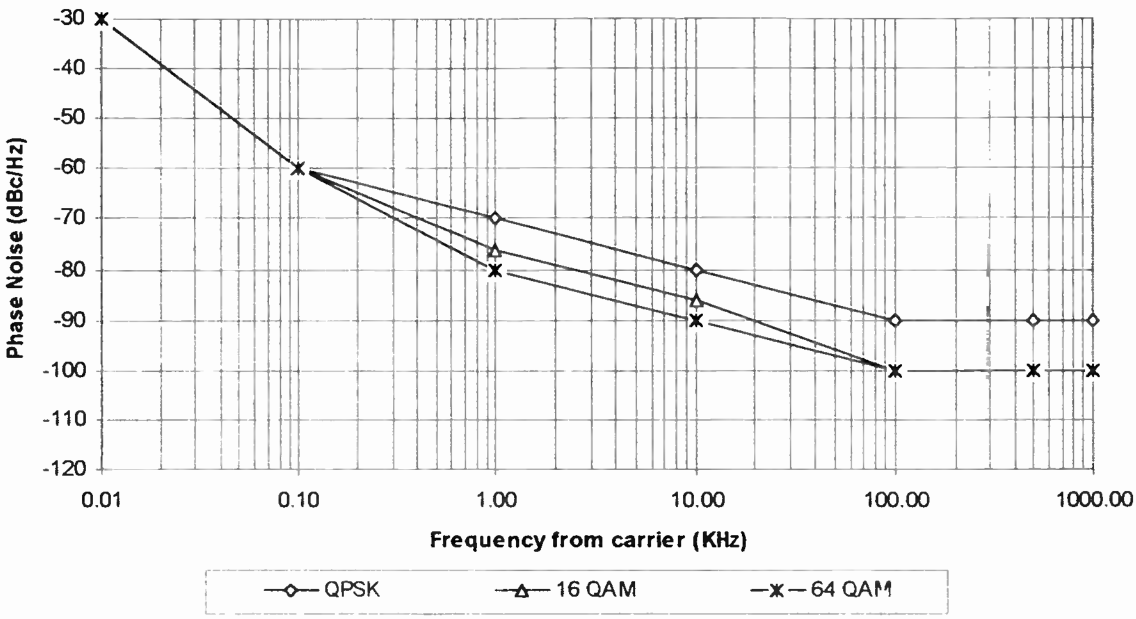

Figure 6.1-20. LO phase noise required for QPSK, 16-AQM and 64-QAM modulation.

$$G_p = P_{out}/P_{in}$$

or

$$P_{out}(\text{dBm}) = G_p(\text{dB}) + P_{in}(\text{dBm}).$$

The output power at the 1 dB gain compression point, called P_{1dB}, is

$$P_{1dB}(\text{dBm}) = G_{1dB}(\text{dB}) + P_{in}(\text{dBm}).$$

Substituting $G_{1dB}(\text{dB}) = G_o(\text{dB}) - 1$, into the above equation gives

$$P_{1dB}(\text{dBm}) - P_{in}(\text{dBm}) = G_o(\text{dB}) - 1.$$

The equation shows that the 1 dB gain compression point is that point at which the output power minus the input power in dBm is equal to the small signal power gain minus 1 dB. A typical plot of P_{out} versus P_{in}, illustrating the 1 dB gain compression point is shown in Figure 6.1-21.

In the digital radio transmitter that employs linear modulation, distortion can be caused by the power amplifier operating near or beyond $G_{1dB}(\text{dB})$. This distortion is caused by intermodulation (IM) products that arise when two or more sinusoidal frequencies are applied to a non-linear amplifier. The output of the amplifier will contain additional frequencies called *intermodulation products.* For example, if two sinusoidal signals

$$v(t) = a \cos 2\pi f_1 t + b \cos 2\pi f_2 t$$

are applied to a nonlinear amplifier whose output voltage can be represented by the power series

$$v_o(t) = \alpha_1 v(t) + \alpha_2 v^2(t) + \alpha_3 v^3(t)$$

the output signal will contain frequency components at dc, f_1, f_2, $2f_1$, $2f_2$, $3f_1$, $3f_2$, $f_1 \pm f_2$, $2f_1 \pm f_2$, and $2f_2 \pm f_1$. The frequencies $2f_1$ and $2f_2$ are the second harmonics, $3f_1$ and $3f_2$ are the third harmonics, $f_1 \pm f_2$ are the second order intermodulation products (since the sum of the f_1, and f_2 coefficients is 2), $2f_1 \pm f_2$, and $2f_2 \pm f_1$ are the third order intermodulation products (since the sum the f_1, and f_2 coefficients is 3, and so on). The input and output power spectra for a typical solid-state amplifier is shown in Figure 6.1-22.

Figure 6.1-22 shows that the third-order intermodulation products at $2f_1 - f_2$ and $2f_2 - f_1$ are very close to the fundamental frequencies f_1, and f_2 and (typically) fall (typically) within the amplifier bandwidth, producing distortion in the output.

The digital radio system that employs linear modulation and operates the power amplifier near or into

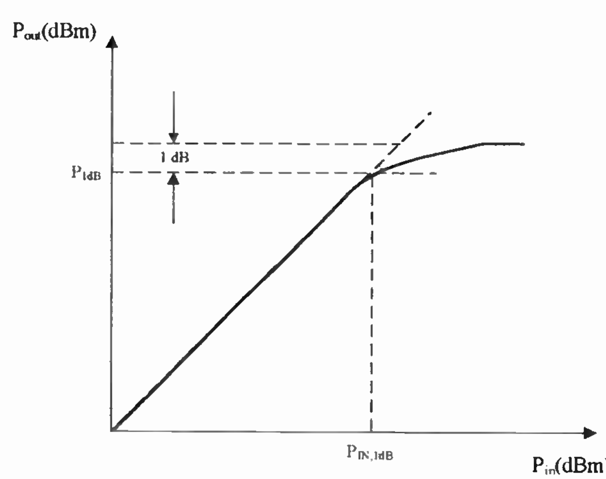

Figure 6.1-21. The 1 dB gain compression point.

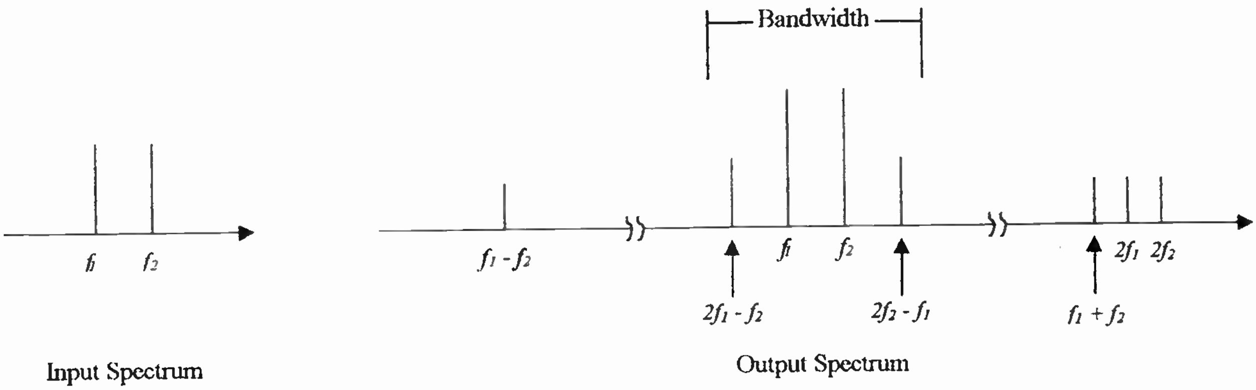

Figure 6.1-22. Input and output power spectrum.

saturation (beyond G_{1dB}(dB)) will see distortions that are caused by the third order IM products. The distortions can be seen as a spreading of the spectrum that can occupy up to three times the bandwidth of the original spectrum. Third order IM distortion will degrade BER performance and can cause interference to adjacent channels.

The severity of third order IM distortion is a function of where the amplifier output level is operating in relation to its P_{1dB} point. In addition, the more complex the modulation scheme, the larger the required P_{1dB} back off to minimize IM distortion. Table 6.1-4 shows the typical power amplifier back offs for FSK, QPSK and QAM modulation.

Figure 6.1-23 shows the spectrum plots of a 16-QAM 70 MHz modulated signal at the modem output and the same signal upconverted to 7,037.8 MHz at the transmitter output. In this case the transmitter power amplifier was backed off by 6 dB from P_{1dB}. It is important to note that even at this operating point, some spreading still occurs.

Finally, the amplified signal is bandpass filtered and directed to the antenna system for free space transmission. At the far end of the free space path the modulated microwave signal is captured by the receive antenna system.

Receiver

The receiver in the digital radio link is the device that receives the modulated signal from the antenna system, filters it, amplifies it, downconverts it to IF, filters and amplifies it again and then delivers it to the demodulator for signal processing back to baseband. A simplified block diagram of a digital radio receiver is shown in Figure 6.1-24.

In the digital link, the receiver performs the lion's share of the work. In Figure 6.1-18, the 4-, 16- and 64-QAM signal constellations were shown. The figure shows that as the value of M (M = 4, 16, 64) increases, the space between the constellation points decreases. For the digital link to operate, the digital receiver must be capable of resolving which signal point was transmitted. For 64-QAM modulation, it has to resolve 64 points. For 512-QAM modulation, it has to resolve 512 points!

All of the transmitter issues, previously discussed concerning LO phase noise and amplifier linearity, hold true for the digital receiver. In addition to these internal concerns, the receiver is also susceptible to

Table 6.1-4

outside disturbances that tend to deteriorate system performance. It is an understatement to say that the receiver must be capable of resolving which signal point was transmitted. The receiver must be capable of resolving which signal point was transmitted in the presence of transmitter distortions, receiver distortions, white Gaussian noise, co-channel and/or adjacent channel interference and multipath distortions.

The transmitter and receiver internal distortions can be reduced by employing low phase noise local oscillators and operating internal amplifiers sufficiently below their P_{1dB} point.

Additive white Gaussian noise is unavoidable. The bandwidth efficient modem requires a higher E_b/N_o for a given symbol rate as the number of bits per second per Hertz is increased.

Co-channel and/or adjacent channel interference in most cases can be avoided by frequency allocation management, channel filtering and meeting spectral masks.

Multipath distortions are caused by the transmission channel itself. To minimize dispersive distortions the broadcast engineer must design the link to avoid ground reflections, implement space and/or frequency diversity and employ adaptive equalization.

System Considerations

The implementation of digital video line-of-sight (LOS) radio links is accelerating in the broadcast industry primarily due to the emergence of MPEG-2 technology. Once the broadcast engineer overcomes the fear of change, they will realize the advantages that a well designed digital link offers. In digital radio systems, thermal and intermodulation noise accumulation can to a large extent be disregarded over the network. Noise becomes a more isolated problem between points of regeneration. This is an overwhelming advantage over analog transmission, where the primary concern of the broadcast engineer is noise accumulation.

The unit of digital radio performance is (BER rather than S/N noise accumulation) which was the measures for analog radio link design. The BER is the ratio of the number of *errored* bits received to the *total* number of bits received over a given time interval. In digital telephony systems, the BER threshold is approximately $10e^{-3}$; this was established around the distribution of voice data. In digital video radio systems, the BER threshold is approximately $10e^{-6}$; this criterion is established around the video encoding and decoding equipment.

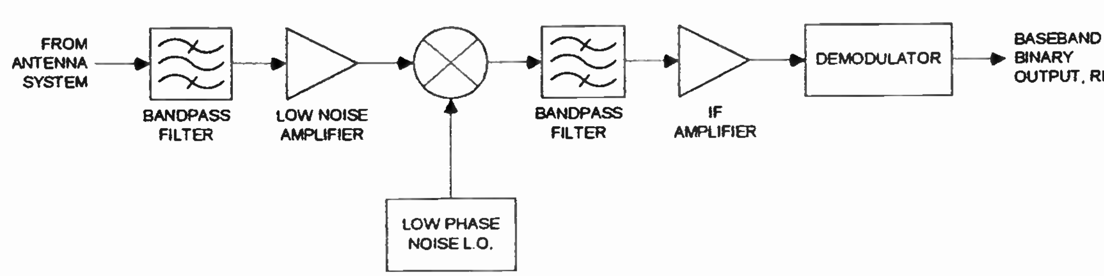

Figure 6.1-24. Simplified block diagram of a digital receiver.

Fade Margin

For a well designed LOS microwave path that is not subjected to diffraction fading or surface reflections, multipath conditions provide the dominant factor for fading below 10 GHz. Above 10 GHz, the effects of rainfall determine maximum path lengths through system availability criteria.

Digital radios react to fading differently than their analog counterparts. Analog systems are more concerned with a thermal fade margin. Digital systems are more concerned with the dispersiveness of a path. How well the radio operates in a dispersive environment is call the *dispersive fade margin*. In a digital video radio system the fade margin consists of four factors that are power added to give the *composite fade margin* (CFM) (sometime referred to as *effective fade margin*).

1. *Thermal fade margin (TFM)* (or flat fade margin) is the algebraic difference between the normal RSL and the $10e^{-6}$ BER outage threshold for flat non-dispersive fades.
2. *Dispersive fade margin (DFM)* also referenced to the $10e^{-6}$ BER, is defined by the radio equipment manufacturer. It is determined by the type of modulation, the effectiveness of the adaptive equalization employed in the receive path (if used) and the multipath signal delay time. For purposes of characterization, the multipath delay time has been standardized to 6.3 ns. The manufacturer characterizes a modem by introducing a 6.3 ns frequency response notch into the IF passband. The center of the notch is stepped across the passband. At each frequency step, the depth of the notch is adjusted to produce a $10e^{-6}$ BER. The result of a typical radio response is shown in Figure 6.1-25. The response shown is referred to as the *equipment signature, M* or *W curves*. The DFM characterizes the digital radio's robustness to dispersive fades; a DFM greater than 50 dB is a good baseline criterion.
3. *External interference fade margin (EIFM)* is the receiver threshold degradation due to external system, independent of thermal noise.

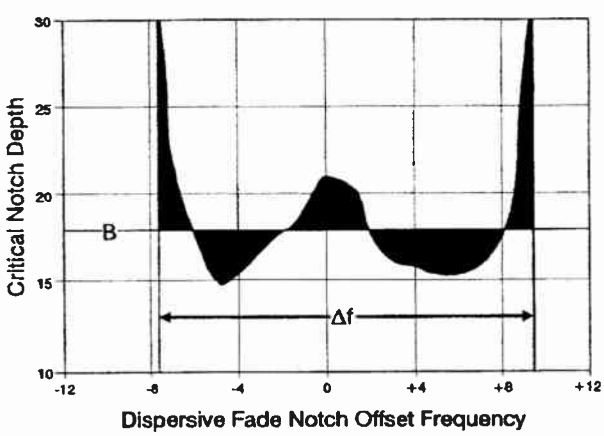

Figure 6.1-25. Dispersive fade margin measurement.

4. *Adjacent channel interference fade margin (AIFM)* is the receiver threshold degradation due to interference from adjacent channel transmitters in one's own system. This is normally a negligible parameter except in the cases of frequency diversity and multiline hot standby systems.

The four fade margins are power added to derive the CFM as follows:

$$\text{CFM} = 10\log(10^{-\text{TFM}/10} + 10^{-\text{DFM}/10}\,10^{-\text{EIFM}/10} + 10^{-\text{AIFM}/10})$$

The outage time due to multipath fading is calculated by:

$$T = (rT_o \times 10^{-(\text{CFM}/10)})/I_o$$

where

T = outage time in seconds
r = fade occurrence
T_o = $(t/50)(8 \times 10^6)$ = length of fade season in seconds
t = average annual temperature in degrees Fahrenheit
CFM = composite fade margin
I_o = space diversity improvement factor; factor = 1 for no diversity; ≥ 1 for space diversity.

The fade occurrence factor, r, is calculated from the basic outage equation for atmospheric multipath fading:

$$r = c(f/4)(D/1.6)^3 \times 10^{-5} \quad \text{(English)}$$

$$r = c(f/4)D^3 \times 10^{-5} \quad \text{(metric)}$$

where

c = climate or C factor (see Figure 27)
f = frequency (GHz)
D = path length (miles or km)

The space diversity improvement factor I_o may be calculated by:

$$I_o = 7 \times 10^{-5} s^2(f/D) \times 10^{\text{CFM}/10}, s \leq 50\text{ ft (English)}$$

$$I_o = 1.2 \times 10^{-3} s^2(f/D) \times 10^{\text{CFM}/10}, s \leq 15\text{ m (metric)}$$

where, s, is the vertical antenna separation in meter (feet), center to center.

The antenna spacing rule of thumb in a diversity system is a minimum of 200 wavelengths. For example, one wavelength at 6 GHz is 5 cm. The required separation, then would be 5 × 200 or 10 m (approximately 33 ft).

The climate or "C" factor shown in Figure 6.1-26, is a constant that is used in the fade occurrence equation that emulates climate and terrain effects on propagation. Mountain and dry climates are areas of good propagation conditions and have a C factor of 0.25. Paths over or near water and gulf coastal areas are of difficult propagation conditions and have a C factor of 6.

The following system parameters of an actual digital video microwave link show the different climate and terrain regions of the United States affect digital radio performance:

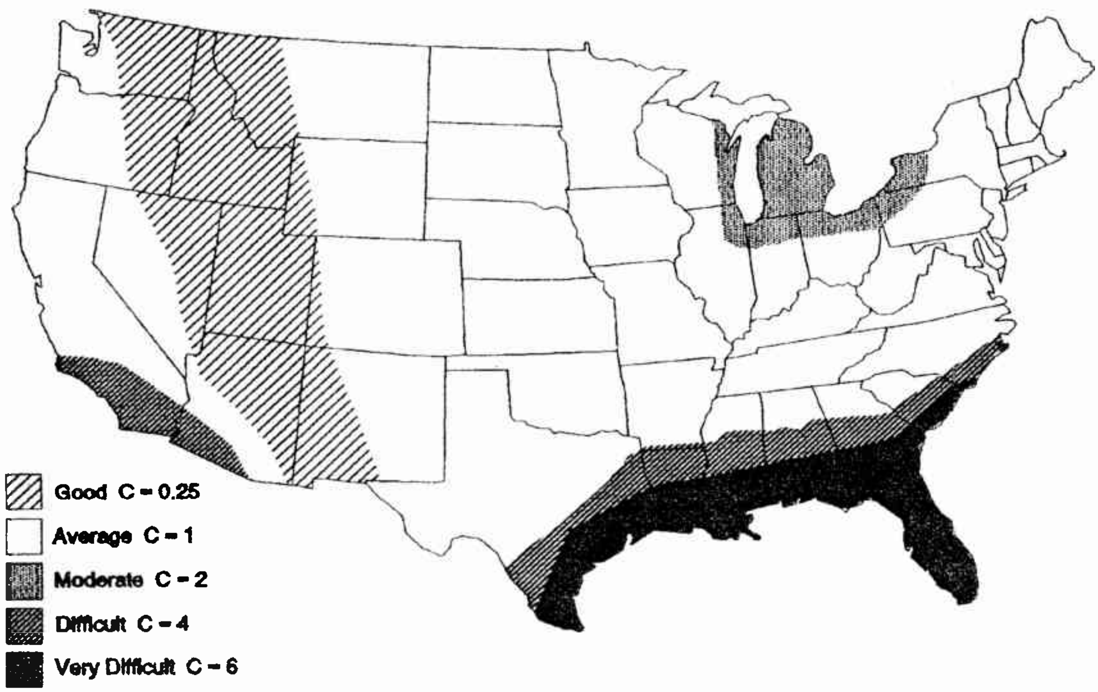

Figure 6.1-26. Values of climate factor for the continental United States.

Transmit frequency: 7,012.5 MHz
Modulation type: 16-QAM
Data rate: 44.736 Mbps
Transmit power: +27 dBm
Receiver threshold: −80 dBm at a BER of $10e^{-6}$

Dispersive fade margin: 50 dB
External interference fade margin: negligible
AIFM: negligible
Annual average temperature: varies according to Figure 6.1-27

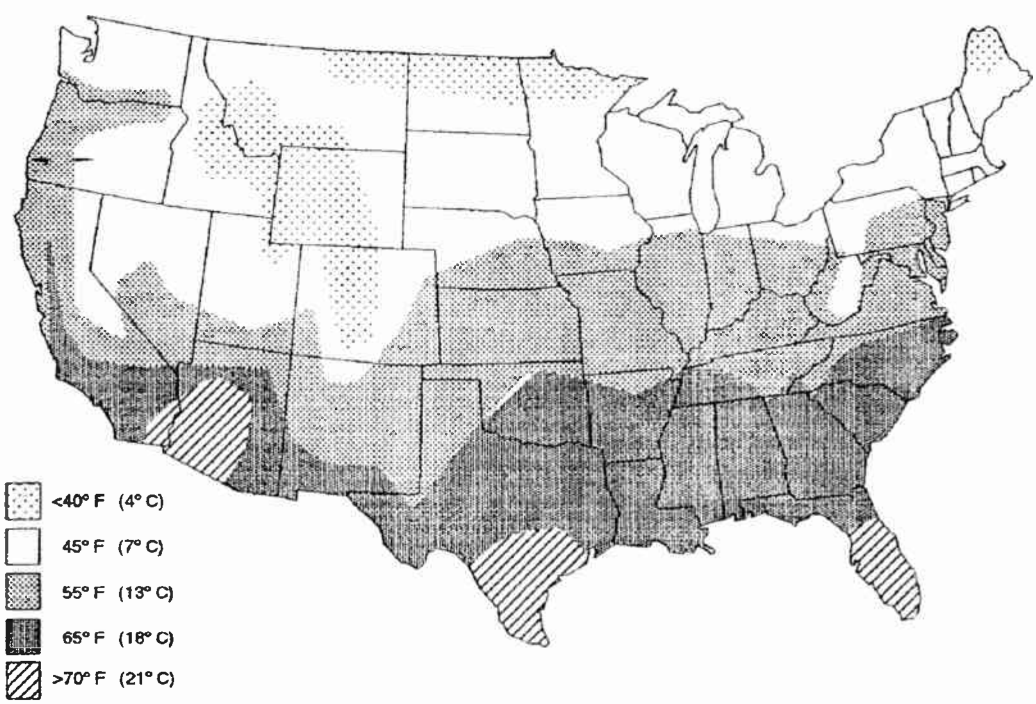

Figure 6.1-27. Average annual temperature for the United States.

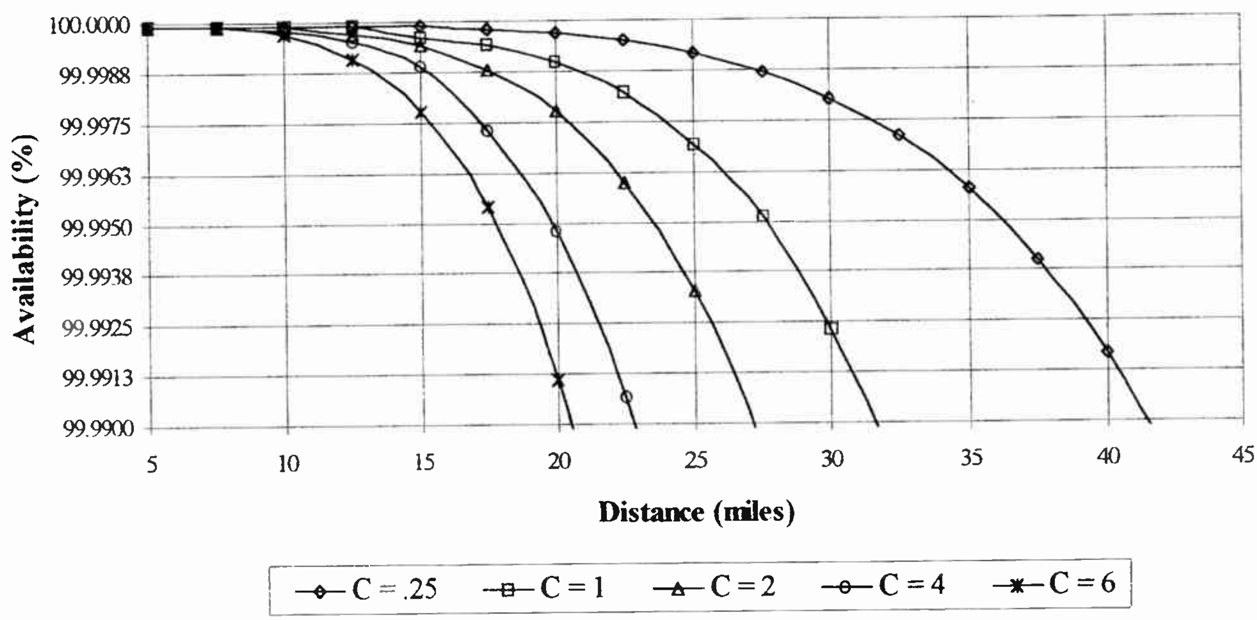

Figure 6.1-28. Link availability as a function of C factor and distance (no diversity).

Path length: varies from 5 to 50 miles
Antenna Diameter: 8 feet with a gain of 41.5 dB
Waveguide lengths: two 300-foot lengths at a loss of 1.4 dB per 100 ft.

With this system information the availability for this link as a function of path length and C factor can be calculated. For this example, assume no effects due to earth bulge or surface reflections. The result of this example is shown in Figure 6.1-28.

To improve the link availability over long paths and difficult propagation areas space diversity can be employed. Space diversity improvement plays such a significant role in increasing path reliability, that it often allows higher interference levels that degrade (reduce) the composite fade margin of many digital links.

Figure 6.1-29 shows the previous example with space diversity. The antenna spacing for this case was approximately 200 wavelengths (approximately 30 ft).

The space diversity improvement factor (I_o) may underestimate diversity improvements for small an-

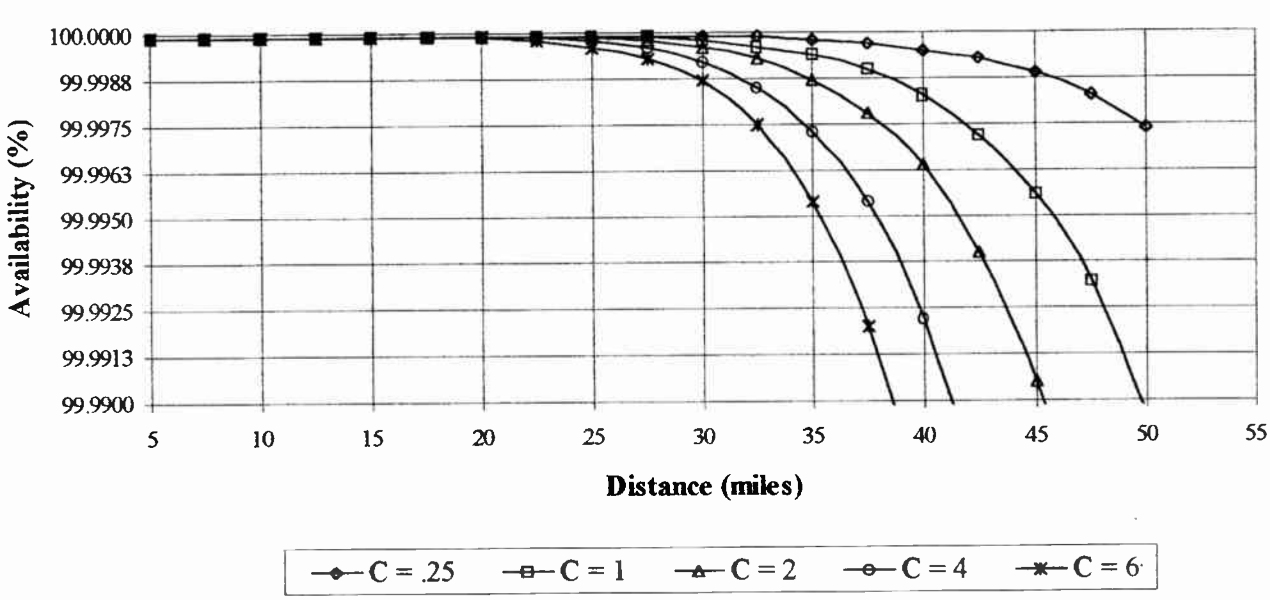

Figure 6.1-29. Link availability as a function of C factor and distance (with space diversity).

tenna spacings and overestimate diversity improvement for large antenna spacings on flat land microwave links.

Angle diversity is an alternative approach to space diversity when atmospheric dispersive fading is the issue. Angle diversity employs a monopulse sum and difference beam to achieve angular displacement. The monopulse beams are created by a hybrid antenna feed. The hybrid outputs are connected in a manner similar to a space diversity configuration. The sum beam is fed into a receiver and the difference beam is fed into a receiver. A typical angle diversity antenna system is shown in Figure 6.1-30.

If one beam exhibits multipath fading, the second beam, due to a vertical angular difference in pattern, will have a different signal relationship from the multipath ray and will have a stronger signal and less fading than the first. By switching between beams, the maximum fade on the path may be significantly reduced. This is true for dispersive multipath fading in digital radio systems that have sufficient thermal fade margin of at least 40 dB.

Digital Video LOS Microwave Repeaters

Digital LOS microwave repeaters completely demodulate the incoming signal to baseband (to the raw electrical signal of "1s" and "0"). This full demodulation permits regeneration of the "1s" and "0s." The outgoing signal is squared up and retimed. Regenerative repeaters are an essential key to digital transmission in that the noise stops at the repeater.

The regenerated baseband signal is remodulated, upconverted and transmitted on a different frequency. RF and IF repeaters are not recommended for digital microwave systems because such repeaters do not have the vital regeneration stage.

PRIMARY POWER & BACKUP

With improvements in equipment and systems, engineering the reliability of the primary power source becomes a major factor in overall system availability. Where the terminals are in studios or TV transmitter sites the ac supplies may well be protected with standby generators; in this case, ac sourcing is the obvious choice. At repeaters, the ac may be supplied to a remote site by overhead lines and these may be subject to interruption under adverse weather conditions. Since solid-state microwave equipment has essentially low power requirements, batteries are the most popular form of standby power. Where long outages are to be expected (12 hours or more) an ac generator will be needed to recharge the batteries: this can be fuelled by gasoline, diesel or liquified natural gas (propane). In addition, the use of solar power should be considered.

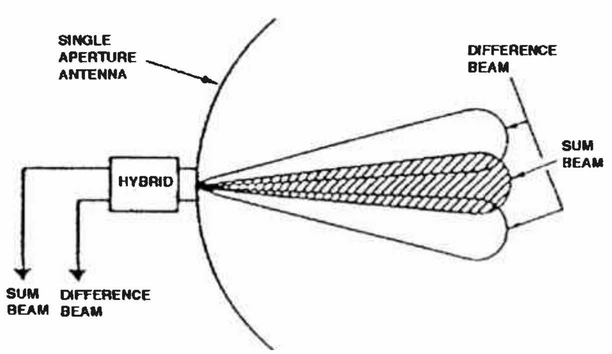

Figure 6.1-30. A typical angle diversity antenna system.

Industrial lead-acid batteries are the most common type. They can be sealed to prevent evaporation of liquid, reducing maintenance and the need to ventilate the explosive gas given off when a battery is charged at too high a rate. The cells are floated across the charger, which supplies the station load until the ac fails. Since different types of lead-acid cell have different float voltages (2.15, 2.2 and 2.23 VDC for lead-antimony, lead-calcium and lead-selenium respectively) it is important that the charger and battery are matched—for this reason it is recommended that both are ordered from the same supplier.

It must be remembered that a battery of 12 cells with a nominal voltage of 24 VDC will float at 26.8 VDC, dropping to 24 when the charging fails, and finally falling to 21 VDC at the end of the standby time. At a minimum, the electronic equipment must accept this range. To determine the capacity of each cell required to give a particular standby time (H hours) the steady current drain must be determined (A amperes). Depending on the type of regulation used in the electronic equipment this may be higher at 26.8 VDC or 21 VDC (usually the latter)—take the higher value.

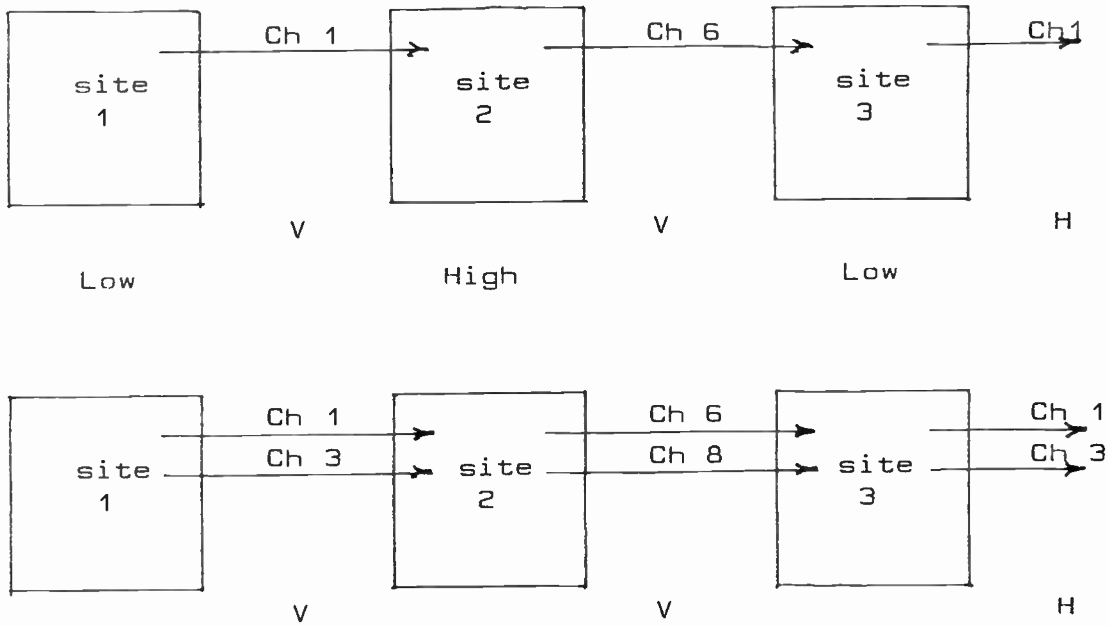
To arrive at the required cell capacity, multiply A by H to get the capacity in ampere-hours (AH). The minimum size of charger (C amperes) to meet the station load and at the same time recharge a discharged battery in R hours is given by:

$$C = (A + AH) \times 1.1/R$$

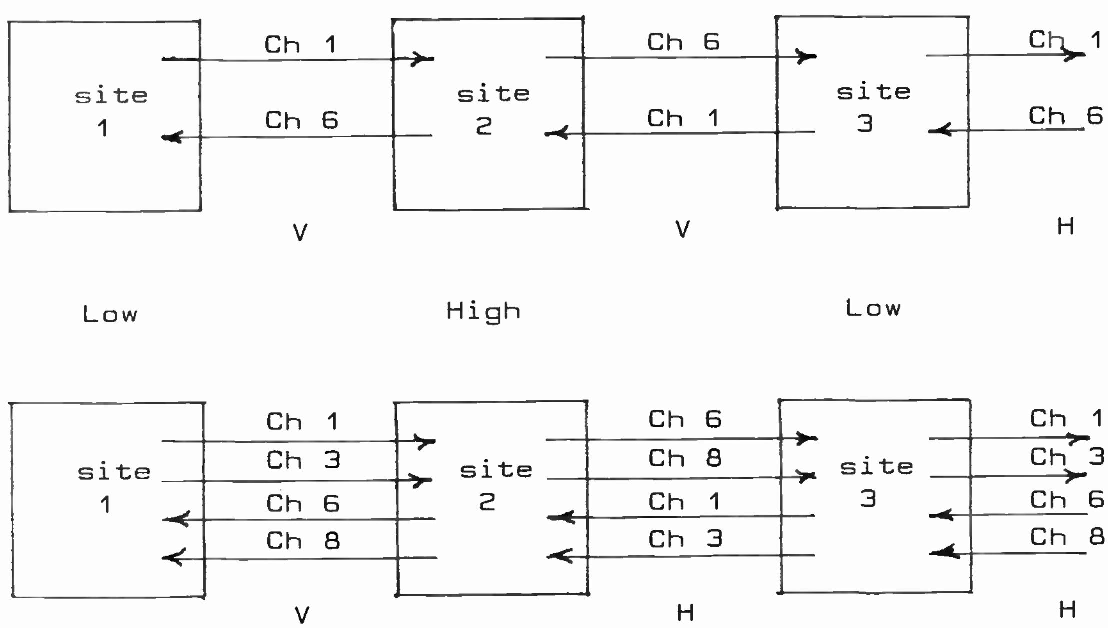
Since charger failure would lead to station failure after H hours it is common practice to use a duplicated charger for full protection at key sites; in that case each charger need only have the capacity A amperes rather than C as calculated above. The chargers must be designed to share the load.

The battery acts as a large capacitor, reducing the ripple voltage generated by the charger and protecting against powerline surges. A good charger will have low voltage protection to isolate the battery when discharged and over voltage protection and charge rate limiting to protect against surges and gassing by the cells. When diesel generators are used as the primary source of power, they should be run at 75% or more of their rating (after allowing for any derating for altitude).

Solar power using photovoltaic cells is attractive as there are no moving parts requiring maintenance. However, the batteries used to maintain the supply during hours of darkness or heavy overcast (which



A: One-channel and two-channel simplex systems



B: One-channel and two-channel duplex systems

Figure 6.1-31. Recommended initial and expanded frequency plans; channels 2, 4, 7, 9 can be added on the opposite polarisation, and channels 5, 10 can be used for spur routes.

could exist for several days in some parts of the country) can be the most expensive part of the installation. It may pay to have a small ac generator and charger to back up the batteries if the solar input fails for more than three days, rather than batteries to maintain the supply for six days, for example. Such a generator could also power lights and test equipment during routine site visits.

FREQUENCY PLANNING

Frequency coordination for the broadcast microwave industry has been primarily a local case-by-case process through cooperation by the respective chief engineers. Most areas, through the local chapter of the Society of Broadcast engineers (SBE), maintain an up-to-date log of existing licenses and proposed applications.

Ideally, frequency planning for future growth should follow certain simple ideas. Foremost among these is the concept of dividing each available band into *high* and *low* parts and trying to keep the transmitters at a given site in one or other part of the band. This ensures the maximum utilization of frequencies at every site. Adjacent channels should be cross polarized; second channels on a given route should be co-polarized on the next-but-one channel; if a *go* channel is on an odd channel then the corresponding *return* channel should be on an even channel to avoid intermodulation products (2A-B). The diagrams of Figure 6.1-31 illustrate this practice.

Frequency Re-use

Microwave antenna discrimination provides a degree of isolation that very often allows the reuse of the same channel at the same or a nearby site. On parallel routes where the terminals at each end are several hundred yards apart, it is often possible to use the same channel on both routes but in different directions. Every case has to be studied carefully to take account of the free space losses and the angular discrimination of the antennas.

TIA Telecommunications Systems Bulletin TSB 10-F *Interference Criteria for Microwave Systems* specifies a 60 dB co-channel carrier/interferer ratio for analog FM video systems. This is an ideal, but in many cases may not prove possible. Lowering the C/I ratio will raise the effective noise level and hence reduce the fade margin. Given a threshold of -85 dBm the noise level will be approximately -95 dBm and an interferer at -95 dBm will double the noise level and raise the threshold to -82 dBm. This, or an even higher level, may be acceptable in a difficult situation. The interferer must at all times be below the threshold of the receiver or capture will occur if the wanted signal fails.

FCC LICENSING

All broadcast microwave systems, whether for fixed or mobile applications, must be licensed by the FCC. The application is filed under Part 74 of the FCC Rules on Form 415 with pertinent characteristics and the Type Acceptance Identification Number provided by the manufacturer of the chosen equipment.

Frequency coordination for clearance of the requested frequencies is the responsibility of the local area engineers. In contrast, licensing by common carriers, industrial service and common antenna radio systems (CARS) band operators is supported by formal frequency coordination studies. Broadcast engineers should be aware and careful when applying for channels in the 12.7–13.25 GHz band. This band is shared with CARS and cable TV operators and is in wide use in most areas.

The details in Form 415 are straightforward and the instructions that are supplied by the FCC are very thorough. There is a main form and four schedules. The main form is required with all applications, as is Schedule A (Transmit Site Data). Note that the output power given in the Type Acceptance is a maximum; when quoting antenna input power and effective radiated power (ERP) the true transmitter power less any feeder losses (for input power) and plus the antenna gain (dBi) for ERP, should be quoted. Copies of Schedule B (Frequency Data) and Schedule C (Path Data) are required for each path in a multihop system. Schedule D (Passive Repeater Stations) is only needed when these are involved. The emission designator is normally provided by the equipment supplier.

Frequency agile portable transmitters are typically licensed for all the channels that they can provide. For example, at 2 GHz all seven channels are submitted on a single license application.

Broadcasters and others using this *Handbook* should refer to the FCC *Code of Federal Regulations* and to their attorneys for complete up-to-date information.

TELEVISION TRANSMITTERS

GERALD W. COLLINS, ROBERT J. PLONKA
HARRIS CORPORATION, QUINCY, IL

INTRODUCTION

Significant advances continue in TV transmitter technology. New technology and ideas have been introduced to continue to provide high quality TV signal transmission while improving reliability, reducing maintenance and lowering overall cost of ownership. These new technologies include solid-state high power amplifiers, improvements in UHF tube transmitters and digital transmission. Further, the FCC continues its policy of technical deregulation which allows more flexibility in transmitter design and system operation. This chapter discusses the relevant technology and provides the information needed for selection, installation, operation and maintenance of TV transmitters in today's environment.

TV transmitters may be considered to comprise two essential components, the *exciter* and the *RF power amplifier* (PA). The exciter provides the signal processing functions required to convert a baseband TV signal into a modulated RF signal on the assigned channel. These functions include baseband signal processing, modulation, precorrection and equalization, upconversion, bandlimiting and amplification to a relatively low power RF signal. While different methods are used for different signals, all functions must be performed whether the baseband signal is video, audio or digital data for digital television (DTV). Because the output of the exciter is a modulated RF signal, most commercially available exciters may be considered low power transmitters.

The PA provides the muscle to amplify the modulated RF signal to the desired level for transmission. Thus the PA technology to perform this function is key. Both solid-state and tube devices are available in commercial equipment. For VHF channels, solid-state devices predominate. For UHF, both solid-state and tube devices are used. Other key functions in the PA, common to all amplifier technologies include ac distribution, ac to dc power conversion, cooling and control.

TV transmitters are unique in that no other application requires such high levels of linear RF power generation while operating virtually uninterrupted. This has led to the development of specialized techniques to assure highly efficient and reliable operation. The need for high effiency has led to the near universal use of partially saturated Class AB final power amplifiers. This, in turn, has resulted in the development of precorrection and equalization techniques required to compensate for nonlinearities inherent in this class of operation. To achieve the levels of reliablility required, redundant system architectures that minimize single point failures are used.

EXCITERS FOR ANALOG TV

Exciter performance is the key to excellence in TV transmission. The exciter performs baseband video and audio processing, modulation, precorrection, equalization and upconversion functions. Some of these functions are common with exciters for digital transmission.

Visual Modulator

The *visual modulator* receives a video baseband signal, processes and converts it to a fully modulated vestigial sideband signal. Since intermediate frequency (IF) modulation is used, most of the signal processing occurs in the video stages and IF stages. The basic block diagram of an IF modulated transmitter is shown in Figure 6.2-1. For this discussion, the modulator is considered to include all blocks through the IF processor.

Video Processing

For transparent transmission of the incoming signal, it is important to optimize the incoming signal. It is often difficult to define where the station processing ends and the transmitter video processing begins. Typically some video processing is done external to the transmitter by a processing amplifier.

The main functions of the exciter video processing circuitry are:

- Obtain proper sync to video ratio
- Remove common mode signals
- Provide overall video level control
- DC restoration
- Prevent overmodulation
- Frequency response correction

Direct current restoration (clamping) is important because picture brightness information is contained in the dc component of the video signal. If ac coupling is used in the video circuitry, the dc level will tend to vary as the capacitors in the coupling circuits charge and discharge. Alternating currents coupling is convenient since differences in ac and dc ground can be allowed without introducing distortion. By clamping a particular level (such as sync tip or *back-porch*)

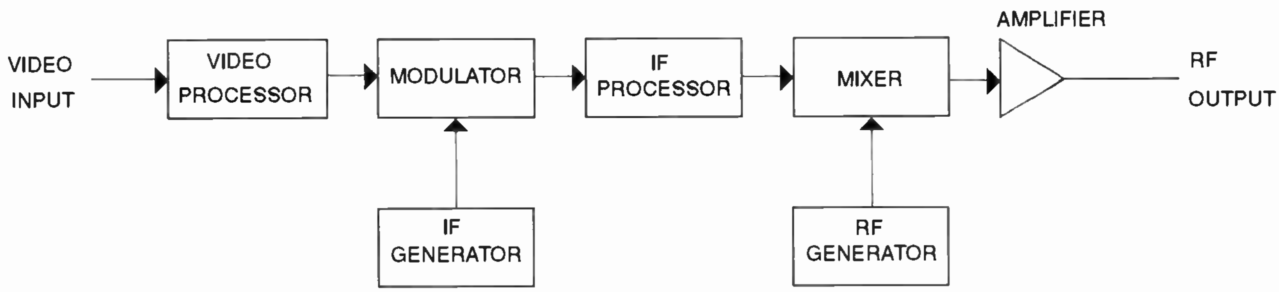

Figure 6.2-1. IF modulated transmitter.

during each line to a fixed voltage, the correct dc level is applied to the modulator.

Common mode signals such as noise or ac hum can be removed by using a differential input for the video input stage. It is desirable to use an RF choke at the video input to prevent rectification of ambient RF and remodulation of the main signal.

White peak limiting is used to prevent modulation from reaching 0% or to keep the carrier from being pinched off as shown in Figure 6.2-2. When an intercarrier TV receiver encounters a carrier that has been pinched off, it temporarily has no signal to receive and the automatic gain control (AGC) adjusts to maximum gain. Since there is nothing but noise, the noise is greatly amplified, transferred to the aural intercarrier and becomes audible as a buzz.

High-frequency peaking circuits are often used to compensate for long video signal transmission line runs in a transmitter plant.

In UHF exciters, the horizontal and vertical sync portions of the TV signal may be detected and sent to klystron pulsers.

Precorrection can be accomplished by changing the gain of a video amplifier over a portion of the total video signal. The threshold of the gain change is set at a certain level of the video signal. Differential phase can be corrected by splitting the video signal into two paths which are in quadrature at the color subcarrier. Phase changes can be obtained by changing the gain of only one path over a portion of the video waveform.

Modulator

In nearly all IF modulated transmitters, the modulator is a broadband, balanced diode mixer. It is configured for maximum rejection of the local oscillator signal and biased so as to provide excellent linearity, low noise and capability to achieve carrier cutoff. A schematic of a typical balanced mixer is shown in Figure 6.2-3. The video signal is dc offset to provide the proper modulation level and is used to control the attenuation of the diodes. Peak of sync corresponds to maximum IF envelope output and white corresponds to minimum IF output. The output signal of the modulator is a double sideband AM signal having the proper depth of modulation (12.5%).

Visual Group Delay Compensation

Group delay distortion appears as color smear and halo effects on edges. On a waveform monitor the effects may be seen using the 2T and modulated 12.5T contained in the composite test signal (see Figure 6.2-4). Pulse responses with unacceptable group delay may include exaggerated pre- or post-ringing on 2T and modulated 12.5T base line disturbance. Low-frequency group delay and amplitude errors are referred

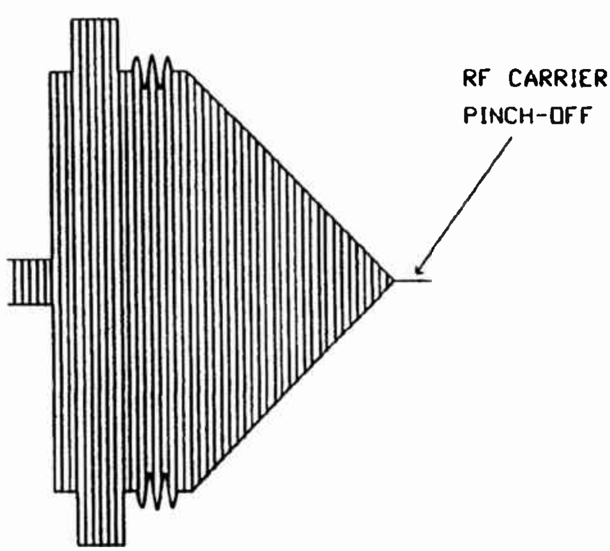

Figure 6.2-2. RF carrier pinch-off.

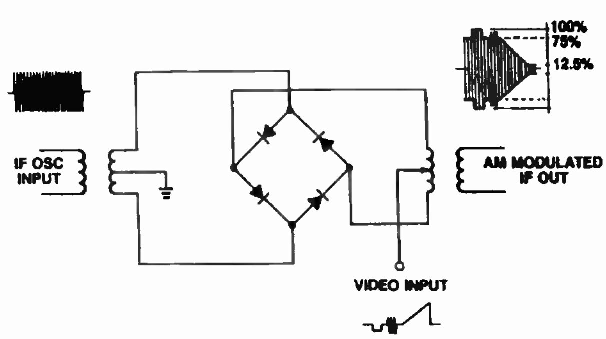

Figure 6.2-3. Balanced mixer.

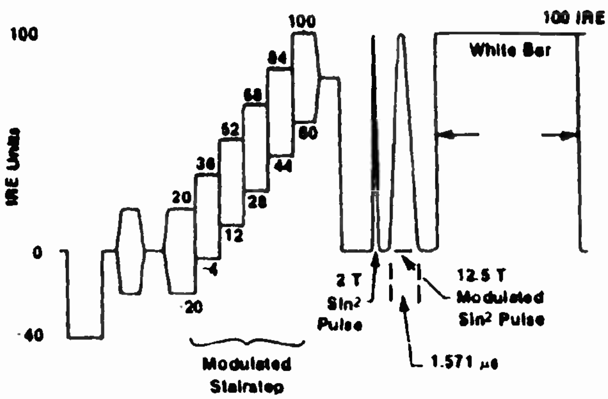

Figure 6.2-4. Composite test signal.

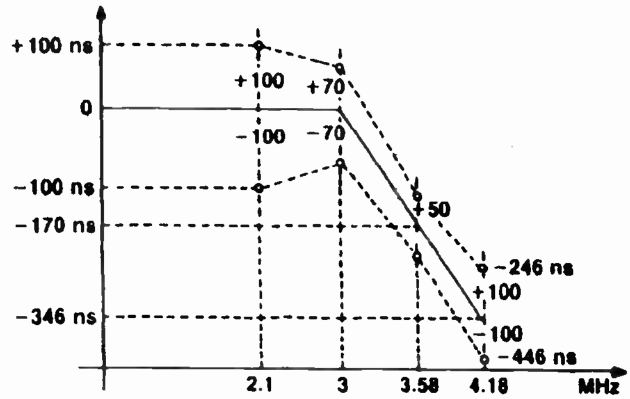

Figure 6.2-6. Predistorted group delay curve.

to as *short-time waveform distortions*. Figure 6.2-5 shows typical distortions of a 2T pulse.

Intermediate Frequency and Video Delay Compensators

The techniques used to accomplish group delay equalization at baseband or IF are similar in concept. Both active and passive equalizers may be employed. Intermediate frequency group delay correction is necessary to correct group delay errors below visual carrier while not affecting the signal above visual carrier. Above visual carrier, both IF and video correctors are effective. If the group delay error affects only the high-frequency side of the passband, equalization can be accomplished at video. This is the case for most visual-aural notch diplexers.

The FCC requires the TV transmitter to predistort group delay according to the curve shown in Figure 6.2-6. The purpose is to compensate for the delay caused by discrete LC aural notch filters in TV receivers. The notch filter in TV receivers is necessary to prevent the aural carrier from mixing with the detected video and chroma subcarrier signals and producing visible spurious beats.

Passive Group Delay Equalizer

A common form of a passive group delay equalizer is shown in Figure 6.2-7. It provides a flat frequency response and a nonlinear group delay which peaks at resonance. This circuit is referred to as a *passive all-pass network*. It can be understood by examination at frequencies well below and above resonance. At low

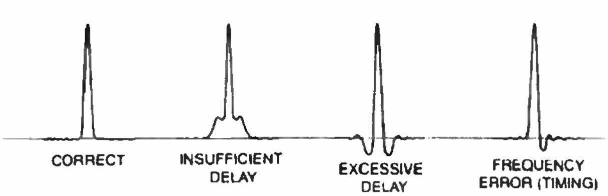

Figure 6.2-5. Typical distortion of a 2T pulse.

frequencies the network can be approximated by a low series inductive reactance due to L1 in which the output voltage leads in phase. At high frequencies well above resonance, the circuit can be approximated by a series capacitive reactance due to C1 in which the output voltage lags in phase. The output is constant across the band. The phase of the network is plotted in Figure 6.2-8. A plot of the group delay is shown in Figure 6.2-9.

Active Group Delay Equalizer

As in the passive type, this network has a constant amplitude versus frequency response and a nonlinear phase response. The action of an active *all-pass network* can be best seen using the simplified schematic of Figure 6.2-10. The phase of voltage (e_1) plotted as a function of frequency traces out a circle with maximum amplitude and zero phase at resonance. Voltage (e_2) has a constant amplitude and phase.

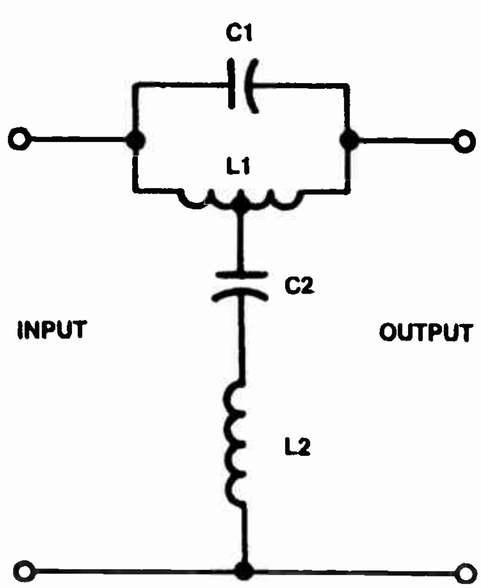

Figure 6.2-7. Passive all-pass network.

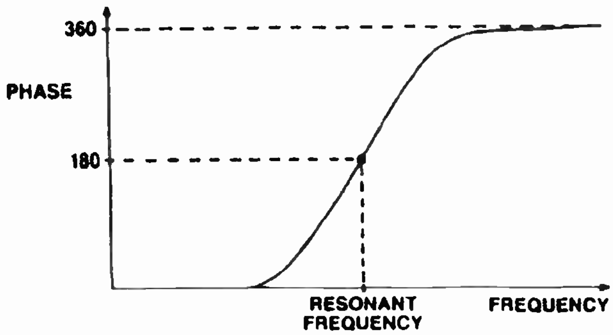

Figure 6.2-8. All-pass network phase response.

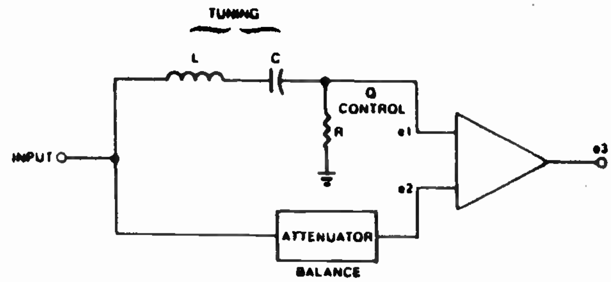

Figure 6.2-10. Active all-pass network.

When voltage e_1 is equal to twice (e_2), the output voltage of the summing amplifier, (e_3), has the characteristics of an ideal all-pass network. The output amplitude is constant and the resonator tuning determines the frequency of maximum group delay. The resonator "Q" determines the magnitude of delay. For the case where voltage e_1 is larger than twice e_2, the output has an amplitude peak at resonance. If e_1 is smaller, the output has a dip at resonance.

Vestigial Sideband Filter

The FCC requires that the radiated signal have a major portion of the lower sideband (vestigial sideband) suppressed. In addition, the upper sideband signal must be contained within 4.75 MHz of the visual carrier. With IF modulation the filtering is in the low-power stages. Transmitter manufacturers use solid-state filters using *surface acoustic wave* (SAW) technology to accomplish the filtering requirements.

The electrodes in a saw filter act like tapped delay lines and are designed to scale the amplitude and delay the signal (see Figure 6.2-11). The length, spacing and number of the electrodes determine the wave shaping properties of the filter. The output is selectively attenuated depending on the time delay and signal frequency relationship. This type of filter is called *transversal* because the attenuation is controlled by delay lines rather than resonators. The wavelength of an IF acoustic signal is approximately 0.003 in. The short wavelength allows the filter to be very compact. Because the transducers are on the surface, photographic masks can be used to accurately control their physical dimensions. The photographic mask lends itself to modern manufacturing techniques and insures a reproducible filter with a permanent amplitude versus frequency response and group delay.

A characteristic of a transversal filter is that group delay can be set independently of the amplitude. The independent nature of group delay and amplitude allows a manufacturer to provide almost any type of group delay curve across the passband, such as a constant delay or the TV receiver group delay equalization curve.

Although the FCC does not require attenuation of visual signals in the aural passband, video signal components can cause interference called visual-to-aural crosstalk. Reduction of visual-to-aural crosstalk is essential to the proper transmission of stereo sound and other subcarrier broadcast services. High resolution cameras and character generators can produce spectral components at 4.5 MHz and beyond. Without sufficient attenuation these signals can cause distortion, especially in aural subcarriers which are more sensitive to visual crosstalk than the main aural signal. SAW filters

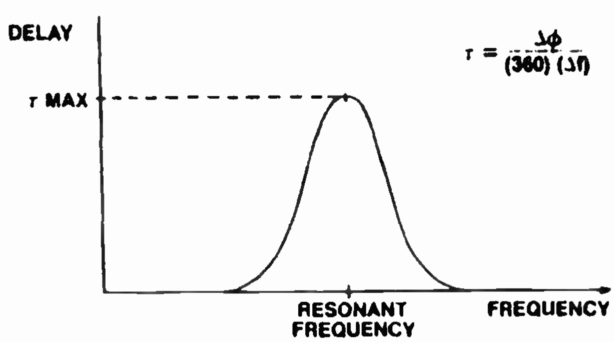

Figure 6.2-9. All-pass network group delay.

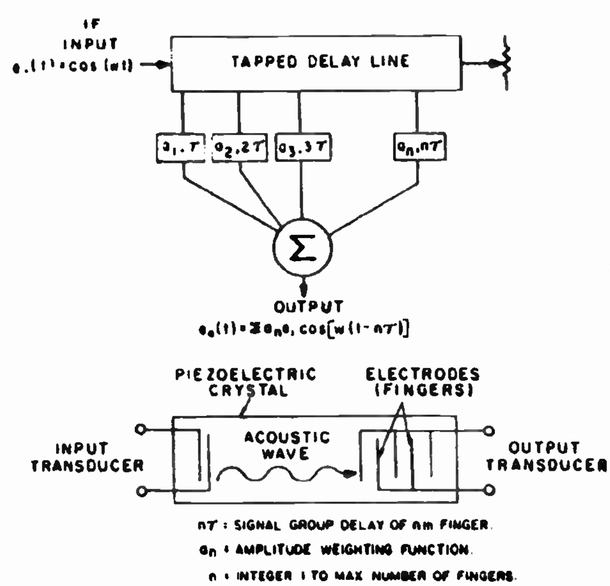

Figure 6.2-11. Saw filter.

thus are able to perform many functions simultaneously (bandwidth shaping, group delay equalization and visual to aural crosstalk reduction).

Distortion products can be created by SAW filters due to signal reflections (triple transit) and direct feedthrough. These distortions cause time echoes displaced either before or after the desired responses. In the frequency domain these echoes show up as ripples in the passband (see Figure 6.2-12). A given echo will contribute uniquely to the amplitude, phase and group delay characteristics by the addition of a ripple component in the passband. The amplitude of the ripple is proportional to the echo level and its period is proportional to the reciprocal of the SAW time delay.

SAW group delay varies sinusoidally with the same period as the passband ripple. Magnitude, however, is a function of echo level and is inversely proportional to time delay. It is, therefore, not a sure test of signal distortion. The group delay ripple for long delayed echoes will give peak-to-peak values which have no correlation with conventional signal distortion estimates. For that reason, fast peak-to-peak group delay errors that occur at greater frequency than the reciprocal of the filter time delay can usually be ignored.

Intermediate Frequency Linearity Precorrection

An alternative to video correction is to provide the correction at IF. There are advantages to correcting

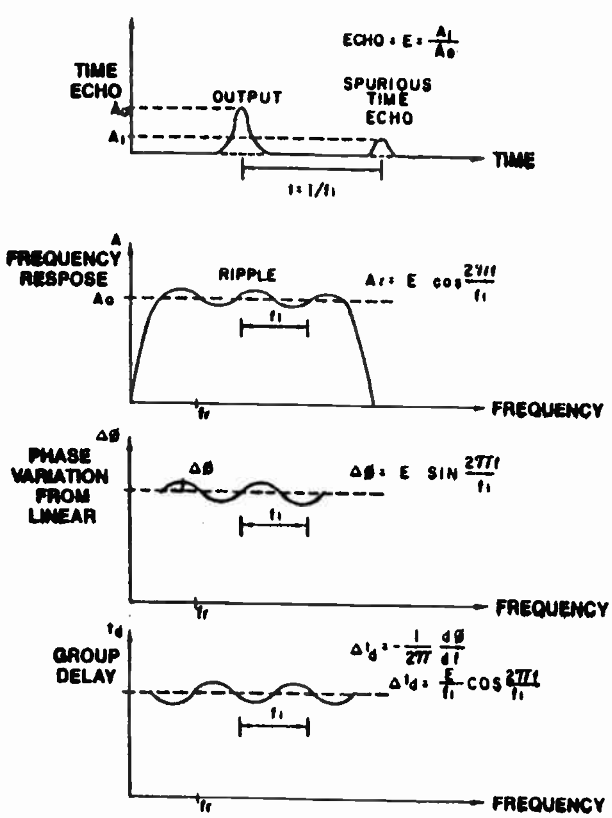

Figure 6.2-12. Response, phase, and delay ripples caused by time echoes.

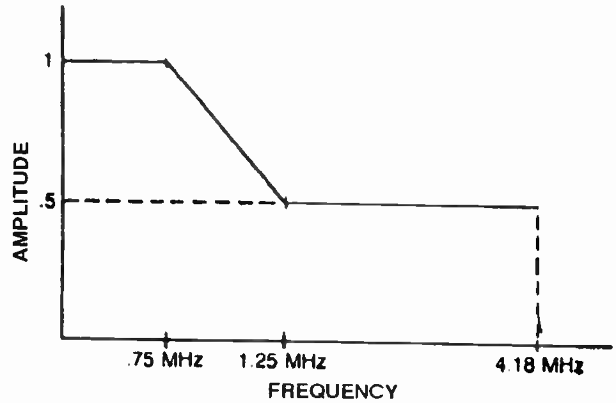

Figure 6.2-13. Frequency response of ideal diode detector.

at IF. Since most distortions are caused in the high power RF amplifiers after vestigial sideband filtering, a corrector placed after the vestigial sideband filter can more accurately predistort the modulated signal. Any precorrection spectra generated at IF after the VSB filter will produce energy components which can cancel intermodulation products generated in the final amplifier stage. This is particularly important in the cases of pulsed klystron transmitters or common amplification.

Correction of distortion at IF is particularly helpful for chroma distortions. Chroma spectra at 3.58 MHz has only single sideband information and thus less energy than equivalent luminance signals. An ideal diode detector frequency response of the NTSC modulation signal is plotted in Figure 6.2-13. It is seen that beginning at 0.75 MHz the video begins to fall to 6 dB. For video signals lower than 0.75 MHz, the RF spectrum is double sideband and has twice the peak RF voltage.

Intermodulation products are caused in high-power amplifiers by a nonlinear transfer function. As the power output increases towards saturation, amplitude compression and phase lag occurs. The nonlinear transfer function gives rise to mixing products which occur at sum and difference frequencies around the visual carrier. This process creates the frequency spectra of the lower sideband, commonly referred to as *lower sideband reinsertion*.

Intermediate frequency correctors for amplitude distortion are usually similar in concept to video differential gain correctors. Linearity correctors generally use diodes which are set to conduct at a specific level of the IF modulated signal. When the diodes conduct, the gain or attenuation is reduced as needed.

An example of a basic gain expansion circuit is shown in Figure 6.2-14. The signal is normally attenuated a fixed amount by using a resistive L-pad. The diodes are normally reverse biased by equal dc voltages. Reducing the dc voltage permits the diodes to conduct on the signal peaks. This inserts additional resistance in parallel with the series arm of the L-pad attenuator thereby decreasing the attenuation. Varying

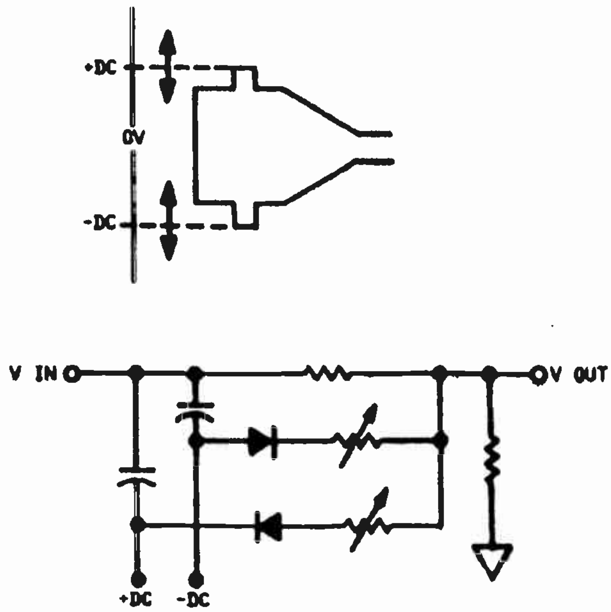

Figure 6.2-14. Basic gain expansion circuit.

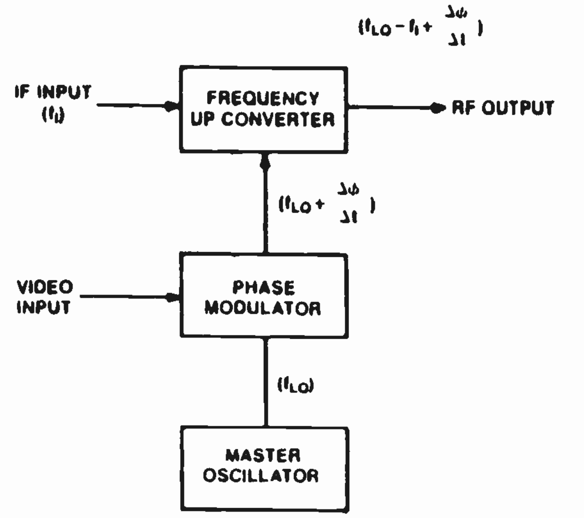

Figure 6.2-15. Master oscillator phase modulator block diagram.

the resistance in series with the diodes provides for variable gain expansion.

Incidental Carrier Phase Modulation (ICPM)

Phase distortions in high-power amplifiers produce ICPM or spectral components in quadrature with the modulation signal. Fast video amplitude changes such as a step or pulse will cause larger incidental phase spectral components than slow changes. Receivers make this condition worse by attenuating the lower sidebands below 0.75 MHz. The receiver then responds to the extra sidebands created by the phase modulation as if they were amplitude modulated single sidebands, producing spikes. The faster the rise time of the signal, the more high-frequency energy is present, resulting in edge distortions in the displayed picture.

The picture impairment is similar to simultaneous group delay and differential phase errors in that edges are less sharp and color hue changes with brightness. On a waveform monitor, overshoots are visible as trailing edges and as rounding on leading edges. These overshoots vary in severity depending on how close to saturation the power amplifier is driven.

Audio impairment is produced by ICPM in receivers employing intercarrier conversion. Intercarrier receivers use an AM or synchronous detector to produce a 4.5 MHz aural IF from the composite video IF. Any phase modulation present on the visual carrier is then transferred to the aural intercarrier. In monaural baseband audio, the increasing amplitude versus frequency effect of ICPM is nullified by deemphasis to some degree. With multichannel sound, however, there is no deemphasis applied to the baseband stereo signal, and thus the distortion is more pronounced at the stereo subchannel and pilot frequencies. To counteract the effects of ICPM and other noise sources on the stereo subchannel, audio companding is employed. Although the audio companding process can reduce some of the effects of ICPM, correction is essential in delivering clear, low-noise audio to intercarrier receivers.

There is no defined level of ICPM for a given stereo performance level since the signal to buzz ratio is highly dependent on the picture spectral components. (Refer to the *EIA Recommended Practices* for current recommendations on ICPM limits.)

ICPM precorrectors can be grouped into two types: those using a phase modulator and those operating on the signal directly. The phase modulator uses video to modulate the IF or master oscillator with a phase characteristic opposite that of the nonlinear amplifier. A phase modulator can also operate on the IF signal directly using a video signal to set the amount of modulation. A block diagram of a master oscillator phase modulator is shown in Figure 6.2-15.

ICPM precorrectors operating directly on the IF signal can be implemented several ways. Direct precorrection at IF is similar in concept to baseband differential phase precorrection (see Figure 6.2-16). In both cases, the visual signal is split into two paths which are in phase quadrature. In the IF corrector, the entire

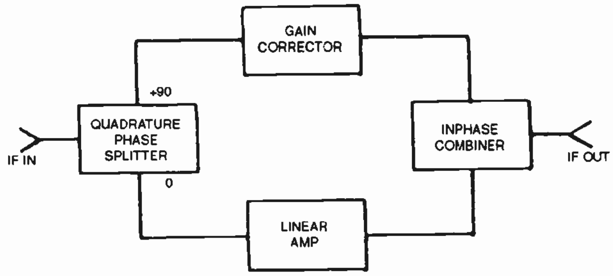

Figure 6.2-16. Direct IF ICPM corrector.

channel of frequencies is in quadrature, whereas in the video precorrector only the chroma band is in quadrature. One method of implementation is to modify the quadrature signal gain function with level dependent diode expansion or compression circuits. This can be done using the same techniques as in the linearity corrector.

The vector diagram in Figure 6.2-17 illustrates nonlinearities and the operation of the ICPM and linearity correctors. The desired output signal is represented by the left vector. Uncorrected the transmitter output signal is phase shifted and compressed. To compensate, the signal in the exciter is precorrected by an amplitude expansion and a correction in quadrature. When the resultant signal is amplified, the output signal is the desired TV signal.

Aural Modulator

In its most basic form, the aural modulator consists of some audio processing and an FM modulated IF oscillator.

Audio Processing Circuits

To ensure that the transmitter is not the limiting factor in audio (monaural and stereo) reproduction, it is desired that the transmitter add as little distortion to the incoming signal as possible.

Baseband audio of the BTSC Multichannel Television Sound (MTS) System (mono, stereo, second audio program (SAP) and professional channels (PRO)) include frequency components to 105 kHz. Emphasis must be placed on phase linearity, low distortion, reduction of any amplitude ripples and roll-off over the stereo passband to achieve good stereo separation and minimum crosstalk between the main stereo and the SAP channels.

While unbalanced coaxial inputs are used for the MTS input to the aural exciter, it is necessary to use some form of common mode rejection to reduce the possibility of hum and noise from getting directly into the audio stages.

All errors in phase linearity and amplitude response within the audio circuitry contribute to stereo separation degradation. As a general rule, amplitude roll-off should be less than 0.1 dB and departure from phase linearity should be less than 1° for good quality stereo.

IF Modulation

With the MTS system, intermodulation (IMD) and harmonic distortion products lie in the stereo channel or the SAP channel and will degrade stereo separation or crosstalk into the SAP channel. In addition, IMD products generated in the stereo channel may lie in the mono or SAP channel. Modulated oscillator linearity requirements include flat modulation sensitivity versus frequency up to 47 kHz minimum, and typically, out to 120 kHz.

As the MTS signal is upconverted to the aural RF carrier frequency, the residual FM of the local oscillator signal becomes a determining factor. The level of FM produced by the local oscillator should be 10 dB lower than the modulated oscillator. Synthesized sources should be tested for spurious frequencies which may show as FM noise. To ensure low-power stages do not contribute any group delay or amplitude roll-off, wideband amplifiers should be used.

Compensation of Aural Passband for Optimum Stereo Performance

Group delay equalization for the aural transmitter IF section of the aural modulator effectively corrects the adverse group delay in the diplexer. The end result is improved TV stereo separation. Equalization of the FM bandpass allows the use of lower cost, single-cavity notch diplexers. Stagger-tuned dual-cavity notch diplexers have been used to provide the broad bandwidth desired for good stereo separation and neg-

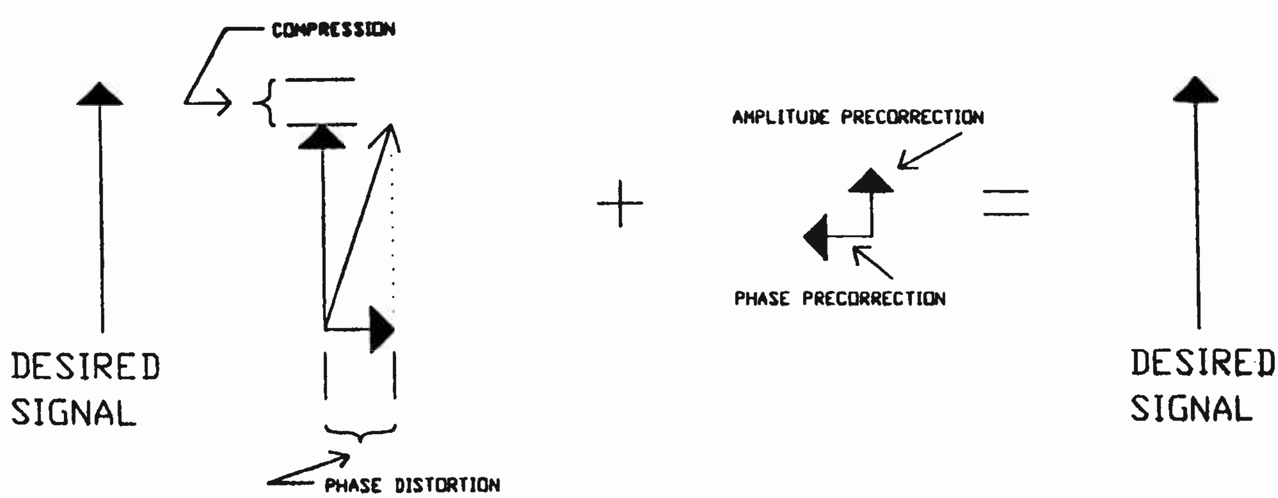

Figure 6.2-17. Vector representation of precorrection.

ligible crosstalk between the different MTS components. However, dual-cavity notch diplexers introduce more group delay in the visual path and are more expensive than single-cavity diplexers.

The notch diplexer is a passive device and under first consideration it may seem strange that it can introduce distortion and stereo separation errors. The basic problem is that the FM stereo signal is sensitive to the notch diplexer group delay and amplitude response over the occupied bandwidth of the FM signal.

The group delay and amplitude response of a single-cavity diplexer is shown in Figure 6.2-18. It is a typical notch diplexer optimized for minimum aural reject power. The bandpass is somewhat narrow and the group delay is steep. Fortunately, the response curves show a high degree of symmetry which makes equalization possible.

The group delay equalization concept as applied here is essentially a *feed-forward scheme.* Feed-forward is used to describe the technique of generating equalization early in the RF lineup for the purpose of correcting distortions occurring downstream in the system. Feed-forward is operated open loop (without feedback) and is manually adjusted for optimum operation.

Aural IF Group Delay Equalization

The equalization technique of adjusting the circuit to produce an inverse curve of that of the diplexer is the same as that used on the visual signal. There is, however, a significant difference between group delay correction on a FM system versus an AM system. The aural transmitter must incorporate group delay correction at RF or IF to compensate for group delay distortions occurring in the diplexer. *Group delay correction before the FM modulation process is not effective for equalizing group delay occurring at RF.* The reason for this is that the occupied bandwidth of an FM signal increases or decreases as a function of baseband signal level. Figure 6.2-19 shows the occupied bandwidth when the carrier is deviated 25 kHz compared to a typical notch diplexer group delay curve. When the baseband signal level is increased, the FM deviation increases and a number of additional significant sidebands are generated beyond the acceptable group delay curvature region. The result is distortion in the demodulated FM signal.

In addition, as the baseband high-frequency content increases (a stereo signal) significant sidebands extend even further increasing the demodulated distortion. Figure 6.2-20 shows the spectral content of a TV stereo signal with notch diplexer group delay curves overlayed. The equalizer location in the aural transmitter system is shown in Figure 6.2-21.

The circuit configuration is shown functionally in Figure 6.2-22. The measured amplitude and group delay is shown in Figure 6.2-23. An ideal precorrection circuit without any circuit losses would have a flat

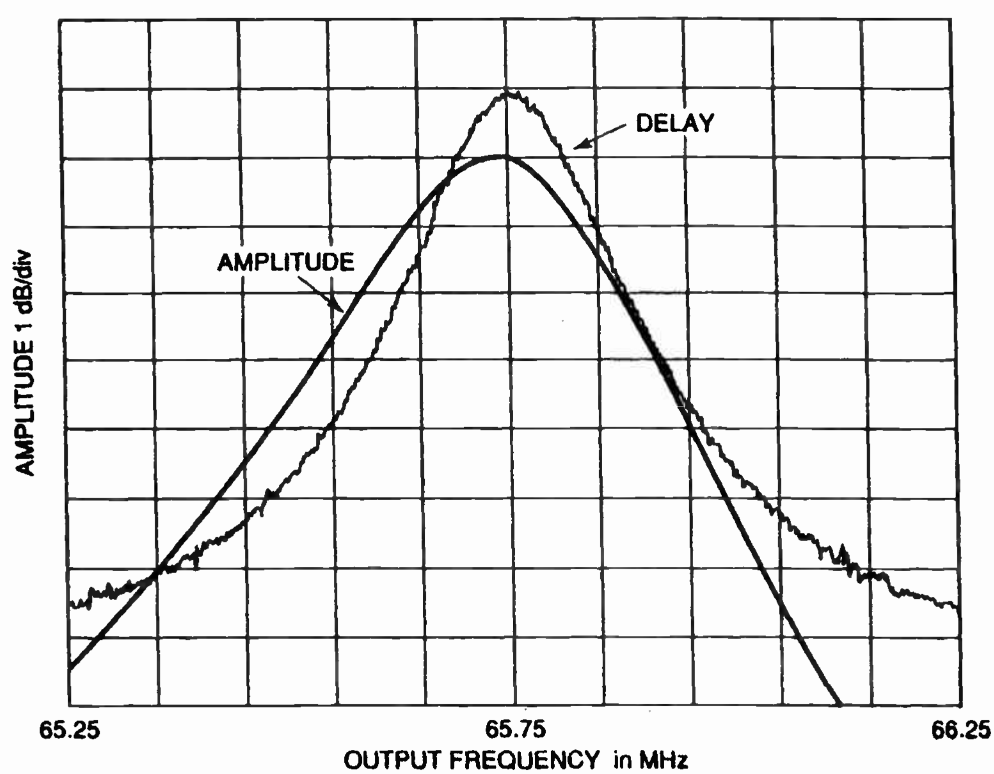

Figure 6.2-18. Typical single cavity diplexer amplitude and group delay.

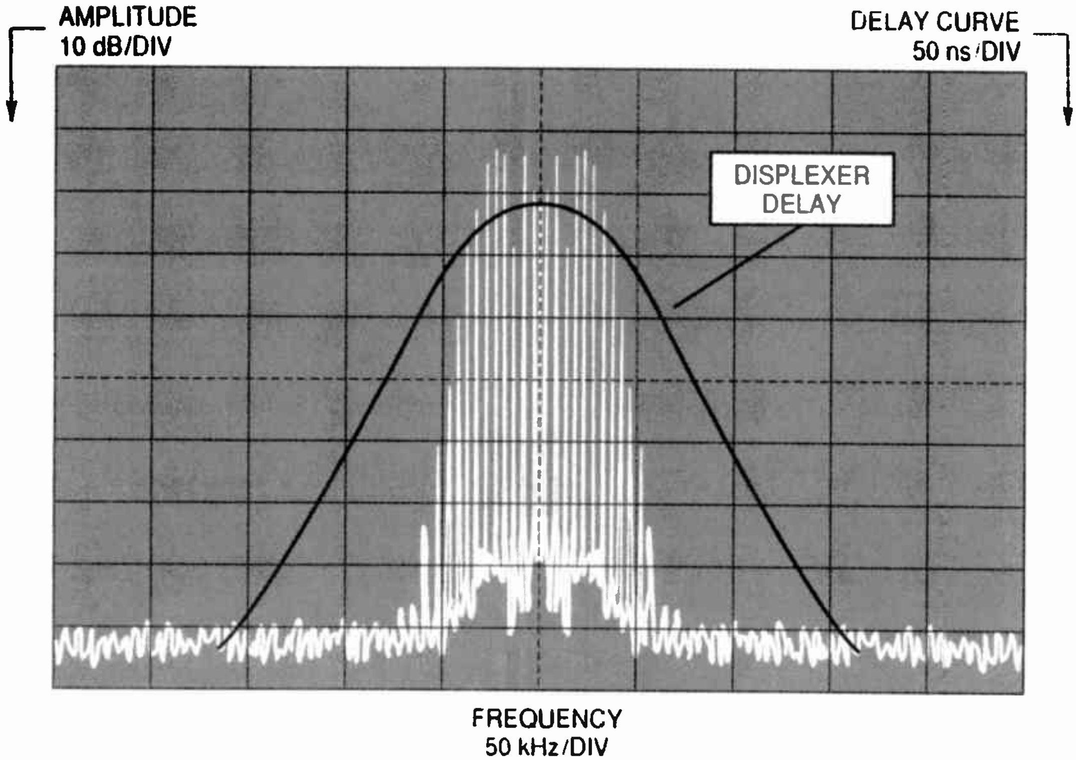

Figure 6.2-19. Occupied bandwidth with 25 kHz deviation with overlayed notch diplexer bandwidth.

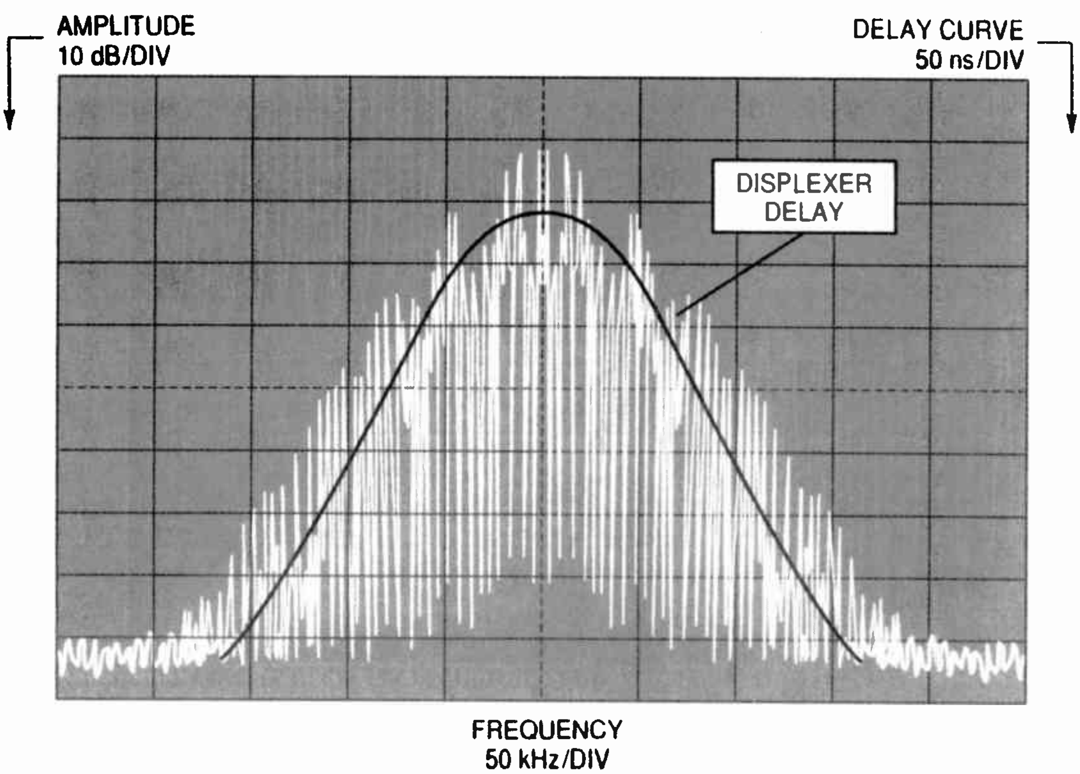

Figure 6.2-20. Occupied bandwidth of TV stereo signal with 55 kHz deviation and overlayed notch diplexer bandwidth.

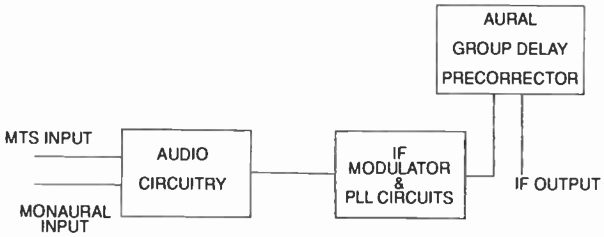

Figure 6.2-21. Aural indicator exciter with group delay precorrector.

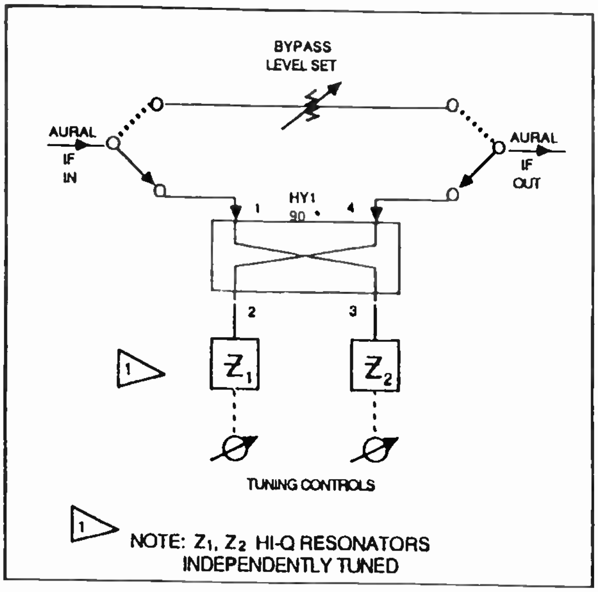

Figure 6.2-22. Aural group delay corrector functional block diagram.

response without a dip. The response dip is very useful, however, because it also provides a first-order correction to the notch diplexer amplitude response.

Figure 6.2-24 shows the system equalization when the delay corrector is switched in and switched out. A significant amount of equalization is achieved over the occupied bandwidth of a stereo signal.

The effect on stereo separation is shown in Figure 6.2-25. More than 10 dB stereo separation improvement can be obtained over midband audio frequencies.

Common Amplification

Traditionally, TV transmitters have used separate RF amplifier chains for the visual and aural signal paths. Assuming a single antenna and feed line, this requires a high level diplexer to combine the visual and aural signals prior to transmission. With the introduction of inductive output tubes as final amplifiers, it has become popular to combine the visual and aural signals in the exciter and amplify them together in the following stages.

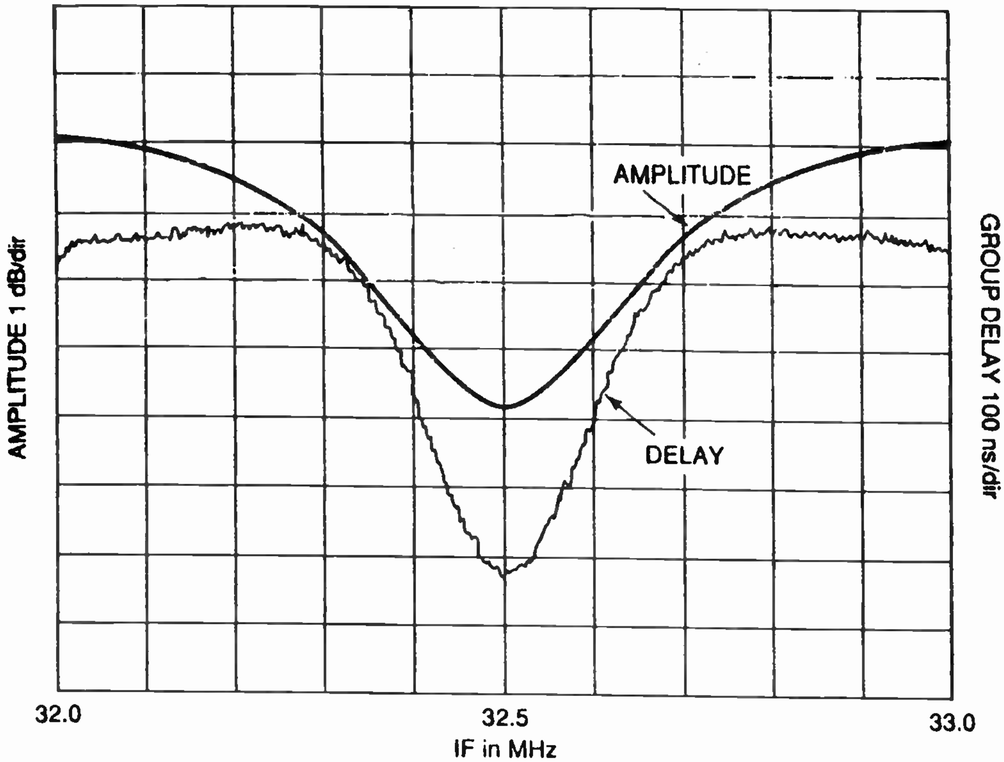

Figure 6.2-23. Aural group delay corrector measured results.

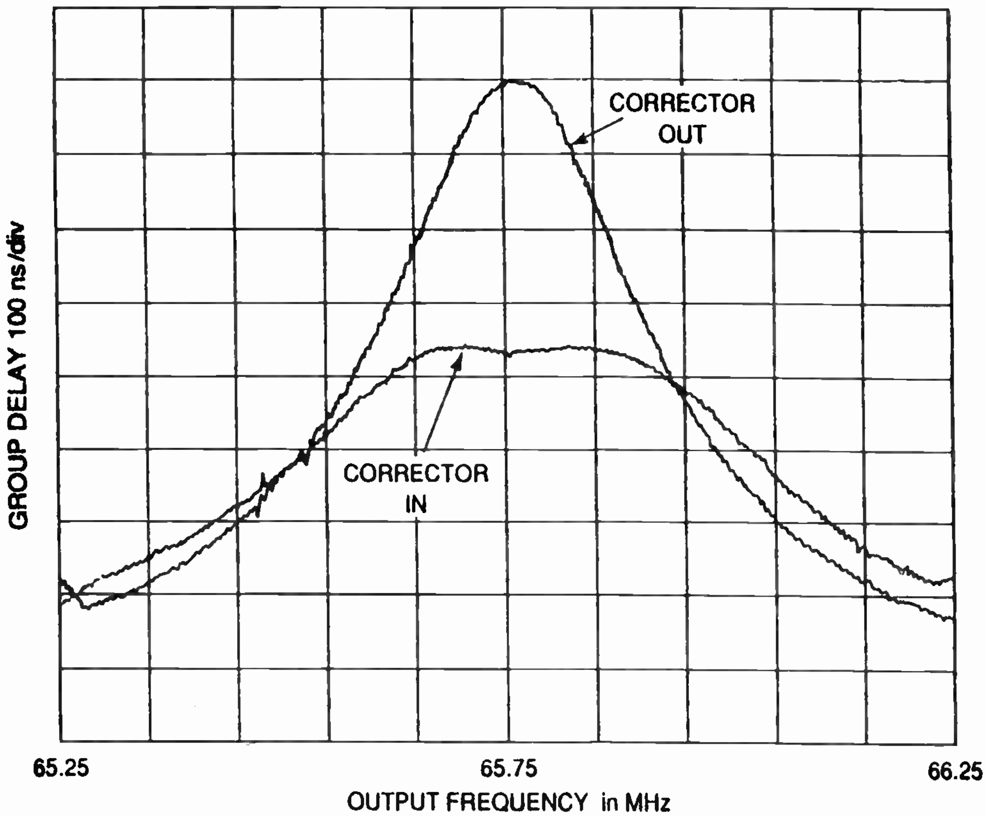

Figure 6.2-24. Overall transmitter delay with aural delay corrector switched in and out.

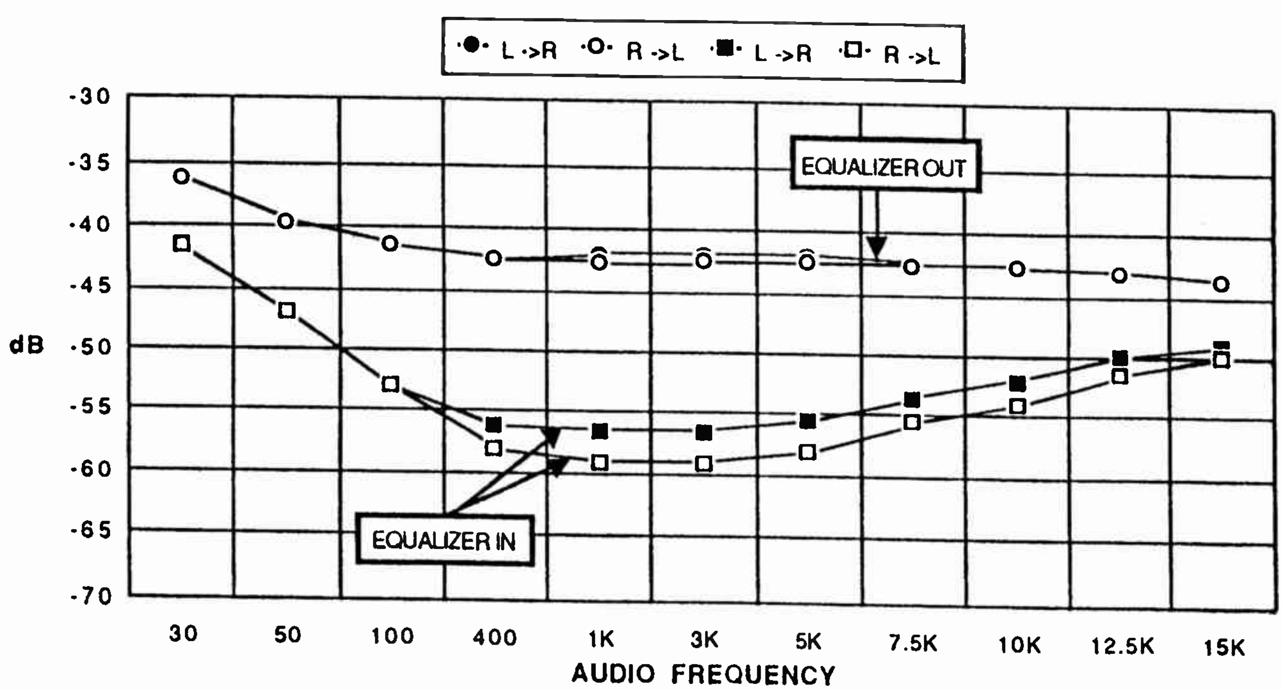

Figure 6.2-25. TV stereo separation with and without group delay equalizer.

Even though very linear amplifiers are used, some residual nonlinearity remains. This has the effect of mixing the visual, color and aural signals to produce in-band as well as the out-of-band IMD and cross modulation products. The out-of-band products sufficiently removed from the channel of operation are attenuated by the high level filter. However, in-band products can be removed only by making the transmitter sufficiently linear to reduce these products to adequate levels. This requires the use of highly effective correction circuits in the IF and/or RF signal paths. For example, the IMD at ±920 MHz can be precorrected by low level IF circuitry.

Up Conversion

Transmitters employing IF modulation generate the following frequencies: visual IF, aural IF, and master oscillator signal(s) for translating visual and aural IF to the final carrier frequencies. These oscillators have been implemented with either digital synthesizer techniques or crystal oscillators. An advantage of the synthesizer is that only one crystal is needed at a single standard frequency for all TV channels. The crystal oscillator approach, however, may involve simpler circuitry.

The two commonly used IF frequencies are 37 MHz and 45.75 MHz. There are many reasons for selecting one IF frequency or the other. One advantage of 37 MHz is that the temperature drift sensitivity of most IF components such as the SAW filter, is related directly to carrier frequency. Thus the lower IF has a 12% less drift sensitivity than components at 45.75 MHz. The second harmonic of 37 MHz falls in between channels 4 and 5 so as not to cause interference. On the other hand, 45.75 MHz is a common demodulator IF which can be useful for IF troubleshooting. Temperature drift may be minimized at either IF by maintaining the SAW filter at a stable temperature.

The important performance characteristics of an oscillator are phase noise, frequency stability over time and temperature extremes and level of microphonics.

In replacing a crystal, it is important to follow the recommendations of the oscillator manufacturer to ensure proper operation. Synthesizer performance should be properly maintained to prevent inadvertent phase noise and spurious frequency generation.

Offset Frequency Control

The limited number of available channels for TV broadcasting makes it necessary to assign the same carrier frequencies to many stations. To avoid interference between stations operating on the same frequency (co-channel interference), geographical separation and radiated powers are carefully selected.

Co-channel interference between television stations appears to viewers as a horizontal pattern of alternating light and dark bars on the viewing screen—very much like the shadows cast by venetian blinds. It has been demonstrated that the visibility of these bars varies cyclically as a function of the difference in frequency of the interfering carriers (see Figure 6.2-26). The

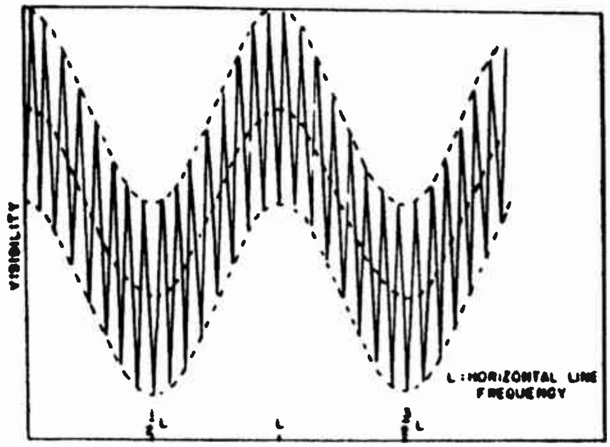

Figure 6.2-26. Co-channel interference.

interference is least visible when the carriers are offset by odd multiples of one-half the line frequency (15734 kHz). Fine grain maxima and minima occur when the frequency offset is an integer multiple of the frame frequency (29.97 Hz).

Ideally, stations would be offset by odd multiples of one-half the line frequency to provide minimum interference visibility. However, a third station in the same area would be offset from one of the other stations by an even multiple of the line frequency. Hence, maximum visibility of the interference would occur. Therefore, 10 kHz offsets currently are used in the United States to provide approximately equal reduction of the interference patterns for any number of stations in geographical proximity (see Figure 6.2-27).

Precise Frequency Offset

Although it is not practical to utilize the gross minima occurring at odd multiples of one-half the line frequency, use of the fine grain minima, occurring at even multiples of the frame frequency, is very advantageous in reducing the visibility of co-channel interference.

The nearest even multiple (334th) of the frame frequency to the 10 kHz offset is 10010 Hz. In a three station arrangement, one station will have zero offset and the other two stations will be offset by ±10010 Hz. Changes in the frequency differences of 5 Hz have a negligible effect on the reduction of the interference visibility.

To maintain the precision offset within 5 Hz requires maintaining each visual carrier frequency within 2 or 3 Hz. Maintaining a television transmitter to such tight frequency tolerances requires an extremely stable frequency source. (Note that 3 Hz stability is required in the case of an adjacent DTV signal.)

In exciters using two independent oscillators (one for IF and one for the local oscillator), the visual carrier signal may be derived from mixing the oscillators together and comparing that signal to the reference signal in the comparator. The resultant error signal can be

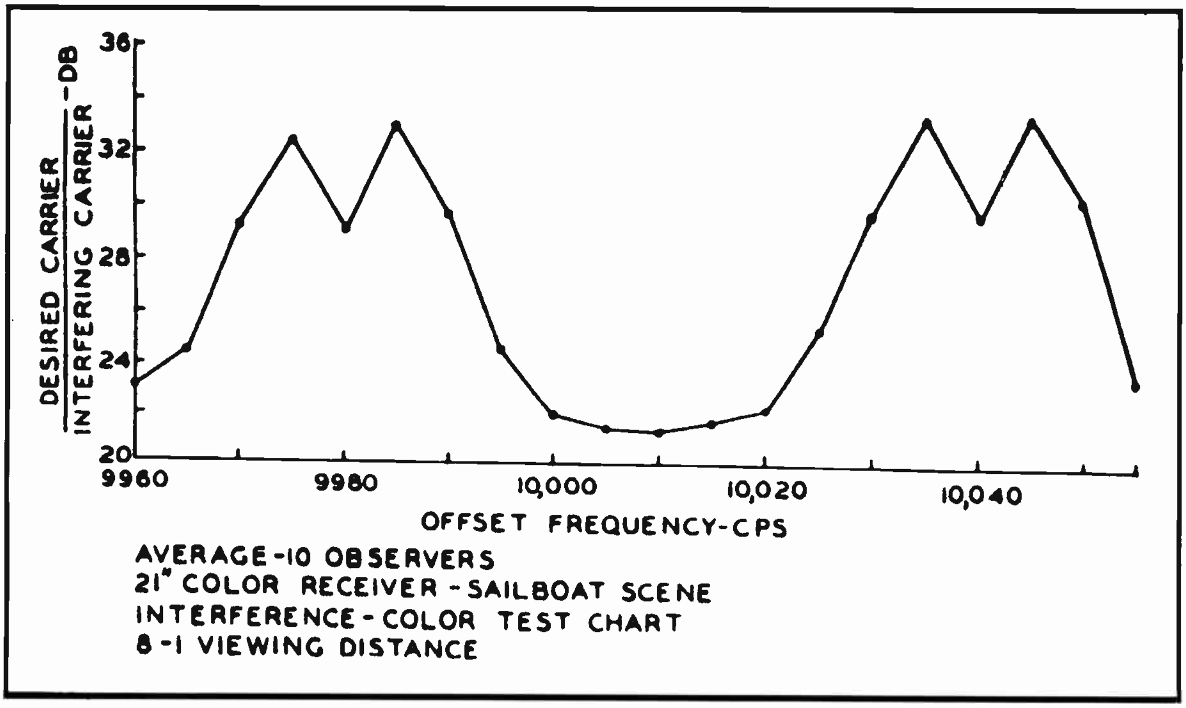

Figure 6.2-27. 10 kHz offset pattern.

used to adjust one of the oscillators, preferably the local oscillator. For exciters using synthesizers, the synthesizer reference oscillator is compared to the precise frequency standard in the phase detector and the resultant error voltage is used to adjust the synthesizer oscillator.

By phase locking the visual carrier to a stable reference oscillator, the master oscillator acquires the stability of the reference source. Sources which use an internal WWV receiver/comparator to self-correct or an atomic frequency standard can easily provide the stable reference source required. These reference sources allow a transmitter to be maintained within a few hertz of a desired frequency indefinitely.

RF Amplifiers

The last active stage in a typical exciter is the RF amplifier. For visual signals in separate amplification, combined aural and visual signals in common amplification and for digital signals, it is important that this amplifer have a linear transfer characteristic in amplitude and phase and flat, symmetric frequency response and minimum group delay variation across the modulation passband. For visual only signals, the required bandwidth is at least 4.5 MHz. For common amplification and digital signals at least 6 MHz bandwidth is required.

For optimum stereo performance a nonlinear amplifier with flat response and group delay across the modulation pass band is required. Since frequency modulation and demodulation is a nonlinear process these is not a one to one correspondance between RF amplitude/phase response and baseband stereo separation and crosstalk. A 3 dB bandwidth of 1.5 MHz provides excellent stereo and SAP performance.

EXCITERS FOR DTV

With the introduction of digital transmission technology, the broadcast engineer must be familiar with the equipment required to broadcast high speed digital signals as well as the more familiar analog video and audio signals. There are many aspects of exciter design that are common to analog and digital transmission. This is especially true of the upconversion and IF precorrection and equalization sections. Baseband processing and modulation are the portions of the exciter most affected by digital transmission.

The modulation used in the ATSC terrestrial broadcasting standard is 8-level vestigial sideband (8 VSB). Figure 6.2-28 shows the conceptual implementation of 8 VSB. Data are taken 3 bits at a time and converted to 8-level pulses which are applied to a baseband filter. The filter is offset in frequency by one-fourth the symbol rate to produce a baseband version of 8 VSB. There are many ways to implement the 8 VSB modulator, but the objective of all approaches is to produce the signal as in the conceptual representation.

Modulator

Figure 6.2-29 shows the functional block diagram of a typical 8 VSB modulator. Data formatted and

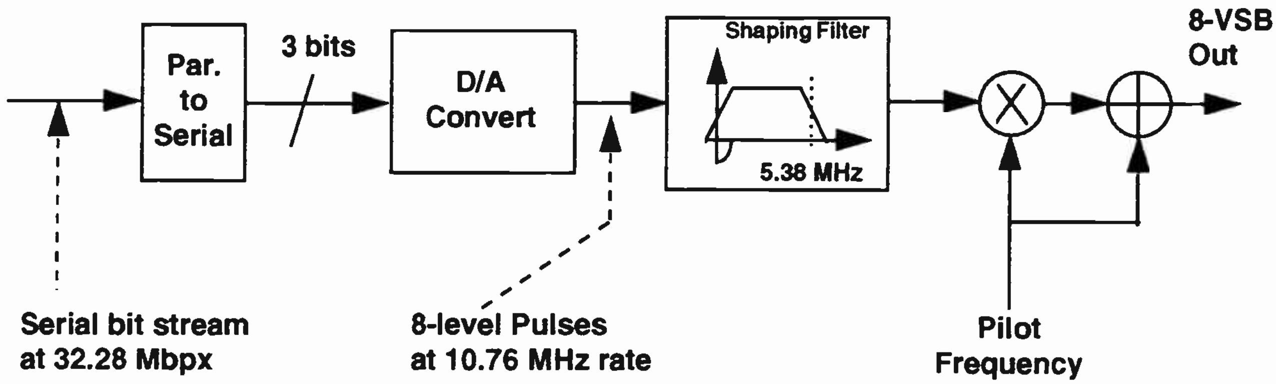

Figure 6.2-28. 8 VSB Conceptual block diagram.

encoded in accordance with ATSC specifications emerges from the transport-to-transmisson layer and is presented 3 bits at a time at the 10.76 MHz symbol rate to the baseband digital Nyquist filter. After digital filtering, the data is in the form of a 10.76 MHz digital IF. It is then converted to an analog IF signal using a high speed digital-to-analog converter (DAC). The analog IF output is filtered by a x/sinx correction filter, the purpose of which is to compensate for the sinx/x response inherent in the square pulses emerging from the DAC. A low-pass filter is also required to attenuate the image frequency before the first IF is upconverted to the second IF at 45 MHz. From the second IF the 6 MHz bandwidth 8 VSB signal is upconverted to carrier.

Signal Envelope of 8 VSB

Figure 6.2-30 shows the typical signal envelope of 8 VSB modulation. Note the great variability in the envelope peaks. This time-varying peaking is the source of the large peak-to-average ratio. The variability in the envelope gives rise to requirement of very linear power amplification. Figure 6.2-31 shows the spectrum measured from a typical modulator. The spike in the spectrum on the left side indicates the presence of the pilot carrier.

Hardware Design

The 8 VSB modulator consists of three major functions: the transport-to-transmission layer converter or channel coding, the Nyquist filter and IF conversion (see Figure 6.2-32).

Transport/Transmission Layer Conversion

The ATSC has defined the data transport layer to be a 19.389 Mb/s data stream. The data is formatted into 8 bit bytes, and 188 bytes per frame, each frame consists of 187 bytes of data plus one byte reserved as a sync byte. The resulting payload is the 19.389 Mb/s data stream.

Channel coding protects the data from noise and interference by adding redundancy prior to transmission. This redundancy is decoded by the receiver to correct for errors introduced by transmission. The modulator performs the channel coding by implementing frame synchronization, data randomization, Reed-Solomon (R-S) encoding, data interleaving, trellis encoding and field and frame sync insertion (see Figure 6.2-33). The purpose of the randomizer is to disperse the payload data energy in pseudo-random fashion to assure that the spectral energy is constant over the channel bandwidth. This is necessary to assure optimum transmission and reception. The next functions are designed to protect the data from transmission errors. This is a two stage process. R-S coding is used in the first stage. This is a forward error correction code suitable for correcting block errors due to bursts of noise and interference. The code selected is capable of correcting up to 10 byte errors per block. This is accomplished by adding 20 parity bytes to each 187 byte block of the payload. Interleaving of the data provides additional error protection. This convolutional byte interleaver spreads the data bytes from each R-S block over time so that a long burst of noise is required to overrun the R-S error protection. Trellis or convolutional coding is used as the second stage of

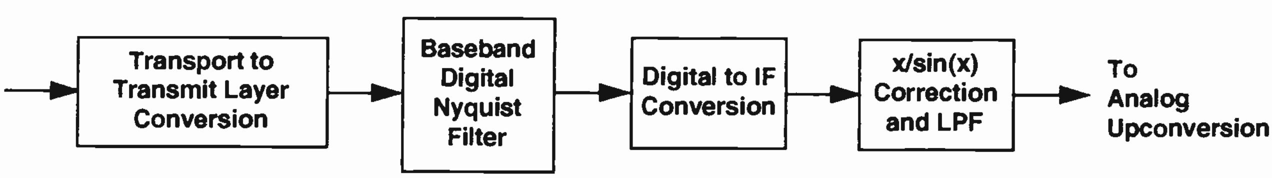

Figure 6.2-29. Typical DTV 8 VSB modulator.

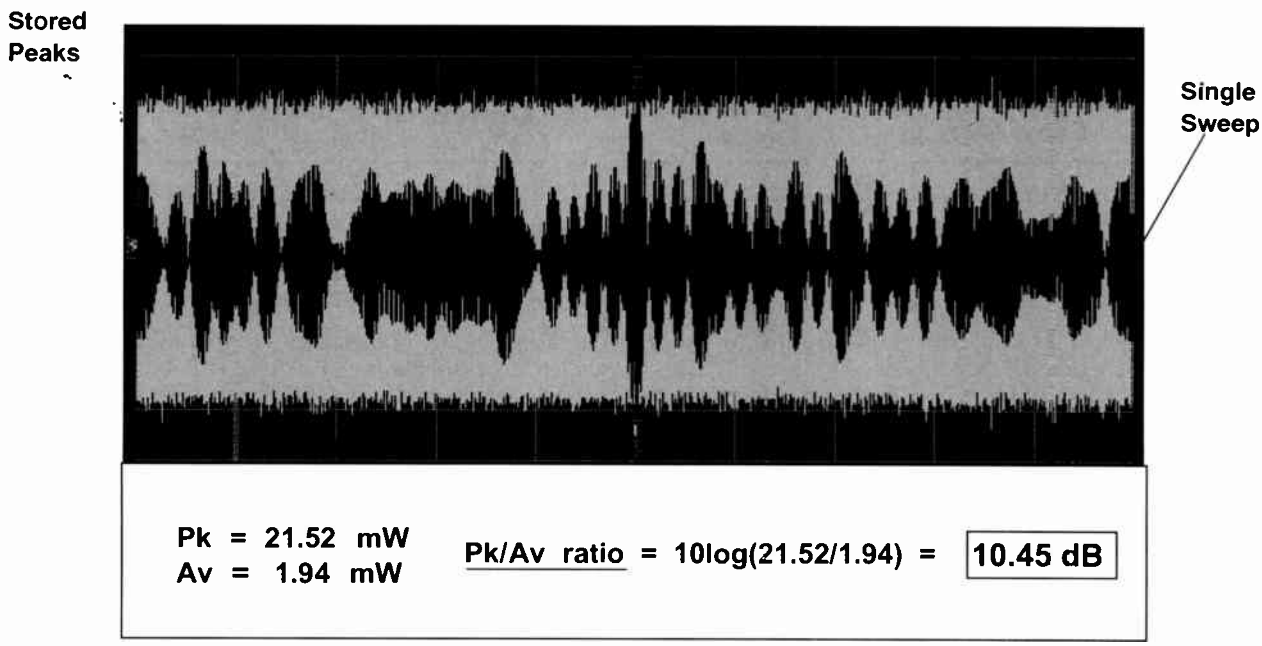

Figure 30
DTV RF waveform

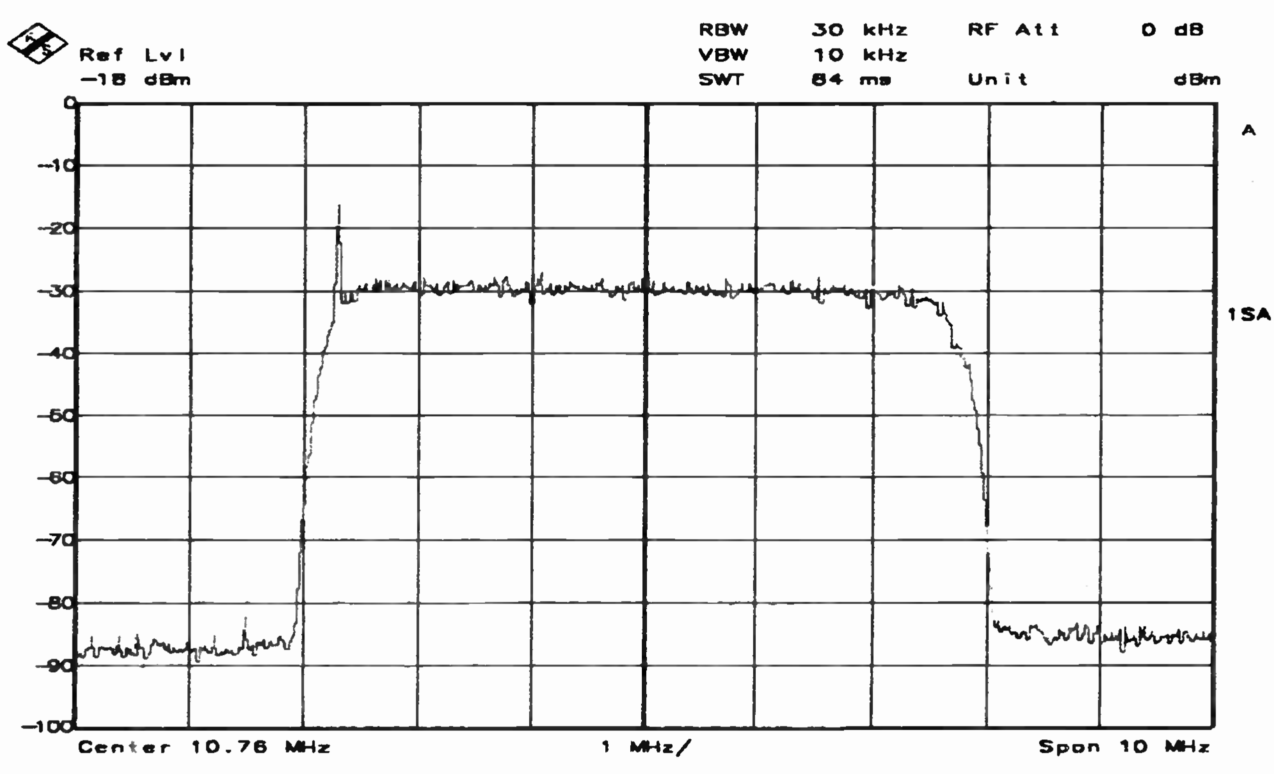

Figure 6.2-31. Measured spectrum.

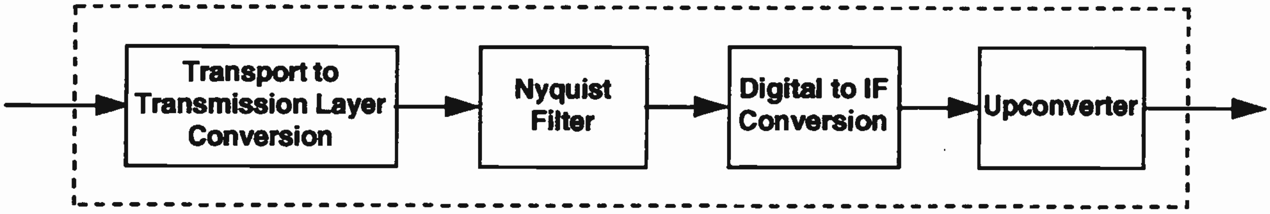

Figure 6.2-32. DTV exciter.

error correction. This is used to used to improve the S/N threshold against white noise. A 2/3 rate code with one unencoded bit is used. The signaling waveform used with the trellis code is an 8 level (3 bit) one dimensional constellation. Trellis code interleaving is also used. Following these encoding processes, field/frame and data segment syncs are inserted by means of a multiplexer.

Nyquist Filter

The *Nyquist Filter* is a root-raised cosine filter with ideal alpha factor of 0.1152. This filter, if perfectly implemented, limits the spectrum to 6 MHz bandwidth (5.38 MHz + 11.52%). A perfect filter, however, is not possible due to filter tap limitations and finite resolution. The filter is a complex filter to accommodate the vestigial sideband function. In addition, the low level VSB pilot is added to the signal at a constant RF level. The pilot aids carrier recovery and is used to remove phase ambiguity.

Careful attention must be given to signal peaks that arise due to the bandlimiting function of the Nyquist Filter. Some peaks exceed a 6 to 7 dB peak-to-average signal ratio. These peaks are generally clipped in the power amplifier stages to maximize PA efficiency. The effect of the clipping is not considered serious because of the rarity of large peaks. The key is to provide sufficient headroom in power amplifiers so that the spectral mask can be met with appropriate precorrection.

In-band equalization may be programmed into a DTV modulator using software to generate an equalization function unique to each transmitter at the time of manufacture. Equalization is applied by modifying the IF digital filter coefficients in the modulator which are then held in modulator memory as shown in Figure 6.2-34. This function can also be performed adaptively by digital signal processing (DSP) to assure optimum operation of the transmitter as operating conditions change. A companion demodulator is required to provide a sample of the output from which the DSP updates the coefficients as transmitter characteristics vary.

Upconversion & Final Amplification

The requirements for upconversion and final amplification for digital transmission are similar to those for analog signals. The IF frequencies selected will be different and there may be two stages of upconversion rather than one; however, the important performance characteristics of oscillator phase noise, frequency stability, and susceptibility to microphonics remain the same. As with analog visual and aural signals, it is important that the final amplifer have a linear transfer characteristic in amplitude and phase and flat, symmetric frequency response and minimum group delay variation across the modulation passband. For digital signals at least 6 MHz bandwidth is required.

For DTV transmitters operating on channels immediately adjacent to (above) and within 88 km of a transmitter on a NTSC channel, the pilot frequency must be maintained 5.082138 MHz above the visual carrier frequency of the NTSC transmitter within a tolerance of ±3 Hz. This requires that both carriers be locked to a common, highly stable source.

POWER AMPLIFIER DESIGN CONSIDERATIONS

Aside from near linear, transparent performance, it is essential that TV transmitters operate efficiently with minimum lost air time. Efficient power conversion, while important at VHF, is unusually important for UHF transmitters. This factor is expected to impact more stations as the DTV service comes on-line, pre-

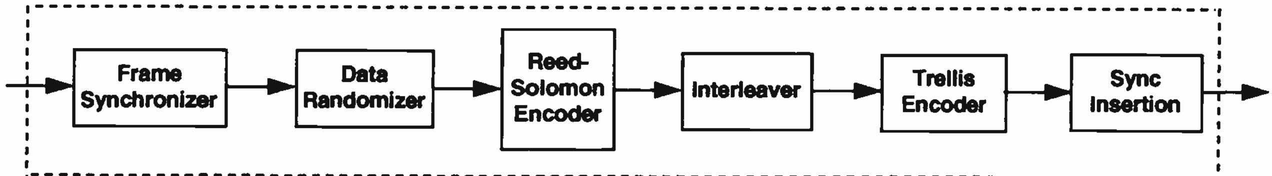

Figure 6.2-33. Transport to transmission conversion.

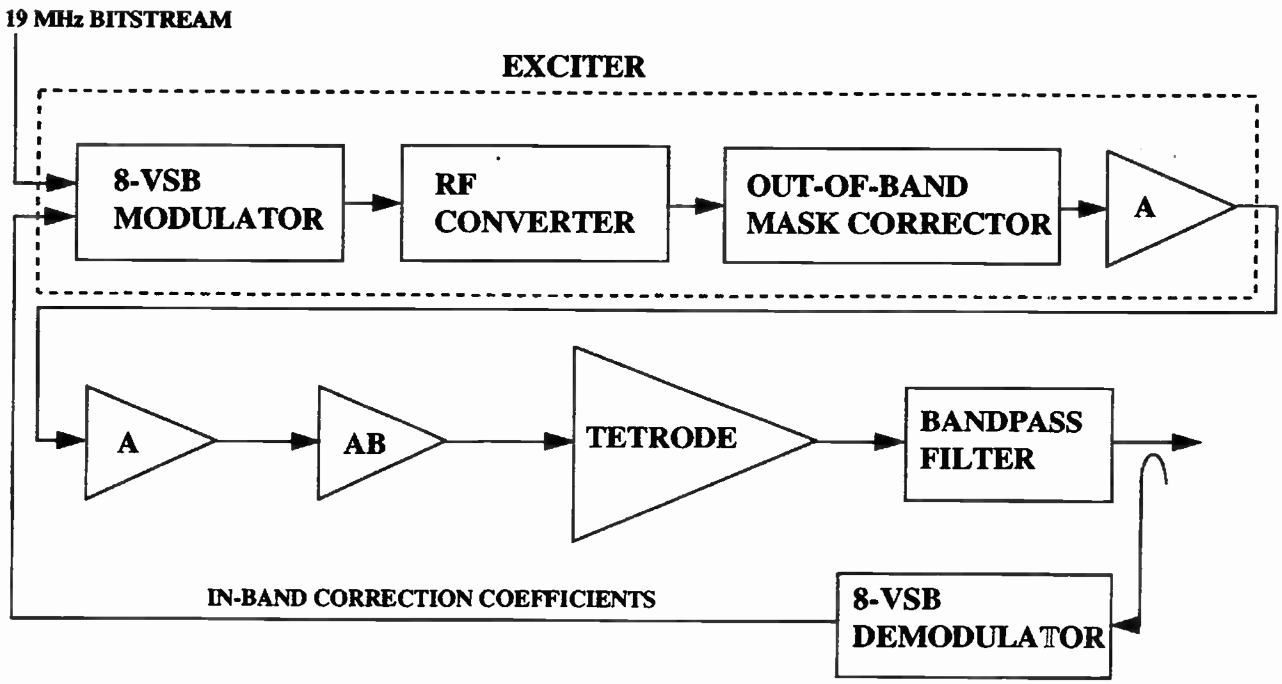

Figure 6.2-34. Block diagram of a tetrode DTV transmitter.

dominately in the UHF band. Many stations operate continuously unattended, making reliability a key requirement.

Reliability

There are many factors which can affect the reliability of a TV transmitter. Overall design philosophy, device technology, module design, control architecture, power supplies, cooling and cabinet design are critical areas which must be considered. Consider a transmitter design which uses circuits in series with no system redundancy; if one device fails, the entire transmitter fails. Figure 6.2-35 shows a system of three series devices with no redundancy. If each device (a, b, c) has a probability of survival (P) of 0.5 over some time interval the probability of the system surviving $P(s)$ is given by the formula:

$$\begin{aligned} P(s) &= P(a) \times P(b) \times P(c) \\ &= 0.5 \times 0.5 \times 0.5 \\ &= 0.125 \end{aligned}$$

If three identical devices are operated in parallel (Figure 6.2-36) and only one is required for adequate operation of the system, the probability of the system surviving is greatly enhanced. The overall system survival probability now becomes:

$$\begin{aligned} P(s) &= P(a) + P(b) + P(c) \\ &\quad - P(a)P(b) - P(a)P(c) - P(b)P(c) \\ &\quad + P(a)P(b)P(c) \\ &= 1.5 - 0.25 - 0.25 - 0.25 + 0.124 \\ &= 0.875 \end{aligned}$$

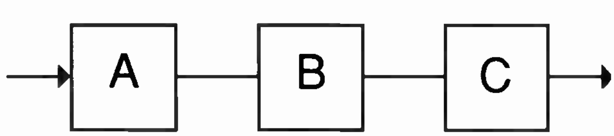

Figure 6.2-35. Circuits in series.

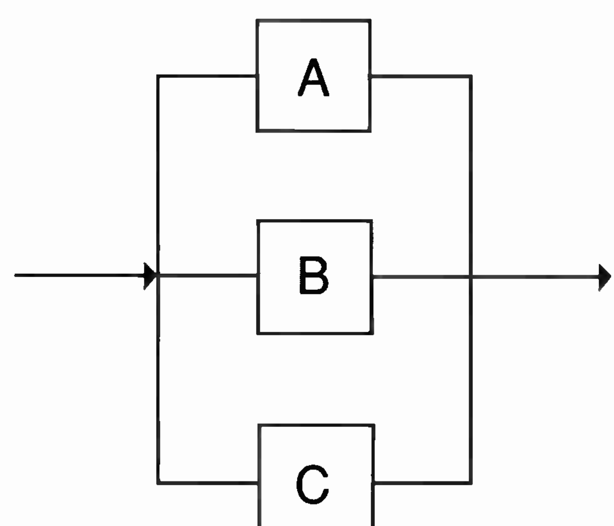

Figure 6.2-36. Circuits in parallel.

On-Air Availability

Related to reliability, but perhaps even more important, is on-air availability. On-air availability is the percentage of time the transmitter is available for service, defined by the following equation:

$$\text{On-Air Availability} = \frac{\text{MTBF}}{\text{MTBF} + \text{MTTR} + \text{MPMT}} \times 100\%$$

where:

MTBF = Mean Time Between Failures (hours)
MTTR = Mean Time To Repair (hours)
MPMT = Mean Preventative Maintenance Time (hours)

It is apparent there is little point in designing a transmitter that has a high MTBF figure if, due to poor design and mechanical packaging, it takes an inordinate length of time to make repairs, or the transmitter has to be shut down frequently for routine preventative maintenance.

Many stations have very short sign-off windows or operate 24 hours a day. This often results in a less-than-optimum maintenance schedule which can lead to premature failure or out-of-tolerance operation. One way to reduce the amount of off-air maintenance time is by making provisions for on-air maintenance or to have redundant transmitters. This significantly reduces the MPMT.

Several design factors should be considered for optimum on-air availability:

- High reliability for the fundamental circuits
- Provision for fast, easy access to all subassemblies
- Maximum use of like parts and subassemblies. Because fewer items are needed, this allows a TV station to maintain a full inventory of spares. If spares are on hand, it follows that the repair time is much shorter
- Repair of transmitter at subassembly level. A subassembly which has been removed can then be repaired by station personnel or returned to the manufacturer for exchange.

Efficiency

When the fundamental concept of efficiency is applied to TV transmitters several factors must be considered. For purposes of determining total power consumed, the ac to RF conversion efficiency is the parameter of interest. For systems with unity power factor, determining the ac input power is relatively straightforward. For power factors less than unity, the relative phase of the fundemental voltage and current must be determined. In addition, in systems generating significant line harmonics, the relative level of these harmonics must be known. Power factor is expressed either as displacement power factor or total or true power factor.

Displacement power factor is is the cosine of the phase between the voltage and current at the fundamental frequency. It is equal to the total power factor only for an undistorted sine wave.

Total power factor is the ratio of total power to the apparent power, given by:

$$\text{PF} = \text{ac power input (watts)/V (volts) I (amps)}$$

Determination of input power is somewhat simplified by considering only the dc to RF conversion process. In this case it is necessary to determine the voltage and current provided by the power supply(s) for the final amplifiying devices. While this is a useful tool for comparison purposes, it has the disadvantage of ignoring the power consumed elsewhere in the transmitter such as driver stages, cooling systems, filament and magnet power and control. If these powers are to be included in the efficiency calculation, they must be determined separately.

For NTSC transmitters, determination of output power is equally complex. Transmitters are commonly rated in terms of peak sync visual power. Exclusive use of this number neglects the aural output. In addition some amplifier technolgies may exhibit efficiencies greater than 100% using visual peak power. This has given rise to the use of figure of merit defined as:

$$\frac{\text{Visual peak sync output power}}{\text{dc input power at 50\% APL}}.$$

This definition is valid for transmitters using separate amplification. For common amplification, the aural output and input powers must be added to the numerator and denominator, respectively. Typical figures of merit for common tube amplifiers operating in separate amplification are shown in Table 6.2-1.

Consider a typical klystron amplifier in pulsed operation. Direct current input power is calculated as follows:

$$\begin{aligned}\text{DC input power} &= \text{Beam voltage}\\ &\quad \times [(\text{Beam } I_{sync} \times \text{Sync duty cycle})\\ &\quad + (\text{Beam } I_{video} \times \text{Video duty cycle})]\end{aligned}$$

For 60 kW output, dc input power = 24[(5.5 × .08) + (3.7 × .92) = 92.2 kW

$$\text{Figure of merit} = 60/92.2 = 0.65$$

For digital transmitters, the situation is somewhat simpler. The output power most readily measured is the average level which is constant. Since the audio

Table 6.2-1
Typical figures of merit for common tube amplifiers operating in separate amplification.

AMPLIFIER DEVICE	FIGURE OF MERIT
TETRODE	.9–1.0
INTEGRAL CAVITY KLYSTRON	.65–.75
EXTERNAL CAVITY KLYSTRON	.65–.75
KLYSTRODE OR IOT	1.1–1.3
DEPRESSED COLLECTOR KLYSTRON	1.2–1.3

is encoded with the video, there is no separate aural amplifier. Thus the dc to RF efficency is readily calculated as a ratio of the average RF output to the dc input.

SOLID-STATE TRANSMITTERS

Technological advances in bipolar and field effect transistors (FET) have made the development of solid-state high power, linear amplifier modules for TV applications both practical and cost effective. By combining RF modules, it is practical to create transmitters at any power range up to 75 kW. Solid-state transmitters maintain their performance over extended periods of time due primarily to the fact that they have no tuning controls nor filament emission degradation with time. No warm up time is required—solid-state transmitters produce full rated power within seconds of activation.

Solid State Devices

Both bipolar and FET technology exist today as suitable RF amplification devices. Power amps are operated in class AB for the best trade-off of efficiency and linearity. Driver stages usually contain Class A amplifiers.

Although both device types have merit, FETs have some advantages over bipolar devices. FETs have a higher amplification factor than bipolar transistors, helping to reduce the number of driver stages. Higher supply voltages help to reduce the current capacity of the power supply. Simpler bias circuitry minimizes parts count.

RF Amplifiers

Combining several RF power modules to achieve the desired transmitter output power increases the parallel redundancy and the on-air availability. Output power of 1–2 kW per module has been adopted by nearly all manufacturers based on overall cost, practical weight, and size limitations.

Self protection of each PA module against various fault conditions is good engineering practice. By using self protecting modules, the cabinet control logic and overall transmitter control logic can be kept simple, thus improving overall reliability. Self diagnostics for the module aid in minimizing time to repair. Protection from over-voltage, overdrive, VSWR, overtemperature and ensuring proper load sharing among devices is essential to maintaining amplifiers for long life. It is desirable that one subassembly failure not cause another subassembly to fail.

Modular amplifiers which can be removed while hot improve overall on-air availability. If an amplifier module fails, the transmitter continues to function indefinitely without disrupting transmitter operation. If a spare PA amplifier is on hand, it can be used while the failed unit is repaired.

Temperature compensated regulated supplies for the amplifiers are important. Otherwise, power output varies as temperature or supply voltage changes.

Combiners and Dividers

There are several methods used for combining RF power for the solid-state amplifier modules. An effective method is the use of in-phase N-way combiners. Three common examples are described.

Microstrip Wilkinson Combiner

Figure 6.2-37 shows an example of a Microstrip Wilkinson Combiner. Microstrip is used to carry the RF power. When all amplifiers are operating, equal voltages are presented to each node of the load resistor so that no power is dissipated. When an amplifier failure occurs, the power is distributed between the load and the output. The impedance of the transmission lines and the length of the lines is selected to achieve the desired impedance transformation. Balanced reject loads are used to absorb RF power in case of amplifier failure and to provide isolation between amplifiers.

The combiner is housed in a shielded casing so that outside fields cannot alter the balanced configuration. The reject loads are cooled by conducting heat through the flange to the heatsink where the heat is exchanged to the moving air stream. This type of combiner is used generally for lower numbers of amplifiers (two to six).

Ring Combiner

Figure 6.2-38 shows an example of a ring combiner. The higher power handling capability of the coax lines used in this combiner allows a range of amplifiers to be combined (two to 20). It also provides isolation between amplifiers using reject loads which are not in the direct RF path to the output. The operation of the multiport combiner is easily understood by considering a two-way version (see Figure 6.2-39). Each transmission line is a quarter wavelength. When equal voltages are applied to both input ports (both amplifiers operating), the combined signal arrives at the output. This is true because the distance from each input port to the output is electrically equal whether the signal follows the shorter or longer path, the signal from one amplifier arrives at the load port out of phase with that

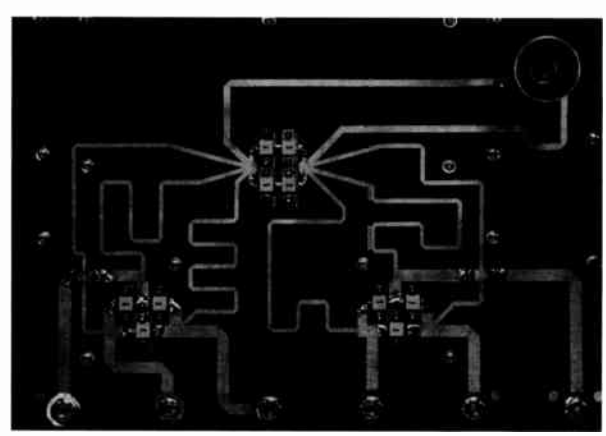

Figure 6.2-37. Microstrip Wilkinson combiner (Photo courtesy of Larcan).

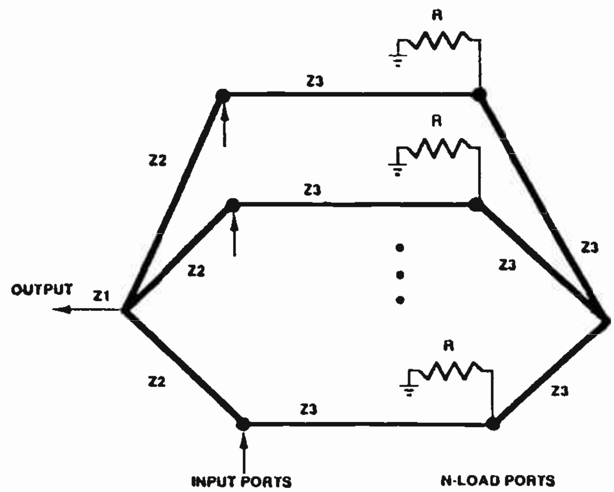

Figure 6.2-38. N-way ring combiner.

from the other amplifiers so no power is dissipated and the signals from amplifier 1 arriving at input port 2 via the short and long paths are out of phase and vice versa. *Under normal conditions, all power appears at the output, none is absorbed in the loads, and there is complete isolation between amplifiers.*

Power is absorbed in the load resistors only when an amplifier is not operating. Assume that only amplifier number 1 is operating. The signal path is electrically equal not only for the long and short paths to the output, but also, for the right and left paths to either load. The power from the operating amplifier is split equally between the output and the isolation loads. Due to the isolation inherent in the network, the input ports remain matched even when one or more amplifiers are removed.

Since the transmission line that connects the amplifier port to the output port is a quarter wavelength long and 75 Ω transmission line is used, the 50 Ω amplifier impedance is transformed to: $(75/50) \times 75 = 112.5$ Ω. For combining N amplifiers, the impedance at the output combiner junction is 112.5/N. This impedance is then matched to 50 Ω.

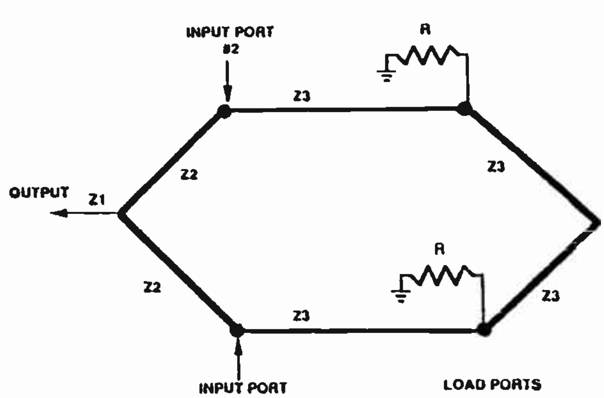

Figure 6.2-39. Two way ring combiner.

The reject loads are mounted to a grounded structure. One method of cooling the loads is to use a heat pipe for the mounting structure. In case of amplifier removal, the reject load temperature rises, the fluid in the lower section of the heat pipe heats until it vaporizes. The vapor rises to the finned area where the heat is exchanged to the moving air stream. The vapor condenses as it releases its heat and returns to the bottom of the pipe to repeat the cycle.

Starpoint Combiner

Starpoint combiners are simple low loss devices and operate in the following manner. Consider parallel operation of four sources of equal phase and amplitude, each with a source impedance of 50 Ω and no interaction. The resulting source impedance is 12.5 Ω. All that is needed to complete the combining process is to transform this impedance to 50 Ω. Obviously, this concept can be extended to any value of "N." The "Q" of the impedance transformation determines the combiner bandwidth. For optimum bandwidth it may be necessary to combine and transform in several corporate steps. In reality, the combined amplifiers have slightly differing phases and amplitudes. As in any combiner design, this represents a combining loss that must be accounted for. A flat air spaced stripline structure may be used to provide a combiner with extremely low resistive loss.

This simple combining technique works best only if all inputs are present. If a failure occurs the isolation may be insufficient to prevent interaction between modules, especially for small values of "N." Using circulators at the output of each module resolves this, producing a combiner with excellent isolation and bandwidth. Circulators not only provide port-to-port isolation but also protect against high VSWR due to icing and other causes. The combiner band split should be consistent with module and circulator bandwidth.

Combining Multiple Amplifier Cabinets

When combining RF power amplifiers, they must be matched in phase and gain for maximum power to the antenna and minimum power to the reject load. Electronic phase shifters and attenuators should have the capability for remembering their settings in case of ac power failure.

Cooling System

Proper cooling of the solid-state modules is important for high MTBF. The MTBF of a transistor essentially doubles for every 10°C drop in the junction temperature. Distributed cooling systems employing more than one fan offer good redundancy. Current motor/fan technology has matured to the point where a few larger direct drive fans are as reliable as many smaller fans. Since many RF power amplifiers may be employed, a large volume of air is needed to adequately cool the heatsinks. Low pressure fans or blowers may be used if heatsink fin density is not high. This aids in reducing audible noise. The heat is distributed over a large volume of air and the temperature rise is relatively low.

Automatic Gain Control (AGC)

AGC is used to maintain constant power output from the transmitter. Ambient temperature changes will cause gain changes in a solid-state amplifier. RF drive power must be changed to maintain constant power output. A detected RF sample of the PA output may be fed to an input of a comparator. The exciter output sample or a voltage proportional to the exciter output is applied to the other input of a comparator. The dc output is then integrated and fed to an attenuator which varies the RF drive level at a low power level. Alternatively, the RF sample may be taken from an intermediate stage. In this case, other means must be used to temperature compensate the output stage or some power reduction with temperature must be tolerated.

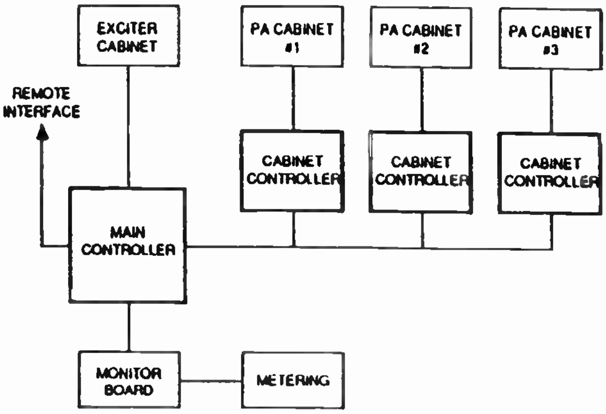

Figure 6.2-40. Distributed control and monitoring.

Power Supplies

Power supply design is critical to the reliability of a solid-state transmitter. Since FET and bipolar devices are low voltage devices, the power supplies which serve them must provide low voltage and high current. High reliability connections must be guaranteed in the dc distribution. Since available power output from a transistor varies as

$$Po = \frac{(V)^2}{2R_L}$$

it is desirable that the supply remain very tightly controlled over incoming ac line variation. Since the amplifier current demand varies with picture level (for NTSC), the power supply output voltage must remain stable from low load (white picture) to high load (peak sync output). Efficiency of the power supply is important since the lost power results in heat as well as unnecessarily high utility costs. Any voltage or current transients should be significantly suppressed before reaching the amplifier transistor device. Transmitters should successfully pass the applicable portions of the ANSI/IEEE C62.41 Transient Testing Standard (also referred to as the IEEE-587 Standard).

Alternating Current Distribution

A reliable method of ac distribution provides power to modular RF amplifier cabinets through a parallel system. Each cabinet is protected by a separate ac breaker external to the transmitter. This concept allows a cabinet to be safely serviced while the remaining cabinets are operational. Phase monitors guard against low voltage, loss of phase or reversal of phase.

Control Systems

If individual amplifier modules and power supplies are self protecting, control and monitoring functions can be simple and straightforward. One approach for the control system is to use a single controller to control and monitor all the functions of the transmitter. Another approach is to distribute the control system throughout the transmitter. The distributed control system can be designed so that the failure of any individual controller does not affect the operation of the others.

Both distributed control and centralized control systems are shown in Figures 6.2-40 and 41. After ac power failure, the controller should have backup memory to restore the transmitter to the same operating condition as before.

A system of indicators is essential to quick fault diagnosis. Typical status conditions which may be displayed are: exciter fault, VSWR fault, VSWR foldback, power supply fault, controller fault, air loss, door open, fail-safe interlock, phase loss, module fault, visual drive fault, aural drive fault and external interlock(s).

VSWR foldback reduces power during high VSWR operation, such as antenna icing, and restores RF power to normal when difficulties are removed. Other options used to enhance the on-air capability may include dual exciters, 20% aural power and redundant drive chains. A block diagram of a solid-state transmitter with VSWR foldback is shown in Figure 6.2-42.

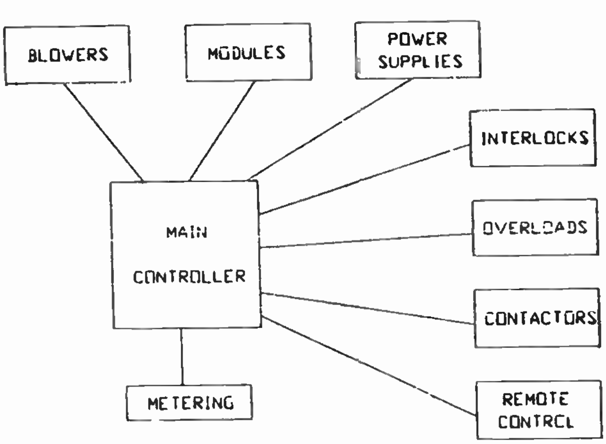

Figure 6.2-41. Centralized control system.

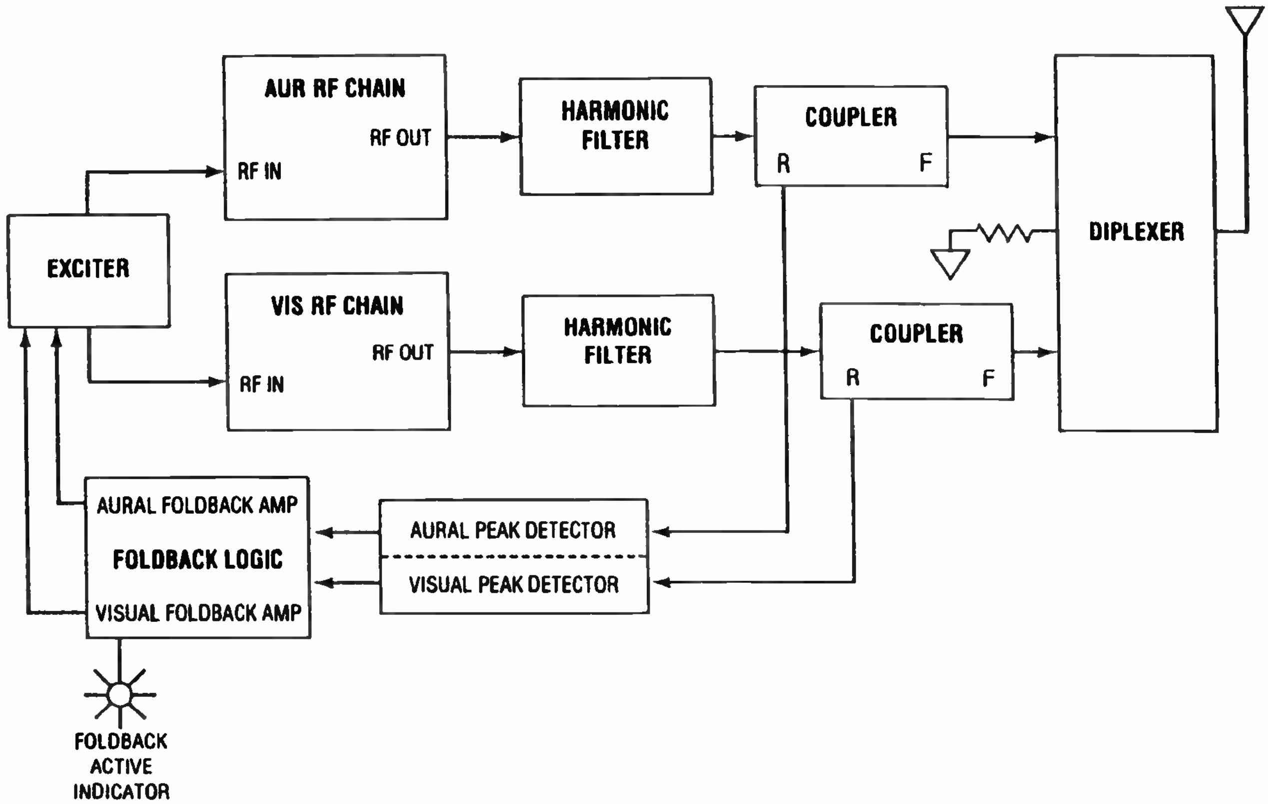

Figure 6.2-42. VSWR foldback block diagram.

UHF TUBE TRANSMITTERS

Due to higher transmitter power, power consumption and efficency are of utmost importance for UHF transmitters. A variety of tube technologies are available to address this requirement. Some are most suited for lower power transmitter designs, others are more appropriate for the highest power requirements. These technologies include tetrodes, klystrons, multiple depressed collector klystrons (MSDC) and inductive output tubes (IOT).

Tetrodes and Diacrodes

Tetrode refers to a generic category of four element tubes suitable for the linear amplification of RF signals to the power levels for required for broadcasting. This discussion is limited to water cooled UHF TV tubes made available in recent years. These tetrodes are of cylindrical construction. The inner diameter of the anode of a typical 30 kW peak sync tetrode is barely 2 inches in diameter. The anode is domed at the upper end to make it watertight. The water jacket is a watertight container around the anode. Element spacing is quite close, especially the spacing between the control grid and the cathode which is barely .003 in. Gain is an inverse function of the control grid to cathode spacing while a direct function of control grid to anode spacing. Figure 6.2-43 is a horizontal cross sectional sketch of a typical power tetrode.

Tetrodes are biased for Class AB operation and are, therefore, more efficient than the Class A klystron. Tetrodes operating at UHF at higher power are made possible due to advances in ceramics and ceramic-to-metal bonding, pyrolytic grid structures and the method of anode cooling. They exhibit excellent envelope and RF linearity requiring only the degree of correction normally seen in VHF transmitters. The tradeoff for performance in these areas is lower power gain than most other amplifiers. Gain for a tetrode is about 15 dB.

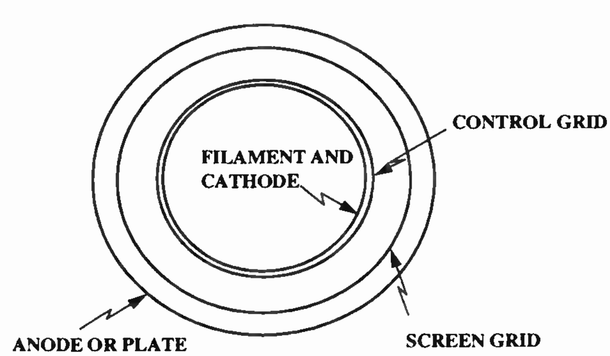

Figure 6.2-43. A horizontal cross section of a typical power tetrode showing the relative placement of the four elements.

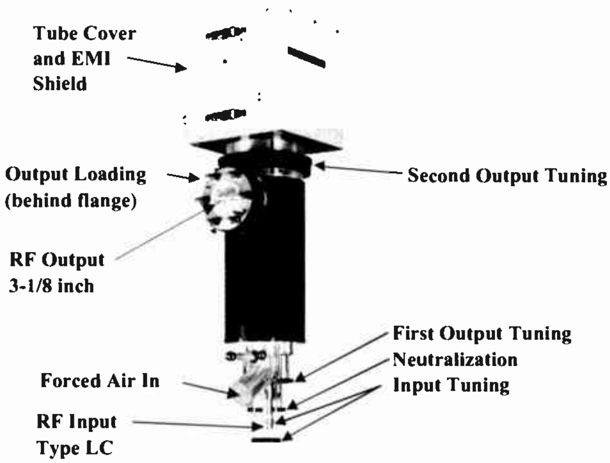

Figure 6.2-44. A representative cavity for the tetrode is shown. RF drive connects to the bottom while the output is taken from the side through the 3-1/8th in. EIA flange.

Modern UHF power tetrodes for linear television applications are capable of combined visual and aural amplification. Ten percent aural power is the norm and tubes are rated according to peak sync power with the aural carrier. For example, a typical UHF tetrode may be rated at 30 kW peak sync. Ten percent aural power is assumed giving a PEP rating of 52 kW. It is capable of 43 kW peak sync if the aural carrier is amplified separately.

Connections to these tubes are made at the base by means of concentric ring conductors, staggered in height and mating to a socket which sits above the tuning sections of the input and output networks. This allows nearly all the RF current to flow in the lower two thirds of the tube's vertical structure, the upper end being open circuited. Since the tube sits above the cavity sections, tuning is not disturbed when the tube is removed or inserted. Because inner electrode capacitances vary from tube to tube, some touch-up retuning is required. Tuning is not done at full power but at milliwatt levels.

Typical tetrodes are operated in grounded grid. Neutralization is required, but it is a one time physical setting and does not change from tube to tube. The tetrode is cathode driven with a low "Q" input tuning section. Output power is taken from the anode through a double tuned cavity section with loading control. The grids are grounded for RF. The tubes are cooled with distilled water. Cooling water must be non-conductive since it comes in contact with anode voltage. A representative cavity is shown in Figure 6.2-44.

The tetrode node voltage is much lower than that of the klystron. No special standoff requirements are necessary and the negative supply line of the power supply is grounded. The cathode is at dc ground potential.

Contributing to the service life of modern tetrodes is the water cooling of anode and screen grid. The method used is a process in which the water coming in contact with the anode surface is allowed to vaporize to the *nucleate boiling* state within tiny pits on the anode surface as illustrated in Figure 6.2-45. As soon as the vapor enters the main water stream a few thousandths of an inch above the surface, it condenses, releasing its heat content to the main stream. Nucleate boiling is enhanced by deliberately roughening the anode surface providing millions of boiling sites uniformly spread over the surface. If the anode surface were visible and not hidden under a watertight cap, nucleate boiling would be recognized by the formation of nearly microscopic bubbles, which quickly condense and disappear. Film boiling is maintained in between nucleate boiling sites.

The screen grid is also water cooled, but no boiling takes place.

The important electrical characteristics of a 30 kW peak sync tetrode are shown in Table 6.6-2. The basic structure of these tubes is silver-plated copper and ceramic with pyrolytic graphite grids and a thoriated tungsten directly heated cathode. Filament currents are high to minimize cathode current modulation of the cathode temperature.

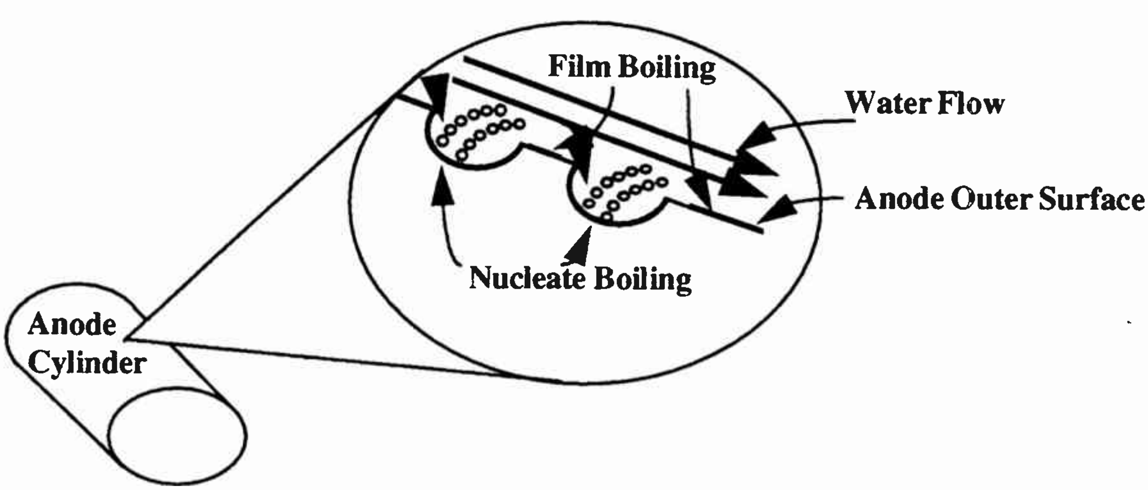

Figure 6.2-45. Cooling of the anode surface.

Table 6.2-2
Typical power tetrode electrical characteristics.

$P_{out\ PEP}$	52 kW
$P_{out\ peak\ sync}$	30 kW
10% Aural?	Yes
One dB Bandwidth	12.8 MHz
Circuit Configuration	Grounded Grid
Integral to the Cavity?	No
Power Gain	15 dB
IMD	−48 dB no correction
Neutralization	Yes
Sync Compression	5 IRE no correction
Plate (Anode) Voltage	8500 V
Anode Current Idle	2.5 A
Anode Current Black	5.6 A
Screen Grid Voltage	650 V
Screen Grid Current Black	40 mA
Control Grid Voltage	−120 V
Control Grid Current Black	20 mA
Filament Voltage	5.1 V ac or dc
Filament Current	180 A

Drive power is in series with the input/output circuits which are in series. Since the cathode is the driven element, its current is nearly identical to the anode current. Thus power gain is realized from the voltage gain.

The *Diacrode®* is also basically a four element tetrode. The same construction is used even though the shape is nothing like that of the tetrodes. Figure 6.2-46 shows a three dimensional cutaway drawing. It is made of the same materials as the tetrodes and fits into the same socket in the same cavity modified only slightly to accommodate the extra height for an external element. The operating voltages are the same except for the filament, but it delivers twice the power. (Diacrode® is a registered trademark of Thompson Tubes Electroniques.)

The flat shape allows a geometrical modification of the anode structure so that the top of the tube may be fitted with an external circuit element electrically connected between the anode (8500 VDC) and screen grid (600 VDC). The RF current and voltage distribution is shown in the drawing at the left of Figure 6.2-47.

The external circuit element is a high "Q" cylindrical coaxial transmission line electrically RF connected between the anode and screen grid. It has an insulating layer of .005 in. kapton between the cylinders used as a dc block.

Along the length of the cylinder is a circular sliding RF short circuit between the two cylinders. The purpose of the upper high "Q" transmission line section, tuned to be a shorted quarter wavelength is to reflect an open circuit to the vertical center of the anode. This causes the vertical open circuit or current minimum within the tube to be at the vertical halfway point. The result is a voltage maximum at the same point. Both vertical halves of the tube are used to make power. Since there are two current maximums, one at the usual place at the base and one at the sliding short in the upper transmission line, anode current is doubled, but operating voltages remain the same as the tetrode. The setting of the upper cavity section is quite broad with only three settings to cover the UHF band from channel 14 to channel 69.

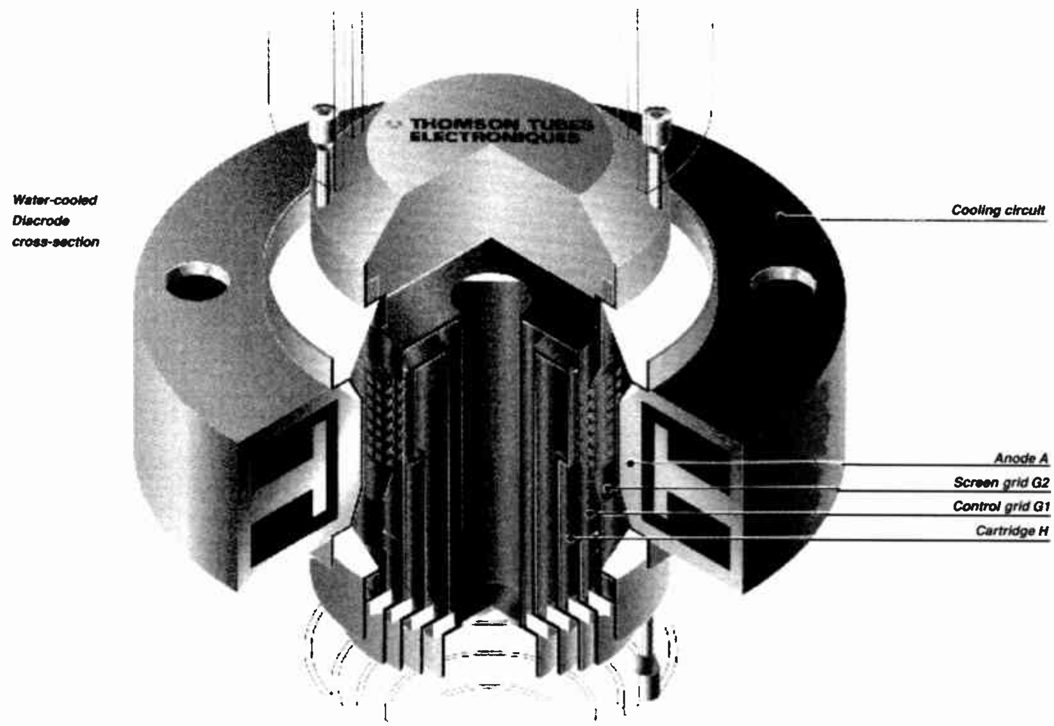

Figure 6.2-46. A three dimensional cutaway of a Diacrode® showing all four elements of the tube and anode water path.

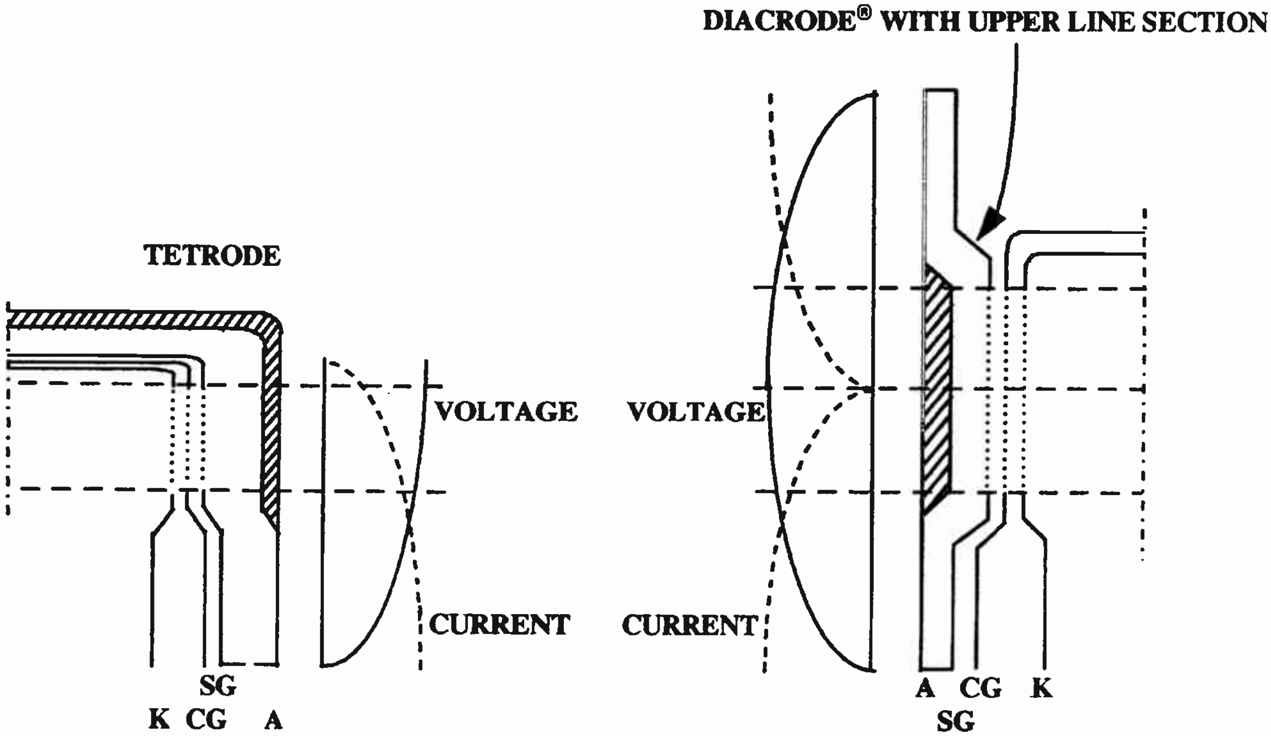

Figure 6.2-47. The upper shorted quarter-wave line section above the Diacrode® causes two current maximums instead of the single one in the tetrode.

The Tetrode Transmitter

A block diagram of a NTSC tetrode transmitter using a 30 kW tetrode is shown in Figure 6.2-48. It is an IF modulated combined amplification transmitter requiring almost 1 kW of drive power. Drive is supplied by two solid-state Class AB amplifier drawers having gain of about 23 dB. Correction circuits include low frequency linearity, differential gain, differential phase and sync compression, all performed at video and ICPM, stereo pilot protection, in-band intermodulation distortion and cross modulation, all performed at IF.

For good linearity the control grid and screen grid power supplies must be well regulated. These supplies are capable of modulating the amplified signal if allowed to shift with modulated drive level. It is not necessary to regulate the anode supply since the tetrode is not saturated and is relatively insensitive to anode voltage variations. Both oil filled and dry supplies may be used for the anode voltage source. Oil has a cooling advantage over convection or forced air cooling.

The filament supply must also be well regulated and should be capable of two different voltages: full voltage according to the value in Table 6.2-2 and about 20% of full voltage. The latter is known as *black heat* voltage and is used when the tube is in off air, standby mode. No cooling of any kind is needed during black heat.

Black heat is used to reduce the time to on-air, since the filament is already warm, and to reduce the thermal stress of going to full filament power. The filament voltage should be gradually increased from the black heat value to full value over a period of 60 seconds. Likewise, it should be gradually decreased at the end of the broadcast day for longest life.

It is imperative that the control circuitry be designed so that faults, over-voltage and over-current situations quickly disconnect the power supplies from the tube. It is also imperative that the cooling system be maintained in proper operating condition. Blocked air filters or reduced water flow due to blockages will shorten tube life even though the control system judges conditions are adequate to operate. The control system should be designed so that the transmitter will remain on air as long as minimum cooling requirements are met. The transmitter should be designed to have warning indicators posted on the front panel, available by remote monitoring. When a trip occurs, the high voltage power supply should be removed within 15 msec and dc output of the screen grid power supply immediately shorted to ground while being disconnected from the ac mains.

Klystrons

The *klystron* uses velocity modulation in the amplifying device. The electron beam emitted from the cathode is accelerated to high velocity by the electric field between the cathode and anode and is directed into the RF interaction region, as shown in Figure 6.2-49. An external magnetic field is employed to focus

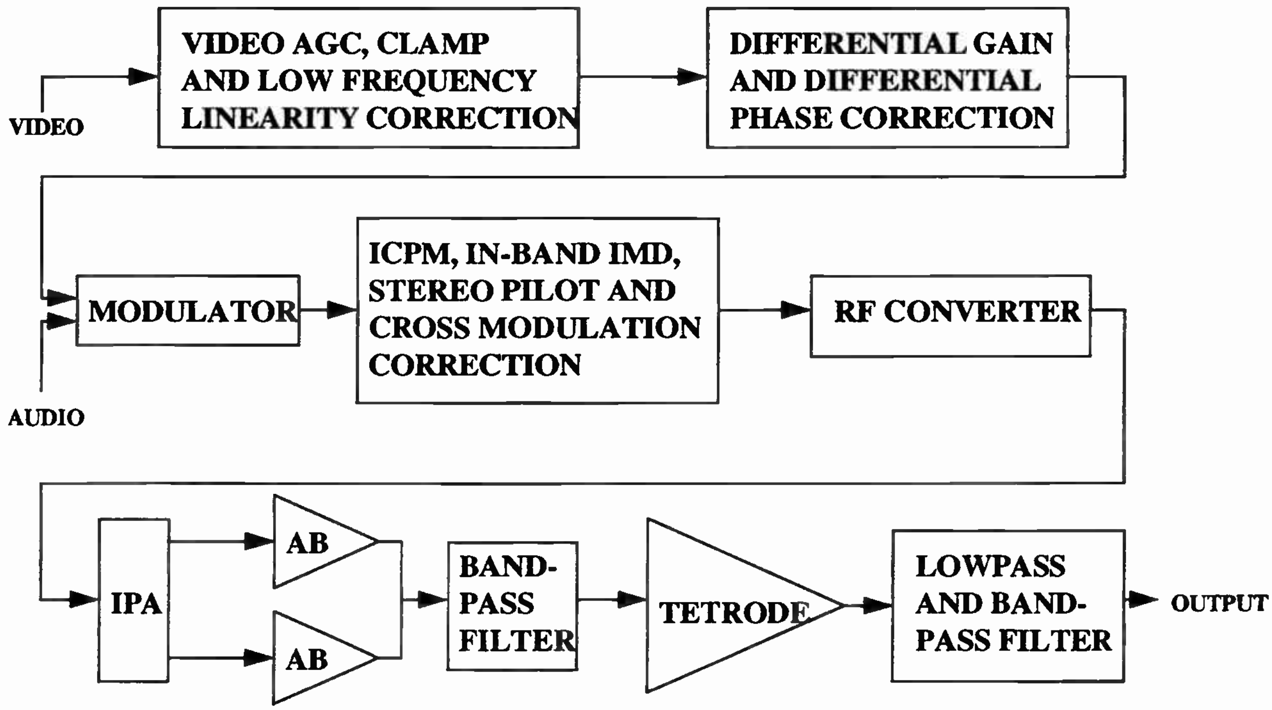

Figure 6.2-48. Block diagram of a 30 kW common amplification tetrode transmitter.

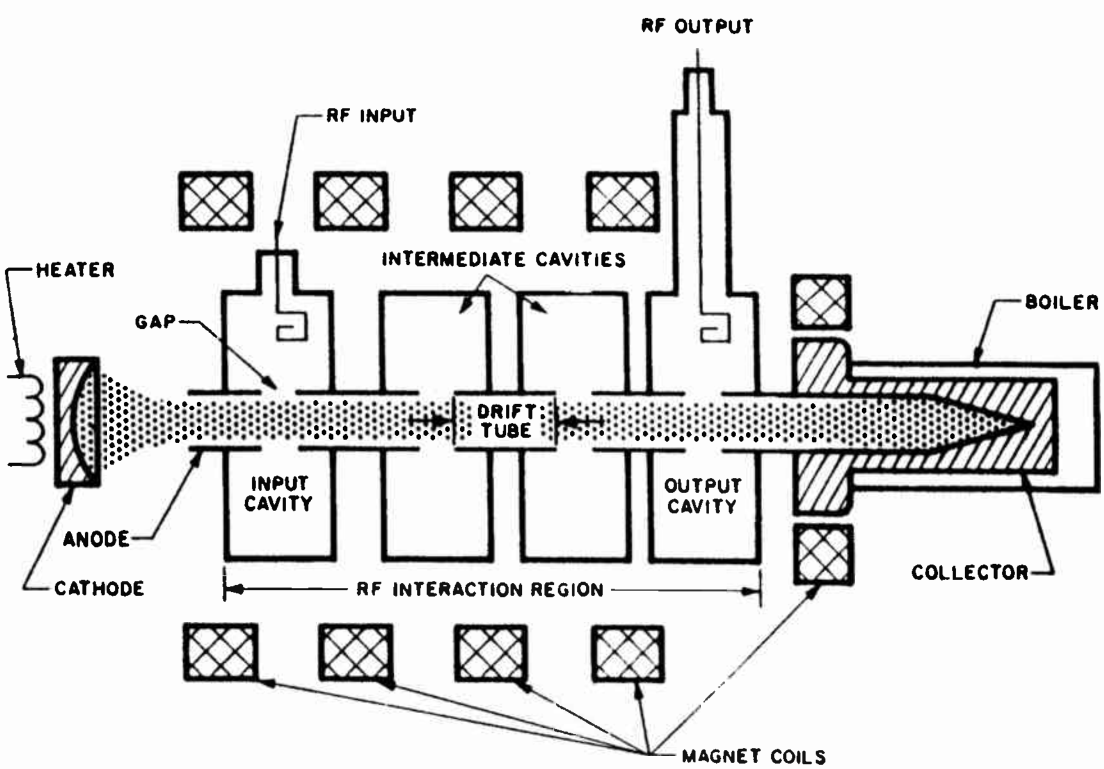

Figure 6.2-49. Principal elements of a klystron.

the beam as it passes through the tube. The electron beam impinges on the collector, which dissipates the beam energy and returns the electron current to the beam power supply.

The RF interaction region, where the amplification occurs, contains resonant cavities and field-free drift space. The first resonant cavity (the input cavity) is excited and a RF voltage is developed across the gap. Since electrons approach the input cavity gap with equal velocities and emerge with different velocities, the electron beam is said to be *velocity modulated.* As the electrons travel down the drift tube, bunching develops and the density of electrons passing a given point varies with time.

The RF energy produced by this interaction is extracted from the beam and fed into a coaxial or waveguide transmission line by means of a coupling loop in the output cavity. The dc beam input power not converted to RF energy is dissipated in the collector. The cavities can be mounted external to the klystron or can be included in the vacuum envelope. The resonant frequency of each of the cavities is adjusted by changing the volume of the cavity in external cavity klystrons, or the capacitance of the drift tube gaps is changed in integral cavity klystrons.

The RF energy is fed through a coaxial line with its center conductor inserted into the cavity. The end of the center conductor is formed into a loop. This is a simple one-turn transformer which couples energy into the cavity as shown in Figure 6.2-50. Intermediate cavities may have their loops coupled into RF loads to vary the "Q" of the cavities thus to change the overall bandpass characteristics.

All cathodes have an optimum operating temperature. The operating temperature of the cathode must be high enough to prevent variations in heater power from affecting the electron emission current (beam current). However, the temperature of the emitting surface must not be higher than necessary, since excessive temperature can reduce cathode life.

There are two electrodes which may control the beam current: the modulating anode and a lower voltage (0 to 1,400 V) electrode typically used for pulsing the beam current. If the low voltage electrode is connected to the cathode, the modulating anode voltage controls beam current. Perveance is a function of the geometry of the cathode-anode structure. This can be calculated using the following equation:

$$I_b = KV_b^{3/2}$$

where:

K = Perveance
I_b = Beam current in amperes
V_b = Beam voltage

Figure 6.2-51 shows the relationship between beam current and voltage described in the previous equation. In example A, if a modulating anode of 4,000 V with respect to the cathode beam voltage produces a beam current of 0.6 A, the intersection point lies at a perveance expressed as 2.4×10^{-6} or 2.4 micropervs. Operating condition B illustrates a practical television transmitter situation in which a common beam supply of 18 kV is used to power both the visual and aural klystron. The visual tube operates at a beam current of approximately 5.0 A if the modulating anode is connected (through an isolating resistance) to the body of the tube, and the perveance is 2.1 micropervs. Since the aural output power required is much less, the dc input power is less than that required to operate the

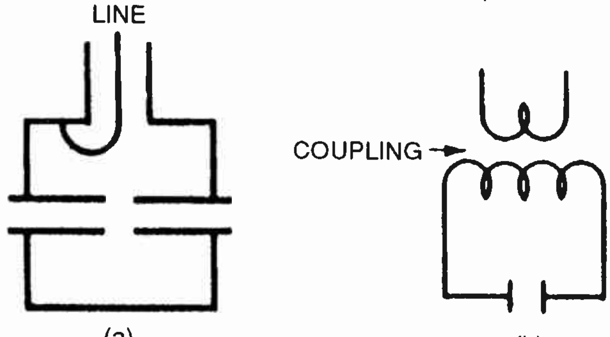

Figure 6.2-50. Loop coupling and equivalent circuit.

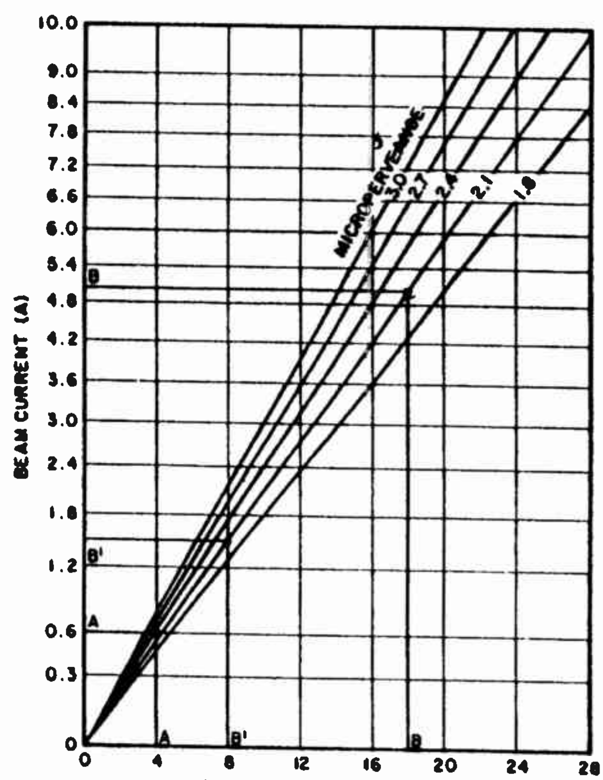

Figure 6.2-51. Beam current variation with modulating anode voltage.

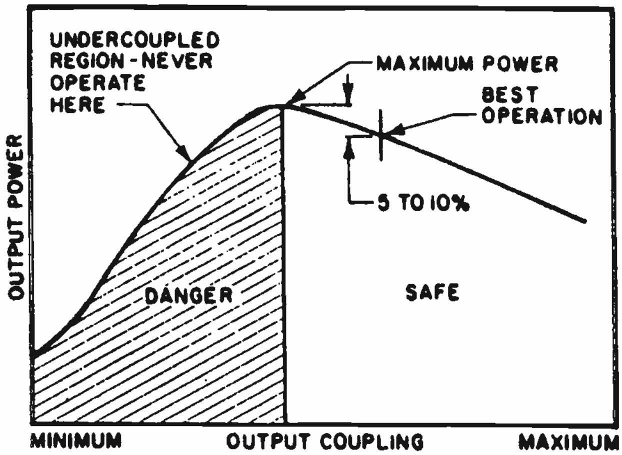

Figure 6.2-52. Adjustment of output coupling control.

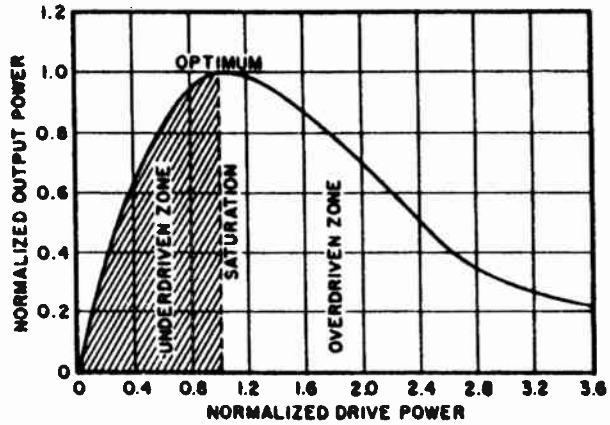

Figure 6.2-53. RF output power as a function of RF drive power.

visual tube. Points B′ indicate that if the modulating anode is supplied with only 8 kV (through a voltage divider), the intersection with the 2.1 microperv line yields a beam current of only 1.5 A, thus accomplishing the necessary reduction of input power for aural service.

Electromagnets are placed around the klystron to develop a magnetic field along the axis of the electron beam. This controls the size of the electron beam and keeps it aligned with the drift tubes. If the magnetic field is interrupted or insufficiently controlled, the electron beam will land on surfaces other than the collector and may destroy the tube.

The output cavity is generally tuned to the carrier frequency. It is essential to operate with the coupling loop adjusted so the output cavity is slightly over coupled. Figure 6.2-52 shows the relationship of output power to proper coupling loop adjustment. If the coupling loop is adjusted so that the cavity is under-coupled, arcing and ceramic fracture resulting in klystron failure may occur.

Figure 6.2-53 shows output power as a function of drive power. As expected, when drive power level is low, output power is low. As the level of drive power increases, output power increases until an optimum point is reached. Beyond this point, further increases in drive power result in less output power. In the zone labeled *Underdriven,* output power increases when the input power is increased. The point labeled *Optimum* represents the maximum output power obtainable. The tube is said to be saturated at this point, since any further increase in drive only decreases the output power. The zone formed at the right side of saturation is labeled *Overdriven.* To obtain maximum output power, sufficient drive power must be applied to the tube to reach the point of saturation. Operating at drive level beyond saturation point only overdrives the tube, decreasing output power, and increasing the amount of beam interception at the drift tubes (body current). Klystrons tuned for TV service are operated within the underdriven zone.

Figure 6.2-54 shows how output power changes with various levels of drive power applied under different tuning conditions. Point A represents saturation for a synchronously tuned tube. Points B and C show saturation reached by tuning the penultimate (closest to the output cavity) cavity to higher frequencies. Increasing the penultimate cavity frequency beyond Point D no longer increases output power. Instead, it reduces the output power as shown at Point E.

The input coupling is adjusted for the best tradeoff of minimum reflected power and best overall bandpass.

Operating a klystron at saturation improves efficiency but requires more linearity and phase compensation. By using a pulser to switch to a higher beam current during sync and back to a lesser current during video, the average beam current is significantly reduced. The practical limit of reduction of the video beam current is the point at which tip of burst and back porch distortion is not correctable.

With beam current pulsing, the effective "Q" of the electron beam and cavity combination is altered. This results in passband tilt from visual carrier down to the upper edge of the passband. This requires readjustment

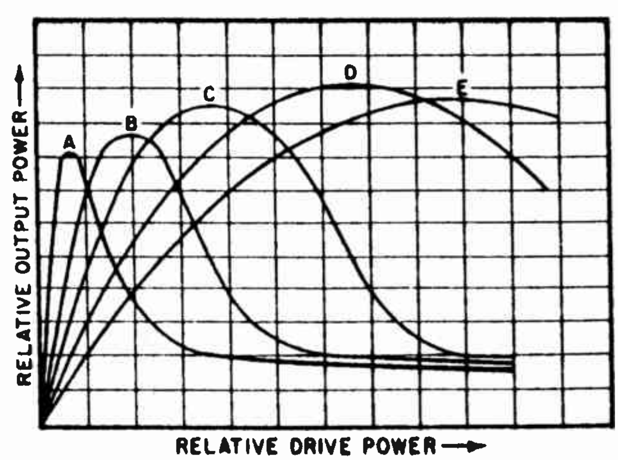

Figure 6.2-54. Output power variation with drive power under different tuning conditions.

of the cavities to obtain a flat response. Tilt of as much as 7 dB has been observed.

In static (nonpulsed) operation, the tube is supplied with enough beam current to saturate at 100% power with a small amount of headroom for changes in beam voltage. In pulsed operation only enough beam current is supplied to saturate at 100% power during sync. The amount of beam current reduction during video is dependent upon operating channel, perveance, available drive power and precorrection capability.

The optimum value of beam current must be experimentally determined. However, figures of merit of 77% have been achieved. The absolute value of the pulsed efficiency is directly proportional to, and therefore limited by, the efficiency obtained for nonpulsed operation. In order to prevent severe burst and back-porch distortion, a small amount of amplifier headroom is needed, approximately 2% to 5%.

Pulsed operation for klystrons is accomplished by connecting the beam control electrode to a voltage source of 0 to − 1,400 V with respect to the cathode. During sync, the pulser operates at 0 V. During the video portion of the signal, values of − 400 to − 800 V are used to achieve reliable high efficiency operation.

In some transmitters, sync is actually reduced or removed from the input video. As the beam current is pulsed, the klystron gain change increases the RF power to produce the proper sync level.

Effect of Pulsing on Transmitter Precorrection

Very little can be done to reduce ICPM by klystron tuning or selection of magnet current. Also, ICPM increases rapidly near saturation of the klystron.

The phase shift through a klystron changes due to the beam current (when the klystron is pulsed during sync). When the klystron switches back to the video current level, the previous value of phase returns. ICPM correctors operating at the exciter IF introduce a correction signal equal and opposite to the distortion produced by the klystron. A phase modulation stage in the exciter may be keyed by sync and adjusted to precorrect for incidental phase distortions caused in the klystron during pulsing.

When amplifiers are operating very close to saturation during the color burst, more differential gain and differential phase correction may be needed. Modern exciters can fully precorrect these conditions.

Sync pulse oscillations may appear as ringing when the klystron is operated at saturation. This may exhibit itself as a tearing of the picture. This ringing is believed to be caused by secondary electron feedback enhanced by the reverse gain of the klystron cavities. Rebiasing the tube slightly out of saturation will eliminate the ringing.

Multi-stage Depressed Collector (MSDC) Klystrons

Klystron amplifiers operate by converting energy from a beam of electrons to RF output power. At full output power, about half of the beam power is converted to output power. Correspondingly, half the dc input power remains on the beam as it exits the cavity region. In a standard klystron this *spent electron beam* energy is dissipated as heat. The MSDC klystron, however, operates on the *spent electron beam*, recovering its energy to reduce the dissipation. In the depressed collector technology, power recovery in the collector region is accomplished by decelerating the electrons in the spent beam. This is done by providing an electric field in the collector such that the electrons are slowed before they strike the collector wall. A collector composed of multiple elements is utilized, with each element operated at a negative potential with respect to ground. Consequently, the collector potentials are referred to as being *depressed* below ground.

The interaction process has produced a wide range of velocities for individual electrons. The collector geometry is carefully selected to provide an electric field shape which sorts the impinging electrons according to their velocity, reducing their energy as much as possible, yet ensuring that all electrons strike one of the elements and are not reflected into the electron beam.

Figure 6.2-55 shows the resulting collector configuration. The collector is composed of five elements and is designed to operate with equal voltages between elements. For a 60 kW klystron, the voltage per collector stage is typically 6.25 kV. This means that element 1 is at ground potential, element 2 is at − 6.25 kV, element 3 is at − 12.5 kV, element 4 is at − 18.75 kV and element 5 is at full cathode potential of − 25 kV. To make sure that the electron beam is optimized before entering the collector region, a refocus coil is provided just ahead of the collector.

The significant benefit of the depressed collector klystron is the reduction in power consumption for a given power output. The individual collector beam

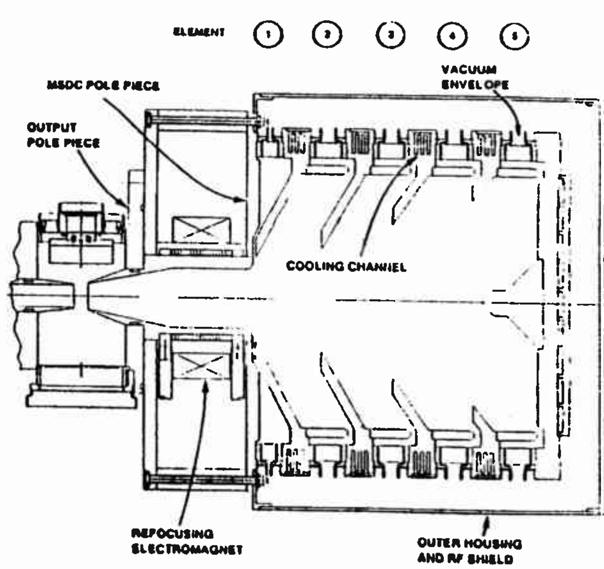

Figure 6.2-55. UHF-TV MSDC design.

currents vary depending on the picture level. Since the recovering of the spent beam takes place in the collector, it has essentially no impact on the tuning and normal precorrection of the klystron. The depressed collector technique can be applied to either external or integral cavity klystrons.

Since the power dissipated in the collector is reduced, only six gallons per minute of high purity water coolant is needed. The efficiency of the MSDC is dependent upon the transmitter configuration. Figures of merit of 1.2 to 1.6 have been obtained in transmitter installations in the field.

Transmitter Design Using Multiple Depressed Collector Klystrons

The primary differences in this transmitter from a standard klystron transmitter are in the beam supply and the cooling system. Figure 6.2-56 shows the power connections made to a MSDC klystron. Since the RF performance of the MSDC klystron is the same as the standard klystron, there are no differences in the RF driver chain.

The cooling system of a MSDC klystron transmitter uses a two-stage heat transfer system as shown in Figure 6.2-57. A two-stage system is chosen to allow outside heat exchangers to be used. The cooling system consists of a high purity water loop and a glycol-water mixture loop. High purity water (resistivity of 200,000 Ω cm or more) must be used with the cooling system to prevent current flow between collectors. To remove ions, free oxygen and other possible contaminants from the water, a three-stage purification loop is used. The filter cartridges sample part of the water flow so the whole system is continuously cleaned. The filter cartridges can be replaced without taking the transmitter off the air.

Separate beam supplies for each klystron are frequently used. Since the currents from the beam supplies change dependent on the power level, there are video frequency currents present on the power supply leads. Therefore, sufficient bypassing and power supply high voltage wire shielding is required. Monitoring each section of the beam supply current is required to obtain the currents for power dissipation calculations.

Protection circuitry should include magnet overcurrent and undercurrent trip points, beam supply overcurrent and overvoltage sensors (for each collector), water flow sensors, arc detectors within the 3rd and 4th cavities and sufficient interlocks to prevent personnel from accidentally coming in contact with high voltage.

Inductive Output Tube (IOT)

The IOT combines features of a tetrode and a klystron. Hence, the tradename *Klystrode*® is also used. The electron beam is constrained similar to that of a klystron—that is, by electromagnets. The modes of operation of the IOT are similar to that of a tetrode. However there are significant differences due to the different geometries. (Klystrode® is a registered trade mark of CPI.)

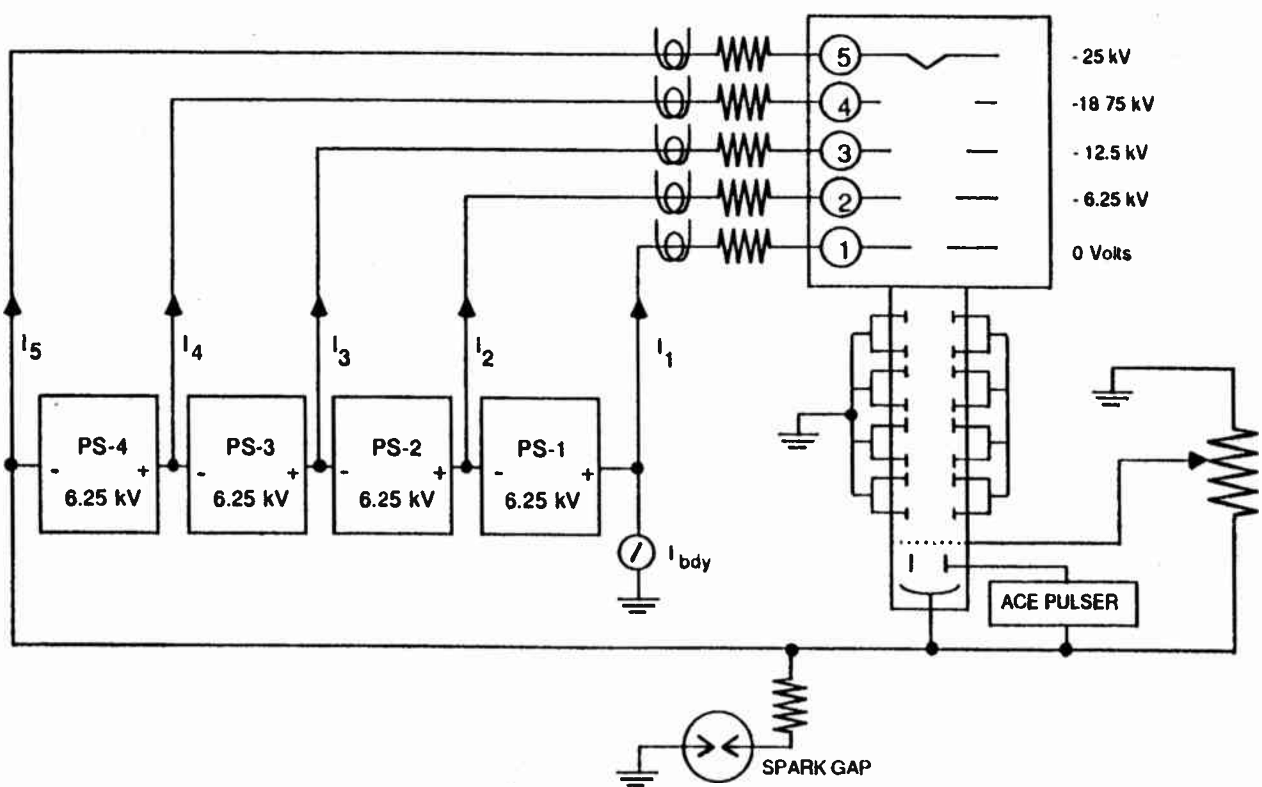

Figure 6.2-56. MSDC high voltage connections.

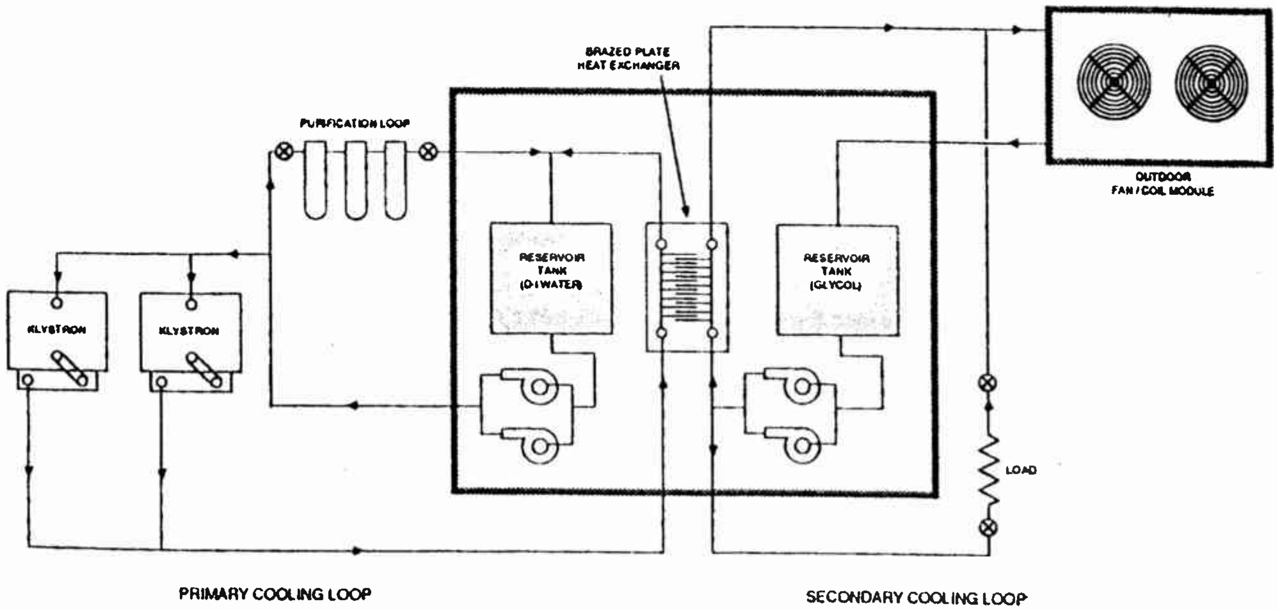

Figure 6.2-57. TV 60 UM heat exchanger system.

An IOT is shown schematically in Figure 6.2-58. It is composed of an electron gun—very similar to a klystron—a control grid, an input cavity, accelerating anode, drift tube, output cavity and collector. The electrodes are arranged linearly, unlike the concentric configuration of a tetrode. It is physically smaller than a klystron weighing approximately 400 lbs including the tuning cavities and magnet assembly. The tube itself weighs about 60 lbs.

The electron beam is formed at the cathode, density modulated with the input signal applied to a grid and then accelerated through the anode aperture. In its bunched form, the beam drifts through a field-free region and then interacts with the RF field at the drift tube gap in the output cavity. Power is extracted from the beam in the output cavity in the same manner as a klystron. The grid structure may intercept some electrons causing a small amount of grid current. This will increase if the tube is overdriven.

Input power is applied to the control grid via a resonant cavity. The grid is biased negatively near cutoff as a Class B or Class AB amplifier. The first part of the tube may be thought of as a triode with a perforated anode through which the electron beam is guided by electric and magnetic fields. The beam is bunched at the radio frequency and is accelerated by the high anode potential. It passes through the anode extension cylinder, which is an electrostatic shield, and then interacts with the RF field in the output gap. The spent beam is dissipated in the collector, which is separate from the output RF interaction circuit.

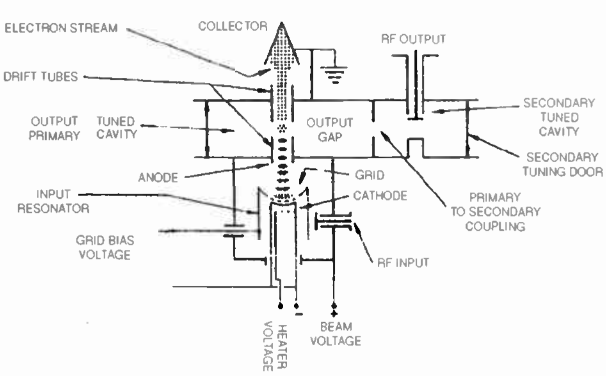

Figure 6.2-58. Klystrode schematic.

The tuned input and output circuits are external to the vacuum envelope. The input circuit consists of a stub tuner and resonant coaxial cavity, which match the drive source to the high impedance grid. Also included is a circuit which provides a dc block for high voltage. The output cavity is clamped to the body of the tube with techniques similar to those used for external cavity klystrons. The output circuit is double-tuned to achieve the bandwidth required for visual service. The double-tuned output circuit consists of a primary cavity clamped to the body and an iris- or loop-coupled secondary cavity. The output transmission line is probe coupled to the electric field or loop coupled to the magnetic field in the secondary cavity. (Coupling methods are different for different manufacturers.) Variable controls are used to adjust primary and secondary cavities to the same resonant frequency. Additional controls are used to adjust the intercavity and output couplings. Because the tube has only two cavities, it is much shorter than a klystron. The magnetic field requirements of the tube are produced by a solenoid powered by a supply of about 6 to 7 V at 25 to 30 A.

The high voltage circuitry is contained within a shielded compartment on top of the input circuit. This circuitry consists of various filters to contain the fields and prevent instabilities at video frequencies. High voltage grid bias and filament power enter this section via high voltage cables.

The fundamental benefit of the IOT is that it may operate as a Class B amplifier, resulting in high efficiency. Thus the beam current (I_b) is proportional to the RF drive signal (V_g), following the modulation envelope according to the three halves law:

$$I_a = K(V_g + V_a/\mu)^{3/2}$$

where μ is the amplification factor. The perveance (K) is proportional to the cathode area and inversely proportional to the square of the grid to cathode spacing. The drive voltage is not normally high enough to cause the instantaneous grid voltage to become positive. Although the efficiency of the IOT is dependent upon the transmitter configuration, figures of merit of 1.2 to 1.4 have been obtained for 60 kW visual service from transmitter installations in the field. In aural service, the IOT is tuned the same as for visual service. A single tube covers the entire UHF operating band, although two slightly different input cavities are required.

Power gain in either visual or aural service is about 21 dB. Thus drive power is about 500 W for the visual and 50 W for the aural (assuming 10% nominal aural power). A typical transfer curve is shown in Figure 6.2-59. The amount of nonlinearity is similar to a tetrode; the transfer function is "S" shaped. The nonlinearity of the beam current causes distortion of the fundamental UHF component and generation of signals at multiples of the UHF frequency. Harmonics do not excite the output cavity and therefore do not affect the quality of the transmitted signal. The linearity improves as the quiescent current is increased from zero, becoming optimum when at 8 to 9% of the maximum value. The transfer characteristic eventually saturates at high power levels, as is the case with all power amplifier devices. However, in an IOT, the grid voltage may be driven positive with respect to the cathode for short periods of time. This enables the tube to amplify the high power, short duration signal peaks present in digital TV signals, and also to transmit the high peak envelope power that occurs during common amplifier operation in an analog transmitter. The nonlinearity

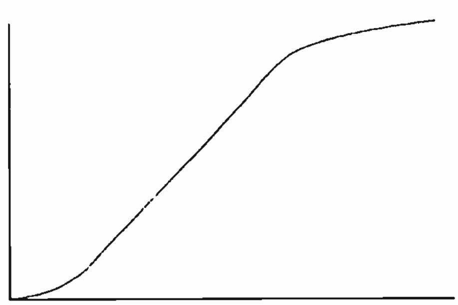

Figure 6.2-59. IOT transfer curve.

increases as the load impedance is increased to boost efficiency. Limited bandwidth of the input circuit also increases nonlinearity.

The IOT may also be used in multiplexed or common amplification mode. For example, a 60 kW tube may be used at 40 kW visual with a 10% aural signal. Intermodulation products at ±920 kHz from visual carrier generated by the tube can be precorrected by low level IF and/or RF circuitry.

Cooling of the IOT at the 60 kW power level under maximum ambient temperature conditions requires about 25 gallons per minute of water for the collector. The body of the tube is also water cooled. A 50:50 water/glycol solution is typically used in cold climates without any special water purification. The input and output cavities are air cooled. The 15 kW and 40 kW IOTs may be air cooled. The volume of air and air pressure needed are comparable to a tetrode of similar power.

Transmitter Design Using IOT

Support circuitry for the IOT consists of the necessary drivers, precorrection, power supplies and protection circuitry. An IOT transmitter block diagram using common amplification is shown in Figure 6.2-60.

The IOT uses a beam voltage of 32 kV to 36 kV. Since the beam current changes with modulation, video frequency currents are required from the beam supply. The beam supply must be designed to provide excellent regulation from no load to full load and to also provide a low source impedance for all video frequencies. In the event of a high voltage failure, the beam supply should limit the energy dumped into an arc. The supply, being stiffer, requires a triggered crowbar circuit to limit the beam supply arc energy. A block diagram of a *crowbar circuit* is shown in Figure 6.2-61.

The grid bias supply of −10 to −70 V with respect to the cathode floats with the beam voltage. A simple method of developing the grid voltage is to use zener diodes connected between the power supply and the tube cathode connection and tap the grid to the appropriate zener to obtain the desired bias current. As with klystrons, the magnet power supply must have sufficient energy storage that the beam remains focused until the beam decays. A power supply for the ion vacuum pump is needed with appropriate sensors for the protection circuitry. Other protection circuitry provided in the IOT transmitter is similar to that needed in the klystron transmitter.

TRANSMITTERS FOR DIGITAL TELEVISION (DTV)

Each of the transmitter technologies previously described have been found to be suitable for transmission of DTV. Early in the development of the DTV transmission system, klystron, MSDC and solid-state amplifiers were used for over the air transmission tests. More recently, experimental stations have gone on air using both IOT and solid-state final amplifiers. Just as for

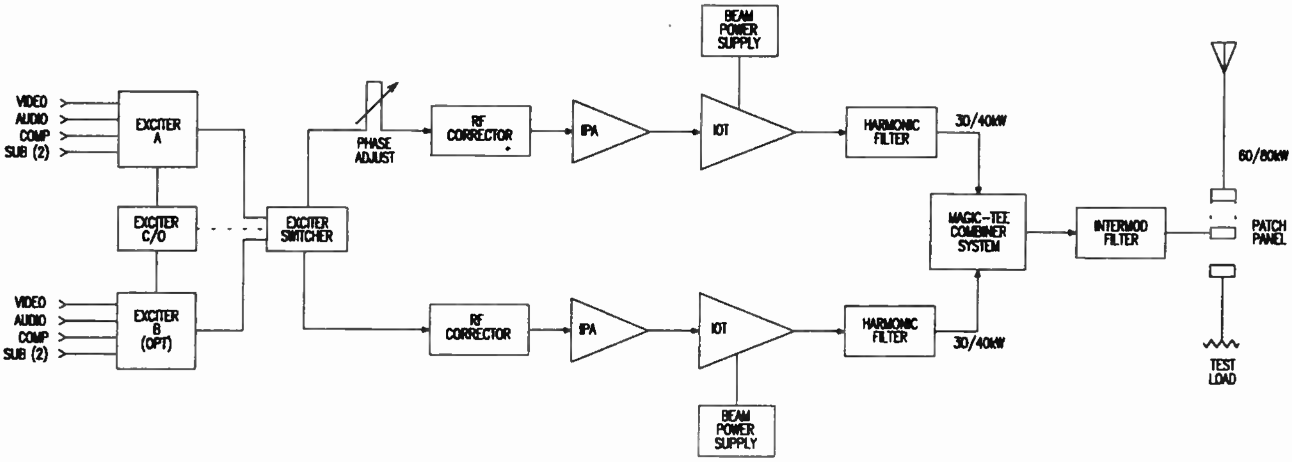

Figure 6.2-60. IOT transmitter block diagram.

NTSC, the key requirements for the final amplifier include adequate peak and average power rating, a linear transfer function and adequate bandwidth. The average DTV power afforded by a tetrode or IOT is about 40% of the NTSC peak sync power rating. Anode voltage is increased slightly from that used for NTSC for best in-band and out-of-band performance. Solid-state amplifiers will produce DTV power in excess of 30% of their NTSC peak power rating.

Even though station effective radiated power (ERP) and transmitter power output (TPO) are defined on the basis of average power, the tradition of transmitter power rating according to NTSC peak sync power has been carried forward so that most transmitters and tubes identified by means of their approximate power capability. However, average power rating is always available and should be used when selecting equipment.

Peak power rating is difficult to measure because of the random nature of the DTV signal. A peak-to-average ratio of 6 to 7 dB is usually assumed, although peaks as high as 11 dB above the average level have been measured. In practice, knowledge of the peak power is not as critical as with NTSC. The important parameters are average DTV power to support the target ERP and linearity of the transmitter sufficient to meet the FCC radiation mask specification. If these parameters are satisfied, the actual peak power need not be known with precision.

The distortion to DTV is highly dependent on the characteristics and number of driver stages. For both tube and solid-state finals, the driver stages are normally solid-state, some of which usually are operated in Class AB. The ideal transfer curve would be that of a Class A amplifier. However, this would result in high levels of dissipation and attendant cooling and power supply issues. To overcome the out-of-band products generated in the Class AB stage(s), a RF linearity correction circuit may be used. Both compression and crossover correction capability is required to suppress out-of-band intermodulation products at the band edge up to 10 dB. Alternatively, a feed forward amplifier design maybe used to provide the linearity of a Class A amplifier without the efficiency penalty. A bandpass filter is required for out-of-band suppression 3 MHz above and below the channel band edge.

The prime power required for digital transmitters is somewhat simpler to determine, compared to NTSC transmitters. The ac power required will be very nearly constant since the RF output is constant. There is no separate aural amplifier, so there is no need to consider variations in visual power and the aural power. In general, the power required will be less than for the

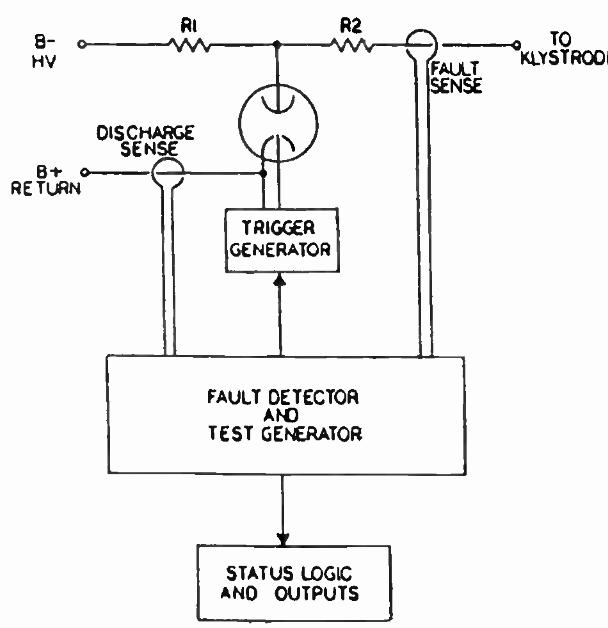

Figure 6.2-61. Triggered crowbar circuit.

corresponding peak NTSC power using the same type of amplifier technology in the same band. Likewise the cooling load is constant and somewhat lower than for NTSC.

PERFORMANCE MEASUREMENTS

The quality of the broadcast television transmitted signal is the responsibility of the broadcaster. Intermediate frequency modulation, solid-state SAW vestigial filters and sophisticated precorrection circuits make transparent performance possible. Precision demodulators with synchronous detection and SAW filters are capable of near ideal detection. Test waveforms and digital signal synthesis provide accurate test signal generation to complement transmission facilities.

The Electronic Industries Association Standard RS-508 takes into account empirical quality factors and reflects a common denominator for new transmitter performance. This standard is a valuable reference document which describes performance parameters, standards and methods of measurements.

A thorough proof-of-performance at the time of installation is an invaluable record of normal operating performance. It also serves as verification of proper signal quality and emission standards. The number of detailed measurements required after the proof usually can be limited since several performance characteristics are a measure of the same impairment. Also, some test waveforms are more useful for transmitter adjustment than others.

Transmitter measurements can be considered in two primary categories: frequency response and linearity.

In the time domain, 2T modulated sine squared pulses and multiburst waveforms are used in identifying and correcting linear distortions. In the frequency domain, swept amplitude and group delay measurements can be used, but are normally reserved for out-of-service testing.

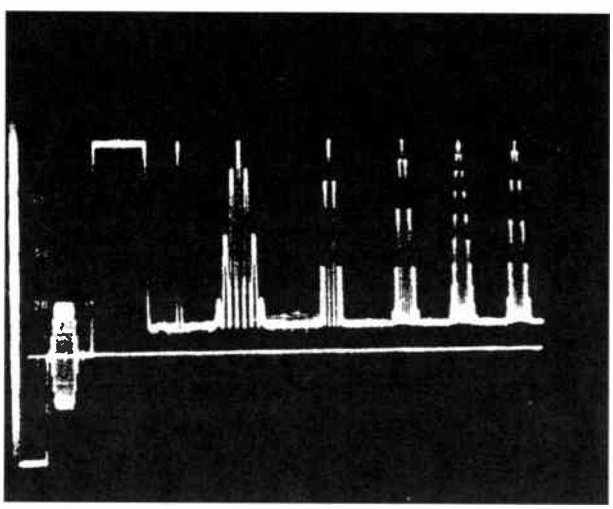

Figure 6.2-62. Multipulse test waveform.

The multipulse signal shown in Figure 6.2-62 may also be used to analyze group delay. The multipulse signal consists of a gray flag (80 IRE), 2T pulse and five sine squared pulses (one 25T pulse and four 12.5T pulses) modulated with five discrete frequencies.

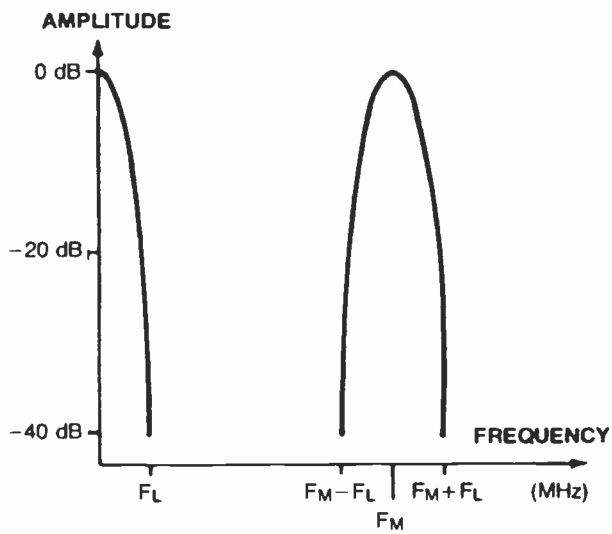
The modulated pulses contain low-frequency and high-frequency information, as illustrated in Figure 6.2-63. If the low-frequency spectra and the high-frequency spectra are delayed equally, the results will be a symmetrical modulated pulse with the same shape as the input. The gain versus frequency distortion will alter the base line flatness but will not change pulse symmetry. Delay errors will result in an asymmetrical pulse baseline. Combinations of group delay and gain errors are shown in Figure 6.2-64.

A method of quantifying these distortions uses the waveform graticule shown in Figure 6.2-65. This graticule was arrived at empirically and represents constant perceptible distortion levels. This shows that overshoots closer to the desired pulse are not as perceptible as ringing further away. The desired K factor graticule (2%) is overlayed on a waveform monitor and the group delay corrector is adjusted until the 2T waveform lies entirely within the graticule. This technique is often preferred to swept group delay measurements because the results are in terms of perceptibility.

To ascertain the carrier frequency of a station operating under precision frequency control, measurement equipment should meet the following accuracy requirements:

VHF Low Band	$+2.5 \times 10^{-9}$
VHF High Band	$+1 \times 10^{-9}$
UHF	$+3 \times 10^{-10}$

Frequency counters with the above accuracy and calibration traceable to the National Institute for Stan-



$F_L = \dfrac{1}{\text{H.A.D.}}$

F_M = MODULATING FREQUENCY

Figure 6.2-63. Energy spectrum for modulated pulses.

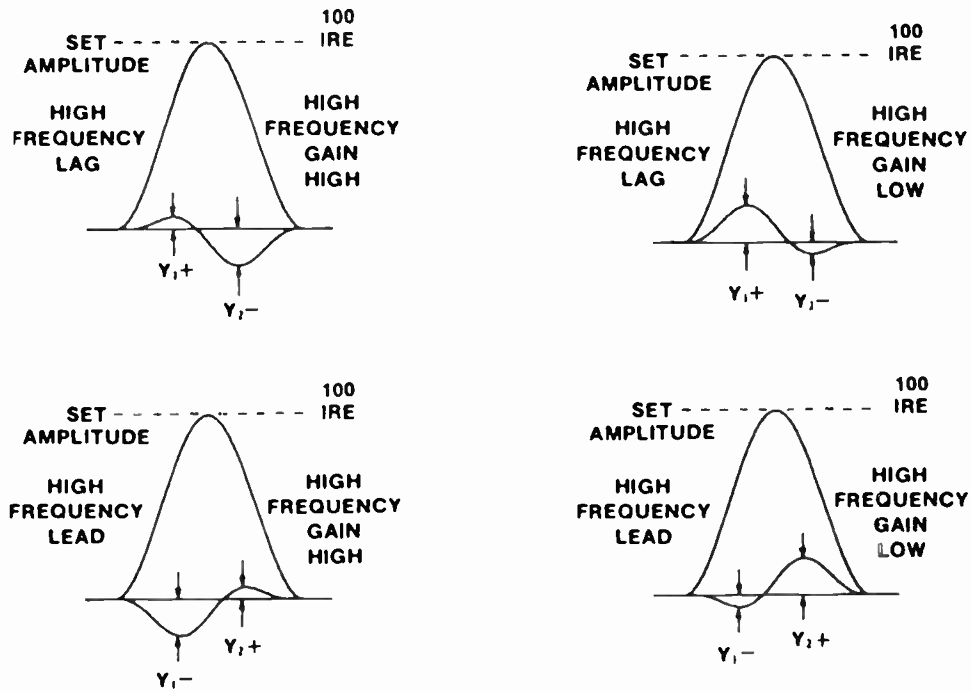


Figure 6.2-64. Modulated sine-squared pulses with gain and phase errors.

dards and Technology (NIST) may be used for making these measurements.

To test for nonlinear distortions as a function of average picture level (APL), one line of the video waveform is alternated with four lines containing a static luminance level. Figure 6.2-66 contains a modulated staircase with three average picture levels.

Modern transmitters are designed for unattended operation for extended periods of time. A properly adjusted transmitter operating with adequate cooling and regulated power lines may need only be checked in detail every three or four months or whenever a major component is replaced or repaired.

The following pretest checklist and sequence of tests are presented as a general guide for a properly adjusted transmitter. Many adjustments are interrelated and require returning to previous tests to verify proper performance. The test sequence is intended to minimize the number of adjustments.

Pretest Checks:
- Test equipment
- Input video
- Output transmission line, station load, and antenna
- Alternating current mains input
- Record meter readings, adjustment settings and key performance parameters

Transmitter Test Sequence
1. Exciter linear and nonlinear performance
2. Intermediate and driver linear amplifier performance
3. Swept frequency response

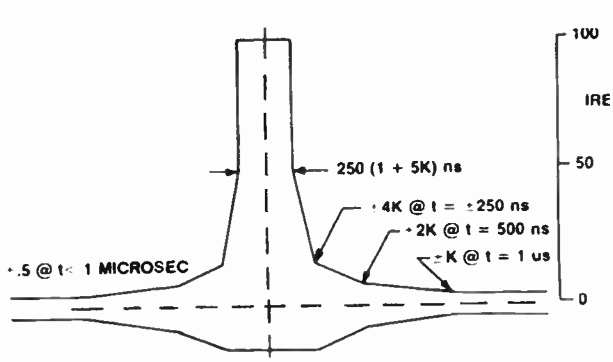

Figure 6.2-65. 2T sine-squared pulse graticule.

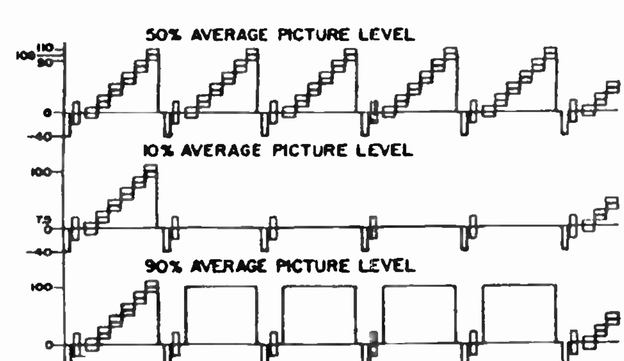

Figure 6.2-66. Modulated staircase waveform.

4. Modulation depth (includes UHF pulser and sync ICPM adjustments)
5. Power output meter calibration
6. Nonlinearity response (differential gain, ICPM, differential phase)
7. Linear response checks (group delay, pulse tests, composite waveform K factors)
8. Record meter readings, adjustment settings and key performance parameters.

During periodic measurement and adjustment, it is a good practice to record meter readings and adjustment settings before and after the test. These recordings will indicate normal setting range and can aid in getting the transmitter to near normal in the event of mistuning errors during adjustments.

In order to make satisfactory measurements of video signals, adequate test equipment is required. Measuring the output of a television transmitter at baseband requires a precision television demodulator. For greatest accuracy, this demodulator should provide a zero carrier reference pulse for determining percentage of modulation and have both synchronous and envelope detection modes.

For most baseband measurements, a video waveform monitor is all that is needed. The waveform monitor should include a provision for making measurements on vertical interval test signals (VITS) and provide filtering to allow separate examination of the luminance and chrominance components of color signals.

In addition to the waveform monitor, a vectorscope must be used for making differential gain and phase measurements. If a greater level of accuracy is desired in timing measurements, a conventional oscilloscope with an associated digital counter/timer is a great asset. For off-air monitoring, a picture monitor is convenient for quickly identifying gross video degradation.

Maintenance logs should include date, time, duration of outages, corrective action taken, and if possible, cause of failures.

Monitoring TV Multichannel Sound

Maintaining a high quality aural signal requires high quality monitoring facilities. To be able to perform the proof-of-performance measurements is another important reason to have a monitor that demodulates the RF signal and separates the components in the composite MTS signal for analysis.

An ideal modulation monitor should:

- Demodulate the composite signal from the aural carrier
- Separate the components in the composite MTS signal for measurements
- Provide in service monitoring capability
- Be suitable for proof of performance measurements
- Contain a precision (BTSC) expander.

Testing for Digital Television

The key measurements required for a DTV transmitter proof-of-performance include output power, pilot frequency, intermodulation products (IMD), error vector magnitude (EVM) IMD and harmonic levels.

1. The RMS output power may be measured with with a calorimeter.
2. The pilot frequency may be measured with a frequency counter or spectrum analyzer. The results should be the frequency of the lower channel edge plus 309,440.6 Hz, ±200 Hz, unless precise frequency control is required.
3. The FCC rules in 73.622 (h) states the power level of emissions on frequencies outside the authorized channel of operation must be attenuated no less than the following amounts below the average transmitted power within the authorized channel. In the first 500 kHz from the channel edge the emissions must be attenuated no less than 47 dB. More than 6 MHz from the channel edge, emissions must be attenuated no less than 110 dB. At any frequency between 0.5 and 6 MHz from the channel edge, emissions must be attenuated no less than the value determined by the following formula:

   $$\text{Attenuation in dB} = -11.5(\Delta f + 3.6)$$

   where: Δf = frequency difference in MHz from the edge of the channel.

   This attenuation is based on a measurement bandwidth of 500 kHz. Other measurement bandwidths may be used as long as appropriate correction factors are applied. Measurements need not be made any closer to the band edge than one half of the resolution bandwidth of the measuring instrument. Emissions include sidebands, spurious emissions and radio frequency harmonics. Attenuation is to be measured at the output terminals of the transmitter (including any filters that may be employed). In the event of interference caused to any service, greater attenuation may be required.

   In practice, it is recommended that the IMD level be measured with the resolution bandwidth set for 30 kHz throughout the frequency range of interest. This results in an adjustment to the FCC formula to account for the difference in the resolution bandwidth as stated in the rule. The adjustment is computed to be 10 log (6/.5) or 10.8 dB. Under this test condition the measured level should be −36 dB from the mid band levels to the shoulder levels.
4. Output harmonics may be measured with a spectrum analyzer. They should be at least −110 dB below the mid-band power level.
5. Measure the error vector magnitude (EVM). At the time of this writing, the only known test equipment available for measuring this parameter is a vector signal analyzer.

The output power, pilot frequency, in-band frequency response and adjacent channel spectrum should be measured periodically to assure proper transmitter operation. These parameters can be measured while the transmitter is in service with normal programming.

PREVENTATIVE MAINTENANCE

A good preventative maintenance program includes periodic inspection and cleaning of the equipment. A vacuum cleaner is preferred to remove dust instead of compressed air which will simply blow the dirt onto something else. A paintbrush can be used to dislodge dust from delicate circuit boards. Avoid using a nylon bristled brush with a plastic handle as the static charge may damage CMOS or other static sensitive components. A natural bristle brush with wooden handle and metal binding is recommended.

High voltage wires and insulators must be cleaned with denatured alcohol, or other cleaner capable of removing the dirt without leaving any residue. Meter cases are cleaned with nonstatic cleaner.

Air filters should be replaced or cleaned to maintain adequate air flow to the equipment. A second set of washable filters saves time when using a single transmitter in critical service by quickly switching the clean filters and washing the dirty ones later. Blowers should be inspected to see if the curved fins are filled with debris that would reduce air flow. Motor windings may collect a layer of dirt and interfere with the cooling of the motor itself. The fins of high-power tubes must be cleaned of debris which may have passed through the air filters. Bearings should be lubricated and checked for excessive noise.

Color change in silver plated cavity parts is a sign of overheating and may require the disassembly of the cavity to check for obstructed air passages of loose connections. Set-screws in gear and chain drive tuning mechanisms should be checked for tightness. Black silver-oxide is a good conductor and need not be removed. Small parts should be dipped in Tarnix® for cleaning. Be sure to flush the parts after cleaning to remove any residue. Scotch-Brite® is a good nonmetallic cleaning pad for silver plated parts. Do no remove the plating when cleaning these parts.

High current wires may move during turn-on surges and can suffer abrasions which may cause an arc if not properly dressed from sharp edges. Wiring on terminal boards may loosen through thermal cycling and vibration. All connections must be checked to be sure they remain tight. If wires need to be replaced, the correct gauge, voltage rating and temperature rating must be considered when selecting the replacement.

Edge connectors on printed circuit boards should be cleaned with Cramolin® or other cleaner. A small amount is applied to the connector and then removed with a lint-free cloth. Do not use pencil erasers as this will remove gold or silver plating from the edge traces, and could degrade the connection or create an intermittent. The sulfur in the eraser causes chemical reaction to the edge connector material.

Backup systems or emergency modes of operation should be checked periodically. Relays should be exercised to keep contacts polished.

Transmitter site cleaning should include a check of the building for such things as leaks in the roof which may cause damage to the transmitter, and the presence of insects or small animals.

Intake blowers with filters capable of creating positive pressure in the room can minimize the need for cleaning.

Careful records must be maintained in order to establish a good history for future reference. Such a log will include a description of what was done, when it was done and the name of the person that performed the work. Seasonal events such as harvesting in farm locations, severe weather, construction projects in and around the transmitter building can require special action, but usually a pattern will emerge that allows the maintenance to be scheduled on a regular basis.

A complete set of meter readings taken when the equipment is working properly and updated weekly or monthly can greatly assist problem diagnosis.

Create a maintenance program with weekly, monthly quarterly, semi-annual and annual tasks evenly spread throughout the year. The following list of items can be used to develop a maintenance routine:

Maintenance Items

- Prefilter manometer readings
- Inspect prefilters
- Replace prefilters
- Post-filter manometer readings
- Cabinet input air manometer reading
- Inspect transmitter air filters
- Replace transmitter air filters
- Vacuum cabinets
- Clear tube fins
- Measure blower currents
- Clean fan blades and motor windings
- Check connections for tightness
- Inspect MOVs.

Recommended Data to be Recorded

- All parameters on meters or user displays
- Direct current input power and calculate dissipation
- Transmitter currents in black picture and at idle (no RF drive).

Visual Performance Checks

- Ensure proper video level
- Establish proper sync level
- Optimize differential gain
- Optimize ICPM
- Optimize differential phase
- Optimize group delay using T pulses
- Assure proper power calibration
- Secure proper audio processor setup
- Optimize swept response.

Aural Performance Checks

- Ensure proper modulation levels
- Establish proper SCA input levels
- Assure proper power calibration

- Secure proper audio processor setup
- Optimize audio frequency response
- Check and minimize distortion
- Optimize stereo separation
- Check and minimize crosstalk between MTS channels.

Control System Checks

- Authenticate proper operation of all interlock circuits
- Verify proper operation of all overload circuits
- Confirm proper operation of all control processes (VSWR foldback, filament timing, coax switches, etc.).

AIR SYSTEMS FOR TRANSMITTERS

Transmitters dissipate large amounts of power. Air which has already passed through the equipment and has picked up heat must be removed from the immediate vicinity to prevent the hot air from being recirculated. In addition, provisions must be made for sufficient intake air to replace that which has been circulated.

To provide adequately for hot air exhaust and fresh air intake, the maximum and minimum environmental conditions in which the equipment may operate, and the following information from the equipment manufacturer should be known:

Altitude: ______________________ (feet)

Max. temp: ______________________(°C)

Min. temp: ______________________ (°C)

Total air volume through the transmitter: ________ ____________ (CFM)

Pressure drop within the critical portion of the air circuit (across the transmitter tube for example) ____________ (inches of water)

Air temperature rise through the transmitter: ______ ____________ (°C)

Air exhaust area (A): ________________ (Sq. Ft)

Equipment layouts usually provide an area for heated air to exit from the top of the cabinet. The size and location of this exhaust area is usually shown on a manufacturer supplied outline drawing.

Most broadcast equipment internal air systems are designed to be operated into free space (back pressure of 0.0 in. of water) so exhaust ducts must have minimum loss. Good practice is to design for no more than +0.1 in. of water pressure in the duct close to the exhaust area of the transmitter.

Any exhaust installation other than a large cross-section duct (equal to the cross-section of the transmitter exhaust port) with no bends, and with a long radius turn outside the transmitter building for weather protection, will need an exhaust blower or fan.

The recommended system is sized only for cooling the transmitter. Any additional cooling load in the building must be considered separately when selecting the air system components. The transmitter exhaust should not be the only exhaust in the room as heat from the peripheral equipment would be forced to go out through the transmitter.

The *sensible-heat* load is the sum of heat loads such as solar radiation, heat gains from equipment and lights and personnel in the area that is to be cooled.

The following exhaust duct design illustrates the key cooling concepts:

$$\text{Air volume through transmitter} = 325 \text{ CFM (ft}^3\text{/min)}$$

$$\text{Air exhaust area (A)} = 3.4 \text{ square ft}$$

$$\text{Air exhaust velocity (V)} = \frac{325 \text{ CFM}}{3.4 \text{ ft}^2} = 94.5 \text{ ft/min}$$

Air velocity of 94.5 ft/min is relatively low allowing a transition to a smaller diameter pipe if desired. Assume a transition to a 10 in. diameter pipe.

$$A = \frac{\pi D^2}{4 \times 144} = \frac{\pi(100)^2}{4 \times 144} = .545 \text{ square ft}$$

$$V = \frac{325 \text{ CFM}}{\text{dia. pipe } .545 \text{ ft}} = 596 \text{ ft/min}$$

The air friction in a 10 in. diameter pipe is 0.06″ per 100 ft of pipe at a flow of 325 CFM (see Figure 6.2-67). Assuming there is 20 ft of straight pipe to a roof, with two 90° elbows to turn the pipe down for weather protection, the total loss of the exhaust is estimated as follows:

$$\frac{20}{100} \times 0.06'' = 0.012 \text{ inches of water (pressure drop in 20 ft of pipe)}$$

Consider the static pressure drop of two 90° elbows, to give a 180° bend in the pipe. From Figure 6.2-68

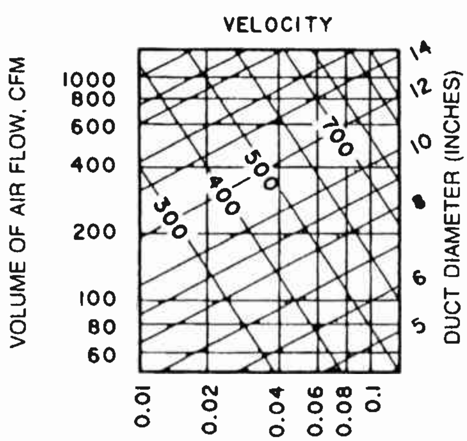

Figure 6.2-67. Friction loss in pipes.

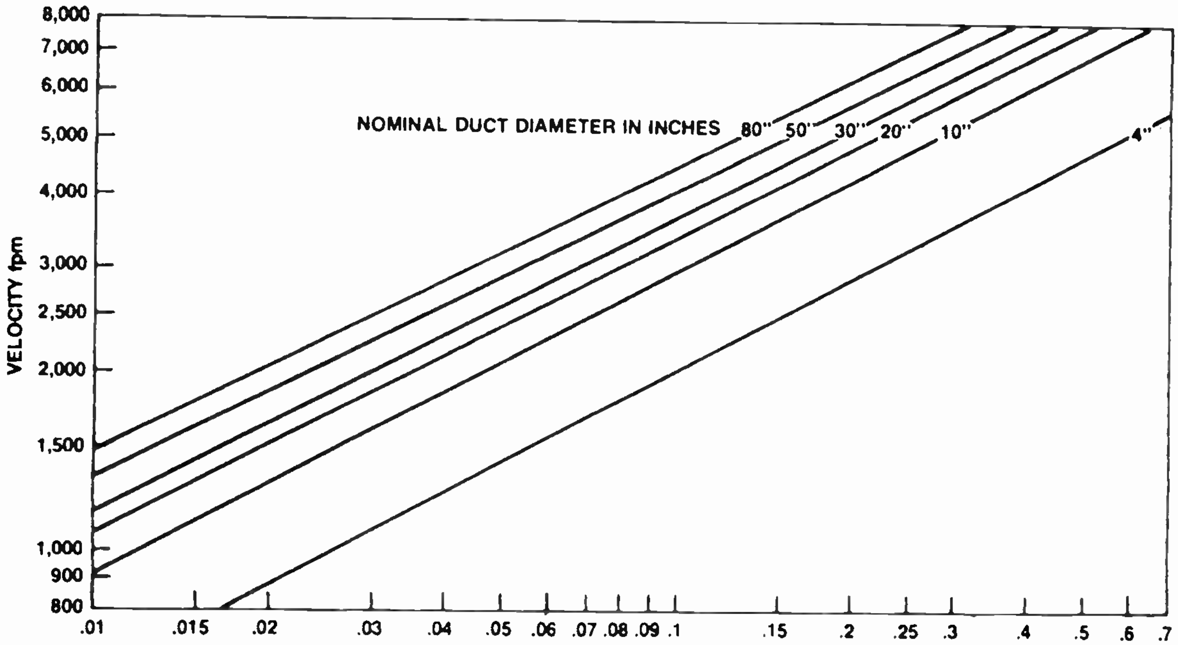

Figure 6.2-68. Friction loss in 90° elbow.

a 10 in. elbow at 900 ft/min gives less than 0.01 pressure drop. There is just under 600 ft per minute in the system. Conservatively, add .01 for each 90° elbow and .12 for the 20 ft section of 10 in. pipe.

0.012″ + 0.01″ + 0.01″ = 0.032 inch of water (total pressure drop)

No exhaust fan is necessary since 0.032 in. is less than the 0.1 in. pressure that requires a fan.

The installer may have a problem exhausting the transmitter in this simple fashion (for example a roof exit is not available). It may be required to add two additional 90° elbows and a straight run of 10 in. pipe 100 ft long. The pressure drop in the exhaust system is then:

Friction loss in 20 ft of 10 in. dia. pipe	0.012
4 elbows × .01 in. of water (each)	0.04 in.
Friction loss/100 ft of 10 in. dia. pipe	0.06 in.
	0.112 in. of water

The 0.112 in. of pressure now exceeds the level at which a fan is needed.

The performance curve for the fan, shown in Figure 6.2-69, indicates that it will deliver 325 to 330 CFM into 0.1 in. of water. This is sufficient to handle all transmitter air and overcome all estimated duct losses.

The outline drawing in Figure 6.2-70 shows a typical exhaust duct and blower system. The recommended minimum ceiling height to properly handle exhaust air as shown is 12 ft. The outline drawing also indicates a typical air intake and prefilter system.

These calculations are for a very simple air system. Most television transmitters have multiple enclosures with large volumes of air required. In these cases, the equipment user is required to combine the heat exhaust air from several enclosures into a complex duct system. When these circumstances occur, the safest practice is for the user to contract for the services of a heating, ventilating and air conditioning (HVAC) consultant. The cost involved in having the best possible air ex-

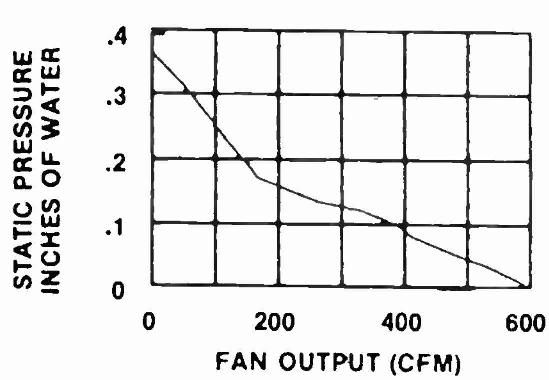

Figure 6.2-69. Fan performance curve.

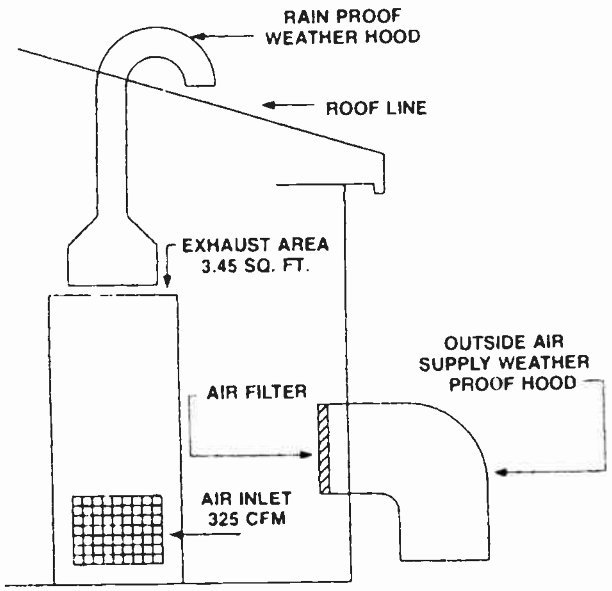

Figure 6.2-70. Suggested intake and exhaust duct installations.

haust and supply system will pay in extended transmitter life and lower service costs.

The intake vent and blower should be sized to provide a slight positive room pressure. Installing a manometer to sense pressure drop across the filters helps determine replacement interval of prefilters.

If existing space will not permit the construction of the transmitter manufacturer's recommended air system, care must be taken to modify the design to fit the available space and still properly cool the transmitter.

Additional flushing air is recommended for the removal of heat from any surrounding equipment that shares space with the transmitter. It is a recommended input air be no greater than 5°C above ambient.

Air Conditioning

It is a common practice to set the transmitter into a sealed wall forming a plenum chamber. The plenum is supplied with outside air and separate air conditioning is provided for the front side to cool personnel and source equipment.

In areas with severely polluted air, it may be necessary to run the transmitter on air conditioned air to avoid bringing in corrosive salts or gaseous contaminants.

The amount of air conditioning will depend on several factors. It is strongly recommended that the air conditioning be shared by a number of units rather than one large central system so that operation can continue in the event of the failure of one unit. Air conditioning units are usually specified by *ton* of cooling capacity with *one ton* equal to 12,000 btu per hour.

Consult experienced professionals in the area of HVAC design to achieve the desired result and to prevent problems.

KEY TERMS

Baseband. The video, audio or digital signal supplied from program input equipment. For analog TV in the United States, these signals are defined by the NTSC standard. For digital TV in the United States, the input signal is defined by the Advanced TV Standards Committee Standard A53.

Efficiency. Fundementally, the ratio of RF output power to input power, expressed as percent. For TV transmitters, special conditions apply (see section on TV transmitter efficiency).

Reliability. The degree to which equipment will operate without failure or off-air time. Quantitatively, reliability is often expressed as the *mean time between failures* (MTBF); alternatively, availablity is a useful measure.

Linearity. Refers to the degree with which the transmitter output voltage is directly proportional to the input. Common terms used to quantify the degree of transmitter nonlinearity include low-frequency or *luminance nonlinearity*, *differential gain* and *AM to AM conversion*. Output phase may also be a function of input level. The deviation from ideal linear phase is often quantified as incidental carrier phase modulation (ICPM), differential phase and AM to PM conversion.

Differential Gain. Nonlinear chroma gain as a function of luminance level. A change in the color saturation results.

Differential Phase. Nonlinear chroma phase as a function of luminance level. A change in hue results.

Low-Frequency or Luminance Nonlinearity. The change in luminance gain as a function of brightness level.

Linear Distortions. Distortions to the transmitted signal that are not level dependent. They are introduced by linear components in the transmission path. These components include any device with a non-constant frequency response such as matching networks, cavities, filters, diplexers and other tuned circuits. Variations in amplitude and phase are included.

Group or Envelope Delay. Nonuniform delay of different frequencies over the signal bandwidth; the first derivitive of phase with respect to frequency. It is caused by nonlinear phase as a function of frequency inherent in RF amplifiers, filters, combiners and other output devices. In general, the closer the amplitude roll-off is to the passband, the higher the group delay distortion.

Nonlinear Distortions. Distortions to the transmitted signal introduced by non-linear components in the transmission path. These components include any device whose output voltage is not directly proportional to input such as power amplifiers operating near compression.

Precorrection. A technique or circuit introduced to compensate for nonlinear distortion. The objective is to provide a complementary transfer function that, when operating on the nonlinear transfer function, will minimize nonlinear distortion. Precorrection may be introduced in the baseband, IF or RF sections of the system and may be manually or adaptively adjusted.

Equalization. A technique introduced to compensate for linear distortions. The objective is to provide a complementary transfer function that, when multiplied with the frequency response function, will minimize linear distortion. Equalization may be introduced in the baseband, IF or RF sections of the system and may be manually or adaptively adjusted.

Transport Layer Interface. (The interface between the DTV baseband signal generation equipment or studio to transmitter link (STL) and the DTV transmitter.) It is defined by SMPTE standard 310 M.

Luminance Nonlinearity. The change in luminance gain as a function of brightness level.

Surface Acoustic Wave. The propagation of waves on the elastic surface of a piezoelectric crystal. The wave propagation is roughly the speed of sound, and therefore called *acoustic.*

Common Amplification. Use of a power amplifier with sufficient bandwidth and linearity in which the visual and aural signals are combined at low level and amplified together.

Microphonics. The susceptibility of a circuit or system to mechanically induced phase and frequency shifts.

Error Vector Magnitude (EVM). A useful quantitative measure of the quality of a digital transmission system or subsystem. It is the RMS value of the vector magnitude difference between the ideal constellation points and the actual constellation points of the I/Q diagram, expressed in percent. EVM is usually computed as an average over several samples. A perfect digital transmission system would exhibit an EVM of 0%.

Eye Pattern. A convenient method for visually assessing the performance of a digital transmission system. The signal is displayed on a scope set to trigger at the symbol rate. The persistence of the scope creates a composite of all possible waveforms. At each level of the 8 VSB signal, the resulting pattern resembles the human eye. The degree to which the eyes are open is a measure of the signal quality. Eyes open 100% correspond to EVM of 0%.

MULTICHANNEL TELEVISION SOUND

EDMUND A. WILLIAMS
ADVANCED TELEVISION SYSTEMS ENGINEERING
PUBLIC BROADCASTING SERVICE
ALEXANDRIA, VA[1]

INTRODUCTION

Multichannel television sound (MTS) is a generic term for the process of adding subcarriers to the aural carrier of an NTSC television station. The development of a stereo MTS system was accomplished through the Broadcast Television Systems Committee (BTSC) of the Consumer Electronics Manufacturers Association (CEMA), formerly known as Electronic Industries Association (EIA), and is known as the BTSC system for television stereo sound. Subcarriers in the BTSC system are designed to be received by the public and may be used for stereophonic sound and, simultaneously, a secondary audio program (SAP) channel for a second language or other program related aural service. A third subcarrier, in the BTSC system, may be used by the broadcaster for professional uses such as news crew cues, transmitter telemetry or other digital or analog, aural or data services. The BTSC stereo system is completely compatible with monophonic receivers.

Non-BTSC subcarriers may be used for a different stereo system or for non-program related material. However, such signals must not interfere with BTSC equipped television receivers.

Modern broadcast television transmitters, built after 1984, are designed to accommodate multichannel sound. Older transmitters are likely to require revised tuning procedures and more attention to total performance will be necessary to prevent degradation to the stereo signal. Most importantly, new testing and measurement techniques are required to insure that the BTSC multichannel sound signals are transmitted to the receiver in good condition.

The introduction of BTSC multichannel sound as an all-industry recommendation allows receiver manufacturers to develop new models that offer good stereo performance. In 1997, over 50% of all television receivers sold in the U.S. had BTSC stereo. Nearly 50% of all U.S. TV homes have one or more stereo television receivers. Nearly all television programs are produced in stereo. More than 90% of all television stations in the U.S. have BTSC transmission capability. Nearly all video services available to the public (VCR, Cable TV, satellite, video disk, DVD) contain stereo sound tracks.

The adoption of the BTSC system accelerated the use of stereo sound tracks for television program production. Handling the stereo sound throughout the broadcast facility in turn created challenges to audio design and production, installation, distribution, operation and maintenance.

During the introduction of the new stereo service, many stations employed stereo synthesizers to provide viewers with an immediate sensation on newly acquired stereo television receivers. Because a large portion of original program material is now produced in stereo, the synthesizer is no longer needed, nor desired, in the audio chain. Using the synthesizer anywhere in the audio chain other than in the production studio can severely degrade mono and stereo sound (and enhancements such as surround sound) which in turn may cause distraction and discomfort to the viewer.

Background

The EIA established a laboratory and conducted transmission tests on several multichannel television sound systems. The system selected by the committee uses the transmission parameters developed by Zenith Electronics Corporation and the noise reduction system developed by dbx Incorporated. This combination, called the BTSC Multichannel Television Sound system, was recommended to the FCC as an industry-wide standard and adopted on March 29, 1984 in the *FCC's Second Report and Order of FCC Docket 21323.* While not specifying the BTSC system as such, the FCC provided protection to the establishment of the BTSC system that in turn has resulted in a well developed *de facto* standard. Some excerpts from the FCC rules include:

1. BTSC equipped receivers are protected from interference from other MTS subcarrier schemes (see Section 73.682(c) of the FCC CFR).
2. *Bulletin OET-60A*, published by The FCC Office of Science and Technology (formerly Engineering and Technology), is the document that contains the BTSC specifications described in FCC Rule 73.681.
3. Stations are permitted to implement any other MTS system of subcarriers needed if no interference is caused to receivers designed to BTSC specifications or to regular monophonic sound television receivers.

While the BTSC system is not a standard as such, the Commission provided the next best thing—protection. Therefore, transmitter and receiver manufacturers can

[1] Contributions to this chapter provided by Eric Small, Modulations Sciences, Inc., Somerset City, NJ.

produce equipment conforming to the BTSC system with full knowledge that a compatible, protected MTS system is recognized by both FCC and industry. CEMA also developed and published *BTSC System: Television Multichannel Sound Recommended Practices*, a set of recommended operating practices aimed mainly at transmitter and receiver manufacturers.

Television stations may employ aural subcarriers for virtually any purpose as long as they do not interfere with the BTSC system or normal monophonic receiver operation.

All stations contemplating stereo operation should obtain a copy of *Bulletin OET-60A* entitled *Multichannel Television Sound Transmission and* Audio *Processing Requirements for the BTSC System.*

It should be noted that the multichannel sound system adopted for use in the U.S. is unique. Multichannel sound transmission schemes used in other countries have different configurations. The Japanese MTS carries either a stereo sound channel or a second language channel but not both simultaneously. West Germany adopted a two carrier sound transmission system providing either stereo or second language. In Great Britain, a digitally modulated carrier for stereo sound is inserted just above the normal monaural FM carrier. Except for Japan, all countries that employ the NTSC system have adopted the BTSC MTS system. In comparison, the U.S. system with its combination of AM and FM subcarriers, can simultaneously transmit stereo and a separate program or second language, and a subcarrier for professional or non-public uses. Further, the U.S. system allows stations to employ other subcarrier arrangements, when not using the BTSC system, to serve specific station requirements.

A noise reduction or *companding* (compression and expansion) system for both the stereo and separate audio program channels was designed into the BTSC system from the beginning. A high performance compressor is built-in to all BTSC encoders. A matching expander is built-in to all BTSC decoders. They are, therefore, part of the complete system design and not simply an add-on feature.

THE BTSC SYSTEM

The design of the BTSC MTS considered several major performance objectives and considerations including:

- Full sound fidelity
- Compatibility with existing monophonic sound television receivers
- Ease of implementation in transmitters
- The ability of the MTS signals to pass through cable television systems, master antenna systems and TV translators
- The ruggedness to withstand typical transmission impairments (noise, multipath, interference) in the path between the transmitter and receiver.

The BTSC MTS is designed to be compatible with existing monophonic television receivers and provide high quality stereo sound transmission. The system requirements and performance capability are as follows:

- The BTSC MTS is compatible with existing monophonic television receivers. Establishing the correct operating levels in the stereo encoder is essential for proper stereo and monophonic operation. Monophonic performance is also a function of the balance of the original audio program material and the distribution and processing within the broadcast plant.
- The system provides both a stereo and a separate audio program (SAP) channel simultaneously. The SAP channel is available on most BTSC equipped television receivers. The quality of the SAP channel, while limited compared to the stereo and mono channels, depends on the original program material and the processing used in the broadcast facility.
- There are provisions for other professional use (PRO) or station use subcarriers. The PRO channel may be used for a variety of purposes for station operations or commercial services. It cannot be received on consumer television receivers.
- A noise reduction (companding) system is employed for both stereo and second audio program channels. Nearly 30 dB subjective reduction in noise is achieved through circuit design, compression algorithm, precision components, proper setup and routine maintenance. The decoders used in all consumer BTSC equipped television receivers are matched to the encoders used in the transmitter. CEMA publishes a detailed description *EIA Television Systems Bulletin #5*, of the entire BTSC system entitled *Television Multichannel Sound BTSC System Recommended Practices* which is used by manufacturers of television transmitters, receivers, cable television headend equipment and add-on adapters and other equipment that contains BTSC encoders and decoders.
- The aural FM carrier frequency deviation capability in the aural transmitter exciter and associated amplifiers must be increased to accommodate the new BTSC subcarriers. The peak deviation for monophonic transmission remains at 25 kHz. With stereo, SAP and PRO the main FM carrier peak deviation will increase to 73 kHz. Insufficient bandwidth in aural transmission components will result in distortion and crosstalk between audio channels in the receiver.

Excellent stereo audio quality and separation between stereo and SAP channels can easily be obtained from BTSC stereo exciters. However, the transmission system will degrade some performance parameters, depending upon how well the RF components are adjusted and maintained.

Table 6.3-1 shows the MTS performance objectives that can be achieved with properly operating BTSC and aural RF transmission equipment, routine maintenance and use of good quality and calibrated test equipment.

Degradation to any of the performance parameters will occur under the following conditions:

- Crosstalk: Non-linear RF amplifiers, excessive incidental carrier phase modulation (ICPM.)

Table 6.3-1
MTS performance objectives.

Channel	Frequency Response	Noise	Distortion
Main (monophonic)	20–15 kHz ± 1 dB	>58 dB	<1.0%
Stereo (difference)	100–15 kHz ± 1 dB	Dyn*	<1.0%
Separate Audio Program (SAP)	50–10 kHz ± 2 dB	Dyn*	<2.0%
Professional Use (PRO)	100–3 kHz ± 3 dB	>40 dB	<5.0%
Stereo Separation	>40 dB (without NR encoding)		
Crosstalk into SAP or PRO	>50 dB		
Crosstalk into Main (any)	>60 dB (40 dB for stereo into main)		

*Dyn indicates that the noise varies dynamically with program content and the characteristics of the noise reduction system. Subjectively, the noise will normally be 60 dB below peak operating levels.

- Poor frequency response, noise and distortion: Audio circuitry in stereo encoder or exciter.
- Noise reduction system artifacts such as pumping or changes in level: Improper adjustments in encoder (do not adjust without knowledge of the system and proper instrumentation).
- Buzz in the received audio: Excessive ICPM in the transmitter, video over-modulation, video energy in the aural carrier passband.

The BTSC System Transmission Format

The transmission format of the BTSC baseband configuration is shown in Figure 6.3-1. The monophonic component (L + R) is transmitted as a standard FM signal as in the past. The stereophonic component is transmitted as a difference or left minus right (L − R) signal and based on the current U.S. FM stereo broadcast model that is familiar to most broadcast engineers. Subcarriers for cues, data, telemetry or other station related purposes may also be employed. Space for professional use, non-public subcarriers is provided in the aural baseband. Figure 6.3-2(a) shows how the BTSC signal is configured at the transmitter. Figure 6.3-2(b) shows how BTSC is handled in a typical receiver.

Monophonic Channel

The monophonic, or sum channel (L + R), is maintained at its present place in the aural baseband and continues to have 25 kHz peak deviation and the standard 75 μsec preemphasis. The addition of BTSC or MTS subcarriers, while increasing the total deviation of the main FM carrier to 73 kHz, does not result in any degradation to the normal monophonic sound in existing receivers. The monophonic channel is maintained at 25 kHz deviation unlike FM radio broadcasting where the mono channel is reduced when transmitting stereo. This would result in lowering the signal-to-noise ratio of the aural channel and the loudness of the sum channel compared with stations not operating with the BTSC system. Increasing the total deviation provides the room for the stereo, SAP and PRO subcarriers to be added to the aural baseband.

The fidelity of the main channel monophonic audio is not adversely affected. However, because the sidebands of the stereo subcarrier are close to the main channel audio, and to prevent crosstalk between channels, BTSC stereo encoding equipment incorporates

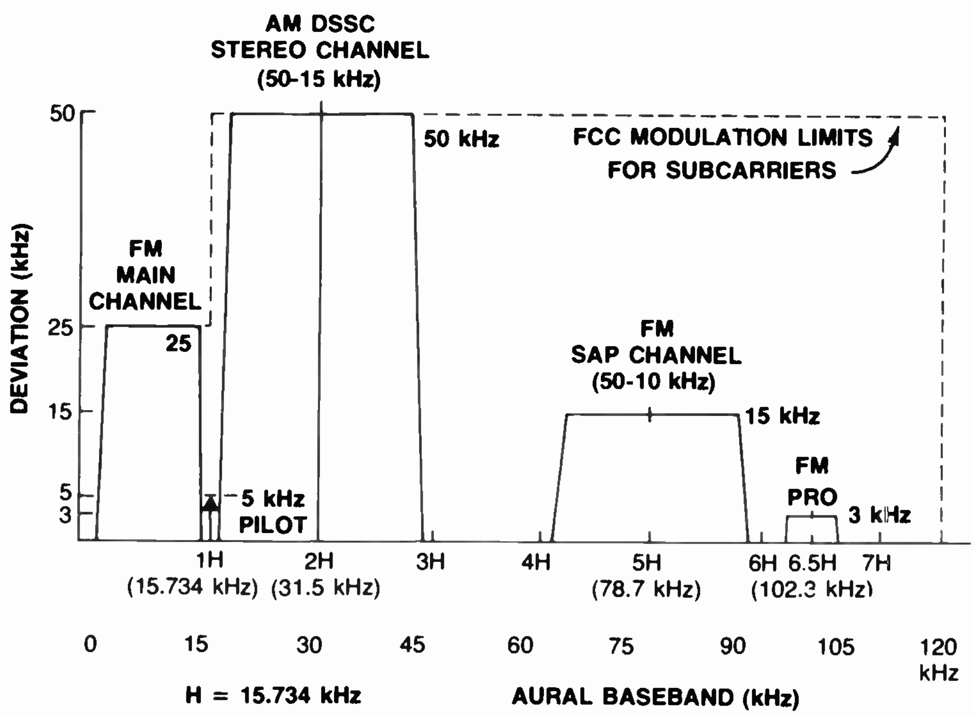

Figure 6.3-1. BTSC MTS baseband.

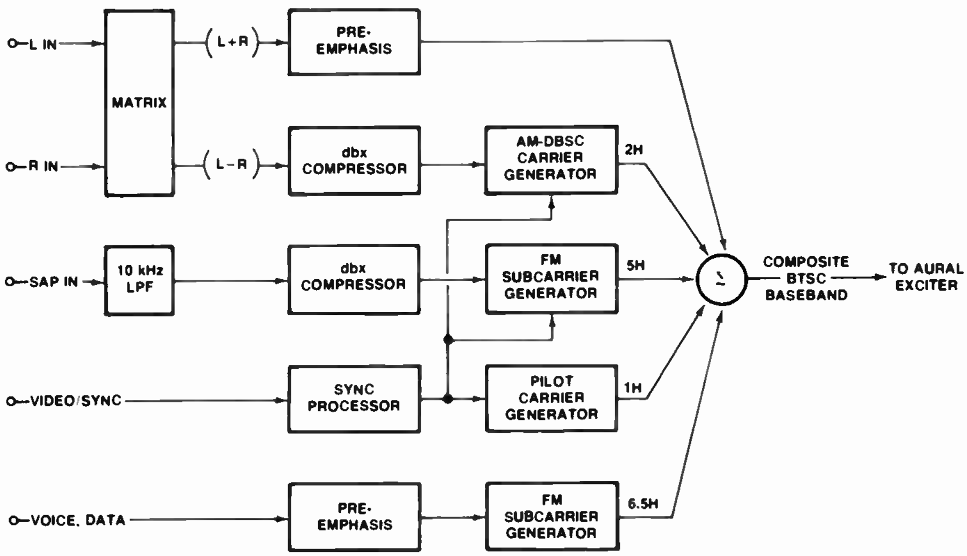

Figure 6.3-2(a). Typical MTS transmitter encoder.

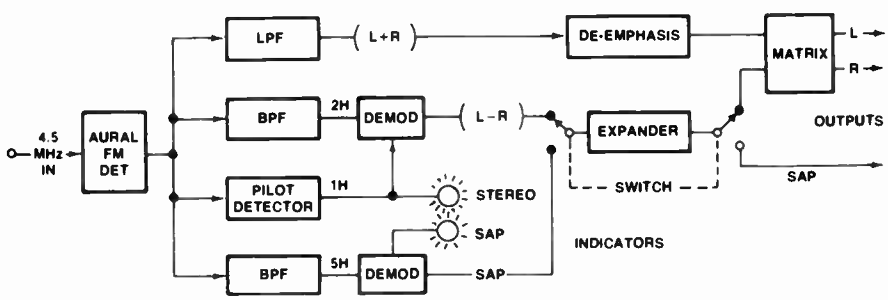

Figure 6.3-2(b). Typical MTS receiver decoder.

sophisticated low pass filters in the audio circuits that limit the frequency response of each audio channel to 15 kHz (more typically 14 kHz).

Stereo Subcarrier

The stereophonic subchannel is an amplitude modulated, double sideband, suppressed carrier subcarrier. The carrier is suppressed to avoid wasting modulation capability. The subcarrier operates at twice the NTSC video horizontal scanning rate of 15.734 kHz or 31,468 kHz. Station video sync is fed to the encoder to maintain synchronism with the video. The subcarrier is modulated with the stereophonic difference signal or left minus right (L − R). Maximum peak deviation of the main carrier (injection) by the stereo subcarrier energy (not the carrier itself which is suppressed) is 50 kHz.

The modulation level is related to the companding system algorithm and is normally quite high during stereo program material due to the compression. However, because of the nature of stereophonic sound (little correlation between the sum and difference channels) a form of interleaving takes place that, in effect, prevents the deviation of the main carrier from becoming simply the sum of the two components that would appear to produce a total of 75 kHz. Instead, the maximum rarely exceeds 50 kHz. This is because a *left-only or right-only* signal originating from the studio would produce only a 50% modulated signal in the mono channel though it produces a high modulation level in the difference channel.

The difference channel of the BTSC system employs the dbx noise reduction circuit (the compression portion of the compandor) which precisely controls the maximum modulation level of the difference signal. The preemphasis varies according to the level and frequency of the sound entering the compressor. While the combined deviation of main (L + R) and stereo (L − R) carriers rarely produce more than 50 kHz deviation of the main channel, most stereo encoders incorporate some form of peak limiting device in these channels to prevent over deviation.

Note that the difference channel is nonlinear by design. That is, the compandor processes the audio signal differently at low levels than at high levels. When conducting tests on the difference and SAP channels, a 75 μsec preemphasis network is substituted for the compressor. Consult the alignment instructions provided by the manufacturer for specific tests and setup requirements.

The selection of the center frequency of the stereophonic subcarrier is based on its relationship with the 15.734 kHz horizontal frequency (H) component of the video in both the transmitter and the receiver. Crosstalk caused by video signal circuits, power supply and RF paths in the transmitter generally occurs at multiples of "H" and therefore is canceled or at least substantially reduced in the receiver without significantly affecting general stereo audio quality.

The first harmonic of "H" (15.734 kHz), present to some extent in many transmitter and receiver audio circuits, is above the hearing range of most viewers and not normally audible. Receiver audio circuits generally employ notch or low pass filters to eliminate all but vestiges of "H" at the audio output. The second harmonic falls at 2H (31,468.6 Hz) which is the frequency of the BTSC stereo subcarrier. By locking the stereo subcarrier frequency to the video sync, the harmonic and subcarrier remain in phase and no beat occurs.

Modulation of the 2H harmonic by 59.94 Hz field rate sync components of the video signal can also occur in either the transmitter or receiver. The sharp rise time of the 60 Hz component causes the 60 Hz sound to have the characteristic buzz that is heard on some receivers. A related *buzz-beat* effect is reduced with high pass filters in the stereo subchannel in the receiver to remove unwanted audio components below about 100 Hz that can beat with the 59.94 Hz buzz. While this has virtually no effect on the stereo audio quality, it substantially reduces the low frequency buzz and hum caused by the field rate modulation.

Placing the stereo subcarrier, with its 15 kHz sidebands, so close to the upper end of the main audio channel invites potential crosstalk problems. Therefore, it is essential that the subcarrier frequency be an integer multiple of "H" as previously described. Placing the stereo subcarrier at higher or odd multiples of "H" is not desirable due to the much higher noise levels encountered in the upper portion of the aural baseband and the potential for problems with phase locked loop audio detector circuits in the receiver. A higher subcarrier frequency would also have made the addition of the SAP channel more difficult to implement as well.

The buildup of noise in the aural baseband, shown in Figure 6.3-3, illustrates why the stereo subcarrier is placed as low as possible in the baseband and indicates the necessity for the audio companding system. In FM modulation systems, noise increases at a rate of 6 dB for each doubling of the bandwidth. As a result, the noise the stereo subcarrier would add to the received dematrixed sound is about 23 dB. This is reduced about 6 dB because the stereo subcarrier deviates the main carrier by 50 kHz compared to the main channel deviation of 25 kHz. The resulting degradation in signal-to-noise is only about 18 dB. Further, modulation components caused by the horizontal and vertical sync signals also add to the noise buildup. Both interference sources are overcome by the 30 dB BTSC noise reduction system.

Using an AM modulated, double sideband, suppressed carrier subcarrier for the stereo channel also provides several other significant advantages over an FM subcarrier. AM subcarrier technology is well known and developed within the FM broadcast industry. Circuit performance has been raised to near perfect levels. Moreover, AM offers lower theoretical distortion levels than would be possible for FM given the limited spectrum available (30 kHz) for transmission of the stereo subcarrier, and provides an opportunity for future enhancements of the aural channel (by quadrature modulation or other compatible modulation schemes). The 15 kHz frequency response of the stereo subchannel also properly complements that of the main channel.

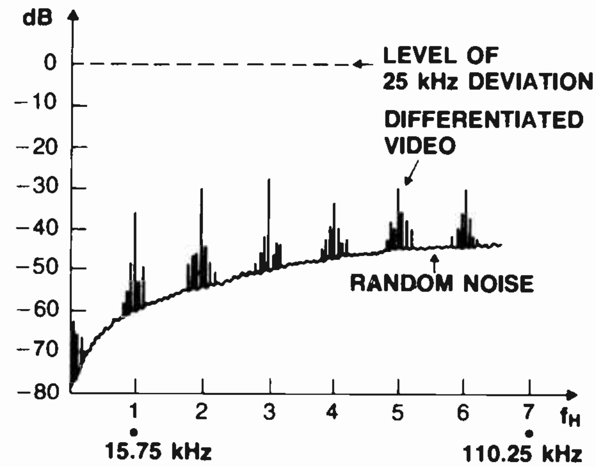

Figure 6.3-3. Spectrum of noise on the received aural baseband. (Courtesy of J.J. Gibson, RCA)

Pilot Carrier

The amplitude modulated stereo subcarrier is transmitted with the carrier suppressed. To provide a reference for the AM detector, an unmodulated pilot signal is transmitted at the TV horizontal line rate of 15.734 kHz that is one-half the subcarrier frequency. The pilot is used in the receiver to reinstate the carrier on the exact frequency and phase as the original. This is similar to the technique employed in broadcast FM stereo transmission systems.

For BTSC stereo, the pilot is locked to the video horizontal sync rate of 15.734 kHz. The pilot modulates the main aural carrier to a deviation of 5 kHz (±0.5 kHz). The stereo encoder requires a feed from the companion video signal to obtain its frequency reference. While it is possible that stereo sound receivers could use the horizontal sync information obtained from the receiver video circuits for the reference, there are receivers that do not process the video when decoding the stereo audio and therefore would not have a reference to synchronize the stereo detector.

The pilot also is used to activate the stereo circuits and indicators in the receiver. Therefore, the pilot must be protected from extraneous signals near the pilot frequency in the aural baseband.

Pilot Carrier Protection

Section 73.682(c)(3) of the FCC Rules requires that modulation components around the BTSC pilot frequency of 15.734 kHz (+ or −20 Hz) be attenuated to 0.125 kHz deviation (46 dB below maximum modulation of 25 kHz). This is the case whether the station is operating with multichannel sound or monophonic sound.

A disadvantage with having the pilot at the horizontal rate is that there may be some residual horizontal sync modulation components and crosstalk in older transmitters or in program audio content that can cause false indications of stereo and improper operation of stereo decoders in BTSC receivers. Crosstalk from horizontal sync can occur in the exciter or amplifiers of older transmitters. Problems of this sort must be solved by broadcasters and manufacturers by adequately shielding or isolating the sync components of the video from the audio circuits in transmitting and receiving equipment. Modifications may be necessary to existing transmission equipment. The level of horizontal sync modulation and crosstalk components in the visual transmitter 4.5 MHz above the visual carrier can be controlled by installing low pass video filters, adjusting transmitter visual RF circuits or improving the 4.5 MHz rejection in the transmitter combiners or diplexers.

Low level sync modulation components with sufficient amplitude to cause false triggering of BTSC receivers can also occur by acoustic pickup by microphones that are in close proximity of video monitors in studios, news sets and in announce booths. Installation of identical high quality low pass or notch filters in the stereo audio path after the last switching point in the broadcast plant will effectively eliminate horizontal sync stray acoustic or magnetic pickup in the studio from interfering with processors, STL facilities and the BTSC encoder at the transmitter. The characteristics of such a low pass filter are shown in Figure 6.3-4. Filters should be installed ahead of devices with preemphasis so as not to compound the problem. For example, a standard 75 μsec preemphasis network has about 15 dB gain at 15 kHz.

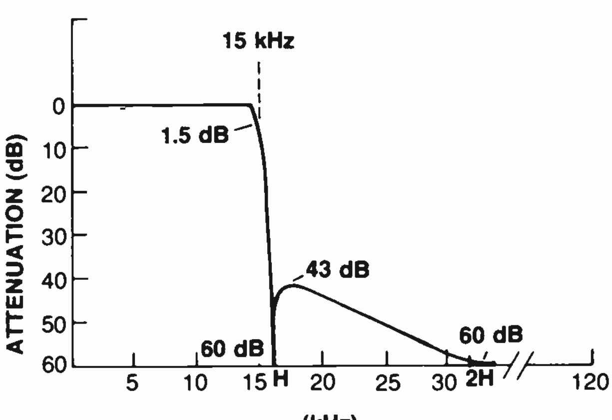

Figure 6.3-4. Audio input low-pass filter.

Operators of monophonic transmitters should also check their facilities for residual horizontal sync signals in either the aural transmitter or in the combining network at the output of the transmitters. The monophonic audio input to the transmitter should incorporate a 15 kHz low pass filter to prevent false triggering of the stereo indicator on television receivers.

The Separate Audio Program Channel

BTSC MTS transmissions may include a separate audio program (SAP) channel in addition to stereo. While the SAP channel may be program related or not, as the station chooses, it is nevertheless designed for reception by the public. If it desired to use the SAP channel for non-public uses, the injection level of the subcarrier must be kept below the receiver threshold (about 5 kHz). If not, viewers with the SAP option switch on their receivers may wonder about the material if it is not related to the video program in some manner.

The SAP channel subcarrier, an FM subcarrier, is located at exactly 5H (78.671 kHz) in the aural baseband (see Figure 6.3-1). Although somewhat noisier at this location in the baseband than if it were placed at 4 H, there is less chance for crosstalk with the main or stereo channels. The same BTSC noise reduction system on this channel provides an adequate signal-to-noise ratio. The audio frequency response is limited to a maximum of 12 kHz (typical response is 10 kHz). The use of the companding system eliminates the need for separate preemphasis in the SAP channel.

The SAP subcarrier is frequency modulated by program material to a maximum deviation of 10 kHz. The subcarrier injection into the main carrier is limited to a peak deviation of 15 kHz. That is, the subcarrier modulates (deviates) the main carrier by 15 kHz. The subcarrier frequency is locked to 5H when not modulated.

The maximum injection level of 15 kHz of the main carrier by the SAP subcarrier is important. Receivers with SAP decoding equipment will detect the presence of the subcarrier and provide either automatic or manual switching and an indicator light. The receiver SAP decoder is designed to activate when the injection level reaches 8 to 10 kHz. Below this level the receiver will ignore the presence of a subcarrier. To use this portion of the baseband for some purpose other than program related audio, a subcarrier with an injection of 3 to 5 kHz would probably be ignored by most SAP receivers. A non-public use of the SAP subcarrier cannot occur at the same time as regular program related SAP channel operation but could be used during stereo or monophonic operation.

The SAP channel uses the same dbx noise reduction scheme as the stereo subcarrier. This permits a single expander decoder to be used in the receiver for either stereo or SAP. Most receivers provide either stereo or SAP output but not both at the same time. To make both available simultaneously a receiver would need two expanders. Alternatively, the SAP output could be provided without expansion but the output would be highly compressed. The sound would be acceptable for some vocal material but would be objectionable for most music.

The Companding System

Companding is a term used frequently in the telecommunication industry to describe what broadcasters call noise reduction, a process well known to studio audio technicians. Its use is restricted to systems where there is control over both ends of the circuit. Examples include magnetic analog audio recorders, microwave and satellite circuits and telephone lines used for program transmission. Simply stated, noise reduction is compressing the dynamic range at the sending end and expanding the signal an equal amount at the receiving end of the circuit. In the process of expansion the noise is reduced. Until the development of the BTSC MTS system, noise reduction techniques could not successfully be used for over-the-air transmission because a complimentary expander is required in the receiver. BTSC MTS required the use of expanders in the receiver from the beginning of the service. As a result, BTSC MTS is the first broadcast service to use companding as an integral part of the transmission system. dbx, Inc. developed the BTSC companding system.

Some FM broadcast stations employ a limited range compression arrangement for an over-the-air noise reduction system. However, because few receivers are equipped with the corresponding expander, the compression must be held to about only 10 dB in order to avoid producing undesirable side effects and becoming objectionable to a listener without a decoder.

Noise reduction was built-in to the BTSC MTS system from the beginning of the service and therefore a high performance system is employed. Figure 6.3-5 graphically depicts how a typical noise reduction system alters the dynamic range of the program material during transmission according to the content. Dynamic

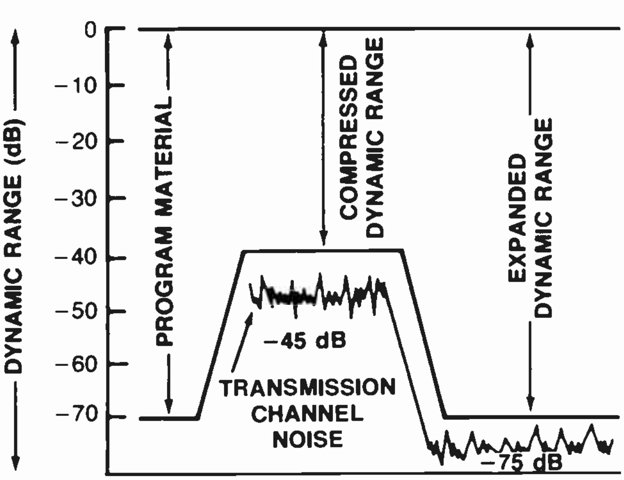

Figure 6.3-5. Typical noise reduction action.

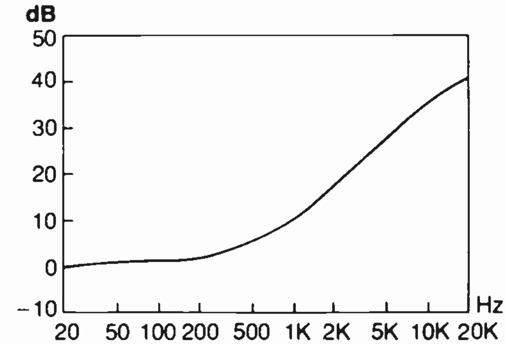

Figure 6.3-6(a). Fixed preemphasis frequency response.

range is reduced from 70 dB to about 40 dB. A matching expander in the receiver restores the dynamic range.

The companding system employed by the BTSC MTS system was specifically designed to operate in the comparatively hostile environments presented by television transmitters, signal propagation, retransmission systems (cable TV, MATV, translators) and the receiver itself. Thermal and impulse noise, multipath distortion and *intercarrier buzz* generated by transmitter and receiver all combine to present formidable obstacles for the companding system to overcome.

The companding system used in the BTSC system employs a combination of fixed preemphasis, *spectral* compression and amplitude compression. The fixed preemphasis combines the familiar 75 μsec rising frequency response with a 390 μsec network. The resulting curve is shown in Figure 6.3-6(a). By itself this extremely steep preemphasis curve would cause problems with high audio frequencies. To avoid this, a dynamic spectral compressor (variable preemphasis) circuit is employed to increase the gain of low level, high frequency material and reduce the gain of high level, high frequency audio. Only frequencies above about 200 Hz are affected. High frequency material is increased during transmission by as much as 30 dB at low levels but virtually not at all at high levels. Figure 6.3-6(b) illustrates the dynamic characteristics of the spectral compressor. A complicated algorithm controls

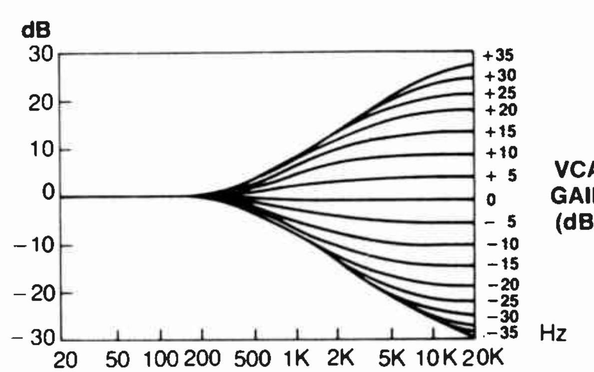

Figure 6.3-6(b). Spectral compressor, frequency-response range.

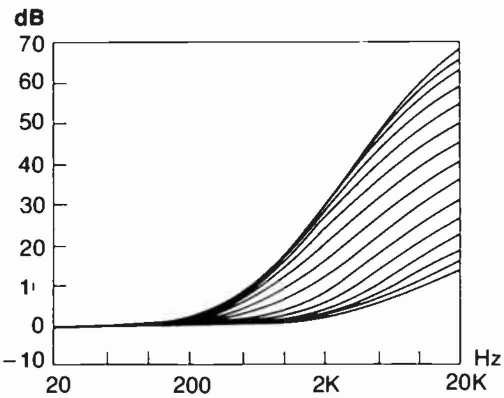

Figure 6.3-6(c). Frequency response range of spectral compressor and fixed preemphasis.

the fixed and variable preemphasis to produce the sharply rising frequency response shown in Figure 6.3-6(c). The third feature of the companding system is the amplitude compressor which reduces the dynamic range of the input signal by a factor of 2:1 for low frequencies, and 3:1 for high frequencies. In other words, a 40 dB dynamic range audio signal is reduced to 15 to 20 dB or less for transmission as shown in Figure 6.3-7. In addition to dynamic range compression, the maximum input level applied to the stereo subcarrier is reduced to just below the maximum modulation of the subcarrier. This feature provides some headroom to accommodate instantaneous peaks without resorting to clipping. High level transients are clipped to avoid severe distortion during reconstruction of the compressed signal in the receiver expander.

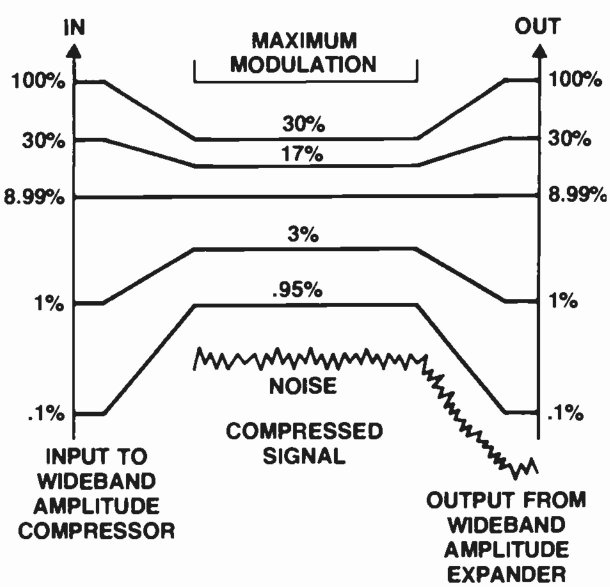

Figure 6.3-7. Companding of (L − R) and SAP. (Courtesy of dbx, Inc. dbx is a registered trademark of Harmon International, Sandy, Utah, USA.)

The equivalent 75 μsec mode in the companding system uses a precision 75 μsec network in place of the nonlinear dbx compressor when tests for separation, crosstalk and noise tests conducted. In this mode the exciter contains only linear elements which allows routine adjustments on the exciter and transmitter and measurements of the main, stereo and the SAP channels to be performed more accurately and very much as conventional FM broadcast stereo exciters. CEMA publishes the *Compandor Complexity Analyses* that supplements *OET Bulletin #5* described earlier.

The use of compandors and noise reduction systems has gained wide acceptance throughout the broadcast industry. It is not unusual for any given program to undergo noise reduction processing several times by the time it reaches the viewer. The mistracking of a single companding system in the chain can result in substantial errors in the resulting sound that can be more objectionable than the problems the compandor was designed to solve. In order to prevent audible artifacts from occurring, only the highest quality processing and noise reduction systems should be employed and these must be correctly operated and properly maintained.

Professional Use Channel

The PRO channel, which is not designed to be received by the public, can be used by broadcasters for many purposes such as voice cues, signaling and data transmission. The PRO channel is located at 6.5H (102.28 kHz, ±500 Hz) in the BTSC baseband as shown in Figure 6.3-1. The carrier need not be locked to "H". The peak deviation of the frequency modulated subcarrier is 3 kHz. The peak deviation (injection) of the main carrier by the PRO subcarrier is 3 kHz. When used for voice or audio transmission, a modulation limiter, 3.4 kHz bandlimiting filter and a 150 μsec preemphasis network are normally employed. For data transmission the limiter, preemphasis network and filter are bypassed.

Other Subcarriers

In addition to providing for stereo and SAP subcarriers, the FCC permits television stations to use any other scheme of subcarriers on the aural carrier as long as they do not interfere with the normal operation of monophonic or BTSC television receivers. When not transmitting stereo or SAP, broadcasters may elect to use the aural baseband for subcarriers for non-program related purposes. Virtually any kind of subcarrier for program material or data may be transmitted using AM, FM, other analog or digital modulation methods. Subcarriers may be placed in the aural baseband between 16 and 120 kHz but must avoid the BTSC pilot and SAP frequencies. While any number of subcarriers may be used, the maximum deviation of the main carrier by these subcarriers is limited to a total of 50 kHz. The total modulation of the aural carrier including main channel sound and non-BTSC subcarriers may not exceed 75 kHz.

Stations should avoid placing non-public subcarriers

Table 6.3-2
Typical modulation monitor functions.

Signal	Monitored Parameter
Main channel (L + R)	25 kHz peak deviation
Stereo channel (L + R)	50 kHz peak deviation
Main and stereo	50 kHz peak deviation
Pilot carrier injection	5 kHz peak deviation
SAP modulation	10 kHz peak deviation
SAP injection	15 kHz peak deviation
Other subcarrier	3 kHz peak deviation
Total composite	73 kHz peak deviation

within ±10 kHz of the SAP subcarrier frequency unless the injection level of the subcarrier is kept well below 5 kHz deviation. The use of a single subcarrier using the full 50 kHz deviation should be avoided because of the potential of crosstalk into the main channel in some receivers unless extensive compatibility testing is conducted. Multipath in the propagation path can exacerbate crosstalk with large subcarriers.

Modulation Summary

The FCC permits the BTSC MTS signal to modulate the aural carrier a total peak deviation of 73 kHz. This is produced by the combined main monophonic and stereo subcarrier deviation of 50 kHz, the pilot subcarrier deviation of 5 kHz, the SAP subcarrier deviation of 15 kHz and the PRO subcarrier of 3 kHz for a total of 73 kHz (see OET-60A section D(b)(6)). Table 6.3-2 lists the MTS modulation components that should be monitored regularly.

Other subcarrier arrangements may modulate the main carrier to an additional peak deviation of 50 kHz. The combined main monaural channel of 25 kHz and non-BTSC subcarriers of 50 kHz shall not exceed 75 kHz deviation (see Section 73.68(c)(9) of the FCC CFR).

TRANSMISSION REQUIREMENTS

Many of the technical rules in Part 73 of the FCC CFR that described quality characteristics of the transmitted signal were deleted by the FCC in 1984. Those rules, requiring stations to meet certain distortion, frequency response and signal-to-noise performance levels, were eliminated in favor of marketplace pressures on stations to maintain high quality levels. Thus, there are no FCC rules which require minimum audio quality performance levels in the AM, FM or TV broadcast service. The FCC Rules that permit stations to transmit MTS also do not specify performance objectives. However, rules which serve to control interference have been maintained.

In addition to FCC and CEMA publications transmitter and BTSC encoder and modulation monitor manufacturers also publish booklets and manuals describing potential problems encountered in preparing transmission systems of BTSC audio along with methods for measurement and problem correction. Some of these are listed in the references at the end of this chapter.

The BTSC MTS performance objectives achievable under normal operating conditions are shown in Table 6.3-1. While most of the objectives indicate the potential for high audio quality, the stereo separation figure may be of some concern to those familiar with the much higher performance of the FM stereo system. While more than 30 dB separation can be achieved in practice with BTSC, separation values greater than 30 dB produce little subjective improvement. The nonlinear circuits in the companding system and the critical adjustments which must be made in the BTSC encoding system may result in less than the typical 40 dB or more separation normally achieved in broadcast FM stereo operation. The tracking gain between the mono and stereo channels is the single most important operating characteristic that determines the relative separation between channels as shown in Figure 6.3-8a.

While it may be possible to balance the gain to a tenth of a dB between the sum and difference channels in FM radio stereo transmission, a balance is about 0.5 to 0.8 dB is typical for the BTSC system. This is because the noise reduction system compresses the stereo channel by as much as 30 dB, which magnifies the difference when received, decoded and expanded in the TV receiver. However, with high stability circuits and attention to balance 40 dB stereo separation can be obtained.

Phase shift between audio channels also reduces stereo separation. Only a few degrees difference can reduce separation to 30 dB or less as shown in as shown in Figure 6.3-8b. When combined with channel gain differences, separation will be further reduced. Incorrect stereo channel carrier phase error and stereo pilot phase error also contribute to reduced stereo separation as shown in Figure 6.3-8c.

A major feature of the BTSC MTS system is that there is no stereo noise penalty as there is with FM stereo radio. Because the FM stereo radio subchannel has no companding it is subject to the increased noise in the channel baseband by as much as 23 dB. In FM radio the main or L + R channel must also be reduced by 8 to 10% to accommodate the addition of the pilot subcarrier. With BTSC MTS, the aural carrier deviation is increased when adding the pilot and stereo subcarriers. Thus, there is no reduction in deviation of the mono signal during BTSC stereo transmission as there is when adding stereo in broadcast FM radio operation.

The crosstalk performance values are the single most important technical parameters with which the broadcaster must be concerned for the BTSC system. Most crosstalk is caused by components and systems external to the stereo transmission equipment itself. Nonlinearities in the TV aural exciter and power amplifier stages, combining networks, antenna switching components and the antenna itself are locations in the signal path where crosstalk can be generated. In general, crosstalk into the stereo signals from the SAP will be less than crosstalk from the main channel into the SAP signal. As long as crosstalk levels do not exceed the

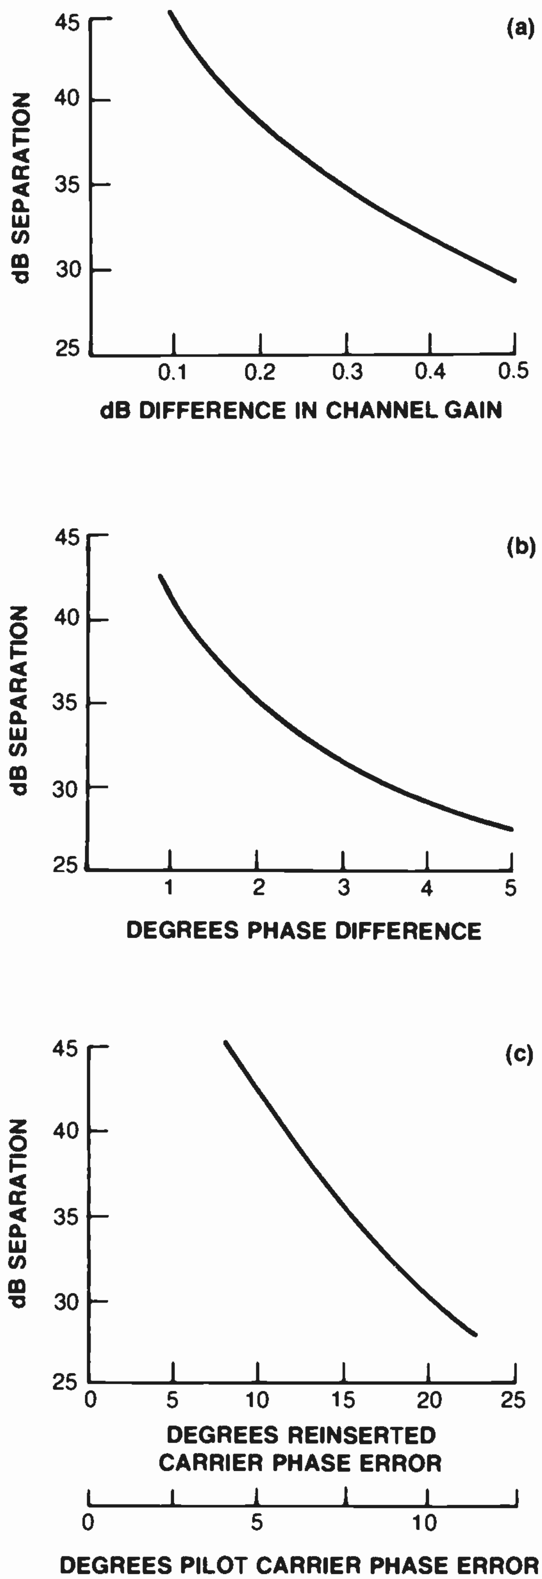

Figure 6.3-8. Stereo separation versus (a) amplitude difference between main and stereo channels, (b) phase difference between main and stereo channels, and (c) error in phase of pilot or reinserted carrier.

CROSSTALK	OBJECTIVES
MAIN INTO STEREO	>40 dB
STEREO INTO MAIN	>40 dB

SAP INTO MAIN	>60 dB
OTHER SUB INTO MAIN	>60 dB
OTHER SUB INTO STEREO	>60 dB

Figure 6.3-9. Crosstalk objectives.

levels shown in Figure 6.3-9, most crosstalk will be concealed by the companding system.

Other sources of crosstalk are multipath distortion due to poor transmission line and antenna VSWR, multipath (ghosts) during the propagation of the transmitted wave and improper matching in the receiving antenna system. In general, the companding system can conceal noise and crosstalk in the stereo and SAP channels subjectively by as much as 30 dB.

Setting Modulation Levels

The most important means for maintaining good stereo separation is to correctly set modulation levels of the L − R stereo subcarrier. Errors of less than 0.5 dB will result in a reduction of stereo separation to 30 dB, the FCC minimum. For best performance, levels must be set to an accuracy of 0.3 dB to help account for crosstalk problems in other parts of the system. While levels can be estimated with modulation monitors, the best method for setting levels to this accuracy is to use the Bessel null procedure with a highly accurate, low distortion audio test signal and an RF spectrum analyzer.

Visual Over-Modulation

One way to reduce buzz in television receivers is for the broadcaster to insure that the video modulation level is never allowed to exceed the FCC maximum of 87.5%. Video levels that vary widely during program production and transients from character and graphics generators can easily cause the visual modulation level to approach 100% or carrier cut-off. At this point the aural detector in intercarrier type television receiver loses its reference (the aural carrier) and the result is a strong 59.94 Hz buzz in the received audio. Proper adjustment of video processing equipment will eliminate this problem as a source of buzz. In some cases it may be necessary to add high quality low pass filters to the video outputs of character and graphics generators to limit the high frequency content.

Incidental Carrier Phase Modulation

The control of ICPM in the visual transmitter is also an important performance characteristic of the transmitter that will affect the quality of multichannel sound.

ICPM in visual transmitters must be adjusted and maintained to less than 3° during the luminance portion of the video and less than 5° during sync in order to keep buzz to acceptable levels as shown in Table 6.3-3.

Table 6.3-3
Intercarrier buzz and buzzbeat levels.
(Courtesy of J.J. Gibson, RCA)

Degrees ICPM →	1°	2°	3°	4°	5°
Baseband buzz level in dB below 25 kHz dev. ("worst case")	−50	−44	−40	−38	−36
Stereo SBR dB	56	50	46	44	42
SAP buzzbeat THD dB	−49	−43	−39	−37	−35

Nyquist slope eqv. ICPM = $\begin{cases} 2.4° \text{ at (L − R) subc.} \\ 6° \text{ at SAP subc.} \end{cases}$

Excessive ICPM in the transmitter will cause an audible and annoying buzz in intercarrier sound television receivers. The buzz will be modulated by the action of the expander and increase the level of annoyance.

Intercarrier type receivers, typical of most receivers, are used for multichannel sound reception because of their high immunity to common mode phase modulation that can occur in non-linear active devices or distribution and conversion systems that are found in the path of the television signal before it reaches the receiver. Common mode phase modulation often occurs in TV translators, MATV downconverters, and cable television headend and set-top converter equipment.

In intercarrier type receivers, the aural and visual carriers beat together in the video detector to produce the 4.5 MHz aural IF signal. Because common mode phase modulation affects both carriers, the phase modulation is factored out of the 4.5 MHz carrier. Therefore, ICPM that occurs on the visual carrier in the transmitter, which is independent of the aural carrier, will produce undesired phase modulation of the 4.5 MHz aural carrier in the receiver and the result will be the familiar buzz.

Phase modulation in the local oscillator of up and down converters can be caused by the power supply or mechanical vibration or if the phase of the composite signal is changed by a non-linear amplifier. Phase modulation is common mode when both aural and visual carriers are affected equally. This would be the case when the aural signal is carried as a subcarrier on the visual carrier rather than treated as separate signals as is the case in many broadcast transmitters.

Intercarrier receivers carry the aural signal to the detector as a subcarrier of the visual carrier. Translators and most cable television systems carry the aural through headend processors as a subcarrier. Therefore, if phase modulation is introduced in these systems, it is common mode and will be rejected by the receiver. Intercarrier sound receivers cannot reject phase modulation that is introduced independently into the visual or aural carriers at the transmitter or in subsequent equipment or systems.

Phase modulation in the visual transmitter can be caused by hum in the carrier frequency or upconverter oscillators and by non-linearities in the visual modulator, IF and power amplifier stages. Phase correction circuits in the video modulator can compensate for most ICPM problems. UHF transmitters which use klystron anode pulsers to achieve higher operating efficiencies may have phase modulation introduced by the pulser modulating the visual amplifier power supply at the video field rate (59.94 Hz) and the line rate (15.734 kHz). The high frequency component is not heard by most viewers but the low frequency component is heard by all as a raspy buzz. An anode pulser on the visual amplifier can cause crosstalk through the common power supply into the aural amplifier. The resulting 15.734 kHz modulation, if high enough, can cause false indications of the stereo indicator on BTSC MTS television receivers.

Measuring and Correcting ICPM

ICPM is manifested as differential phase in the demodulated video. Measurement instrumentation requires a TV demodulator with both envelope and quadrature video detectors and a waveform monitor with the ICPM graticules. After measuring ICPM or listening for buzz on a stereo television receiver to determine if ICPM is present, phase adjustments in the modulator or upconverter and retuning the RF stages will result in substantial improvements. ICPM adjustments, if provided on the transmitter exciter, will also affect video differential phase. The ICPM problem should be addressed and solved first, then the video correction circuits can be adjusted to compensate for differential phase.

ICPM is more noticeable on television receivers equipped for BTSC stereo sound because ICPM affects subcarriers to a greater extent than the main channel. In addition, improved audio performance in the new multichannel receivers makes existing buzz more noticeable. Therefore, stations that implement BTSC multichannel sound should check their transmitters for ICPM with an ear toward improving the quality of the mono sound on mono receivers as well as stereo on new MTS receivers.

Synchronous Amplitude Modulation

Synchronous amplitude modulation (SAM), occurs when the frequency swing of the aural carrier is greater than the flattest portion of the tuned circuits through which the carrier passes. A reduction of the carrier occurs where the passband begins to roll-off as shown in Figure 6.3-10. The effect is to cause amplitude changes to the RF carrier during FM modulation. The SAM is in sync with the FM, hence the name synchronous AM. SAM is made worse if the aural RF carrier is not centered within the passband of the tuned circuits in the aural transmitters, combiners and diplexers. While most TV transmitter systems provide adequate aural RF bandwidth, the position of the carrier within the passband is critical and should be checked regularly.

SAM manifests itself as intermodulation distortion which in turn causes an increase in crosstalk between

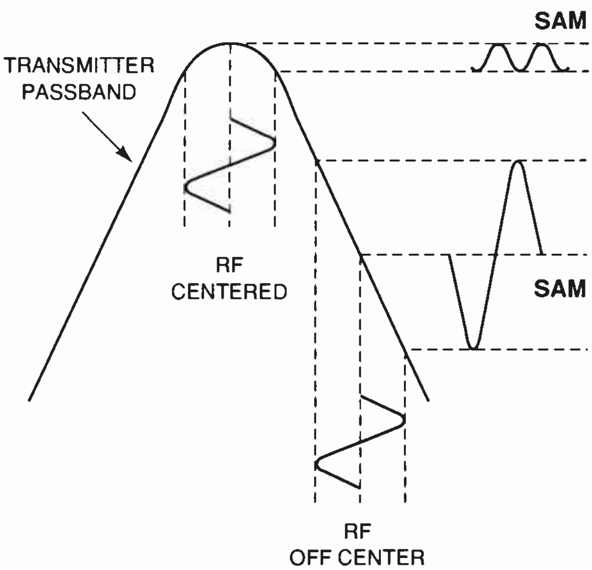

Figure 6.3-10. Synchronous Amplitude Modulation (SAM).

channels and decreased stereo separation. The SAP and PRO channels are more susceptible to SAM than the main channel especially during high levels of main channel modulation when the frequency swing is greatest.

Compatibility with Monophonic Receivers

During the development of the BTSC MTS considerable effort was spent evaluating the effect of a fully loaded BTSC system on existing monophonic television receivers. Extensive compatibility testing of a wide range of receiver makes and models, under adverse transmission conditions, revealed that the BTSC System caused virtually no significant degradation to either the sound or picture of the desired or adjacent channel.

BTSC sound transmission will not introduce additional buzz or distortion in existing monophonic receivers. On the other hand, non-linear circuits and the resulting amplitude modulation to phase modulation (AM-to-PM) conversion will nearly always produce buzz which will be more objectional in stereo than in mono. Most of the buzz heard in mono or stereo receivers is usually created in the transmitter or the cable TV system in the form of ICPM or video over-modulation.

Modern monophonic television receivers should not experience significant degradation when receiving a BTSC MTS signal. In fact, monophonic receivers may actually exhibit a noticeable improvement in performance when tuned to BTSC stereo transmissions due to the improved performance of the stereo exciter, broadband aural RF systems and lower ICPM in visual transmitter components.

These desirable side benefits easily offset the slight reduction in monophonic modulation level which occurs when transmitting a mostly left or right channel sound. Because the main channel is the sum of left plus right, a right-only or left-only signal will produce up to 6 dB less modulation than the sum signal. However, program producers seldom employ left or right-only signals except for sound effects and music. Virtually all dialog is placed in the center (L + R) so there will be no reduction in modulation.

Compatibility with Cable Television Systems

Most broadcast television signals are carried by cable television systems. In 1997, about 65% of TV households had at least one receiver connected to a cable system. It is important, therefore, that broadcasters be concerned with the quality of the audio as well as the video signal as carried on cable television systems.

The BTSC MTS system was specifically designed to pass through properly adjusted cable television and master antenna TV (MATV) headend and distribution equipment and subscriber terminals. The concern that the lower sideband of the upper adjacent visual carrier might affect the wider BTSC MTS modulated aural carrier of the lower channel has not been confirmed in practice. In general, those cable TV systems which process off-air signals in an RF mode (that is, where the aural carrier is not demodulated) will have little difficulty in successfully passing an acceptable BTSC MTS signal through the system. The same is true of the RF conversion type set-top converters used by CATV systems.

On the other hand, cable systems with demodulating type headend or subscriber terminal equipment may not be able to pass MTS signals without substantial degradation to the stereo signal due to the use of low pass filters in the composite audio portions of demodulator facilities where stereo and SAP subcarriers are filtered out or severely distorted. However, newer cable headend equipment process BTSC stereo with very little degradation by carrying the BTSC composite signal through at IF (such as 4.5 MHz).

The baseband type set-top converter poses the greatest threat to BTSC stereo if the audio is demodulated within the converter itself. This is often done to permit the audio level, as well as the channel, to be controlled by a remote control device. BTSC stereo will not reliably pass through such devices and both stereo and SAP signals will be lost.

Most cable television systems maintain the visual-to-aural carrier ratio at 15 to 17 dB compared with the normal 7 to 10 dB for broadcast. This can add 5 to 10 dB more noise and buzz to the BTSC signal in the cable system. Therefore, it is important that the broadcaster limit degradation to the broadcast BTSC signal in order to insure that stereo carriage on cable systems is satisfactory.

The BTSC MTS signal should pass, without significant degradation, through amplitude and frequency modulated link (AML, FML) microwave systems or fiber optic systems used by many cable companies for wide area distribution of multiple channels.

Cable companies also routinely convert discrete stereo audio received from satellite program sources into BTSC stereo in NTSC modulators for distribution to subscribers. In some instances, less than full BTSC performance is achieved from these typically low cost modulators.

Television broadcasters will find it advantageous to determine how their stereo sound is processed in cable TV systems on which their station is carried and conduct routine performance tests. Most television stations routinely check the quality of the visual signal on cable TV systems which can introduce several additional active elements between the broadcast transmitter and home receiver. Basic audio tests for noise, stereo separation, pilot level, SAP channel quality and crosstalk between SAP and main channels should, at the very least, be conducted semi-annually at the output of a subscriber terminal on the largest cable systems carrying the station. This procedure will help insure that the cable company is properly handling (quality and loudness) the broadcast signal as well as cable satellite channels. A BTSC receiver of known characteristics and standard audio test instrumentation is needed to conduct the tests on the BTSC MTS signal. Such tests can be conducted with ordinary signal generators and audio level meters.

Compatibility with Television Translators

Many television broadcast signals are carried to remote communities by the use of translators that use RF power amplifiers ranging in size from 1 W to 1 kW.

Television translators that use heterodyne or direct RF conversion techniques normally do not cause degradation to BTSC MTS signals if the translator is properly maintained. Some translators, however, receive little attention unless they fail completely or viewers report poor performance.

Translators that separately process the visual and aural carriers may require modifications or adjustments to accommodate the BTSC MTS signal. Improvements include a wider bandwidth for the aural signal to accept the subcarriers in the BTSC signal, good visual transmitter oscillator stability to reduce ICPM and correct RF tuning to reduce SAM. Remodulating translators that demodulate and process the video also process the audio as a 4.5 MHz subcarrier similar to cable TV systems and have improved RF bandwidth characteristics with the result that little degradation occurs to the BTSC signal. Reducing the BTSC signal to wideband audio baseband with subcarriers requires a very linear FM modulator in order to accommodate the complex BTSC baseband.

Modulation Monitoring

Monitoring the modulation and conducting routine tests of the BTSC system can be accomplished by either a spectrum analyzer plus the standard audio instrumentation or a BTSC modulation monitor which provides continuous modulation information on all critical operating parameters. Stations must have the ability to monitor main mono channel, stereo composite, pilot, SAP, (and PRO channel, if used) and overall aural modulation levels during normal operation. Virtually all commercial modulation monitors provide the means to make accurate measurements of all operating parameters and technical tests. Table 6.3-2 lists the regularly monitored MTS transmission parameters.

Operating Practices

A compilation of transmission impairments that can cause stereo audio impairments is shown in Table 6.3-4.

Stereo synthesizers, used by some stations to provide a sense of stereo during monophonic programming, should not be used in place of or in addition to stereo encoding. Synthesizers can cause loss of localization of stereo sound sources because some program material accurately generates center channel information. Further, the effects of surround sound and other special aural techniques may be lost if the synthesizer is employed.

Table 6.3-4
Effects of transmission impairments.

FM detect	✓				✓	✓

ICPM, visual carrier over-modulation, severe group delay and phase distortion in the visual amplifier will cause buzz in the received audio and loss of stereo separation. These two characteristics are the most sensitive to problems with the stereo generator and RF systems.

Adjustment of the BTSC stereo encoder and dbx compressor circuits (used in both stereo and SAP channels) is not recommended without a thorough understanding of the overall system and appropriate test equipment. The service manuals for the stereo exciter contain the specific procedures for routine maintenance.

Ordinary harmonic distortion in the BTSC stereo baseband (50 Hz to 120 kHz) will result in increased crosstalk between channels. In order to keep crosstalk within limits distortion must be maintained to less than 0.5%.

FCC rules require all stations to provide protection to the pilot frequency by limiting modulation in the vicinity of the pilot 15,734 Hz (±20 Hz) to no more than 46 dB below 50 kHz deviation. The BTSC pilot frequency is immediately adjacent to the upper end of the frequency response for the main L+R channel. It is essential that monophonic as well as stereo stations insure the BTSC pilot is protected to avoid causing improper operation of stereo receivers and false stereo indications. While all MTS stereo exciters incorporate low pass filters with a sharp cut-off above 14 kHz, monophonic stations should install such a filter if adequate protection is not otherwise provided (see Figure 6.3-4). Measuring the pilot protection can be performed with a BTSC modulation monitor or a spectrum analyzer.

Many stations prefer to locate the stereo encoding equipment at the studio and transmit a composite MTS signal to the transmitter over an STL. The STL in effect becomes another section of the RF path where degradation to the BTSC signal can occur. Stereo separation, a good indicator of overall performance, will suffer if the baseband BTSC signal is degraded. In order to maintain at least 30 dB separation at the output of the transmitter, the STL should have at least 40 dB separation to compensate for degradation in the transmitter and elsewhere in the RF path. This means that the phase and amplitude frequency response across the 73 kHz baseband of the STL must be maintained to less than 0.1 dB combined with no more than 1° phase error as shown in Figure 6.3-11. This level of performance is achievable with modern BTSC encoding equipment.

For good stereo operation it is necessary that the left and right channels remain well separated ahead of, within, and at the end of the transmission chain.

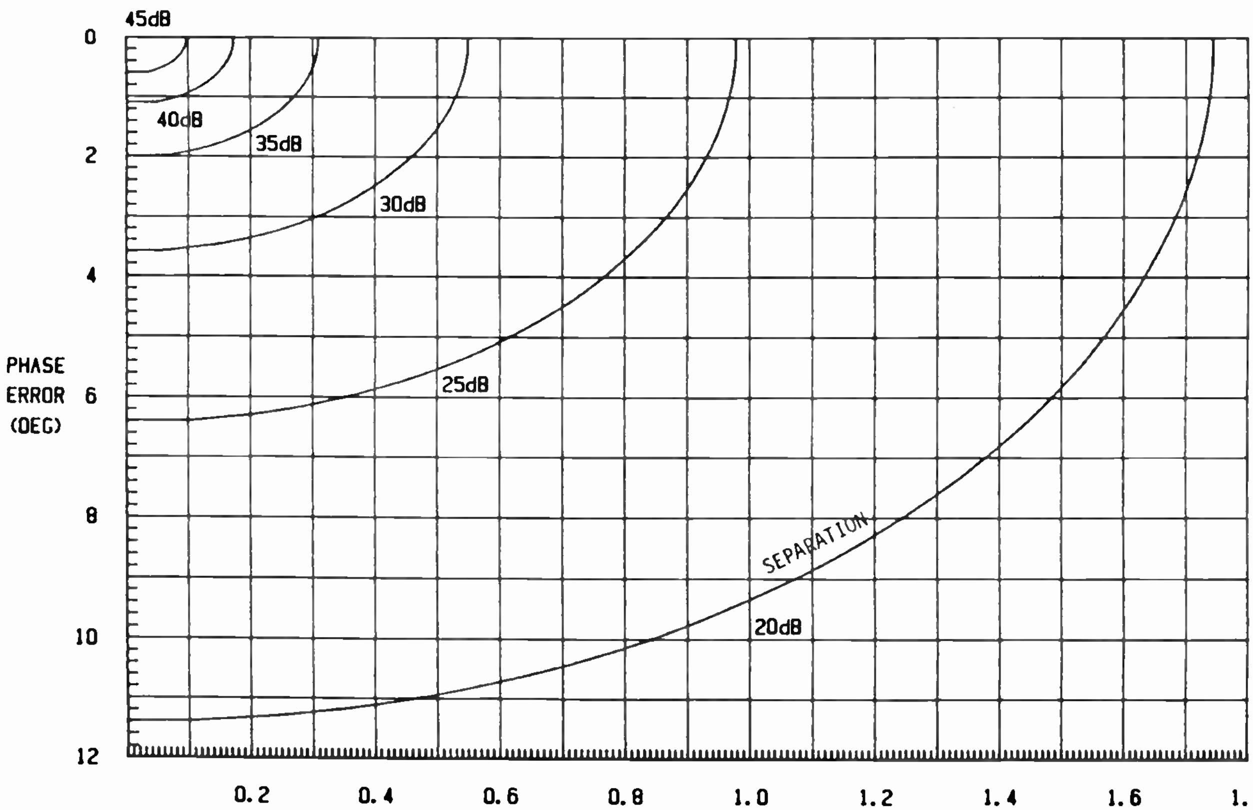

Figure 6.3-11. BTSC Separation vs. combined amplitude and phase errors in the composite baseband. (Courtesy Broadcast Electronics, Inc.)

The amplitude and phase of the left and right signals must be nearly identical and the phase of the pilot carrier must be maintained. Channel separation as a function of these three factors is given in the equation in Figure 6.3-12:

Separation in dB

$$= 20 \log 10 \frac{[(\cos \varphi + S/M \cos \Phi)2 + (\sin \varphi)2]}{[(\cos \varphi - S/M \cos \Phi)2 + (\sin \varphi)2]}$$

Where:

- M = the gain of the main (L + R) path
- S = the gain of the stereo (L − R) path
- Φ = the phase error of the reinserted 2H subcarrier (twice the error of the 1H pilot carrier)
- φ = the difference in phase between the L + R and L − R paths

Figure 6.3-12. Formula for calculating phase and amplitude changes.

Total Harmonic Distortion (THD) and intermodulation distortion on the composite STL must not exceed 0.25% to maintain crosstalk between channels at acceptable levels. If the SAP and PRO channels are also included in the composite baseband, the baseband performance values cited above must extend to 106 kHz.

Placing discrete stereo audio channels on the STL remains popular because most stereo encoders are located at the transmitter. Variations in the performance of discrete audio channels will produce less degradation of the stereo signal than will the same performance STL characteristics on the BTSC composite signal.

The BTSC stereo system has not become attractive for use on satellite transmission circuits for the reasons cited above for composite STL systems.

Off-air monitoring is essential to the maintenance of good stereo and monophonic sound. Reversed channel polarity (sometimes called *phase reversal*) on one channel may cause the stereo sound to be slightly degraded on stereo receivers but severe degradation will result to the sound on monophonic receivers. By using a consumer receiver for audio monitoring, buzz caused by over-modulation or ICPM can be detected at the station. Many stations employ both stereo and monophonic monitoring of the transmitted audio in order to insure that stereo imaging and channel polarity are correct.

The implementation of multichannel sound in a television facility which has not dealt with stereo or multiple audio channels in the past will find the experience to be a challenge. Virtually all audio equipment in the station will need to be reviewed, reworked, rewired, or replaced when adding new audio channels. Videotape machines, routing switchers, master control switching and monitoring, studio audio facilities and the STL will require close examination to determine how to implement extra sound channels. Videotape equipment with two sound channels may require new test procedures to determine that the phase relationships between channels is correct.

Special attention must be paid to audio processing. There will be a tendency towards maximizing the loudness of the signal rather than moderate processing which will result in more acceptable stereo sound quality. Sounding louder than the competition is fashionable in FM radio broadcasting but may not be necessary for television.

Multichannel sound equipped television receivers have substantially improved audio systems which will reveal audio faults now concealed by most television receivers. As a result, special attention must be devoted to the audio transmission facilities of all television stations, whether transmitting monophonic or multichannel sound.

6.4
TELEVISION DATA BROADCASTING

KELLY T. WILLIAMS
NATIONAL ASSOCIATION OF BROADCASTERS, WASHINGTON, DC
NEIL MITCHELL
PHILIPS SEMICONDUCTORS, SUNNYVALE, CA

INTRODUCTION

Changes in telecommunications markets and technologies are challenging TV broadcasters to broaden the definition of their business and address new market opportunities. One of these opportunities, which has excellent market potential, is the business of *data broadcasting* or *datacasting*.

The datacasting business is on the brink of becoming an explosive growth market. This is evidenced by the growth in demand for traditionally wireline based services such as the Internet and on-line services. With the advent of mobile computing, users will continue to want to have access to information services, but without connecting to a telephone line. Even in a home or business environment there are advantages to a wireless connection to information services, such as no requirement for additional phone lines and ease of installation. Datacasting promises to be a useful opportunity for television broadcasters looking to respond to the demand for data based information services.

The purpose of this chapter is to provide a fundamental understanding of the regulatory and technical issues of data broadcasting and to look at some of the potential applications for digital television. It begins with an overview of datacasting and its general applications, reviews regulatory issues and surveys the National Television Systems Committee (NTSC) technologies that are currently authorized by the FCC. The second section of this chapter examines specific datacasting applications that could be supported by the Advanced Television Systems Committee (ATSC) digital television system.

NTSC DATACASTING

What is Datacasting?

Generally, datacasting can be defined as the simultaneous delivery of digital information from a central source to a large number of geographically dispersed receivers. Specifically, current television datacasting uses the NTSC signal as the delivery mechanism for data based information. One very basic example of this is the closed caption system which sends digital information via the station's vertical blanking interval (VBI), at a modest rate of 480 bits per second (bps), to special decoders. Once decoded, the information is displayed on the TV screen as text.

Datacasting Applications

Television data broadcasting can be used to provide a multitude of services to businesses and consumers. Some of those applications are:

- Station information (call letters, network affiliation, etc.)
- Station program information (program schedules)
- Sports information (statistics)
- Traffic and weather information
- Internet information (news group and e-mail delivery)
- Electronic billboard content information
- Public utility load management

These are examples of applications that broadcasters can initiate themselves. There are additional applications and services that broadcasters could provide in partnership with other content providers, such as:

- Financial information (stock services)
- News services (newspapers, directed industry news)
- Web pages
- Interactive software
- Specialized business services (credit card verification data)

The potential for developing applications for data broadcasting is almost endless. So long as there is a demand for some type of digital information, TV data broadcasting can provide an innovative solution for wireless delivery.

Datacasting Regulations

The Federal Communications Commission (FCC) has allowed VBI based datacasting for some time. In addition to closed captions (Section 73.682(a)(21) of the FCC's Rules) there has been a general provision in the Rules for the *Telecommunications Service on the Vertical Blanking Interval* since March 4, 1985. As such, it is now general knowledge that broadcasters can place information, either analog or digital in nature, in their VBI without prior authorization from the FCC. This provision is found in Section 73.646 of the FCC Rules.

On June 21, 1996, the FCC adopted a *Report and Order* in MM Docket No. 95-42 that expanded TV broadcast stations' authority to use certain datacasting technologies without seeking the prior approval from the Commission. The FCC amended its rules to allow TV stations to transmit ancillary data in the NTSC television signal. The Commission approved systems from four companies for use by TV broadcasters: Yes! Entertainment Corporation, A. C. Nielsen Company, Digideck, Inc. and WavePhore Inc.

The FCC started this proceeding in May 1995, seeking to determine how best to permit data broadcasting technologies to be integrated into the NTSC broadcast television service. The *Notice of Proposed Rule Making* (NPRM) was initiated partially in response to a letter to the Commission from WavePhore requesting a declaratory ruling that licensees may, without prior Commission authorization, use WavePhore technology to transmit digital data signals.

The Commission, however, also had a number of unresolved requests for authorization that it bundled into this proceeding. In addition to the four companies listed previously, this proceeding also considered requests from Airtrax, Incorporated and En Technology. However, the Commission only approved the previously listed companies in the *Report and Order*. The FCC did subsequently approve the use of En Technology's system but only for limited use. The FCC also later approved a datacasting system from Microsoft.

FCC Approved Technologies for NTSC

A.C. Nielsen's AMOL System

Automated Measurement of Lineup (AMOL) is a proprietary VBI based technology that operates on line 22, the first line of active video. In the *Report and Order* in MM Docket No. 95-42, the FCC granted permanent authority to Nielsen to operate its system on line 22, but on a non-exclusive basis. Previously, Nielsen had been operating on a temporary, conditional authority issued by the FCC in November 1989.

Digideck, Incorporated

Digideck was a participant in the National Data Broadcasting Committee (NDBC) evaluation program. It was through this participation that the Commission approved its technology for use by broadcasters. The NPRM in MM Docket No. 95-42 did not discuss Digideck's technology; however, the work of the NDBC was submitted into the record of the proceeding and it included laboratory test information on both Digideck and WavePhore. The Electronic Industries Association (EIA) and NAB, on behalf of the NDBC submitted the laboratory data and the Commission approved use of the Digideck system.

Digideck's technology places a small carrier in the TV RF passband 1 MHz below the TV picture carrier and delivers a data rate of 525 kbps. A full system description of Digideck's technology is contained in Appendix B as part of the NDBC Final Report.

En Technology

En Technology's system encodes data in the VBI as well as over the visible portions or the TV picture (the data replaces the active video) transmitted by the television station. This system called *Cybercast* (originally *Malachi*) can deliver anywhere from 125.7 kbps (VBI) to 2.3 Mbps (full screen) to PC's equipped with a special *TV modem*. The modem can be programmed to permit reception of data in a variety of formats from VBI to any configuration of on-screen data. The on-screen data may be configured to start on any line of video, span any number of lines of video and any portion of each line of video, for applications where a mix of data and video is required.

Extended Data Service (XDS)

Extended Data Service (XDS) is a VBI data broadcasting scheme that allows broadcasters to send information about the station and its programming to consumers, such as the station's call sign, network affiliation, program title, length of the program and other information. The XDS data is interleaved with closed caption data on line 21 of the TV signal and its technical specification is documented within EIA Standard 608. XDS is also the technology that will likely be used to implement the V-chip blocking functions in TV receivers. The exact methodology will be determined pending the outcome of the FCC's TV ratings proceeding.

In May 1993, XDS was approved for use in the *Report and Order* in MM Docket No. 92-305 (which amended Rule sections 73.682 and 73.699 authorizing enhanced closed captions and other data services on field 2 of line 21).[1] Today there are only a handful of TV receiver models that respond to XDS, but that number is growing.

Microsoft/Yes! Entertainment

On October 24, 1996, the FCC approved Microsoft Corporation's data broadcasting technology. In a letter to Microsoft, the Commission stated that broadcast stations could use Microsoft's technology without prior authorization from the FCC. The Commission approved the use of this system because it is ostensibly the same as the technology developed by Yes! Entertainment Corporation that the Commission authorized in the *Report and Order* in MM docket No. 95-42. The Commission stated that the timing, amplitude and frequency parameters of Microsoft's technology were all within those of the Yes! system and thus should not pose problems for broadcasters.

Microsoft's system inserts data in the horizontal overscan area of the of the baseband television signal. It uses a one microsecond wide pulse (9.2–10.2 μs) placed between the end of the horizontal blanking interval and the beginning of the picture (the *back porch*) on each video line. The data is not placed on lines 1–24 of each field in order to avoid the VBI and any data being carried there. A data "1" symbol is represented by a luminance value of 80 IRE and a data "0" is represented by level of 7.5 IRE. The transmitted bit rate is approximately 14 kbps.

---

[1] This *Order* also reserved VBI line 19 for the ATSC Ghost Canceling Reference signal.

Teletext

In addition to closed captioning, another VBI data broadcasting service that has been in existence for some time is the *North American Basic Teletext Specification* (NABTS) or *Teletext.* Teletext is a technology that was developed in the 1970s as a method of delivering text information that could be displayed on a TV screen. It became very popular in Europe and Canada but never really caught on in the United States. NABTS specifies the use of multiple VBI lines and supports data rates up to approximately 56 kbps. Its technical specification is documented within EIA Standard 516. In recent years, NABTS has emerged as a general purpose VBI data delivery system because the technology is mature and very robust.

WavePhore, Incorporated

WavePhore was a participant in the NDBC evaluation program. Their TVT1/4 technology was approved for use by broadcasters in MM Docket No. 95-42. That proceeding was started partially because of a *Request for Declaratory Ruling* sent to the Commission by WavePhore. WavePhore's technology encodes baseband video in such a way that a subcarrier appears at the edge of the video passband in the RF signal. This system delivers a data rate of approximately 300 kbps. A complete system description is included in Appendix B as part of the NDBC Final Report.

National Data Broadcasting Committee (NDBC)

The NDBC was formed in 1993 and was co-sponsored by the National Association of Broadcasters and The Consumer Electronics Manufacturers Association (CEMA—a sector of the EIA). The Committee's purpose was to evaluate technologies that could be used for high-speed data broadcasting via over-the-air NTSC television transmissions. The NDBC held a total of ten meetings. The first was on September 16, 1993, and the last was held on December 17, 1996. The committee was co-chaired by a representative from both the broadcasting and consumer electronics industries. The co-chairs were Mr. Lynn Claudy, NAB and Mr. Werner Wedam, Sharp Laboratories of America representing CEMA.

The NDBC had two working groups—the Evaluation Working Group chaired by Mr. Bernard Caron (Communications Research Centre) and the Testing Working Group chaired by Mr. Victor Tawil (Association for Maximum Service Television). Originally, five companies submitted proposals for consideration in response to the committee's request for proposals but only two advanced to laboratory testing: WavePhore and Digideck.

Laboratory Testing

The committee evaluated the Digideck and WavePhore systems in laboratory tests during 1994 and 1995. The tests were performed at the Advanced Television Test Center (ATTC) in Alexandria, Virginia and were completed in October 1995. The laboratory program included the following tests that examined:

- Degradation to the host NTSC system
- Out of band emissions
- Impact on VBI services
- Interference
- The susceptibility of the data broadcasting systems to impairments

Numerous other tests were performed on the two candidate systems in order to observe issues such as recordability and real time delay. In June 1996, based on the results of the lab tests, the committee recommended both systems for evaluation through a field testing program.

Field Testing

The NDBC conducted field tests on Digideck's television data broadcasting system during the fall of 1996. (Just prior to beginning the tests, WavePhore elected not to participate in field test program.) The goal of the tests was to evaluate the performance of the data broadcasting system in over-the-air transmission conditions. The tests began on August 1, 1996 and were conducted in and around the Washington, DC metropolitan area.

The data signal was broadcast from two local stations: WJLA (Ch 7) and WETA (Ch 26). Measurements were taken at distances up to 45 miles away. Measurements at 100 outdoor locations were completed on August 30, 1996, and ten in-home sites were completed on September 18. The field test report indicated that satisfactory reception of data broadcast using Digideck's system at VHF was found at 93% of the test sites as compared to 82% satisfactory NTSC reception. At UHF, over 74% of locations had satisfactory data reception compared to 62% for NTSC.

The field test report was approved at the December 17, 1996, meeting and it stated that overall, the test results indicate that the Digideck's system provides data broadcasting service generally equivalent to the NTSC service area.

Final Actions

The NDBC voted at its final meeting on December 17, 1996, to create an *NDBC Final Report* that would include all of the technical work of the committee. In March 1997, that report was submitted to the FCC to become part of the Commission's technical record in Docket 95-42 on data broadcasting services. For a copy of the report contact NAB Science and Technology at (202) 429-5346.

ATSC DATACASTING

In addition to high definition video and multichannel audio, the new ATSC television standards support data broadcasting or *datacasting.* Datacasting may have just as much impact on the success of digital television as the audio and video.

ATSC datacasting services delivered at multi-megabit per second speeds and new intelligent receivers have the potential to make digital TV (DTV) far more valuable to the consumer and give broadcasters an opportunity to offer new services, generate additional revenue and accelerate the consumer migration to the new broadcast standard. The challenge for broadcasters is to begin to develop effective data content and services to support the next round of intelligent ATSC devices.

Two Datacasting Categories

ATSC datacasting applications are generally grouped in two categories:

- **Enhanced Television.** Data content related and synchronized to video program content.
- **Data Broadcast.** Data services not related to program content. An example would be current traffic conditions, stock market activity or even subscription services that utilize ATSC conditional access capabilities. Data broadcast bandwidth could also be sold to third parties for a wide range of applications not related to broadcast television.

This chapter will focus primarily on the enhanced television applications for ATSC datacasting applications that could redefine consumer expectations for television. It will describe a range of likely applications that could be supported by the proposed ATSC standards and the intelligent ATSC receivers and PC based receivers that manufacturers are developing.

There are a number of ways the ATSC datacasting capabilities could be used to enhance program content and provide a compelling reason for consumers to purchase an ATSC converter box for their existing television—or even a complete digital television.

Based on the specifications detailed in both proposed standards, and the capabilities that the consumer electronics companies are considering for their ATSC receivers, what follows is a description of what a viewer might see within next few years if they have an intelligent ATSC receiver.

The viewer is watching a travel program. When there is datacasting content related to the program, an icon could appear on the screen in an unobtrusive manner (see Figure 6.4-1). If interested in seeing more information, the viewer could push a button on the remote.

Figure 6.4-2. ATSC Screen with second level menus.

The next level of information, also unobtrusive, could identify the types of content available (see Figure 6.4-2).

If a category looks enticing, the viewer could select the category—for example *travel*, then choose whether to the view information immediately or bookmark it and retrieve it later (see Figure 6.4-3). Bookmarking would instruct the receiver to store the data in local memory for later use.

If the viewer decided to look at the datacasting content immediately, the moving video image could shrink and reveal additional menus allowing the viewer to go a level or two deeper for information (see Figure 6.4-4). Again, the viewer could bookmark it (store it for later viewing), view it on screen immediately or even print it.

Another feature being considered by many receiver manufacturers is a built-in reverse communications channel (such as a modem) and Internet browser. The ATSC standard will likely support links to a related website, allowing receivers with Web browsers to automatically connect to a website to support interactive applications, even ordering goods and services.

If there is a reverse communications channel, the viewer could request additional information, generate an automatic e-mail or transparently link to an Internet site.

Notice the ad in the lower right side of the screen in Figure 6.4-4. Datacasting can provide new opportunities for advertising, in this case a resort hotel in the area.

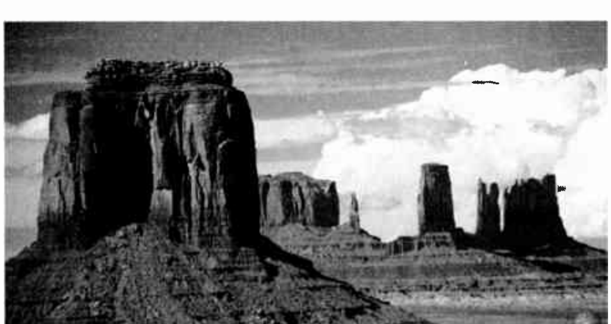

Figure 6.4-1. ATSC display with datacast icon.

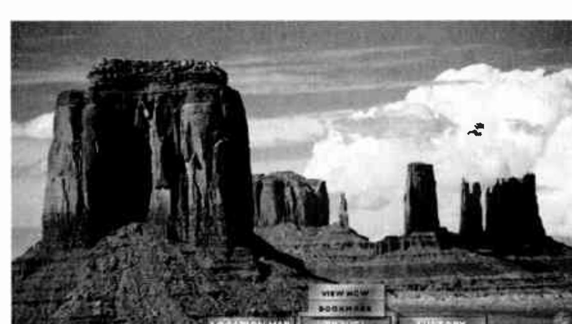

Figure 6.4-3. ATSC screen with *bookmark view now* menus.

Figure 6.4-4. ATSC screen with reduced picture area and hotel ad.

Figure 6.4-6. Football game screen.

Distracting the Viewer

Producers, broadcasters and most import advertisers have voiced concerns about distracting a viewer with data content during the program and the possibility of moving the viewer's attention away from the television program to the Internet. These are valid concerns with no clear answers. Nevertheless broadcasters, producers and advertisers are already developing scenarios for enhancing program content with datacasting.

For advertising, one technique with great potential is expanded use of placement promotions—a viewer watching anything from a situation comedy to a home improvement program could have immediate access to anything shown in the program. If a viewer liked the clothing, the furniture or the car, with the push of a button more detailed information could be available immediately. The value of product placements in home improvement shows could increase significantly if a viewer could obtain more information about the product and where to purchase it.

For conventional advertising, datacasting could give viewers the opportunity to respond immediately if they wanted more information. In Figure 6.4-5 information about biking events, products and where-to-buy are available. Datacasting could also support a second level of advertising enhancement. Once the viewer has responded to the primary message, datacasting gives the advertiser an opportunity to promote related products. In this ad for bicycles, a second level menu can also promote helmets and clothing. If the receiver supports a reverse communications channel, the viewer could respond directly to the advertiser, register for a related biking event, or even purchase a product.

In a sporting event, when the datacasting icon appears, the viewer could push a button on the remote to bring up the next level of menus and select a category, for example, merchandise, and decide to look at it immediately (see Figure 6.4-6). The viewer could select a team to see what is available and even purchase it, all the while watching the game.

There is enough data carrying capacity in the ATSC standard to download information to support multiple menus—every possible menu selection in this example could easily be downloaded in less than 10 seconds. Of course the receiver would have to be equipped with enough memory to store the various menus. The proposed standard will likely have a provision to carousel data, that is broadcast it multiple times, making it available to support a viewer's selection within seconds even if the receiver does not have sufficient memory to store all of the data necessary to support a series of menu options. There is also enough broadcast data capacity to send pictures and multimedia content—video and audio—and use new techniques such as immersive photography and JAVA applets.

Datacasting could also enhance news programs. For this example (Figure 6.4-7), video content in a 4:3 aspect ratio is used allowing the news program to be simultaneously broadcast for NTSC and ATSC viewers. But the ATSC viewers would have immediate access to additional information such as transcripts, still images and related stories. A digital viewer could

Figure 6.4-5. Diablo bike ad.

Figure 6.4-7. News screen.

also have access to local information such as weather, traffic and more.

Even with the same video program content, this scenario demonstrates how ATSC datacasting can provide benefits to consumers who simply purchase a relatively low-cost ATSC converter box capable of supporting datacasting.

Of course, a broadcaster could use datacasting to provide local information such as weather and traffic 24 hours a day, making the television in the family room a primary source for instant information. Broadcasters might also offer specialized subscription services that could entice select groups of viewers to tune to their station for specialized information. For example a broadcaster could add doctors, financial professionals and other select demographic groups to its audience because of the unique subscription services it offers.

Standards for Intelligent Receivers

Consumer electronics and PC manufacturers are actively designing a new generation of flexible DTV receivers capable of processing and displaying datacasting content. There are three standards. The fundamental one way data transport, the protocol for a return channel to enable interactive services and receiver environment standard. The receiver environment standard defines the processing software and application program interface routines.

The standards allow content to be created in a single format that would automatically be presented in alternative formats depending on the receiver's capabilities integrated very well with the Application Execution Engine and Java framework making them relatively platform independent.

Existing Web authoring tools should be usable by content development as well as support reuse of most existing Web content. Reformat of content datacasting applications and TV display can be performed. Existing transaction and order fulfillment servers used for Web-based services are supported.

Links between a program related website and a broadcast program are supported. A viewer can interact with the content included in the datacasting stream or a broadcaster could easily create links between the broadcast program and a program related website.

Support for Web browsing in order to support useful datacasting services is not required. Low cost receivers will be able to process and display datacasting content without requiring a browser and reverse communications channel.

Program related content is supported with techniques to synchronize data content to specific segments of a video stream and precise layout control for data content to coexist with a video image.

DTV Receivers

DTV receiver manufacturers have several options to develop receivers capable of handling datacasting. One is the traditional PC architecture.

An alternative approach taken by several consumer electronics companies is to use low cost programmable media processors. These processors handle ATSC stream demultiplexing, decoding, plus control and communications functions on a single chip. Some of these media processor chips can even support a complete Internet browser, software modem and video e-mail.

It is clear that consumers will soon expect digital television receivers to bring more than just TV into their homes. ATSC datacasting already has producers developing enhanced content for their programs, advertisers and consumer products companies testing how to use datacasting effectively and the consumer electronics and PC companies developing the next generation of intelligent, programmable DTV receivers to bring new services into viewers' homes.

6.5
TRANSMISSION SYSTEM CONTROL AND MONITORING

JOHN E. LEONARD, JR., CONSULTANT
GENTNER COMMUNICATIONS CORPORATION, SALT LAKE CITY, UT

INTRODUCTION

Transmission system control and monitoring is often simply perceived simply as transmitter remote control. However, it must also be recognized that, unlike radio, television is more station specific with regards to transmitting equipment and how it must operate. While radio has AM and FM, television has VHF, UHF, lower power stations, boosters and translators. Translators exist in FM, but television has typically regarded them in a different manner. Before exploring what is now taking place, a brief review of the current regulations for transmitter remote control is appropriate.

In 1953, the Federal Communications Commission (FCC), under Part 73 of its Rules and Regulations, permitted remote control of broadcast transmitters. Initially AM radio stations, up to a given power level, were authorized to operate via remote control. By 1957, most radio stations were allowed to operate with remote control. The first television transmitter remote control operation was permitted in 1963. At that time only UHF stations could use transmitter remote control. In 1971, VHF finally had the ability of remote controlling their transmitters. Also at that time, all classes of broadcast transmitters had remote control capability available in some way.

In 1977, the radio rules underwent some changes, and in 1984 the Rules were amended to have remote control under a uniform code; in addition, there was a relaxation of certain previous requirements.

The most recent Rules changes occurred in late 1995 and impacted full power television (Part 73) and all other over-the-air television (Part 74). The FCC action under MM Docket No. 94-130 (FCC 95-412) recognized unattended operation of broadcast stations and it updated transmitter control and monitoring requirements. These regulatory requirement changes within Part 73, specifically for television, are the focus of this chapter. The changes in Part 74 relate to low power television and translators and simply mirrored those requirements within Part 73. Current industry practices and typical equipment used will also be discussed.

Digital television (DTV) was officially introduced to the industry in 1996 through on-air field tests. DTV is addressed in this chapter, but keep in mind that DTV was in the early stages of implementation at this writing. Other chapters of this *Handbook* covering related subjects will also be cross-referenced here.

APPLICABLE REGULATIONS

UHF television began using transmitter remote control in 1963 and VHF in 1971. The 1984 Rules amendments placed remote control under a uniform code and relaxed some previous requirements. The changes that occurred in 1995 from the FCC MM Docket No. 94-130 (FCC 95-412) affected all areas of broadcast. Part 73 will receive principal attention here. Specifically, unattended operation and *automatic transmission systems* (ATS) were among the areas addressed. FCC 95-412 created Parts 73.1300 and 73.1350 and revised Part 73.1400. These sections have become the principal controlling parts of the FCC Rules and Regulations in relation to transmitter remote control.

It is interesting to note the parts that were removed by FCC 95-412. Sections 73.1410 *Remote Control Operation*, 73.1500 *Automatic Transmission System* and 73.1550 *Extension Meters* were all deleted.

The *Discussion, Universal Application* section of FCC 95-412, Paragraph 10, contained the following:

> Therefore, all types of standard (AM, FM and TV) stations, as well as international broadcast stations will be permitted to operate unattended. The same permission applies to low power TV (LPTV) with locally originated programming.

Also involved was the implementation of Emergency Alert System (EAS). At the time of the adoption of FCC 95-412, EAS was still a new concept. (EAS must be observed when operating via remote control, attended or unattended.) Chapter 1.12, *EAS Standard* presents detailed information about EAS.

The specific permissible methods of remote transmitter control added by FCC 95-412 were the use of the public switched telephone network in lieu of the previous dedicated interconnecting circuits or lines. While it removed Section 73.1500 (Automatic Transmission System) this Docket redefined ATS and how it can be used. In Section 73.1580 the Docket also clarified the transmission inspection requirements to be *periodic*. The clarification of ATS is found in 73.1350 and 73.1400. Also clarified in Section 73.1635, *Special Temporary Authorizations* (STA), was the relationship to Section 73.1350 (and the interrelationship to other sections).

In general, remote operation of any broadcast transmitter is under the control and the responsibility of the licensee. In the *Discussion, Unattended Operation* section of FCC 95-412, Paragraph 7 was added:

> 7. The Commission, based upon its experience in enforcing broadcast rules, concurs with the majority opinion that waiver of Section 318 of the Act to permit unattended operation is not likely to result in an increase in operation outside the tolerances specified in the Rules or the station authorization and will not adversely affect the public interest. Significant technical malfunctions should quickly become obvious and we do not anticipate their continuance for significant periods of time. The waiver appears further justified for reasons of efficiency, in order that our broadcast licensees can best decide how to allocate resources to ensure compliance. Therefore, the rules relating to station operators will be eliminated or revised as proposed in the Notice so as to permit unattended broadcast station operation.

In essence the prevailing concept from FCC 95-412 is broadcasters should do what is best for their station in relation to remote control. But it also indicates that each station must be sure that what it is doing is appropriate. No longer has the Commission attempted to provide specific requirements in lengthy Rules and Regulations. Rather, the sections referenced by the current Rules simply need to be understood in for each station's precise situation.

With DTV coming into being, there were specific section(s) added to the Rules and Regulations to accommodate digital transmitters. While digital television transmitters are clearly different from existing analog transmitters, the actual operating theories remain such that the current applicable sections will apply.

Sections 73.1300, 73.1350 and 73.1400 are reproduced at the end of this chapter in Appendix A. Section 73.691, *Visual Modulation Monitoring* is also of importance, as are 73.1820 *Station Log* and 73.1870 *Chief Operators.*

CURRENT PRACTICES

Transmitter remote control came into existence first to keep stations on the air and second to do so while saving money. Remote control was not intended to alter the method of operation for a given television station. Remote control must keep the station on the air, and monitor what is occurring. This application becomes a lofty requirement for remote control with ATS-type possibilities and exacting modulation monitoring needs.

Radio has its own unique requirements for remote control as does television (see Chapter 4.9 *AM Antenna Coupling and Phasing Systems*). With television (existing, analog transmitters) the first technical difference relates to the fact that a TV transmitter is actually two transmitters—one FM in nature (the aural transmitter) and the other AM in nature (the video transmitter). Basic technical differences exist for the monitoring requirements of each. The specifics of each transmitter determine what parameters must be monitored.

Modulation monitoring of the transmitter must occur. Section 73.691 outlines the visual modulation monitoring requirements and references 73.682. 73.682 provide the particulars of both the analog visual and the aural transmitters. It is common practice to separate the actual signal measurement and monitoring from the transmitter remote control system. Some stations, however, do interrelate transmitter remote control with signal measurement and modulation monitors.

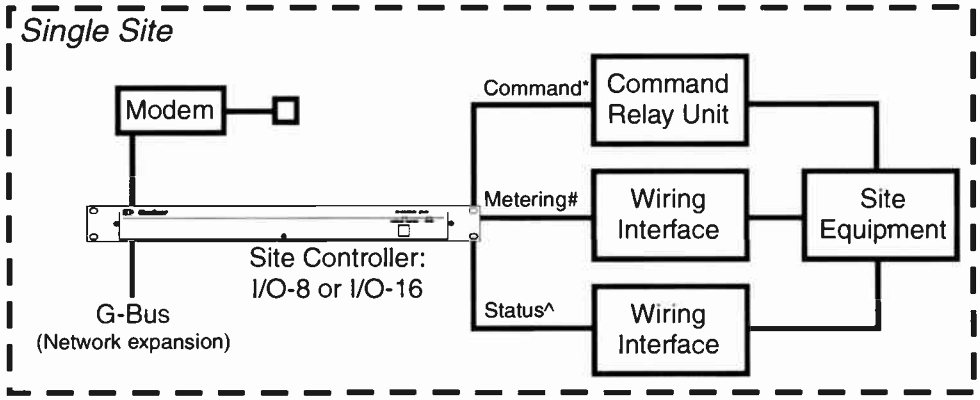
As is evident from an examination of the Rules, the actual delineation is left undetermined. This enables the interrelationship of monitoring equipment and transmitter remote control equipment, making ATS—and similar—possibilities almost unlimited.

Transmitter remote control equipment has had several classic characteristics that relate specifically to the transmitter. First, is the ability to present or display actual parameter values in real-time (metering). Second is the ability to issue commands—the ability to actually control something. Finally, a simple go/no-go display or indication is provided (status). The requirements of specific transmitters have made the implementation of these functions unique to broadcasting. A general overview of transmitter remote control functions is given in Figure 6.5-1.

Metering has unique requirements created by the parameter being monitored. For example, the measurement of transmitter RF power output is of significant importance. To ensure that the transmitter remote control system is presenting the correct numeric value, calibration or verification of power output is necessary. One factor that impacts this parameter is the method used to sample power. Because the reflectometer is the standard device used for power measurement, the mathematical relationship of the sampled value to the value delivered to the remote metering system is critical. Many transmitter remote control systems include various modes of operation for each metering channel. With this equipment being microprocessor based, power-to-linear conversion is practical for multiple metered channels.

Some will also choose to use the classic indirect method of determining power output, where the input parameters of the amplifier are multiplied and a mathematical correction is applied based upon the actual efficiency of the specific amplifier. Transmitters that produce a sample of power output that is linear in nature also are available thus making this interface easier.

Recent Rules revisions have fostered an interrelationship between the capabilities of the modulation monitoring equipment and the remote control equipment. This interconnection concept makes possible



* Either a solid-state type or dry-contact closure output. Typically this type of equipment has these as a joined pair (two outputs) and referred to as raise/lower. This was due to the original need to control the output power of the transmitter.

Commonly referred to as a DC sampling voltage. This DC voltage has a direct relationship to the actual transmitter parameter. These are typically in the range of 0.5 to 3.5 Vdc.

^ Typically a single or double-state condition, such as a dry-contact closure or it can be in a solid-state or digital condition or state. This digital state further simplifies the direct interface between this and other monitoring equipment.

Figure 6.5-1. Typical transmitter remote control equipment input/output configurations.

unique ATS implementations that are specific to a single transmitter site.

Modern transmitters provide what their manufacturers view as required elements for proper operation. Power output, at the proper level, may be the prime area of concern for a station. A review of the *FCC TV Broadcast Station Self-Inspection Checklist* (Bulletin CIB-18TV) confirms the emphasis on control and metering of output power from the transmitter. To be understood from that review is the need for maintaining and monitoring power output, turning the transmitter on and off, monitoring modulation and observing the functionality of tower lights.

Input and Output Functions

The primary function of a transmitter remote control system is monitoring and controlling the transmitter. With the emerging need to monitor more than just the basic transmitter parameters, both metering and status inputs may need to interface with other equipment, such as modulation monitors. The specifics of such interfaces are determined by the actual specifications of the equipment involved. As an example, it could be useful to take an over modulation output signal from a modulation monitor and interface it with a status input. The status inputs could also be interfaced with security systems and other ancillary devices. A similar capability exists with metering inputs.

Remote control equipment manufacturers provide sampling devices for a variety of parameters. Many of these devices relate to the metering input functions. Examples include temperature, ac line voltage and current. Such sensors can be used to observe of the operating parameters of tower lights (if not equipped with their own sensors), air conditioning equipment and other critical systems.

The command output interface may assume one of many forms. As is noted in Figure 6.5-1, both solid-state and dry-contact closure command outputs are useful for transmitter remote control. The dry-contact (relay) interface is usually the most flexible, although it is also usually the most expensive. A similar situation can occur with status inputs. The specific requirements of some status inputs may dictate an interface device. Specific solutions in this area are typically provided by the remote control equipment manufacturer.

Transmitter Interface

Modern television transmitters—as a general rule—include all of the remote control interfaces required for normal applications. As such, connection of the transmitter to the remote control system is a comparatively simple task. The actual physical locations of this equipment may present more of a challenge than the electrical specifications.

Attention must, however, be paid to the exact characteristics of the sample provided by the transmitter and the input needs of transmitter remote control equipment. For metering interface to the remote control equipment, some transmitters may require a dc isolation amplifier or similar device. The same caution applies to the status input and command output interface. Verifying all specifications when planning a new system is advisable. Extensive discussion of interface methods and devices is given in Chapter 4.7, *Transmission System Control and Monitoring*.

Automatic Transmitter System Operations (ATS)

As stated previously, an ATS system can be established by the station licensee. Such operation may, in fact, be provided from the combination of a number of separate systems. Depending upon the class of license and its related transmitter, ATS may be performed totally by the transmitter itself. Such capabilities can also be combined with those of the transmitter remote control system to enhance the overall capabilities.

Modern transmitter remote control equipment has the capability of comparing actual metering inputs with preset values. When those values are exceeded, the remote control equipment can initiate a correcting action, or simply sound some form of alert to report that the condition has happened and exists (or existed). The same function also is common with status inputs. Some tower lighting control systems have similar capabilities. When these multiple capabilities are then combined with other smart devices and systems, the ATS capabilities can become almost unlimited.

Automatic Transmitter Logging Systems

Certain transmitter remote control systems have the ability to meet not only ATS requirements, but also some of the recording capabilities required by the Rules. In the past this function was referred to as *automatic logging*. Some existing transmitter remote control equipment can provide at least segments of what the current Rules require, given the interconnection possibilities presented. Considering the calibration confirmation requirements in the current Rules, it is the author's interpretation that a totally automatic logging system for a station may not be currently economically feasible. Recording the calibration of all the systems involved in an ATS system may go beyond the capabilities readily available. Still, certain elements are in place today that fulfill many of the stated requirements.

For example, Figure 6.5-2 is a screen capture of a computer based logging (recording) transmitter remote

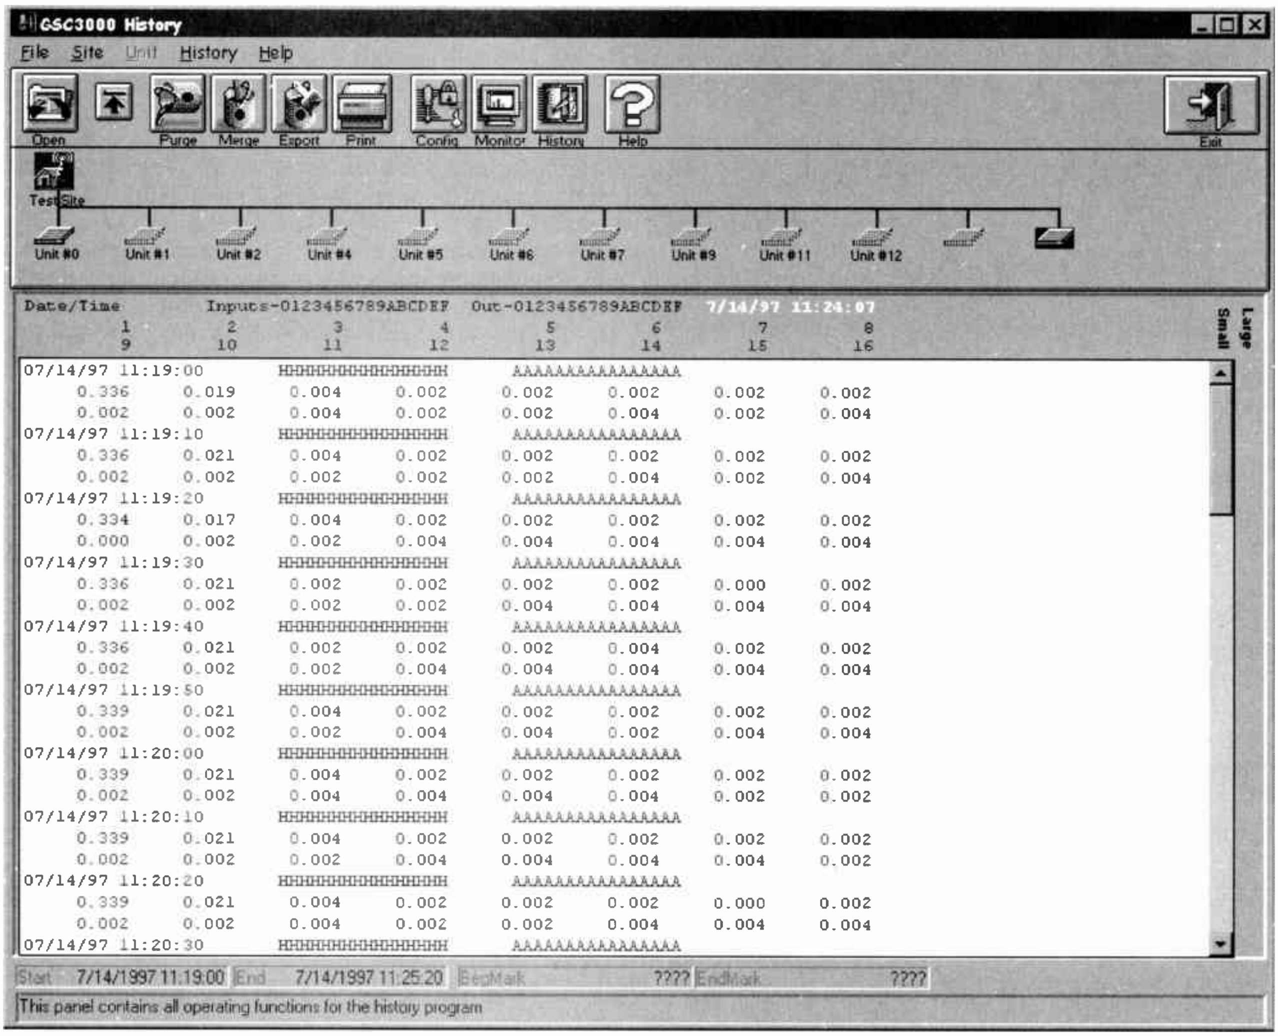


Figure 6.5-2. Data stored within a PC Windows® presentation from networked transmitter remote control equipment.

control system. Such logging can meet the majority of the determined needs. Again, preplanning for installation of the transmitter remote control can be of great help.

CURRENTLY AVAILABLE EQUIPMENT

Transmitter remote control equipment has historically been classified by the number of *channels*. These channels relate to metering capability, status capability and command capability. Some noticeable changes have recently occurred in the equipment specifically supplied for remote television transmitter operation. As the word *digital* became prominent in television in general, the same technology found its way into transmitter remote control equipment. The addition of networking capabilities to this type of equipment is having and will continue to have a significant impact. Networking adds expansion capabilities to the numbers—number of channels and number of sites.

In a classic remote control system, information is simply moved from one place to another, usually from the transmitter site to the studio. The information moved is the remote display of metered values, such as plate or emitter voltage and currents, plus power output. Status is used for indicated situations. Included also is the issuing of commands back to the site. These functions have been accomplished in a digital manner for some time. The 1984 Rules change added capabilities that some in the industry had clearly favored. Those basic capabilities were the use of standard dial telephone circuits and the use of touch-tone command capability with voice response for information feedback. The equipment that provided those capabilities was microprocessor based and also had internal decision making capabilities. Those capabilities are what then permitted unattended operation without human supervision, resulting in the 1995 Rules changes.

The equipment that is available today is all digital; many—perhaps most—are microprocessor based. This creates an environment in which the total system can have the ability to be smart. By smart the implication made is the equipment, on its own, makes a decision or takes action. Advanced transmitters also include such capabilities, as do some modulation monitoring equipment. Thus, by combining the transmitter remote control equipment with a smart modulation monitor (and a smart transmitter, if so equipped) the transmitter site location can thus become an ATS system.

In the original physical conception of a transmitter remote control system, two units were used—the transmitter and the studio. Predictably, one was physically located at the studio, and the other was at the transmitter site. Television requirements, as compared with radio applications, can dictate a massive transmitter remote control requirement. Each station has its own particular situation. Many have two or more transmitters—a main and backup or standby. Additional transmitter sites also can exist, such as for translators and booster transmitters. A television station, thus, can have many transmitters at many different locations.

Communication between these distant points typically occurs in some analog or digital form. One analog form that entered the industry with the 1984 Rules revisions was the use of a telephone instrument as the studio unit of the system. A touch-tone (DTMF) type instrument became one end, with the transmitter unit accepting DTMF codes for commands and producing a synthesized voice for the returning data. This type of unit used a microprocessor (thus it had smarts). While television typically has used this concept, it was not until 1995 that this approach became the principal method of television transmitter remote control. Other digital systems were used, with the other end typically being either a digital studio unit or a personal computer (PC).

Attributes and options for current remote control systems include the following:

- Studio/transmitter unit, with PC monitoring (at either or both locations): interconnection via a dedicated telephone line or interconnection via a dedicated wireless link
- Transmitter unit, with personal computer monitoring: interconnection locally, at transmitter, between PC and unit; interconnection via a dedicated telephone line; interconnection via a dedicated or shared wireless link; or interconnection via the public switched telephone network (PSTN).

A *dedicated wireless link* typically refers to the use of sound channels on a two-way video studio-to-transmitter link, or a sound channel to the transmitter site and a subcarrier on the aural transmitter for return data or data within the video. The *wireless links* using PSTN and plain old telephone system (POTS) interconnections refer to cellular or similar systems. A graphic presentation is given in Figure 6.5-3.

The PC has been linked to transmitter remote control for some time. The various operating systems of the PC have garnered much attention in the last few years. DOS was supplemented by Windows, then Windows moved to Windows 95, and to Windows NT. Figure 6.5-4 shows a Windows based remote control display. The graphic presentations provided by the operating system support multiple ways of presenting the conventional metering, status and command information. In Figure 6.5-4, metering is presented numerically as well as by bar graph.

Networking transmitter remote control has taken a major step forward by combining the strengths of the dedicated transmitter remote control system with the PC. The use of PC based smarts provides a number of user benefits, including:

- An accurate time base (time-of-day and date)
- Reliable and flexible supervisory command and data acquisition capability
- A near infallible memory capability for operation and recording data
- Addressability and changeability
- Multiple communications capabilities and types
- Off-the-shelf manufacturing economies of scale.

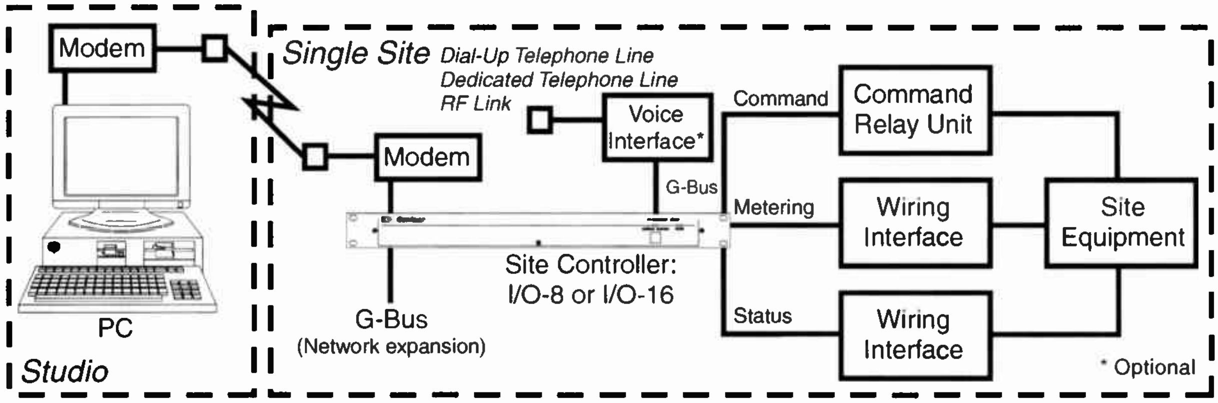

Figure 6.5-3. Possible interconnecting circuits for transmitter remote control equipment.

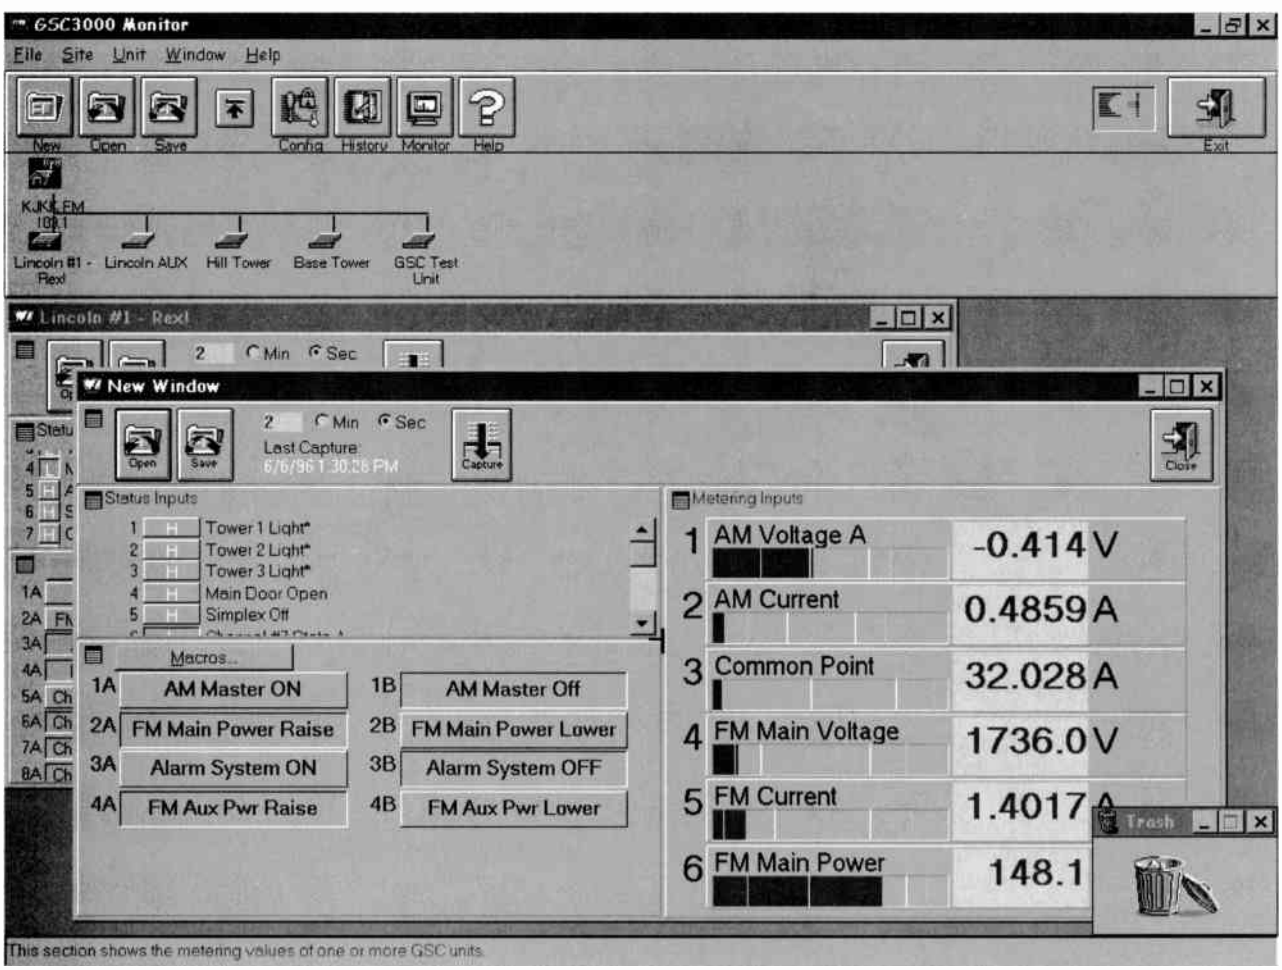

Figure 6.5-4. PC Windows® presentation from networked transmitter remote control equipment.

Networking includes more than just selection of the type of interconnecting circuit to be used. Rather, it enables an enormous expansion of capabilities. With the support of a controlling processor, a number of additional capabilities can be added, including:

- Limit monitoring and checking against preset points at multiple levels for each metering channel
- Selection, from each preset point, whether the measured value has created what can be classified as an alarm
- Selection, from each preset point, whether the measured value has crossed the point at which a command output should be activated
- The capability, beyond issuance of a command, to activate a chain of preprogrammed events—in other words, a macro
- Accomplish, from a status channel, with a change of state, the three previous points (alarm, issue command or start macro)
- Use of the internal time base (clock/calendar) within the unit to issue a command or to activate an internal macro at a preselected moment
- Recording the occurrence of any of the previous set points within its non-volatile memory for subsequent examination and reporting
- Establishment of an interlink with one or more other local unit.

These are just some of the internal capabilities that can exist within a computer based remote control system. The interconnection capabilities, given the networking concept, go beyond the type of circuit needed at the transmitter site. Because the unit is processor based, expansion is possible. This expansion can occur on a network and between units. Each unit also has its own unique channel capability. Processors are best used when with another processor—thereby creating multiple networks. (Figure 6.5-5 presents some of these capabilities.) While each unit shown in the Figure is a separate entity, they combine to make a system that is greater than the sum of its component parts. A common protocol enables communications at the local area network (LAN) level. The LAN can be open and unrestricted or manufacturer unique and proprietary.

The individual ports shown in the Figure 6.5-5 system support outward communications, such as a hardwired LAN or a modem. Local communications, being

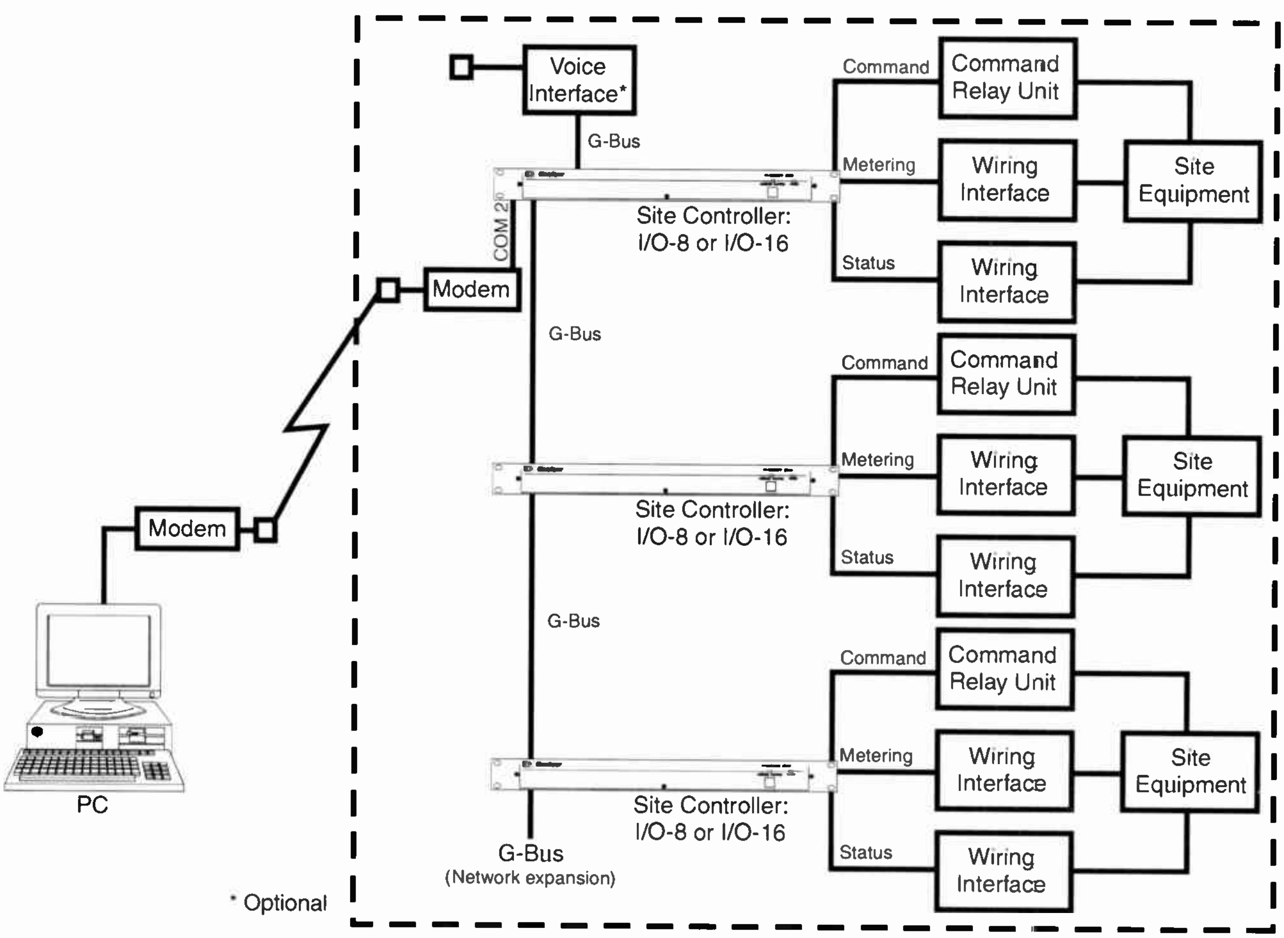

Figure 6.5-5. Networks used for transmitter remote control equipment.

pure data, can occur directly with a PC at the site. Multiple ports permit the unit to communicate not only with a local PC, but with a remotely located PC via a standard modem or other link. Through the use of a standard modem, the need for actual interconnection circuits can be simplified. Both 2-wire and 4-wire modems exist, thus supporting most commonly available analog communication circuits.

Figure 6.5-6 shows an actual transmitter status log. Note, at the top of the Figure is the date, the site and the time. The *header* then follows, with licensee, business address, call letters, channel and frequency, the remote control address, the transmitter address and the specific time being presented in the record. Next, are the actual entries selected, in a column format. Next is the measured data at the prescribed intervals, in this case, the data is taken every hour.

Further note the station's decision to have operators sign the printed log. This provides the station with an independent record of the individual they have placed in the transmitter operator position and the times that individual has been present. Other stations have made a conscious decision to have this capability, let it record, but have their operators maintain a handwritten log.

The network based remote control system is further refined in the configurations shown in Figures 6.5-7–6.5-9. Figure 6.5-7 illustrates the arrangement for one transmitter site and one studio. Figure 6.5-8 shows a site with expanded channel needs. The use of the POTS interconnection is shown. Figure 6.5-9 demonstrates how the network concept can expand as the number of transmitter sites increases. A voice interface may also be used to further enhance flexibility. When the PC and voice interface capabilities are combined, a system can be created to meet user specifications and needs.

For EAS applications, some interesting uses of available remote control equipment have appeared at some television stations. EAS equipment has the ability to digitally store the audio message delivered to it as part of an alert. The presence of that audio message is then sensed by a DTMF/synthesized voice transmitter remote control unit. The remote control can also relay the actual audio to the individual accessing it.

CONCLUSIONS

The FCC, with MM Docket No. 94-130 (FCC 95-412), created the opportunity for new technologies to be used in broadcasting. Without this docket, it is questionable whether transmitter remote control would have received the attention it deserved. FCC 95-412 motivated the development of networking capabilities within transmitter remote control, and the ATS potentials that now exist are unprecedented. This ATS capability may—in fact—prove very advantageous for television transmitter operation. These capabilities, and the new features that they offer, are now under the authority and control of the licensee. The new technologies, thus, can be used in the most efficient way for individual television stations.

APPENDIX A

FCC Regulations Parts—73.691, 73.1300, 73.1350, 73.1400, 73.1580, 73.1635, 73.1820, & 73.1870

§ Sec. 73.691 Visual Modulation Monitoring.

(a) Each TV station must have measuring equipment for determining that the transmitted visual signal conforms to the provisions of this subpart. The licensee shall decide the monitoring and measurement methods or procedures for indicating and controlling the visual signal.

(b) In the event technical problems make it impossible to operate in accordance with the timing and carrier level tolerance requirements of Sec. 73.682 (a)(9)(i), (a)(9)(ii), (a)(12), (a)(13), and (a)(17), a TV broadcast station may operate at variance for a period of not more than 30 days without specific authority from the FCC: provided that, the date and time of the initial out-of-tolerance condition has been entered in the station log. If the operation at variance will exceed 10 consecutive days, a notification must be sent to the FCC in Washington, D.C., not later than the 10th day of such operation. In the event normal operation is resumed prior to the end of the 30 day period, the licensee must notify the FCC upon restoration of normal operation. If causes beyond the control of the licensee prevent restoration of normal operation within 30 days, a written request must be made to the FCC in Washington, D.C., no later than the 30th day for such additional time as may be necessary.

§ Sec. 73.1300 Unattended Station Operation.

Broadcast stations may be operated as either attended (where a designated person is responsible for the proper operation of the transmitting apparatus either at the transmitter site, a remote control point or an ATS control point) or unattended (where highly stable equipment or automated monitoring of station operating parameters is employed). No prior FCC approval is required to operate a station in the unattended mode. Regardless of which method of station operation is employed, licensees must employ procedures which will ensure compliance with Part 11 of this chapter, the rules governing the Emergency Alert System (EAS).

§ Sec. 73.1350 Transmission System Operation.

(a) Each licensee is responsible for maintaining and operating its broadcast station in a manner which complies with the technical rules set forth elsewhere in this part and in accordance with the terms of the station authorization.

(b) The licensee must designate a chief operator in accordance with Sec. 73.1870. The licensee may designate one or more technically competent persons

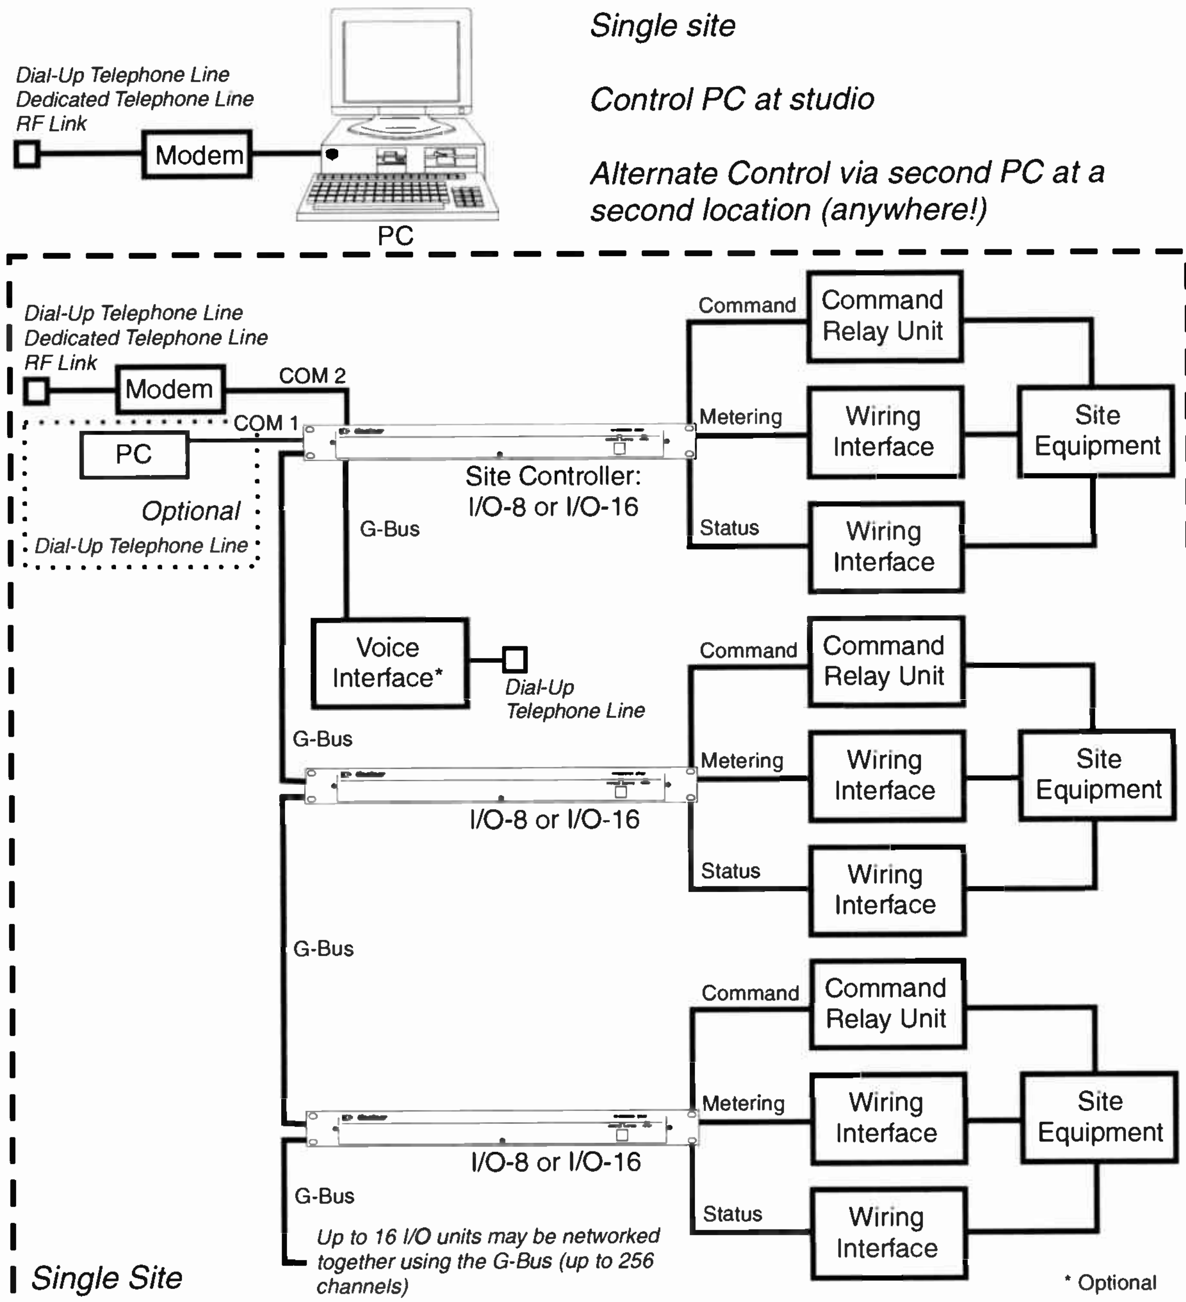

Figure 6.5-8. Another site of networking-type transmitter remote control equipment using POTS interconnection.

to adjust the transmitter operating parameters for compliance with the technical rules and the station authorization.

(1) Persons so authorized by the licensee may make such adjustments directly at the transmitter site or by using control equipment at an off-site location.

(2) The transmitter control personnel must have the capability to turn the transmitter off at all times. If the personnel are at a remote location, the control system must provide this capability continuously or must include an alternate method of acquiring control that can satisfy the requirement of paragraph (d) of this section that operation be terminated within 3 minutes.

(c) The licensee must establish monitoring procedures and schedules for the station and the indicating instruments employed must comply with Sec. 73.1215.

(1) Monitoring procedures and schedules must enable the licensee to determine compliance with Sec. 73.1560 regarding operating power and AM station mode of operation, Sec. 73.1570 regarding modulation

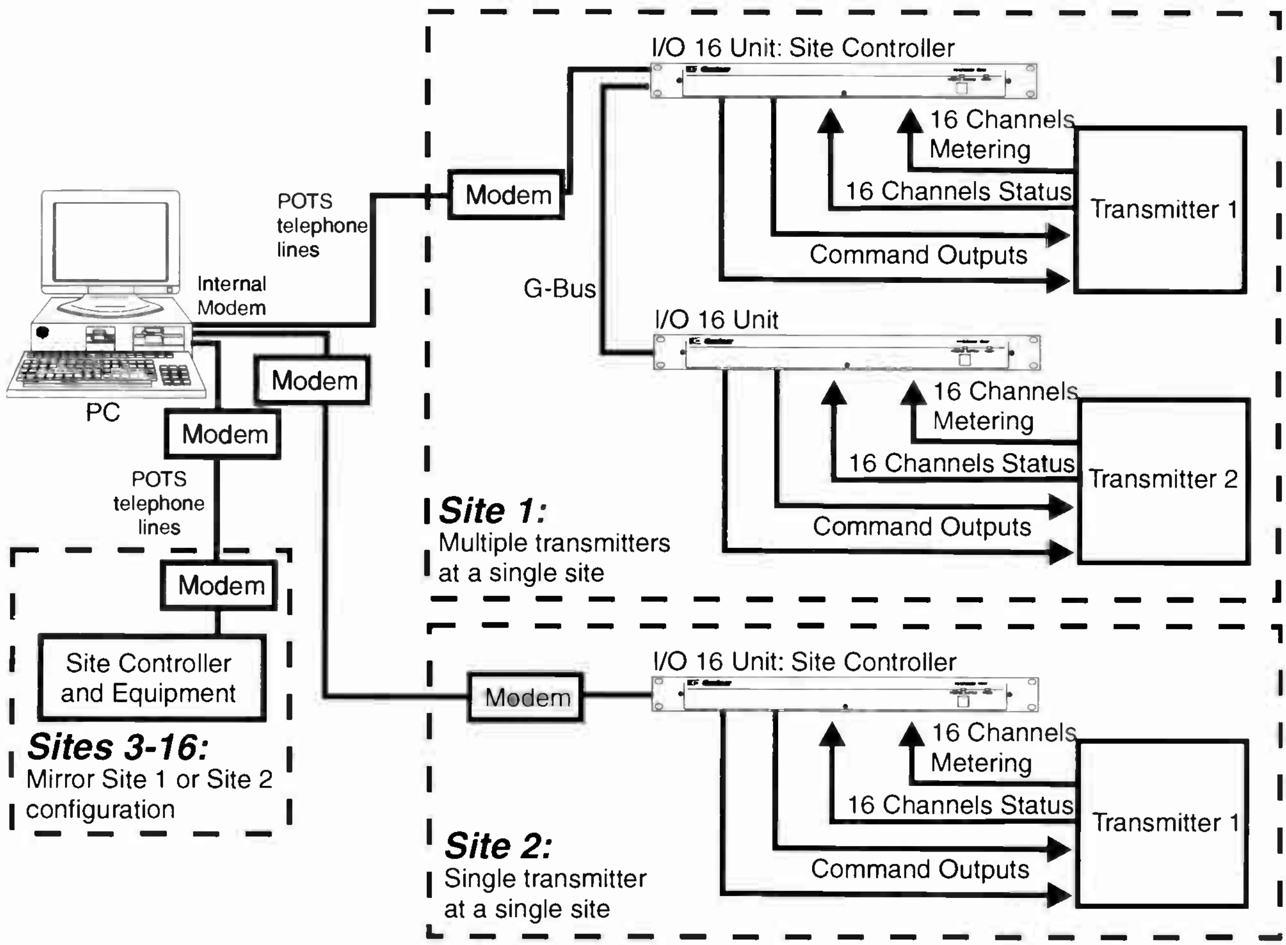

Figure 6.5-9. Overview of networking-type transmitter remote control equipment at 16 sites using POTS interconnection.

levels, and, where applicable, Sec. 73.1213 regarding antenna tower lighting, and Sec. 73.69 regarding the parameters of an AM directional antenna system.

(2) Monitoring equipment must be periodically calibrated so as to provide reliable indications of transmitter operating parameters with a known degree of accuracy. Errors inherent in monitoring equipment and the calibration procedure must be taken into account when adjusting operating parameters to ensure that the limits imposed by the technical rules and the station authorization are not exceeded.

(d) In the event that a broadcast station is operating in a manner that is not in compliance with the technical rules set forth elsewhere in this part or the terms of the station authorization, and the condition is not listed in paragraph (e) of this section, broadcast operation must be terminated within three hours.

(1) Examples of conditions that require termination of operation include excessive power or excessive modulation.

(2) Additional examples for AM stations are any mode of operation not specified by the station license for the pertinent time of day or hours of operation and any condition of antenna parameters or monitoring points out of the tolerances specified elsewhere in this part or by the station's instrument of authorization. For these conditions, operation must be terminated within three minutes unless antenna input power is reduced sufficiently to eliminate any excess radiation.

(3) For AM stations using directional arrays, additional procedures apply when array operating parameters are at variance, monitoring points exceed specified limits, or authorized directional mode capability is lost. See Sec. 73.62, Directional antenna system tolerances; Sec. 73.158, Directional antenna monitoring points; and Sec. 73.1680(b), Emergency antennas.

(e) If a broadcast station is operating in a manner that is not in compliance with one of the following technical rules, operation may continue if the station complies with relevant alternative provisions in the specified rule section.

(1) AM directional antenna system tolerances, see Sec. 73.62;

(2) AM directional antenna monitoring points, see Sec. 73.158;

(3) TV visual waveform, see Sec. 73.691(b);

(4) Reduced power operation, see Sec. 73.1560(d);
(5) Reduced modulation level, see Sec. 73.1570(a);
(6) Emergency antennas, see Sec. 73.1680.

(f) The transmission system must be maintained and inspected in accordance with Sec. 73.1580.

(g) Whenever a transmission system control point is established at a location other than at the main studio or transmitter, notification of that location must be sent to the FCC in Washington, D.C. within 3 days of the initial use of that point. This notification is not required if responsible station personnel can be contacted at the transmitter or studio site during hours of operation.

(h) The licensee must ensure that the station is operated in compliance with Part 11 of this chapter, the rules governing the Emergency Alert System (EAS).

§ 73.1400 Transmission System Monitoring and Control.

The licensee of an AM, FM or TV station is responsible for assuring that at all times the station operates within tolerances specified by applicable technical rules contained in this part and in accordance with the terms of the station authorization. Any method of complying with applicable tolerances is permissible. The following are typical methods of transmission system operation:

(a) Attended operation:

(1) Attended operation consists of ongoing supervision of the transmission facilities by a station employee or other person designated by the licensee. Such supervision may be accomplished by either:

(i) Direct supervision and control of transmission system parameters by a person at the transmitter site; or

(ii) Remote control of the transmission system by a person at the main studio or other location. The remote control system must provide sufficient transmission system monitoring and control capability so as to ensure compliance with Sec. 73.1350.

(2) A station may also be monitored and controlled by an automatic transmission system (ATS) that is configured to contact a person designated by the licensee in the event of a technical malfunction. An automatic transmission system consists of monitoring devices, control and alarm circuitry, arranged so that they interact automatically to operate the station's transmitter and maintain technical parameters within licensed values.

(3) A hybrid system containing some remote control and some ATS features is also permissible.

(4) In the case of remote control or ATS operation, not every station parameter need be monitored or controlled if the licensee has good reason to believe that its stability is so great that its monitoring and control are unnecessary.

(b) Unattended operation: Unattended operation is either the absence of human supervision or the substitution of automated supervision of a station's transmission system for human supervision. In the former case, equipment is employed which is expected to operate within assigned tolerances for extended periods of time. The latter consists of the use of a self-monitoring or ATS-monitored and controlled transmission system that, in lieu of contacting a person designated by the licensee, automatically takes the station off the air within three hours of any technical malfunction which is capable of causing interference.

§ Sec. 73.1580 Transmission System Inspections.

Each AM, FM, and TV station licensee or permittee must conduct periodic complete inspections of the transmitting system and all required monitors to ensure proper station operation.

§ Sec. 73.1635 Special Temporary Authorizations (STA).

(a) A special temporary authorization (STA) is the authority granted to a permittee or licensee to permit the operation of a broadcast facility for a limited period at a specified variance from the terms of the station authorization or requirements of the FCC rules applicable to the particular class of station.

(1) A request for a STA should be filed with FCC in Washington, DC at least 10 days prior to the date of the proposed operation.

(2) The request is to be made by letter and shall fully describe the proposed operation and the necessity for the requested STA. Such letter requests shall be signed by the licensee or the licensee's representative.

(3) A request for a STA necessitated by unforeseen equipment damage or failure may be made without regard to the procedural requirements of this section (e.g. via telegram or telephone). Any request made pursuant to this paragraph shall be followed by a written confirmation request conforming to the requirements of paragraph (a)(2) of this section. Confirmation requests shall be submitted within 24 hours. (See also Sec. 73.1680 Emergency Antennas).

(4) An STA may be granted for an initial period not to exceed 180 days. A limited number of extensions of such authorizations may be granted for additional periods not exceeding 180 days per extension. An STA necessitated by technical or equipment problems, however, may, in practice, be granted for an initial period not to exceed 90 days with a limited number of extensions not to exceed 90 days per extension. The permittee or licensee must demonstrate that any further extensions requested are necessary and that all steps to resume normal operation are being undertaken in an expeditions and timely fashion. The license of a broadcasting station that fails to transmit broadcast signals for any consecutive 12-month period expires as a matter of law at the end of that period, notwithstanding any STA or provision, term, or condition of the license to the contrary.

(5) Certain rules specify special considerations and procedures in situations requiring an STA or permit temporary operation at variance without prior authorization from the FCC when notification is filed as prescribed in the particular rules. See Sec. 73.62, Directional antenna system tolerances; Sec. 73.157, Antenna testing during daytime; Sec. 73.158, Directional

antenna monitoring points; Sec. 73.691, Visual modulation monitoring; Sec. 73.1250, Broadcasting emergency information; Sec. 73.1350, Transmission system operation; Sec. 73.1560, Operating power and mode tolerances; Sec. 73.1570, Modulation levels: AM, FM, and TV aural; Sec. 73.1615, Operation during modification of facilities; Sec. 73.1680, Emergency antennas; and Sec. 73.1740, Minimum operating schedule.

(b) An STA may be modified or cancelled by the FCC without prior notice or right to hearing.

(c) No request by an AM station for temporary authority to extend its hours of operation beyond those authorized by its regular authorization will be accepted or granted by the FCC except in emergency situations conforming with the requirements of Sec. 73.3542, Application for Emergency Authorization. See also Sec. 73.1250, Broadcasting Emergency Information.

§ Sec. 73.1820 Station Log.

(a) Entries must be made in the station log either manually by a person designated by the licensee who is in actual charge of the transmitting apparatus, or by automatic devices meeting the requirements of paragraph (b) of this section. Indications of operating parameters that are required to be logged must be logged prior to any adjustment of the equipment. Where adjustments are made to restore parameters to their proper operating values, the corrected indications must be logged and accompanied, if any parameter deviation was beyond a prescribed tolerance, by a notation describing the nature of the corrective action. Indications of all parameters whose values are affected by the modulation of the carrier must be read without modulation. The actual time of observation must be included in each log entry. The following information must be entered:

(1) All stations: (i) Entries required by Sec. 17.49 of this chapter concerning any observed or otherwise known extinguishment or improper functioning of a tower light:

(A) The nature of such extinguishment or improper functioning.

(B) The date and time the extinguishment or improper operation was observed or otherwise noted.

(C) The date, time and nature of adjustments, repairs or replacements made.

(ii) Any entries not specifically required in this section, but required by the instrument of authorization or elsewhere in this part.

(iii) An entry of each test and activation of the Emergency Alert System (EAS) pursuant to the requirement of part 11 of this chapter and the EAS Operating Handbook. Stations may keep EAS data in a special EAS log which shall be maintained at a convenient location; however, this log is considered a part of the station log.

(2) Directional AM stations without an FCC-approved antenna sampling system (See Sec. 73.68):

(i) An entry at the beginning of operations in each mode of operation, and thereafter at intervals not exceeding 3 hours, of the following (actual readings observed prior to making any adjustments to the equipment and an indication of any corrections to restore parameters to normal operating values):

(A) Common point current.

(B) When the operating power is determined by the indirect method, the efficiency factor F and either the product of the final amplifier input voltage and current or the calculated antenna input power. See Sec. 73.51(e).

(C) Antenna monitor phase or phase deviation indications.

(D) Antenna monitor sample currents, current ratios, or ratio deviation indications.

(ii) Entries required by Sec. 73.61 performed in accordance with the schedule specified therein.

(iii) Entries of the results of calibration of automatic logging devices (see paragraph (b) of this section) or indicating instruments (see Sec. 73.67), whenever performed.

(b) Automatic devices accurately calibrated and with appropriate time, date and circuit functions may be utilized to record entries in the station log Provided:

(1) The recording devices do not affect the operation of circuits or accuracy of indicating instruments of the equipment being recorded;

(2) The recording devices have an accuracy equivalent to the accuracy of the indicating instruments;

(3) The calibration is checked against the original indicators as often as necessary to ensure recording accuracy;

(4) In the event of failure or malfunctioning of the automatic equipment, the person designated by the licensee as being responsible for the log small make the required entries in the log manually at that time;

(5) The indicating equipment conforms to the requirements of Sec. 73.1215 (Indicating instruments—specifications) except that the scales need not exceed 5 cm (2 inches) in length. Arbitrary scales may not be used.

(c) In preparing the station log, original data may be recorded in rough form and later transcribed into the log.

§ Sec. 73.1870 Chief Operators.

(a) The licensee of each AM, FM, or TV broadcast station must designate a person to serve as the station's chief operator. At times when the chief operator is unavailable or unable to act (e.g., vacations, sickness), the licensee shall designate another person as the acting chief operator on a temporary basis.

(b) Chief operators shall be employed or serve on the following basis:

(1) The chief operator for an AM station using a directional antenna or operating with greater than 10 kW authorized power, or of a TV station is to be an employee of the station on duty for whatever number of hours each week the station licensee determines is necessary to keep the station's technical operation in compliance with FCC rules and the terms of the station authorization.

(2) Chief operators for non-directional AM stations operating with authorized powers not exceeding 10 kW and FM stations may be either an employee of the station or engaged to serve on a contract basis for whatever number of hours each week the licensee determines is necessary to keep the station's technical operation in compliance with the FCC rules and terms of the station authorization.

(3) The designation of the chief operator must be in writing with a copy of the designation posted with the station license. Agreements with chief operators serving on a contract basis must be in writing with a copy kept in the station files.

(c) The chief operator is responsible for completion of the following duties specified in this paragraph below. When these duties are delegated to other persons, the chief operator shall maintain supervisory oversight sufficient to know that each requirement has been fulfilled in a timely and correct manner.

(1) Inspections and calibrations of the transmission system, required monitors, metering and control systems; and any necessary repairs or adjustments where indicated. (See Sec. 73.1580.)

(2) Periodic AM field monitoring point measurements, equipment performance measurements, or other tests as specified in the rules or terms of the station license.

(3) Review of the station records at least once each week to determine if required entries are being made correctly. Additionally, verification must be made that the station has been operated as required by the rules or the station authorization. Upon completion of the review, the chief operator or his designee must date and sign the log, initiate any corrective action which may be necessary, and advise the station licensee of any condition which is repetitive.

(4) Any entries which may be required in the station records. (See Sec. 73.1820.)

6.6
WAVEGUIDE

JERRY WHITAKER
EDITOR-IN-CHIEF

INTRODUCTION

Any structure that guides electromagnetic waves can be considered a *waveguide*. Most often, however, this term refers to closed metal cylinders that maintain the same cross-sectional dimensions over long distances.

As the operating frequency of a system reaches into the UHF band, waveguide based transmission line systems become practical. From the mechanical standpoint, waveguide is simplicity itself. There is no inner conductor; RF energy is *launched* into the structure and propagates to the load. Several types of waveguide are available, including rectangular, square, circular and elliptical. Waveguide offers several advantages over coax. First, unlike coax, waveguide can carry more power as the operating frequency increases. Second, efficiency is significantly greater with waveguide at higher frequencies.

Rectangular waveguide is commonly used in high-power transmission systems. Circular waveguide may also be used, especially for applications requiring a cylindrical member, such as a rotating joint for an antenna feed. The physical dimensions of the guide are selected to provide for propagation in the dominant (lowest-order) mode.

Waveguide is not without its drawbacks, however. Rectangular or square guide constitutes a large windload surface, which places significant structural demands on a tower. Because of the physical configuration of rectangular and square guide, pressurization is limited, depending on the type of waveguide used (0.5 psi is typical). Excessive pressure can deform the guide shape and result in increased VSWR. Wind also may cause deformation and ensuing VSWR problems. These considerations have led to the development of circular and elliptical waveguide.

PROPAGATION MODES

Propagation modes for waveguide fall into two broad categories:

- Transverse electric (TE) waves
- Transverse magnetic (TM) waves

With TE waves, the electric vector (*E vector*) is perpendicular to the direction of propagation. With TM waves, the magnetic vector (*H vector*) is perpendicular to the direction of propagation. These propagation modes take on integers (from 0 or 1 to ∞) that define field configurations. Only a limited number of these modes can be propagated, depending on the dimensions of the guide and the operating frequency.

Energy cannot propagate in waveguide unless the operating frequency is above the *cutoff frequency*. The cutoff frequency for rectangular guide is:

$$F_c = \frac{C}{2 \times a}$$

Where:
F_c = waveguide cutoff frequency
C = 1.179×10^{10} in/s (the velocity of light)
a = the wide dimension of the guide

The cutoff frequency for circular waveguide is defined by the following equation:

$$F_c = \frac{C}{3.14 \times a'}$$

Where: a' = the radius of the guide

There are four common propagation modes in waveguide:

- $TE_{0,1}$, the principle mode in rectangular waveguide
- $TE_{1,0}$, also used in rectangular waveguide
- $TE_{1,1}$, the principle mode in circular waveguide. $TE_{1,1}$ develops a complex propagation pattern with electric vectors curving inside the guide. This mode exhibits the lowest cutoff frequency of all modes, which allows a smaller guide diameter for a specified operating frequency
- $TM_{0,1}$, which has a slightly higher cutoff frequency than $TE_{1,1}$ for the same size guide. Developed as a result of discontinuities in the waveguide, such as flanges and transitions, $TM_{0,1}$ energy is not coupled out by either dominant or cross-polar transitions. The parasitic energy must be filtered out, or the waveguide diameter picked carefully to reduce the unwanted mode.

The field configuration for the dominant mode in rectangular waveguide is illustrated in Figure 6.6-1. Note that the electric field is vertical, with intensity maximum at the center of the guide and dropping off sinusoidally to zero intensity at the edges. The magnetic field is in the form of loops, which lie in planes that are at right angles to the electric field (parallel to the top and bottom of the guide). The magnetic field

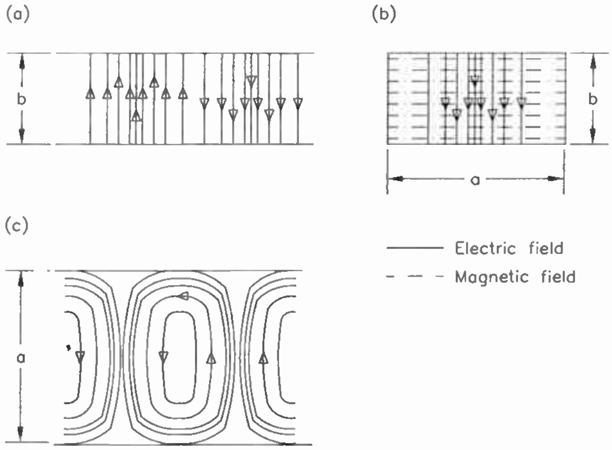

Figure 6.6-1. Field configuration of the dominant or $TE_{1,0}$ mode in a rectangular waveguide: (a) X axis, (b) Y axis, (c) Z axis.

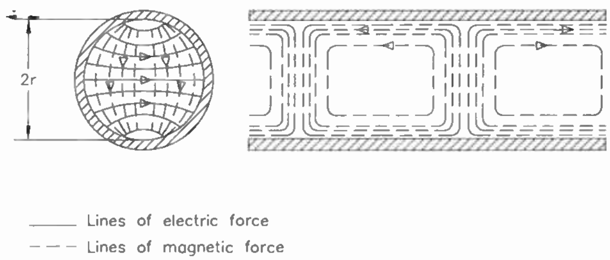

Figure 6.6-2. Field configuration of the dominant mode in circular waveguide.

distribution is the same for all planes perpendicular to the *Y*-axis. In the *X* direction, the intensity of the component of magnetic field that is transverse to the axis of the waveguide (the component in the direction of *X*) is at any point in the waveguide directly proportional to the intensity of the electric field at that point. This entire configuration of fields travels in the direction of the waveguide axis (the *Z* direction in Figure 6.6-1).

The field configuration for the $TE_{1,1}$ mode in circular waveguide is illustrated in Figure 6.6-2. The $TE_{1,1}$ mode has the longest cutoff wavelength and is, accordingly, the dominant mode. The next higher mode is the $TM_{0,1}$, followed by $TE_{2,1}$.

Dual Polarity Waveguide

Waveguide will support dual polarity transmission within a single run of line. A combining element (*dual polarized transition*) is used at the beginning of the run, and a splitter (polarized transition) is used at the end of the line. Square waveguide has found numerous applications in such systems. The $TE_{1,0}$ and $TE_{0,1}$ modes are theoretically capable of propagation without cross coupling, at the same frequency, in lossless waveguide of square cross section. In practice, surface irregularities, manufacturing tolerances and wall losses give rise to $TE_{1,0}$ and $TE_{0,1}$ mode cross-conversion. Because this conversion occurs continually along the waveguide, long guide runs are usually avoided in dual polarity systems.

Efficiency

Waveguide loses result from the following:

- Power dissipation in the waveguide walls and the dielectric material filling the enclosed space
- Leakage through the walls and transition connections of the guide
- Localized power absorption and heating at the connection points.

The operating power of waveguide may be increased through pressurization. Sulfur hexafluoride is commonly used as the pressurizing gas.

Ridged Waveguide

Rectangular waveguide may be ridged to provide a lower cutoff frequency, and thereby permit use over a wider frequency band. One and two-ridged guides are used (see Figure 6.6-3). Increased bandwidth comes at the expense of increased attenuation, relative to an equivalent section of rectangular guide.

Circular Waveguide

Circular waveguide offers several mechanical benefits over rectangular or square guide. The wind load of circular guide is 2/3 that of rectangular waveguide. It also presents lower and more uniform windloading

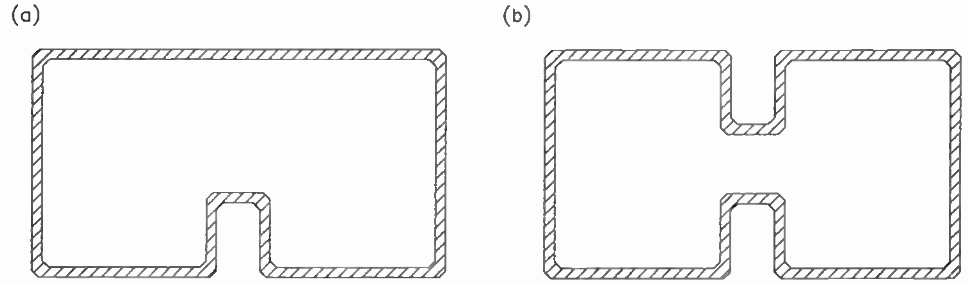

Figure 6.6-3. Ridged waveguide: (*a*) single-ridged; (*b*) double-ridged.

than rectangular waveguide, reducing tower structural requirements.

The same physical properties of circular waveguide that give it good power handling and low attenuation also result in electrical complexities. Circular waveguide has two potentially unwanted modes of propagation, the cross-polarized $TE_{1,1}$ and $TM_{0,1}$ modes.

Circular waveguide, by definition, has no short or long dimension and, consequently, no method to prevent the development of *cross-polar* or *orthogonal* energy. Cross-polar energy is formed by small ellipticities in the waveguide. If the cross-polar energy is not trapped out, the parasitic energy can recombine with the dominant mode energy.

Parasitic Energy

Hollow circular waveguide works as a high-Q resonant cavity for some energy and as a transmission medium for the rest. The parasitic energy present in the cavity formed by the guide will appear as increased VSWR if not disposed of. The polarization in the guide meanders and rotates as it propagates from the source to the load. The end pieces of the guide, typically circular-to-rectangular transitions, are polarization sensitive (see Figure 6.6-4(a)). If the polarization of the incidental energy is not matched to the transition, energy will be reflected.

Several factors can result in this undesirable polarization. One cause is out-of-round guides that result from non-standard manufacturing tolerances. In Figure 6.6-4, the solid lines depict the situation at launching: perfectly circular guide with perpendicular polarization. The dashed lines show how certain ellipticities cause polarization rotation into unwanted states, while others have no effect. A 0.2% change in diameter can produce a −40 dB cross-polarization component per wavelength. This is roughly 0.03 in. for 18 in. of guide length.

Other sources of cross-polarization include twisted and bent guides, out-of-roundness, offset flanges, and transitions. Various methods are used to dispose of this energy trapped in the cavity, including absorbing loads placed at the ground and/or antenna level.

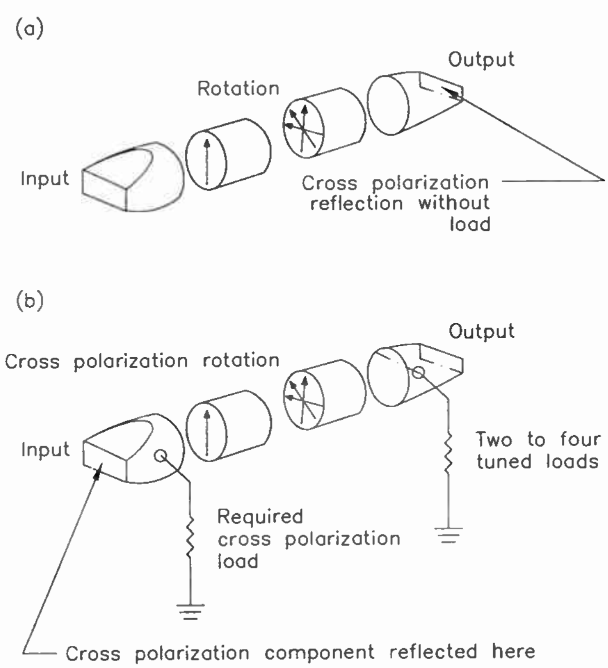

Figure 6.6-4. The effects of parasitic energy in circular waveguide: (*a*) trapped cross-polarization energy; (*b*) delayed transmission of the trapped energy.

Doubly-Truncated Waveguide

The design of *doubly truncated waveguide* (DTW) is intended to overcome the problems that may result from parasitic energy in a circular waveguide. As shown in Figure 6.6-5, DTW consists of an almost elliptical guide inside a circular shell. This guide does not support cross-polarization; tuners and absorbing loads are not required. The low windload of hollow circular guide is maintained, except for the flange area.

Each length of waveguide is actually two separate pieces: a doubly truncated center section and a circular outer skin, joined at the flanges on each end. A large hole in the broadwall serves to pressurize the circular outer skin. Equal pressure inside the DTW and inside the circular skin ensures that the guide will not breathe or buckle as a result of rapid temperature changes.

DTW exhibits about 3% higher windloading than circular waveguide (because of the transition section at the flange joints), and 32% lower loading than comparable rectangular waveguide.

Impedance Matching

The efficient flow of power from one type of transmission medium to another requires matching of the field patterns across the boundary to launch the wave into the second medium with a minimum of reflections. Coaxial line is typically matched into rectangular

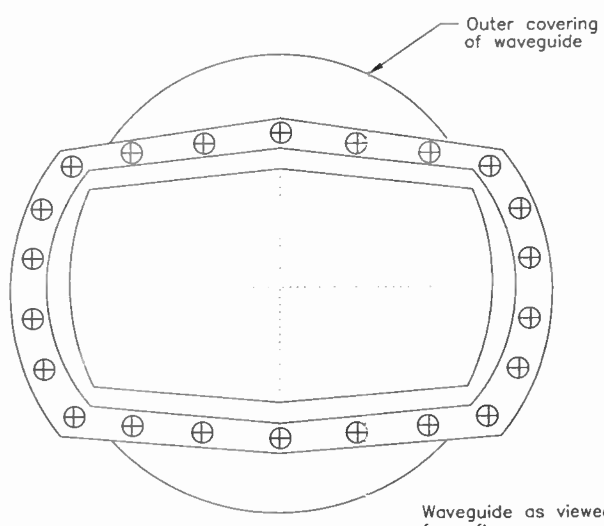

Figure 6.6-5. Physical construction of doubly-truncated waveguide.

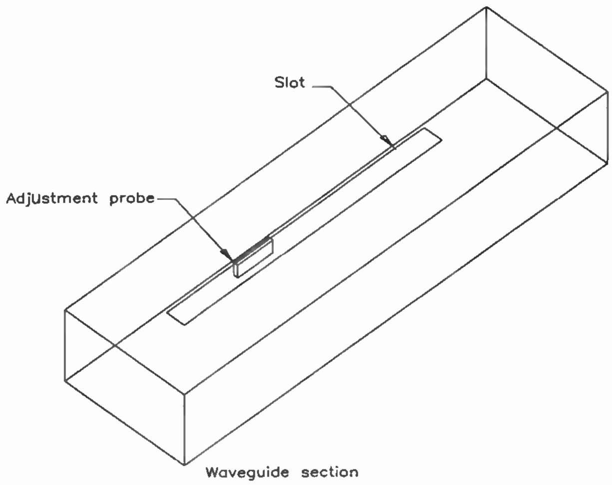

Figure 6.6-6. A probe configured to introduce a reflection in a waveguide that is adjustable in magnitude and phase.

waveguide by extending the center conductor of the coax through the broadwall of the guide, parallel to the electric field lines across the guide. Alternatively, the center conductor can be formed into a loop and oriented to couple the magnetic field to the guide mode.

Standing waves are generally to be avoided in waveguide for the same reasons that they are to be avoided in coaxial transmission lines. Accordingly, it is usually necessary to provide impedance matching systems in waveguides to eliminate standing waves. One approach involves the introduction of a compensating reflection in the vicinity of a load which neutralizes the standing waves that would exist in the system because of an imperfect match. A probe or tuning screw is commonly used to accomplish this, as illustrated in Figure 6.6-6. The tuning screw projects into the waveguide in a direction parallel to the electric field. This is equivalent to shunting a capacitive load across the guide. The susceptance of the load increases with extension into the guide up to ¼ wavelength. When the probe is exactly ¼ wavelength long, it becomes resonant and causes the guide to behave as though there was an open circuit at the point of the resonant probe. Probes longer than ¼ wavelength but shorter than ¾ wavelength introduce inductive loading. The extent to which such a probe projects into the waveguide determines the compensating reflection, while the position of the probe with respect to the standing wave pattern to be eliminated determines the phasing of the reflected wave.

Dielectric slugs produce an effect similar to that of a probe. The magnitude of the effect depends upon the following considerations:

- The dielectric constant of the slug
- Thickness of the slug in an axial direction
- Whether the slug extends entirely across the waveguide.

The phase of the reflected wave is controlled by varying the axial position of the slug.

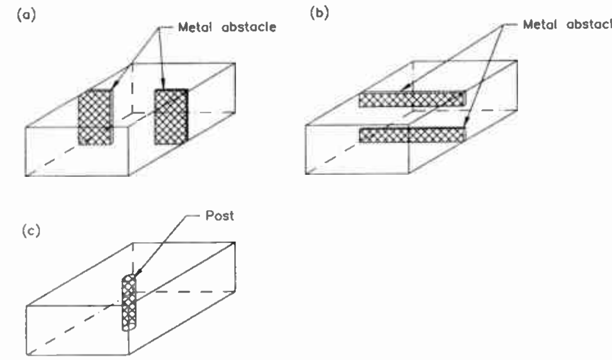

Figure 6.6-7. Waveguide obstructions used to introduce compensating reflections: (*a*) inductive window, (*b*) capacitive window, (*c*) post (inductive) element.

There are several alternatives to the probe and slug for introducing controllable irregularity for impedance matching, including a metallic barrier or *window* placed at right angles to the axis of the guide, (see Figure 6.6-7). Three configurations are shown:

- The arrangement illustrated in Figure 6.6-7(a) produces an effect equivalent to shunting the waveguide with an inductive reactance
- The arrangement shown in Figure 6.6-7(b) produces the effect of a shunt capacitive susceptance
- The arrangement shown in Figure 6.6-7(c) produces an inductive shunt susceptance.

The waveguide equivalent of the coaxial cable tuning stub is a *T* section, (see Figure 6.6-8). The magnitude of the compensating effect is controlled by the position of the short-circuiting plug in the branch. The phase of the compensating reflected wave produced by the branch is determined by the position of the branch in the guide.

Waveguide Filters

A section of waveguide beyond cutoff constitutes a simple high pass reflective filter. Loading elements in the form of posts or stubs may be employed to supply the reactances required for conventional lumped-constant-filter designs.

Absorption filters avoid the reflection of unwanted

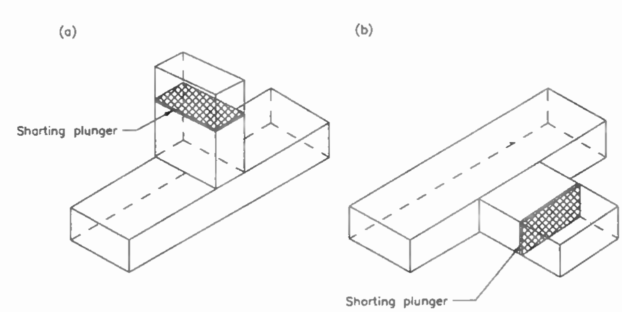

Figure 6.6-8. Waveguide stub elements used to introduce compensating reflections: (*a*) series *T* element, (*b*) shunt *T* element.

energy by incorporating lossy material in secondary guides that are coupled through so called *leaky walls* (small sections of guide beyond cutoff in the passband). Such filters are typically used to suppress harmonic energy.

SYSTEM CONSIDERATIONS

Waveguide system installation is both easier and more difficult than traditional transmission line. There is no inner conductor to align, but alignment pins and more bolts are required per flange. Transition hardware to accommodate loads and coaxial-to-waveguide interfacing is also required.

Flange reflections can add up in phase at certain frequencies, resulting in high VSWR. The length of the guide must be chosen so that flange reflection buildup does not occur within the operating bandwidth.

Flexible sections of waveguide are used to join rigid sections or components that cannot be otherwise aligned. Flexible sections also permit controlled physical movement resulting from thermal expansion of the line. Such hardware is available in a variety of forms. Corrugated guide is commonly produced by shaping thin-wall seamless rectangular tubing. Flexible waveguide can accommodate only a limited amount of mechanical movement. Depending on the type of link, the manufacturer may specify a maximum number of bends.

Tuning

Circular waveguide must be tuned. This process is a two-step procedure. First, the cross-polar $TE_{1,1}$ component is reduced, primarily through *axial ratio compensators* or *mode optimizers.* These devices counteract the net system ellipticity and indirectly minimize cross-polar energy. The cross-polar filters may also be rotated to achieve maximum isolation between the dominant and cross-polar modes. Cross-polar energy manifests itself as a net signal rotation at the end of the waveguide run. A perfect system would have a net rotation of zero.

In the second step, tuning slugs at both the top and bottom of the waveguide run are adjusted to reduce the overall system VSWR. Tuning waveguide can be a complicated and time consuming procedure, but—normally—once set, tuning does not drift and must be redone only if major component changes are made.

Waveguide Hardware

Increased use of waveguide has led to the development of waveguide based hardware for all elements from the output of the transmitter to the load. Waveguide based filters, elbows, directional couplers, switches, combiners and diplexers are available. The RF performance of a waveguide component is usually better than the same item in coax. This is especially true in the case of diplexers and filters. Waveguide based hardware provides lower attenuation and greater power handling capability for a given physical size.

Cavity Resonators

Any space completely enclosed by conducting walls can contain oscillating electromagnetic fields. Such a cavity possesses certain frequencies at which it will resonate when excited by electrical oscillations. These *cavity resonators* find extensive use as resonant circuits at VHF and above. Advantages of cavity resonators over conventional LC circuits include:

- Simplicity in design
- Relatively large physical size compared with alternative methods of obtaining resonance. This attribute is important in high-power applications
- High Q
- The cavity can be configured to develop an extremely high shunt impedance.

Cavity resonators are commonly used at wavelengths on the order of 10 cm or less.

The simplest cavity resonator is a section of waveguide shorted at each end with a length l equal to

$$l = \frac{\lambda_g}{2}$$

Where λ_g = the guide wavelength

This configuration results in a resonance similar to that of a ½ wavelength transmission line short-circuited at the receiving end. A sphere or any other enclosed surface (irrespective of how irregular the outline) may also be used to form a cavity resonator.

Any given cavity is resonant at a number of frequencies, corresponding to the different possible field conditions that can exist within the space. The resonance having the longest wavelength (lowest frequency) is termed the *dominant* or *fundamental resonance.* The resonant wavelength is proportional to the size of the resonator. If all dimensions are doubled, the wavelength corresponding to resonance will likewise be doubled. The resonant frequency of a cavity can be changed by incorporating one or more of the following mechanisms:

- Altering the mechanical dimensions of the cavity. Small changes can be achieved by flexing walls, while large changes require some form of sliding member
- Coupling reactance into the resonator through a coupling loop
- Introducing a movable copper paddle into the cavity. A paddle placed inside the resonator will affect the normal distribution of flux and tend to raise the resonant frequency by an amount determined by the orientation of the paddle.

The Q of a cavity resonator has the same significance as for a conventional resonant circuit. Q can be defined for a cavity by the following relationship:

$$Q = 2\pi \frac{E_s}{E_l}$$

Where E_s = energy stored and E_l = energy lost per cycle.

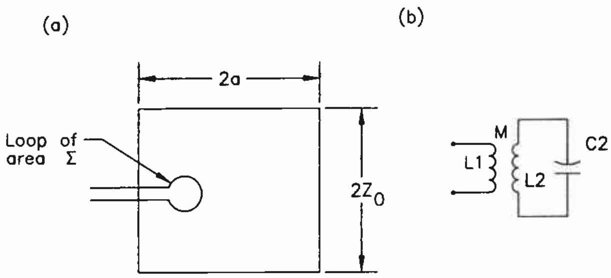

Figure 6.6-9. Cavity resonator coupling: (*a*) coupling loop, (*b*) equivalent circuit.

The energy stored is proportional to the square of the magnetic flux density integrated throughout the volume of the resonator. The energy lost in the walls is proportional to the square of the magnetic flux density integrated over the surface of the cavity. In order to obtain high Q, the resonator should have a large ratio of volume to surface area, because it is the volume that stores energy and the surface area that dissipates energy.

Coupling can be obtained from a resonator by means of a coupling loop or coupling electrode. Magnetic coupling is accomplished through the use of a loop oriented so as to enclose magnetic flux lines existing in the desired mode of operation. This technique is illustrated in Figure 6.6-9. A current passed through the loop will excite oscillations of this mode. Conversely, oscillations existing in the resonator will induce a voltage in the coupling loop. The magnitude of the coupling can be controlled by rotating the loop; the coupling reduces to zero when the plane of the loop is parallel to the magnetic flux. Coupling of a resonator may also be accomplished through the use of a probe or opening in one wall of the cavity.

SYSTEM LAYOUT CONSIDERATIONS[1]

Typical system configurations for different types of waveguide are shown in Figure 6.6-10.

Because of the large size of bends, transitions, etc., and the differential expansion between waveguide and tower, careful coordination with the tower engineer and waveguide manufacturer is essential to prevent problems during installation and operation.

In addition, the horizontal run must be long enough to withstand the flexing caused by expansion in the much longer vertical run. Figure 6.6-11 provides a guide to determine this length for circular waveguide systems. As can be seen, the horizontal run needs to be about 10% of the vertical for shorter systems and 5% for long systems. Always consult the manufacturer for confirmation prior to finalizing locations of the tower and transmitter building.

[1] This section is an excerpt from Chapter 2.3 "Transmission Lines" from the *NAB Engineering Handbook, 8th edition.* 1992, pp. 153–160.

Horizontal and Vertical Straight Sections

Straight sections range from 11.5 to 12 ft depending on waveguide type and channel of operation. Follow the manufacturer's catalog recommendations.

The most common starting point for developing the list of required straight sections is the waveguide elbow located at the base of the tower. Working toward the building from the bend, the standard lengths recommended by the manufacturer are used back through the building opening. If the dimension of the final mating pieces cannot be determined accurately, specify a *length to be advised* piece. This will alert the manufacturer that a section must be made available based on last minute measurements.

The vertical run is laid out by stacking lengths end-to-end until the appropriate height is reached for positioning the top anchor plate. The same rule for a *to be advised* length should be applied as in the horizontal run.

Additional pieces will be needed between this point and the input to the antenna. As indicated in the figures, these will be a combination of waveguide-to-coax transitions, waveguide bends and special waveguide lengths. Since the waveguide is fastened rigidly at the top of the run, and the antenna is fastened rigidly at its mounting plate, the waveguide in-between must also be allowed to grow and shrink due to thermal expansion and contraction. U-link bends or 90° elbows are the most common method for allowing the necessary *flexing* movement.

Tower Top

The vertical run is secured at the top end with an anchor plate or milkstool which must be carefully located on the tower to line up with the hangers for the vertical run and with the antenna inter-connecting components. The milkstool hanger concept (Figure 6.6-12(a)) provides adjustment in all directions to allow for minor field variations.

Hangers

Thermal expansion in both vertical and horizontal runs, depicted in Figure 6.6-13, causes both to change positions. At the lower portion of the vertical run, lateral braces (Figure 6.6-12(b)) are used to provide lateral support while allowing this shifting of position to occur. The supporting hangers for the horizontal run must also allow for an increased amount of movement at this area.

A spring hanger (Figure 6.6-12(c)) is required on all other sections of waveguide in both the horizontal and vertical runs to provide the expansion/contraction capability necessary. For spring hanger and lateral brace mounting details, the manufacturer's installation bulletins should be thoroughly reviewed. With careful engineering and attention to all the necessary details, the hangers should attach to both the horizontal bridge and the vertical support structure with a minimum of difficulty.

Keep in mind that the coefficients of thermal expan-

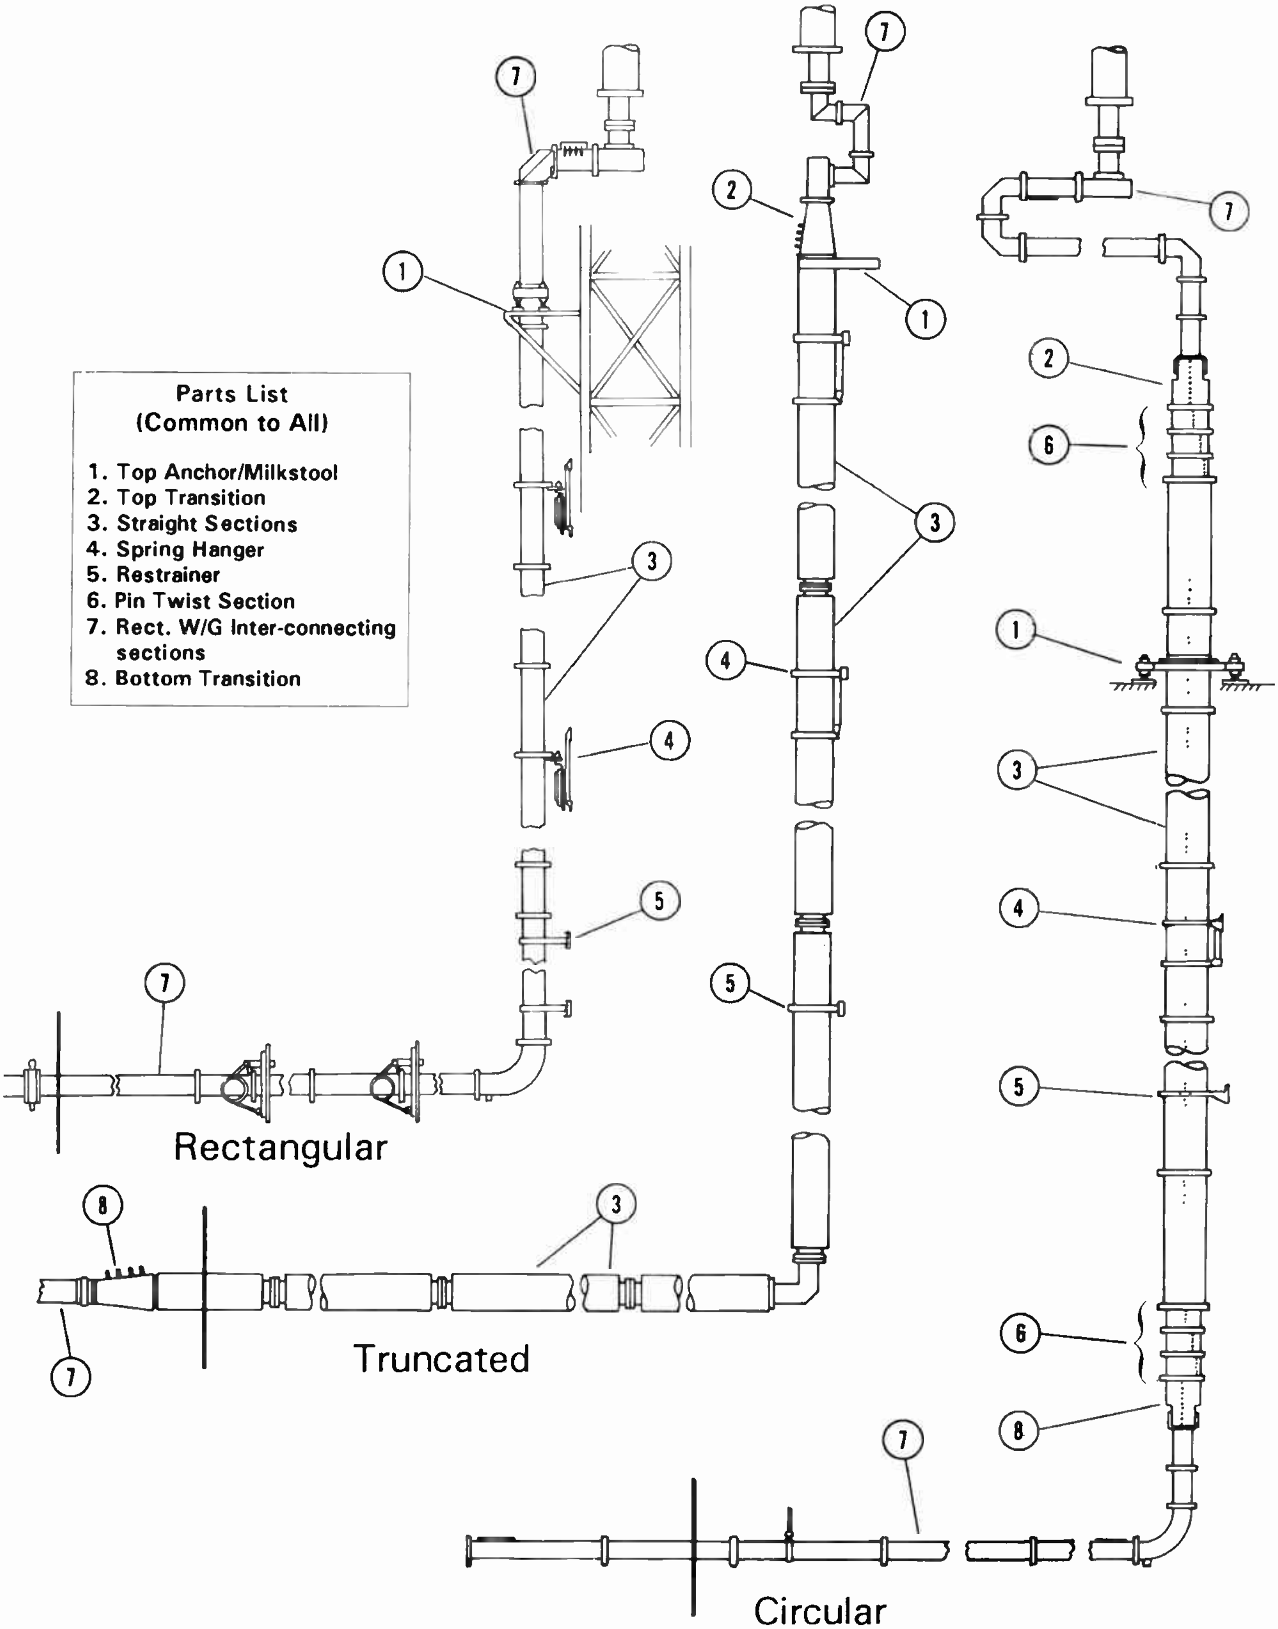

Figure 6.6-10. Typical waveguide system layouts.

Vertical Run Height (feet)	Minimum Horizontal Run Length (feet)					
	GLW			DTW		
	1350	1500	1750	1350	1500	1750
2000	75	90	100	72	84	120
1500	66	77	87	60	84	108
1000	54	61	70	60	72	96
500	38	42	49	48	60	84

Figure 6.6-11. Typical manufacturer's recommendations for determining minimum length of horizontal run to provide for expansion of vertical run.

sion are 13×10^{-6} per degree F for the aluminum waveguide, and approximately 6.5×10^{-6} per degree F for the tower steel. This results in a relative differential movement of about 3/4 in. per 100 ft for a 100°F temperature swing (2.5 cm per 40 m for a 56°C temperature swing). Also, the ambient temperature of the guide and the tower are different due to the additional heating effect of the RF power being transmitted. The resulting expansion/contraction must be accommodated by providing sufficient clearance between all waveguide components and the tower or bridge (see Figure 6.6-13).

Transitions and Associated Components

Rectangular waveguide systems may include transitions as shown in the typical layouts of Figure 6.6-10. Rectangular to coaxial transitions are most commonly used to interface the main waveguide run to the antenna and, if equipped with a coax input, the diplexer. Single polarized circular and doubly truncated waveguide systems will also use transitions from their shape to standard rectangular waveguide at both ends (see Figure 6.6-12(d)).

Single polarized circular systems incorporate multisection pin twists (Figure 6.6-12(e)) at the transitions to facilitate alignment of the electric field (E-field) with the mating rectangular waveguide feeding the antenna and transmitter. This simplifies both the layout of the waveguide system on the tower and the installation. In rectangular only systems, special twist sections are needed to rotate the run as required for proper alignment.

Installation

Pages could be written about the handling and installation practices appropriate for waveguide sections. A summary of the major considerations is presented here.

The crew contracted to do the installation will play a major role in the success of the project. Select one with experience, credentials and recent references. This is not a good place to try to save a few dollars.

If the waveguide will be stored at the site prior to installation, keep the interior surfaces dry and clean by covering the sections with plastic sheeting. Tape the sides and ends securely to keep out wind-driven rain and dirt.

Hanger Installation

Before uncovering any waveguide sections, install all the hangers on the tower and the horizontal bridge. Follow the detail drawings developed by the tower manufacturer to insure the proper interface between the hanger and the tower. Due to the significant windload which the waveguide run will place on the tower, it is important that these instructions be followed carefully.

As shown in the system layout drawings of Figure 6.6-10, several types of hangers will be utilized—a fixed hanger at the top of the tower, spring hangers down the tower, lateral restrainers near the base of the tower and horizontal spring hangers beneath the bridge. Spring hangers with additional travel are provided with certain types of installations to accommodate the larger displacement near the base of the tower in both the vertical and horizontal runs. Be sure that the manufacturer's instructions are followed when installing hangers.

After installation, all hangers must provide the necessary movement to allow waveguide and flange displacement of the type shown in Figure 6.6-13 with no interference at any tower member.

Waveguide Installation

Installation of straight sections usually starts at the base of the tower after properly locating the E-plane bend for clearance at both anticipated temperature extremes. However, single polarized circular waveguide is installed from the top down to eliminate the need for special field-cut circular sections in the vertical run.

Straight sections are normally provided with an O-ring groove in one flange only. This allows the sections to be installed with the groove facing up to provide a cavity for centering the O-ring and prevent pinching when bolting mating flanges together. Check for a uniform gap around the flange perimeter after torquing all flange hardware. A pinched O-ring will ultimately need repair since it will cause VSWR changes, arcing, pressure leaks—or all three.

As mentioned above, be sure the bend at the base of the tower is placed in a location which provides freedom of movement for both the vertical and horizontal runs when differential thermal expansion occurs. As indicated, this differential amount can be approximated using the "3/4 in/100 ft" (2.5 cm/40 m) guideline. Note that this will be true for both the vertical and horizontal runs, assuming steel is used for the tower and the horizontal bridge. This general rule is based on a 100°F (56°C) change in temperature. Thus, if the temperature is expected to increase 50°F (28°C) from the ambient at time of installation, the amount of differential *expansion* will be one-half that previously indicated. However, remember that *shrinkage* will also occur as the temperature drops 50° (28°C) from the ambient, so the same amount of upward movement must also be accommodated.

Waveguide flanges in mating sections are normally

aligned by pins prior to tightening hardware. Make sure the installers attach these pins to their tool pouches using a long, strong cord. This will prevent the pins from inadvertently being dropped and, subsequently, not used. Misaligned flanges will cause power to be reflected at the point, adding to system VSWR and reducing transmission efficiency.

Pressurization

Positive dry air or nitrogen pressure should be maintained inside transmission lines to prevent breathing. Ambient air can enter the line through the joints due to changes in atmospheric pressure. As the temperature drops, the moisture will condense on the internal surfaces of the waveguide. The accumulation of enough moisture in the waveguide can cause large changes in performance by increasing attenuation, system return loss, or both.

Rectangular waveguide, due to its shape, is usually not pressurized to levels greater than 0.25 psig to prevent distorting or bulging between the flanges. Circular and truncated waveguides, on the other hand, can be pressurized at levels from 0.5 to 2 psig thereby reducing the likelihood of moisture penetration from the breathing process.

Due to the large volume of enclosed air and large surface area of the guide, sudden changes in ambient temperature and/or solar heating can cause fast changes in internal pressure. A pressure relief value is needed to bleed off rapid increases in pressure which can occur as the rising sun warms up the waveguide. When cooling occurs (due to clouds, sunset, etc), the pressurization system must have the capacity to provide the required dry air volume quickly.

Due to the cyclic nature of waveguide pressurization systems (pressure relief followed by replacement of the purged volume), automatic dry air systems are more functional than nitrogen tank pressure systems since the latter would need regular replacement.

Testing

Electrical testing of waveguide systems should be performed after any of the following have occurred:

- Initial installation prior to applying power
- VSWR/reverse power trip
- Signal fluctuations of in-line waveform monitors or signal analyzers.

The purpose of such tests is to verify that the overall performance of the system is as good as expected. Large amounts of reflected power reduce system efficiency, create the potential for ghosting in television applications and may even cause transmitter shutdown. It is advantageous to test new systems while installation personnel are still on site. Common tests performed are VSWR/return loss sweep and RF pulse test. Network analyzers with time domain capabilities can be used for overall system performance checks and are excellent devices for locating discontinuities not detectable by RF pulse testing.

Sweep Test

The *sweep test* is a frequency domain test that measures the return loss of the transmission line over the operating channel bandwidth. This will determine how efficiently energy is being transferred from the transmitter system into the transmission line. The measurement is typically performed at the gas barrier inside the transmitter building by applying a 6 MHz swept signal to the transmission line through a directional coupler or return loss bridge. A sample of the forward signal is compared to the reflected signal and the return loss or VSWR can be calculated. If a network analyzer is used, the calculation is done automatically, and the return loss/VSWR versus frequency is displayed on a screen. This test must be done with the end of the line terminated in either an antenna or load. Note that the effects of the terminating device will be included in the measurement.

Since power levels are highest at the visual carrier frequency, most waveguide systems are optimized for return loss at that frequency. The goal is at least 32 dB return loss (1.05 VSWR) which means less than a tenth of one percent of the transmitted power will be reflected back toward the transmitter. For a 120 kW UHF application, this translates to less than 120 W of reflected power and a power transfer efficiency of greater than 99.9%.

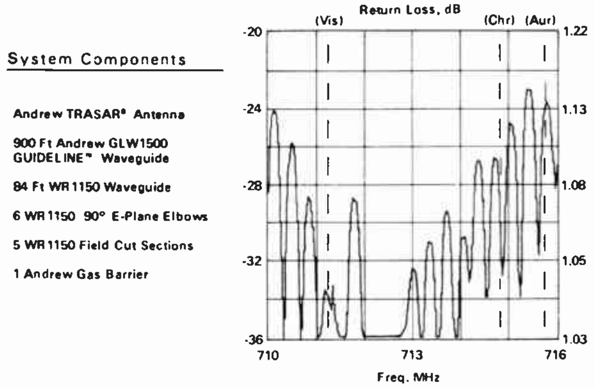

Figure 6.6-14. Sweep VSWR test results at channel 54 on 1,000 ft circular waveguide system.

A return loss sweep test of a circular waveguide system for a 240 kW application at Channel 54 is shown in Figure 6.6-14. This system included 900 ft of 15 in. circular waveguide in the vertical run, 100 ft of WR 1150 rectangular waveguide in the horizontal run, numerous bends and field cut sections, plus gas barrier and transmitting antenna. The maximum return loss level is about 23–24 dB (1.22 VSWR) at the edges of the band. At visual carrier, return loss is about 34 dB (1.04 VSWR).

The effects of discontinuities having repetitive spacing in a waveguide system, such as the flange joints, are shown clearly in Figure 6.6-15(a). The high VSWR spikes in this rectangular waveguide system occur at specific reject frequencies in the 200 MHz test bandwidth. A system utilizing different section lengths would cause these reject frequencies to change. For this reason, waveguide section lengths vary from about 11 to 12 ft depending on UHF operating channel in the same manner that rigid line lengths vary from 19 to 20 ft. Selecting the correct length insures that no VSWR spikes will occur near the 6 MHz operating band.

Rectangular waveguide systems capable of broadband operation are now being provided for special applications. Figure 6.6-15(b) shows the same waveguide system after adjusting flange tuners to reduce the effects of flange mismatch.

RF Pulse Test

An RF *pulse test* will display the performance of the line in the time domain. This test displays impedance changes versus time and allows the correlation of relative electrical performance of components to general location in the system when the propagation velocity is known. The test is performed by applying CW signal bursts of various widths to the system and detecting the reflected signals versus time with a receiver having characteristics simulating an ideal video response. A 0.25 μsec (2T) pulse has the spectrum of a normal video signal and is used to optimize the system for average picture content. The far end reflections are

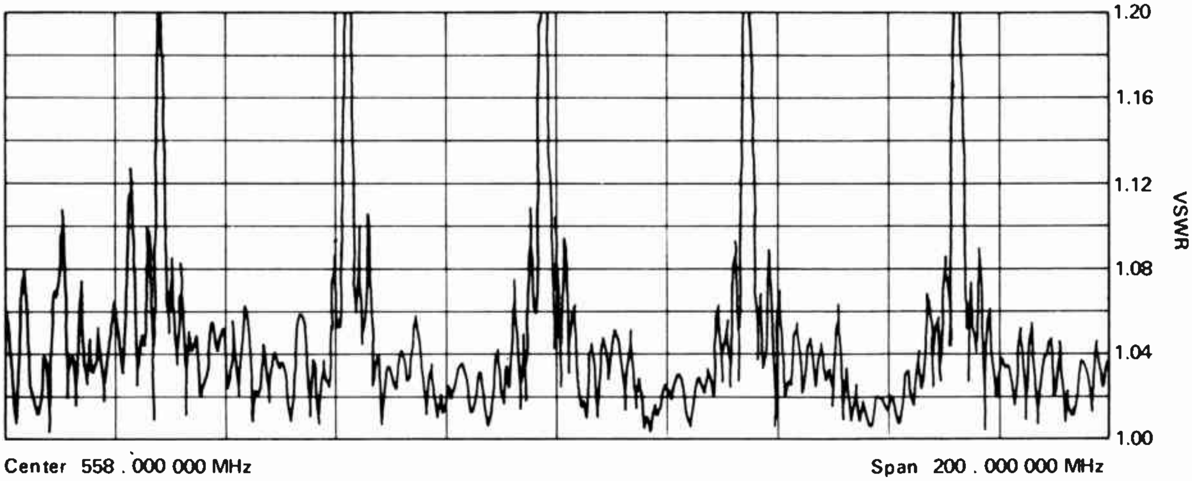

Figure 6.6-15(a). Broadband (200 MHz) test of rectangular waveguide system to show high VSWR "spikes" at frequencies corresponding to flange joint spacing.

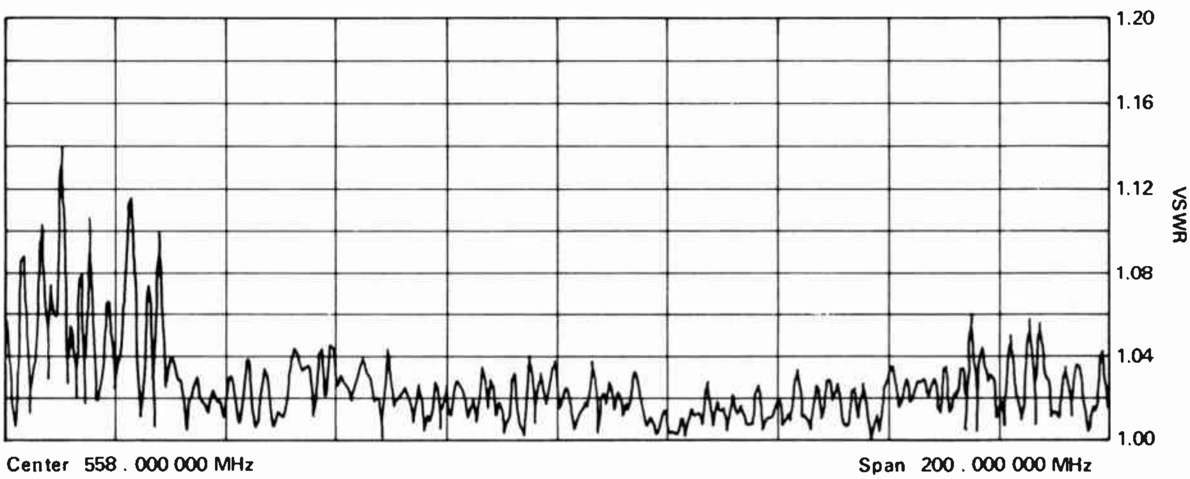

Figure 6.6-15(b). Same waveguide system optimized for broadband application using tuners at flange joints to counteract flange mismatch.

noted carefully to assure meeting the −32 dB return loss level in order to prevent noticeable ghosting. Because of the pulse width required to simulate the video information, this method does not have the positional resolution of a time-domain reflectometer (TDR). However, it provides excellent information regarding the system's transmission performance and can also detect gross problems such as misaligned flanges and pinched O-rings.

The main disadvantage of this test is that there is no standard off-the-shelf equipment package available. Therefore, correct interpretation of the test results is somewhat dependent on the skill and experience of the operator.

An RF pulse test curve for the 15 in. circular waveguide system described earlier is shown in Figure 6.6-16. As can be seen, there is nothing between the bottom gas barrier up to and including the antenna with a return loss worse than about 40 dB (1.02 VSWR) at the visual carrier frequency of 711.25 MHz.

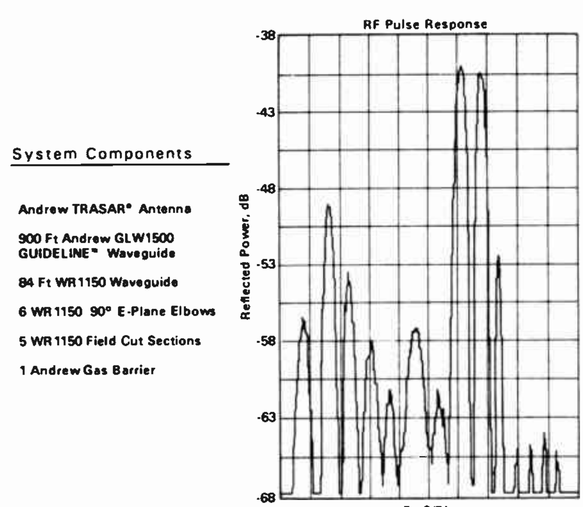

Figure 6.6-16. RF pulse test results on system shown in Figure 6.6-14.

INTRODUCTION

The components that connect, interface, transfer and filter RF energy within a given system—or between systems—are critical elements in the operation of a television station. Such hardware determines—to a large extent—the overall performance of the RF plant. In order to optimize the performance of a station's transmission system, it is necessary to first understand and optimize the components upon which the system is built.

SWITCHING

Many transmitter installations require some type of switching in the transmission line system. The complexity of this switching will depend on the individual needs of the station. It can be as simple as a three-port patch panel to connect the output of the transmitter to the station load, or as complex as a multiple transmitter antenna installation.

Patch Panels

Patch panels provide a convenient method of rerouting the interconnecting transmission lines between various inputs and outputs in the transmitter plant. Since they are manual devices and cannot be changed very rapidly, their use is limited to maintenance functions or as a secondary means of switching.

Coaxial Patch Panels

Coaxial patch panels can have any number of ports, but the more common have 3, 4 and 7 ports. They consist of the appropriate number of quick disconnect connectors mounted on a panel, and interconnecting transmission lines, usually in the form of U-lines.[1] The connectors are spaced so that the U-links may be used to interconnect any two ports (see Figure 6.7-1). For example: the connectors of a three-port patch panel would form an equilateral triangle.

Interlock switches are used to prevent transmitter power from being applied until the U-links are in the proper positions and properly seated. Power handling capabilities of the patch panels are essentially the same as the mating transmission lines.

[1] Short lengths of transmission line with connectors on both ends.

Waveguide Patch Panels

Waveguide patch panels are used in much the same way as their coaxial counterparts. However, since waveguide is larger and inflexible, and most transmitter installations use rectangular waveguide inside the transmitter building, the patch panels aren't quite as versatile. Generally, waveguide patch panels are only available as a three-port unit (see Figure 6.7-2).

Since the waveguide is rectangular, the ports must be in a straight line in either the broad wall or narrow wall plane.

Manual Coaxial Switches

Manual coaxial switches are generally available in either single-pole-double-throw (SPDT) or four-port transfer type configurations. They have two distinct advantages over the manual patch panels: ease of operation and speed of switching.

Most manual coaxial switches have either a lever or knob that is turned to change positions of the switch (see Figure 6.7-3). This can be accomplished in a few seconds, compared to minutes to change a manual patch panel. Like patch panels, manual coaxial switches have interlock switches to turn off the transmitters during switching.

Figure 6.7-1. Seven-port patch panel.

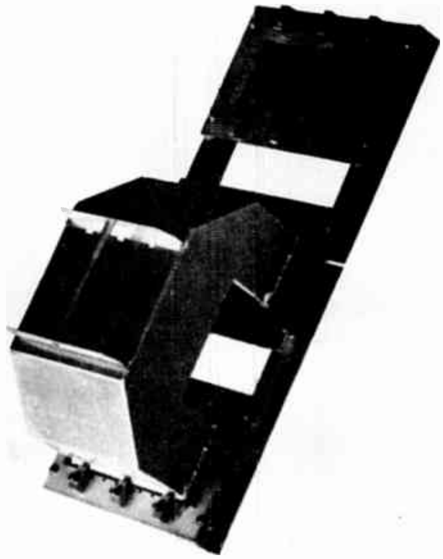

Figure 6.7-2. Three-port E-plane waveguide patch panel.

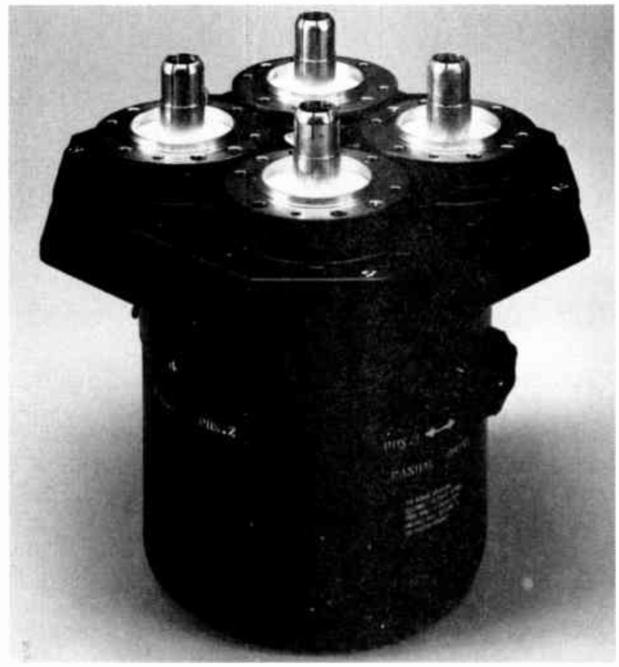

Figure 6.7-3. Coaxial rotary switch.

Power ratings of coaxial switches are approximately 80% of the equivalent coaxial transmission line. Since they are more complicated to build, they cost more than a patch panel. In order to accomplish the same functions performed by a seven-port patch panel, several switches will be required, because they are only available in three-port SPDT and four-port transfer configurations.

Motorized Coaxial Switches

Generally, motorized coaxial switches are similar to manual switches. To reduce production costs, many of the parts are the same.

Usually, the RF portion of the switch is the same for either manual or motorized switches. The knob or lever is replaced with a motor drive assembly. The motor drive system requires some type of control system to start and stop the motor in the switching sequence.

Most motorized switches are available with a choice of motor voltages, with 115 vac being the more common, and various control circuit voltages. A small control relay isolates the switch from the control circuits of the transmitter system. Generally, both sides of the control relays are available in the electrical connector. Therefore, the user must supply a power source to energize the control relay.

Rotary motorized coaxial switches are available for 1-5/8″, 3-1/8″, 4-1/16″ and 6-1/8″ cable systems. These switches will change positions in approximately two seconds. Their frequency range is good up through the TV frequencies. Some of the larger switches are limited in their use in the UHF range because of possible moding problems.

For use at higher power levels and high frequencies, another type of switch was developed. This is a motorized U-link type switch (see Figure 6.7-4). Its power ratings are essentially the same as the comparable transmission line. Sizes for of 3-1/8″, 4-1/16″, 6-1/8″, 8-3/16″, and 9-3/16″ cable systems are available. Because of the mass of the moving parts of the larger switches, switching time is increased to approximately 10 seconds.

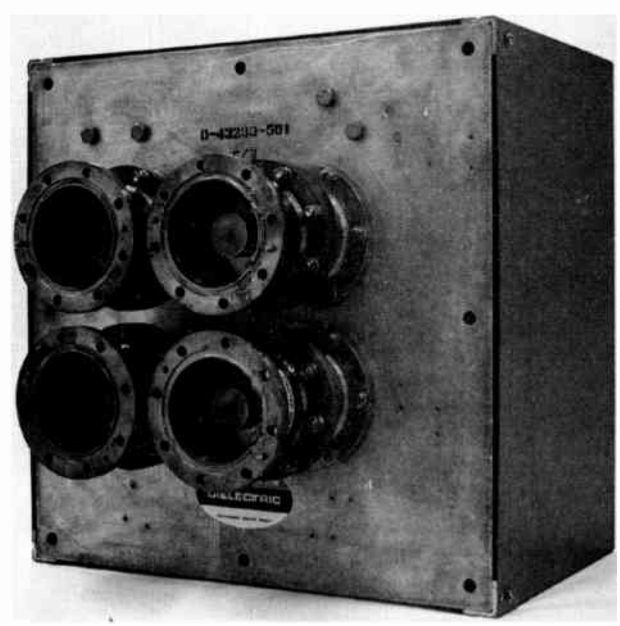

Figure 6.7-4. High power coaxial switch.

Waveguide Switches

Waveguide switches are available in three-, four-, and five-port versions. The RF sections of both manual and motorized switches are usually the same. Manual units will have a knob or handle to change the positions of the switch. Motorized units have the manual drive replaced with a motor drive assembly. Some type of motor control circuit is required.

The four-port transfer switch shown in Figure 6.7-5 is an E-plane type of switch. Both E-plane and H-plane units are available. The four-port units usually take the form of crossed waveguide, with the ports 90° apart. Within the switch is a metal back plate that has fingerstock around the four sides which contact the waveguide case. The back plate is positioned at a 45° angle to the ports of the switch. Thus, two ports of the switch will be connected together in the form of an elbow. In one position, the top port is connected to the right hand port, while the bottom port is connected to the left hand port. In the other position, the opposite is true.

The control circuits of the waveguide switch are similar to those in the coaxial switches. Various motor and control voltages are available. The waveguide switch is equipped with some type of interlock switches to turn off the transmitters during the switching process. A five-port switch is shown in Figure 6.7-6.

FILTERS

Filters are used in broadcasting to limit the undesirable emissions from transmitters. More specifically, it is necessary to limit the harmonic content of transmitters to prevent interference at higher frequencies with other services. In addition, it is necessary to limit the intrusion of other RF signals into the final stage of transmitters as a result of antenna coupling.

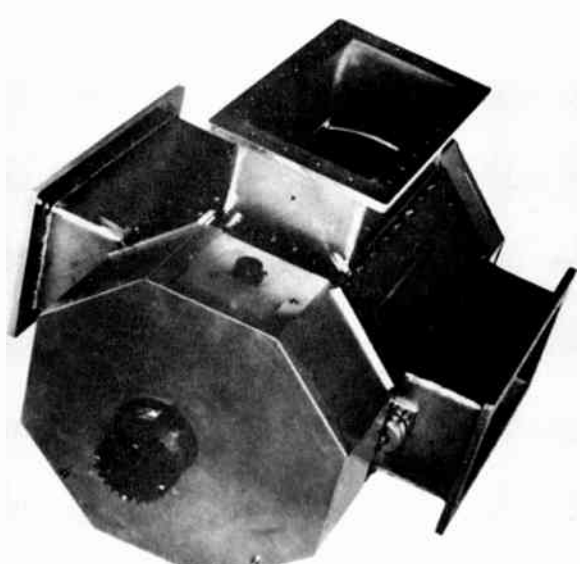

Figure 6.7-5. Four-port E-plane waveguide switch.

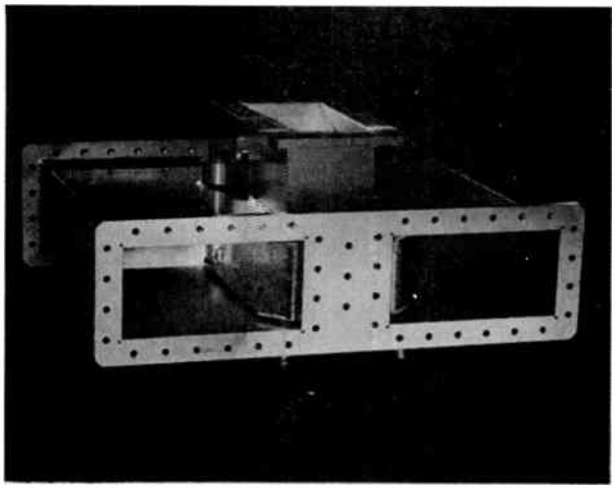

Figure 6.7-6. Five-port waveguide switch. (Courtesy Micro Communications, Inc.)

Harmonic Filters

Harmonic filters are commonly used on the output of all transmitters used for broadcast applications. They can be built for use with either coax or waveguide. The decision to use one form over the other is a matter of convenience (size), performance and cost.

The coaxial form is used in the lower portions of the broadcast spectrum, namely VHF-TV, and portions of UHF bands. For low band VHF, coaxial harmonic filters are used since the common EIA line sizes from 3-1/8 to 6-1/8 in. coaxial can handle these power levels without degradation due to higher order modes. Waveguide would have to be greater than 60 in. to operate in the fundamental mode at these frequencies.

Harmonic filters will pass the fundamental frequency with efficiencies of about 98% or -0.1 dB insertion loss. They will reject the second through the fifth harmonic with attenuation of -40 to -50 dB. By virtue of their function of attenuating harmonics they are, by necessity, designed to handle a limited segment of the band (less than one octave). Table 6.7-1 lists the typical way the band is divided.

The skirt of the attenuation curve must have a slope sufficiently large to pass the highest fundamental frequency and reject the lowest frequency in the second harmonic. A filter with nine to eleven stages will normally provide 40 to 50 dB rejection at the low end of the second harmonic.

A waveguide harmonic filter is normally used at frequencies on the high end of the UHF band. This is necessary for several reasons. Larger coaxial sizes will support the generation of higher order modes near the high end of the frequency spectrum for UHF TV. Higher order modes will be sustained at a frequency where

$$\text{Wavelength} = \pi(a + b)$$

Table 6.7-1
Filter types as a function of frequency.

Channel	Fundamental	2nd Harmonic	Typical Construction
2–3	54–66 MHz	108–132 MHz	Coaxial
4–6	66–88 MHz	132–176 MHz	Coaxial
7–13	174–216 MHz	348–432 MHz	Coaxial
14–43	470–650 MHz	940–1300 MHz	Coaxial
44–52	650–698 MHz	1300–1396 MHz	Coaxial or Waveguide
52–69	698–806 MHz	1396–1612 MHz	Waveguide

where a and b are the radii of inner and outer conductors. Larger coax sizes are also needed to handle the power levels authorized in the UHF band. 8-3/16 inch-75 Ω line will support higher order modes at frequencies just above Channel 56, and 9-3/16 inch-75 Ω cable at frequencies just above Channel 40. But the construction of a coaxial filter is a cascade of larger and smaller diameter inner conductors. The larger inner conductors essentially cause moding to occur at longer wavel engths or lower frequencies. This phenomenon lowers the effective frequency at which coaxial filters can be used.

Waveguide filter must, therefore, be used above channel 40 when transmission line power levels exceed the rating of 6-1/8″ coaxial. One type is commonly called a *waffle iron filter* because the broad walls of the waveguide resemble the top and bottom plate in a waffle iron. A waffle iron harmonic filter in WR 1150 waveguide can be used between channels 40 and 69.

Harmonic filters are usually supplied with transmitters since the transmitters cannot meet FCC Rules with regard to harmonic content without a filter. The broadcaster will seldom need to buy a harmonic filter unless he has experienced a severe transmission line failure or acquired a used transmitter.

Band-Pass and Band-Stop Filters

Band-pass filters are used sometimes in combination with band-stop filters to control another class of spurious emission problems. The transmitter (with its harmonic filter) is capable, in the absence of other RF signals, of producing transmissions which are free of any emissions. Potential problems arise, however, when the transmission facilities of two or more broadcast channels are located very close to one another.

Assume, for example, that Channel A and Channel B use antennas on the same tower. Channel A's antenna, in addition to transmitting its primary signal, also receives some of Channel B's signal. The magnitude of this received signal depends on the gain and bandwidth of Antenna A at the frequency of Channel B as well as the distance between the two antennas. Several spurious signals can be generated in Transmitter A and transmitted on the air as a result of the presence of RF from Channel B. The transmitter will usually, because of its limited bandwidth, provide several dB turn around loss for this spur. The most troublesome spur will occur at a frequency which is

$$F = 2A - B$$

A comparable problem could occur in Transmitter B where

$$F = 2B - A$$

The magnitude of the spur will be equal to the power level of the coupled signal minus the turnaround loss. So, if Channel B is present in Channel A's transmission line at a level of −40 dB down from Channel A's power level, and Transmitter A provides −10 dB turn around loss, then a spur will likely exist at (F = 2A − B) with an amplitude of −50 dB from Channel A's amplitude. In order to comply with FCC Rules for FM, therefore, a filter would have to be installed in Channel A's transmission line which would pass Channel A with minimal insertion loss (usually −0.15 dB) and provide −30 dB rejection at Channel B. This would lower the spur level to −80 dB below Channel A's transmission line level.

Another example of spurious emissions occurs when a Channel 14 or Channel 69 system is located in close proximity to land mobile communications. Two types of interference have been noted in this situation:

1. An intermodulation product of visual, aural or color signals mixing to produce a spur at a frequency used by the land mobile system.
2. The power generated by the TV station simply overloads the front end of land mobile receivers, although the carrier signals of each are at different frequencies.

The first situation must be addressed by providing filters in the TV station's system to reduce the resulting intermodulation. Figure 6.7-7 illustrates how the intermodulation was suppressed at Channel 69 in Hollywood, Florida.

The second situation must be addressed by installing a filter in the land mobile receiver system. This can generally be achieved with much smaller hardware, when required.

The decision to use band-pass versus band-stop filters should be based on the nature and extent of the problem. Each type has virtues and limitations which make them suitable for certain problems.

The typical response curves for several combinations are presented in Figures 6.7-8–6.7-11. The band-stop (as depicted in Figures 6.7-8 and 9) is characterized by rapidly rising skirts which make these filters particularly suited to rejecting frequencies that are extremely close to the desired frequency (frequencies displaced by as little as 0.8%). However, due to their sharp response, they are more prone to drifting with temperature than the band-pass configuration. They can be built so that drifting does not affect their desired performance, if manufacturers design them to minimize this tendency. Band-stop cavities are used in VHF and UHF diplexers, but are not used to protect one TV channel from another since their band-stop widths are generally too narrow to reject an entire TV channel.

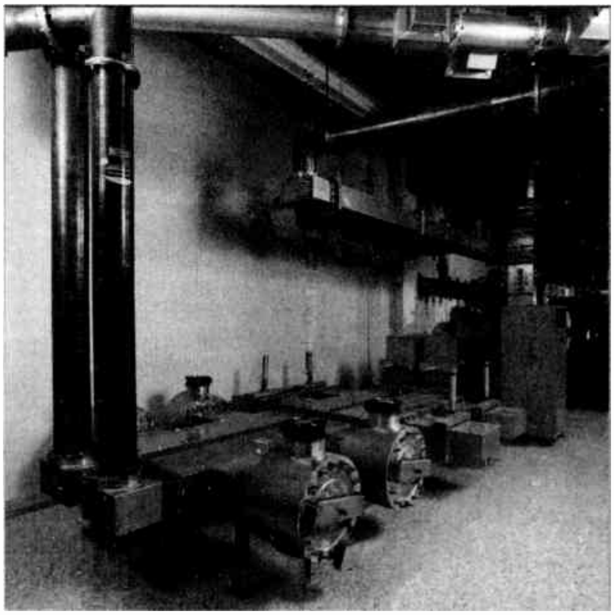

Figure 6.7-7. Notch filters at visual and aural inputs in Hollywood, Florida (Courtesy Home Shopping Network.)

The notch responses shown were plotted near 100 MHz. The center frequency can be scaled to anywhere in the VHF or UHF band, and similar percentage bandwidth would be obtainable. Figure 6.7-8 depicts the response of a single-cavity notch. Figure 6.7-9 shows a dual-cavity response.

Band-pass filter responses for a four-cavity and five-cavity filter are shown in Figures 6.7-10 and 6.7-11. Again, these were measured near 100 MHz and their percentage bandwidth would be obtainable at any other frequency in VHF or UHF spectrum. The skirt selectivity is not as sharp for band-pass cavities as for band-stop cavities. This suggests that more stages will be needed in band-pass cavities to obtain the same attenuation as a band-stop cavity. The band-pass cavity, however, has some advantages; since the pass-band is broad, it is not affected by drifting due to temperature changes. The reject curves are also located symmetrically about the pass band.

The formula for locating the spur

$$F = 2A - B$$

will always place the spur at exactly the same distance, frequency wise, from the pass-frequency, but on the

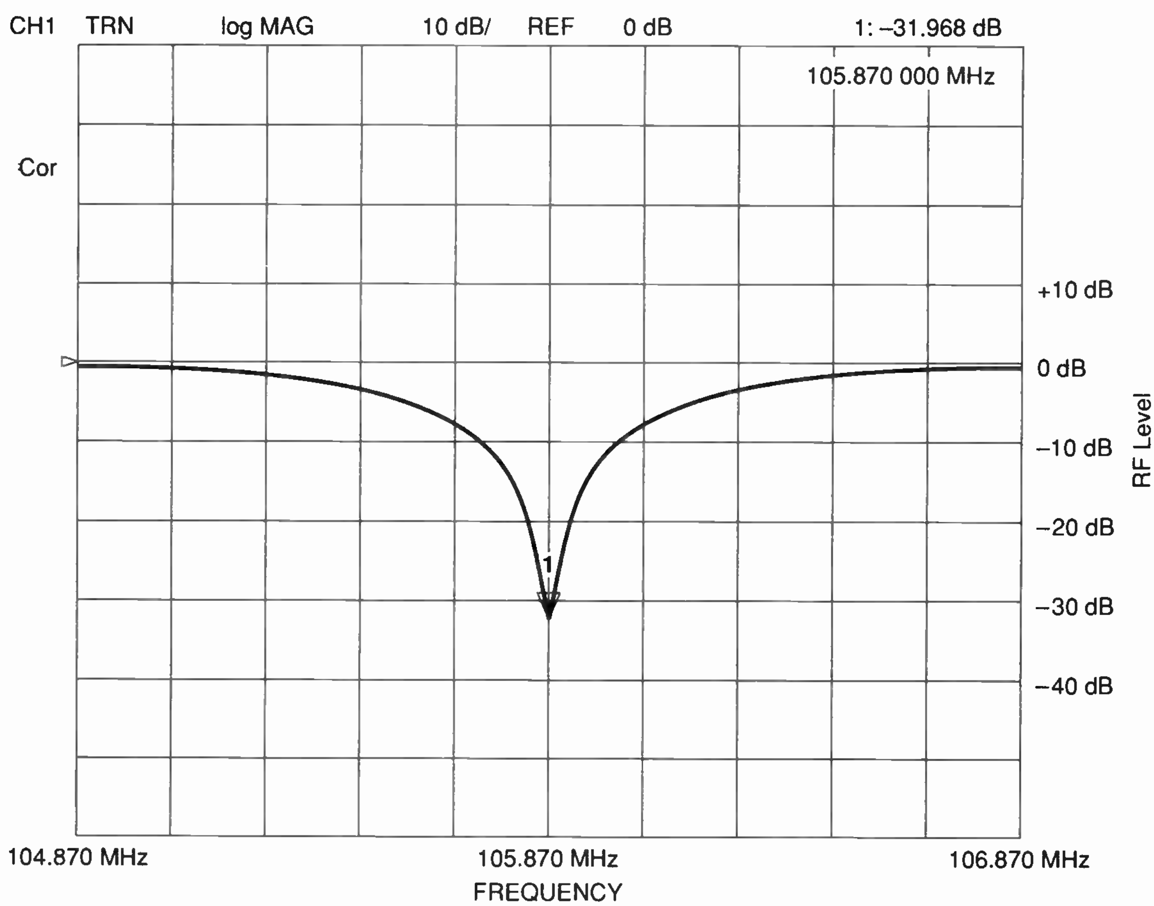

Figure 6.7-8. Single-cavity notch filter response 31.9 dB.

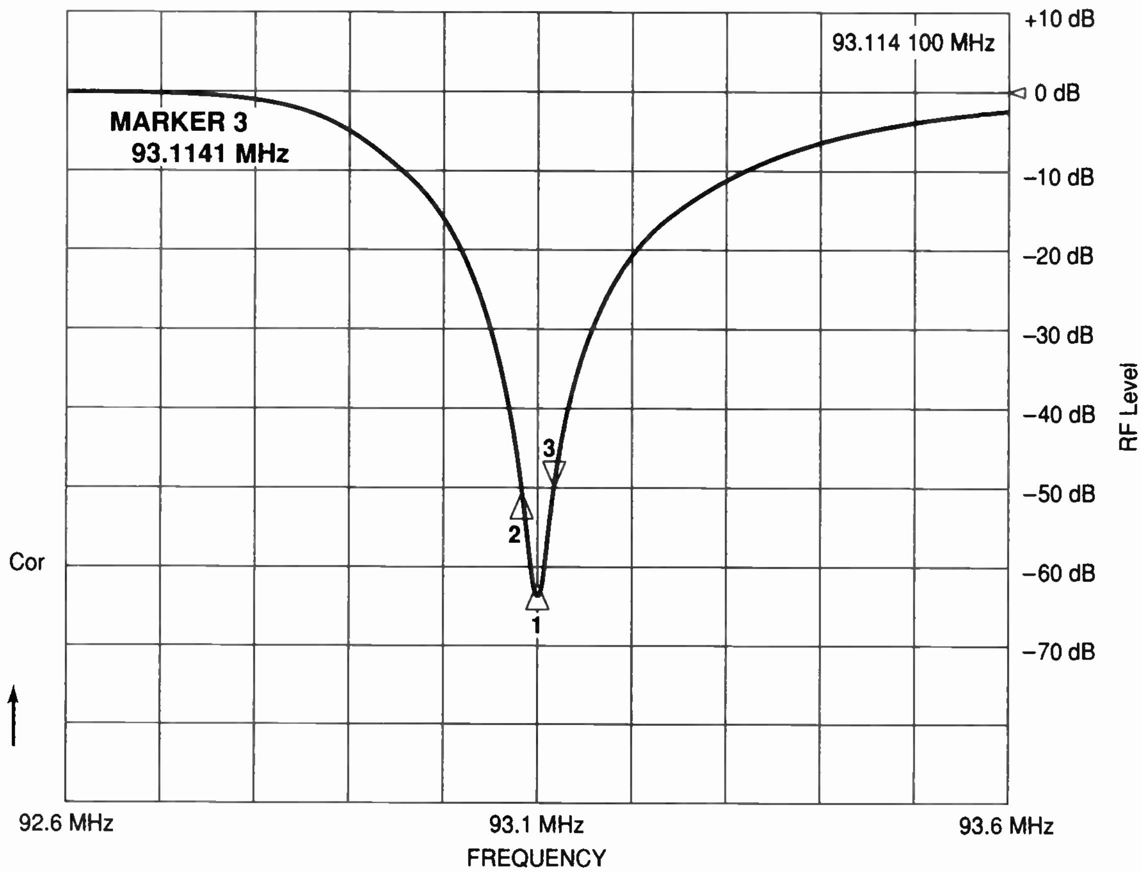

Figure 6.7-9. Dual-cavity notch filter response 64 dB.

opposite side of the pass band. So the band-pass filter attenuates the incoming RF on one side and the resulting spur on the other side of the pass band. It also has the advantage of attenuating all frequencies sufficiently removed from the pass band. This is especially useful when multiple interferences are detected.

Combinations of band-pass and band-stop are also available in a single filter. They can be visualized by superimposing a band-stop and a band-pass filter response with the notch located at the edge of the pass band. These filters are useful when interference is caused by a combination of one frequency close to the desired frequency and multiples further removed from it.

All of these responses in the VHF and FM bands can be achieved with coaxial cavities approximately 3/8 in. wavelength long and 12 to 24 in. in cross section (see Figure 6.7-12). In the UHF band they can be produced by using coaxial cavities or waveguide cavities. These filter systems also serve as building blocks for the diplexing and multiplexing systems discussed in the next section.

Once a decision is made to use band-pass, band-stop or a combination of both filters for a particular application, it is important to specify a few additional parameters to insure that the filter does not degrade to the audio or visual content of the broadcast signal.

For example, if a filter is used to prevent Channel B from entering the transmitter of Channel A, the filter will pass Channel A and reject Channel B. But the reject curve for Channel B must not infringe upon the bandwidth of Channel A. Therefore, an insertion loss variation must be specified across the operating bandwidth and perhaps beyond. At FM, where these filters are commonly used, insertion loss variation can be kept within

$$<0.1 \text{ dB}, \pm 200 \text{ kHz}$$

when either the notch is sufficiently removed in frequency or the pass band is broad enough. The edge of the reject skirt in either configuration is also characterized by a large deviation in group delay. Group delay is defined as a change in phase divided by a change in frequency.

$$\text{Group delay} = \frac{\text{Change in phase}}{\text{Change in frequency}}$$

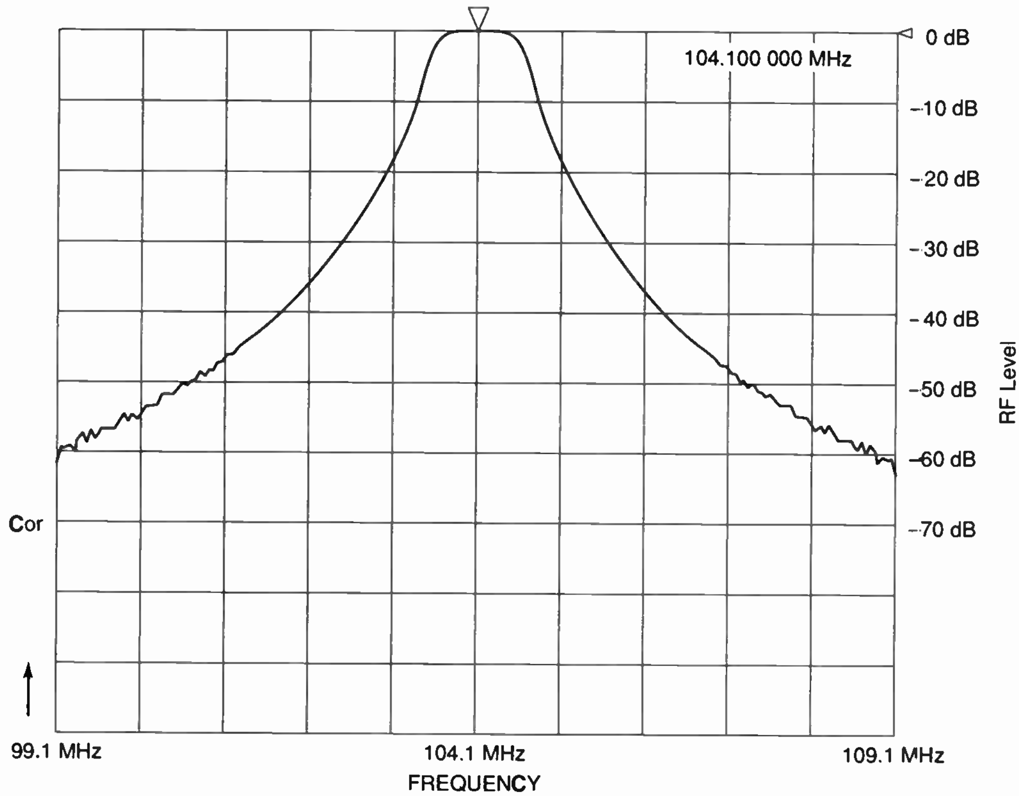

Figure 6.7-10. Four-cavity band-pass filter response.

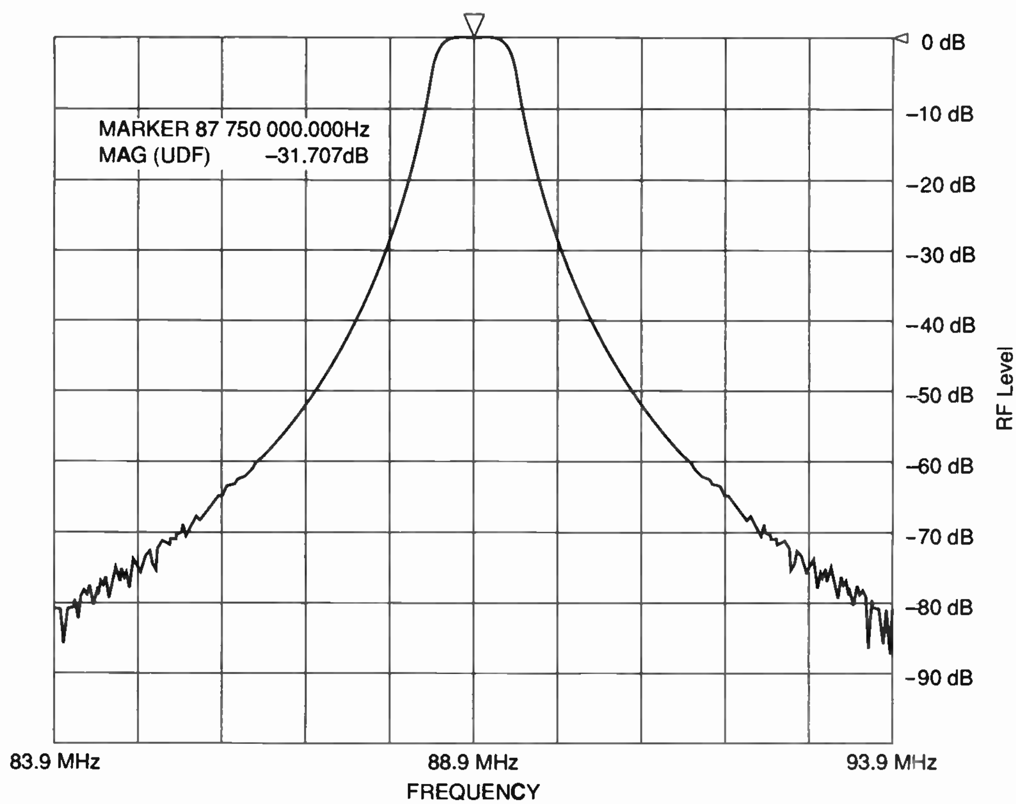

Figure 6.7-11. Five-cavity band-pass filter response.

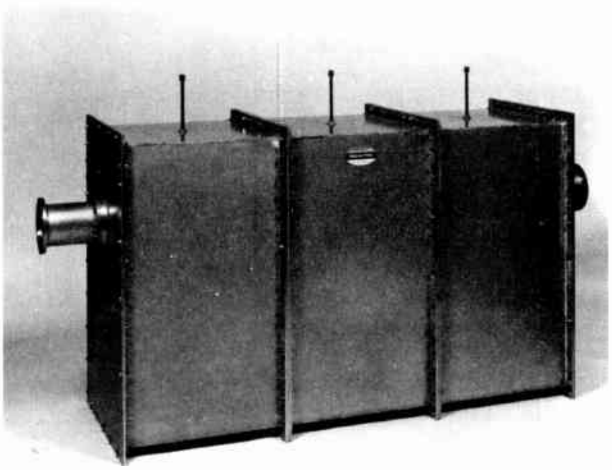

Figure 6.7-12. Three-cavity band-pass filter.

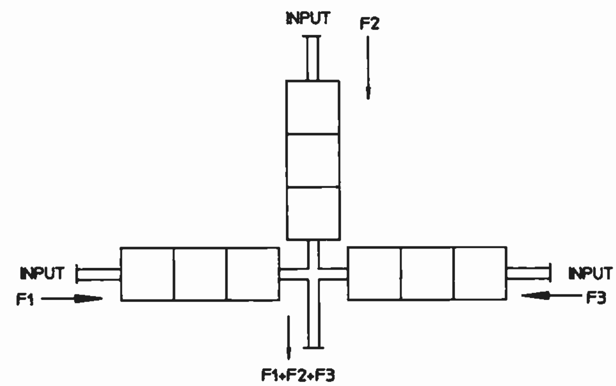

Figure 6.7-13. Schematic tee diplexer.

Group Delay Correctors

The group delay response of a band-pass filter is U-shaped. A device which uses a hybrid in conjunction with two notch cavities produces a group delay response shaped like an inverted U. Since group delay is additive, the positive group delay of the band-pass added to the negative group delay of this corrector causes cancellation at the band edges relative to center frequency. The group delay correctors thereby produce a relatively flat group delay. These were first developed as high power devices used in multiplexers. They have since been developed for low power applications and are now used in FM applications and in the aural input of TV diplexers.

Diplexers and Multiplexers

Diplexers and multiplexers are devices which allow broadcasters to combine two or more frequencies in a common transmission line while providing the isolation needed to prevent either transmitter from generating spurious emissions. Figures 6.7-13, 6.7-14, 6.7-15, and 6.7-16 provide schematic examples of configurations which can provide, in varying degree, the necessary response.

In the tee diplexer, each input leg contains either a band pass or a band-stop filter (see Figure 6.7-13). Each of these filters is characterized by a good voltage standing wave ratio (VSWR) and low insertion loss within the pass band. The slope of the reject curve away from center frequency is completely dependent on the number of cavities in each leg. Therefore, F1 and F2 must be separated sufficiently in frequency to allow the reject skirt to reach a rejection sufficient to obtain the desired isolation. All of this isolation (other than the 3 dB split of the tee) must be provided by the filter cavities. Figures 6.7-10 and 6.7-11 show rejection to be expected with deviations from center frequency. In general, F1 and F2 must be widely separated for band-pass legs and each operating band must be narrow for band-stop legs. In addition, this configuration has limitation when multiple frequencies must be combined.

Figure 6.7-14 illustrates the branch combiner for three or more channels. This device is not generally used for inputs greater than 10 W since the VSWR's and bandwidths are not as good as those in the constant impedance units shown in Figures 6.7-15 and 6.7-16. Broadcasters with tight budgets may still consider these units if they are willing to accept some performance degradation.

Figures 6.7-15 and 6.7-16, respectively, are band-stop and band-pass versions of a constant impedance diplexing configuration in common usage today at VHF and UHF frequencies. In both configurations 3 dB hybrids are used on both ends of the system and there will be an equal number of cavities in each leg between the hybrids. With the exception of the load on the isolated port and possible differences in line size, each system is electrically symmetrical about lines running through the center, both vertically and horizontally. These systems have similar response in both coaxial and waveguide configurations.

The band-stop system of Figure 6.7-15 is typically used for visual to aural diplexers in television applications.

F1, in that case, would be aural and F2 would be visual. Aural would enter at F1, be split into both legs of the hybrid, and then be reflected by the notch cavities. The reflected signal would pass through the same hybrid as before but recombine in the output port.

The visual signal (F2) would enter the rightmost hybrid, split into the two lines with cavities, pass the cavities unattenuated and recombine into the output.

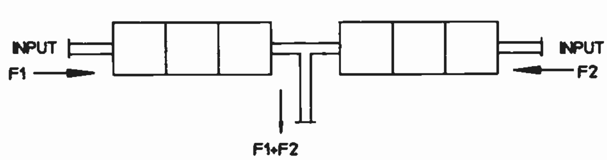

Figure 6.7-14. Schematic branch diplexer.

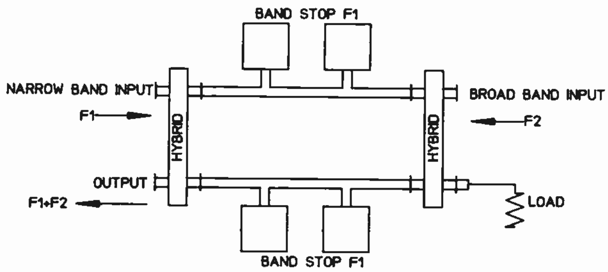

Figure 6.7-15. Schematic band-stop constant impedance diplexer.

In most TV diplexers, the second cavity in each leg would be tuned to 3.58 MHz below the visual carrier. This is the lower sideband of the visual color signal. The signal enters F2 with the visual signal and is reflected, in a manner similar to the aural signal, except that this signal is reflected into the load and absorbed.

An analysis would show the isolation of visual (F2) to aural (F1) would be due solely to the isolation inherent in the leftmost hybrid. Over a 6 MHz bandwidth, this is typically 35 dB, but can be as high as 45 dB with special care. The isolation from aural (F1) to visual (F2) is due to two components. The notches produce 27 dB typically and the rightmost hybrid about 35 dB, for a total of 62 dB.

In previous years, this type of diplexer has been used at FM frequencies, but the poor isolation in one direction required the addition of supplementary cavities on the F1 input. In addition, the group delay for this approach was four times higher than achievable with a band-pass system and the lack of symmetry and inverted shape made group delay compensation more difficult. The bandwidth, while adequate for the aural component of a TV system, has proven to be too narrow for FM applications resulting in incidental amplitude modulation.

The notch type constant-impedance diplexer has been widely used for TV applications with excellent results.

The band-pass constant-impedance diplexer, shown in Figure 6.7-16, is widely used for high-power diplexing or multiplexing applications in FM. It is occasionally used for diplexing complete TV signals, each containing visual plus aural. Several units can be cascaded together, each module providing a separate station's input. Since the cavities are band-pass units,

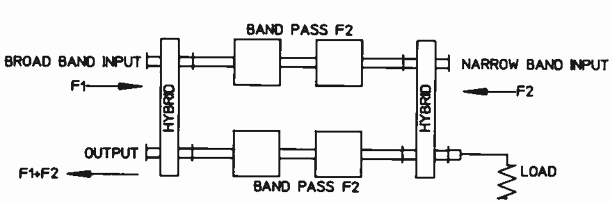

Figure 6.7-16. Schematic band-pass constant impedance diplexer.

only one channel passes through them and all others are reflected. For this case F2 becomes an individual-station input. The signal is split by the hybrid and passes with minimal attenuation through the cavities to recombine in the output. Any channel (other than F2) sufficiently spaced to be rejected by the cavities will be injected at F1, be split by the hybrid and then reflected by the cavities. The reflected signal recombines in the hybrid to exit through the output port.

An analysis of isolation in this case shows a deficiency in isolation from F2 to F1. The isolation is entirely that inherent in the hybrid. Across a 20 MHz bandwidth at FM, that isolation is typically 35 dB. The isolation from F1 to F2 is very good since it is due to the combined effects of the rejection of the cavities (which is >25 dB) and the hybrid (which is 35 dB) for a combined total of 60 dB.

If a module is used for each channel, then the adjacent module provides the additional rejection to increase the deficient isolation from F2 to F1 to 60 dB.

Figure 6.7-17 shows a four station multiplexer that is using band-pass modules to combine three FM stations with a channel 6. The taller module passes channel 6. Two supplementary notches are shown to the left of the channel 6 module to supplement the isolation from channel 6 (aural) to a closely spaced FM channel.

Figure 6.7-18 shows a VHF notch diplexer used to combine visual and aural. It functions as the schematic in Figure 6.7-15 shows.

Figure 6.7-19 shows a UHF waveguide notch diplexer. It also functions as shown in Figure 6.7-14. Figure 6.7-20 shows a UHF low power TV notch diplexer while Figure 6.7-21 is a photograph of a high band low power TV notch diplexer.

In the UHF portion of the band, where the visual transmitter is capable of amplifying the audio if diplexed low level, special motor-driven devices may be used in waveguides to detune the notch so that the entire content of the TV channel can be amplified by the visual transmitter, fed into the broadband port and recombined into the output without being attenuated by the notches.

TRANSMITTER SYSTEMS

In the following section, several methods of connecting one or more transmitters to the antenna system will be discussed. It would be impossible to cover all of the possible combinations. Therefore, only some of the basic configurations will be discussed. These can be modified or expanded to suit the individual station's requirements. Most broadcast equipment manufacturers will be happy to assist in designing custom systems.

A Caution About Interlocks

When designing an RF output system with motorized coaxial switches, it is essential to make sure that the transmitter cannot produce RF power when the switch contacts open. Most coaxial switches are con-

Figure 6.7-17. Four-channel multiplexer: Channel 6, plus three FM's. Corpus Christie, Texas.

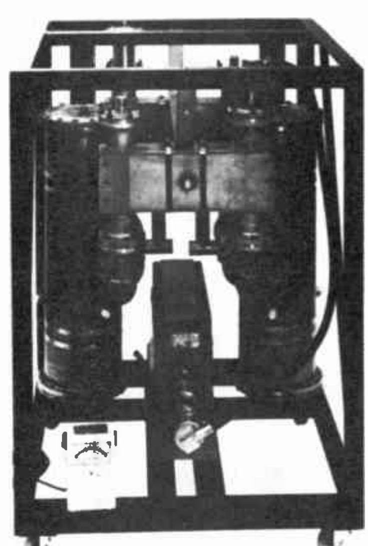

Figure 6.7-18. High band VHF notch diplexer.

structed so that the interlock kills the transmitter before the RF contacts open. However, this timing will vary between different types of switches. Also, the time it takes a transmitter to stop producing RF in response to the interlock signal will vary. Therefore,it is a good idea to check this timing. It may be necessary to turn off the transmitter a short time before commanding the coaxial switch to change positions. If the transmitter is still producing RF power when the RF contacts open, the contacts switch will be burned.

Single and Alternate Main Transmitter Systems

Figure 6.7-22 illustrates a single TV transmitter system utilizing a seven-port patch panel. The patch panel would allow the visual or aural component or the diplexer output to be terminated in station load. If the transmitter has multiplex capability (amplifying both the visual and aural signals in the visual amplifier), the visual amplifier could be connected directly to the antenna, bypassing the diplexer.

An alternate main transmitter with a coaxial switch

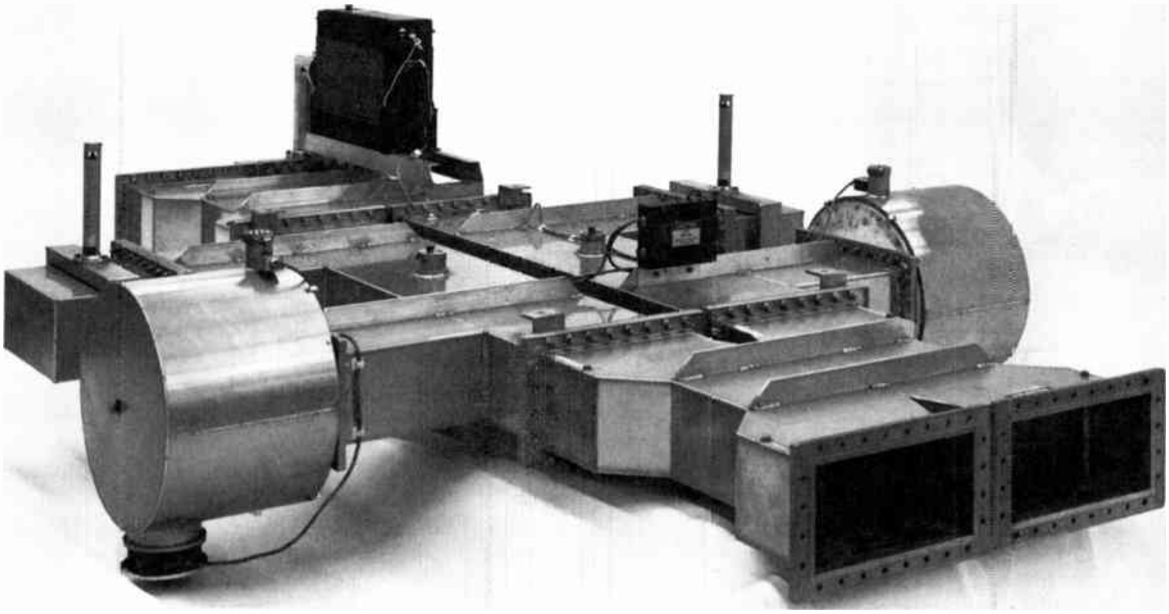

Figure 6.7-19. WR11500 waveguide notch diplexer.

is shown in Figure 6.7-23. A single ended (combined) transmitter would connect as shown. A conventional TV transmitter would require two switches.

Parallel Transmitters

Parallel transmitters are two complete transmitters whose output is combined to double the available output power. In addition to the increased output power, the parallel transmitter has additional advantages, such as redundancy. When one of the transmitters fails, the output power will drop to quarter power. If switching is provided in the output system, the output power can be increased to half power by bypassing the output combiner. This switching can take place at any convenient time after the failure.

In its simplest form, a parallel transmitter consists of an exciter modulator, input power divider, two amplifier sections, output power combiner and reject load (see Figure 6.7-24). In order to properly combine the input signals, they must be of the proper phase and amplitude. These relationships vary with the various types of combiners.

VHF Parallel Transmitters (Coaxial)

In VHF parallel transmitters, the output combiner is usually a 3 dB, 90° hybrid. In order to properly combine

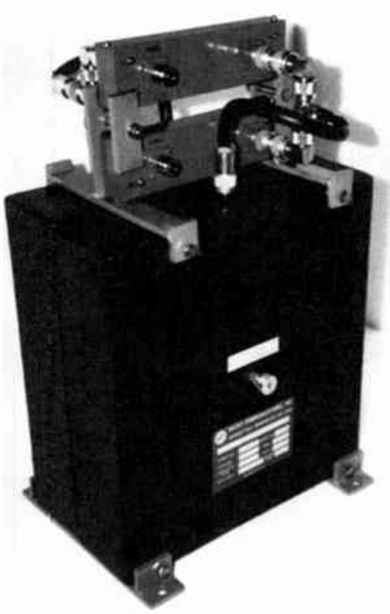

Figure 6.7-20. UHF low-power TV notch diplexer. (Courtesy Micro Communications, Inc.)

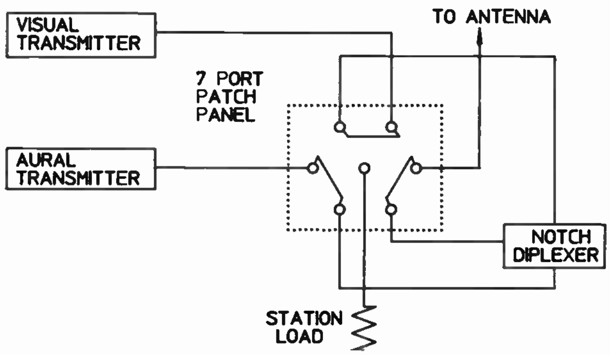

Figure 6.7-22. RF flow diagram TV transmitter with seven-port patch panel.

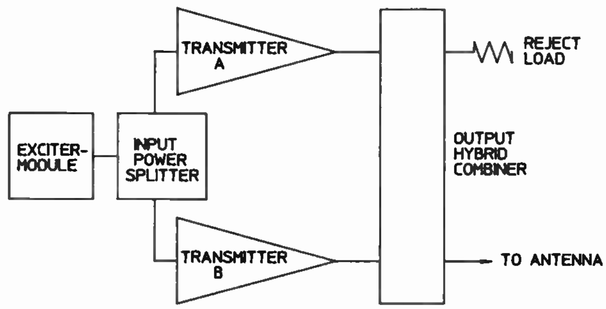

Figure 6.7-24. Basic parallel transmitter.

the two transmitter signals, the hybrid requires that the signals be of equal amplitude and phased in quadrature (90°). Assuming that the amplifier sections of the transmitters are identically tuned and that the electrical path lengths and gain are the same, then the input power divider must provide two signals that are of equal amplitude and phased in quadrature. A 3 dB hybrid will provide this type of power division, but other types could be used. An in-phase power divider with a 90° delay in one output would work just as well.

Figure 6.7-25 shows the relationship of phase error to output power of the parallel transmitter system. With no phase error (input signals to the output hybrid in quadrate) 100% of the available transmitter power will be delivered to the antenna. If there is a 90° phase error, both signals in-phase, the power will be divided equally between the antenna and reject load. All available transmitter power will be dissipated in the reject load if the phase error is 180°. A phase error of 20° will only result in an output power reduction of approximately 3%. This would indicate that the phasing is not critical for output power considerations.

The relationship between relative amplitude of the two transmitters and output power is shown in Figure 6.7-26. The graph assumes that one of the transmitters is operating at full power and that output power of the second transmitter is varied from zero to full power. If only one transmitter is operating, the output power will be only 25% of the normal combined output power. With only one input signal, the output hybrid acts as a power divider, applying half the power to the antenna and the other half to the reject load. The power being fed to the antenna is 25% of the normal combined transmitter power. If one of the transmitters is operated at half its normal output power while the other transmitter is operated at full power, the combined output power will be approximately 73% of the normal combined power. Since the two transmitters are only generating 75% of the normal combined power, only about 2% of the power is being dissipated in the reject load. Therefore, not much power is wasted in the reject load. The maximum power that the reject load should be required to dissipate is half of one transmitter's power.

Thus far, only the basic parallel transmitter system has been discussed. It was assumed earlier that the amplifier sections of the transmitters were identically tuned, having the same electrical path lengths and gain. From a practical viewpoint this could be done, but with difficulty. Therefore, most parallel transmitter systems provide a means of controlling the phase and gain of the transmitters that is independent of the tuning. This usually means an attenuator for gain and a phase shifter for the phase. Some transmitters use a gain control

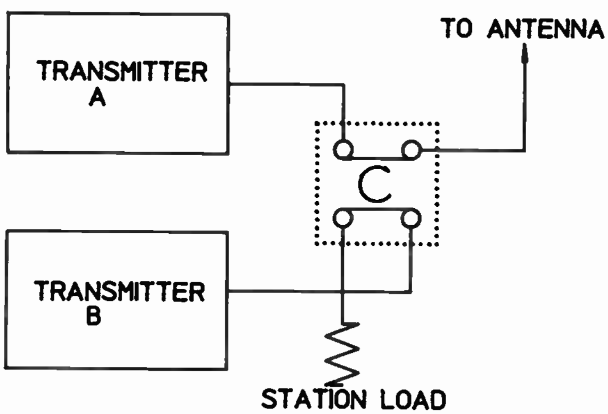

Figure 6.7-23. RF flow diagram with alternate main transmitter.

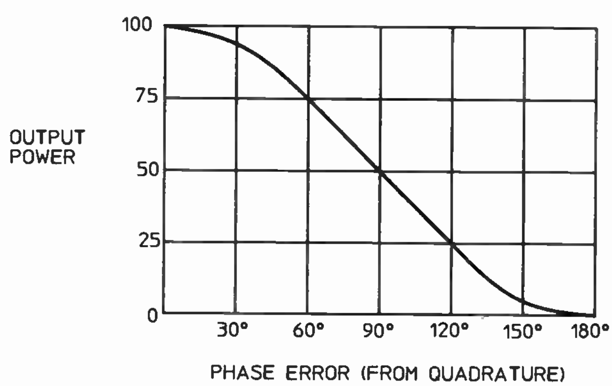

Figure 6.7-25. Relative output power versus phase error.

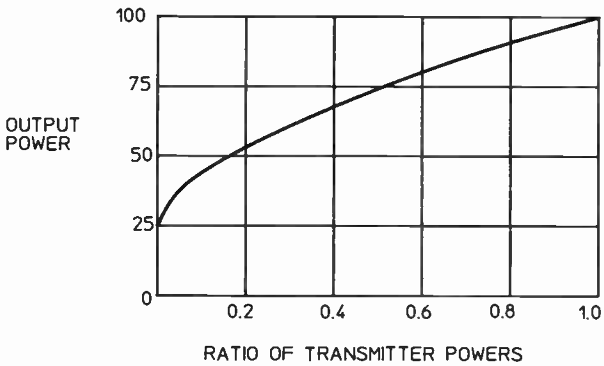

Figure 6.7-26. Relative output power versus amplitude ratio.

within the amplifier section and one of the input matching controls of the power amplifier to accomplish these adjustments. This practice is probably more common in FM than TV since the FM bandwidth is smaller.

One of the major advantages of parallel transmitters in television is the reduction of ghosts or reflections from the antenna. Ghosts occur when a portion of the power is reflected from the antenna back to the transmitter, re-reflected and finally radiated. The distance between the original image and the ghost as shown on a TV receiver can be used to determine the approximate location of the reflection in the transmitting antenna system. Since the horizontal frequency of the TV is 15,734 kHz, the full horizontal line would be equal to 63.6 μsec. The length of the visible portion of the horizontal line is 53.1 μsec. Therefore, the time between the image and the ghost can be measured. This time, when compared to the speed of light, will yield the distance the reflected signal had to travel to produce the ghost.

It must be kept in mind that the reflected signal had to travel from the point of origination down the transmission line to the transmitter and back up the transmission line to the antenna to be radiated. The velocity of propagation of the transmission line must also be taken into account.

The use of the 3 dB hybrid in the parallel transmitter will reduce the reflected signals that produce the ghosts. When the reflected energy from the antenna is applied to the output of the 3 dB hybrid, it is split into two signals at the two transmitter inputs. These signals will be phased 90° apart and will continue until they are re-reflected by the output circuitry of the transmitters. The signals will then be applied to the inputs of the 3 dB hybrid. However, their phases are such that instead of combining in the antenna output, they will combine in the reject load of the parallel transmitter. For optimum ghost reduction the electrical path lengths between the hybrid and transmitter inputs must be the same. The use of slugs or other tuning devices can upset the phase balance or electrical length of the system.

One method to measure the effectiveness of a system for ghost reduction is to measure the reverse VSWR of the system. This is accomplished by placing open or short circuits on the transmission lines that would connect to the transmitter outputs and measuring the VSWR at the output of the combining system. Thus, the path of the ghost signal is being measured. Ideally, this path should be as good as the forward VSWR of the system. However, from a practical standpoint, a VSWR of 1.1:1 or better will reduce the ghosting. It should be noted that equal electrical line lengths are needed for quadrature type combining networks. For systems using in-phase type combining networks there must be a 90° delay in the proper input. To offset this delay, a 90° delay can be inserted in the input circuitry of the opposite transmitter.

Figure 6.7-27 shows a complete output switcher for a parallel television transmitter. For single-ended transmitters such as used in FM, only half the system would be required. This figure shows the switching options of the output hybrid combiner. There are normally four modes of operation:

- A and B combined to the antenna
- A and B combined to the station load
- A to the antenna and B to the station load
- B to the antenna and A to the station load.

As drawn, the diagram is shown in the A and B to the antenna mode. By rotating S3 and S6, the system is changed to the A and B combined to the station load mode. If S1, S2, S4 and S5 are changed, Transmitter A will be connected to the antenna while Transmitter

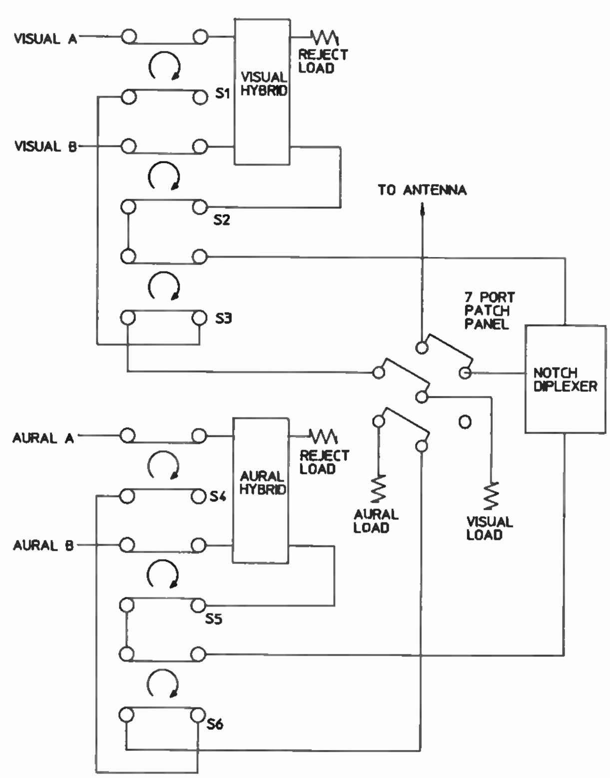

Figure 6.7-27. RF flow diagram for output switcher.

B will be connected to the station load. If S3 and S6 are rotated, the transmitters will switch Transmitter A to the station load while Transmitter B is connected to the antenna.

Since a parallel transmitter is really two complete transmitters, there should ideally be two exciter-modulators. Some manufacturers may offer the second exciter modulator as an option. By adding a switch on the input of the input power divider, either exciter modulator could be selected. This would provide redundancy, should the active exciter modulator fail. Since the power level of the exciter modulator is usually fairly low, the switching could be done under power, which would allow the switching to be automatic. By using relatively fast switches, the transfer could be done with only a small carrier interruption.

Automatic operation of the output switching system Is not usually done. Stations would rather choose when the carrier break occurs, since it will be noticeable to the audience. In lower power installations, the carrier break will be two seconds or less. With higher power switches the break could be up to ten seconds.

Again referring to Figure 6.7-27, the combined output of the visual hybrid must pass through S2 and S3. Therefore, these switches must be sized to carry the combined power. Some systems will add another coaxial switch (S7) on the output of the visual hybrid as shown in Figure 6.7-28. This higher power switch will allow the other three switches to be of a smaller size, since the combined power will only be applied to S7. It would then be necessary to add another station load for the combined signal at S7. Generally, this will

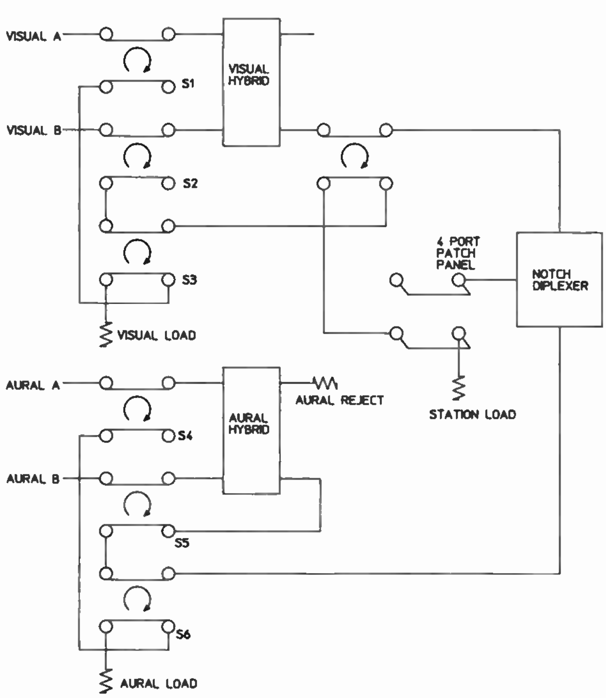

Figure 6.7-28. RF flow diagram for high power output switcher.

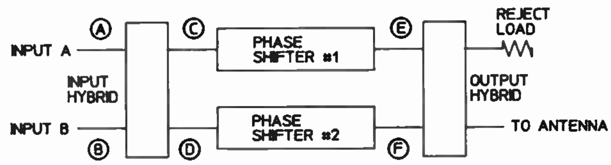

NOTES:

1. INPUTS A+B ARE IN PHASE
2. PHASE SHIFTER #2 WILL USUALLY CONTAIN A FIXED 90° SECTION AND A VARIABLE 90° SECTION.

MODE	PHASE SHIFTER #1	PHASE SHIFTER #2
A+B ANTENNA	0	90
A-ANTENNA B-LOAD	90	90
B-ANTENNA A-LOAD	0	180

Figure 6.7-29. Schematic of basic switchless combining system.

reduce both the physical size and the cost of the parallel transmitter system. A television system requires a diplexer of some type in order to combine the aural and visual signals. The output switching system usually contains a patch panel which allows the output of the diplexer to be routed either to the antenna or the station load. The output switching system must also contain the necessary monitoring points for combined power and reject power.

VHF Switchless System (Coaxial)

The switchless system also combines the outputs of two transmitters operating in parallel.

As with the switch method, it provides four modes of operation:

- A and B combined to the antenna
- A and B combined to the station load
- A to the antenna and B to the station load
- B to the antenna and A to the station load.

There are several methods to accomplish these mode changes without the switches. A basic system is shown in Figure 6.7-29 and consists of two 90° hybrids, a reject load, and some type of phase shifting device. The method used to shift the phases defines the various options. Therefore, the basic system will be presented here, and then the different methods of accomplishing the phase shift will be discussed.

Since the switchless system contains two hybrids, one must understand how the hybrid operates. The 90° hybrid can be used as either a power divider or a power combiner. In the switchless system both are used.

When used as a power combiner, the hybrid will combine two signals that are equal in amplitude and phased in quadrature. Again referring to Figure 6.7-29, if two equal amplitude signals are applied to points E and F, with the signal at F lagging in phase by

90°, the signals will be combined into the antenna. Conversely, if the signal at point E is lagging by 90°, the signals will be combined into the load.

If a signal is applied to the A input of the hybrid (now being used as a power divider), it will be split into two signals of equal amplitude that are phased 90° apart. The signal appearing at Point C will be in phase with the input signal (Point A), while the signal at Point D will lag the input signal by 90°.

The converse is true for a signal being fed into the B input. The signal at Point D will be in-phase, while the signal at Point C will lag 90°. If two signals that are in-phase are applied to inputs A and B, then each of the outputs (Points C and D) will have two signals, one in-phase with the inputs and one lagging by 90°.

If the switchless system is set in the A and B to the antenna mode, phase shifter #2 must have 90° more phase shift than phase shifter #1. The two signals at Point F will lag the two signals at Point E. In this situation, the signals will combine in the antenna output.

If either of the phase shifters are set for an additional 90° of phase shift, the system will be in one of the single transmitter modes of operation. If phase shifter #1 is changed, then Transmitter A will be routed to the antenna, while Transmitter B will be terminated in the station load. Should phase shifter #2 be changed, Transmitter B will be routed to the antenna, while Transmitter A is terminated in the station load.

There are three methods of sending output from the combined transmitters to the station load:

- A coaxial switch or patch panel could be used at the antenna output to route this output to a separate station load
- The combined transmitters could be routed to the reject load by moving the additional 90° phase shift in phase shifter #2 to the #1 phase shifter
- The transmitter outputs could also be combined into the reject load by changing the input phases to the switchless system. By adding 180° delay to the A input the combined transmitter output will be routed to the reject load.

The latter two methods will require that the power rating of the reject load be increased to the combined power level instead of that of a single transmitter. They also require that the antenna receive any power that is not absorbed in the reject load.

There are several methods of changing the phase of the RF signals in the switchless system.

- Probably the most familiar method of changing the phase at higher power levels is the line stretcher. It is a piece of transmission line whose length can be changed. For convenience, it often takes the form of a U-link, or trombone, so that the connectors can be mounted and the U-link moved to change the length.
- Another method uses a 90° hybrid with movable short circuits on two of the arms (see Figure 6.7-30). If a signal is applied to the input (Point A), the hybrid will divide it into two equal signals that are phased 90° apart. The signal at Point D will lag by 90°. The short circuits attached to Points C and D will reflect the two signals back to the hybrid. The phase of the two signals will be delayed by twice the electrical length of the short circuits. If the two short circuits are the same length, the relative phases of the two signals will still be 90°. Since the signal at Point D is lagging by 90°, the two signals will combine into the output (Point D). By changing the length of the short circuits, the delay or phase shift through the circuit will change. If the short circuits are moved 90°, the phase shift through the circuit will change. If the short circuits are moved 90°, the phase shift through the circuit will be 180°. The signal must travel from the hybrid to the short circuit and then return to the hybrid, twice the distance of the short circuit. The two short circuits must be moved together in order to make the hybrid combine the reflected signals properly.
- Figure 6.7-31 shows several methods of making a short circuit needed in the above circuit. It could be the traditional short (a piece of movable metal contacting the inner and outer conductors of the transmission line)
- A *deep short* could be used which moved the ringer contacts one quarter wavelength away from the short. This greatly reduces the amount of current that the fingers are required to carry. A *non-contacting short* may be used. It is a pair of cylinders that are a quarter wavelength long and shorted at one end. The sizes of the cylinders are such that they fit between the inner and outer conductors of the transmission line. The shorted cylinders are insulated from the transmission line, thus forming a capacitor. The capacitor is large enough to have very little impedance at the operating frequency, therefore, it appears as a short circuit
- Another method of creating phase shift is to use an open circuit. A short section of the center conductor is removed from a shorted piece of transmission line. The transmission line appears as an open circuit, since there is very little capacitance between the

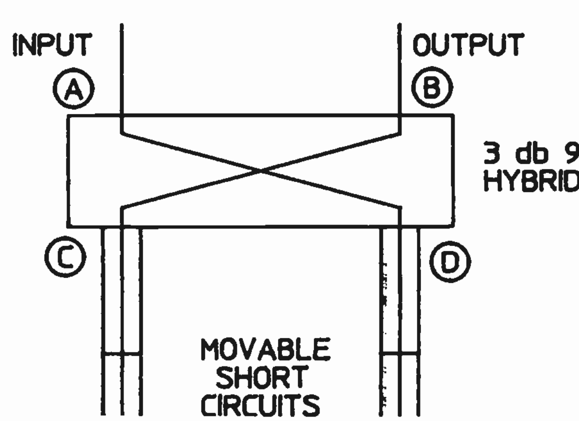

Figure 6.7-30. Variable phase shifter assembly.

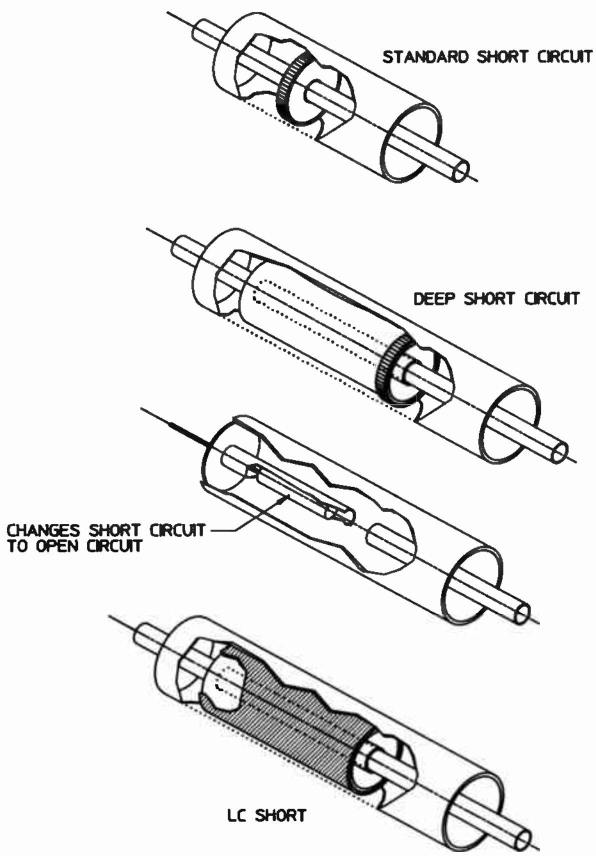

Figure 6.7-31. Variable phase shifter options.

two pieces of cut center conductor. By moving an insulated metal probe across the gap in the cut center conductor, a large amount of capacity is created. This causes the transmission line to appear as a short circuit, thus changing the phase.

All of the methods mentioned will change the phase and allow the switchless system to operate. Each method has advantages and disadvantages that should be taken into consideration upon purchasing a switchless system.

A typical flow diagram for a VHF switchless system is shown in Figure 6.7-32 and a diagram for a coaxial Opto-SX is shown in Figure 6.7-33.

The switchless system does not require that the transmitters be turned off during the switching process. Since there is no carrier break, the length of switching is not important. Switching may be done with no regard to program content.

The switchless system will offer the same ghost reduction capability as other types of parallel transmitters. Since the two signals from the transmitters are applied to the switchless system in-phase, there must be an external phase shift to take advantage of the ghost reduction feature. A 90° phase shift must be added between the output of one of the transmitters and the switchless system. This will delay the reflected signal in that path 90° as it passes from the output system to the transmitter, and another 90° as it passes from the transmitter back to the output system. The two reflected signals will now be 180° out-of-phase, and thus be combined in the reject load. Since a 90° delay was added to one of the transmitter signals, it will be necessary to add an equal phase shift to the other transmitter so that the two signals will combine in the antenna output. This delay can be added to the input circuits, allowing the ghost reduction circuit to operate properly.

Safety Considerations

There are some safety aspects of the switchless system that were not present in the switch type systems. In a switch type system, the transmitters were isolated by the mechanical switch when operating in the single transmitter mode. The switchless system does not have that isolation. Its isolation is provided only by the

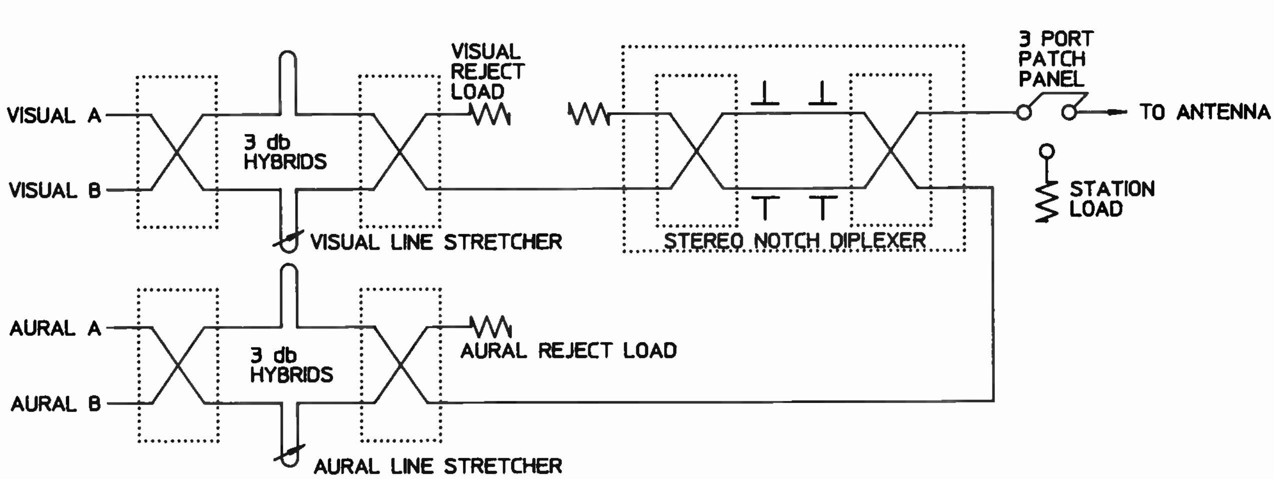

Figure 6.7-32. RF flow diagram VHF switchless system with diplexer.

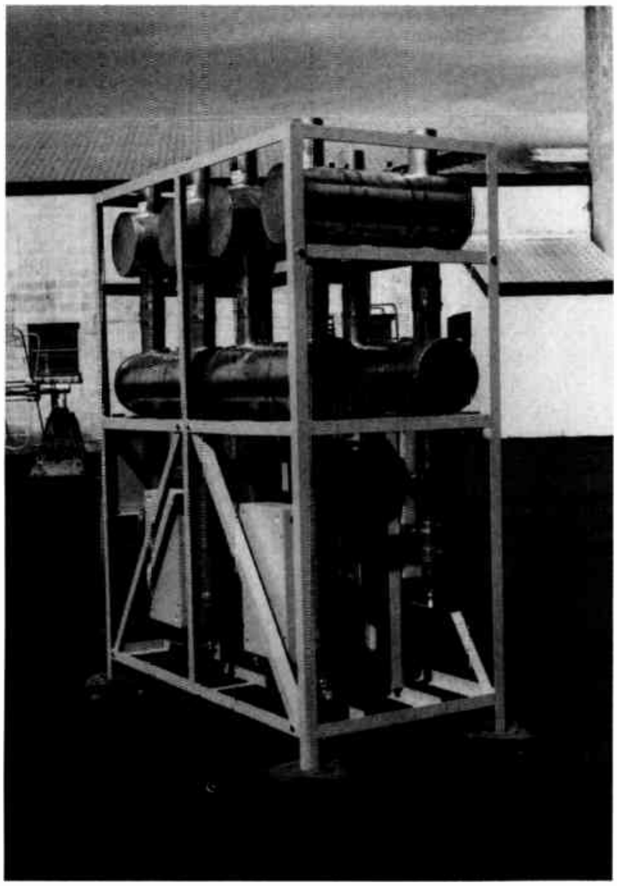

Figure 6.7-33. VHF switchless "Opto-SX" switcher. Includes aural and visua. inputs.

two hybrids. Therefore, the 60 dB or better isolation provided by the coaxial switches, is not present in the switchless system. It is possible that voltages could be present on an input, even though the transmitter driving that input is turned off. It is necessary to make sure that safety devices are used to protect technicians. It would be a good idea to delay maintenance on the system until both transmitters could be turned off.

UHF Parallel Transmitters (Waveguide)

UHF parallel transmitters are different from their VHF counterparts. Because of the power rating of the output device (typically 30 kW to 60 kW), purely parallel transmitters are not as common as in VHF. While there are quite a few 110 to 120 kW transmitters operating, these are not true parallel transmitters, as only the visual klystrons are operating in parallel. A 220 to 240 kW transmitter is the more common parallel UHF transmitter. The UHF transmitters also have aural multiplex capabilities, which reduce the need for parallel aural amplifiers.

A typical RF flow diagram for a waveguide output switching system is shown in Figure 6.7-34. It contains four waveguide transfer switches, a hybrid combiner and a reject load. S1 and S2 switch the input of the system around the hybrid for single transmitter operation. S3 determines whether the transmitter signals will be routed through the diplexer, while S4 routes the output of the diplexer to the antenna or station load. The aural amplifier is routed directly to the diplexer. This system would have the four basic modes of operation:

- Visual A and B combined to the antenna
- Visual A and B combined to the station load
- Visual A to the antenna and visual B to the station load
- Visual B to the antenna and visual A to the station load.

In addition, each of the modes could be operated either multiplexed or normal.

Recent developments in diplexers have simplified the switching systems. Aural notch detuners allow the multiplexed signals to pass through the notch diplexer rather than being switched around it. The detuners raise the aural notch cavity's frequency so that it is above the aural carrier. This allows the multiplexed visual carrier to pass through the diplexer, just as the visual signal does normally.

A station's RF output switching system is usually unique. Either the RF layout of the system will be slightly different, or the mechanical layout of the system must be adapted to the transmitter building. Since this is usually the case rather than the exception, most manufacturers are equipped to handle these situations. Figure 6.7-35 shows a system with coaxial patch panels and switches on the input and a waveguide patch panel on the output of the diplexer.

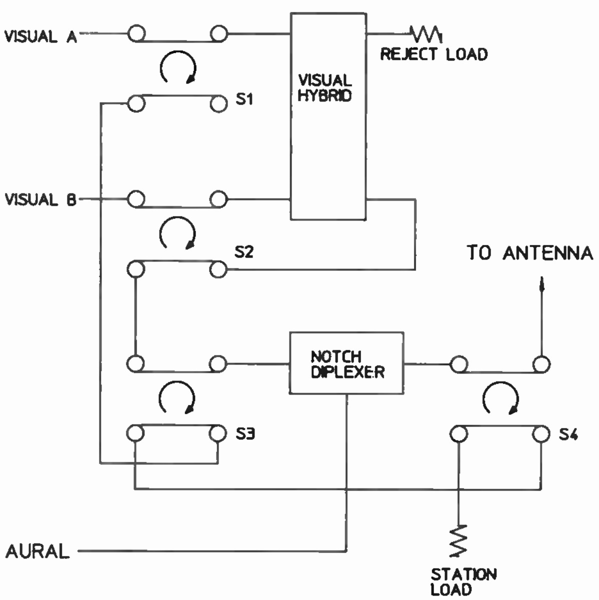

Figure 6.7-34. RF flow diagram of output switcher with parallel visual amplifiers.

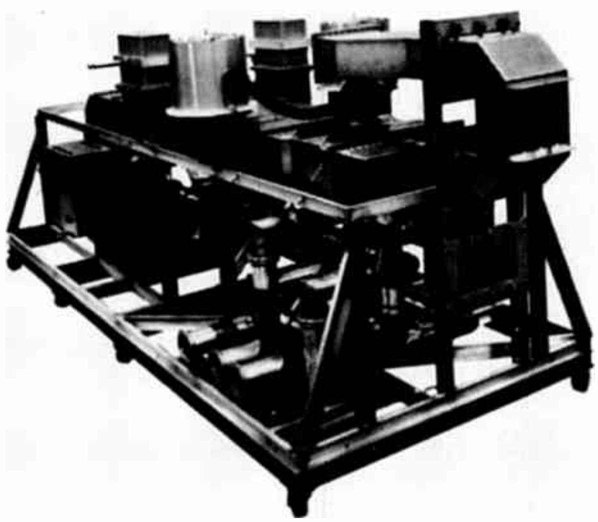

Figure 6.7-35. Output switcher 100 kW UHF transmitting system.

UHF Switchless System (Waveguide)

One of the more recent developments in RF switching is the switchless phase shifter system. These combine the outputs of higher power UHF amplifiers and can be used for either aural or visual service. This system consists of a 3 dB, 90° hybrid, a dual phase shifter, a reject load, and a magic tee (180° hybrid) and is shown in Figure 6.7-36. To better understand how the system operates, it is essential to examine the individual components.

The magic tee (180° hybrid) works much like a 90° hybrid. The difference is the amount of phase difference that it provides. When it is used as a splitter, the outputs will either be in phase or 180° out-of-phase, depending on which input is being driven. When used as a combiner, the magic tee will combine signals that are in-phase into the main output; if the signals are 180° out-of-phase it will route them to the coupled output.

Each phase shifter consists of a movable piece of dielectric material inside a section of waveguide. When the dielectric material is against the side wall of the waveguide, the phase shift will be at the minimum. As the dielectric material is moved toward the center of the waveguide, the phase shift of the signal going through the waveguide will increase. By choosing the type and amount of dielectric material, the device can be adjusted to produce 90° of phase shift. The amount of phase shift with the dielectric material against the side wall is not important in this instance. The critical element is that the phase shifts through the two units be equal.

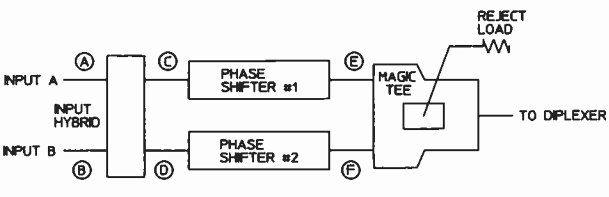

Figure 6.7-36. Block diagram UHF switchless switcher.

Assume that there is no phase shift through the unit when the dielectric material is against the side wall and 90° when it is in the center of the waveguide. If a signal is applied to the A input of the hybrid, it will be split into two signals of equal amplitude that are phased 90° apart. The signal appearing at Point C will be in-phase with the input signal (Point A), while the signal at Point D will lag the input signal by 90°. The relationship of the signals at C and D will be reversed for inputs at B. If the result of each of these scenarios is superimposed on one another to simulate the normal mode of operation with signals at both A and B, the outputs C and D each contain two signals at equal amplitude and 90° phase difference. The hybrid effectively causes these signals to be vectorially summed with an equivalent output of amplitude = 2, and phase = −45°. Although these signals have been delayed 45° with respect to the input, they are now in phase with one another at ports C and D.

With the assumption that the phase shifters have no phase shift when set to the minimum position, the signals at the output of the input hybrid (Points C and D) would be applied to the input of the magic tee (Points E and F). There will be signals present at both Points E and F that are in phase with the input signal. The signal at Point E is produced by amplifier A, while the signal at Point F is produced by amplifier B. Since these signals are equal amplitude and in-phase they will combine into the main output of the magic tee. At the same time, because the other two signals at Point E and F are equal in amplitude and in-phase, they will combine into the main output of the magic tee. At the same time, the other two signals at Point E and F are equal in amplitude and in-phase, therefore, they will combine just as the other signals did. Since these signals are not in-phase at the output of the magic tee, the resultant signal will be the vector sum.

By inserting 90° of shift in-phase shifter #1, a new mode is created. The phases at the output of the hybrid (Points C and D) will be the same as before. Since 90° is added between Points C and E, the phases at E will now be 90° for the signal from input A and 180° for the one from input B. Therefore, on the inputs of the magic tee, the signals from input A are in-phase, while the signal from the B input are 180° out-of-phase. The in-phase signals will add at the main output of the magic tee while the signals that are 180° out-of-phase will add in the coupled output.

If phase shifter #1 is returned to the minimum position and phase shifter #2 is set for 90° of phase shift, the signals from the B input will add in the main output, while the signals from the A input will add in the coupled output. By adding the phase shift in the #2 phase shifter, the signals at Point F will be 90° for the one from input B and 180° for the one from input A. Thus, the signals from input B will be in-phase at

Figure 6.7-37. UHF 120 kW switchless diplexer.

the inputs of the magic tee, while the ones from input A are 180° out-of-phase.

Thus far, three modes of operation have been accomplished within the switchless system. The fourth mode, both transmitters combined to the station load, can be done two ways. If the phase of the input signals are changed from in-phase to 180°, the combining that takes place will be applied to the coupled output (reject load) rather than to the main output. The second method is to add a switch to the output of the system to allow the output to be connected to the antenna or the station load. The latter seems to be the more common method at the present time.

The switchless phase shifter can be changed under power, since there are no contacts to break and make. The only part that is moving is the dielectric material in the phase shifter section. Since the full power of one transmitter can be applied to the reject load, the load must be capable of handling that power.

In the past, switching systems changed the RF path by mechanically moving the parts of a switch. A typical switch will have around 60 dB of isolation between the paths of the switch. In the switchless system there is no mechanical isolation. Isolation is provided by the hybrid and by the magic tee within the system. Typically, this isolation will be on the order of 35 to 45 dB, which is sufficient for good performance. However, operators must be aware that the isolation that they provide in a switch type system is not there in the switchless system. Therefore, when maintenance is being performed on the system or one transmitter, there may be a small amount of power present from the other transmitter. A typical system is shown in Figure 6.7-37.

Three Tube Switchless Combiner

The three tube switchless combiner (Dielectric, U.S. Patent #4,951,013) is another type of UHF combiner. Previously, it was not recognized that widely different amplitude of visual inputs could be combined with a switchless system. Once two tubes of a 180 kW system have been combined, the resulting 120 kW must be combined with the remaining 60 kW. The three-tube switchless enables other phase choices in addition to 0°, 90° and 180° from the phase shifters. By allowing for 19°, for example, the high efficiencies of a two-tube system may be obtained with the three tube system (see Figure 6.7-38).

This approach is also usable at VHF, should the need arise.

High Power Isolators[2]

The high power ferrite isolator offers the ability to stabilize impedance, isolate the RF generator from load discontinuities, eliminate reflections from the load and absorb harmonic and intermodulation products.[2] The isolator can also be used to switch between an antenna or load under full power, or combine two or more transmitters into a common load.

Isolators are commonly used in microwave transmitters at low power to protect the output stage from

[2] This section contributed by Jerry Whitaker, editor-in-chief.

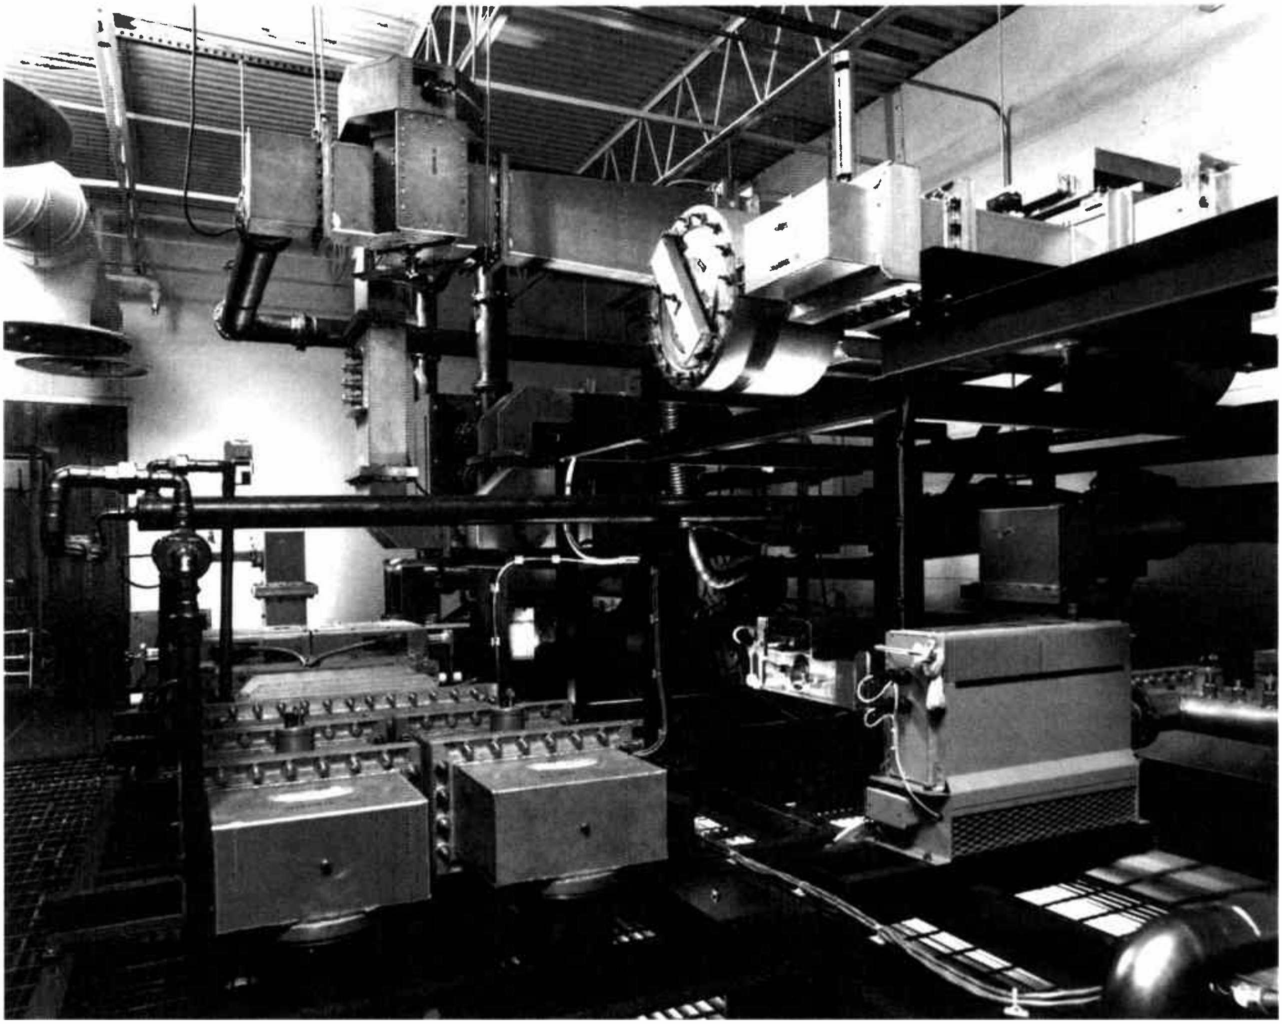

Figure 6.7-38. 180 kW three-tube switchless at channel 50 in Tampa, Florida. (Courtesy of Home Shopping Network).

reflections. Until recently, however, the insertion of the ferrite made use of isolators impractical at high power levels (10 kW and above). Ferrite isolators are now available that can handle 400 kW or more of forward power with less than 0.1 dB of forward power loss. Experimental models have been demonstrated that can handle 4 MW.

High power isolators are three-port versions of a family of devices known as *circulators.* The circulator derives its name from the fact that a signal applied to one of the input ports can travel in only one direction, as shown in Figure 6.7-39. The input port is isolated from the output port. A signal entering port 1 appears only at port 2; it does not appear at port 3 unless reflected from port 2. An important benefit of this one-way power transfer is that the input VSWR at port 1 is dependent only on the VSWR of the load placed at port 3. In most applications, this load is a resistive (dummy) load that represents a perfect load to the transmitter.

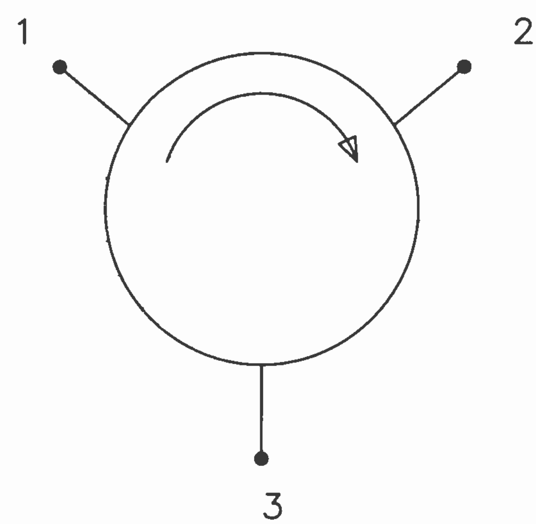

Figure 6.7-39. Basic characteristics of a circulator.

The unidirectional property of the isolator results from magnetization of a ferrite alloy inside the device. By polarizing the magnetic field of the ferrite correctly, RF energy will travel through the element in only one direction (port 1 to 2, port 2 to 3 and port 3 to 1). By reversing the polarity of the magnetic field RF flow in the opposite direction is possible. Recent developments in ferrite technology have resulted in high isolation with low insertion loss.

The ferrite is placed in the center of a Y-junction of three transmission lines, either waveguide or coax. Sections of the material are bonded to form a thin cylinder perpendicular to the electric field. Even though the insertion loss is low, the resulting power dissipated in the cylinder can be as high as 2% of the forward power. Special provisions must be made for heat removal. It is the heat removal capability that makes high power operation possible.

The insertion loss of ferrite has been kept low so that minimal heat is dissipated. Values of ferrite loss on the order of 0.05 dB have been produced. This equates to an efficiency of 98.9%. Additional losses from the transmission line and matching structure contribute slightly to loss. The overall loss is typically less than 0.1 dB, or 98% efficiency.

The ferrite element is usually water-cooled in a closed-loop system that uses an external radiator.

Applications

The high power isolator permits a transmitter to operate with high performance and reliability despite a load that is less than optimum. The problems presented by ice formations on a transmitting antenna provide a convenient example. Ice buildup will detune an antenna resulting in reflections back to the transmitter and high VSWR. If the VSWR is severe enough, transmitter power will have to be reduced to keep the system on the air. An isolator, however, permits continued operation with no degradation in signal quality. Power output is affected only to the extent of the reflected energy, which is dissipated in the resistive load.

A high power isolator can also be used to provide a stable impedance for devices that are sensitive to load variations, such as klystrons. This allows the device to be tuned for optimum performance regardless of the stability the RF components located after the isolator. Figure 6.7-40 shows the output of a klystron operating into a resistive load, and into an antenna system. The power loss is the result of an impedance difference. The periodicity of the ripple shown in the trace is a function of the distance of the reflections from the source.

Hot Switch

The circulator can be made to perform a switching function if a short circuit is placed at the output port. Under this condition, all input power will be reflected back into the third port. The use of a non-contacting high power stub on port 2 permits redirecting the output of a transmitter to the third port.

At odd quarter wave positions, the stub appears as a high impedance and has no effect on the output port.

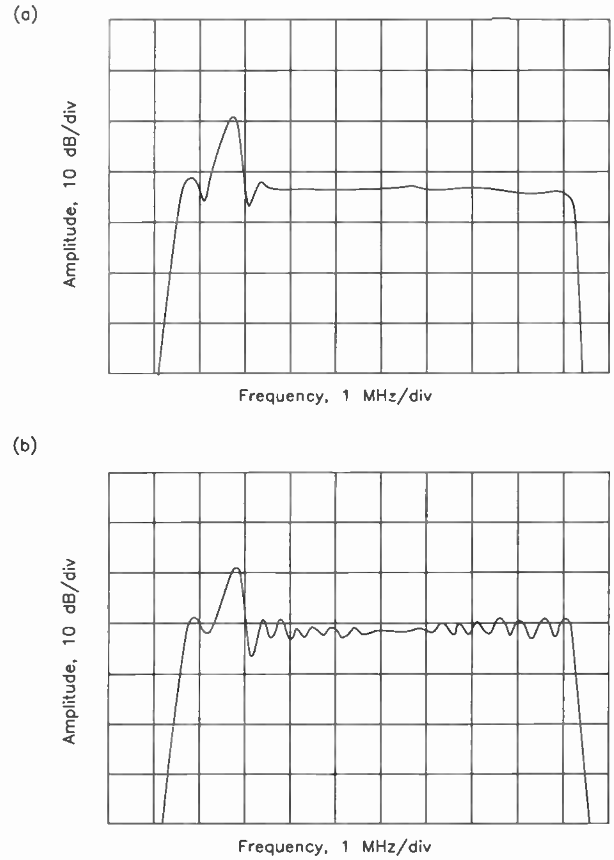

Figure 6.7-40(a). Output of a klystron operating into a resistive load, and into an antenna system (b). (Courtesy of Micro Communications, Inc.)

At even quarter wave positions, the stub appears as a short circuit. Switching between the antenna and a test load, for example, can be accomplished by moving the shorting element ¼-wavelength.

Diplexer

An isolator may be configured to combine the aural and visual outputs of a television transmitter into a single output for the antenna. The approach is shown in Figure 6.7-41. A single notch cavity at the aural

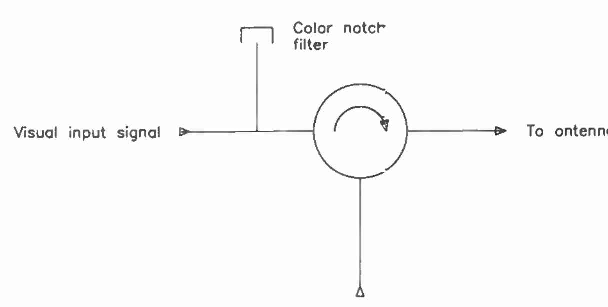

Figure 6.7-41. Use of a circulator as a diplexer in television applications. (Courtesy of Micro Communications, Inc.)

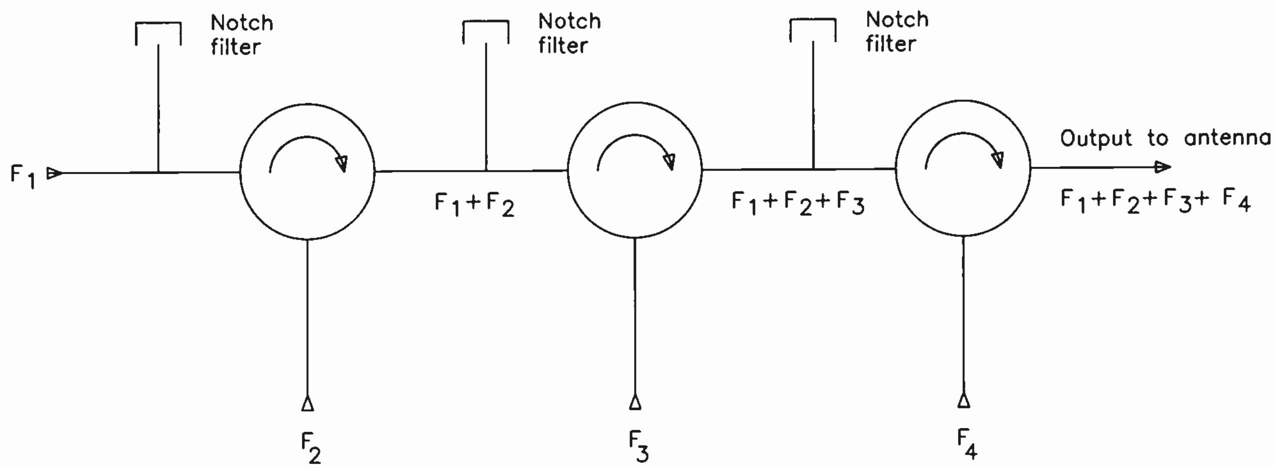

Figure 6.7-42. Using multiple circulators to form a multiplexer.

frequency is placed on the visual transmitter output (circulator input) and the aural signal is added (as shown). The aural signal will be routed to the antenna in the same manner as it is reflected (because of the hybrid action) in a conventional diplexer.

Multiplexer

A multiplexer can be formed by cascading multiple circulators, as illustrated in Figure 6.7-42. Filters must be added, as shown. The primary drawback of this approach is the increased power dissipation that occurs in circulators nearest the antenna.

CHANNEL-COMBINING CONSIDERATIONS

A number of techniques are practical to utilize an existing tower for both NTSC and DTV transmissions. Combining RF signals allows broadcasters to use an existing structure to transmit NTSC and DTV from a common line and antenna or, in the case of a VHF and UHF combination, to utilize the same line to feed two separate antennas.

During the transition period from NTSC to DTV, many broadcasters may choose to use the existing tower to transmit both NTSC and DTV channels. Some may choose to add a new line and DTV antenna; others may combine their DTV with NTSC and transmit from a common antenna and line; and still others may choose to consolidate to a new structure common to many local channels. For most stations, it is a matter of cost and feasibility.

Channel combiners (multiplexers and diplexers) suitable for DTV applications include:

- **Constant impedance.** Designs that consist of two identical filters placed between two hybrids
- **Starpoint.** Designs that consist of single bandpass filters phased into a common output tee
- **Resonant loop.** Types that utilize two coaxial lines placed between two hybrids, the coaxial lines are of a calculated length
- **Common line.** Types that use a combination of band-stop filters matched into a common output tee.

In addition, the *dual-mode channel combiner* (Micro Communications) is a device that shows promise for using a single transmission line on a tower to feed two separate antennas. Dual-mode channel combining is the process by which two channels are combined within the same transmission line, but in separate orthogonal modes of propagation.

The device combines two different TV channels from separate coaxial feedlines into a common circular waveguide. Within the circular waveguide, one channel propagates in the TE_{11} mode while the other channel propagate in the TM_{01} mode. The dual-mode channel combiner is reciprocal and, therefore, also may be used to efficiently separate two TE_{11}/TM_{01} mode-isolated channels that are propagating within the same circular waveguide into two separate coaxial lines. This provides a convenient method for combining at the transmitters and splitting at the antennas.

6.8
ANTENNAS FOR TELEVISION BROADCASTING

THOMAS J. VAUGHAN
T. VAUGHAN & ASSOCIATES, MANCHESTER, NH

INTRODUCTION

This chapter begins with a review of technical terms and FCC considerations followed by a review of antenna design considerations as they relate to these demands, as well as a review of specific applications. The chapter concludes with a review of current broadcast antennas and antenna systems.

TECHNICAL TERMS

Definitions of the following terms, consistent with FCC and industry usage, are important to the discussions in this chapter.

Effective Radiated Power

The product at the antenna input power and the antenna power gain is the effective radiated power (ERP).

Polarization

The polarization (the orientation of the electric field) can be linear horizontal, or circular. If circular is used, the term ERP applies to the horizontal and vertical components separately.

Azimuth Pattern (Horizontal Plane)

An azimuthal pattern is a plot of the free-space radiated field intensity versus azimuth angle at a specified vertical angle with respect to a horizontal plane (relative to smooth earth) passing through the center of the antenna.

A horizontal pattern is an azimuthal pattern when the specified vertical angle is zero.

For higher gain antennas where beam tilt is employed, the azimuthal pattern at the specified beam tilt is significant. In general it has been customary to determine television broadcast antenna radiation by an azimuthal pattern at the specified beam tilt and a sufficient number of vertical plane patterns taken at various frequencies in the channel.

An omnidirectional antenna is defined as one that is designed to radiate the same signal strength in all azimuthal directions. Antennas with variations up to ± 3 dB have rendered satisfactory service and are considered to be omnidirectional.

A directional antenna is one, which is designed to radiate more signal in one azimuthal direction than in other azimuthal directions.

Vertical Pattern (Elevation Plane)

The vertical pattern is a plot of free-space radiated field intensity, measured in the far field versus vertical angle in any specified azimuth plane, which contains the center of the antenna and the center of the earth.

The far field or Fraunhofer region, as usually defined, extends beyond a point where the distance between the transmitting and receiving point is

$$\frac{2a^2}{\lambda}$$

where "a" is the length of the radiating portion of the antenna and λ is the wavelength.

A requirement for the broadcast service is that a free-space radiated field should not be influenced by the proximity of the earth in such a way as to set up a nonuniform field over the antenna aperture. Proper precautions must be taken to accomplish this.

Antenna Gain

Gain is the ratio of the maximum power output at any angle from the subject antenna, to the maximum power from a thin, loss less, half wave, horizontally polarized dipole having the same power input.

Antenna gain depends on several factors, including:

- The amount of power concentrated in the maximum direction
- Losses in the antenna, which include ohmic and other losses such as energy radiated at polarizations other than the desired one.

The amount of power concentrated in the maximum direction can be determined by a comparison with a reference antenna or by integrating the total power flow through a sphere, which is done by taking a sufficient number of vertical and azimuthal patterns.

Both methods are capable of giving accurate results when the proper precautions are taken. Ohmic losses are taken into account in the comparison method or can be calculated when using the power integration method. Cross-polarized radiated energy can be measured. The measurement of gain must be carefully done with a full knowledge of all the problems that are involved. The measurement of gain used in the calculation of ERP for a circular polarized antenna must be made relative to a horizontal dipole. The directivity gain of a 1/2-wavelength dipole antenna relation to an isotopic antenna is 1.64. The gain of a circular polarized transmitting antenna relative to a like circular polarized receiving antenna will be 3 dB higher than that of a horizontally polarized dipole receiving antenna.

Gain requirements for a television broadcast antenna depend on the transmitter power, economics and field-intensity requirements as determined by the terrain and population distribution.

The maximum ERP (Effective Radiated Power) currently permitted by FCC is:

Channels 2 to 6	100 kW
Channels 7 to 13	316 kW
Channels 14 to 69	5,000 kW

Economics is a factor in antenna choice. As a general rule, for a required ERP the combined costs of transmitters and antennas are less when a higher gain antenna is used.

Impedance

Input impedance is the complex impedance looking into the antenna terminals throughout the television channel.

Most antennas are designed for the same input impedance as the standard transmission line at the antenna terminal. Impedance matching requirements for television antennas are generally more severe than for other types of service because reflected energy, which would occur when the antenna does not terminate the line properly, can cause ghosting and voltage peaks on the transmission line which could result in damage to the antenna, couplings and transmission line.

RADIATING CHARACTERISTICS

The television broadcast transmitting antenna should have an onmidirectional pattern in the azimuth plane and a narrow beam in the elevation plane. For an omni-antenna the gain is approximately one per wavelength per like polarization. Most broadcast antenna elements are spaced one wavelength apart, therefore, the gain of a linear polarized antenna is approximately equal to the number of elements.

Elevation Pattern

The elevation pattern is the product of the element pattern times the array pattern (see Figure 6.8-1).

$$F(\theta) = E_n(\tau) \sum_{n=1}^{N} A_n e^{j[(2\pi ns)\sin\tau + \delta_n]}$$

Where $E_n(\tau)$ = element elevation pattern $\approx \cos^m(\theta)$
s = element spacing
τ = elevation angle
δ_n = phase of *n*th element
A_n = amplitude of *n*th element

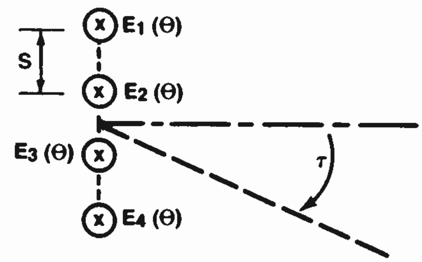

Figure 6.8-1. Elevation pattern calculation.

The resultant antenna elevation pattern for a four element array pattern spaced 1.02 wavelength with a $\cos^2(\theta)$ element pattern is shown in Figure 6.8-2.

As the spacing between the elements in the array pattern is increased, grating lobes begin to move closer to the main beam. The element pattern will no longer drive the grating lobe to zero at ±90°, resulting in high side lobes.

Figure 6.8-3 shows the patterns for a four element array with 1.30λ spacing. Although the main beam will narrow as the element spacing increases, energy will be lost in the high side lobe resulting in an over all loss of gain. The optimum spacing is one wavelength for a cos θ element pattern. Figure 6.8-4 shows power gain versus element spacing for multiple bay antennas.

Azimuth Patterns

The ripple content of the azimuth pattern is dependent on the element pattern and the distance to the phase center as illustrated in Figure 6.8-5.

$$F(\phi) = \sum_{n=1}^{N} E_n(\phi) A_n e^{j[(2\pi)\cos(\phi - \phi 2_n) + \delta_n]}$$

Where $E(\phi)$ = element pattern
ϕ = azimuth angle
δ_n = phase of *n*th element
A_n = amplitude of *n*th element
ρ = distance to phase center (in wavelengths)

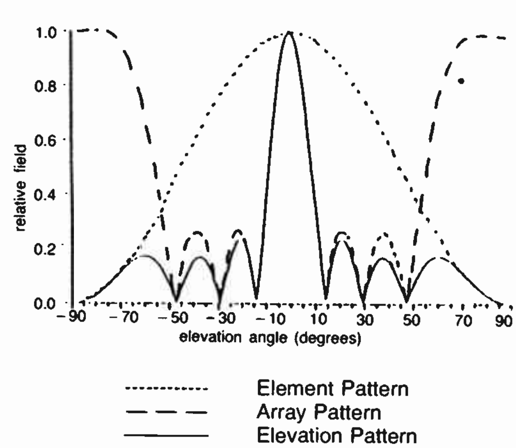

Figure 6.8-2. Elevation pattern for a four-element array with $\cos^2(\theta)$ element pattern and 1.02λ element spacing.

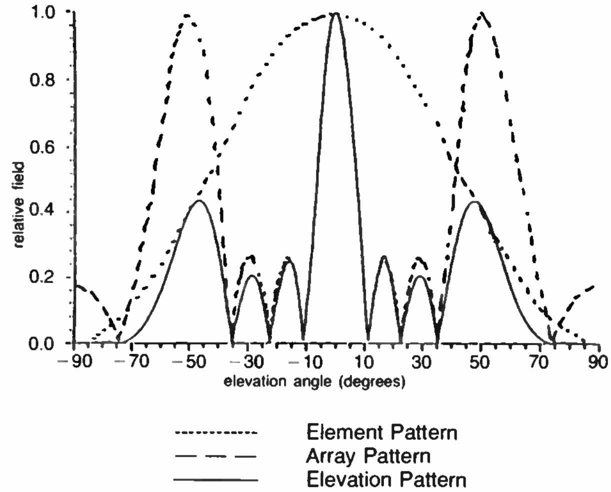

Figure 6.8-3. Elevation pattern of four-element array with $\cos^2(\theta)$ element pattern and 1.30λ element spacing.

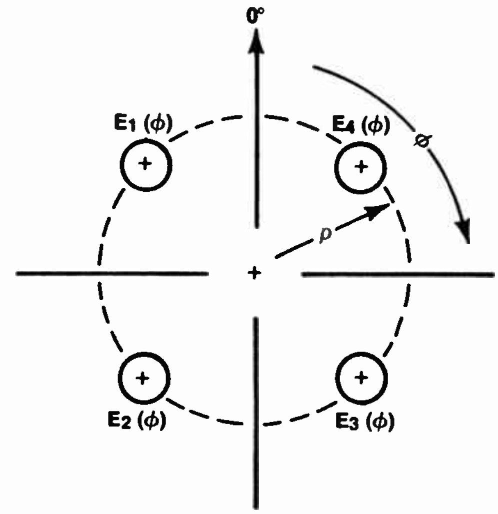

Figure 6.8-5. Azimuth pattern calculation.

The value of ρ for a panel antenna is dependent on the panel width. The value for a coaxial slotted antenna is dependent on the size of the coax line which in turn is dependent on the power handling capability of the line.

The value of ρ for waveguide slotted lines is dependent on the mode of operation which is a minimum of a half wavelength. This makes waveguide fed slot antennas practical only at UHF frequencies.

For some antennas, such as cross dipoles or turnstiles, the value of ρ is zero. Others such as panels, or slotted coax, or waveguide have a value of ρ from 0.25λ to 2.0λ as shown in Figure 6.8-6.

The ideal element pattern for a three-sided tower is $E = \cos(\theta)$; and for a four-sided tower it is $E = \cos^2(\theta)$. The ripple content of four panels with a $\cos^2(\theta)$ element pattern and phase center spacing of $\rho = 0.5, 1.5$ is shown in Figure 6.8-7.

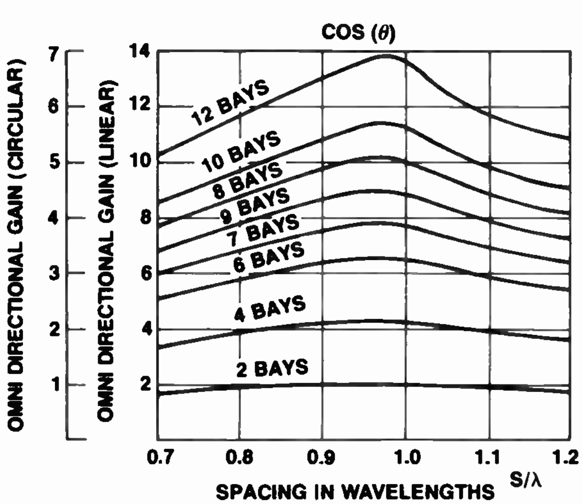

Figure 6.8-4. Power gain versus element spacing.

RADIATING STRUCTURES

There are a number of possible radiating structure designs. The most common will be discussed in this section.

Slot Antenna

The slot antenna is similar to a dipole (see Figure 6.8-8).

Currents in the slot antenna spread out over the entire sheet (in which the slot is cut) and radiation takes place from both sides of the sheet.

The resemblance between the two becomes even more pronounced when it is recognized that the field patterns of the two will be equivalent if the physical dimensions of the slot and the cross section of the dipole are the same.

Furthermore, the impedance of the slot is proportional to the admittance of the dipole of the same dimensions by the relationship

$$Z \text{ slot} = \frac{35{,}476}{Z \text{ dipole}}$$

and the bandwidth characteristics are essentially the same for both.

Actually, the previous discussion is rigorously accurate only if the sheet is of infinite extent, but it is substantially correct if the edge of the sheet is half a wavelength from the slot.

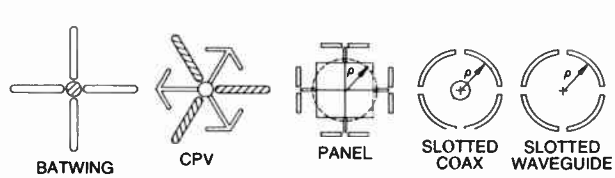

Figure 6.8-6. Azimuth pattern of four-side antenna viewed from the end.

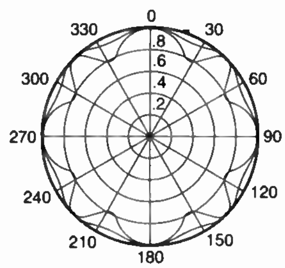

Figure 6.8-7. Arrangements of radiating elements. Azimuth versus relative field.

Bending the sheet into a cylinder results in another form of slot antenna which also takes on characteristics of a stack of coaxial rings as shown in Figure 6.8-9.

The slotted cylindrical tube can have an inner conductor and be coaxial in form or have no inner conductor and be a cylindrical waveguide.

Panel Antennas

A panel antenna has either dipoles or loops mounted $\lambda/4$ in front of a reflecting sheet. These antennas will have a directional [($\cos(\theta)$ or $\cos^2(\theta)$)] pattern in the azimuth and elevation planes depending on how it is mounted. Figure 6.8-10 shows typical panel antennas configurations.

The pattern of a panel antenna is directional since the energy radiated from the element sees its image in the ground plane resulting in a $\lambda/2$ spaced end-fire radiator. The dipoles in the *doublet panel* are spaced $\lambda/2$ and are effective in eliminating downward radiation.

Traveling Wave Antenna

Traveling wave slot antennas can be either resonant (*standing wave*) or nonresonant (*traveling wave*). Most are bottom fed. When the far end is shorted, an infinite standing wave is set up in the transmission line (either coax or waveguide). When the slots are appropriately sized and spaced, energy will be coupled out. The amplitude and phase developed across the aperture will result in a high gain antenna. The bandwidth requirements for broadcast limits this technique to narrow band or single channel applications. Several traveling wave antennas are illustrated in Figure 6.8-11.

The most common bottom fed traveling wave array is the nonresonant slot array. The number of half wave-

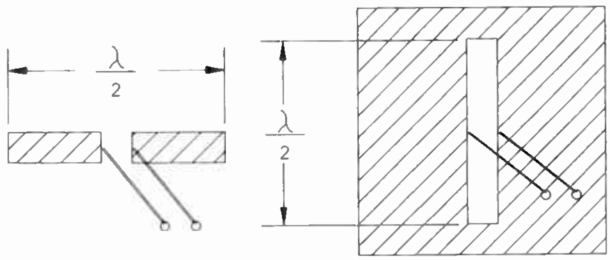

Figure 6.8-8. Dipole/slot equivalence.

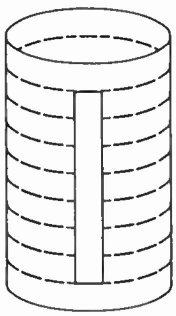

Figure 6.8-9. Slot in cylindrical sheet.

length slots arranged about the periphery is dependent on the shape of the pattern desired. The slots, circumferentially arranged around the antenna structure, are usually displaced by $\lambda/4$ and spaced vertically one wavelength apart. The slot coupling from the bottom to the top increases since the power radiated progressively reduces the power on the line. This method produces an amplitude taper across the aperture that provides null fill. With all nonresonant arrays, there is a small amount of energy leftover. This is radiated in specially designed end loaded slots or in the opposite polarization. Circular polarization can be obtained by orienting successive slots 90° and exciting them in phase quadrature, or exciting a vertically polarized radiator located near the slot.

The linear polarized spiral (helix) is essentially a strip transmission line mounted over a ground plane; the spacing controls the radiation. Each element is a $\lambda/2$ radiator and because of the orientation, the vertical components cancel. The choice of pitch angle and length along the circumference of the spiral, will result in very good horizontally polarized broadside radiation.

The circular polarized spiral or multi-arm helix consists of multiple wires mounted around a large cylinder forming a current sheet. The optimum parameters are a complex function of the number of arms, the length of one coil and the spacing to the support pole.

Excellent circularity can be obtained since in any heading the radiation is essentially that from a current ring.

Curve	Transmitter Power	Antenna Gain	ERP
------------	60 kW	40	2,400 kW
— — —	120 kW	20	2,400 kW
————	240 kW	10	2,400 kW

Figure 6.8-12. Signal versus antenna gain at UHF.

ERP

In determining the ERP required to serve the area under consideration, there is a trade off between using a low power transmitter and a high gain antenna, or high transmitter power and low antenna gain.

For VHF antennas, the transmitter power to antenna gain ratios are fairly well established. For channels 2 to 6, antennas usually use gain values from about 4 to 6 depending upon the length of the transmission line run. For the channels 7 to 13 band gain values vary from 12 to 18. For UHF antennas, higher antenna gains are required. Because of the much shorter wavelength at UHF frequencies, antenna with gains on the order of 20 to 30 can be built economically. At $0.10 per kW/hr, it costs $1,500/yr to generate 1 kW of RF power for a typical UHF TV station.

However, the higher gain results in narrowing the main beam. For a given transmitter input, the high gain antenna may sacrifice local coverage for more distant coverage. As the gain of the antenna increases, the beamwidth narrows. The position of the nulls and side lobes will move out from the tower.

The distance in miles from the tower is:

$$R = \frac{H}{5{,}280 \tan \theta}$$

Where:

H is the height in feet and
θ is the elevation angle

Field Strength

The elevation pattern and relative field versus distance are shown in Figure 6.8-12 for a UHF antenna on a 1,000 ft tower with constant ERP but different amounts of antenna gain.

Note that if the ERP and height above average terrain (HAAT) are held constant, there will be no change far in the far field signal strength. Figure 6.8-12 shows there is no change in relative field for the three normalized antenna patterns from 0° to 0.5°. This corresponds to a radio horizon of 20 mi.

As the gain of the antenna is reduced, the main beam will widen from 1.6° (gain 40) to 7.2° (gain 10). The null will move from 6 miles to 1.6 miles. The signal strength near the antenna will increase by 10 to 20 dB. It should be noted that this increase makes a very strong signal (100 dBμ) much stronger (120 dBμ).

Therefore, if a higher gain antenna is contemplated, the local field intensities should be calculated, using the FCC (50, 50) propagation curves. It is desirable to maintain a 100 dBμ level over the important local

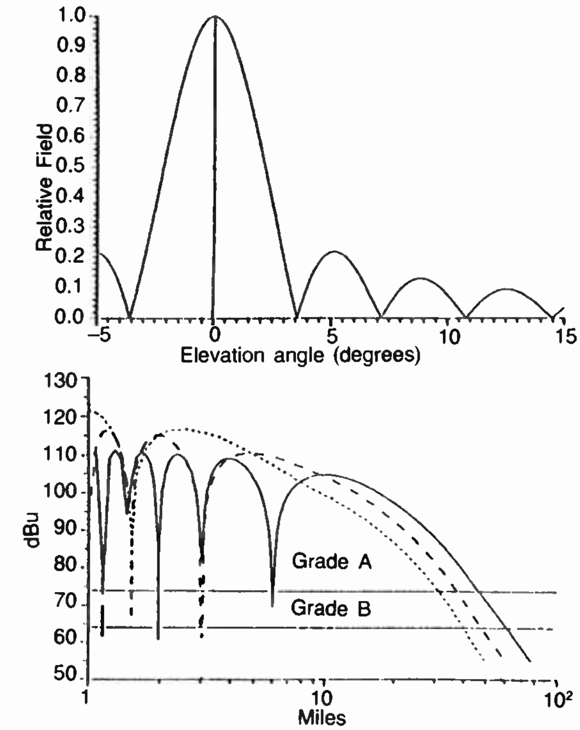
Table 6.8-1
Field intensities for specified contours.

	LoV	HiV	UHF
Channel	2–6	7–13	14–80
City Grade	74 dBμ	77 dBμ	80 dBμ
Grade A	68 dBμ	71 dBμ	74 dBμ
Grade B	47 dBμ	56 dBμ	64 dBμ

area to be covered. Most UHF antennas are designed to accomplish this with an ERP of the order of 2.5 MW at 1,000 ft. In hilly terrain, it may be desirable to increase the field by 10 dB or more; and in heavily populated cities with large building, by 6 dB or more. The field intensity specified by the FCC for the different grade levels is shown in Table 6.8-1.

If fields of this order cannot be achieved with a high gain antenna, the transmitter power should be increased.

Relative field and field intensity versus distance are shown in Figure 6.8-13 for a fixed antenna gain on a tower of 500, 1,000 and 2,000 ft.



Curve	Transmitter Power	Antenna Gain	ERP	HAAT
....	120 kW	20	2,400 kW	500 ft
— — —	120 kW	20	2,400 kW	1,000 ft
————	120 kW	20	2,400 kW	2,000 ft

Figure 6.8-13. Field intensity versus antenna height.

POLARIZATION

Polarization, illustrated in Figure 6.8-14, is defined by the plane of the electric vector (E). Elliptical polarization is the most general form. In general, an elliptically polarized wave may be expressed in terms of x and y components given by:

$$Ex = E_1 \sin(\omega t - \beta z)$$
$$Ey = E_2 \cos(\omega t - \beta z + \delta)$$

The condition for linear polarization is when either E_1 or E_2 is zero with the orientation usually horizontal.

The condition for circular polarization is when $E_1 = E_2$ and δ equals 90°, (the two components must be quadrature in both space and time).

The transmitted wave of FM and TV broadcasting signals is specified by the FCC to be linear and in the horizontal plane. AM radio on the other hand is linear and in the vertical plane. FCC regulations permit the radiation of circular polarization (CP) provided the component does not exceed the licensed ERP.

The possible advantages of using circular polarization for television are:

- Less critical receive antenna azimuth orientation; permitting good reception on all types of indoor antennas including rabbit ears, whips and rings.
- Improvement in service and penetration because the two orthogonal fields horizontal and vertical, have the same power, giving a power density twice that for a horizontal signal, alone.
- Improved coverage at the fringe area, due to twice the power density. Improvements on the order of 3 dB can be expected, moving the Grade B contour out by a calculated five to eight kilometers.

Many of the stations that changed to CP also moved their transmitting plants and changed the heights of their antennas, making a direct measured signal comparison between horizontally polarized (HP) and CP impossible. Experiences reported by stations using circular polarization indicate:

- Receiving antenna orientation is less critical, specifically for rabbit ear and whip antennas.
- Fringe area coverage has improved.
- No ill effects have taken place.
- No change in adjacent or co-channel interference has been reported.

BEAM TILT

Beam tilt is sometimes used to aim the main vertical beam tangential to the earth toward the (radio horizon), if the relative height of the antenna is such that substan-

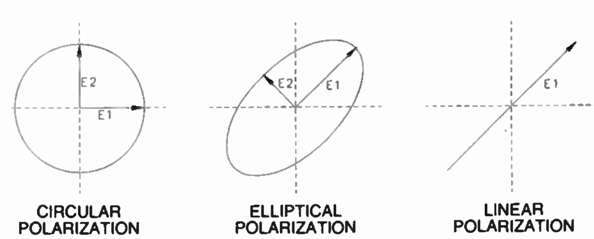


Figure 6.8-14. Polarizations.

tial energy is being radiated above the horizon. The distance to the radio and optical horizon can be determined from Figure 6.8-15.

Note that the height over the service area may not necessarily be the height over average terrain especially in mountainous areas. Also, if a body of water limits the service area, as in the case of Los Angeles, with the transmitter on nearby Mt. Wilson, it may be desirable to mechanically tilt the main beam to a point somewhat below the radio horizon.

In some cases, beam tilt may be desirable to improve local coverage. Electrical beam tilt can be used but it reduces the power gain, especially for a higher gain antenna. However, the increase in local coverage is generally a more important consideration than the slight loss of power gain. Electrical beam tilt is accomplished by delaying the energy fed to upper elements or the upper section of a split feed antenna as shown in Figure 6.8-16.

NULL FILL

The amount of null fill, and the number of nulls that need to be filled, depends upon how close the populated area is to the transmitter site. Allowance should be made for population movement towards the site in the future.

If the transmitter site is in the center of the population area or on the edge of it, consideration should be given to having null fill.

The exact amount of first and second null fill is not critical. Anything greater than 5% will usually result in signals much greater than *city grade*. The null depth (dB) in signal strength will correspond to the difference between the first null and first side lobe (dB).

The effects of null fill on signal strength is shown in Figure 6.8-17.

A combination of null fill and beam tilt is shown in Figure 6.8-18. A beam tilt of 1° will usually result in a 10 dB improvement in near-in coverage. Note that null fill and beam tilt have little effect on distant signal coverage.

POWER CAPABILITY

Power in television broadcast transmission systems is usually in terms of *peak power*, which is the instantaneous power developing during the peak of the synchronizing pulse in the visual transmitter. Since the black level signal is 0.75% of the total voltage value of the pulse, the black level power for a totally black picture is 56% of the peak-to-peak sync power. The duty cycle of the synchronizing pulses, both horizontal and vertical, adds about 4% to this power so that black level power is 60% of the peak TV power. Since the aural transmitter is usually 10% of the peak TV power, the total heating or continuous wave (CW) power of the TV signal is 66% of the peak TV power. The average power level (APL) of the video signal with typical program measures over a long period of time, 4.32 dB (37%) below the peak TV power.

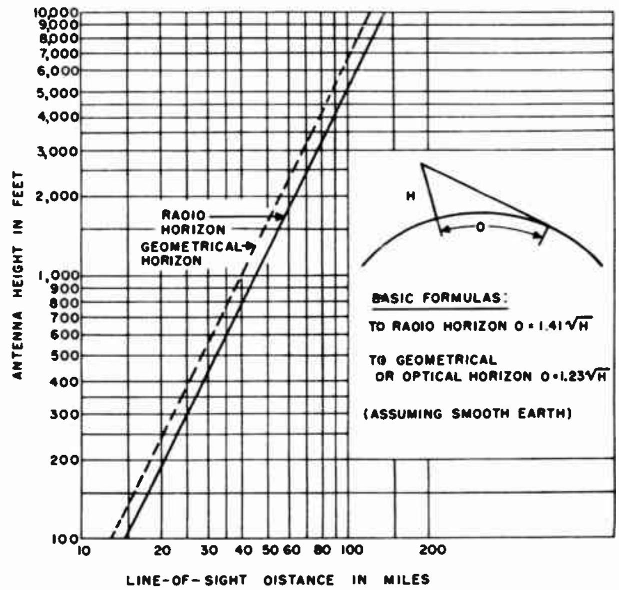

Figure 6.8-15. Distance to radio horizon versus height.

The design of all TV antennas should allow for a sufficient safety margin to handle the peak-to-peak sync level, imperfections in the transmission line, VSWR, changes in pressure and the aural power. Long transmission lines feeding the antenna will usually attenuate this figure by 10% to 20%.

Unwanted Antenna Radiation

The antenna pattern is the product of the array pattern times the element pattern. The array pattern for one wavelength spacing has a downward and upward lobe as large as the desired main lobe. If the element pattern is not a $\cos(\theta)$ function, the element pattern will not drive the array downward lobe to zero, resulting in a very large signal in the vicinity of the tower base. Figure 6.8-19 shows the resultant antenna pattern with a $\cos^{1.0}(\theta)$, where N = 0.0, 0.5 and 1.0.

Care should be exercised in making sure the element pattern has a distribution in the elevation plane of $\cos(\theta)$ or $\cos^2(\theta)$.

A well designed antenna system should not create a nonionizing radiation problem. The tower height is usually selected for maximum signal coverage and should therefore be high enough above the ground so the downward radiation is well below the safe ANSI levels.

Equally important would be the power density level on nearby towers, which could result in tower maintenance personnel being exposed to high energy levels when in the main beam of the antenna on a nearby tower.

The distance in feet along the main beam to the 1 mW/cm^2 contour for maximum ERP and the height above ground to the 1mW/cm^2 contour is listed in Table 6.8-2.

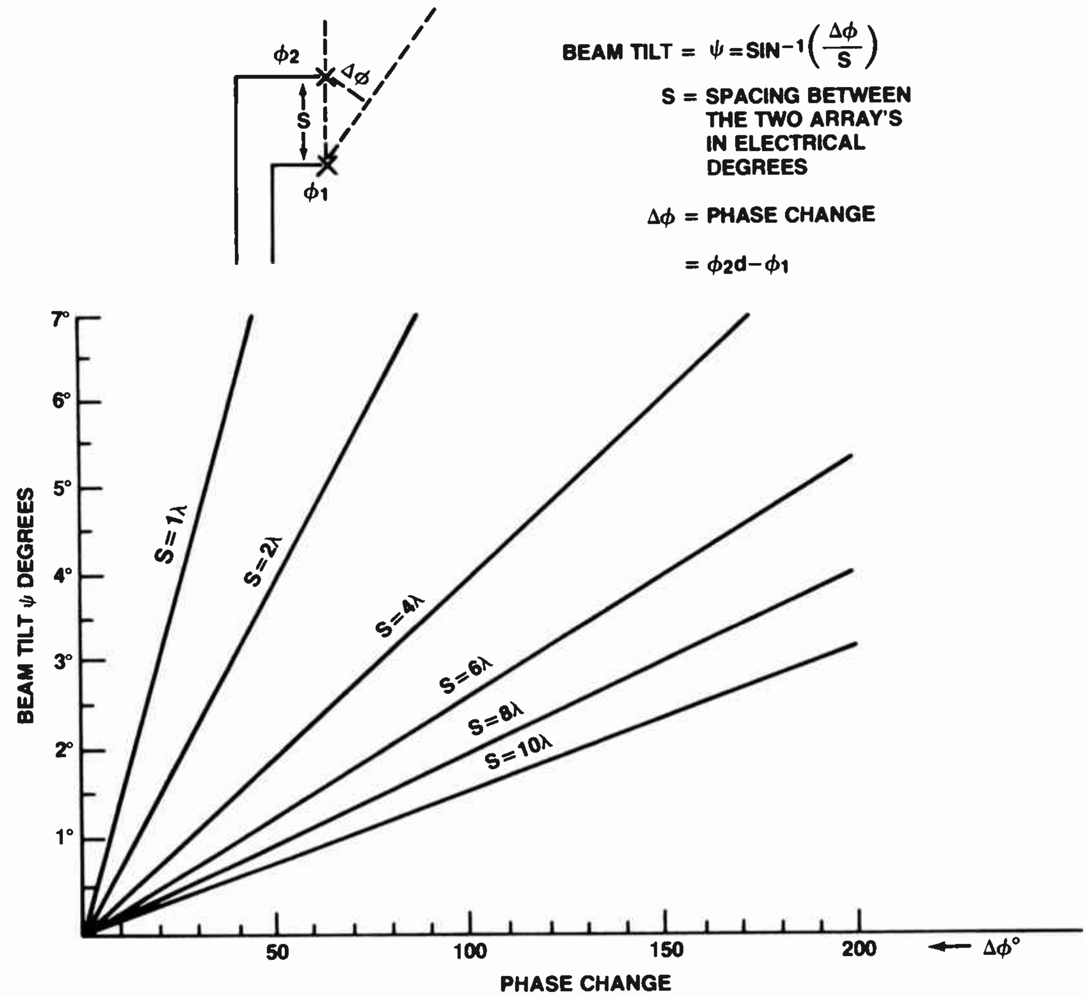

Figure 6.8-16. Beam tilt versus element phase change ($\Delta\phi$).

ANTENNA CHARACTERISTICS

The primary purpose of an input VSWR specification is to insure a good match to the transmission line. If the mismatch is a great distance away, the reflected power may be of such magnitude that it travels back to the transmitter where it is will be re-reflected back to the antenna and radiate. It will than appear as a secondary image or ghost on the television picture. The image is delayed by twice the length of the transmission line.

Subjective experiments have established that the reflection at the carrier should be no greater than 3% of the incident voltage.

Empirically derived data of objectional reflection VSWR that will cause ghosting as a function of distance in microseconds from the transmitter to the antenna is shown in Figure 6.8-20.

The dashed line represents the minimum detectable reflection readable on the window pulse.

Due to the concentration of energy, the VSWR at the picture carrier should be kept fairly low at this frequency. The values below visual carrier are not as critical since the slope in the receiver cuts off most of the energy below the carrier. The VSWR in the visual pass band should be as shown in Figure 6.8-21.

There are two locations of reflections that will cause ghosts: the lower elbow complex and the combination of the upper elbow complex and the antenna.

The upper elbow complex and the antenna reflection would be more objectionable than the lower elbow complex, because of its distance and displacement ($1/\Delta f$) rather than its magnitude. A 5% (VSWR 1.10) echo would not be as objectionable at 0.2 μsec as it would be at 2.0 μsec, as shown in Table 6.8-3.

Transmission Line and Components

Testing the antenna system determines that:

- The transmission line and components are properly assembled
- The reflections from the antenna and other components at or near the tower top are sufficiently low so that no visible ghost occurs

Figure 6.8-18. Null fill and beam tilt.

- The impedance presented to the transmitter will result in the maximum transfer of energy.

For an extremely broadband device, like a coaxial transmission line which is usually designed to cover the entire, or at least, a large portion of the TV band, the time-domain reflection (TDR) is the most effective test to determine if the line and components have been properly assembled.

Note that VSWR measurements made at the input to the transmission line measure the combined input impedance at that point only, and not the discreet reflections that can cause ghosts.

The TDR, on the other hand, will measure the reflection on a time rather than frequency basis so the exact position and magnitude of the reflection can be determined.

A high VSWR at this point is an indication of a mismatch between transmission line and antenna. For example, a VSWR of 1.22 is a return loss of 20 dB

(99% of the power is transferred to the antenna system and 1% is reflected).

There are usually two sources of reflection assuming that the line itself is reflectionless.

- Lower elbow complex—VI
- Upper elbow complex and antennas—V2

When measured at the input to the system these can be thought of as two vectors. Each vector individually will rotate about the preceding vector at a frequency corresponding to the distance from the point of measurement (see Figure 6.8-22).

The frequency of rotation can be calculated as follows:

$$\Delta f = \frac{496^*}{L} \text{ coax}$$

$$\Delta f = \frac{496^*}{L} (\lambda_o/\lambda_g) \text{ waveguide}$$

*Half the velocity of light. L in feet.

Close reflections (approximately 100 ft) will have a period equivalent to 5 MHz; distant reflections (approximately 1,000 ft) will have a period equivalent to 0.5 MHz. The individual and combined reflections are shown in Figure 6.8-23.

The use of a *network analyzer* with TDR is effective in determining the location and magnitude of the antenna system VSWR and sources of reflection. Measurement of VSWR in both frequency and time domains for an antenna and 1,700 ft of transmission line (waveguide) is shown in Figure 6.8-24 (a) and (b). The near and far reflections are quite apparent in the frequency domain.

At UHF frequencies where the transmission line guide wavelength is 2 to 3 ft a 50°C temperature change on a 1,000 ft tower can result in electrical length changes of λ/4 to λ/2 wavelength. This is significant in

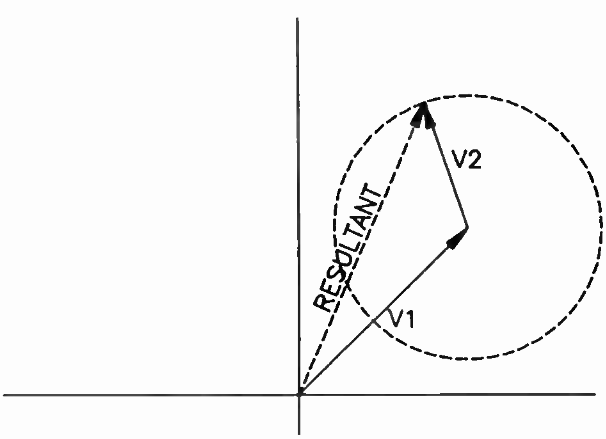

Figure 6.8-22. Vector relationship.

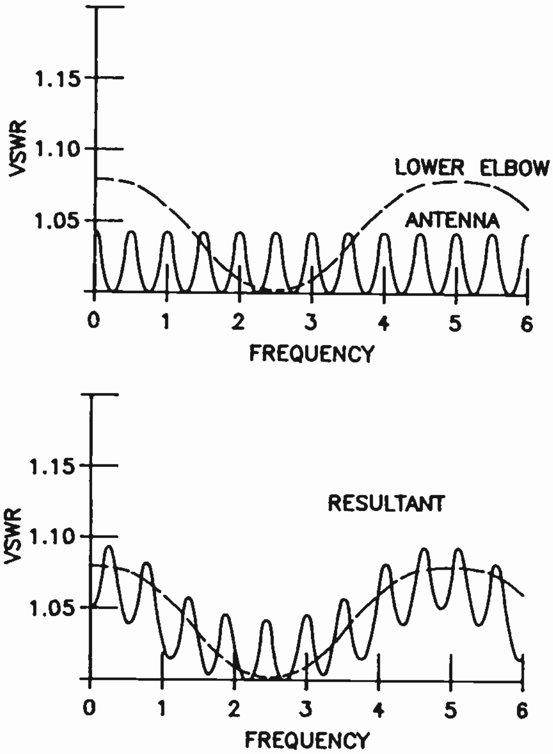

Figure 6.8-23. Example of combined reflections.

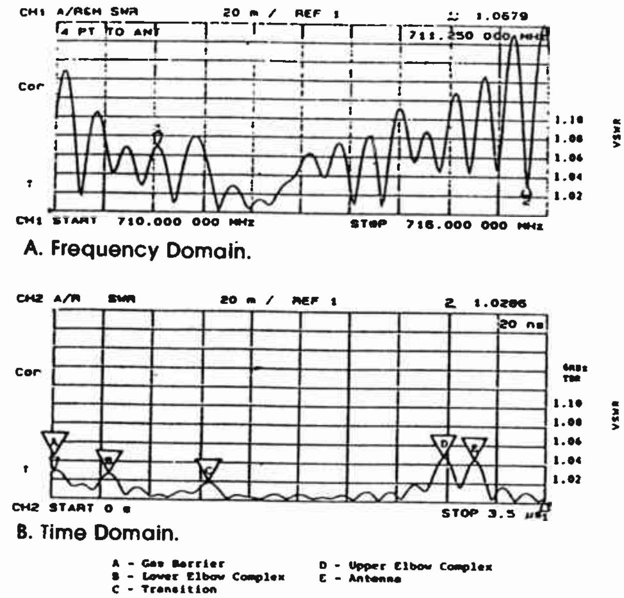

Figure 6.8-24. VSWR of antenna and waveguide (1,700 ft) frequency domain and time domains.

dual feed systems where the differential change can cause beam tilt.

Deflection and Wind Load

Guy tension in guyed towers is usually adjusted so that the tower deflects as a straight member.

Towers for broadcast service, when so specified, are designed for maximum deflection of 0.5°, which means that the top plate will deflect this amount for the maximum wind velocity. For instance, a 40 lb tower will thus deflect 0.5° for a 100 mph wind. Since tower deflection varies as the square of the wind velocity, the deflection will be 0.125° for a 50 mph wind.

Structurally a free standing antenna can be considered as a cantilever beam in which the deflection increases toward the end. Antenna deflection is stated as the angle from the vertical of the chord that connects the base to the top of the antenna.

The movement of the antenna beam and the variation in signal strength for a 50 mph and 100 mph wind is shown in Figure 6.8-25 and summarized in Figure 6.8-26.

The 50 mph wind condition is one that may occur 25 times a year at a 1,000 ft elevation, and about four times a year at a 500 ft elevation (see Table 6.8-4).

The 100 mph wind is a design limit figure which rarely occurs, and one during which there would probably be little television viewing. Most outdoor receiving antennas would probably be severely damaged in such a wind, and power service seriously curtailed.

Antenna Feed Systems

The feed system of a television broadcast antenna is that portion of the transmission system having its input at the antenna terminal (which is at the top of the vertical run of coaxial transmission line in the tower) and its output at the radiating elements.

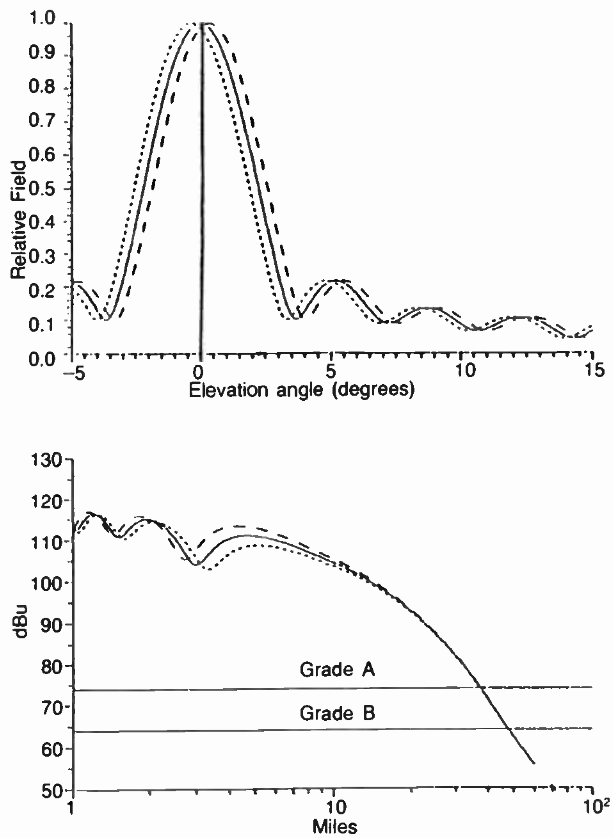
Most antenna gain specified by the manufacturer takes the losses of the feed system into account. Therefore, when system gains are calculated, the feed system loss can be excluded.

In the television broadcasting field, three types of feed systems are in wide use: *branching*, *standing wave* and *traveling wave feed systems*.

Branching Feed Systems

Branching feed systems are necessary for all-band antennas (an antenna that covers the full VHF or UHF band) and since they are center fed, they eliminate beam steering or beam tilt.

This feed system progressively divides the power as shown in Figure 6.8-27. It is used when the radiators are individual elements, each with their own terminal—such as a dipole or panel. The system shown in (Figure 6.8-27(a)) will have a narrower impedance bandwidth than (Figure 6.8-27(b)) since, for economy, one eight-way power divider is used. The junction impedance is $Z_i/8$. If the element impedance is 50 Ω, the power divider must transform 6.25 Ω to 50 Ω. The system shown in (Figure 6.8-27(b)) uses two-way power dividers and is sometimes called a *corporate feed*. Although it has a broader bandwidth, it is less economical since there are seven power dividers with additional interconnecting cables. Null fill and beam



Curve	Wind	Transmitter Power	Antenna Gain	ERP

————	0	120 kW	20	2,400 kW

Figure 6.8-26. Field strength changes with 100 mph wind.

tilt is accomplished by changing the length of the feed cables or using unequal power dividers, or both.

A problem branching feed systems is the presence of the feed line in the aperture of the lower elements. The feed lines can cause reradiation and distort the azimuth pattern. The branching feed system can be more effectively used with panel antennas that require a center support tower or mast where the transmission lines are behind the antenna.

Standing Wave Feed Systems

A coaxial or waveguide transmission line can be shorted at the far end, resulting in standing waves along the length of the line. If slots or coupling probes are appropriately sized and positioned, the RF energy can be radiated and a desired amplitude and phase distribution across the aperture can be obtained. This resonant array structure has a desirable feature; all coupling parameters are the same and equally spaced. Its disadvantages are a narrow bandwidth, and it can only be used at high VHF and UHF frequencies (Figure 6.8-28).

Traveling Wave Feed

The traveling wave feed system operates on the principle of a gradual attenuation (radiation) of the input signal as it progresses from the input along the aperture of the antenna. An application of this principle is the *slot antenna* or *spiral antenna* (see Figure 6.8-29).

Table 6.8-4

Antenna and Tower	0.352	1.414

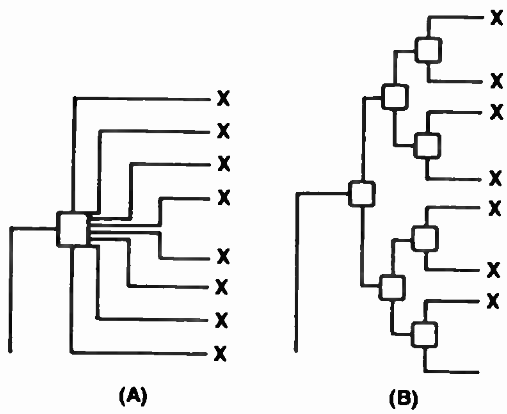

Figure 6.8-27. Branching feed systems.

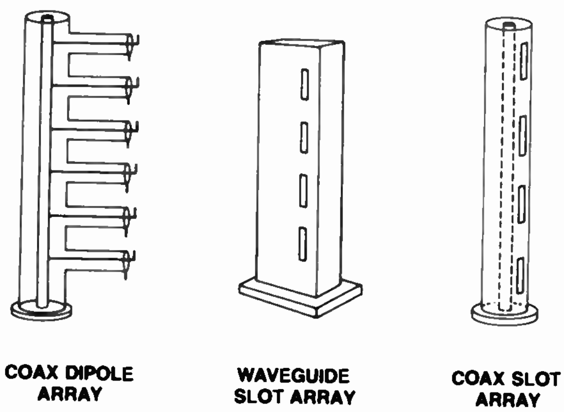

Figure 6.8-28. Slotted arrays.

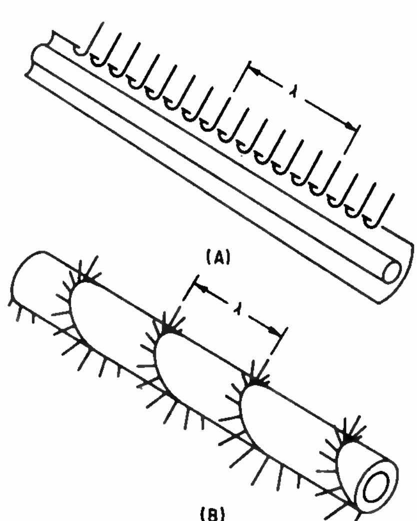

Figure 6.8-29. Traveling wave excitation.

Figure 6.8-29(a) shows the principle of this feed system using short rod radiators to illustrate the theory. A number of uniformly spaced radiators per wavelength are loosely coupled to a coaxial line. Because of the number of radiators and the relatively slight reflection between them, the effect is essentially that of a uniform loading. The result is a uniformly attenuated traveling wave in the line. Since a traveling wave has a linear phase characteristic, the excitation of each successive radiator will be lagging from the previous one by an amount, which depends on the spacing between the radiators and the velocity of propagation in the line. If the radiators are alike, their currents will have the same phase relationship as the excitation. Thus the radiating currents will be successively lagging, and repetition of phase occurs after every guide wavelength.

To obtain an omnidirectional pattern, the radiators, instead of being in line, can be moved around the periphery to form a *spiral* as shown in Figure 6.8-29(b). For a horizontal main beam, the pitch of the spiral has to be equal to the guide wavelength in the transmission line. In this arrangement all the radiators in any one vertical plane on one side are in phase, and the phase difference between radiators in different planes equals the azimuth angle difference between the planes. That is, the phase rotates around the periphery. The rotating phase produces a rotating field. Because of the relatively small amount of current change from layer to layer, an onmidirectional pattern is produced.

ANTENNA TYPES

The types of antennas available can be grouped into the following categories:

- Top or side mounted
- Linear or circular polarization
- High power, low power

Antenna types and characteristics are summarized in Table 6.8-5.

The prime purpose of the tower is to support the antenna. The antenna should have the required radiation characteristics to deliver a satisfactory signal to the viewer. Since it is desired to cover as large a viewing area as possible, tall towers are used. It is not uncommon for antennas to be mounted on 1,000 ft, 1,500 ft or 2,000 ft towers. These tall towers are guyed triangular towers with face dimensions of 5 to 10 ft.

The cost of a tower is heavily dependent on the wind load presented by the tower the transmission line and antenna. For VHF antennas, the antenna wind load is the most significant parameter. For UHF antennas the transmission line or waveguide is the more significant factor.

The length of the antenna is related to the channel, or wavelength and the gain requirements (Table 6.8-6).

The ideal onmidirectional antenna would be a small diameter, infinitely stiff pole. The smallest cross sec-

Table 6.8-5
Commonly used television transmitting antennas.

	Horizontal Polarization		Circular Polarization	
	Top Mtd	Side or Tower Mtd	Top Mtd	Side or Tower Mtd
VHF Low Band	Batwing	Butterfly Doublett H-Panel	TDM	
VHF High Band	Batwing Traveling Wave	Butterfly Doublett H-Panel	Spiral Slot&Dipole Slot&Director	TCP CBR Arrowhead Ring
UHF	Slot Coax Wave Star Trasar	Doublett	Slot&Z Dipole Slot&Dipole Slot&Director	Slot&Dipole Slot&Dipole Slot&Director

tion that can resonant is $\lambda/2$. Therefore, the antenna cross-section is also dependent on the wavelength.

At low VHF frequencies the resonant half wave element of 8 ft is sufficiently large so that a support pole can be used in the center with the antenna mounted outside (such as a batwing antenna). On the other hand, at UHF frequencies the resonant half wavelength of 1 ft is so small that the resonant elements must be outside the support pole or the support pole itself must be a radiator like a slotted coax or waveguide array.

Ideally, omnidirectional antennas should be fed from the bottom, so there are no feed lines in the aperture of the antenna to distort the pattern. If feed lines are required for the upper elements, they should be on the inside. Of course, this is not possible for waveguide arrays. A conflicting requirement is that the diameter of the feed line be large enough to satisfy the power handling requirements, yet small enough not to create pattern distortion.

To minimize pattern distortion by the tower, the antennas should be mounted on top of the tower rather than on the side

The wavelength of high VHF and UHF antennas is such that the resonant half wavelength is too small to be a satisfactory structural member.

The radiating element for many UHF antennas is either the slot or dipole excited from an internal source such as coaxial or waveguide.

Most slotted arrays are traveling wave structures which are bottom fed and contain many slots. The greater the number of slots the narrower the bandwidth, and the greater the beam steering or tilt between the visual and aural frequencies.

Some slotted arrays use the outer conductor (coax), or the waveguide itself as the structural member.

Table 6.8-6
Dimensions of typical antenna.

	Wavelength	Length for Maximum Gain	Maximum Gain
Low VHF	16 ft	100 ft	6
High VHF	5 ft	90 ft	18
UHF	2 ft	120 ft	60

Panel antennas are fed from the back of the panel and require a secondary structural member to support the panels. This can be the tower itself. Three or four panels must be mounted around the tower to produce an omnidirectional pattern.

Panel antennas, when fed with a corporate type feed harness, can preserve the wide bandwidth of the dipole and cover the full high VHF band (174–216 MHz) or UHF band (470–800 MHz).

VHF ANTENNAS

Linear Polarized

Superturnstile/Batwing

The first antenna developed for commercial service was the *Superturnstile*. It consists of a central sectionalized steel pole upon which is mounted the individual radiators, or *batwings*. These radiators are mounted in groups of four around the pole in north-south and east-west planes to form a *section*. The sections are stacked one above the other to obtain the desired gain. Figure 6.8-30 illustrates this construction.

Each of the radiators at the batwing antenna is fed by its own feed line. The impedances are carefully

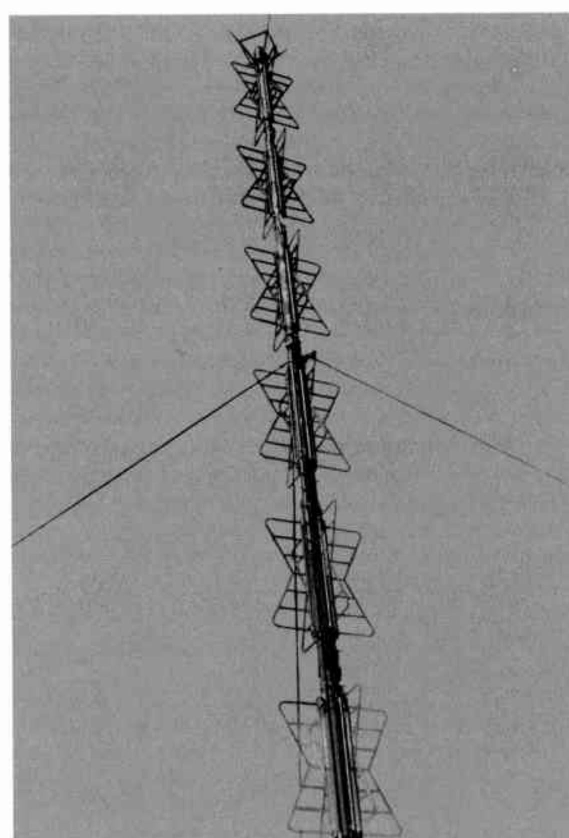

Figure 6.8-30. Superturnstile/batwing antenna (Courtesy of Dielectric).

matched. The feed lines, in turn, are combined at junction boxes which perform the dual function of feeding power simultaneously to all feed lines, and transforming the combined impedance of these lines to that of the transmission line. This latter function is achieved by the use of three-stage transformers immediately below the junction box.

At the base of the antenna, a combining network is used when there are more than two junction boxes. These networks accomplish power division between portions of the antenna, if desired. Batwing antennas are manufactured in various gains from 3 to 12 for channels 2 to 6 and gains of 6 to 18 for channels 7 to 13. They can also be designed for various types of null fill and they have been used in stacked and candelabra installations.

The batwing antenna is wideband and can be used for two channels. A number of them are operating at channels 4 and 5 or channel 6, and an FM channel and also in various combinations in the channel 7 to 13 range.

Traveling Wave

The traveling wave (TW) antenna is a slot antenna with a traveling wave feeding the slots (see Figure 6.8-31).

The TW antenna is a coaxial line, with pairs of slots in the outer conductor spaced at intervals of a quarter wavelength throughout its length. Probes at the center of each slot distort the field within the line to place voltages across the slots. These, in turn, drive currents on the periphery, setting up a radiated field. Attenuation of the signal by withdrawal of a portion of the power at each slot, reduces it to a very low value at the upper end of the antenna. There, a special pair of slots, designed to match the line, radiates the remaining power.

Operation of the TW antenna can be better understood if the section of the aperture having pairs of slots are recognized as being, in effect, dipoles.

Successive pairs of slots are alternately in one plane and in another at 90° to it, so that the antenna can be simulated by stacked dipoles with a 90° angle between successive layers.

In a given plane, reversal of the direction of feed every half wavelength (by placing the probes on opposite sides of the slots) together with the half wave change in phase of the signal as it passes along the aperture through this distance, results in all the *dipoles* in that plane being fed in phase.

The same action takes place in the other plane, except that they are fed 90° out of phase with the first plane, owing to their 90° displacement along the antenna.

Each plane of dipoles radiates essentially a figure eight pattern. Since the planes are fed in quadrature, addition of the patterns results in an omnidirectional pattern. Because of the circular cross-section and the lack of obstructing radiators, the resulting horizontal pattern is almost nearly circular.

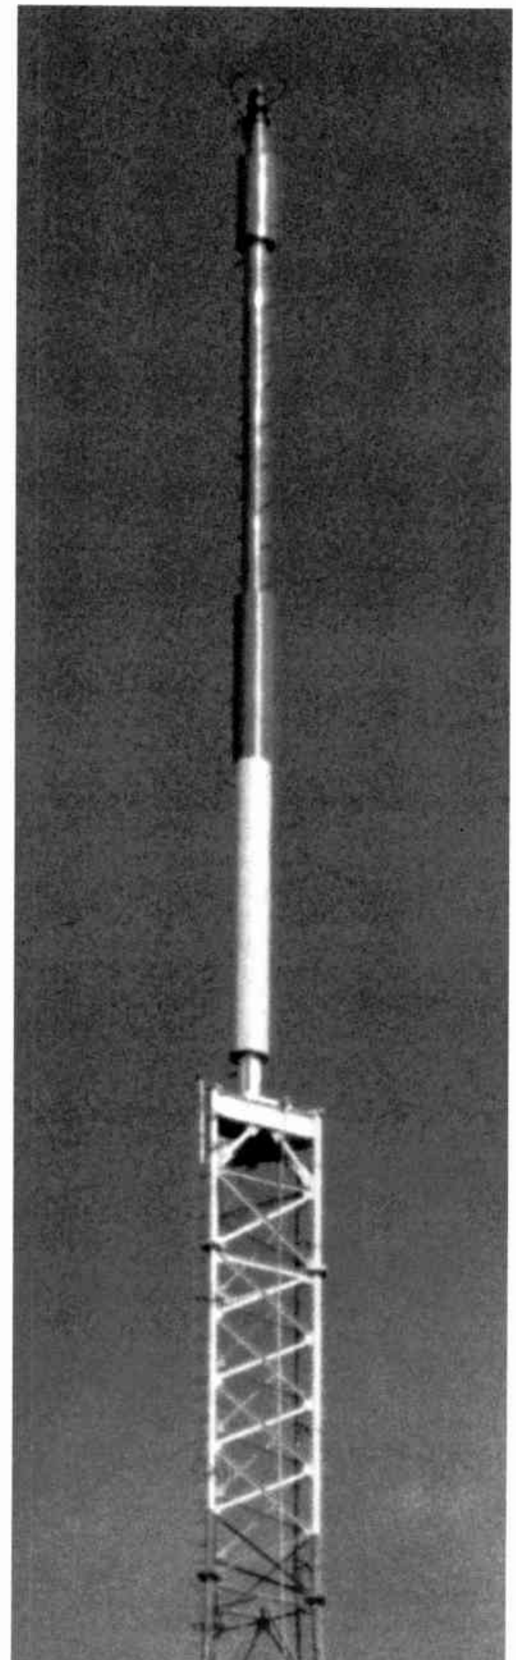

Figure 6.8-31. Traveling wave antenna (Courtesy Dielectric).

Panels

The panel antenna is designed to wrap around the tower. Four panels are needed for a square tower where each panel must radiate a $\cos^2(\theta)$ element pattern. For a triangular tower, each element must radiate a $\cos(\theta)$ element pattern for an omnidirectional pattern.

A wide variety of azimuth and elevation patterns can be obtained by using fewer panels or changing the power division to the panels.

The panels are 0.7λ to 0.9λ in vertical length and spaced approximately one wavelength.

The radiating elements may be either single dipoles like the H-panel *rhombus* in Figure 6.8-32(a) or *delta dipole* (*butterfly*) in Figure 6.8-32(b) which is essentially a folded back batwing or dual dipoles.

The *dual dipole* in Figure 6.8-32(c) is designed to minimize downward radiation and consists of a pair of dipoles spaced a half wavelength apart.

The impedance bandwidth at the panel antenna is very wide and capable of handling more than one TV channel. The bandwidth can be further improved with the four-side configuration by using phase rotation. That is, 90° between each panel in the bay. The impedance at the four-way power divider will be conjugate for every two panels, resulting in wider bay impedance bandwidth than the element itself.

Circular Polarized

Transmission Dual Mode (TDM)

The TDM shown in Figure 6.8-33 is a circularly polarized antenna for channel 2 to 6, and is designed for tower top mounting. It is capable of replacing an existing six-bay Superturnstile without any increase in tower windloading.

The TDM antenna utilizes seven layers of radiators in a slanted dipole configuration with three radiators mounted symmetrically around the pole per layer. Each of the three radiators is fed in phase by a single feedline. Only 21 feedlines are required for the entire antenna. A branch type feed system is used to achieve excellent vertical pattern stability. One junction box feeds the upper four layers and another feeds the lower three layers, each box fed by a 3 1/8" line. This feature allows for standby capability in the event of weather related or other damage. The TDM can be supplied with deicers and/or radomes depending upon environmental requirements.

The unique design of the TDM provides for excellent pattern circularity and axial ratio. Axial ratio measurements are performed on a complete full scale as-built antenna standing vertically at the factory. Since all elements are excited, the mutual effects of adjacent elements are considered.

Circularly-Polarized "V" (CPV)

The CPV antenna shown in Figure 6.8-34 is a circular, polarized top-mounted antenna consisting of three cross "V" dipoles mounted at 120° intervals around a vertical mast. The dipoles are segmented by three vertical grids like a corner reflector, used both for isolation and to shape the element for good circularity. The cross dipoles are fed in phase quadrature and radiate circular polarization from each element.

A branching feed system is used with the lines fed up the mast. Null fill and beam tilt are accomplished by changing the electrical length of the feed cables.

Panel

The cross dipole panel antenna consists of dual dipole feed in both space and time quadrature, a necessary condition for circular polarization.

The transmission circularly polarized (TCP) series uses dipoles shown in Figure 6.8-35(a) and are in the form of a clover leaf mounted on front of a ground plane or panel. The four elements generate the required $\cos(\theta)$ element pattern. By tilting the ground plane edges forward, as a partial corner reflector, further shaping can be obtained.

The circularly basket reflector (CBR) series in Figure 6.8-35(b) consists of fat dipoles mounted in a basket. The element pattern is controlled by the diameter and depth of basket. The ring panel antenna in Figure 6.8-35(c) is a large resonant loop mounted against a ground plane. The ring is approximately one wavelength circumference and hence radiate a circular polarized wave in all planes perpendicular to the panel.

The arrowhead dipole in Figure 6.8-35(d) is similar to the other cross dipoles. The shaping of the element pattern is accomplished by tilting back the dipole to broaden the E-plane pattern.

Spiral

The spiral antenna is designed for tower top mounting. The antenna is composed of sections, each operating under the principals of a traveling wave antenna. Each section consists of two or more stainless steel coils (radiating elements) wound around the supporting pole. A *beltline* feed system is used in each section to excite the radiating elements. The phase initiating the traveling wave is a function of the number of coils used.

Each section is terminated with radiating end loads on each coil to radiate the remaining energy. These loads minimize the reflections of energy from the far end of the radiator back toward the input, which would affect the traveling wave illumination and distort the pattern.

Vertical pattern characteristics such as gain, null fill and beam tilt are determined by a number of factors; the number of wavelengths *wrapped* around the pole, the spacing of the radiators off the pole, the pitch (angle of wrap) around the pole and the phasing between the vertical sections. The antenna is deiced by low voltage, high current dc to heat the radiating coils. A spiral antenna under test is shown in Figure 6.8-36.

Slotted Coax

The circular polarized slotted antenna in Figure 6.8-37 is similar to the linear polarized slotted antenna with the addition of vertical radiators.

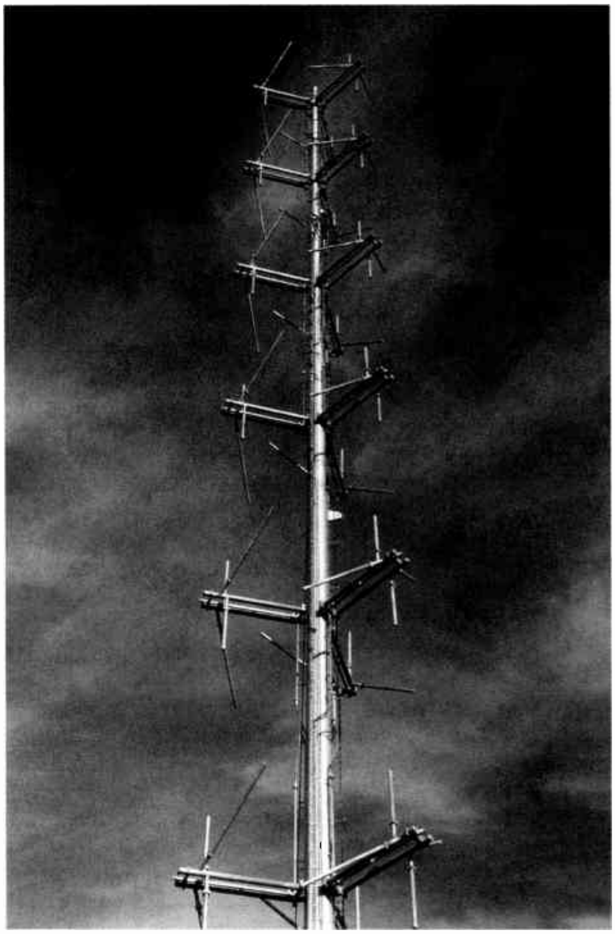

Figure 6.8-33. TDM antenna (Courtesy Dielectric).

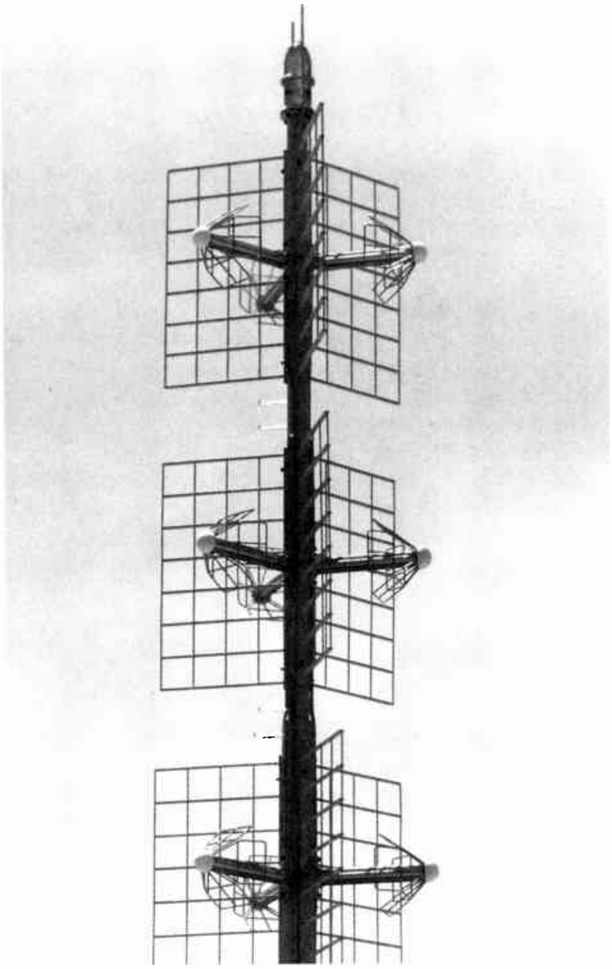

Figure 6.8-34. CPV antenna (Courtesy Harris).

The vertical radiators are located outside the array and the energy coupled to them from the slot is in phase quadrature.

Any polarization from elliptical to circular can be obtained by adjusting the length of the radiators.

UHF ANTENNAS

Linear Polarized

Slotted Coaxial

The UHF *pylon antenna* in Figure 6.8-38 is a coaxial transmission line with radiating slots in the outer conductor. The number of slots (per layer) around the circumference is determined by the horizontal pattern; such as one slot for a skull shaped pattern, two for a peanut shaped pattern, three for a *trilobe* pattern and four or more slots, depending on outer cylinder diameter, for an omnidirectional pattern.

The layers are located at one wavelength spacings along the antenna, with the number of layers determined by the vertical gain and pattern. The radiation parameters of phase and amplitude are determined by a combination of slot length and coupler bar diameter. This allows discreet control of the illumination along the antenna aperture at every wavelength resulting in vertical pattern control and shaping. It also allows for maximum aperture efficiency and, in conjunction with the extremely low cross-polarized radiation component of a slot, produces the highest vertical gain for a given antenna length. The antenna is a bottom fed traveling wave resonant antenna. Some antennas *launch* the energy into the coax radiating section at the center. Others *feed* the coax radiating section at the center. The bottom coax feed is located inside the radiating coax feed. The pylon uses a radome to cover the radiating slots only.

One version is omnidirectional bottom fed traveling wave waveguide slot antenna. Since it is waveguide, no inner conductor is required. The signal propagates in the TM mode. The resultant current rings on the inside wall are interrupted by slots cut in the wall. The slots have radome covers.

Another version is designed to radiate a cardioid pattern and has a single row of slots. This is also a bottom fed traveling wave waveguide array operating in the TE_{01} mode. This is built by exciting the fields

in a rectangular waveguide and rolling the waveguide into a cylinder.

Slotted Director

The *slot director antenna* in Figure 6.8-39 is linearly polarized with a single row of slots with directors to fill in the low signal on the opposite side of the slots.

The slots are one wavelength long on one wavelength centers. Each is fed directly at the slot from a high-power strip line feed. Each section is up to 8λ's

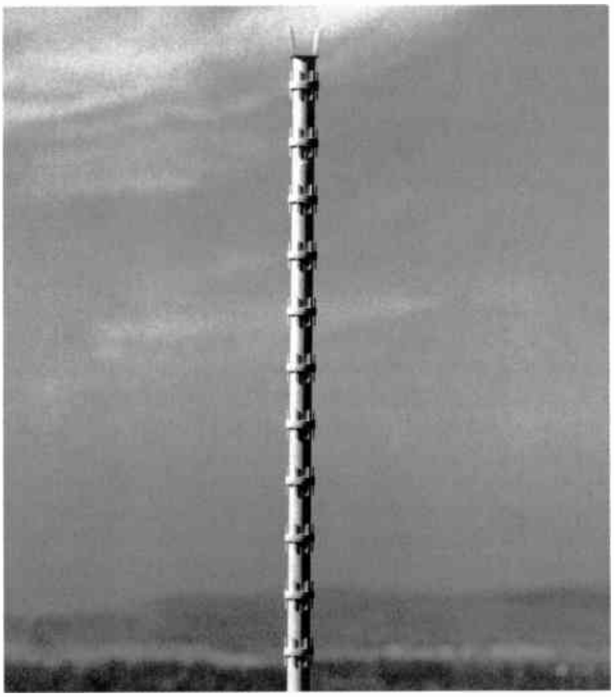

Figure 6.8-37. CP slotted antenna (Courtesy Andrew).

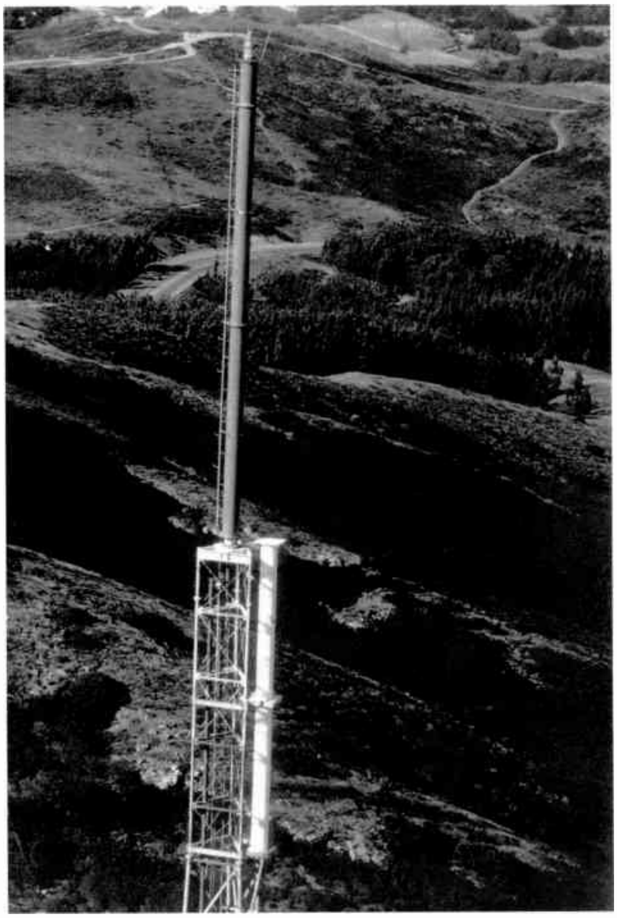

Figure 6.8-38. UHF Pylon antenna (Courtesy Andrew).

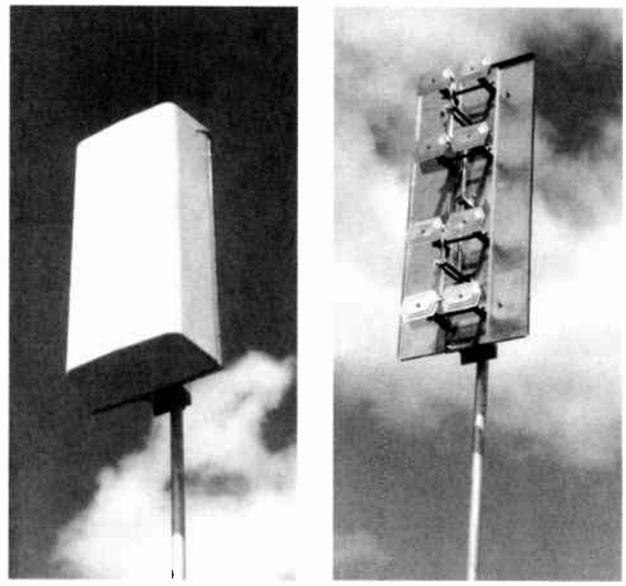

Figure 6.8-40. Doublet array antenna (Courtesy MCI).

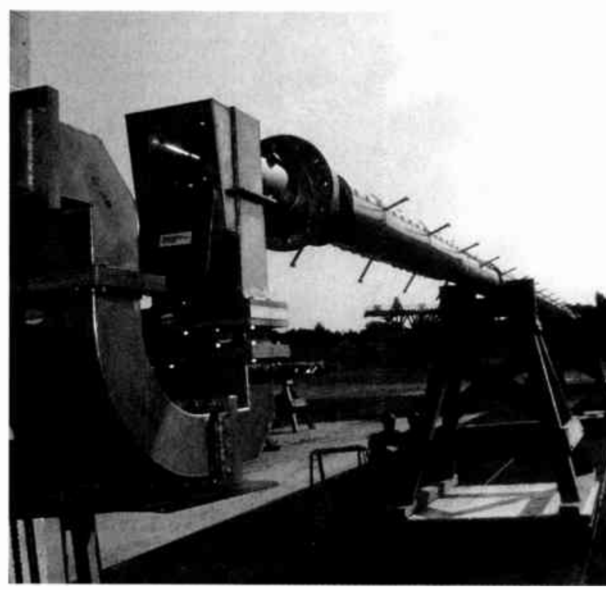

Figure 6.8-41. E-type antenna.

and four sections are usually stacked for the desired gain.

Each section is branch fed while the slots in each section are fed in a traveling wave manner.

Doublet Array

The doublet array panel antenna in Figure 6.8-40 consists of two pairs of dual dipoles, each pair spaced slightly greater than one wavelength apart.

The dual dipole antenna is two broadband dipoles spaced half wavelength apart.

The half wavelength spacing reduces the coupling and cancels the downward radiation thereby increasing the gain.

The doublet array has a VSWR less than 1.10:1 from 470 to 800 MHz.

Arrays composed of doublet arrays can be arranged to produce omni or directional patterns, and can handle four or more high power channels.

E-Type Antenna

The E-type antenna is a high power version of the slotted coaxial antenna (see Figure 6.8-41). It uses a bottom, end feed design incorporating a high power waveguide to coax transition. This specially designed transition allows the antenna to accommodate powers up to 280 kW peak NTSC for omnidirectional service. The E-type is a true traveling wave design which provides a null free elevation pattern.

Circular Polarized Antennas

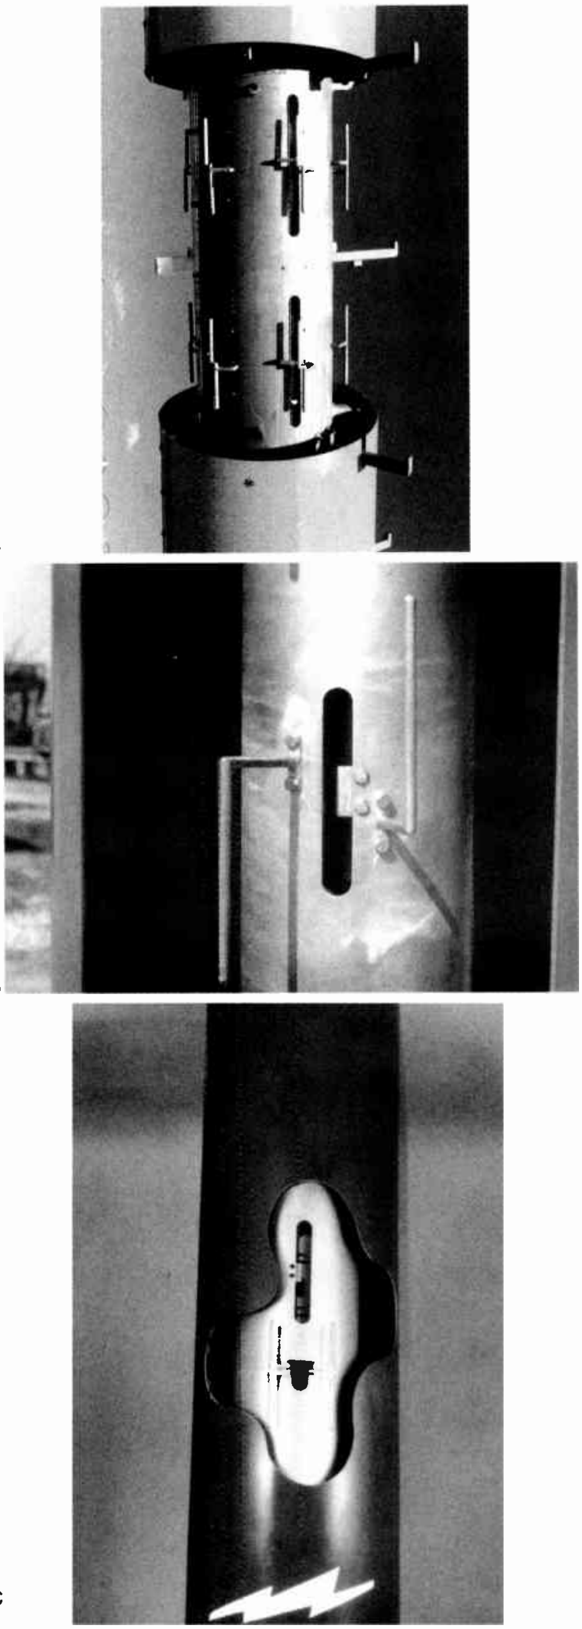
Slotted Coax

The UHF circular polarized slot antennas are similar to the linear polarized slot antenna.

The slot cut in the wall will radiate a horizontally polarized signal. If a vertical dipole is placed above or near the slot, energy will be coupled to the dipole and reradiated as a vertically polarized component.

The number of slots about the periphery of the cylinder can be varied to obtain omni or directional patterns.

The circular polarized pylon antenna in Figure 6.8-42(a) uses a Z dipole located directly above the



A

B

C

Figure 6.8-42. Circular polarized antennas. (a) Z dipole antenna (dielectric), (b) Wave Star vertical dipole antenna (Harris), (c) Trasar vertical dipole antenna (Andrew).

slot, and radiates a vertical component in phase quadrature with the same elevation pattern as the horizontally polarized slot. The size and spacing of the graduated dipole can be used to control the amount of vertical component radiation.

A vertical dipole configuration is shown in Figure 6.8-42(b).

Another configuration consists of a series of slotted arrays that uses a vertical dipole located between the slots, as shown in Figure 6.8-42(c).

The pylon circular polarized type of antennas can be either end fed or center fed. The center fed array can be fed internally for a top mounted location or externally fed for side mounted installations.

The antennas in Figures 6.8-42(b) and 6.8-42(c) are traveling wave circular polarized and each have a TM_{01} mode circular waveguide feed system for very high power applications.

All of the traveling wave slotted arrays have a cylindrical radome covering the full array.

ANTENNA TESTS

Antennas must be tested to determine if the necessary requirements for impedance and patterns are met. Impedance tests are usually run on all production antennas. Pattern tests are normally run on prototype and custom antennas.

Custom antennas are always impedance tested before shipment. These measurements should be made with the antenna completely assembled and in an area free of reflections. Using an impedance plotter or network analyzer a determination of the antenna reflection characteristic can be made.

A pattern measurement test is conducted for two reasons: 1) to determine the gain as compared with a dipole for which a substitution method could be used; and 2) to determine the amount of radiation at all vertical and horizontal angles which have an influence on the coverage.

Pattern tests can conducted on full or partial scale models of the final antenna. Scale models have an advantage of reduced size that permits high gain antennas to be tested in an anechoic chamber, free of reflections (from the ground or nearby objects that occur when conducting full scale tests on a range).

DTV ANTENNA SYSTEM CONSIDERATIONS

The availability of suitable locations for new television transmission towers is diminishing, even in the secondary markets and it is practically nonexistent in major markets. Even after the hurdles of zoning variance and suitable tower location are overcome, FAA restrictions and environmental concerns may delay the construction of a new tower for years. Not surprisingly, many broadcasters are looking at the pros and cons of using existing towers to support their new DTV antennas even though the prime tower top spots are occupied.

For any given antenna, directional or omnidirectional, the tower will modify the as designed antenna patterns. For optimum coverage, the as installed patterns must be known not just at the carrier frequency but throughout the entire channel before the relative position of the antenna and its azimuthal pattern orientation can be fixed. There is usually one position that will provide the optimum coverage without exceeding the structural limitations of the tower. This optimum position can be calculated. Coverage considerations are particularly important to DTV because all undesired energies, such as reflections, translate into a loss of coverage, whereas in NTSC the undesired energies translate primarily into a loss of picture quality.

Another transmission optimization technique that holds promise for DTV is CP. Although mixed results were achieved in the use of CP for NTSC broadcasts, DTV applications may prove more amenable to improvement through the use of this technique. The transmission of CP has obvious drawbacks in the form of a 2× increase in required transmitter power and transmission line, and a more complex antenna. (The 2× increase comes from the fact that ERP is measured in just one radiation plane.) For the DTV signal, *polarization diversity* can be achieved if the vertically polarized signal is transmitted through CP. A polarization diversity system at the antenna can provide missing signal level when one of the horizontal or vertical signal components experiences a deep fade. The inherent diversity attributes of CP operation could, thus, be put to good use in reducing the cliff edge effect of the terrestrial DTV signal.

Implementation Issues

The requirements for DTV antenna type are the same as for NTSC. The antenna should have structural integrity, be capable of mounting on tall towers, be efficient (have maximum gain for minimum length with minimum loss and reflection) and be able to handle power consistent with the ERP and feed line power requirements. In addition the antenna manufacturer must be able to shape the radiation pattern to satisfy coverage and interference requirements.

The FCC had considered using vertical polarization to decrease the coupling between NTSC and DTV antennas. Had this been specified it would have required a new class of antenna to be developed for DTV.

The antennas available today and described in this chapters satisfy all of the DTV requirements including the multi-channel requirements.

NTSC coverage is based on power (ERP) and height (HAAT) using the FCC F (50, 50) field strength prediction curves. From this simple curve, (one for each band) a grade A and B signal level is determined which is defined as the contours. The contour identified the maximum reach of the station signal from which the demographics of the station is determined.

The new DTV prediction requirements specify a different signal level for determining the contour and uses a different statistical model. If the station is to match the DTV and NTSC coverage, it is necessary to first determine a new NTSC contour using the new statistical model and terrain criteria. The NTSC contour using the new procedure will result in a contour that is not the same as the present NTSC contour and the antenna pattern requirement will very likely be different than the original NTSC pattern. For example, if the original antenna was an omnidirectional pattern, the recalculated pattern may not be omnidirectional; in fact, it may result in a pattern that is not physically realizable. To produce a DTV geographical contour that matches the revised NTSC contour in every case will not be possible as the rules are now written in OET Bulletin #69.

Adjacent channel interference is a function of side band splatter and filter requirements. Satisfying the FCC mask will result in high group delays at band edge. Field measurements especially for high power systems will be necessary to determine the effect the high group delay will have on performance and the requirements for the new filter designs.

6.9 TELEVISION FIELD STRENGTH MEASUREMENT (54 MHz-806 MHz)

JOSEPH W. STIELPER, ANN GALLAGHER
MOFFET, LARSON & JOHNSON, INC. (MLJ) ARLINGTON, VA

INTRODUCTION

This chapter will discuss planning a program of television broadcast field strength measurements and the analysis of the resulting data. It is not intended merely as a cookbook describing the actual taking of television broadcast field strength measurements; most field strength meter instruction books are adequate for this purpose.

It is anticipated that many measurements will be made on digital television (DTV) signals that are presently beginning and will ultimately replace analog transmissions. DTV signal quality measurements will require new equipment and techniques; however, measurements of DTV field strength are currently made with standard analog equipment. The only additional changes are switching the meter's detector from "peak" to "average" and making appropriate adjustments to the data analysis to allow for the use of a meter designed to receive analog signals.

The advent of DTV has raised the question of the appropriate "metric" for television coverage. In this chapter, we will continue to use field strength, since the Federal Communications Commission (FCC) continues to define coverage in these terms. By definition, field strength is the strength of the electric field at the point of interest, typically, the receiving antenna, and is customarily measured in mV/m or μV/m. These values can be converted to equivalent plane wave power density (W/m^2 or mW/cm^2) by relating voltage to the impedance of the medium (120π or 377Ω). Similarly, by taking into account the effective area of the receiving antenna and transmission line loss, receiver input power can be calculated.

While the discussions in this chapter focus on television field strength measurements, similar techniques and methods apply to measurements in the FM broadcast band as well.

MEASUREMENT OBJECTIVES

Why take measurements? Television field strengths may be measured to accomplish several objectives. These may include:

- Determination of actual (as opposed to predicted) coverage contours or coverage of a particular area
- Evaluation of the performance of transmitting systems
- Measurement of spurious emission
- Evaluation of the effect of factors such as terrain and vegetation on coverage.

Other special studies that may require field strength measurements include those involving interference reduction or making frequency allocation decisions. The ongoing DTV measurement programs have sweeping goals generally different from those described above and hence are not described in detail here.

Measurements Versus Predictions

It is not necessary or even customary to take measurements to estimate the overall coverage of a station or the station's coverage of a particular area such as its city of license. There are numerous propagation models available that may be used to predict field strength and coverage. These models vary in complexity from the administratively convenient but overly simplistic FCC $F_{(50,50)}$ curves to complex models which trace rays along the path from the transmitter to one or more receiving locations. Currently, the *Longley-Rice* model is used for DTV allocation and interference studies. More recently developed models based on the geometrical theory of diffraction (GTD) may be better suited to this purpose.

The FCC Rules specify the propagation model that must be used to determine coverage for Commission purposes, although additional showings using alternate models may be made. The FCC Rules also contain measurement and analysis procedures that must be followed if the results of measurements are to be accepted by the Commission. For in-house use, there are no such constraints, and any propagation model or measurement scheme may be used. The engineer is thus faced with the choice between measurements or predictions and calculations. The choice is not always clear. Predictions may be made in the comfort of one's office, with no concern over equipment availability or weather. Measurements, carefully taken and interpreted, can determine the signal levels actually available. The choice hinges on the answers to the questions:

- Which is more accurate or reliable?
- Will the results be filed with the FCC?
- What are the relative costs?

To a greater or lesser degree, propagation models consider the terrain and the environment between the transmitting and receiving antennas in a simplified fashion. Complex terrain and environmental situations involving multiple obstacles and reflections are reduced to much simpler models with one or two diffracting obstacles, usually described as spheres, wedges or knife edges. Many prediction routines do not consider the effect of environmental clutter such as buildings and trees. Such clutter may be more significant than terrain, particularly at UHF frequencies. In many cases it is not clear which of the many propagation models is appropriate. Because predictions often yield contradictory answers, there is a tendency to conclude that taking measurements will resolve the problem. Indeed, the FCC generally prefers measurements to propagation predictions, especially in contested situations. However, unless care is taken in the planning and execution of the measurement program, the results may not be an improvement on predictions and may be misleading. In summary, the methodology of any prediction or measurement program must be critically reviewed before basing decisions on the results.

[2] Digital TV coverage is characterized by a single grade due to its threshold effect and assumed single standard for reception.

Standards and Definitions

The quality of service is related to field strength by considerations of receiver sensitivity and noise figure, receiving antenna gain and transmission line loss and tolerable signal-to-noise ratios (S/N). The DTV planning factors used by the FCC in developing DTV standards are shown in Appendix A. The required fields for established grades of service vary with the frequency assignment. Table 6.9-1 lists the frequency bands employed by television broadcast stations. The bandwidth of each channel is 6 MHz.

Table 6.9-2(a) lists values of median field strength required for various grades of analog television service in the absence of interfering signals as established by the FCC's Technical Standards.[1] Interfering signals from other transmitters on the same or adjacent channels may limit service to higher values of field strength. Table 6.9-2(b) shows revised estimates of the fields required in the various television bands to provide acceptable grades of service based on the practical experience of operating stations and the findings of the Television Allocations Study Organization (TASO).[2] The TASO study has never been officially adopted by the Commission and may now be obsolete. The present FCC standards for analog television may also be obsolete, but the concepts have taken on practical meanings and are still useful.

A number of changes in the definition of television coverage grades based upon the TASO studies and other data have been proposed from time to time since the adoption of the present definitions. A review of the rationale for the analog VHF contour definitions and some potential revisions are presented in *FCC Report FCC/OCE RS 77.01.3.* Table 6.9-2(c) lists DTV coverage standards as adopted in the *Sixth Report and Order* in *MM Docket No 87-268* based upon the planning factors of Appendix A.

Table 6.9-1

Frequencies Employed for Television Broadcasting Service

Channel Number	Frequency (MHz)
2–4	54–72
5–6	76–88
7–13	174–216
14–69	470–806

Grades of service for analog television, as defined in Table 6.9-2, refer to the median field strength with respect to both location and time, at a receiving antenna of nine m (approximately 30 ft) above ground. The median value of field strength is the value exceeded for at least 50% of the time at the best 50% of the receiving locations. The presence of trees, buildings, and terrain irregularities often result in considerable variation in field strength from one location to another, even within relatively small areas.[4–9] The variation in field strength with location must be taken into account in measuring field strength as well as in specifying service.

At this writing, the FCC DTV rules define service in terms of F(50,90) (that is, the field strength at 50% of the locations, 90% of the time) and require the calculation of distances to a prescribed service contour. For UHF the coverage contour of the above table is adjusted by the *dipole factor.* The resulting contour in dBu is given by $41 - 20 \text{ Log } (f/615)$, where f is the center frequency of the TV channel in question. In the absence of measurements to determine time fading factors during the measurement period, the engineer will probably assume that the measurement represents the median (50%) value with respect to time. Thus, coverage measurements will require adjustment by an appropriate fading factor to reflect 90% of the time. For DTV allocation purposes, the *Longley-Rice* propagation model is used to predict field strength. In general, both coverage and interference are predicted. Although coverage is for 90% of the time, interference is predicted for 10% of the time as for analog interference. Interference is usually not measured and in the case of cochannel interference could not be measured simultaneously with standard field strength meters. For comparison of measured data with *Longley-Rice* predictions, comparison with the predicted median may be used unless measured fading factors are available.

The following are scoring grades commonly used for visual and aural signals. The visual scale follows the TASO six-point system.[2] The aural scale is taken from International Telecommunications Union (ITU-R) Recommendation 262. These first two scales are used for the subjective rating of one aural or visual signal. Comparative scales may also be used where appropriate. Comparative tests tend to yield data that is more reliable and repeatable than tests on one signal.

Table 6.9-3

TASO Picture Quality Scale

Grade	Name	Description
1	Excellent	The picture is of extremely high quality, as good as you could desire.
2	Fine	The picture is of high quality, providing enjoyable viewing. Interference is perceptible.
3	Passable	The picture is of acceptable quality. Interference is not objectionable.
4	Marginal	The picture is poor in quality, and you wish you could improve it; interference is somewhat objectionable.
5	Inferior	The picture is very poor but you could watch it. Definitely objectionable interference is present.
6	Unusable	The picture is so bad you could not watch it.

Table 6.9-4

International Telecommunications Union (ITU-R) Aural Scale

Grade	Quality	Impairment
5	Excellent	Imperceptible
4	Good	Perceptible but not annoying
3	Fair	Slightly annoying
2	Poor	Annoying
1	Bad	Very annoying

Obviously, with minor editing, the TASO scale may be adapted for aural use. The definitions would aid in improving repeatability in evaluation of the quality of aural signals. The following is the seven grade ITU-R aural comparison scale which may also be used for visual signals.

Table 6.9-5

ITU-R Comparison Scale

3	Much better
2	Better
1	Slightly better
0	The same
−1	Slightly worse
−2	Worse
−3	Much worse

PLANNING A MEASUREMENT PROGRAM

Before the start of measurements, a plan should be designed to consider the objectives of the field strength survey. For example, the constraints imposed by a survey to determine coverage of a station are different and generally less restrictive than those imposed by propagation studies. Design of a program to evaluate the performance of transmitting systems is likely to be the most difficult and require even more careful planning than programs for other purposes. Suggestions for designing measurement programs for each of the above objectives are presented in the following sections as well as a discussion of the techniques of actual field strength measurement. There are several basic considerations affecting all types of measurement programs that should be addressed. These include the choice of antenna height for the measurements and allowance for factors such as weather that are beyond the control of the engineer.

Measurement Antenna Height

The FCC Rules require measurements using a 9 m (30 ft) receiving antenna height. The bulk of reliable data was taken at 9 m, and the broadcast coverage contours are based upon this height. Thus, a 9 m receiving antenna height is appropriate for data to be filed with the FCC, for direct coverage measurement or for direct comparison with most other data.

Making measurements at 9 m introduces a number of practical problems (including personnel safety) which are discussed in a later section. For in-house use, another antenna height may be appropriate. If, for example, it is desired to evaluate the signal strength available to typical suburban viewers, it may be more appropriate to use a lower antenna to simulate indoor, set-top antennas. Measurements taken at a lower height may be, if necessary, adjusted to reflect the standard 9 m height. However, the variation in field with height may not follow simple laws. Because of the uncertainty of the magnitude of the adjustment, the adjusted results are inherently less precise than measurements taken at nine meters. Adjustment factors are discussed more fully in a subsequent section.

Measurement of Coverage

The coverage of a broadcasting station and the technical quality of the service provided are determined, in part, by the strength of the received signal as well as other factors. Currently available methods of predicting field strengths and service contours of television stations are only approximate, and even the best methods of calculating field strengths often fail to take into account variations due to important local conditions. In general, for making decisions affecting a station's operation, the most useful determination of station coverage is provided by properly made field strength measurements. This section describes measurement programs for this purpose.

A measurement program to determine coverage may be laid out using radials as in the method described in the FCC Rules for propagation studies (Section 73.686(b)). For example, eight radials spaced 45° apart typically starting with true north might be utilized. Additional radials, if necessary, may be added to obtain more refined coverage data. Under the FCC procedure measurement locations are evenly spaced at 2 mile (3 km) intervals. The point selection process defined in the FCC Rules is primarily intended to insure statistical randomness, that is, to minimize the effect of unintended biases that may affect the data. It also assures that the measured propagation path is a true radial. For in-house coverage studies, there may be no need for the measurement locations to be exactly on a true radial route at random 2 mile (approximately 3 km) increments as required by the FCC Rules. Because many TV transmitting sites are located near the center of cities it is often convenient to take measurements along more or less radial roads. Selection of measurement locations need not be random but may be influenced by population density or the desire to obtain data in particular areas.

Because actual picture or sound quality is only partially correlated with field strength, this may be only part of the answer sought when there are questions concerning coverage. For example, multipath causes ghosts in analog television pictures, raises the noise floor in DTV and causes distortion in analog TV aural (FM) signals, particularly to stereo signals. Such effects can be determined accurately by subjective observations. Care must be taken to ensure that the receiving test equipment and environment represent actual conditions. Observations made with high gain receiving antennas at 9 m (approximately 30 ft) may lead to erroneous conclusions if typical viewer reception relies on low gain indoor antennas essentially at ground level. For analog signals, it is often useful to make picture and sound recordings in addition to the field strength measurements. Recordings tend to significantly reduce problems such as variations among observers, repeatability and inaccurate reporting of the type of impairment. Recordings of analog signals can be used to measure signal parameters such as the amplitude and delay of ghost signals in the lab without transporting necessary equipment into the field, although recording equipment may introduce some distortion.

Analog recordings or DTV measurements are usually made in conjunction with field strength measurements using mobile runs or clusters of points. Ideally, picture quality should be obtained for a known field strength, preferably representing the median at the location. However, it may be difficult to select a point of a mobile run corresponding to the median value. Thus, the beginning or end of a run is often used for convenience; in this case, the field strength at the recording point should be noted.

For DTV there is no impairment of picture quality caused by noise or multipath as long as the symbol error rate (SER) does not exceed a threshold value. Thus, picture recordings are generally meaningless except in non-steady-state conditions. For example, there may be cases where man-made noise occurs in bursts which are short in duration compared to the time required to complete DTV measurements. Picture observations and recordings can provide information on instantaneous impairment. At any given location the most important value is the available margin over the required signal to noise of the system. The margin determines the reliability at that location. A number of DTV parameters may be measured at a selected location. These include SER, S/N, noise floor and fade margin, including the effect of multipath on the noise floor.

The results of field strength coverage surveys of analog signals are customarily presented as contour maps, showing lines of constant median field strength which represent the outer limits of various grades of service. A typical map of measured television station coverage is shown in Figure 6.9-1. Methods of preparing contour maps are described in detail in "Analysis of Measurements to Depict Coverage."

Analysis of Measurements to Depict Coverage

If a measurement height of other than 9 m (approximately 30 ft) was used, the received fields must be adjusted to the field expected at a receiving antenna height of 9 m above ground to obtain the location of standard contours. An antenna height of 3 m (approximately 10 ft) is often used when the results will not be filed with the FCC. It has been common practice to assume that field strengths (basic units of V/m) increase linearly with antenna height, as indicated by classical plane earth propagation theory. For this assumption the relationship between the field, E_{30}, which would be expected at 30 ft (approximately 9 m) and the field E_H, measured at a receiving antenna height H_r is $E_{30}/E_H = 30/H$. For example, the ratio of the field at 30 ft (approximately 9 m) to the field at 10 ft (approximately 3 m) is $30/10 = 3.0$, or 9.5 dB.

The application of the linear height-gain function discussed above is recommended only in relatively smooth terrain. In rolling or rough terrain the following height gain factors were recommended by TASO to convert from 3–9 m (approximately 10–50 ft) fields.

Table 6.9-6
Smooth Rolling Unobstructed Hilly Rough

Channel	Smooth Unobstructed Terrain	Rolling Hilly Terrain	Rough Terrain
2–6	9.5 dB	8 dB	7 dB
7–13	9.5 dB	7 dB	5 dB
14–83	9.5 dB	5 dB	2 dB

Median fields, as established in accordance with a radial or modified radial procedure described above, are plotted as a function of distance from the transmitter, and a smooth curve is fitted through the plotted points. Figure 6.9-2 is a typical graph showing the plotted field strengths as a function of distance from the transmitter, together with the smooth curve fitted to the plotted points. The points may be plotted with

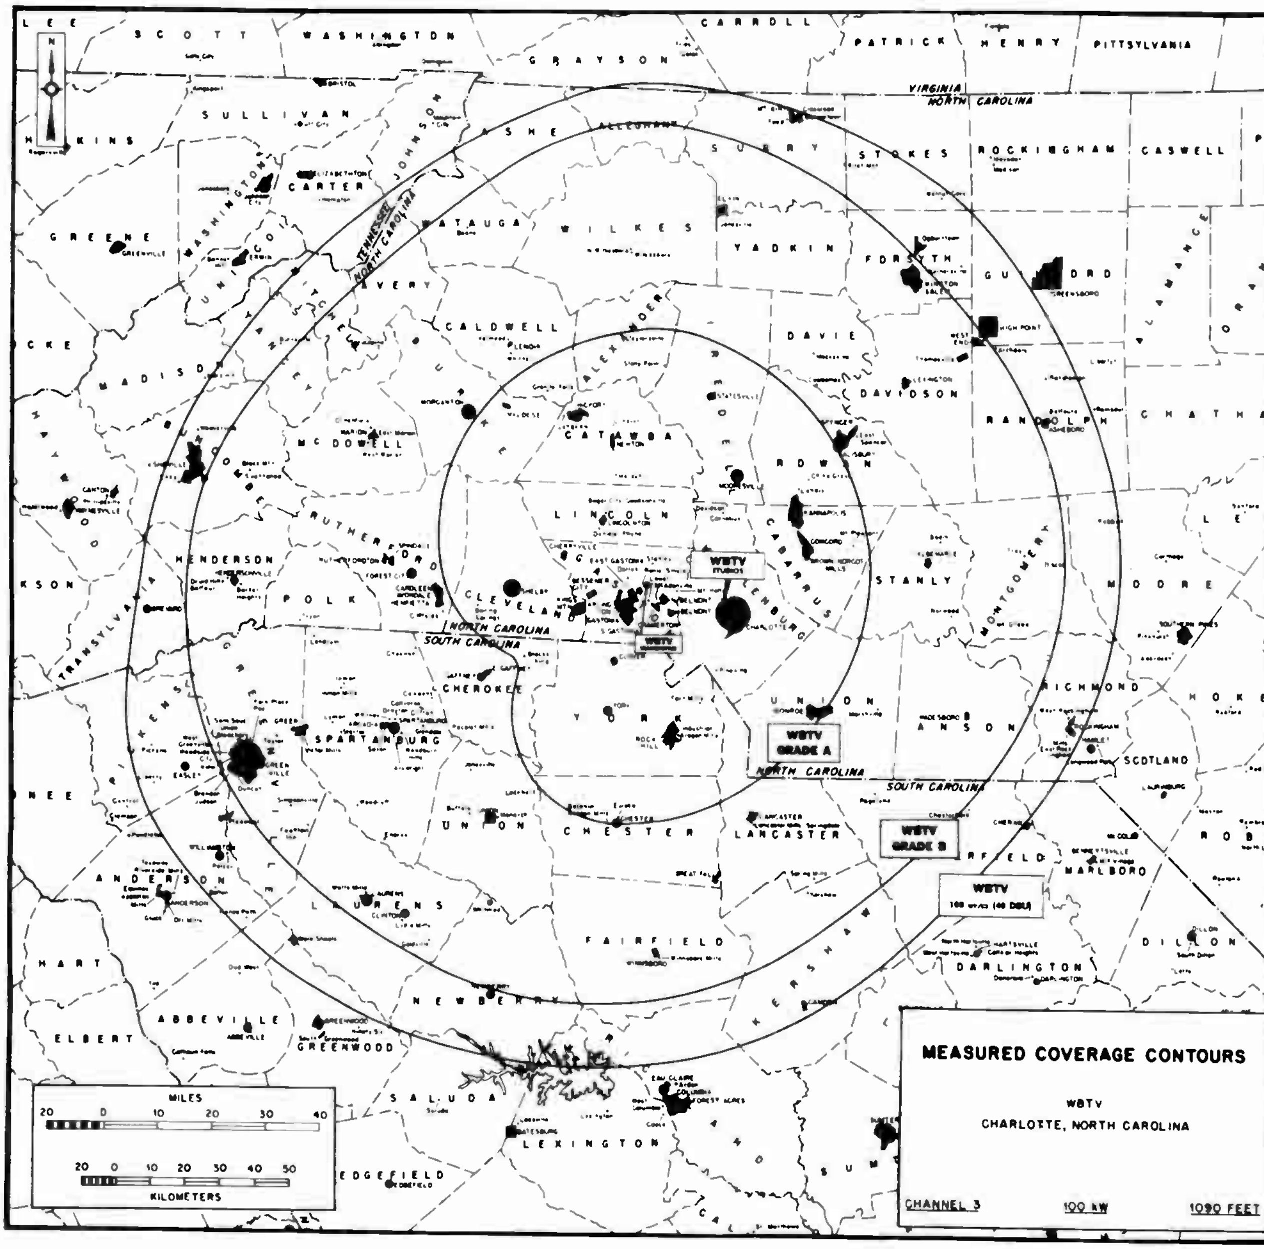

Figure 6.9-1. Map showing measured service contours for an analog operating television station. *(Courtesy of Jefferson-Pilot Broadcasting Company.)*

standard off-the-shelf spreadsheet software. Such software normally contains curve fitting routines. The solid curve is a simple linear fit to the measured data. Often, a first. second or third order polynominal is used to fit the data. The dashed curve in Figure 6.9-2 is the predicted field strength calculated using the propagation curves and prediction methods specified in the FCC Television Broadcast Technical Standards.[19]

Individual graphs of median field strength versus distance as shown in Figure 6.9-2 are prepared for each of the directions along which the measurements were made; the distances to the desired field strength contours, selected from Table 6.9-2 are then plotted on a suitable map and contours are drawn to produce a finished map such as shown in Figure 6.9-1. In some cases a mountain ridge may cause an abrupt decrease in field strength and define the limit of coverage. In this case, the curve-fitting procedure may not be appropriate. or only for distances less than the distance to the ridge. That is. data beyond the ridge should not be fitted in order to avoid incorrect bias of the data unaffected by the ridge.

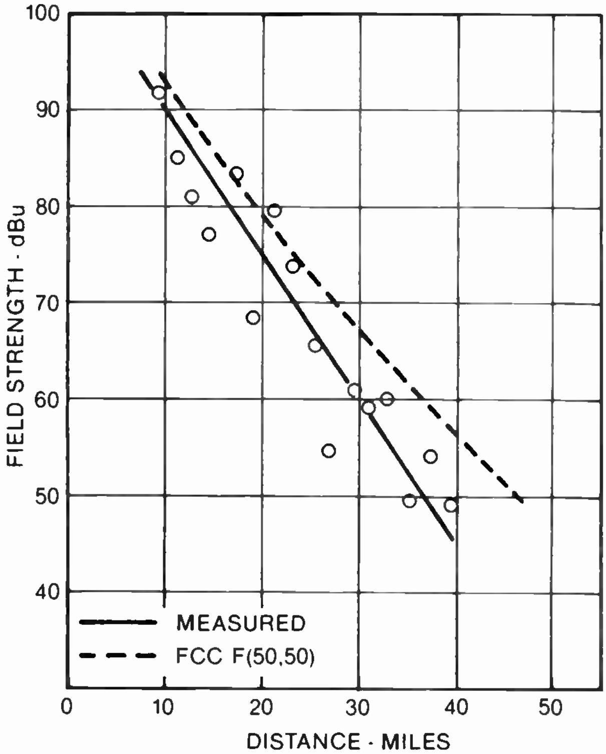

Figure 6.9-2. Graph of measured field strength versus distance for a typical radial series of measurements. The results of each mobile run are shown. The solid line is the *best fit curve* through the points. The dashed line is the predicted field strength from the FCC curves.

At present, DTV allocations are based on the *Longley-Rice* propagation model. In the case of existing stations, the goal is to replicate the station's Grade B contour on the assigned DTV channel. The DTV Effective Radiated Power (ERP) is derived at the station's antenna height above average terrain (HAAT) so that the F(50,90) DTV service contour replicates the F(50,50) analog Grade B. However, coverage and interference are based on predictions of field strength in cells (bins) 2 km (1.2 miles) on a side. There are approximately 8500 bins within the Grade B contour of a low VHF TV station with an antenna height of 1000 ft (300 m). Thus, it is generally not practical to measure field strength at even one location in each bin to verify predicted DTV coverage. Predicted DTV coverage using the *Longley-Rice* model is shown in Figure 6.9-3. Such maps also usually show predicted interference areas. Other than sampling at a limited number of locations, the only practical procedure would be to "drive test" with an antenna mounted on a vehicle roof. This procedure is described in the section on drive testing.

Transmitting System Evaluation

Field strength measurements are occasionally used to assess the performance of a station's transmitting system, particularly the operation of the antenna. The difficulty is in separating the effect of propagation factors from the effect of the transmission system. Ideally, comparison of transmission from the antenna to be tested should be made with that from a standard antenna. The standard antenna would be a low-gain antenna of known characteristics mounted near the antenna under test. This procedure is described in detail in the TASO report.[2] The procedure is rarely feasible.

- Measurements on two or more stations operating in the same frequency band are often used to determine if one is not performing properly. Differences in facilities and location must be considered in the analysis of the data. Vertical plane pattern effects may be minimized by avoiding locations near any of the transmitting sites or by adjusting data based on antenna vertical plane patterns. The uncertainty in the results is proportional to the number and degree of the adjustments that are made; numerous measurements should be taken to reduce the uncertainty.
- Comparisons of measured data with standard propagation curves such as the FCC Rules curves or smooth earth curves must be used with caution. The standard deviation of measured data used to draw the FCC curves is 7.7 dB at low VHF, 6.8 dB at high VHF, and 9.3 dB at UHF after adjustment for terrain.[10] Even in smooth terrain, field strength is affected by other factors such as trees, buildings, and atmospheric variations.
- In hilly terrain, the effect of clutter, terrain, and atmospheric variations can be minimized by selecting sites near the transmitting antenna to minimize atmospheric effects and ensure that ray path clearance over all obstacles can be obtained. This clearance should be at least 0.6 Fresnel zone. The radius of a full Fresnel zone is given by:

$$H_0 = 2280 \sqrt{\frac{d_1 d_2}{f(d_1 + d_2)}}$$

where:

H_0 = Fresnel zone radius in ft
d_1 = Distance from transmitting antenna to obstacle in miles
d_2 = Distance from receiving antenna to obstacle in miles
f = Transmitting frequency in MHz

Application of this criterion is illustrated by Figure 6.9-4. Even if such ray clearance over all obstacles can be obtained, reflections, especially from terrain, may often modify field strength. Allowance for reflections can only be achieved by using mobile runs and by taking measurements at a large number of locations to "average out" reflection effects.

Field strength measurements intended to evaluate system performance are sometimes taken in an aircraft in an attempt to reduce terrain effects. However, there are several problems associated with aircraft measurements, including:

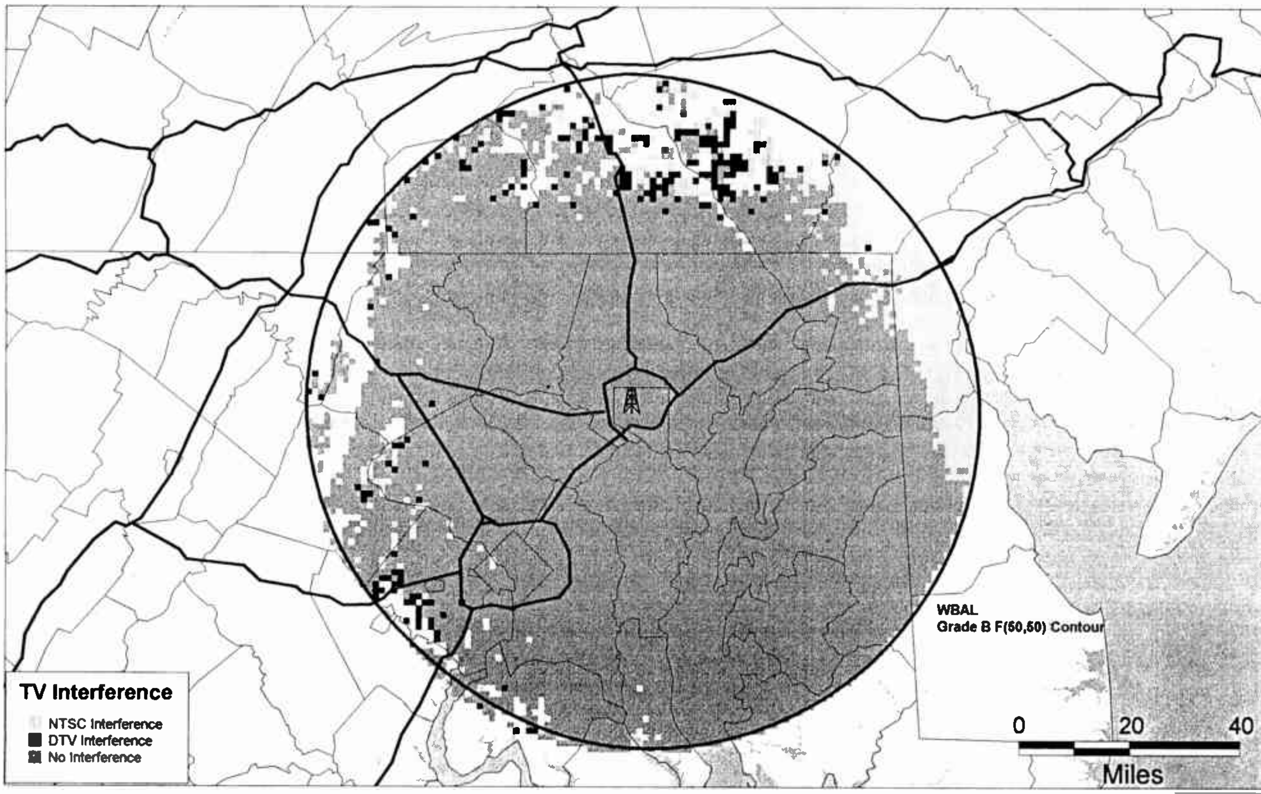

Figure 6.9-3. Predicted Coverage using the Longley—Rice propagation model and the replicated Grade B Contour.

- Determination of the actual location of the aircraft relative to the transmitting system under test
- Constraints on the design of the program imposed by the aircraft's performance
- Mounting of the receiving antenna on the aircraft to minimize the effect of the airframe on the receiving antenna pattern without creating a hazard

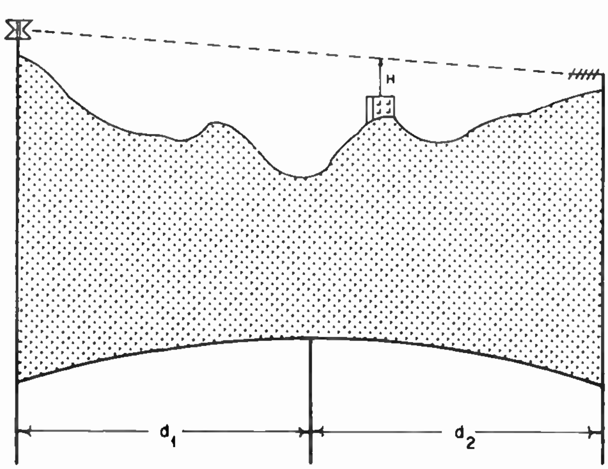

Figure 6.9-4. Illustration of required ray clearance to avoid obstacle loss.

- Uncertainties, such as actual path loss, that limit the accuracy of the measurement of absolute gain of the transmitting system under test.

The methods for determining the location of the aircraft or maintaining the desired location vary from simple manual techniques to control using electronic location measures such as Global Positioning System (GPS). In the most basic case, an altimeter is used to maintain the desired height. A more or less circular route can be flown by flying over known ground locations. At the other end of the scale a completely electronic system can be used. Such systems are used in Europe because proof measurements are routinely required after construction.

Reflections are a limiting factor in antenna measurement whether measurements are taken on a test range, on the ground or on an aircraft. In the latter case, the standard procedure is to fly close to the antenna under test so that the reflecting ground will likely be illuminated by a relatively low ERP. The distance should not be selected arbitrarily but should be based upon the vertical pattern of the antenna. Ideally, a helicopter should first be used to measure the antenna's vertical plane pattern at a number of locations to select the radius of the horizontal plane flight. If this is not feasible, a *range measured* or theoretical vertical plane pattern should be used. If possible, the radius should be selected so that the depression angle of a ground-reflected ray falls in a null of the vertical plane pattern. For the case of a well smoothed vertical pattern, the flight radius may not be optimized, but the engineer should estimate the uncertainty so that unwarranted validity is not attached to the data. Error estimates may be made based upon theoretical reflection coefficients in NBS Technical Note No. 101.1.[2]

If measurements are taken on circularly polarized signals, in most circumstances, care should be exercised to avoid flying at distances where the angle of incidence of the ground-reflected ray would be at or near the Brewster angle. At this angle, a vertically polarized wave changes phase and the magnitude of the reflection coefficient approaches zero. This would be desirable when measuring vertically polarized only signals to minimize the effect of ground reflections. Vertically polarized only transmissions rarely, if ever, occur in television. If the angle of incidence approximates the Brewster angle, it will be difficult to compare the results between the two planes of polarization of circularly polarized signals because of the differences in reflection coefficient between vertically and horizontally polarized signals.

Even if Brewster angle problems are avoided and an aircraft flight path is carefully controlled, ground reflections will likely cause apparent, but fictitious variations, in measured antenna patterns. For example, at an aircraft and antenna height of 300 m (984 ft) and a flight radius of 2 km (1.2 miles), a change of 10 m (approximately 33 ft) in ground elevation at a reflecting point or aircraft elevation changes the reflected ray path length by approximately 5 m (approximately 16 ft). This is more than one half wavelength at all TV broadcasting frequencies. Thus, relatively small changes in the elevation of the reflecting point or aircraft can completely change the phase of a reflected ray. In this example, if the magnitude of a reflected ray is only one-tenth of that of a direct ray, the expected variation caused by ground reflections is approximately ±0.9 dB. Because of the effect of ground reflections, measurements at varying distances should be taken to average out these effects.

Perhaps the most difficult aspect of aircraft measurements is the accurate determination of the gain of the receiving antenna as mounted on the aircraft. The aircraft and the antenna transmission line can change antenna gain significantly from the nominal "free space" value. Unless receiving antenna gain is accurately known, only relative antenna patterns can be measured. The best method would be to measure receiving antenna gain by measurements on transmitting installations of precisely known ERP.

Analysis of Measurements to Evaluate Antenna System Performance

The following description applies to data taken on land at locations where at least 0.6 Fresnel zone clearance is obtained over all obstacles; data from aircraft measurements may be analyzed in a similar fashion. For aircraft measurements, essentially continuous data is analyzed; in ground measurements, discrete data is used.

If a station uses an omnidirectional antenna, the data may first be analyzed by neglecting noncircularity. For a directional (or an omni) antenna with a measured or theoretical pattern and known orientation, measured data may be adjusted for the horizontal antenna pattern. Relative field strength may then be determined assuming free space propagation for comparison with the antenna's theoretical or range-measured vertical plane pattern. The result of such an analysis is shown in Figure 6.9-5. Data may also be analyzed by comparing measured to predicted field strengths for free space propagation. If the antenna is performing properly the median difference should be small and approach the accuracy of the test procedure. The median difference between measured and predicted strength for the data shown in Figure 6.9-5 is 1.2 dB that is, measured field strength exceeded predicted field strength.

A comparison of measured field strengths may also be used to analyze measurements on different signals. Adjustments to allow for fairly small differences in height and location can be made directly to the measured ratio of field strength. In decibels, a factor of 20(log(height ratio)) can be used. For example, to adjust for a height difference between 800–1,000 ft (approximately 240–300 m) a factor of 1.9 dB is added to the lower height data. For distance adjustment, a factor of 40(log(distance ratio)) may be used. In this case (for example for distances of 9 and 10 miles (or approximately 15 and 16 km), 1.8 dB would be added to the data at 10 miles (approximately 16 km). This procedure is best used on stations on the same frequency, such as comparison between a main and standby antenna. By using this technique it is not necessary to calculate predicted field strength. This procedure is less desirable than the use of the Fresnel zone method because of uncertainties in the propagation paths of the two signals and uncertainty in the adjustment factors. The adjustment factors are based on the plane earth propagation model which may not be apropriate at some locations, for example, at a location where free space propagation obtains.

PROPAGATION AND OTHER SPECIAL STUDIES

Section 73.686 of the FCC Rules describes the procedures to be employed for field strength measurements used in TV propagation studies. This procedure is basically the technique developed by TASO. The actual field strength measurement procedure is discussed later in this chapter. The FCC procedure is intended primarily to yield data that may be analyzed to study the effect of terrain and other local influences on field strength. Measurement programs intended for other purposes may require substantially different plans. For example, measurements primarily intended to determine the effects of clutter, such as trees and buildings, should be taken, if possible, in smooth terrain to eliminate the effect of terrain.

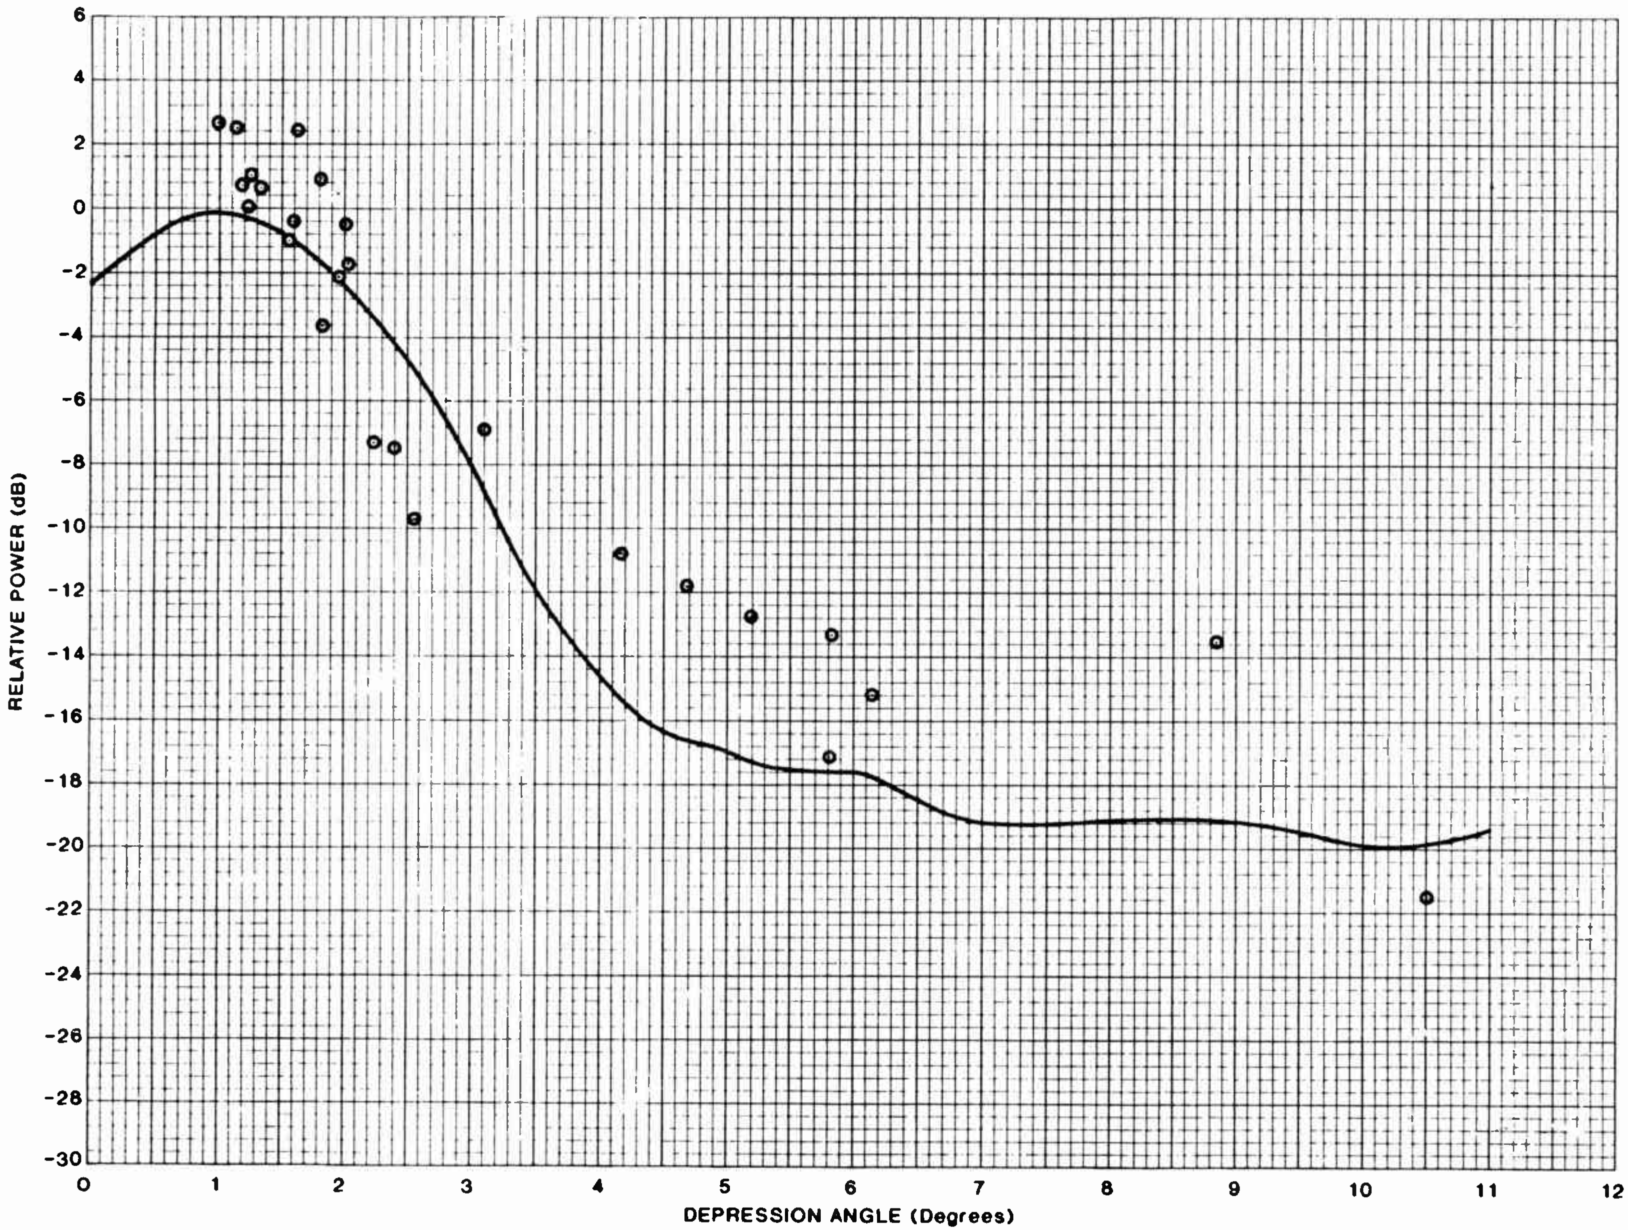

Figure 6.9-5. Comparison of data based upon field strength measurements with antenna vertical plane pattern.

Measured field strength for propagation studies may be compared to calculated field strength for a number of propagation models.[10–13] In this manner, the validity of the model may be assessed or factors for clutter may be determined. Measurement programs have been conducted to evaluate field strength time variation factors. In this case, field strength measurements are recorded at fixed locations over a period of time.

Field strength measurements may be an integral part of special field tests, particularly with regard to interference studies, allocation proposals and changes in TV operation. Examples of such field tests in the past include those on VHF TV-Land Mobile channel sharing, tests relating to the problem of educational FM interference to Channel 6 and on circular polarization for television. Extensive measurements were made in southern California in the study of propagation between Santa Barbara and San Diego regarding the proposed allotment of television Channel 10 to Santa Barbara. The presently ongoing DTV studies are also an example of a special program. Detailed discussion of such special projects is beyond the scope of this chapter; however, the basic techniques of field strength measurement discussed herein are valid for special programs. In addition, many of the topics discussed in planning coverage, transmission equipment evaluation and pure propagation tests are appropriate for use in special tests.

DTV Measurements

As discussed briefly above, DTV parameters can be measured; the special equipment needed is reviewed below. Data from the initial DTV field tests indicated good correlation between field strength and observations of picture quality for UHF transmissions although correlation was poorer at VHF. Subsequently, a protocol was developed for DTV field testing, and tests are proceeding using the protocol. A brief summary of the protocol follows. Measurements are made on arcs of constant distance from the DTV station and at selected locations on radial routes. In addition measurements are taken at "grid" locations which are determined by a grid laid out on a map. The radial and grid programs are similar to plans based upon the FCC Rules. All measurements are made with a 9 m (approximately 30 ft) antenna height and a directional receiving antenna directed towards the DTV station. Measurements of received signal level and DTV parameters are usually made at one point at each location although mobile field strength runs may be made. The segment error rate, equalizer output, signal and pilot levels and S/N are measured. To determine fade margin, white noise is added to the received signal. Multiple measurements are taken when a low margin is measured to determine if improvements can be achieved. These include measurements after changes in antenna height and antenna orientation as well as moving the test van.

Measurement of Spurious Emission

It is occasionally necessary to measure spurious radiated field strength from TV broadcast facilities to show compliance with FCC Rules after installation. Requirements regarding the level of spurious signals relative to carrier level are specified in Section 73.687 of the FCC Rules for TV transmitting systems. Such field strength measurements are nominally regulated by Section 2.993 of the FCC Rules. Because this section is quite vague, it is recommended that the person intending to take measurements determine acceptable procedures from FCC laboratory personnel before undertaking the measurements.

Drive Testing

In the mobile radio services, "drive testing" is often used to measure coverage and to conduct propagation studies, particularly to "optimize" propagation parameters for the prediction of coverage and interference. Drive testing has also been performed to a limited extent in FM broadcasting. In drive testing, a receiving antenna is mounted on a vehicle roof and continuous measurements may be taken on any road. There are a number of problems with TV drive testing. Most TV transmissions are, or, in the case of DTV, will be horizontally polarized. The receiving antenna must be omnidirectional and an omnidirectional, horizontally polarized rooftop antenna is difficult to design, particularly at the lower VHF frequencies. The vehicle will affect the antenna pattern particularly in the vertical plane. However, most DTV allotments, especially during the transition period, are in the UHF band. At UHF, design of a horizontally polarized omnidirectional antenna for vehicular operation should be feasible. The sensitivity of such a system will be lower than that of a measurement system that employs elevated directional antennas. In other words, for a given transmitting system, the range measured by a drive testing system will be shorter than that of a conventional measurement system. As in any other measurement program, care should be exercised in the design of a drive testing program so that the reliable data are gathered and to ensure that biases are minimized. As described in the section on practical field strength meters, it is necessary to insure that noise does not contribute significantly to the field strength indication. Two other potential sources of bias result from driving on streets approximately radial from the transmitting site and on major highways such as interstates. In these cases, the effect of clutter is generally much less than in residential areas where TV viewing occurs.

The antenna height on a vehicle in drive testing will, in many cases, be more representative of actual heights in a community and the data may be more useful for coverage measurements than will measurements at 9 m (approximately 30 ft). Drive testing may be helpful in evaluating potential power increases and comparative coverage from different sites where stations are presently operating.

Data obtained by drive testing may be used for comparison with predictions based on various propagation models and to derive *clutter factors.* Generally to derive *clutter factors,* an attempt should be made to characterize receiving environments; there may multiple environment types in a survey area. Data may then be segregated by environment, and factors may be determined for various environmental types. In any case, calculations of predicted field strength should be performed for the antenna height used in the survey to avoid height gain adjustments.

BASIC EQUIPMENT PRINCIPLES

Field strengths in the VHF and UHF bands (30–3000 MHz) are ordinarily measured by determining the voltage which the field induces in a half-wave dipole. The basic relationships can be expressed in several forms. The power transferred between two half-wave dipoles in free space separated by a distance, d, is given by:

$$P_r/P_t = 2(1.64)(\lambda/4\pi d)^2 \qquad [2]$$

where:

P_r = Received power
P_t = Transmitted power
λ = Wavelength in same units as d
d = distance between transmitting and receiving antennas

In terms of the field at the receiving dipole, the power delivered to a matched load by a half-wave dipole in a field of E volts/m is

$$P_r = (0.0186E\lambda)^2 \text{ watts} \qquad [3a]$$

where λ is expressed in meters.

Or, alternatively, in dB relative to one watt (dBW)

$$P_r = F - 20\log f - 105.1 \qquad [3b]$$

where f is the frequency in MHz and the field strength, F, is in dBu.

For a resistive load of R ohms, the voltage V developed across a matched load by a dipole in a field E is

$$V = (E\lambda\sqrt{R})/53.7 \text{ [volts]} \qquad [4]$$

The fundamental problem presented, therefore, is that of measuring the developed radio frequency (RF) voltage by a practical instrument of acceptable accuracy.

The voltage measuring device is ordinarily separated from the antenna by a length of cable. The cable introduces loss, and any impedance mismatch must be sufficiently small that calibration errors are not introduced by differences between the antenna and cable impedance and the internal impedance of the calibrating oscillator.

The following paragraphs describe the basic components used for field strength measurement using the standard FCC methods. The system described is the conventional system using chart recorders and manual analysis of recorded data. Digital sampling may be used to replace, entirely or at least in part, manual techniques. Discussions of the procedures for use of both chart recorders and digital recorders are included in order to aid engineers who may prefer either method.

Practical Field Strength Meters

Field strength meters are calibrated receivers that fall into three basic categories:

- Receivers that contain a precision oscillator and attenuator and use direct comparison between meter readings produced by the received power and the output of the oscillator
- Receivers that use a precision oscillator to adjust receiver gain to produce a direct reading meter
- Receivers that are direct reading but do not contain a calibrating oscillator.

Field strength meters of Type 3 are not considered suitable for precision field strength measurements. In addition, spectrum analyzers may be used for field strength measurements; the use of such instruments is discussed below.

Figure 6.9-6 is a block diagram of a practical Type 1 field strength meter. Type 2 meters are more common now; however, the purpose of the following discussion is to illustrate measurement principles. The Type 1 meter is more suitable for this purpose. The antenna delivers its received power to a transmission line leading to the receiver input. If the receiver input is unbalanced to ground, a balance-to-unbalance transformer (balun) is required. The transmission line between the antenna and the receiver is shielded to avoid stray pickup.

The RF attenuator shown serves two purposes: to avoid overloading of the receiver input on strong signals and to improve the impedance match when the receiver input impedance is substantially different from the characteristic impedance of the transmission line. It is frequently omitted when not required for either of these purposes.

The signal at the receiver input is amplified and converted to the intermediate frequency. Amplification and attenuation at the intermediate frequency permit operation over a wide range of field strengths; further range is provided by the receiver gain control. The rectified receiver output operates the indicating meter.

In operation, the attenuators and gain control are adjusted to provide an on-scale reading of the indicating meter. The receiver input is then switched between the output of the transmission line and the output of the calibrating oscillator, which is tuned to the frequency being measured. The output of the calibrating oscillator is adjusted to a predetermined fixed value using the RF power monitor, and the calibrated attenuator is adjusted until the indicating meter deflection is the same as that obtained from the antenna and transmission line.

For this condition, the voltage at the output of the calibrated attenuator is the same as that from the antenna and transmission line. By taking line and balun losses into account and applying 4 above, the field at the antenna required to produce this voltage can be determined. The relationship between field strength and receiver input voltage is usually expressed as $E = KV$, where K is a function of frequency. Figure 6.9-7 is a typical graph showing values of K for a VHF field strength meter.

A typical commercial field strength meter of professional quality is shown in Figure 6.9-8. The instrument

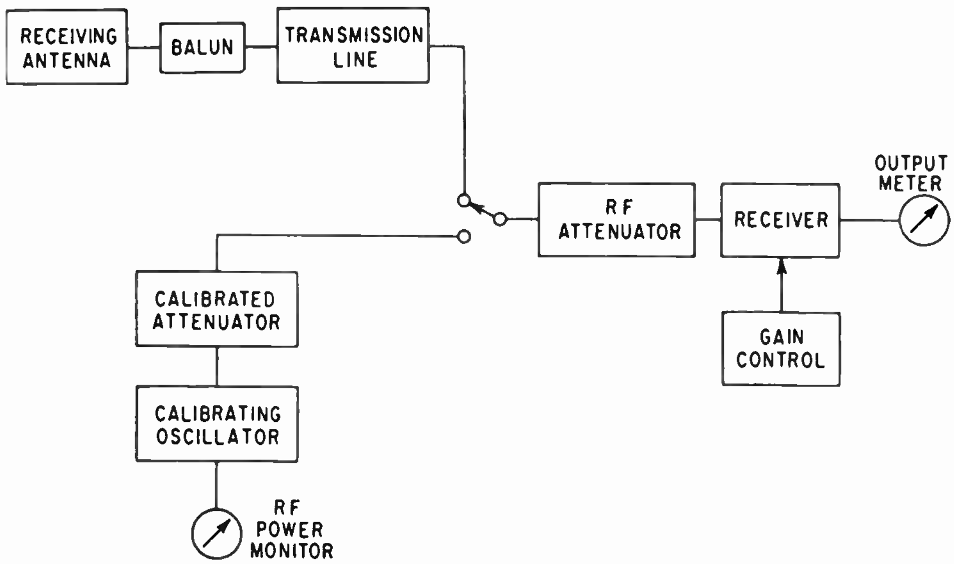

Figure 6.9-6. Block diagram of practical field strength meter.

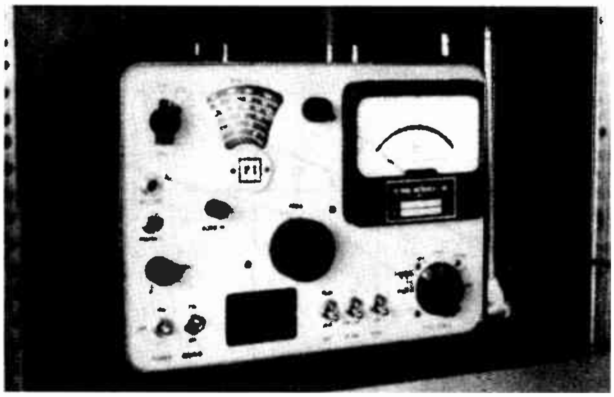

Figure 6.9-8. A VHF meter of professional quality.

shown is a Potomac Instruments type FIM-71, covering the VHF, FM, and television band from 54–216 MHz. A companion instrument, the FIM-72, which is similar in appearance, covers the UHF television band from 470–806 MHz.

Accurate instrument calibration is essential in measuring RF fields. During use, the calibration of the instrument described is provided by the calibrating RF voltage source, which is usually an integral part of the field strength meter (see Figure 6.9-8). The calibration of the oscillator and the calibration of the instrument as a whole must in turn be established and maintained by reference to laboratory standards.

The most direct laboratory calibration of the complete field strength meter is established by generating a known standard field in which the receiving antenna is placed. Standard field ranges have been developed and constructed at both UHF and VHF and are sometimes used in primary calibration of field strength meters.[14,15] Most commercial laboratory calibrations, however, are made by removing the dipole elements from the standard antenna and applying a known RF voltage at the proper frequency to the dipole terminals in series with an impedance equal to the receiving-antenna impedance. The calibration of the balun, line and receiver is established in terms of this applied voltage, which is then related to field strength through Equation 4.

Figure 6.9-9. Equipment set up for field strength measurement.

The calibration of the internal reference oscillator section includes the calibration of both the oscillator proper and the variable-output attenuator, if employed. The attenuator is usually of the inductively coupled piston type,[16] which depends only on its dimensions for proper functioning. This can be checked against the correct dimensions or against a laboratory standard attenuator. The oscillator can be compared with a standard oscillator, or its output can be measured with a laboratory standard such as a bolometer bridge.[16] This calibration is normally, but not necessarily, performed by the manufacturer.

Measured Signal Power

If measurements are made on the visual carrier of an analog television station, the difference between the peak and average powers of the transmission must be taken into account. This can be done by establishing a calibration in terms of average power for a still scene (such as test pattern or black picture), or a peak-reading meter can be employed to indicate the level of the synchronizing peaks. Such peak-reading meters are an integral part of professional commercial field strength meters such as the one illustrated in Figure 6.9-8. For DTV measurements, the standard is average power, so that peak reading is not required.

Spectrum analyzers may be used to replace standard field strength meters to permit the simultaneous measurement of multiple signals. If the multiple signals are not arriving from a common direction, for example, from an "antenna farm," an omnidirectional receiving antenna must be used. In the case of analog television measurements, care must be exercised to ensure that peak of sync is measured. At fixed points, the "peak hold" feature may be used to measure peak of sync. The total power of an FM signal is constant, so the level of an analog TV aural carrier may be used if a peak detector is not available. However, the power of an FM carrier diminishes under modulation. To obtain accurate measurements (particularly mobile measurements) on aural TV FM signals, the spectrum analyzer must be adjusted to "see" the bandwidth of each signal. In addition, intermodulation signals may be generated within the spectrum analyzer itself. If there is any doubt, the validity of signals should be checked.

Equipment for Field Strength Measurements

In addition to the field strength meter, several accessory items are needed when making a field strength survey. The principal items and their use are described in the following paragraphs and include:

- A special receiving antenna
- An antenna supporting mast
- A chart or digital recorder
- Power supplies.

Figure 6.9-9 shows the field strength meter, chart recorder, and some additional equipment for a survey.

The size and weight of the equipment usually dictate that it be mounted in an automobile or light truck. As discussed in Appendix A, all of this equipment, including the field strength meter, should be grounded to the vehicle frame. Figure 6.9-10 shows a van with elevated mast supporting a UHF antenna and containing the mounted equipment of Figure 6.9-9.

In addition to taking field strength measurements, it is often desired to use other equipment such as the television monitor shown in Figure 6.9-9. A vehicle devoted to general field test programs should have sufficient space available for special equipment including monitors, waveform scopes and magnetic recorders.

For DTV measurements, standard TV field strength meters are operated in the average power mode. In addition, an adjustment must be made to allow for the difference in bandwidth between the meter and the DTV signal as well as other characteristics of meters designed for analog measurements. Presently, bandwidths of the meter must be adequate for measuring peak of sync for analog signals, approximately 0.5 MHz, whereas for DTV received power is averaged over the full 6 MHz channel. The adjustment factor for the meter shown in Figure 6.9-8 is approximately 12 dB taking into all factors into account when the meter is tuned to the center of the TV channel. That is, true DTV received voltage is 12 dB greater than indicated. Engineers should consult the manufacturer of the meter to obtain the appropriate correction factor. Adjustment factors can be determined for individual meters by measurement; the manufacturer of the meter should also be consulted in this case. As can be seen from Table 6.9-2, DTV coverage standards are approximately 20 dB lower than corresponding analog values. Even allowing for differences in modulation, field strength meters designed to measure analog signals may lack the necessary sensitivity to measure DTV signals near the coverage limit. Use of directional receiving antennas can generally compensate for this problem. A low noise amplifier (LNA) can also be used to improve sensitivity. The LNA should be mast-mounted ahead of the transmission line if an elevated antenna is employed. The specifications of the meter coupled with receiving antenna gain and line losses, can be used to calculate system sensitivity. The system sensitivity should be several dB lower than the minimum signal to be measured, particularly at UHF. The noise floor should be determined by noting the meter reading when the antenna input is terminated with its characteristic impedance. The contributions of the meter noise can be eliminated by assuming power addition between noise and signal and adjusting the measurement downward. Alternatively, measurements less than a margin above the noise floor could be ignored; 6 dB is generally an acceptable margin. The error introduced would be less than 1 dB.

The equipment used to conduct specific DTV measurements can also be used to measure field strength. This equipment is described in a later section. Present DTV measurement equipment is not necessary nor particularly suitable for mobile field strength measurements.

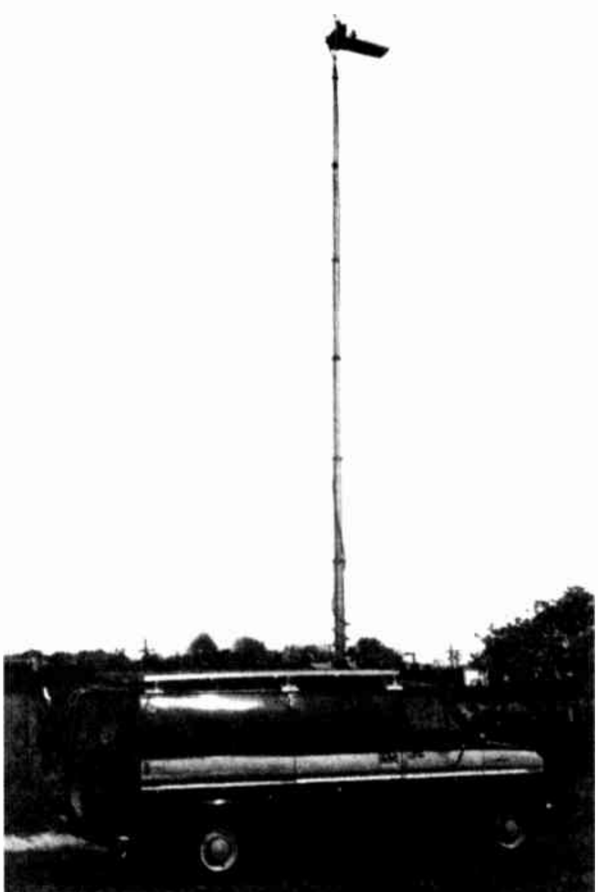

Figure 6.9-10. Van equipped for making field strength measurements with 30 foot antenna height.

Receiving Antennas

The measurement survey can be made by employing the standard dipole antenna furnished with a field strength meter, or other antennas can be utilized. It is often desirable to use an antenna other than the standard antenna for actual measurements. Standard antennas are usually not mechanically sturdy. If measurements are to be taken at a large number of locations, especially with extensive driving between locations, it may be more practical to use a rugged or readily replaceable antenna and thus minimize the probability of damaging the calibrated antenna. For subjective evaluations of analog signals or measurement of DTV parameters such as delay spread, the antenna should be representative of antennas actually used in the area by the public.

Where measurements are to be taken on several channels at each location, use of standard antennas requires that the length be adjusted for each channel within a band. It is also necessary to change antennas for VHF and UHF bands. Broadband antennas such as log periodics can significantly speed up the measurement process by eliminating the need to change antennas. Broadband antennas must be calibrated against the appropriate standard antenna to be useful.

An antenna that is essentially omnidirectional in the horizontal plane does not require orientation as the vehicle is moved; however, it is more common to use a receiving antenna with directivity. Directional receiving antennas possess gain which is especially useful for UHF measurements, and their directivity is useful to eliminate unwanted interfering signals. Directional receiving antennas also tend to discriminate against reflected signals, thus reducing apparent variation in measured field strength. A directional antenna can also be used to improve system sensitivity.

The antenna employed for the measurements must be calibrated on the measurement vehicle because of ground and vehicle proximity effects.[18] The differences in the calibration curves of Figure 6.9-7 are caused by ground proximity effects. The received field is first measured using the standard dipole antenna mounted on the vehicle at the measurement height. The antenna to be used in making the survey is then mounted on the vehicle, at the height to be employed in making the survey, and the receiver input voltage is determined with the receiving antenna at the same spot in the field. The procedure should be repeated several times and the median or average gain should be used. If an omnidirectional receiving antenna is used, the circularity of the pattern of the antenna as mounted on the vehicle must be determined. The antenna pattern is best established by rotating the vehicle with the antenna mounted as for measurements, and recording field strength and measuring antenna gain as above. If the vehicle cannot be rotated, an alternate comparable procedure must be followed.

The gain of a directional service antenna can be established relative to a dipole antenna by means of measurements with the antenna stationary as described above, but more consistent results are often obtained by making short mobile runs over identical paths and recording the signals from the two antennas. In either case, a location essentially free of standing waves should be used. For either procedure, the voltage gain of the service antenna G_s, relative to the standard dipole antenna G_d is $G_s/G_d = V_s/V_d$, where V_s and V_d are the voltages delivered to the receiver input using the service and standard dipole antennas, respectively. The power gain in dBd is 20 Log(G_d). If the transmission line or balun between the antenna and receiver is different from the standard cable and balun supplied with the instrument, the antenna calibration must include the measurement system cables and baluns even if standard equipment is used. Ideally, actual transmission line loss is measured and used in field strength determination.

Horizontally polarized receiving antennas are normally used for field strength measurements. At the present time, FCC Rules require that TV stations operate with horizontal only, or dual or circular polarization. If measurements on a vertically polarized field are desired, precautions must be taken to reduce the effect of coupling between the vertically polarized antenna and the supporting mast and vertical run of transmission line. In the case of horizontal polarization, the transmission line and mast are at right angles to the receiving antenna and thus exert negligible effect on reception. For vertical polarization, the line and mast are parallel and generally close to antenna elements. The receiving antenna pattern and gain may therefore differ significantly from free space pattern and gain. The standard antenna furnished with the field strength meter is used for measurement or calibration of another antenna, preferably directional. This measurement antenna may then be mounted close to the mast, and the gain is determined compared to the standard antenna which is offset from the mast. The standard antenna should be mounted at least one and preferably two wavelengths away from all metallic vertical components. This requirement presents a mechanical problem at the lower VHF frequencies. This measurement antenna is then calibrated against the standard antenna cantilevered out from the mast about two wavelengths. Thus, in the vicinity of the standard antenna, the transmission line is at right angles to the antenna. Since the mast and vertical run of transmission line are relatively distant from the antenna, the calculated variation in gain is only about ±0.5 dB when the standard antenna is cantilevered out by two wavelengths. The result is that the effect of the mast and transmission line on the measurement antenna is compensated for in the calibration.

Normally, directional receiving antennas are oriented for maximum field strength at the beginning of a mobile run. A GPS system and associated software can be used to determine the azimuth to the pertinent station to orient the receiving antenna. This is particularly useful when reflections cause ambiguous indications of the direction of the maximum. If GPS is not available, moving the vehicle can often change the effect of reflections and permit satisfactory orientation. In some cases, the direct signal can be maximized and orientation in the direction of the station achieved by orienting the antenna approximately in the direction of the station. A short mobile run can then be made to maximize signal strength. The antenna can then be "peaked" at location where the direct signal is strongest, and effects of reflections are minimal. In some cases, a reflected signal may be the maximum and orientation towards the station may not be appropriate.

Antenna Supporting Mast

The receiving antenna is ordinarily supported at a height of 2–9 m (approximately 6–30 ft) above ground, depending on the measuring technique employed. For the short heights, a simple mast of metal or plastic tubing can be used. For the standard 9 m (approximately 30 ft) height, a special pneumatic mast is normally used to raise and lower the antenna, and the mast arrangement should permit the vehicle to move over limited distances with the mast elevated.

The measuring unit shown in Figure 6.9-10 employs a telescoping mast typically constructed of aluminum tubing elevated by compressed air or nitrogen. The mast descends under gravity when the pressure is released. A handle inside the vehicle permits the mast to be rotated to orient the receiving antenna. Electronic news gathering (ENG) vans are normally equipped with a telescoping mast. Such masts may have tilt and pan heads that may be used for antenna orientation.

Operation with an elevated antenna involves a number of safety hazards posed by the measurement vehicle. Power lines are the principal overhead obstruction of concern. The avoidance of these hazards, equipment grounding and operation after encountering a hazard are discussed in Appendix A. These safety procedures were taken from the TASO Report[2] with minor modifications that update the procedures and description.

Recorder

For measurements made with the vehicle in motion, a chart or digital recorder is employed. A chart recorder can be driven from the vehicle speedometer or a clock drive motor. Excitation of the recorder is provided by a dc amplifier, which usually is built into the field strength meter or may be a separate accessory.

When the chart recorder is employed, the recorder pen element must be calibrated against the receiver output indicator of the field strength meter. The dc recorder is adjusted for balance at the ends of the meter scale, and a calibration curve is prepared for intermediate values.

Instead of a chart recorder, an analog-to-digital (A/D) converter can be used to sample field strength to permit computerized analysis of the measured data. A/D converters are available off-the-shelf enable the user to set the sample rate and generate recorded values. Portable laptop computers can be used to store and process the measurement data from the converter. Software can be included to analyze the data from a run to report the statistics of the run. The rate should be set sufficiently high so that the median, minimum, maximum and variance of the run data can be determined with precision.

Ideally, sample rate is a function of the frequency of the signal being measured. For reflection from a single source, the shortest wavelength of a standing wave is one-half of the actual wavelength. To provide reconstruction of the wave pattern to determine maxima and minima, a minimum of two samples per standing wave should be taken. For example, if channel 69 (the worst case) is measured the wavelength is approximately 1.2 ft (approximately 37 cm) and a sample should be taken every 0.3 (9 cm) ft or less (2.4 km per hour or 67 cm per second). Thus, if a vehicle travels at 1.5 miles per hour or 2.2 ft per second at least 7.3 samples per second should be taken. This is well within the capability of available A/D converters. However, the response time of field strength meters, including the recorder output, may be relatively slow which is not a problem when using chart recorders. Thus, increasing sample rate cannot compensate for excessive vehicle speed. To make matters worse, multiple reflections will tend to decrease the wavelength of standing waves. The worst case occurs when the field strength does not contain a direct constant component and consists entirely of reflected components. For an infinite number of reflections the resultant field is Rayleigh distributed. TV signals are not normally Rayleigh distributed, particularly for low VHF when an elevated antenna is used. There is a strong constant component of field strength so that field strength follows a Ricean distribution. Ideally, more study needs to be done to specify recommended sampling rates.

The issue of length of the mobile run arises naturally from the foregoing discussion of sample rate. The 100 ft (30.5 m) length of the rules is an arbitrary value developed originally by TASO. In some cases, it may be too short to determine the local median, let alone maximum and minimum values. The rules specify the length as of *at least* 30.5 m (100 ft) (emphasis added). Thus, it is important when writing test protocols not to limit the run length to 100 ft (30.5 m). With a chart recorder or other graphic display, the engineer can observe the recordings. With an A/D converter a running average can be reported so that the engineer can determine if the average is stabilized and is not significantly increasing or decreasing. If the average has not stabilized run length should be increased, if feasible. In some cases on a 100 ft (30.5 m) there will not be even one cycle of the local standing wave and thus the run should be extended if feasible. Usually such cases are at low VHF where the standard deviation is low and there is inherently more certainty regarding the data. Often, more cycles of the standing wave pattern can be observed when running toward or away from the transmitting site. A run oriented directly toward or away from the transmitting site should be used when feasible. The length of a run to determine a local mean was determined for Rayleigh distributed signal (worst case) for mobile radio signals.[29] For an error of ± 1 dB, a run length of 40 wavelengths is required. This criterion is only met for 100 ft (30.5 m) runs for frequencies in the UHF band. Application of this criteria to Channel 2 implies that a run length of approximately 700 ft (approximately .2 km) should be used. TV signals do not normally have a Raleigh, but rather a Ricean distribution as discussed above. In addition, the standard deviation of measurements of low VHF signals is less than that of mobile signals. Although the 700 ft (approximately .2 km) value is an overestimation, more study is required to determine minimum length for mobile runs. In summary, runs should be at as low a speed as is practical, should be as long as feasible, considering safety of the personnel and the observed data and should employ a high sample rate.

Power Supplies

The power drain of the measuring equipment can be fairly substantial, especially if much accessory equipment is employed. It is usually preferable to provide a power source for the measuring equipment separate from the vehicle battery. This may consist of a separate battery bank to operate the meter and accessories, or a separate 115 V ac alternator may be mounted in the vehicle. The latter is employed to operate the ancillary equipment shown in Figure 6.9-9.

DTV Equipment

Equipment such as antennas and transmission lines used to conduct DTV measurements are essentially the same as those employed in analog measurements. If field strength only is desired, analog field strength meters adjusted as described above may be used. Presently there is no equipment available designed expressly for DTV measurements, including field strength and other parameters.

Presently DTV measurements employ a vector signal analyzer, such as an Hewlett Packard type HP 89441A, to conduct measurements. This instrument permits both time and frequency domain measurements, as well as amplitude and phase measurements. S/N or noise threshold measurements may also be made, generally with an external noise source. This analyzer is relatively insensitive, and low noise amplifiers are generally used at the input to improve sensitivity. This instrument is extremely expensive and thus its use is not expected to be widespread.

MEASURING PROCEDURES AND TECHNIQUES

The FCC TV Technical Standards prescribe methods for making measurements to be submitted to the Commission. These or similar methods are also usually used in making other surveys such as measurements of station coverage. Variations from the official procedure are frequently introduced, some of these variations are discussed under earlier headings. The following paragraphs summarize the present requirements of the Commission's Standards.

The individual measurements consist of short mobile runs (at least 30 m (approximately 100 ft) along the road) at each location so chosen, with the receiving antenna at the 9 m (approximately 30 ft) height. If measurements are made on multiple stations for comparison purposes, it is desirable to mark the beginning or end points for each run to ensure that the run is made over identical paths on each channel. Before making the measurement run, the gain of the field strength meter is adjusted according to the calibration procedure for the meter that is used. The recorder output of the meter may also be checked to verify that the meter and chart recorder or A/D converter are functioning properly.

The chart or other recorder is used to record the field strength meter output, and the median, minimum and maximum values of the field for each recording are determined from the recording. When using a chart recorder precise determination of the median is usually made after completion of the survey. It is also useful to use the meter's calibrating oscillator to make a trace of an estimated median value on the chart paper after each run. The median of the run is estimated and the output of a precision attenuator may be adjusted to the estimated median. This provides an additional calibration check and permits a rapid preliminary calculation of field strength that is often useful to monitor the progress of a survey. Thus, if measured values out of the expected range are obtained, the engineer may cease taking measurements and thoroughly check the measurement system.

Figure 6.9-11 shows a sample of a typical chart recording obtained by this method. Certain field strength meters do not include built-in adjustable attenuators such as shown in Figure 6.9-8; however, there is usually an oscillator output which may be fed through an external attenuator to the input to achieve this calibration. The median, maximum and minimum values from the chart are then converted to received field strength by combining the individual calibrations of the antenna, transmission line, field strength meter, dc amplifier and chart recorder as discussed above.

When using an A/D converter to yield digital records, software may be developed to permit such checks after each run so that measured minimum, maximum and median field strength are known during the survey.

FCC Standard Method For the Collection of Propagation Data

The following discussion summarizes the FCC procedure in making field strength measurements for propagation studies. The forms for recording and submission of data and other technical requirements are presented in Section 73.686(b) of the Rules.

The Commission's Technical Standards require field strength measurement surveys to be made with mobile equipment along at least eight radial lines from the transmitter. The radials need not be laid out along bearings separated by 45° (beginning with true North) as is standard for contour prediction. Measurements are required to be taken from 16 km (approximately 10 miles) in increments of 3 km (approximately 2

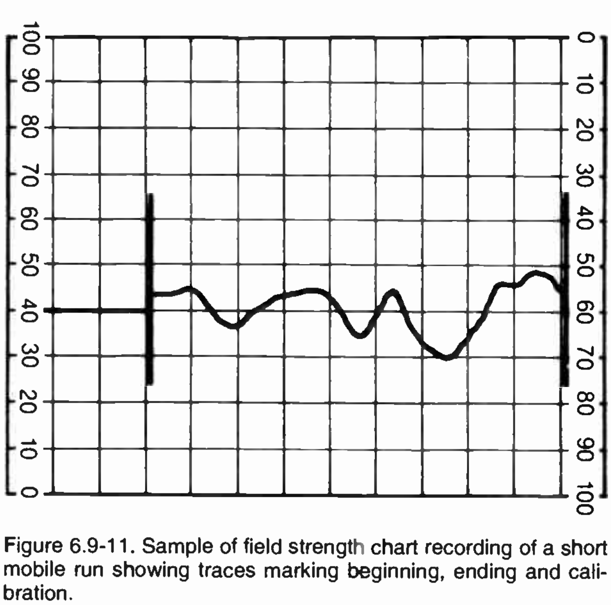

Figure 6.9-11. Sample of field strength chart recording of a short mobile run showing traces marking beginning, ending and calibration.

miles) in each direction. If it is desired to establish contour location, the distance should extend somewhat beyond the field strength contour which the engineer desires to establish. The routes are selected to encounter representative terrain and to permit interpolation between adjoining radials. A precise radial line is laid out from the transmitter on topographic maps to the distance to which measurements are to be made. Along this radial line, measuring locations are marked at exact 3 kilometer (approximately 2 mile) intervals, beginning at exactly 16 km (approximately 10 miles) from the transmitting antenna. The actual measurements are made precisely on the radial, at locations as close as possible to the exact 3 kilometer (approximately 2 mile) marks established as described. The ground elevation of the actual measurement location should be approximately the same as that of the intended location.

FCC STANDARD METHOD FOR MEASUREMENT OF COVERAGE OF COMMUNITIES

Section 73.686(c) of the FCC Rules describes the procedures for the measurement of service to specific communities for TV stations. These rules outline a measurement pattern that is in the form of a rectangular geographic grid overlying a map of the community. Measurements are made at locations as close as possible to the intersecting points on the grid.

The number of measurement points must be at least 15 or $0.1\sqrt{P}$ (whichever is greater) where P is the population of the community. Additional requirements describing documentation and calibration are contained in the rules.

The Rules also contain a statistical procedure to analyze field strength. This method fits the measurement data to a normal distribution and yields the median or average field strength in a community. The analysis may be graphical or numerical. This result is not completely compatible with other FCC Rules. The principal city coverage rules, either analog or digital, for example, are based upon the determination of the location of a coverage contour. This difficulty can be eliminated by using a grid that is not truly rectangular but consists of radials and orthogonal arcs. This plan permits both radial and grid analysis although there may be too few points on a radial for a good radial analysis. Since the resulting grid is not perfectly rectangular, use of this plan should be cleared with appropriate FCC personnel before undertaking measurements when the results will be filed with the Commission.

Practical Problems Encountered in Making Field Strength Surveys

Before any field strength measurement survey is undertaken, the radiated power of the transmitting installation must be established as closely as possible. The transmitter output power should be determined by means of the dummy load and maintained as closely as possible to the proper value throughout the survey. The radiated power is established from the measured transmitter output power, taking into account the antenna power gain and the transmission line and diplexer losses.

The use of a 9 m (approximately 30 ft) receiving antenna mounted on a vehicle in motion on a public right-of-way requires special permission from police or highway authorities in most states. These requirements vary among the individual states, but full details can be obtained from the state police or highway headquarters in the various state capitals.

The operation of such a 9 m (approximately 30 ft) mast presents safety hazards which require the exercise of utmost caution. In addition to proper grounding (discussed earlier) the TASO field strength measuring specification includes a special appendix (included here as Appendix B) dealing with overall safety requirements. When measurements are made with an elevated antenna, the need for caution must be borne in mind at all times.

Time Variation of Field Strength

Fairly substantial variations in field strength with time are frequently noted, particularly near and beyond the radio horizon, although significant variations occur at other distances.[10-12] These variations may be relatively rapid, occurring over a period of a few minutes, or slow variations may appear over periods of several hours. Field strength variations also follow diurnal patterns. There are also long term seasonal variations. In some areas during certain seasons there are cycles repeating over intervals of several days that apparently follow weather patterns. Average field strengths in the United States are usually lowest during winter afternoons, and higher than average fields may be observed during the evening hours and during summer. The variations in field strength with the passage of time must be taken into account in planning and making field strength coverage surveys.

The observed fluctuation of the field near the horizon is believed to be due principally to variations in the refractivity gradient of the lower atmosphere, which in turn is determined by the temperature, humidity and barometric pressure gradients. Measurements for coverage surveys should not be made during changing weather conditions or if weather fronts are known to be in the area.

The variations in field strength with time often result from causes which are not readily apparent and it is frequently difficult to determine whether typical propagation conditions prevail. One method that has been proposed and tried with some success is that of establishing fixed recording stations in one or more directions, at locations near the expected outer limit of the measurement program and recording the received signal over a period of several days or longer, if feasible. These recordings will give an indication of the signal to be expected under average conditions; the coverage survey measurements particularly near and beyond the horizon can be made during a period when recordings indicate propagation conditions to be typical. Measurements should not be made on days when these recordings indicate excessively high or excessively low field strengths. Measured data may be adjusted to reflect "average" conditions, although the adjustment factor would be a function of distance.

APPENDIX A DTV PLANNING FACTORS

System Independent Planning Factors Recommended by the Advisory Committee.

Planning Factor	Low VHF	High VHF	UHF
Geometric mean frequency (MHz)	69	194	615
Dipole Factor, dBm-dBu, $[K_d]$ (dB)	− 111.8	− 120.8	− 130.8
Thermal noise, $[N_t]$ (dBm)	− 106.2	− 106.2	− 106.2
Antenna Gain, $[G]$ (dB)	4	6	10
Download line Loss, $[L]$ (dB)	1*	2*	4*
Antenna minimum front to back ratio	10**	12**	14**
Receiver noise figure, $[N_r]$ (dB)	10	10	7
Time Probability factor, $[dT]$ (dB)	***	***	***
Location probability for 50% availability, $[dL]$ (dB)	0	0	0

* for 50 ft (15 m) of coax
** Ratio of forward gain to maximum response over rear 180° receiving antennas manufacturer's objectives are 14, 16, 20
*** The time probability factor is defined by the difference $F_{(50,10)}$ minus $F_{(50,50)}$; these two values are determined from the FCC charts in Section 73.699 of the Rules. This factor is a function of frequency band, distance and antenna height.

For the above quantities in [ ] and a required carrier to noise ratio of C_n, the required field strength (F) is then:

$$F = C_n - K_d + N_t - G + L + N_r + dT$$

APPENDIX B SAFETY

The following recommended safety precautions are based, in part, upon those developed by TASO for "Mobile Field Strength Measurements With Antennas Elevated 30 Feet Above Ground." When TASO formed, the field strength measurement procedure contained in the FCC Rules specified use of an antenna height of 10 ft (approximately 3 m) despite the fact that the 30 ft (approximately 9 m) standard for predicted fields was in the Rules. As discussed above, the field strength height gain factor for adjusting data from 10–30 ft (approximately 3–9 m) is not constant. Accordingly, TASO decided to use a 30 ft (approximately 9 m) height and a series of surveys were begun. It became apparent after a series of unfortunate accidents that the measuring of field strength at television frequencies can also be extremely dangerous where observations, especially mobile, are made at the 30 ft (approximately 9 m) level. The danger here is not with the field strength measuring equipment but with contact with primary electrical power circuits and, to a lesser extent, potential traffic hazards. In view of the dangers associated with field strength measuring, there are certain precautions that must be taken in addition to the specific precautions included within this memo for safety in operation of the field strength measuring vehicle. These general precautions include:

- Never take chances
- Always have two qualified, trained people present during measurement surveys
- Do not service or work on equipment when the power is turned on
- Never work on electrical equipment containing high voltages unless there are at least two persons present
- To reduce the risk of lethal currents across the heart, keep one hand in a pocket at all times
- Everyone who has occasion to work in the field on measurement programs should have a knowledge of a current certification in the best methods of artificial respiration and CPR.

Measurement Vehicle Construction Safety Considerations

Since it is possible that the mast or antenna of the measuring vehicle may come in contact with extremely high voltages, the construction of the vehicle should be such as to reduce to the absolute minimum the possibility of lethal differences of potential or voltages within the vehicle. The secure electrical bonds referred to herein must be made with a view towards the hundreds or thousands of amperes that may be involved in the event of an accident.

- All antenna elements which are directly connected to the transmission line must have a secure electrical bond to the mast, and the mast must be bonded to the vehicle chassis
- The outer conductor of all transmission lines used with the mast must have a secure electrical bond to the top of the mast
- The vehicle shall be equipped with appropriate warning lights to be operated when the mast is elevated
- The outer conductor of all transmission lines must have a secure electrical bond to the vehicle as soon after entering the vehicle as possible
- All electrical equipment (field strength meters, recorders, receivers, and signal generators) must have secure electrical bonding to the vehicle chassis
- The vehicle shall be equipped with a light readily visible to the vehicle driver which indicates that the mast is under pressure or elevated
- The vehicle should have a window in the roof to allow the driver or engineer, to view the mast and antenna.

The vehicle shall also be supplied with certain safety equipment, as follows:

- A pair of high voltage rubber gloves with protecting leather gauntlets. The rubber gloves should be tested at least once a year and a memo including the date of test and the testing organization included in the carrying box for the gloves. All major power companies have provision for making these tests
- A nonmetallic safety pole 8 ft (approximately 2 m) minimum for handling hot wires
- An appropriate fire extinguisher, preferably Halon, for Class A, B and C fires. This should be checked in accordance with the manufacturer's instructions.

Operational Safety Precautions

The foregoing equipment safety precautions are intended to enhance operator safety in the event of an accident. These precautions will only be effective as long as the equipment is in good working condition. Therefore, it is important that all safety precautions outlined in the foregoing paragraph be checked each morning before beginning the day's work. The following procedures apply when the mast will be elevated:

- Measurements at night with the mast elevated should not be permitted. In addition, the mast should not be raised during periods of poor visibility; small diameter power lines are often difficult to see. Although the authors believe that work at night and under other poor visibility conditions should not be permitted, TASO permitted night work under certain circumstances. The precautions were: No night work is permitted without prior written approval. If permission is given, it will include additional detailed precautions for the specific job for which approval is given. Prior to approving night work, the specific measurement locations must be surveyed during daytime hours for potential hazards
- The mast must not be elevated unless two operators are present
- The location for elevating the mast must be carefully chosen, both to prevent contact with overhead obstructions and to avoid being a traffic hazard. The mast must not be elevated on busy urban streets or heavily traveled rural highways. The chosen area must be reasonably level and, if a mobile run is contemplated, the vehicle must traverse the path before the mast is raised
- After selecting the location for measuring, the following procedure shall be used for elevating the mast. The driver and the engineer will both step out of the vehicle and examine the overhead area for obstructions. The engineer may then return to the vehicle and elevate the mast. If a mobile run is to be made, the driver must walk ahead, examining the path for overhead obstructions and leave a marker at the end of the chosen path. If repeated measurements are to be made along the same path, the starting point should also be marked so that neither end of the examined path is passed. The vehicle may then be driven between the markers
- When the measurements are completed, the driver shall, without stepping out of the vehicle, determine that the overhead area is free for the lowering of the mast. The driver must also make a personal observation that the mast has been fully retracted before driving to the next measuring area.

Emergency Procedure

If the procedures outlined here for the safe operation of field strength measuring are followed, there should be no need for emergency procedures. However, the authors felt it worthwhile to outline some emergency procedures to be followed in the event of some unforeseen accident involving overhead obstructions. Observe the following precautions:

- The obstruction with which you are entangled may carry high voltage
- The vehicle you are in may be at a high potential with respect to ground, so stop and think
- Under no circumstances should the transmission line (associated with the field strength measuring gear) be touched. The grounding connections may have broken due to mechanical strain or have burned up due to extremely high currents
- Without leaving the vehicle, study your predicament carefully to determine your best course of action. It may be one of the following:

  a. Backing the vehicle up
  b. Driving the vehicle ahead
  c. Lowering the mast
  d. Raising the mast further
  e. Getting away from the vehicle

Whatever you do, remember the vehicle may be at a high potential with respect to ground. Do not take chances. Jump clear. Be sure no one else approaches the scene or comes in contact with the vehicle.

ACKNOWLEDGMENT

The assistance of present and former associates Howard T. Head, J. M. Bixby and Eric-Paul Bomgren in preparation of this article, particularly this edition, is sincerely appreciated.

AUTHOR'S NOTE

Much of the present knowledge of wave propagation in these frequency bands has been derived from field strength coverage surveys on operational television stations. The information gained from these commercial coverage surveys has added to the body of scientific knowledge, but field strength measurement surveys employing special techniques are often needed to supply data for special problems. Examples of such special techniques are discussed under other headings in this article. It is better to design a program to measure specific factors, foliage loss for example, than to use general coverage measurements in an attempt to achieve the desired goal.

6.10
FIBER OPTIC TRANSMISSION SYSTEMS FOR BROADCASTING[1]

C. ROBERT (BOB) PAULSON
OMNIMEDIA® COMMUNICATION, WESTBOROUGH, MA

LIGHTWAVE SYSTEM DESIGN AND PRINCIPLE OF OPERATION

Signal transmission through either wired or wireless transmission media is accomplished by conditioning the input information signal to make it compatible with the characteristics of the transmission medium. The simplest system (Figure 6.10-1) transmits analog or digital electrical signals at *baseband* (the original signal waveform itself), typically through a copper based one or two-wire circuit. The input electrical signal amplifier on the receive end may contain an *equalizer* which changes received signal amplitude and/or phase as a function of frequency to compensate for the attenuation characteristics of the copper transmission medium (twisted pair of wires or coaxial cable).

A *modulator* is required to transmit signals electromagnetically through space, or through a glass or plastic fiber. Changes in the input signal amplitude are used to vary the amplitude, frequency or phase of a radio frequency carrier, or used to vary a light source's output intensity around a mid-level brightness (see Figure 6.10-1). Propagation of this light source into free space, or through light conductors, such as fiber optic material, follows essentially the same laws which describe the propagation of radio frequency electromagnetic radiation from radio wave antennas.

Signal transmission using fiber optic technology is accomplished by varying the flow of photons in a transparent optical fiber (typically smaller in diameter than a human hair), rather than the amplitude and frequency of radio waves in free space or the electrons in a copper wire. A basic fiber optic transmission system (Figure 6.10-2) consists of an optical transmitter terminal, a fiber circuit which can range in length from a short patch cord to up to 50 km of tandem fiber sections and an optical receiver terminal.

Design efficacy of a fiber optic transmission system is characterized by its ability to maximize the amount of light coupled into, propagated through, and coupled out of the fiber.

Semiconductors designed as optical transmission system light sources emit light energy in the infrared/visible light regions of the electromagnetic spectrum (see Figure 6.10- 3). At the transmitter terminal light source output, a tiny lens focuses its diverging light rays into glass fiber conductor (also called an *optical waveguide*). The signal carrier is essentially a monochromatic (or *single wavelength*) light source.

Inputs to the optical transmitter can be anything from analog sound (bandlimited to 25 kHz) to moving images with bandwidth up to 3 GHz and beyond. When digitized, the input signals' binary digital representations range from 56 kbps to 3 Gbps and beyond. The voltage modulating the light source may consist of one analog or digital electrical input, or many individual signals multiplexed together. The optical transmitter driver contains electronic processing circuit modules to condition (preemphasize) the input signal, and is followed by an *electrical* to *optical* (E/O) *transducer,* a complex, solid-state semiconductor device which converts electrical input energy into optical energy. Preemphasis is done to maximize system end-to-end performance. The unmodulated optical source output intensity (power) of the transmitter is expressed in dBm (decibels referred to 1 milliwatt of power) and is typically in the range from 0 to -30 dBm.

The group of optical rays delivered into the fiber constitutes the (intensity modulated) *carrier* of the information. The exact characteristics of these light rays propagated through a fiber are determined by the size and construction of the fiber. Maxwell's equations show that light does not travel randomly through a fiber; rather, it is channeled into *modes.* A mode is the path of one ray of a discrete wavelength through a fiber.

At the receive end, the attenuated intensity-varying light emitted from the fiber is focused onto a solid-state photo detector (photodiode) which transduces the light intensity variations back into an electrical signal. Typical threshold sensitivity of photodiodes (the input power level below which it can not differentiate the light signal from its own internal noise) is in the range of -25 to -35 dBm. Then, subsequent circuit components amplify, demodulate, reequalize and/or reconstruct the signal into its original form. These receiver terminal components are the complement of the transmitter's electrical input modules.

Conversion of an *electrical domain* input signal to an *optical domain* output signal is a complex process. Simply described, electron flow into the semiconductor causes a loss of input *bandgap energy,* which is released from the top surface of the semiconductor or at an edge as a steady state light at about 50% of maximum intensity.

[1] Some of the historical material in this chapter first appeared as Chapter 4.4 in the *NAB Handbook Seventh Edition*, authored by Pete Mountanos.

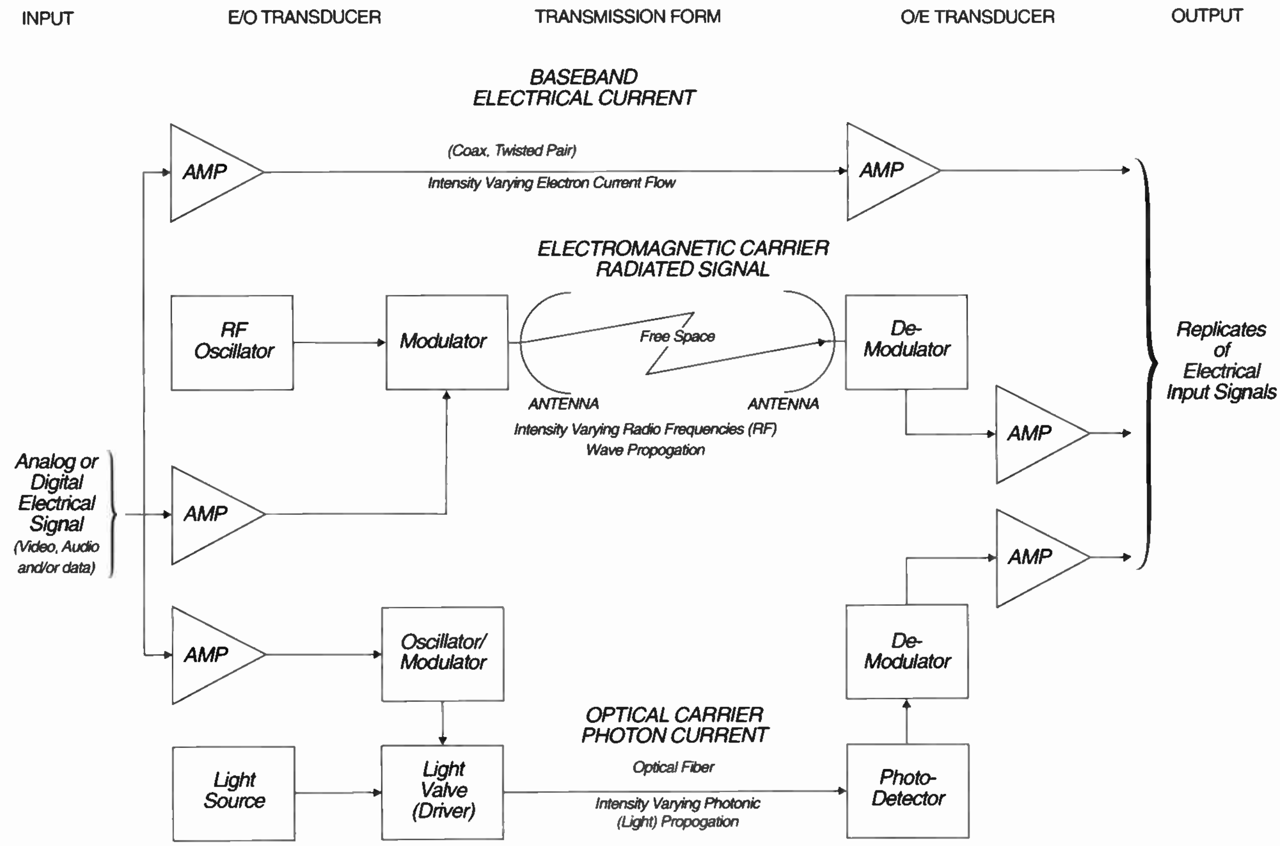

Figure 6.10-1. Means of electrical signal transmission.

Information carried as a time varying analog signal or a binary digital signal is processed into an electrical current flow, which time varies or switches the steady state electron current magnitude symmetrically above and below that value. This produces a corresponding intensity variation of the light output. However, the transducing process is not linear (see Figure 6.10-4). Therefore, the amplitude of the input electrical signal is processed by a limiter to prevent driving the output intensity into the nonlinear extremes of this transfer characteristic curve. This conservative approach limits intermodulation distortion (IMD) that would otherwise occur, but also establishes a maximum bound on signal-to-noise ratio (SNR) of the fiber system.

Light Propagation Fundamentals

Frequencies of light used in fiber optic transmission are in the range of 300–400 THz (10 × E14), several orders of magnitude higher on the electromagnetic frequency scale than the highest frequency radio waves (see Figure 6.10-3). Light waves are more commonly described in terms of wavelength (expressed in nano-

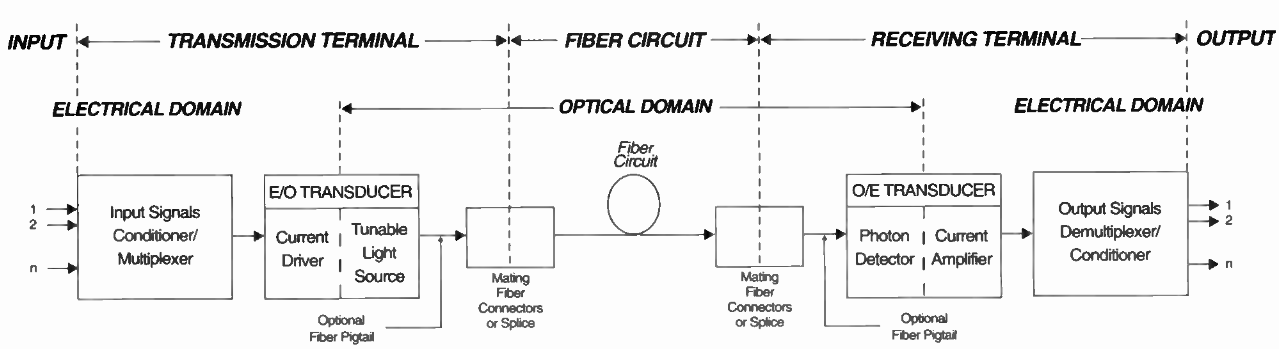

Figure 6.10-2. Terminal components in point-to-point (p-p) fiber transmission circuit.

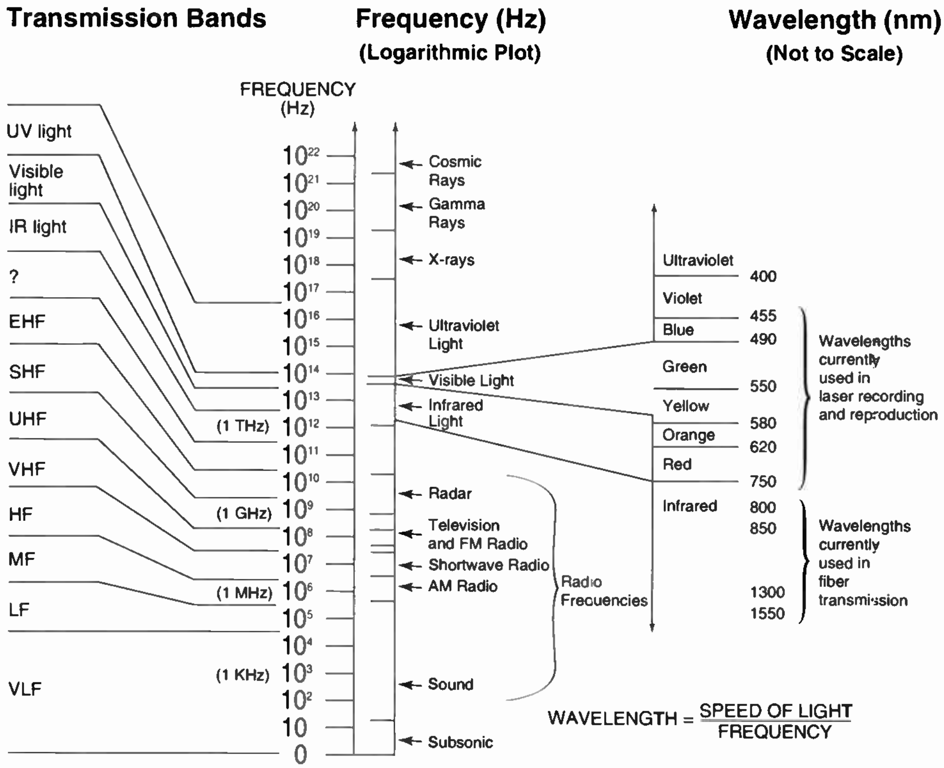

Figure 6.10-3. Electromagnetic spectrum (IR, visible and UV light spectra expanded). *(Adapted from AMP, Inc. Illustration with permission.)*

meters) rather than frequency. The region extending from 800–1600 nm is of greatest interest because today's glass fiber formulations propagate these wavelengths most efficiently (see Figure 6.10-5).

The speed (velocity) of light and all other higher and lower (electromagnetic) frequencies in free space is 300,000 km/sec. Light travels at measurably slower

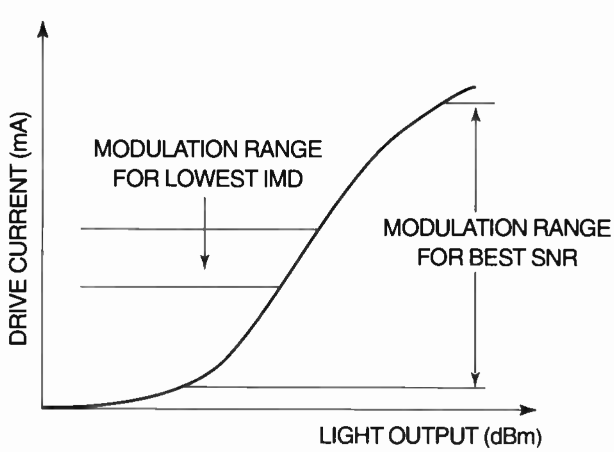

Figure 6.10-4. Drive current/light transfer characteristic of photodiode. A restricted modulation index is necessary when employing analog modulation techniques, to limit harmonic and intermodulation distortion products.

velocities in gas and solid media such as optical glass fibers. Each light wavelength propagates at different velocities in each medium (see Figure 6.10-6). When an electromagnetic wave crosses the boundary between one medium and any other, its propagation velocity changes. This is manifested as either a change in the direction (refraction) or reflection of the light wave.

The index of refraction "n" is a dimensionless number expressing the ratio of the velocity of light in free space (c) to its velocity in a specific medium (v)

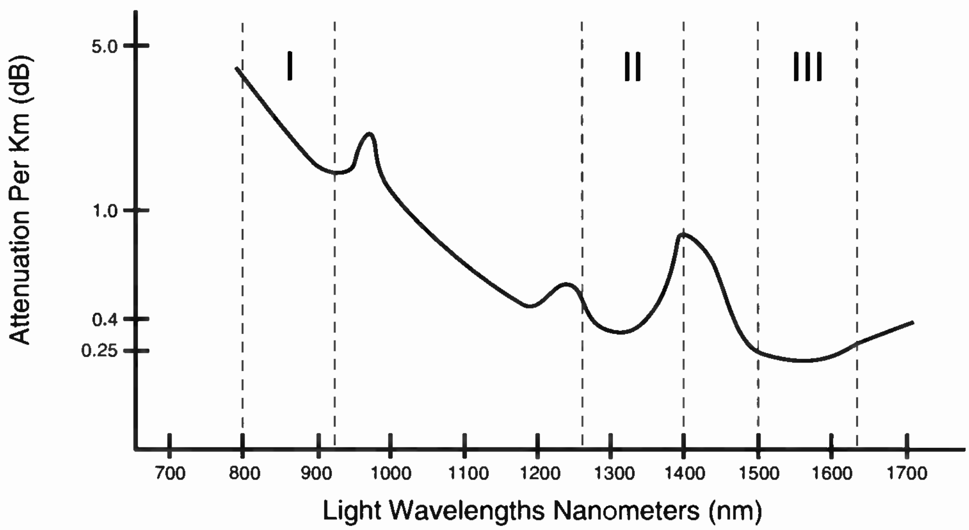
$$n = c/v$$

The magnitude of refraction of a ray of light as it passes from one material to another depends on the magnitudes (n_1 and n_2) of the refractive indices of the two materials (see Figure 6.10-7—reference normal is the line perpendicular to the interface of the materials). The angle of incidence is the included angle between the incoming ray and normal, and the angle of refraction the included angle between normal and the refracted ray. At small incidence angles, most of the light passes across the boundary and the transmitted ray is refracted away from the normal. As the angle of incidence increases to a *critical angle*, the angle of refraction is 90° from normal. For angles larger than the critical angle, the light is totally internally reflected (see Figure 6.10-7(c) and Figure 6.10-8).

A. Defacto Standard Light Wavelengths (Nanometers-nm)

Nominal Spectrum (nm)	Window	Fiber Types	
		MULTIMODE	SINGLEMODE
850 ± 30 *Short Wavelength*	I	X	
1300 ± 30 *Long Wavelength*	II	X	X
1550 ± 30 *Extra Long Wavelength*	III		X

B. Fiber attenuation versus light wavelength characteristics



C. Typical optical fiber attenuation ranges

Fiber		Optical Loss (dB/km)			
SIZE	TYPE	780 nm	850 nm	1300 nm	1550 nm
9/125 µm	**S M**	3.0	**2.5**	0.5 - 0.8	**0.2 - 0.4**
50/125 µm	**M M**	3.5 - 7.0	**2.5 - 6.0**	0.7 - 4.0	**0.6 - 3.5**
62.5/125 µm	**M M**	4.0 - 8.0	**3.0 - 7.0**	1.0 - 4.0	**1.0 - 4.0**

200/230 µm	**M M**		**1 2**		

Figure 6.10-5. Fiber attenuation versus light wavelength characteristics. Attenuation per unit length continues to be reduced steadily, through improved fiber drawing techniques and reduction in impurities. It is now approaching the theoretical limits of silica-based glass at the 1300 and 1500 nm wavelengths.

Medium	Refraction index	Propagation time (ns/m)
Vacuum	1.0	3.333
Air	1.003 (rounded to 1)	3.334
Water	1.33	4.444
Fused quartz	1.46	4.860
Glass	1.5	5.014
Diamond	2.0	6.686
Silicon	3.4	11.366
Gallium Arsenide	3.6	12.034

Figure 6.10-6. Typical indices of refraction. Although the index is measurably affected by light wavelength, the influence of wavelength on the index in optical fibers is small enough to be ignored in determining them. *(Table created by integrating copyright information from AMP, Inc. and Force, Inc. publications, with their permission.)*

Numerical aperture (NA) is a measure of the amount of light source output coupled into the fiber:

$$NA = (n_1^2 - n_2^2)^{1/2}$$

Note that the NA's magnitude is determined by the magnitude of the difference of two indices of refraction—the *core* index and the *cladding* index.

The figurative circular *acceptance cone* (ϕ) of the fiber (Figure 6.10-9) is derived from the numerical aperture:

$$\phi = \sin^{-1} NA$$

Larger cones gather more light from rays entering at larger angles, but suffer from higher modal dispersion. The converse is true for smaller acceptance cones. Lower NAs generally translate to a higher *fiber bandwidth.* (The optimum NA for long distance transmission of broadband television signals is about 0.2.)

Optical Fiber Propagation Fundamentals

Fiber Construction Basics

An optical fiber has three concentric components, the *core, cladding* and *buffer* (see Figure 6.10-10). The innermost core is the light conductor. It accepts the light source rays directed into it by the light source lens. Since these rays were independently diverging as they entered the lens, they will converge into the fiber at all angles within an acceptance cone (see Figure 6.10-8) determined by the critical angle (see Figure 6.10-6). The surrounding cladding reflects light impacting its boundary at greater than the critical angle back into the core.

The buffer is the outer cylinder of light absorbing material surrounding the cladding. It may be a solid material bonded to the cladding (tight buffer), or a larger diameter opaque tube in which the fiber runs without tension (loose buffer). The interior of a loose buffer may be filled with an inert gas.

Fiber Types

Of the many ways to classify fibers, the most informative is by refractive index profile and number of modes accepted. The two main types of multimode fiber index profiles are *step* and *graded.* In a step index multimode fiber, the core has a uniform index with a step index change at its boundary with the cladding (see Figure 6.10-11). The lowest order mode travels down the center while higher order modes strike the core-cladding interface at angles above the critical angle. As a result, simultaneously departing angular rays progressively fall behind the first order ray as they propagate down the fiber. This spreading is called *modal dispersion.*

In a graded index multimode fiber (Figure 6.10-11) the core's index is not uniform; it is highest at the center and decreases until it reaches the cladding. This reduces modal dispersion, because the core is essentially a series of concentric rings with increasingly lower refractive indices. Since light travels faster in a lower index medium, light farther out from the fiber axis travels faster. Further, since high order modes have a faster average velocity than low order modes, all modes tend to arrive at a point at nearly the same time. Rays of light are not sharply reflected by the core-cladding interface, they are refracted successively by differing layers in the core.

Single-mode step index fiber has a very small diameter step index core, but has the same cladding diameter as the two most widely used multi-mode fibers (see Figure 6.10-11). Modal dispersion is eliminated by making the core small, typically 7 to 10 μ (1/6 the diameter of a human hair), rather than in excess of 50 μ. At this diameter, only the direct (parallel to the

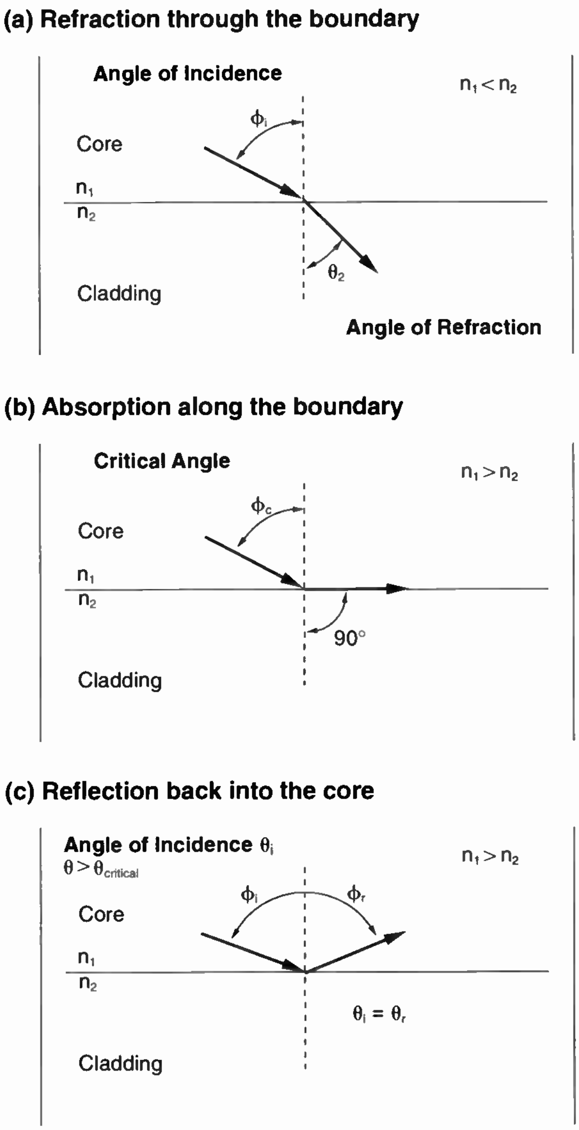

Figure 6.10-7. Lightwave refraction principles. The refraction index of the core n_1 is always less than that of the cladding n_2. Light incident on the boundary at less than the critical angle ϕ_i propagates through the boundary, but is refracted away from the normal to the boundary (a). At the critical angel ϕ_c, along the boundary (b). Light incident on the boundary at angles ϕ_i above the critical angle, is totally internally reflected (c). *(Adapted from Force, Inc. illustration with permission.)*

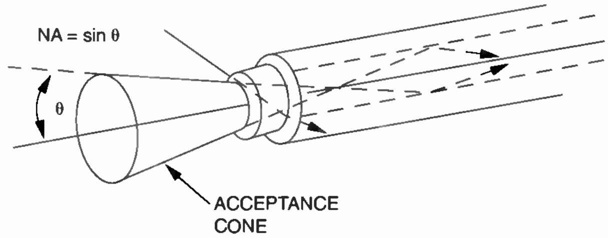

Figure 6.10-9. Light ray acceptance cone geometry. The acceptance cone is an imaginary right angle cone extending outward coaxially from the fiber's core. It is a measure of the light-gathering capability of a fiber. Its ray acceptance angle, called the Numerical Aperture (NA) of the fiber is uniquely determined by the refractive indices of that fiber's core and cladding. *(AMP, Inc. copyright illustration, used by permission.)*

fiber axis) mode is propagated. The single-mode of propagation is appropriate for long distance transmission of high bandwidth signals.

Refraction Index Ratio and Numerical Aperture Relationships

To maximize reflection of bounce-propagating rays, the cladding's index of refraction must be measurably lower than the typical core value of approximately 1.5 (compared to air's 1.003) (see Figure 6.10-12). Decreasing the cladding's index toward 1.40 dramatically increases the fiber's NA, therefore widening the acceptance cone angle and increasing the allowable input power level. On the other hand, this will cause the signal exiting the fiber to have substantially increased modal dispersion.

Fiber Choices

Three designs of optical fiber are now used in the telecommunications industry for broadband signal transmission (see Figure 6.10-13). It is difficult to identify a single best choice, when all performance parameters of all design options are considered.

Multi-mode 50 μm core fiber was the first commercially available in the 1980s. It is no longer installed in common carrier networks, but is popular for private installations because it is easy to terminate and its bandwidth distance product is adequate for some short distance broadband signal transport needs.

Multi-mode 62.5 μm core fiber was originally developed by AT&T because there was less need for precision termination, it had less attenuation, and it would

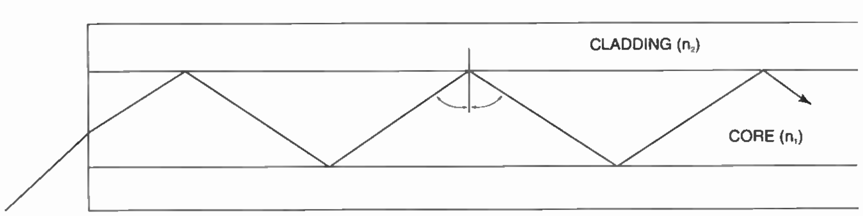

Figure 6.10-8. Total internal reflection. Rays of light incident on the core/cladding boundary at greater than the critical angel, determined by the quotient n_1/n_2, propagate down the fiber's core at a velocity determined by that fiber's value. (See Figures 6.10-6 and 6.10-7.) One ray is shown to keep the diagram simple. (See Figures 6.10-11 and 6.10-12.) *(AMP, Inc. copyright illustration, used by permission.)*

accept substantially higher light power inputs than would 50 μm fiber. These attributes somewhat offset its 50% lower bandwidth-distance product.

Single-mode fiber became the medium of choice for telecommunications industry use when it became widely available in the late 1980s. Its nominal 9 μm core eliminates distance limitations imposed by modal dispersion, the narrower spectral width lasers which it accommodates reduce chromatic dispersion and the order of magnitude bandwidth distance product increase (with respect to 50 μm fiber) far offsets the increased precision needed for termination.

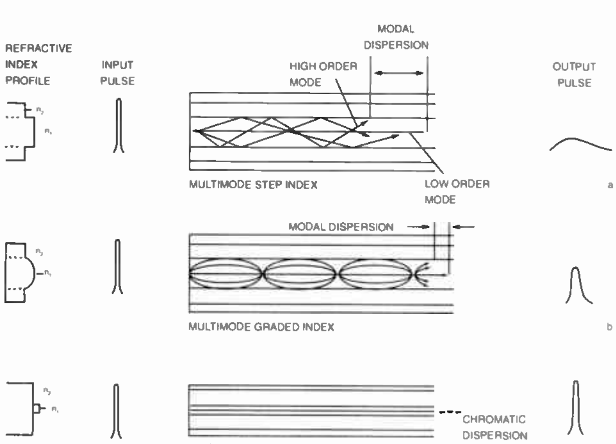

Figure 6.10-11. Optical fiber types. The core diameter and its refractive index characteristics determine the light propagation path or paths within the fiber's core. *(AMP, Inc. copyright illustration, used by permission.)*

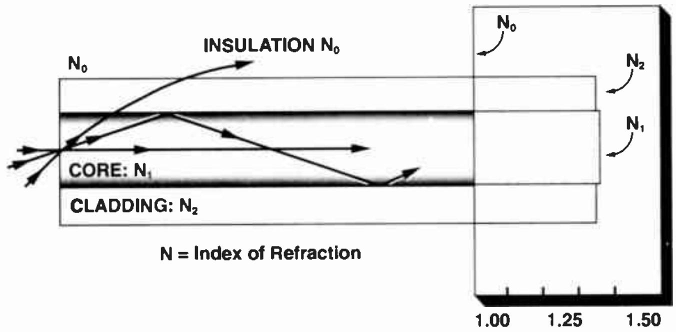
Attenuation

Loss of power (attenuation) during light propagation in a fiber is due to: light absorption resulting from impurities in the core and propagation paths in the cladding and scattering (reflection in the core) caused by impurities in the light path. Fiber attenuation from both causes is specified in decibels per kilometer. For commercially available fibers, attenuation ranges from under 0.5 dB/km for premium single-mode fibers to 1000 dB/km for large core plastic fibers. (Since emitted light is expressed as a power quantity, ±3 dB as a power quantity represents a doubling or halving of any reference power level.) Refer to fiber vendors' catalogs exact absorption and scattering loss figures for specific products.

Attenuation and light wavelength are also uniquely related in fiber transmission systems (see Figure 6.10-5). Most fibers have medium loss values (3 to 5 dB/km) in the 800–900 nm wavelength range, low loss values (0.6–1.5 dB/km) in the 1,150–1,350 nm range, and very low loss values (less than 0.5 dB/km) in the 1,550 nm range. (These wavelength ranges are known as Windows I, II and III, respectively). Optimum fiber circuit performance is achieved by choosing the fiber type and light source wavelength as a function of required bandwidth and transmission distance.

Dispersion

Dispersion in fiber transmission systems produces effects analogous to pulse flattening caused by high frequency attenuation in copper cable, as illustrated in Figure 6.10-14. It is the limiting factor in determining the bandwidth of a fiber circuit, and is most easily



n_2	MATERIAL NA	ACCEPTANCE CONE HALF ANGLE	ACCEPTANCE CONE FULL ANGLE
1.40	.538	32.6	65.2
1.41	.512	30.8	61.6
1.42	.483	28.9	57.8
1.43	.453	26.9	53.8
1.44	.420	24.8	49.7
1.45	.384	22.6	45.2
1.46	.344	20.1	40.2
1.47	.298	17.4	34.7
1.48	.244	14.1	28.3
1.49	.173	9.9	19.9

Figure 6.10-12. Cladding reflective index n_2 influences on NA and acceptance angle of step index MultiMode fiber. The core refractive index n_1 is specified at 1.5. Insulating material (N_0) surrounding cladding absorbs light refracted through the cladding/insulation boundary. *(Illustration created by integrating copyright information from AMP, Inc. and Force, inc. publications, with their permission.)*

understood by examining the propagation of a precise square wave pulse train at the fiber input. As this pulse train propagates down the fiber, each pulse will first become wider and more round-shouldered. Eventually, all the pulses will flatten down to a series of wavering crests indistinguishable from each other.

Modal dispersion in multi-mode fiber is quantified by the spread of ray arrival times, caused by the different path lengths traveled by bouncing rays (as depicted in Figure 6.10-11). These rays may individually be at different wavelengths, but this is of little consequence in multi-mode fiber transmission.

Chromatic dispersion in single-mode fiber is due to the fact that solid-state light sources are not *mono chromatic* (do not emit light of a single wavelength). As previously mentioned, the propagation velocity of light varies directly with its wavelength. The magnitude of chromatic dispersion is a function of both the light source's *spectral bandwidth* and the circuit length. A special class of long wavelength distributed feedback (DFB) lasers with a narrow output spectrum is now available for propagation of information on single mode fibers over 50 km or more.

Bandwidth-Distance Products

Dispersion effects, and length of a given fiber transmission circuit combine to uniquely define the bandwidth or information carrying capacity of a fiber. This situation has no equivalent analog in electrical signal transmission theory. The quantification of this performance parameter is a multiplication product called the *bandwidth-distance product,* expressed in megahertz/kilometers, and serves as a numerical figure of merit for a fiber (see Figure 6.10-13).

Again, using the propagation of a pulse as an example is helpful. Fourier theory establishes that a precisely square cornered pulse consists of a fundamental frequency plus an infinite series of in-phase odd harmonics. Square wave pulse train flattening in fiber transmission, caused by modal or chromatic dispersion, is analagous to pulse train flattening in copper transmission caused by circuit capacitance.

High rate data streams are essentially streams of short pulses. By the bandwidth distance concept, it is obvious that for a given fiber, bit rates must be slower when the data stream must travel longer distances. When the direct rays representing the leading edge of bit "n" in a stream arrive before the last reflected rays representing the trailing edge of bit "n − 1," bit errors will occur and the delivered signal is likely to contain little or no recoverable information. Dispersion phenomena must therefore be considered when choosing a fiber type, so that the bit stream to be transmitted over a given circuit length will not arrive with unrecoverable bit errors.

In choosing a fiber type for installation in a given transmission circuit, the product of the bandwidth (in MHz) to be transmitted and the length of the optical

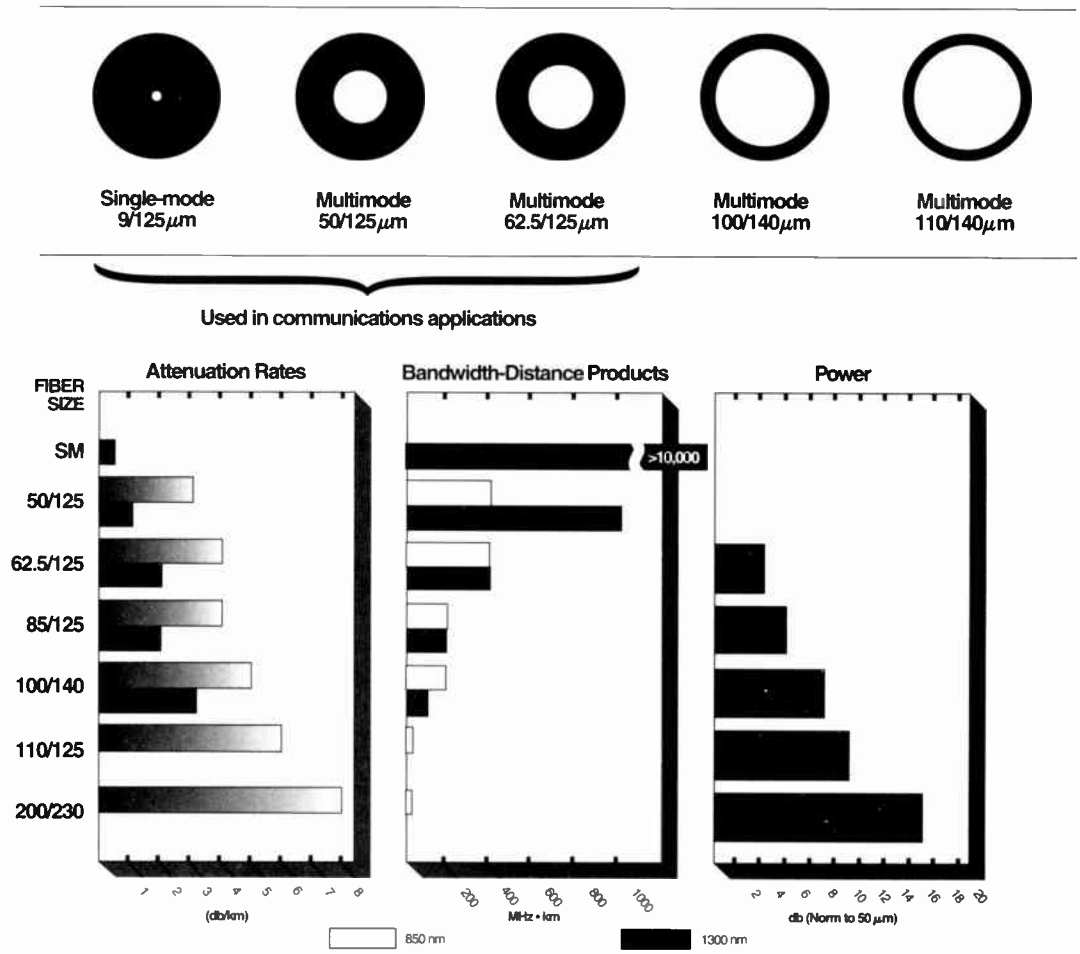


Figure 6.10-13. Popular fiber sizes. Attenuation per unit length, bandwidth distance products, and power handling capabilities are determined by the magnitude of the core diameter and the core's material and refractive index. *(Illustration created by combining Two Force, Inc. copyright illustrations, used by permission.)*

circuit (in km) must be less than the bandwidth-distance product figure of merit number (see Figure 6.10-13).

Fiber Transmission System Components

Optical sources in fiber communications transmission systems are either *light emitting diodes* (LEDs) or *injection laser diodes* (ILDs). The LED is a more incoherent source (it has a larger spectral bandwidth) than is an ILD. The LED is characterized by output power levels well below 0 dBm in the order of -10 to -30 dBm. It operates at slower speeds, because of the hysteresis (lag) of changes in light intensity to changes in input voltage (see Figure 6.10-4). However, its cost is considerably less than that of an ILD. It is quite suitable for applications requiring transmission across distances under 10 km and modulation bandwidths that accommodate data streams of less than 100 Mbps. LEDs operate in the 850 and 1300 nm windows.

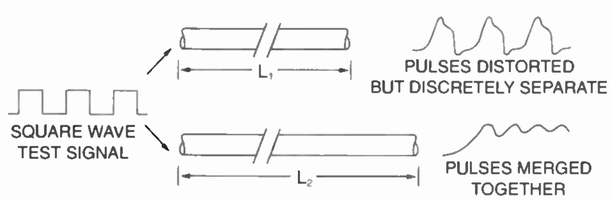

Figure 6.10-14. Lightwave pulse propagation principles. Modal and chromatic dispersion characteristics of a fiber determine the maximum frequency of modulating signal which can be recovered at the end of a fiber of any given length.

ILDs are capable of power outputs on the order of 0 dBm and higher. Upper power limits are a matter of device cost and permissible radiation levels. Although ILDs cost substantially more than LEDs, they operate in the 1300 and low attenuation 1550 nm windows. Their combination of low attenuation and high modulation frequency make them cost justifiable as sources in systems which must operate over extended distances, or which must transport large numbers of signals or both.

Selecting an optical source for a fiber transmission system requires a careful evaluation to insure that its modulation frequency limit is greater than the bandwidth to be transmitted, and that it provides enough optical power at the appropriate wavelength, to satisfy the distance requirement. Another important consideration is the fact that optical devices do not turn on with the linear characteristics of solid-state high speed gates (see Figure 6.10-4).

Light source cost factors are constantly changing, driven both by cost/demand volume relationships and manufacturing process refinements. Historically, low cost 850 nm devices were adequate for short distance transportation of narrowband signals. Today, 1,300 nm LED sources are popular because of their unit costs and lower attenuation figures. However, 1,300 nm lasers driving single-mode fiber have been standardized as components of choice in two SMPTE Standards—*SMPTE 292 M for 1.485 Gbps HDTV Signal Transmission* and *SMPTE 297 M for 143 Through 360 Mbps Digitized SDTV Signal Transmission.*

Both the telecommunications and the television industry are making increasing use of 1550 nm DFB lasers and single-mode fibers, both because laser prices are beginning to fall and dispersion-shifted fiber is becoming available.

Light Detectors

Light detectors perform a complementary function to light sources—converting incident optical energy to electrical energy. Detectors in fiber transmission systems are positive intrinsic negative (PIN) or avalanche photo diode (APD) semiconductors. The limiting sensitivity (threshold) in detecting weak incoming signals determines link performance.

In an ideal PIN diode, each incident photon creates an electron hole pair in the semiconductor lattice. This in turn sets one electron flowing in the external circuit. If the received light is weak, the generated current may not be strong enough to overcome the noise inherent in the diode and receiver circuit. In such cases, it is desirable to increase the detector output before processing by the receiver. Such amplification is generated in an avalanche photo diode. A reverse bias adds several electron volts of energy to each liberated electron to provide amplification of the received signal.

Repeaters

A fiber transmission circuit's maximum useful length is a function of six independent variables:

- Signal bandwidth to be transported
- Transmitter launch power
- Fiber, splice and connector pair attenuation
- Modal and chromatic dispersion characteristics
- Receiver threshold sensitivity
- Minimum end-to-end transmission circuit performance specifications set by the user.

Analog circuits 50 km long are now possible. Digital circuits equipped with bit error detection and correction overhead can operate for perhaps this distance and more.

The first generations of analog and digital repeaters developed to extend these transmission distances operated at electrical baseband. The repeater terminal is literally a receiver whose demodulator is hardwired to the modulator of a transmitter. This design is crudely equivalent to creating a long distance telephone circuit by holding the earpiece of one old-fashioned two-handed telephone to the mouthpiece of another.

Analog domain repetition in this fashion has a limit of four or five tandem sections and a transmission distance maximum of 150–200 km. Digital domain repeaters (regenerators) have no such limit, as long as bit errors are detected and corrected at each regenerator prior to retransmission.

Second generation repeaters operating entirely in the light domain have no direct equivalent in electrical signal transmission products (see Figure 6.10-15). Two signals are input to the passive coupler (an 8 m length of Erbium-doped fiber)—the 1,300 nm optical signal to be amplified and a 10–50 mW pump laser operating at 980 or 1490 nm. The photonic interaction of the pump laser with the optical carrier signal results in the synthesis of a new optical carrier with 20–30 dB higher power, modulated with the original information, but operating at a nominal 1550 nm wavelength.

This increase in wavelength (from 1,300–1,550 nm) presented a significant problem to longhaul common carriers with fiber networks optimized for 1,300 nm carrier transmission. Further research and development has resulted in equipment with amplified output carriers operating within the 1,300 nm window.

Switching

First generation fiber transmission circuit switchers operate at electrical baseband. Advantages of optical transmission and switching are not confined to broadband video image transmission, fortunately. Optical domain switching and interconnection of computer components is necessary to develop the next generation of super high speed, massively parallel number crunching engines. Efforts to develop optical switchers are underway in telecommunications and computer industry advance research labs.

First generation all-optical switchers will reach the market early in the next decade.

Video and Audio Signal Transmission Fundamentals

Information to be transported by optical fiber transmission systems may be modulated as amplitude mod-

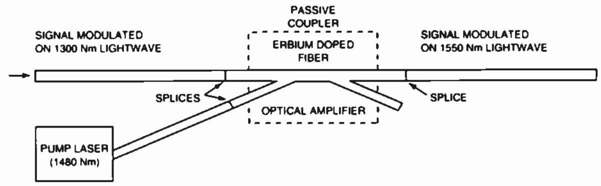

Figure 6.10-15. Block diagram of first generation optical amplifier (repeater).

ulation (AM), frequency modulation (FM) or digital pulse code modulation (PCM) waveforms.

Amplitude Modulation

AM is the simplest form of modulation. The instantaneous amplitude of the input signal directly controls the output intensity of the light source. For an NTSC standard video input signal, the *peak white* maximum amplitude results in maximum light intensity and the *tip-of-sync* the minimum. Because of the nonlinear transfer characteristic (see Figure 6.10-4) of LED sources, intermodulation distortion (IMD) is introduced into the fiber-borne video signal when such modulation characteristics are implemented. In addition, the Signal to Noise Ratio (SNR) of the signal is directly correlated to the optical power, and attenuation in a system lowers SNR directly. Further, since most optical devices do not completely *turn off* (particularly lasers) there is always an optical noise floor present. AM modulation technique is no longer used in the design of video broadcast signal transmission products.

Frequency Modulation

FM overcomes the SNR and IMD limitations of amplitude (intensity) modulation. FM requires more electronics, but removes the problems of signal quality from the optical domain to the electrical domain. For FM, ancillary audio and data signals are first multiplexed over the video baseband onto separate FM subcarriers. This video/audio signal group is then frequency modulated on a carrier in the 30 MHz range (and higher), to produce a single signal with a fixed amplitude excursion. Its value then modulates the light source over a linear portion of its range.

Required SNR and IMD performance specifications are achieved in the design of the frequency modulator.

Digital PCM

A fiber transmission system is most transparent when it is operated in a pulsed mode. It is therefore particularly complementary to signals which are presented to it as fixed amplitude FM or a digital bit stream. In telephony applications, the relatively narrow bandwidth of a single voice channel can be efficiently digitized and multiplexed with up to 10,000 + other similar channels on a single fiber. Received quality of a digitally transmitted voice channel is markedly better than analog, because of the complete absence of thermal noise, impulse noise and distortion endemic to analog transmission.

Electrical Driver Signal Multiplexing Techniques

Frequency Division Multiplexing (FDM)

The FDM *technique of combining multiple AM or FM* carriers is widely used in coaxial cable distribution based systems. Unfortunately, the nonlinearity of optical devices operated in the intensity modulation mode results in substantial and often unacceptable noise and intermodulation distortion in the delivered signal channel. Wide and selective spacing of carriers ameliorates this problem to some degree. Some FDM fiber transmission system specifications, although unacceptable to broadcasters for backhaul applications, nevertheless represent a gratifying improvement in video (and audio) signal quality delivered to cable system subscribers or transmitted in videoconferencing networks.

Digital Time Division Multiplexing (TDM)

Television signal group transmission systems of the 21st century will operate entirely in the digital domain. All the technology needed to create, process, store and transmit images in the digital domain has already been invented. The issues of when, why and how the day of all-digital operation will arrive are currently in the realms of politics and economics. When resolved, they will establish an environment which fosters and drives fast issuance of many needed standards.

Wavelength Division Multiplexing (WDM)

Multiplexing optical streams in the optical domain reduces the number of optical fibers required to meet any specific transmission requirement (see Figure 6.10-16). Multiple independent fiber transmission systems operating at different optical wavelengths can be transported over a single fiber as is, by combining them in a passive optical multiplexer. This is a simple product in which optical feeds from multiple optical transmitters are fused together and then spliced into the transporting fiber. Demultiplexing these optical signals at the receiver end of the circuit is accomplished in an opposite oriented passive optical demultiplexer. The multiple output fibers are coupled into photodetectors through wavelength selective optical filters.

Options for coupling light sources of different wavelengths were very limited when the *NAB Engineering Handbook, Eighth Edition*, was written. In the most rudimentary design, a fiber could transmit two or three lightwave circuits without receiver optical filtering, one wavelength each from the 850, 1,300 and 1,550 nm windows, traveling in the same or opposite directions. A more advanced feasibility demonstration system used 1,280, 1,300 and 1,320 nm wavelengths from Window II to transport an analog HDTV video signal's red, green and blue components. Sharply tuned optical filters provided received signal separation. Audio signals were multiplexed on a separate optical carrier.

Since then, AT&T Bell Labs and numerous other fiber R&D labs have been focusing on development of *dense wave division multiplexing* (DWDM). The design objective was to increase fiber circuit capacity and revenues sufficiently to offset costs of the DWDM multiplexers. One early 1997 Bell Labs demonstration featured a single semiconductor laser whose light output could be filtered into over 200 discrete light sources. Laser manufacturers can now offer a range of products operating at guaranteed specified wavelengths within the window, with narrow spectral bandwidths in the order of a few nanometers. Optical filter manufacturers similarly are now offering products with

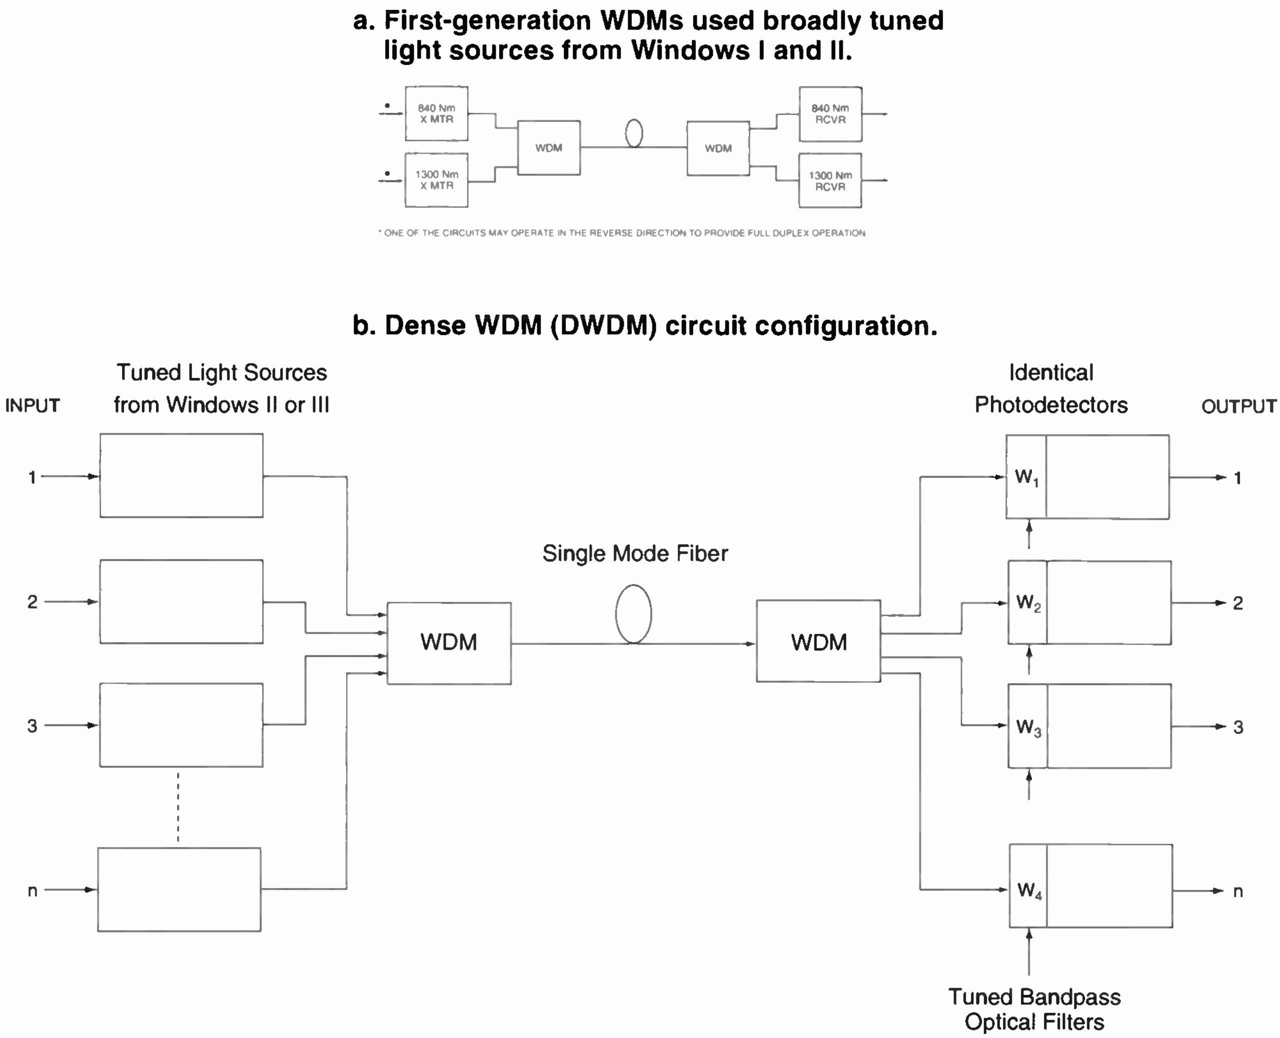

Figure 6.10-16. Wave Division Multiplexer (WDM) circuit configurations. WDMs are passive devices created by fusing optical fiber pigtails (short lengths) together. The most uniform of a fiber circuit transporting multiple light wave carriers results from use of specifically tuned light sources from either the 1300 or 1550 nm Windows II or III (DWDM), one single-mode fiber may be used for full duplex (FDX) operation by transmitting the Window II and III carrier bundles in opposite directions.

narrow passbands centered around specific wavelengths.

Many new considerations are therefore important in specifying DWDM systems. First, adequate separation (measured in dB of rejection) between optical channels is required. Optical crosstalk between channels results in lowering the effective SNR of the link.

Secondly, installation of passive multiplexers and optical filters in fiber circuits results in significant optical attenuation (1–5 dB per device). As a result, the maximum transmission distance is reduced.

Lastly, the output wavelength of optical light sources can change over temperature. Consequently, the tuned bandwidth of the WDM components must be wide enough to accommodate this drift.

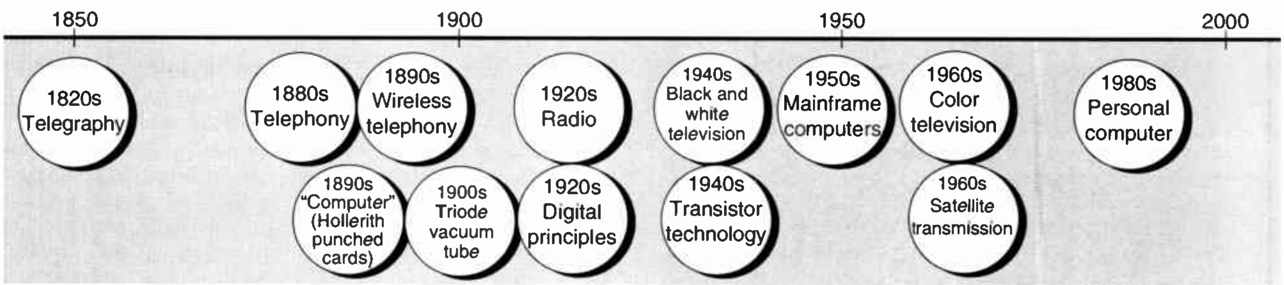
Constantly changing cost/benefit equation variables and their assumed constants are making WDM and DWDM more cost justifiable. However, costs for defining and achieving adequate, economically justifiable optical isolation are unknown. Further, the techniques are only appropriate for digital systems whose carrier to noise characteristics can overcome power losses in the WDM components.

SYSTEM DESIGN AND APPLICATIONS EVOLUTION

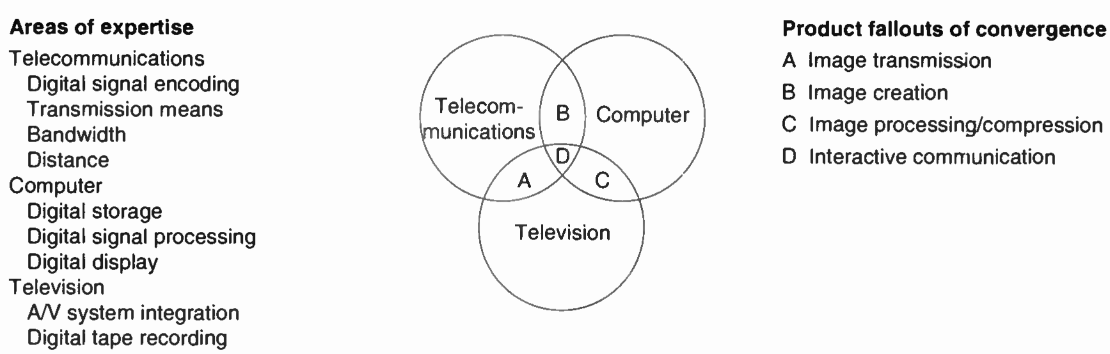
Applications of telecommunications, computer and radio/television technologies began as distinct and separate solutions to common human communication needs (see Figure 6.10-17(a)). They were designed to provide reception at a distance of information, entertainment and/or education, as aural or visual inputs to the ears and eyes. During WW II, however, computer technologists were stifled by the performance shortcomings in the vacuum tube technology developed to process and transport electrical analog signal forms.

AT&T Bell Labs researchers Shockley, Brattain and Bardeen provided the needed technological breakthrough in 1947—transistor technology. Embracing it as their own undergirding technology base, computer technologists in the late 1960s began to develop digital signal processing products whose speed and versatility and cost and size immediately began to follow Moore's Law predictions (see Figure 6.10-18). And thus began a period of inexorable convergence of these once disparate radio/television, computer and telecommunications technologies (see Figure 6.10-17(b)).

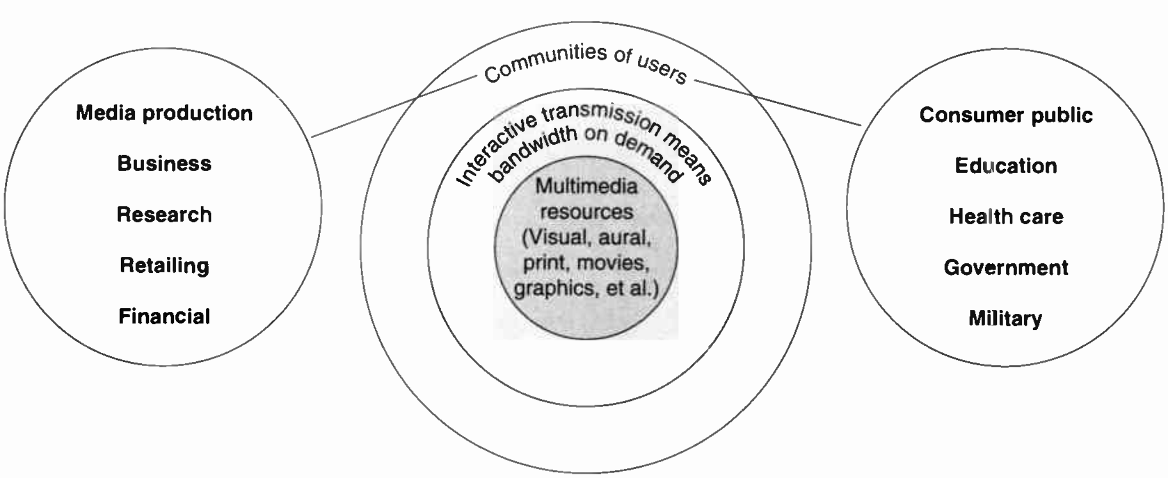
Convergence of these technologies will continue until they are one and they foster the development of one universal, all-digital, two-way interactive entertainment/information/education system (see Figure 6.10-17(c)).



a. Time line of disparate communications technology births.



b. 1960s beginnings of disparate technologies convergence.



c. 21st century spheres of electronic communications production, storage and dissemination.

Figure 6.10-17. Technology development relationships. Over the past 150 years they have changed from disparate and totally unrelated (a) to overlapping and converging today (b). If convergence overlapping continues into the 21st century the result might be one technology creating products for all information transportation applications (c). That end requires that many globally dispersed organizations issuing interface standards all agree on one standard, an unlikely occurrence.

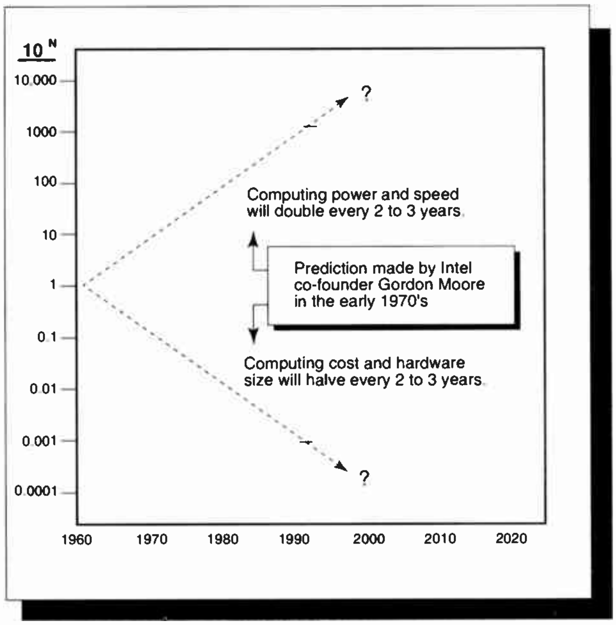


Figure 6.10-18. Semi-log plot of *Moore's Law.* Dr. Gordon Moore postulated it in the 1970s a few years after he co-founded Intel, Inc. Based on Intel's early years of chip performance/pricing trends, the Law still generally applies. The 2 to 3 years doubling/ halving period has shrunk to about 18 months, and may become less than a year in the 21st century, and has no predict able end. Applying the Law to the manufacturer of automobiles, its import becomes astounding. A Mercedes or Cadillac which could be purchased in the 1960s for around $10,000, provided about ten miles of travel per gallon of gas. Their tenth generation successors purchase in the 1990s would have been priced at under $10.00, and would have provided 10,000 miles of travel per gallon!

All-digital Television Operations

This section's purpose is to highlight the emerging indispensable role of fiber optic technology in designing future proof 21st century television signal transmission systems. This technology must initially coexist with but ultimately replace many of the copper wire and microwave wireless systems which have served the industry's 20th century signal transportation needs.

Broadband/Wideband Considerations

To telecommunications engineers, *broadband* describes a transmission circuit with a throughput of about 1.5 Mbps maximum. The 45 Mbps (DS-3) digital transmission scheme for 4.2 MHz NTSC video signal transmission is *super broadband.* This service has been marketed to broadcasters with the same finesse used by Henry Ford in the early 1900's: "We'll sell you any color car you want as long as its black." As television producers and broadcasters embrace each new bit rate (serial digital NTSC, "601" component video, MPEG-2 MP/ML, MPEG-2 4:2:2P/HL for HDTV, etc.), a new interface at that transmission rate is eventually introduced by a pioneering codec manufacturer. However, the bit stream is diligently reduced to a payload rate below 45 Mbps before it sees the light.

To television production and broadcasting engineers, broadband describes a transmission circuit which will accept an uncompressed video signal with per color analog bandwidth as high as 8–10 MHz for NTSC R, G and B and 20–30 MHz for HDTV. It also describes the digital equivalent throughputs of 270 Mbps (digital component 4:3 video and four AES/EBU audios, per SMPTE Standard 259M) and 1.485 Gbps (digital component 16:9 video and eight AES/EBU audios, per SMPTE HDTV Standard 292M). Those signals are the real numbers for broadcast quality.

To top end non-broadcast television users (educational and medical applications), a 1.544 Mbps (T1) transmission circuit is broadcast quality (better than S-VHS), most acceptable for transmission of full-motion NTSC color video (143 Mbps uncompressed). Corporate communications videoconferencing and retailing industry users accept sub-T1 circuits as broadcast quality.

Transmission Circuit Location Designators

Popular telecommunications industry acronymic designators of circuits used for signal transmission are local, metropolitan and wide area networks (LANs, MANs and WANs). These three descriptors are inadequate to describe the spatial areas which TV producers and broadcasters must traverse with transmission circuits—buildings, campuses and oceans. Figure 6.10-19 summarizes these (in italics to denote they are the author's creations), along with descriptions of their spatial coverage areas.

Fiber Technology History and Applications Evolution

Principles of lightwave transmission by total internal reflection in a stream of water were first demonstrated to London's Royal Society in 1870 by Sir John Tyndall. In 1880, Alexander Graham Bell used modulated sunlight to transmit voice communications in his patented photophone. During the pre-WW II years, researchers developed systems for transmitting images through glass rods.

After the WW II hiatus of all technological development for commercial purposes, practical applications of the principle of total internal reflection concentrated on glass rods. Development of the medical fiberscope in the mid 1950s prompted glass rod researcher N. S. Kapany to name the technology fiber optics. In 1958, Bell Labs scientists A. L. Schawlow and C. H. Townes were the first to convert electrical energy to light energy in a device they named the *laser* (light amplification by the stimulated emission of radiation). Lasing action in a Gallium Arsenide (GaAs) semiconductor was achieved in 1962.

Research to develop commercially viable applications of lightwave technology began immediately (see Figure 6.10-20). In the 1970s, the telecommunications industry began to see the light through installations of first generation fiber optic transmission systems. In the 1980s, fiber cables began to replace terrestrial and satellite microwave at a rapid pace, for continental and

Acronym	Descriptor	Location
LAN	Local	Within a room or part of a building, generally installed and owned by the premises tenant (UTP and coax cables)
BAN	Building	Circuits connecting LANs within a building, which may be installed and owned either by the premises tenant or the building's landlord (UTP, coax and MM fiber cables)
CAN	Campus	Circuits connecting BANs within a user's premises, both installed and owned by a local common carrier and bought by the premises owner for installation by an outside contractor (UTP, coax, MM and SM fiber cables)
MAN	Metropolitan	(Generally) Circuits installed on, under or over public rights of way, installed and owned by LECs (Local exchange carriers) or ASPs (Alternative service providers) (SM fiber cables and terrestrial pt-pt microwave)
WAN	Wide	Large groups of circuits interconnecting MANs within a contiguous land mass, generally also within a country's political boundaries, installed and owned by IECs (Inter-exchange carriers) (SM fiber cables and satellite microwave)
GAN	Global	Large groups of circuits interconnecting WANs, both across countries' political borders and across ocean floors (SM fiber cables and satellite microwave)

Figure 6.10-19. Hierarchy of circuit location and function designators.

transoceanic long distance telephone call transmission, respectively.

By 1990, lightwave conducting fiber cables had become the backbones of the world's long distance telephone networks. Multiple fiber cables carrying upwards of 10,000 digitized voice and computer digital data channels on each fiber were strung on telephone poles, buried in conduits and trenched under ocean floors. Fiber installation in intracity trunking cables is now a fast-growing application. Cable industry use of fiber in interhead end backbones and fiber-to-the-curb (FTTC) is similarly fast growing.

Fiber Transmission Advantages

Advantages of fiber optic transmission over alternative copper wire and terrestrial and satellite microwave media have not changed, except in magnitude, since they were first articulated in the 1980s. These advantages include the following:

- **Bandwidth.** Maximum information carrying bandwidth of a transmission system is determined by the frequency of the carrier on which the information is modulated. The 30–300 THz spectrum of infrared light frequency carriers are three to four orders of magnitude (1,000–10,000 times) higher than the 1.5 Gbps highest digital video frequency found in an HDTV production facility (see Figure 6.10-3).

  The enormous transmission bandwidth capabilities of lightwave systems are expressed in megahertz-kilometers. Single-mode fibers have bandwidth distance products of 10,000 and higher (see Figure 6.10-13). That translates into a 10 GHz bandwidth for a 1 km fiber circuit. At a transmission packing density of 4 bits per cycle, the digital throughput maximum of this circuit would be 40 Gbps.

- **Low loss.** Fibers provide substantially lower attenuation than copper cables and twisted pairs and require no equalization circuits to correct for high frequency rolloff. Signal attenuation in premium quality single-mode fiber is of the order of 0.5 dB/km and is falling as this technology is improved. Unrepeatered transmission of high bit rate digital signals over 50 km and longer is now commonplace. Signal loss in splices, connectors and patch panels is constantly falling, from 1 dB each downward toward 0.1 dB, as mechanical precision in connectorization and splicing steadily improves.

  The available power of this bandwidth can alternatively be utilized inside a facility. Digital video, audio and data signals can be pushed through the typical maze of mechanically spliced and connectorized tandem cable sections, switch points and patch panels interposed between source and destination equipment.

- **Optical and electrical signal characteristics.** Fibers and their coatings are composed of dielectric

DECADE	ANALOG SYSTEMS	DIGITAL SYSTEMS
1950s	Development of gas laser light sources.	Early research in transmission of digitized sound signals.
1960s	First implementations of fiber optic transmission system principles.	Early efforts to develop multiplexed systems for digitized voice and data transmission.
1970s	First practical systems for analog signal transmission over fiber, through intensity (amplitude) modulation of light source by signal baseband video signal combined with FM subcarriers for ancillary sound and data channels.	Common carrier industry implementation of DS() hierarchy of transmission services for digitized voice and data. First long-haul fiber optic transmission systems.
1980s	1984 - Introduction of single television channel per fiber (STVC/F) transmission systems with baseband video and multiplexed audio FM'd onto nominal 30 MHz carrier. 1984 - Introduction of short-distance multi-fiber RGB graphics systems. 1988 - Introduction of proprietary multiple television channel per fiber (MTVC/F) systems.	Rapid deployment of fiber in common carrier long haul circuits and IEC trunks. Sporadic utilization of DS3 services by broadcast industry. Utilization of sub-DS1 services in videoconferencing. First implementations of STVC/F and MTVC/F systems for full bandwidth NTSC signal transmission.
1990s	Rapid deployment of MTVC/F trunking and distribution networks in local cable systems. Continuing desultory sales of STVC/F systems in private networks. Sporadic broadcast industry utilization of MTVC/F Metropolitan Area Networks (MANs) for back haul of news and local remotes.	First implementations of B-ISDN and SONET systems for transmission of full bandwidth NTSC television signals and high resolution graphics and HDTV signals.
Early 21st Century	Analog transmission systems become historical curiosities.	User setup and use of digital common carrier networks for image transmission become as simple and cheap as DDD phone calls.

Figure 6.10-20. Chronology of development of fiber systems for analog and digital transmission of video, audio and ancillary data signals.

material, which serves to electrically isolate the transmitter and receiver terminals in a fiber circuit from one another. Hum and interference caused by differences in the earth ground potential of separated installations are thereby eliminated.

Complete isolation of separated installations from each others' electrical grounds is assured if the strength material (messenger) in multiple fiber cables is also a dielectric. Also, the *shortest route* between source and destination locations can be chosen, since proximity of fiber cables to equipment with large motors and power transformers does not create problems.

Finally, lightwave transmission produces no electromagnetic radiation which can couple into adjacent fiber or copper circuits. Conversely, lightwave transmissions are impervious to contamination from external sources of electromagnetic interference (EMI) or radio frequency interference (RFI).

- **Size and weight.** Single optical fibers used in television signal transmission have diameters less than a human hair (typically 900 μ—microns millionths of a meter). Copper transmission circuits require a pair of wires, each many times larger, stiffer and heavier than a fiber. A group of cables to carry the same quantity of signals as one fiber will be a hundred or more times larger and heavier than that fiber.

  Total installation costs are much lower for either a temporary field or a permanent studio fiber installation than for a similar copper-based coax or triax system. Fiber cable is the only alternative for circuit capacity expansion when ducts are full of copper, through replacement of each copper circuit with a bundle of fibers. Most common carriers now install fiber on all new construction except for subscriber loops.

  Technicians pulling fiber cables are far less likely to incur workman's compensation covered injuries. Further, they can complete installs and takeouts in 50% or less than the time it takes for coax and triax. This advantage should have the same impact on production truck design as the switch from three camera pickup tubes to three CCD sensors impacted portable and studio camera packaging size and styling.

- **Ruggedness.** All-dielectric cables with appropriate outer sheathings and environment-resistant connectors can be installed in toxic, liquid, flammable and extreme temperature environments and buried without compromising signal transmission integrity. Ruggedized (MIL SPEC tactical) cable designs survive *almost* any hostile treatment during installation or use. Cruelties still to be overcome are those inflicted by installers who playfully bend cables severely to see if they can be broken (they generally can't, but microbends appearing at core/cladding interfaces will impair light flow) and golf course lawnmowers that suck up and twist cables until they both they and the lawnmower are damaged.

  Golf shoe, ski pole spikes and tank treads are not predators which can crush or penetrate MIL SPEC cables. Bending and tension caused by traverses over parapets several stories above ground have no effect on fiber health or performance. In fact, glass fiber has tensile strengths in the order of 600 kpsi, compared to copper's nominal 100 kpsi.

- **Safety.** Lightwaves can not cause spark hazards like electron currents. Careless handling of a fiber cable can not cause bodily harm. Dropping it in a puddle will not damage equipment connected to it.

- **Security.** Lightwave signal flow produces no external manifestation of its existence. Stealing the signal therefore requires physical intrusion into the fiber, which lowers the fiber's output light intensity. Appropriate light output level monitoring makes undetected theft unlikely. Costs for encryption and decryption equipment can thereby be avoided.

Television Industry Applications Chronology

The advantages of fiber over copper for signal transmission quickly became obvious to telecommunications industry systems designers, and motivated a few early 1970s television industry visionaries to test out commercially viable applications in the transmission of electrical signals. Justifications for the employment of fiber continue to proliferate and grow in magnitude.

Tutorial Appendix

TELECOMMUNICATIONS INDUSTRY MAGIC NUMBERS

Analog-to-Digital Signal Conversion Mathematics

Television industry *magic numbers* began being incorporated into SMPTE interface standards in the mid 1980s. Their specific values were not created arbitrarily by television engineers, however. Their synthesis was rooted in the *Nyquist theorem*, first articulated by AT&T Bell Labs scientist and mathematician H. Nyquist in 1924 and 1928.[2] Fellow Bell Labs scientist Claude Shannon defined limits of a noisy channel's Nyquist signal transmission capabilities in 1948.

In brief, 50 to 75 years ago, Nyquist and Shannon wrote the book which today guides engineers developing digital television, radio and audio equipment and transmission media. Two related precepts can be articulated from their bodies of research.[3] Nyquist defined the minimum sampling frequency, for converting analog signals with specified high frequency cutoffs to binary serial digital representations, as twice the highest frequency to be recovered. Setting the sampling frequency of an A/D converter at this frequency will enable reconstitution of the digital bit streams back to exact replications of the original voltage-analog varying signals. Shannon defined the maximum bit rate which can be transported on transmission channels with measurable amounts of Gaussian (continuous, hissy) noise at their outputs, as a logarithmic function of the signal's channel input signal power "S" related to the channel's output noise "N" power. The mathematical expressions for Nyquists and Shannon's theorems are:

$$f_S = 2f_C \text{ (Nyquist's Theorem)} \qquad (1)$$

where f_S is the A/D converter sampling frequency in Hz, and f_C is the highest (cutoff) frequency in Hz of a spectrum of analog signals which can be transmitted over a noiseless channel; and

$$C = W \log_2(1 + S/N) \text{ (Shannon's Theorem)} \qquad (2)$$

[2] H. Nyquist, "Certain Factors Affecting Telegraph Speed," *Transactions A.I.E.E. 1924* and "Certain Topics in Transmission Theory," *Transactions A.I.E.E. 1928.*

[3] Martin, James, "The Maximum Capacity of a Channel," *Telecommunications and the Computer*, Third Edition, Prentice-Hall, Inc., Englewood Cliffs NJ, Chapter 23, p. 413 et seq 1990, 1976.

where "C" is the maximum bit rate (bits/sec) which can be recovered, "W" is the bandwidth (highest analog frequency being digitized and transmitted), "S" is the *rms* power of the transmitted signal measured at the channel input, and N is the *rms* power of the white noise (random, Gaussian fluctuations) measured in the absence of signal at the channel output.

Note that in Equation 1 the Nyquist sampling rate is the minimum needed to digitally represent the entire analog signal bandwidth as a two-state (1, 0) binary digital signal (1 bit resolution), for transmission on noiseless channels. Equation 2 establishes that channel noise disqualifies 1 bit resolution as inadequate to guarantee full bandwidth analog recovery of the transmitted signal.

To hold the recovered signal bandwidth as close to the original cutoff frequency of the sampled signal as possible, SMPTE Standard 259M first specified a minimum resolution (bits per sample) of 8 bits. This resolution provides digital code representations of a 1 V signal for 255 levels (nominal 4 mV) between 0 and 1 V (2^8 bit resolution = 256). This resolution was and still is adequate for digital representation of analog composite NTSC and PAL signals.

However, 10 bit resolution is now used in digital component video signal processing systems. Postproduction house users of the first generation of digital component video editing and recording systems immediately discovered that second generation tape playbacks of editing sessions contained *coffee rings* of hue shifts of saturated colors in flat fields. This was caused by the D/A converter's (DAC) toggling of the eighth bit between 0 and 1 in the presence of white noise approaching 4 mV amplitude.

For system designers' information, the coffee ring syndrome occurs primarily in second generation images created originally by essentially noiseless graphic imaging computer work stations. Television camera outputs contain enough thermal noise to break up the ring pattern into uniform acceptable noise throughout a flat color field. However, concatenation of digital numbers created in computer generated graphics can also create flat fields. This process can result in long strings of binary 1s or 0s, which can cause a DAC to lock for the remainder of each scanning line on which these long strings are present.

This occurrence of this unacceptable color impairment is reduced but not entirely eliminated by increasing sample resolution to 10 bits. The SMPTE standard's specification change was easy to effect. The original issuance provided for unassigned ninth and tenth bits in anticipation of such a need.

The presence of these illegal bit strings can have an even more deleterious impact in a fiber optic transmission system's electrical-to-optical (E/O) converter stage. These unpredictable aberrations seen in a reconstituted analog video image, after its digitization and transportation within a television facility, are therefore easily multiplied when a fragile signal is subsequently digitally reprocessed during its trip through a common carrier's digital infrastructure.

Tariffed Telecommunications Services Magic Numbers

DS-X/TX Hierarchy

Existing longhaul common carrier circuits operate at throughput bit rates which are different from but compatible with uncompressed single or time division multiplied television signal bit rates. However, the switching nodes which pass signals from circuit to circuit can be literal *bit bottlenecks*. Some codecs in use by common carriers have circuitry that can switch 45 Mb segments of a high-speed digital transmission system, but they are the exception. One common carrier offers a user controllable 45 Mb service which can be used for coast-to-coast transportation of television signals. These services and promised future broadband transmission services are described in the next section.

Means for digital transmission of analog voice (telephone traffic) signals were originally developed by the Bell System two decades ago, to multiplex groups of voice bandwidth (30–3000 Hz) signals onto unshielded twisted pairs in high circuit count trunking cables. These time division multiplexed (TDM) systems offered two advantages over FDM systems: substantially more channels could be carried on each pair of wires and transmitted voice quality was dramatically improved by elimination of IMD and noise reduction.

Level 0 in the hierarchy of transmission speeds is 64,000 bps. This rate accommodates one 56,000 bps digitized voice channel, which is created by sampling the voice signal at a 4000 Hz rate and digitizing the sample to 7 bit resolution. This level is synonymously referred to as both "T0" (T-zero) and "DS-0," referring to publications of tariffs and digital signaling rates.

Level 1, popularly known as the *Bell System T1 Carrier,* has a digital signaling rate (DS-1) of 1.544 Mbps. It has a capacity of 24 voice channels. The only other widely tariffed level in this hierarchy available to broadcasters is DS-3 (T3), with a signaling rate of 44.734 Mbps (familiarly called 45 Mb.) It has a capacity of 28 T1 channels, for a total of 672 voice channels.

DS-2 services (6.312 Mbps signaling rates) are not currently widely tariffed. However, this rate is compatible with bit rates created by compression of video signals in MPEG-2 encoders.

Interfaces to T1 and T3 transmission services can be provided within a broadcast plant by several competing types of common carriers. These include the original 22 Bell System telephone companies (telcos), now called Regional Bell Operating Companies (RBOC) owned by the seven Baby Bells (RHCs—Regional Holding Companies), and by the growing number of dozens of new providers including independent telephone companies, alternative services providers, cable companies, wireless cable companies, regional cable interconnects, electric utilities, rail transportation companies, state highway departments and startup and established longhaul broadband transmission services providers.

All of these organizations also run fiber cables under city streets and into buildings. The wireless terrestrial and satellite microwave transmission services serve broadcasters via dishes on station towers and roofs.

Non-broadcasters utilize T0, sub-T1 (primarily 384 and 768 kbps), and T1 transmission services to establish point-to-point and point-to-multipoint videoconferencing networks at the lowest possible line costs. Broadcasters currently rate the received quality of the compressed bandwidth NTSC full motion video used for video conferencing between terrible and unacceptable for the purpose of broadcast signal distribution. These services can nevertheless be most acceptable in the television production and broadcasting industry for the slow scan transmission of still images.

Further, sub-T1 may one day become acceptable for distribution of MPEG-2 compressed network and syndicated programming to TV stations and cable head ends delivering several compressed standard definition (SD) signals over their 6 MHz channels.

If T3 transmission of NTSC video/stereo audio television signals is to become acceptable for network program distribution as well event backhaul, a T3 television recording standard is also needed. One encoding/decoding cycle of T3 signal may now be deemed acceptable. But second or third or more codec iterations will inevitably occur when T3 backhauled programs are retransmitted on a T3 distribution network, or re-recorded down the network to accommodate local scheduling needs. Tandem multiple codecs create their own objectionable artifacts. They could be avoided by establishing hamstringing T3 re-recording practices or reduced by recording all T3 backhauled programming onto a T3 digital television recorder for editing it in a T3 digital video/audio editing suite—which presently no manufacturers in the broadcast industry have shown any interest in producing.

Broadband Integrated Services Digital Network

Integrated services digital network (ISDN) is a narrowband service. Its capabilities that are not related to broadcasters' full motion, color video/surround sound audio transmission needs in any easily understandable way. Its three channels require a digital terminal, originally introduced in the $1000 price range, for their creation. Described as "*2B + D*," the "B" channels operate at 64 kbps and the "D" channel at 16 kbps. The B channel traffic can be either digitized voice, a high-speed digital transmission or the slow-scan transmission of a single frame of video.

Grouping of 2, 4 or 6 B channels yields transmission rates of 128, 256 and 384 kbps, providing faster transmission of higher resolution stills and higher frame rate motion image sequences. They should find favor for use in remote archive browsing, if the circuits can be user-established, dialed up and bandwidth expanded on demand, and are as available as DDD telephone service.

Switched Megabit Data Service (SMDS)

This service's name once invoked the inference that it would have applications for broadcasters in at least local and regional dialup switched transmission of television signals.

Synchronous Optical Network (SONET)

Hardware already exists for converting a 45 Mbps T3 signal into a synchronous transport signal level 1 (STS-1) electrical signal for transportation on an OC-1 carrier. Higher levels of the hierarchy of interest to broadcasters and HDTV advocates are OC-3 at 155.52 Mbps (accommodating a full bandwidth NTSC video/4-channel audio signal D2 and proposed D3 140 Mbps signal), and OC-12 at 622.08 Mbps (accommodating digitized wide-screen/high resolution images and accompanying sound with little or no compression). Some of the half dozen companies now advertising the availability of SONET hardware even predict the near future availability of bandwidth on demand services.

As this book went to press, this truly broadband (by television industry definition) service is still more of a future promise than a reachable reality. A new service at 270 Mbps has been offered in some areas which may offer a better cost-performance trade-off for broadcasters.

6.11 SATELLITE EARTH STATIONS AND SYSTEMS

JAMES H. COOK, JR.
SCIENTIFIC-ATLANTA, INC., ATLANTA, GA

INTRODUCTION

The use of satellite technology for communications is highly developed and in widespread use throughout the world. In three decades, it has progressed from a technology of limited acceptance to one of routine provision of services, including television and radio broadcast services. This acceptance has been based on the unique characteristics of satellites placed on the geosynchronous satellite orbit. The capability of a single quasi-stationary repeater in the sky, visible to large, contiguous regions, offers unique distribution capabilities for broadcast services. Satellite communications is also particularly useful for long distance communication services, for services across oceans or difficult terrain and for point-to-multipoint services.

Satellites in the geosynchronous orbit rotate from west to east. They appear fixed in space to earth stations on the ground because they orbit in synchronism with the earth's rotation. A satellite that is closer to the earth orbits faster; one that is beyond synchronous orbit rotates slower than the earth. Compare the 90 minute orbit of the Space Shuttle, that operates roughly 150 miles above the earth, with the 28 day orbit of the moon. Satellites located in the 22,300 mile high geosynchronous orbit have direct lines of sight to almost half the earth, as shown in Figure 6.11-1, therefore geostationary satellites are in effect unmanned relay stations. Except for small regions near the North and South Poles, widely separated earth stations can be seen from a single satellite.

Communications by satellite was made possible by parallel advances in space technology and electronics. In 1945 Arthur C. Clarke, the noted British scientist and science fiction writer, proposed relay stations in geostationary orbit for satellite communications. It took until 1963 for advances in technology, in solid-state electronics and in the thrust capability of rockets, to allow the placing of a satellite into a stationary orbit.

Communication by satellite is completely different from that by long-distance radio. Long distance communication at radio frequencies is possible because the *ionosphere*, produced by bombardment of the upper atmosphere by the sun, usually acts as a mirror to

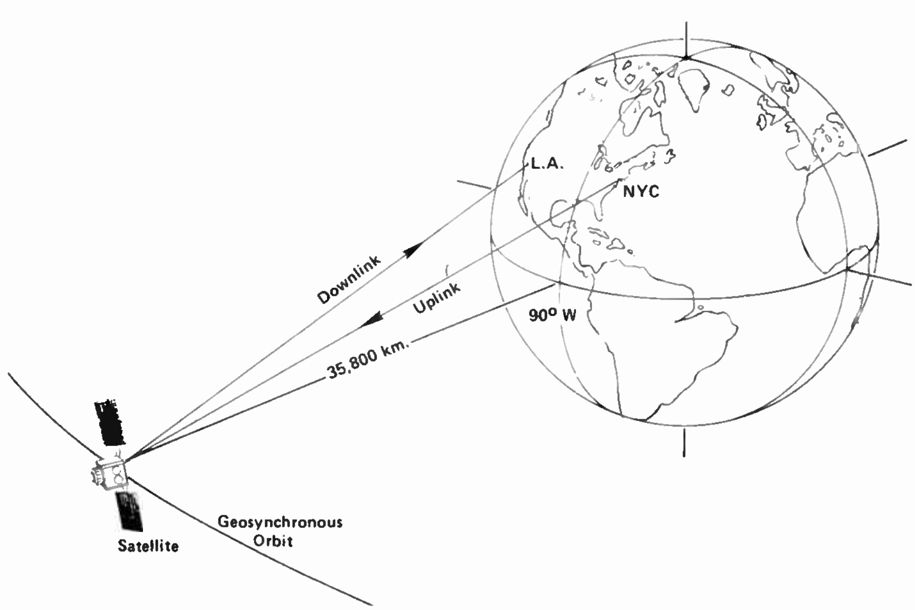

Figure 6.11-1. Satellite in geosynchronous orbit.

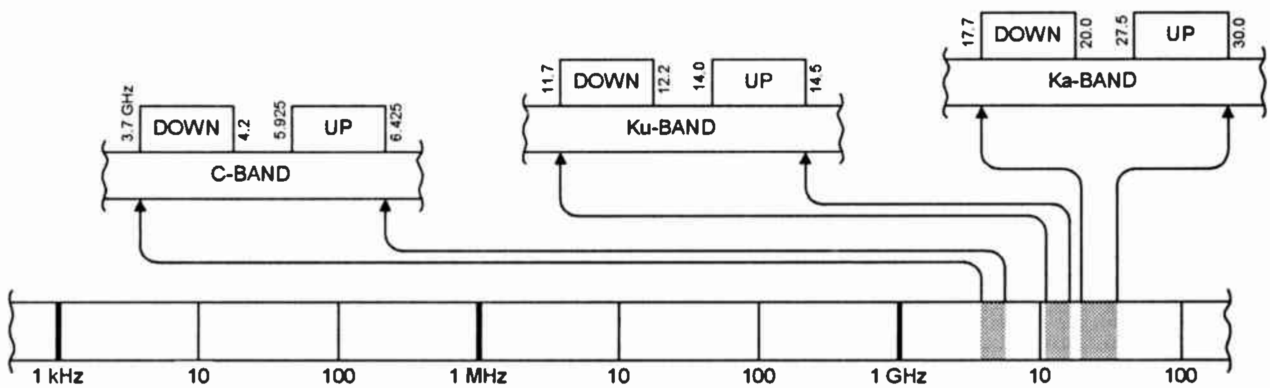

Figure 6.11-2. Frequencies in the microwave range of communications satellites.

reflect certain radio waves back to earth. As the frequency increases, a critical point is reached where the ionosphere ceases to act as a reflector, letting the waves pass through into space. Of course, television signals in the frequency range above 54 MHz do not usually lend themselves to long distance transmission. Therefore, long distance transmission of television signals was accomplished by either coaxial cable or terrestrial microwave links prior to the advent of satellite communications. Transmission of radio frequency, (RF) signals through the medium of fiber optics offers another choice of television distribution today.

Frequency

Communication satellites operate at microwave frequencies as shown in Figure 6.11-2. At microwave frequencies the ionosphere is always virtually transparent regardless of sunspot activity or time of day, permitting continuous, almost loss free transmission to and from satellites in orbit. In the United States the domestic commercial communications satellite networks operate in the fixed satellite services (FSS) frequency bands as defined by the Federal Communications Commission. Most of the domestic systems operate in either the C-band (6 and 4 GHz) or Ku-band (14 and 12 GHz) frequency ranges with C-band generally preferred because of superior propagation characteristics. The Ka-band frequencies (30 and 20 GHz) are also set aside for FSS operation and the use of these frequencies is expected to become quite prevalent in the early 2000s. The primary use in the United States to this date has been with experimental satellites (NASA Advanced Communications Technology Satellite, ACTS).

International systems provide services on a global basis (global beams) to all countries visible from a single orbit location and on a regional basis with spot beams. *Intelsat* and Intersputnik are examples of this type of system, using both C-band and Ku-band. The international satellite communication frequency bands are similar to the U.S. frequencies at C-band, but somewhat different at Ku-band. The frequency bands are determined by joint negotiations by the countries of the world through the auspices of the Radio Communications Sector of the International Telecommunications Union (ITU-R). International systems have begun to use an extended C-band frequency range of 3.4 GHz to 4.2 GHz rather than the 3.7 GHz to 4.2 GHz US band as well as 11.2 GHz to 11.7 GHz for downlink transmissions.

Satellite Stationkeeping

It was stated that the synchronous satellite appears stationary in space. Actually, a synchronous satellite is never perfectly stationary, because a number of forces including the pull of the sun and the moon perturb its orbit. If left alone, the satellite would eventually drift out of orbit. To overcome this, the position of the satellite is continuously monitored by an earth station, called a telemetry, tracking and command (TT&C) station and small jets of propellant such as hydrazine are used to keep it in position within a *station-keeping box*. The station-keeping box is typically a square $\pm 0.1°$ or less on each side and oriented with the sides parallel and perpendicular to the orbital plane. Sufficient rocket propellant must be carried on board to last for the satellites, predicted life, usually from 7 to 10 years. In the international arena, *COMSAT* has introduced a technique to extend the life of a satellite during its later years.[1] This technique, the *COMSAT Maneuver,* allows the satellite to drift north and south an increasing amount as the satellite approaches its end of life with excursions of several degrees by the time the rocket propellant is entirely spent. The *COMSAT Maneuver* increases the service life of the satellite by a number of years, but places the burden of tracking the satellite position on the earth station. Recently the *COMSAT Maneuver* has been used with some U.S.

[1] COMSAT is a publicly held satellite communications company, created by an act of Congress in 1963, and historically has represented the U.S. in the international satellite consortia Intelsat and Immarsat.

satellites at or near their end-of-life operation, resulting in significant economic benefits.

Satellite Footprint

The transmitting and receiving antennas on the satellite are designed to cover only specific desired regions of the earth's surface. This has several purposes. It concentrates the power radiated from the satellite into the desired direction, increases the sensitivity of its receiving antennas and helps prevent interference with signals from other satellites. The part of the earth's surface covered by a satellite is called the satellite's footprint. The footprint may cover one or more relatively localized regions of the earth or almost a complete hemisphere. A typical footprint is shown in Figure 6.11-3. The footprint is, of course, not sharply defined. Signal strengths tend to peak near the center of the footprint and roll off steeply past the 3 dB contour. Global or regional beams are usually shaped such that a particular defined section of the earth's surface is illuminated by the satellite's radiated signal. For example, a United States domestic satellite would probably limit the footprint such that its neighboring countries were illuminated with minimum signals to minimize interference possibilities. This is necessary since several countries share the same portions of the orbital arc.

Polarization

Electromagnetic waves and antennas are always *polarized* in some manner. The polarization may be linear, circular or elliptical. For the purposes of discussion elliptical polarizations will be dismissed as being nonideal cases that are intended to be either linear or circular. Linear polarizations and circular polarizations are aligned in space as shown in Figure 6.11-4. A linearly polarized antenna receives maximum power from an incident linearly polarized wave if the *tilt angles* of the wave and the antenna polarizations are aligned in space as in Figure 6.11-4(a). The wave is then said to be *co-polarized* or *polarization matched.* As the tilt angle of the wave or antenna rotates from co-polarization, the received power decreases. When the tilt angles are 90° apart as shown in Figure 6.11-4(b), the antenna is *cross polarized* to the wave and receives no power from it. The antenna and the wave then have *orthogonal* polarizations. A given wave can have two orthogonal polarizations which exist simultaneously and carry different information without interference. This principle, *frequency reuse,* is used to increase the "information capacity" of satellites and of the geosynchronous orbit.

Circular polarizations have either right hand (RHC) or left hand (LHC) senses. RHC and LHC polarizations are orthogonal. A circularly polarized satellite and a circularly polarized earth station are co-polarized if they have the same senses and are cross-polarized if they have the opposite senses. The relative tilt angles of circular polarized antennas and waves are of no consequence and are not defined. This represents an advantage of circular polarization over linear polarization since the tilt angle of the earth station does have to be adjusted for a particular satellite. On the other hand, circularly polarized antennas tend to cost more than linearly polarized antennas due to the increased complexity of the feed components. Most domestic satellites are linearly polarized while INTELSAT satellites are for the most part circularly polarized.

SATELLITE SYSTEM CHARACTERISTICS

The design of a satellite communication system is an intricate process, involving trade offs between many variables to obtain maximum performance at a reasonable cost. The major cost and complexity trade off occurs between satellite and earth stations, or more

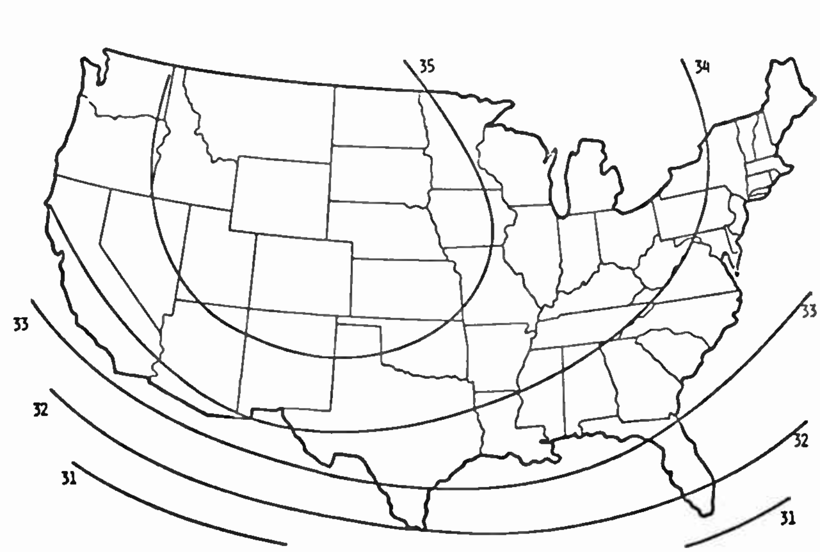

Figure 6.11-3. Satellite footprint.

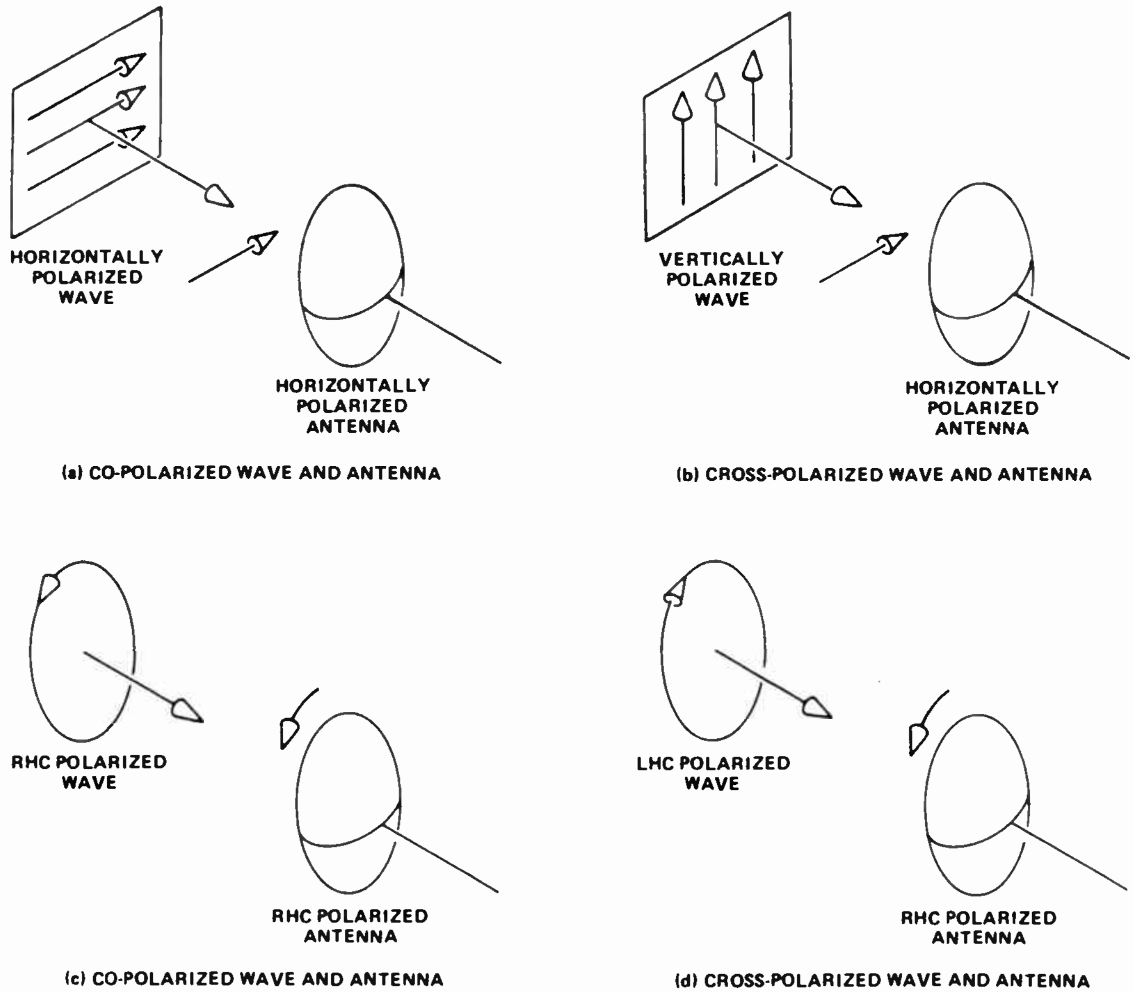

Figure 6.11-4. Linear and circular polarizations; a) co-polarized wave and antenna; b) cross-polarized wave and antenna; c) co-polarized wave and antenna; d) cross-polarized wave and antenna.

generically, between space segment and ground segment. The dominating design factors in both segments for systems using geostationary satellites are:

Space Segment

- Weight and size of satellite
- DC power generated on board
- Dimensions and complexity of satellite antennas

Ground Segment

- Allocated frequency bands
- Earth stations antenna size and RF capabilities
- Earth stations multiple access techniques

The weight of the satellite is limited by the high cost of launching a spacecraft into geostationary orbit, typically $40,000–$50,000 per kilogram. For a satellite of limited weight and size, a limited number of solar cells can be deployed which defines an upper limit on the dc power available for the communication transponders. The size and power limitations translate into the fact that the spacecraft has a limited RF output power, which then must be transmitted onto particular areas of the earth, (e.g., the continental United States).

Furthermore, power densities over the earth's surface are limited, depending on operating frequency bands, to allow interference free coexistence with terrestrial systems operating in the same frequencies. The result of all of this is the signals arriving from communication satellites are inherently weak, typically -120 to -160 dBW/m^2 and therefore relatively large receiving ground antennas must be utilized.

Multiple access and multiple destinations are distinctive virtues of satellite communications. The methods by which a large number of earth stations share one satellite or one transponder providing the required connectivity (multiple access techniques), also have a significant impact on system design. The multiple access can be achieved by sharing the transponder bandwidth in separate *frequency* slots, frequency division multiple access (FDMA), or the transponder availability in discrete *time* slots, time division multiple access (TDMA). A third technique, code division multiple access (CDMA) or spread spectrum, shares the transponders by allowing *coded* signals to overlap in time and frequency.

A satellite communication system must be designed to meet certain minimum performance standards, within limitations of transmitted power, RF bandwidth and antenna sizes. The most important performance criterion for analog systems is the signal-to-noise ratio (SNR or S/N) in the information channel or baseband. In digital systems the performance measurement criterion is bit error rate (BER).

SNR and BER depend on a number of factors, such as the predetection (incident upon the receive antenna) carrier-to-noise-density ratio (C/N_0) and the carrier-to-noise ratio (C/N) in the receiver, the type of modulation and the RF and baseband bandwidths. In the following section the design and analysis of satellite communications links in terms of C/N_0 will be conducted. Therefore, the carrier power received in an earth station receiver and the noise power density in the receiver need to be calculated to establish the operating link C/N_0.

Since satellites are inherently power limited, there will be invariably a modulation technique whereby a trade off of bandwidth for power will make the baseband S/N larger than the RF C/N in analog systems and will optimize BER in digital systems.

Satellite Transmission Modes for Television

Analog and digital formats are both used for the transmission of television signals via satellite. FM has been the prevalent analog technique because:

- It minimizes the effects of non-linearities in the transmission channel
- It is immune to AM noise
- Power-limited systems can take advantage of the wider bandwidth to increase the C/N
- Various processing techniques can be employed to optimize video transmission (multiplexing, preemphasis and threshold extension)

The choice of the optimum modulation index **m**, the ratio of the FM deviation to the highest modulating frequency f_m, is critical. Bandwidth and deviation are related by Bandwidth = $2(\mathbf{m} + 1)f_m$. The spectral distribution of a FM signal as a function of **m** is shown in Figure 6.11-5. The selection of the optimum deviation must be based on the number of channels to be transmitted, the type of baseband signal (component or composite), the signal quality requirement, the power received and the available bandwidth. A typical value

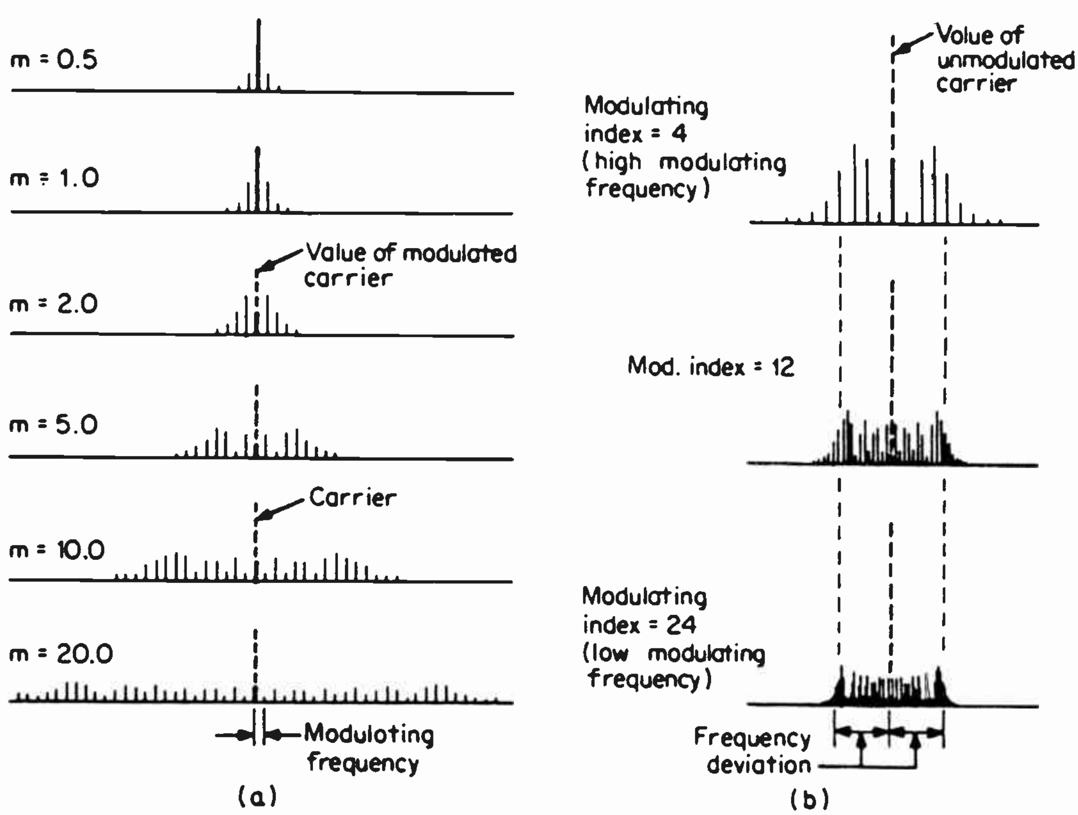

Figure 6.11-5. Spectra of frequency modulated signals a) frequency spectra with increasing frequency deviation and constant modulating frequency; b) frequency spectra with constant frequency deviation.

of peak Δf for a C-band satellite transponder with a nominal bandwidth of 36 MHz is 10.75 MHz.

For satellite transmission, in addition to the deviation of the carrier by the signal, it is usually necessary to subject the main carrier to a low-frequency deviation. This spreads the high concentration of carrier and sideband energy over a larger range of the spectrum and permits higher satellite effective radiated power (ERP) without exceeding the FCC's limit on watts/meter^2/kHz downlink power density.

Preemphasis/deemphasis is employed in FM systems for the transmission of video to compensate for the increase in thermal noise with increasing frequency. CCIR Recommendation 567 specifies a standard 75 μsec preemphasis, for example.

A characteristic of FM is that the detected S/N for the video signal is higher than its C/N ratio. This difference is the FM improvement factor; satellite transmission takes advantage of this improvement, provided the received C/N is greater than the receiver operating threshold.

Threshold extension demodulation (TED) is a common technique used in FM receivers to reduce video impulse noise when the C/N drops below the receivers's operating threshold. Above threshold, the receiver acts like a standard discriminator; when C/N drops below threshold, TED circuitry automatically switches to a narrow bandwidth.

Digital Transmission

Satellite systems are used for the transmission of digital information. A typical digital transmission uplink consists of a modem, upconverter and power amplifier. The modem converts digital information to and from a modulated carrier. The center frequency of the modulated carrier positions the signal within a satellite transponder. The upconverter converts the modulated-carrier to a satellite frequency and thus selects the transponder of the satellite.

The earth station component used to convert digital information to a format suitable for transmission by satellite is referred to as a modem (an acronym for modulator/demodulator. The modem accepts a digital data input signal and outputs an intermediate frequency, typically a range centered on either 70- or 140-MHz, containing the modulated digital information.

A modem for use in satellite systems is similar to modems used for telephone circuits. However, satellite modems generally operate at much higher bit rates and, in addition, contain special features specifically for satellite link use.

Transmitted digital data is first applied to the encoder section of the modem for forward error correction (FEC) encoding. This process adds redundancy to the bitstream, by appending additional bits to the original information, to provide error detection and correction capability. The signal is then scrambled using a standard algorithm to ensure random data. This ensures that the signal spectrum will be noise-like in nature, and minimize the possibility of spinious energy from transmission.

The aggregate data (original data plus error correction bits) is applied to the modulator for modulation onto an IF carrier. The IF carrier is selectable, typically in the range of 50 to 90 MHz (for 70 MHz operation), or 100 to 180 MHz (for 140 MHz operation). The center frequency of the modem modulator is tuned to position the signal within the satellite transponder.

A satellite digital transmission system is characterized by data interface, data rate, code rate and modulation scheme. Data rate refers to the number of bits per second transmitted by the modem. The data rate is typically front panel selectable. Typical ranges of rates are from 32 kbps to 3 Mbps selectable in increments as small as 1 bps. Modems typically support a number of data interfaces. The data interface refers to the connector and signal levels. Typical data interfaces are DS1, CEPT, EIA-422, V.35 and MIL-188/114. Code rate refers to the FEC-encoding scheme. In some modems, the code rate is selectable. The code rate configuration is referred to as m/n. "m" refers to the number of original bits per block of transmitted bits. "n" refers to the number of original bits plus error correction bits per block of transmitted bits. Thus, a code rate of 3/4 means that for every input three data bits, four data bits are transmitted. Thus a 1024 kbps modem operating with a code rate of 3/4 would transmit 1365 kbps over the satellite channel.

The modulation scheme refers to the method of indicating data bits. Two common modulation schemes employed in satellite transmission systems are binary phase shift key (BPSK) and quadrature phase shift key (QPSK). These modulation schemes generate periodic phase shifts referred to as *symbols.* The symbol rate (the number of symbols per second) and data rate determines the amount of bandwidth required in the channel.

In BPSK, two phase shifts are used to represent two unique states. For this case the symbol rate is equal to the transmission rate. The QPSK scheme uses four phase shifts, thus transmitting two bits per symbol. For QPSK, the symbol rate is equal to half the transmission rate. QPSK requires less bandwidth than BPSK, but requires increased performance from the channel.

Advantages of Digital Television

The advantages of digital technology for television processing, including production, storage and distribution will make its use dominant in coming years. These advantages are: perfect multigeneration reproducibility, precise time and level controls, digital storage and signal processing, data compression, easy manipulation by computers and generation of multimedia constant, incorporation in digital transport packets for packet switching (ATM), broadband digital communication (B-ISDN) and, error control.

The 1982 adoption of ITU-R Recommendation 601 (CCIR601), for component television and the adoption of MPEG-2 by the International Standards Organization (ISO) and the International Electrotechnic Committee (IEC) in 1993 were major milestones for the industry.

The use of digital compression techniques, removing statistical redundancy (entropy coding) and taking advantage of psychophysics to remove irrelevant information (perceptual coding), allows the data rate of high quality television to be reduced by significant factors (~50) making its use very attractive in conservation of bandwidth. This technique is being used to deliver high quality television to millions of subscribers via direct broadcast satellite today.

C-Band Satellites

C-band was initially favored for communications satellites because of the favorable propagation characteristics at these frequencies. The specific bands in most common use are the 5925 MHz to 6425 MHz (uplink) and the 3700 MHz to 4200 MHz (downlink) band pair. U.S. domestic FSS requires the use of 36 MHz bandwidth channels placed on 40 MHz centers. A satellite using a single polarization can provide 12 such transponders, although all new satellites are mandated to be frequency reuse and provide 24 such transponders. Frequency reuse is implemented by the use of orthogonal polarizations and by staggering the microwave carriers of alternate transponders. As an example of a typical satellite, the transmit and receive frequency plans of a GE/RCA Satcom satellite are shown in Figure 6.11-6. The numbered brackets represent each channel. The bandwidth of the channel is represented by the width of the bracket. The carrier frequency, shown above the channel number, is centered on each channel. The signals of alternate transponders in the frequency plan of Figure 6.11-6 are nominally orthogonal. If they were exactly orthogonal and the associated earth stations were ideal (with respect to polarization), there would be no interference caused by the overlapping sideband energy of adjacent transponders. In practice, the polarizations of the antennas of the satellite and earth stations are not ideal. Some small amount of interference occurs, but the combination of nearly orthogonal polarizations and the use of the staggered frequency plan provides for high quality transmission under almost all weather conditions.

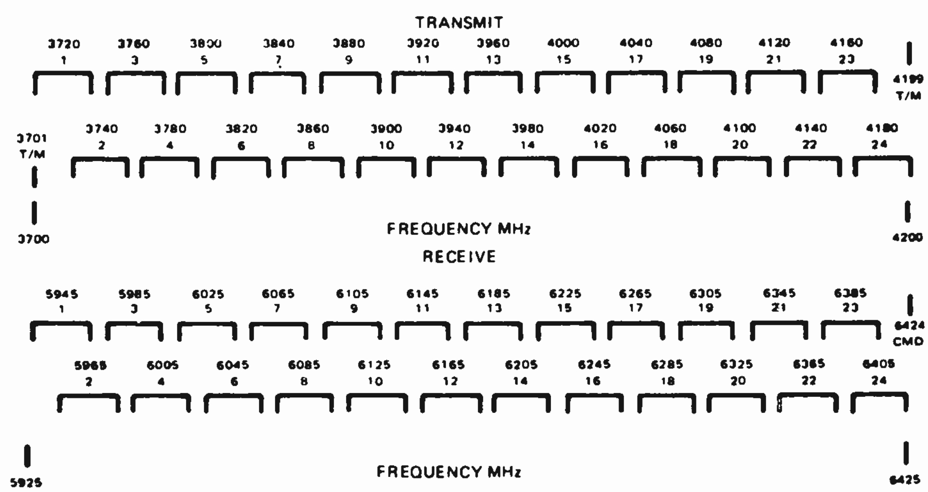
Ku-Band Satellites

The first systems using the 14.0 GHz to 14.5 GHz (uplink) band and the 11.7 GHz to 12.2 GHz (downlink) band were launched in 1976 by Satellite Business Systems (SBS). The higher propagation loss characteristics at these frequencies require higher spacecraft equivalent isotropic radiated power (EIRP) to achieve the same transmission performance as C-band frequencies and this is obtained from the use of greater spacecraft antenna gains, readily achievable at the higher frequencies. Since the Ku-band frequencies are not shared with terrestrial systems (as is the case of C-band) the power flux density (PFD) limitation is less stringent and there is no requirement for coordination with terrestrial microwave systems. The high powers permit the use of very small earth station antennas at or near the user's premises. This results in important economic advantage for many services and makes the use of this frequency band very attractive. Even so, a good part of the higher satellite power achievable is necessary to offset the additional attenuation that is experienced at these frequencies during heavy rain conditions.

There is no mandated frequency plan for transponders in this frequency band, although typical transponder bandwidths are 36 to 72 MHz. Since the bandwidth is the same as C-band it is possible to have a similar 24 transponder, 36 MHz frequency plan with 40 MHz channel spacings when frequency reuse is utilized.

Two of the more important differences between C-band and Ku-band are the following:

- C-band FSS share frequencies with terrestrial microwave systems. This places constraints on the location



NOTE: NUMBER BELOW CHANNEL CENTER FREQUENCY REFERS TO TRANSPONDER IDENTITY.

Figure 6.11-6. GE/RCA Satcom satellite frequency plans.

of C-band earth stations and it limits the permissible downlink power density.

- Ku-band signals are subject to significant attenuation in heavy rainfall

The advantages and disadvantages of C-band and Ku-band, which result from these and other differences, are summarized in Table 6.11-1.

Ka-Band Satellites

The commercial application of Ka-band satellites is only in its infancy years. The NASA ACTS experimental satellite has allowed successful demonstration of the use of the 17.5 GHz to 22.5 GHz downlink and 29.5 GHZ to 34.5 GHz bands for various services. It is inevitable that these bands will be used in the future for video applications, with considerable interest in narrow casting for particular regions of the country.

In mid-1998, the FCC granted licenses to thirteen companies for 73 geosynchronous satellites which will operate in the Ka-band.

Table 6.11-1
Merits of C- and Ku-Band for Satellite Communications.

C-band Advantages
Less susceptible to rain outages. Established manufacturing infrastructure. Antenna surface tolerance can be achieved by various techniques that lend themselves to low cost manufacturing.
C-band Disadvantages
Frequency band is congested because it is shared with terrestrial microwave, making frequency coordination a requirement. Requires relatively large antennas because of low satellite EIRP levels and the necessity of narrow half-power beamwidth to allow two degree spaced satellites. Avoiding terrestrial interference can make site selection a difficult process. The use of artificial shielding to block interference can increase total system cost. Faraday rotation of polarization can affect system performance. Satellite dispersal signal is required to prevent harmful interference to terrestrial stations, resulting in more stringent video receiver clamping specifications.
Ku-band Advantages
Frequency band is only used for satellite communication. Smaller antennas may be used because of higher gain and higher satellite EIRP. Easier site selection because of smaller size of antenna and lack of terrestrial interference. Narrower antenna beamwidth is desirable in reduced orbital spacing Suitable for direct-to-home application. Lower reception equipment cost. Flexibility in channelization plan. Not affected by Faraday rotation. No satellite dispersal signal disadvantages.
Ku-band Disadvantages
Affected by rain attenuation and depolarization. Narrow beamwidths of antennas may require more rigid mounts Reflector surface tolerance requirements restrict manufacturing techniques and increase cost. Waveguide and coaxial transmission line losses are quite high. Noise temperature of Low Noise Amplifiers may cause the use of large antennas to achieve desired G/T.

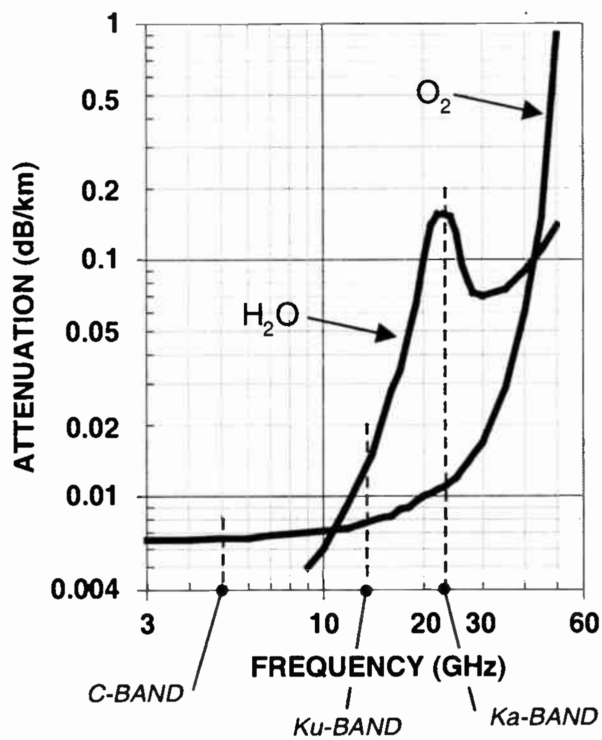


Figure 6.11-7. Signal attenuation versus frequency due to atmospheric oxygen and rainfall.

The Ka-band, in the context of fixed-and mobile-satellite communications services, refers to the downlink frequency band of 17.7–20.0 GHz, and the uplink frequency band of 27.5–30.0 GHz. It is a new band in a regulatory sense, having been created in July 1996 when the FCC allocated these frequencies for this service. In early 1998, the satellite industry completed an agreement on an orbital location assignment plan for the Ka-band satellites being proposed, which was adopted by the FCC and followed by the issuance of licenses for satellite system construction and operation.

Ka-band signals suffer from greater attenuation due to the presence of rain and atmospheric oxygen, than do C-band and Ku-band services. This is illustrated in Figure 6.11-7, where the approximate center of each band is marked by a dashed line. This attenuation problem has historically made Ka-band rather unattractive for satellite communications, but scarcity of spectrum in other bands as well as advances in satellite communications technology have together brought about a change in that situation.

In addition to core satellite voice, data, and video offerings, Ka-band licensees will provide many low cost, global broadband interactive services such as:

- Desktop-to-desktop videoconferencing
- Direct-to-home video
- Distance learning and corporate training
- Internet access

- Telemedicine
- Electronic transaction processing
- Satellite news gathering

Regulatory Issues

Satellite communication systems are governed by the FCC in the United States and by the ITU on the international level. The governing agencies assign frequency bands of operation, satellite performance characteristics and orbit location and provide technical specifications of radiated power density and radiation gain patterns for the earth stations. The FCC is the licensing body for all transmit earth stations in the United States and licenses C-band receive only earth stations at the owner's request. The FCC Rules and Regulations, Part 25, form the basis of the applicable documents which must be followed for the planning and implementation of any FSS band satellite communication system.

The FCC amends and interprets the rules as the technology and the requirements of satellites changes through amendments, decisions and declaratory orders; therefore, it is recommended that the FCC be contacted at the time of system planning to obtain the latest rules and regulations. The FCC established precedents for the minimum diameter apertures and sidelobe gain envelopes for earth station antennas operating in the FSS bands at the beginning of these services in the early 1970s to minimize interference between terrestrial systems and satellite systems and between satellite systems. These precedents have been modified through the years as the use of satellite services has increased. The more significant recent rulings pertaining to earth station antenna performance have resulted in improved antenna radiation patterns in the close-in sidelobe region and have established maximum radiated power densities for antennas diameters less than 9 m in diameter for C-band operation and 5 m in diameter for Ku-band operation.

The FCC Rules and Regulations Part 25.209 pertaining to antenna gain envelopes is mandatory for all transmit antennas. Excerpts from this standard follow (refer to the current rules publication for the entire text):

a) The gain of any antenna to be employed in transmission from an earth station in the fixed satellite service shall lie below the envelope defined below:
   1. In the plane of the geostationary satellite orbit as it appears at the particular earth station location:

$[29 - 25\log(\theta)]$ dBi	$1° \leq \theta \leq 7°$
$+8$ dBi	$7° < \theta \leq 9.2°$
$[32 - 25\log(\theta)]$ dBi	$9.2° < \theta \leq 48°$
-10 dBi	$48° < \theta \leq 180°$

   where θ is the angle in degrees from the axis of the main lobe and dBi refers to the dB relative to an isotropic radiator. For the purposes of this section, the peak gain of an individual sidelobe may not exceed the envelope defined above for θ between 1° and 7°. For θ greater than 7°, the envelope may be exceeded by 10% of the sidelobes, but no individual sidelobe may exceed the envelope by more than 3 dB.
   2. In all other directions:
   Outside the main beam, the gain of the antenna shall lie below the envelope defined by:

$[32 - 25\log(\theta)]$ dBi	$1° \leq \theta \leq 48°$
-10 dBi	$48° < \theta \leq 180°$

   where θ is the angle in degrees from the axis of the main beam and dBi refers to dB relative to an isotropic radiator. For the purpose of this section, the peak gain of an individual sidelobe may be reduced by averaging its peak level with the peaks of the nearest sidelobes on either side, or with the peaks of the two nearest sidelobes on either side, provide that the level of no individual sidelobe exceeds the gain envelope given above by more than 6 dB.

b) The off-axis cross-polarization isolation of any antenna to be employed in transmission at frequencies between 5925 and 6425 MHz from an earth station to a space station in the domestic fixed-satellite service shall be defined by:

$[19 - 25\log(\theta)]$ dBi	$1.8° < \theta \leq 7°$
-2 dBi	$7° < \theta \leq 9.2°$

c) Any antenna licensed for reception of radio transmission from a space station in the fixed-satellite service shall be protected from radio interference caused by other space stations only to the degree to which harmful interference would not be expected to be caused to an earth station employing an antenna conforming to the standards defined in paragraphs a. and b. of this section.

d) The standards specified in paragraphs a. and b. of this section shall apply to all new earth station antennas initially authorized after February 15, 1985 and to all earth stations antennas after March 11, 1994.

e) The operations of any earth station with an antenna not conforming to the standards of paragraph a. and b. of this section shall impose no limitations upon the operation, location and design of any terrestrial station, any other earth station, or any space station.

f) An earth station with an antenna not conforming to the standards of paragraphs (a) and (b) of this section will be routinely authorized after February 15, 1985 upon a finding by the Commission that unacceptable levels of interference will not be caused under conditions of uniform 2° orbital spacings.

g) The antenna performance standards of small antennas operating in the 12/14 GHz band with diameters as small as 1.2 meters starts at 1.25° instead of 1° as stipulated in paragraph (a) of this section.

The FCC further acknowledged that the envelope defined above is only a reference envelope in the receive band. Receiving antennas do not have to conform to this envelope to be eligible for licensing. Facilities with performance worse than the reference envelope must, of course, be prepared to accept potentially higher interference levels. The interference levels should be calculated based on typical measured radiation patterns, site location and for a desired satellite or satellites. This analysis may result in acceptable receive-only carrier-to-interference performance for antennas meeting $[32 - 25\log(\theta)]$ envelope even with orbital spacings as small as 2°, since discrimination, that is, peak on-axis gain to sidelobe gain, is the important determining factor, not an arbitrary sidelobe gain performance envelope relative to isotropic.

FCC License

The FCC requires licensing of transmitting earth stations and permits licensing of receive only (RO) earth stations. It is desirable for a broadcaster to license a C-band RO earth station, since licensing protects the station from future interference from domestic microwave systems.

The FCC Rules and Regulations are ever evolving therefore it is strongly suggested that the FCC be contacted before filing to obtain the latest regulations and regulatory procedures effective at the time of the filing. For example, in December 1996, International Bureau Docket No. 95-117 *Report and Order* streamlined the Rules and Regulations for Satellite Application and Licensing Procedures. This Docket eliminated a series of previous forms that contained redundant information and simplified them into a single form, Form 312.

The application for a C-band RO terminal is filed on Form 312, Main Form and Schedule B. The earth station must conform to the provisions of Paragraph 25.131of the FCC Rules and Regulations. The filing requirements for a transmit station use the same Form 312, Main Form and Schedule B and must include the information specified in Paragraph 25.130 of the FCC Rules and Regulations.

SYSTEM PERFORMANCE ANALYSIS TECHNIQUES

Considering an RF link as illustrated in Figure 6.11-8 with transmit power P_t and transmit gain G_t, the effective isotropic radiated power, EIRP, for the station along the main beam of the antenna is the product $G_t{*}P_t$. At a distance R meters from the transmitter, the radiated flux density, S, becomes:

$$S = (G_tP_t)\frac{1}{4\pi R^2}k_a \qquad \text{Watts/m}^2 \qquad [1]$$

where k_a = atmospheric attenuation factor < 1.

If an antenna with an effective area in square meters, A_e, is receiving this flux density, the received carrier level, C, at the antenna output is:

$$C = SA_e = (P_tG_tA_e)\frac{1}{4\pi R^2}k_a \qquad \text{Watts} \qquad [2]$$

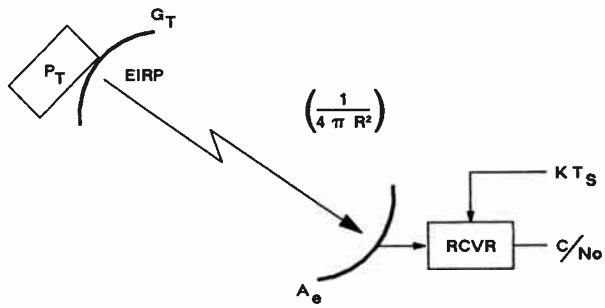

Figure 6.11-8. RF link diagram.

At the same antenna output point, the effective noise power density, N_o is given by:

$$N_o = kT_s \qquad \text{Watts/Hertz} \qquad [3]$$

where: k = Boltzmann's constant = $1.38{*}10^{-23}$ Joules/K or −228.6 dB.
T_s = System noise temperature in degrees Kelvin

We can assume the atmospheric attenuation factor to be unity with very small error (in particular for C-band and Ku-band links refer to Figure 6.11-7), therefore, the carrier-to-noise density ratio C/N_0 can be expressed by:

$$\frac{C}{N_o} = (P_tG_tA_e)\frac{1}{4\pi R^2}\frac{1}{kT_s} \qquad [4]$$

A fundamental relationship in antenna theory is that the gain, G_r and the effective area of an antenna, A_e, are related by:

$$A_e = G_r\frac{\lambda^2}{4\pi}\ \text{m}^2 \qquad [5]$$

Substituting this relation into the expression for C/N_o,

$$\frac{C}{N_o} = (P_tG_tG_r)(\lambda/4\pi R)^2\frac{1}{kT_s} \qquad [6]$$

or

$$\frac{C}{N_o} = EIRP\frac{G_r}{T_s}(\lambda/4\pi R)^2\frac{1}{k} \qquad [7]$$

The factor $(\lambda/4\pi R)^2$ is often inverted and defined as the spreading loss or space loss factor. This spreading loss can also be expressed as:

$$L_s = (4\pi Rf/c)^2 \qquad [8]$$

where: c = Speed of light = $3{*}10^{+8}$ meter/second
f = Frequency in Hertz

Link calculations are usually carried out in dB rather than directly from the above relations because of ease of working in common logarithms. C/N_o in dB can be calculated by:

$$(C/N_o)\ \text{dB} = 10\log(C/N_o)$$

$$(C/N_o)\ \text{dB} = EIRP - L_s + (G/T) + 228.6 \qquad [9]$$

where: $EIRP = 10\log(G_t P_t)$ dBW

$$L_s = 20\log(4\pi Rf/c)\ \text{dB} \qquad [10]$$
$$= 92.45 + 20\log R\ (\text{km}) + 20\log f\ (\text{GHz})$$

$$(G/T) = 10\log(G_r/T_s)\ \text{dB/K} \qquad [11]$$

Alternately, C/N_o can be expressed in terms of flux density, S, as:

$$(C/N_o) = S + (G/T) - A_i + 228.6\ \text{dBHz} \qquad [12]$$

$$S = EIRP - L_s + A_i\ \text{dBW/m}^2 \qquad [13]$$

where A_i is the effective aperture of an isotropic radiator in dB:

$$A_i = 10\log(4\pi/\lambda^2) \qquad [14]$$

Equation (9) is a fundamental tool for characterizing space link performance. It will be utilized later when calculating overall satellite link performance.

Earth Station Receive Figure of Merit G/T

G/T is the figure of merit of a receive system. It is primarily a function of the gain of the antenna along with the antenna noise temperature, first amplifier noise temperature and losses located between the antenna and the first amplifier. The importance of the term *G/T* in Equations [9] and [12] cannot be overstated. Examination of the C/N_o expression shows that for a given available transmitting power and information format (and thus bandwidth), the only available method of controlling the received signal quality that can be used by the downlink operator is through the system *G/T*. Note that the *G/T* provides a direct dB relationship with C/N_o.

Figure 6.11-9 shows a block diagram of a typical receive system. Each device in the RF path has an associated gain or loss and a noise temperature. These contributions are combined to reflect the noise power weighted by the gain distribution through the chain. The earth station *G/T* is given by:

$$(G/T) = G_a - 10\log(T_s)\ \text{dB/K} \qquad [15]$$

where: G_a = Antenna gain referenced to LNA input (dBi)
T_s = System noise temperature referenced to LNA input (K)

The system noise temperature, T_s, referenced to the LNA input can be calculated by adding as noise powers the equivalent noise temperatures of all noise contributors, weighted by the net gain between the point in which that noise is been added and the LNA input, that is:

$$T_s = (T_a/L_w) + T_o(L_w - 1)/L_w + T_{vswr} + T_{lna} + [(L_t - 1) + L_t(F_r - 1)]*T_1/G \qquad [16]$$

where: T_a = Antenna noise temperature (K)
L_w = Waveguide loss between antenna and LNA (linear power ratio)
L_t = Transmission loss between LNA and receiver (line power ratio)
T_o = Ambient temperature (K)
T_1 = 290 K
T_{lna} = LNA noise temperature (K)
T_{vswr} = LNA-Antenna impedance mismatch noise temp. (K)
F_r = Receiver Noise Figure (linear power ratio)
G = Net gain between LNA input and receiver input (linear, includes interconnect cable loss)

The antenna temperature is usually minimum at zenith, typically 15 to 25° for a low loss, C-band antenna with low wide angle sidelobes. As the elevation angle decreases, the antenna temperature increases because more of the higher level sidelobes look at the earth which has a temperature of about 290 K. A typical curve of the variation of noise temperature with elevation angle is illustrated in Figure 6.11-10. Similarly, Figures 6.11-11-a and 6.11-11-b show typical *G/T* system performance for different antenna diameters as a function of elevation angle for C-band and Ku-band, respectively.

Satellite Transponder

The orbiting spacecraft provides a one hop carrier relay over a wide geographic area. In C-band systems the uplink signal is transmitted near 6 GHz, received by

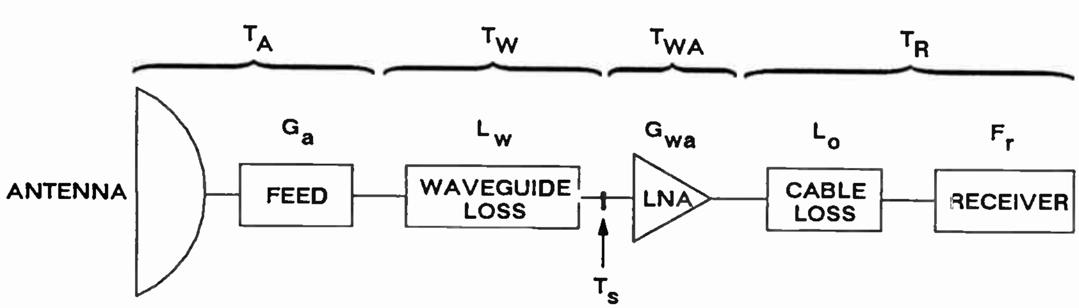

Figure 6.11-9. G/T system diagram: receive-only earth station.

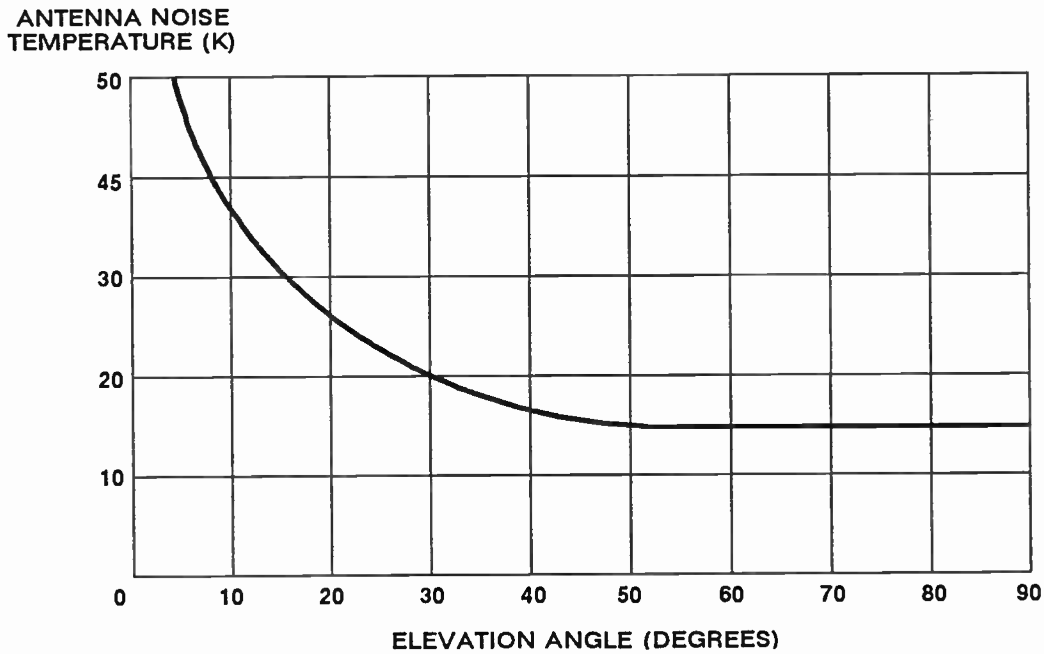

Figure 6.11-10. Typical antenna noise temperature variations with elevation angle.

the satellite, amplified, translated in frequency, filtered and retransmitted near 4 GHz. Likewise, in Ku-band systems the uplink occurs in the 14 GHz range and the downlink in the 12 GHz, and in Ka-band systems, the 30 GHz and 20 GHz ranges, respectively (see Figure 6.11-2).

Since the satellite serves as a transmit/receive station, it must be characterized by a *G/T* for the uplink side and by saturated EIRP for the downlink side. To couple the uplink and downlink signal strengths and as a definition of the transponder sensitivity, the uplink RF spectral flux density required at the satellite to saturate the transponder is also specified (saturation flux density or SFD). These three satellite parameters vary with geographic location. Contour maps called footprints are usually available for assessing these variations. Typical footprints for C-band and Ku-band satellites are shown in Figures 6.11-12 and 6.11-13, respectively.

Another important parameter which characterizes the transponder performance is the input/output power transfer and the intermodulation response. Both performance parameters are normally specified in terms of input back-off (BO_i) and output back-off (BO_o) back-off, that is, as a function of the power reduction expressed in dB with respect to saturation. Figures 6.11-14 and 6.11-15 show typical transponder response for a satellite equipped with a travelling wave tube (TWT) type power amplifier.

Satellite Link Analysis

With the preliminary procedures and formulations described previously, link calculations can be conducted. First, the distance or slant range from the satellite to the earth station needs to be determined so that the space loss may be calculated. From orbit geometry and Equation 10 above, the space loss expressed in dB is found to be:

$$L_s = 185.05 + 10\log[1 - 0.295\cos(H)\cos(\Delta L)] + 20\log f \qquad [17]$$

where: H = Latitude of earth station
ΔL = Difference in longitude for earth station and satellite
f = Frequency in GHz

The overall satellite link can now be calculated.

Uplink C/N

From equation (9), the uplink $(C/N_o)_u$ becomes:

$$(C/N_o)_u = EIRP_u - L_u + (G/T)_s + 228.6 \qquad [18]$$

or

$$(C/N_o)_u = S - A_i + (G/T)_s + 228.6 \qquad [19]$$

and

$$S = SFD - BO_i \qquad [20]$$

where: S = Flux density (dBW/m^2)
L_u = Uplink space loss (dB)
$EIRP_u$ = Uplink EIRP (dBW)
$(G/T)_s$ = Satellite G/T (dB/K)
A_i = 21.5 + 20 log f (GHz) (dB/m^2)
SFD = Saturation flux density (dBW/m^2)
BO_i = Transponder input Back-Off (dB)

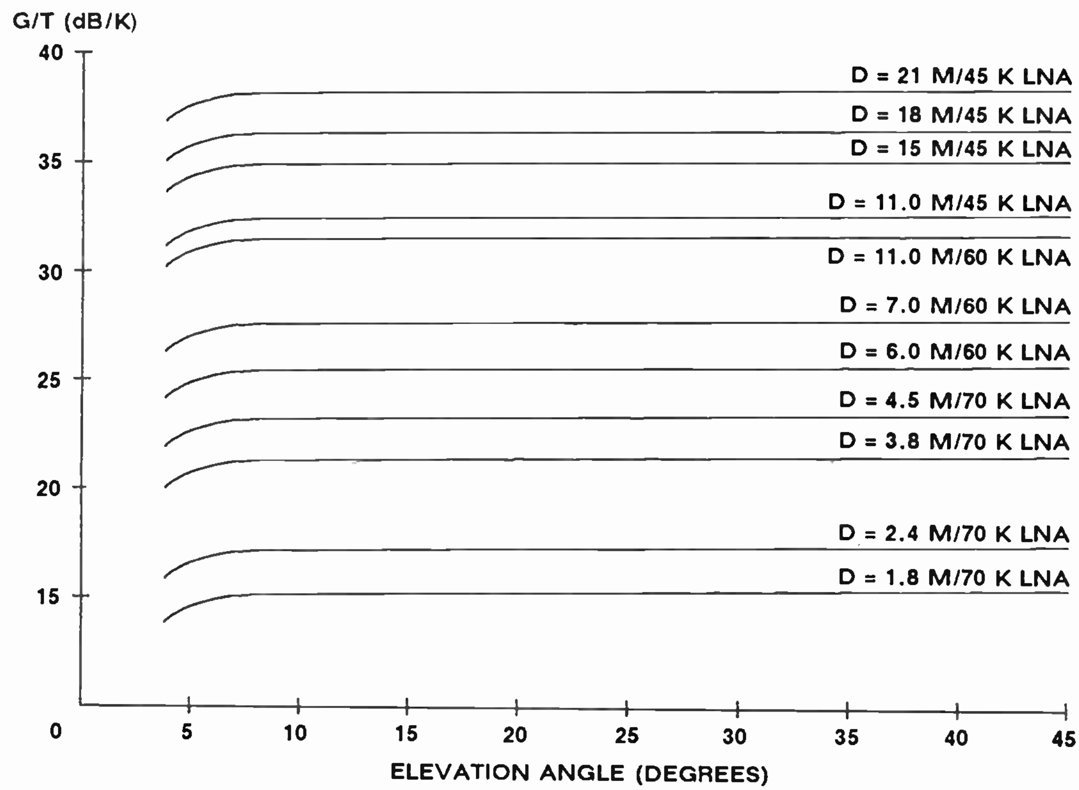

Figure 6.11-11a. Typical C-band g/T system performance versus elevation angle for different commonly used antenna diameters.

Figure 6.11-12b. C-band satellite G/T footprint.

Downlink C/N

Likewise the downlink $(C/N_o)_d$ can be calculated by:

$$(C/N_o)_d = EIRP_d - L_d + (G/T)_{e.s} + 228.6 \qquad [21]$$

and

$$EIRP_d = EIRP_s - BO_o \qquad [22]$$

where: $EIRP_d$ = Downlink EIRP (dBW)
$EIRP_s$ = Saturated EIRP (dBW)
L_d = Downlink space loss (dB)
$(G/T)_{e.s}$ = Earth station G/T (dB/K)
BO_o = Transponder output Back-Off (dB)

It is important to note that Equations 20 and 22 are related by the non-linear power transfer function of the transponder, therefore, for transponder operation below saturation the input and output relationship needs to be resolved graphically with the aid of Figure 6.11-15 or its equivalent.

Once uplink and downlink noise contributions are determined the composite link performance in terms of total carrier to noise density ratio $(C/N_o)_t$ can be readily obtained by simple noise power addition since the uplink and downlink contributions are incoherent. This yields:

$$(C/N_o)_t = \{(C/N_o)_u^{-1} + (C/N_o)_d^{-1}\}^{-1} \qquad [23]$$

Figure 6.11-13b. Ku-band satellite G/T footprint.

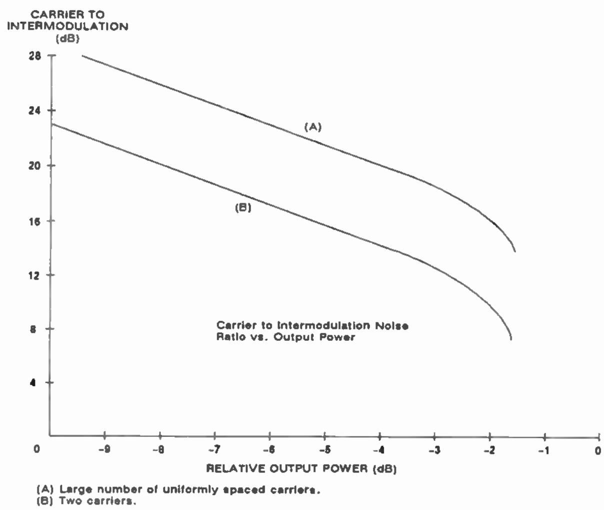

Figure 6.11-14. Output power normalized to single carrier saturation point.

This equation represents a simplified situation in that only thermal noise is added to the carriers. In actuality there are other sources of perturbations and interference; transponder non-linearity is the cause of some of the more important ones. As shown in Figure 6.11-15, operating the transponder near maximum power for better efficiency implies that compression, due to the instantaneous non-linear transfer characteristic of the amplifier relative to the signal amplitude, becomes more significant. Under this condition, when more than one frequency is amplified, interaction between the signals occurs and consequently a spectrum of spurious frequencies or intermodulation products is generated.

Particularly, the so called third order intermodulation product of the form $(2f_1 - f_2)$, a consequence of the third order non-linearity of the transponder, constitutes a significant interfering signal since it is the largest product and it falls in the same operating bandwidth of the information signal. Figure 6.11-14 shows how carrier-to-intermodulation ratio varies as a very sensitive function of the transponder operating output back-off.

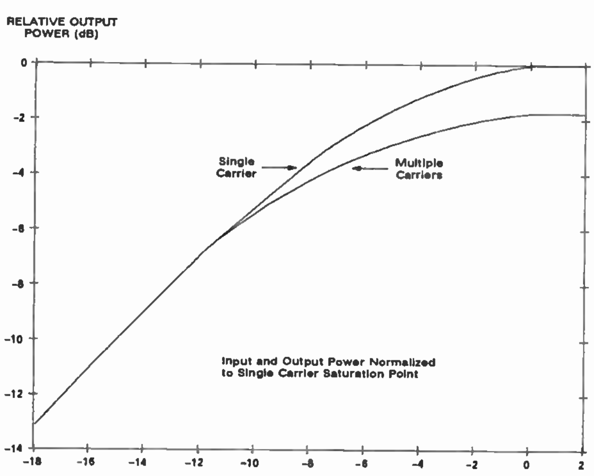

Figure 6.11-15. TWT power transfer characteristics.

System C/N

Figure 6.11-16 depicts a complete satellite link. Other sources of interference have been added, such as uplink interference due to off beam radiation from other earth stations and uplink cross-polarization isolation, combined, represented by the quantity $(C/I_o)_u$. Similarly in the downlink the quantity $(C/I_o)_d$ represents the combined effects of downlink cross-polarization isolation and adjacent satellite interference. When all these terms are considered the total link $(C/N_o)_t$ can be calculated by:

$$(C/N_o)_t = \{(C/N_o)_u^{-1} + (C/I_o)_u^{-1} + (C/N_o)_d^{-1} + (C/I_o)_d^{-1}\}^{-1} \quad [24]$$

Figure 6.11-17 shows the typical interaction of the different terms in Equation 24 as a function of transponder input back-off and in the presence of thermal and intermodulation noise. The total $(C/N_o)_t$ can be maximized by reducing the transponder input drive and adjusting the transponder gain. Backing off the TWT reduces $(C/N_o)_u$ and also $(C/N_o)_d$ (through the input/output relationship of the transponder), but as $(C/N_o)_I$ increases rapidly when the input drive is reduced, an optimum value of $(C/N_o)_t$ is obtained at a specific back-off level. Interference noise can be kept down by proper antenna design, transponder sensitivity and frequency coordination of satellite services.

Rain Effects on System Performance

Rain is the dominant factor in satellite propagation for frequencies above 10 GHz. Rain propagation has been studied intensively [10] since the late 1960s and only a brief discussion will be presented here. Due to the basic interaction of electromagnetic waves with water in liquid form, raindrops cause absorption, scattering and depolarization phenomena. Absorption and

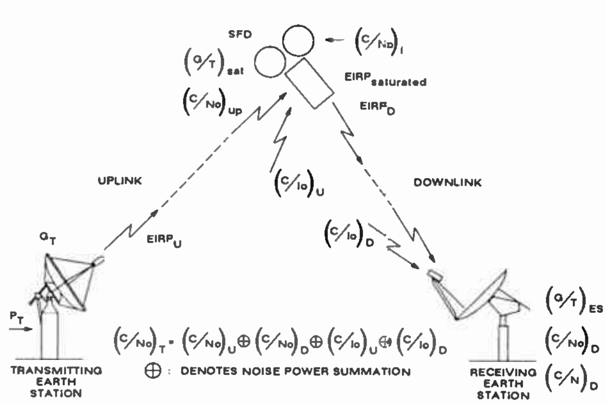

Figure 6.11-16. Satellite link model.

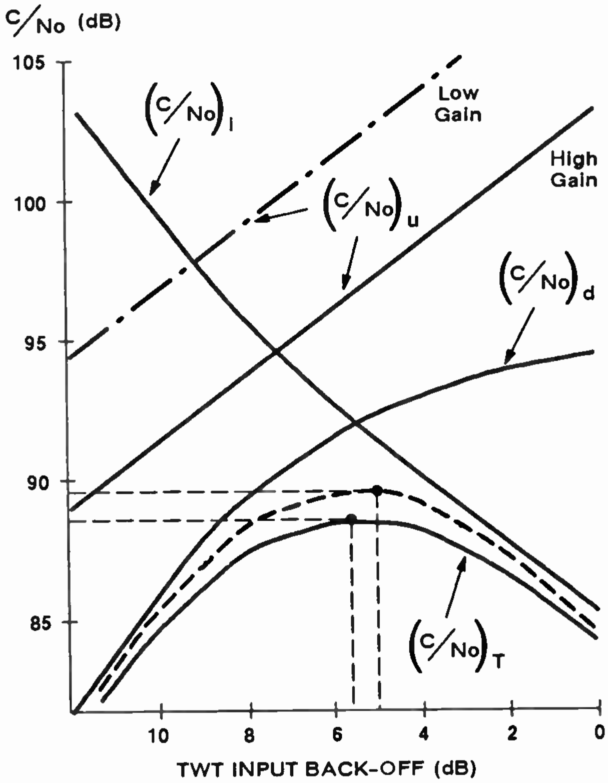

Figure 6.11-17. Optimum TWT operation.

scattering result in signal attenuation and an increase in sky noise temperature, with the consequent degradation of the received C/N_o. Depolarization has an effect on dual polarization systems and creates interference between cross-polarized signals.

Signal Attenuation

The amount of attenuation depends fundamentally on the rain intensity or rain rate and the signal path

Figure 6.11-19. Rain rate climate regions for Europe. (From NASA Propagation Effects Handbook for Satellite System Design, ORI TR 1679.)

length in rain. Rainfall data are available for most parts of the world; different types of climates have been defined and boundaries of their regions identified. Figures 6.11-18 through 20 show the NASA rain rate climate regions. The long term behavior of rain is described by the cumulative probability distribution or exceedence curve. This gives the percentage of time that the rain rate exceeds a given value. Table 6.11-2 gives the rain-rate distribution values versus per cent of year for the various rain climate regions of Figures 6.11-18 through Figure 21. Figures 6.11-21 (a) and (b) plot the rain rate cumulative probability distributions for the regions presented on the previous maps.

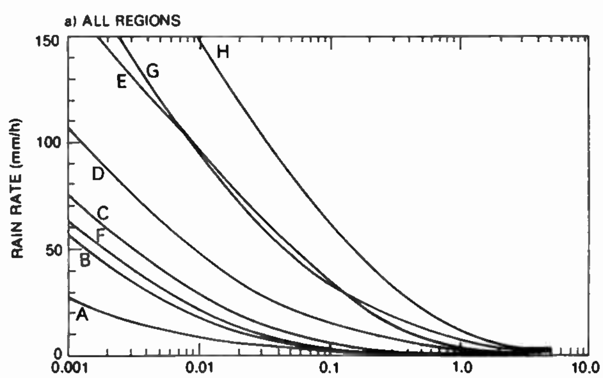
Source: NASA Propagation Effects Handbook for Satellite Systems Design, ORITR 1679

The calculation of the rain attenuation involves two basic steps. The first step is to determine the rain rate in mm/hr as a function of the cumulative probability of occurrence. This probability will be defined by the grade of service or availability of the link to be provided. The second step consists of the calculation of the actual rain attenuation associated with the rain rate that was exceeded with such probability.



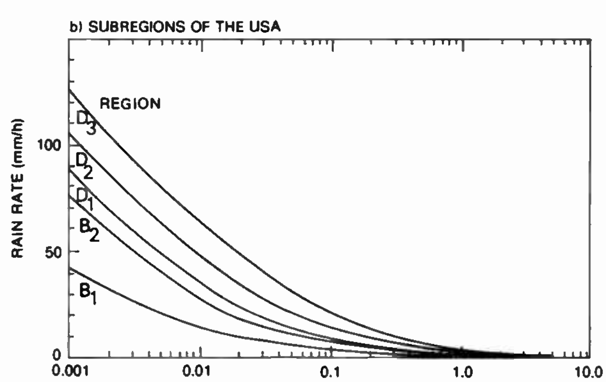


Figure 6.11-21. Rain rate cumulative probability distributions for the regions presented on the previous maps. (reprinted from Louis J. Ippolito, R.D. Kaul, and R.G. Wallace, Propagation Effects Handbook for Satellite Systems Design [NASA Reference Publication 1082(03)], National Aeronautics and Space Administration, Washington, DC, June 1983. Courtesy of NASA.)

The attenuation per unit of length (specific attenuation), λ_r (dB/Km), is tied to the rain rate R (mm/hr), by the empirically derived relationship:

$$\lambda_r = a(f)R^{b(f)} \quad \text{(dB/km)} \qquad [25]$$

where $a(f)$ and $b(f)$ are frequency dependent coefficients. For the frequency range between 8.5 and 25 GHz, Equation 25 becomes:

$$\lambda_r = 4.21*10^{-5} f^{2.42}*1.41*f^{-0.0779} R \quad \text{(dB/km)} \qquad [26]$$

The attenuation per unit length is heavily frequency dependent, Figure 6.11-22 shows frequency dependence of λ_r for various rain rates.

Introducing the concept of equivalent path length, $L_e(R)$, the total rain attenuation in decibels is simply:

$$Ar = \lambda_r L_e(R) \quad \text{(dB)} \qquad [27]$$

Equivalent path length is primarily determined by the height of the freezing level or 0° isotherm, which depends on latitude, season and rain rate, the cosecant of the elevation angle and site altitude. For latitudes within ±30°, the freezing level is at 4.8 km. Curves of equivalent path lengths versus elevation angle and for different rain rates are shown in Figure 6.11-23.

The rain attenuation is required to be added to the satellite link as a margin to allow the specified availability under fading conditions. Figures 6.11-24(a) and (b) show typical rain attenuations versus rainfall rate in the transmit and receive Ku-bands for different elevations angles.

Noise Contribution

In addition to the attenuation, rain also degrades the performance of a satellite link by increasing the earth station antenna noise temperature. In clear weather the antenna sees the cold background of space, but in rain it receives thermal radiation from the raindrops. The increase in antenna noise temperature due to rain, T_r, may be estimated by:

$$T_r = 280(1 - 10^{-A/10}) \quad \text{(K)} \qquad [28]$$

where A is the rain attenuation in decibels. Figure 6.11-25 shows the impact of the rain contribution of noise temperature on the normal clear sky *G/T* for different clear sky system temperatures. The *G/T* degradation corresponding to the rain attenuation for the stipulated link availability also must be added to the satellite downlink. This is to provide sufficient margin to compensate for the combined rain effect of signal attenuation and noise increase.

The allocations of rain fade margins in the uplink and downlink can be done independently, corresponding to specific availability requirements of the uplink or downlink and consistently with the availability requirement of the total link. The assumption is that, due to the localized nature of the rain fades, the uplink fade and downlink fade can be considered as two statistically independent processes. Therefore, total link availability can be obtained as the reciprocal of the

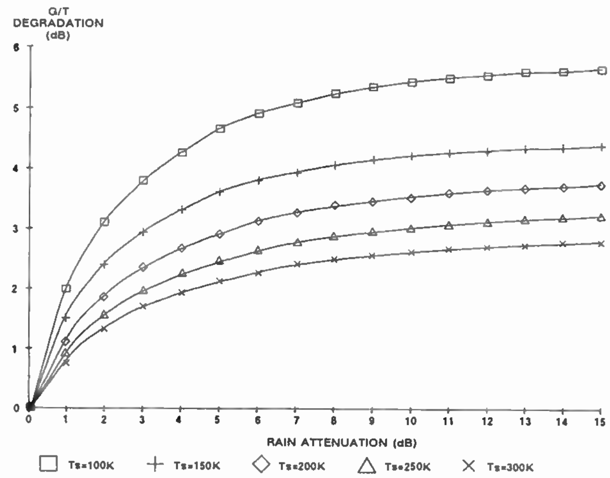

Figure 6.11-25. G/T rain degradation.

summation of the uplink and downlink outages calculated as if they occurred independently and one at a time.

Example of System Link Calculation

Table 6.11-3 shows a typical satellite link budget for a video uplink and downlink for Ku-band operation where a 5 dB uplink power control has been applied to mitigate the effects of rain fade in the uplink. A C-band link budget would contain similar terms but the uplink power control to mitigate the effects of rain would not be necessary.

Baseband Performance Link Analysis

As stated previously, the overall quality of the delivered baseband signal can be expressed in analog systems by the S/N or in digital systems by the BER. Other performance parameters such as phase and frequency

linearity and intersymbol interference, can be utilized to fully characterize quality as is common in any transmission system. However, since satellites are inherently wide band repeaters, S/N and BER are the most sensitive performance factors that depend on link operational parameters.

The C/N_o versus S/N performance of different modulation schemes can be characterized by rather simple mathematical equations. The most common analog modulation technique in satellite transmission is frequency modulation (FM). Because of its simplicity and the low cost of the receivers and demodulators, FM is widely utilized in the transmission of television signals. Equation 29 allows the computation of the S/N as a function of C/N_o and modulation parameters.

$$(S/N)_w = C/N_o + 10\log(12\Delta F^2/B_v^3) + W \quad [29]$$

or in terms of carrier-to-total-noise power ratio in a bandwidth B:

$$(S/N)_w = C/N + 10\log(12\Delta F^2/B_v^3) + 10\log(B/B_v) + W \quad [30]$$

where:

$(S/N)_w$ = Weighted Signal-to-noise Ratio (dB)
C/N_o = Carrier-to-noise density ratio (dB)
ΔF = Peak composite video deviation (MHz)
B = IF predetection noise bandwidth (MHz)
B_v = Video filter bandwidth (MHz)
W = Deemphasis and weighting improvement (dB)

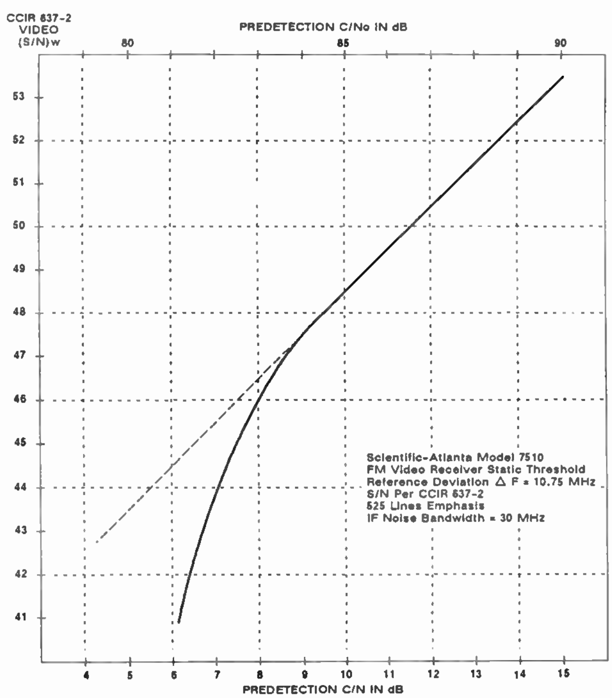

Figure 6.11-26. Signal-to-noise ratio performance of FM video demodulator vs. C/N and C/N_o.

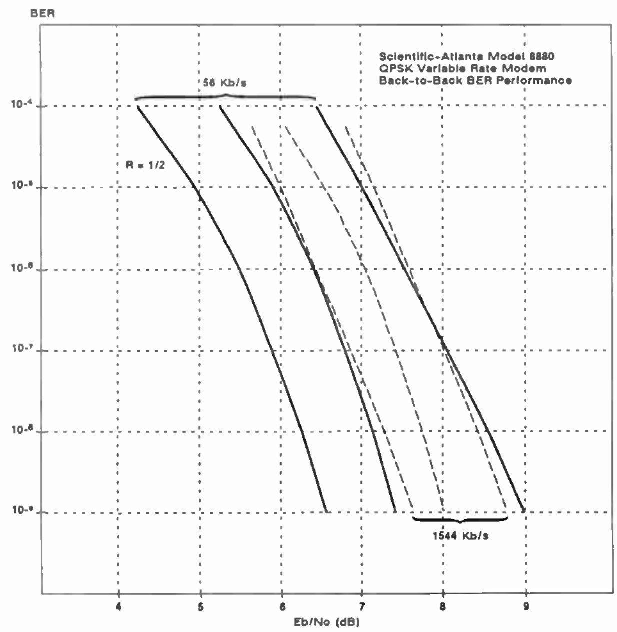

Figure 6.11-27. BER modem performance vs. bit energy over noise density ratio.

For NTSC and 30 MHz bandwidth these parameters are typically: ΔF = 10.75 MHz, B = 28 MHz, B_v = 4.2 MHz and W = 13.8 dB. Figure 6.11-26 shows the result of Equation 29 with the previous transmission parameters at high levels of C/N. The departure from a linear relationship at low values of C/N is not predicted by Equation 29 but represents the actual performance of typical FM demodulator. This phenomenon is known as the *threshold effect.*

In digital satellite systems the most common modulation technique is phase shift keying (PSK). Variations of this technique are known as binary PSK or BPSK in the case that logic symbols zeros and ones are mapped into RF signals 180° apart in phase; and as Quadrature PSK or QPSK when the phases are 90° apart. In recent years 8PSK, using 40° phases, has also come into widespread use. The BER performance of these systems is evaluated as a function of the energy per bit of information transmitted (E_b) versus noise density, E_b/N_o. Sophisticated digital coding and decoding techniques exist that, by adding error control bits to the information data stream, allow substantial improvements in BER that can translate into transmit power reductions of up to 5 dB. The ratio between the uncoded data rate and the coded one is called coding rate (R). Figure 6.11-27 shows the performance of a typical QPSK modulator and demodulator for different data and coding rates.

Earth Station Block Diagram

The block diagram of Figure 6.11-28 depicts an earth station capable of providing uplink services for both encrypted video and data in the vertical and hori-

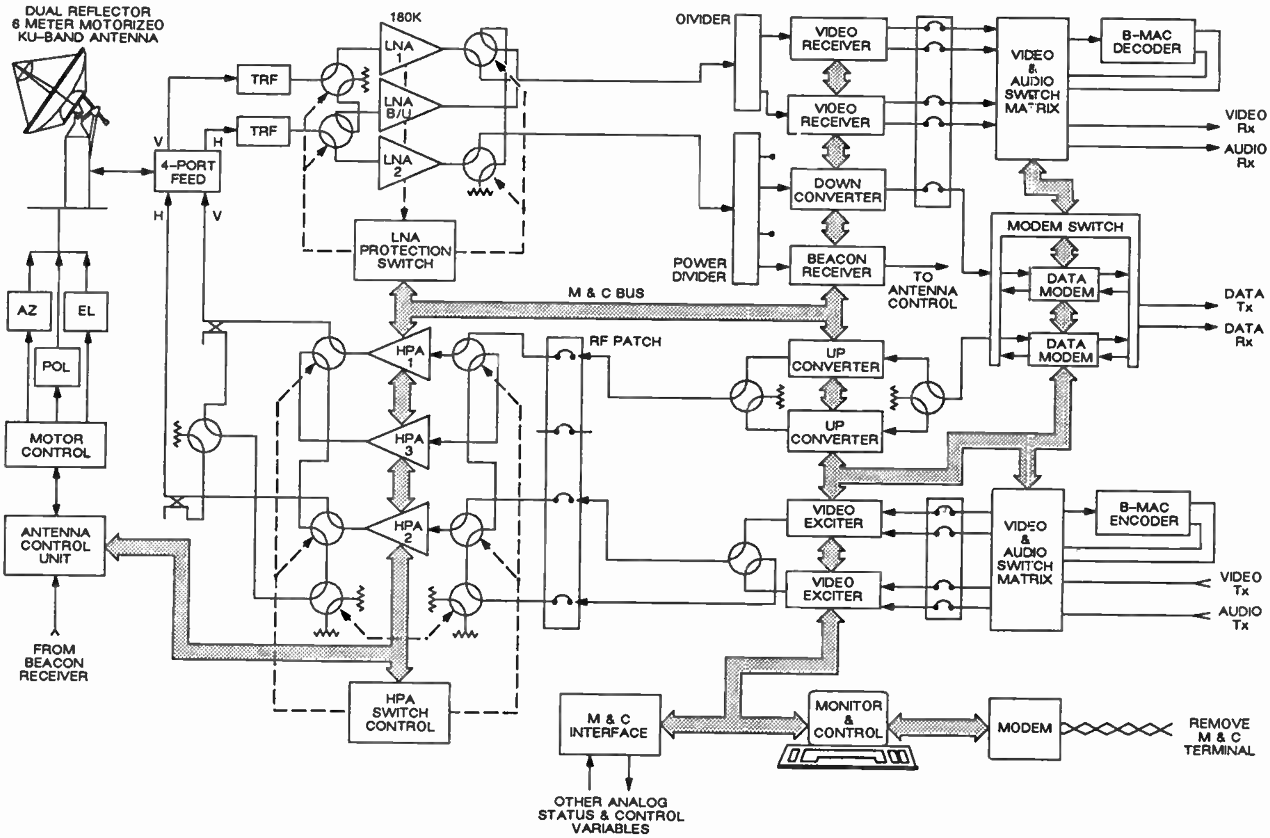

Figure 6.11-28. Encrypted video and data broadcast earth station block diagram.

zontal polarizations simultaneously. All subsystems are redundant for maximum reliability. The backup video exciter and HPA are also capable of occasional video uplinks through transmit couplers in either polarization. A computer based monitor and control system, by means of a serial control bus, offers centralized operation of the complete earth station with the ability of monitoring all status and controlling all variable parameters of every subsystem from the local or remote terminals.

Figure 6.11-29 shows the block diagram of the corresponding dual polarization receive only terminal. This low cost earth station, with an L-band (950 MHz to 1450 MHz) inter-facility link (IFL) can provide simultaneous reception of encrypted video and data.

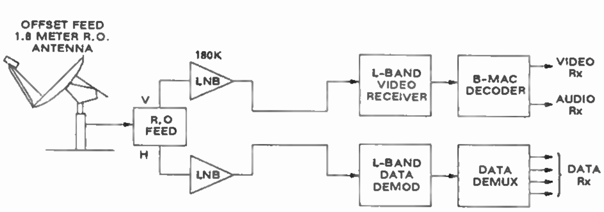

Figure 6.11-29. Receive-only earth station for encrypted video and data broadcast.

Interference Analysis

The consideration of interference in a satellite communication system is important, not only from the standpoint of the desired satellite signal being interfered with, but also as it applies to the satellite signals generating interference into other systems. It is mandatory for a proposed satellite transmit system in the United States to submit a coordination filing that includes an interference analysis to the FCC. This analysis must show the impact of the proposed system on existing operational systems and must satisfy the allowable interference requirements of the FCC. Coordination for receive only systems is not mandatory and is only necessary when a C-band system desires interference protection from future terrestrial systems.

In August 1983, the FCC finalized a new satellite orbital assignment plan based on a frequency and polarization plan to allow satellite spacing to be reduced from the previous 4° to 2° with an interim average spacing of 2.5° at C-band. The implementation of this plan depended on several important technical achievements including:

- The adoption of a [29 − 25 log(θ)] dBi peak sidelobe envelope for angles off boresight between 1 and 7°
- Frequency reuse for all satellites

- Adjacent satellite, same frequency transponders being orthogonally polarized
- Homogeneity of satellite EIRP and saturation flux density characteristics for minimum spacing

Model for Interference Analysis

The interference analysis presented in the following sections is based on models for the antenna characteristics, the spectral characteristics for the desired and interfering carriers and assumes the final implementation of a uniform 2° spaced satellite environment about the geostationary orbital arc.

Antenna Characteristics

The primary characteristic of the antenna which affects the interference analysis is the angular discrimination, the gain differential between the on-axis gain and the gain of an off-axis angle for the interfering source. For this analysis, the copolarized radiation patterns of the assumed earth station antennas are characterized by the $[29 - 25 \log(\theta)]$ dBi envelope. The cross-polarized radiation patterns are characterized by $[19 - 25 \log(\theta)]$ dBi envelope (see Figure 6.11-30). In actuality, the antenna radiation sidelobe may fall below or above these reference envelopes by some predetermined acceptable level. Any sidelobes that are below the reference envelope and at the appropriate pointing angles of adjacent satellites would reduce the interference and, conversely, any sidelobes above the envelope pointing at adjacent satellites would increase the interference. The cross-polarization discrimination of 10 dB is assumed to apply for clear sky conditions. It should be pointed out that during periods of heavy rain, the polarization of the incoming/outgoing signals may be affected such that the full 10 dB is not realized.

Satellite Characteristics

The analysis that follows is based on a satellite deployment model with cofrequency transponders on adjacent satellites being cross-polarized with each other. The calculations are performed with this model

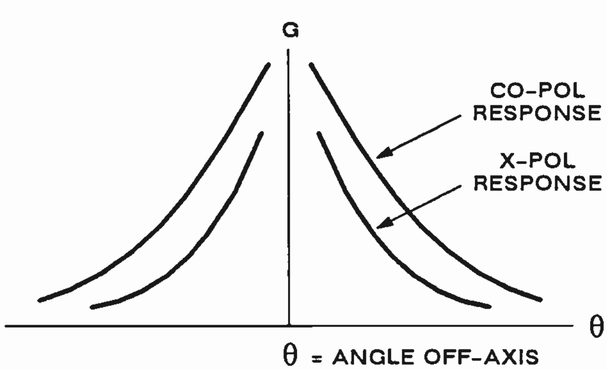

Figure 6.11-30. Earth station antenna radiation characteristics.

to demonstrate the expected results in a uniform satellite environment. Three cases of this model are examined:

1. A homogeneous model in which interfering and desired satellites have the same saturation flux density and radiated EIRP. (The radiation patterns yield the same signal strength at any given location on the ground.)
2. A model in which the interfering satellite EIRP exceeds the desired satellite EIRP by 2 dB.
3. A model in which the interfering satellite EIRP exceeds the desired satellite EIRP by 4 dB.

Note that the spacecraft antennas are assumed to have a minimum cross-polarization discrimination of 35 dB.

EIRP is a very important consideration. Antenna and transponder characteristics are such that their initial EIRP contours on the earth's surface are not identical. Differences in the initial EIRP contours and differences in transponder aging must be considered in a practical system. An orbital spacing plan that is predicated on differential EIRPs of less than 2 dB represents an impractical burden, both on the satellite manufacturers, and on the FCC in assuring compliance with a more stringent specification. Therefore, it is suggested that the calculations for the second case (2 dB variations in EIRPs) be taken as representing a practical case.

The calculations will also be based on geosynchronous rather than topocentric angles and do not include stationkeeping inaccuracies. An average topocentric angle for the contiguous United States (CONUS) can be estimated by multiplying the geocentric angle by 1.08.

Sources of Interference

Interference into a geostationary satellite communication system can originate from several sources, including the following:

- Adjacent satellite signals
- Internal cross-polarization signals (half transponder frequency offsets)
- Terrestrial microwave signals (does not apply for Ku-band or Ka-band)

These three are analyzed separately in the following paragraphs and then combined to determine the total interference into the system.

Adjacent Satellite Interference

Interference from adjacent satellites occurs in two ways: uplink interference from earth stations transmitting to adjacent satellites and downlink interference from adjacent satellite transmission into the desired earth station. The interference in both the uplink and downlink consists of many signals (23 of 24 channels for a fully loaded frequency reuse satellite), but it is primarily caused by the co-frequency channels/or transponders and the two half transponder bandwidth offset-channels in a frequency reuse system, Figure 6.11-31. The particular interferers for the C-band example system are the following:

a) The co-frequency, cross-polarized channel on the first adjacent satellite on each side.
b) The two 20 MHz offset-frequency, co-polarized channels on the first adjacent satellite on either side.
c) The co-frequency, co-polarized channel on the second adjacent satellite on either side.
d) The two 20 MHz offset-frequency, cross-polarized channels on the second adjacent satellite on either side.

The contribution to interference from satellites at orbital positions greater than 4° from the desired satellite tends to be noise-like in that it is the result of a number of small, relatively non-coherent signals.

The equations for calculation of the adjacent satellite interference are given below:

$$(C/I)_u = (EIRP)_{es} - \sum_{i=1}^{N} \oplus \{(EIRP)_i - [G_i - G(\theta_i)] + F_i + P_i\} \quad [31]$$

where:

$\sum_{i=1}^{N} \oplus$ = Series power summation
$(EIRP)_{es}$ = Earth station radiated power in dBW
$(EIRP)_i$ = Effective radiated power of interfering earth station in dBW
G_i = Peak gain of the interfering earth station in dBi
$G(\theta)_i$ = Gain of the interfering earth station in direction (θ) in dBi
F_i = Frequency discrimination factor for ith earth station
P_i = Polarization discrimination factor for ith earth station

$$(C/I)_d = (EIRP)_{sat} + G_{es} - \sum_{i=1}^{N} \oplus \{(EIRP)_i + G_{es}(\theta_i) + F_i + P_i\} \quad [32]$$

where

$(EIRP)_{sat}$ = Effective radiated power of satellite in the direction of the receive earth station in dBW
G_{es} = Gain of the receive earth station in dBi
$G_{es}(\theta_i)$ = Gain of the receive earth station in the direction θ_i in dBi
F_i = Frequency discrimination factor for the ith earth station
P_i = Polarization discrimination factor for the ith earth station
N = Number of transponders considered ($N \geq 3$)
M = Number of adjacent satellites considered ($M \geq 4$, typically 8, 4 on each side)

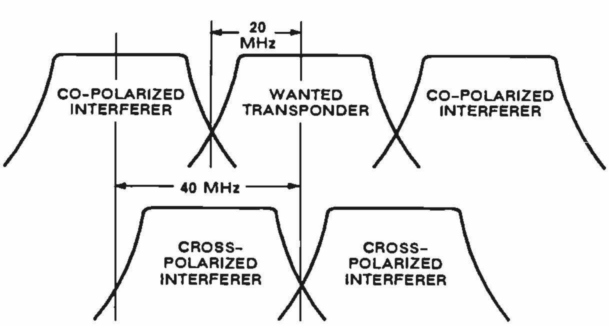

Figure 6.11-31. Frequency reuse transponder plan.

The total adjacent satellite interference is then calculated by combining the uplink and downlink contributions in a power summation manner.

$$(C/I)_{adj.sat} = (C/I)_u \oplus (C/I)_d \quad [33]$$

The polarization discrimination factor in the previous equations is the system discrimination rather than that of the receive or transmit antenna alone. A well designed dual linearly polarized antenna can achieve excellent cross-polarization discrimination on or near the main beam axis (greater than 35 dB or 40 dB relative to the copolarized energy) and reasonable rejection of the cross-polarized signals in the close-in sidelobe regions. The adjacent satellite signals are received through the sidelobes of the earth station, and the $[19 - 25 \log(\theta)]$ envelope is assumed in the analysis. This assumption, rather than being conservative, may be optimistic when one considers the interactions of the ionosphere and atmosphere on the transmitted signals (from the earth station and/or the satellites) and the polarization angle alignment between satellites. A more conservative analysis may assume a slightly reduced discrimination of perhaps $[21 - 25 \log(\theta)]$ for the cross-polarized sidelobe energy in the off-axis regions.

The frequency discrimination factor is related to the spectra of the desired and undesired signals. This factor can range from 0 to 12 dB depending upon the interfering power from the different services. For example, the F_i term, where an FM/TV signal is interfering with a FM/TV signal occupying the same bandwidth, would be 0 dB. For a 20-MHZ offset-frequency FM/TV signal, with a 36 MHz bandwidth, F_i could range from 3 to 15 dB depending on the characteristics of the video signals. It is suggested that for typical FM/TV a value 6.5 to 8.0 dB is realistic. The 8.0 dB value is suggested by the FCC, but a conservative value of 6.5 dB will be used in the example analysis.

Internal Interference

The internal interference in a satellite system is primarily due to the two adjacent 20-MHz offset-frequency channels. The interfering power from different services has been calculated by convolving the power spectra of the individual services. This data, taken together with the appropriate polarization discrimination term, determines the amount of interference and is given in Table 6.11-4. The polarization discrimination

Table 6.11-4
Summary of Internal Interference for TV/FM Service.

I.			Uplink Pol Disc		Downlink Pol Disc
Satellite			35.0 dB		35.0 dB
Ground Station			35.0		35.0
Faraday			35.0		29.0
Resultant			28.0 dB		26.0 dB
II. Atmospheric Effect—25° Elevation Angle					
% Time	Rain Rate		Uplink		Downlink
99.0	0.5 in/hr		30.5 dB		33.0 dB
99.9	1.5 in/hr		21.0		25.0
99.99	3.0 in/hr		16.5		20.0
III. Resultant Polarization Discrimination					
% Time			Uplink		Downlink
99.0			23.1 dB		22.8 dB
99.9			17.8		19.5
99.99			14.5		16.5
IV. Carrier-to-Interference TV/FM					
% Time	$(XPD)_u$	$(XPD)_d$	$(C/I)_u$	$(C/I)_d$	$(C/I)_s$
99.0	23.1	22.8	27.1	26.56	23.81
99.9	17.8	19.5	21.2	21.26	18.22
99.99	14.5	16.5	18.6	17.96	15.26

term, is dependent on the climatic conditions which are dealt with in Table 6.11-4 by a percent of time condition.

Terrestrial Interference

Terrestrial microwave carriers are centered on frequencies offset by 10-MHz from the satellite carriers. To analyze the effects of terrestrial carriers on the FM/TV system, it is necessary to determine the power level of the interfering signal and the spillover of the terrestrial carrier spectra into the passband of the receiver. The first factor involves site details, such as angular discrimination and distance to the interfering transmitter. The second factor can be computed from the spectral distribution projected for the terrestrial carrier and the filter characteristic of the receiver. For the purpose of this analysis, it is assumed the *C/I* due to terrestrial microwave is 25 dB.

Interference Analysis for FM/TV Service

The interference for the FM/TV service is based on the following parameters:

Parameter	Specification
Transponder EIRP	34 dBW
Antenna Size (diameter)	
Transmit	10 m
Receive	3 m, 4.5 m 7 m, or 10 m
Uplink IRP	80 dBW
Transmit Power	4.5 kW

Each of the antennas listed previously is presently used in FM/TV systems. Many are licensed and regulated and therefore protected from interference in certain respects. Many receive only earth stations are unlicensed and therefore not protected. The result of the analyses is presented in Figures 6.11-32 through 6.11-35. Each figure includes three cases of desired signal EIRP relative to the interfering signal EIRP and the effect of variable terrestrial interference is shown.

Sun Transits and Eclipses

Communication satellite systems experience predictable service interruptions involving the sun. A sun transit outage occurs when the pointing angles from a receiving earth station to a satellite and to the sun so nearly coincide that the additional noise power presented by the sun renders transmission unusable. A solar eclipse occurs when the earth shadows the sun from the satellite. The eclipse event is not as serious as the sun transit event since the satellite has battery backup systems to augment the solar primary power.

Daily sun transits of all geostationary satellites serving an earth station occur during one week in the spring and again in the fall. The exact dates depend primarily upon the latitude of the receiving earth station. The geometry and duration associated with a sun transit are controlled by the off-axis gain of the earth station antenna, the receiving system noise temperature, the solar noise power profile and the minimum acceptable

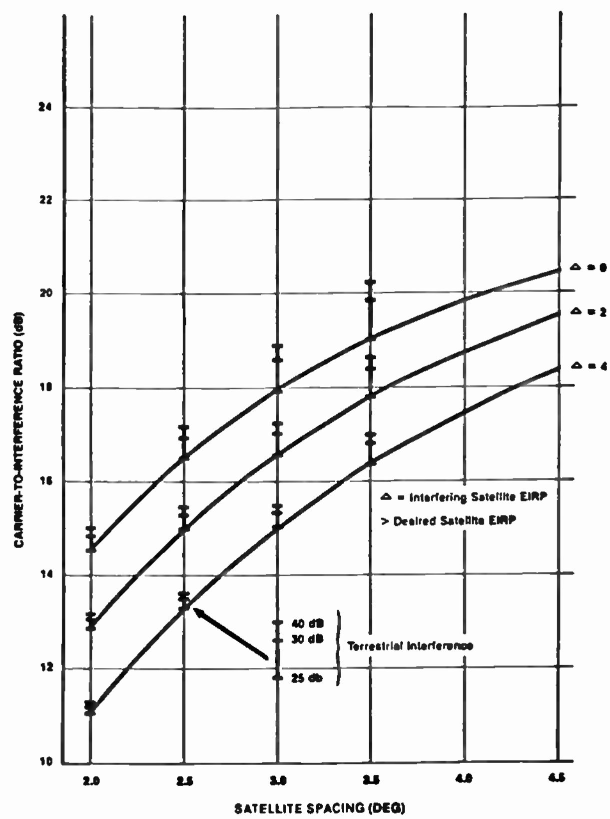

Figure 6.11-32. Carrier-to-interference ratio vs. satellite spacing for a 10-meter uplink and a 3-meter downlink. FX = 6.5 dB, PX = 10 dB. Co-Pol 29-25 Log θ envelope and adjacent satellite polarization interleaving.

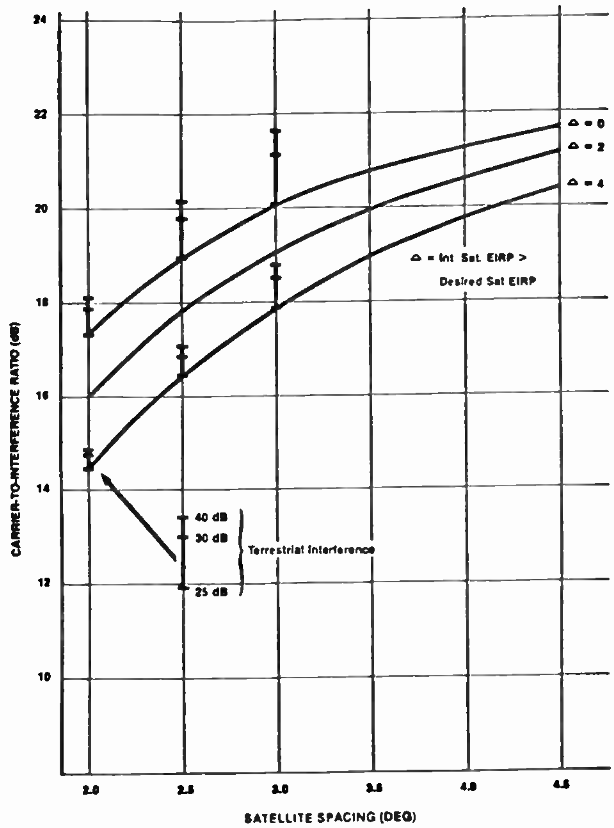

Figure 6.11-33. Carrier-to-interference ratio vs. satellite spacing for a 10-meter uplink and a 4.5-meter downlink. FX = 6.5 dB, PX = 10 dB. Co-Pol 29-25 Log θ envelope and adjacent satellite polarization interleaving.

S/N ratio. In late February or early March, short daily outages affect earth station systems situated near the United States-Canadian border. Two or three days later these systems experience maximum outages lasting five minutes or more, depending upon transmission parameters and permissible *S/N*. Outages at these earth station locations end after an additional two to three days and the sun transit outage paths progress southward at a rate of about 3° latitude per day. All outages affecting United States earth station antenna systems above north latitude 26° cease prior to mid-March. Conversely, in the fall the daily outages progress from south to north, affecting southern United States earth stations beginning October 1 and ending in the north about mid-October.

Eclipses of geostationary satellites can be expected for a total of about 90 evenings per year in the spring and fall. Eclipses occur near apparent midnight of the time zone at each satellite's longitude, beginning in late February or early March and ending mid-April. Fall events begin about September 1 and end mid-October. Eclipses of about 70 minutes duration occur on the dates of the spring and fall equinoxes. Communication satellites are provided with batteries to prevent circuit outages and to maintain pointing, attitude control, stationkeeping, telemetry and command capabilities during eclipses.

EQUIPMENT CHARACTERISTICS

An earth station system is made up of four major subsystems: the antenna subsystem, the transmitting subsystem, the receiving subsystem and the monitor and control subsystem.

Antenna

The antenna is one of the more important component parts since it provides the means of transmitting signals to the satellite and/or collecting the signal transmitted by the satellite. The antenna must not only provide the gain necessary to allow proper transmission and reception, but also must have radiation characteristics that discriminate against unwanted signals and minimize interference into other satellite or terrestrial systems. A further function of the antenna is to provide the means of polarization discrimination of unwanted signals. The individual communication system operational parameters dictate to the antenna designer the necessary electromagnetic, structural and environmental specifications necessary for the antenna.

Antenna requirements can be grouped into several major categories: electrical or RF, control systems,

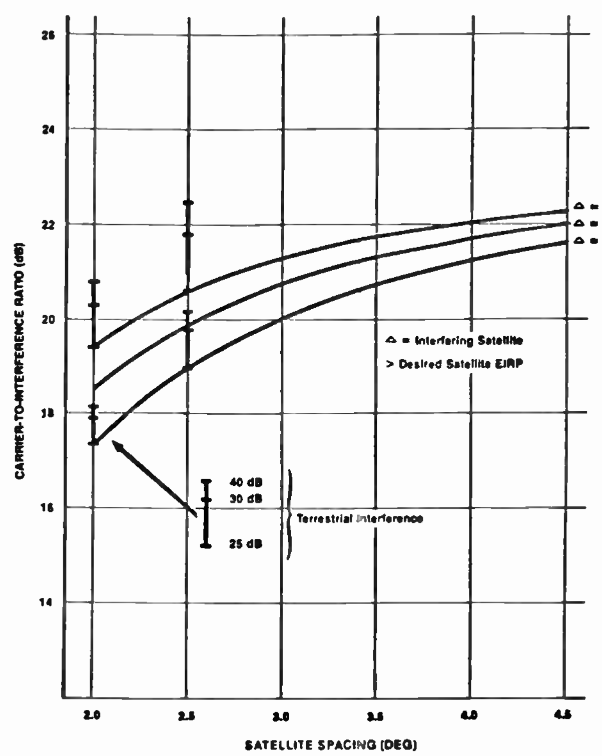

Figure 6.11-34. Carrier-to-interference ratio vs. satellite spacing for a 10-meter uplink and a 7-meter downlink. FX = 6.5 dB, PX = 10 dB. Co-Pol 29-25 Log θ envelope and adjacent satellite polarization interleaving.

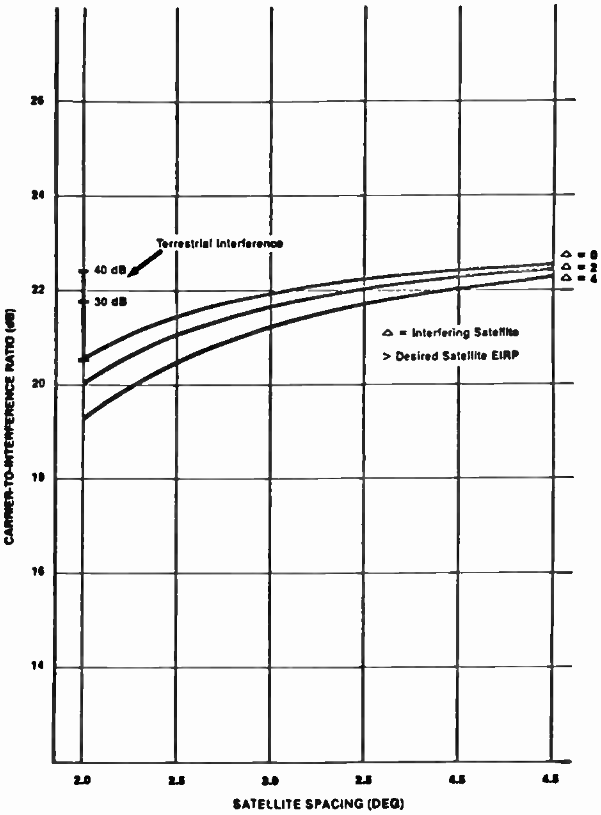

Figure 6.11-35. Carrier-to-interference ratio vs. satellite spacing for a 10-meter uplink and a 10-meter downlink. FX = 6.5 dB, PX = 10 dB. Co-Pol 29-25 Log θ envelope and adjacent satellite polarization interleaving.

pointing and tracking accuracies, environmental and miscellaneous requirements such as radiation hazard, primary power distribution, etc. Table 6.11-5 summarizes many of the more important parameters of an earth station antenna.

Electrical Performance

The primary electrical specifications of an earth station antenna are gain, noise temperature, VSWR, power rating, receive/transmit group delay, radiation pattern, polarization, axial ratio, isolation and *G/T*. All of the parameters except the radiation pattern are determined by the system requirements. The radiation pattern should meet the minimum requirements set by the FCC and/or the ITU-R. Earth stations that operate in a regulated environment in the United States domestic system must meet the requirements set forth in the FCC regulations for earth station antennas pertaining to antenna aperture diameter, sidelobes, and/or radiated power density (see Part 25, paragraph 25.209 of the FCC Rules and Regulations).

The desired radiation properties to satisfy the communication system design dictate the choice of the type of antenna to be employed as an earth station. The three most important radiation properties are gain, sidelobe performance and noise temperature. Most earth station antennas are designed to maximize gain and minimize noise, thereby maximizing *G/T*. These two criteria have led to the predominance of reflector type antennas for earth station applications although other types of antennas such as arrays have been used.

Types of Earth Station Antennas

Several types of earth station antennas are now in use within the United States and abroad. These antennas can be grouped into two broad categories: *single beam antennas and multiple beam antennas.* A single beam earth station antenna is defined as an antenna which generates a single beam which is pointed toward a satellite by means of a positioning system. A multiple beam earth station antenna is defined as an antennas that generates multiple beams by employing a common reflector aperture with multiple feeds illuminating that aperture. The axes of the beams are determined by the location of the feeds. The individual beam identified with a feed is pointed toward a satellite by positioning the feed without moving the reflector. The dual-frequency antennas may be considered another class of antennas as they produce two coincident simultaneous beams and as such are categorized as single beam antennas.

Single Beam Antennas

The majority of the earth station antennas in use today are single beam antennas. Single beam antenna types used as earth stations are paraboloidal reflectors with focal point feeds (prime focus antenna), dual

reflector antennas such as the Cassegrain and Gregorian configurations, horn reflector antennas, offset-fed paraboloidal antennas and offset-fed, multiple reflector antennas. Each of these antenna types has its own unique characteristics and the advantages and disadvantages have to be considered when choosing them for a particular application.

Axisymmetric Dual Reflector Antennas

The predominant choice of most system operators has been the dual-reflector Cassegrain antenna. Cassegrain antennas can be divided into three primary types:

- The classical Cassegrain geometry employing a paraboloidal contour for the main reflector and a hyperboloidal contour for the subreflector (Figure 6.11-36). The paraboloidal reflector is a point focus device with a diameter D_p and a focal length f_p. The hyperboloidal subreflector has two foci. For proper operation, one of the two foci is the real focal point of the system and is located coincident with the phase center of the feed; the other focus, the virtual focal point, is located coincident with the focal point of the main reflector.
- A geometry consisting of a paraboloidal main reflector and special shaped, quasi-hyperboloidal subreflector. The geometry of Figure 6.11-37 is appropriate for describing this antenna. The main difference between the classical Cassegrain and this antenna is the subreflector has been designed such that the overall efficiency of the antenna has been enhanced, thereby yielding improved gain performance. This technique is especially useful with antenna diameters of approximately 30–100 wavelengths; for example, a 5 m antenna in the 6/4 GHz frequency band.
- A generalization of the Cassegrain geometry consisting of a special-shaped, quasi-paraboloidal main reflector and a shaped, quasi-hyperboloidal sub-

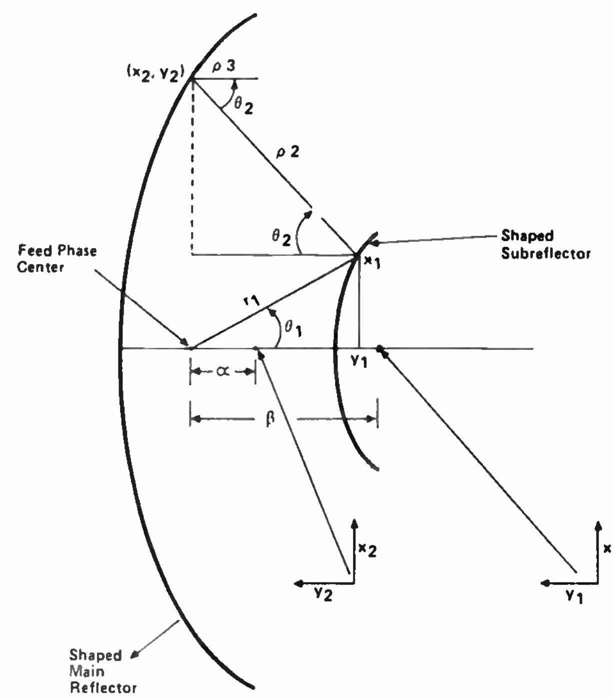

Figure 6.11-37a. Dual-shaped reflector geometry.

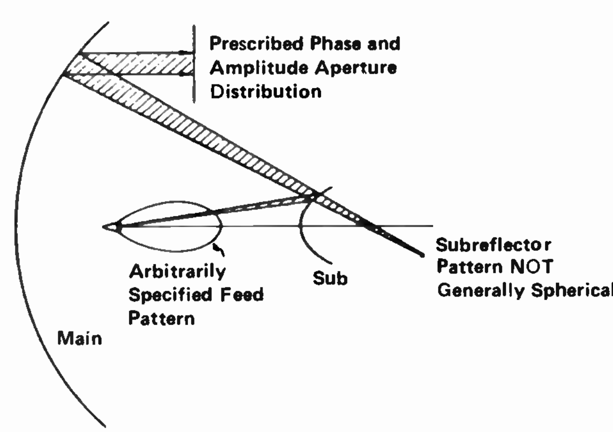

Figure 6.11-37b. Circularly symmetric dual-shaped reflectors.

reflector. The subreflector is shaped to redistribute its incident energy such that the illumination of the main reflector is optimized for high gain and desired radiation pattern. The main reflector is then shaped to correct the phase of the aperture field such that it is in-phase. The feed must have a high beam efficiency and its radiation pattern should be circular symmetric. This technique allows the antenna designer to synthesize the surfaces to achieve an arbitrary aperture distribution.

The dual reflector antenna offers excellent gain performance and for aperture sizes larger than approximately 75 wavelengths the sidelobe performance can meet the FCC pattern requirements. Dual reflector designs are employed for earth station antennas for apertures as small as 50 wavelengths to as large as 500 wavelengths.

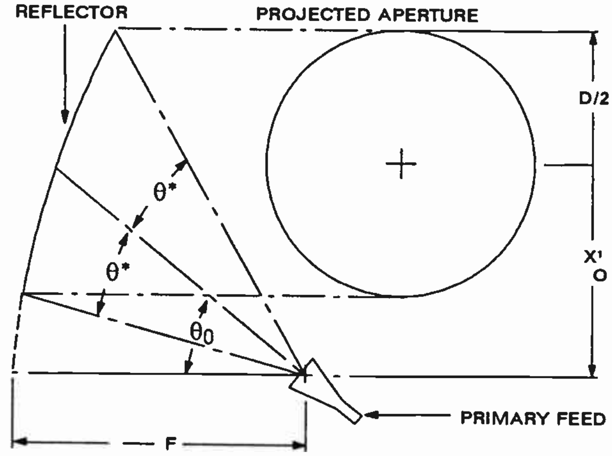

Figure 6.11-38. Single offset reflector antenna.

Prime Focus Fed Paraboloidal Antennas

The prime focus fed paraboloidal (PFFP) antenna is another of the most often employed antennas for earth stations. This type of antenna can have excellent sidelobe performance in all angular regions except the spillover region around the edge of the reflector, but even in this region the pattern requirements of the FCC can be met. This antenna configuration has a lower cost than dual reflector antennas and offers a good compromise choice between gain and sidelobes. Its basic limitations are in its location of the feed for transmit applications and for aperture sizes less than approximately 30 wavelengths, the blockage of the feed and the feed support structure raises the sidelobes with respect to the main beam such that it becomes exceedingly difficult to meet the FCC sidelobe requirements. The PFFP antenna is used for many receive only earth station antennas as well as for transmit/receive applications when only one transmit polarization is required.

Offset-Fed Reflector Antennas

The offset-fed reflector antenna, Figure 6.11-38, has been used primarily in small aperture antennas for VSAT applications. The offset-fed reflector antenna can employ a single main reflector or multiple reflectors, with two reflectors the more prevalent of the multiple reflector designs. The offset, front-fed reflector, consisting of a section of a paraboloidal surface, eliminates the direct aperture blockage from the feed and feed supports and minimizes diffraction scattering by removing the feed and feed support structure from direct illumination of the aperture current distribution. The sidelobe patterns of small apertures can meet the FCC and ITU-R requirements. The limitations of the offset-fed single reflector antenna are in its polarization performance, reduced cross-polarization performance off-axis for linear polarizations and beam squints in opposite directions for two orthogonal circular polarizations. The offset geometry typically means higher manufacturing cost except in the case of small, single piece reflectors such as employed in the VSAT applications.

The offset dual reflector antenna, Figure 6.11-39, can be designed to have all the desirable characteristics of an axisymmetric antenna with increased gain and lower sidelobes. The polarization problems associated with the single offset reflector design can also be compensated for with a two reflector antenna design. The only disadvantages of the offset dual reflector antenna are its high cost of manufacturing for large apertures consisting of multiple sections and the complexity of its mount geometry and its associated high cost.

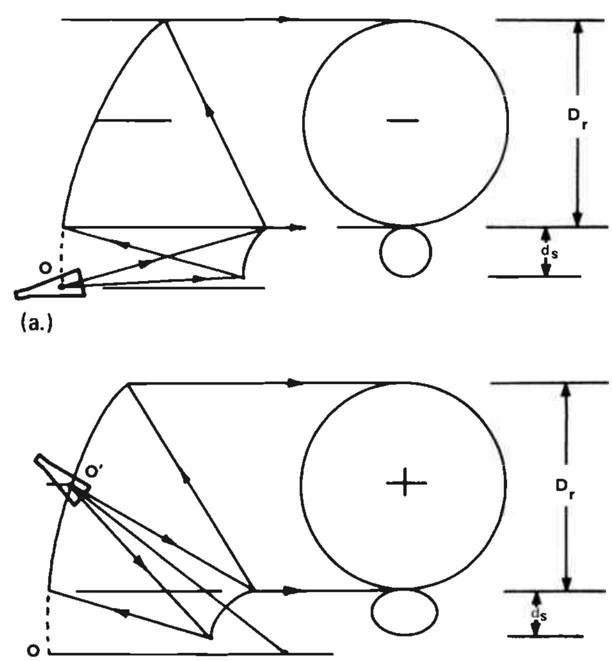

Figure 6.11-39. Offset dual-reflector geometries a) double-offset geometry, (feed phase center and paraboloidal vertex at 0); b) open cassegrainian geometry (feed phase center located at 0'; paraboloidal vertex, at 0).

Beam Waveguide Antennas

The beam waveguide antenna, Figure 6.11-40, utilizes a beam waveguide transmission system to minimize the loss between a multiple reflector antenna and its feed which is located below the rotating axis of the positioning system. This configuration allows the HPA and LNA subsystems to be housed indoors and convenient for maintenance and repair. The beam waveguide design is applicable for very large apertures and is very costly to manufacture. The use of beam waveguide systems has been primarily for 30 m C-band (*Intelsat*) Standard "A" earth stations and for some TT&C earth stations.

Multiple Beam Antenna

Several multiple beam antenna (MBA) configurations, are used for earth station applications (see Figure 6.11-41). These include the spherical reflector, the torus antenna and a class of offset-fed, Cassegrain antennas. All of these configurations employ multiple feeds to generate the multiple beams. The multiple feeds must be physically small such that the individual beams may be pointed at desired satellites. When the desired satellites are spaced as close as 2° apart, the MBA antenna may not be practical. The obvious advantage of the MBA antenna is that a single antenna installation can transmit or receive signals to several satellites simultaneously. The disadvantages are the complexity of the feed arrangements for maintaining pointing for several satellites at the same time when the primary antenna aperture, the main reflector, remains fixed with respect to the earth's coordinates and the stringent requirements for the initial installation of the antenna system. As a result of these disadvantages the MBA antenna is not often employed as an earth station antenna.

Reflector Feed Configurations

There are many different feed configurations used in earth station antennas. The feed configurations are typically classified by the number of transmit and receive ports available. The frequency bands of operation are those specified above for FSS operation in the United States or the appropriate FSS bands for international services. Note that C-band or Ku-band refers to the frequency segments for both transmit and receive bands.

The more popular feed systems are classified as follows:

Two-Port Feed configuration may have two orthogonally polarized receive ports or a single transmit port and a single receive port. The transmit and receive ports may be either co-polarized or cross-polarized with respect to each other. The two-port feed are available in either C-band or Ku-band.

Figure 6.11-41. Multiple beam configuration.

Three-Port Feed has two receive ports and a single transmit port. The receive ports provide for two orthogonal polarizations. The three-port feeds are available in either C-band or Ku-band.

Four-Port Feed provides for dual polarization capability for both the transmit and receive applications. This feed configuration is also referred to as a frequency reuse feed. The four-port feed configurations are available for either C-band or Ku-band.

Dual Band Feed provides for the simultaneous reception of C-band signals and Ku-band signals from a hybrid satellite. The dual band feeds are typically a single aperture, that is the C-band and Ku-band radiating apertures occupy the same space and usually sacrifice gain and sidelobe performance to provide the dual frequency operation. This is true for the single reflector and dual reflector designs.

An alternate configuration that does not sacrifice radiation performance utilizes a dual reflector geometry where the subreflector is a frequency selective surface (fss). This configuration typically uses a prime focus C-band feed, a fss subreflector which is transparent to C-band and reflective for Ku-band and a Ku-band dual-reflector feed. The Ku-band feed may be as simple as a single-port feed to a full frequency reuse, four-port feed, whereas C-band is a prime focus, receive-only feed.

Mechanical Performance

The mechanical design of an earth station antenna must provide the structural integrity to accurately point the antenna beam towards the desired satellite and to maintain the pointing accuracy within the environmental conditions for the locale. Further, the mechanical design of the antenna must ensure the required tolerance of the radiating surface such that the radiation performance of the antenna is not compromised. The antenna pedestal must also provide the means to steer the antenna beam to the satellites of interest.

The location and size of an earth station antenna system (antenna, pedestal or mount, electronics and control housing) usually make it subject to local building codes. The code which is almost universally accepted is the *American Standard Building Code Requirements for Minimum Design Loads in Buildings and Other Structures, ANSI A58.1*. Paragraph 1.3 of that Standard states:

> Buildings or other structures and all parts thereof, shall be designed and constructed to support safely all loads, including dead loads, without exceeding the allowable stresses (or ultimate strengths when appropriate load factors are applied) for the materials of construction in the structural members and connections. When both wind and earthquake loads are present, only that one which produces the greater stresses need be considered and both need not be assumed to act simultaneously.

The loads that must be safely supported by an earth station antenna system are the weight of the antenna and the attached equipment, the expected ice and snow load, earthquake load and the wind load. Of these, the wind load is usually the largest single contributor to the stress and deflection of the structure.

Earth station antennas have a specification that is variously called maximum wind, survival wind, or withstand wind. These terms should be considered synonymous. At the manufacturer's specified survival wind the system must be safely supported without exceeding the allowable stresses for the materials. Survival wind, as defined herein, when combined with ice and dead weight results in the *Design Load* as defined in Standard EIA-222C. In addition to survival wind, two other sets of wind conditions are usually specified, the operational wind velocity and the drive-to-stow wind velocity. The operational wind velocity is the maximum value at which the antenna system fully meets the performance specifications. The drive-to-stow wind velocity is the maximum value the antenna may be driven through the azimuth and elevation actuators to the prescribed stow position (usually zenith).

Positioning Systems

There are two broad classes of positioning systems used for satellite earth station antennas. One class consists of orthogonal two-axis configurations; the other is the one-axis or single-axis configuration. The two-axis systems are characterized by the orientation of the lower most axis with respect to the earth. A two-axis system having its lower axis perpendicular to the ground is called an *elevation-over-azimuth* (see Figure 6.11-42a). One that has its lower axis parallel to the ground (see Figure 42b) is called *X-Y*. One that has its lower axis parallel to the earth's axis of rotation is called an *hour angle-declination or polar* (see Figure 6.11-42c). Each of the three positioning systems has the beam-axis or pointing direction perpendicular to the upper axis. Providing there are no physical limitations, all three types can theoretically point in any direction.

Development of single-axis antenna mounts was brought about by efforts to reduce the costs and to simplify the positioning of the antenna beam with respect to the geostationary orbit. This geometry has restricted applications due to its lack of capability to follow satellites in inclined orbits and its inherent error as the pointing transverses the geostationary arc.

The elevation-over-azimuth positioner has become the choice for most systems. Figure 6.11-43 is a graph of azimuth and elevation angles versus a particular site latitude and longitudinal difference between the satellite and the site. The horizontal and vertical rectangular coordinates are site latitude and difference longitude, respectively. The curved lines running toward and labeled at the top of the graph are the required azimuth angles (add 180° if satellite is west of site, subtract from 180° if satellite is east of site). The curved lines running toward and labeled at the left margin (down to 15°) are the required elevation angles. (The elevation lines of 10° and below are labeled at the top of the graph.) To determine the required azimuth and elevation pointing angles, find the satellite site longitudinal difference and move vertically on this line until it intersects the horizontal latitude line. At this intersection interpolate between bounding azimuth and elevation curves for the requiring angles.

The azimuth and elevation angles to a particular geostationary satellite can be calculated using the satellite longitude, Z; the site longitude, Y; the site latitude X; and the following equations:

$$C = Z - Y \quad \text{degrees} \qquad [34]$$

$$A(\text{azimuth}) = 180 + \tan^{-1}[\tan(C)/\sin(X)] \quad \text{degrees} \qquad [35]$$

$$E(\text{elevation}) = \tan^{-1}\left\{\frac{\cos(C)*\cos(X) - 0.15126}{[\sin^2(C) + \cos^2(C)*\sin^2(X)]^{1/2}}\right\} \quad \text{degrees} \qquad [36]$$

All of the other environmental conditions at a particular site should be addressed, such as effects of solar radiation, lightning strikes, damage by salt water, acid rain and pollution gases, in the planning and implementation of the earth station system.

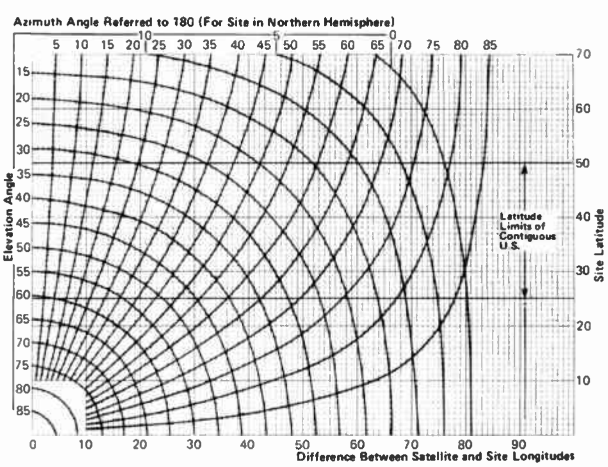

Figure 6.11-43. Universal azimuth-elevation look angles.

Pointing and Tracking

The pointing and tracking accuracy are two very important considerations for a earth station antenna system. Pointing accuracy is defined as the precision with which an antenna can be held (for fixed position antenna) or steered under the specified operating conditions. The pointing error is a measure of pointing accuracy and is defined as the space angle difference between the command vector and the actual position of the antenna communication RF axis. Pointing error is usually specified to less than 0.2 of the half power beamwidth (HPBW), of the antenna in the transmit frequency band. Tracking accuracy is the precision with which an antenna can track a source under specified operating conditions. The tracking error is a measure of tracking accuracy and is defined as the space angle difference between the communication RF axis of the antenna and the vector to the RF source. Tracking error is usually specified to be less than 0.1 of the HPBW. Table 6.11-6 lists the sources of error that should be considered in an overall budget or calculation of pointing accuracy and tracking accuracy.

Many earth station systems operate in the point mode, that is, there is no requirement for automatic tracking of the satellite. This condition exists when

Amplifier drift	Backlash
Servo noise	

the satellite orbital location is maintained within a small fraction of a degree (<0.1°) and when the earth station antenna half power beamwidth is sufficiently broad (>0.5°). Automatic tracking may become necessary as the antenna becomes large in terms of wavelengths (very narrow RF beam) or if the satellite is allowed to transverse an inclined orbit. The complexity of the tracking system is determined by the overall system accuracy requirements and the allowance in EIRP and *G/T* that is budgeted for impaired operation.

A hierarchy of pointing and tracking systems is as follows:

a) Initial fixed pointing is satisfactory (receive only)
b) Repointing of the antenna is required to switch between various satellites or to correct for satellite motion
c) Tracking is required to correct for satellite drift. Satellite position vs. time is known and program track is satisfactory
d) Automatic tracking is necessary but can be satisfied by a simple step-track system
e) Full automatic tracking is necessary (extended inclined orbits)

The simple step-track system is satisfactory for most satellite communication applications when automatic tracking is required. The step-track systems generate tracking information by moving the RF beam in several steps, comparing the signal level, deciding the proper direction to move for the next step and then continuing this process until the RF signal is maximized. The step-track system uses a very low frequency servo loop and therefore will not track out such disturbances as wind. Step-track can be susceptible to fade conditions unless the sampling circuitry is preset to cut off when a large signal loss is evident. Steptrack may also be augmented with a program track mode whereby the satellite movement is memorized and then followed by a memory command circuit.

Fully automatic tracking systems are typically used for TT&C earth stations or for those earth stations operating under extreme conditions with very narrow RF beamwidths. The automatic tracking configurations include conical scan, electronic beam scanning (Single Channel Monopulse, ESCAN) and three channel monopulse. The electronic scanning and three channel monopulse techniques offer the advantage of providing a data channel and a transmit channel without tracking modulation superimposed on the signals. This is not possible with the conical scanning technique.

Transmit Electronics

The transmit subsystem consists of equipment from baseband to the high power RF amplifier. These electronics include baseband processors for combined video and audio signals, modulators, upconverters and high power RF amplifiers. Subcarrier modulators are used to insert various audio signals on the video signal prior to the wideband modulation of the signal.

Analog Video Services

Baseband Processor

The incoming analog video signal is first processed by the baseband processing module. The video signal is preemphasized for either 525-line (NTSC) or 625-line (PAL/SECAM) operation and passed through a low pass roofing filter. Preemphasis acts to improve the output video signal-to-noise ratio by compensating for the increase in noise density with frequency (triangular noise) which is characteristic of the receiver's FM demodulator. (The preemphasis is removed by a deemphasis network after the receiver discriminator).

Energy dispersal modulation is applied to the incoming video signal. Satellite transmissions of video signals are processed in this manner to disperse the RF spectrum thus preventing concentration of energy. This reduces interference with terrestrial microwave and other satellite links and reduces intermodulation among the multiple carriers which exist in a real satellite. Energy dispersal modulation is applied using a triangular waveform with apexes located at the vertical intervals of the video signal.

Subcarrier Modulator

Each subcarrier modulator inputs an audio signal and modulates that signal onto a carrier positioned in the range between 5.0 and 8.5 MHz. Typical subcarrier frequencies are 6.2 MHz and 6.8 MHz. Most video exciters synthesize the center-frequency of the subcarrier with a resolution (stepsize) of 10 kHz. Generally, a subcarrier modulator will allow for selection of preemphasis. Frequency deviation (the amount of frequency modulation applied) is also typically adjustable between 50 kHz and 500 kHz peak.

Wideband Demodulator

The wideband modulator frequency modulates the composite signal (baseband video and subcarriers) onto a 70 MHz IF carrier. The frequency deviation is adjustable up to 15 MHz peak. The modulation bandwidth of the output signal for NTSC video is approximately 36 MHz for full transponder application.

Upconverter

The upconverter converts the modulated 70 MHz IF signal to a frequency range compatible for satellite transmission. Generally, the signal is converted to C-band or Ku-band.

Video Exciters

Most commercial-use video signals transmitted by satellite are of two types: a broadcast quality commercial television signal or compressed, digitally encoded representation of a video signal.

Compressed digital video is typically used by private business television networks for training and internal communication on secure channels.

Analog Video Exciter

A system that transmits conventional analog video, as used for broadcast quality transmission, will use a video exciter. The video exciter inputs a set of baseband signals and outputs a single signal suitable for transmission over a satellite link. The center-frequency of the output signal generated by the video exciter is a frequency in the range of the frequency band in use (5.925 to 6.425 GHz for C-band, 14.0 to 14.5 GHz for Ku-band). The set of baseband signals typically consists of a video signal and one or more audio signals. In some cases, one of the audio signals is used to encode a data control channel. A block diagram of a typical video exciter is shown in Figure 6.11-44.

Digital Video Codecs

A system used for transmission of compressed digital video uses a video codec (coder/decoder) to sample the applied analog video and audio waveforms, generating a digital representation of the input signals. Additionally, most codecs perform compression to reduce the bit rate of the signal. At least two formats of digital video are represented as broadcast quality. First, the D2 format encodes video at approximately 112 Mbps. This format is sometimes used for studio tape playback and recording of programming. Second, a 45 Mbps system is available for transmission of video over DS3 digital circuits. DS3 is a standard rate (45.3 Mbps) available from common carriers.

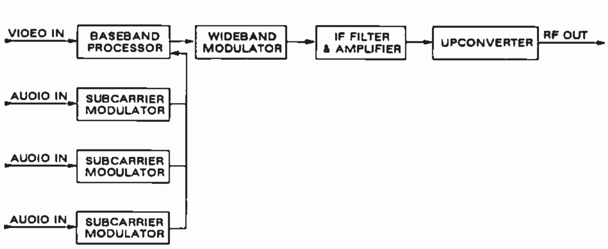

Figure 6.11-44. Typical video exciter block diagram.

High-Power Amplifier

The high power amplifier (HPA) amplifies the RF output signal from the upconverter to the required power level for transmission to the satellite. Amplifiers for satellite video applications are typically sized in the range from 1 W to 3 kW. Amplifiers in the 1 to 10 W range are available in solid-state configurations. Travelling wave tube (TWT) amplifiers are available in configurations up to approximately 750 W. For power levels above 750 W, Klystron tube amplifiers are used.

Video uplink systems using U.S. domestic C-band satellites usually employ 3.0 kW Klyston HPA's. However, newer applications using higher power Ku-band satellites typically use lower power TWT amplifiers. Three hundred watt TWT amplifiers are commonly used in occasional video service applications such as education, private business networks and satellite news gathering.

The HPA usually contains bandpass filters to reject harmonics and power sampling circuits for monitoring the output transmit power and the reflected power from the antenna. Often, protection circuitry is added to turn off the HPA when the reflected power exceeds some predetermined level.

Automatic Transmit Identification System

With the increase in uplink activity in the 1980's, there has been a growing problem with interference between carriers. Most incidents are unintentional, but there have been reported cases of malicious interference. To counter the problem, the FCC introduced a requirement that video uplinks must incorporate an automatic transmit identification system (ATIS), to identify the source of the transmission. The ATIS signal is a FM subcarrier positioned at 7.1 MHz. The ATIS subcarrier contains a message composed of international Morse code characters to identify the source of the signal and provide a telephone number for communication with its operator. The message is repeated every 30 seconds and includes a unique 10 digit ID code that is unchangeable by the operator. The subcarrier frequency of 7.1 MHz was chosen since it is very close to the second harmonic of the color subcarrier and therefore not useable for any possible revenue source. The subcarrier injection level of −26 dB referenced to the unmodulated main carrier represents a reasonable compromise between ATIS system sensitivity, resistance to interference and power taken from the main carrier. This injection level is approximately 0.05 of the normal level of a monaural TV associated audio subcarrier.

Audio Service

Audio signals are transmitted by satellite in both analog and digital form. Most of the domestic U.S. nationally distributed audio material is delivered in digital format. The satellite distribution encodes program material in digital form at the source and distributes the information in that form.

Other networks (state and regional networks) transmit audio using single channel per carrier (SCPC) systems. These systems frequency modulate the applied audio signal onto a carrier and upconvert the signal to a satellite compatible frequency range.

Digital Audio Transmission

The digital audio system supports four types of signals: voice-grade, 7.5 kHz audio, 15 kHz audio and data. The 7.5 kHz and 15 kHz audio signals are sampled at 16 kHz and 32 kHz respectively. The signal is digitized with a 15 bit converter and u-law companded to 11 bits plus a parity bit. The voice-grade signal is digitized with a continuously variable slope delta modulation (CVSD) scheme producing a digital bit rate of 32 kbps. The resultant set of digital signals are multiplexed into a single T1 (1.544 Mbps) bit streams for transmission to the earth station. The T1 signals are routed to the earth station over redundant paths. The earth station receives the multiple, redundant T1 bit streams and demultiplexes the data into the original set of digital signal components.

These component digital signals are then multiplexed into a 7.68 MHz aggregate bit stream. The 7.68 Mbps data is forward error correction encoded, modulated onto a 70 MHz IF carrier and upconverted/amplified to a C-band or Ku-band frequency for satellite distribution. For more information on the digital transmission of the digital information, see the previous section on digital transmission.

Typical bit rates for a 15 kHz audio channel using conventional pulse code modulation (PCM) is 512 kbps. Companding techniques reduce this bit rate to 384 kbps. The availability of low cost, high performance digital signal processing (DSP) integrated circuits have now resulted in more effective compression techniques for digital audio encoding. Techniques such as sub-band coding and frequency domain transforms are used to provide typical bit rates of 128 kbps for the same 15 kHz audio channel. Thus, DSP techniques have provided dramatic increases in spectrum efficiency.

Receive Electronics

The receive electronics are similar in scope to the above transmit subsystem but, of course, operate in the reverse order. First the incoming RF signal is filtered, amplified, downconverted (optional, depending on the frequency band of operation) and passed to the receiver where the signal is further downconverted, amplified and demodulated to baseband.

Low-Noise Amplifiers/Low-Noise Converters

The first active signal processing of a downlinked satellite signal occurs at the low noise amplifier (LNA) or low noise block/converter (LNB). Traditional C-band broadcast applications have used a LNA mounted at the antenna connected to the indoor electronics

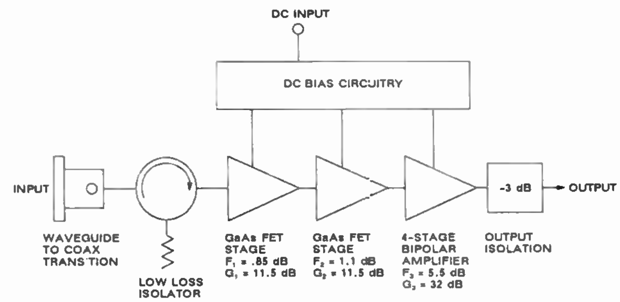

Figure 6.11-45. LNA block diagram.

through a length of coaxial cable. Typical Ku-band systems use a LNB at the antenna that amplifies and downconverts the signal to L-band (950 MHz to 1450 MHz). The functions of the LNA are as follows:

- Provide high gain and low noise to establish high system *G/T*
- Provide transition from antenna waveguide to TEM coaxial cable. Since long waveguide runs are expensive, the LNA is designed to accept a waveguide input and provide a coaxial line output
- Provide adequate mechanical strength to permit mounting directly to the antenna waveguide and to allow connection of a long coaxial cable to the unit
- Provide RFI/EMI tight weatherproof housing for circuitry

A block diagram of a typical LNA is shown in Figure 6.11-45.

Video Receivers

The video receiver takes the received satellite signal and produces a collection of baseband signals. The baseband signals are a video signal and one or more audio signals. Traditionally, broadcast quality applications used C-band video receivers. However, with the increased use of Ku-band and decreasing costs for LNB's, many users have converted to L-band systems. A block diagram of a typical video receiver is shown in Figure 6.11-46. The downconverter converts the input RF signal to an intermediate frequency, typically 70 MHz. The demodulator acquires the modulated video signal from the 70 MHz signal.

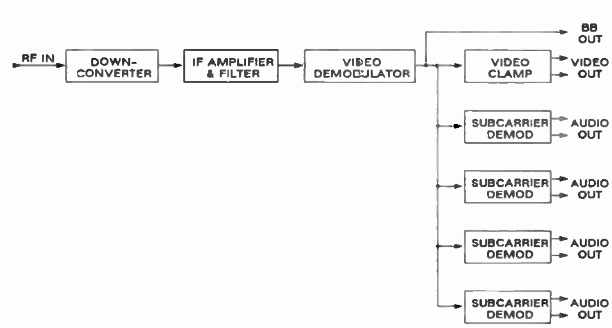

Figure 6.11-46. Typical video receiver block diagram.

Downconverter

The downconverter converts the RF-input signal to a intermediate frequency (IF) prior to demodulation. This intermediate frequency is typically 70 MHz. The downconverter will provide either a single input or multiple inputs for multiple antenna, multiple polarization operation. Single input downconverters require an external relay to select the appropriate polarization input. Modern video receivers typically provide up to four inputs to provide convenient use for two antenna, dual-polarization operation.

The downconverter inputs a signal in range of 3700 MHz to 4200 MHz for C-band operation or in the range of 950 MHz to 1450 MHz (L-band) for C- and Ku-band operation. For the latter case, the LNB downconverts the input RF signal to L-band frequencies.

IF-Filter/Amplifier

The output of the downconverter is routed to the 70 MHz IF filter/amplifier. The signal is first bandpass filtered. In the early days of satellite video services the video receivers provided a single IF filter bandwidth, however, most video receivers offered today provide multiple IF filter bandwidths to provide convenient half transponder as well as full transponder operation. Some video receivers provide up to six IF filter bandwidths. Six IF filter bandwidths are economical because of the availability of surface acoustic wave (SAW) filters for this application.

Demodulator

The filtered, amplified IF signal is fed to the demodulator for FM demodulation. The output of the demodulator is the baseband video and multiple audio subcarriers.

Video Processing

After demodulation, the video baseband contains the 30 Hz triangular energy dispersal waveform which is removed by a circuit referred to as the clamp. A low pass filter is applied to remove the audio subcarrier from the video baseband signal.

Subcarrier Demodulator

Video receivers generally provide up to four audio subcarrier demodulators and provide baseband audio (generally 600 Ω balanced) outputs.

Digital Demodulator/Downconverter

Digital data is extracted from a intermediate frequency carrier by the demodulator section of a modem. (For detailed information about the operation of the modem, refer to the section on digital transmission). The digital demodulator separates the transmitted data stream from the carrier. The transmitted data stream is then processed by the FEC decoder removing the error correction bits, correcting detected errors and outputting the received data and clock signals.

Protection Switching

With the exception of receive only systems most satellite transmission systems contain redundant subsystems to facilitate very high availability specifications. Satellite teleports advertise availability specifications as high as 99.995%. Protection switching implements automatic subsystem redundancy. The protection switch monitors one or more online subsystems for failure. Upon detecting a failure in the subsystem, the protection switch switches the inputs and outputs from the online unit to the backup unit and configures the backup to the configuration of the failed online unit.

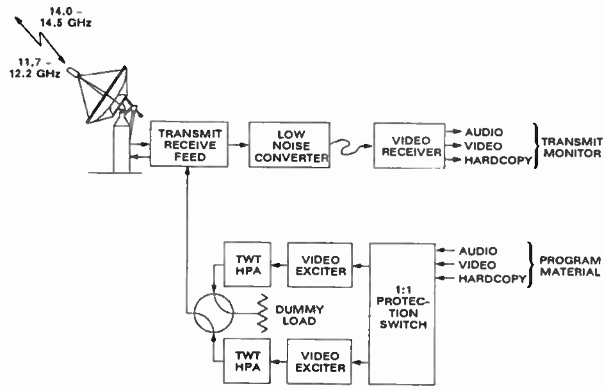

Figure 6.11-47. Redundant Ku uplink protection system.

The configuration of the subsystems protected by a protection switch is referred to as m:n. "m" refers to the number of backups available. "n" refers to the number of online units monitored and protected by the protection switch. "1:1" refers to the simplest configuration—a single backup is available to replace a single online unit. A typical 1:1 protection system for a Ku-band uplink in shown in Figure 6.11-47. A typical 1:1 C-band downlink is shown in Figure 6.11-48. Operation of the 1:1 configuration is simplified in that the backup may be tuned to the same configuration as the online unit; switching to the backup merely requires switching the source of the input and output signals from the online unit to the backup. An example of a larger configuration is "2:6", where two backup units are available to protect six online units. These larger configurations are used for large multiple-channel uplinks. The larger configurations become more cost-effective as the number of online channels increases.

Monitor and Control Systems

Monitor and control refers to systems used to monitor earth station components for failures and provide manual and automatic control of the components.

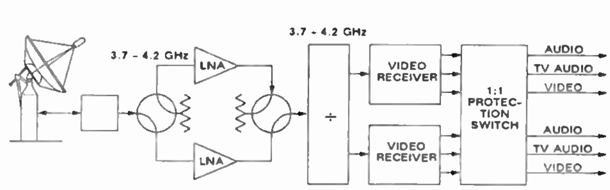

Figure 6.11-48. C-band redundant downlink protection system.

These systems are widely used for a variety of reasons. First, even though most earth station components provide front panel monitor and control functions, there are generally too many earth station components to monitor from the front panels of the respective components. A monitor and control system provides a single point of monitoring and control for the operator thus easing the operator workload allowing the operator to handle more transmissions. Second, many earth stations are located remotely from the studio. A monitor and control system provides remote monitoring and control (operation) of the earth station. Remote operation is facilitated through the use of a low speed data circuit between the earth station equipment and the monitor and control computer in the studio. This circuit is typically a subcarrier on a microwave-radio channel, a dial-up phone circuit with computer modems, or a dedicated EIA-422 hard wire connection for distances less than 1000 m.

Earth Station Control Computer

Monitor and control systems are based upon the use of a general purpose computer executing applications software designed for monitor and control of communications systems. This computer is referred to as the earth station controller.

Operator Interface

Earth station control computers provide a video monitor for display and a keyboard for operator interaction. The system displays earth station status in the form of a hierarchical, graphical display. The upper level display shows a high level block diagram of the earth station. The operator may selected more detailed displays of subsystems by selecting the subsystem symbol from the screen. The earth station components/subsystems are coded with color to indicate state. Typical color conventions for earth stations are as follows:

- Blinking red indicates an unacknowledged alarm
- Red indicates an acknowledged alarm
- Amber indicates ready or standby; Green indicates online/OK/normal.

In some cases, an audible alarm is provided. When a new alarm condition occurs, the audible alarm is turned on. The operator must acknowledge the alarm to turn off the audible alarm.

Earth Station Interface

The computer interfaces to the earth station components through a number of interfaces, including serial, contact closure and other customer supplied interfaces.

- **Serial Interfaces.** The most common interface is a serial ASCII protocol based interface. The interface is usually a asynchronous character oriented scheme utilizing EIA-232C or EIA-422 signal levels. EIA-232C interfaces are used for short cable distances (computer to device) less than 5 m or for connection to a modem. EIA-422 interfaces may be used for cable lengths of up to 1000 m and are used in multidrop mode thus allowing many devices to share a single interface port.
- The protocols are usually ASCII based since there is no satellite communication standard and most vendors use their own version of a interface protocol. Thus, earth station computers must offer a number of serial equipment interface ports and also support a variety of protocols on those ports.
- **Contact Closure Interfaces.** The second type of interface commonly used is the contact closure interface. Older components typically provided contact closure interfaces and offered no serial interface functions. Many of these components are still in use today. In addition, there are components such as waveguide switches and shelter alarms (intrusion, air conditioner, emergency generator, etc.) that only offer a contact closure interface. For example, a waveguide switch may provide two status points and two control points. Thus, earth station computers must provide some method of monitoring and controlling status and contact closure controls. Some vendors offer systems that connect the contact closure directly to the computer. Others offer general purpose interfaces that reside in the earth station and interface to the earth station computer through a serial interface.

Status inputs to the earth station computer are usually optically isolated. The earth station computer supplies the optical isolator. The monitored device sinks current through the isolator to indicate one of two states. The alternate state is no current flow.

Control outputs are of two types. The most flexible interface is the Form C output. The Form C output provides a common connection and a normally opened (NO) and normally-closed (NC) connection. The second type of control output is the open collector output. This interface provides a connection to the collector of a transistor to sink current. One control state is with the transistor on thus sinking current from the controlled device. The alternate state is with the transistor off.

- **Vendor Supplied Computer Interfaces.** A third type of earth station interface is a vendor supplied, device specific contact closure adaptor. Most TWT amplifiers provide contact closure based remote monitor and control interfaces. Additionally, forward and reflected power indications are provided by a signal with voltage level proportional to power. Additionally, some TWT amplifier's require a analog current signal to control the attenuator. However, most TWT amplifier vendors offer a interface adaptor that converts the contact closures to a serial protocol based EIA-232-C or EIA-485 interface. These adaptors reside in the rack with the TWT amplifiers and connect to the earth station computer through a serial connection.

CONCLUDING REMARKS

There are many additional aspects of the design, installation, operation and maintenance of an earth station antenna system that have not been discussed in this chapter. The site selection and preparation are, in particular, critical to the successful operation of the system as well as the foundation design. Details of this aspect of the earth station design should be accomplished with the help of qualified consulting engineers and frequency coordination experts. The operations building and/or equipment houses should be in close proximity to the earth station, if possible, but remote operation is possible. The power requirements for the earth station should also be carefully planned to provide adequate power for the electronics, including the transmitter equipment and any power required for antenna deicing where applicable.

6.12
LOW POWER TELEVISION

PETER TANNENWALD
IRWIN, CAMPBELL & TANNENWALD, P.C., WASHINGTON, DC

INTRODUCTION

Conventional full service television broadcasting is built on the concept of high powered single-channel stations with wide area coverage. This service is presently supplemented by two lower powered terrestrial television technologies: low power television/translators operating on conventional TV channels and multichannel multipoint distribution service/instructional television fixed service (MMDS/ITFS) operating in the 2500–2690 MHz band.

Low Power Television and TV Translators

The FCC first authorized TV translators in 1956 as a way to bring television service to remote areas or areas shielded by terrain obstacles. Program origination (was prohibited) until 1982, when low power television (LPTV) service was created as a way to introduce new local programming services to markets that might otherwise not have television service. There are currently some 2,000 licensed LPTV stations and 5,000 licensed translators, several hundred of which are in Alaska. In addition, the FCC authorizes conventional TV stations to operate on-channel boosters to fill in coverage gaps. Very few boosters are in operation since there are not many situations where it is possible to transmit on-channel without risking interference to the primary station signal.

Because of FCC power limitations, LPTV stations and TV translators have in the past generally used 1 W or 10 W transmitters at VHF and 1 kW transmitters at UHF. However, in 1997 the FCC replaced limitations on transmitter power output (TPO) with limitations on effective radiated power (ERP), so higher power transmitters are expected to be used by many stations in the future. Very high gain antennas are commonplace, resulting in UHF ERP levels in excess of 100 kW, although with correspondingly narrow vertical apertures.

With the elimination of TPO limits, licensees may move toward higher powered transmitters and lower gain antennas to avoid the size, wind load and narrow vertical apertures associated with high gain antennas. Coverage generally extends from five to 30 miles from the transmitter, but is highly dependent on terrain and other obstacles, and whether other interfering signals are present. ERP limits under the new rules will permit wider area coverage. The FCC protects from interference only the 62 dBu contour for low band VHF, the 68 dBu contour for high band VHF and the 74 dBu contour.

In the past, the FCC accepted applications for new LPTV stations and TV translators and for major changes in existing stations only during designated filing windows, usually one week in length and announced in advance. Minor change applications, defined as those which involve no new frequency or new service area, may be filed at any time.

Mutually exclusive applications had been subject to lotteries rather than comparative hearings in the past, but the Balanced Budget Act of 1997 repealed the FCC's authority to use lotteries. It is expected that mutually exclusive applications will be subject to competitive bidding in the future, but until the FCC completes a rule making it is not known what kind of window or other timing system will be used for filing new applications.

New full power television stations, either analog (NTSC) or digital (DTV), may displace LPTV stations and translators at any time. Displaced stations may file applications to change channel without waiting for an application filing window and therefore have priority over new applicants in applying for an available spectrum. If no new channel can be found that does not cause interference, the displaced stations must go dark. The FCC has indicated that it is unlikely to accept any applications for new LPTV or translator stations or for major changes in existing stations until it has finalized the regulations for new DTV service.

In contrast to the full power system, where applications are accepted only for channels listed in the national allotment table adopted by rule making, a LPTV station or translator may be built wherever it will not cause interference to other stations. Thus the allocation system is similar to AM radio, except that interference analyses are done solely on the basis of a special FCC computer program for NTSC-to-NTSC interference. (The FCC will also entertain special terrain shielding showings.) LPTV stations and translators are required to protect digital TV stations as well as NTSC stations, and the FCC's new digital TV rules include interference ratios for determining NTSC-to-DTV and DTV-to-NTSC interference.

LPTV stations and translators are governed by Part 74 of the FCC's Rules, although Section 74.780 lists some Part 73 rules that apply to LPTVs and translators. Operating requirements for LPTV are generally more lenient than for full-power television stations, but LPTV stations eligible for must-carry status on cable television systems are subject to all Part 73 programming requirements. LPTV stations are also subject to certain Emergency Alert System (EAS) requirements; translators may rely on EAS messages transmitted by the station they rebroadcast. Like all broadcast stations, unattended operation is permitted, subject to certain monitoring requirements for alerting an operator when equipment malfunctions.

Design considerations for LPTV stations and translators are similar to those for full power stations, except that the costs are much more modest. Equipment is smaller and less expensive and requires much less power. A transmitter site at the highest elevation is desirable, unless a lower elevation is needed to avoid causing prohibited interference to another station. Antenna design is critical, because extremely high gains and directional patterns are so common. Studio equipment may be high-grade consumer type, such as Super-VHS, when dictated by economic considerations. There are no rules currently in place to allow LPTV stations or translators to transmit digital signals, but the FCC has promised to conduct a future rule making on the subject and has issued some experimental digital transmission licenses to LPTV stations.

MMDS and ITFS—Wireless Cable

The multichannel multipoint distribution service (MMDS) and the instruction television fixed service (ITFS) are multichannel, microwave based technologies that transmit in the 2500–2690 MHz band (S-band). They therefore require an adapter (downconverter) at each receiving location in order to be received on a consumer type television receiver. Operation is omnidirectional rather than point-to-point, except where directionalization is required to avoid interference to another station. Transmitter power levels have traditionally been 10 W, but the FCC now authorizes operation at 100 W, subject to an interference showing, and most MMDS operators seek 100 W authorizations. Because of the area of spectrum in which these services operate, propagation is generally line-of-sight, and an unobstructed view of each receiving location is more important than power levels.

There are 31 MMDS and ITFS channels available, each 6 MHz wide, with one extra channel in major markets. Originally known as MDS, MMDS was a single-channel common carrier service at 2150 MHz (Channel 1), which is still available. In major markets, a second 6 MHz channel is available at 2162 MHz (Channel 2); in smaller markets, the second channel is restricted to only 4 MHz and is intended for nonvideo use (Channel 2A). The 31 channels at 2500–2690 MHz are divided into groups A through H, each with four 6 MHz channels, except for the H group, which has only three. The A and B groups are interleaved, as are the C and D, E and F and G and H groups. MMDS licenses are awarded by the FCC through an auction process. ITFS applications are filed during designated filing windows.

Originally, the A through G groups were reserved for ITFS and used by educational institutions for closed circuit instruction. The H group was allocated for private use in the operational fixed service (OFS). As entrepreneurs began developing the idea of using this spectrum for pay movies and other video services, the FCC came to recognize that the technology had the potential to compete with multichannel cable television. Thus the term *wireless cable* was born. The FCC reallocated the E and F groups, and most recently the H group, to MMDS. It also gave MMDS licensees the option of operating privately rather than as common carriers, so that the licensee of the station and the video programmer may be the same entity instead of separate ones as they were in the common carrier mode.

MMDS operators are also permitted to lease unused time on ITFS channels, which often includes up to 148 hours a week. Restrictions against holding licenses for more than one MMDS channel group have been eliminated so MMDS operators can potentially put together a relatively large number of channels to compete with wired cable service. Using a technique known as *channel mapping*, MMDS operators can automatically switch consumer receivers from one channel to another. The consumer perceives this as a full-time commercial service and is unaware that each channel is being diverted to instructional use during the 20 hours a week required by the FCC.

MMDS stations are given 45 dB protection from interference within a 15 mile radius of the transmitter, as are ITFS stations during hours when they are being leased to MMDS operators. During hours of instructional operation, ITFS stations have no fixed interference protection radius, but individual receive sites that are reported to the FCC and specified on the station license are protected regardless of their distance from the transmitter. Precise channel offset may be used to reduce co-channel protection to as little as 28 dB, but only if the licensees of both stations involved consent.

MMDS and ITFS services are based on the use of all channels, including first adjacent channels, even though the consumer type television receivers on which programming is displayed are not designed to reject strong first adjacent channel interference. Some adjacent channel protection can be built into downconverters. However, the principal technique to avoid adjacent channel interference is collocation of transmitters. The FCC's interference rules providing for a 0 dB first-adjacent channel protection ratio can best be achieved if both stations are at the same site. The FCC permits one licensee to force another to collocate at the newcomer's expense, subject to certain conditions.

In 1996, the FCC issued a declaratory ruling concerning digital transmissions in these services, and in 1997 issued the first permanent license for digital MMDS operation. Operators who wish to do so will now be able to convert to digital transmission using modified or new hardware with a choice of several modulation formats.

SYSTEM DESIGN CONSIDERATIONS

System design begins with the need for coverage of a geographical area by a television signal source. This source may consist of a single channel of NTSC video, a group of channels, a multichannel array of encoded channels or digital compressed TV signals.

Although differences exist in the propagation characteristics in VHF, UHF and S-band signals, coverage is primarily *radio line-of-sight*. Coverage is often more limited by terrain than the transmission power selected. It is generally most effective to choose the highest available site with suitable facilities and select the lowest transmitter power that will provide the required coverage. The usefulness of a particular site is often influenced by the difficulty in delivering input signals to the site, and the availability of a building, ac power and tower space. Table 6.12-1 indicates typical coverage areas achieved with the nominal output powers most commonly selected in these low power services.

Table 6.12-1 assumes minimal terrain roughness, analog transmission and a reasonable transmitter site. Conditions affecting a particular system can substantially alter the coverage areas achieved. Figures in the table were derived from FCC coverage curves and extrapolations to S-band.

Propagation Characteristics

In a TV radio frequency (RF) system, coverage beyond visible line-of-sight can be achieved by *refraction* or *diffraction*.

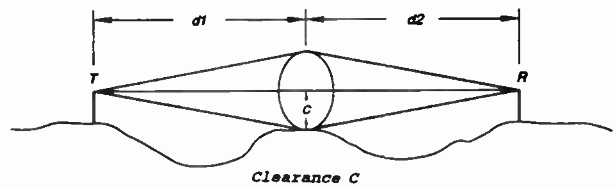
Refraction is the bending of electromagnetic waves that occurs as a signal propagates through different densities of the atmosphere. This effect causes signals to be extended beyond visible line-of-sight. While the effect is somewhat frequency dependent (in the frequency range in which these services operate), it can be approximated by considering the earth to be of a larger radius. Special graphical techniques, such as 4/3 earth radius graph paper, can be used to estimate the propagation between particular points (see Figure 6.12-1). This approach is useful in determining if sufficient clearance is available at a translator site as well as the potential for successful coverage of a particular area to be served. While variations in atmospheric conditions can modify the nominal value of refraction, the 4/3 earth radius approach is sufficient to estimate propagation in most U.S. domestic applications.

Table 6.12-1
Typical signal coverage in miles.

	Coverage in Miles			
Transmitter Power (W)	1	10	100	1,000
VHF	6	22	N/A	N/A
UHF	4	16	22	28
2.5–2.7 GHz	3	12	20	N/A

A cross section of a path between sites shows a series of concentric circles known as *Fresnel zones*. Six-tenths of the first Fresnel zone clearance is desirable to achieve propagation with near free-space path loss. The first Fresnel zone size is calculated in Equation 6.12-1.

Diffraction is an additional bending of the wave and occurs as signals approach an obstruction. This effect varies according to the smoothness of the obstructing surface relative to the wavelength of the propagating signal. The most dramatic effect is known as *knife edge* diffraction. This common phenomenon prevents visible line-of-sight into an area shadowed by a hilltop, but allows coverage of signal into the shadowed area. Signal levels in the *diffraction region* fall off rapidly. Nevertheless, it is a common method of receiving signals at a site behind a structure. Figure 6.12-2 shows the loss of signal in the diffraction as well as the results of path clearance in excess of 0.6 first Fresnel zone.



where:

$$C = 0.6F_1$$

and:

F_1 = first Fresnel Zone radius

$$F_1 = 31.6\sqrt{\frac{\lambda d_1 d_2}{d}} = 548\sqrt{\frac{d_1 d_2}{fd}}$$

d_1 = distance to near end of path (km)

d_2 = distance to far end of path (km)

d = $d_1 + d_2$ = total path length (km)

λ = wavelength (m)

f = frequency (MHz)

Equation 6.12-1. Patch clearance.

Receiver Sensitivity

A factor that may be frequency dependent is receiver sensitivity. S-band and UHF receivers are often less sensitive than VHF receivers. Receiver sensitivity can be determined by measuring system noise figure. Noise figure is defined in Equation 6.12-2.

$$\text{Noise Figure} = 10 \log_{10} (NF)$$

where:

$$NF = \frac{S/N^{input}}{S/N^{output}}$$

and:

S/N is the ratio of Signal Power to Thermal Noise Power

Equation 6.12-2. Noise figure.

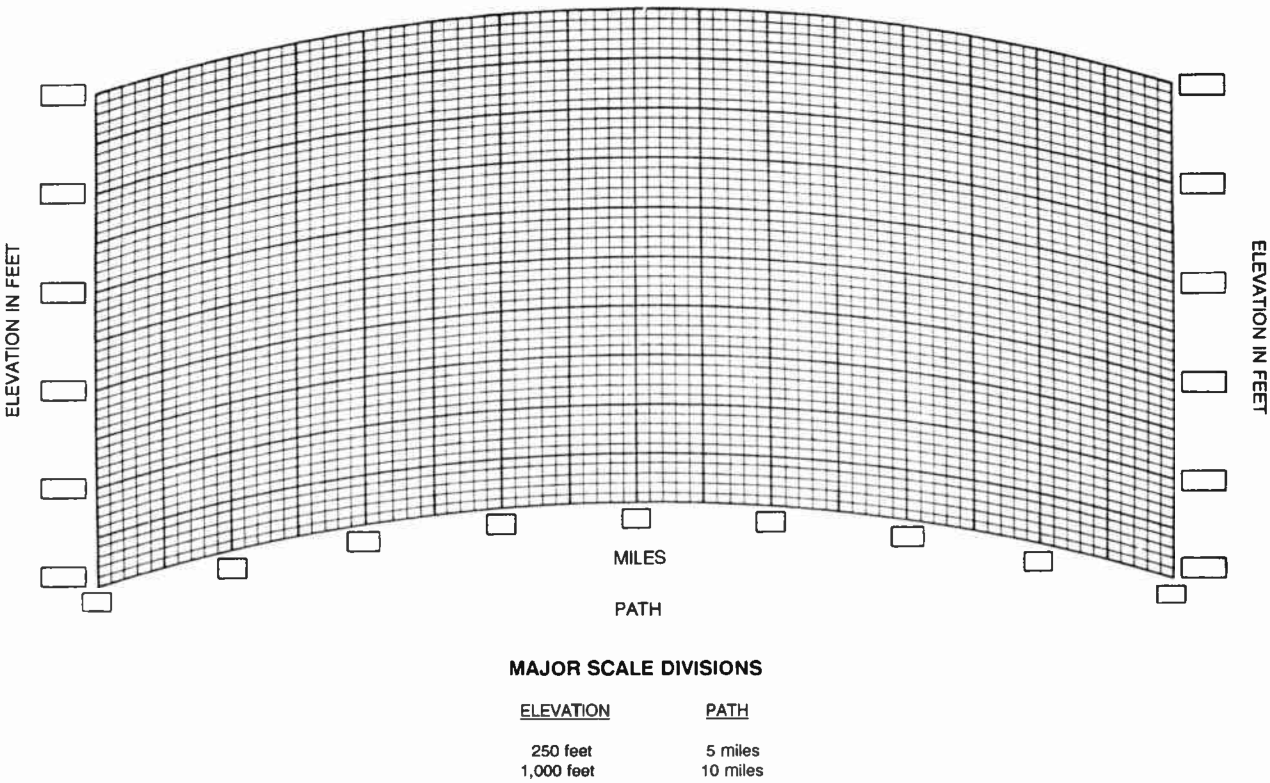


Figure 6.12-1. 4/3 earth radius path profile.

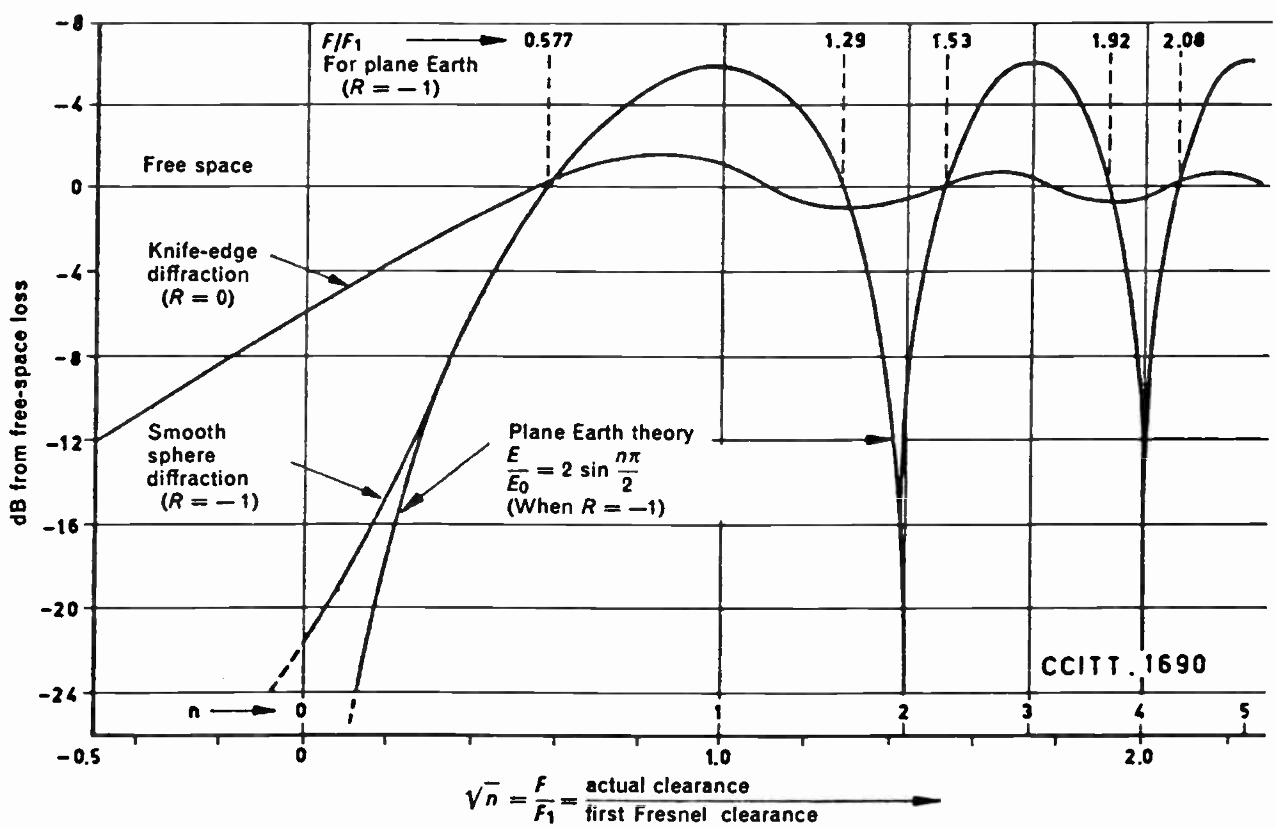

Figure 6.12-2. Path clearance.

As a signal is processed by a system, the degradation of the signal-to-noise ratio is affected by the noise contributed by the system. A low noise figure indicates that a system adds little thermal noise to the signal. Lower noise figures are more easily achieved at lower frequencies because of available electronic device technology. Recently, however, gallium arsenide field effect transistors (FETs) have become available that provide S-band noise figures comparable to the best noise figures available at VHF and with relatively little cost difference. Noise figures on the order of 1 dB to 7 dB are typical in these services.

An additional noise source often exists at VHF. In low band VHF channels, noise other than normal thermal noise may be present due to atmospheric or electrical discharges. This fact limits the usefulness of the low band VHF channels in some translator and LPTV applications. In these cases, the dominant noise source may limit the ability to receive low band VHF channels at a translator site or at ultimate viewer locations. For this reason it is customary, when possible, for high band VHF channels to be selected over low band VHF for translators and LPTV services. However, UHF channels are often preferred because of the higher power limit authorized by the FCC and the greater likelihood of finding available spectrum.

Output Power

FCC Rules establish standard power limits for the low power services. LPTV stations operating in the VHF band have an ERP limit of 3 kW. UHF stations are limited to 150 kW, operating in the NTSC mode. When digital operation begins, the limits will be 300 W at VHF and 15 kW at UHF. Circularly polarized (CP) operation is authorized and results in the doubling of transmitter power, although the availability of effective CP receive antennas is limited. In the ITFS and MMDS bands, a TPO of 10 was formerly a common nominal power rating, but 50 W and 100 W are increasingly common power levels in this service.

Boosters are often limited by system considerations. The classic on-channel repeater or booster receives an input channel or channels and simply amplifies and rebroadcasts the signal into a shadowed area with a directional antenna pattern. To avoid feedback, this requires a high gain amplifier and a high degree of isolation from the transmit-to-receive antenna. Systems of this type are generally limited to 1 W or less per channel, but operate with increased power if special shielding techniques are employed. Feeding of boosters via FM microwave eliminates this feedback problem.

Another limitation on ERP is the requirement to protect other stations from interference. The contours to which other LPTV stations and translators and ITFS/MMDS/and operational fixed service (OFS) stations must be protected are shown in Table 6.12-2. LPTV and translator stations must protect the Grade B contour of full power television stations, in accordance with ratios in Section 74.705 of the FCC's Rules.

Table 6.12-2
Protected coverage.

Service	Protected Contour or Required Separation	FCC Rules
LPTV/TRANSLATORS CH. 2–6	62 dBu Field Strength Boundary	Part 74.707 (a)(1)(i)
LPTV/TRANSLATORS CH. 7–13	68 dBu Field Strength Boundary	Part 74.707 (a)(1)(ii)
LPTV/TRANSLATORS CH. 14–69	74 dBu Field Strength Boundary	Part 74.707 (a)(1)(iii)
ITFS	50 Mile Separation	Part 74.903(b)
MMDS (OMNI PATTERN)	15 Mile Radius	Part 21.902 (d)
OFS	50 Mile Separation	Part 94.63

Channel Selection

The channel selection process involves compliance with the interference protection requirements of FCC Rules. LPTV stations and translators operate on a *secondary* basis. They are permitted to use a channel if they accept the risk that they may have to select and move to a new channel if the channel is later assigned for full power use, or if the LPTV or translator would cause interference to a full power station operating on a different channel (such as adjacent channel or UHF taboo interference).

The FCC's reallotment of TV channels 60–69 for public service use, undertaken at the direction of Congress, will also affect LPTV stations and translators since no more applications are currently being granted for new LPTV stations on these channels. Existing stations will eventually be required to relocate to lower channels unless they are able to purchase their existing channels in future spectrum auctions. The possibility of using Channels 60–69 as a transitional home for LPTV stations and translators during the DTV transition remains to be resolved by the FCC.

Because translators depend on output-to-input frequency separation to achieve isolation, it is advisable to provide several channels of separation between a translator input and translator output channel, although a minimum guardband of one empty channel may be used.

Multichannel System

Multichannel combining techniques may be employed to allow the transmission of more than one channel from a single transmit antenna. The standard technique involves using selective channel filters coupled through a directional device into a common transmission line. Important considerations involve insertion loss per channel, power handling capability, channel combiner size/cost and antenna system bandwidth. Channel combiners for the ITFS/MMDS band are available that efficiently couple up to 16 alternate channels onto a single transmission line. The transmission of adjacent channels can be accomplished through the use of separate transmit antenna systems, broad band hybrid couplers or special filters.

Antennas

Transmit antennas often concentrate power in a desired direction. Calculated as antenna gain, this concentration of power is a measure of the effectiveness of radiation of an antenna compared to a simple dipole antenna or a point source radiator. Two important parameters determine antenna gain: *vertical beam width* and *horizontal beam width*.

Power is concentrated vertically in a narrow beam by the use of stacked radiators. The signal emanating from this array adds in-phase in the direction of the main beam and cancels in other directions, effectively increasing the power transmitted in the main radiation pattern of the antenna. The azimuth pattern of the antenna is determined by the placement of the radiating elements, which are normally arrays of dipoles or of slots in a waveguide. Both types of antennas are widely used from VHF through S-band.

While a variety of antenna patterns are available, the most common patterns are the *omnidirectional* and *cardioid*. The omnidirectional attempts to radiate power equally in all horizontal directions. A cardioid pattern is shown in Figure 6.12-3.

This basic pattern and its variations are available with antenna gains from 10 dB to 18 dB, depending on the number of bays of radiating elements utilized. Vertical beam width narrows with increased horizontal gain as seen in Figure 6.12-4.

Additional considerations in antenna selection and specifications are *beam tilt* and *null fill*. Beam tilt involves radiating the horizontal pattern of the antenna slightly away from the horizon. Beam tilt provides coverage into terrain below the antenna, an objective commonly accomplished by specifying − 1/2° or − 1° of beam tilt. Null fill provides a small amount of radiation in the direction of an antenna null to provide some degree of coverage in the area of signal cancellation.

Directional antennas constructed with parabolic or

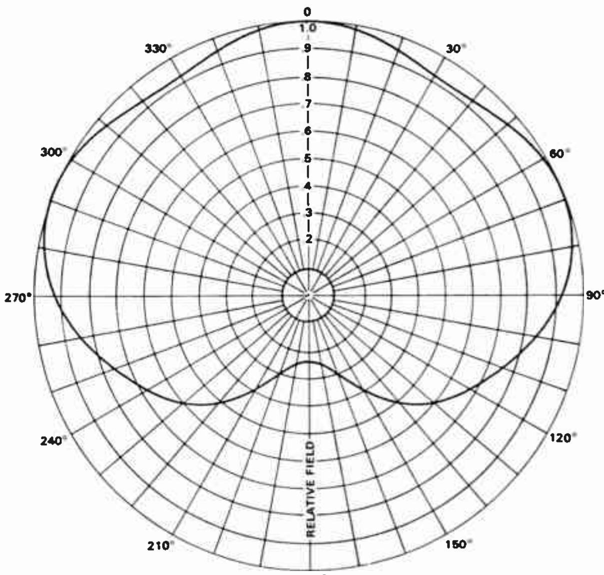

Figure 6.12-3. Cardioid antenna pattern. (Courtesy Andrew Corporation.)

cylindrical reflectors are occasionally used for transmission but are commonly used for receive purposes at repeater sites and at ITFS/MMDS receive locations. This type of antenna is very directional compared to standard transmitting antennas, and gains above 20 dB are common. Horizontal beam widths less than 6° can easily be achieved. A common receive antenna with specifications is shown in Figure 6.12-5.

Antennas have limitations in power handling and bandwidth, although antennas with special capabilities are manufactured and sold at higher costs.

Site Requirements

Transmitter sites are normally located on hilltops, in tall buildings or at convenient tower locations. In addition to the obvious requirements for receiving and transmission hardware, a site should be selected to provide the desired coverage with the available antenna mast and selected antenna. Site requirements encompass three issues: environmental considerations, ac power requirements and grounding and transient protection.

Environmental Considerations

Electronic equipment is designed to operate over a normal range of temperatures and within a reasonable range of moisture and dust conditions. Maintaining appropriate room temperatures and equipment cleanliness improves the reliability of a system. A good rule of thumb concerning equipment reliability is the common rule applied to chemical reactions: most reactions double in speed for each 10°C (50°F) rise in temperature. Since many detrimental environmental effects, such as contact corrosion, are chemical reactions by nature, the speed of chemical reactions will affect equipment longevity. Corrosion, metal migration in transistors and the degradation of electrolytic capacitors closely follow this general rule.

Maintaining low temperatures at a site will usually enhance reliability. Most equipment operates comfortably in ambient temperatures as low as 0°C (32°F). Temperatures above 35°C (95°F) will normally be outside the range the equipment was originally tested in and should be avoided.

It is advisable to provide filtered air to a building and a method of easily removing and cleaning the building air intake filters. The cleanliness of air filters and metal heatsink surfaces will affect cooling system efficiency. Most air filters are washable, and a supply of water with detergent should be available at a site. If equipment is exhausted directly to the outside, provide a substantial supply of unrestricted building intake air. Most transmitter cooling systems are not designed to overcome substantial air pressure drops.

Moisture is another site consideration. Equipment normally operates above room temperature, making condensation of water on the equipment unlikely. However, in some instances it may be necessary to provide additional site heating to keep the equipment dry. It may also be desirable to prefilter or route inlet air through baffles or ductwork to eliminate water drop-

lets. Exhaust air should be directed away from the direction of prevailing wind. Although exhaust air screens necessary to prevent birds and animals from entering the building, if not regularly cleaned the screens may become clogged and adversely affect equipment cooling. Automatic motor-controlled louver systems can be used to allow the equipment to maintain a reasonable room temperature in cold weather. However, if the motorized louver system malfunctions, it can result in equipment overheating. Louver systems that rely on air pressure to open must be used with caution, since additional pressure drop is incurred.

AC Power Requirements

Site requirements for power must take into account transmitter demands, cooling/heating requirements, test equipment and lighting needs. A 1 kW UHF transmitter typically draws more than 25 A of ac current at 230 ac volts. A 1 kW UHF transmitter will produce about 4,000 W of exhaust heat that must be vented from the room or cooled with an air conditioning system. This converts to 13,600 Btu per hour of air conditioning requirement.

In a multichannel system it is advisable to provide an ac shut-off per cabinet. This permits power to be shut down in a particular cabinet so maintenance can take place while the other cabinets continue to operate. Wall circuit breakers are thermally operated devices and should be sized substantially above the equipment requirements to allow for in-rush transients and thermal heating of the building. It is common to run conduit directly to cabinets for higher power systems. Lower power transmitters can often be plugged into standard ac outlet strips.

Grounding and Transient Protection

Transmitter sites require an effective earth ground to minimize ac hum problems, provide ac line transient protection and allow a safe path for lightning induced current. A site ground should bond the ground provided from the power company with a grounding rod associated with the tower. A copper-clad steel grounding rod buried in the earth and connected to the tower, building structure and ac power line ground is standard practice. It is also advisable to add a ground strap, often constructed with flat copper strapping or heavy copper braid, from equipment cabinets to the site ground. Transmission grounding kits, which are available for all standard transmission line cables, provide a low resistance method of connecting the ground system to the main transmission line.

Transient protection is necessary on both the ac line and RF transmission lines. Most modern transmitters incorporate some form of internal transient protection. The most common method is the installation of transient devices across the ac line and from each ac line connection to chassis ground. These transient protectors are often of the metal oxide varistor (MOV) type and are available in various voltage ratings. Because of the wide variation of power line voltages often present at transmitter sites, choose the highest rating varistor that will provide the required transient protection. For example, it is often desirable to use a 150 V MOV instead of a 135 V MOV to minimize transient protector damage from a momentary high line condition. The higher voltage MOV will typically provide the necessary momentary transient protection. By connecting MOVs from line-to-line and line-to-chassis ground, common mode and unbalanced transients are clipped. Large MOVs can be installed at the ac power box to provide additional protection. More sophisticated transient protectors that insert inductive elements in series with the ac line prior to transient protection are also available.

RF input and RF output transmission lines should incorporate proper grounding kits on the outside shield of the cable. Direct current return paths should be provided in receiver and transmitter circuitry to reduce the danger of damage from static buildup of the RF transmission line center conductor. Harmonic filters that employ shorted quarter-wave trap sections provide a low resistance dc return path to ground and further enhance the RF transmission line transient protection.

Long transmission lines that run between a transmitter site and a tower can result in lightning induced transient damage. Improved bonding between the site and the tower may be necessary. Enhanced transient capability of the receiver or transmitter circuit through the use of spark gap capacitors and low voltage transient protectors can also enhance reliability. Contact the equipment manufacturer to solve specific transient damage problems.

HARDWARE ANALYSIS

Describing the range of hardware required to cover VHF through S-band requires a general approach. Most television transmitters can be divided into three sections: modulator, upconverter and final amplifier. The modulator processes incoming video and audio and performs the basic modulation process at intermediate frequency (IF). The upconverter heterodyne converts the signals to the desired output frequency and provides additional processing such as level control and precorrection. The final amplifier raises the signal level to the desired output power. Peripheral equipment often includes encoding and multichannel combining equipment.

Heterodyne translators are similar except that the modulator is replaced by a receiver assembly that converts the input signal to IF. Boosters have two standard configurations: a simple on-channel amplifier and a video-fed transmitter.

A full RF transmission system requires suitable transmission lines, filters, antennas and other monitoring components. Receive hardware consists of down-conversion equipment and decoding hardware.

Transmitters—NTSC

A modulator performs the function of producing a vestigial sideband amplitude-modulated picture carrier and a frequency-modulated aural carrier at convenient intermediate frequencies. Since signal level during demodulation determines picture brightness, accurate modulation levels that are independent of average picture levels must be maintained. This is accomplished with a video clamp circuit that holds either sync tip or black level to a specific voltage level. Other video processing, such as differential phase correction and video sync stretch, can also be accomplished prior to modulation. It is also desirable to add white clipping and sync spike clipping prior to modulation to prevent overmodulation or incorrect output levels at the output of the modulator. Vestigial sideband filtering is achieved with a suitable surface acoustic wave (SAW) filter after modulation. These filters provide stable, accurate characteristics with sharp roll-off and reasonably flat delay variation across the band.

Aural modulation is usually frequency modulation of an IF carrier. Standard IF frequencies chosen in most modulators are 45.75 MHz for visual and 41.25 MHz for aural. These frequencies correspond to the standard IF of television sets and other common test equipment such as demodulators. With the advent of Broadcast Television Systems Committee (BTSC) stereo television, it became desirable to have an FM modulator capable of wide deviation with low distortion. It also became desirable to phase lock the center frequency of the FM carrier to the visual IF oscillator to maintain accurate visual/aural frequency separation. This can be accomplished with a very narrow band phase-locked loop that maintains the average center frequency of the FM carrier. FM modulators normally have a preemphasized audio input for standard baseband audio, and a wideband unbalanced input without preemphasis for composite audio input signals. Some modulators provide a separate filtered input for incorporating high-frequency subcarriers.

Figure 6.12-6 illustrates the functional block diagram of a typical modulator/upconverter amplifier assembly. Intermediate frequency processing is performed to linearize the RF characteristics of the output amplifier array. This linearization is a combination of amplitude and phase precorrection. Amplitude precorrection is accomplished with attenuators that are bypassed at specific signal levels by the cut-in of biased diodes. This can be achieved with little phase variation, and the sharpness of the amplitude response characteristic can be easily adjusted to match the opposite characteristics of the amplifier.

Phase correction or, more accurately, incidental carrier phase modulation (ICPM) correction can be accomplished by demodulating a sample of the IF visual carrier. The demodulated video is used to drive a phase modulator in line with the IF signal. By adjusting the amplitude and shape of the video sign, accurate compensation for phase errors that occur in the transmitter's output amplifier can be provided.

Automatic level control is an additional function that usually takes place at IF. A control loop maintains a constant IF or RF output level, and drift is compensated by adjusting a voltage-controlled attenuator at IF.

Upconversion occurs in a double balanced mixer at low level. Filtering and amplification raise the level to the amplitude necessary for detection and metering. The last section of most transmitters is final amplification. Modern transistor designs can produce 1 kW of output in UHF and 100 W of output in S-band.

Transmitters—Digital

The transmission of high bit rate information in a fixed 6 MHz channel requires an efficient modulation system. Quadrature amplitude modulation (QAM) and vestigial sideband amplitude modulation (VSB) can provide the required efficiencies. Both techniques have been well developed or are currently in an advanced

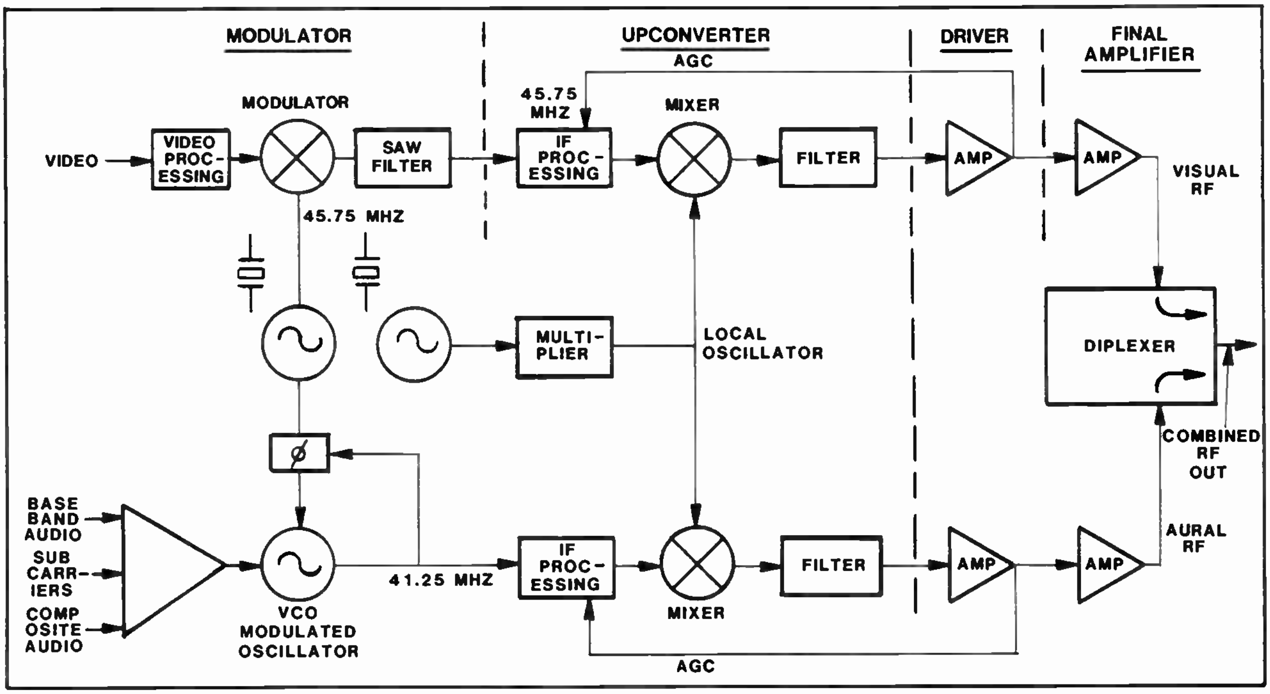

Figure 6.12-6. Television transmitter block diagram.

stage of testing. Transmitters for QAM and VSB combine IF digital modulators with upconverters and amplifiers modified or designed for digital signals.

LPTV, MMDS and ITFS services can use these digital formats in accordance with regulations in place or pending for each service. The DTV Standard adopted by the FCC for full power broadcast television is an 8VSB system. While translators and most LPTV systems will likely use the same system, it is not yet known whether any operators will seek or be authorized by the FCC to use QAM for subscription or other specialized services.

Translators

A heterodyne translator can be configured by replacing the modulator with a suitable UHF or VHF receiver. By using the same IF and operating level of the modulator, this change can be accomplished simply. The receiver needs to provide the necessary gain and filtering to avoid interference from other channels as well as avoid interference from the translator output. Adding a preamplifier at the receive antenna is a common way to reduce the system noise figure to the lowest possible level.

SAW filters are normally used in modern translators to provide filtering of adjacent channel products. As in transmitters, SAW filters provide extremely sharp selectivity with relatively constant delay characteristics. When the output amplifier is linear enough to allow operation with multiplexed IF signal, SAW filter bandwidth is chosen to pass the visual and aural carriers. For externally diplexed output amplifiers, it is necessary to provide a signal separation function in the receiver. Receivers have been developed to split the visual and aural IF carriers to allow separate processing in the following upconverter and amplifier assemblies. The splitting of the aural carrier is complicated by the fact that the incoming signal may arrive with a carrier frequency error. In addition, the incoming signal may contain stereo or other subcarrier information. These problems can be resolved with a phase-locked loop that tracks the incoming frequency and aural IF SAW filters that allow the full aural spectrum to pass.

Translator receivers require a very wide automatic gain control range. This allows receivers to be used at sites with very small input signals as well as large input signals. Some designs incorporate switchable attenuators that adjust the automatic control range of the receiver to the expected range of the input signal.

Digital translators generally will utilize the heterodyne translation technique previously described with certain modifications to filtering, power control and electrical parameters as required by the particular digital modulation format.

Boosters

Boosters can be licensed as microwave fed transmitters. In this configuration, the hardware is essentially identical to video fed transmitters.

The earliest boosters predate television translator service. The first documented boosters were installed in 1948 in Oregon. These boosters, and the others that followed were simple on-channel amplifiers connected to receive and transmit antennas. In this configuration, the system is stable and provides useful signal coverage

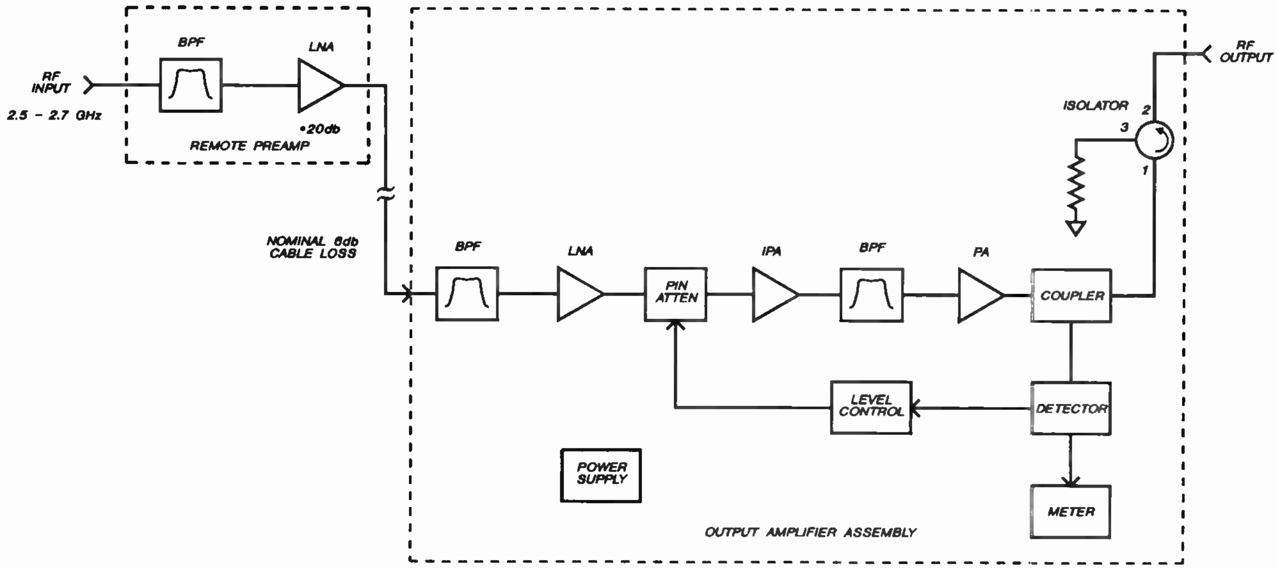

Figure 6.12-7(a). Multichannel booster block diagram.

if the antenna isolation substantially exceeds the amplifier gain. Common booster gains typically begin at 40 dB. With a directional transmitting antenna, an area within several miles of the booster site can be served. Multichannel boosters have been used in the ITFS/ MMDS band for some years. The functional block diagram of an advanced booster design is shown in Figure 6.12-7.

In this design, a remote preamplifier is mounted at the receiver antenna. A coaxial cable connects the preamplifier to the final amplifier assembly, which allows physical separation of the gain blocks, improves the stability of the system and reduces the system noise figure. The final amplifier includes a power detection circuit and automatically controlled attenuator. This feedback control loop adjusts the gain of the amplifier to maintain the output power within the capabilities of the output amplifier. Selection of the proper filters in this design enables it to work in a narrow band or multichannel environment. Open-loop gain exceeds 80 dB, and the output amplifier has up to 10 W of peak envelope power capability. This allows relatively high power levels to be transmitted. Pending booster regulation changes are expected to simplify the licensing of boosters. In other countries, boosters are performing an important function of both filling in shadowed areas and extending the coverage of low power systems.

Transmission Lines, Filters and Antennas

Both coaxial and waveguide transmission lines can be used in S-band. At VHF and UHF frequencies, coaxial transmission lines vary in diameter from 1/2 in. to 3 1/8 in. The efficiency of transmission lines varies with frequency and size. The insertion loss of various types of coaxial cable at different frequencies is shown in Table 6.12-3.

Table 6.12-3
Transmission line losses.

	Approximate Loss Per 100 Feet in Decibels				
Band	1/2" Foam	7/8" Foam	1 5/8" Air	3" Air	Elliptical Waveguide
LOW-BAND VHF	0.5	0.25	0.15	0.1	N/A
HIGH-BAND VHF	2	1	0.6	0.4	N/A
UHF	1	0.5	0.3	0.2	N/A
S-BAND	4	2.5	1.25	N/A	0.4

Both elliptical or rectangular waveguide can be used at S-band. Waveguide losses are substantially lower than coaxial transmission line losses, but the cost of waveguide is higher. Flexible elliptical waveguides are often used to feed transmit antennas in this frequency range. (EW17 and EW20, manufactured by Andrew Corporation, are typical elliptical waveguides for this frequency range.) Rectangular waveguide is widely used in channel combining networks to minimize losses. (WR340 and WR284 are common rectangular waveguide sizes for this frequency range.) Coaxial components in a channel combiner and transmission line network can be eliminated by using suitable waveguide components, such as E-plane and H-plane elbows, directional couplers and filters.

A harmonic and trap filter assembly feeding the transmission line is often used in the VHF and UHF frequency range. In the S-band, it is also common to include a multichannel combining network. Notch filters are often required in low level diplexed assemblies to trap out-of-band spurious emissions.

A multichannel environment requires several channels to be coupled onto a common transmission line. This can be achieved by using a multiplexing filter. While this filter can take several forms, a typical directional filter allows a specific channel to be directionally coupled to the output and rejects signals of other fre-

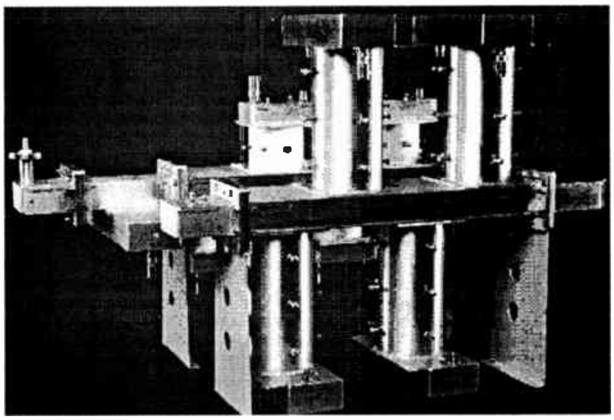

Figure 6.12-8. Typical directional filter.

quencies that pass over the filter unattenuated (see Figure 6.12-8). A diagram of a multichannel directional filter is shown in Figure 6.12-9.

Transmitting antennas are normally of the slot or stacked dipole design. A typical LPTV antenna with directive elements attached is shown in Figure 6.12-10. Side mounting can affect the pattern of a transmitting antenna. Fortunately, computer programs are available that can predict the impact on the pattern and allow this effect to be addressed in system design (see Figure 6.12-11).

S-Band Receiving Equipment

A typical receiving system for S-band is shown in Figure 6.12-12. In this system, a directional receive antenna couples signal into a broad band block downconverter, which heterodyne converts the signal to VHF superband. The signal is then decoded and remodulated onto a low band VHF channel.

Digital service is a more complex but similar technique of extracting the desired program material from the received input and converting it into a standard NTSC signal for television viewing.

The Receive Antenna

Receive antennas vary from 12 dB gain corner reflectors to 36 dB gain parabolic dish designs. A short

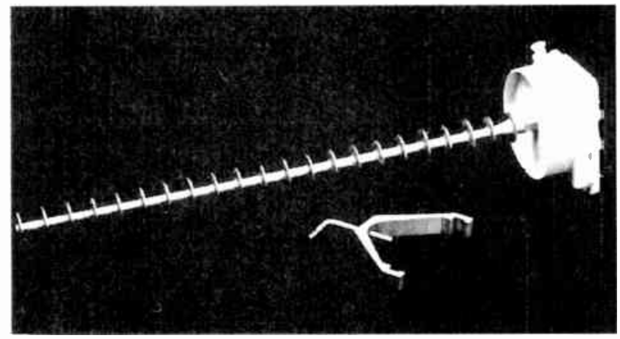

Figure 6.12-14. ITFS/MMDS downconverter. (Courtesy California Amplifier.)

jumper usually connects the antenna feed directly to the downconverter, although in some designs the receive feedhorn is directly mounted to the downconverter. A typical antenna is shown in Figure 6.12-13.

Downconverters

The key characteristics of downconverters are sensitivity, signal handling capability, gain, spurious products, phase stability and reliability (see Figure 6.12-14 for a typical example).

Sensitivity is achieved through the use of low noise transistor stages preceding the mixer. Noise figures of 4 dB are typical.

Signal handling capability is a limitation in a multichannel environment. The front-end mixer and the VHF output amplifier are both sources of distortion, which takes the form of composite triple beat, a common cable television distortion characteristic. Distortion can be minimized through improved mixer design and increased VHF amplifier output capability. It can be tested with a two-tone input test signal with the objective of achieving -27 dBm per tone at the input of the converter without significant output distortion.

The gain of a downconverter is generally not critical unless there are long transmission line feeders after the converter. A normal range for converters is 17 dB to 30 dB. Downconverters with as much as 40 dB of gain are available, but these units may suffer from output signal distortion because of high signal levels in the output amplifier.

Spurious products are a significant problem in many cases. Downconverters use various local oscillator techniques to achieve clean local oscillator signals, including phase-locked loops, dielectric resonators, free-running voltage-controlled oscillators (VCO) and SAW oscillators. Spurious products in the output band should be suppressed at least 50 dB below normal output levels.

Phase jitter is a result of local oscillator electrical noise and mechanical vibration sensitivity. This characteristic leads to horizontal streaking in the picture and difficulty in phase lock demodulating television signals. Especially important in digital systems, phase jitter can be observed on a spectrum analyzer tuned to an output unmodulated carrier.

Decoders—Analog

Decoders typically have synthesized front-ends and specialized IF decoding circuitry. Addressability is a desirable characteristic of decoders but adds to the cost of the unit. Decoders designed for cable television service will occasionally have difficulty with the widely varying levels in an MMDS system and may be unable to handle the normal adjacent channel variations that it experiences. The time constant of an automatic gain control of the decoder may also be inappropriate for an MMDS signal environment. As MMDS systems grow, it is expected that new decoders developed specifically for this service will become available.

Since decoders heterodyne convert or remodulate the signal onto a low band output VHF carrier, additional video and audio signal degradation may be incurred.

Decoders—Digital

In addition to the RF and IF signal processing present in analog decoders, digital units must demodulate a specific 6 MHz channel, demultiplex the desired program, decompress the bit stream and ultimately reconfigure the signal into NTSC format video and audio. Powerful large-scale integrated circuit chips are now available to perform many of these functions, and commercially available digital decoders are now available for several digital modulation standards.

6.13
CABLE TELEVISION SYSTEMS

WALTER S. CICIORA, Ph.D.
SOUTHPORT, CT

INTRODUCTION

According to A. C. Nielson, cable television service is enjoyed by more than 65 million U.S. households, market penetration of over 67%. Cable service passes 96% of U.S. households.

Because cable television has been so successful and has enjoyed such vigorous growth and acceptance, it has spawned competitive technologies, including pre-recorded media (pre-recorded tape and disk sales and rentals) and direct broadcast satellite (DBS), as well as the interest of the telephone industry. Its high visibility has also attracted the attention of regulators and legislators since important public policy issues are involved. Understanding what cable television is, how it works and its economics will help decision makers in these arenas. This understanding will also aid technologists in determining which technologies are appropriate for cable television applications and which are not. For some readers, the main interest in this chapter is simply a better understanding of the technology that supplies their home with video. This chapter is intended for technical professeionals who require a briefing on cable television in the United States.[1]

Historical Perspective

Cable television is an important part of the way in which the citizens of the United States are informed and entertained. It provides large numbers of television channels to more than half of the U.S. population in a cost-effective way.

Prior to the 1990s, cable television systems were not intended to be general purpose communications mechanisms. Their primary and often sole purpose was the transportation of a variety of entertainment television signals to subscribers. Thus, they needed to be one-way transmission paths from a central location, called a headend, to each subscriber's home, delivering essentially the same signals to each subscriber. Then as now, the signals were intended for use with the consumer electronics equipment that subscribers already owned. This equipment was built to operate on the then current U.S. television technical standard called the National Television Systems Committee (*NTSC*) after the organization that created it in 1941. This black-and-white television standard was modified in 1953 to provide compatible color information to color television receivers and again in 1984 to add compatible stereo sound.

Cable television's original purpose was to deliver broadcast signals in areas where they were not received in an acceptable manner with an antenna. These systems were called community antenna television (CATV). In 1948, Ed Parson of Astoria, OR, built the first CATV system consisting of twin-lead transmission wire strung from housetop to housetop. In 1950, Bob Tarlton built a system in Lansford, PA, using coaxial cable on utility poles under a franchise from the city and Jerrold Corporation's antenna booster amplifier. Martin Malarkey opened his cable system in Pottsville, PA, within a week of Tarlton. Malarkey used Radio Corporation of America (RCA) Antennaplex equipment, which was originally developed for the in-house distribution of the National Broadcasting Company's (NBC's) signals in the RCA building in New York City. Malarkey also organized and developed the National Community Television Association (NCTA), which later was renamed the National Cable Television Association.

In most CATV systems, off-air signals were not available or were very weak because of the terrain or the distance from television transmitters. In some areas, such as New York City, multiple signal reflections and shadows cast by buildings made reception difficult. In both of these environments, a hard-wire method of delivery of signals to subscribers was welcomed. The first operators of these systems were retail TV receiver dealers who sought to expand the market for the sale of their products by also providing the signals the products required. By the late 1960s, nearly all of the areas of the United States that could benefit from a community antenna had been served. Growth in the cable industry all but stopped.

In the mid 1970s, an embryonic technology breathed new life into cable television. This technology was satellite delivery of signals to cable systems, which added more channels than were available from terrestrial broadcasters. While satellites and earth stations were very expensive investments, these programming

[1] It is based on a CableLabs' publications by this author titled, "Cable Television in the United States, An Overview," which is available on CableLabs' Website: www.cablelabs.com/publications.html See also: Modern Cable Television Technology: Video, Voice, and Data Communications by W. Ciciora, J. Farmer, D. Large, Morgan Kaufmann Publishers, 1999. Also, see www.ncta.com/directory.html for the latest cable statistics.

pioneers understood that the costs could be spread over many cable operators who, in turn, could serve many subscribers.

Three categories of signals came into existence, all of which sparked new excitement in the business:

- *Super stations*—local stations that were distributed nationally over satellite and became mini-networks. (The Turner Broadcasting System of Atlanta, GA pioneered the concept)
- Specialized channels for news, sports, weather, education, shopping
- Movie channels such as Home Box Office (HBO). (Cable television became much more than just a community antenna for areas with poor reception: it became a means of receiving programming otherwise unavailable.)

Today, cable subscribers are offered a variety of video services. The foundation service required of all subscribers is called *basic* and includes off-air channels, some distant channels and some satellite-delivered programs. (The satellite programs include the super stations and some of the specialty channels.) *Pay television* constitutes premium channels, usually with movies and some special events, which are offered as optional channels for an extra monthly fee. Some cable systems offer *pay-per-view* (PPV) programming, which is marketed on a program-by-program basis. Recent movies and special sports events are the mainstay of PPV programming. *Impulse pay per view* (IPPV) allows the subscriber to order the program spontaneously, even after it has begun. The ordering mechanism usually involves an automated telephone link or, occasionally, two-way cable.

Ways of providing conditional access to allow for a limited selection of service packages at differing price points are often included in the cable system. Simple filters remove the unsubscribed channels in some systems, while elaborate video and audio scrambling mechanisms involving encryption are used in other cable systems.

During the early-to-mid-1980s, a wide variety of other services were offered to cable subscribers: videotext, teletext, other forms of electronic publishing and information age services, home security and digital audio programming. Subscribers in the 1980s showed a remarkable lack of interest in these services. It is interesting to speculate on the reasons for this disinterest, but the negative experience was without exception. While subscribers were enthusiastic about video, particularly entertainment-oriented video, other services left them cold. As a result, cable operators began concentrating their cable system design efforts on efficient, cost-effective video delivery.

Recently, the World Wide Web has generated popular interest in interactive services. Consequently, cable operators are adding high-speed modems and ancillary signals to their offerings. A number of cable operators are also providing telephony services; some major cable operators have merged with telephone companies to merge the two technologies into a unified network.

The late 1980s and early 1990s brought a high level of interest and excitement over the Information Superhighway, also called the National Information Infrastructure (NII). A variety of drivers are energetically pushing the NII. Early efforts came from the telephone industry as it sought to justify upgrading heavily depreciated plant. Since the twisted pair plant did a fine job of delivering plain old telephone service (POTS), another reason for replacing it was needed. The reason had to have a heavy appetite for bandwidth. Digitized voice did not fill the bill since it could be handled over the existing twisted copper pairs. Only computer data and digitized video could provide a justification for declaring the twisted copper pair obsolete. So the telephone systems began a quest for permission to add fiber and digital technology to the rate base. The U.S. Congress consequently decided that a vast government-sponsored program was needed to build the information superhighway and the NII was born.

The cable industry realized that it had a major advantage in this race since it passes 96% of all TV households with a truly wide band delivery means. The cable and telephone industries strove unsuccessfully to convince government that a publicly funded program was not needed. Private industry, they felt could do the job effectively and efficiently.

Since cable television systems must utilize the public right-of-way to install their cables, they, like power, telephone and gas companies, must obtain a franchise from local governmental authorities. This is a non-exclusive franchise. However, experience with multiple cable systems has shown that the economics of the business generally only support one system per community.

Spectrum Reuse

Compared with nearly any other communications need, video is a bandwidth hog. While telephone-quality voice needs only 3 kHz of spectrum and high fidelity sound takes 20 kHz or so (40 kHz for stereo), the current video standard consumes 4.2 MHz. High definition television (HDTV) requires about 30 MHz for each of the red, green and blue signals that make up a color picture. Extensive bandwidth compression techniques reduce the amount of spectrum required by HDTV to the 6 MHz allowed by the Federal Communications Commission (FCC). These signals must then be modulated onto carriers to deliver multiple signals to the consumer's equipment.

For NTSC, each television channel consumes 6 MHz because of vestigial sideband amplitude modulation, VSB-AM. Compared with double sideband amplitude modulation's need for 8.4 MHz, VSB-AM transmits one complete sideband and only a vestige of the other. (At the time the standard was created, electronics consisted of vacuum tubes. It was important to avoid the complexities of single sideband receivers while not consuming the bandwidth required by double sideband transmission.) VSB was an effective compromise for the constraints of the times. The design requirements of practical filters determined the amount of sideband included. The consumer's receiver selects the channel to be watched by tuning a 6 MHz portion of the assigned spectrum. In the terrestrial broadcast environment, channels must be carefully assigned to prevent interference with each other. The result of this process is that most of the terrestrial broadcast television spectrum is vacant. Although better television antennas and television circuits would allow more of the spectrum to be utilized, with 250 million receivers and more than 150 million VCRs in consumers' hands, the changeover process to upgraded systems would be difficult, costly and require approximately 20 years.

The rest of the terrestrial spectrum that is not assigned to broadcast has other important uses. These include aircraft navigation and communications, emergency communications, and commercial and military applications. The terrestrial spectrum is too limited to supply the video needs of the U.S. viewer.

Cable television is made possible by the technology of coaxial cable. Rigid coaxial cable has a solid aluminum outer tube and a center conductor of copper-clad aluminum. Flexible coaxial cable's outer conductor is a combination of metal foil and braided wire, with a copper-clad, steel center conductor. The characteristic impedance of the coaxial cable used in cable television practice is 75 Ω. The well-known principles of transmission line theory apply fully to cable television technology.

The most important characteristic of coaxial cable is its ability to contain a separate frequency spectrum and maintain the properties of that separate spectrum so that it behaves like over-the-air spectrum. This means that a television receiver connected to a cable signal will behave as it does when connected to an antenna. A television set owner can become a cable subscriber without buying additional consumer electronics equipment; much of the cable service can be enjoyed simply by connecting the TV or VCR to the cable system. Other services are enjoyed through adapters provided as part of the cable subscription. The subscriber can also cancel the subscription and not be left with useless hardware. This ease of entry and exit from an optional video service is a fundamental part of cable's appeal to subscribers.

Since the cable spectrum is tightly sealed inside an aluminum environment (the coax cable), a properly installed and maintained cable system can use frequencies assigned for other purposes in the over-the-air environment. This usage takes place without causing interference to these other applications and vice versa. New spectrum is "created" inside the cable by the reuse of spectrum. In some cable systems, dual cables bring two of these sealed spectra into the subscriber's home, with each cable containing different signals.

The principal negative of coaxial cable is its relatively high loss. Coaxial cable signal loss is a function of its diameter, dielectric construction, temperature and operating frequency. A ballpark figure is 1 dB of loss per 100 ft (30.5 m). Half-inch diameter aluminum cable has 1 dB of attenuation per 100 ft (30.5 m) at 181 MHz; at 1 in. (2.5 cm) diameter, the attenuation drops to 0.59 dB per 100 ft (30.5 m). The attenuation of cable varies with the square root of the frequency. Thus, the attenuation at 216 MHz (within TV channel 13) is twice that of 54 MHz (within TV channel 2) since the frequency is four times as great. If channel 2 is attenuated 10 dB in 1,000 ft (.3 km), channel 13 will be attenuated 20 dB.

CABLE NETWORK DESIGN

While current cable practice involves extensive use of fiber in new construction and upgrades, it is important to understand cable techniques used prior to fiber's introduction. This is partly because a significant fraction of cable systems have not yet upgraded to fiber and because these older cable techniques illustrate important cable technical principles.

Since cable television of the 1980s was not a general-purpose communications mechanism, but rather a specialized system for transmitting numerous television channels in a sealed spectrum, the topology or layout of the network was customized for maximum efficiency. The topology that has evolved over the years is called *tree-and-branch architecture*. Many small and intermediate sized systems fit this model. When analyzed, most large systems can be seen as having evolved from this prototype.

There are five major parts to a traditional coaxial cable system:

- the headend
- the trunk cable
- the distribution (or feeder) cable in the neighborhood
- the drop cable to the home and in-house wiring
- the terminal equipment (consumer electronics).

Flexible coaxial cable is used to bring the signal to the terminal equipment in the home. In the simplest cases, the terminal equipment is the television set or VCR. If the TV or VCR does not tune all the channels of interest because it is not cable compatible, a converter is placed between the cable and the TV or VCR tuner.

Broadcast channels 2 through 13 are not in a continuous band. Other radio services occupy the gaps. Cable can reuse these frequencies because its spectrum is self-contained within the coaxial environment. The cable converter has a high quality broadband tuner and output circuitry which puts the desired cable channel on a low band channel not occupied in the local off-the-air spectrum. Typically this is channel 2, 3, 4 or 5. The TV or VCR is tuned to this channel and behaves as a monitor. If programming of interest to the subscriber is scrambled, a descrambler is required; it is usually placed in the converter. Figure 6.13-1 shows the cable frequency plan.

The home is connected to the cable system by the flexible drop cable, typically 150 ft (45.7 m) long. See Figure 6.13-2.

The distribution cable in the neighborhood runs past

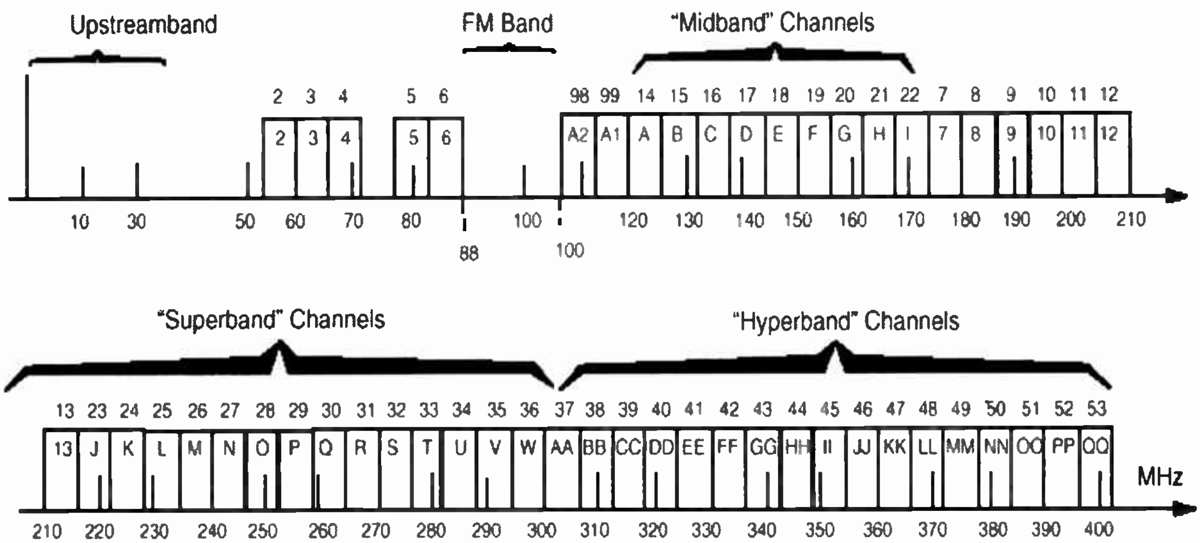

Figure 6.13-1. Frequency plan. Numbers above the rectangles are the Electronics Industry Association designations. Historical designations are inside the rectangles. While the upper frequency shown is 400 MHz, modern cable systems have bandwidths approaching 1 GHz.

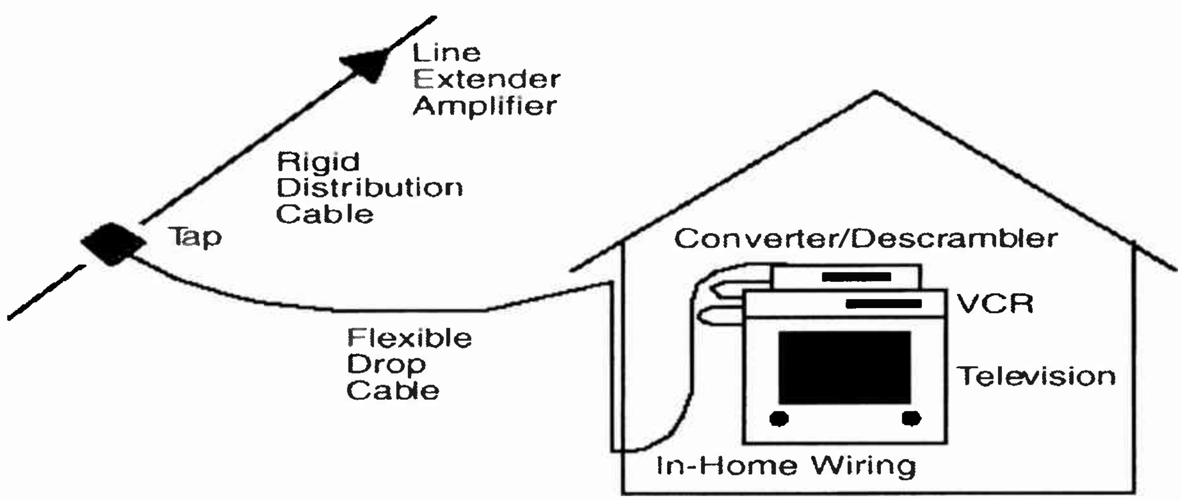

Figure 6.13-2. Terminal equipment and cable drop.

the homes of subscribers. This cable is tapped so that flexible drop cable can be connected to it and routed to the residence. The distribution cable interfaces with the trunk cable through an amplifier called a *bridger amplifier,* which increases the signal level for delivery to multiple homes. One or two specialized amplifiers called *line extenders* are included in each distribution cable. Approximately 40% of the system's cable footage is in the distribution portion of the plant and 45% is in the flexible drops to the home (see Figure 6.13-3.)

The trunk part of the cable system transports the signals to the neighborhood. Its primary goal is to cover distance while preserving the quality of the signal in a cost-effective manner. Current practice uses fiber to bring the signal to the neighborhood. Older cable systems that haven't been rebuilt or upgraded still have coaxial cable in the trunk portion of the cable plant. With coaxial cable, broadband amplifiers are required about every 2,000 ft (.6 km) depending on the bandwidth of the system. The maximum number of amplifiers that can be placed in a run or *cascade* is limited by the build up of noise and distortion. Twenty or 30 amplifiers may be cascaded in relatively high-bandwidth applications. Older cable systems with fewer channels may have as many as 50 or 60 amplifiers in cascade. Approximately 14% of a cable system's footage is in the trunk part of the system.

The headend is the origination point for signals in the cable system. It has parabolic or other appropriately shaped antennas for receiving satellite-delivered program signals, high gain directional antennas for receiving distant TV broadcast signals, directional antennas for receiving local signals, machines for playback of taped programming and commercial insertion and stu-

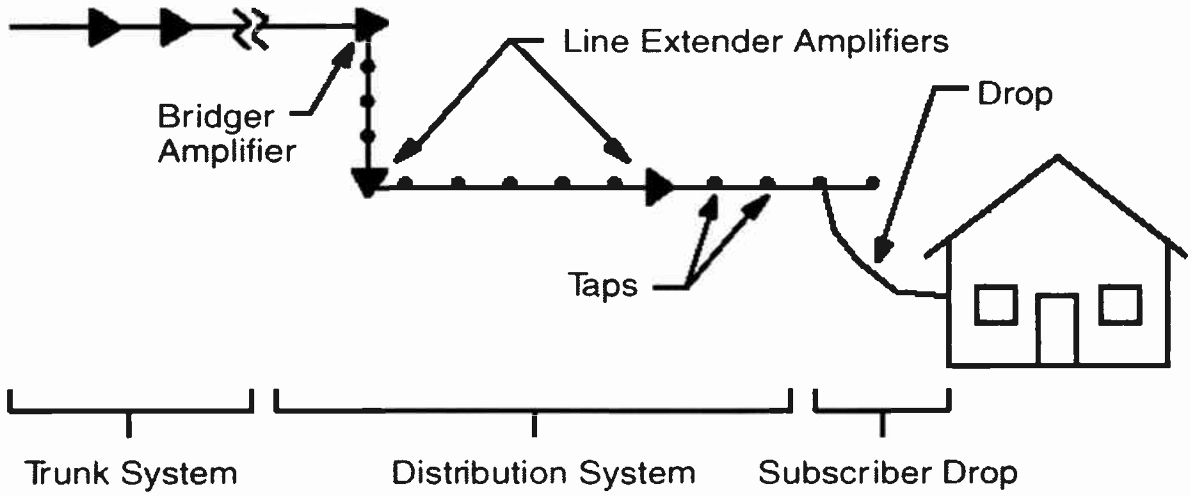

Figure 6.13-3. Distribution plant.

dios for local origination and community access programming (see Figure 6.13-4).

Local origination is programming over which the cable operator has editorial control. It can range from occasional coverage of local events to a collection of programming almost indistinguishable from that of an independent broadcaster. Often mobile coverage of events is provided with microwave links back to the headend or back-feed of the signal up the cable system to the headend.

Community access is channel and/or time availability mandated by the local franchise for programming by community groups. The cable system typically cannot exercise editorial control over quality or content of community access programming.

When the whole picture is assembled, the tree shape of the topology is evident. The trunk and its branches become visible. See Figure 6.13-5.

Signal Quality

The ultimate goal of the cable system is to deliver pictures of adequate quality at an acceptable price while satisfying stockholders, investors and holders of the debt generated by the huge capital expenses of building the cable system plant. This is a difficult balancing act. It would be a simple matter to deliver very high quality video if cost were not a consideration. Experience teaches that subscriber satisfaction is a complex function of a variety of factors led by program quality and variety, reliability of service, video and sound quality and the amount of the subscriber's cable bill.

The principal picture impairments can be divided into two categories—coherent and noncoherent. Coherent impairments result in a recognizable interfering pattern or picture. They tend to be more objectionable than non coherent impairments of equal strength.

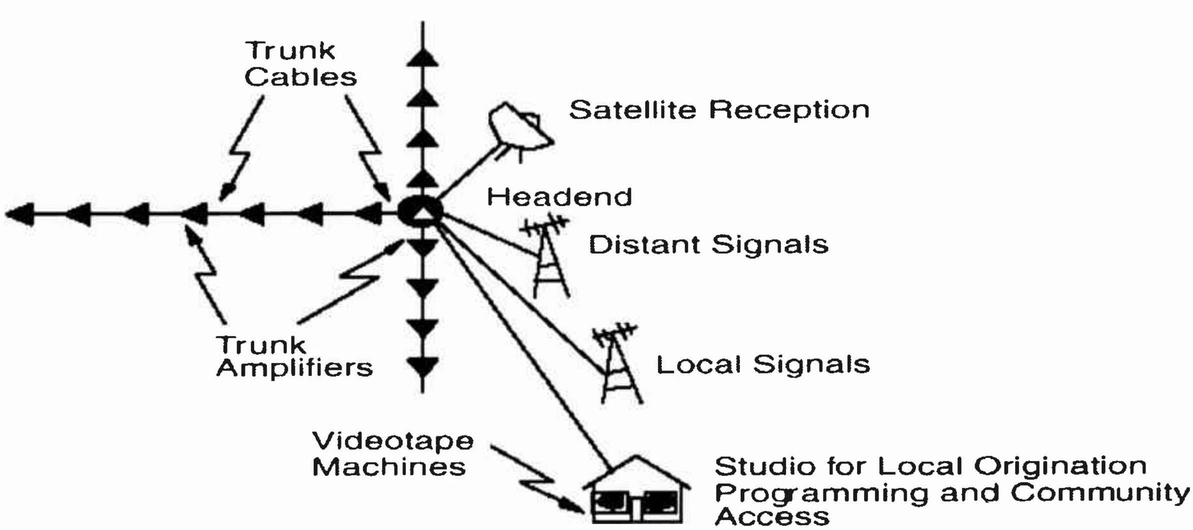

Figure 6.13-4. Cable system headend.

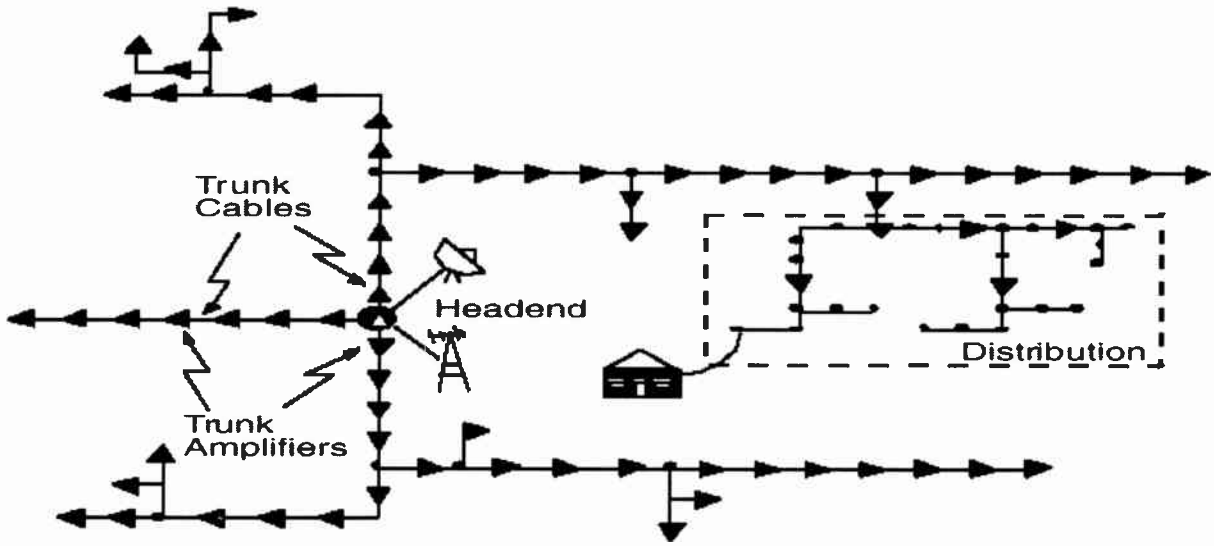

Figure 6.13-5. Tree-and-branch topology.

The principal noncoherent picture impairment is noise. Random noise behavior is a well-understood part of general communications theory. The familiar Boltzmann relationship (noise figure concepts) applies fully to cable television technology. Random noise is the consequence of the statistical nature of the movement of electric charges in conductors. This noise is inescapable and creates a signal of its own. If the intended analog signal is ever allowed to become weak enough to be comparable to the noise signal, it will be polluted by it, yielding a snowy pattern in pictures and a seashore-sounding background to audio.

Noise levels are expressed in cable system practice as ratios of the video carrier to the noise in a television channel. This measure is called the carrier-to-noise ratio (CNR) and is given in decibels (dB). The target value for CNR is usually 45–46 dB or higher. Noise in the picture, called snow, is just visible when CNR is 43–44 dB. Snow is objectionable at CNRs of 40–41 dB.

Coherent interference includes ingress of video signals into the cable system, reflections of the signal from transmission-line impedance discontinuities, cross modulation of video and cross modulation of the carriers in the video signal. This latter phenomenon gives rise to patterns on the screen which are called *beats*. These patterns often look like moving diagonal bars or herringbones.

The evaluation of signal quality takes place on two planes, objective and subjective. In the objective arena, measurements of electrical parameters are used. These measurements are repeatable. Standardized, automated test equipment has been developed and accepted by the video industries. Table 6.13-1 lists the parameters usually considered important and the values of good, current practice. They are described in the remaining text.

The ultimate performance evaluation involves the subjective reaction of viewers. One example of the difficulties experienced is the fact that different frequencies of noise have differing levels of irritation. High frequency noise tends to become unnoticeable while low frequency noise creates large moving blobs which are highly objectionable. Subjective reactions to these phenomena are influenced by such factors as the age, gender, health and attitude of the viewer. The nature of the video program, the characteristics of the viewing equipment and the viewing conditions also impact the result.

Table 6.13-1
Signal quality target values.

Parameter	Symbol	Value
Carrier/Noise (CNR)	C/N	48–50 dB
Composite Second-Order	CSO	−53 dB
Composite Triple Beat	CTB	−53 dB
Signal Level at TV		0–+3 dBmV

Signal processing in the TV receiver changes the impact of signal impairments. Noise in the band of frequencies used to transmit color information is demodulated and converted into lower frequency, more objectionable noise. Noise in the synchronization part of the TV signal can cause the picture to break up entirely, resulting in much greater impairment than the same strength noise confined to other portions of the signal.

In 1959, the Television Allocations Study Organization (TASO) studied the amount of noise, interference and distortion viewers will tolerate in a TV picture. The results were expressed in a five-point scale with grades named excellent, fine, passable, marginal and inferior. These are very old data.

It is important to realize that the demand for signal quality is a function of time. Fifteen to 20 years ago, consumer electronics products were not capable of displaying the full resolution of the NTSC signal.

Gradually, these products improved with high-end models capable of more performance than the NTSC signal can deliver. The Super VHS and Hi-8 video tape systems have greater resolution than broadcast NTSC. As time progresses, the level of performance of consumer electronics will continue to increase. As digital television (DTV) and HDTV are introduced, still more demands will be made on cable system performance. The trend to larger screen sizes also makes video impairments more evident.

Cable System Tradeoffs

The experienced cable system designer of the 1980s learned how to balance noise, nonlinear distortions and cost to find a near optimal balance. The various configurations of then available components were thoroughly explored and the best choices understood. The explosion of technology in the 1990s changed all of this carefully sorted-out technique and dramatically increased the options available to the cable system designer. Construction of optimum designs now requires knowledge, experience, creativity and a complete familiarity with the latest components.

Signals in cable systems are measured in dB relative to 1 mV across 75 Ω. This measure is called dBmV. Applying the Boltzmann noise equation to 75 Ω cable systems yields an open-circuit voltage of 2.2 microvolts in 4 MHz at room temperature. When terminated in a matched load, the result is 1.1 microvolts. Expressed in dBmV, the minimum room-temperature noise in a perfect cable system is −59.17 dBmV.

Starting at the home, the objective is to deliver at least 0 dBmV, but no more than 10 dBmV to the terminal on the television receiver. Lower numbers produce snowy pictures, and higher numbers overload the television receiver's tuner, resulting in cross modulation of the channels. If a converter or descrambler is used, its noise figure must be taken into account. There are two reasons for staying toward the low side of the signal range: cost and the minimization of interference in the event of a signal leak caused by a faulty connector, damaged piece of cable or defects or inadequate shielding in the television receiver. Low signal levels may cause poor pictures for the subscriber who insists on unauthorized splitting in the home to serve multiple receivers. Working our way back up the plant, we need a signal level of 10 dBmV to 15 dBmV at the tap to compensate for losses in the drop cable.

The design objectives of the distribution part of the cable system involve an adequate level of power not only to support the attenuation characteristics of the cable but to allow energy to be diverted to subscribers' premises. Energy diverted to the subscriber is lost from the distribution cable. This loss is called *flat loss* because it is independent of frequency. Loss in the cable itself is a square-root function of frequency and is therefore contrasted to flat loss. Because of flat losses, relatively high power levels are required in the distribution part of the plant, typically 48 dBmV at the input to the distribution plant. These levels force the amplifiers in the distribution part of the plant to reach into regions of their transfer characteristics which are slightly nonlinear. As a result, only one or two amplifiers, called line extenders, can be cascaded in the distribution part of the plant. These amplifiers are spaced 300–900 ft (91.4 m–274.3 m) apart depending on the number of taps required by the density of homes.

Because the distribution part of the plant is operated at higher power levels, nonlinear effects become important. The television signal has three principal carriers: the video carrier, the audio carrier and the color subcarrier. These concentrations of energy in the frequency domain give rise to a wide range of *beats* when passed through nonlinearities. To minimize these effects, the audio carrier is attenuated about 15 dB below the video carrier.

When cable systems only carried the 12 VHF channels, second-order distortions created spectrum products which fell out of the frequency band of interest. As channels were added to fill the spectrum from 54 MHz to as much as 750 MHz (1 GHz in a couple of systems), second-order effects were minimized through the use of balanced, push-pull output circuits in amplifiers. The third-order component of the transfer characteristic dominates in many of these designs. The total effect of all the carriers beating against each other gives rise to an interference called CTB. CTB is measured with a standard procedure involving 35-channel carriers. In a 35-channel cable system, about 10,000 beat products are created. Channel 11 suffers the most with 350 of these products falling in its video passband. Third-order distortions increase about 6 dB for each doubling of the number of amplifiers in cascade. A 1 dB reduction in amplifier output level will generally improve CTB by 2 dB. If these products build to visible levels, diagonal lines will be seen moving through the picture. When these components fall in the part of the spectrum that conveys color information, spurious rainbows appear.

If we assign a design level of noise and nonlinear distortion at the subscriber's television receiver that is below the threshold of visibility, we can create a budget of noise and distortion to be "spent" in the various parts of the system design. The distribution part of the system has relatively high powers and eats up most of the budget for nonlinear distortions. On the other hand, little of the noise budget is consumed. It can be allocated to the trunk part of the system, which brings the signals into the neighborhood.

The design objective of the trunk part of the cable system is to move the signal over substantial distances with minimal degradation. Because distances are significant, fiber or lower-loss cables are used. One-in. (2.5 cm) and 0.75 in. (1.9 cm) diameter cable is common in the trunk while 0.5-in. (1.3 cm) cable is found in the distribution. Signal levels in the trunk at an amplifier's output are 30–32 dBmV depending on the equipment used.

It has been determined through analysis and confirmed through experience that optimum noise performance is obtained when the signal is not allowed to be attenuated more than about 20–22 dB before being amplified again. Amplifiers are said to be *spaced* by 20 dB. The actual distance in feet is a function of maximum frequency carried and the cable's attenuation characteristic. High-bandwidth cable systems have their amplifiers fewer feet apart than older systems with fewer channels. Since attenuation varies with frequency, the spectrum in coaxial cable develops a *slope*. This is partially compensated with relatively simple equalization networks in the amplifier housings.

The attenuation of the cable is a function of temperature and aging of components. These amplifiers use a pilot signal to control automatic gain control (AGC) circuits. A second pilot signal at a substantially different frequency than the first allows the slope of the attenuation characteristic to be monitored and compensation to be introduced with automatic slope control (ASC) circuits. Thus, long cascades of amplifiers can, once properly set up, maintain their performance over practical ranges of temperature and component aging.

Since the signal is not repeatedly tapped off in the trunk part of the system, high power levels are not required to feed splitting losses. As a result, signal levels are lower than in the distribution portion of the plant. Typical levels are about 30 dBmV. For the most part, the amplifiers of the trunk are operated within their linear regions. The principal challenge of trunk design is keeping noise under control. Each doubling of the number of amplifiers in the cascade results in a 3 dB decrease in the CNR at the end of the cascade and a 6 dB increase in the amount of CTB.

If the noise at the end of the cascade is unacceptable, the choices are to employ lower noise amplifiers, shorter cascades or a different technology such as microwave links or fiber optic links.

Cable Economics

The most recent figures compiled (for 1997) indicate that the U.S. cable industry has 11,517 cable systems. These range in size from a few hundred customers to the largest system, which serves about a million subscribers in New York City and is operated by Time Warner. The cable industry employs about 125,000 people and has annual revenues of $33 billion ($25 billion from subscriptions and about $8 billion from advertising).

The economics of cable television is governed by a number of factors. Included in these are the cost of construction, the cost of programming, the willingness of subscribers to pay for the service and the operating costs of the system.

It is difficult to define a typical cable system because of the variety of local factors. However, a rough approximation of such an entity is a 54-channel two-way capable, one-way activated system with 50,000 subscribers. Population density is about 75 homes per mile of cable plant. Penetration of subscribers is about 67% of homes passed. The current cost to build such a system is between $600 and $1,200 per subscriber, depending on local geography, economics and construction rules. The cost of cable system construction varies greatly depending on the circumstances of the location. A major variable is whether the cable system plant is underground or on poles; in the United States, only about 20% of the plant is underground.

Figure 6.13-6 shows an approximate distribution of cable construction costs. The labor to install each component is included with the cost of that component. Hardware includes the mechanism for supporting the cable. In aerial construction, a strong, heavy wire called *strand* is mounted on the poles. Strand also supports amplifiers and passive components. The passive devices split the signal and tap into the cable for distribution to the home. A thinner wire, called *lashing*, is spiral wrapped around the cable and strand to support the cable. Electronics includes amplifiers and microwave links.

The market value of cable systems recently sold varies from $1,800 to a high of almost $2,500 per subscriber. These values are determined by both the current cash flow and the potential for increased penetration and new revenue streams. The capital-intensive cable business is currently experiencing dramatic increases in programming costs.

According to statistics gathered in 1997 by the NCTA, the cable industry trade organization subscribers paid about $27 per month for basic service and $8.29 per month for each optional pay service such as HBO. While not every basic subscriber takes an optional pay service, some take more than one. Average per month subscription revenue is about $37.75.

TECHNICAL DETAIL

This section concentrates on issues relating to the technical performance of cable systems. Some generaliza-

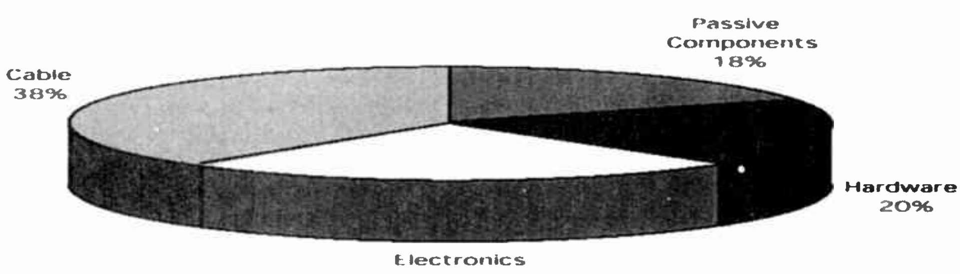

Figure 6.13-6. Distribution cable plant costs.

tions have been made in order to group explanations. This section is intended to serve as a briefing, so selective tradeoffs were made on the amount of detail given. There are always exceptions, for cable systems do not neatly fall into clear types.

System Configurations and Trends

A cable system's configuration consists of:

- The headend (the signal reception, origination, and modulation point)
- Main, coaxial trunk (or tree) cable, which runs through central streets in communities
- Coaxial distribution (branch) cable to the customer's neighborhood, including distribution taps
- Subscriber drops to the house
- Subscriber terminal equipment (television sets, converter/descramblers, VCRs).

Distribution plant is sometimes called *feeder* plant. Programming comes to the headend by satellite signals, off-air signals from broadcast stations and signals imported via terrestrial microwave. Signals originating from the headend are from a co-located studio facility, VCRs, character generators or commercial insertion equipment.

Plant mileage is calculated using the combined miles (kilometers) of strand that support the coaxial cables in the air and the footage of trenches where cables are installed in the ground. There are about a million miles (1.6 km) of plant in the 11,517 U.S. cable systems in existence in 1997.

Extension cables, or *drops*, interconnect main coaxial plant lines to customers' homes. They are not included in plant mileage. Drop cables are smaller in diameter than mainline coaxial cable plant. They interconnect between a *power splitter*, called a *multitap directional coupler*, and the customer's interface, usually a television set. The tap is located in the utility easement. In an average cable system there will be 6,625 ft (2 km) of drop cable per plant mile and 7,040 ft (2.1 km) of hard-line coaxial cable. Other interesting statistics include an average of 75 homes per mile, 67% penetration, drop length of 125 ft (38.1 m) and 1:3 trunk footage-to-feeder footage ratio. To put it another way, more than 50% of the total plant is drop cable and associated F-connectors, which are the connectors used to connect coaxial cable to equipment. About half of service calls are related to problems with the drop portion of the plant. About one-third of the drop-related service calls are caused by problems at the F-connectors. Cable systems replace approximately 30% of drops annually.

Industry Trends

ATV will put pressure on operators to expand plant bandwidth.

The last few years have brought exciting trends employing new technologies. Fiber is now installed to upgrade older systems and as part of rebuilds and new builds. The old trunk system of long cascades of amplifiers is now considered obsolete. Work on new amplifier technologies will allow a realization of cable's inherent bandwidth, which exceeds 1 GHz.

A bandwidth of 1 GHz contains 160 slots of 6 MHz. These can be allocated to NTSC, DTV and to new services. The most exciting potential lies with utilizing video compression technology to squeeze 6–12 NTSC-like quality signals in a 6 MHz slot. This opens the door for multiple hundreds of channels. Near video on demand becomes practical (the most popular movies could be repeated every few minutes to minimize the wait time before a movie starts). The average wait time could be made shorter than the trip to the video store, the subscriber would not have to make a second trip to return the movie and the movie would always be in. A microprocessor can keep track of which channel to return to should the subscriber wish to take a break. It is possible to design systems that behave as if they are switched even though they remain more like a traditional cable tree-and-branch structure.

Channelization

There are three channelization plans to standardize the frequencies of channels. The standard assignment plan has evolved from the frequency assignments that the FCC issued to VHF television broadcast stations.

The second channelization plan is achieved by phase locking the television channel carriers. The incrementally related carriers (IRC) plan was developed to minimize the effects of third-order distortions generated by repeated amplification of the television signals as they pass through the cable plant. As channel capacities increased beyond 36 channels, composite, third-order distortions became the limiting distortion.

The third channelization type is the harmonically related carriers (HRC) plan. It differs from the standard and IRC plan by lowering carrier frequencies by 1.25 MHz. With HRC, carriers are phase locked and fall on integer multiples of 6 MHz starting with channel 2 at 54 MHz. This plan was created to further reduce the visible impact of amplifier distortions.

The channelization plans were designed to reduce the visibility of distortion products by making their frequencies synchronous with the interfered carrier. Since carriers present in the downstream signal path add to the distortions, cable systems carry nonvideo carriers at a level that is 13–17 dB below the video carrier's amplitude. This drastically reduces distortion contributions. With broadcast TV channels carried on cable, special processing equipment is used to reduce the aural carrier. This amplitude reduction does not significantly affect the audio signal-to-noise ratio (SNR) quality of monaural television sound. However, this lower level created SNR problems at the end of the cable system for higher bandwidth signals such as FM stereo. When stereo television audio was developed, careful attention was focused on encoding techniques that would promote SNR immunity of the difference channel.

FM radio services are carried at an amplitude that is 15–17 dB below channel 6's video carrier level. The services are carried on cable in the FM band slot of 88–108 MHz. In an IRC channel plan, channel 6's aural carrier falls at 89.75 MHz, which reduces the available FM band to 90–108 MHz.

Low-speed data carriers are transmitted in the FM band or in the guard band between channels 4 and 5 in a standard frequency plan. The amplitude of these carriers is at least 15 dB below the closest video carrier level.

Signal Transportation Systems

Transportation systems were developed to deliver high quality signals from the central headend point to remote headend or hub locations where cable signals are injected into cable trunking systems. The increase in channel capacity and subsequent need to decrease amplifier cascades directly affected the development of transportation systems. Urban franchises cover large areas yet wish to transmit downstream signals from a common headend point. Other motivating factors include increased local programming originating from the cable system's studio, the requirement to deliver city government programming originating from municipal locations, a new business opportunity for the insertion of local commercials to satellite-delivered services and the development of PPV programming.

Several transportation methods have become popular over the last 10 years: amplitude modulated microwave link (AML), frequency modulated microwave link (FML), frequency modulated coaxial link (FMCL), amplitude modulated coaxial supertrunks and fiber interconnects.

AML and FML Microwave Links

AML allows the delivery of the entire downstream cable spectrum through the air to reception points located 8–10 miles (12.9–16.1 km) away from the microwave transmit site. An AML microwave transmitter provides adequate power to deliver signals to eight reception hubs. The advantage of AML is that the receiver simply performs a wide band, block down conversion. The entire downstream frequency spectrum (50–400+ MHz) is reproduced at an appropriate level for direct insertion into the cable plant, without the need for individual channel frequency shifting or processing. The only equipment required at an AML reception site is the microwave receive antenna and a microwave receiver. These can be mounted to a small tower or telephone pole.

AML up converts each television channel and combines it at its respective microwave frequency, with one frequency per channel, using a complex wave guide system. In some cases, each channel added lowers the maximum power per channel. This may either shorten path lengths or increase the probability of signal degradation during rain fades.

One of the main uses of FML is to cover distances not feasible with AML or where video SNR in excess of 56 dB is required. FML is a single-channel, frequency-modulated microwave transmission system. FML occupies significantly more bandwidth than amplitude modulated systems, from 12.5–25 MHz per channel, depending on path length. Fewer channels are available for use. Since this transmission system delivers FM signals, demodulation and VSB-AM and frequency translation must occur before insertion into the cable plant. The FML system is often used to deliver specialized programming (local origination) to a remote headend.

Amplitude Modulated Coaxial Supertrunk

The amplitude modulated supertrunk transportation system can be as simple as a conventional coaxial trunk transporting VSB-AM signals between two headends. Or the supertrunk can link a primary headend directly to the beginning of the normal cable distribution trunk. The television channels can be combined at their final frequency assignments for direct insertion into the distribution trunk. Or they can be grouped to fit into a reduced coaxial bandwidth (5–108 MHz) for transportation on a special service coaxial trunk. An example of this trunk is a mid-split system, which is a bi-directional trunk using 158–330 MHz downstream and 5–108 MHz upstream.

Another variation of AM supertrunk is split-band trunking. The spectrum from 50–450 MHz is split into two groups of 30 television channels each and inserted on two side-by-side trunks that connect two sites. The signals are equally loaded onto two trunk cables to improve television signal quality. This is achieved because the distortion produced is directly related to the number of channels carried on each trunk cable.

Whenever signals are not transported on their final frequency assignment, frequency translation devices called *channel processors* are used to frequency shift the television signals. AM supertrunks can be similar to cable distribution trunks. The difference is that the AM supertrunk uses high technology trunk amplifiers, such as *feedforward*. These transport with significantly less distortions and better CNR.

Fiber Interconnect

Fiber optic transportation systems are now used. Currently, analog video fiber technology is preferred for this application, although occasionally cable systems use digital video. The focus of current research is to optimize fiber optic transmitters, amplifiers and receivers.

The initial application of this technology took place in Orlando, FL, in 1988 as a backup to microwave links. Heavy rain caused these links to fade or suffer complete blockage. Automatic equipment switches to the fiber link. The AM fiber technology is now commonly used instead of microwave in many applications.

Digital fiber links are used when video signals are partially transported in a digital common carrier network. The video interfaces used operate at a DS-3 rate of 45 Mbps, which routes through common carrier points of presence and switching networks.

Frequency Band Usage

There are several ways to increase channel capacity. If the actual cable is in good condition, channel capacity is upgraded by modifying or replacing the trunk and distribution amplifiers. If the cable has seriously deteriorated, the cable plant is completely rebuilt.

Upgrades (Retrofitting) and Rebuilds

An upgrade is defined as a plant rehabilitation process that results in the exchange or modification of amplifiers and passive devices (such as line splitters, directional couplers and customer multitaps). Nearly all upgrades involve adding (or increasing the amount of) fiber from the headend to the neighborhood. A simple upgrade requires new amplifier circuit units called *hybrids*. A full upgrade replaces all devices in the system. In an upgrade project, most of the feeder cable is retained. Goals of an upgrade project include increasing the plant's channel capacity and system expansion to outlying geographic areas. Upgrades are often the least expensive solution to providing expanded service.

In a rebuild, the outside plant is replaced. Customer drops are replaced on an as-needed basis. The strand that supported the old cable is occasionally retained. A rebuild is the most expensive solution to providing upgraded service. It requires a minimum of system downtime, since both old and new plant are active for a period of time. This allows the customer's drop to be switched directly from the old system to the new.

Once the plant has been rebuilt or upgraded, customers are provided newer converters with additional capabilities. The displaced units are moved to other systems or used for the basic tier of service.

System Distortion and System Maintenance

Constraints on the design and implementation of cable systems are imposed by each device used to transport or otherwise process the television signal. Each active device adds small distortions and noise to the signal. Even passive devices contribute noise. The distortions and noise compound so that with each additional device the signal becomes less perfect.

Any nonlinear device, even bimetallic junctions, cause distortions. The primary contributors are the slight nonlinearities of amplifiers. Because the amplifiers are connected in cascade, the slight damage to the signal accumulates.

Noise in any electronic system can come from many sources. The major source is the random thermal movement of electrons in resistive components. For a cable system at 20°C or 68°F, the thermal noise voltage in a single channel's bandwidth will be 1.1 microvolts or −59.1 dBmV. This is the minimum noise level or noise floor. Noise contributions from amplifiers add on a power basis, with the noise level increasing 3 dB for each doubling of the number of identical amplifiers in cascade. Eventually, the noise will increase to objectionable levels. The difference between the radio frequency (RF) peak level and the noise level is measured to quantify the degree of interference of the noise power. The power levels in watts are compared as a ratio. This is called the signal-to-noise ratio (S/N). In a cable system, the apparent effect of noise is its interference with the video portion of the TV channel. This level is compared to the video carrier and called the CNR.

As the CNR value decreases, the interference of noise with the signal becomes visible as a random fuzziness or *snow*, that can overwhelm the picture resolution and contrast. The point where the picture becomes objectionably noisy to viewers is at a CNR of 40 dB. In well-designed systems, the CNR is maintained at 46 dB, preferably at 48–50 dB. While an increase in signal level would improve the CNR, unfortunately, there can be no level increase without increases in distortions.

The distortion products of solid-state devices used in cable amplifiers are a function of the output levels and bandwidths. The higher the signal level, the greater the distortion products produced. Modern amplifiers use balanced configurations which almost completely cancel the distortion caused by the squared term of the amplifier's transfer characteristic. The dominant remaining distortions are called triple beats and are caused by the cubed term. Because distortion products add on a voltage basis, the CTB-to-carrier ratio changes by 6 dB for each doubling of the number of amplifiers in cascade, whereas the CNR decreases by 3 dB for each doubling.

The operating parameters of amplifiers determine the number that can be cascaded and, hence, the distance that can be covered. This is critical to the design philosophy of coaxial trunks in cable systems. While fiber is now used in trunk construction and rebuilds, the following discussion demonstrates important cable principles nonetheless. It also helps explain the importance of fiber in overcoming coaxial cable's limitations.

A cable system's operating limits are defined in terms of its noise floor and distortion ceiling. The noise floor and distortion ceiling are a function of the number of amplifiers in cascade for a system at 300 MHz. A cascade of 46 trunk amplifiers is possible while realizing a 46 dB CNR and a 53 dB CTB. However, other operating realities dictate that substantially more headroom for both distortion and noise be incorporated into the design. The other factors to consider include: change in cable attenuation and noise with temperature, AGC and ASC tolerances, system frequency response, accuracy of field test equipment, designs anticipating DTV and maintenance probabilities. In the example cited, allowing 1 dB of AGC/ASC change, a 3 dB peak-to-valley and 2 dB of test equipment uncertainty results in a 6 dB tolerance. Limiting distortion, CTB, implies that the cascade should only be half the length predicted in the chart, or 23 amplifiers.

The foregoing discussion is applicable only to the trunk portion of the system. As signal levels are increased in the distribution sections, additional allowances must be made in the system design. As a rule of thumb, CNR is determined primarily by the conditions of trunk operation, and signal-to-distortion ratio (SDR) primarily by the conditions of distribution operation.

Two other factors limit the geography of a cable system. Cable attenuation rises with increasing frequency. More equal gain amplifiers are required to transmit the signal a given distance. But noise limits the maximum number of amplifiers used. The second factor is that amplifier distortion is a function of channel loading: The more channels carried, the greater the distortions.

To obtain optimum cascade length, AGC/ASC tolerance, accurate alignment, calibrated test equipment and well-founded system maintenance programs are of paramount importance. Maintenance programs are designed to ensure that system alignment is kept within acceptable limits. Where trunk lines carry signals through cascades of up to 40 trunk amplifiers, it is crucial that each amplifier have a flat amplitude-versus-frequency response. The additive effects of even minimal amplitude response variations in each amplifier create significant system flatness problems at the end of long cascades.

Maintaining Amplitude Versus Frequency Response

A maintenance program objective should be to achieve a system amplitude versus frequency response of less than $[(N/10) + 1]$ dB peak-to-valley. This will minimize the degradation of CNR which occurs in channels that fall in the valleys of the system response. Here N is the number of trunk amplifiers in the cascade. It is imperative that the optimum response is maintained at each amplifier. Recommended practice calls for no more than 3 dB difference in adjacent channel video carrier amplitudes provided to the customer. All channels must fall within a 12 dB overall passband response window.

The common method of evaluating a system's frequency response is a *sweep generator* that injects a rapidly swept carrier over the system's passband. The sweep generator is set to sweep from 50 MHz to the upper system passband frequency with a duration time as short as 1 millisecond. The field sweep receiver is then synchronized to the generator. The portable receiver provides a display of the system's response at each amplifier as the maintenance technician progresses through the trunk cascade.

Another tool for checking system flatness is the *spectrum analyzer*. To determine the overall system response, the individual video carrier amplitude of each television channel is measured. Because the carrier amplitudes are usually adjusted for a sloped amplifier output to minimize distortion products, more interpretation is needed with a spectrum analyzer. The sweep system allows the amplifiers to be adjusted for the flattest response.

Excessive response variations can cause additional distortions since some carriers will now exceed the amplitude at which the system's amplifiers were designed to operate. To keep these response variations from becoming excessive, amplifier manufacturers make a response control device known as a *mop-up circuit*. It is installed at periodic locations in trunk amplifiers throughout the cascade. These mop-up circuits are tunable filters adjusted to remove small peaks (less than 1.5 dB) caused by the amplifiers or cable. Incorrect use of these devices to solve defective equipment problems (bad cable sections, splices or line passives) can cause impairment to a video channel by changing its in-band frequency response or its chrominance-to-luminance delay characteristics.

Group Delay through the Cable Plant

Trunk amplifiers with bidirectional capability exhibit group delay as a result of the band-splitting diplex filters. The visible effect of the filtering is a loss of resolution in the picture. The diplex filters, which are high-pass and low-pass filters with a 40 MHz crossover frequency, are part of the trunk amplifier's circuitry.

Channels 2, 3 and 4 suffer from the repeated effects of the filtering. Other locations where filtering occurs are apartment complexes, hotels/motels and hospitals, where channels are deleted from the spectrum by special band stop filters. Locally originated channels are inserted in the deleted portions of the spectrum.

Filtering occurs at the headend or hub in connection with channel processing equipment or the channel modulators. The effects of these filters are taken into account when the headend equipment is designed. With only one of these devices per channel, the delay effects of this equipment rarely create problems. However, with some configurations of signal transportation systems, additional single-channel or multiple-channel filtering may take place and cause delays at hubs.

System Reflections

Signal reflections occur throughout the cable plant and are called *microreflections*. They are caused by the individual slight errors in impedance match. The severity of the mismatch is measured by the magnitude of the return-loss ratio. The larger the return loss, the better. Perfection is infinite. Mismatches include connectors, splices and even damage to the cable itself. As an example, if a splice installed in a trunk line approximately 150 ft (45.7 m) past an amplifier. The splice, which may only have a 12 dB return loss, reflects signals back upstream that have only been attenuated by 13.5 dB (1.5 dB in cable attenuation plus the return loss of the splice). The reflected signals then arrive back at the output of the amplifier attenuated by a total of 15 dB (1.5 dB additional cable loss for the upstream trip plus the previous 13.5 dB). The signals are now reflected by the amplifier's output mismatch; a return loss of 16 dB is common. At this point, the reflected signal has an amplitude that is 31 dB below the primary signal and delayed by the round-trip propagation through 300 ft (91.4 m) of cable, which takes about 350 nanoseconds. The signal is horizontally delayed approximately 1/7 in. (3.6 mm) on a 27-in. (68.6 cm) television set. This is not enough to become a visible ghost or second image. However, depending on the relative phases of the RF carriers of the primary and reflected signal, the visual effect may be enough to cause a softening of a previously well-defined luminance level transition. With repeated mismatches, the crispness of the pictures may be noticeably reduced. This softening effect is easily seen on displays of character generated text pages.

Phase Noise

Phase noise is added to the original signal through modulation and frequency conversion processes. A significant amount of phase noise must be added to the video carrier before generated impairments become perceptible. Narrow band phase noise (measured 20 kHz from the video carrier) in a TV channel produces variations in the luminance and chrominance levels that appear as an extremely grainy pattern within the picture. The perceptibility level of phase noise on the video carrier is 53 dB below the carrier at 20 kHz. If the frequency conversion or modulation processes are operating close to specification, phase noise impairments should not be perceptible on the customer's TV unless the converter/descrambler is malfunctioning or is of poor quality.

Amplifier Distortions and Their Effects

Amplifier technology based on feedforward and power-doubling techniques increase power levels with fewer distortions. However, additional sources of minutely delayed signals have been created. The signal delays produced in these amplifiers have similar end results in picture degradation as the delayed signals generated by reflected signals in the cable plant. But they are caused by a different mechanism. These amplifiers use parallel amplification technology; the signals are split, separately amplified and then recombined.

With a feedforward amplifier, the signals are purposely processed with delay lines. If the propagation time is not identical through each of the amplifiers' parallel circuits, signals will be recombined that are delayed by different amounts of time. In most circumstances, the amount of differential delay is small and will not produce a visible ghost, but it may cause loss of picture crispness. Since the hybrids used in these amplifiers are normally provided in matched pairs or in a single hybrid package, these delays are only a problem when the hybrids are not replaced as a matched set.

In systems that carry more than 30 channels, CTB is the limiting distortion. However, cross modulation (X-MOD) distortion, which is often the limiting factor in systems with less than 30 channels, can reappear as the controlling factor in dictating system design. The HRC and IRC channelization plans discussed previously were developed to minimize the visible degradation in picture quality that is caused by CTB.

X-MOD is one of the easiest distortions to identify visually. Moderate cross-modulation appears as horizontal and vertical synchronizing bars that move across the screen. In severe cases, the video of multiple channels is visible in the background.

Moderate CTB is the most misleading distortion since it appears as slightly noisy pictures. Most technicians conclude that there are low signal levels and CNR problems. CTB becomes visible as amplifier operating levels exceed the design parameters. Once CTB reaches a severe stage, it becomes more readily identifiable because it causes considerable streaking in the picture.

CSO can become a limiting factor in systems that carry 60 or more channels and use the HRC or IRC channelization plans. This distortion appears as a fuzzy herringbone pattern on the television screen. The CSO beats fall approximately 0.75 MHz and 1.25 MHz above the video carrier in a television channel. An IRC channelization will frequency-lock these beats together while increasing their amplitude relative to the carrier level.

Hum modulation caused by the 60-Hz amplifier powering is identified by its characteristic horizontal bar that rolls through the picture. If the hum modulation is caused by the lack of ripple filtering in the amplifier power supply, it will appear as two equally spaced horizontal bars that roll through the picture.

Frequency Bands Affected by RF Interference

Discrete beat products can be difficult to identify by the displayed picture impairment. Radio frequency interference that leaks into the cable system from nearby RF transmitters causes spurious carriers to fall in the cable spectrum. Common sources of signal leakage are cracked cables and poor quality connections. When either of these situations happens, strong off-air television and FM radio broadcast signals interfere.

If television stations are carried at the same frequency on cable as broadcast and the headend channel processing equipment is phase locked to the off-air signal, the effects of this interference will be ghosting. The ghost appears before (to the left of) the cable signal since propagation time through the air is less than through cable. If the signals are not phase locked together, lines and beats appear in the picture.

Under HRC or IRC, the headend channel processing and modulating equipment are already locked to a reference oscillator. It is not possible to lock the unit to both the cable channelization plan and the off-air signal. In the IRC plan, it may be desirable to unlock a channel from the reference source and lock it to the off-air station. However, the group phase locking advantage is lost. Several dB of distortion resistance on that channel is sacrificed. With HRC systems, video carrier frequencies fall 1.25 MHz lower than their off-air channel's counterpart. It is impossible to carry any channel on the off-air assignment unless the upper adjacent channel slot is not used. With the exception of the new 550 MHz cable systems, the interference from these sources is limited to the VHF channels 2–13 and the FM broadcast spectrum of 88–108 MHz.

Often there is interference from off-air signals due to consumer electronics hardware design. If the internal shielding of the equipment is inadequate, the internal circuits will directly pick up the signal. This phenomenon is called *direct pick-up interference* (DPU) and is the original motivation for cable converters. Those early set-top boxes tuned no more channels than the TV set, but they protected against DPU by incorporating superior shielding and connecting to the TV set through a channel not occupied off-air.

DPU can be misleading. When the subscriber switches to an antenna, he might receive better pictures than from the cable connection. He concludes that his TV receiver is operating correctly and the cable system is faulty. The only convincing argument is a demonstration with a receiver that does not suffer from DPU. Viacom Cable has measured off-air field intensities of eight volts per meter. The German specification for immunity to DPU is four volts per meter. The United States has no such specification. However, TV receivers sold in the U.S. are built to comply with the Canadian specification of one-tenth of a volt per meter. This is inadequate. VCR tuners are generally inferior to TV tuners because the VCR market is even more price competitive. The Electronic Industries Association (EIA) and NCTA Joint Engineering Committee (JEC) are studying this issue under their work on IS-23, the Interim Standard on the RF cable interface.

The second most likely sources of radio frequency interference are created by business band radios, paging systems and amateur radio operators. These signals leak into the cable system and interfere with cable channels 18 through 22 and channels 23 and 24 (145–175 and 220–225 MHz). It is easy to determine that these signals are caused by an RF transmitter because of the duration of the interference and, sometimes, by hearing the broadcast audio. Since the signals are broadcast intermittently, it is almost impossible to determine the exact location(s) of ingress. Cable systems that operate above 450 MHz may find severe forms of interference. They are subjected to high-power UHF television stations, mobile radio units and repeaters as well as a group of amateur radio operators signals in the top 10–12 channels. The extreme variation of shortwave signals in time and intensity makes locating the point(s) of infiltration of these signals difficult.

The upstream 5–40 MHz spectrum is a problem for operators who have two-way cable systems. There are many sources of interference and these signals accumulate upstream. In two-way plant, a single leak in the system can make that portion of the upstream spectrum unusable throughout the entire plant; in the downstream spectrum, a leak may only affect a single customer's reception.

Signal Security Systems

Means of securing services from unauthorized viewership of individual channels range from simple filtering schemes to remote controlled converter/descramblers. The filtering method is the commonly used method of signal security and is the least expensive.

Trapping Systems

There are two types of filtering or trapping schemes: *positive trapping* and *negative trapping*. In the positive trapping method, an interfering jamming carrier(s) is inserted into the video channel at the headend. If the customer subscribes to the secured service, a positive trap is installed at the customer's house to remove the interfering carrier. The positive trapping scheme is the least expensive means of securing a channel where less than half the customers subscribe.

A drawback to positive trap technology is its defeatability by customers who obtain their own filters through theft, illegal purchase or construction. Another drawback is the loss of resolution in the secured channel's video caused by the filter's effect in the center of the video passband. Preemphasis is added at the headend to correct for the filter's response, but loss of picture content in the 2–3 MHz region of the baseband video signal remains. New positive trap schemes take advantage of sharper *surface acoustic wave* (SAW) or *crystal filter* technology. This approach allows the interfering carriers to be positioned a few kilohertz away from the secured channel's video carrier in contrast to 2.25–2.75 MHz with the conventional approach. Illegal construction of these filters is much more difficult. The new technology has the promise of achieving greater signal security and a higher quality picture for the authorized customer, but at a higher price.

Negative trapping removes signals from the cable drop to the customer's home. The trap is needed for customers who do not subscribe and is the least expensive means of securing a channel when over half the customers subscribe. The negative trap is ideal. There is no picture degradation of the secured channel because the trap is not in the line for customers who take the service. A drawback occurs for customers who do not subscribe to the secured service but want to view adjacent channels. These customers may find a slightly degraded picture on the adjacent channels due to the filter trapping out more than just the secured channel. This problem becomes more significant at higher frequencies, due to the higher Q (efficiency) required of the filter circuitry. From a security standpoint, it is necessary for the customer to remove the negative trap from the line to receive an unauthorized service. Maintaining signal security in negative trapped systems depends upon ensuring that the traps remain in the drop lines.

Scrambling and Addressability

There are two classes of scrambling technologies: RF synchronization suppression systems and baseband scrambling systems.

The concept of addressability should be considered separately from the scrambling method. Non-addressable converter/descramblers are programmed via internal jumpers or a semiconductor memory chip called a programmable read only memory (PROM) to decode the authorized channels. These boxes' authorizations must be physically changed by the cable operator. Addressable converters are controlled by a computer-generated data signal originating at the headend either in the vertical blanking interval (VBI) or by an RF carrier. This signal remotely configures the viewing capabilities of the converter. IPPV technology is supported by addressable converter/descrambler systems.

RF Synchronization Suppression Systems

Converter-based scrambling systems that perform encoding and decoding of a secured channel in an RF format comprise the commonly used scrambling technology. There are two basic RF scrambling formats. The more common is known as *gated* or *pulsed* synchronization suppression. With this method, the horizontal synchronizing pulses (and with some manufacturers, the vertical synchronization pulses) are suppressed by 6 dB and/or 10 MHz dB. This is done in the channel's video modulator at the intermediate frequency (IF). The descrambling process in the converter/descrambler occurs at its channel output frequency. This is accomplished by restoring the RF carrier level to its original point during the horizontal synchronization period. Variations of this method pseudo-randomly change the depth of suppression from 6 dB to 10 dB or only randomly perform suppression.

The other less popular format is known as *sine-wave* synchronization suppression. In this format, the scrambling effect is achieved by modulating the video carrier signal with a sine wave. This causes the synchronization to be suppressed as well as changes the characteristic content of the basic video information. This encoding process is performed at the IF frequency in the channel's video modulator at the headend. The decoding process in the converter/descrambler is accomplished by modulating the secured channel with a sine wave of the same amplitude and frequency as in the headend, but whose phase is reversed.

A phase-modulated RF scrambling technique based on precision matching of SAW filters constructed on the same substrate has been introduced. This low cost system is extending operators' interest in RF scrambling techniques for use within addressable plants.

Baseband Scrambling Systems

Baseband converter/descrambler technology provides a more secure scrambling technology for delivering video services. The encoding format is a combination of random or pseudo-random synchronization suppression and/or video inversion. Because the encoding and decoding are performed at baseband, these converter/descramblers are more complex and more expensive.

Maintenance of the system's video quality is an ongoing issue. The encoders are modified video processing amplifiers; they provide controls to uniquely adjust different facets of the video signal. The potential for set-up error in the encoder, in addition to the tight tolerances that must be maintained in the decoders, has presented challenges to the cable operator.

A recent extension to baseband video scrambling involves the addition of digitized and encrypted audio to the video signal's vertical and horizontal synchronization pulse intervals. While there are issues of Broadcast Television Systems Committee (BTSC) stereo compatibility, providers of these products claim that the combination of video scrambling with audio encryption provides the highest degree of security afforded by the industry.

Off-Premises Systems

The off-premises approach is compatible with recent industry trends to become more consumer electronics friendly and to remove security-sensitive electronics from the customer's home. This method controls the signals at the pole rather than at a decoder in the home. This increases consumer electronics compatibility since authorized signals are present in a descrambled format on the customer's drop. Customers with cable-compatible equipment can connect directly to the cable drop without the need for converter/descramblers. This allows the use of all VCR and TV features.

Signal security and control in the off-premises devices take different forms. Nearly all off-premises devices are addressable. Specific or all channels are controlled remotely. While there were several attempts to take modified addressable converter/descramblers and enclose them on the pole, this approach was not successful. The system was costly and less consumer friendly than having the converter/descrambler in the home because it delivered only a single channel at a time to the entire residence. With the growth of multiple TV and multiple VCR homes, this is an unacceptable limitation.

Interdiction technology involves a scheme similar to that of positive trap technology. In this format, the pay television channels to be secured are transported through the cable plant in the clear (not scrambled). The security is generated on the pole at the subscriber module by adding interference carrier(s) to the unauthorized channels. An electronic switch is incorporated allowing signals to be turned off. In addition to being consumer electronics friendly, this method of security does not degrade the picture quality on an authorized channel.

The Signal and the Customer's Equipment

The common devices at the cable drop to the customer's home are grounding safety devices called *ground blocks* and a two-way signal splitter that sometimes has a built-in grounding terminal.

Some systems use ground blocks or two-way splitters that incorporate a high-pass filter. These filters are used in two-way plant to minimize RF ingress into the cable plant in the 5–30 MHz reverse (upstream) spectrum. These filters have a low enough crossover frequency not to cause group delay in the downstream video channels.

Splitters or ground blocks should have little effect on picture quality provided there is adequate signal to handle the splitter's loss. The signal strength may be below specifications due to an excessively long drop or more activated cable outlets in the house than the cable design anticipated. To compensate, some systems use an alternating current (ac) powered drop amplifier. These amplifiers can create problems—a reduced CNR or increased distortions.

Consumer electronics switching devices, designed to allow convenient control and routing of signals between customer products and cable systems' converters/descramblers, have built-in amplification stages to overcome the losses associated with the internal splitters. These amplifiers add distortions or noise. When most cable systems were designed, consumer electronics switching devices were not taken into account because they did not exist.

Signal splitting in VCRs can be a problem. To compensate for recording SNR deficiencies, inexpensive VCRs sometimes split the signal unequally between the by pass route and the VCR tuner. This gives the VCR a stronger signal than the TV receiver to improve VCR performance. In addition, this strategy reduces the quality of the signal routed to the TV. When it is compared with VCR play-back, the disparity in performance is reduced.

Consumer Electronics Compatibility

Formed under the sponsorship of EIA and the NCTA, the JEC brings together technical representatives from the cable and consumer electronics industries to find ways to make cable service and consumer electronics products more compatible. It was soon recognized that the cable subscriber and the consumer electronics customer were one and the same. In order to better serve that customer, cooperation between the two industries was necessary.

For decades the two industries had evolved slowly but without coordination. As technology began to accelerate, a serious divergence became apparent. It was the consumer who ultimately suffered. The high-minded goal of improving the situation for the consumer ran into a few practical problems.

On the consumer side, costs were very critical issues. Additional expense is hard to recover in higher prices because of the extreme competitiveness of the electronics industry. That competitiveness is a consequence of the ability to produce larger quantities of very reliable, high quality products than the marketplace can easily absorb. This over capacity makes price almost impossible to sustain, much less raise. The nature of technology is such that it is impossible to contain it. Any technical advance quickly spreads throughout the industry, making differences between most brands difficult for the consumer to distinguish.

On the cable side, technology made possible experimentation in new services and the expansion of channel capacity. Many of these experimental services failed. Because these services were offered in set-top boxes owned by the cable operator, the consumer was protected from financial loss when service experiments end up in disappointment. Additionally, the basis of subscription service was the ability to deny that service to those who choose not to pay. If service is easily available to all, few would pay. Without payment, programming cannot be purchased and those who create that programming cannot be compensated. So signal security is critical to the delivery of subscription services.

Early on, it was clear that three things were needed to resolve much of these difficulties:

- A channel plan vs. frequency
- Tuner specifications
- A decoder interface.

A major feature of cable television is its self-contained spectrum. Because this spectrum is isolated from the spectrum in the environment, the usual restrictions placed on broadcast television do not apply. The entire spectrum can be filled with television signals. Early cable practice utilized a variety of methods for labeling these channels. This diversity made it difficult to use a common labeling scheme for consumer electronics products with extended tuning range. A frequency plan was necessary to allow common nomenclature.

These cable signals can be very well controlled in their relative strength. This is in sharp contrast to broadcast signals. To prevent broadcast co-channel interference, channels are spaced. The VHF and UHF bands have gaps where others have claim on the spectrum. It is common for the broadcast tuner to attempt to tune a distant weak signal centered between nearly adjacent strong local signals. Thus the demands on tuners designed for broadcast and for cable are very different. It is difficult to make a tuner that performs well in both situations.

A most serious difference in the requirements of tuners designed for cable and those designed for broadcast is the issue of direct pick up. A broadcast tuner needs minimal shielding; the spectrum being tuned is only occupied by the broadcast signal. A cable tuner has another problem. Because the propagation speed through cable is about two thirds that of free space, the broadcast signal arrives at the TV first. A few microseconds later, the cable signal arrives. If the tuner directly responds to the over-the-air signal, the two signals will be mixed and interference will result. The solution to this problem is covered by a now-expired U.S. patent, the Mandell patent (3,333,198, July 25, 1967). The cable signal is selected by a tuner specifically designed for the purpose. It is well shielded and has the ability to discriminate against immediately adjacent channels. One constraint is relaxed. Signal levels across the tuned band differ only slightly in level. This tuner's output is converted to a single channel chosen to be one not used locally. Therefore, there is no off-air signal to be directly picked up by the TV and mixed with that delivered by the cable system. The problem of direct pick up is solved only because the output of the converter is a single channel on a frequency not used locally.

The use of the set-top converter solves one problem but makes the TV's tuner useless. Those features which depend on the tuner are also made inoperable. In particular, the remote control that came with the TV or VCR is only used to turn those devices on and off. The set-top's remote control changes channels. In the case of the VCR, the timer that changes channels is crippled because it cannot change the channels of the converter. Taping different channels consecutively becomes impossible.

In order for a cable ready TV or VCR to provide acceptable performance when connected to cable, it has to have a minimum amount of shielding to make it immune to direct pick up interference. Also, it must not radiate spurious signals up the cable. These signals can come from the local oscillator or from the harmonics of all of the digital signals which provide on-screen displays and drive other features. These signals can cause interference to other receivers in the same residence or in adjacent residences if they are allowed to enter the cable. All of these issues have been covered by a cable RF specification.

Cable's requirement for signal security caused the need for set-top boxes to move beyond mere frequency conversion. It took on the function of descrambling of signals in the early 1980's. If a cable ready TV or VCR were designed with adequate tuning range, adequate shielding against direct pick-up and the ability to handle a full spectrum of adjacent signals without overload, it might still require a set-top descrambler. This would duplicate the circuitry in the TV, provide slight additional signal degradation and interfere with certain features built into TVs and VCRs. The solution to this problem was the decoder interface connector. This was a 20-pin connector on the back of TVs and VCRs that brought video and audio signals out of the consumer electronics product for external processing. The descrambled signals were returned to the consumer electronics product for display or recording. The Decoder Interface connector was given the name *MultiPort* by the EIA because it was envisioned to have multiple uses. The main advantage of the MultiPort was that it made scrambling nearly transparent to the user. Cable subscribers loved it. Somewhere between 300,000 and a million TVs were produced with the plug. Several thousand descrambler plug-ins were made. However, only certain segments of the cable industry promoted the MultiPort. Much of the rest of the industry experienced so few complaints from subscribers that they didn't feel motivated. Additionally, many of these cable operators were enjoying a healthy revenue stream from the rental of remote controls. Since the MultiPort didn't need an additional remote control, that revenue stream was threatened. Another practical problem was locating consumers who bought MultiPort equipped sets. The consumer electronics industry lost patience. They did not promote the feature and most consumers who acquired these products had no idea what they had purchased. To this day, there are several hundred MultiPort plug-ins still in cable operator inventories. Knowledgeable installers call this to the attention of subscribers when they stumble across an old MultiPort TV. This results in a happy customer.

In an attempt to improve upon and formalize the MultiPort, the JEC created a standard that was adopted by the American National Standards Institute (ANSI): the ANSI/EIA 563 Decoder Interface Standard. Even though it was a closely related cousin to the MultiPort, this standard was never implemented in products and was retired.

In 1992, Congress passed the Cable Act which has far reaching implications for cable system operation and economics. An amendment to the Cable Act requires the FCC to create rules to improve the compatibility between consumer electronics products and cable operations. These rules regulate the conditions under which scrambling can be employed and provide a technical definition for cable-ready products. That definition included the channel plan created by the JEC, specifications on tuner performance and the inclusion of a decoder interface connector. Products that do not comply with the Commission's technical specifications cannot be sold as cable ready, cable compatible or under any other term which might mislead consumers.

Under these rules, cable operators will be required to provide plug-in modules for those subscribers who have cable-ready products and request the modules. Cable service will have to be compatible with the decoder interface.

The technical details of the decoder interface are many and complex. They are found in the interim standard EIA-105.1 and EIA-105.2. The first describes the physical interface and the second the minimum protocols needed to operate the system. The decoder interface supports digital plug-ins that will allow analog receivers to be used for the reception of digital signals at standard resolution.

As complex and difficult as the decoder interface has been, the DTV future presents even more interesting challenges for the consumer interface. The still embryonic technology is evolving at a rapid pace taking advantage of the fact that we can now afford to put well over a million transistors into consumer products to process signals. Additional millions of transistors can be included in memory elements. This tremendous processing power offers a wide variety of options for digital video compression and new interactive and MultiMedia services. The biggest unknowns center on the consumer.

The very nature of digital systems accommodates the ability to do something in software and to allow digital components to be reconfigured electronically. Thus, closely related but not necessarily identical approaches can be handled with little or no extra cost. This was not easily possible in the analog world. As more functionality is absorbed into software based systems, the need for a single strictly enforced standard is diminished. Multiple approaches and self-adaptation will ease the burden.

The 1996 Telecommunications Act included a section requiring the FCC to create rules pertaining to the retail availability of set-top terminals. The FCC issued a *Report and Order* in June 1998 (FCC 98-116, CS Docket No. 97-80). The decoder interface is an appropriate choice for these needs with analog signals.

Another issue becomes important as we move to subscriber ownership of the electronics that implement services (in most cases, the set-top box). In the old paradigm, the service provider answered questions and supplied training in the use of the equipment. The equipment was repaired at no additional cost. If the service failed to enjoy sustaining support, the cable operator absorbed the equipment loses. In the new world of subscriber ownership, the retailer and manufacturer of the equipment must stand ready to answer questions on usage and provide training and repair. The consumers' expectations must be adjusted to accept situations in which the equipment becomes no longer useful because the service failed or was replaced with a improved version. The cable operator will no longer be absorbing the losses since the equipment is no longer his.

An additional complication arises. If subscriber-owned set-top boxes introduce interfering signals into the cable system, they will have to be disconnected. If the subscriber insists on using them, that subscriber will have to be disconnected. There will be charges for service calls to solve these problems. Consumer will be angry when the hardware they purchase cannot be used on the cable system because of interference it may cause.

The Hybrid/Fiber Coax Architecture

A cable system can be considered to be made up of three main parts: trunk, feeder and drop. The trunk is intended to cover large distances, up to ten miles. When the trunk is made of coaxial cable, amplifiers are required about every 2,000 ft (.6 km). Surprisingly, the trunk portion of the cable plant only covers about 12% of the total footage. The feeder portion of the cable system supports taps for subscribers. It has a maximum length of about a mile and a half. This limitation comes from the fact that energy is tapped off to feed homes. Consequently, the power levels must be relatively high. These higher power levels reach into the slightly nonlinear regions of the amplifiers. As a result, only a few amplifiers can be used before the distortion begins to negatively impact the picture quality. Approximately 38% of the total footage in a cable system is in the feeder portion of the plant. The drop is the flexible cable which goes to the home. It has a maximum length of 400 ft (122 m). Typically, it is more like 150–200 (45.7–61 m)ft in length. Approximately half of the total footage of cable in a system is in the drop and the flexible wiring in the home.

The feeder portion of the cable plant is a hotbed of activity. Every day new subscribers are added and others are removed. Approximately 20% of Americans move to a new residence every year. When they move out, the drop is usually disconnected. When they move to their new residence, the drop must be re-connected. It is important that the technology used in the feeder portion of the trunk supports this constant activity. It must be "craft-friendly"; that is, it must be easy to work in. The trunk portion of the cable plant is relatively stable. There are very few changes made.

The lasers that drive the fibers are expensive, costing many thousands of dollars. The receivers that convert the optical energy into signals TVs and VCRs can use are also relatively expensive. To be practical, these components must serve hundreds of subscribers each so that the costs can be shared. This is accomplished by fibers which feed small coaxial systems, which in turn serve a few hundred to a couple thousand subscribers.

The HFC architecture has made it possible to cost effectively increase bandwidth, signal quality and reliability, while reducing maintenance costs and retaining a craft-friendly plant. It makes two-way service practical. The bandwidth of coaxial cable has no sharp cut off. It is the cascade of amplifiers which limits the bandwidth. Twenty to forty amplifiers in cascade not only reduce bandwidth but also constitute a severe reliability hazard. Overlaying low-loss fiber over the trunk portion of the plant eliminates the trunk amplifiers. This in turn leaves only the distribution portion of the plant with its relatively short distances and only two or three amplifiers. Wider bandwidth is thus facilitated. Two-way operation becomes practical for two reasons. First, the fiber itself is not subject to ingress of interfering signals. Secondly, the cable system is broken up into a large number of small cable systems, each isolated from the others by its own fiber link to the headend. If ingress should cause interference in one of these small cable systems, that interference will not impair the performance of the other portions of the cable plant. The Time Warner Quantum cable system has been in operation for several years at 1.047 GHz and 150 analog channels.

Today it is common practice to install passive components (taps, splitters, amplifier housings) which will pass 1 GHz. Actual 1 GHz amplifiers are still too costly. However, some systems are being built "GHz ready" so that the addition of GHz amplifier modules will upgrade the system with little waste of installed plant. While GHz capability is a future possibility, 750 MHz upgrades are commonplace today.

The fiber backbone approach breaks the cable system into a multitude of much smaller cable systems with amplifier cascades limited to four to six amplifiers. Each of these small cable systems is fed with a fiber link to the headend (see Figure 6.13-7). The advantages include significantly lowered vulnerability to amplifier outages, reduced bandwidth restrictions and noise build-up due to amplifiers in series and greatly reduced ingress. The latter effect makes two-way cable practical. A major attraction of the fiber backbone is that its implementation cost is low. Fiber is over lashed onto the existing trunk plant. The in-place cable is broken into segments and used for the small-scale cable systems. Some of the amplifiers are reversed in direction. Nothing is wasted.

If we now turn our attention to the distribution plant, we find that we must run higher signal levels to support the tapping of energy to serve drops to customers. The higher signal levels mean that we begin to reach into nonlinear areas of the amplifier's operating characteristic. Nonlinear distortion builds up. In addition, the taps are not perfectly impedance-matched to the cable. Consequently, the signal is reflected back and forth between the taps, resulting in a smearing of the picture.

Rogers Cable of Canada has suggested the answer to these difficulties. They have called their technique "Super Distribution." In one form of its implementa-

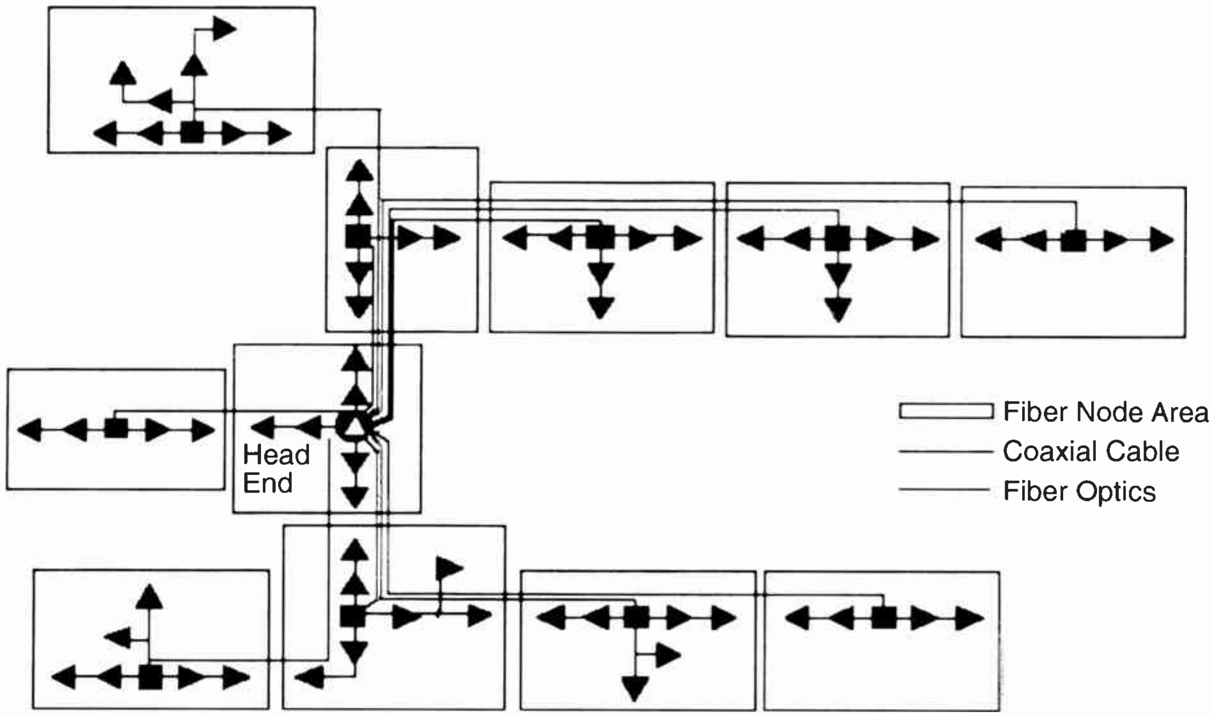

Figure 6.13-7. Cable systems with fiber optic backbone trunk.

tion, line-extender amplifiers are structured to have up to three hybrid amplifier chips. One feeds the next line extender amplifier, one feeds half of the taps back to the previous line extender and the third feeds half of the taps to the next line extender. The existing tapped feeder cable is cut in half between line extenders. New, untapped cable is overlashed to connect line extenders. The consequences are that the signal level between amplifiers is lower since that cable is not tapped. The signal level on the tapped runs is lower because they are shorter. Nonlinearities are reduced, and they do not build up as in the previous structure. Also, signal leakage may be less of a problem because of the lower signal levels. In addition, the number of taps in series in any cable is drastically reduced, thereby reducing the amount of micro-reflections experienced by any one subscriber. This technique effectively cures the ills of the distribution portion of the plant (see Figure 6.13-8).

With fewer amplifiers in series, the constraints on their design and operation are reduced. Higher bandwidths become practical.

Compression

The interest in digital television goes back several decades. Long before digital television was practical for consumer use, it held interest for military and professional applications. The principal attractions are those of all digital signals: the ability to transmit signals over arbitrarily long distances and to store the signals without degradation, the ability to process signals for security and other purposes, the ability to remove unnecessary redundancy to increase transmission and storage efficiency, and the ability to add appropriate coding and redundancy so signals can survive harsh transmission environments. Even as early as the late 1960s, work on digital television for broadcast and consumer applications was underway. At that early date, Zenith Radio Corporation worked on the digitization of television signals for the purpose of enhancing scrambling for an over-the-air subscription television service.

Compression along with digital modulation has given massive capacity to the cable spectrum. Compression gained its first industry wide momentum in the pursuit of HDTV—also called Digital Television (DTV). The analog bandwidth of signals from an HDTV camera consists of approximately like 30 MHz each of red, blue and green. Nearly 100 MHz of analog signals would require more than a gigabit per second for straight digital transmission. The FCC, which sets federal regulations on spectrum usage, only allows 6 MHz! As a result, there is a need to remove a lot of the redundancy in the picture. The same technology can be used to squeeze multiple standard definition signals into the same 6 MHz. When Compression is used to put multiple current quality signals into 6 MHz, the result is called standard definition television (SDTV).

It is commonly felt that movies may eventually be digitized effectively at a 1.5 Mbps rate while live video may require 3 Mbps to 5 Mbps. Data rates currently used in trials are somewhat higher because of the preliminary nature of the equipment. When more ad-

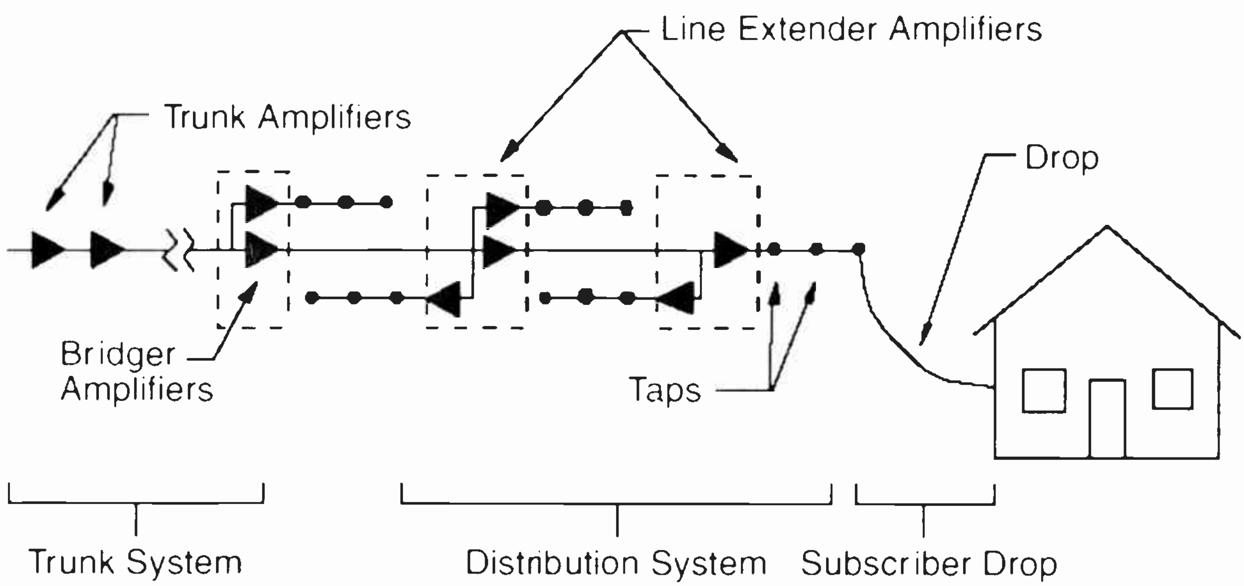

Figure 6.13-8. Super distribution plant.

vanced digital video compressors become available, data rates should be lowered at least a little more. The reasons for the lower data rate with movies stems from two main factors. First, movies have a 24 frames per second rate while video has 30 frames per second. Motion reproduction in video is better than in movies, but there is a 20% increase in data required for the same image quality. Secondly, movies can be processed in non-real time. This means that they can be iteratively processed. The compressor parameters can be adjusted on a scene by scene basis. Much more processing can be brought to bear since the computations do not have to be done in real time.

Digital Transmission

There are two distinct aspects to the digitization of video and audio. The first is called *Source Coding*. Source coding is the conversion of the source information into digital form and its processing to meet certain objectives. The objectives include the amount of resolution, the tolerance for artifacts, the maximum data rate, and the cost constraints. All of these objectives dictate the kind of processing that makes sense for any particular application.

Channel Coding tailors the signal for the medium used. The characteristics of satellite, broadcast, cable, microwave, twisted pair, fiber optics, video disc, magnetic tape, etc. are quite different. Some media are essentially noise free. Other media have little random noise, but extensive bursty noise. Still other media are plagued with multipath and co-channel interference while media exist with essentially none of these difficulties. These varieties of characteristics yield different requirements for modulation and error protection, which are the fundamental techniques of channel coding.

A signal may experience multiple channel codings and re-codings. For example, the signal may start out on video tape at a satellite uplink using the type of channel coding appropriate for magnetic media. It might then be conveyed via satellite to a broadcast affiliate using channel coding appropriate for a satellite link. It could then be broadcast over the air using channel coding for that environment. Finally, it might be picked up by a cable system headend and put through the cable system using channel coding designed for fiber optics and cable. Each of these links would use a different modulation method and error protection scheme designed to optimize performance in its environment. The source coding remains the same; the channel coding changes to fit the media. Since the spectrum in the cable plant is very well behaved, two or more broadcast source coded signals might be combined in one 6 MHz cable channel.

Modulation serves the same purpose for digital signals as it does for analog signals. While digital signals can conveniently utilize time division multiplexing, frequency division multiplexing remains an important part of the plan. There are several reasons for this. Practically, digital circuits are limited in their speed. They cannot support a TDM structure for the entire GHz spectrum of cable. Breaking the spectrum into 6 MHz pieces relaxes the speed requirement on the digital circuits. TDM can be utilized within each of the 6 MHz channels.

Additionally, FDM facilitates the transition from analog television to digital television. No cable system is known to have plans to convert all signals to the digital format. Those cable systems which are adding digital, are doing it for those customers who want more. They are adding it to the current collection of analog channels. In many cases, the analog scrambling is left in place. The investment in analog set top boxes is too great to abandon. By separating the spectrum into two areas, one for analog channels and one for digital channels (including TDM), a rational transition to digital technology is accomplished.

Unfortunately, the modulation methods chosen for use on cable (QAM) and for over-the-air transmission are different. The ATSC standard selected a Vestigial Sideband Modulation (VSB) method with a reference carrier. This was done because the broadcast environment must contend with co-channel interference between multiple digital television signals, between digital television and NTSC, and between NTSC and digital television signals. The VSB method has been specifically designed for this environment. The reference carrier aids the television tuner in acquiring the signal when the channel is changed.

Two VSB structures were created. The over-the-air 8-VSB structure has a payload of almost 20 Mb/s and can carry one HDTV signal with relative robustness. Since cable has a more disciplined spectrum with fewer challenges, a 16-VSB version was created which has less error immunity and double the data capacity. It can carry two HDTV signals.

The Advanced Television Test Center (ATTC) completed tests of 16-VSB on cable in Charlotte, North Carolina. The 16-VSB system tested delivered 38.5 Mbps in all locations. Some older cable systems were included in the tests. The longest amplifier cascade was forty-eight! Fiber links and microwave Amplitude Modulated Links (AMLs) were also included. 256-QAM is expected to be able to deliver similar results. Thus it is possible to transmit twelve compressed movies in 6 MHz at 3 Mbps.

Current thinking is to allocate the lower end of the down stream cable spectrum to analog signals. This covers the 50 MHz to 450 MHz (or 550 MHz) frequencies. A basic unscrambled tier of broadcast signals would be at the low end of the spectrum. At higher channel numbers, trapped pay services or analog scrambled services would be supplied. Above 450 or 550 MHz, digital signals would be provided to the band edge located at 750 MHz or 1 GHz. Thus, from 200 MHz (33 six MHz channels) to 550 MHz (91 six MHz channels) will be available. With twelve movies per 6 MHz, 396 to 1092 movies may be offered simultaneously. Of course, digitized video signals (rather than movies) may also be offered by reducing the total number of programs.

OpenCable™

CableLabs, the cable industry's research and development consortium has created a number of purchasing specifications on behalf of the industry. These are not standards, since CableLabs is not an accredited standards setting organization. Rather, these specifications define the functionality and external parameters of products used in cable but leave the internal details to the manufacturers. For example, CableLabs will not specify a single microprocessor or operating system for these applications. But, to insure interoperability, CableLabs establishes a certification program to verify that the products comply with the specification and will perform satisfactorily.

OpenCable™ is one such specification. The goal for OpenCable™ is to create a multi-vendor interoperable environment of digital set top terminals. OpenCable™ is intended to facilitate a range of new interactive services and function that are more like a digital set top computer than just a digital set top terminal. An important objective is competitive supply of all of the elements of the system including the advanced set top terminal, its operating system, core applications and plug-ins, conditional access system, platform management system, billing, provisioning and subscriber management systems.

The procedure began with a Request For Information, RFI, sent to leading computer and consumer electronics companies. Twenty-three companies responded. From these submissions, CableLabs solicits vendors to author specific elements of the suite of specifications. An Intellectual Property, IP, pool is created with cross licensing of all IP required for the specification. Implementation IP not inherently required by the specification is left to vendors to license in their normal fashion.

Key OpenCable™ interfaces include the formats for digital cable television, consumer privacy systems, copyright protection system, interfaces for high-speed connection to the Internet and interfaces required to author interactive applications.

A *Harmony Agreement* for Digital Standards has been achieved. Five open layer standards, including MPEG-2 video, the Dolby Digital audio AC-3 system, MPEG-2 transport multiplex, ATSC service information tables, and the International Telecommunications Union ITU-J.83 Annex B modulation system are included in the agreement. The modulation system calls for 64 quadrature amplitude modulation (QAM) carrying 27 Mb/s and 256 QAM carrying 40 Mb/s with concatenated trellis code plus enhancements such as variable interleaving depth for low latency in delay sensitive applications. All of these agreements have been endorsed by CableLabs and most have been adopted as digital standards by the Society of Cable Telecommunications Engineers.

OpenCable™ will use an implementation of the federally published core data encryption standard (DES). By utilizing common core encryption, operators will not have to duplicate the transmission of programming and related content in order to implement dual conditional access. While operators would still need to maintain separate headend control systems to control each supplier's set top terminals, the conditional access data can be carried in a single unified bit stream.

CableLabs will implement a vendors certification process where by specific products can be tested for compliance with the OpenCable™ specifications. The certification process will allow these devices to be made available to consumers through retail outlets.

CableLabs recommends that its member utilize the specifications for their procurements. However, members will make their own procurement decisions. This is not a joint purchasing agreement.

The Digital Video Standard for Cable

The Society of Cable Telecommunications Engineers, SCTE, is an accredited American National Standards Institute, ANSI, organization which utilizes the due-process methods required by ANSI to set standards for the cable industry. This is the mechanism by which Digital Video for use on cable is standardized. These SCTE standards are an integral part of OpenCable™.

This Digital Video Transmission Standard for Cable Television describes the framing structure, channel coding, and channel modulation for a cable television realization of a digital multi-service distribution system. The standard applies to signals which can be distributed via satellite directly to a cable systems, as is the usual cable practice. The specification covers both 64 and 256 QAM.

The modulation, interleaving and coding is tailored to the characteristics of cable system practice in North America. The modulation is selected by the cable system to be either 64-QAM or 256-QAM. The forward error correction approach utilizes a concatenated coding approach that produces low error rates at moderate complexity and overhead. The system goal is one error event per 15 minutes. The input data format is MPEG-2 transport.

Two modes are supported: Mode 1 for use with 64-QAM with a symbol rate of 5.057 Ms/s and Mode 2 for use with 256-QAM with a symbol rate of 5.361 Ms/s. Higher order QAM may be considered in the future as warranted by experience.

The cable channel, including optical fiber, is a bandwidth-limited linear channel, with a balanced combination of white noise, interference, and multi-path distortion. The QAM technique used, together with adaptive equalization and concatenated coding is well suited to this application and channel.

The transport layer for MPEG-2 data is comprised of fixed length packets having 188 bytes. One byte is for synchronization purposes followed by three bytes of header contain service identification and scrambling and control information. This is followed by 184 bytes of MPEG-2 or auxiliary data. The data stream is transmitted serially with the MSB first. The first packet byte is transmitted as a checksum which is replaced by a sync byte having a fixed value of 47HEX by the QAM demodulator.

Interleaving is used to enable the correction of burst noise errors.

Competition

The combination of HFC and compression have dramatically and completely changed the course of cable's evolution. An important reality which must be appreciated in creating the next vision of cable's future is that technology cannot be contained. The nature of technology is that it is available to all who wish to apply it. Thus the HFC architecture has been adopted by many in the telephone industry as a practical approach. "Fiber to the home" has essentially been abandoned. Likewise, compression is available to all who wish to compete with cable. From the consumer's perspective, it's the programming that matters. The delivery mechanism and the industry delivering the programming are secondary as long as certain minimum standards of signal quality, reliability, and cost are maintained.

One of cable's main advantages in the past has been massive capacity due to a wider bandwidth than is available to most potential competitors. Compression makes much of that advantage available to many potential competitors by more efficient utilization of whatever bandwidth those competitors have available.

The cable franchise is almost always non-exclusive. Those who consider cable to be overly profitable were always able to gather up investors and build a second or third cable system and compete. This has been attempted in a number of situations only to result in financial losses in most cases. It's only human nature to believe that "The grass is always greener on the other side." There have only been a few instances of success following this course of action.

Except for building a second cable system, there really was no effective method of deploying direct competition to cable before compression. Cable's high bandwidth gave it so much programming that other delivery means were anemic in comparison. Compression changes that. Now it is possible for a competitive service to be launched with sufficient programming to be a reasonable alternative even with less available actual bandwidth.

Video delivery competition comes from several sources:

- Direct Broadcast Satellite
- Telephone plant delivering video
- Alternative cable plant builders
- Microwave Multipoint Delivery System (MMDS)
- Broadcast
- Physical distribution

The vision of cable in the late 1990s has to include the reality that government regulation will play a bigger role. That role will limit what can be done and how it can be financed. It will also impact the way competitors behave and change the balance between cable and its opponents.

The Video Services

There appear to be three kinds of visions for video service under discussion:

1) Video Electronic Publisher
2) Video Common Carrier
3) Video Internet

These three visions vary considerably in how practical they are and how closely they approach reality.

The Video Electronic Publisher is the model of traditional cable television. The cable operator selects programming thought to be of interest to subscribers and packages it in convenient form. A selection of local off-air channels, satellite delivered programming, and local origination is divided into tiers. If the cable operator selects and packages programming which interests the subscriber, the reward is acceptance and profits. If the programming does not please the subscriber, the result will be financial difficulties.

This service is a broadcast service in that all subscribers get essentially the same programming. A possible exception is that in some cases, special ethnic programming is delivered on a neighborhood by neighborhood basis. This takes advantage of the fact that several different trunk lines leave the cable headend and go to diverse geographic areas. The signaling is mostly one-way. The only need for two-way is for the ordering of Impulse Pay Per View (IPPV) programs. There are over a hundred and sixty programs on satellites which could be packaged and delivered to subscribers. Other ideas for new channels arise continuously. In the analog world, there is only capacity to carry about eighty total channels. After local broadcasters and other mandated channels are accommodated, there is room for only around sixty of these satellite delivered programs.

This cable service consists of several levels. Basic Service includes all of the mandated broadcast channels plus the Public, Educational, and Government (PEG) channels required by the local franchise. The 1992 Cable Act requires that these channels be unscrambled. A group of tiers can then be created out of the satellite delivered channels. The tiers can be as simple as just one cluster or a set of clusters based on genre of programming. When a set of channels is offered on an individual channel basis, that service is called "a la carte". At the next level are pay channels such as HBO or Showtime. These are premium channels with a substantially higher price. They are sold on a monthly subscription basis. Next are IPPV channels which sell individual program viewings. These consist mostly of movies, but also include concerts and sporting events. A special case of IPPV is True Video On Demand (TVOD) or Near Video On Demand (NVOD) to be discussed below in more detail. Then there are the new MultiMedia and interactive services which are considered part of the National Information Infrastructure (NII) or the Information Superhighway.

The 1992 Cable Act has given broadcasters new rights. Broadcasters are allowed to choose between *must carry* status or *retransmission consent* status. Must Carry status means that the broadcaster's signal must be carried on the channel number the broadcaster selects. That selection is made from those channel numbers occupied on two specified dates or the broadcaster's own channel number. Selection of Must Carry status foregoes any right to compensation for the signal. Alternatively, broadcasters can choose Retransmission Consent status which precludes cable carriage without the consent of the broadcaster. The broadcaster and the cable operator negotiate on the terms. Broadcasters can change their status every three years.

The Video Common Carrier

The Video Common Carrier model is sometimes called video dial tone. As can be assumed from its name, this is the kind of service proposed by many telephone operators. While originally fiber to the home was proposed, all such projects now involve an HFC architecture. Like the Video Electronic Publisher model, this model has a portion of its programming which is essentially a broadcast service. Everyone gets the same signals in this part of the Video Common Carrier service. The main difference is that the video dial tone provider does not have any editorial control over what is presented. In principle, enough capacity is provided so that any programmer who wishes carriage can have it on a non-discriminatory basis. The Video Common Carrier model is mostly one-way down stream signaling with a small up-stream capacity for ordering programming.

The second portion of the Video Common Carrier model includes subscriber selection of programming either through a NVOD or a TVOD approach. TVOD implements the full promise of Video Dial Tone.

There are some proposals to use Asymmetric Digital Subscriber Loop (ADSL) technology with switching. A relatively low bit rate signal is switched onto the subscriber twisted pair copper loop based on a very low bit rate request signal sent to the point of origination. In this model, no common services exist. All services are specifically requested one at a time. Decompression converts the digital signal into a form suitable for display on consumers' TVs and VCRs.

The Video Internet

The Video Internet is the most visionary and least practical approach of all. It envisions a symmetrical capacity in both directions. Subscribers can obtain all the normal cable services plus they can originate programming and send it to those who would wish to view it. This is the most expensive of the three service models and has the least in common with the cable plant already installed.

The Video Internet requires digital video switching and symmetrical or near-symmetrical signal capacity. The costs of implementing this kind of service will be very high. Unlike the current Internet service, whose costs are partially government supported, the Video Internet would be expensive to use. It remains to be seen if consumers will find these services of enough value to be willing to pay the price suppliers would need to ask.

An interesting irony exists when digital video and digital voice services are compared. People watch video for hours and video requires mega (millions of) bits per second. People talk on the telephone for minutes and voice requires only kilo (thousands of) bits per second. The ratio of the number of bits needed for telephony compared to the number of bits needed for video is in the range of hundreds of thousands! If bits are bits and their transport and switching comes at a given cost, either digital video will be incredibly expensive and digital voice affordable or digital video will be affordable and digital voice essentially free! If this is not the case, then the "bits are bits" paradigm must be somehow violated.

TVOD versus NVOD

A major choice to be made is that between TVOD and NVOD. Here is where the practicality and the reality of the vision of the Information Super Highway come into stark contrast. The greatest unknown is what do the consumers want and what are they willing to pay.

TVOD is any video, any time, with full virtual VCR functions. That is the ability to do stop, fast forward, rewind, pause, slow motion, etc. It doesn't take too much to realize that this is essentially impossible. There must be some compromises. The question is how much compromise will be acceptable to the consumer? What is the consumer's desire in the trade off between cost and convenience?

NVOD is an engineering approximation to TVOD. It is based on the Pareto Principle which states that most of the desire for video will be for the most popular titles. Perhaps 80% of all demand will be for the top 20% of titles—perhaps for even fewer. So the first engineering approximation is to limit the number of titles. The next is to limit the frequency of access. Rather than allow everyone instant (or near instant) access to the video of their choice, the most popular movies will be stagger started on several channels. In the Time Warner Quantum system in Queens, New York, the top five movies were stagger started about every half hour. Thus, the maximum wait time for a top movie to start is a half hour. The average wait time is fifteen minutes. Since they were approximately two hours long, each of these movies required four channels. The Quantum cable system has 1 GHz of bandwidth and 150 analog channels.

With compressed digital video, it is possible to offer many more movies with much more convenient start times. The target for wait times in NVOD is to make most of them slightly less than the time to drive to the video store. An example can be illustrative.

Consider a cable system with a 750 MHz maximum frequency. The range of frequencies from 50 MHz to 450 MHz is allocated to ordinary analog television. (Below 50 MHz, the system is used for up-stream communications.) This 400 MHz of spectrum contains 66 analog 6 MHz channels. This would make a fine ordinary cable service.

The 300 MHz from 450 MHz to 750 MHz contains 50 channels of 6 MHz each. If we are able to compress movies into 3 Mbps data streams and if we use a modulation scheme such as 16 VSB which has a payload of 38.5 Mbps, we'll be able to carry a dozen movies in each 6 MHz frequency slot. Since there are 50 of these slots, there are a total of 600 synthetic channels for movies.

Consider offering the top ten movies (each approximately 135 min long) on twelve synthetic channels each. This makes the stagger time 11.24 min and occupies 120 total synthetic channels. Now put the next twenty most popular movies on eight synthetic channels each for a repeat time of 16.9 minutes. 160 channels will be used up. Put the next forty most popular movies on roughly half hour repeats (like in the Quantum system). That will take four channels each and occupy a total of 160 channels. Take sixty more movies and repeat them continuously in sixty more channels. We have 130 movie titles occupying 500 synthetic channels. This leaves us with 100 channels.

In the remaining 100 channels, all analog scrambled signals will be duplicated in the digital format so that a digital subscriber doesn't need any analog processing. This will likely take another twenty channels. This leaves eighty channels for continuous repeat of short subjects such as shopping channels dedicated to single categories each.

This provides a tremendously convenient and comprehensive service with no switching and no complex head end server. The head end is a rather straight forward play back center.

PC versus TV and Interactivity

There is a great deal of debate about what the consumer of the future will expect in a television set. Those from the computer industry want to build TVs into PCs and those from the consumer electronics industry want to build PCs into TVs. Of course, the whole world seems to want to put PCs into set-top boxes.

A few moments of thought about how these products are used should shed some light on what is the evolution likely to be supported by consumers. All one needs to do is recall how it feels to be in the family room watching TV with someone who has a remote control in hand and is flipping channels. Certainly, this is the lowest level of interactive television. Anything more interactive may not be appreciated by others in the room. The conclusion seems to be that interactive television is an individual activity.

Now consider the information packing density of the television screen. The NTSC television technical standard can just barely support text consisting of forty characters across and twenty rows. That is woefully inadequate for anyone who has used modern personal computers. The input device for a television set, the remote control, is also very limited. It is easy to conclude that the proper instrument for serious information highway work (or play) is the personal computer.

The user of the personal computer is accustomed to upgrading performance, to spending a few hundred dollars on software or hardware modules, and to monthly subscriptions to on-line services costing ten to twenty dollars. The average personal computer user spends thousands of dollars on the hardware and software and sees great utility from this. There may even be a motivation of providing learning opportunities for the children.

Contrast this with the average TV and VCR user. They have spent not thousands but mere hundreds of dollars for their equipment. That equipment has relatively low resolution, low speed, and has minimal other capabilities. These are the consumers who complained bitterly about monthly cable bills of around twenty dollars for basic and ten for premium service. The average TV lasts twelve to fifteen years and the average VCR about five. They are not upgradeable in any way.

The TV and VCR are likely to be used when the day is done and there is no more energy left and it's "wind down" time. For most people interested in or capable of "interactivity" the personal computer is where it's done. Even when these highly interactive people turn on their TV or VCR, it's because they have no more energy to interact with anything! They just want good passive entertainment.

The Electronic Program Guide, Interactivity for the Common Man

While we have concluded that the interactivity vision is primarily a personal computer activity, there are a limited number of very appropriate interactive applications the consumer will likely want for the TV receiver and VCR. By far the most promising is the electronic program guide (EPG). The EPG is most appropriate because it fits the TV and VCR application. It helps the consumer navigate through the multitude of channels. There is a consumer motivation to learn to use it.

An interesting form of EPG is the *mood guide*. It is based on the theory that there are a limited number of moods viewers have when they turn on the TV. Those moods can be studied and understood and programming categorized so that it is associated with the set of moods. When the TV is turned on, the first thing seen is a list of possible moods. The viewer reflects briefly and then indicates the mood of the moment. The EPG responds with all the programming which is appropriate to the moods of the viewer. It also suggests what may be available later for viewing or taping. Thus the likelihood that the viewing experience will be satisfying is increased.

Another important role for the EPG is to keep a record of which types of programs each family member watches. Over a period of a few months, enough information is gathered to allow the EPG to advise the viewer that programming consistent with past viewing patterns is available for viewing or taping. It becomes less likely that programming of interest will be missed. This increases the value of the subscription to the subscriber and increases retention. In general, the satisfaction of the consumer increases.

The EPG contains all of the information necessary for automatic operation of a VCR. The time, the channel, and the program category are available in digital form. The consumer's main responsibility is to ensure blank tape is loaded in the machine!

The EPG is interactivity for the common man.

The Fax Machine, E-Mail & the NII for the Common Man

In the early 1990s, e-Mail and the Internet have become important parts of the professional work place. Those who are enthusiastic about these modern communication tools envision them becoming part of ordinary daily life for nearly everyone in the late 1990's. This may be the case for a minority; but the reality is that the average consumer does not have the interest or the skills to work these systems.

However, there is a very cost effective device which is much easier to use and nicely demonstrates the Pareto Principle: The fax machine. The fax machine is rapidly becoming a consumer electronics product. There are a large number of models under $250 and the price is rapidly approaching $100.

Even more importantly, the fax machine is easy to use. It does not require any complicated ability to navigate through menus or complex computer commands. The fax machine requires minimal skills to operate. It requires no touch typing. Nearly everyone can operate the fax machine. The Information Super Highway for the fax machine already exists: the phone system.

In many cases, the fax machine can send a page at less than the cost of postage. Certainly, the speed of delivery is greater and more assured. When e-Mail and other alternatives are considered, the fax machine is an extremely cost effective and easy to use alternative.

The fax machine is e-Mail and the National Information Infrastructure for the common man!

Section 7: Signal Measurement and Testing

Introduction by Randy Hoffner, ABC, New York, NY

The rapid advances of digital technology for radio and television applications have redefined the requirements of signal measurement and analysis. Contrary to popular belief, digital is not perfect. Problems still develop. Such problems, in fact, are often more difficult to identify than their analog counterparts. Within this environment, of course, is the continued requirement for maintenance of existing analog devices and systems. These demands are being met with advanced test instruments and built-in diagnostic systems for new hardware. Despite the powerful new tools available to broadcast engineers today, the greatest need continues to be the training of maintenance personnel. Machines do a very good job of taking measurements, and a rather poor job of interpreting them. In this section, both instruments and procedures are examined.

"The ability to quantify audio signals in terms of characteristics and qualities is paramount in audio engineering." Stanley Salek simplifies audio measurement in his chapter entitled, *Analog Audio Signal Analysis.*

Handbook Editor-in-Chief, Jerry Whitaker, prepares engineers to move "full speed ahead into the digital domain" in his *Video Signal Analysis* chapter.

The section concludes with Donald Markley's analysis of radio frequency signals.

7.1 ANALOG AUDIO SIGNAL ANALYSIS

STANLEY SALEK, P.E.
HAMMETT & EDISON, INC., CONSULTING ENGINEERS, SAN FRANCISCO, CA

AUDIO MEASUREMENT

The ability to quantify audio signals in terms of characteristics and qualities is paramount in audio engineering. Comparisons can be made with reference to established standards and requirements, including measurements relating to amplitude, frequency content, distortion, noise and phase. The observation of such attributes allows a virtually complete characterization of an analog electrical audio system.

In the broadcast environment, audio measurements are used to gauge the overall quality of equipment such as amplifiers, recording systems, mixing consoles, digital audio devices and other networks throughout the overall broadcast signal path.

Amplitude Measurement

The most basic of needs in audio measurement is to determine a value relating to the size, or amplitude, of an audio signal. Since an audio waveform is rapidly changing, methods have been developed to convert peak, root mean square (RMS) and average values of the changing waveform into corresponding proportional dc voltages that can be more easily observed.

There are specific cases where the peak value is the most direct measure of magnitude. It gives an indication of the largest excursions (either positive or negative) of an audio waveform. As shown in Figure 7.1-1, the audio signal is applied to an absolute value circuit, which rectifies the waveform such that the output is all positive. A diode is then used to couple into C and R. These serve as memory and decay time elements, respectively, that can be adjusted in value to conform to the ballistics desired. Although the output is still changing with time, along with the input, the excursions corresponding to the peak values of the original waveform are much slower and more easily observed on metering devices. As the value of resistor R is increased, the decay time of the output is proportionally increased as well. If the resistor is completely removed, a peak hold circuit results.

Peak (actually peak-to-peak) functions can also be observed on an oscilloscope, although this technique is often impractical because of the difficulty in reading the random waveforms typical in most audio material. Storage oscilloscopes can perform a peak-to-peak hold function.

While there are many cases where the peak value is of considerable use, the RMS value of a signal is generally most meaningful since it gives indication of the energy content of the signal without regard to its waveform. In audio measurement, however, it is usually simpler to detect the average amplitude of a given waveform and relate it to an associated RMS value, with reference to a sine wave. The RMS level can be defined as follows:

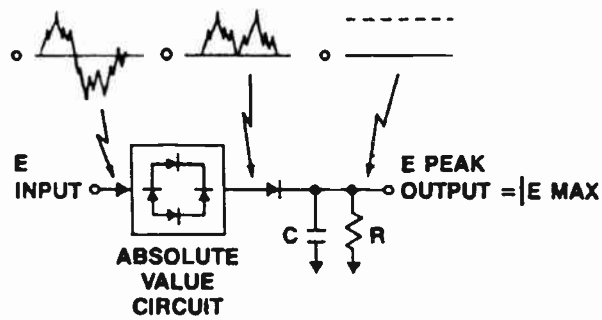

Figure 7.1-1. Peak value detection.

$$E_{rms} = \sqrt{\frac{E_1(t)^2 + E_2(t)^2 + \cdots + E_n(t)^2}{n}}$$

where E_1 through E_2 are successive measurements over a total of n samples. As can be seen from its name, the value is computed by taking the average of n samples of E squared. Performing the square root function completes the calculation. This function is also commonly referred to as *true RMS*.[1] Figure 7.1-2 shows how this is accomplished electrically.

Through the use of the absolute value circuit of Figure 7.1-1 and the R/C configuration found in the RMS detector of Figure 7.1-2, an average detector can

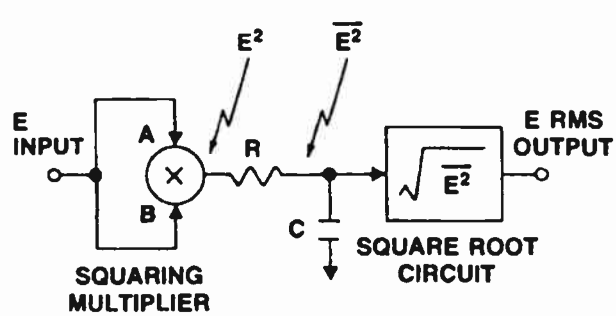

Figure 7.1-2. True RMS detection.

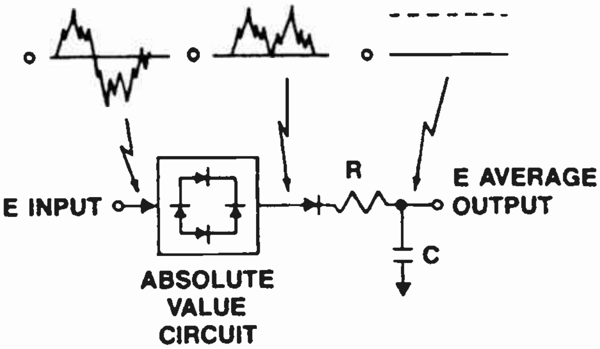

Figure 7.1-3. Average value detection.

be made, as shown electrically in Figure 7.1-3 and mathematically:

$$E_{average} = \frac{E_1(t) + E_2(t) + \cdots + E_n(t)}{n}$$

In terms of audio perception, the average value of an audio signal is related to program material density, where the peak value described earlier relates to a maximum. Since the peak value defines the upper limit of allowable modulation in a transmission system, it is often technically desirable that the peak-to-average ratio be as low as possible to attain highest perceived loudness and signal-to-noise ratio (SNR). Achieving this effect may require compromising aesthetic goals and may not always be appropriate, depending on the type of program material.

The decibel (dB), is a unit for comparing relative levels of voltage or power signals in transmission systems. In broadcast audio systems, the most common representation of decibels is dBm. This is the value of a signal with reference to 1 mW into a 600 Ω load. The level in dBm of a signal can be found using the following relation:

$$\text{dBm} = 20 \log\left(\frac{E}{0.775}\right)$$

where E is the voltage level to convert. The number 0.775 represents the voltage level reference of 0 dBm. Note that, strictly speaking, this formula is only true when the circuit impedance is 600 Ω. In practice, the formula is used typically without regard to the impedance level. Voltage levels obtained from the peak, RMS, and average circuits described previously can be used for possible values of E. When this is done, some common types of metering can be synthesized to observe the activity of audio material.

Metering

Two popular types of metering for the characterization of program audio are the *standard volume unit indicator*, commonly known as the *volume unit* (VU) meter, and the *peak program meter* (PPM). Although VU metering has been more common in U.S. broadcast equipment, the standard PPM indicator is often found as well, especially in audio mixing consoles.

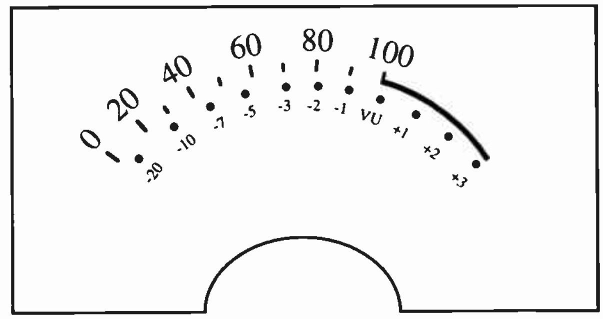

Figure 7.1-4(a). VU meter.

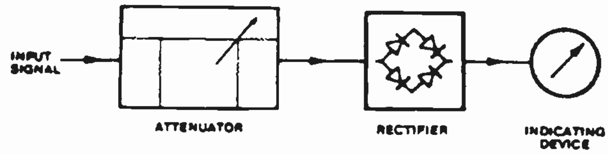

Figure 7.1-4(b). Block diagram of the stages of a typical volume unit indicator.

The VU meter was introduced in 1939 to serve as a standard program level indicating device (see Figures 7.1-4(a), 7.1-4(b)).[2] Its original purpose was to be the reference between broadcasters (as well as other programming suppliers) and the telephone company. A VU meter is the combination of a bridge rectifier, a resistive attenuator and an ammeter with an approximately voltage linear scale to produce an average responding ac voltmeter. The VU meter is calibrated such that it reads 0 VU across a circuit in which a sinusoid develops 1 mW in a resistance equal to the circuit impedance (0.775 volts RMS across 600 Ω). This allows the meter to be powered directly by a 600 Ω program line, with the attenuator typically set to read 0 VU at +8 dBm.

Beyond reading continuous tones, VU meter dynamic characteristics are set so that it will display 99% of its steady state reading on a sine wave tone burst 300 ms long, with a fall to 5% of the reading in 300 ms. Essentially an average responding device, the VU meter will not respond to short duration program peaks. Therefore, levels normally should be set with a 10 dB margin (headroom) before the point of clipping.[3]

The PPM is designed to read nearly the full peak value of the audio signal (see Figures 7.1-4(c), 7.1-4(d)). It uses a rectifier and an integrator, producing a fast rise and slow fall effect on the display device. Typical standards require the PPM to read −2 dB, ±0.5 dB of the steady state value for a tone burst of 10 ms, and take 2.8 seconds for the pointer to fall 20 dB.[4]

Typically, a PPM exhibit flats frequency response and is calibrated such that the nominal peak program level corresponds to a 0 dB meter reading near full scale (generally +16 dBm).

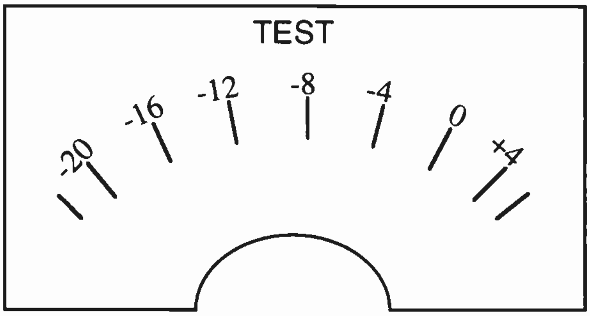

Figure 7.1-4(c). Arrangement of a typical peak program meter scale.

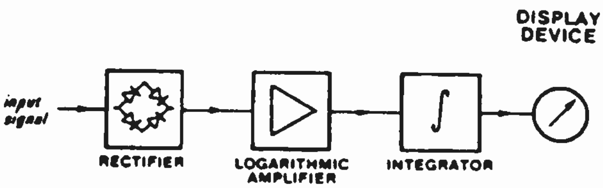

Figure 7.1-4(d). Block diagram of the stages of a typical PPM.

Other types of metering devices have been developed to read wideband audio in a simultaneous mode. One such system consists of an LED bar graph display exhibiting peak program content. Riding upon this is a brighter display (utilizing the same display elements) corresponding to VU standards. Such an indicator allows continuous monitoring of program material compression and dynamic characteristics. Another system combines a VU movement meter with peak indicating LED flashers. A *hold* function is sometimes associated with these flashers to allow an operator sufficient time to observe the approximate peak content.

FREQUENCY ANALYSIS

Amplitude analysis methods, as described in the previous section, are generally used to provide an indication of signal levels simultaneously over the entire audio range. It is sometimes more desirable, however, to be able to measure discrete frequencies in an audio system, allowing frequency response measurement as well as dynamic measurement of energy content throughout the audio spectrum.

Simply stated, frequency response is the capability of a device or system to pass or amplify equally, all frequencies within a specified range.[5] As far as audio in the broadcast environment is concerned, the range of interest is generally 50 Hz to 15 kHz or 20 kHz. Although few musical instruments produce fundamental frequencies greater than 4 kHz and the human voice much above 1 kHz, the reproducing device or system must be able to pass the harmonics that accompany the fundamental frequencies. Without adequate bandwidth or with uneven frequency response, an unnatural *coloration* of the perceived sound becomes evident. To overcome this potential problem, a great deal of care is taken to construct amplifiers with very flat frequency response to high frequencies. Since the responses of series connected amplifiers are additive, care must be taken to verify the flatness of each device in a system.

Several methods are available to measure audio frequency response. They include *discrete frequency measurement* and *swept frequency methods. Parallel analysis* and *Fast Fourier transform* (FFT) techniques also can be used.

The discrete frequency measurement method is uncomplicated and inexpensive. A simple measurement system consists of a low distortion audio frequency oscillator and a wideband ac voltmeter. A typical audio frequency oscillator is shown in Figure 7.1-5. The oscillator output is connected to the input of the device or system to be characterized. The voltmeter is used to observe the level at the output of the device, or at a desired intermediate point in a system.

The measurement is done by first setting the generator output level to the nominal input operating level of the device. Generally, a 400 Hz or 1000 Hz frequency is chosen initially in high fidelity audio systems. The device output level is read on the ac voltmeter, and this quantity is noted as a 0 dB relative reference. Provided the generator itself has a flat frequency response, measurements at frequencies through the audio band can be taken while recording the corresponding dB output levels with respect to the reference. A convenient and commonly used technique is to increment the frequency in a 1, 2, 5 sequence (20 Hz, 50 Hz, 100 Hz, 200 Hz, etc.). This method permits plotting the final response data on 4-cycle LOG/LIN graph paper, providing regularly spaced frequency increments horizontally. The logarithmic amplitude data are plotted along the horizontal axis, with the zero dB relative reference placed in a convenient position on the linear vertical axis.

Although the discrete frequency measurement technique is straightforward, it is also often tedious and time-consuming. Numerous frequency measurements must be made to ensure adequate testing. This method is most usable in the response measurement of single ended devices that do not have a suitable input port for connection to an audio generator. Transcription equipment, such as compact disc players are examples of these types of devices. Test recordings supplied by the equipment manufacturer and other sources are used to provide the tones necessary for discrete frequency response characterization.[6,7]

Swept Frequency

A faster and more efficient means of measuring frequency response is the swept frequency method. This process employs a sweep frequency generator as a signal source and measures response over the entire range of interest in one sweep. The detector for these measurements is most often a tracking type that follows the signal source and measures a narrow band of frequencies centered around the source frequency. Use

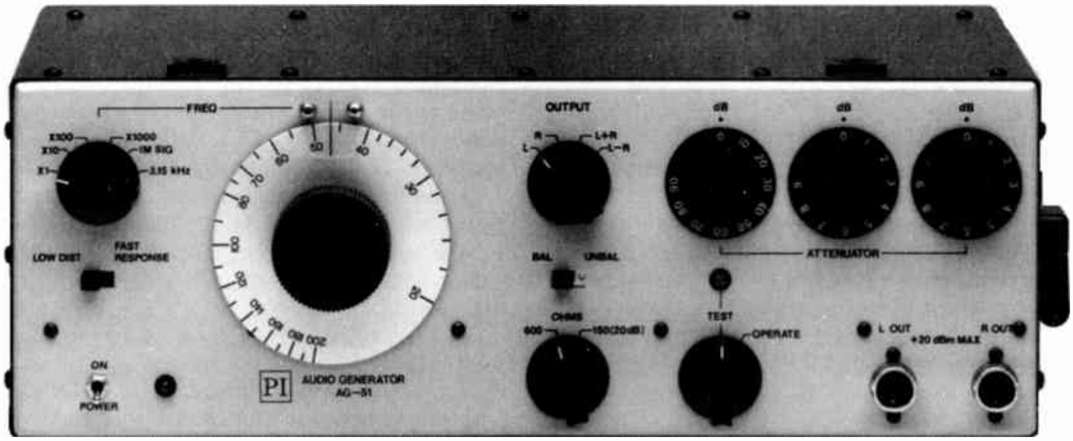

Figure 7.1-5. Audio frequency generator designed for broadcast use.

of a tracking detector is a better guarantee that the amplitude measured is that of the tone generator and is not influenced by spurious noise or harmonics.

Devices specifically designed to conduct swept frequency measurements include wave analyzers and spectrum analyzers. Wave analyzers, which are no longer commonly available, must be used with plotters to provide a hard copy data plot, while spectrum analyzers directly produce response images on a built-in display. A representative spectrum analyzer, which is specifically intended for audio frequency use, is shown in Figure 7.1-6.

Figure 7.1-7 shows a typical setup for measuring amplifier frequency response using the swept frequency method. The signal source used to drive the test device is the tracking oscillator output of the analyzer. The device output is terminated with an appropriate characteristic load impedance and connected to the analyzer input. Measurement of the frequency response is made by manually or automatically sweeping the analyzer across the frequency range of interest. A plotter, a scope-type camera, or a printer (if the analyzer supports one) can be used to provide a permanent record of the test device response characteristics.

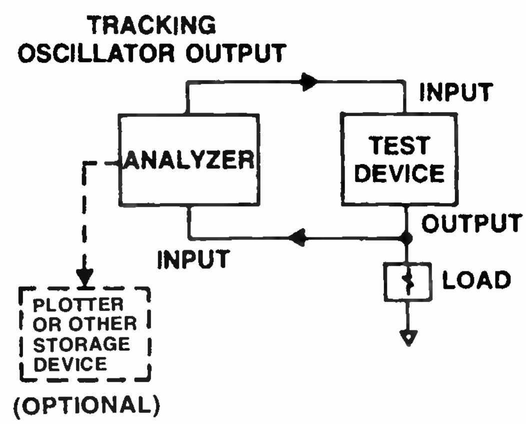

Figure 7.1-7. Frequency response measurement using swept method.

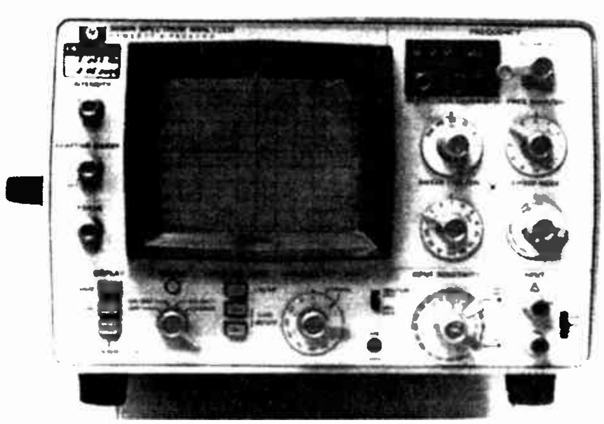

Figure 7.1-6. Spectrum analyzer intended for audio use.

The swept frequency method also can be used to measure the overall frequency response of multiple-track audio recorders. The tracking oscillator signal is connected to the record amplifier input and the output is taken from the playback amplifier output, allowing recording and playback frequency response measurement to be done all at once. However, a time delay between input and output signals may exist, caused by the physical displacement between record and playback heads in analog recurring systems. This effect can be corrected simply by using a very slow sweep speed or a wider measurement bandwidth.

Real Time Analyzer

A *real time audio analyzer* (RTA) consists of a sequential collection of one octave or one-third octave filters having individual detectors and indicators at each output. The program audio is simultaneously fed to the inputs of all the filters. The output signal of each filter is proportional to the amount of energy

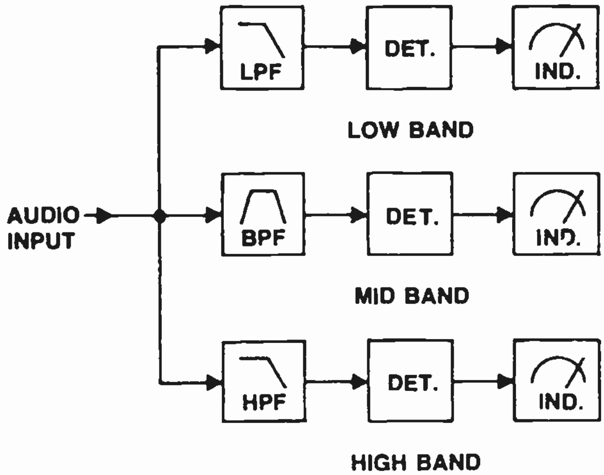

Figure 7.1-8. Basic real-time analyzer.

occurring in that particular frequency band. This technique is also referred to as *parallel analysis.*

A simplified version of an RTA is presented in Figure 7.1-8. As shown, it is intended to break the audio band into three sections using low-pass, band-pass and high-pass filtering. Signal detectors are then used to condition the audio for display on a suitable indicator, one set for each of the three bands. The detectors can be (and often are) the same peak, RMS or average circuits described earlier. Typical readout indicators are bar graph displays with dB-calibrated scales. When arranged side by side, the readouts provide a graphical presentation of amplitude versus frequency, similar to spectrum analyzer display. Unlike the spectrum analyzer, however, an RTA does not rely on a fixed sweep speed.

Parallel techniques using the RTA are often used for dynamic program material and room acoustics analysis.[8] This type of analyzer is also useful for measuring frequency response of audio devices when used in conjunction with a *pink noise* source. Pink noise has a constant mean squared voltage per octave of frequency. This characteristic makes it popular in audio work, since it allows correlation between successive octaves by ensuring the same voltage amplitude is available as a reference. By connecting the pink noise source to the input of a device to be characterized and the RTA to its output, a response curve can be displayed almost instantly. The characteristic response of pink noise is shown in Figure 7.1-9, as compared with *white noise.* White noise is unweighted, since its response is flat with frequency, except that it is attenuated for frequencies above the audio spectrum.

Although often prohibitive in cost, network and FFT analyzers are also exceptionally useful in audio frequency domain measurements. Network analyzers are swept analysis instruments, used to characterize two-port networks (devices having an input and output) as to frequency, phase and delay responses. They are employed where substantial accuracy in the measurement of these parameters is required. RF subsystem

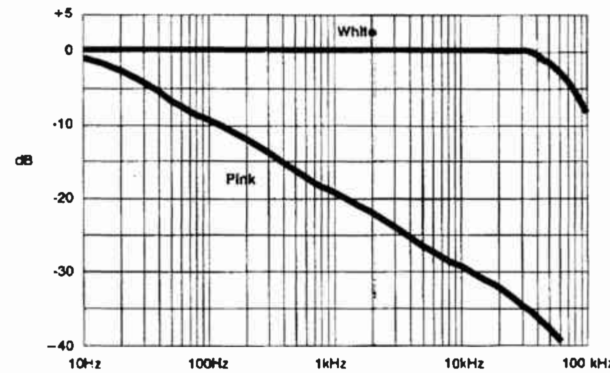

Figure 7.1-9. Response versus frequency for white noise and pink noise.

and semiconductor device design have been the major application for network analyzers, although some newer generation equipment includes audio-frequency coverage. In the case of audio systems, network analyzers allow precision response measurement of amplifier and filter designs.

FFT analyzers have the ability to convert a snapshot sampling of an audio or other time-varying source and mathematically transform the result into a display of the frequency components present. Because the conversion process is done by a specialized digital signal processing (DSP) microcomputer, an FFT analyzer often can produce a complete spectrum display as much as an order of magnitude faster than conventional swept spectrum analyzers. FFT analyzers are most helpful in low frequency measurement, where a swept analyzer would require a very slow sweep time to resolve closely spaced components. As their costs have been decreasing, FFT analyzers are becoming increasingly popular for audio system analysis and measurement.

DISTORTION MEASUREMENT

When a two-port device is driven beyond its range of linear operation or through areas of discontinuity, signal distortion occurs. As a result, additional frequencies appear at the device output that were not present at its input. In cases where distortion becomes extreme, it can be identified through listening. Odd-order distortion (such as clipping distortion) can become audible at around 1.25%. Even-order distortion, characterized by a coloration of the program material, becomes audible at about 5%. Generally, systems with a wider frequency response capability need to maintain lower distortion levels to be acceptable. Since distortion is not always obvious to many people, techniques are available to measure its various types.

Classic audio distortion can be characterized in two basic ways: *harmonic distortion* and *intermodulation distortion.* While the two associated methods produce uncorrelated measurement values, each gives a quantitative result of device quality in terms of a single number. Although total harmonic distortion (THD) content is determined by only one method, intermodulation distortion (IMD) has several accepted measurement practices, including the SMPTE and CCIF methods. *Transient intermodulation* (TIM) distortion is another commonly measured type of IMD. Digital audio signals can be characterized using THD and IMD methods, but they also are susceptible to other types of distortion.

Harmonic Distortion

Harmonic distortion is a measure of individual harmonic amplitudes with respect to the amplitude of the fundamental frequency. In practice, harmonics greater than third order often add little to the resultant value because of their negligible amplitude. THD is defined as:

$$\text{THD\%} = 100\frac{\sqrt{A_2^2 + A_3^2 + A_4^2 + \cdots + A_n^2}}{A_1} \quad (4)$$

where A_2 through A_n are the amplitudes of the individual harmonics and A_1 is the amplitude of the fundamental.

As seen in Figure 7.1-10, a 1 kHz sine wave with harmonic distortion shows only minor differences when it is overlaid with an undistorted signal (as viewed on an oscilloscope). The amplitude and slope errors do not lead directly to a numeric result. But when a spectrum photo of the same waveform is observed (Figure 7.1-11), the above relation can be applied. With the fundamental at 0 dBm (0.775 V), the second harmonic at -26 dBm (38.8 mV), and the third harmonic at -50 dBm (2.5 mV), the harmonic distortion can be calculated:

$$\text{THD\%} = 100\frac{\sqrt{(0.0388)^2 + (0.0025)^2}}{0.775} = 5.0\% \quad (5)$$

Although spectrum analysis can produce accurate THD measurement results, a simpler and more cost effective procedure that produces a direct numeric quantity is more popular. Figure 7.1-12 shows the block diagram of a typical THD analyzer. An oscillator (with much less harmonic distortion than the device or system to be measured) is connected to the test device input. The distorted output signal of the device is filtered to remove A_1, the fundamental component. This produces a signal that, when RMS detected, is proportional to the THD imposed by the device being tested.

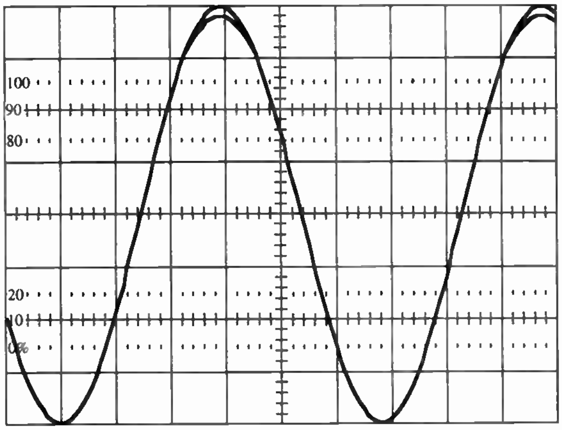

Figure 7.1-10. Comparing the distorted output of an amplifier with its undistorted 1 kHz input component.

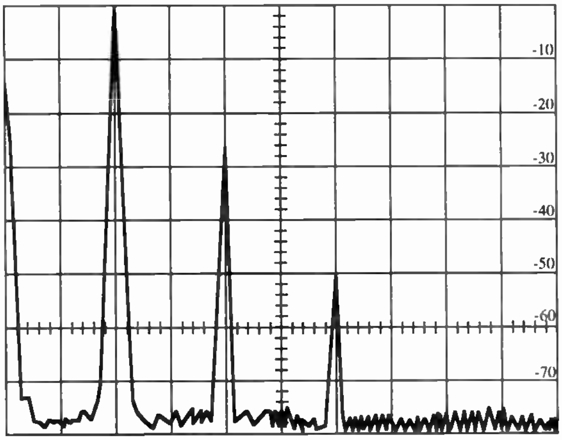

Figure 7.1-11. Measuring THD with a spectrum analyzer (V: 10 dB/div; H: 500 Hz/div).

THD measurement is often conducted using the same 1, 2, 5 sequence of frequencies mentioned for discrete response measurement. The THD results can be plotted on the same graph to characterize the device under test on a single page. THD measurements may be taken over various input levels, but as the level is reduced, noise characteristics may affect the readings. In such cases, the spectrum analyzer method could produce more meaningful results.

Intermodulation Distortion (IMD)

The intermodulation method of measuring distortion uses a test signal composed of two sinusoidal signals of different frequencies (except for TIM measurement, to be covered shortly). After summation, they produce the effect of an amplitude modulated carrier when applied to a circuit having IMD. The intermodulation method is useful because the harmonic distortion of the signal sources do not affect the measurement.

The SMPTE method uses a low frequency (f_1) and a relatively high frequency (f_2) signal (usually 60 Hz and 7 kHz, respectively) that are mixed at a four to one amplitude ratio (see Figures 7.1-13 and 7.1-14). This method involves the measurement of the relative amplitude of the modulation sidebands added to the higher frequency signal. For diagnostic purposes, it is often useful to determine even-order and odd-order distortions separately, although this is best done by spectrum measurement techniques. Even-order distortion usually can be characterized by the ratio of the sum of the amplitudes of only the two second-order

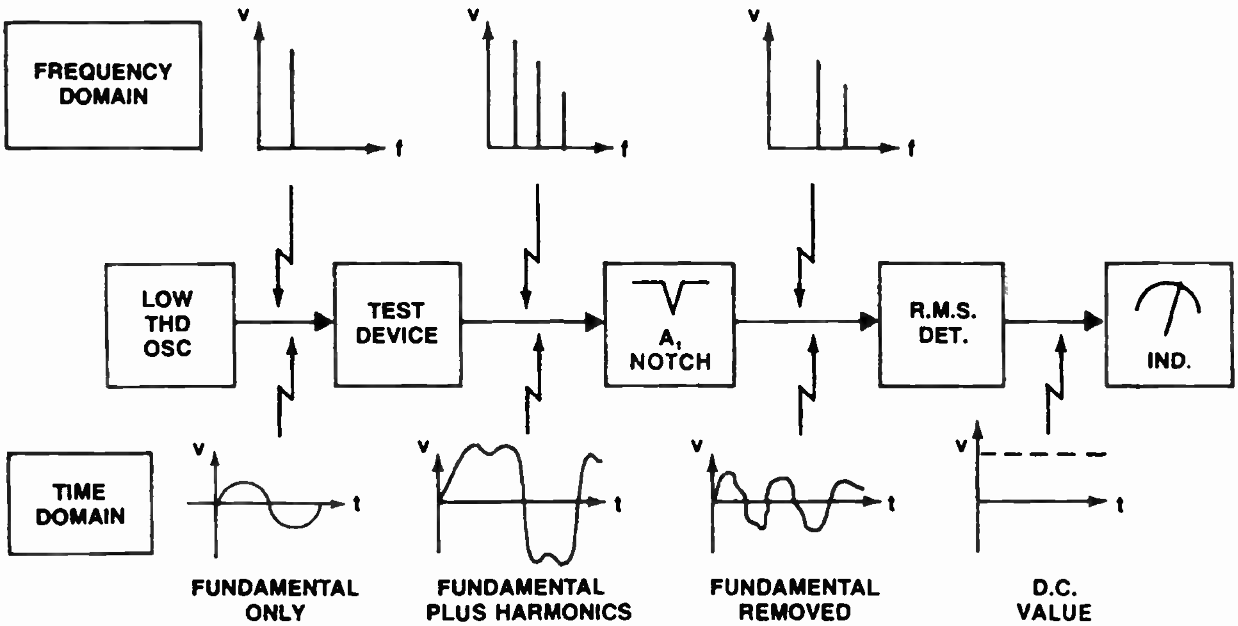

Figure 7.1-12. THD analyzer.

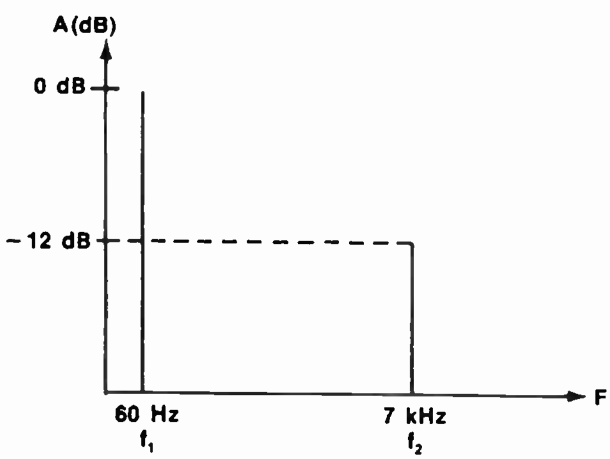

Figure 7.1-13. Spectrum of SMPTE IMD input test signal ratios.

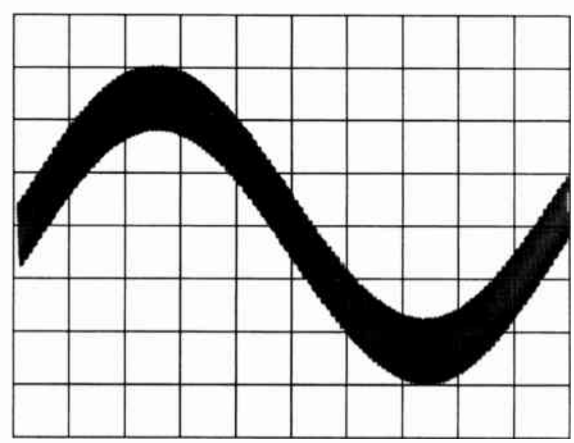

Figure 7.1-14. SMPTE IMD test signal as viewed on an oscilloscope.

spurious frequencies, $f_2 - f_1$ and $f_1 + f_2$, to the amplitude of the carrier signal, f_2

$$\text{SMPTE IMD\%} = \left[\frac{A_{(f_2-f_1)} + A_{(f_1+f_2)}}{A_{f_2}}\right] \times 100 \quad (6)$$

(second order)

In a similar manner, odd-order distortion can be characterized by the ratio of the sum of the amplitudes of the two third-order spurious frequencies, $f_2 - 2f_1$ and $2f_1 + f_2$ to the amplitude of f_2:

$$\text{SMPTE IMD\%} = \left[\frac{A_{(f_2-2f_1)} + A_{(2f_1+f_2)}}{A_{f_2}}\right] \times 100 \quad (7)$$

(third order)

Figure 7.1-15 shows the output signal of an amplifier with IMD, as viewed on an oscilloscope. Note the elongated trough as compared to Figure 7.1-14. As with THD, spectrum analysis can be used to determine the numerical amount of distortion present. Intermodulation sidebands can be seen around f_2 in the spectrum photo of Figure 7.1-16. Second- and third-order distortion percentages for this example are calculated as follows:

$$A_{f_2} = -12 \text{ dBm} = 195 \text{ mV}$$

$$A_{(f_2-f_1)} = A_{(f_1+f_2)} = -38 \text{ dBm} = 9.76 \text{ mV}$$

$$\text{SMPTE IMD\%} = \left[\frac{9.76 + 9.76}{195}\right] \times 100 = 10.0\%$$

(second order)

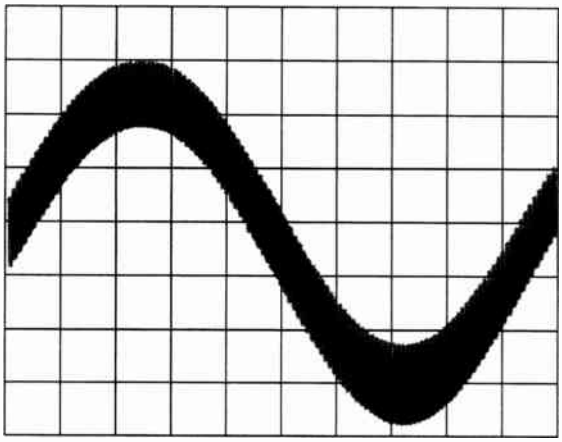

Figure 7.1-15. Output of an amplifier exhibiting significant SMPTE IMD.

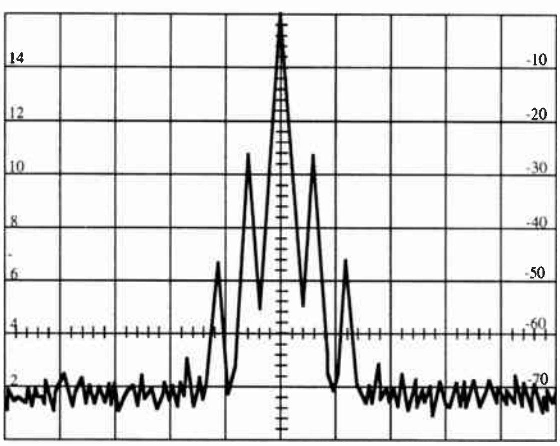

Figure 7.1-16. SMPTE IMD measurement. (V: 10 dB/div. Top of screen −12 dBm; H: 100 Hz/div. Center frequency: 7.0 kHz).

$$A_{(f_2-2f_1)} = A_{(2f_1+f_2)} = -58\ \text{dBm} = 0.98\ \text{mV}$$

$$\text{SMPTE IMD\%} = \left[\frac{0.98 + 0.98}{195}\right] \times 100 = 1.0\% \tag{8}$$

(third order)

As is shown, the contribution of even-order distortion products is usually greater than that of the odd-order. To express the result as a single quantity, the vector sum of the two quantities is taken:

$$\text{SMPTE IMD\%} = \sqrt{(\text{IMD\%Even})^2 + (\text{IMD\%Odd})^2} \tag{9}$$

(total)

$$= \sqrt{10^2 + 1^2} = 10.05\%$$

As with THD, SMPTE IMD has a direct method of numeric solution, as shown in the block diagram of Figure 7.1-17. The two test frequency oscillators are summed to produce the $f_1 + f_2$, signal, which is then applied to input of the device to be tested. The distorted output signal is high-pass filtered to remove the f_1 fundamental component, leaving only the amplitude modulated f_2 component. Using a standard AM demodulator and low-pass filter, the residual f_1 component is obtained. After RMS detection, a dc level proportional to the distortion is produced that can be viewed on a direct reading indicator.

Wow and flutter is a term that describes a special case of IMD normally associated with analog audio tape recorders. It is caused by variations in tape velocity across the recording and/or reproducing heads, due to imperfections in the mechanical drive system. These variations result in frequency modulation of the recorded and reproduced signal. The frequency spectrum obtained is similar to that of the SMPTE IMD measurement method, except the f_1 low frequency signal is generated by fluctuations in tape speed and is not of any set amplitude.[5]

To measure wow and flutter, a test tape containing a prerecorded 3 kHz (or 3.15 kHz) tone is played. Using an audio spectrum analyzer, for example, the amplitude of the first sideband (A_m) with reference to the 3 kHz amplitude (A_0) is measured. The frequency of the flutter (F_m) also must be known. Then the following relation can be used to approximate the percentage of wow and flutter present:

$$\text{WOW \& FLUTTER\%} = \frac{2(A_m)(F_m)}{(A_0)(3\ \text{kHz})} \times 100 \tag{10}$$

(peak-to-peak)

For example, if the first sideband (either upper or lower) amplitude is 10 dB below the 3 kHz maximum amplitude (0.316 V with reference to an arbitrary 1 V amplitude at 3 kHz) and is at a frequency of 4 Hz, the wow and flutter would be 0.084%.

The CCIF intermodulation method uses a combination of two higher frequency sinusoidal signals (f_3, f_4) of equal amplitude. They are typically 1 kHz apart and found at 5/6 kHz, 14/15 kHz, or 19/20 kHz in many applications. One of the spurious frequencies generated is low in frequency while others are gathered around the two driving frequencies. Figures 7.1-18 and 7.1-19 spectrally show the driving frequencies before and after passing through a test amplifier. As with SMPTE IMD measurement, the generated spurious products can be classified as even-order or odd-order. Even-order distortion is expressed as the ratio of the amplitude of the difference component ($f_4 - f_3$) to the sum of the two driving frequencies (f_3, f_4):

$$\text{CCIF IMD\%} = \left[\frac{A_{(f_4-f_3)}}{A_{f_3} + A_{f_4}}\right] \times 100 \tag{11}$$

(second order)

Odd-order distortion is determined by calculating the ratio of the sum of the amplitude of the two third-

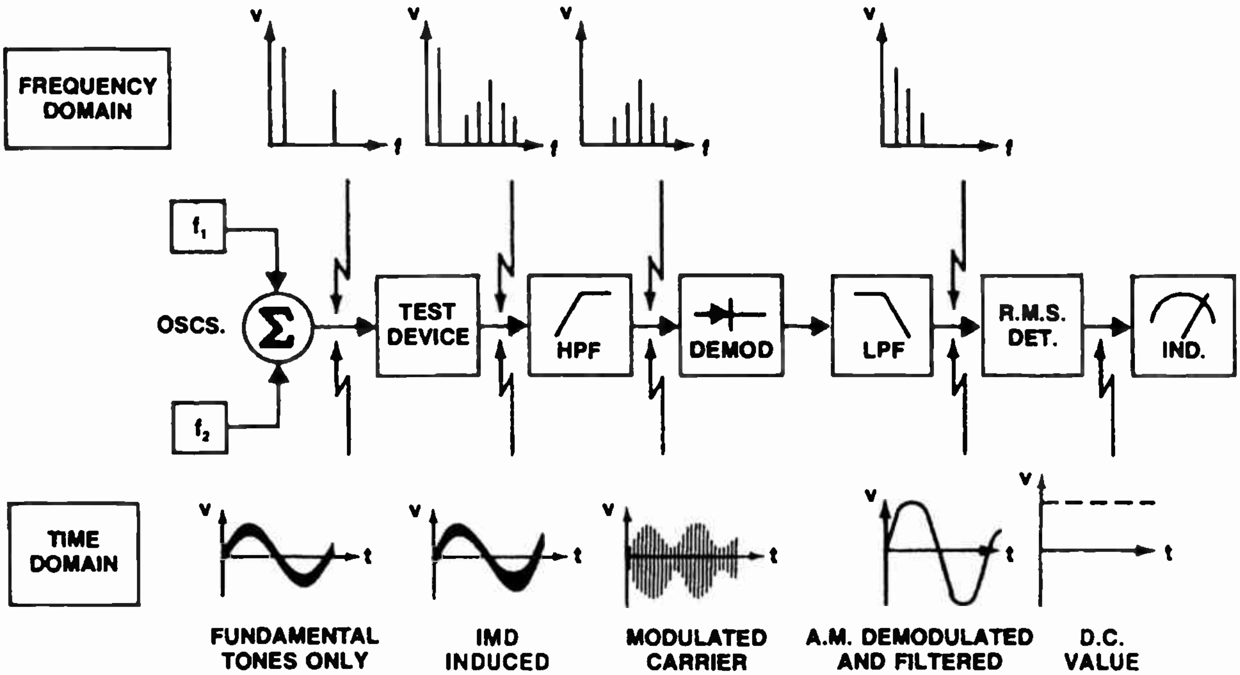

Figure 7.1-17. SMPTE IMD analyzer.

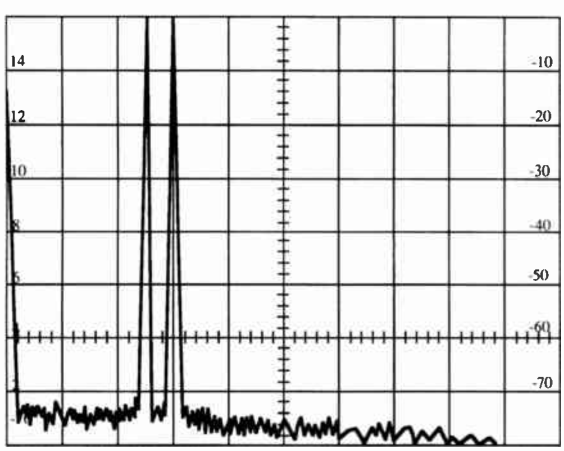

Figure 7.1-18. Spectrum of CCIF IMD test signal. (V: 10 dB/div; H: 2 kHz/div).

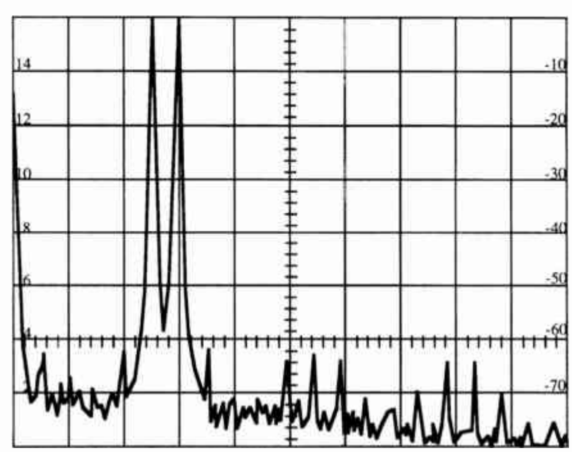

Figure 7.1-19. CCIF IMD measurement example. (V: 10 dB/div; H: 2 kHz/div).

order products, $2f_3 - f_4$ and $2f_4 - f_3$, to the sum of the amplitudes of the two driving frequencies, f_3 and f_4:

$$\text{CCIF IMD\%} = \left[\frac{A_{(2f_3-f_4)} + A_{(2f_4-f_3)}}{A_{f_3} + A_{f_4}}\right] \times 100 \quad (12)$$

(third order)

In the case of Figure 7.1-19, the driving frequencies f_3 and f_4 are at 5 kHz and 6 kHz, even-order product at 1 kHz, and third-order products at 4 kHz and 7 kHz, respectively. Distortion percentages for this example are calculated as follows:

$$A_{f_3} = A_{f_4} = 0\text{ dBm} = 775\text{ mV}$$

$$A_{(f_4-f_3)} = -64\text{ dBm} = 0.49\text{ mV}$$

$$\text{CCIF IMD\%} = \left[\frac{0.49}{775 + 775}\right] \times 100 = 0.032\%$$

(second order)

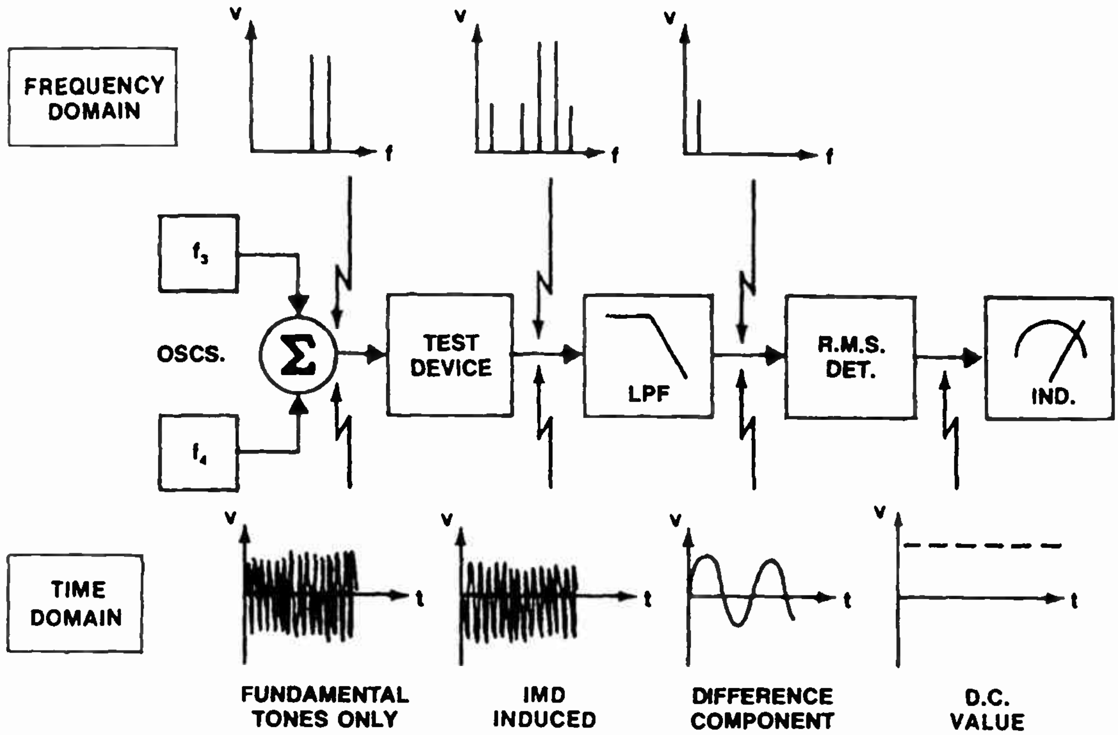

Figure 7.1-20. CCIF second-order IMD analyzer.

$$A_{(2f_3-f_4)} = -62 \text{ dBm} = 0.62 \text{ mV}$$

$$A_{(2f_4-f_3)} = -61 \text{ dBm} = 0.69 \text{ mV}$$

$$\text{CCIF IMD\%} = \left[\frac{0.62 + 0.69}{775 + 775}\right] \times 100 = 0.085\% \quad (13)$$

(third order)

It is a common practice for direct reading metered analyzers to measure only the amplitude of the difference product ($f_4 - f_3$) with respect to the driving signal amplitudes. The device that performs this task is called a *CCIF second-order difference frequency distortion analyzer.* Figure 7.1-20 illustrates how the measurement is made.

TIM distortion is found only in amplifiers that utilize negative feedback. When this feedback is excessive, a fast rising transient signal applied to the input of the amplifier can produce an internal overshoot that saturates the circuits in the amplifier.

The most popular procedure used to measure TIM distortion is the *sine square wave method.* The test signal employed uses a square wave (f_{sq}) to induce nonlinearity in the test device by saturating the amplifier's internal current, caused by its alternate rises and falls. Mixed with this square wave is a low level, high-frequency sine wave (f_{si}), which is unrelated harmonically. As defined, the frequency of the square wave is 3.18 kHz and that of the sine wave 15 kHz, where the peak-to-peak amplitude ratio of the former to the latter is four to one.[9] Before summation, the square wave is low-pass filtered using a first order design having a cutoff frequency of 30 kHz. This reduces the harmonics outside of the band of interest that could damage the device being tested. The composite wave form produced is shown in Figure 7.1-21 and spectrally in Figure 7.1-22.

Using the test setup shown in Figure 7.1-23, an amplifier can be measured for TIM. Mathematically, TIM distortion produced by the sine square wave method is defined as:

$$\text{TIM\%} = \frac{\sqrt{A1^2 + A2^2 + \cdots + A9^2}}{A_{si}} \times 100 \quad (14)$$

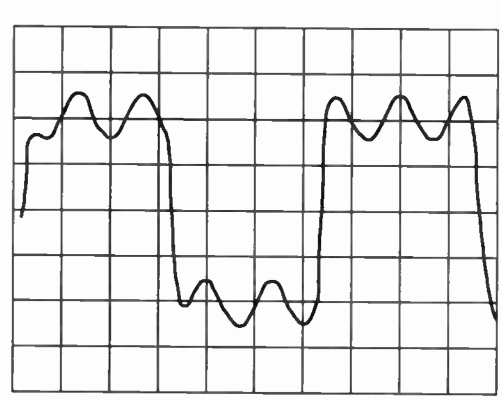

Figure 7.1-21. TIM test signal.

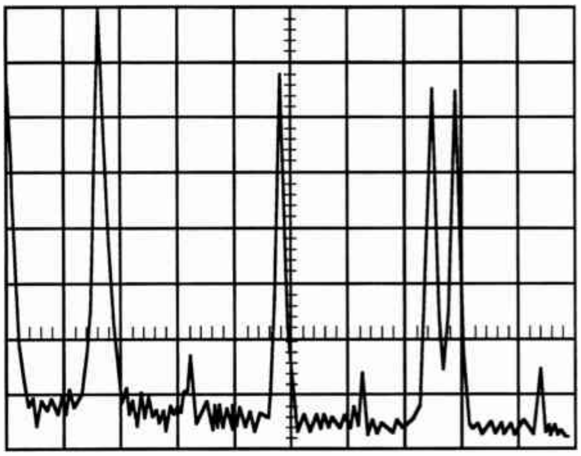

Figure 7.1-22. Spectral view of TIM test signal (V: 10 dB/div; H: 2 kHz/div).

where $A1$ through $A9$ represent the amplitudes of the distortion product present in the audio band and A_{si} is the amplitude of the sine wave. Values for the $A1$–$A9$ components are shown in Table 7.1-1.

Figure 7.1-24 shows the TIM distortion products produced by an amplifier that only displayed negligible THD, SMPTE IMD and CCIF IMD percentages. Using Formula 14, it can be determined that this amplifier is producing about 20% TIM distortion.

Other TIM measurement methods include a sawtooth wave method that takes amplifier slew rate into account and a noise-square wave method, where the sine wave of the sine-square wave method is replaced by a narrow band noise spectrum.[10]

Filtering as part of distortion measurement is often useful to remove components that are of little interest and as a diagnostic aid.[11] This is especially true with THD measurement. A 20 kHz or 30 kHz high-pass filter placed in series with the output of the device being measured is useful for testing broadcast equipment. This is often an acceptable practice, since the harmonics produced outside the transmission bandwidth can be eliminated, producing a more realistic result.

Table 7.1-1

Component	Relation	Frequency, kHz
A1	fsi – fsq	11.82
A2	fsi – 2fsq	8.64
A3	fsi – 3fsq	5.46
A4	fsi – 4fsq	2.28
A5	|fsi – 5fsq|	0.90
A6	|fsi – 6fsq|	4.08
A7	|fsi – 7fsq|	7.26
A8	|fsi – 8fsq|	10.44
A9	|fsi – 9fsq|	13.62

A high-pass filter also can serve as an important analytical aid. With a cutoff frequency in the 400 Hz range, it can be placed in series with the test device's output and used to determine the contribution of line frequency hum (60 Hz in the U.S.) to a THD measurement utilizing a fundamental frequency of 1 kHz or greater. Verification of adequate grounding used in the test setup also can be observed.

Care must be taken, however, when filtering is used in IM measurement. It is important to verify that in-band distortion components are not inadvertently removed. Also, extremely sharp cutoff filter designs may produce overshoot components that could affect measurement results.

An analyzer capable of performing many of the distortion tests previously described, as well as frequency response measurements, is shown in Figure 7.1-25.

NOISE MEASUREMENT

In audio engineering, noise is a random energy distribution in which individual spectral components are

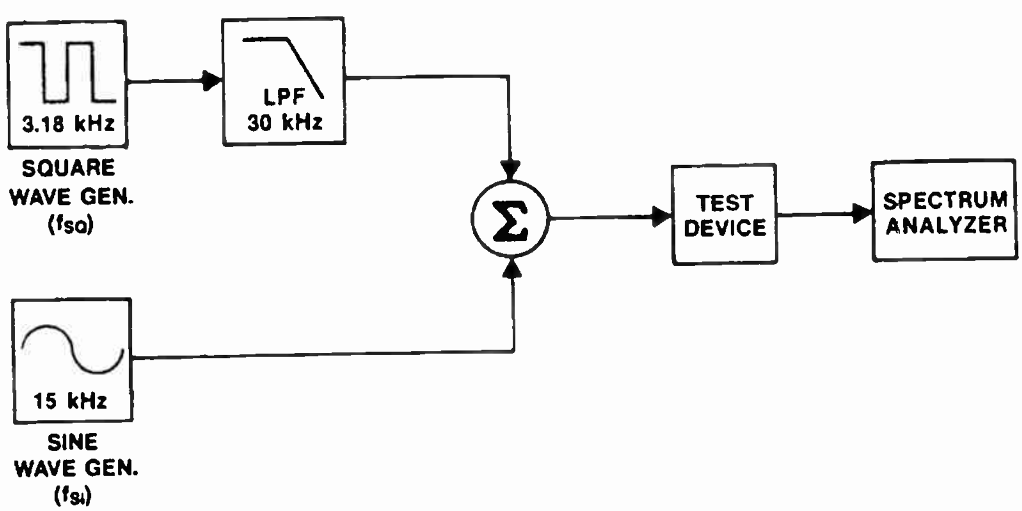

Figure 7.1-23. TIM distortion analysis test setup.

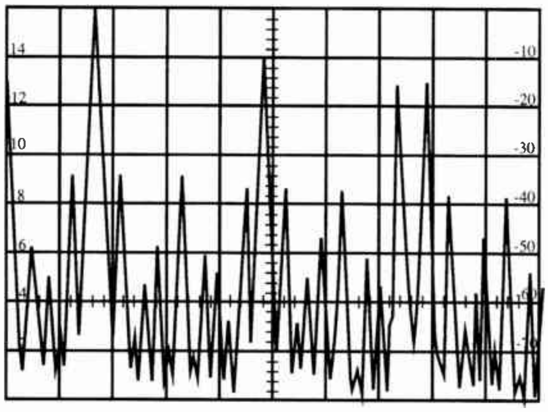

Figure 7.1-24. Spectral view of TIM distortion product measurement (V: dB/div; H: 2 kHz/div).

not clearly resolved. Primary sources of noise in analog circuits and amplifiers are in the resistive circuit elements.[12] It is important to control noise in amplifiers as their gain increases to preserve a high signal to noise ratio, which is the ratio of the operating signal level to the noise level inherent in the amplifier itself.

To understand the origin of the noise, we can model a passive resistive element as a noiseless resistor in series with a noise voltage generator, E_r:

$$E_r = \sqrt{4KTBR}\,(\text{volts}) \tag{15}$$

where:

K = Boltzman's constant (1.38×10^{-23} W-Sec/°K)
T = Temperature in degrees Kelvin
B = Noise bandwidth (Hz)
R = Resistance in Ω

As can be seen from the equation, noise voltage is a physical phenomenon that can be worsened by an increase in any of the variable factors. Therefore, noise cannot be eliminated but it can be reduced. This is often done by proper selection of the resistive components, because of an additional factor known as excess noise, which is proportional to the voltage drop across the resistor and related to the material from which it is made. Of the different available types, carbon composition resistors are prone to the most excess noise contribution while metal-film devices show the least.

At times, the actual spectral distribution of noise is of less importance than the noise voltage within a given bandwidth for comparison purposes. For audio frequencies, a 15 or 20 kHz bandwidth is of interest. With a low pass filter in this range connected in series with an amplifier output, and the input of the amplifier grounded, an unweighted but band limited noise measurement can be made. When the noise output level is obtained, it can be expressed as a ratio with a standard operating level and reference frequency. This produces an indication of the amplifier's SNR.

When the gain of the amplifier is known, this same technique can be used to determine equivalent input noise voltage. The voltage of the noise that would be found at the input of the amplifier if the amplifier were completely noiseless.[12]

The measurement of a noise voltage quantity over a given frequency bandwidth in order to determine SNR does not provide a complete characterization, because the noise spectrum can occupy all or part of the same bandwidth.[13] For example, two amplifiers with identical SNRs can sound very different because one may have a uniform noise spectrum and the other may have most of the noise concentrated over a limited frequency range. Hence, the latter amplifier would sound noisier than the former, having to do with the way the ear perceives the loudness of a signal that is uniform in amplitude across the radio band. To make comparative noise measurements more meaningful, several weighting filters have been used to alter noise spectra over the frequency band of interest.

"A" weighting is based on the inverse of early measurements by Fletcher and Munson of the ear's sensitivity at low sound pressure levels.[14] A more recently developed weighting curve utilizes the CCIR/ARM

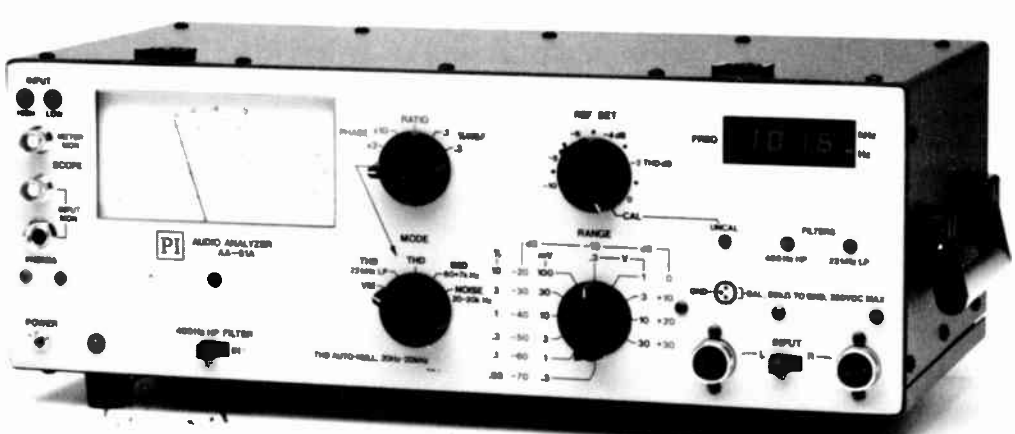

Figure 7.1-25. Analyzer capable of performing audio response and distortion measurements (Courtesy Potomac Instruments, Inc.).

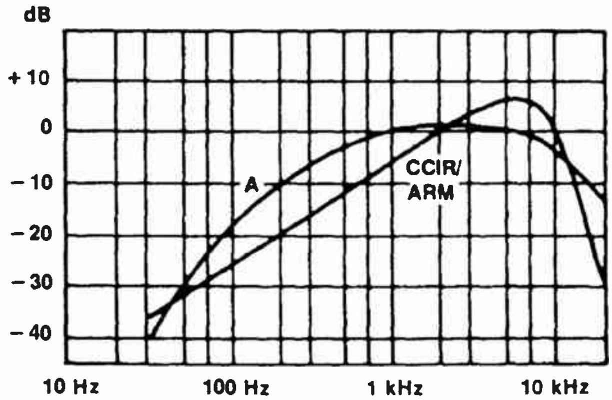

Figure 7.1-26. Noise measurement weighting schemes.

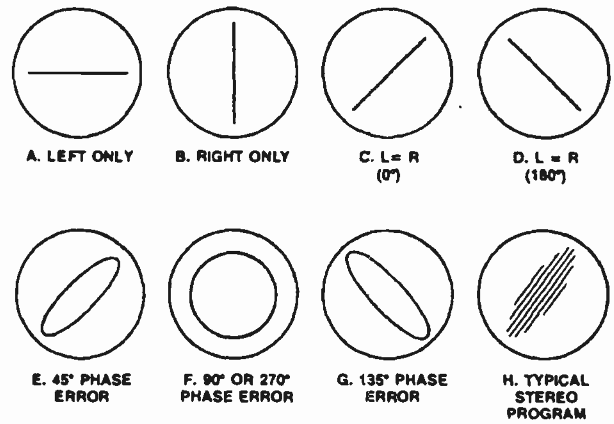

Figure 7.1-27. Interpretation of Lissajous patterns.

method, an updated scheme which places the zero dB reference at 2 kHz instead of 1 kHz.[15] It is believed that this method, which is based on the obtrusiveness as well as the levels of different kinds of noise, provides a more commercially acceptable result when used to characterize modern, wide range audio equipment. Figure 7.1-26 compares the two curves.

PHASE MONITORING AND MEASUREMENT

An (L + R) summation is the monophonic compatible signal for AM, FM, and TV stereo broadcasting. Separation information is usually transmitted via an (L − R) signal. Since these two signals are created through a summation and difference process of the original left and right channel stereophonic source, it is important that they can be recombined properly at the receiver.[16] Amplitude and phase errors must be minimized in the transmission system to accomplish this goal. Phase measurement is important in accomplishing this task.

In a stereo program system, if left and right audio information is correlated but delayed in phase, the error would not be evident on a stereophonic receiver. A monophonic signal, however, would be degraded because of inexact summation. This problem is common to analog audio tape recording. Periodic azimuth adjustment or *phasing* of the heads is often done. A test tape containing a high frequency tone is played while azimuth is adjusted to minimize the difference signal between the two channels.

A *phase meter* can be used to simplify this task. A simple version would take phase and amplitude variances into account simultaneously by functioning as a two-input subtractor. When both characteristics are identical in each of the channels, the output becomes zero. A meter that measures only phase information compares the zero-crossing times of the two input signals, and the resulting time difference is used to generate a dc voltage proportional to the phase difference.[17] Phase detectors operating in this manner often limit the input signals in order to remove all amplitude information.

More popular, however, is the *Lissajous figure method,* involving the use of an oscilloscope in the X-Y mode. The patterns produced are shown in Figure 7.1-27. An oscilloscope is connected such that the left channel audio causes an X-axis sweep and right channel audio produces a Y-axis sweep as shown in Figure 7.1-27(a) and 7.1-27(b) respectively. When each channel contains the same program material, the pattern of Figure 7.1-27(c) is produced. This is the L + R axis. If one of the channels is inverted, the pattern of Figure 7.1-27(d) becomes evident (this is often called the L − R axis). Program material that follows this axis is said to be inverted in polarity because no sum or L + R information is present.

During alignment of analog tape reproducing equipment, when discrete tones are used, the patterns of Figures 7.1-27(e), 7.1-27(f), and 7.1-27(g) are commonly seen when phase errors exist between the two channels. Stereo program material, in unprocessed form, generally modulates the L + R axis while simultaneously deviating in the L − R direction to a lesser amount, as shown in Figure 7.1-27(h).

7.2
VIDEO SIGNAL ANALYSIS

JERRY WHITAKER
EDITOR-IN-CHIEF

INTRODUCTION

As video technology steams full speed ahead into the digital domain, the shortcomings and degradations associated with analog technology that video engineers have come to accept and deal with—are rapidly disappearing. In their place, however, are new problems. Digital devices and systems bring their own unique mix of issues that must be addressed, including:

- **Quantization.** The quantization process, by design, discards information. It takes an analog waveform with infinite variability and blocks it into a collection of bits, the number of which is determined by the bit length of the system.
- **Concatenation.** Defined as the connection of elements end-to-end, concatenation for video and audio describes the effects of chaining compression and decompression systems.
- **Video Processing.** It is commonly assumed that as long as a video clip is manipulated in the digital domain, it will not be degraded. In a general sense this is true, however, certain operations will discard information that cannot be recreated downstream. Changes in sizing, adjustment of color hue and saturation and adjustment of luminance values are just some of the operations that can result in degradation of the signal unless proper precautions are taken. Something as simple as improper gamma setup on monitors can result in a host of problems as the signal meanders through the production process. Once picture information is discarded, it cannot be completely recreated.
- **Transmission.** In order for a digital video signal to be useful, it usually must be moved from one spot to another. This almost always involves codecs and a transmission medium. This medium may be coax, fiber or a radio frequency link. With any of these systems, degradations are possible—some are more vulnerable than others. An RF link usually has the greatest level of exposure to interfering signals. Coax, on the other hand, is basically closed to outside influences but has a finite cable length over which reliable communications can take place.

The important message here is that digital is not always perfect and that the need for test equipment and quality control does not disappear simply because a room full of analog boxes is replaced with a computer workstation. Furthermore, just because the picture looks good on a local monitor does not mean that it will look good (or at least look the same) at the end of a terrestrial or satellite link.

New test instruments are rising to the challenge posed by the new technologies being introduced to the video production process. As the equipment used by broadcasters and video professionals becomes more complex, the requirements for advanced, specialized maintenance tools also increases. These instruments range from simply go/no-go status indicators to automated test routines with pre-programmed pass/fail limits. Video quality control efforts must focus on the overall system, not just a particular island.

The attribute that makes a good test instrument is really quite straightforward: accurate measurement of the signal under test. The attributes important to the user, however, usually involve the following:

- Affordability
- Ease of use
- Performance

Depending upon the application, the order of these criteria may be inverted (performance, ease of use, affordability). Suffice it to say, however, that all elements of these specifications combine to translate into the user's definition of the ideal instrument.

The memory functions of the new breed of instruments provide important new capabilities, including archiving test setups and reference waveforms for ongoing projects and comparative tests. Hundreds of files typically can be saved for later use. With automatic measurement capabilities, even a novice technician can perform detail-oriented measurements quickly and accurately.

In the rush to embrace advanced, specific-purpose test instruments, it is easy to overlook the grandparents of all video test devices—the *waveform monitor* and *vectorscope*. Just because they are not new to the scene does not mean that they have outlived their usefulness.

The waveform monitor and vectorscope still fill valuable roles in the test and measurement world. Both, of course, have their roots in the general purpose *oscilloscope*. This heritage imparts some important benefits. The scope is the most universal of all instruments, combining the best abilities of the human user and the machine. Electronic instruments are well equipped to quickly and accurately measure a given amplitude, frequency, or phase difference—they perform calculation-based tasks with great speed. The human user, however, is far superior to any machine in interpreting and analyzing an image. The waveform monitor and vectorscope presents to the user—in an instant—wealth of information that allows rapid characterization and understanding of the signal under consideration.

Assessment of Color Reproduction

A number of factors may contribute to poor color rendition in a display system. To assess the effect of these factors, it is necessary to define system objectives, then establish a method of measuring departures from the objectives. Visual image display may be categorized as follows:

- **Spectral color reproduction.** The exact reproduction of the spectral power distributions of the original stimuli. Clearly, this is not possible in a video system with three primaries.
- **Exact color reproduction.** The exact reproduction of tristimulus values. The reproduction is then a metameric match to the original. Exact color reproduction will result in equality of appearance only if the viewing conditions for the picture and the original scene are identical. These conditions include the angular subtense of the picture, luminance and chromaticity of the surround and glare. In practice, exact color reproduction often cannot be achieved because of limitations on the maximum luminance that can be produced on a color monitor.
- **Colorimetric color reproduction.** A variant of exact color reproduction in which the tristimulus values are proportional to those in the original scene. In other words, the chromaticity coordinates are reproduced exactly, but the luminances all are reduced by a constant factor. Traditionally, color video systems have been designed and evaluated for colorimetric color reproduction. If the original and the reproduced reference whites have the same chromaticity, if the viewing conditions are the same, and if the system has an overall gamma of unity, colorimetric color reproduction is indeed a useful criterion. These conditions, however, often do not hold. In which case, colorimetric color reproduction is inadequate.
- **Equivalent color reproduction.** The reproduction of the original color appearance. This might be considered as the ultimate objective, but it cannot be achieved because of the limited luminance generated in a display system.
- **Corresponding color reproduction.** A compromise by which colors in the reproduction have the same appearance that colors in the original would have had if they had been illuminated to produce the same average luminance level and the same reference white chromaticity as that of the reproduction. For most purposes, corresponding color reproduction is the most suitable objective of a color video system.
- **Preferred color reproduction.** A departure from the preceding categories that recognizes the preferences of the viewer. It is sometimes argued that corresponding color reproduction is not the ultimate aim for some display systems, such as color television, and that it should be taken into account that people prefer some colors to be different from their actual appearance. For example, suntanned skin color is preferred to average real skin color, and the sky is preferred bluer and foliage greener than they really are.

Even if corresponding color reproduction is accepted as the target, some colors are more important than others. For example, flesh tones must be acceptable—not obviously reddish, greenish, purplish or otherwise incorrectly rendered. Likewise, the sky must be blue and the clouds white, within the viewer's range of acceptance. Similar conditions apply to other well-known colors of common experience.

Chromatic Adaptation and White Balance

With properly adjusted cameras and displays, whites and neutral grays are reproduced with the chromaticity of D65. Tests have shown that such whites (and grays) appear satisfactory in home viewing situations even if the ambient light is of quite different color temperature. Problems occur, however, when the white balance is slightly different from one camera to the next or when the scene shifts from studio to daylight or vice versa. In the first case, unwanted shifts of the displayed white occur, whereas in the other, no shift occurs even though the viewer subconsciously expects a shift.

By always reproducing a white surface with the same chromaticity, the system is mimicking the human visual system, which adapts so that white surfaces always appear the same, whatever the chromaticity of the illuminant (at least within the range of common light sources). The effect on other colors, however, is more complicated. In video cameras, the white balance adjustment usually is made by gain controls on the R, G and B channels. This is similar to the von Kries model of human chromatic adaptation, although the R, G and B primaries of the model are not the same as the video primaries. It is known that the von Kries model does not accurately account for the appearance of colors after chromatic adaptation, and so it follows that making simple gain changes in a video camera is not the ideal approach. Nevertheless, this approach seems to work well in practice, and the viewer does not object to the fact, for example, that the relative increase in the luminances of reddish objects in tungsten light is lost.

Overall Gamma Requirements

Colorimetric color reproduction requires that the overall gamma of the system—including the camera, display, and any gamma-adjusting electronics—be unity. This simple criterion is the one most often used in the design of a video color rendition system. However, the more sophisticated criterion of corresponding color reproduction takes into account the effect of the viewing conditions. In particular, several studies have shown that the luminance of the surround is important. For example, a dim surround requires a gamma of about 1.5 for optimum color reproduction.

Display Resolution and Pixel Format

The pixel represents the smallest resolvable element of a display. The size of the pixel varies from one type of display to another. In a monochrome CRT, pixel size is determined primarily by the following factors:

- Spot size of the electron beam (the current density distribution)
- Phosphor particle size
- Thickness of the phosphor layer

The term pixel was developed in the era of monochrome television, and the definition was—at that time—straightforward. With the advent of color-triad-based CRTs and solid-state display systems, the definition is not nearly so clear.

For a color CRT, a single triad of red, green and blue phosphor dots constitutes a single pixel. This definition assumes that the mechanical and electrical parameters of the CRT will permit each triad to be addressed without illuminating other elements on the face of the tube. Most display systems, however, will not meet this criterion. Depending on the design, a number of triads may constitute a single pixel in a CRT display. A more all-inclusive definition for the pixel is: the smallest spatial information element as seen by the viewer.[1]

Dot pitch is one of the principal mechanical criteria of a CRT that determines, to a large extent, the resolution of the display. Dot pitch is defined as the center-to-center distance between adjacent green phosphor dots of the red, green and blue triad.

The pixel format is the arrangement of pixels into horizontal rows and vertical columns. For example, an arrangement of 640 horizontal pixels by 480 vertical pixels results in a 640 × 480 pixel format. This description is not a resolution parameter in itself, simply the arrangement of pixel elements on the screen. Resolution is the measure of the ability to delineate picture detail; it is the smallest discernible and measurable detail in a visual presentation.[2]

Pixel density is a parameter closely related to resolution, stated in terms of pixels per linear distance. Pixel density specifies how closely the pixel elements are spaced on a given display. It follows that a display with a given pixel format will not provide the same pixel density, or resolution, on a large screen (such as 19 in. diagonal) as on a small screen (such as 12 in. diagonal).

Television lines is another term used to describe resolution. The term refers to the number of discernible lines on a standard test chart. As before, the specification of television lines is not, in itself, a description of display resolution. A 525-line display on a 17 in. monitor will appear to a viewer to have greater resolution than a 525-line display on a 30 in. monitor. Pixel density is the preferred resolution parameter.

Contrast Ratio

The purpose of a video display is to convey information by controlling the illumination of phosphor dots on a screen, or by controlling the reflectance or transmittance of a light source. The contrast ratio specifies the observable difference between a pixel that is switched on and one that is in its corresponding off state:

$$C_r = \frac{L_{on}}{L_{off}}$$

Where:

C_r = contrast ratio of the display
L_{on} = luminance of a pixel in the on state
L_{off} = luminance of a pixel in the off state

The area encompassed by the contrast ratio is an important parameter in assessing the performance of a display. Two contrast ratio divisions typically are specified:

- **Small area.** Comparison of the on and off states of a pixel sized area
- **Large area.** Comparison of the on and off states of a group of pixels

For most display applications, the small area contrast ratio is the more critical parameter.

Color Bar Test Patterns

Color bars are the most common pattern for testing encoders, decoders and other video devices. The test pattern typically contains several bars filled with primary and complementary colors. There are many variants, which differ in color sequence, orientation, saturation and intensity.

The standard color bar sequence is white, yellow, cyan, green, magenta, red, blue and black. This sequence can be produced in RGB format by a simple 3 bit counter. The typical specification of color bar levels (ITU-R Rec. BT.471-1, *Nomenclature and Description of Color Bar Signals*) is a set of four numbers separated by slashes or dots and giving RGB levels as a percentage of reference white in the following sequence:

white bar/black bar/max colored bars/min colored bars

For example, 100/0/100/25 means 100% R, G and B on the white bar; 0% R, G and B on the black bar; 100% maximum of R, G and B on colored bars; and 25% minimum of R, G and B on colored bars (see Figure 7.2-1).

Some color bar patterns merit special names. For example, 100/0/75/0 bars are often called EBU bars or 75% bars, and 100/0/100/25 bars are known as BBC bars. Nevertheless, the CCIR four number nomenclature remains the only reliable specification system to designate the exact levels for color bar test patterns.

The SMPTE variation is a matrix test pattern according to SMPTE document 1-1990 *Alignment Color Bar Test Signal for Television Picture Monitors*, that consists of 67% of the field containing seven (without black) 75% color bars, plus 8% of the field with the *new chroma set* bars blue/black/magenta/black/cyan/

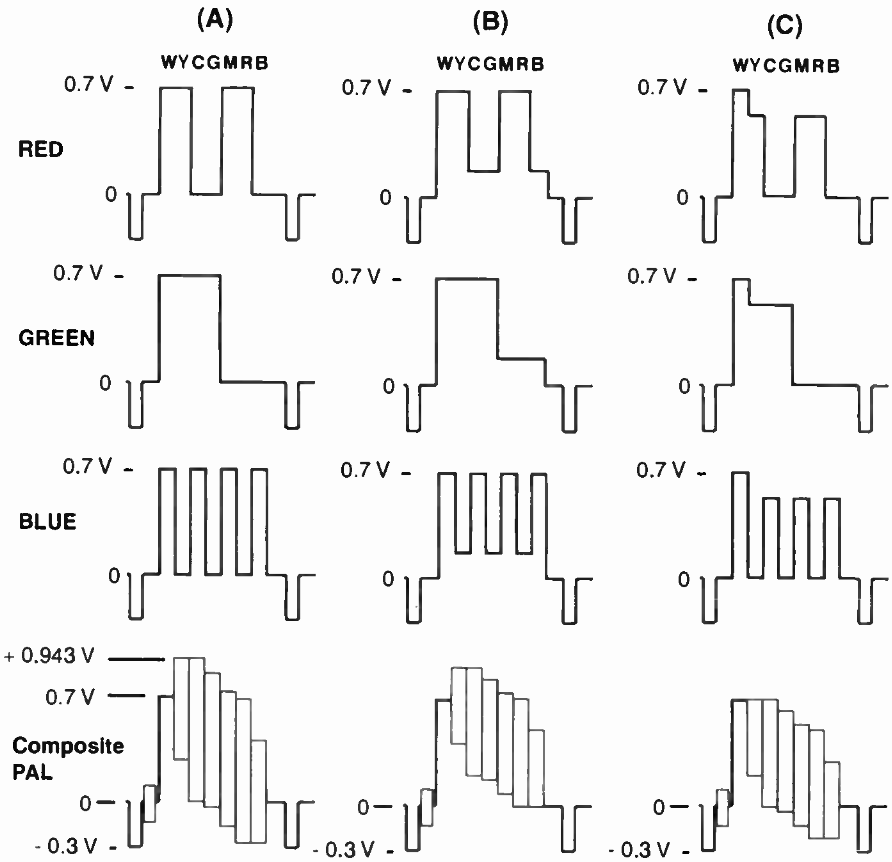

Figure 7.2-1. Examples of color bars nomenclature: (a) 100/0/100/0 color bars, (b) 100/0/100/25 color bars, (c) 100/0/75/0 color bars. *(Courtesy of Snell & Wilcox.)*

black/white) and the remaining 25% containing a combination of −I, white, Q, black and the black set signal (a version of PLUGE).

Chroma gain and chroma phase for picture monitors are usually adjusted by observing the standard encoded color bar signal with the red and green CRT guns switched off. The four visible blue bars are set for equal brightness. The use of the chroma set feature greatly increases the accuracy of this adjustment because it provides a signal with the blue bars to be matched vertically adjacent to each other. Because the bars are adjacent, the eye can easily perceive differences in brightness. This also eliminates effects resulting from shading or purity from one part of the screen to another.

The EIA color bar signal is a matrix test pattern according to RS-189-A, that consists of 75% of the field containing seven (without black) 75% color bars (same as SMPTE) and the remaining 25% containing a combination of −I, white, Q and black.

Conventional Video Measurements

Although there are a number of computer based television signal monitors capable of measuring video, sync, chroma and burst levels (as well as pulse widths and other timing factors), sometimes the best way to see what a signal is doing is to monitor it visually. The waveform monitor and vectorscope are oscilloscopes especially adapted for the video environment. The waveform monitor, like a traditional oscilloscope, operates in a voltage-versus-time mode. While an oscilloscope timebase can be set over a wide range of intervals, the waveform monitor timebase triggers automatically on sync pulses in the conventional TV signal, producing line and field rate sweeps, as well as multiple lines, multiple fields and shorter time intervals. Filters, clamps and other circuits process the video signal for specific monitoring needs. The vectorscope operates in an X-Y voltage-versus-voltage mode to display chrominance information. It decodes the signal in much the same way as a television receiver or a video monitor to extract color information and to display phase relationships. These two instruments serve separate, distinct purposes. Some models combine the functions of both types of monitors in one chassis with a single CRT display. Others include a communications link between two separate instruments.

Beyond basic signal monitoring, the waveform monitor and vectorscope provide a means to identify and analyze signal aberrations. If the signal is distorted, these instruments allow a technician to learn the extent of the problem and to locate the offending equipment.

Although designed for analog video measurement and quality control, the waveform monitor and vectorscope still serve valuable roles in the digital video facility.

Basic Waveform Measurements

Waveform monitors are used to evaluate the amplitude and timing of video signals and to show timing relationships between two or more signals. The familiar color bar pattern is the only signal required for these basic tests. Figure 7.2-2 shows a typical waveform display of color bars. It is important to realize that all color bars are not created equal. Some generators offer a choice of 75% or 100% amplitude bars. Sync, burst and setup amplitudes remain the same in the two color bar signals, but the peak-to-peak amplitudes of high frequency chrominance information and low frequency luminance levels change. The saturation of color, a function of chrominance and luminance amplitudes, remains constant at 100% in both modes. The 75% bar signal has 75% amplitude with 100% saturation. In 100% bars, amplitude and saturation are both 100%.

Chrominance amplitudes in 100% bars exceed the maximum amplitude that should be transmitted. Therefore, 75% amplitude color bars, with no chrominance information exceeding 100 IRE, are the standard amplitude bars for NTSC. In the 75% mode, a choice of 100 or 75 IRE white reference level may be offered. Figure 7.2-3 shows 75% amplitude bars with a 100 IRE white level. Either white level can be used to set levels, but operators must be aware of which signal has been selected. SMPTE bars have a white level of 75 IRE as well as a 100 IRE white flag.

The vertical response of a waveform monitor depends upon filters that process the signal in order to display certain components. The flat response mode displays all components of the signal. A chroma response filter removes luminance and displays only chrominance. The low-pass filter removes chrominance, leaving only low frequency luminance levels in the display. Some monitors include an IRE filter, designed to average-out high-level, fine-detail peaks on a monochrome video signal. The IRE filter aids the operator in setting brightness levels. The IRE response removes most, but not all, of the chrominance.

If the waveform monitor has a dual filter mode, the operator can observe luminance levels and overall amplitudes at the same time. The instrument switches between the flat and low-pass filters. The line select mode is another useful feature for monitoring live signals.

Sync Pulses

The duration and frequency of the sync pulses must be monitored closely for conventional video. Most waveform monitors include 0.5 ms or 1 ms per division magnification (MAG) modes, which can be used to verify H-sync width between 4.4 μs and 5.1 μs. The width is measured at the −4 IRE point. On waveform

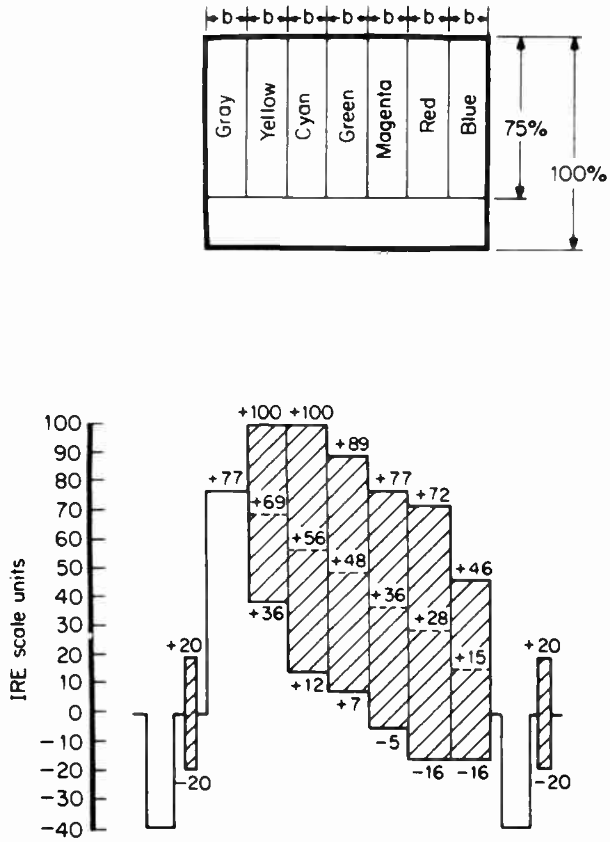

Figure 7.2-3. EIA RS189A color-bar displays: (a) color displays of gray and color bars, (b) waveform display of reference gray and primary/complementary colors, plus sync and burst.

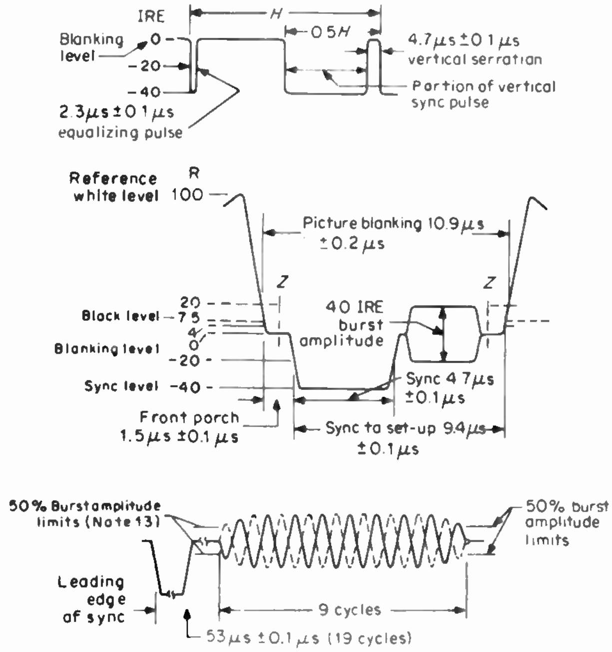

Figure 7.2-4. Sync pulse widths for NTSC.

monitors with good MAG registration, sync appearing in the middle of the screen in the 2 line mode remains centered when the sweep is magnified. Check the rise and fall times of sync and the widths of the front porch and entire blanking interval. Examine burst and verify there are between 8 and 11 cycles of subcarrier.

Check the vertical intervals for correct format, and measure the timing of the equalizing pulses and vertical sync pulses. The acceptable limits for these parameters are shown in Figure 7.2-4.

Basic Vectorscope Measurements

The vectorscope displays chrominance amplitudes, aids hue adjustments and simplifies the matching of burst phases of multiple signals. These functions require only the color bar test signal as an input stimulus. To evaluate and adjust chrominance in the TV signal, observe color bars on the vectorscope. The instrument should be in its calibrated gain position. Adjust the vectorscope phase control to place the burst vector at the 9 o'clock position. Note the vector dot positions with respect to the six boxes marked on the graticule. If everything is correctly adjusted, each dot will fall on the crosshairs of its corresponding box, as shown in Figure 7.2-5.

The chrominance amplitude of a video signal determines the intensity or brightness of color. If the amplitudes are correct, the color dots fall on the crosshairs in the corresponding graticule boxes. If vectors overshoot the boxes, chrominance amplitude is too large; if they undershoot, it is too small. The boxes at each color location can be used to quantify the error. In the radial direction, the small boxes indicate a ±2.5 IRE error from the standard amplitude. The large boxes indicate a ±20% error.

Figure 7.2-5. Vectorscope display of a color bar signal. *(Courtesy of Tektronix.)*

Other test signals, including a modulated staircase or multiburst, are used for more advanced tests. It is important to take a good look at how these signals appear immediately after they come out of the waveform generator. Knowing what the undistorted signal looks like simplifies the identification of distortions.

Line Select Features

Some waveform monitors and vectorscopes have line select capability. They can display one or two lines out of the entire video frame of 525 lines. (In the normal display, all of the lines are overlaid on top of one another.) The principal use of the single line feature is to monitor vertical interval test signals (VITS). VITS allows in-service testing of the transmission system. A typical VITS waveform is shown in Figure 7.2-6. A full field line selector drives a picture monitor output with an intensifying pulse. The pulse causes a single horizontal line on a picture monitor to be highlighted. This indicates where the line selector is within the frame to correlate the waveform monitor display with the picture.

Distortion Mechanisms

The video system should respond uniformly to signal components of different frequencies. In an analog system, this parameter is generally evaluated with a waveform monitor. Different signals are required to check the various parts of the frequency spectrum. If the signals are all faithfully reproduced on the waveform monitor screen after passing through the video system, it is safe to assume that there are no serious frequency response problems.

At very low frequencies, look for externally introduced distortions, such as power line hum or power supply ripple, and distortions resulting from inadequacies in the video processing equipment. Low frequency distortions usually appear on the video image as flickering or slowly varying brightness. Low frequency interference can be seen on a waveform monitor when the dc restorer is set to the slow mode and a 2 field sweep is selected. Sine wave distortion from ac power line hum may be observed in Figure 7.2-7. A bouncing APL signal can be used to detect distortion in the video chain. Vertical shifts in the blanking and sync levels indicate the possibility of low frequency distortion of the signal.

Field rate distortions appear as a difference in shading from the top to the bottom of the picture. A field rate 60 Hz square wave is best suited for measuring field rate distortion. Distortion of this type is observed as a tilt in the waveform in the 2 field mode with the dc restorer off.

Line rate distortions appear as streaking, shading or poor picture stability. To detect such errors, look for tilt in the bar portion of a pulse-and-bar signal. The waveform monitor should be in the 1H or 2H mode with the fast dc restorer selected for the measurement.

The multiburst signal is used to test the high frequency response of a system. The multiburst includes packets of discrete frequencies within the television passband, with the higher frequencies toward the right of each line. The highest frequency packet is at about 4.2

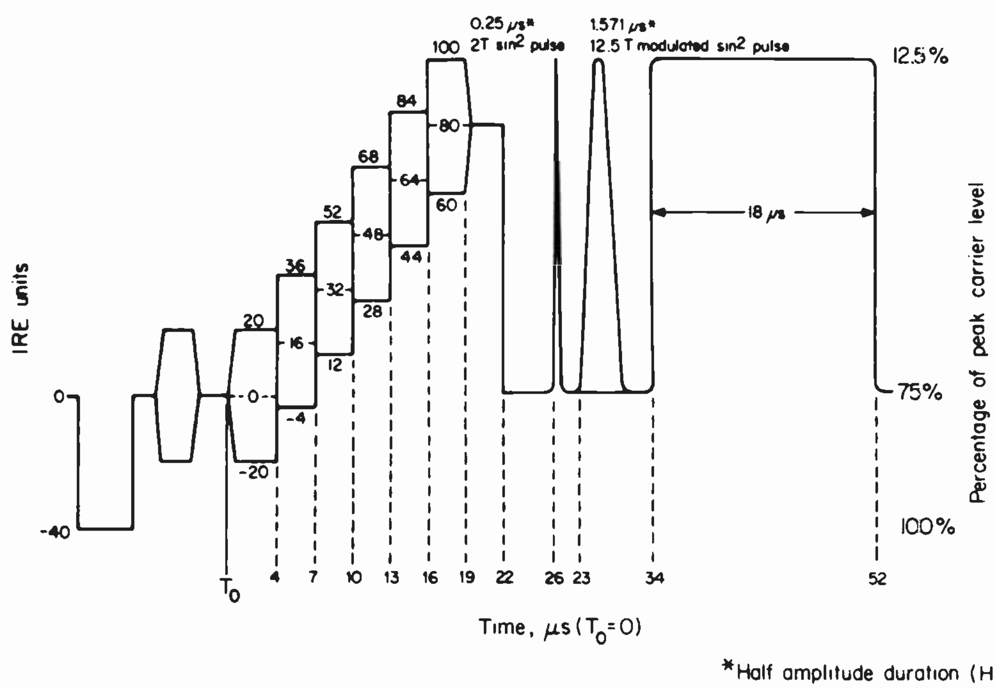

Figure 7.2-6. Composite vertical interval test signal (VITS) inserted in field 1, line 18. The video level in IRE units is shown on the left; the radiated carrier signal is shown on the right.

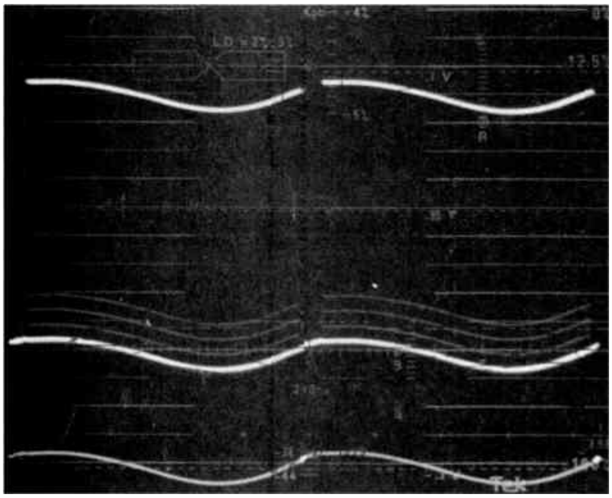

Figure 7.2-7. Waveform monitor display showing additive 60 Hz degradation. *(Courtesy of Tektronix.)*

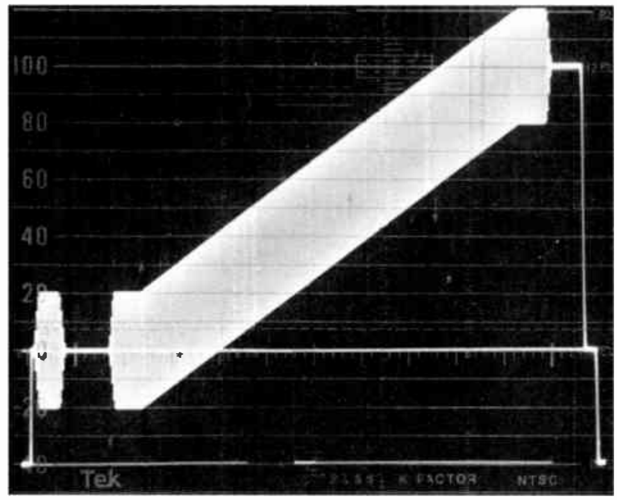

Figure 7.2-9. Waveform monitor display of a modulated ramp signal. *(Courtesy of Tektronix.)*

MHz, the upper frequency limit of the NTSC system. The next packet to the left is near the color subcarrier frequency (3.58 MHz) for checking the chrominance transfer characteristics. Other packets are included at intervals down to 500 kHz. The most common distortion is high frequency rolloff, seen on the waveform monitor as reduced amplitude packets at higher frequencies (see Figure 7.2-8). The television picture exhibits loss of fine detail and color intensity when such impairments are present. High frequency peaking, appearing on the waveform as higher amplitude packets at the higher frequencies, causes ghosting on the picture.

Differential Phase

Differential phase (df) distortion occurs if a change in luminance level produces a change in the chrominance phase. If the distortion is severe, the hue of an object will change as its brightness changes. A modulated staircase or ramp is used to quantify the problem. Either signal places chrominance of uniform amplitude and phase at different luminance levels. Figure 7.2-9 shows a 100 IRE modulated ramp. Because df can change with changes in APL, measurements at the center and at the two extremes of the APL range are necessary.

To measure df with a vectorscope, increase the gain control until the vector dot is on the edge of the graticule circle. Use the phase shifter to set the vector to the 9 o'clock position. Phase error appears as circumferential elongation of the dot. The vectorscope graticule has a scale marked with degrees of df error. Figure 7.2-10 shows a df error of 5°.

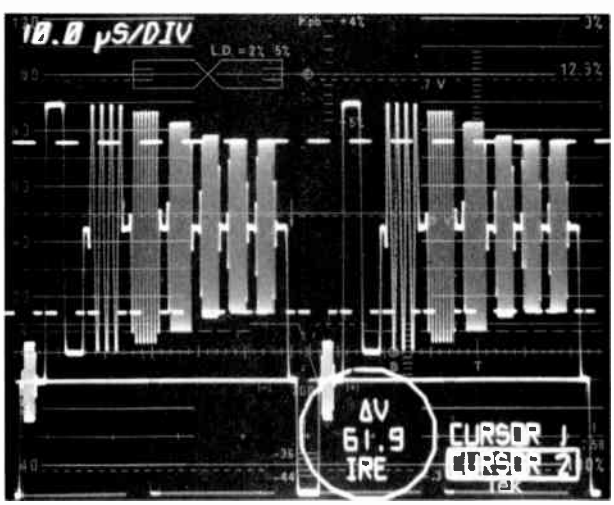

Figure 7.2-8. Waveform monitor display of a multiburst signal showing poor high frequency response. *(Courtesy of Tektronix.)*

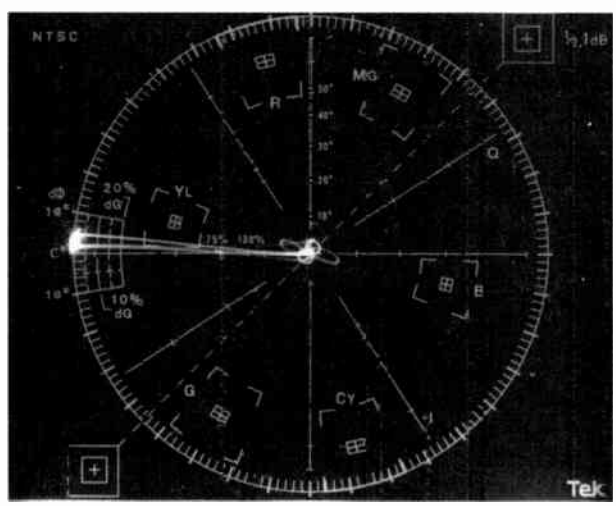

Figure 7.2-10. Vectorscope display showing 5° differential phase error. *(Courtesy of Tektronix.)*

More information can be obtained from a swept R-Y display, which is a common feature of waveform monitor and vectorscope systems. If one or two lines of demodulated video from the vectorscope are displayed on a waveform monitor, differential phase appears as tilt across the line. In this mode, the phase control can be adjusted to place the demodulated video on the baseline, which is equivalent in phase to the 9 o'clock position of the vectorscope. Figure 7.2-11 shows a df error of 5° with the amount of tilt measured against a vertical scale. This mode is useful in troubleshooting applications. By noting where along the line the tilt begins, it is possible to determine at what dc level the problem starts to occur. In addition, field rate sweeps enable the operator to look at df over the field.

A variation of the swept R-Y display may be available in some instruments for precise measurement of differential phase. Highly accurate measurements can be made with a vectorscope that includes a precision phase shifter and a double-trace mode. This method involves nulling the lowest part of the waveform with the phase shifter, then using a separate calibrated phase control to null the highest end of the waveform. A readout in tenths of a degree is possible.

Differential Gain

Differential gain (dG) distortion refers to a change in chrominance amplitude with changes in luminance level. The vividness of a colored object changes with variations in scene brightness. The modulated ramp or staircase is used to evaluate this impairment with the measurement taken on signals at different APL points.

To measure differential gain with a vectorscope, set the vector to the 9 o'clock position and use the variable gain control to bring it to the edge of the graticule circle. Differential gain error appears as a lengthening of the vector dot in the radial direction. The dG scale at the left side of the graticule can be used to quantify the error. Figure 7.2-12 shows a dG error of 10%.

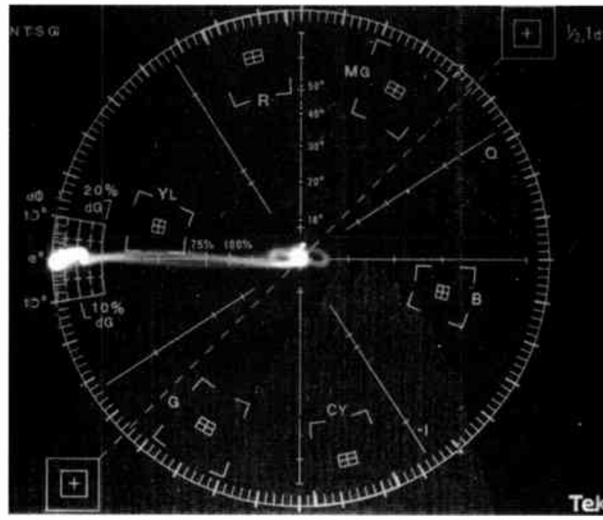

Figure 7.2-12. Vectorscope display of a 10% differential gain error. *(Courtesy of Tektronix.)*

Differential gain can be evaluated on a waveform monitor by using the chroma filter and examining the amplitude of the chrominance from a modulated staircase or ramp. With the waveform monitor in 1H sweep, use the variable gain to set the amplitude of the chrominance to 100 IRE. If the chrominance amplitude is not uniform across the line, there is dG error. With the gain normalized to 100 IRE, the error can be expressed as a percentage. Finally, dG can be precisely evaluated with a swept display of demodulated video. This is similar to the single trace R-Y methods for differential phase. The B-Y signal is examined for tilt when the phase is set so that the B-Y signal is at its maximum amplitude. The tilt can be quantified against a vertical scale.

Automated Video Signal Measurement

Video test instruments based on microcomputer systems provide the maintenance engineer with the ability to rapidly measure a number of parameters with exceptional accuracy. Automated instruments offer a number of benefits, including reduced setup time, test repeatability, waveform storage and transmission capability and remote control of instrument/measurement functions. Typical features of this class of instrument include the following:

- Waveform monitor functions
- Vectorscope monitor functions
- Picture display capability
- Automatic analysis of an input signals
- RS-232 and/or GPIB I/O ports

Figure 7.2-13 shows a block diagram of a representative automated video test instrument. Sample output waveforms are shown in Figure 7.2-14.

(a) (b)

Figure 7.2-14. Automated video test instrument output charts: (a) waveform monitor mode display of color bars, (b) vectorscope mode display of color bars. *(Courtesy of Tektronix.)*

Automated test instruments offer the end-user the ability to observe signal parameters and to make detailed measurements. The instrument depicted in Figure 7.2-13 offers a Measure Mode, in which a captured waveform can be expanded and individual elements of the waveform examined. This instrument provides interactive control of measurement parameters, as well as graphical displays and digital readouts of the measurement results. Figure 7.2-15 illustrates measurement of sync parameters on an NTSC waveform.

Another feature of many automated video measurement instruments is the ability to set operational limits and parameters that—if exceeded—are brought to the attention of an operator. In this way, operator involvement is required only if the monitored signal varies from certain preset limits. Figure 7.2-16 shows an example error log.

				Violated Limits Lower	Upper

Applications of the Zone Plate Signal

The increased information content of advanced high-definition display systems requires sophisticated processing to make recording and transmission practical.[3] This processing uses various forms of bandwidth compression, scan-rate changes, motion-detection and motion-compensation algorithms and other techniques. Zone plate patterns are well suited to exercising a complex video system in the three dimensions of its signal spectrum: horizontal, vertical and temporal. Zone plate signals, unlike most conventional test signals, can be complex and dynamic. As a result, they are capable of simulating much of the detail and movement of actual video, exercising the system under test with signals representative of the intended application. These digitally generated and controlled signals also have other important characteristics needed in test waveforms for video systems.

A signal intended for meaningful testing of a video system must be carefully controlled, so that any departure from a known parameter of the signal is attributable to a distortion or other change in the system under test. The test signal also must be predictable, so that it can be accurately reproduced at other times or places. These constraints usually have led to test signals that are electronically generated. In a few special cases, a standardized picture has been televised by a camera or monoscope—usually for a subjective, but more detailed, evaluation of overall performance of the video system.

A *zone plate* is a physical optical pattern, which was first used by televising it in this way. Now that electronic generators are capable of producing similar patterns, the label zone plate is applied to the wide variety of patterns created by video test instruments.

Conventional test signals, for the most part limited by the practical considerations of electronic generation, have represented relatively simple images. Each signal is capable of testing a narrow range of possible distortions; several test signals are needed for a more complete evaluation. Even with several signals, this method may not reveal all possible distortions or allow study of all pertinent characteristics. This is true especially in video systems employing new forms of sophisticated signal processing.

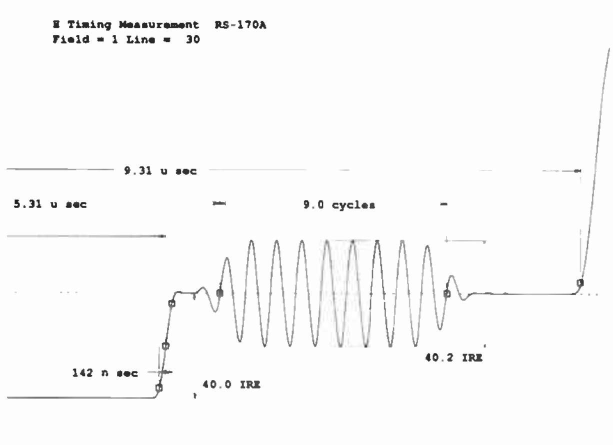

Figure 7.2-15. Expanded view of a sync waveform with measured parameters. *(Courtesy of Tektronix.)*

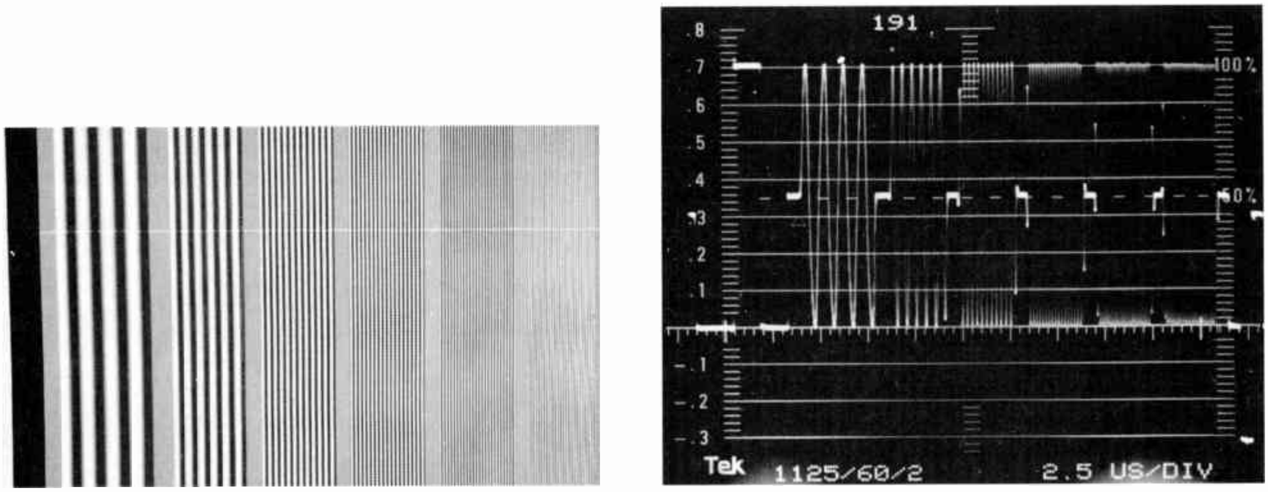
Simple Zone Plate Patterns

The basic testing of a video communication channel historically has involved the application of several single frequencies—in effect, spot-checking the spectrum of interest.[3] A well-known and quite practical adaptation of this idea is the *multiburst signal*, shown in Figure 7.2-17. This test waveform has been in use since the earliest days of video. The multiburst signal provides several discrete frequencies along a TV line. Figure 7.2-17(a) and other photographs in this section, show the beat effects introduced by the screening process used for photographic printing. This is largely unavoidable. The screening process is quite similar to the scanning or sampling of a television image—the patterns are designed to identify this type of problem.

The frequency-sweep signal is an improvement on multiburst. Although harder to implement in earlier generators, it was easier to use. The frequency-sweep signal, illustrated in Figure 7.2-18, varies the applied



(a) (b)

Figure 7.2-17. Multiburst video test waveform: (a, left) picture display, (b, right) multiburst signal as viewed on a waveform monitor (1H). *(Courtesy of Tektronix.)*

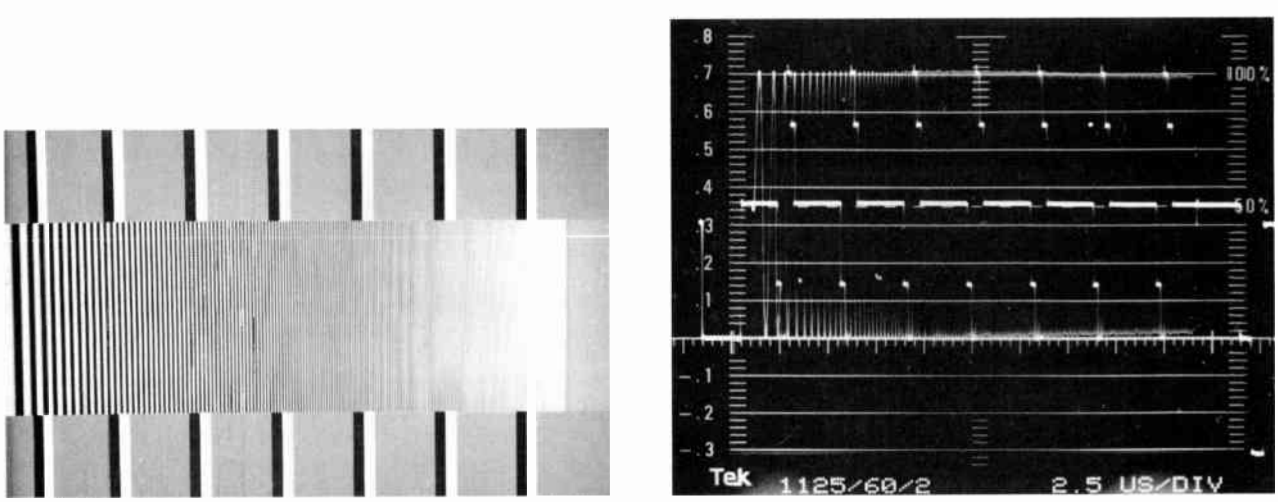
signal frequency continuously along the TV line. In some cases, the signal is swept as a function of the vertical position (field time). Even in these cases, the signal being swept is appropriate for testing the spectrum of the horizontal dimension of the picture.

Figure 7.2-19 shows the output of a zone plate generator configured to produce a horizontal single frequency output. Figure 7.2-20 shows a zone plate generator configured to produce a frequency-sweep signal. Electronic test patterns, such as these, may be used to evaluate the following system characteristics:

- Channel frequency response
- Horizontal resolution
- Moiré effects in recorders and displays
- Other impairments

Traditionally, patterns that test vertical (field) response have been less frequently used. As new technologies implement conversion from interlaced to progressive scan, line-doubling display techniques, vertical antialiasing filters, scan conversion, motion detection or other processes that combine information from line-to-line, vertical testing patterns will be more in demand.

In the vertical dimension, as well as the horizontal, tests may be done at a single frequency or with a frequency-sweep signal. Figure 7.2-21 illustrates a magnified vertical-rate waveform display. Each dash in the photo represents one horizontal scan line. Sampling of vertical frequencies is inherent in the scanning process, and the photo shows the effects on the signal waveform. Note also that the signal voltage remains



(a) (b)

constant during each line, changing only from line-to-line in accord with the vertical dimension sine function of the signal. Figure 7.2-22 shows a vertical frequency-sweep picture display.

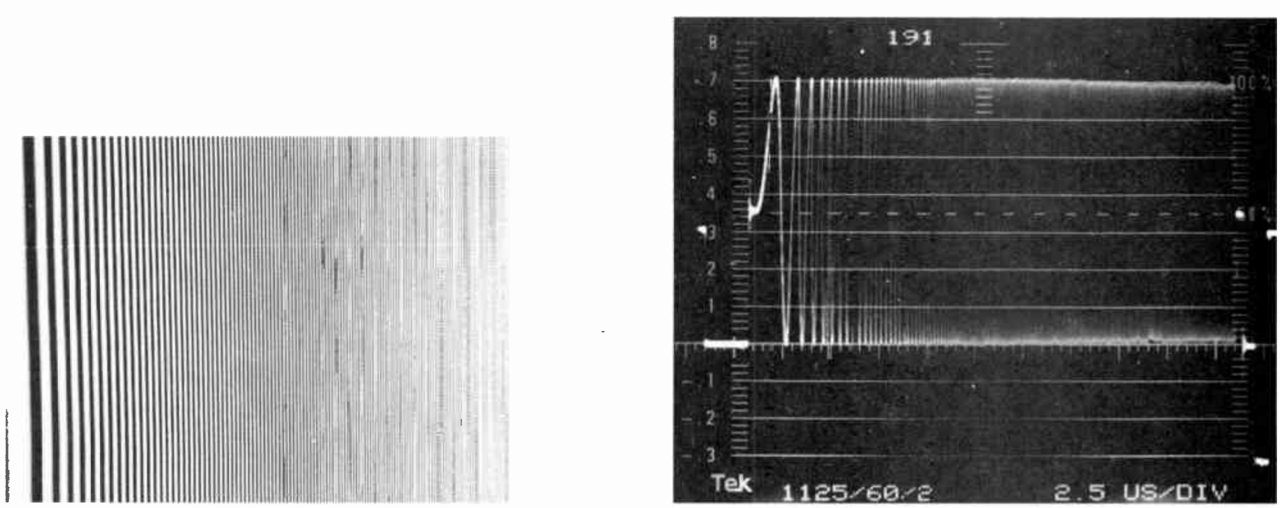
The horizontal and vertical sine waves and sweeps are quite useful, but they do not use the full potential of a zone plate signal source.

Producing the Zone Plate Signal

A zone plate signal is created in real time by a test signal generator.[3] The value of the signal at any instant is represented by a number in the digital hardware. This number is incremented as the scan progresses through the three dimensions that define a point in the video image: horizontal position, vertical position and time.

The exact method by which these dimensions alter the number is controlled by a set of coefficients. These coefficients determine the initial value of the number and control the size of the increments as the scan progresses along each horizontal line, from line-to-line vertically and from field-to-field temporally. A set of coefficients uniquely determines a pattern, or a sequence of patterns, when the time dimension is active.

This process produces a sawtooth waveform; overflow in the accumulator holding the signal number effectively resets the value to zero at the end of each cycle of the waveform. Usually, it is desirable to minimize the harmonic energy content of the output signal; in this case, the actual output is a sine function of the number generated by the incrementing process.



(a) (b)

Complex Patterns

A pattern of sine waves or sweeps in multiple dimensions may be produced, using the unique architecture of the zone plate generator.[3] The pattern shown in Figure 7.2-23, for example, is a single signal sweeping both horizontally and vertically. Figure 7.2-24 shows the waveform of a single selected line (line 263 in the 1125/60/2 HDTV system). Note that the horizontal waveform is identical to the one shown in Figure 7.2-18(b), even though the vertical dimension sweep is now also active. Actually, different lines will give slightly different waveforms. The horizontal frequency and sweep characteristics will be identical, but the starting phase must be different from line-to-line to construct the vertical signal.

Figure 7.2-25 shows a 2-axis sweep pattern that is most often identified with zone plate generators, perhaps because it quite closely resembles the original optical pattern. In this circle pattern, both horizontal and vertical frequencies start high, sweep to zero (in the center of the screen), and sweep up again to the end of their respective scans. The concept of 2-axis sweeps actually is more powerful than it might first appear. In addition to purely horizontal or vertical effects, there are possible distortions or artifacts that are apparent only with simultaneous excitation in both axes. In other words, the response of a system to diagonal detail may not be predictable from information taken from the (individual) horizontal and vertical responses.

The Time (Motion) Dimension

Incrementing the number in the accumulator of the zone plate generator from frame-to-frame (or field-to-field in an interlaced system) creates a predictably different pattern for each vertical scan.[3] This, in turn, creates apparent motion and exercises the signal spectrum in the temporal dimension. Analogous to the single frequency and frequency-sweep examples given previously, appropriate setting of the time-related coefficients will create constant motion or motion sweep (acceleration).

Specific motion-detection and interpolation algorithms in a system under test may be exercised by determining the coefficients of a critical sequence of patterns. These patterns then may be saved for subsequent testing during development or adjustment. In an operational environment, appropriate response to a critical sequence could ensure expected operation of the equipment or facilitate fault detection.

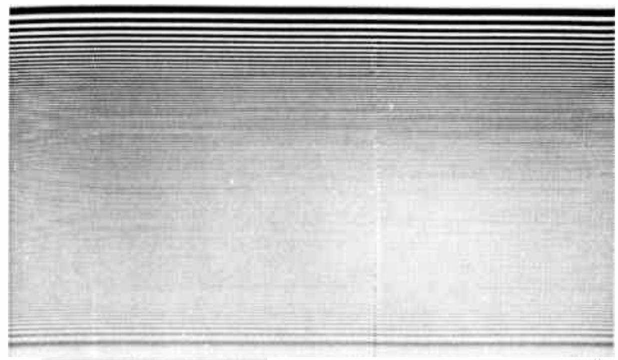

Figure 7.2-26. Vertical frequency-sweep picture display. *(Courtesy of Tektronix.)*

Although motion artifacts are difficult to portray in the still-image constraints of a printed book, the following example gives some idea of the potential of a versatile generator. In Figure 7.2-26, the vertical sweep maximum frequency has been increased to the point where it is zero-beating with the scan at the bottom of the screen. (The cycles/ph of the pattern matches the lines/ph per field of the scan.) Actually, in direct viewing, there is another noticeable artifact in the vertical center of the screen: a harmonic beat related to the gamma of the display CRT. Because of interlace, this beat flickers at the field rate. The photograph integrates the interfield flicker, thereby hiding the artifact, which is readily apparent when viewed in real time.

Figure 7.2-27 is identical to the previous photo, except for one important difference-upward motion of 1/2-cycle per field has been added to the pattern. Now the sweep pattern itself is integrated out, as is the first-order beat at the bottom. The harmonic effects in center screen no longer flicker, because the change of scan vertical position from field-to-field is compensated by a change in position of the image. The resulting beat pattern does not flicker and is easily photographed or, perhaps, scanned to determine depth of modulation.

A change in coefficients produces hyperbolic, rather than circular 2-axis patterns, as shown in Figure 7.2-28. Another interesting pattern, which has been used for checking complex codecs, is shown in Figure 7.2.29. This is also a moving pattern, which was altered slightly to freeze some aspects of the movement for the purpose of taking the photograph.

Display Measurement Techniques

A number of different techniques have evolved for measuring the static performance of picture display devices and systems.[4] Most express the measured device performance in a unique figure of merit or metric. Although each approach provides useful information, the lack of standardization in measurement techniques

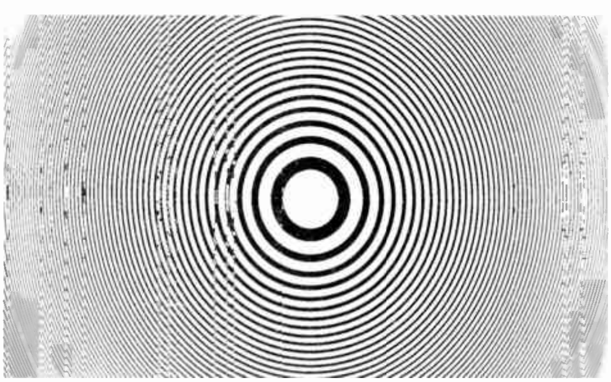

Figure 7.2-25. The best known zone plate pattern, combined horizontal and vertical frequency-sweeps with zero frequency in the center screen. *(Courtesy of Tektronix.)*

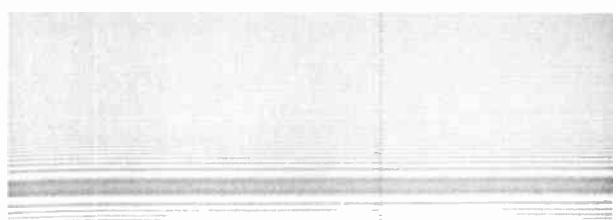

Figure 7.2-27. The same vertical sweep as shown in Figure 7.2-26, except that appropriate pattern motion has been added to freeze the beat pattern in the center screen for photography or other analysis. *(Courtesy of Tektronix.)*

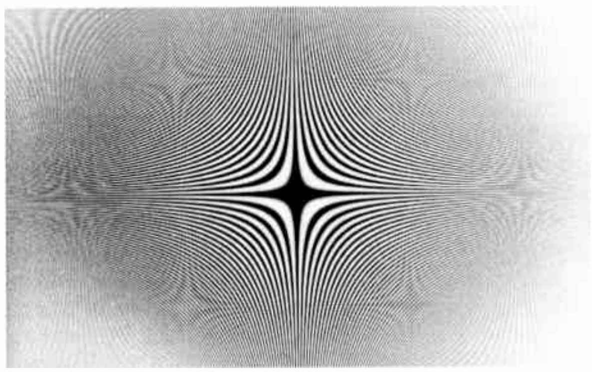

Figure 7.2-28. A hyperbolic variation of the 2-axis zone plate frequency-sweep. *(Courtesy of Tektronix.)*

makes it difficult or even impossible to directly compare the performance of a given class of devices.

Regardless of the method used to measure performance, the operating parameters must be set for the anticipated operating environment. Key parameters include:

- Input signal level
- System/display line rate
- Luminance (brightness)
- Contrast
- Image size
- Aspect ratio

If the display is used in more than one environmental condition-such as under day and night conditions-a set of measurements is appropriate for each application.

Viewing Environment Considerations

The environment in which a video display device is viewed is an important criterion for critical viewing situations. Applications in which color purity and adherence to set standards are important require a standardized (or at least consistent) viewing environment.

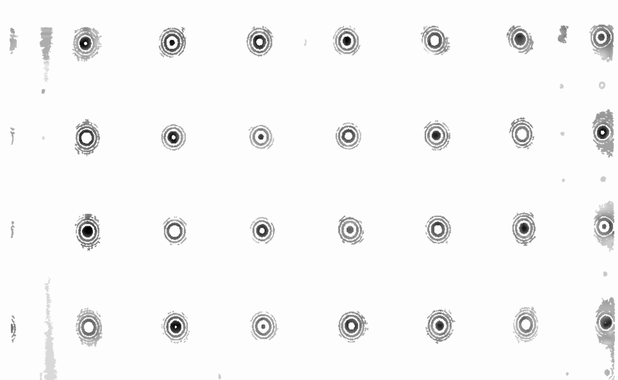

Figure 7.2-29. A 2-axis frequency sweep in which the range of frequencies is swept several times in each axis. Complex patterns such as this may be created for specific test requirements. *(Courtesy of Tektronix.)*

For example, textile colors viewed on a display with a white surround will appear different than the same colors viewed with a black surround. By the same token, different types of ambient lighting will make identical colors appear different on a given display.

SMPTE has addressed this issue with recommended practice (RP) 166-1995, which specifies the environmental and surround conditions that are required in television or video program review areas for the "consistent and critical evaluation" of conventional television signals.[5] Additionally, the practice is designed to provide for repeatable color grading or correction. A number of important parameters are specified in RP 166-1995, including the following:

- The distance of the observer from the monitor screen should be 4 to 6 picture heights for SDTV displays
- The observer should view the monitor screen at a preferred angle in both the horizontal and vertical planes of 0° ± 5° and, in any event, no greater than ±15° from the perpendicular to the midpoint of the screen
- The viewing area decor should have a generally neutral matte impression, without dominant colors
- Surface reflectances should be nonspecular and should not exceed 10% of the peak luminance value of the monitor white.

The *Recommended Practice* suggests placing the monitor in a freestanding environment 2.5-5 screen heights in front of the wall providing the visual surround. Another acceptable approach is to mount the monitor in a wall with its face approximately flush with the surface of the wall. It is further recommended that all light sources in use during picture assessment or adjustment have a color quality closely matching the monitor screen at reference white (D65).

It is often necessary to have black-and-white monitors surrounding one or more color monitors in a studio control room. According to RP 166-1995, the black-and-white monitors should be the same color temperature as the properly adjusted color monitors, 6500 K. Black-and-white monitors are normally equipped with P4 phosphors, at about 9300 K. This cooler color temperature prevents the background surrounding the color monitors from remaining neutral. Most black-and-white monitors can be ordered with 6500 K phosphors.

Picture Monitor Alignment

The proper adjustment and alignment of studio picture monitors is basic to video quality control. Uniform alignment throughout the production chain also ensures consistency in color adjustment, which facilitates the matching of different scenes within a program that may be processed at different times and in different facilities. SMPTE has addressed this requirement for conventional video through RP 167-1995. The *Recommended Practice* offers a step-by-step process by which color monitors can be set. Key elements of RP 167-1995 include the following.[6]

- **Initial conditions.** Setup includes allowing the monitor to warm up and stabilize for 20 to 30 minutes. The room ambient lighting should be the same as it is when the monitor is in normal service, and several minutes must be allowed for visual adaptation to the operating environment.
- **Initial screen adjustments.** The monitor is switched to the setup position, in which the red, green and blue screen controls are adjusted individually so that the signals are barely visible.
- **Purity.** Purity, the ability of the gun to excite only its designated phosphor, is checked by applying a low-level flat-field signal and activating only one of the three guns at a time. The display should have no noticeable discolorations across the face.
- **Scan size.** The color picture monitor application establishes whether the overscan or underscan presentation of the display will be selected. An underscanned display is one in which the active video (picture) area, including the corners of the raster, is visible within the screen mask. Normal scan brings the edges of the picture tangent to the mask position. Overscan should be no more than 5%.
- **Geometry and aspect ratio.** Display geometry and aspect ratio are adjusted with the crosshatch signal by scanning the display device with the green beam only. Correct geometry and linearity are obtained by adjusting the pincushion and scan-linearity controls so that the picture appears without evident distortions from the normal viewing distance.
- **Focus.** An ideal focus target is available from some test signal generators; if it is unavailable, multiburst, crosshatch or white noise can be used as tools to optimize the focus of the displayed picture.
- **Convergence.** Convergence is adjusted with a crosshatch signal; it should be optimized for either normal scan or underscan, depending upon the application.
- **Aperture correction.** If aperture correction is used, the amount of correction can be estimated visually by ensuring that the 2T pulse has the same brightness as the luminance bar or the multiburst signal when the 3 and 4.2 MHz bursts have the same sharpness and contrast.
- **Chrominance amplitude and phase.** The chrominance amplitude and phase are adjusted using the SMPTE color bar test signal and viewing only the blue channel. Switching off the comb filter, if it is present, provides a clear blue channel display. Periodically, the red and green channels should be checked individually in a similar manner to verify that the decoders are working properly.[9]
- **Brightness, color temperature and gray scale tracking.** The 100-IRE window signal is used to supply the reference white. Because of typical luminance shading limitations, a centrally placed PLUGE signal is recommended for setting the monitor brightness control.[10] The black set signal provided in the SMPTE color bars also can be used for this purpose.
- **Monitor matching.** When color matching two or more color monitors, the same alignment steps should be performed on each monitor in turn. Remember, however, that monitors cannot be matched without the same phosphor sets, similar display uniformity characteristics and similar sharpness. The most noticeable deviations on color monitors are the lack of uniform color presentations and brightness shading. Color matching of monitors for these parameters can be most easily assessed by observing flat-field uniformity of the picture at low, medium and high amplitudes.[6]

As more experience is gained with DTV based systems, operating parameters such as those detailed in this section will no doubt be updated to take into consideration the unique attributes and requirements of HDTV.

Picture-Quality Measurements for Digital Television

Picture quality measurement methods include subjective testing, that is always used-at least in an informal manner-and objective testing, which is most suitable for system performance specification and evaluation.[7] A number of types of objective measurement methods are possible for digital television pictures, but those using a human visual system model are the most powerful.

As illustrated in Figure 7.2-30, three key testing layers can be defined for the modern television system:

- **Video quality.** This consists of signal quality and picture quality.
- **Protocol analysis.** Protocol testing is required because the data formatting can be quite complex and is relatively independent of the nature of the uncompressed signals or the eventual conversion to interfacility transmission formats. Protocol test equipment can be both a source of signals and an analyzer that locates errors with respect to a defined standard and determines the value of various operational parameters for the stream of data.
- **Transmission system analysis.** To send the video data to a remote location, one of many possible digital data transmission methods may be used, each of which imposes its own analysis issues.

Table 7.2-1 lists several dimensions of video quality measurement methods. Key definitions include the following:

- **Subjective measurements.** The result of human observers providing their opinions of the video quality.
- **Objective measurements.** Performed with the aid of instrumentation, manually with humans reading a calibrated scale or automatically using a mathematical algorithm.
- **Direct measurements.** Performed on the material of interest, in this case, pictures (also known as picture-quality measurements).
- **Indirect measurements.** Made by processing specially designed test signals in the same manner as the pictures (also known as signal quality measurements). Subjective measurements are performed only

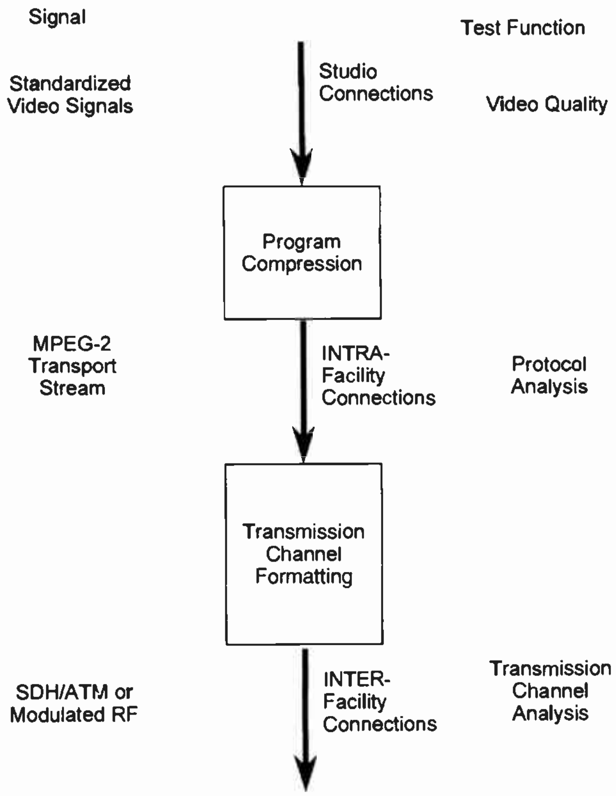

Figure 7.2-30. Video testing layers for digital television.[7]

in a direct manner because the human opinion of test signal picture quality is not particularly meaningful.
- **In-service measurements.** Made while the program is being displayed, directly by evaluating the program material or indirectly by including test signals with the program material.
- **Out-of-service.** Appropriate test scenes are used for direct measurements and full-field test signals are used for indirect measurements.

In the mixed environment of compressed and uncompressed signals, video quality measurements consist of two parts: signal quality and picture quality.

Signal/Picture Quality

Signal quality measurements are made with a suite of test signals as short as one line in the vertical interval.[7] In a completely uncompressed system, such testing will give a good characterization of picture quality. This is not true, however, for a system with compression encoding/decoding because picture quality will change based on the data rate, complexity, and encoding algorithm. Picture quality measurements, instead, require natural scenes (or some equivalent thereof) that are much more complex than traditional test signals. These complex scenes stress the capabilities of the encoder, resulting in nonlinear distortions that are a function of the picture content.

Out-of-service picture quality measurements are similar to indirect signal quality measurements in one aspect: the determination of the system response to a high quality reference. However, they actually measure the degradation in reference picture quality rather than that of a synthetic test signal. In-service, such signals determine the response to program material and its degradation through the system. If the program material is easy, the measurement may not have a great deal of practical value.

Objective indirect signal quality measurements are a reasonably good way to determine the picture quality for uncompressed systems. That is, there is a good correlation between subjective measurements made on pictures from the system and objective measurements made on a suite of test signals using the same system (see Figure 7.2-31). The correlation is not perfect for all tests, however. There are distortions in composite systems, such as false color signals caused by poorly filtered high frequency luminance information being detected as chroma. These distortions are not easily measured by objective means. Also, there are objective measurements that are so sensitive they do not directly relate to subjective results. However, such objective results often are useful because their effect will be seen by a human observer if the pictures are processed in the same way a number of times.

The use of digital compression has expanded the types of distortions that can occur in the modern television system. Because signal quality measurements will not do the job, objective picture quality measurements are needed, as illustrated in Figure 7.2-32. The total picture quality measurement space has increased because of subjective measurements that now include

Table 7.2-1
Video Quality Definitions.[7]

Parameter	In-Service	Out-of-Service
Indirect measurement		
Objective signal quality	Vertical interval test signals	Full-field test signals
Direct measurement		
Subjective picture quality	Program material	Test scenes
Objective picture quality	Program material	Test scenes

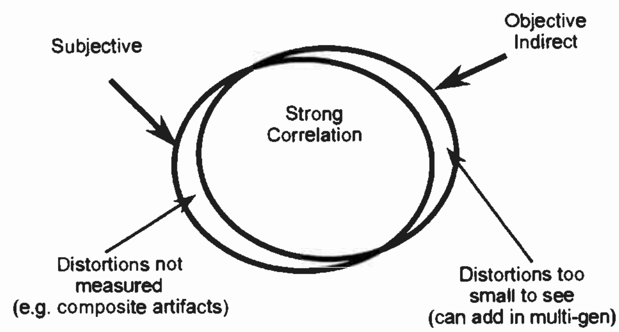

Figure 7.2-31. Functional environment for traditional video measurements.[7]

multi-minute test scenes with varying program material and variable picture quality. The new objective measurement methods must have strong correlation with subjective measurements and cover a broad range of applications.

Even with all the objective testing methods available for analog and full bandwidth digital video, it is important to have human observation of the pictures. Some impairments are not easily measured, yet are obvious to a human observer. This situation certainly has not changed with the addition of modern digital compression. Therefore, casual or informal subjective testing by a reasonably expert viewer remains an important part of system evaluation and/or monitoring.

Automated Picture Quality Measurement

Objective measurements can be made automatically with an instrument that determines picture degradation through the system.[7] Two somewhat mutually exclusive ways are available for classifying objective picture quality measurement systems. Although there are several practical methods with a variety of algorithmic approaches, they may be divided into the following classes:

- **Feature extraction.** An essentially independent analysis of input and output pictures.
- **Picture processing.** The complete input and output pictures are directly compared in some manner and must be available at the measurement instrument.

From a system standpoint, the *glass box* approach utilizes knowledge of the compression system to measure degradation. An example would be looking for blockiness in a DCT system. The *black box* approach makes no assumptions about operation of the system.

In feature extraction, analysis time is reduced by comparing only a limited set of picture characteristics.

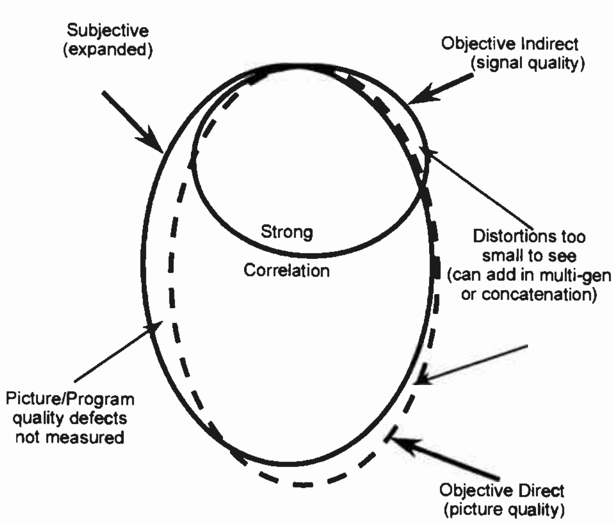

Figure 7.2-32. Functional environment for digital video measurements.[7]

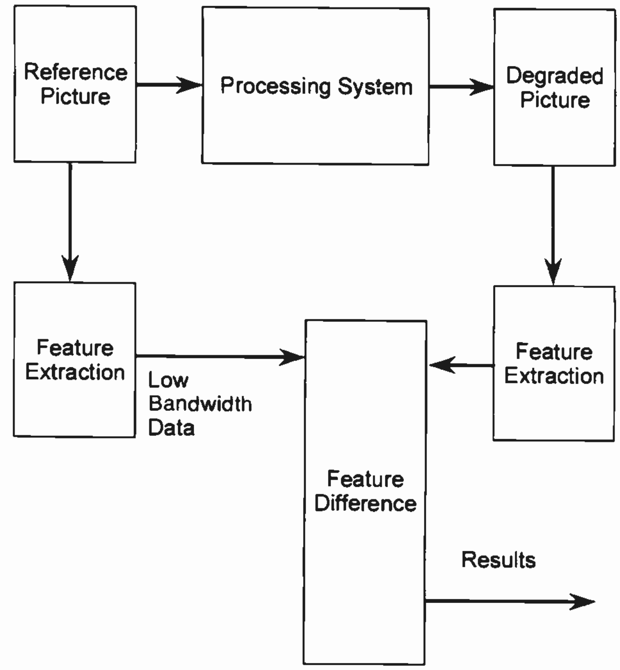

Figure 7.2-33. Block diagram of the feature-extraction method of picture-quality analysis.[11]

These characteristics are calculated and the modest amount of data is embedded into the picture stream. Examples of compression impairments would be block distortion, blurring/smearing or mosquito noise. At the receiver, the same features of the degraded picture are calculated, providing a measure of the differences for each feature (see Figure 7.2-33). The major weakness of this approach is that it does not provide correlation between subjective and objective measurements across a wide variety of compression systems or source material. For the picture processing scheme, the reference and degraded pictures are filtered in an appropriate manner, resulting in a data set that may be as large as the original pictures. The difference between the two data sets is a measure of picture degradation, as illustrated in Figure 7.2-34.

The need for a standard for objective measurements has been addressed in ANSI T1.801.03.[8] (See reference 7 for several variations and improvements to the basic ANSI toolbox.) Because of the limitations of the ANSI method, work continues with the goal of refining objective measurement methods.

A number of approaches have been proposed by researchers using the human visual system (HVS) model as a basis. Such a model provides an image quality metric that is independent of video material, specific types of impairments and the compression system used. The study of the HVS has been going on for decades, investigating such properties as contrast sensitivity, spatio-temporal response and color perception. Perhaps one of the best-known derivatives of this work is the JNDmetrix (Sarnoff/Tektronix).[9]

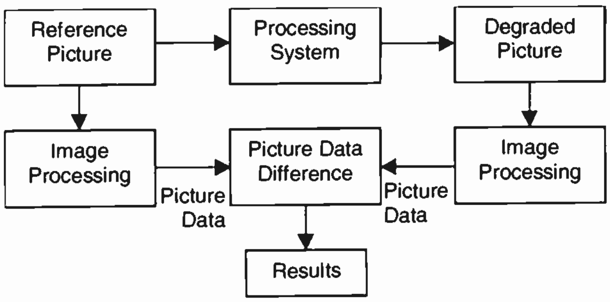

Figure 7.2-34. Block diagram of the picture differencing method of picture-quality analysis.[11]

Serial Digital Bit Stream Analysis

The creation, processing, storage and transmission of video in a digital form has numerous, well-documented advantages over analog signals. It is no surprise, therefore, that use of the serial digital interface (SDI) and serial digital transport interface (SDTI) extension to move signals within and among facilities is increasing every year, to the point now where it is commonplace. As with all good things, however, there are a few hidden problems lurking in the background.

Specifications for the interconnection of digital video signal paths are established with the purpose of setting limits for deviation that will permit proper operation under a variety of conditions. Like analog signal specifications, digital signal specs also establish the limits within which the sending equipment must operate and the receiving equipment must accept.[10] In the digital environment, small violations of the specified limits will usually cause no detrimental affect in the resulting image; this is the nature of digital information transfer, and one of its better known attributes.

The SDI, naturally, concerns itself with transfer of data from one point to another. It follows, then, that three elements must be considered in an analysis of system reliability:

- Transmitter
- Receiver
- Interconnecting medium

If we accept that professional digital video products meet the required SDI specifications (a fair assumption), then the interconnecting medium must be the focus of attention when SDI system design and maintenance is concerned. Given the foregoing, the point of attention is the receiver, or more correctly put, the signal delivered to the input terminals of the receiver.

A digital receiving device has a latitude of acceptable variation within which reliable recovery of data will occur (see Figure 7.2-35). Variations within the high state and low state (as shown) will cause no lost information. Variations greater that the stated specifications may also permit complete information recovery if the performance of the receiver is superior to the nominal (minimum and/or maximum) specification. However, as the state change excursions extend beyond the low state and high state tolerance bands, the performance of the receiver will become unpredictable. Eventually, catastrophic errors will be generated that cannot be masked or recovered by the system.

Reliable operation of a video facility dictates that safety margins be measured and documented, and-in some cases-monitored on a prescribed schedule. The latter case would apply to mission critical links, such as inter-facility lines that would take the plant down if they failed. Also, systems subject to physical stress, such as remote truck equipment, would qualify for regular signal quality analysis.

SMPTE RP 259M

SMPTE RP 259M, the 10 bit 4:2:2 component digital video protocol, produces a signal of 270 Mbps. RP 259M, thus, provides all of the bandwidth necessary to accommodate 8 or 10-bit ITU-R Rec. 601 video, with audio if required, in real time and using conventional 75 Ω coaxial cable.[11] (See reference 12 for the specifications for SMPTE 259M.) Key among the specifications are the peak-to-peak value of 0.8 V and the rise time (transition time) of 0.75 to 1.5 ns. If the signal transmission path had infinite bandwidth and no group delay, the 259M signal would appear as a perfect square wave pulse train. No path is ideal, of course, and herein lies the potential for problems.

As stated previously, the weak link in an SDI system is the path from the transmitter to the receiver, typically several runs of coax interconnected through a router and/or patch bay. The cable itself represents the greatest problem potential when long path lengths are required. Coax can be modeled as an infinite network of inductive and resistive components in series, with distributed shunt capacitance. This, in effect, describes a low-pass filter whose poles increase in number and whose corner frequency moves closer to zero with extending length. Such attenuation with increasing frequency and distance can deteriorate the SDI signal to the point that it becomes unusable.

It is intuitive that different video signals result in different data patterns in a digital system. Consider the case of successive "ones," as illustrated in Figure 7.2-36. This condition results in a true square wave of 50% duty cycle (due to the encoding specified by

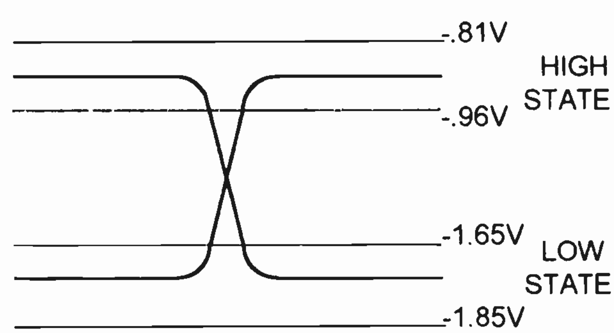

Figure7.2-35. Example of valid data acceptance bands for a digital signal.[10]

RP 259M). Real-life video, of course, results in a unpredictable variety of ones and zeros, producing-in effect-rectangular square waves whose duty cycle is less than 50%.[13] This condition requires a more dense spectrum of harmonics to property define. It follows that considerable low and high frequency harmonics will be present in the SDI signal (significant energy can extend to beyond 1 GHz).

Jitter

Jitter is a related distortion mechanism that may be observed in the SDI/SDTI signal. Jitter is defined as the difference in timing between where a data transition should occur and where it actually does occur. As illustrated in Figure 7.2-37, imperfections in the generation and transmission of the data stream can result in displacement of the transition points to either before or after their proper locations. This timing offset can remain relatively stable, or oscillate between two or more points in time. The latter case is what most engineers consider to be jitter. Minimizing jitter is critical to the performance of SDI based systems.

In order for the receiver to be able to decode the logic levels of the SDI signal, a clock is recovered from the data stream. This recovered clock is used to facilitate decoding of the received data. Because the data transfer is asynchronous, sufficiently large variations in time can result in received data being incorrectly interpreted. Lost data is the result.

The Serial Digital Cliff

Generally speaking, the recovered signal from an SDI/SDTI link is either perfect or basically worthless. An SDI link that is experiencing zero errors, or just a few errors, is considered to be on the operational plateau of the SDI reliability curve. As the link is extended or the S/N otherwise degrades, the system moves forward to the error cliff. As the link progresses over the knee of this cliff, errors climb rapidly to a point sufficient to swamp error control mechanisms built into the SDI system. The path, thus, becomes unusable. Avoiding this well-documented cliff effect requires careful attention to system planning, installation, maintenance and on-going quality control.

Measurement of the S/N of the principle spectral elements in the SDI bit stream is an effective way to

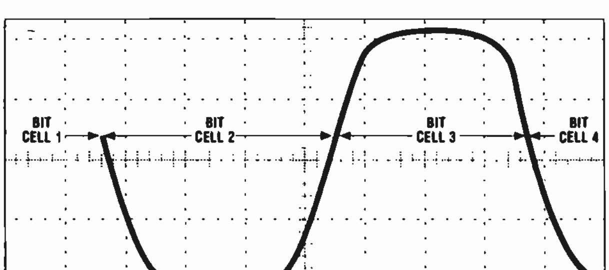

Figure 7.2-36. A portion of a SMPTE 259M datastream showing three successive ones.[13]

determine how far a path is from the error cliff. For ITU-R Rec. 601 SDI, experience has shown that there are two spectral components whose S/N values are useful in determining the overall health of the link.[17] These are the fundamental frequency of 135 MHz and its third harmonic (405 MHz). It should be noted that because of the coding method used, the fundamental frequency for a component SDI link is not 270 Mbps, but one-half of that value (135 Mbps).[13]

The third harmonic is easy to observe with a spectrum analyzer. At the output of most SDI drivers, the third harmonic starts approximately 35 dB above the noise floor. This compares with the fundamental 135 MHz frequency at 45 to 50 dB above noise. Tests demonstrate that after this signal has passed through approximately 300 meters (1,000 ft) of high quality coaxial cable, the third harmonic is typically down to 8 to 10 dB above the noise floor. As the third harmonic signal approaches 6 dB above the noise floor, clock recovery becomes unreliable and large numbers of errors begin to occur.

As the error cliff is approached, the displayed error rate at the receiver may increase from one per day to one per frame over a S/N range difference of just 3 dB or less. Such a link can become unusable even though the level of the fundamental experiences only modest attenuation through the path.

Pathological Testing

There are a number of tools that can be useful in determining how close a path is to the knee of the cliff. One readily available method is the use of pathological test signals. As outlined previously, the receiver circuitry of an SDI/SDTI link must regenerate the clock signal. To facilitate decoding, most SDI receivers incorporate a signal equalizing circuit to boost the high frequencies of the incoming waveform. This permits easier clock regeneration and data-value determination. Pathological test signals produce bitstreams that stress these circuits.

There are a large number of signal forms that fall under the general category of pathological testing. One common signal stresses the clock regeneration and equalizing circuits by producing values for C and Y that force the SDI bit scrambling circuits to produce a run of 19 zeros and a single one approximately every frame. Another common signal puts the values of C and Y such that a run of 20 ones, followed by 20 zeros periodically, is produced. There are-in fact-thousands of possible C and Y combinations that will stress the receiver.

Measurements under real-world conditions have found that a path will fail under testing with a pathological signal at received levels approximately 2 dB higher than where a typical program (non-pathological) signal will fail.[13] Such tests, therefore, can help to identify whether a given SDI path is at or near the error cliff.

Measuring Jitter

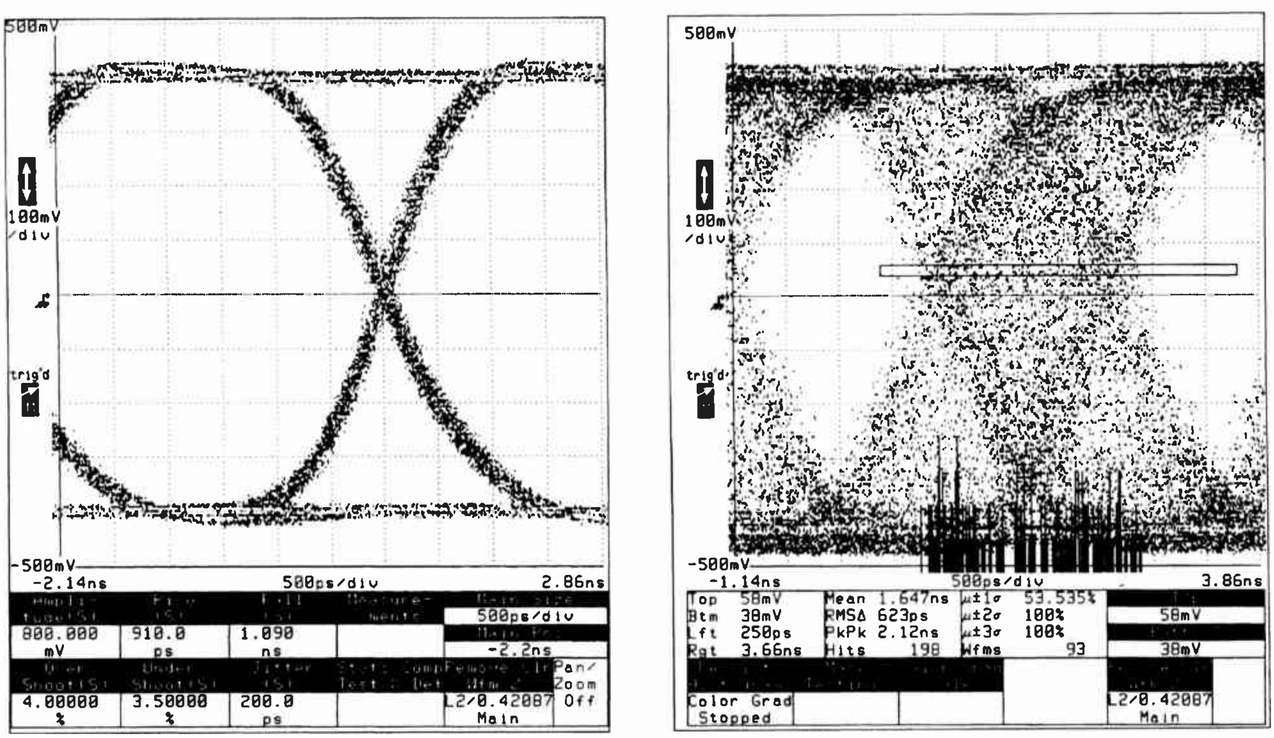
Test equipment is available to measure and characterize the amount of jitter in a link. Several approaches can be taken. One, recommended in SMPTE RP-184, extracts a clock signal from the data stream, which is divided by a given value and used to trigger an eye pattern display. The divisor is typically the same value as the word size (10 bits). This method will, thus, mask any word-related jitter, which is usually quite small. Figure 7.2-38 illustrates jitter measurement using a digitizing oscilloscope.

Quantifying Errors

Errors in digital systems are usually quantified by the bit error rate (BER), which is simply the ratio of bits in error to total bits. Table 7.2-2 gives the BER for one error over different lengths of time for various television systems.[14] BER is a useful measure of system performance where the S/N at the receiver is such that noise-produced random errors occur.

Bit scrambling is used in the SDI system to lower the dc content of the signal and to provide sufficient zero crossings for reliable clock recovery at the receiver.[12] It is the nature of the descrambler that a single bit error will cause an error in two words (samples). Furthermore, there is a 50% probability that the error will occur in one of the words being in the most significant, or next to the most significant, bit position. The resulting error rate of 1 error/frame will be noticeable by a reasonably patient observer. This situation, clearly, is unacceptable in professional video applications.

Figure 7.2-39 shows the block diagram of a basic serial digital transmitter and receiver system. The intuitive method of testing the serial link is to add cable to the point where the link is unusable. Because coax is not itself a significant source of noise, it is the noise figure (NF) of the receiver that will determine the basic operating S/N of the system. Assuming an automatic equalizer in the receiver (which is usually the case), as more cable is added, eventually the signal level resulting from coax attenuation will cause the



(a) (b)

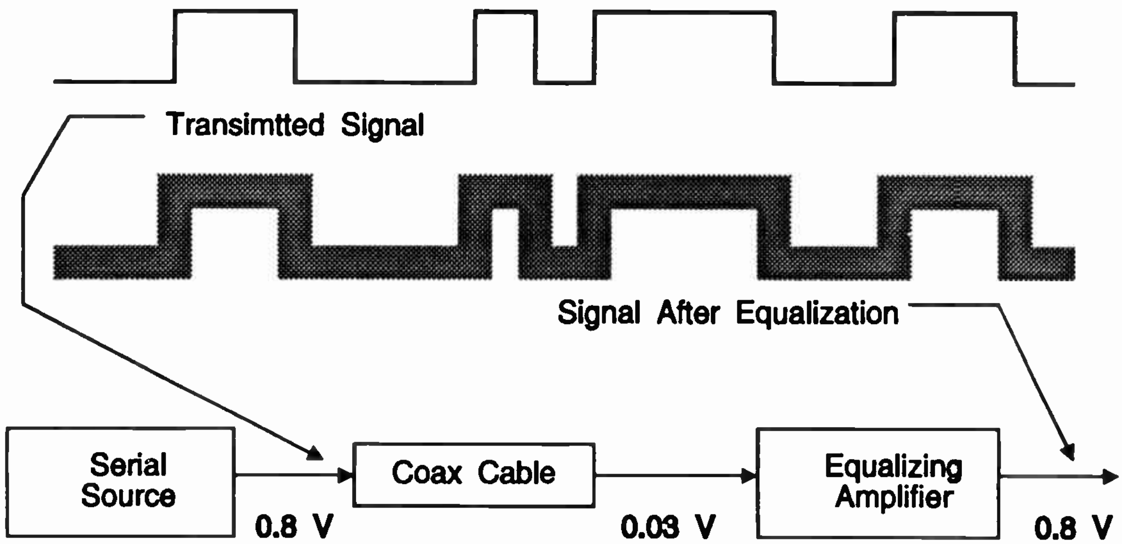

Figure 7.2-39. Basic serial digital transmitter/receiver system. Note typical voltage levels (for composite video) and the function of the equalizing amplifier.[14]

S/N in the receiver to degrade to the point that errors occur.

Based on the scrambled non-return-to-zero-inverted (NRZI) channel code used with SDI and assuming gaussian-distributed noise, a calculation using the error-function provides theoretical values for error rate as a function of S/N, as shown in Table 7.2-3.[14] An examination of the table will show that for composite (NTSC) serial digital transmission, a 4.7 dB increase in S/N changes the resulting condition from 1 error/frame to 1 error/century. For composite digital, the calibration point for the calculation is 400 m of Belden 8281 coax. Other types of cable can be used with adjustments made for the calculation point, if necessary.

The same theoretical data can be expressed to show error rates as a function of cable length, as given in Table 7.2-4.[14] (This data is reproduced in graph form in Figure 7.2-40). There is a sharp knee in the graph as cable length is extended beyond a certain critical point (380 m, or approximately 1,250 ft, for composite digital video). Similar results are obtained for other standards; the critical point calculation is 360 m for PAL and 290 m for ITU-R Rec. 601 video. Cable lengths and headroom scale proportionally. Good engineering practice would suggest a minimum of 6–8 dB margin for reliable SDI transmission.

Practical systems include equipment that does not necessarily completely reconstitute the signal in terms of S/N. For example, sending the SDI signal through a distribution amplifier or routing switcher may result

Table 7.2-3

Error Rate as a Function of S/N for Composite Serial Digital.[14]

in a completely useful, but not completely standard signal that is sent to a receiving device. The characteristics of this non-standard signal could include both jitter and noise. The sharp knee characteristic of the system, however, would remain, occurring at a different amount of signal attenuation.

Eye Diagram

Most engineers are familiar with an oscilloscope display of repetitive waveforms such as sine, square or triangle waves. These are known as single value displays because each point on the time axis has only a single voltage value associated with it.[16]

When analyzing a digital telecommunications waveform, single value displays are not very useful. Real communications signals are not repetitive, but instead consist of random or pseudorandom patterns. A single value display can only show a few of the many different possible one/zero combinations. A number of pattern dependent problems will be overlooked if they do not occur in the small segment of the waveform appearing on the display of the conventional oscilloscope.

The eye diagram overcomes the limitations of the single value display by overlapping all of the possible one/zero combinations on the screen. Eye diagrams are multivalued displays in that each point on the time axis has multiple voltage values associated with it.

The eye diagram has become a valuable tool in analyzing digital communications systems because of the unique properties that it is capable of displaying.

7.3
RADIO FREQUENCY SIGNAL ANALYSIS

DONALD MARKLEY
MARKLEY & ASSOCIATES, PEORIA, IL

INTRODUCTION

The analysis of radio frequency (RF) signals has benefited greatly from the newer generation of digital test equipment. In particular, the digital spectrum analyzer and vector network analyzer have changed the way in which transmitted signals and RF networks can be analyzed and adjusted.

In its simplest form, the spectrum analyzer can be visualized as a self-tuning receiver with adjustable bandwidth. The operator selects the center frequency around which measurements are desired. The receiver bandwidth and the width of the band of frequencies to be measured are then set. The spectrum analyzer then scans across those frequencies and displays all received signals. With analog systems, the display was sometimes difficult to interpret as certain combinations of sweep characteristics resulted in a display that was not constantly visible. Experienced operators learned to cope with the display and, through experience, could evaluate even the weakest of signals. However, digital spectrum analyzers have made it much easier for the occasional or new user to benefit from the device.

The digital spectrum analyzer functions in a similar fashion to a traditional analog device as far as general measurement principles are concerned. In fact, it is often possible to switch to a totally analog display. However, in the digital display mode, the unit will display each measured signal without fading between signal traces. The display is simply updated each time the system measures the desired frequencies. For transient measurements, the system holds the display as long as desired to show a single trace. Most modern units will also store one or more sets of measurements for plotting or printing using a computer interface.

An additional feature of the digital spectrum analyzer is the ability to store the maximum value of the signal noted on any frequency within the selected band or frequencies over a period of time. This feature is particularly useful in the analysis of spurious signals or the observation of a modulation envelope.

NATIONAL RADIO SYSTEMS COMMITTEE (AM RADIO)

Standard broadcast stations are required to perform an annual measurement of spurious radiation and the occupied bandwidth of their signals. Section 73.44 of the Federal Communications Commission (FCC) Rules specifically identifies the instrument to be used as a suitable swept-frequency RF spectrum analyzer. The instrument must use a 300 Hz resolution bandwidth and perform the measurement over a 10 minute period. The peak signal values at each frequency during that period are to be displayed.

Other specialized receivers may be used but, in the case of any disagreement over the results, the peak storing spectrum analyzer is to be used to determine the correct value. The Rules also specify the manner in which the measurements are to be performed. In particular, the station must be operated normally and the measurements taken at approximately 1 km from the center of the antenna system. The Rules further explain how this is to be done for directional systems.

It is often difficult to obtain enough signal to perform the measurement at the specified 1 km distance, especially for lower powered stations. Loop antennas are available that provide good response and gain characteristics. In addition, the use of a loop antenna can eliminate the signals of other stations through proper orientation. Still, even the loop does not always yield sufficient signal to allow for the dynamic range necessary to show compliance with the limits in the Rules. In such cases, a preamplifier may be added to the system as long as its response does not significantly alter the overall frequency response of the system.

Figure 7.3-1 illustrates the results of an AM modulation envelope measurement. The limits specified by the FCC are shown on the plot. In addition to the basic envelope, the Rules require measurement of the harmonics of the station's assigned frequency. All harmonics are to be either 43 + Log (power in watts) or 80 dB below the carrier, whichever is the lesser attenuation. Stations operating at less then 158 W are only required to show harmonic attenuation of at least 65 dB.

While measurement of the station's harmonics can be performed with the spectrum analyzer, the results are often masked by noise. More accurate results can often be obtained by using a field-strength meter in combination with a calibrated antenna. One significant source of error in measuring harmonics with a spectrum analyzer is the gain of the antenna used. The gain will vary considerably over the band of frequencies from the carrier to the third harmonic. Accurate measurements can only be obtained when the entire system is calibrated. Antennas of known gain are available, but it is much easier to simply use a field-strength meter for such measurements.

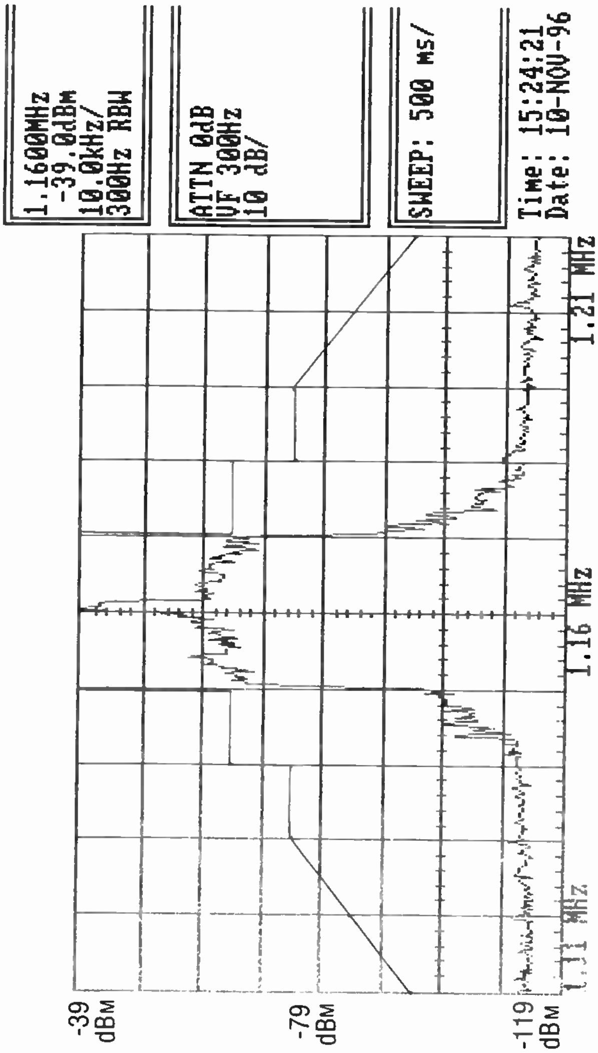

Figure 7.3-1. NRSC measurement of AM transmitter with FCC limits.

TELEVISION SIDEBAND MEASUREMENTS

The FCC has rigorous requirements for the sideband response of television transmitters. The measurements to confirm proper operation, as well as the tuning of the transmitters themselves, require both a spectrum analyzer and a suitable signal generator. The more common method of measurement has involved the use of a sideband adapter which, together with the spectrum analyzer, provides a stable and easily analyzed waveform.

The most common sideband adapter is the Tektronix 1405, although the use of that unit requires a spectrum analyzer that has been modified for such use. The units are interconnected so that their frequencies track. The sideband adapter generates a test signal which sweeps the selected television channel and includes markers to aid in determining the system frequency response. Figure 7.3-2 shows the response of a UHF television

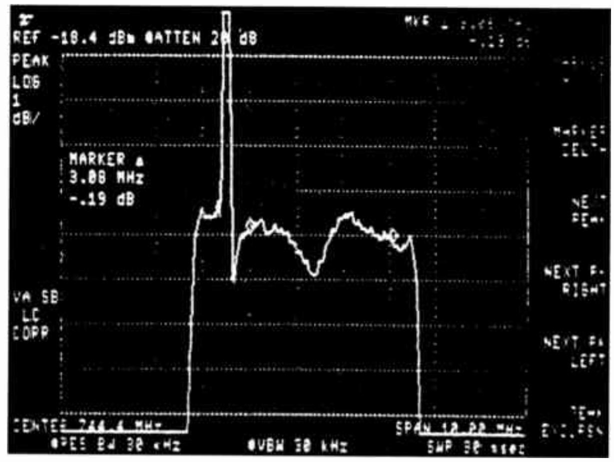

Figure 7.3-2. Television transmitter sideband response.

transmitter using a sideband adapter. In that figure, the vertical scale is 1 dB/div.

An additional method of sweeping the TV transmitter uses a (sin x)/x signal from a digital television test signal generator. The wide frequency response of that signal, together with the accuracy inherent in modern spectrum analyzers, provides sufficient accuracy to meet the FCC's measurement requirements. An additional advantage of this method is that the cost of a separate sideband adapter is avoided.

Tracking Generator Measurements

A general problem exists when a signal generator and spectrum analyzer are used to measure the frequency response of systems. In simplest terms, the signal generator only generates one frequency at any given instant. The generator then sweeps continuously over a desired band of frequencies or, in the case of modern, digitally swept generators, moves in increments across that band. Since the spectrum analyzer can only measure one frequency at a given instant, some means must be found to cause the analyzer to perform measurements on the same frequency that is being generated at that time. This is accomplished with a device known as a *tracking generator*.

The tracking generator is either installed in a spectrum analyzer or mounted externally and connected directly to an analyzer. The two units are synchronized so that the settings on the analyzer controls also determine the method in which the generator operates. The result is that the generator frequency and the frequency measured by the analyzer are the same at all times. For analog equipment, the output of the tracking generator, when connected directly to the input of the spectrum analyzer, will appear as a straight line at the generator output magnitude. For digital equipment, the output of the tracking generator may appear as a row of pulses.

Figure 7.3-3 demonstrates one way this equipment can be used. The device under test is simply connected between the tracking generator output and the input to the spectrum analyzer. Since the magnitude of the tracking generator signal output is known, this test

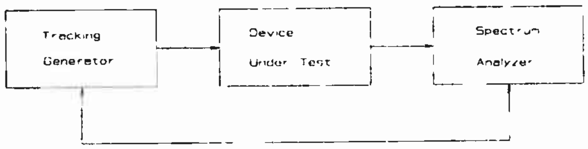

Figure 7.3-3. Block diagram of tracking generator and spectrum analyzer test setup.

setup allows the frequency response of the device to be measured very accurately over the range of interest. It must be noted that this measurement only shows the magnitude of the response. The spectrum analyzer is a scalar device and does not provide vector (magnitude and phase) data.

Using a return loss bridge, the tracking generator and spectrum analyzer combination can measure the return loss from antenna systems. The return loss can in turn be used to calculate voltage standing wave ratio (VSWR) and the reflection coefficient of the load as shown in Equation 1.

$$|\Gamma| = 10^{(RL/20)}$$

$$\text{VSWR} = \frac{1 + |\Gamma|}{1 - |\Gamma|} \qquad [1]$$

Where: Γ = Reflection Coefficient
RL = Return Loss in dB

However, measurements made on a system in this fashion do not provide sufficient information to determine the location of any problems in the system—only the frequency response of the overall system is measured. Determining the location of faults requires either vector measurement information or the use of a time domain reflectometer.

Time Domain Reflectometers

The time domain reflectometer (TDR) applies a pulse or step of voltage to a transmission line or antenna system. An oscilloscope is normally used as the display device and is supplied signals from the TDR. The oscilloscope is usually operated in the *x-y* mode with the horizontal and vertical signal provided directly from the TDR. The oscilloscope displays the measured signal on the transmission line input as a function of time. Some TDRs incorporate an LCD display or a chart recorder.

The applied pulse will travel down the cable at a known rate which is the velocity of propagation of the cable under test (usually available from the cable manufacturer). When the pulse passes an irregularity or discontinuity in the cable, a portion of the pulse will be reflected back to the source. The strength of the reflection will be determined by the impedance change at the point of the discontinuity. Equation 2 can be used to determine the coefficient of reflection at the impedance change. The reflected signal is simply equal to the incident signal, or the pulse, multiplied by the coefficient of reflection.

$$\Gamma = (Z - Z_0)/(Z + Z_0) \qquad [2]$$

Where: Γ = Reflection coefficient
Z = Impedance at discontinuity
Z_0 = Characteristic impedance of line

The reflected signal travels back to the input of the transmission line where the TDR is connected. The distance from the TDR to the irregularity is determined by Equation 3. The factor of ½ in that equation is needed to account for the fact that the signal travels over the distance from the TDR to the fault twice, first in the forward direction and then in the reverse direction. An antenna on the end of the transmission line will normally look like either an open or a short circuit to the TDR pulse—an antenna that has dc continuity will appear to be a short with a reflection coefficient of −1; if the antenna is an open at dc, it will appear to be an open circuit with a reflection coefficient of +1.

$$d = 3 \times 10^2 \times Vp \times t/2 \qquad [3]$$

Where: d = Distance to fault in meters
Vp = Velocity of propagation in cable
t = Time between incident and reflected pulse

A TDR is usually equipped with an adjustable delay calibrated in distance to fault. The initial adjustment of zero distance establishes a reference on the oscilloscope. The delay can then be adjusted to place any reflected signal at the same reference point. The distance to the fault is then read directly from the TDR. The distance to the fault is only accurate if the instrument has been calibrated for the correct velocity of propagation. This is relatively easy to do if the exact length of the cable is known. The velocity of propagation setting can be adjusted until the reflection from the end is at the correct distance. All points between the TDR and the end of the cable will then also be at the correct distance.

Newer TDR equipment may allow for keypad entry of the velocity of propagation value. In some cases, the type of transmission line is selected by the user from the display and the velocity is then automatically selected by the unit. Again, the calibration can be checked easily if the cable length is known.

The sensitivity of TDR measurements is usually limited by the noise level present on the line. With an antenna present at the end of the line, the RF noise level present may mask minor reflections. Two solutions exist to that problem. One is to use a higher powered TDR. The other, easier method is to terminate the transmission line in either an open or a short circuit. The more complete the open or short is made, the smaller the discontinuity that can be seen. A good TDR on a tightly sealed rigid transmission line should be able to see every connection between sections as well as the insulators along the center conductor.

A line that has experienced an arc across one of the insulators will leave a carbon path although that path can be very difficult to find. Obviously, the TDR does not use a sufficiently high voltage to cause the arc to reoccur. If the line can be tightly sealed to lower the noise floor as much as possible, the location of the carbon path may become visible. Faults of this type are very difficult to find when operating at test instrument power levels. Fortunately, their location will probably become quite evident after the normal transmitter power level recreates the arc a few more times.

Situations do exist that will cause highly misleading indications on a TDR. For example, a gradual change in the line impedance (versus distance) will not cause a distinct reflection leading the operator to conclude that no problem exists. This situation can occur when an air dielectric line with a slight slope in the horizontal run accumulates water from being improperly pressurized. The impedance change along the line will be gradual as the level of the water approaches the center conductor. To the TDR, the gradual change does not present a clean point of reflection and the overall change in the line may be missed. To avoid this pitfall, the operator should always try to first identify (using the TDR) the end of the line. If it appears to be missing, a problem obviously exists which the TDR method cannot identify.

NETWORK ANALYZER MEASUREMENTS

The digital network analyzer is essentially an accumulation of pieces of test equipment in one box. This equipment includes a synthesized signal generator, up to three separate receivers, a controller/analyzer system and a display. Depending upon the model, the system may also include a reflection or transmission test set and, in some cases, an "s-parameter" test set. Figure 7.3-4 is a block diagram of a typical network analyzer.

Traditionally, analog network analyzers were swept-frequency devices and were not as capable of compensating for system errors (such as test setup amplitude distortions) as are the newer digital systems. Some attempts were made with the analog instruments to add self-correcting circuits. However, the build-up of system noise, as more and more components were added, tended to reduce the ability of the system to measure very low values of VSWR. The newer digital analyzers have eliminated that problem.

The digital network analyzer does not do swept-frequency measurements. Rather, the band of interest is analyzed on a point-by-point basis. The initial instructions to the system controller include the number of points to be measured. That number of measurement points is then uniformly (or in some cases logarithmically) distributed over the range of interest. For each point, the generator and receivers are set to a selected frequency. Once the generator has locked on frequency, the output is directed to a transmission test set or s-parameter test set. For illustrative purposes, assume that the more common transmission test set is in use. Within the transmission test set, the signal from the generator is divided into two equal signals. One of these is returned to one receiver channel as a reference. The other signal is applied to a return loss bridge or directional coupler. This second signal is then routed to the system under test. The reflected signal then goes to another network analyzer receiver channel for comparison to the reference signal. The difference between those signals represents the reflection coefficient.

In a scalar network analyzer, the system performs the required calculations and the results are displayed as the simple magnitude of the reflection, the return loss in dB or the VSWR. Such a VSWR plot is shown in Figure 7.3-5. Traditionally, the display has been a CRT, although some of the newest models have changed to LCD displays. That change has resulted in a significant reduction in system weight without any reduction in the quality of the presentation. A vector network analyzer goes further in determining both the magnitude and the phase of the reflected signal. That allows a Smith Chart presentation of the measured impedance as shown in Figure 7.3-6. Some systems also permit a display of phase only as well as a polar plot of the system impedance. Markers can be used to identify the critical points such as visual carrier, aural carrier or color carrier frequencies.

A major feature of digital vector network analyzers is the ability to calibrate the unit in the field. To do this, three accurate terminations are required. The normal procedure is to use a short circuit, an open circuit and a calibrated termination. The open and short circuits are placed in their respective connectors at the same location as the load in the resistive termination. In addition, the open is shielded to eliminate any errors due to stray RF signals. For each of the three terminations, the system measures the impedance of the termination at each of the frequencies across the selected range. After the three sets of measurements are completed, a set of correction coefficients is calculated to correct the measured data to accurately represent an open, a short and a perfect 50 Ω resistive load. That correction matrix is used on all subsequent measurements to compensate for system errors. This corrects for cable leakage or resistance problems, errors in the power divider and return loss bridge and other minor system variations. However, the final result is only as accurate as the calibrating devices.

If the network analyzer, after undergoing calibration, determines the system VSWR at some frequency to be 1.05, the result is actually based on the value of the resistive termination being 50 Ω with zero reactance. Any error in the value of the termination causes a corresponding system error in all measurements performed by the system. As a result, the operators of these systems usually guard their terminations zealously, particularly on the road.

The ability to calibrate the system in the field has opened an additional level of measurement ability. In the past, it was necessary to lift the measurement equipment to the top of the tower if measuring the actual antenna was desired (assuming that this discussion refers to a large antenna). With the ability to calibrate the system using the three precision terminations, it is possible to perform the calibration at the

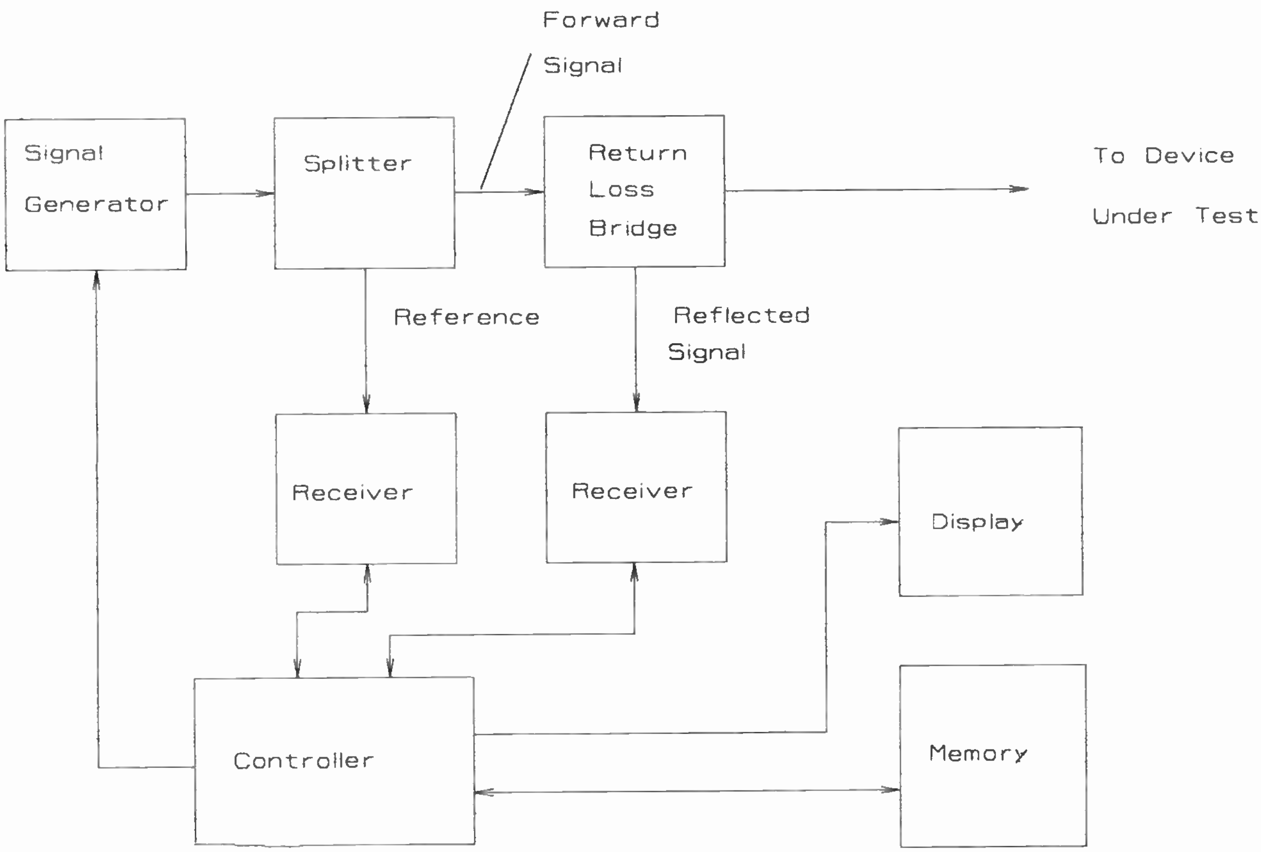

Figure 7.3-4. Generic block diagram of a network analyzer.

load end of the transmission line rather than at the output of the test equipment, correcting for the presence of the transmission line. Once calibrated, the display will now show the actual VSWR of the antenna itself irrespective of the connecting hardware. Due to other developments, to be discussed later, that particular measurement is not as necessary as it was in the past. However, it is still useful when elements of the antenna need to be tuned in the field.

A major problem occurs when performing measurements on antenna systems, particularly in the UHF television band. The adapters used to convert from

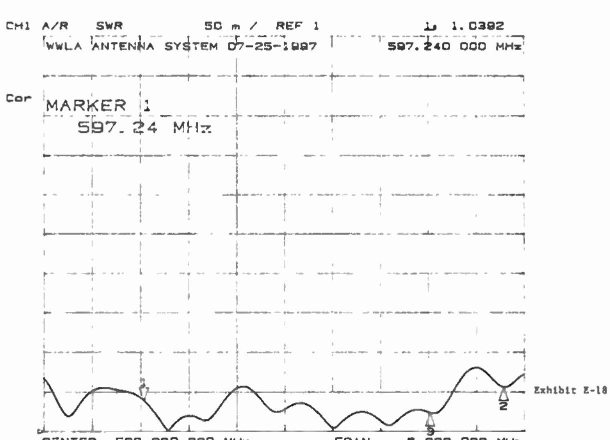

Figure 7.3-5. VSWR plot of TV antenna and transmission line.

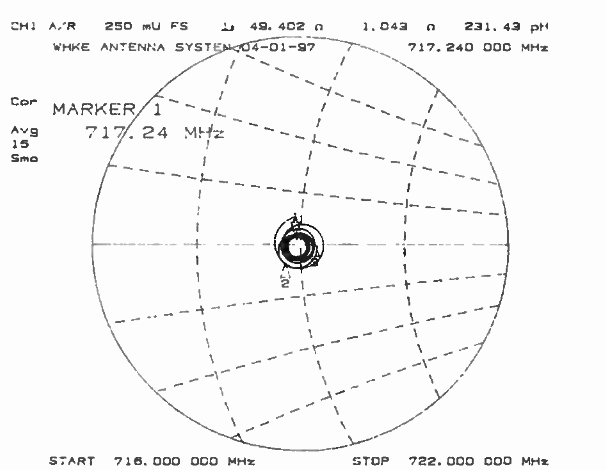

Figure 7.3-6. Smith Chart plot of TV antenna and transmission line with good impedance match at the antenna.

type N connectors to large transmission lines must be carefully tuned to eliminate errors. Without tuning, it is not unusual for adapters (from type N to 6 1/8 in. or larger cable) themselves to introduce a VSWR of 1.1:1 or more. When measuring VSWR system values of less than 1.05:1, such errors in the adapters are unacceptable. When manufactured, these adapters are often tuned using a slotted line, an approach not normally available in the field. In any case, the purpose of all of the initial tuning and calibration is to eliminate the errors caused by the instrumentation itself.

Modern television transmitting antennas are normally tuned for a VSWR of 1.05 or less at visual carrier, 1.08 or less at aural and color carriers and a maximum value of 1.1:1 across the 6 MHz channel. Some antenna manufacturers predict the necessity of tuning DTV antenna systems for a minimum return loss of 30 dB across the channel. That corresponds to a VSWR of 1.065:1. Clearly, good instrument calibration will be important when making measurements of these types.

Simulated TDR Measurements

When tuning transmitting antennas, a TDR does not provide any information concerning the match to the antenna itself. In fact, since the antenna normally appears to be either an open or a short at dc, the antenna will present a very large reflection. On the other hand, measurement of the VSWR with a network analyzer or a spectrum analyzer with a tracking generator will not provide any information concerning the location of a mismatch in the band of frequencies of interest. It is here that another feature of the vector network analyzer becomes of interest. It is possible to determine the distance to faults at RF frequencies and the magnitude of those faults.

When the network analyzer performs the measurement of the reflection coefficient at the selected number of points, it is building a series of values that represent the system response as a function of frequency. This can be said to be a function in the frequency domain. When the Inverse Fourier Transform (Equation 4.) is applied to that measured data, the result is the response expressed in the time domain. That is, the response demonstrates the distance to faults along the line and the magnitude of those faults. For the analysis of TV antenna systems, that response is calculated across the 6 MHz channel and shown as VSWR versus distance.

$$f(t) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} F(w)c^{iwt}\,dw \qquad [4]$$

where:
$f(t)$ = Function of time
$F(w)$ = Function of frequency
$w = 2\pi f$
f = Frequency in hertz

There are some precautions to be taken in determining the distance to faults by this method. Due to the limitation on the amount of data used in the calculation, some erroneous indications can occur due to a phenomena called aliasing. The maximum distance range to avoid aliasing is determined by Equation 5 and is a function of the frequency span over which the measurements are performed, the number of data points used and the relative propagation velocity of the transmission line.

$$d\,\text{max} = (1.5 \times 10^8)(Np)(Vp)/(F_2 - F_1) \qquad [5]$$

where:
d max = Maximum measurement distance without aliasing
Np = Number of measurement points
Vp = Velocity of propagation
F_1 = Starting frequency
F_2 = Stopping frequency

The most common problem in the analysis of TV transmitting antenna systems is the mismatch between the transmission line and the antenna at the input to the antenna. Figure 7.3-7 shows the time domain response of a UHF TV antenna system with a minor mismatch at the input of the antenna. Normally, such a mismatch is eliminated through the use of a fine matching network or a variable transmission line trans-

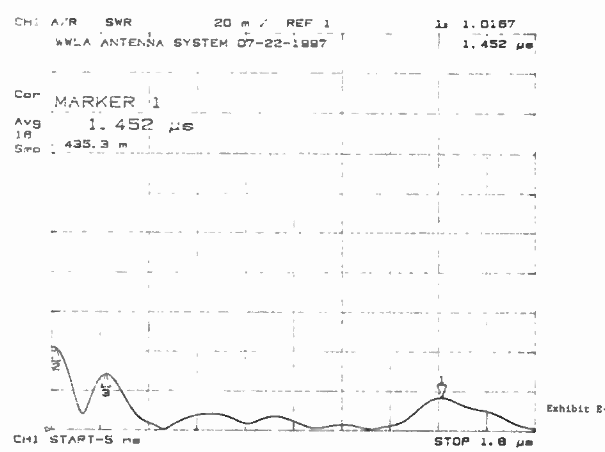

Figure 7.3-7(a). Time domain of TV antenna system with marker 1 at elbow complex at top of transmission lien before tuning.

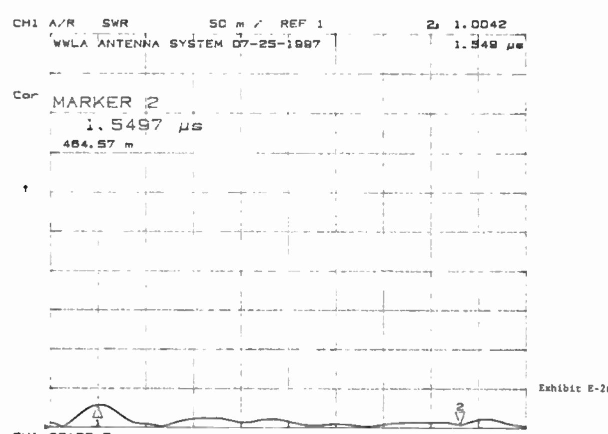

Figure 7.3-7(b). Time domain of TV antenna system with marker 1 on antenna input after system tuning.

former at that point in the system. As a rough rule of thumb, UHF antennas should be tuned for a maximum VSWR of 1.03 for the 6 MHz span of frequencies in the desired channel. To find problems with the transmission line system, the analysis should be made over a much broader range of frequencies. The greater the range of frequencies and the larger the number of points measured, the more detailed the information will be concerning the distance to faults. For one popular system, measurements are taken at 1601 points permitting details as small as the connections at each flange to be seen on a rigid coaxial line.

Waveguide Analysis

Due to its basic nature, a TDR will not work on a waveguide system because a waveguide does not work at low frequencies. Therefore, a TDR will always see a waveguide as an open circuit occurring at the transition from coaxial cable to the waveguide. However, in its simulated TDR mode, the network analyzer can determine the distance to any mismatch along a waveguide. For rectangular or truncated elliptical waveguides, this allows the location of mismatches to be determined. Tuning sections can then be installed (or tuning straps in the case of standard rectangular waveguide). Circular waveguide at UHF frequencies is normally not adjustable in the field other than the transitions from rectangular waveguide or coaxial cable.

Figure 7.3-8 shows the results of a properly tuned antenna system with waveguide. The network analyzer normally will store such information on a disk which permits the data to be displayed by simple printers.

FREQUENCY AND AURAL MODULATION MONITORING[1]

Various types of modulation monitors are discussed in this section, together with the FCC Rules with which modulation monitors and transmitter emissions must comply.

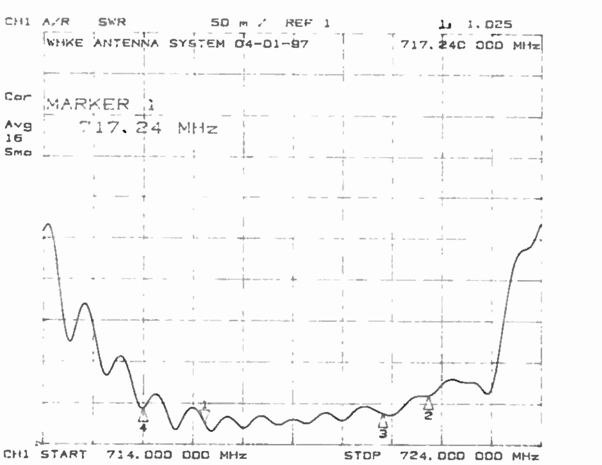

Figure 7.3-8. VSWR plot of tuned system. TV antenna with waveguide.

Modulation monitors are specialized, highly accurate and very low distortion instruments. They replace several more complicated, general purpose test instruments of similar accuracy as well as provide a convenient means for complying with FCC Rules.

Broadcast station monitors fall into two categories: frequency monitors and modulation monitors. These two functions are sometimes combined into one unit and sometimes packaged as separate units.

Broadcast aural modulation monitors are also classified according to the type of modulation to be monitored:

- AM monaural
- AM stereo
- FM monaural (and Subsidiary Communications Authority (SCA) as needed)
- FM stereo (and SCA as needed)
- TV monaural
- TV stereo (and multichannel sound)

Frequently, monaural and stereophonic functions are combined in one instrument for the convenience of the user.

WHY MONITOR THE TRANSMITTER

The three major reasons for using frequency and aural modulation monitors at a broadcast station are, described in the following sections.

Coverage

Because coverage of the broadcast service area is enhanced by a high modulation level, it is desirable to maintain the modulation level at the maximum legal limit in order to maintain good coverage and improve signal-to-noise ratio (SNR) for the audience.

Proof of Performance

By using the monitor as a precision test instrument, the station engineer can perform proof-of-performance measurements to ensure that the transmitter is within the modulation and frequency technical specifications of the manufacturer and the operating requirements of the FCC. The FCC no longer requires a regular "proof of performance." However, stations are still required to meet certain technical requirements.

Most aural modulation monitors have built-in facilities to measure baseband audio frequency response and signal-to-noise ratio. Outputs are provided for total harmonic distortion measurements by an external distortion analyzer. Modulation monitors with stereo and SCA functions can measure stereo separation, subcarrier injection levels, crosstalk between service channels, and provide demodulated outputs for stereo and SCA channels. Aural broadcast modulation monitors are often comprised of several integrated pieces of test equipment to test many functions of aural transmitters.

Compliance with FCC Rules

The monitor enables the station engineers to operate the transmitter in accordance with FCC Rules regarding aural modulation levels and carrier frequency tolerances. In addition, Part 73.1590(a) requires proof-of-performance measurements of all main transmitters, except Class D non-commercial educational FM stations operating under 10 W, to be taken as follows:

- Upon initial installations
- Upon modifications of transmission facilities
- Installation of AM stereo
- Installation of FM SCA or stereo
- Installation of TV stereo or subcarrier
- Annually on AM stations
- When required by other, special provisions of the station license.

FCC RULES AFFECTING MONITORING

The FCC no longer specifies the type of aural modulation monitor or measuring equipment a broadcast station must use. Therefore, it is the responsibility of the station licensee to decide what monitoring equipment is needed to ensure that the station transmitter emissions comply with FCC frequency and modulation requirements.

Frequency Monitoring

Part 73.1540(a) of the FCC Rules requires that center frequencies of AM, FM and TV stations must be measured or determined as often as necessary to ensure that they are maintained within the tolerances stated in FCC Rule 73.1545 as follows:

AM stations: The carrier frequency for monophonic transmissions or the center frequency for stereophonic transmissions must be within ±20 Hz of the assigned frequency.

FM stations: The center frequency must be within ±2000 Hz of the assigned frequency (±3000 Hz for transmitters having a power output of 10 watts or less).

TV stations: The visual carrier frequency must be within ±1000 Hz of the assigned frequency. The aural carrier frequency must be 4.5 MHz ±1000 Hz above the actual visual carrier frequency.

Aural Modulation Limits

Part 73.1570 of the FCC Rules states that modulation percentage is to be maintained at the highest level consistent with good transmission quality and broadcast service, not to exceed the following limits:

AM stations: Modulation of the carrier must not exceed 100% on negative peaks of frequent recurrence, or 125% on positive peaks at any time. There are additional regulations for AM stereo and telemetry transmissions.

FM stations: Total modulation must not exceed 100% on peaks of frequent recurrence referenced to 75 kHz deviation. However, stereo stations simultaneously providing subsidiary communication services (SCA) on subcarriers may increase the total peak modulation 0.5% for each 1.0% of subcarrier injection modulation; but the total carrier modulation must not exceed 110%. If two or more SCA subcarriers are used in conjunction with the stereo channel, the maximum allowable peak deviation is ±82.5 kHz or 110%.

TV stations: In general, the total modulation of the aural carrier must not exceed ±25 kHz deviation (monaural) on peaks of frequent recurrence. Stations transmitting multiplexed subcarrier signals on the aural carrier must limit the modulation of the aural carrier by the arithmetic sum of the subcarrier(s) allowable deviation and the total modulation must not exceed ±75 kHz deviation.

Modulation requirements for stations transmitting aural subcarriers as part of encoded subscription programs are stated in the application for FCC approval and contained in FCC Rule 73.682(b).

Modulation requirements for Broadcast Television Systems Committee (BTSC) stereo sound are subject to the criteria set forth in FCC Rule 73.682(c) and FCC Office of Engineering and Technology (OET) Bulletin 60A. Also see Chapter 6.3, *Multichannel Television Sound.*

ESSENTIAL FEATURES OF FREQUENCY MONITORS OR METERS

The primary standard of frequency measurements is the standard frequency maintained by the National Institute of Standards and Technology (NIST), which was formerly the National Bureau of Standards (NBS), or their standard broadcast signals of stations WWV, WWVB. Frequency monitors or meters must be capable of accurately measuring and displaying the carrier frequency requirements. Recommended resolution for AM monitoring is 1 Hz while FM and TV monitors should provide a resolution of 10 Hz or better. These tolerances call for an extremely accurate and stable internal frequency standard with an aging rate of 1 part per million (ppm) per year or better which is traceable to NIST.

If the transmitter is to be monitored at some distance from the transmitter site, a built-in or external preselector is generally required to raise the input level for receiving the signal off-the-air.

The following features are highly desirable in a frequency monitor:

- Digitally tuned RF preselector for multiple off-air applications
- Digitally tuned RF preselector for multiple off-air applications combined with the aural modulation monitor
- An output to operate an alarm when preset frequency limits are exceeded
- Provision for calibrating the internal frequency standard against an NIST station or other highly accurate standard
- An output for automatic logging.

Peak Modulation Duration

Although the FCC's current rules contain no precise definition of the maximum allowable peak modulation duration, some manufacturers of modulation monitors are using the pre-1983 de facto rules as their design guidelines. The *de facto* rules allowed a 1 millisecond response time for the peak modulation indicators and the permissible over-modulation limit was 10 counts per minute.

ESSENTIAL FEATURES OF AN AURAL MODULATION MONITOR

At a minimum, all aural modulation monitors should have a quasi-peak reading modulation meter to give a direct indication of modulation percentage. Meter accuracy should be ±4% or better. Other desirable features common to all modulation monitor are:

- Peak indicators, accurate to ±2% or better, to indicate when maximum positive and negative modulation peaks are occurring
- Adjustable peak indicator trigger points to indicate when modulation peaks exceed preset levels
- Adjustable peak modulation duration detecting circuit in the event the FCC and the broadcast community agree upon the maximum allowable peak duration
- An internal modulation level calibrator to check the accuracy of the modulation meter and peak flashers and a means for recalibrating the meter and peak flasher circuits.
- An output to operate an over-modulation alarm or a built-in alarm
- An output to operate an external alarm or a built-in alarm for when the modulation drops below a certain level (10%) for a specified period of time
- Outputs for a remote meter and peak flasher.

AM Monitors

AM monaural modulation monitors should possess the features described in the preceding paragraph. If an RF preselector is used for off-air monitoring with the monitor, its sensitivity should be approximately 100 μV for a 35 dB signal-to-noise-ratio (SNR) and 1 mV for a 50 dB SNR. Selectivity should be at least −40 dB at ±40 kHz, and image rejection should be at least 50 dB. The RF preselector must be very linear to avoid causing erroneous readings on the modulation monitor.

It is also desirable that the AM modulation monitor be equipped with NRSC deemphasis circuits so that the audio output of the monitor matches that of the AM transmitter modified with the NRSC audio response characteristics.

AM stereo monitors should have the following additional features:

- L + R and L − R channel decoding and outputs
- L and R channel separation measurement capability
- L and R channel SNR measurement capability
- L and R channel frequency response measurement capability
- Pilot carrier injection level measurement capability
- Channel crosstalk measurement capability
- Signal output for distortion measurements.

FM Monitors

FM monitors should have at least a 70 dB signal-to-noise ratio. The discriminator must have a distortion figure of 0.1% or better and a baseband frequency response of at least 25 Hz to 100 kHz, so that it can pass and accurately measure an SCA channel up to 92 kHz. FM monitors often consist of both frequency and modulation monitors in one package.

If an RF preselector is used for off-air monitoring, its intermediate frequency (IF) amplifier should have a linear phase response curve, yet be narrow enough to reject adjacent channels. A built-in multipath detector is highly desirable to help minimize multipath interference. The FM monitor should be equipped to measure synchronous and non-synchronous AM noise of the FM carrier.

FM stereo monitors should be able to measure:

- The L + R channel level (30 Hz to 15 kHz)
- The L − R channel level (23 to 53 kHz)
- The 19 kHz pilot injection level
- The 38 kHz subcarrier level
- Crosstalk between main channel and subcarriers
- Separation of left and right channels (up to 60 dB).

If one or more SCA subcarriers are transmitted, an SCA monitor should be used in addition to the FM stereo modulation monitor. The SCA monitor is usually an add-on to the main unit, which takes a composite feed from the demodulated output of the baseband monitor. Some manufacturers offer an optional RF and baseband demodulator, so that the SCA monitor can be used independently from the main monitor. The capability for user selection of SCA frequencies is important for future expansion of SCA service.

The SCA monitor should be able to measure:

- Modulation percentage
- SCA injection level on the composite signal
- Signal-to-noise ratio
- Crosstalk.

The SCA modulation measurement should be selectable for ±4 kHz or ±6 kHz as the level for a meter indication of 100%. FM monitors often include both modulation and frequency monitoring in one package.

Analog TV Monitors

The features for analog TV monaural and stereo monitors are similar to those for FM monitors. When transmitting BTSC multichannel sound, the operator should be able to monitor the main channel and stereo channel as well as SAP and PRO channels (if they are utilized). Monitoring the modulation level of the BTSC signal is extremely important for achieving good stereo separation.

BTSC Stereo Separation and Modulation Accuracy

Stereo separation in the BTSC format is sensitive to gain and phase errors in the transmission path. This is because the L + R and L − R signals are treated differently. In particular, L − R is companded while L + R is simply preemphasized and deemphasized. The L − R and L + R signals must arrive at the receiver's decoder matrix, which yields L and R, with very small errors in gain and phase across the aural baseband from 50 Hz to 50 kHz. Figure 7.3-9 shows how stereophonic separation is affected by gain and phase errors in the L − R signal relative to the L + R signal at the input of the final matrix.

Subjective tests have shown that an average listener begins to "perceive" a loss in the spatial character of stereophonic music material when the separation drops below 18 dB. A separation of 15 dB ± 3 dB is considered "adequate" by the average listener.

Although the subjective effects of separation depend on the spectral distribution and other aspects of the audio material, it appears that a good engineering objective for the entire system is for the separation to exceed 20 dB in the mid-range, decreasing somewhat at frequencies above 8 kHz. Figure 7.3-9 shows that a separation of 20 dB requires a gain error smaller than 1 dB, and a phase error of less than 10°. The BTSC standards require that the separation of the radiated signal exceed 30 dB in the mid-band from 100 Hz to 8 kHz, but that is may decrease at low frequencies to 26 dB at 50 Hz, and to 20 dB at 14 kHz. This requires that the gain and phase errors in the mid-band be less than 0.3 dB and 3.0°, respectively.

The total modulation level accuracy in BTSC stereo is more critical than in FM stereo radio broadcasting to produce acceptable stereo separation. Because the L + R and L − R signal paths in BTSC are processed differently, a small change of modulation level in the BTSC system will affect the stereo separation. This is because the amplitude and phase relationship between the L + R and L − R channel is altered. If the total modulation level of the BTSC system is not maintained accurately, the dbx decoder in the receiver will see an incorrect RMS level and reproduce an L − R signal with altered amplitude and phase. That is, if an incorrect L − R signal is fed to the decoding matrix, the consequence will be poor stereo separation. Because the RMS level to the input of the decoder is directly proportional to the total modulation level, the total modulation level in the BTSC transmitter must, therefore, be accurately monitored in order to maintain good stereo separation and high quality audio performance.

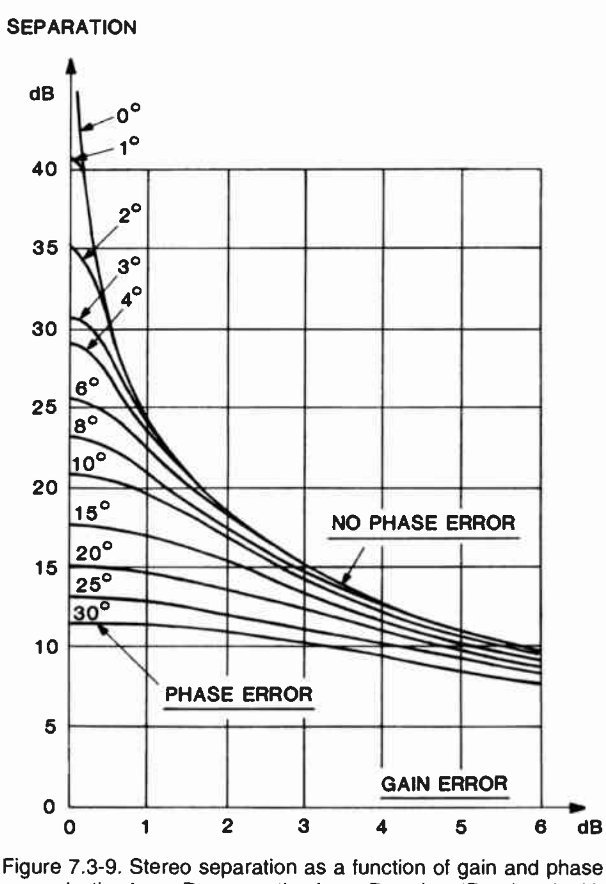

Figure 7.3-9. Stereo separation as a function of gain and phase errors in the L − R versus the L + R paths. (Reprinted with permission from TFT, TV Aural Proof of Performance Guide.)

ON-SITE MONITORING TECHNIQUES

In a studio-transmitter collocated operation, the monitor is normally connected directly, or through an attenuator, to an RF sampling point of the transmission line feeding the antenna via a directional coupler. It is important to know the RF voltage level of this sampling point so that it meets the input requirement of the monitor.

AM Monitoring

Most AM frequency monitors display carrier frequency error rather than actual carrier frequency. Typically, a front-panel digital display indicates the carrier deviation in Hz from its assigned frequency, and a lighted "+" or "−" indicates whether the carrier is above or below the carrier frequency.

The modulation percentage of a monaural AM carrier is normally displayed directly on a front-panel meter.

Peak flashers, used on some monitors, are intended to catch fast transients and peaks that the meter cannot respond to. There may be one flasher to indicate maximum allowable negative peaks (100%) and another to indicate maximum allowable positive peaks (125%). The monitor may also have an adjustable peak flasher which can be preset by means of digital switches so that it flashes when the modulation percentage exceeds the preset switch value.

For monitoring modulation of an AM stereo transmitter, an AM stereo monitor or a stereo monitor plus a compatible AM modulation monitor is required. The equipment should permit the operator to simultaneously read the modulation percentage on both left and right channels and to measure separation between channels and crosstalk between the main channel and subchannels.

FM Monitoring

A typical FM frequency monitor digitally displays carrier frequency error in Hz (rather than display actual carrier frequency) and indicates whether the carrier is above or below its assigned frequency. The RF input level must be adjusted so that sufficient signal is available for measurement but not so high that overloading occurs. In addition to monitoring the FM stereo transmitter carrier frequency, it should be possible to monitor the stereo pilot carrier frequency as well.

On a typical monaural FM monitor, the modulation percentage is normally displayed on a front-panel meter. Generally, either positive, negative or combined modulation peaks can be selected for monitoring. Some monitors also provide peak flashers to indicate modulation peaks that exceed a preset percentage. The RF input must be adjusted to the correct level, as described in the instruction manual, before accurate readings can be taken.

For monitoring a stereo FM transmitter, a modulation monitor with a compatible stereo monitor must be used. Left channel, right channel and total modulation are generally read on front-panel meters. With the typical monitor, these meters can also be used to measure separation between the left and right channels as well as crosstalk between the main channel and subchannels.

SCA monitors are usually accessories to the baseband monitor. They are either fed from the FM composite signal or from the RF carrier through a separate FM demodulator.

Analog TV Monitoring

The typical TV frequency monitor will provide separate displays of the visual carrier, aural carrier and intercarrier frequency errors (rather than actual carrier frequency). The RF input to the monitor should be adjusted to the correct level as described in the instruction manual before measurements are made.

Aural modulation percentage can be read from a front-panel meter. If the TV transmitter is also transmitting BTSC stereo sound, a monitor with a stereo decoder for left and right channels must be used. If a SAP channel is employed, a SAP monitor should also be used to monitor modulation and frequency.

Due to the critical relationship in BTSC stereo separation between the recovery of the companded L − R channel and the modulation level of the transmitter described previously, it is essential to maintain accurate modulation levels when broadcasting multichannel television sound. One convenient method of achieving this objective is to monitor the pilot carrier injection level, which has a constant level. After calibration of modulation levels for maximum stereo separation, the pilot carrier injection level is the best reference for maintaining maximum stereo performance.

OFF-SITE MONITORING TECHNIQUES

For remote, off-air monitoring, the monitor should incorporate a built-in preselector (RF amplifier) or an external RF preselector connected to an outdoor antenna. Some preselectors are capable of measuring and indicating carrier frequency error. Such preselectors, when combined with a modulation monitor, provide a compact complement of monitoring equipment.

Off-site monitoring techniques are generally the same as on-site techniques. RF input level to the preselector or monitor must be carefully adjusted, as described in the manufacturers' instruction manuals. It is even more important to know the RF level so that it does not overload the RF preselector and create intermodulation products. Some monitors are equipped with a multipath detector which enables the user to rotate the receiving antenna for minimum multipath interference.

CALIBRATION AND MAINTENANCE

Frequency monitors should be calibrated periodically to ensure accurate measurement of transmitter carrier frequency error. The time between calibrations depends on the frequency of the monitor's internal standard, which in turn depends on the operating frequency of the transmitter. For a monitor having an internal crystal standard that has been correctly calibrated once and that has an aging rate of 1 ppm per year, the following calibration schedule is recommended:

Transmitter Frequency	Calibration Interval
AM band	Every 12 months
FM band	Every 12 months
Low VHF Analog TV band (Ch 2–6)	Every 12 months
High VHF Analog TV band (Ch 7–13)	Every 6 months
UHF Analog TV band	Every 3 months

After the first few calibrations, the interval may be lengthened if the drift observed in the first few checks warrants it.

There are a number of ways the internal frequency standard in a monitor can be calibrated:

- Use a high quality frequency counter having a resolution of 1 Hz display and a time base that is calibrated against a secondary standard having a accuracy of at least 1×10^{-8}
- If the frequency display can be operated in a general-purpose counter mode, a frequency standard of higher accuracy than the monitor's internal standard can be used with the counter to calibrate the internal standard. The external standard is connected to the counter input, and the internal standard (which furnishes the time base for the counter) is adjusted so that the counter displays the exact frequency of the external standard
- If a receiver capable of receiving one of the NIST stations (WWV at exactly 5, 10 and 15 MHz) is available and if the monitor has an output from its internal standard that is an exact subharmonic of the

frequency of the NIST station being received, the monitor internal standard can be calibrated by adjusting its frequency to zero beat with the NIST station frequency.

Aural Modulation Monitor Calibration

The aural modulation meter and peak flashers should be calibrated regularly. Most monitors have built-in calibrators, so that meter and flasher accuracy can be checked by simply pressing front-panel switches and observing the peak flashers and the meter reading. If the reading is in error, a simple adjustment usually corrects the error.

If the built-in modulation calibrator is of the frequency marker type for establishing the $\pm 100\%$ peak modulation level, and the frequency markers are generated from single crystal sources, the accuracy can usually be maintained within $\pm 1\%$. If this type of monitor is being used, it is not necessary to calibrate the FM modulator using a Bessel null method.

If an FM modulation monitor has no internal calibrator, the monitor must be calibrated against a laboratory standard or by means of a Bessel null measurement using a spectrum analyzer and a precision audio frequency generator.

If an AM modulation monitor has no internal calibrator, the monitor can be calibrated using an RF generator. The generator must be capable of very low distortion amplitude modulation, and the level of this modulation should be accurately observed by using a high quality oscilloscope.

An AM monitor is usually calibrated by comparing the peak amplitude of the waveform against an amplitude reference established by an oscilloscope with high linearity. A digitally generated reference is frequently used as a built-in calibration standard as in an FM modulation monitor.

Maintenance

A broadcast station monitor should be maintained in the same way as other precision laboratory instruments. If should be calibrated regularly as described in the preceding paragraphs. Manufacturers also offer this type of service to their customers.

DIGITAL TELEVISION (DTV) MEASUREMENT ISSUES[2]

For analog signals, some transmission impairments are tolerable because the effect at the receiver is often negligible, even for some fairly significant faults.[3] With DTV, however, an improperly adjusted transmitter could mean the loss of viewers in the Grade B coverage area (or worse). DTV reception—of course—does not degrade gracefully, it simply disappears. Attention to several parameters are required for satisfactory operation of the 8VSB modulation system used by DTV. First, there is the basic FCC requirement against creating interference to other over-the-air services. To verify that there is no leakage into adjacent channels, out-of-band emission testing is required. Second, while for NTSC analog TV, there is concern with SNR performance, in the DTV case the desired-to-undesired signal ratio (D/U) is measured.

In DTV, flat frequency response across the channel passband is required comparable to that required by analog transmitters. A properly aligned DTV transmitter exhibits many of the same characteristics as a properly aligned analog unit, including flat frequency response and group delay, with no leakage into adjacent channels. Where analog TV is concerned, group delay problems result in chromanance/luminance delay, which can degrade the displayed picture but still leave it viewable. Group delay problems in DTV transmitters, however, result in intersymbol interference (ISI) and a rise in the bit error rate (BER), possibly causing the receiver to drop in and out of lock. Even low levels of ISI may cause receivers operating near the edge of the cliff to lose the picture completely. Amplitude and phase errors may cause similar problems, again resulting in reduced viewer coverage.

Eye patterns and BER have become well-known parameters of digital signal measurement, although they may not always be the best parameters to monitor for 8VSB transmission. The constellation diagram and modulation error ratio, on the other hand, provide insight into the overall system health. RF constellations are displayed on the (I) in phase and (Q) quadrature components of the received RF signal, commonly displayed on the X and Y axes of the constellation diagram, respectively. Constellations of tight vertical dot patterns with no slanting or bending indicate proper operation, as illustrated in Figure 7.3-10(a). Since 8VSB levels are the in-phase signal they are displayed left to right.

An 8VSB signal is a single sideband signal with a pilot carrier added. In a single sideband signal, phase does not remain constant. Therefore, the constellation

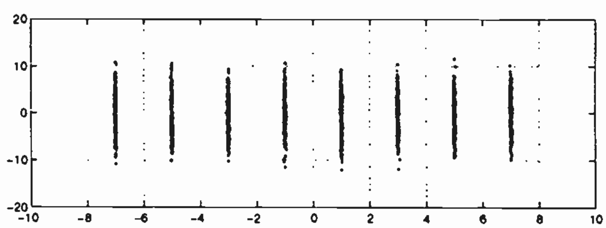

Figure 7.3-10(a) and (b). 8 VSB constellation diagram: (a) a near-perfect condition, (b) constellation diagram with noise and phase shift (the spreading of the pattern is caused by noise; the slant is caused by phase shift).

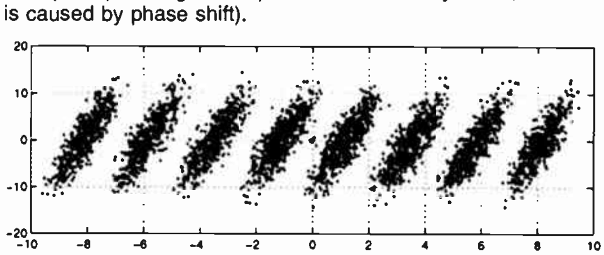

points (dots) occur in a vertical pattern. As long as the dot pattern is vertical and the points form narrow lines of equal height, the signal is considered good and can be decoded.

Figure 7.3-10(b) shows an 8VSB signal that has noise and phase shift. Noise is indicated by the spreading of the dot pattern. Phase problems are indicated by the slant along the Q-axis.

While BER is a valid measurement for 8VSB, a better approach involves monitoring the modulation error ratio (MER), which usually will reveal problems before the BER is affected. In many cases, MER can provide enough warning time to correct problems that would result in an increase in the BER. MER provides an indication of how far the points in the constellation have migrated from the ideal. There can be considerable migration before boundary limits are exceeded. Degradation in the BER is only apparent when those limits have been exceeded.

Principle DTV System Parameters

The FCC, in its Memorandum Opinion and Order on Reconsideration of the *Sixth Report and Order* on DTV (February, 1998), specified the out-of-band emissions mask for terrestrial transmission. The order requires that transmitter out-of-band emissions be attenuated consistent with the following:

- In the first 500 kHz from the authorized channel edge, emissions must be attenuated no less than 47 dB below the average transmitted power
- At more than 6 MHz from the channel edge, emissions must be attenuated no less than 110 dB below the average transmitted power
- At any frequency between 0.5 and 6 MHz from the channel edge, emissions must be attenuated no less than the value determined by the following formula, which is based on a measurement bandwidth of 500 kHz: attenuation in dB $= -11.45(\Delta f + 3.6)$, where $\Delta f =$ the frequency difference in MHz from the edge of the channel.

When the interference level of the spectral distribution as defined here is not low enough for the operational conditions of a particular application, other spectral distributions should be considered.[4]

In-band Signal Characterization

The quality of the in-band emitted signal can be specified and measured by determining the departure from the 100% eye opening. This departure, or error, has three components:

- Circuit noise (white noise)
- Intermodulation noise caused by various non linearities
- Intersymbol interference

The combination of all of these effects can be specified and measured by an error vector magnitude. This measurement is described in Reference 4.

Power Specification and Measurement

Conventional NTSC broadcast service allows a power variation ranging between 80% and 110% of authorized power. These values correspond to -0.97 dB and $+0.41$ dB, respectively. Because of the cliff effect at the fringes of the service coverage area for a DTV signal, the allowable lower power value will have a direct impact on the DTV reception threshold. A reduction of 0.97 dB in transmitted power will change the DTV threshold of 14.9 dB (which has been determined to yield a 3×10^{-6} error rate) to 15.87 dB, or approximately a one mile (1.6 km) reduction in coverage distance from the transmitter. Therefore, the average power of the DTV transmitted signal is of significant importance.

The ATSC recommends a lower allowed power value of 95% of authorized power and an upper allowed power value of 105% of authorized power.

OTHER MEASUREMENT CONSIDERATIONS

It is impossible to cover all of the measurement requirements for a particular installation in this chapter. Transmitter manufacturers usually provide extensive documentation on the tests and measurements recommended and/or required for their products. In-factory or on-site instruction is also available from many firms. Because the purchase of a transmitter or antenna system is a sizeable investment, the instrumentation and educational requirements of upgrading an RF plant should be considered before the purchase of equipment, not afterwards.

Section 8: Ancillary Broadcast Systems

Introduction by Al Resnick, ABC, New York, NY

Within the last decade, the radio industry has seen explosive growth in studio and transmission facility construction. Stations and studios have been bought, sold and modified at a record pace. With the dawn of DTV, a similar construction boom is likely for television.

Building a new studio or transmission facility is a major undertaking. Many engineers dream about becoming involved in such a project. The difference between a project being a dream or a nightmare often rests in the preparations and planning.

Studio design and construction is the most visible and is—arguably—the most important task of the broadcast engineer. This work involves not only the physical space of the facility, but also the infrastructure, which includes everything from the ac power and grounding subsystems to the broadcast equipment itself. The provision of a proper environment is fundamental to the safe and reliable operation of a station. Consolidation of duties has brought us back to the drawing board to consider more efficient floor plans that maximize the use of space and time.

The successful planning and construction of a broadcast facility is always time well spent and can deliver benefits as quickly as the start of construction as well as efficiency and flexibility of the physical plant long into the future. Learn how to ensure a successful project for your station in Frank Rees, Jr.'s *Broadcast Facility Planning and Construction* chapter.

Much of today's broadcast equipment is computer based. Most computer-based equipment is seldom ready to operate instantly upon application of power. The facilities planner must evaluate options to keep modern equipment operating through those times when the local electrical supply has problems. Learn how to protect your ac power system from damage as *Handbook* Editor-in-Chief, Jerry Whitaker provides a guide to the wide range of power conditioning and isolation equipment in his *AC Power Conditioning* chapter.

W. E. Dewitt's comprehensive *Facility Grounding Practices* chapter defines grounding and lists the reasons and methods for proper grounding, discusses equipment grounding, system grounding and earth connections, and applies recommended facility grounding practice to the safe design and construction of electronics installations.

As the section concludes, Jerry Whitaker weighs in once again with valuable information for maximizing reliable operation when faced with emergency situations in his *Standby Power Systems* chapter.

8.1
BROADCAST FACILITY PLANNING AND CONSTRUCTION

FRANK REES, JR.
REES ASSOCIATES, DALLAS, TX

INTRODUCTION

Planning and construction of a broadcast facility must combine today's state-of-the-art excellence with the flexibility and unknown elements of tomorrow. With the correct approach, this is not a daunting task. By understanding short-term and long-term needs, broadcast facility owners can create a building and infrastructure that is geared to sustain a station throughout the next half-century.

A STRATEGY FOR SUCCESS

No one understands more clearly the sweeping technological changes impacting the broadcast industry than the individuals that are currently limited by their physical environment as a result of its changes. The impact of these technological changes can be staggering. Considering some broadcast facilities may not have the capacity to handle current needs, the facility cannot begin to support changes anticipated within the next few years. When launching into the planning and construction of a broadcast facility, meeting these current and future needs requires careful consideration and a well defined strategic process.

When detailing a successful planning and construction strategy for a broadcast facility, it is imperative that owners keep several important elements in mind. Flexibility is primary and function dictates design needs. The final design must accommodate construction and operational efficiencies. Finally, choose the planning and construction team wisely. When planning for design and construction of a broadcast facility, the elements of flexibility, efficiency and a quality team are paramount.

Flexibility is the linchpin of planning. The owner must plan for current and future needs. Planning takes knowledge of the industry and an intuition for the future. A good plan must allow for technology and equipment that currently does not even exist.

There must be efficiency in design. Efficiency in the design of a broadcast facility reduces the initial cost, lowers the operational cost and allows the staff to be more productive in their everyday tasks. To achieve this efficiency, each team member has to be focused on specific goals to form a concise overall plan. Focusing the many different disciplines required to design a broadcast facility requires a strong team leader who is knowledgeable of the numerous disciplines, as well as the owner's needs, as they relate to a broadcast facility.

The planning and construction team is three-pronged, it includes the owner, architects/engineers/consultants and contractor. By combining these three integral team players, a multidisciplinary effort results in a clear, masterful approach to the planning and construction of a broadcast facility.

Success of the project is highly contingent upon the degree of the owner's participation and willingness to provide the information vital to the creation of building plans. The owner must be involved in all phases of the project in a formal, aggressive way if the project is to successfully come to fruition. After all, the owner's vision is what gives substance to the project.

The architects are the experts who guide and lead the team from the planning stages through construction. From there they move toward completing a building that masters design, flexibility and function and provides an infrastructure to support these elements on a short and long-term basis. The experience of the architect cannot be overlooked. A poor choice can cost time and dollars now and in the future.

The architect's design team also includes professionals uniquely qualified to design the various engineering systems of a broadcast facility. This roster of professionals includes electrical, mechanical, structural and acoustical engineers and broadcast system engineers and integrators, as well as other consultants.

The same philosophy of selecting a qualified architect applies to the contractor. It is important that the construction professional is involved from the planning phase through the construction process of a broadcast facility.

In summary, flexibility, efficiency of design and a quality team are the key components of the strategic planning process. These elements should support the project goals and objectives and create the framework to successfully plan and construct a broadcast facility.

THE PLANNING, DESIGN AND CONSTRUCTION PHASES

Development of a broadcast facility is like a journey—it requires careful planning and a detailed road map.

The Planning Process

The planning process should be developed prior to the design of the actual structure, to obtain a comprehensive overview of the proposed facility. This process serves as the road map, which analyzes the entire trip from the beginning, and defines the building's size, cost and time of completion by studying every aspect of the project.

During the development of the facility plan, the owner typically has two primary goals:

- Improve the functional quality of the facility and thus the value of the completed project by involving everyone (station management and staff as well as architects, builders and systems engineers) in the planning and design of the facility
- Minimize the cost and time required to design and construct the facility.

Following is an outline of ten suggested components that are the basis for a meaningful process for the planning and construction of a broadcast facility:

- Project issues are those broad stroke components that define the overall operational, business and facility requirements for the success of the facility. These issues guide the project goals and can also range from the technical to the aesthetic expectations for the project
- If applicable, an existing facility analysis is completed to determine if it is appropriate to utilize the existing facility for the future or if there is a need for new construction
- Planning criteria includes those principles that direct the design team to adhere to basic design guidelines including Americans with Disabilities Act (ADA) requirements, energy efficiency, function driven planning and future expansion strategies. Adaptability and visually pleasing qualities can both be a part of the overall project requirements
- A functional space program outlining the requirements of each portion of the broadcast facility is developed. This lists the size and quantity of each functional space within the facility. This functional description is most useful when all aspects of the space are listed including furniture, equipment, unique lighting and electrical and mechanical systems. The program can also define where each space belongs in the overall scheme
- A building systems description and quality statement which outline the method of construction and level of quality of all portions of the broadcast facility must be developed as a basis for the probable budget statement
- A project development schedule which outlines the time necessary for all planning, design, corporate approval, construction, broadcast equipment installation, move in/startup and other activities necessary to achieve the target on-air date for the facility
- Facility concepts and site analyses which outline the size and location of all portions of the broadcast facility including future expansion
- A probable budget statement which outlines the costs of all portions of the broadcast facility including construction, furnishings, technical equipment, development costs and other related expenses. A guaranteed maximum cost for the building could be established if the level of contractor involvement allows for a clear understanding of the scope of the work
- A cash flow schedule indicating total and monthly project cash flow requirements is incorporated into the development schedule
- Design studies to show the physical appearance of the completed project.

The Design Process

Once the planning process has been completed, the subsequent phases of design and construction can begin. The design and construction process can easily be divided into five significant phases:

- Schematic design
- Design development
- Construction documents
- Bid negotiation/pricing
- Construction.

Each of these phases works independently, and together, to bring about the best end product.

All the best planning for design and construction, however, cannot succeed without giving proper attention to the *construction process*. It is important to choose a construction process approach that is best suited to the project and a construction professional whose experience and expertise can support building a highly technical facility.

Preparing your Building for Digital Television

Whether renovating an existing station or building a new television facility, today's digital television facility needs will be different from yesterday's analog plant. As an organization plans for the project, whether it involves one channel or multiple channels, proper planning for the organization's facility, studio and transmission needs will ensure success.

The Technical Core

Heating, ventilation and air conditioning systems (HVAC) in the technical areas require very reliable temperature and humidity control as well as redundancy to keep the sophisticated electronic equipment from shutting down due to excessive temperature conditions (above 85° F). The HVAC systems must be designed to ensure continuous uninterrupted service. The use of self contained *computer room air conditioning* (CRAC) units with built in redundancy (dual compressors or with chilled water with direct expansion backup) is common in the electronic rack room and related technical operations areas. Proper humidity control can be easily achieved with these units when used in conjunction with proper vapor barrier placement. Proper unit location and acoustical design is required to address acoustical concerns in critical listening technical and production spaces.

Reliable power is an extremely critical component in digital radio or television stations. Two separate sources of primary electrical service are often obtainable from the local power company via power from two substations or two separate power grids. However, the ability to quickly switch from the main to an alternate power source is critical. The power company will provide information on power characteristics for a given location. If two power sources are not available then a standby generator may be required. The generator should be sized to carry the critical loads of the facility, including HVAC systems for the technical and transmitter areas. An *uninterruptible power supply* (UPS) will also be required to bridge the time gap when power is switched over and the standby generator comes on-line or to give personnel time to power down computer based systems with volatile memory.

Electrical service for a facility can easily be designed to separate the load into several branches. This will allow technical power to be isolated from mechanical equipment, studio lighting and normal building power to minimize the cost to provide clean power to the critical technical areas.

A properly designed technical *grounding system* is critical to station operations. A *lightning protection system* is desirable and will minimize damage to sensitive electronic components and pay for itself in the event of a lightning strike.

The design of the *technical core* is also critical for digital broadcast stations. The technical spaces are larger than in the past although individual pieces of equipment may be smaller. With the advent of server technology more equipment requiring more space will be the norm. Much equipment requires the use of 36 in. deep equipment racks. This increase in depth along with considerations for handicap access, required under the ADA, requires more space in the technical areas than ever before. The additional equipment required to broadcast digital television as compared to analog, impacts space requirements along with the requirement of multiple channels transmitting from one facility. The additional rack and equipment space required for multiple channels will require more space as well as more HVAC and electrical systems support. Building systems to support technical core will be much the same as they have been in the past but will require more flexibility.

Technical core spaces will still require a minimum of 18 in. access flooring for cable requirements. Overhead raceway systems could also be an alternative in the distribution of cable systems throughout the building. Similar systems will be required for newsroom operations and editing systems. Typical edit suites will also require the continued use of access flooring.

The key to successful planning and construction of the next generation station will be flexibility. It is imperative that the buildings of tomorrow be more flexible and communicate more easily within itself for the user to enhance its capabilities. Fewer walls and open office modular workstations will become the norm instead of the hard wall offices of the past.

Master Control

Stations that carry multiple DTV channels will impact master control as well as electronic rack room and transmission areas. Monitoring, switching and playback will have varying degrees of impact depending on how many channels are carried and the types of digital video systems utilized.

Studio Control and Post Production Suites

Equipment required for digital production switchers and editing systems required in control rooms and edit suites requires less space than the large bulky consoles of the past. Monitor walls must be designed for visual comfort of personnel within the room with rear access for service provided. The main design concern is the space required for personnel to function properly.

Studios

Studios for DTV will need to be designed to accommodate the 16:9 aspect ratio. The decreasing need for studio space due to virtual sets and digital technology will impact total space requirements of the television station. Floor space will be greater to accommodate the wider shot, however, the required height of the lighting grid may be less in the long-term.

Newsroom

The ability to edit video from the desktop using digital networked systems may reduce the number of traditional viewing and editing stations previously required with analog systems. Reporters and others needing to view or edit video may be able to do so using desktop computers.

Additional Considerations

The distribution of broadband signal systems throughout the station will require that every desktop be connected to the servers and video systems residing in master control and elsewhere. This networked technology will allow team editing and instant communication regardless of the physical layout of the station or individual departments.

Sophisticated computer use will require dedicated computer training rooms to ensure that staff may stay abreast of new software. The ability to broadcast multiple channel CD quality sound and multiple channel standard and high definition video will enable the broadcaster to transmit multiple programs while serving other businesses. This requires operational and facility planning to be accomplished in an orderly systematic manner.

THE CONSTRUCTION PROCESS

Within the construction phase, there are three primary ways to approach the construction process: the *conventional approach* (*competitive bid*), *design/build approach* and *negotiated approach*.

Conventional Approach (Competitive Bid)

Once the construction documents are completed, the bid phase begins. Drawings are issued to a select list of construction professionals who then competitively bid on the project. Typically, the contractor with the lowest bid is awarded the contract. A contract is executed between the owner and the contractor.

Design/Build Approach

Contractor and architect, as a team, design and construct the project. A single contract is executed between the owner and the design team. The design team then provides a complete turn key project for the owner.

Negotiated Approach

The negotiated approach involves preselecting a group of contracting firms for interviews. The construction firm may be selected on previous experience, personnel and/or cost. Just like the architectural firm, the contractor is selected based on qualifications. The construction firm should be included from the beginning of the project through construction of the building.

For broadcast facilities, the negotiated approach is the most frequently used construction process, followed by the design/build approach and the competitive bid approach.

Selecting a Contractor

The construction professional's expertise is an integral part of the project's success and ranges from scheduling, keeping within budgeted dollars and material considerations to constructability. This key player must also have a good knowledge of technical facilities and understand the importance of flexibility for the future.

The determination of who will be retained to construct the new or renovated building is one of the most crucial decisions a broadcast facility owner makes when planning and constructing a broadcast facility. There can be serious trouble from the first day if a contractor or construction professional with the proper qualifications is not selected for the project.

When selecting a general contractor, there are four main areas to investigate:

- Evaluate the history of the firm. A consistent management philosophy has most likely been established if the firm has been in business for at least ten years
- Evaluate the reputation of the firm, its leadership and subcontractors. Does the reputation of the firm and its President coincide with your company standards? Does the contractor have a reputation for litigation with clients and subcontractors?
- Evaluate the firm's financial stability. Select a firm with a net worth of at least half the projected costs of the planned project
- Evaluate the firm's past project record, especially technical facilities. Request a list from the past five years, sorted by year, of total construction costs the firm has completed. Determine the bonding limit of the contracting firm and make sure this dollar amount is at least twice the construction budget. It will guarantee the performance of the contract and the insurance company can also provide valuable information on the company. Ask for a listing of at least three of the company's past projects. Detailed information about each project should include the project's location, construction budget, year built, and contact name at the facility. If a contractor does not have experience with highly technical facilities, that firm is not qualified to construct a broadcast building.

The relationship with the contractor is interactive and long-term. Before the contractor has been selected, request a detailed description of how the firm intends to approach the construction of the broadcast facility. It is important to secure information on how the firm intends to keep the team informed and how they will provide the team with an understanding of what is transpiring during the construction process.

CONCLUSION

When embarking on the venture of planning and constructing a broadcast facility, the key to success begins with clearly defined goals and objectives that incorporate flexibility and efficiency in every aspect of the project. Additionally, achieving short and long-term objectives can be met by using a tested and effectual design approach with a qualified team whose commitment, vision, experience and expertise can guide the planning and construction process through strategic phases. Overall, these elements blend to create a broadcast facility planning and construction mix that will bring the project to an impressive conclusion and create a facility that meets the operational needs of today and provides flexibility for tomorrow.

8.2
AC POWER CONDITIONING

JERRY C. WHITAKER, EDITOR-IN-CHIEF
MORGAN HILLS, CA

INTRODUCTION

Utility companies make a good-faith attempt to deliver clean, well regulated power to their customers. Most disturbances on the ac line are beyond the control of the utility company. Large load changes imposed by customers on a random basis, power factor (PF) correction switching, lightning and accident related system faults all combine to produce an environment in which tight control over ac power quality is difficult to maintain. Therefore, the responsibility for ensuring ac power quality must rest with the users of sensitive equipment—in this case, the broadcaster.

The selection of a protection method for a given facility is as much an economic question as it is a technical one. A wide range of power line conditioning and isolation equipment is available. A logical decision about how to proceed can be made only with accurate, documented data on the types of disturbances typically found on the ac power service to the facility. The protection equipment chosen must be matched to the problems that exist on the line. Using inexpensive basic protectors may not be much better than operating directly from the ac line. Conversely, the use of a sophisticated protector designed to shield the plant from every conceivable power disturbance may not be economically justifiable.

Purchasing transient suppression equipment is only one element in the selection equation. Consider the costs associated with site preparation, installation and maintenance. Also consider the operating efficiency of the system. Protection units that are placed in series with the load consume a certain amount of power and, therefore, generate heat. These considerations may not be significant, but they should be taken into account. Prepare a complete life-cycle cost analysis of the protection methods proposed. The study may reveal that the long-term operating expense of one system outweighs the lower purchase price of another.

The amount of money a facility manager is willing to spend on protection from utility company disturbances generally depends on the engineering budget and how much the plant has to lose. Spending $225,000 on system-wide protection for a major market television station is easily justified. At smaller operations, justification may not be so easy.

The Key Tolerance Envelope

The susceptibility of electronic equipment to failure because of disturbances on the ac power line has been studied by many organizations. The benchmark study was conducted by the Naval Facilities Engineering Command. The far-reaching program, directed from 1968–1978 by Lt. Thomas Key, identified three distinct categories of recurring disturbances on utility company power systems[1]. As shown in Table 8.2-1, it is not the magnitude of the voltage, but the duration of the disturbance, that determines the classification.

In the study, Key found that most data processing (DP) equipment failure caused by ac line disturbances occurred during bad weather, as shown in Table 8.2-2. According to a report on the findings, the incidence of thunderstorms in an area may be used to predict the number of failures. The type of power transmission system used by the utility company also was found to affect the number of disturbances observed on power company lines (see Table 8.2-3). For example, an analysis of utility system problems in Washington, DC, Norfolk, VA, and Charleston, SC, demonstrated that underground power distribution systems experienced one-third fewer failures than overhead lines in the same areas. Based on his research,

Table 8.2-1
Types of Voltage Disturbances Identified in the Key Report[1]

Parameter	Type 1	Type 2	Type 3
Definition	Transient and oscillatory overvoltage	Momentary undervoltage or overvoltage	Power outage
Causes	Lightning, power network switching, operation of other loads	Power system faults, large load changes, utility company equipment malfunctions	Power system faults, unacceptable load changes, utility equipment malfunctions
Threshold[1]	200-400% of rated rms voltage or higher (peak instantaneous above or below rated rms)	Below 80-85% and above 110% of rated rms voltage	Below 80-85% of rated rms voltage
Duration	Transients 0.5-200 (μs wide and oscillatory up to 16.7 ms at frequencies of 200 Hz to 5 kHz and higher	From 4-6 cycles, depending on the type of power system distribution equipment	From 2-60 s if correction is automatic; from 15 min to 4 hr if manual

[1] The approximate limits beyond which the disturbance is considered to be harmful to the load equipment

Table 8.2-2
Causes of Power Related Computer Failures, Northern Virginia, 1976[1]

Recorded Cause	Disturbance: Undervoltage	Disturbance: Outage	Number of Computer Failures
Wind and lightning	37	14	51
Utility equipment failure	8	0	8
Construction or traffic accident	8	2	10
Animals	5	1	6
Tree limbs	1	1	2
Unknown	21	2	23
Totals	80	20	100

Key developed the *recommended voltage tolerance envelope* shown in Figure 8.2-1. The design goals illustrated are recommendations to computer manufacturers for implementation in new equipment.

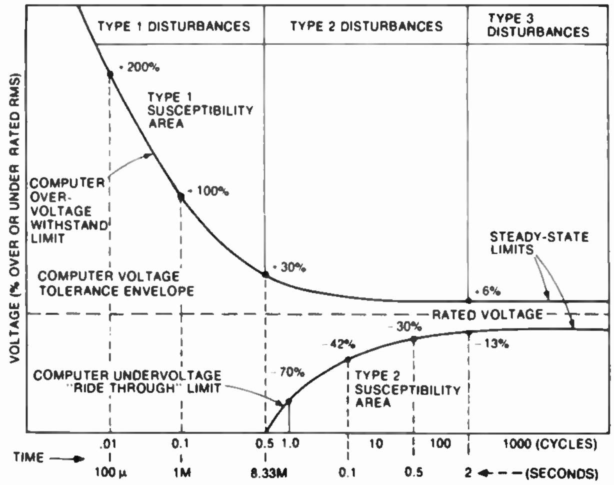

Figure 8.2-1. The recommended voltage tolerance envelope for computer equipment. This chart is based on pioneering work done by the Naval Facilities Engineering Command. The study identified how the magnitude *and* duration of a transient pulse must be considered in determining the damaging potential of a spike. The design goals illustrated in the chart are recommendations to computer manufacturers for implementation in new equipment. In the chart, cycles refer to cycles of 60 Hz ac.[1]

Assessing the Lightning Hazard

As identified by Key in his Naval Facilities study, the extent of lightning activity in an area significantly affects the probability of equipment failure caused by transient activity. The threat of a lightning flash to a facility is determined, in large part, by the type of installation and its geographic location. The type and character of the lightning flash are also important factors.

The *Keraunic number* of a geographic location describes the likelihood of lightning activity in that area. Figure 8.2-2 shows the *Isokeraunic map* of the United States, which estimates the number of lightning days per year across the country. On average, 30 storm days occur per year across the continental United States. This number does not fully describe the lightning threat because many individual lightning flashes occur during a single storm.

The structure of a facility has a significant effect on the exposure of equipment to potential lightning damage. Higher structures tend to collect and even trigger localized lightning flashes. Because storm clouds tend to travel at specific heights above the earth, conductive structures in mountainous areas more readily attract lightning activity. The *plant exposure factor* is a function of the size of the facility and the Isokeraunic rating of the area. The larger the physical size of an installation, the more likely it is to be hit by lightning during a storm. The longer a transmission line (ac or RF), the more lightning flashes it is likely to receive.

The relative frequency of power problems is seasonal in nature. As shown in Figure 8.2-3, most problems are noted during June, July and August. These high problem rates can be traced primarily to increased thunderstorm activity.

Table 8.2-3
Effects of Power System Configuration on Incidence of Computer Failures[1]

Configuration	Number of Disturbances: Undervoltage	Number of Disturbances: Outage	Recorded Failures
Overhead radial	12	6	18
Overhead spot network	22	1	23
Combined overhead (weighted[1])	16	4	20
Underground radial	6	4	10
Underground network	5	0	5
Combined underground (weighted[1])	5	2	7

[1] The combined averages weighted based on the length of time monitored (30 to 53 months).

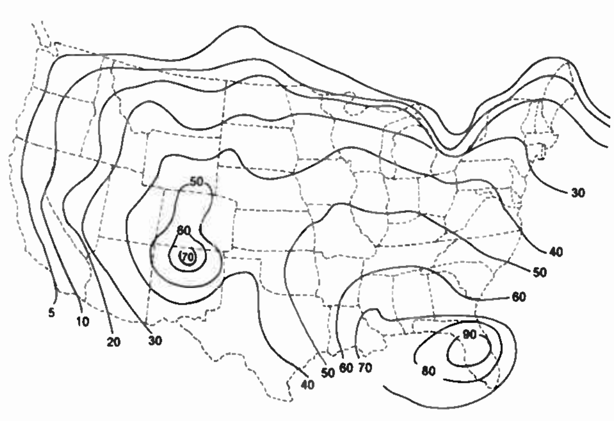

Figure 8.2-2. The Isokeraunic map of the United States, showing the approximate number of lightning days per year.

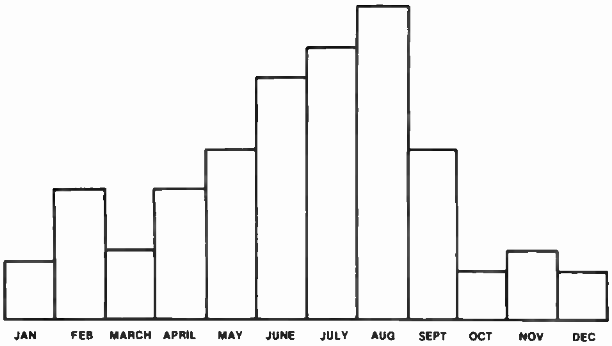

Figure 8.2-3. The relative frequency of power problems in the United States, classified by month.

FIPS Publication 94

In 1983, the U.S. Department of Commerce published a guideline summarizing the fundamentals of powering, grounding and protecting sensitive electronic devices. The document, known as *Federal Information Processing Standards Publication 94*, (FIPS Pub. 94) was first reviewed by governmental agencies and sent to the Computer Business Equipment Manufacturers Association (CBEMA) for review.[2] When the CBEMA group put its stamp of approval on the document, the data processing industry finally had an overarching guideline for power quality.

FIPS Pub. 94 was written to cover *automatic data processing equipment* (ADP), which at that time constituted the principal equipment that was experiencing difficulty running on normal utility supplied power. Since then, IEEE Standard P1100 was issued, which applies to all sensitive electronic equipment-including computer based broadcast systems. FIPS Pub. 94 is a guideline intended to provide a cost/benefit course of action. As a result, it can be relied upon to give the best solution to typical problems that will be encountered, for the least amount of money.

In addition to approving FIPS Pub. 94, the CBEMA group provided a curve that had been used as a guideline for their members in designing power supplies for modern electronic equipment. The CBEMA curve from the FIPS document is shown in Figure 8.2-4. (Note the similarity to the Key tolerance envelope shown in Figure 8.2-1.)

The curve is a susceptibility profile. In order better to explain its meaning, the curve has been simplified and redrawn in Figure 8.2-5. The vertical axis of the graph is the percent of voltage that is applied to the power circuit, and the horizontal axis is the time factor involved (in µs to s). In the center of the chart is the acceptable operating area, and on the outside of that area is a danger area on top and bottom. The danger zone at the top is a function of the tolerance of equipment to excessive voltage levels. The danger zone on the bottom sets the tolerance of equipment to a loss or reduction in applied power. The CBEMA guideline states that if the voltage supply stays within the accept-

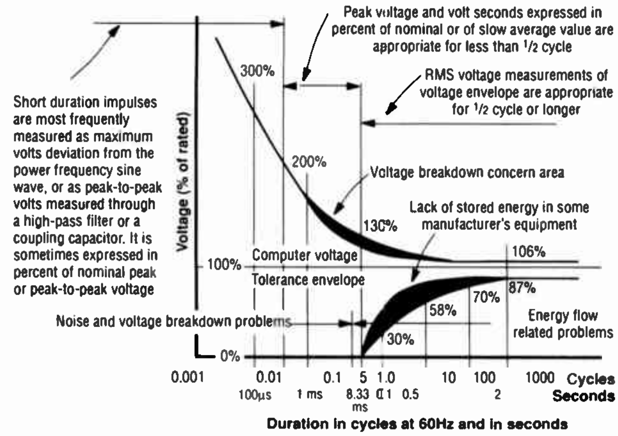

Figure 8.2-4. The CBEMA curve from FIPS Pub. 94.[2]

able area given by the curve, the sensitive load equipment will operate as intended.

Transient Protection Alternatives

A facility can be protected from transient disturbances in two basic ways: the *systems* approach or the *discrete device* approach. Table 8.2-4 outlines the major alternatives available:

- Uninterruptible power system (UPS) and standby generator
- UPS stand-alone system
- Secondary ac *spot network* where power is delivered to a facility via separate paths from the utility company
- Secondary *selective ac network* which is identical to the secondary ac spot network, except that a static transfer switch is included to permit load switching without interruption in service

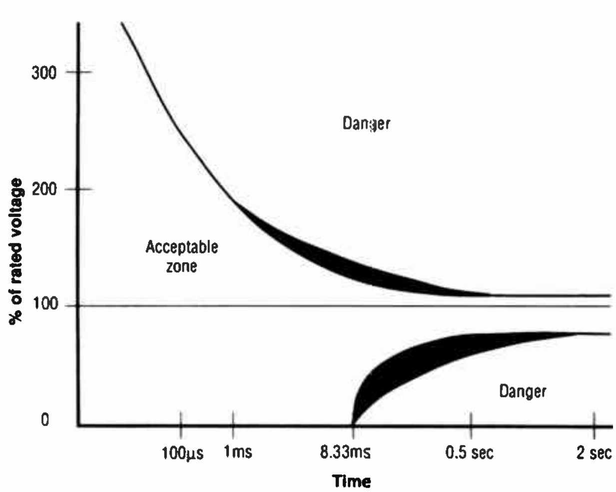

Figure 8.2-5. A simplified version of the CBEMA curve. Voltage levels outside the *acceptable zone* results in potential system shutdown and hardware and software loss.[2]

Table 8.2-4
Types of System-wide Protection Equipment Available to Facility Managers and the ac Line Abnormalities That Each Approach Can Handle[1,2]

System	Disturbance[3] Type 1	Disturbance Type 2	Disturbance Type 3
UPS system and standby generator	All source transients; no load transients	All	All
UPS system	All source transients; no load transients	All	All outages shorter than the battery supply discharge time
Secondary spot network[1]	None	None	Most, depending on the type of outage
Secondary selective network[2]	None	Most	Most, depending on the type of outage
Motor-generator set	All source transients; no load transients	Most	Only brown-out conditions
Shielded isolation transformer	Most source transients; no load transients	None	None
Suppressors, filters, lightning arrestors	Most transients	None	None
Solid state line voltage regulator/filter	Most source transients; no load transients	Some, depending on the response time of the system	Only brown-out conditions

[1] Dual power feeder network.
[2] Dual power feeder network using a static (solid state) transfer switch.
[3] Disturbance types illustrated graphically in Figure 8.2-1.

- Motor-generator set
- Shielded isolation transformer
- Suppressors, filters, and lightning arrestors
- Solid-state line voltage regulator/filter

Table 8.2-5 lists the relative benefits of each protection method. Because each installation is unique, a thorough investigation of facility needs should be conducted before purchasing any equipment. The systems approach offers the advantages of protection engineered to a particular application and need, and (usually) high level factory support during equipment design and installation. The systems approach also means higher costs for the end user.

Specifying System-Protection Hardware

Developing specifications for system-wide power conditioning/backup hardware requires careful analysis of various factors before a particular technology or a specific vendor is selected. Key factors in this process relate to the load hardware and load application. The electrical power required by a sensitive load may vary widely, depending on the configuration of the system. The principle factors that apply to system specification include the following:

- Power requirements, including: voltage, current, power factor, harmonic content and transformer configuration
- Voltage regulation requirements of the load
- Frequency stability required by the load, and the maximum permissible *slew rate* (the rate of change of frequency per second)
- Effects of unbalanced loading
- Overload and inrush current capacity
- Bypass capability
- Primary/standby path transfer time
- Maximum standby power reserve time
- System reliability and maintainability
- Operating efficiency.

An accurate definition of *critical applications* will aid in the specification process for a given site. The potential for future expansion also must be considered in all plans.

Power requirements can be determined either by measuring the actual installed hardware or by checking the nameplate ratings. Most nameplate ratings include significant safety margins. Moreover, the load normally will include a *diversity factor*; all individual elements of the load will not necessarily be operating at the same time.

Every load has a limited tolerance to noise and harmonic distortion. *Total harmonic distortion* (THD) is a measure of the quality of the waveform applied to the load. It is calculated by taking the geometric sum of the harmonic voltages present in the waveform, and expressing that value as a percentage of the fundamental voltage. Critical loads typically can withstand 5% THD, where no single harmonic exceeds 3%. The power conditioning system must provide this high quality output waveform to the load, regardless of the level of noise and/or distortion present at the ac input terminals.

If a power conditioning/standby system does not operate with high reliability, the results often can be disastrous. In addition to threats to health and safety, there is a danger of lost revenue and hardware damage. Reliability must be considered from three different viewpoints:

- Reliability of utility ac power in the area
- Impact of line voltage disturbances on computer based loads
- Ability of the protection system to maintain reliable operation when subjected to expected and unexpected external disturbances.

The environment in which the power conditioning system operates will have a significant effect on reliability. Extremes of temperature, altitude, humidity and vibration can be encountered in various applications. Extreme conditions can precipitate premature component failure and unexpected system shutdown. Most power protection equipment is rated for operation from 0°C to 40°C. During a commercial power failure, however, the ambient temperature of the equipment room

Table 8.2-5
Relative Merits of System-wide Protection Equipment[1,2]

System	Strong Points	Weak Points	Technical Profile
UPS system and standby generator	Full protection from power outage failures and transient disturbances; ideal for critical technical and life-safety loads	Hardware is expensive and may require special construction; electrically and mechanically complex; noise may be a problem; high annual maintenance costs	Efficiency 80-90%; typical high impedance presented to the load may be a consideration; frequency stability good; harmonic distortion determined by UPS system design
UPS system	Completely eliminates transient disturbances; eliminates surge and sag conditions; provides power outage protection up to the limits of the battery supply; ideal for critical load applications	Hardware is expensive; depending on battery supply requirements, special construction may be required; noise may be a problem; periodic maintenance required	Efficiency 80-90%; typical high impedance presented to the load may be a consideration; frequency stability good; harmonic content determined by inverter type
Secondary spot network[1]	Simple; inexpensive when available in a given area; protects against local power interruptions; no maintenance required by user	Not available in all locations; provides no protection from area-wide utility failures; provides no protection against transient disturbances or surge/sag conditions	Virtually no loss, 100% efficient; presents low impedance to the load; no effect on frequency or harmonic content
Secondary selective network[2]	Same as above; provides faster transfer from one utility line to the other	Same as above	Same as above
Motor-generator set	Electrically simple; reliable power source; provides up to 0.5 s power-fail ride-through in basic form; completely eliminates transient and surge/sag conditions	Mechanical system requires regular maintenance; noise may be a consideration; hardware is expensive; depending on m-g set design, power-fail ride-through may be less than typically quoted by manufacturer	Efficiency 80-90%; typical high impedance presented to the load may be a consideration; frequency stability may be a consideration, especially during momentary power-fail conditions; low harmonic content
Shielded isolation transformer	Electrically simple; provides protection against most types of transients and noise; moderate hardware cost; no maintenance required	Provides no protection from brown-out or outage conditions	No significant loss, essentially 100% efficient; presents low impedance to the load; no effect on frequency stability; usually low harmonic content
Suppressors, filters, lightning arrestors	Components inexpensive; units can be staged to provide transient protection exactly where needed in a plant; no periodic maintenance required	No protection from Type 2 or 3 disturbances; transient protection only as good as the installation job	No loss, 100% efficient; some units subject to power-follow conditions; no effect on impedance presented to the load; no effect on frequency or harmonic content
Solid state line voltage regulator/ filter	Moderate hardware cost; uses a combination of technologies to provide transient suppression and voltage regulation; no periodic maintenance required	No protection against power outage conditions; slow response time may be experienced with some designs	Efficiency 92-98%; most units present low impedance to the load; usually no effect on frequency; harmonic distortion content may be a consideration

[1] Dual power feeder network
[2] Dual power feeder network using a static (solid state) transfer switch

can easily exceed either value, depending on the exterior temperature. Operating temperature derating typically is required for altitudes in excess of 1000 ft.

Table 8.2-6 lists key power-quality attributes that should be considered when assessing the need for power-conditioning hardware for a broadcast facility.

MOTOR GENERATOR SET

As the name implies, a *motor-generator* (m-g) set consists of a motor powered by the ac utility supply that is mechanically tied to a generator, which feeds the load (see Figure 8.2-6). Transients on the utility line will have no effect on the load when this arrangement is used. Adding a flywheel to the motor-to-generator shaft will protect against brief power dips (up to 1/2 s on many models). Figure 8.2-7 shows the construction of a typical m-g set. The attributes of an m-g include the following:

- An independently generated source of voltage can be regulated without interaction with line voltage changes on the power source. Utility line changes of ±20% commonly can be held to within ±1% at the load
- The rotational speed and inertial momentum of the rotating mass represents a substantial amount of stored rotational energy, preventing sudden changes in voltage output when the input is momentarily interrupted
- The input and output windings are separated electrically, preventing transient disturbances from propagating from the utility company ac line to the load
- Stable electrical characteristics for the load include output voltage and frequency regulation, ideal sine wave output and true 120° phase shift for three-phase models
- Reduced problems relating to the power factor presented to the utility company power source.

Table 8.2-6
Power-Quality Attributes for Computer-Based Processing Hardware[2]

Environmental attribute	Typical environment	Acceptable limits for computer based systems: Normal	Acceptable limits for computer based systems: Critical
Line frequency	±0.1 to ±3%	±1%	±0.3%
Rate of frequency change	0.5 to 20 Hz/s	1.5 Hz/s	0.3 Hz/s
Over- and under-voltage	(± 5% to +6, −13.3%	+5% to −10%	± 3%
Phase imbalance	2 to 10%	5% max	3% max
Tolerance to low power factor	0.85 to 0.6 lagging	0.8 lagging	less than 0.6 lagging, or 0.9 leading
Tolerance to high steady state peak current	1.3 to 1.6 peak, rms	1.0 to 2.5 peak, rms	Greater than 2.5 peak, rms
Harmonic voltages	0 to 20% total rms	10 to 20% total, 5 to 10% largest	5% max total, 3% largest
Voltage deviation from sine wave	5 to 50%	5 to 10%	3 to 5%
Voltage modulation	Negligible to 10%	3% max	1% max
Surge/sag conditions	+10%, −15%	+20%, −30%	+5%, −5%
Transient impulses	2 to 3 times nominal peak value (0 to 130% Vs)	Varies; 1.0 to 1.5 kV typical	Varies; 200 to 500 V typical
RFI/EMI normal and common modes	10 V up to 20 kHz, less at high freq.	Varies widely, 3 V typical	Varies widely, 0.3 V typical
Ground currents	0 to 10 A plus impulse noise current	0.001 to 0.5 A or more	0.0035 A or less

The efficiency of a typical m-g ranges from 65–89%, depending on the size of the unit and the load. Motor-generator sets have been used widely to supply 415 Hz power to mainframe computers that require this frequency.

System Configuration

There are a number of types of m-g sets, each having its own characteristics, advantages and disadvantages. A simplified schematic diagram of an m-g is shown in Figure 8.2-8. The type of motor that drives the set is an important design element. Direct current motor drives can be controlled in speed independently of the frequency of the ac power source from which the dc is derived. Use of a dc motor, thereby, gives the m-g set the capability to produce power at the desired output frequency, regardless of variations in input frequency. The requirement for rectifier conversion hardware, control equipment and commutator maintenance are drawbacks to this approach that must be considered.

The simplest and least expensive approach to rotary power conditioning involves the use of an induction motor as the mechanical source. Unfortunately, the rotor of an induction motor turns slightly slower than the rotating field produced by the power source. This results in the generator being unable to produce 60 Hz output power if the motor is operated at 60 Hz and the machines are directly coupled end-to-end at their shafts, or are belted in a 1:1 ratio. Furthermore, the shaft speed and output frequency of the generator decreases as the load on the generator is increased. This potential for varying output frequency may be acceptable where the m-g set is used solely as the input to a power supply in which the ac is rectified and converted to dc. However, certain loads cannot tolerate frequency changes greater than 1 Hz/s and frequency deviations of more than 0.5 Hz from the nominal 60 Hz value.

Low slip induction motor driven generators are available that can produce 59.7 Hz at full load, assuming 60 Hz input. During power interruptions, the output frequency will drop further depending upon the length of the interruption. The capability of the induction motor to restart after a momentary power interruption is valuable. Various systems of variable speed belts have been tried successfully. Magnetically controlled

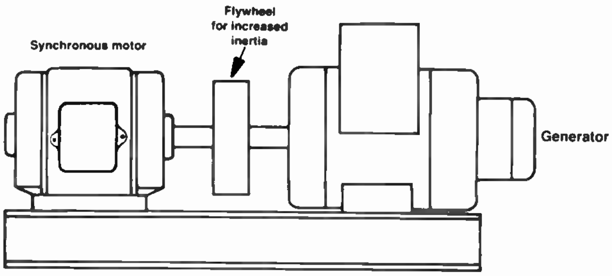

Figure 8.2-6. Two-machine motor-generator set with an optional flywheel to increase inertia and carry through capability.

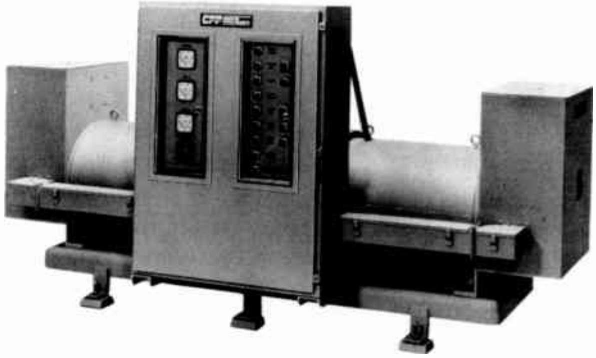

Figure 8.2-7. Construction of a typical m-g set. (*Courtesy of Computer Power Protection.*)

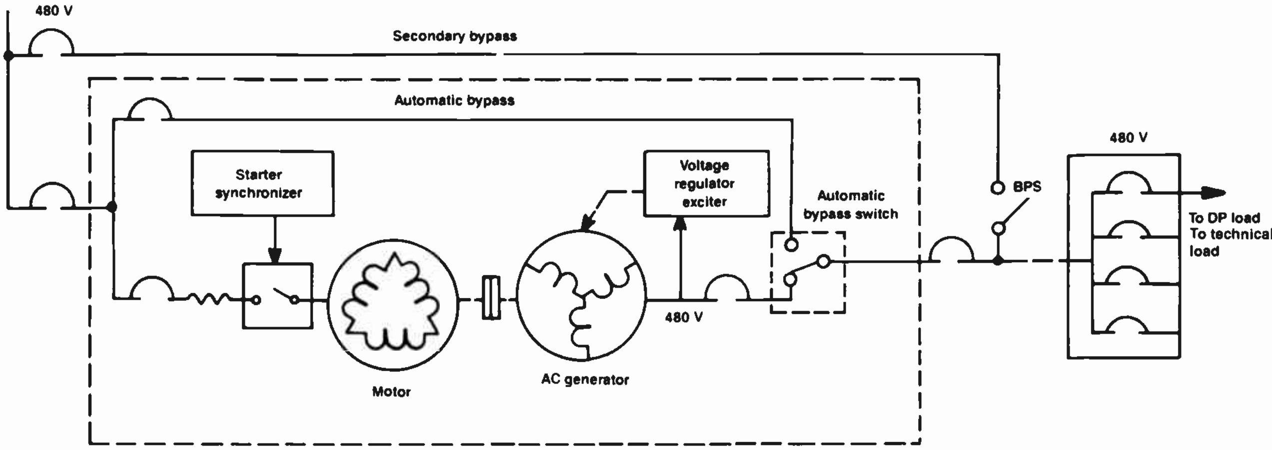

Figure 8.2-8. Simplified schematic diagram of an m-g set with automatic and secondary bypass capability.[2]

slipping clutches have been found to be largely unsatisfactory. Other approaches to make the induction motor drive the load at constant speed have produced mixed results.

Using a synchronous motor with direct coupling or a cogged 1:1 ratio belt drive guarantees that the output frequency will be equal to the motor input frequency. Although the synchronous motor is more expensive, it is more efficient and can be adjusted to provide a unity PF load to the ac source. The starting characteristics and the mechanical disturbance following a short line voltage interruption depends, to a large extent, on motor design. Many synchronous motors that are not required to start under load have weak starting torque, and may use a *pony motor* to aid in starting (see Figure 8.2-9). Those motors designed to start with a load have starting pole face windings that provide starting torque comparable to that of an induction motor. Such motors can be brought into synchronism while under load with proper selection of the motor and automatic starter system. Typical utility company ac interruptions are a minimum of six cycles (0.1 s). Depending upon the design and size of the flywheel used, the ride through period can be as much as 0.5 s or more. The generator will continue to produce output power for a longer

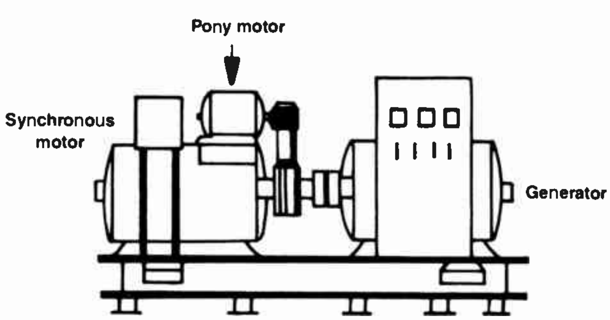

Figure 8.2-9. Use of a pony motor for an m-g set to aid in system starting and restarting.[2]

duration, but the frequency and rate of frequency change will most likely fall outside of the acceptable range of most technical loads after 0.5 s.

If input power is interrupted and does not return before the output voltage and frequency begin to fall outside acceptable limits, the generator output controller can be programmed to disconnect the load. Before this event, a warning signal is sent to the computer system control circuitry to warn of impending shutdown and to initiate an orderly interruption of active programs. This facilitates easy restart of the computers and associated network(s) after the power interruption has passed.

It is important for users to accurately estimate the length of time that the m-g set will continue to deliver acceptable power without input to the motor from the utility company. This data facilitates accurate power-fail shutdown routines. It is also important to ensure that the m-g system can handle the return of power without operating overcurrent protection devices because of high inrush currents that may be required to accelerate and synchronize the motor with the line frequency. Protection against the latter problem requires proper programming of the synchronous motor controller to correctly disconnect and then reconnect the field current supply.

Generators typically used in m-g sets have substantially higher internal impedance than equivalent kVA-rated transformers. Because of this situation, m-g sets sometimes are supplied with an oversize generator that will be lightly loaded, coupled with a smaller motor that is adequate to drive the actual load. This approach reduces the initial cost of the system, decreases losses in the motor, and provides a lower operating impedance for the load.

The most common utility supply voltage used to drive the input of an m-g set is 480 V. The generator output for systems rated at about 75 kVA or less is typically 208 Y/120 V. For larger loads, the most economical generator output is typically 480 V. A 480-208 Y/120 V three-phase isolating transformer usually is included to provide 208 Y/120 V power to the load equipment.

Single-Shaft Systems

There are two basic m-g set machine mechanical designs used for critical load applications: separate motor-generator systems and single-shaft, single-housing units. Both designs can use either a synchronous or induction motor. In each case, there are advantages and disadvantages. The separate machine design (discussed previously) uses a motor driving a physically separate generator by means of a coupling shaft or pulley. In an effort to improve efficiency and reduce costs, manufacturers also have produced various types of single-shaft systems.

The basic concept of a single-shaft system is to combine the motor and generator elements into a single unit. A common stator eliminates a number of individual components, making the machine less expensive to produce and mechanically more efficient. The common stator set substantially reduces mechanical energy losses associated with traditional m-g designs, and it improves system reliability as well. In one design, the stator is constructed so that alternate slots are wound with input and output windings. When it is fed with a three-phase supply, a rotating magnetic field is created, causing the dc-excited rotor to spin at a synchronous speed. By controlling the electrical characteristics of the rotor, control of the output at the secondary stator windings is accomplished.

Common stator machines offer lower working impedance for the load than a comparable two-machine system. For example, a typical 400 kVA machine has approximately an 800 kVA frame size. The larger frame size yields a relatively low impedance power source capable of clearing subcircuit fuses under fault conditions. The output of the unit typically can supply up to seven times the full load current under fault conditions. Despite the increase in frame size, the set is smaller and lighter than comparable systems because of the reduced number of mechanical parts.

Flywheel Considerations

In an effort to achieve higher energy and power densities, m-g set designers have devoted considerable attention to the flywheel element itself. New composite materials and power electronics technologies have resulted in compact flywheel batteries capable of high linear velocity at the outside radius of the flywheel (*tip speed*).[3] The rotational speed of the flywheel is important because the stored energy in a flywheel is proportional to the square of its rotational speed. Therefore, an obvious method for maximizing stored energy is to increase the speed of the flywheel. All practical designs, however, have a limiting speed, which is determined by the stresses developed within the wheel resulting from inertial loads. These loads are also proportional to the square of rotational speed. Flywheels built of composite materials weigh less and hence develop lower inertial loads at a given speed. In addition, composites are often stronger than conventional engineering metals, such as steel. This combination of high strength and low weight enables extremely high tip speeds, relative to conventional wheels.

For a given geometry, the limiting *energy density* (energy per unit mass) of a flywheel is proportional to the ratio of material strength to weight density, otherwise known as the *specific strength*. Table 8.2-7 illustrates the advantage that composite materials offer in this respect.

Recent advances in composite materials technology may allow nearly an order of magnitude advantage in the specific strength of composites when compared to even the best common engineering metals. The result of this continuous research in composites has been flywheels capable of operation at rotational speeds in excess of 100,000 rpm, with tip speeds in excess of 1,000 m/s.

These high speeds bring with them new challenges. The ultrahigh rotational speeds that are required to store significant kinetic energy in these systems virtually rule out the use of conventional mechanical bearings. Instead, most systems run on magnetic bearings. This relatively recent innovation uses magnetic forces to levitate a rotor, eliminating the frictional losses inherent in rolling element and fluid film bearings. Unfortunately, aerodynamic drag losses force most high speed flywheels to operate in a partial vacuum, which complicates the task of dissipating the heat generated by ohmic losses in the bearing electromagnets and rotor. In addition, active magnetic bearings are inherently unstable, and require sophisticated control systems to maintain proper levitation.

The integrated generator of these systems is usually a rotating field design, with the magnetic field supplied by rare earth permanent magnets. Because the specific strength of these magnets is typically just fractions of that of the composite flywheel, they must spin at much lower tip speeds; in other words, they must be placed very near the hub of the flywheel. This compromises the power density of the generator. An alternative is to mount them closer to the outer radius of the wheel, but contain their inertial loads with the composite wheel itself. Obviously, this forces the designer to either derate the machine speed or operate closer to the stress limits of the system.

Maintenance Considerations

Because m-g sets require some maintenance that necessitates shutdown, most systems provide bypass capability so the maintenance work can be performed

Table 8.2-7
Specific Strength of Selected Materials[4]

Material	Specific Strength (in^3)
Graphite/epoxy	3,509,000
Boron/epoxy	2,740,000
Titanium and alloys	1,043,000
Wrought stainless steel	982,000
Wrought high-strength steel	931,000
7000 series aluminum alloys	892,000

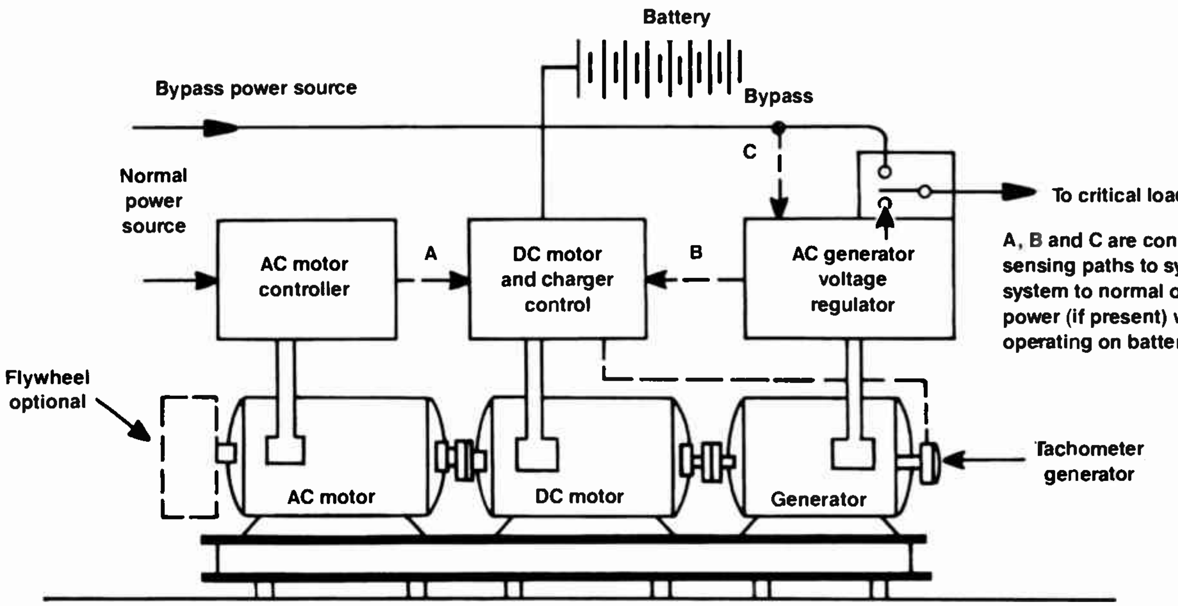

Figure 8.2-10. Uninterruptible m-g set with ac and dc motor drives.[2]

without having to take the load out of service. If the automatic bypass contactor, solid-state switch and control hardware are in the same cabinet as other devices that also need to be deenergized for maintenance, a secondary bypass is recommended. After the automatic bypass path has been established, transfer switching to the secondary bypass can be enabled, taking the m-g set and its automatic bypass system out of the circuit completely. Some automatic bypass control arrangements are designed to transfer the load of the generator to the bypass route with minimum disturbance. This requires the generator output to be synchronized with the bypass power before closing the switch and opening the generator output breaker. However, with the load taken off the generator, bypass power no longer will be synchronized with it. Consequently, retransfer of the load back to the generator may occur with some disturbance. Adjustment for minimum disturbance in either direction requires a compromise in phase settings, or a means to shift the phase before and after the transfer.

The use of rotating field exciters has eliminated the need for slip rings in most m-g designs. Brush inspection and replacement, therefore, are no longer needed. However, as with any rotating machinery, bearings must be inspected and periodically replaced.

Motor-Generator UPS

Critical applications that cannot tolerate even brief ac power interruptions can use the m-g set as the basis for an uninterruptible source of power through the addition of a battery-backed dc motor to the line-driven ac motor shaft. This concept is illustrated in Figure 8.2-10. The ac motor normally supplies power to drive the system from the utility company line. The shafts of the three devices all are interconnected, as shown in the Figure. When ac power is present, the dc motor serves as a generator to charge the battery bank. When line voltage is interrupted, the dc motor is powered by the batteries. Figure 8.2-11 shows a modified version of this basic m-g UPS using only a dc motor as the

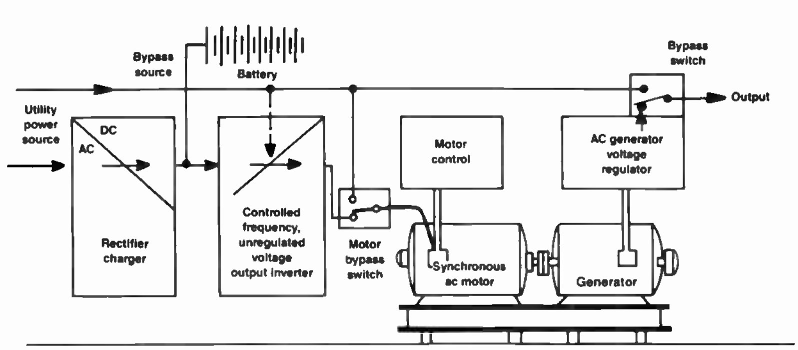

Figure 8.2-11. Uninterruptible m-g set using a single dc drive motor.[2]

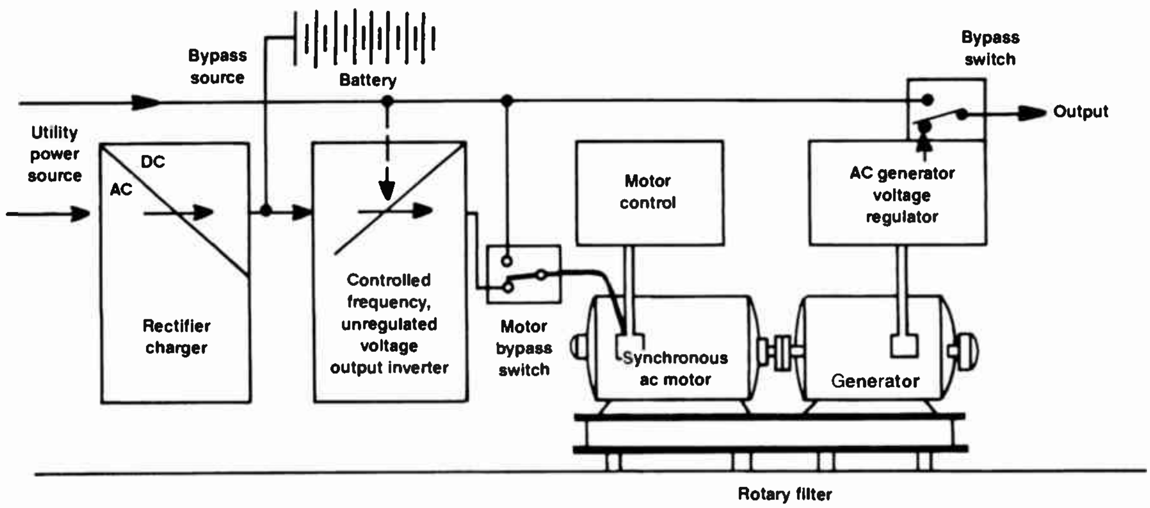

Figure 8.2-12. Uninterruptible m-g set using a synchronous ac motor.[2]

mechanical power source. This configuration eliminates the inefficiency involved in having two motors in the system. Power from the utility source is rectified to provide energy for the dc motor, plus power for charging the batteries. A complex control system to switch the ac motor off and the dc motor on in the event of a utility power failure is not needed in this design.

The m-g UPS also can be built around a synchronous ac motor, as illustrated in Figure 8.2-12. Utility ac energy is rectified and used to drive an inverter, which provides a regulated frequency source to power the synchronous motor. The output from the dc-to-ac inverter need not be a well formed sine wave, nor a well regulated source. The output from the generator will provide a well regulated sine wave for the load. The m-g set also can be operated in a bypass mode that eliminates the rectifier, batteries and inverter from the current path, operating the synchronous motor directly from the ac line.

Kinetic Battery Storage System

As outlined previously, one of the parameters that limits the ride through period of an m-g set is the speed decay of the flywheel/generator combination. As the flywheel slows down, the output frequency drops. This limits the useful ride through period to 0.5 s or so. Figure 8.2-13 shows an ingenious modification of the classic power conditioning template that extends the potential ride-through considerably. As shown in the Figure, an m-g set is used in a UPS based system as an element of the dc supply grid. The major components of the system include:

- Steel flywheel for energy storage
- Small drive motor, sized at 15-20% of the rated system output, to start the flywheel and maintain its normal operating speed
- Variable speed drive (VSD) to slowly ramp the flywheel up to speed and maintain it at the desired rpm
- Generator to convert the kinetic energy stored in the flywheel into electrical energy
- Diode bridge rectifier to convert the ac generator output to dc for use by the UPS bus, which continues to draw usable energy essentially independent of flywheel rpm.

Because the ac output of the generator is converted to dc, frequency is no longer a limiting factor, which allows the dc voltage output to be maintained over a much greater range of the flywheel's rpm envelope.

In operation, the small drive motor spins the flywheel while the variable speed drive maintains the proper motor speed.[5] Because the amount of stored kinetic energy increases by the square of the flywheel rpm, it is possible to greatly increase stored energy, and thus ride through, by widening the flywheel's usable energy output range. These factors permit typical ride through times from 10 s to several minutes, depending on loading and other operating conditions. Among the

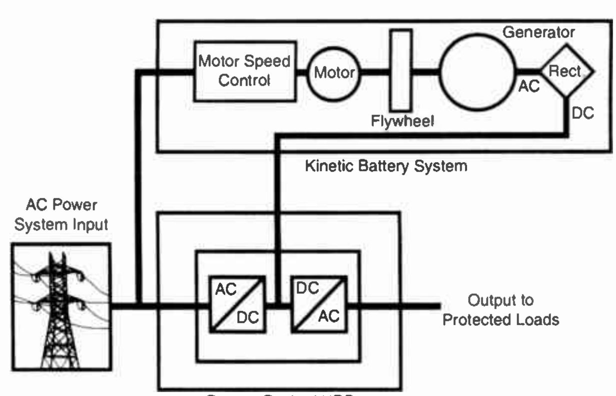

Figure 8.2-13. Functional block diagram of a kinetic battery m-g system for powering a UPS.[5]

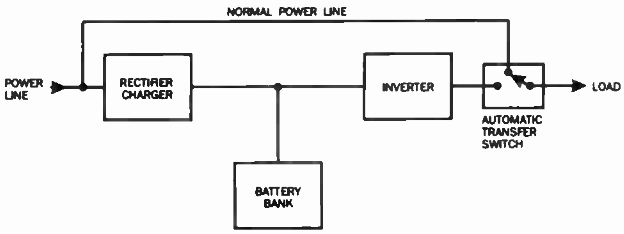

Figure 8.2-14. Forward-transfer UPS system.

benefits of this approach include the reduced cycling of battery supplies and engine-generators systems.

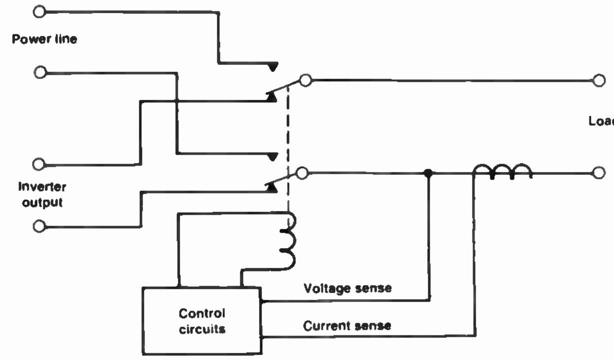

Figure 8.2-16. Electromechanical load-transfer switch.

UNINTERRUPTIBLE POWER SYSTEMS

Uninterruptible power systems (UPS) have become a virtual necessity for powering large or small computer systems where the application serves a critical need, such as broadcasting. Computers and data communications systems are no more reliable than the power from which they operate. The difference between UPS and *emergency standby power* is that the UPS is always in operation. It reverts to an alternative power source, such as the utility company, only if the UPS fails or needs to be deactivated for maintenance. Even then, the transfer of power occurs so quickly (within milliseconds) that it does not interrupt proper operation of the load.

Emergency standby power is normally off and does not start (manually or automatically) until the utility ac feed fails. A diesel generator can be started within 10 to 30 s if the system has been maintained properly. Such an interruption, however, is far too long for computer based hardware. Most systems cannot ride through more than 8 to 22 ms of power interruption. Systems that can successfully ride through short duration power breaks, as far as energy continuity is concerned, still may enter a fault condition because of electrical noise created by the disturbance.

UPS hardware is available in a number of different configurations. All systems, however, are variations of two basic designs:

- *Forward-transfer mode:* the load normally is powered by the utility power line and the inverter is idle. If a commercial power failure occurs, the inverter is started and the load is switched. This configuration is illustrated in Figure 8.2-14. The primary drawback of this approach is the lack of load protection from power line disturbances during normal (utility-powered) operation.
- *Reverse-transfer mode:* The load normally is powered by the inverter. In the event of an inverter failure, the load is switched directly to the utility line. This configuration is illustrated in Figure 8.2-15. The reverse-transfer mode is, by far, the most popular type of UPS system in use for large-scale systems.

The type of load-transfer switch used in the UPS system is another critical design parameter. The continuity of ac power service to the load is determined by the type of switching circuit used. An electromechanical transfer switch, shown in Figure 8.2-16, is limited to switch times of 20 to 50 ms. This time delay may cause sensitive load equipment to malfunction, and perhaps shut down. A control circuit actuates the relay when the sensed output voltage falls below a preset value, such as 94% of nominal. A static transfer switch, shown in Figure 8.2-17, can sense a failure and switch the load in about 4 ms. Most loads will ride through this short delay without any malfunction. To accomplish a smooth transition, the inverter output must be synchronized with the power line.

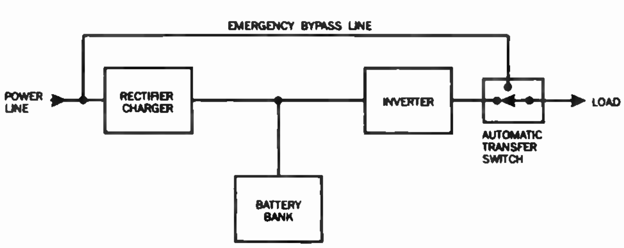

Figure 8.2-15. Reverse-transfer UPS system.

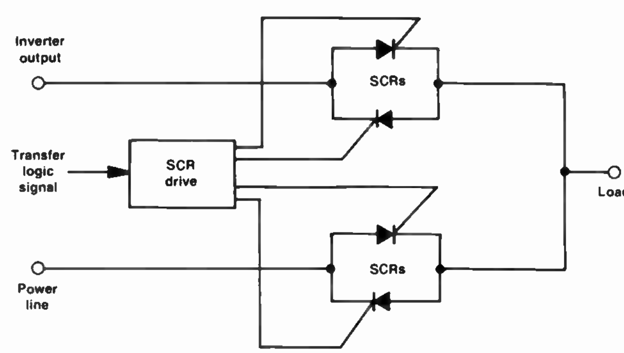

Figure 8.2-17. Static load-transfer switch.

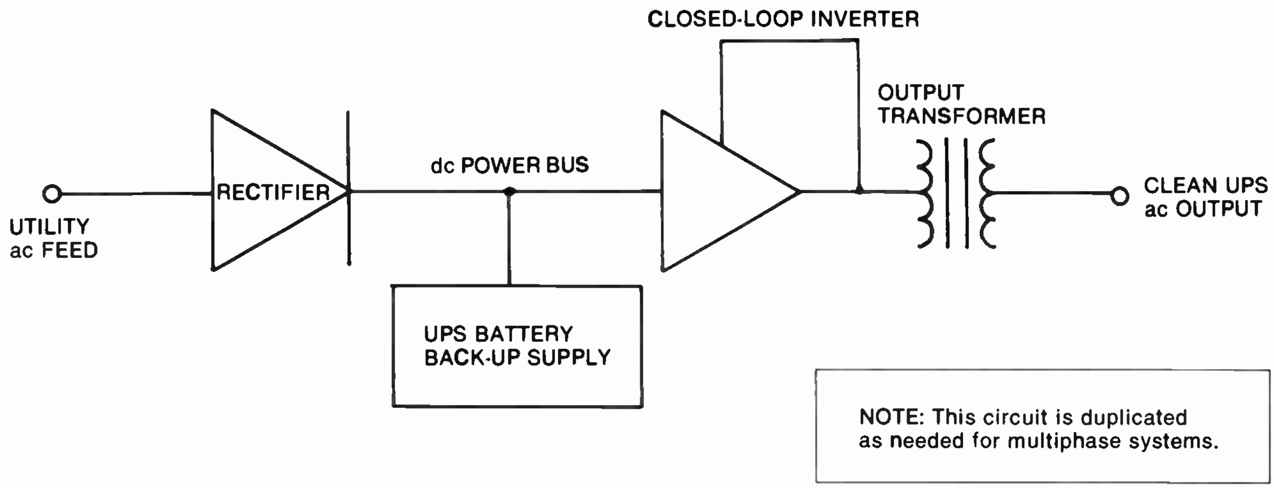

Figure 8.2-18. Block diagram of an uninterruptible power system using ac rectification to float the battery supply. A closed-loop inverter draws on this supply and delivers clean ac power to the protected load.

UPS Configuration

The basic uninterruptible power system is built around a battery-driven inverter, with the batteries recharged by the utility ac line. As shown in Figure 8.2-18, ac from the utility feed is rectified and applied to recharge or *float* a bank of batteries. This dc power drives a single- or multiphase closed-loop inverter, which regulates output voltage and frequency. The output of the inverter is generally a sine wave, or pseudo sine wave (a stepped square wave). If the utility voltage drops or disappears, current is drawn from the batteries. When ac power is restored, the batteries are recharged. Many UPS systems incorporate a standby diesel generator that starts as soon as the utility company feed is interrupted. With this arrangement, the batteries are called upon to supply operating current for only 30 s or so, until the generator gets up to speed. A UPS system intended to power a computer center, is illustrated in Figure 8.2-19.

Power-Conversion Methods

Solid-state UPS systems that do not employ rotating machinery utilize one of several basic concepts. The design of an inverter is determined primarily by the operating power level. The most common circuit configurations include:

- Ferroresonant inverter
- Delta magnetic inverter

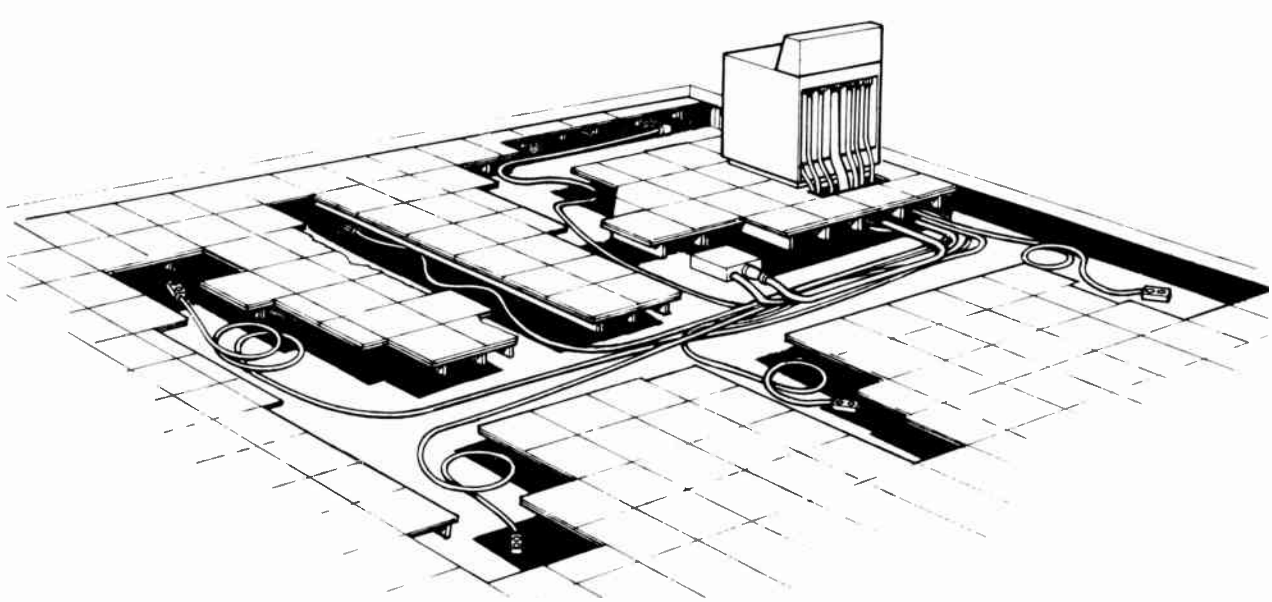

Figure 8.2-19. Installation details for a computer room UPS power conditioner.

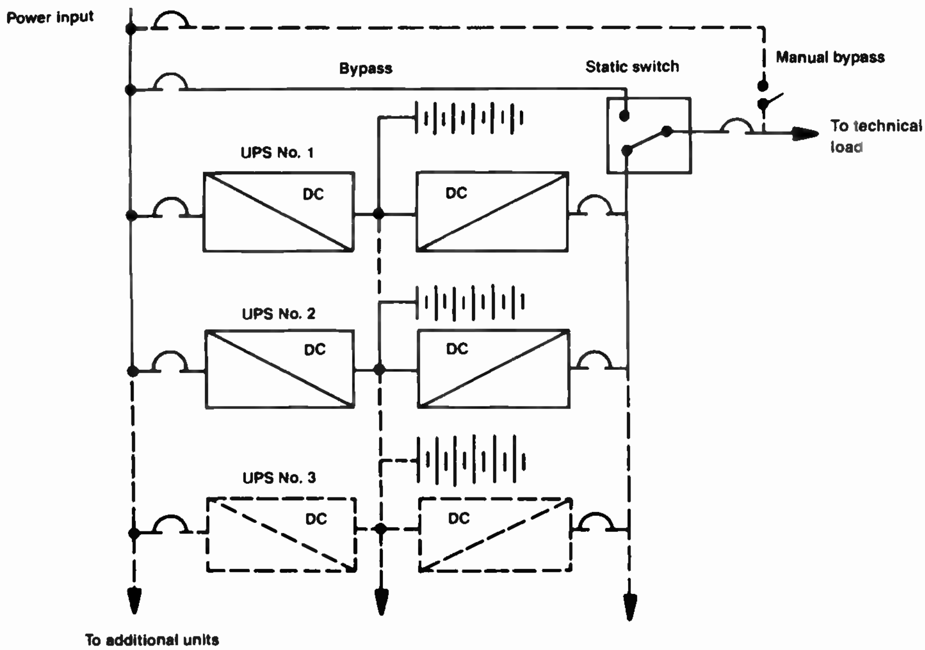

Figure 8.2-20. Configuration of a parallel redundant UPS system.[2]

- Inverter-fed *L/C* tank
- Quasi-square wave inverter
- Step wave inverter
- Pulse-width modulation inverter
- Phase modulation inverter

Redundant Operation

UPS systems can be configured as either a single, large power conditioning/backup unit or as several smaller systems arranged in a *parallel redundant* or *isolated redundant* mode. In the parallel redundant mode, the UPS outputs are connected together and share the total load (see Figure 8.2-20). The power-output ratings of the individual UPS systems are selected to provide for operation of the entire load with any one UPS unit out of commission. In the event of expansion of the broadcast facility, additional UPS units can be added to carry the load. The parallel system provides the ability to cope with the failure of any single unit.

An isolated redundant system, illustrated in Figure 8.2-21, divides the load among several UPS units. If one of the active systems fails, a static bypass switch will connect the affected load to a standby UPS system dedicated to that purpose. The isolated redundant system does not permit the unused capacity of one UPS unit to be utilized on a computer based system that is loading another UPS to full capacity. The benefit of the isolated configuration is its immunity to system wide failures.

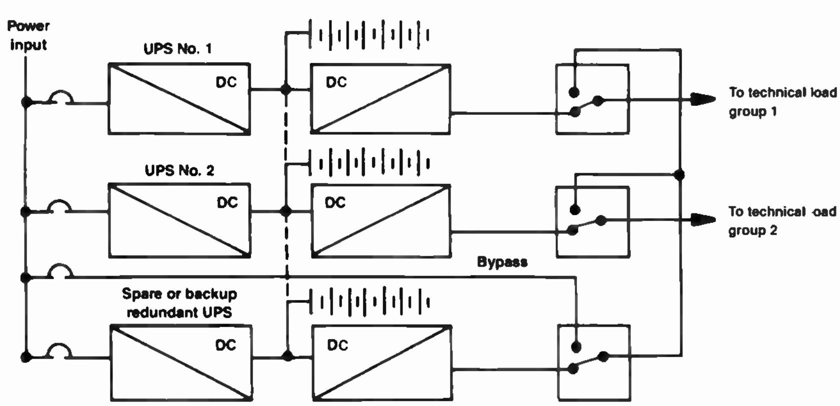

Figure 8.2-21. Configuration of an isolated redundant UPS system.[2]

Output Transfer Switch

Fault conditions, maintenance operations and system reconfiguration require the load to be switched from one power source to another. This work is accomplished with an output transfer switch. As discussed previously, most UPS systems use electronic (static) switching. Electromechanical or motor-driven relays operate too slowly for most loads. Static transfer switches can be configured as either of the following:

- *Break-before-make:* Power output is interrupted before transfer is made to the new source.
- *Make-before-break:* The two power sources are overlapped briefly so as to prevent any interruption in ac power to the load.

Figure 8.2-22 illustrates each approach to load switching.

For critical load applications, a make-before-break transfer is necessary. For the switchover to be accomplished with minimum disturbance to the load, both power sources must be synchronized. The UPS system must, therefore, be capable of synchronizing to the utility ac power line (or other appropriate power source).

Battery Supply

UPS systems typically are supplied with sufficient battery capacity to carry a technical load for periods ranging from 5 minutes to 1 hour or more. Long backup time periods usually are handled by a standby diesel generator. Batteries require special precautions. For large installations, they almost always are placed in a room dedicated to that purpose. Proper temperature control is important for long life and maximum discharge capacity.

Most rectifier/charger circuits operate in a *constant-current* mode during the initial charge period, and automatically switch to a *constant-voltage* mode near the end of the charge cycle. This provides maximum battery life consistent with rapid recharge. It also prevents excessive battery outgassing and water consumption. The charger provides a *float voltage level* for maintaining the normal battery charge, and sometimes a higher voltage to equalize certain devices.

Four battery types typically are found in UPS systems:

- **Semisealed lead calcium.** A gel-type electrolyte is used that does not require the addition of water. There is no outgassing or corrosion. This type of battery is used when the devices are integral to small UPS units, or when the batteries must be placed in occupied areas. The lifespan of a semisealed lead calcium battery, under ideal conditions, is about 5 years

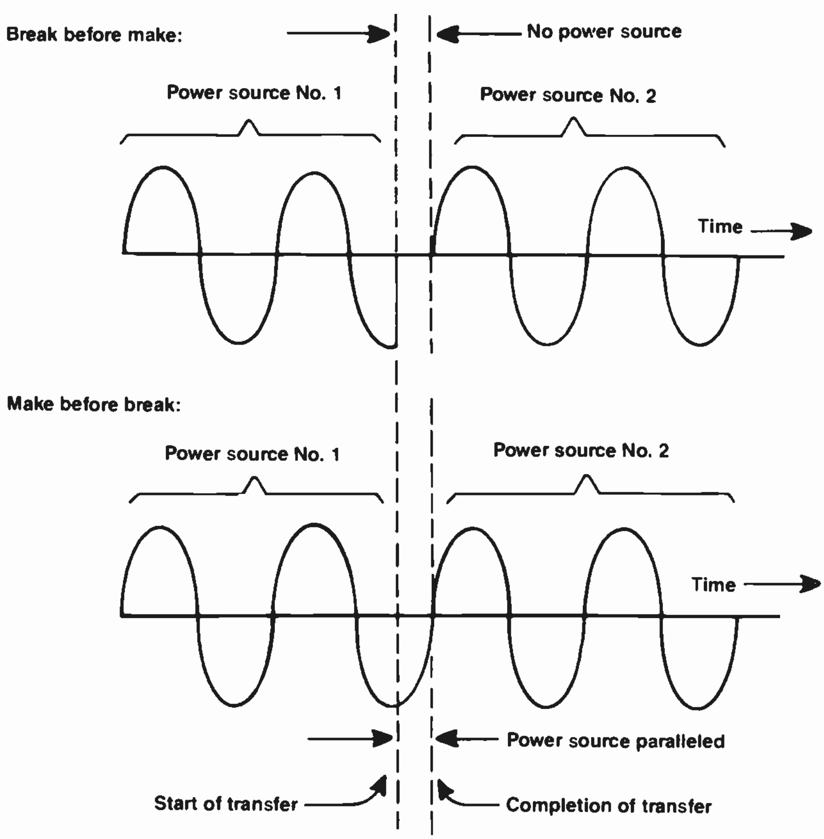

Figure 8.2-22. Static transfer switch modes.

- **Conventional lead calcium.** The most common battery type for UPS installations, these units require watering and terminal cleaning about every 6 months. Expected lifetime ranges up to 20 years. Conventional lead-calcium batteries outgas hydrogen under charge conditions and must be located in a secure, ventilated area
- **Lead-antimony.** The traditional lead-acid batteries, these devices are equivalent in performance to lead-calcium batteries. Maintenance is required every 3 months. Expected lifetime is about 10 years. To retain their capacity, lead-antimony batteries require a monthly equalizing charge
- **Nickel-cadmium.** Advantages of the nickel-cadmium battery includes small size and low weight for a given capacity. These devices offer excellent high and low temperature properties. Life expectancy is nearly that of a conventional lead-calcium battery. Nickel-cadmium batteries require a monthly equalizing charge, as well as periodic discharge cycles to retain their capacity. Nickel-cadmium batteries are the most expensive of the devices typically used for UPS applications.

DEDICATED PROTECTION SYSTEMS

A wide variety of power protection technologies are available to solve specific problems at a facility. The method chosen depends upon a number of factors, not the least of which is cost. Although UPS units and m-g sets provide a high level of protection against ac line disturbances, the costs of such systems are high. Many times, adequate protection can be provided using other technologies at a fraction of the cost of a full-featured, facility-wide system. The applicable technologies include:

- Ferroresonant transformer
- Isolation transformer
- Tap-changing regulator
- Line conditioner

Line Conditioner

A line conditioner combines the functions of an isolation transformer and a voltage regulator in one unit. The three basic types of line conditioners for sensitive load applications are:

- **Linear amplifier correction system.** As illustrated in Figure 8.2-23, correction circuitry compares the ac power output to a reference source, derived from a 60 Hz sine wave generator. A correction voltage is developed and applied to the secondary power winding to cancel noise and voltage fluctuations. A box shield around the primary winding provides common-mode impulse rejection (80 to 100 dB typical). The linear amplifier correction system is effective and fast, but the overall regulating range is limited
- **Hybrid ferroresonant transformer.** As shown in Figure 8.2-24, this system consists of a ferroresonant transformer constructed using circuit isolation techniques. The box and Faraday shields around the primary and compensating windings give the transformer essentially the characteristics of a noise-attenuating device, while preserving the volt-

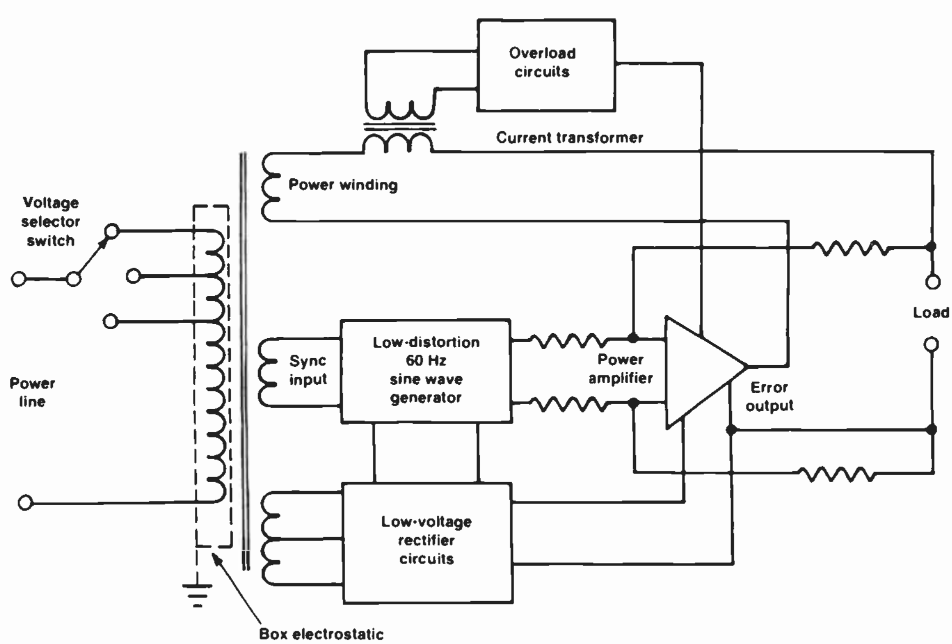

Figure 8.2-23. Power line conditioner using linear amplifier correction.

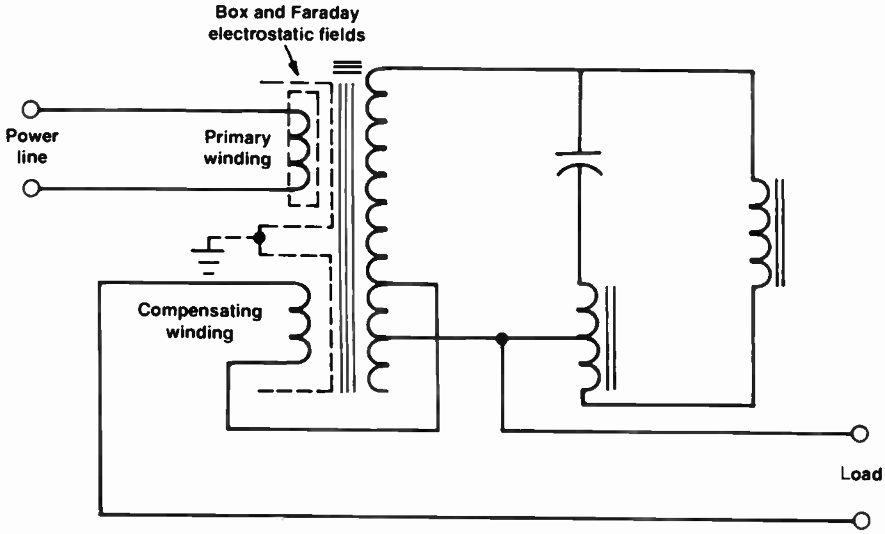

Figure 8.2-24. Line conditioner built around a shielded-winding ferroresonant transformer.

age regulating characteristics of a ferroresonant transformer

- **Electronic tap changing high isolation transformer.** This system is built around a high attenuation isolation transformer with a number of primary winding taps. SCR pairs control voltage input to each tap, as in a normal tap changing regulator. Tap changing also can be applied to the secondary, as shown in Figure 8.2-25. The electronic tap changing high isolation transformer is an efficient design that effectively regulates voltage output and prevents noise propagation to the load.

CONCLUSION

There are, thus, a number of approaches to ac power conditioning that are practical and applicable to broadcast facilities. This chapter only scratched the surface of this topic. Interested readers are referred to the *AC Power Systems Handbook*, 2nd Edition for a detailed examination of the subject.

In the realm of power quality, you get what you pay for. It is rarely practical to shield a facility from every conceivable disturbance that can occur on the ac input line. You can, however, fashion a practical

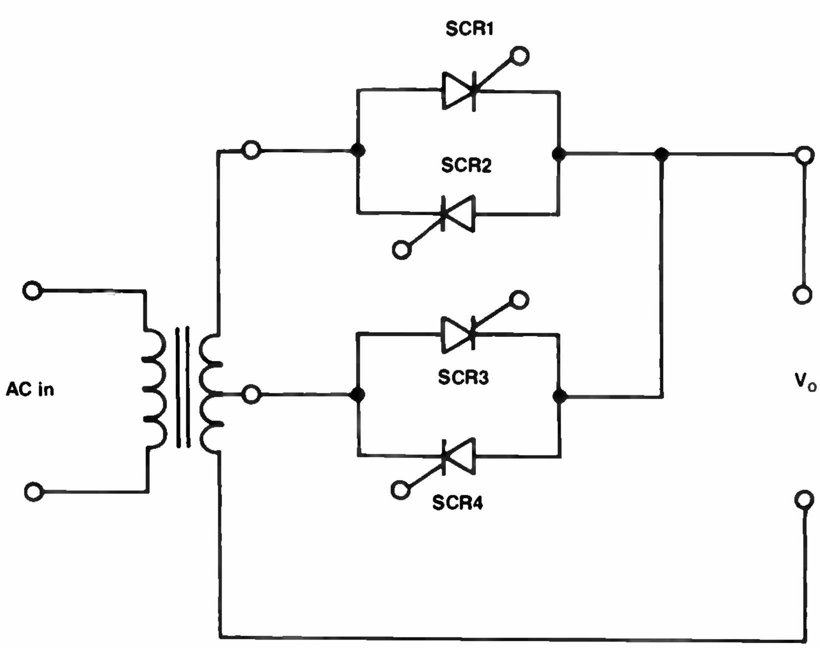

Figure 8.2-25. Secondary-side synchronous tap changing transformer.

and cost-effective protection system that meets the needs of the facility for maximum up-time. ′

8.3
FACILITY GROUNDING PRACTICES

W.E. DEWITT
PURDUE UNIVERSITY, WEST LAFAYETTE, IN

INTRODUCTION

A facility can be defined as something that is built, installed or established to serve a particular purpose.[1] A facility is usually thought of as a single building or group of buildings. The National Electrical Code (NEC) uses the term *premises* to refer to a facility when it defines premises wiring as the interior and exterior (facility) wiring, such as power, lighting, control and signal systems. Premises wiring includes the service and all permanent and temporary wiring between the service and the load equipment. Premises wiring does not include wiring internal to any load equipment.

This chapter will define grounding and list the reasons for grounding; discuss equipment grounding, system grounding and earth connections; apply recommended facility grounding practice to the safe design and construction of electronics installations; and present grounding terminology. Applicable codes and industry standards will be emphasized.

Reasons for Grounding

The Institute of Electrical and Electronic Engineers (IEEE) defines grounding as a conducting connection, whether intentional or accidental, by which an electric circuit or equipment is connected to the earth, or to some conducting body of relatively large extent that serves in place of the earth. It is used for establishing and maintaining the potential of the earth (or of the conducting body) or approximately that potential, on conductors connected to it, and for conducting ground current to and from the earth (or the conducting body).[2]

Based on the IEEE definition, the reasons for grounding can be identified as:

- Personnel safety by limiting potentials between all noncurrent-carrying metal parts of an electrical distribution system all non-current-carrying metal parts of an electrical distribution system and the earth
- Personnel safety and control of electrostatic discharge (ESD) by limiting potentials between all noncurrent-carrying metal parts of an electrical distribution system and earth
- Fault isolation and equipment safety by providing a low-impedance fault return path to the power source to facilitate the operation of overcurrent devices during a ground fault.

The IEEE definition makes an important distinction between *ground* and *earth*. *Earth* refers to planet Earth and *ground* refers to the equipment grounding system, which includes equipment grounding conductors, metallic raceways, cable armor, enclosures, cabinets, frames, building steel and all other noncurrent carrying metal parts of the electrical distribution system.

There are other reasons for grounding not implicit in the IEEE definition. Overvoltage control has long been a benefit of power system grounding, and is described in IEEE Standard 142, *The Green Book*.[3] With the increasing use of electronic computer systems, noise control has become associated with the subject of grounding, and is described in IEEE Standard 1100, *The Emerald Book*.[4]

EQUIPMENT GROUNDING

Personnel safety is achieved by interconnecting all noncurrent-carrying metal parts of an electrical distribution system, and then connecting the interconnected metal parts to the earth. This process of interconnecting metal parts is called *equipment grounding* and is illustrated in Figure 8.3-1, where the equipment grounding conductor is used to interconnect the metal enclosures. Equipment grounding ensures that there is no difference of potential, and thus no shock hazard between noncurrent-carrying metal parts anywhere in the electrical distribution system. Connecting the equipment grounding system to earth ensures that there is no difference of potential between the earth and the equipment grounding system. It also prevents static charge buildup.

System Grounding

System grounding, which is also illustrated in Figure 8.3-1, is the process of intentionally connecting one

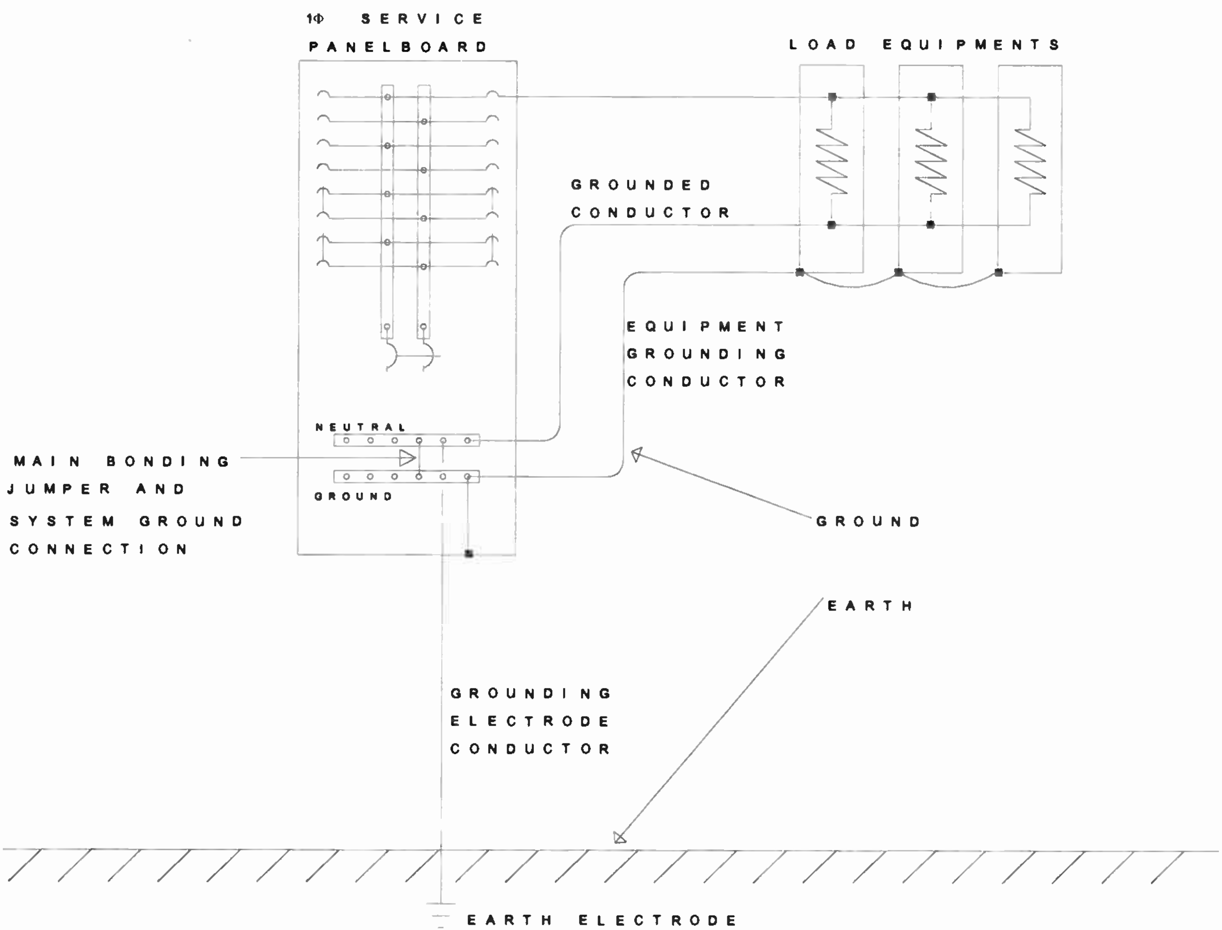

Figure 8.3-1. Equipment grounding and system grounding illustrated.

of the current-carrying conductors of the electrical distribution system to ground. The Figure shows the neutral conductor intentionally connected to ground and the earth. This conductor is called the *grounded* conductor because it is intentionally grounded. The purpose of system grounding is overvoltage control and equipment safety through fault isolation. An ungrounded system is subject to serious overvoltages under conditions such as intermittent ground faults, resonant conditions and contact with higher voltage systems. Fault isolation is achieved by providing a low impedance return path from the load back to the source which will ensure operation of overcurrent devices in the event of a ground fault. The system ground connection makes this possible by connecting the equipment grounding system to the low side of the voltage source. Methods of system grounding include solidly grounded, ungrounded and impedance grounded.

Solidly grounded means that an intentional zero impedance connection is made between a current-carrying conductor and ground. The single-phase (1Φ) system shown in Figure 8.3-1 is solidly grounded. A solidly grounded, three-phase, four-wire, wye system is illustrated in Figure 8.3-2. The neutral is connected directly to ground with no impedance installed in the neutral circuit. The NEC permits this connection to be made at the service only. The advantages of a solidly grounded wye system include reduced magnitude of transient overvoltages, improved fault protection and faster location of ground faults. There is one disadvantage of the solidly grounded wye system. For low level arcing ground faults, the application of sensitive, properly coordinated, ground fault protection (GFP) devices is necessary to prevent equipment damage from arcing ground faults. The NEC requires arcing ground fault protection at 480Y/277V services, and a maximum sensitivity limit of 1200 A is permitted. Severe damage is less frequent at the lower voltage 208 V systems, where the arc may be self extinguishing.

Ungrounded means that there is no intentional connection between a current-carrying conductor and ground. However, charging capacitance will create unintentional capacitive coupling from each phase to ground making the system essentially a capacitance grounded system. A three-phase, three-wire system from an ungrounded delta source is illustrated in Figure 8.3-3. The most important advantage of an ungrounded system is that an accidental ground fault in one phase

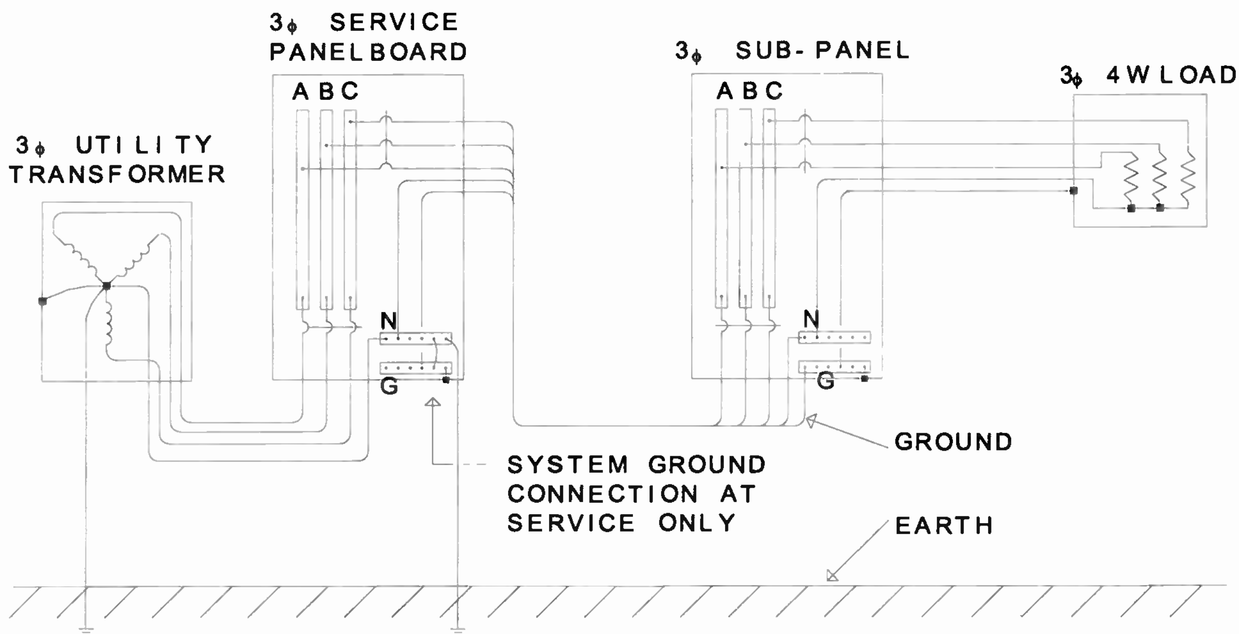

Figure 8.3-2. Solidly grounded wye system.

does not require immediate removal. This allows for continuity of service which made the ungrounded delta system very popular in the past. However, ungrounded systems have serious disadvantages. Since there is no fixed system ground point, it is difficult to locate the first ground fault and to sense the magnitude of fault current.

As a result, the fault is often permitted to remain on the system for a long time. If a second fault should occur before the first one is removed, and the second fault is on a different phase, the result will be a double line-to-ground fault causing serious arcing damage. Another problem with the ungrounded delta system is the occurrence of high transient overvoltages from

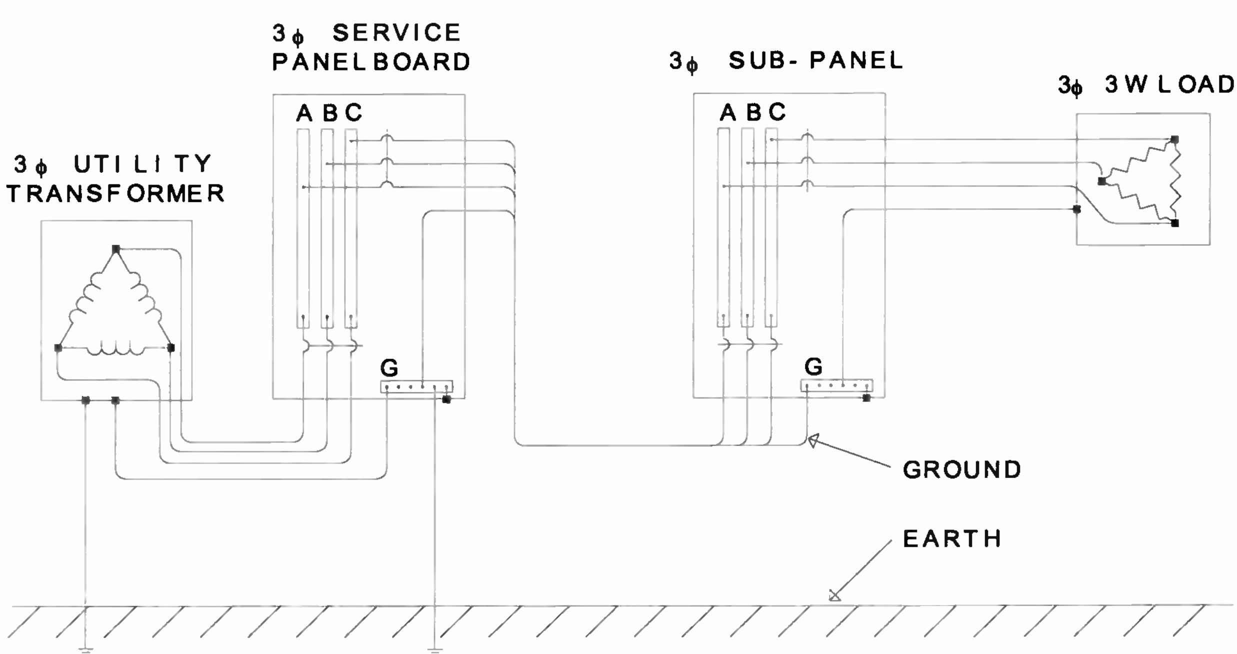

Figure 8.3-3. Ungrounded delta system.

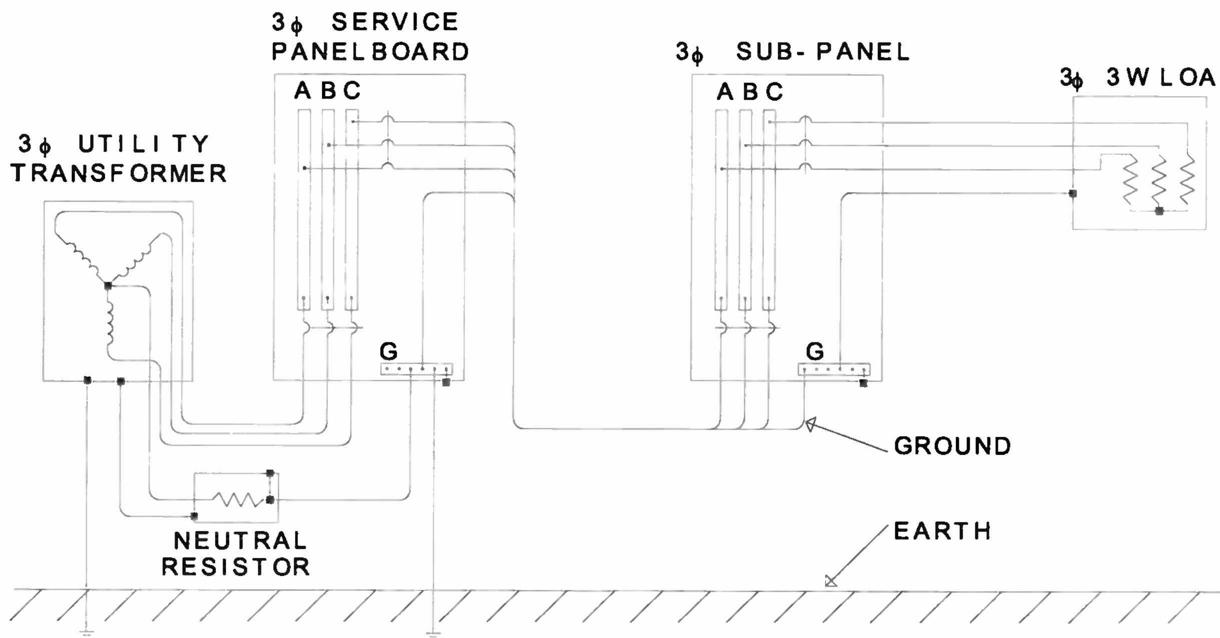

Figure 8.3-4. High resistance grounded wye system.

phase-to-ground. Transient overvoltages are caused by intermittent ground faults, with overvoltages capable of reaching a phase-to-ground voltage of from six to eight times the phase-to-neutral voltage. Sustained overvoltages may ultimately result in insulation failure and thus more ground faults.

Impedance grounded means that an intentional impedance connection is made between a current-carrying conductor and ground. The *high resistance grounded* wye system, illustrated in Figure 8.3-4, is an alternative to solidly grounded and ungrounded systems. High resistance grounding will limit ground fault current to a few amperes, thus removing the potential for arcing damage inherent in solidly grounded systems. The ground reference point is fixed, and relaying methods can locate first faults before damages from second faults occur. Internally generated transient overvoltages are reduced since the neutral to ground resistor dissipates any charge which may buildup on system charging capacitance. Specific requirements for impedance-grounded systems are listed in NEC Article 250.

Table 8.3-1 compares the three most common methods of system grounding. There is no one *best* system grounding method for all applications. In choosing among the various options, the designer must consider the requirements for safety, continuity of service and cost. Generally, low voltage systems should be operated solidly grounded. For applications involving continuous processes in industrial plants or where shutdown might create a hazard, a high resistance grounded wye system, or a solidly grounded wye system with an alternate power supply, may be used. The high resistance grounded wye system combines many of the advantages of the ungrounded delta system and the solidly grounded wye system. IEEE Standard 142 suggests that medium voltage systems less than 15 kV be low resistance grounded to limit ground fault damage, yet permit sufficient current for detection and isolation of ground faults. IEEE Standard 142 also suggests that medium voltage systems over 15 kV be solidly grounded. Solid grounding should include sensitive ground fault relaying in accordance with the NEC.

Table 8.3-1
Comparison of System Grounding Methods.

	System Grounding Method		
Characteristic Assuming No Fault Escalation	Solidly-Grounded	Un-Grounded	High Resistance
Operation of Overcurrent Device on First Ground Fault	Yes	No	No
Control of Internally-Generated Transient Overvoltages	Yes	No	Yes
Control of Steady-State Overvoltages	Yes	No	Yes
Flash Hazard	Yes	No	No
Equipment Damage from Arcing Ground-Faults	Yes	No	No
Overvoltage (on Unfaulted Phases) from Ground-Fault	L-N Voltage	>> L-L Voltage	L-L Voltage
Can serve line-to-neutral loads	Yes	No	No

Earth Connections

The process of connecting the grounding system to the earth is called *earthing*, and consists of immersing a metal electrode or system of electrodes into the earth. The conductor which connects the grounding system to earth is called the *grounding electrode conductor*. The grounding electrode conductor is illustrated in Figure 8.3-1. Its function is to keep the entire grounding system at earth potential (voltage equalization during lightning and other transients) rather than for conducting ground fault current. Therefore, the NEC allows reduced sizing requirements for that portion of the grounding electrode conductor when connected to *made* electrodes (see NEC Article 250 for exact requirements).

The basic measure of effectiveness of an earth electrode system is called *earth electrode resistance*. Earth electrode resistance is the resistance, in ohms, between the point of connection and a distant point on the earth called *remote earth*. Remote earth, about 25 ft from the driven electrode, is the point where earth electrode resistance does not increase appreciably when this distance is increased. Earth electrode resistance consists of the sum of the resistance of the metal electrode (negligible) plus the contact resistance between the electrode and the soil (negligible) plus the soil resistance itself. Thus, for all practical purposes, earth electrode resistance equals the soil resistance. The soil resistance is nonlinear, with most of the earth resistance contained within several feet of the electrode. Furthermore, current flows only through the electrolyte portion of the soil, not the soil itself. Thus, soil resistance varies as the electrolyte content (moisture and salts) of the soil varies. Without electrolyte, soil resistance would be very large.

Soil resistance is a function of soil resistivity. A one cubic meter sample of soil with a resistivity (ρ) of 1 Ω-meter will present a resistance (R) of 1 Ω between opposite faces. A broad variation of soil resistivity occurs as a function of soil types, and soil resistivity can be estimated or measured directly. Soil resistivity is usually measured by injecting a known current into a given volume of soil and measuring the resulting voltage drop. When soil resistivity is known, the earth electrode resistance of any given configuration (single rod, multiple rods, or ground ring) may be determined by using standard equations developed by Sunde, Schwarz, and others[5,6]. Three standard grounding equations are listed.

$$R_1 = \frac{0.52\rho}{lr}\left(\ln\frac{96lr}{Dr} - 1\right) \qquad (1)$$

Where:

R_1 = Resistance in ohms of a single driven ground rod

ρ = Soil resistivity in ohm-meters

lr = Length of ground rod in feet

Dr = Diameter of ground rod in inches

$$R_N = \frac{1}{N}\left[R_1 + \frac{1.05\rho}{S}\left(\frac{1}{2} + \frac{1}{3} + \cdots + \frac{1}{N}\right)\right] \qquad (2)$$

Where:

R_N = Resistance in ohms of N driven ground rods

N = Number of equally spaced ground rods

R_1 = Resistance in ohms of a single driven ground rod

S = Uniform Spacing of ground rods in feet

$$R_{GR} = \frac{0.52\rho}{(N)(lr)}\left[\ln\left(\frac{96lr}{Dr}\right) - 1 + \frac{2K_1 lr}{\sqrt{A}}(\sqrt{N} - 1)^2\right] \qquad (3)$$

Where:

R_{GR} = Resistance in ohms of ground ring configuration

A = Area of coverage at farthest dimensions in square feet

K_1 = Length-to-width ratio coefficient

Length-to-Width Ratio	$\approx K_1$
1	1.37
2	1.31
3	1.26
4	1.22
5	1.18
6	1.15
7	1.12
8	1.10

Earth resistance values should be as low as practicable, but are a function of the application. The NEC approves the use of a single made electrode if the earth resistance does not exceed 25 Ω. IEEE Standard 1100 reports that the very low earth resistance values specified for computer systems in the past is not necessary. Methods of reducing earth resistance values include the use of multiple electrodes in parallel, ground rings, increased ground rod lengths, installation of ground rods to the permanent water level, increased area of coverage of ground rings and use of concrete-encased electrodes, ground wells, and electrolytic electrodes.

EARTH ELECTRODES

Earth electrodes may be *made* electrodes, *natural* electrodes, or *special purpose* electrodes. Made electrodes include driven rods, buried conductors, ground mats, buried plates and ground rings. The electrode selected is a function of the type of soil and the available depth. Driven electrodes are used where bedrock is 10 ft or more below the surface. Mats or buried conductors are used for lesser depths. Buried plates are not widely used because of the higher cost when compared to rods.

[5,6] Sunde, E.D., *Earth Conduction Effects in Transmission Systems*, Von Nonstrand Co., 1949. Schwarz, S.J., *Analytical Expression for Resistance of Grounding Systems*, AIEE Transactions Vol. 73, Part III-B, pp 1011–1016, 1954.

Ground rings employ equally spaced driven electrodes interconnected with buried conductors. Ground rings are used around large buildings, around small unit substations, and in areas having high soil resistivity.

Natural electrodes include buried water pipe electrodes and concrete encased electrodes. The NEC lists underground metal water piping, available on the premises and not less than 10 ft in length, as part of a preferred grounding electrode system. Since the use of plastic pipes in new water systems will impair the effectiveness of water pipe electrodes, the NEC requires that metal underground water piping be supplemented by an additional approved electrode. Concrete below ground level is a good electrical conductor. Thus, metal electrodes encased in such concrete will function as excellent grounding electrodes. The application of concrete encased electrodes is covered in IEEE Standard 142.

A special purpose electrode called the *electrolytic* or *chemically charged electrode*, consists of a ground rod installed in a canister containing an electrolytic salt. The salt absorbs moisture from the atmosphere through *breather* holes at the top of the cannister. As the salt dissolves in the moisture, it forms a homogeneous electrolytic solution. Gravity and changes in atmospheric pressure cause the electrolytic solution to leak out through *weep* holes at the bottom of the cannister. As the electrolytic solution soaks into the surrounding soil, it reduces the soil resistivity and also helps to hold it relatively constant. The result is a consistently lowered and uniform earth electrode resistance.

FACILITIES GROUNDING FOR COMPUTER AND ELECTRONICS EQUIPMENT

Noise control is an important aspect of computer and electronic systems. The process of noise control through proper grounding techniques is called *referencing*. For this discussion, electronic systems will be viewed as a multiplicity of signal sources transmitting signals to a multiplicity of loads. The ideal electronic circuit consists of a simple signal source supplying a load via a pair of leads as shown in Figure 8.3-5.

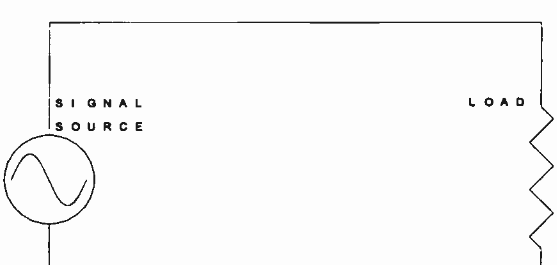

Figure 8.3-5. Ideal electronic circuit.

This source load electronic pair is ideal and free of interference because the impedance of the signal return path is zero and the signal return is a dedicated path.

Practically speaking, however, the impedance of the signal return path is not zero and dedicated return paths for each source load pair are not practical. Packaged electronics systems typically incorporate a common signal reference plane which serves as a common return path for numerous source load pairs (see to Figure 8.3-6(a)). The signal reference plane may be a large dedicated area on a printed circuit board, the metal chassis or enclosure of the electronic equipment, or the metal frame or mounting rack that houses several different units. Ideally, the signal reference plane offers zero impedance to the signal current. Practically, however, the signal reference plane has a finite impedance. The practical result is called *common impedance* or *conductive coupling* (see Figure 8.3-6(b)). Since a practical signal reference plane has a finite impedance, current flow in the plane will produce potential differences between various points on the plane. Source load pairs referenced to the plane will, therefore, experience interference as a result. Z_R is common to both circuits referenced to the plane in Figure 8.3-6(b). Thus, I_1 and I_2 returning to their respective sources will produce interference voltages by flowing through Z_R. The total interference voltage drop felt across Z_R causes the source reference A to be at a different potential than the load reference B. This difference in potential is often called *ground voltage shift* (even though ground may not even be involved), and is a major source of noise and interference in electronic circuits.

Ground voltage shifts can also be caused by electromagnetic or electrostatic fields in close proximity to the source load pairs. The interference source induces interference voltages into any closed loop by antenna action. This loop is called a *ground loop* (even though ground may not be involved). Interference voltages can be minimized by reducing the loop area as much as possible. This may be very difficult if the loop includes an entire room. The interference voltage can be eliminated entirely by breaking the loop.

Within individual electronic equipments, the signal reference plane consists of a metal plate or the metal enclosure or a rack assembly as previously discussed. Between units of equipment that are located in different rooms on different floors or even in different buildings, the signal reference planes of each unit must be connected together via interconnected wiring such as coax shields or separate conductors. This action, of course, increases the impedance between signal reference planes and makes noise control more difficult. Reducing noise caused by common impedance coupling is a matter of reducing the impedance of the interconnected signal reference planes. Regardless of the configuration encountered (circuit board, individual electronic equipment or equipments remotely located within a facility or in separate buildings), the next question to be answered is should the signal reference be connected to ground? Floating signal grounding, single point grounding and multipoint grounding are methods of

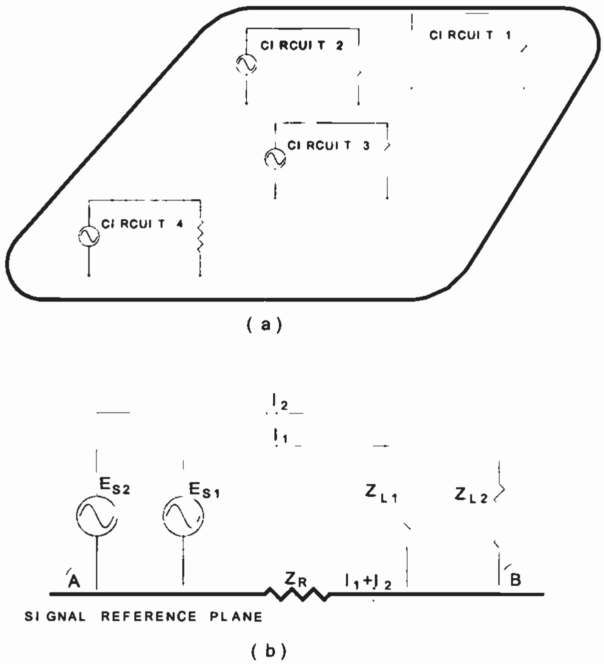

Figure 8.3-6. Equipotential plane.

accomplishing this signal reference to ground connection.

IEEE Standard 1100 recommends multipoint grounding and a signal reference plane for most computer and electronics installations. An ideal equipotential signal reference plane is one which has 0 V (thus zero impedance) between any two points on the plane. Since an *ideal* equipotential plane is not attainable, a *nominal* equipotential plane is accepted. Multipoint grounding connections are made to the plane which ensures minimum ground voltage shift between signal reference systems connected to the plane. Collectively, the current flow in an equipotential plane may be quite large. Between any two equipments, however, the current flow should be low due to the many current paths available.

Practical versions of an equipotential plane include bolted stringer system of a raised computer floor, flat copper strips bonded together at 2 ft centers, copper conductors bonded together at 2 ft centers and single or multiple, flat copper strips connected between equipments.

ISOLATED GROUNDING

Isolated grounding schemes, where the signal reference plane is isolated from equipment ground but connected to an *isolated* electrode in the earth, do not work, are unsafe and violate the NEC. It is thought by some people that the isolated earth connection is *clean* since there is no connection between it and the *dirty* system ground connection at the service entrance. The clean, isolated earth connection is also viewed (incorrectly) as a point where noise currents can flow into the earth and be dissipated. *Kirchoff's Current Law* teaches that any current flowing into the isolated ground must return to the source through another earth connection. Current cannot be dissipated. It must always return to its source. Even lightning current is not dissipated into the earth. It must have a return path (the electrostatic and electromagnetic fields which created the charge buildup and the lightning strike in the first place).

Consider what might happen if the previously described system above is subjected to a lightning strike. Assume that a transient current of 2,000 A flows into the earth and through an earth resistance of 5 Ω between the system ground electrode and the isolated electrode. A more realistic resistance would be even higher, maybe 25 Ω. Two thousand amperes flowing through 5 Ω results in a voltage drop or transient potential of 10,000 V between the two electrodes. Since this potential is impressed between the equipment frame (system ground electrode) and the signal reference plane (isolated electrode), it could result in equipment damage and personnel hazard. Dangerous potential differences between grounding subsystems can be reduced by bonding together all earth electrodes on a facility. A fine print note (FPN) in NEC Article 250 states that the bonding together of separate grounding electrodes will limit potential differences between them and their associated wiring systems.[7]

A facility ground system, then, can be defined as an electrically interconnected system of multiple conducting paths to the earth electrode or system of electrodes. The facility grounding system includes all electrically interconnected grounding subsystems such as the equipment grounding subsystem, the signal reference subsystem, the fault protection subsystem and the lightning protection subsystem.

Isolated ground (IG) receptacles, which are a version of single-point grounding, are permitted by the NEC. Proper application of IG receptacles is very important. They must be used with an insulated equipment grounding conductor, not a bare conductor. Also, only metallic conduit should be used.

SEPARATELY-DERIVED SYSTEMS

A *separately derived system* is a premises wiring system whose power is derived from generator, transformer or converter windings and that has no direct electrical connection, including a solidly connected grounded circuit conductor, to supply conductors originating in another system.[5] Solidly grounded, wye connected, isolation transformers used to supply power to computer room equipment are examples of separately derived systems. Specific requirements for the bonding and grounding of seperately derived systems are listed in NEC Article 250. Other examples of separately derived systems include generators and UPS systems.

[7] NFPA Std 70, *The National Electrical Code*, The National Fire Protection Association, Inc., Quincy, MA, 1996.

KEY TERMS

Grounded Conductor. A system or circuit conductor that is intentionally grounded.

Equipment Grounding Conductor. The conductor used to connect the noncurrent-carrying metal parts of equipment, raceways, and other enclosures to the system grounded conductor, the grounding electrode conductor, or both, at the service equipment or at the source of a separately derived system.

Main Bonding Jumper. The connection between the grounded circuit conductor and the equipment grounding conductor at the service.

Grounding Electrode Conductor. The conductor used to connect the grounding electrode to the equipment grounding conductor, to the grounded conductor, or to both, of the circuit at the service equipment or at the source of a separately derived system.

Service. The conductors and equipment for delivering energy from the electricity supply system to the wiring system of the premises served.

Service Conductors. The supply conductors that extend from the street main or from transformers to the service equipment of the premises supplied.

Service Equipment. The necessary equipment, usually consisting of a circuit breaker or switch and fuses, and their accessories, located near the point of entrance of supply conductors to a building or other structure, or an otherwise defined area, and intended to constitute the main control and means of cutoff of the supply.

Equipotential Plane. A mass of conducting material which offers a negligible impedance to current flow, thus producing zero volts (equipotential) between points on the plane.

Floating Signal Grounding. A non-grounding system in which all electronic signal references are isolated from ground.

Single-Point Grounding. A grounding system in which all electronic signal references are bonded together and grounded at a single point.

Multipoint Grounding. A grounding system in which all electronic signal references are grounded at multiple points.

8.4
STANDBY POWER SYSTEMS

JERRY WHITAKER
EDITOR-IN-CHIEF

INTRODUCTION

When utility company power problems are discussed, most people immediately think of blackouts. The lights go out, and everything stops. With the facility down and in the dark, there is nothing to do but sit and wait until the utility company finds the problem and corrects it. This process generally takes only a few minutes. There are times, however, when it can take hours. In some remote locations, it can even take days.

Blackouts are, without a doubt, the most troublesome utility company problem that a broadcast facility will have to face. Statistics show that power failures are, generally speaking, a rare occurrence in most areas of the country and are short in duration. Studies have shown that 50% of blackouts last six seconds or less, and 35% are less than 11 minutes long. These failure rates usually are not cause for concern to commercial users, except where computer based operations, transportation control systems, medical facilities, and communications sites—including radio and television stations—are concerned.

When continuity of operation is critical, redundancy must be carried throughout the system. The site never should depend upon one critical path for ac power. For example, if the facility is fed by a single step-down transformer, a lightning flash or other catastrophic event could result in a transformer failure that would bring down the entire site. A replacement could take days or even weeks.

Blackout Effects

A broadcast facility that is down for even five minutes can suffer a significant loss of audience that may take hours or days to rebuild. A blackout affecting a transportation or medical center could be life threatening. Coupled with this threat is the possibility of extended power service loss due to severe storm conditions. Many broadcast and communications relay sites are located in remote, rural areas or on mountaintops. Neither of these kinds of locations are well known for their power reliability. It is not uncommon in mountainous areas for utility company service to be out for extended periods after a major storm. Few operators are willing to take such risks with their business. Most choose to install standby power systems at appropriate points in the equipment chain.

The cost of standby power for a facility can be substantial, and an examination of the possible alternatives should be conducted before any decision on equipment is made. Management must clearly define the direct and indirect costs and weigh them appropriately. Include the following items in the cost versus risk analysis:

- Standby power system equipment purchase and installation cost
- Exposure of the system to utility company power failure
- Alternative operating methods available to the facility
- Direct and indirect costs of lost uptime because of blackout conditions.

A distinction must be made between *emergency* and *standby* power sources. Strictly speaking, emergency systems supply circuits legally designated as being essential for safety to life and property. Standby power systems are used to protect a facility against the loss of productivity resulting from a utility company power outage.

STANDBY POWER OPTIONS

To ensure the continuity of ac power, many commercial/industrial facilities depend upon either two separate utility services or one utility service plus on-site generation. Because of the growing complexity of electrical systems, attention must be given to power supply reliability.

The engine generator shown in Figure 8.4-1 is the classic standby power system. An automatic transfer switch monitors the ac voltage coming from the utility company line for power failure conditions. Upon detection of an outage for a predetermined period of time (generally 1 to 10 seconds), the standby generator is started; after the generator is up to speed, the load is transferred from the utility to the local generator. Upon return of the utility feed, the load is switched back, and the generator is stopped. This basic type of system is used widely in industry and provides economical protection against prolonged power outages (5 minutes or more).

The transfer device shown in Figure 8.4-1 is a contactor type, break-before-make unit. By replacing the simple transfer device shown with an automatic over-

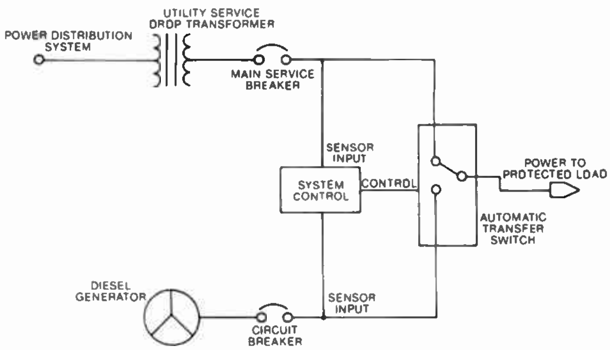

Figure 8.4-1. The classic standby power system using an engine-generator set. This system protects a facility from prolonged utility company power failures.

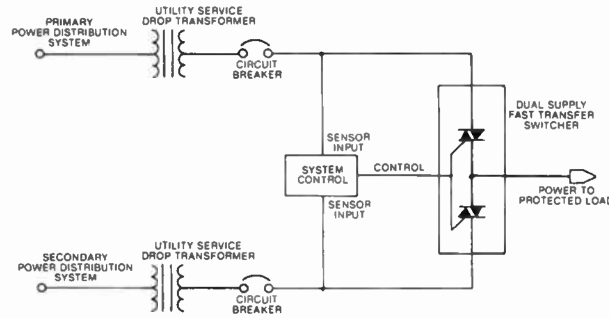

Figure 8.4-3. The dual utility feeder system of ac power loss protection. An automatic transfer switch changes the load from the main utility line to the standby line in the event of a power interruption.

lap (*static*) transfer switch, as shown in Figure 8.4-2, additional functionality can be gained. As described in Chapter 8.2, *AC Power Conditioning*, the overlap transfer switch permits the on-site generator to be synchronized with the load, making a clean switch from one energy source to another. This functionality offers the following benefits:

- Switching back to the utility feed from the generator can be accomplished without interruption in service
- The load can be cleanly switched from the utility to the generator in anticipation of utility line problems (such as an approaching severe storm)
- The load can be switched to and from the generator to accomplish *load* shedding objectives.

Dual Feeder System

In some areas, usually metropolitan centers, two utility company power drops can be brought into a facility as a means of providing a source of standby power. As shown in Figure 8.4-3, two separate utility service drops—from separate power distribution systems—are brought into the plant, and an automatic transfer switch changes the load to the backup line in the event of a main line failure. The dual feeder system provides an advantage over the auxiliary diesel arrangement in that power transfer from main to standby can be made in a fraction of a second if a static transfer switch is used. Time delays in the diesel generator system limit its usefulness to power failures lasting more than several minutes.

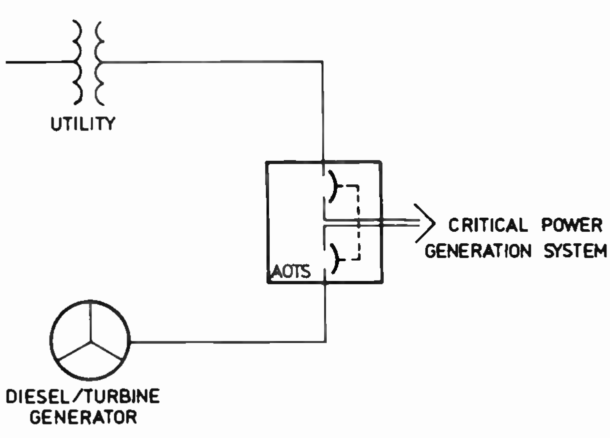

Figure 8.4-2. The use of a static transfer switch to transfer the load from the utility company to the on-site generator.

The dual feeder system of protection is based on the assumption that each of the service drops brought into the facility is routed via different paths. This being the case, the likelihood of a simultaneous failure on both power lines is remote. The dual feeder system will not, however, protect against area-wide power failures, which may occur from time to time.

The dual feeder system is limited primarily to urban areas. Rural or mountainous regions generally are not equipped for dual redundant utility company operation. Even in urban areas, the cost of bringing a second power line into a facility can be high, particularly if special lines must be installed for the feed. If two separate utility services are available at or near the site, redundant feeds generally will be less expensive than engine driven generators of equivalent capacity.

Figure 8.4-4 illustrates a dual feeder system that utilizes both utility inputs simultaneously at the facility. Notice that during normal operation, both ac lines feed loads, and the *tie* circuit-breaker is open. In the event of a loss of either line, the circuit-breaker switches reconfigure the load to place the entire facility on the single remaining ac feed. Switching is performed automatically; manual control is provided in the event of a planned shutdown on one of the lines.

Peak Power Shaving

Figure 8.4-5 illustrates the use of a backup diesel generator for both standby power and *peak power shaving* applications. Commercial power customers often can realize substantial savings on utility company bills by reducing their energy demand during certain hours of the day. An automatic overlap transfer switch is used to change the load from the utility company system to the local diesel generator. The changeover is accomplished by a static transfer switch that does not disturb the operation of load equipment. This application of a standby generator can provide financial return to the facility, whether or not the unit is ever needed to carry the load through a commercial power failure.

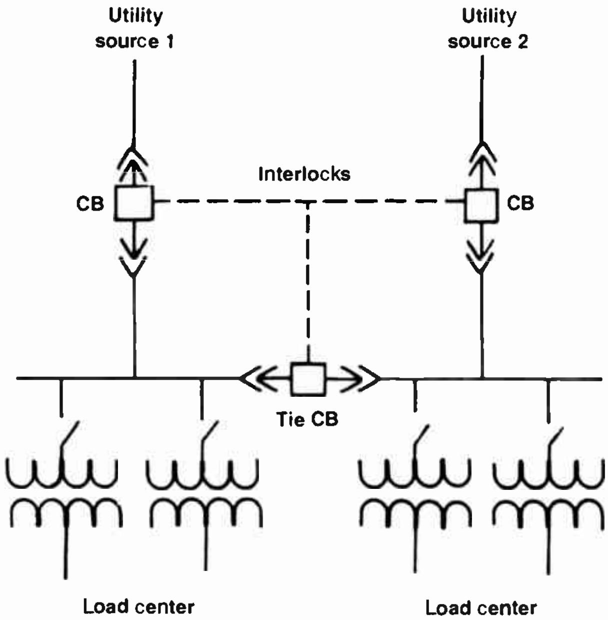

Figure 8.4-4. A dual utility feeder system with interlocked circuit breakers.

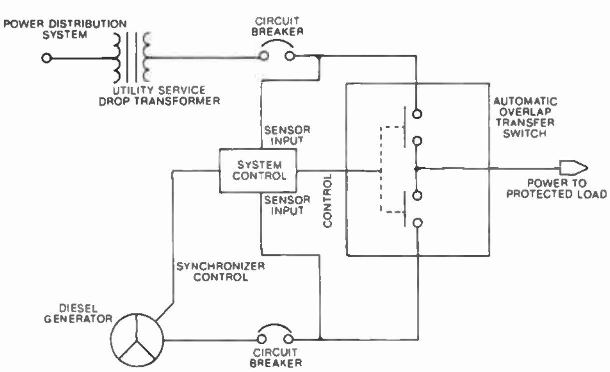

Figure 8.4-5. The use of a diesel generator for standby power and peak power shaving applications. The automatic overlap (static) transfer switch changes the load from the utility feed to the generator instantly so that no disruption of normal operation is encountered.

Advanced System Protection

A more sophisticated power control system is shown in Figure 8.4-6, where a dual feeder supply is coupled with a motor generator (m-g) set to provide clean, undisturbed ac power to the load. The m-g set will smooth over the transition from the main utility feed to the standby, often making a commercial power failure unnoticed by on-site personnel. As discussed in Chapter 8.2, a conventional m-g typically will give up to 1/2 seconds of power fail ride-through, more than enough to accomplish a transfer from one utility feed to the other. This standby power system is further refined in the application illustrated in Figure 8.4-7, where a diesel generator has been added to the system. With the automatic overlap transfer switch shown at

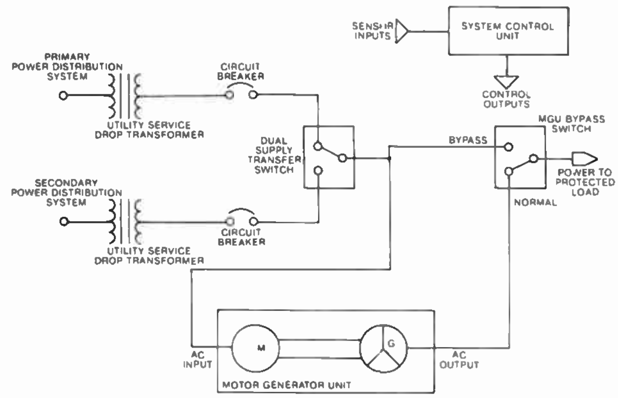

Figure 8.4-6. A dual feeder standby power system using a motor-generator set to provide power fail ride-through and transient-disturbance protection. Switching circuits allow the m-g set to be bypassed, if necessary.

the generator output, this arrangement also can be used for peak demand power shaving.

Figure 8.4-8 shows a simplified schematic diagram of a 220 kW uninterruptible power system (UPS) utilizing dual utility company feed lines, a 750 kVA gas engine-generator, and five dc-driven m-g sets with a 20 minute battery supply at full load. The five m-g sets operate in parallel, each is rated for 100 kW output. Only three are needed to power the load, but four are on-line at any given time. The fifth machine provides redundancy in the event of a failure or for scheduled maintenance work. The batteries are always on-line under a slight charge across the 270 V dc bus. Two separate natural gas lines, buried along different land routes, supply the gas engine. Local gas storage capacity also is provided.

Choosing a Generator

Engine-generator sets are available for power levels ranging from less than 1 kVA to several thousand kVA

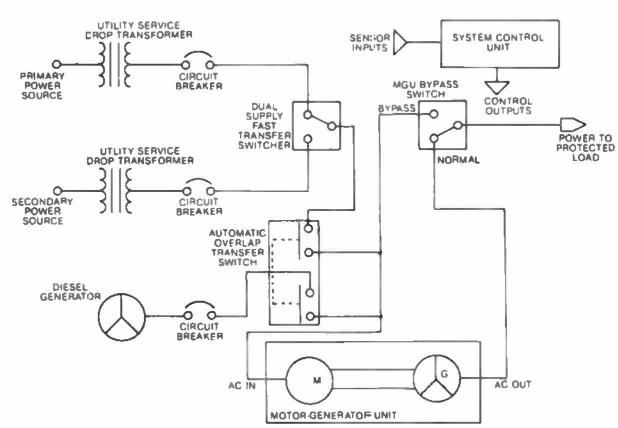

Figure 8.4-7. A premium power supply backup and conditioning system using dual utility company feeds, a diesel generator, and a motor-generator set. An arrangement such as this would be used for critical loads that require a steady supply of clean ac.

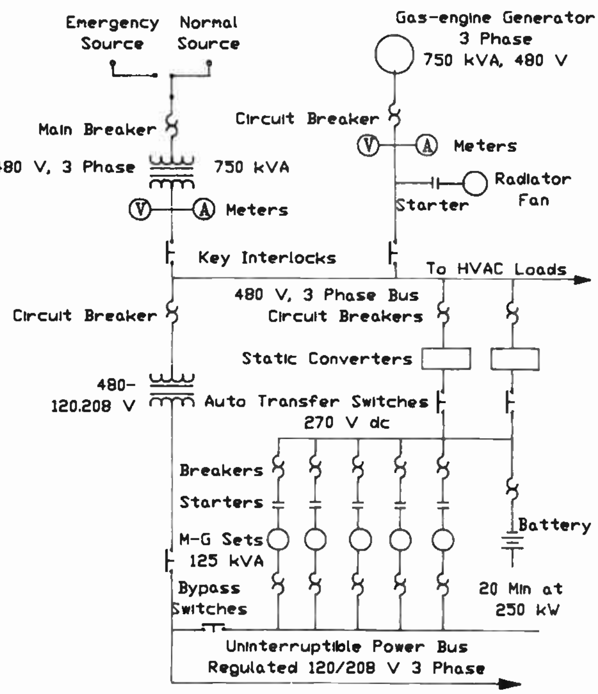

Figure 8.4-8. Simplified installation diagram of a high reliability power system incorporating dual utility feeds, a standby gas engine-generator and five battery-backed dc m-g sets.[1]

or more. Machines also may be paralleled to provide greater capacity. Engine-generator sets typically are classified by the type of power plant used:

- **Diesel.** Advantages: rugged and dependable, low fuel costs, low fire and/or explosion hazard. Disadvantages: somewhat more costly than other engines, heavier in smaller sizes
- **Natural and liquefied petroleum gas.** Advantages: quick starting after long shutdown periods, long life, low maintenance. Disadvantage: availability of natural gas during area-wide power failure subject to question
- **Gasoline.** Advantages: rapid starting, low initial cost. Disadvantages: greater hazard associated with storing and handling gasoline, generally shorter mean time between overhaul
- **Gas turbine.** Advantages: smaller and lighter than piston engines of comparable horsepower, rooftop installations practical, rapid response to load changes Disadvantages: longer time required to start and reach operating speed, sensitive to high input air temperature.

The type of power plant chosen is usually determined primarily by the environment in which the system will be operated and by the cost of ownership. For example, a standby generator located in an urban area office complex may be best suited to the use of an engine powered by natural gas, because of the problems inherent in storing large amounts of fuel. State or local building codes may place expensive restrictions on fuel storage tanks and make the use of a gasoline or diesel powered engine impractical. The use of propane usually is restricted to rural areas. The availability of propane during periods of bad weather (when most power failures occur) also must be considered.

The generator rating for a standby power system should be chosen carefully and should take into consideration the anticipated future growth of the plant. It is good practice to install a standby power system rated for at least 25% greater output than the current peak facility load. This headroom gives a margin of safety for the standby equipment and allows for future expansion of the facility without overloading the system.

An engine driven standby generator typically incorporates automatic starting controls, a battery charger and automatic transfer switch (see Figure 8.4-9). Control circuits monitor the utility supply and start the engine when there is a failure or a sustained voltage drop on the ac supply. The switch transfers the load as soon as the generator reaches operating voltage and frequency. Upon restoration of the utility supply, the switch returns the load and initiates engine shutdown. The automatic transfer switch must meet demanding requirements, including:

- Carrying the full rated current continuously
- Withstanding fault currents without contact separation
- Handling high inrush currents
- Withstanding many interruptions at full load without damage.

The nature of most power outages requires a sophisticated monitoring system for the engine-generator set. Most power failures occur during periods of bad weather. Most standby generators are unattended. More often than not, the standby system will start, run and shut down without any human intervention or supervision. For reliable operation, the monitoring system must check the status of the machine continually to ensure that all parameters are within normal limits.

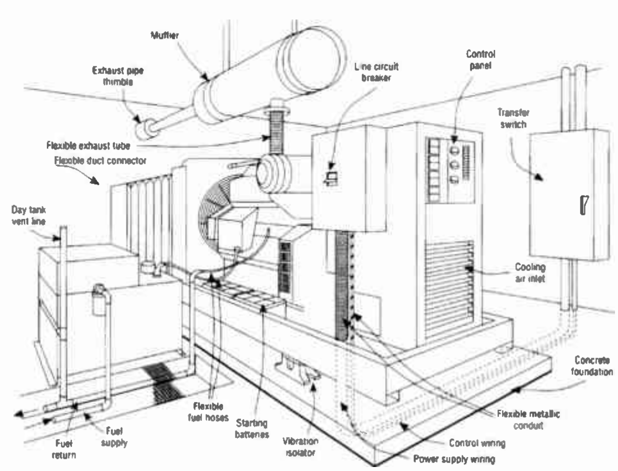

Figure 8.4-9. Typical configuration of an engine-generator set.[2] (*Used with permission.*)

Time-delay periods usually are provided by the controller that require an outage to last from 5 to 10 seconds before the generator is started and the load is transferred. This prevents false starts that needlessly exercise the system. A time delay of 5 to 30 minutes usually is allowed between the restoration of utility power and return of the load. This delay permits the utility ac lines to stabilize before the load is reapplied.

The transfer of motor loads may require special consideration, depending upon the size and type of motors used at a plant. If the residual voltage of the motor is out of phase with the power source to which the motor is being transferred, serious damage may result to the motor. Excessive current draw also may trip overcurrent protective devices. Motors above 50 hp with relatively high load inertia in relation to torque requirements, such as flywheels and fans, may require special controls. Restart time delays are a common solution.

Automatic starting and synchronizing controls are used for multiple engine-generator installations. The output of two or three smaller units can be combined to feed the load. This capability offers additional protection for the facility in the event of a failure in any one machine. As the load at the facility increases, additional engine-generator systems can be installed on the standby power bus.

Generator Types

Generators for standby power applications may be *induction* or *synchronous* machines. Most engine-generator systems in use today are synchronous because of the versatility, reliability and capability of operating independently that this approach provides. Most modern synchronous generators are of the *revolving field alternator* design. Essentially, this means that the armature windings are held stationary and the field is rotated. Therefore, generated power can be taken directly from the stationary armature windings. Revolving armature alternators are less popular because the generated output power must be derived via slip rings and brushes.

The exact value of the ac voltage produced by a synchronous machine is controlled by varying the current in the dc field windings, while frequency is controlled by the speed of rotation. Power output is controlled by the torque applied to the generator shaft by the driving engine. In this manner, the synchronous generator offers precise control over the power it can produce.

Practically all modern synchronous generators use a *brushless exciter.* The exciter is a small ac generator on the main shaft; the ac voltage produced is rectified by a three-phase rotating rectifier assembly also on the shaft. The dc voltage thus obtained is applied to the main generator field, which is also on the main shaft. A voltage regulator is provided to control the exciter field current, and in this manner, the field voltage can be precisely controlled, resulting in a stable output voltage.

The frequency of the ac current produced is dependent on two factors: the number of poles built into the machine and the speed of rotation (rpm). Because the output frequency must normally be maintained within strict limits (60 Hz or 50 Hz), control of the generator speed is essential. This is accomplished by providing precise rpm control of the *prime mover,* which is performed by a governor.

There are many types of governors; however, for auxiliary power applications, the *isochronous governor* is normally selected. The isochronous governor controls the speed of the engine so that it remains constant from no load to full load, assuring a constant ac power output frequency from the generator. A modern system consists of two primary components: an electronic speed control and an actuator that adjusts the speed of the engine. The electronic speed control senses the speed of the machine and provides a feedback signal to the mechanical/hydraulic actuator, which in turn positions the engine throttle or fuel control to maintain accurate engine rpm.

The National Electrical Code provides guidance for safe and proper installation of on-site engine-generator systems. Local codes may vary and must be reviewed during early design stages

UPS Systems

An uninterruptible power system (UPS) is an elegant solution to power outage concerns. The output of the UPS inverter may be a sine wave or pseudo sine wave. When shopping for a UPS system, consider the following:

- Power reserve capacity for future growth of the facility
- Inverter current surge capability (if the system will be driving inductive loads, such as motors)
- Output voltage and frequency stability over time and with varying loads
- Required battery supply voltage and current. Battery costs vary greatly, depending upon the type of units needed
- Type of UPS system—forward-transfer type (where the inverter is normally inactive) or reverse-transfer type (where the inverter is normally active)—required by the particular application. Some sensitive loads may not tolerate even brief interruptions of the ac power source
- Inverter efficiency at typical load levels. Some inverters have good efficiency ratings when loaded at 90% of capacity, but poor efficiency when lightly loaded
- Size and environmental requirements of the UPS system. High power UPS equipment requires a large amount of space for the inverter/control equipment and batteries Battery banks often require special ventilation and ambient temperature control.

Standby Power System Noise

Noise produced by backup power systems can be a serious problem if not addressed properly. Standby generators, m-g sets and UPS systems produce noise that can disturb building occupants and irritate neighbors and/or landlords.

The noise associated with electrical generation usually is related to the drive mechanism, most commonly an internal combustion engine. The amplitude of the noise produced is directly related to the size of the engine-generator set. First consider whether noise reduction is a necessity. Many building owners have elected to tolerate the noise produced by a standby power generator because its use is limited to emergency situations. During a crisis, when the normal source of power is unavailable, most people will tolerate noise associated with a standby generator.

If the decision is made that building occupants can live with the noise of the generator, care must be taken in scheduling the required testing and exercising of the unit. Whether testing occurs monthly or weekly, it should be done on a regular schedule.

If it has been determined that the noise should be controlled, or at least minimized, the easiest way to achieve this objective is to physically separate the machine from occupied areas—this may be easier said than done. Because engine noise is predominantly low-frequency in character, walls and floor/ceiling construction used to contain the noise must be massive. Lightweight construction, even though it may involve several layers of resiliently mounted drywall, is ineffective in reducing low-frequency noise. Exhaust noise is a major component of engine noise but, fortunately, it is easier to control. When selecting an engine-generator set, select the highest quality exhaust muffler available. Such units often are identified as hospital grade mufflers.

Engine-generator sets also produce significant vibration. The machine should be mounted securely to a slab-on-grade or an isolated basement floor, or it should be installed on vibration isolation mounts. Such mounts usually are specified by the manufacturer.

Because a UPS system or m-g set is a source of continuous power, it must run continuously. Noise must be adequately controlled. Physical separation is the easiest and most effective method of shielding occupied areas from noise. Enclosure of UPS equipment usually is required, but noise control is significantly easier than for an engine-generator because of the lower noise levels involved. Nevertheless, the low-frequency 120 Hz fundamental of a UPS system is difficult to contain adequately and massive constructions may be necessary. Vibration control also is required for most UPS and m-g gear.

Batteries

Batteries are the lifeblood of most UPS systems. Important characteristics include the following:

- Charge capacity—how long the battery will operate the UPS
- Weight
- Charging characteristics
- Durability/ruggedness

Additional features that add to the utility of the battery include:

- Built-in status/temperature/charge indicator and/or data output port
- Built-in over temperature and over current protection with auto-reset capabilities
- Environmental friendliness.

The last point deserves some attention. Many battery types must be recycled or disposed of through some prescribed means. Proper disposal of a battery at the end of its useful life is, thus, an important consideration. Be sure to check the original packaging for disposal instructions. Failure to follow the proper procedures could have serious consequences.

Research has brought about a number of different battery chemistries, each offering distinct advantages. Today's most common and promising rechargeable chemistries include the following:

- **Nickel cadmium** (NiCd). Used for portable radios, cellular phones, video cameras, laptop computers and power tools. NiCds have good load characteristics, are economically priced, and are simple to use.
- **Lithium ion** (Li-Ion). Now commonly available and typically used for video cameras. This battery promises to replace some NiCds for high energy-density applications.
- **Sealed lead acid** (SLA). Used for UPS, video cameras, and other demanding applications where the energy-to-weight ratio is not critical and low battery cost is desirable.
- **Nickel metal hydride** (NiMH). Used for cellular phones, video cameras and laptop computers where high-energy is of importance and cost is secondary.
- **Lithium polymer** (Li-Polymer). When commercially available, this battery will have the highest energy density and lowest self-discharge of common battery types, but its load characteristics will likely only suit low current applications.
- **Reusable alkaline.** Used for light duty applications. Because of its low self-discharge, this battery is suitable for portable entertainment devices and other non-critical appliances that are used occasionally.

No single battery offers all the answers; rather, each chemistry is based on a number of compromises.

A battery, of course, is only as good as its charger. Common attributes for the current generation of charging systems include quick-charge capability and automatic battery condition analysis and subsequent *intelligent* charging.

KEY TERMS

The following terms are commonly used to specify and characterize batteries:

Energy Density. The storage capacity of a battery measured in *watt-hours per kilogram* (Wh/kg).

Cycle Life. The typical number of charge-discharge cycles for a given battery before the capacity decreases from the nominal 100% to approximately 80%, depending upon the application.

Fast Charge Time. The time required to fully charge an empty battery.

Self-discharge. The discharge rate when the battery is not in use.

Cell Voltage. The output voltage of the basic battery element. The cell voltage multiplied by the number of cells provides the battery terminal voltage.

Load Current. The maximum recommended current the battery can provide.

Current Rate. The *C*-rate is a unit by which charge and discharge times are scaled. If discharged at 1*C*, a 100 Ah battery provides a current of 100 A; if discharged at 0.5*C*, the available current is 50 A.

Exercise Requirement. This parameter indicates the frequency that the battery needs to be exercised to achieve maximum service life.

Sealed Lead-Acid Battery

The lead-acid battery is a commonly used chemistry. The *flooded* version is found in automobiles and large UPS battery banks. Most smaller, portable systems use the *sealed* version, also referred to as *gelcell* or slA.

The lead-acid chemistry is commonly used when high power is required, weight is not critical, and cost must be kept low. The typical current range of a medium-sized SLA device is 2 Ah to 50 Ah. Because of its minimal maintenance requirements and predictable storage characteristics, the SLA has found wide acceptance in the UPS industry, especially for *point-of-application* systems.

The SLA is not subject to memory. No harm is done by leaving the battery on float charge for a prolonged time. On the negative side, the SLA does not lend itself well to fast charging. Typical charge times are 8 to 16 hours. The SLA must always be stored in a charged state because a discharged SLA will sulphate (a chemical process that ruins the battery). If left discharged, a recharge may be difficult or even impossible.

Unlike the common NiCd, the SLA prefers a shallow discharge. A full discharge reduces the number of times the battery can be recharged, similar to a mechanical device that wears down when placed under stress. In fact, each discharge-charge cycle reduces (slightly)

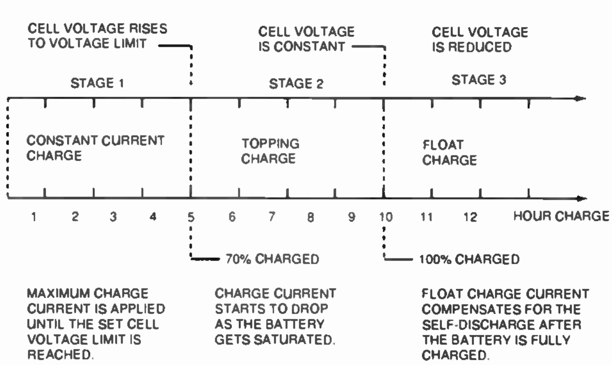

Figure 8.4-10. The charge states of an SLA battery.[3] (*Used with permission.*)

Table 8.4-1
Recommended Charge Voltage Limit for the SLA Battery.[3]

	2.30 V to 2.35 V/cell	2.40 V to 2.45 V/cell
Advantage	Maximum service life; battery remains cool on charge; battery may be charged at ambient temperature exceeding 30° (86°F).	Faster charge times; higher and more consistent capacity readings; less subject to damage because of under charge condition.
Disadvantage	Slow charge time; capacity readings may be low and inconsistent. Produces under charge condition that may cause sulphation and capacity loss if the battery is not periodically cycled.	Battery life may be reduced because of elevated battery temperature while charging. A hot battery may fail to reach the cell voltage limit, causing harmful over charge.

the storage capacity of the battery. This wear down characteristic also applies to other chemistries, including the NiMH.

The charge algorithm of the SLA differs from that of other batteries in that a *voltage-limit* rather than *current-limit* is used. Typically, a multistage charger applies three charge stages consisting of a *constant-current charge, topping charge* and *float charge* (see Figure 8.4-10). During the constant-current stage, the battery charges to 70% in about five hours; the remaining 30% is completed by the topping charge. The slow topping charge, lasting another five hours, is essential for the performance of the battery. If not provided, the SLA eventually loses the ability to accept a full charge and the storage capacity of the battery is reduced. The third stage is the float charge that compensates for self-discharge after the battery has been fully charged.

During the *constant-current charge*, the SLA battery is charged at a high current, limited by the charger itself. After the voltage limit is reached, the topping charge begins and the current starts to gradually decrease. Full charge is reached when the current drops to a preset level or reaches a low-end plateau.

The proper setting of the cell voltage limit is critical and is related to the conditions under which the battery is charged. A typical voltage limit range is from 2.30 V to 2.45 V. If a slow charge is acceptable, or if the room temperature may exceed 30°C (86°F), the recommended voltage limit is 2.35 V/cell. If a faster charge is required and the room temperature remains below 30°C, 2.40 or 2.45 V/cell may be used. Table 8.4-1 compares the advantages and disadvantages of the different voltage settings.

Section 9: Technical Management and Safety

Introduction by Andy Butler, PBS, Alexandria, VA

Is broadcast engineering truly a unique art? Are there specific skills and a definable knowledge base that set a broadcast engineer apart from traditional single discipline practitioners such as electrical or mechanical engineers? That question is certain to spark lively debate any time a group of engineers gathers. This final section may not settle a bar room debate but it is an excellent resource that fully explores the wide variety of diverse disciplines that broadcast engineers must understand.

Veteran engineering director Marvin Born opens with a realistic look at the business of managing a technical facility. As he observes, "the number one priority of any manager is to insure the financial viability of the company." Born details the diverse issues that successful engineering managers must address to meet this responsibility.

One key to an efficient technical facility is good documentation. Fred Baumgartner and Terry Baun have learned this lesson firsthand. They believe that "the cost of neglecting hours of engineering documentation is paid in weeks of reconstruction." This chapter offers excellent advice on what information to keep and how to keep it.

Broadcast stations are complex facilities housing hundreds of discrete devices that must work together smoothly to produce and deliver a final product. The glue that binds the parts together is skillful systems engineering. Gene DeSantis is a veteran designer who offers some great techniques to make certain the broadcast factory you design delivers the best product for the least possible cost and effort.

Broadcast facilities utilize a number of technologies that are dangerous if not used properly. Transmitters of all types produce non-ionizing radiation that can cause severe injury. Kelly Williams shares his considerable knowledge of the hazard and its management. Finally, Cliff Ferris reviews basic "good practices" to avoid electrical shock. Linda Kelly concludes our safety review with a look at tower safety, fall arrest systems and OSHA rules and regulations.

No matter how well a system is planned and constructed disaster will eventually strike. The key to success is to include risk analysis and strategic recovery planning as a key part of your overall facility planning. Richard Rudman offers a carefully considered game plan for attacking the risk/recovery planning analysis.

This is a rich and exciting section that chronicles many of the unique challenges that broadcast engineers face every day.

9.1
MANAGING A TECHNICAL FACILITY

MARVIN BORN
DISPATCH BROADCAST GROUP, COLUMBUS, OH

INTRODUCTION

There is a standing order in any business that forms the foundation for any manager and that order certainly applies in broadcasting. The number one priority of any manager is to insure the financial viability of the company. This is number one because without the company, no other order, policy or direction is needed. The purpose of this chapter is to enhance the business aspect of the engineering department and how it relates to daily operations of the station, from an accounting-finance point of view rather than from a purely a technical point of view.

ACCOUNTING FUNCTIONS

Control is a word heard in the accounting department of every business. The business office's job is to manage the flow of funds in and out of any business and to keep records of all these movements. One such record is the *general ledger*, which is the master record of what happens in any given month. This is an ongoing month-to-month and year-to-year history of the business. Every expenditure, every utility payment and every hour of labor cost will be accounted for in the general ledger. Various parts of the general ledger can be distributed to the department heads to help in maintaining compliance with their budgets. This information is typically called *audit trails* and they provide detailed information on each and every purchase charged to the engineering accounts. The primary purpose of these audit trails is to match purchase orders with the invoices for the vendors. The audit trails also allow engineering managers to keep a running total of what is actually charged to their accounts in a given month. Due to billing cycles in both the vendors and the business office, it is possible that some invoices will be coded and paid in the expected month. Therefore, in one month an engineering department could be under budget, yet the next month be over budget and have to explain what happened. The audit trails will warn engineering managers of missing invoice payments and they can expect the over budget amount the next month. With this information engineering managers can still spend the normal budgets amount for each month without constantly under spending then over spending to catch up with late billing information.

Purchase Orders

Of all the paperwork engineers are expected to do, *purchase orders* (PO) are one of the least popular, but most helpful. POs are an accounting department method of control that shows that the proper authority to purchase has been obtained. POs provide detailed records of departmental spending and aid in projecting departmental budget needs for the next fiscal year. The engineering manager or their assistant must have the discipline to enter each and every purchase order into a computer database, similar to Figure 9.1-1.

The first column is the vendor name, column B is the date the PO was written and column C is the PO number. Column E is the amount for which the PO was written. These four columns are filled in for each PO when it is written. Set the spreadsheet to total the Column E which will yield a running total for year-to-date.

Columns F, G and H have data entered when the PO is paid—do not skip this entry. It is the most useful section of the database. Column D is the general ledger account code number for the item which can be entered either when the PO is written or at payment. The cellular bill is coded to account 350, which is a general small parts account. Code number 355 is a physical plant account code, etc. Column F is the actually amount charged to the account code and paid to the vendor. There can be some differences between what is written and what is actually paid, such as local taxes being added, etc. These two columns will be an automatic tip-off if more material was ordered than authorized so it also acts as an internal control. This is much faster than physically comparing the PO to the invoice. Column F also provides a variance amount between actual and budgeted figures. Column G is the date of approval for payment. This is handy when bills get lost. It also provides a means to monitor turnaround from purchases to payment. (Some companies allow a discount of one or two percent for early payment.)

The final column is a description of the product, such as small parts, heads, cleaning material. Typically the department's annual operating budget has the account codes broken down into individual items, that have high dollar value such as video heads, audio heads, transmitter tubes, etc. If this description column in the PO database matches the operating budget items, the database can be sorted by items.

As a matter of fact this is the whole basis of this extensive database. Sort the database by account code, October PO's

A	B	C	D	E	F	G	H
Vendor	Date	PO Number	Code	Amount	Actual Paid	Date paid	Description
Abekas	10/21/97	5568	350	175			sm parts

Running totals				$5,148	669.92		

Figure 9.1-1. Sample purchase order database.

then by description item. Separate the account codes with several spaces and insert totals for each code. This yields the exact amount spent on each code and each item the previous year. Since broadcast operations do not change that much from year to year, the major part of figuring the operating budget is finished. Additional columns can be added for the number of anticipated future items.

As the years pass, the department will have a number of previous databases to use to project spending needs. Try stripping out the amount paid and the item description and make a new database with the description in column A and each of the years in Column B, C, D, etc. By graphing the amount paid, the department can project the present increase each vendor has been taking each year. This data will help the department defend its budget at the annual meetings.

CAPITAL

The purchase of capital for a broadcast facility is one of the most important functions of a chief engineer and his associates. Not only does capital purchasing have the most of the department's resources at stake, it determines future operating and competing ability for several years to come. A typical method of equipment purchase involves the due diligence study of all specifications, performance history and technical acceptability of equipment. This section will skip the technical methods of equipment selection and move to a more financial method of selecting equipment. The purpose of this section is to remove the emotional factor in equipment selection. It also removes the language barrier between engineers' methodology and the general managers' sales language orientation.

The financial method of evaluation involves analyzing the flow of cash into and out of a piece of equipment. There are three methods of determining the cash benefits of a capital purchase. They are:

- Payback
- Net present value
- Internal rate of return

Payback is the most common and easiest understood method. Simply stated, payback is the amount of time required to recover the capital outlay used to make a purchase. For example, a station purchases a new edit suite, installs it and determines the amount of money that system can generate per session. Assuming one session per day, the payback period is the number of days, months, etc. that pass before the initial cash outlay is returned. The longer the period of time, the less desirable the purchase. Payback does not account for the time value of money. In other words, any interest the money would have generated during the payback time is not accounted for. If the interest were included the period would have been shorter. Further, secondary cash out flows are not included, such as maintenance costs and tax benefits or costs, the most important of which is depreciation. While payback is included here for discussion and educational purposes it is not considered a reliable method of financial analysis due to its short comings.

Net present value (NPV) is a more advanced method of evaluating the performance of a capital investment. Unlike payback, NPV accounts for the cash flows,

SAMPLE NET PRESENT VALUE TABLE

Flow		BT	Tax	AT	Time	Factor	PCFCF	Direction
Buy new		100,000	1	100,000	0		100,000	out

	NET PRESENT VALUE (PVFCF minus COST)						16910	

Figure 9.1-2. Sample net present value table.

over time, both into and out of the financial analysis of the investment. These cash flows are then evaluated in terms of the time value of money.

For example, assume a station is buying a new transmitter for $100,000. It will sell the old transmitter to a local radio station for $10,000. Further it expects this new transmitter to have an expected useful life of five years. It pays 10% interest at the bank. It also plans to sell the new transmitter at the end of five years for $15,000. (Note, five years and 10% cost of capital are used as standard values. refer to the NPV chart Figure 9.1-2).

Flow indicates what the money is doing, BT is a column for values before tax and AT is after tax. Tax is either 1 for no tax, or .4 for 40% tax rate. .6 is tax of .4 subtracted from one (it is what is left after the tax is paid). *Factor* is the value of one dollar at 10% interest for the number of periods indicated in the time column. The values in the Factor column come from a standard interest table. These tables are available in any financial book or can be calculated by most spread sheet software. The PCFCF column is the value in AT multiplied by the factor value. (The amount of money times the value of one dollar for the period of time.) *Direction* refers to which way the money went IN or OUT.

The *Buy New* column is the $100,000 for the new transmitter. There is no income tax involved with the purchase so tax is "1." *Time 0* is the present and there is no time value of money factor for this cash flow. *Present Value Future Cash Flow* (PVFCF) is the actual dollar value of the cash flow corrected for any tax and computed for its value after a period of time. Time 1 is one year, time 2 is two years etc. Time 0 is the present time. There is no tax and no interest due, therefore the present value of the cash flow is $100,000. The "out" in the last column shows that the cash was flowing out. Money was paid (out) for the transmitter.

The second line shows that the old transmitter was sold for $10,000. The direction column shows IN; therefore $10,000 flowed into the analysis and the bank. The $10,000 is subtracted from the new cost for a total of $90,000 spent on the transmitter.

The revenue section is a little more difficult to understand. Using an example, assume the following. The new transmitter will have more coverage than the old one; therefore, it will generate $80,000 per year for each year of service. Since the tax rate is 40%, multiply the $80,000 by .6 (100% less 40% equals 60%, which is equal to .6) which yields $48,000 actual income per year. Multiply the income by the factor for five years and a total of $181,957 which is generated by the new transmitter. Since this is income the direction is IN.

Next, allow that the old transmitter was generating $40,000 per year, times the tax for an income of $24,000. Multiply 24,000 by the factor for a value of $90,978. However, since the station did not really get this money, it is cash flow OUT. For correct analysis the money that the old transmitter earned must be considered.

The expenses involved with the new transmitter and the expenses that would have incurred by the old transmitter must also be considered. Since the new transmitter has more power, it can be assumed that it requires larger tubes at a cost of $10,000 per year. The old transmitter was lower power and its cost of maintenance was only $8,000.

Taking into consideration the taxes on both cash values, then the factor for five years, the $10,000 becomes $22,744 and the $8,000 becomes $18,195. Most important is the direction for the $10,000 is OUT since we spent the money. The $8,000 is IN, money was not spent. Simply put, expenses are money out, whereas revenue is money in.

To demonstrate depreciation, consider a five year method for the new transmitter, but simple depreciation for the old transmitter. Depreciation is a tax benefit that the tax code allows businesses to regain the cost of new equipment through reduced taxes.

The five year method allows a value to be assigned for each year. In this case $15,000 the first year and $22,000 for year two and $21,000 for years three, four and five. The total will be the cost of the new transmitter. Each of the yearly values will be computed for the after tax amount, multiplied by the correct factor yielding the present value in each of the years. Two things are noteworthy here. First, since this is a tax value being returned, the actual tax paid must be computed (not what is left after tax); therefore use .4 as the tax rate which is equivalent to 40%. The factor is from the time value of money tables for one dollar per year. In this case one dollar in year one will be .90909 cents. The direction is IN since cash is received into the analysis. Following the first depreciation line, the tax on $15,000 was $6,000. Project that value to one year in the future, the $6,000 has an actual PCFCF of $5,454. Each of the years two through five are computed the same way.

The old transmitter will be depreciated via the older straight line method. The tax value was $6,000 which represents $9,097 after five years. Notice this was a cash out, since it was money the station will not get, since it sold the transmitter.

Now the whole analysis has been completed. The present value of all future cash flows are $106,910. In simple terms, the new transmitter will generate $106,910 in revenue and depreciation less expenses. However, the actual cost of the new transmitter, $90,000, must be subtracted. The actual money into the business will be $16,910.

The term applied to this final value is Net Present Value (NPV). This simulation of buying a new transmitter has a positive NPV and would be a good business decision financially. The larger the NPV (if it is positive) the better the expenditure is for the company. When the NPV is negative, the company will actually lose money on the deal and would require serious consideration before proceeding with the purchase. As the NPV approaches zero, the capital purchase makes no financial difference.

NPV is a valuable tool to help with the decision making process in purchasing capital equipment. NPV calculations are not the normal domain of the broadcast engineer. Chief Engineers tend to think in terms of how a purchase will enhance the signal, have more coverage or allow expanded production. Their typical presentation at the annual capital meeting is based on technical parameters and not business methods. If the engineer can also provide a sound revenue based analysis along with the technical analysis, he will have a much stronger base for his arguments for purchases. Since general managers or corporate presidents tend to think in financial terms and not technical terms, they will better understand the NPV analysis. NPV is extremely useful in discouraging emotional purchases.

The purpose of this discussion was to present the availability of alternative tools for engineering management. The example presented was brief and simple. The interest rate and tax rates were chosen to make the math easy—they should not be considered typical or real-world. One should consult a financial management text for complete details or have the station's business manager or corporate treasurer help with the analysis the first time through.

The engineering manager must also present their case for the purchase of new equipment. Capital items that are requested by other departments are easier to present. The purchase of sync generators, distribution amplifiers, waveform monitors and audio consoles can be hard to sell. These items are essential for the operation of the station, but they are hidden and they do not directly generate income or ratings. They are not glamorous like SNG and ENG trucks.

To do the pitch, first prepare a normal engineering presentation. Include all the frequency response and noise information, add ease of maintenance and ease of operation. Outline the highlights of the presentation. Now go through the outline and remove every technical term and replace it with plain language.

Take each of these points and apply them to cash flow. For example, the present audio board causes some slight distortion in the program material and has a bad noise figure by today's standards. Point out that this noise and distortion can cause young (age 18 to 34) women to tune away from the station. Then point out how a one and five percent increase in that demographic would affect the ratings and how the ratings increase could affect the revenue. Engineers do not normally work in this area; however, the general manager does not know what a lack of frequency response or system noise can do to the listening audience. If you present the new audio board as having low noise and a frequency response of dc to light, that GM will not connect his low female ratings with the problems in the audio board. While this is a simplistic example, it serves the point. Speak the language of business and present a pitch in that language. Relate how your desired product will either increase revenue or decrease expenses.

THE BUSINESS OF LIVE SHOTS

The Department of Transportation (DOT) imposes a number of rules regarding the driving of trucks requiring a Commercial Drivers License (CDL). While all of the rules apply to the SNG truck driver there are a couple of quirks that make complying with the law difficult. A commercial, over-the-road driver's primary duty is to drive the truck. He can drive for 8 hours and stop to rest and make the appropriate entries in the truck log. The SNG driver's primary duty is not the driving of the truck. It is the uplinking of television information. The truck is a means to that end. The typical scenario is to drive a couple of hundred miles to a news story, set up the truck, handle the story and return home. What causes problems here is the working, but not driving time. A driver can only work fifteen hours before requiring eight hours rest. That is fifteen clock hours not just behind the wheel. For example, the driver arrives at work at 5:00 am and spends an hour preparing his vehicle and then drives five hours to the site of a football game arriving at 11:00 am. He then spends the next four hours setting up the truck and installing cables. He then runs the game which ends at 5:30 pm. His news department requests that he stays for a 6:20 sports live shot, he then spends two hours cleaning up and packing the truck. It is now 8:30 pm. The driver heads home and arrives at 1:30 am the next morning. The driver had worked twelve and a half hours by the end of the game. The live shot and cleanup made the total of fifteen hours.

According to DOT rules, drivers cannot drive a truck after 15 hours without eight hours of rest. This driver should never get behind the wheel let alone drive five hours. In this case the driver was timed out at the end of the game. The manager of an SNG or remote truck that required CDL licenses has to plan ahead and assign a second person to drive the return trip home or allow the driver to stay over. Having a second driver riding in the truck does not count as rest unless the truck has a sleeper berth. In other words, the second driver must be off duty (away from the work site and the game) for a full eight hours before driving the truck or at least have enough driving time left to make it all the way home.

A second more subtle way to time out is the "70 hours in ten days rule." If a driver works 70 hours in a ten day period the driver must have a 24-hour rest period. For example, an SNG driver works a normal five day week and clocks 40 hours. The driver goes home on Friday, but is called out on Saturday, for an SNG remote out of the city. The driver drives all day Saturday, goes on a Sunday remote and has a good night's sleep. The driver is then sent on to another and another remote which together lasts the rest of the week. Each night the driver gets the minimum eight hours rest. The driver arrives back home the following Sunday. What rule was violated? The driver worked more than 70 hours in a 10 day period and drove the truck without the required 24 hours off.

RF

Our CDL scenario concerned the truck driving only. Common sense would indicate that tired operators are more prone to mistakes and the RF equipment on board an SNG truck can provide a real danger. The output of a C- or Ku-Band uplink can easily exceed the maximum RF levels allowed by the FCC.

When a truck is purchased, have it measured for RF levels all around at ground level and on top of the truck. Each employee should carry an active RF monitor with an audible alarm. This device will sound if the employee enters an RF field that exceeds the maximum level. As a minimum, do not allow anyone on the truck when the transmitter is active or, even better, do not buy a SNG truck with a roof platform.

The voltages that operate the klystron amplifiers or traveling tube amplifiers are lethal. Every precaution that is applied to a broadcast transmitter applies to the SNG. Further, trucks are more dangerous, the space is cramped, there is a pressure situation and the operator/driver will have been working longer hours. This is a dangerous combination.

As an engineering manager one should try to anticipate what other people will do and plan for a safe way to service that anticipated need. The typical SNG is not designed to carry passengers in the operating area. However, in a pressure news story someone will suggest they edit while the truck is being driven to the next location. While the danger may be obvious to an engineering manager, other departments may not understand and insist that they be allowed to work in the truck while it is moving. Cover this with the news director and every truck driver, making the driver responsible for the truck safety as well as its operation. Make sure that they have the support to say no to unsafe operations regardless of the believed emergency presented by people who want to take a shortcut.

BUSINESS MANAGEMENT

Somewhere it is said that of the three areas of business administration, accountants record the past, managers handle the present and finance people plan the future. All three aspects are important in their own right and a good engineering manager will know how to use each. The typical engineering manager uses them in a different order. Manage today and provide costs to the accounting plan for the future in a technical way.

Budgeting

There are three documents that relate to accounting: the income statement, the balance sheet and the cash flow statement. Normally, these documents are not available to the engineering department as a whole. A good engineering manager will know of these documents and how they are constructed. They will also know how operations within their department affect the line items on these documents.

The purpose of a balance sheet (shown in Figure 9.1-3) is to account for each dollar within the company. The left side contains all the assets of the company (cash in) such as cash, accounts receivable, property and equipment inventory and of course stockholder equity. While there are many items that can be placed in the asset side, those are the major ones. On the other side are the liabilities, money the company is expected to pay (cash out). The major items will be accounts payable, debt, (short term and long term), accrued taxes and dividends payable. When all the

TELEVISION BUILDERS INC.
Balance Sheet, December 31, 1996

Cash	$11,000	Accounts payable	$18,800
Temporary investments	8,000	Accrued wages payable	10,550
Prepaid expenses	1,200	Income taxes payable	4,650
Accounts receivable	25,500	Mortgage payable	50,000
Inventory	36,300	Common stock	120,000
Plant assets	168,000	Retained earnings	46,000
Total Assets	250,000	Total Equities	$250,000

Figure 9.1-3. Sample balance sheet.

TELEVISION BUILDERS INC.
Balance Sheet, December 31, 1996

Cash	$12,000	Accounts payable	$19,800
Temporary investments	8,000	Accrued wages payable	10,550
Prepaid expenses	1,200	Income taxes payable	4,650
Accounts receivable	25,500	Mortgage payable	50,000
Inventory	36,300	Common stock	120,000
Plant assets	168,000	Retained earnings	46,000
Total Assets	251,000	Total Equities	$251,000

Figure 9.1-4. Sample balance sheet.

accounting is finished, assets should equal liabilities. While the engineering department does not normally see a balance sheet, the engineering department can affect the areas of cash, expenses and inventory as well as plant assets.

If the engineering manager is ordering a large capital purchase that requires a down payment, a note should be sent to accounting informing them of the capital (cash) need in advance. Good business managers will manage the cash such that no large amounts are present in non-interest bearing accounts. They will need some time to transfer funds to the proper account for the down payment. This is the purpose of the cash flow statements. A quick conversation with the business manager will tell how much time is needed for the cash management functions.

Businesses are cyclic, for example, fall has football coverage plus a major rating period and managers expect their staff and maintenance requirements to rise. The same cyclic pattern affects the business office, however, it is typically 30 to 60 days behind. In other words, the business office is paying the bills from the previous two months. While engineering related matters are the engineering manager's foremost concern, be aware of the cycle in the business office and get expenses in on time. Holding invoices too long will cause them to be in the next month's accounts payable and affect the balance sheet as shown in Figure 9.1-4.

The income statement is a financial report with only of one column of information. It lists most of the major items previously mentioned; however, the net income line, the infamous bottom line indicates whether a profit was made or lost for the period covered by the statement. Engineering can have a major effect on this bottom line, especially the operating expense line. That line can be affected by spending money but also by saving money with prudent purchasing practices. Indirectly, the engineering department can affect the income line, with tower rental, remote truck rental and support of news and remote operations. Figure 9.1-5 is a typical income statement for a non-broadcast, manufacturing business. It is used because the broadcast example is different and a basic understanding of a typical balance sheet is necessary.

In any business there are two types of costs or expenses—variable costs and fixed costs. In the example balance sheet there is a cost of goods sold, which includes inventory, purchases for parts and the costs of making the product. What is important to remember is that as the number of products made increases, so does the cost of material and labor to make the product. Likewise, if orders for the product fall so do the cost of goods sold. The line item, *Gross profit on sales* is

Income Statement
January 1, 1996–December 31, 1997

Sales	$460,000
Costs of Goods Sold	360,000
Gross profit on sales	100,000
Operating expenses	50,000
Earnings before Taxes	50,000
Interest expense	30,000
Income Before Taxes	20,000
Taxes	8,000
Net Income	12,000
Common Stock Dividend	10,000
Contribution to Retained Earnings	2,000

Typical income statement for a manufacturing business.

	Profitable	Non-Profitable
Gross Sales	460,000	230,000
Sales commission and variable costs	46,000	23,000
Gross Profit on Sales	414,000	207,000
Operating expenses	276,000	276,000
Earning before tax	138,000	−69,000
Interst expense		
Tax		
Net Income (bottom line)		
Stock Dividend		
Contribution to Retained Earnings		

Typical income statement for broadcast station both profitable and taking a loss.

Figure 9.1-5

the result of subtracting the cost of goods sold from the income generated by the selling of the product.

The other type of cost of doing business is fixed costs. In the manufacturing business this is the operating expenses and mortgage interest expense. Operating expenses include the utilities, maintenance of plant and equipment and labor for non-line item employees, such as the business office and management. When the fixed cost is subtracted from the gross profit from sales, it yields the line item marked *income before taxes.* When the correct amount of tax is then subtracted, the result is the net income or bottom line.

What are the differences for broadcasting? Broadcasters do not manufacture a product, they sell time. But that time must be filled regardless of whether that time is a paying commercial message or a non-revenue public service announcement or station promotional announcement. Stated in a different more business manner: broadcast has very low variable costs (usually only sales commissions) but high fixed costs. Broadcasters pay the electric bill and maintain the machines and antenna towers regardless of what passes through the equipment. Visualize the manufacturing income statement presented and lower the cost of goods sold to $46,000 (which for this example represents the commissions to the sales department). The broadcast station makes a nice profit. However, broadcasters' expenses for operating the station are much higher. Maybe $276,000 for operators, parts, utilities, interest on equipment purchases and maintenance. That leaves a before tax profit of $138,000 (still a nice profit). But, what if there is a downturn in the economy and commercial sales drop to half the normal amount to $230,000 with sales commissions of $23,000 for a gross profit of $207,000? The station now has to fix its schedule with non-revenue spots, but the fixed operating costs of $276,000 remain. The station now has a net loss of $69,000. The high fixed costs made the turn between profit and loss occur very quickly.

A good broadcast engineer will understand how fixed costs affect the bottom line and be cooperative in minimizing them during troubled times. The upside is that during near sold out periods the fixed costs remain the same and station profits will soar just as quickly and dramatically in the other direction. A good engineering manager will know the desires of the general manager in regard to driving the bottom line. They should understand why it is necessary to cut overtime and forgo capital equipment for a given year when times are lean and at the same time understand the requirement to drive the net income up to increase retained earnings on the balance sheet. Good general managers and owners will also understand when to keep the retained earning number high and when to return greater sums of money to the company in the support of larger raises and increased capital purchases. High retained income drives up the stock prices if the company is publicly owned. Insuring the financial viability of the company is the number one job of any manager, general manager, engineering or sales manager. And driving up retained earnings is exactly what they are employed to do. Each department manager does their job in a different way, but the primary job is to have a positive number at the bottom line.

9.2
BROADCAST ENGINEERING DOCUMENTATION

FRED BAUMGARTNER
TCI TECHNOLOGY VENTURES, LITTLETON, CO
TERRENCE M. BAUN
CRITERION BROADCAST SERVICES, MILWAUKEE, WI

INTRODUCTION

Broadcast facilities are designed to have as little downtime as possible. Yet inadequate documentation is a major contributor to the high cost of systems maintenance and the resulting widespread replacement of poorly documented facilities. The cost of neglecting *hours* of engineering documentation is paid in *weeks* of reconstruction.

Documentation is a management function every bit as important as project design, budgeting, planning and quality control, and is often the difference between an efficient and reliable facility and a misadventure. If the broadcast engineer does not feel qualified to attempt documentation of a project, the engineer must at the very least oversee and approve the documentation developed by others.

Within the last few years the need for documentation has increased with the complexity of the broadcast systems. Fortunately, the power of documentation tools has kept pace.

With that in mind, this chapter considers exactly how much documentation is appropriate and how to assemble that documentation. This chapter reviews the current state of good engineering practice in such matters, and outlines the elements of making a business case for the very necessary expense of creating good documentation in broadcast plants.

BASIC CONCEPTS

The first consideration in the documentation process is the *complexity* of the installation. A basic radio facility may require almost no formal documentation, while a large satellite or network broadcast facility may require computerized databases and a full time staff dedicated to documentation updates. Most facilities will fall somewhere in the middle.

A second concern is the need for *flexibility* at the facility. Seldom does a broadcast operation get completely rewired because the cabling wears out or fails. Most often, it is the supporting documentation that has broken down, frustrating the maintainability of the system. Retroactive documentation is physically difficult and emotionally challenging, and seldom generates the level of commitment required to be entirely successful or accurate; hence, a total rebuild is often the preferred solution to documentation failure. Documentation must be considered a hedge against such unnecessary reconstruction.

Finally, consider *efficiency* and speed. Documentation is a prepayment of time. Repairs, rerouting, replacements and reworking all go faster and smoother with proper documentation. If your installation is one in which any downtime or degradation of service is unacceptable, then budgeting sufficient time for the documentation process is critically important.

The Manuals

Equipment manuals are the first line of documentation and deserve our attention and respect. Place those manuals in a centralized location in an order that seems appropriate for your station. Most engineering shops file manuals alphabetically, but some prefer a filing system based on equipment placement. (For example, production studio equipment manuals could be filed together under a *Production Studio* label and might even be physically located in the referenced studio.) Make sure the system is consistent. Few things are as frustrating to a technician as being unable to locate a manual when needing something as simple as a part number or the manufacturer's address.

The Documentation of Conventions

The second essential item of documentation is the statement of *Conventions*. This document contains basic information essential to an understanding of the facility. It should be posted in an obvious location and available to all who maintain the plant. Consider the following examples of conventions:

- Where are the equipment manuals and how are they organized?
- What is the architecture of the ground system? Where is the central station ground and is it a star, grid, or other distribution pattern? Are there separate technical and power grounds? Are audio shield grounded at the source, termination or both locations?
- What is the standard input/output architecture? Is this a +8 dBm, +4 dBm, or 0 dBm facility? Is equipment sourced at 600 Ω terminated at its destination, or left unterminated? Are unbalanced audio

sources wired with the shield as ground or is the low side of a balanced pair used for that purpose? How are XLR-type connectors wired—pin 2 high or low?
- How can a technician disconnect utility power to service line voltage wiring within racks? Where are breakers located, and how are they marked? What equipment is on UPS power, generator or utility power? Whom do you call for power and building systems maintenance?
- Where are the keys to the transmitter? Is the site alarmed?

For such an essential information source—it takes very little time to generate the conventions document. Keep it short—a page or two should be sufficient for most installations, and, if located in a obvious place, will keep the technical staff on track and will save service personnel from stumbling around searching for basic information. This document is the key to preventing many avoidable embarrassments.

The conventions document may be framed and posted behind the master control rack, in the engineering shop, or the CE's office. Wherever it is, be certain that it is prominently displayed.

Documentation Systems

The next step beyond the conventions document is a documentation *system.* There are three primary methods: self documentation, database documentation and graphic documentation. In most cases, a mixture of all three is necessary. In addition to documenting the physical plant and its interconnections, each piece of equipment, whether commercially produced or custom made, must be documented in an organized manner. Likewise there are a number of aids for documenting, labeling cables, wiring, etc. that are covered in the following sections.

Self Documentation

In situations where the facility is small and operations are very routine, self documentation is possible. Self documentation relies on a set of standard practices that are repeated. Telephone installations, for example, appear as a mass of perplexing wires. In reality, the same simple circuits are simply repeated in an organized and universal manner. To the initiated, any telephone installation that follows the rules is easy to understand and repair or modify, no matter where or how large—such a system is truly self documenting. Familiarity with telephone installations is particularly useful, because the telephone system was the first massive electronic installation. It is the telephone system that gave broadcasters relay racks, grounding plans, demarcation and virtually all of the other concepts that are part of today's electronic control or communications facility.

The organization, color codes, terminology and layout of telephone systems is recorded in minute detail. Once a technician is familiar with the rules of telephone installations, drawings and written documentation is rarely required for routine expansion and repair. The same is true of many parts of other facilities. Certainly, much of the wiring in any given rack of equipment can be self documenting. For example, a videotape recorder will likely be mounted in a rack with a picture monitor, audio monitor, waveform monitor and vectorscope. The wiring between each of these pieces of equipment is clearly visible, with all wires short and their purpose obvious to any technician familiar with the rules of video. Further, each video cable will conform to the same standards of level or data configuration. Further documentation is largely unnecessary.

By convention, there are rules of grounding, power and signal flow in all engineering facilities. In general, it can be assumed that in most communications facilities, the ground will be a star system, the power will be individual 20 amp feeds to each rack, and the signal flow will be from top to bottom.

Rules that might vary from facility to facility include color coding, connector pin outs, and rules for shield and return grounding. For example, stereo analog audio might be carried on *zip-stereo* cables (two shielded twisted pair wires married together to appear as lamp cord). It would be reasonable that each audio pair uses red for positive, black for negative and the shield is grounded only at the source end. The right channel may be the green pair and the left, the red pair. If this is consistent throughout the facility, only a simple statement of this is necessary to deal with a very large number of interconnections and a document repeating this convention for each circuit would be unnecessary. However, there is no standard for stereo analog audio, and all of the above conventions are reversed, with no ill effect, in many plants.

To be self documenting, the rules must be determined and all of the technicians working on the facility must know and follow the conventions. The larger the number of technicians, or the higher the rate of staff turnover, the more important it is to have a readily available document that clearly covers the conventions in use.

One thing must be very clear: a facility that does not have written documentation is not automatically self documenting—quite the contrary. A written set of conventions and unfaltering adherence to them are the trademarks of a self documenting facility.

But while it is good engineering practice to design all facilities to be as self documenting as possible, realize that there are limits to the power of self documentation. In the practical world, self documentation can greatly reduce the amount of written documentation required, but can seldom replace it entirely.

Database Documentation

As facilities expand in size and complexity, a set of conventions will no longer answer all of the questions. At some point, a wire leaves an equipment rack and its destination is no longer obvious. Likewise, equipment will often require written documentation as to its configuration and purpose, especially if it is utilized in an uncharacteristic way.

Database documentation records the locations of both ends of a given circuit. For this, each cable must be identified individually. There are two common systems for numbering cables—*ascension numbers* and *from-to coding*. In ascension numbering schemes, each wire or cable is numbered in increasing order, one, two, three ... etc. In from-to coding, the number on each cable represents the source location, the destination location, and normally some identification as to purpose and a unique identifier. For example, a cable labeled 31-35-B6 might indicate that cable went from a piece of equipment in rack 31, to another unit in rack 35 and carries black, it is also the sixth cable to follow the same route and carry the same class of signal.

Each method has its benefits. Ascension numbering is easier to assign and commonly available preprinted wire labels can be used. On the other hand, ascension numbers contain no hints as to wire purpose or path, and for that reason *purpose codes* are often added to the markings.

From-to codes can contain a great deal more information without relying on the printed documentation records, but often space does not permit a full delineation on the tag itself. Here again, supplemental information may still be required in a separate document or database.

Whatever numbering system is used, there really must be a complete listing kept in a database of some kind. In smaller installations, this might simply be a spiral notebook that contains a complete list of all cables, their source, destination, demarcations, signal parameters, etc.

Since all cabling can be considered as a transmission line, all cabling involves issues of termination. In some data and analog video applications, it is common for a signal to *loop-through* several pieces of equipment. Breaking or tapping into the signal path often has consequences elsewhere, resulting in unterminated or double terminated lines. While more forgiving, analog audio has similar concerns. Therefore documentation must include information on such termination.

Analog audio and balanced lines used in instrumentation have concerns of their own. It is seldom desirable to ground both ends of a shielded cable. Again, the documentation must reflect which end of a given shield is grounded.

In many cases, signal velocity is such that the length of the lines and the resultant propagation delay is critical. In such circumstances, this is significant information to be retained. In cases where differing signal levels or configurations are used (typical in data and control systems), it is the documentor's obligation to record those circumstances as well.

However or wherever the database documentation is retained, it represents the basic information that defines the facility interconnections and must be available for updating and duplication as required.

Graphic Documentation

Electronics is largely a graphical language. Schematics and flow charts are more understandable than net lists or cable interconnection lists. Drawings, either by hand, drafting machines and tools, or accomplished on computer aided design (CAD) programs are highly useful in conveying overall facilities design quickly and clearly. Normally the wire numbering scheme captured in a CAD document will follow that used in the database documentation, so that the graphic and text documentation can be used together.

CAD drawings are easy to update and reprint. For this reason, documentation via CAD is becoming more popular, even in smaller installations. Since modern CAD programs not only draw but also store drawings, they can effectively serve as an electronic file cabinet for documentation. While there have been attempts to provide electronic/telecommunications engineering documentation templates and corresponding technical graphics packages for CAD programs, most of the work in this area has been done by engineers working independently to develop their own systems.

Obviously the enormous scope of electronic equipment and telecommunications systems make it impractical for a standard CAD package to suit every user. Imagine, for example, a situation involving construction and documentation of a sound recording studio. Here the CAD program would need specifications on typical studio recording equipment (size, weights, power requirements), cable and connectors used, wiring types, speaker types and sizes, acoustical and environmental constraints, etc. Now imagine this same program when used to document a broadcast television control room—or a radio news room. The database required would be enormous and updating it would be a full time job in itself.

There is one commercially available program, VidCAD™ that has attempted to address this problem for the telecommunications industry. The program, which is basically an extension and augmentation of the AutoCAD™ program, claims an 11,000-product equipment database, and the ability to add equipment upon user request. In addition the program includes sophisticated report generating and wire routing capabilities. Visio Corporation also offers a CAD package (Visio). Undoubtedly, other CAD programs will offer similar features if the industry demand is sufficient.

Update Procedures

Since documentation is a dynamic tool, as the facility changes, so too must the documentation. It is common for a technician to improve conditions by reworking a circuit or two. Most often this fixes a problem that should be corrected as a maintenance item. But often, it plants a time bomb wherein a future change, based on no or incomplete documentation of the previous work, will cause problems.

It is essential that there be a means of consistently updating the documentation. The most common way of accomplishing this is the mandatory *change sheet.* Whenever a technician makes a change it is reported back to those who keep the documentation. If the changes are extensive, the use of the *red-line* drawing and *edit sheet* come into play. The original drawing and database printout, respectively, are corrected with a red pen. This then is used to update the original documentation.

In some cases, the updating process can be tied to the engineering reports or discrepancy process. Most facilities use some form of *trouble ticket* to track equipment and system performance and to report and track maintenance. This same form may be used to report changes required to the documentation or errors in existing documentation. The anticipated integration of maintenance software with documentation software will prove invaluable for this purpose.

DOCUMENT HANDLING AND NETWORKS

As of this writing, computer networking has reached the desktops of most broadcast facilities. Running a document manager on your network permits documentation to be tied together, and made available to all who require access to it. Installation of a complete documentation system on a company intranet would seem to be a useful option.

Imagine being able to pull up a single circuit and quickly locate a series of drawings and database entries that describe that circuit. If you desire, links direct you to related circuits. You could back out to overview documentation of the whole system or focus down to a specific circuit from any computer with access to the network. Imagine being able to call up a drawing from another one of your facilities across the country to recall how a particular installation was handled there. The file card could be imported and customized to fit the new installation. With PC remote-access software, you or your technicians might be able to instruct an operator to perform a route-around by viewing the station documentation from your home PC. It is clear that this type of hypertext documentation can be a viable means of moving documentation into a paperless environment.

Label Systems

The simplest and cheapest label system is the wire-tie tag label that can be written upon with a pen. For systems planned with wire numbers assigned in advance of construction, tags using wrap around clear plastic protectors can be computer printed, making them more legible, durable and less likely to be ripped off when pulled. Computer printed tags can even be generated as part of a documentation program.

A recent development is the hand-held labeling system which generates professionally printed labels right at the job site, allowing installers to create the cable labels as the connections themselves are being made. These units are also useful for creating equipment designation labels and in-house asset numbering tags.

Perhaps the height of cable labeling is the use of stamped-in or cable printing. Typically, this method applies a printed marking either with ink or by slightly melting (branding) the cable jacket every foot or so. The obvious benefit is that the cable can be identified anywhere along its path. Unfortunately, the costs and time involved make this method impractical except for very large facilities.

Equipment Documentation

Plant documentation does not end when all of the circuit paths in the facility are defined. Each circuit begins and ends at a piece of equipment which can be modified, reconfigured or removed from service. One must keep in mind that someone unfamiliar with the equipment will eventually be asked to return it to service. For this reason, a documentation file for each piece of equipment must be maintained.

Equipment documentation contains these key elements: the equipment manual (or a reference to its location), the modification record, the configuration information, and ideally, the maintenance record.

The equipment manual is the manufacturer's original documentation. As mentioned previously, the manuals must be organized in such a manner that they can be easily located. Typically, the manuals are kept at the site where the equipment is installed if practical. Remember that equipment with two *ends* such as STLs, RPUs, or remote control systems need manuals at *each* location!

Of course, if a piece of equipment is of custom construction, there must be particular attention paid to creating a manual. For this reason, a copy of the key schematics and documentation is often attached directly to the equipment. Often, this built-in manual will be the only documentation to survive over the years.

Many pieces of equipment, over time, will require modification. Typically the modification is recorded in three ways. First, internally to the equipment. A simple note glued into the chassis may be suitable, or a marker pen is used to write on a printed circuit board or other component. Second, the changes may be recorded in the manual, either inside the cover, or on the schematic or relevant pages. If the manual serves several machines, this may not be appropriate. If this is the case, a third option is to keep the modification information in a separate *equipment file.*

Equipment files are typically kept in standard file folders and may be filed with the pertinent equipment manuals. Ideally, the equipment file is started when the equipment is purchased, and should contain purchase date, serial number, all modifications, equipment location and a record of service.

The equipment file is the proper place to keep the configuration information. An increasingly large amount of equipment is microprocessor based or otherwise configurable for a specific mode of operation. Having a record of the machine's default configuration is extremely helpful when a power glitch (or an operator) reconfigures a machine unexpectedly.

Equipment files should also contain repair records. With most equipment, documenting failures, major part replacements, operating time etc., serves a valuable purpose. Nothing is more useful in troubleshooting than a record of previous failures, configuration, modifications, and, of course, a copy of the original manual.

Operator/User Documentation

The documentation that this chapter addressed up until now has been exclusively in the realm of construction and maintenance. There is yet another type of documentation, that designed for system users.

User documentation provides, at its most basic, instructions on how to use a system. While most equipment manufacturers provide reasonably good instruction and operations manuals for their products, when those products are integrated into a system another level of documentation may be required. Complex equipment may require interface components that need to be adjusted from time to time, or various machines may be incompatible in some data transmission modes—all of which is very essential to the proper operation of the system.

Such information often resides only in the heads of certain key users and is passed on by word of mouth. This level of informality can be very dangerous, especially when changes take place in the users or maintenance staff, resulting in differing interpretations between operators and maintenance people about how the system normally operates. Maintenance personnel will then spend considerable time tracking hypothetical errors reported by misinformed users.

A good solution is to have the operators write an operating manual and provide a copy to the maintenance department. Such documentation will go a long way toward improving interdepartmental communications and should result in more efficient maintenance as well.

The True Cost of Documentation

There is no question that documentation is expensive—in many cases it may equal the cost of installation. Still, both installation and documentation expenses pale in comparison to the cost of equipment as well as revenue losses due to system downtime.

Documentation must be seen as a management and personnel issue of the highest order. Any lapse in the documentation updating process can result in disaster. Procrastination and the resulting lack of follow through will destroy any documentation system and ultimately result in plant failures, extended downtime, and premature rebuilding of the facility.

Making a business case for documentation is similar to making any business case. Gather together all the costs in time, hardware, and software on one side of the equation, and balance this against the savings in time and lost revenue on the other side. Like transmission line theory, the most efficient operation occurs when the load matches the source—or in this case, when the cost of documentation is equal to the savings.

Engineering managers are expected to project costs accurately, and the allocation of sufficient resources for documentation and its requisite updating is an essential part of that responsibility.

9.3
SYSTEMS ENGINEERING CONCEPTS

GENE DESANTIS
DESANTIS ASSOCIATES, LITTLE FALLS, NJ

INTRODUCTION

Modern systems engineering emerged during World War II. Due to the degree of complexity in design, development and deployment, weapons evolved into weapon *systems* during this time. In the 1960s, the challenges of the space program made a systems engineering approach to design and problem solving even more critical. Indeed, the Department of Defense (DoD) and the National Aeronautics and Space Administration (NASA) are two of systems engineering's staunchest practitioners. With the increase in size and complexity of radio and television systems during that same period, the need for a systems approach to planning, designing and building facilities gained increased attention.

Today, large engineering organizations also use a systems engineering process. Much has been written about systems engineering practices in manuals, standards, specifications, and instructional materials. In 1969, the DoD published MIL-STD-499, to assist government and contractor personnel involved in defense acquisition programs. In 1974, this standard was updated to MIL-STD-499A, which specified the application of systems engineering principles to military development programs and is still in use today.

Likewise, the builders of turnkey radio and television systems and facilities have adopted their own unique systems engineering approaches to projects. The tools and techniques of these processes continue to evolve so that each job can be done better, faster and more economically.

This chapter describes systems theory in a general sense, discusses its application to broadcast television and radio systems engineering and concludes with some practical examples and implementations of the process.

SYSTEMS THEORY

In the broadcast industry, systems engineering can be applied to the engineering of audio, video, radio frequency (RF), control, time code, telecommunications, computer systems and software. Building and vehicle systems, including space planning, power and lighting, environmental control and safety systems, can also benefit from the systems engineering approach. All of these systems are made up of interconnected component elements that are programmed to function together in a facility.

For the purpose of this discussion, a *system* is defined as a set of related elements that function together as a single entity. *Systems theory* consists of a body of concepts and methods that guide the description, analysis and design of complex entities.

Decomposition is an essential tool of systems theory. Using an organized methodology, the systems approach breaks down large complex projects into simpler, more manageable component elements, which are treated, analyzed and designed separately. In the end, all of the components are recombined to build the whole.

Holism is an element of systems theory that recognizes that the end product is greater than the sum of its component elements. In systems theory, modeling and analytical methods take into account all essential effects and interactions within a system and between a system and its surroundings. This avoids errors that result when parts of a system are treated in isolation or consideration is focused on a single aspect of the system.

Another holistic aspect of system theory describes *emergent properties*. These are properties that result from the interaction of system components but are not properties of the components themselves.

Though systems theory deals with concrete systems, *abstraction* is an important feature of systems models. Components are described in terms of their function rather than their form. Graphic models such as block diagrams, flow diagrams, timing diagrams and the like are commonly used.

Mathematical models may also be employed. Systems theory shows that, when modeled in abstract formal language, apparently diverse kinds of systems show significant and useful *isomorphisms* of structure and function. Similar interconnection structures occur in different types of systems. Equations describing the behavior of electrical, thermal, fluid and mechanical systems are often essentially identical in form.

Isomorphism of structure and function implies isomorphism of behavior of a system. Different types of systems exhibit similar dynamic behavior such as response to stimulation.

The concept of *hard* and *soft systems* appears in systems theory. In hard systems, mathematical models can describe the components and their interactions. Soft systems cannot be described so easily. They are mostly human activity systems that imply unpredict-

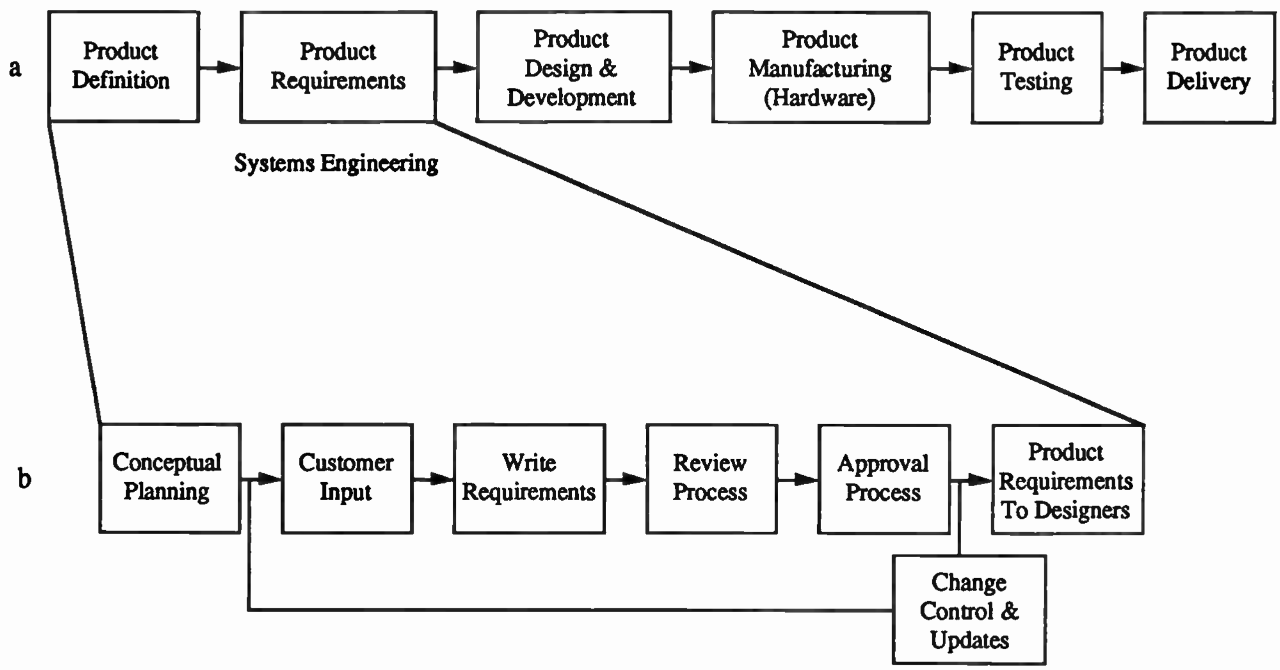

Figure 9.3-1. Product development process (a) showing requirements documentation process (b).

able behavior and non-uniformity. They introduce difficulties and uncertainties of conceptualization, description and measurement. The kinds of system concepts and methodology described above cannot be applied to soft systems.

Systems Engineering

Systems engineering depends on the use of a *process methodology* based on systems theory. To deal with the complexity of large projects, systems theory breaks down the process into logical steps. Even though underlying requirements differ from program to program, a consistent, logical process can be used to accomplish system design tasks. The basic product development process is illustrated in Figure 9.3-1, which shows systems engineering beginning with the description of the product to be designed. Systems engineering encompasses four activities: functional analysis, synthesis, evaluation and decision and a description of system elements (see Figure 9.3-2). The process is iterative, so that with each successive pass, the product element description becomes more detailed. At each stage in the process, a decision is made whether to accept, make changes or return to an earlier stage of the process and produce new documentation. The result of this activity is documentation that describes all system elements and can be used to develop and produce the elements of the system.

Functional Analysis

A systematic approach to systems engineering will include elements of systems theory (see Figure 9.3-3).

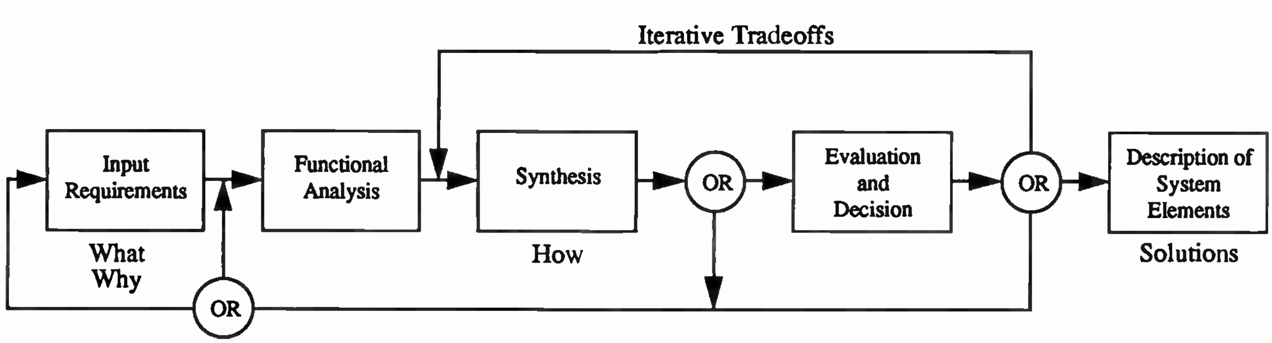

Figure 9.3-2. The systems engineering process. (Adapted from Hoban, F. T., and Lawbaugh, W. M., *Readings in Systems Engineering*, NASA, Washington, DC, pg. 10, 1993.)

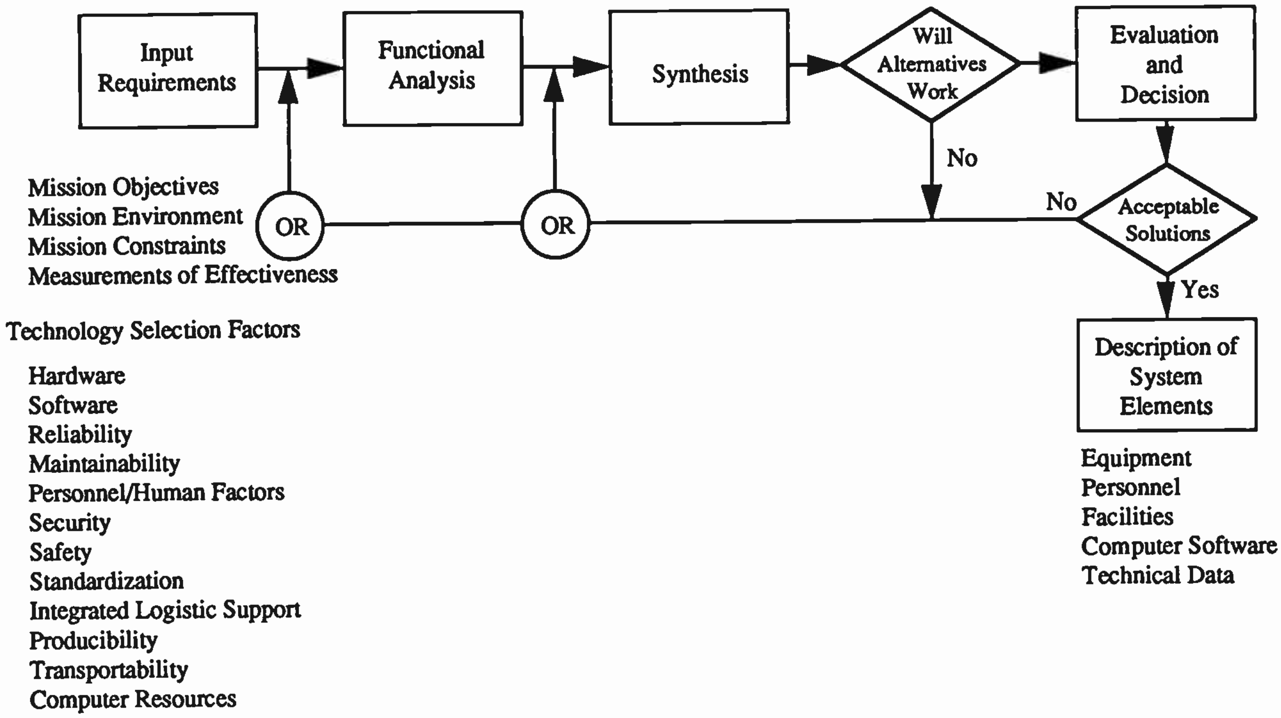

Figure 9.3-3. The systems engineering decision process. (Adapted from Hoban, F. T., and Lawbaugh, W. M., *Readings in Systems Engineering*, NASA, Washington, DC, pg. 12, 1993.)

To design a product, hardware and software engineers need to develop a vision of the product and, ultimately, the product requirements. These requirements are typically based on customer needs researched by a marketing department. (An organized process to identify and validate customer needs will help minimize false starts.) First, system objectives are defined. This may take the form of a mission statement that outlines the objectives, constraints, mission environment and means of measuring mission effectiveness;.

Once the purpose of the system is defined, analysis identifies the requirements and the essential functions the system must perform and why. The functional flow block diagram, a basic tool used to identify functional needs, shows logical sequences and relationships between operational and support functions at the system level. Other functions such as maintenance, testing, logistics support and productivity may also be required in the functional analysis. The functional requirements will be used during the synthesis phase to show the allocation of the functional performance requirements to individual system elements or groups of elements. Following evaluation and decision, the functional requirements provide the functionally oriented data required to describe the system elements.

Analysis of time critical functions is also a part of this functional analysis process, with identification of functions that have to take place sequentially, or concurrently, or on a particular schedule. Timeline documents support the development of requirements for operation, testing and maintenance functions.

Synthesis

Synthesis is the process by which concepts are developed to achieve the functional requirements of a system. Performance requirements and constraints, as defined by the functional analysis, are applied to each individual element of the system, and a design approach is proposed for meeting the requirements. Conceptual schematic arrangements of system elements are developed to meet system requirements. These documents can be used to develop a description of the system elements and can be used during the acquisition phase.

Modeling

Modeling is the starting point of synthesis. Since we must be able to weigh the effects of different design decisions to make choices between alternative concepts, modeling requires determining the quantitative features that describe the operation of the system. We would, of course, like a very detailed model with as much detail as possible describing the system. Reality and time constraints, however, dictate that the simplest possible model be selected to improve our chances of design success. The model itself is always a compromise and is restricted to those aspects that are important in the evaluation of system operation. A model might start off as a simple block diagram with more detail added as needed.

Dynamics

Most system problems are dynamic in nature. The signals change over time, and the components determine the dynamic response of the system. The system behavior depends on the signals at a given instant, as well as on the rates of change of the signals and their past values. The term "signals" can be replaced by substituting human factors, such as the number of users on a computer network, for example.

Optimization

The last concept of synthesis is optimization. Every design project involves making a series of compromises and choices based on relative weighting of the merit of important aspects. Deciding the importance of various features is often subjective but, ideally, the best candidate among several alternatives will be selected.

Evaluation and Decision

Program costs are determined by tradeoffs between operational requirements and engineering design. Throughout the design and development phase, decisions are made based on evaluation of alternatives and their effect on cost. One approach attempts to correlate the characteristics of alternative solutions to the requirements and constraints that make up the selection criteria for a particular element. The rationale for alternative choices in the decision process is documented for review. Mathematical models or computer simulations may be employed to aid in this evaluation decision making process.

Trade Studies

A structured approach is used in the trade study process to guide the selection of alternative configurations and insure that a logical and unbiased choice is made. Throughout development, trade studies are conducted to determine the best configuration that will meet program requirements. In the concept exploration and demonstration phases, trade studies help define the system configuration. They are also used as a detailed

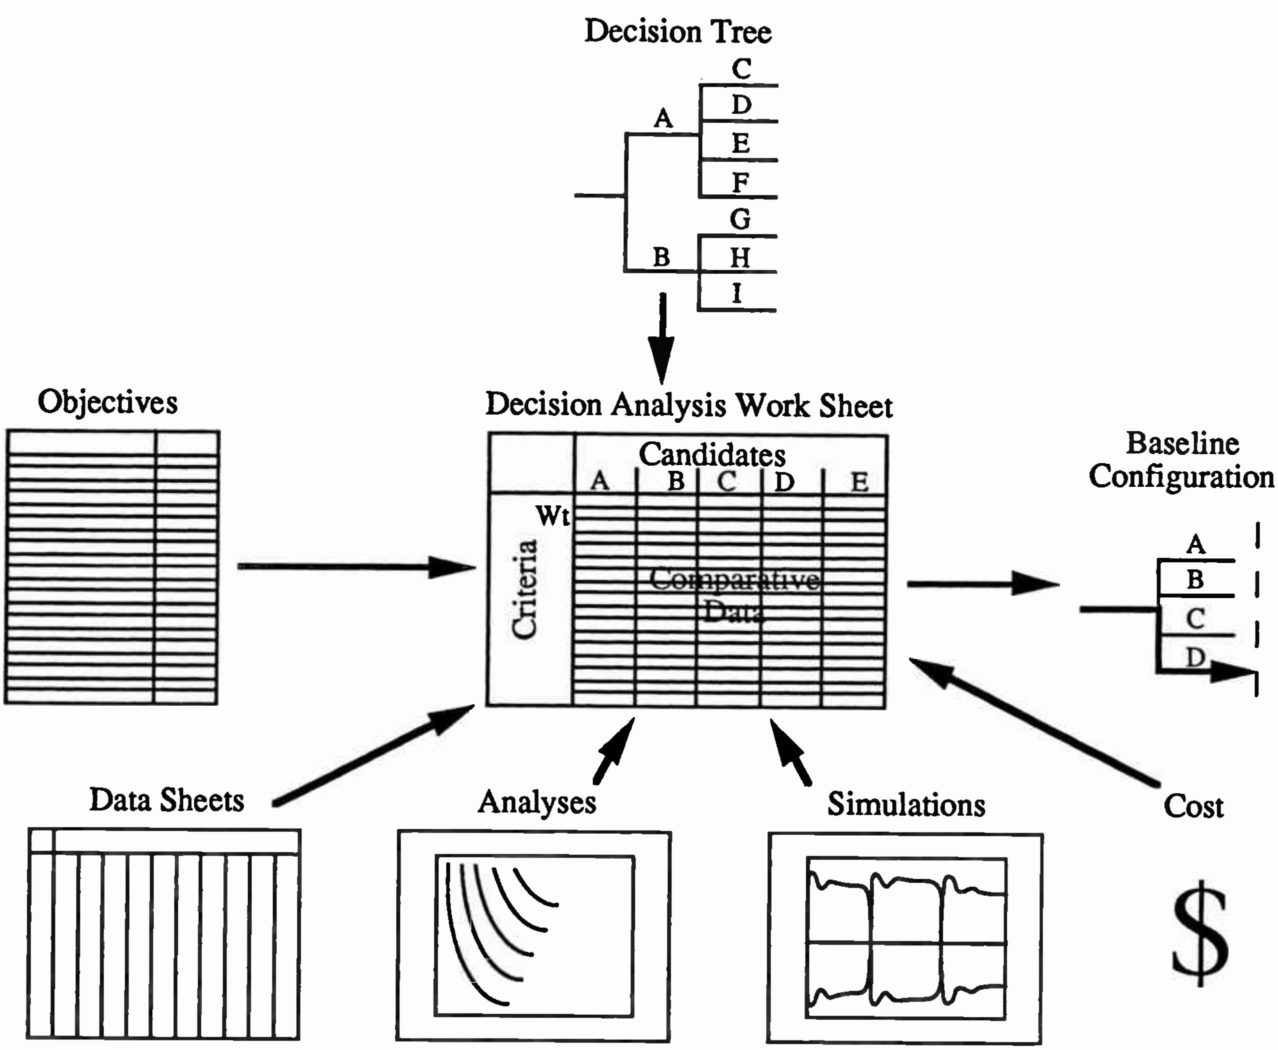

Figure 9.3-4. Trade studies use a systematic approach to decision making. (Adapted from *System Engineering Management Guide*, Contract No. MDA 903-82-C-0339, Defense Systems Management Collage, Virginia, 1983.)

design analysis tool for individual system elements in the full-scale development phase. During production, trade studies are used to select alternatives when changes need to be made. Figure 9.3-4 illustrates the relationship of the various elements that may be employed in a trade study.

Figure 9.3-5 is a flow diagram of the trade study process. To provide a basis for the selection criteria, the trade study's objectives must first be defined. Functional flow diagrams and system block diagrams are used to identify trade study areas that can satisfy certain requirements. Alternative approaches to achieving the defined objectives can then be established.

Complex approaches can be broken down into several simpler areas and a decision tree or *trade tree* constructed to show relationships and the dependencies at each level of the selection process (see Figure 9.3-6). Several trade study areas may be identified as possible candidates for accomplishing a given function, and several alternatives may be candidates for solutions in a given area. The selected candidates are then submitted to a systematic evaluation process intended to weed out unacceptable candidates. Criteria for desirable characteristics are established, although undesirable characteristics may also be included to aid in the evaluation process. Weights are assigned to each criterion to reflect its value or impact on the selection process. This subjective process should also take into account cost, schedule and hardware availability restraints, which may limit the selection.

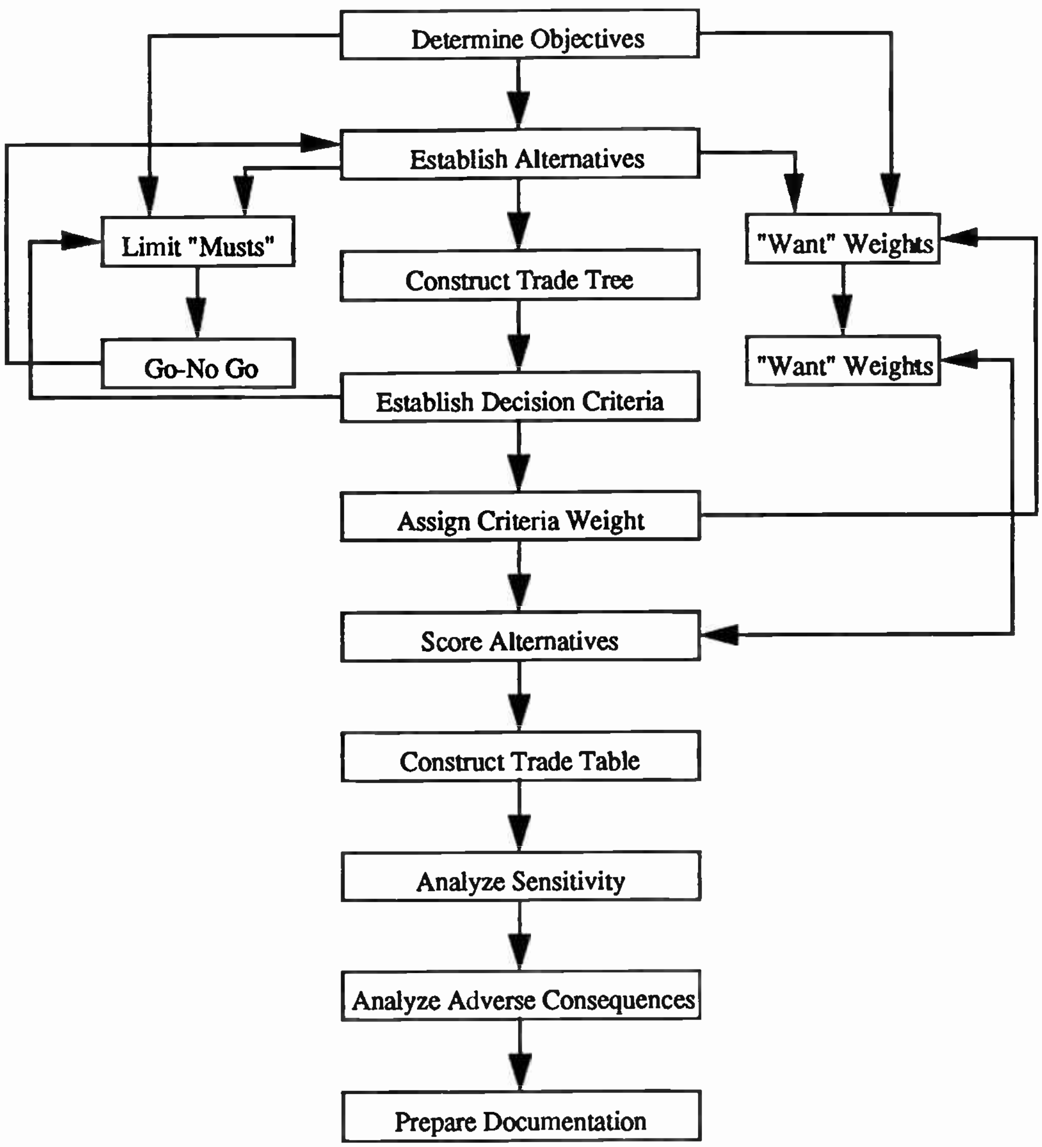

Figure 9.3-5. Trade study process flow. (Adapted from *System Engineering Management Guide*, Contract No. MDA 903-82-C-0339, Defense Systems Management Collage, Virginia, 1983.)

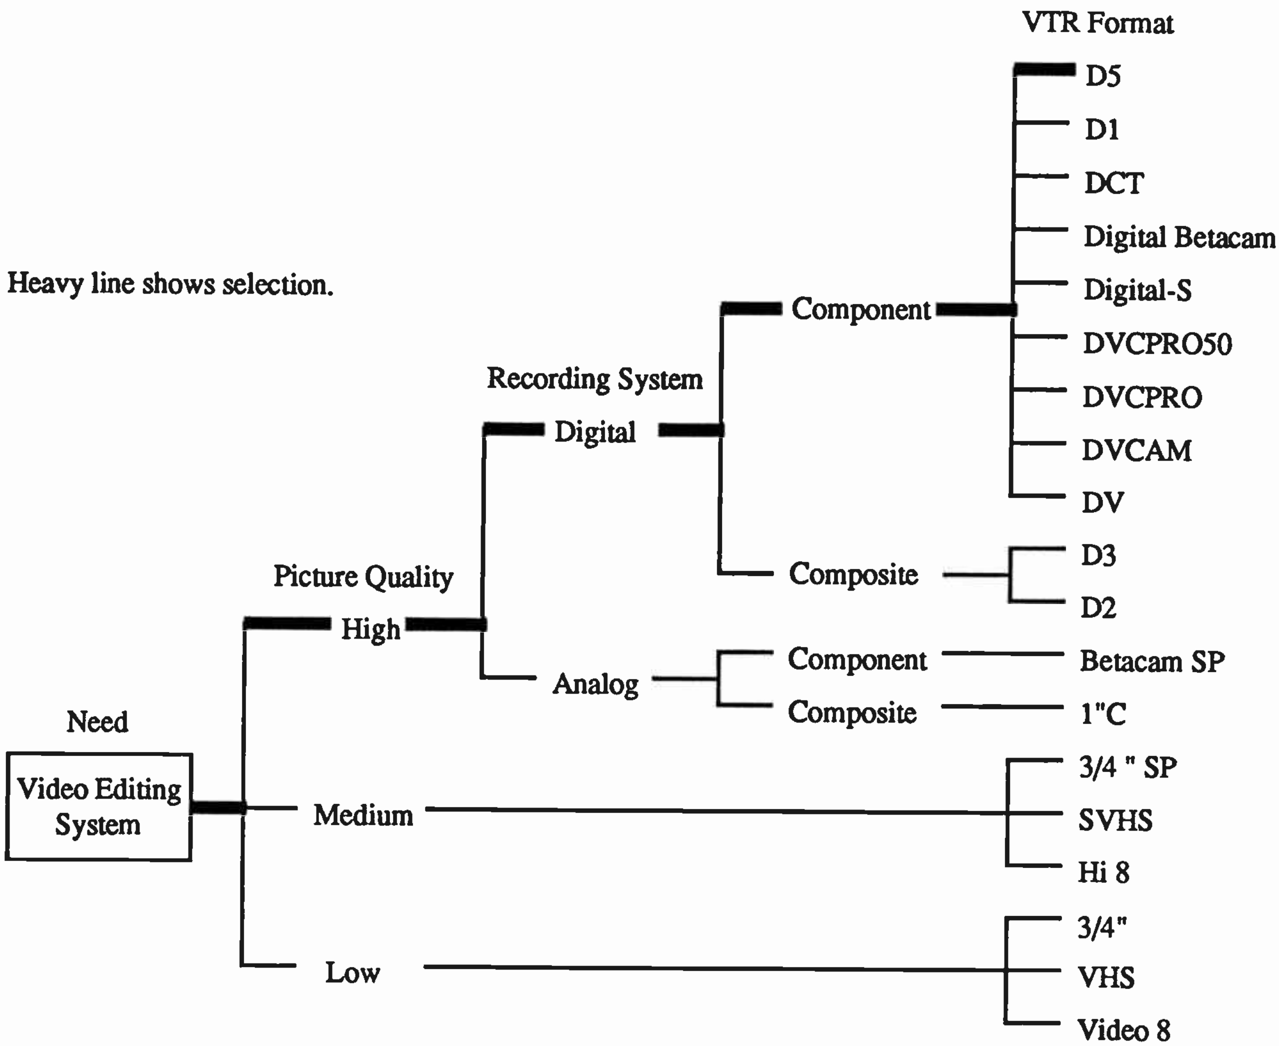

Figure 9.3-6. Trade tree example.

The criteria data on the candidates are then collected and tabulated on a decision analysis work sheet (see Figure 9.3-7). The attributes and limitations are listed in the first column, and the data for each candidate are given in adjacent columns to the right. The performance data are available from vendor spec sheets or may require laboratory testing and analysis to determine. Each attribute is given a relative score from 1 to 10 based on its comparative performance relative to the other candidates. Utility function graphs can be used to assign logical scores for each attribute (see Figure 9.3-8). The utility curve represents the advantage rating for a particular value of an attribute. A graph is made of ratings on the y axis vs. attribute value on the x axis, and specific scores that correspond to particular performance values can then be applied. The shape of the curve may take into account requirements, limitations and any other factor that will influence its value regarding the particular criteria being evaluated. The limits to which the curves should be extended run from the minimum value below which no further benefit will accrue to the maximum value above which no further benefit will accrue.

The scores are filled in on the decision analysis work sheet and multiplied by the weights to calculate the weighted score. The total of the weighted scores for each candidate then determines their ranking. As a rule, at least a 10% difference in score is acceptable as meaningful.

Further analysis can be applied in terms of evaluating the sensitivity of a decision to changes in the value of attributes, weights, subjective estimates and cost. Scores should be checked to see if changes in weights or scores would reverse the choice. How sensitive is the decision to changes in the system requirements or technical capabilities?

A trade table can be prepared to summarize the selection results (see Figure 9.3-9). Pertinent criteria

ALTERNATIVES:		Candidate 1			Candidate 2			Candidate 3		
WANTED	WT		SC	WT SC		SC	WT SC		SC	WT SC
Video Bandwidth (MHz)	10	5.6	10	100	6.0	10	100	5.0	9	90
Signal-to-Noise Ratio (dB)	10	60	8	80	54	6	60	62	10	100
10 bit quantizing	10	yes	1	10	yes	1	10	yes	1	10
Max program length (Hrs)	10	2	2	20	3	3	30	1.5	1.5	15
Read before write capable	5	yes	1	5	yes	1	5	no	0	0
Audio pitch correction avail	5	yes	1	5	no	0	0	yes	1	5
Capable of 16:9 aspect ratio	10	no	0	0	yes	1	10	yes	1	10
Employs compression	-5	yes	1	-5	no	0	0	yes	1	-5
SDI input/output	10	yes	1	10	yes	1	10	yes	1	10
Current installed base	8	medium	2	16	low	1	8	low	1	8
TOTAL WEIGHTED SCORE:				241			234			243

Figure 9.3-7. Decision analysis worksheet example. (Adapted from *System Engineering Management Guide*, Contract No. MDA 903-82-C-0339, Defense Systems Management Collage, Virginia, 1983.)

are listed for each alternative solution, which may be described quantitatively (high, medium or low).

Finally, the results of the trade study are documented in a report that discusses the reasons for the selections and which may also include the trade tree and the trade table.

Having a formal system of change control throughout the systems engineering process will keep all parties informed and prevent changes from being made without proper review and approval. Change control ensures that all documentation is kept up to date, and it can even help eliminate redundant documents. Finally, change control helps control project costs.

Description of System Elements

There are five categories of interacting system elements: equipment (hardware), software, facilities, personnel and procedural data. Performance, design and test requirements must be specified and documented for equipment, components and computer software elements of the system. Environmental and interface design requirements necessary for proper functioning of system elements within a facility must also be specified.

The documentation produced by the systems engineering process controls the evolutionary development of the system. Figure 9.3-10 illustrates the special purpose documentation used by one organization for each step of its systems engineering process.

The requirements are formalized in written specifications. By establishing clear standards for producing specifications, organizations can help reduce the variability of technical content and improve product quality. While the product should not be over-specified to the point of making the design too costly, requirements should also not be so vague or general that the product fails to meet customer needs. In large departmentalized organizations, a commitment to schedules can help ensure that other members of the organization can coordinate their time.

The systems engineering process does not actually design the system but rather produces the documentation necessary to define, design, build and test it. The technical integrity provided by this documentation ensures that the design requirements for the system elements reflect the functional performance requirements, that all functional performance requirements are satisfied by the combined system elements and that such requirements are optimized with respect to system performance requirements and constraints.

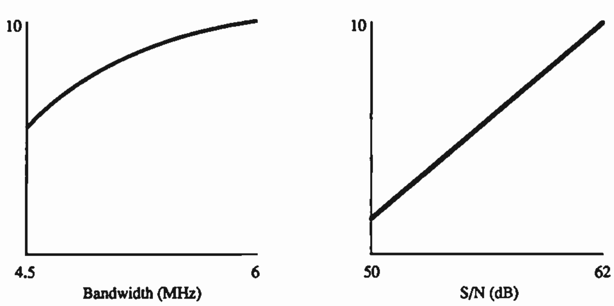

Figure 9.3-8. Attribute utility trade curve examples.

CRITERIA	Cool room only. Only normal convection cooling within enclosures	Forced cold air ventilation through rack then directly into return	Forced cold air ventilation through rack, exhausted into the room, then returned thru the normal plenum
Cost	Lowest. Conventional central air conditioning system used.	High. Dedicated ducting required. Separate system required to cool room	Moderate. Dedicated ducting required for input air.
Performance Equipment Temperature Room Temperature	Poor 80 to 120°F+ 65 to 70°F typical as set	Very Good 55 to 70°F typical 65 to 70°F typical as set	Very Good 55 to 70°F typical 65 to 70°F typical as set
Control Control of equipment temperature	Poor. Hot spots will occur within enclosures.	Very Good.	Very Good When the thermostat is set to provide a comfortable room temperature, the enclosure will be cool inside.
Control of room temperature	Good. Hot spots may still exist near power hungry equipment.	Good.	Good. If the enclosure exhaust air is comfortable for operators, the internal equipment must be cool.
Operator comfort	Good	Good. Separate room ventilation system required can be set for comfort.	Good. When the thermostat is set to provide a comfortable room temperature, the enclosure will be cool inside.

Figure 9.3-9. Trade table example.

Phases of a Typical System Design Project[1]

In the following section, the design of a complex modern video facility is used to illustrate the systems engineering approach.

Design Development

System design is carried out in a series of steps that leads to an operational facility. The bulk of the creative work, including research and preliminary design, are completed in the first phase of the project—the design development phase. During this phase, all project requirements are fully delineated and any constraints identified. Based on initial concepts and information, the design requirements are modified until all concerned parties are satisfied and approval is given for the final design work to proceed. The first objective of this phase is to answer the following questions:

- What are the functional requirements of the product of this work?
- What are the physical requirements of the product of this work?
- What are the performance requirements of the product of this work?
- Are there any constraints limiting design decisions?
- Will existing equipment be used?
- Is the existing equipment acceptable?
- Will this be a new facility or a renovation?
- Will this be a retrofit or upgrade to an existing system?
- Will this be a stand alone system?

In the design development phase, the equipment and functional requirements of each of the major technical areas of the facility are identified. In the case of facility renovation, the systems engineer's first order of business is to analyze existing equipment. A visit is made to the site to gather detailed information about the existing facility. Usually confronted with a mixture of acceptable and unacceptable equipment, the systems engineer must sort out which equipment meets current standards and which items should be replaced. Then, after soliciting input from the facility's technical and operational personnel, the systems engineer develops a list of needed equipment.

One of the systems engineer's most important contributions is the ability to identify and meet the needs of the "customer" and do it within the project budget. Based on the customer's initial concepts and any sub-

[1] Portions of this section were adapted from J.C. Whitaker, G. DeSantis and C. Paulson, *Interconnecting Electronic Systems*, CRC Press, Boca Raton, Fla., Chapter 1, 1992.

	Functional Flow Block Diagrams (FFBD)	Requirements Allocation Sheets (RAS)	Concept Description Sheets (CDS)	Trade Study Report (TSR)	Design Sheet (DS)
Basic Documents	Identify and sequence functions that must be accomplished to achieve system or project objectives. Develop the basics for establishing intersystem functional interfaces and identify system relationships.	Define the requirements and constraints for each of the functions and relate each requirement to the system elements of: a. Equipment b. Facilities C. Personnel d. Procedural data e. Computer software Time Line Sheets (TLS) Present critical functions against a time base in the required sequence of accomplishment.	Constrain the design to stop at a point in the cycle and create, at the gross level, a design or synthesis meeting the FFBD, RAS, TLS, requirements and constraints. Schematic Block Diagrams (SBD) Develop and portray schematic arrangement of system elements to satisfy system requirements.	Select, evaluate and optimize promising or attractive concepts. Document the tradeoff and supporting rationale. Consider all possible solutions within the framework of requirements.	Define, describe and specify performance, design and test criteria for the system elements a. Equipment b. Facilities c. Personnel d. Procedural data e. Computer software
Special Documents	End Item Maintenance Sheet (EIMS), Test Requmt Sheet (TRS), Production Sheets (PS), Logistic Support Analysis Record (LSAR) Identify maintenance, test, and production functions on a specific end item, subassembly, and component basis.				

Figure 9.3-10. Basic and special purpose documentation for systems engineering. (Adapted from Hoban, F. T., and Lawbaugh, W. M., *Readings in Systems Engineering*, NASA, Washington, DC, pg. 10, 1993.)

sequent equipment utilization research conducted by the systems engineer, the desired capabilities are identified as precisely as possible. Design parameters and objectives are also defined and reviewed. Functional efficiency is maximized to allow operation by a minimum number of personnel. Future needs are also investigated at this time, and future technical systems expansion is considered.

After the customer approves the equipment list, preliminary system plans are drawn up for review and further development. If architectural drawings of the facility are available, they can be used as a starting point for laying out an equipment floor plan. The systems engineer uses this floor plan to be certain adequate space is provided for present and future equipment as well as adequate clearance for maintenance and convenient operation. Equipment identification is then added to the architect's drawings.

Documentation should include, but not be limited to:

- Equipment list with prices
- Technical system functional block diagrams
- Custom item descriptions
- Rack and console elevations
- Equipment floor plans

The preliminary drawings and other supporting documents are prepared to record design decisions and to illustrate the design concepts for the customer. Renderings, scale models or full-size mock ups may also be needed to better illustrate, clarify or test design ideas.

Since ideas and concepts have to be exchanged and understood by all concerned parties, good communication skills are essential for team members. By completion of this phase of the project, the physical layout—the look and feel—and the functionality of the facility all will have been decided and agreed upon. If the design concepts appear feasible and the cost is within the anticipated budget, management can authorize work to proceed on the final detailed design.

ELECTRONIC SYSTEMS DESIGN

In a technical facility project, performance standards and specifications for such things as signal quality, stability, reliability and accuracy have to be established up-front. These will determine an acceptable performance level for equipment used in the system and affect the size of the budget. Access and processor speeds are important parameters when dealing with computer driven products. The systems engineer has to confirm whether or not selected equipment conforms to the standards.

At this point it must be determined what functions each system component will be required to fulfill, and how each will function with other components in the system. The management and operations staff usually know what they would like the system to do and how best to accomplish it. In fact, they have probably selected the equipment to do the job. With a familiarity of the capabilities of different equipment, the systems engineer should be able to contribute to this function-definition stage of the process. Questions that need to be answered include:

- What functions must be available to the operators?
- What functions are secondary and therefore not necessary?
- What level of automation should be required to perform a function?
- How accessible should the controls be?

Over-engineering or over-design by engineers and company staff should be avoided when planning technical system requirements. A staff member may, for example, ask for a seemingly simple feature or capability without fully understanding its complexity or the additional cost burden it may impose on a project. Other portions of the system may have to be compromised in order to implement the additional feature. An experienced systems engineer will be able to spot this and determine if the tradeoffs and added engineering time and cost are really justified.

When existing equipment is going to be used, an inventory list should be made as the starting point for developing a final equipment list. Confronted with a mixture of acceptable and unacceptable equipment, the systems engineer usually must sort out what meets current standards and what should be replaced. Then, after soliciting input from facility technical personnel, the systems engineer develops a summary of equipment needs, including future acquisitions. One of the systems engineer's most important contributions is the ability to identify and meet these needs within the facility budget.

A list of major equipment is prepared as part of the systems engineering process. The systems engineer selects the equipment based on experience with the products and on customer preferences and, when feasible, includes existing equipment that can be reused. A number of considerations are discussed with the facility customer to arrive at the best product selection. Some of the major ones include:

- Budget restrictions
- Space limitations
- Performance requirements
- Ease of operation
- Flexibility of use
- Functions and features
- Past performance history
- Manufacturer support

The goal here is to specify equipment that meets the functional requirements of the project efficiently and economically. Simplified block diagrams for the video, audio, control, data and communication systems are drawn, discussed with the customer and presented for approval.

Detailed Design

When the research and preliminary design development are completed, the details of the design are concluded. The design engineer prepares complete detailed documentation and specifications necessary for the fabrication and installation of the technical systems, including all major and minor components. Drawings must show the final configuration and relationship of each component to other elements of the system, as well as how they will interface with other building services, such as air conditioning and electrical power. This documentation must communicate the design requirements to the other design professionals, including the construction and installation contractors.

In this phase, the systems engineer develops final, detailed flow diagrams and schematics that show the interconnection of all equipment. Cable interconnection information for each type of signal is taken from the flow diagrams and recorded on the cable schedule. Cable paths are measured and timing calculations made for signals requiring synchronization (i.e., video, synchronizing pulses, subcarrier and digital audio). These timed cable lengths are entered onto the cable schedule.

The flow diagram is a schematic drawing used to show the interconnections between all equipment that will be installed. It contains much more detail than a block diagram; every wire and cable must be included on the drawings. A typical flow diagram for a video production facility is shown in Figure 9.3-11.

The starting point for preparing a flow diagram varies depending on the information available from the design development phase of the project and on the similarity of the project to previous projects. If a similar system has been designed in the past, the diagrams from that project can be modified to include the equipment and functionality required for the new system. New models of the equipment can be shown in place of their counterparts on the diagram, and only minor wiring changes need to be made to reflect the new equipment connections and changes in functional requirements. This method is efficient and easy to complete.

If the facility requirements do not fit any previously completed design, the block diagram and equipment list are used as a starting point. Essentially, the block diagram is expanded and details added to show all of the equipment and their interconnections as well as to show any details necessary to describe the installation and wiring completely.

An additional design feature that might be desirable for specific applications is the ability to easily disconnect a rack assembly from the system and relocate it. This would be the case if the system were to be prebuilt at a systems integration facility and later moved to

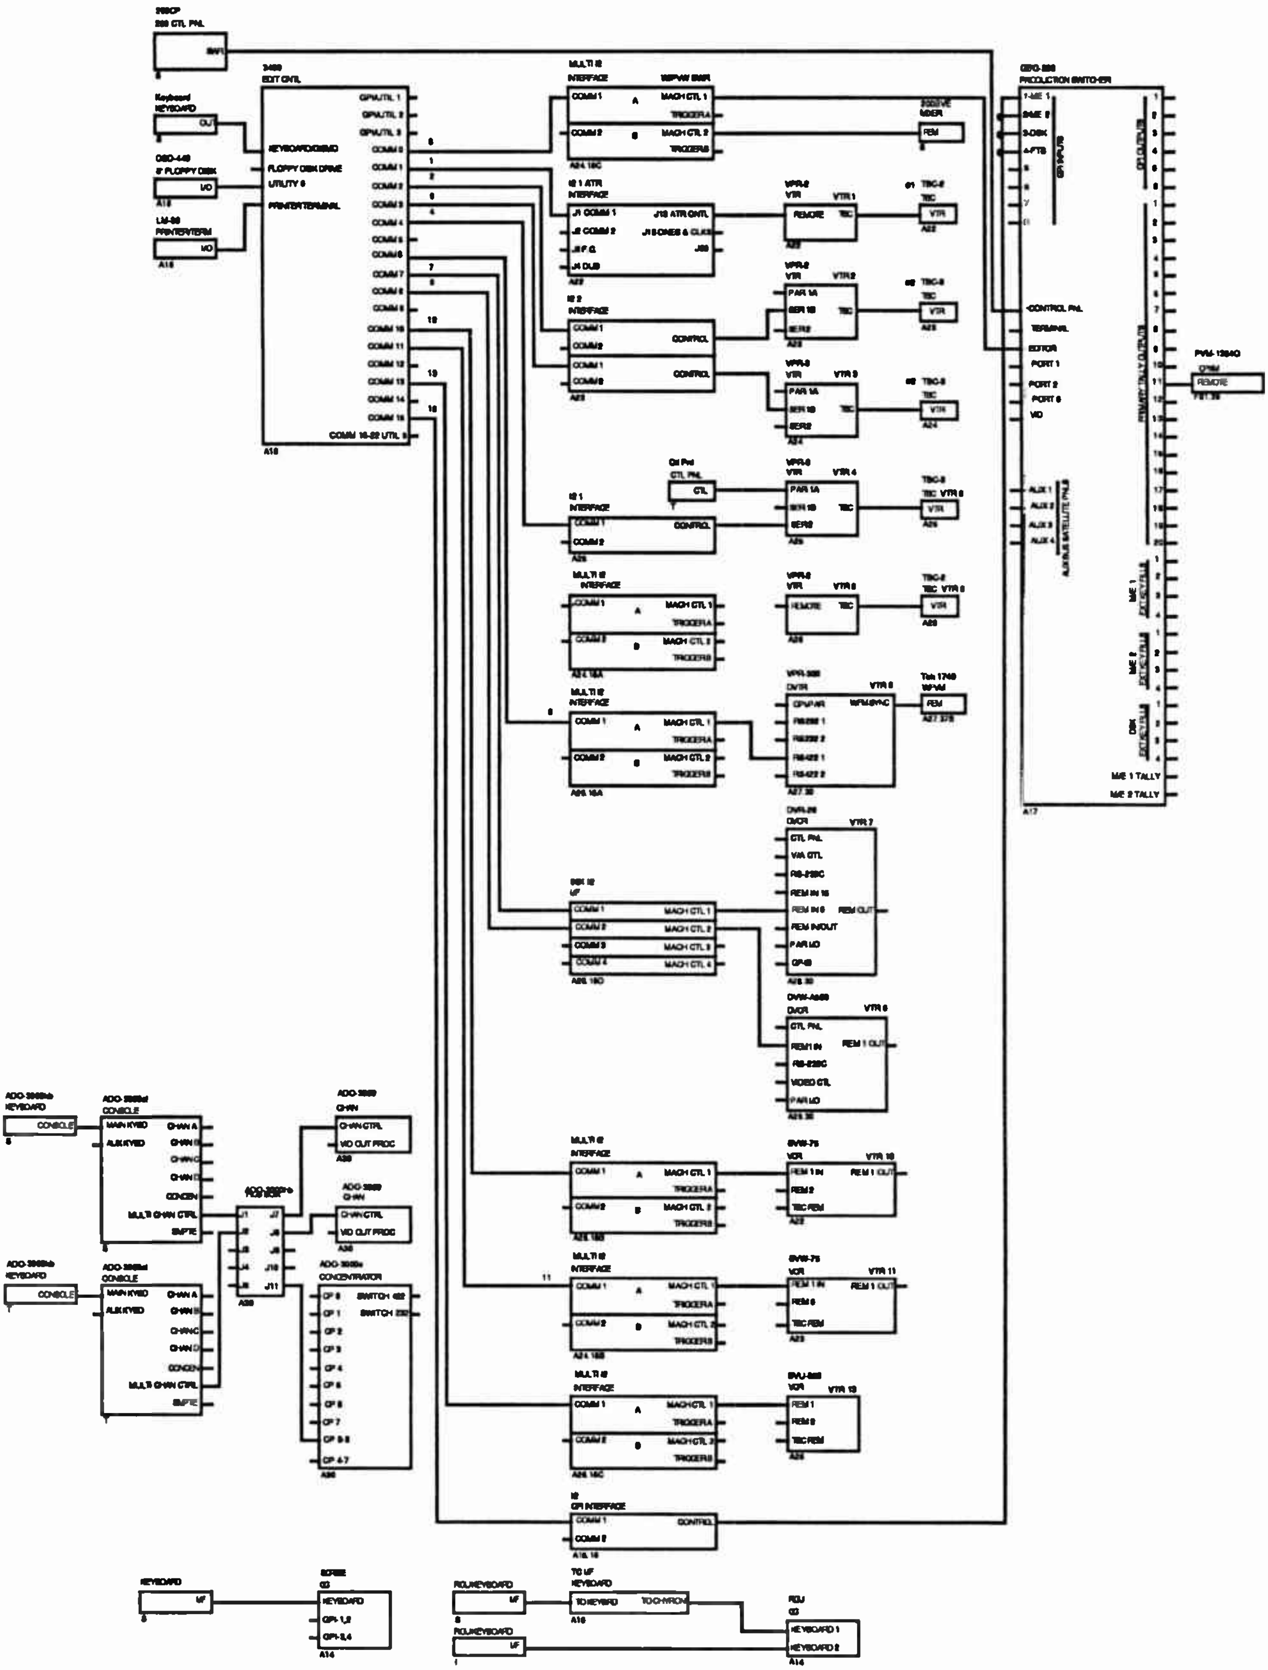

Figure 9.3-11. Video system control flow diagram.

and installed at the client's site. When this is a requirement, the interconnecting cable harnessing scheme must be well planned in advance and identified on the drawings and cable schedules.

Special custom items need to be defined and designed. Detailed schematics and assembly diagrams are drawn, parts lists and specifications are finalized and all necessary details worked out for these items. Mechanical fabrication drawings are prepared for consoles and other custom built cabinetry.

The design engineer provides the architect with layouts of cable runs and connections. Such detailed documentation simplifies equipment installation and facilitates future changes in the system. During preparation of final construction documents, the architect and the design engineer can firm-up the layout of the technical equipment wire ways, including access to flooring, conduits, trenches and overhead wire ways.

Dimensioned floor plans and elevation drawings are required to show placement of equipment, lighting, electrical cable ways, duct, conduit and HVAC ducting. Requirements for special construction, electrical, lighting, HVAC, finishes and acoustical treatments must be prepared and submitted to the architect for inclusion in the architectural drawings and specifications. This type of information, along with cooling and electrical power requirements, also must be provided to the mechanical and electrical engineering consultants (if used on the project) so they can begin their design calculations.

Equipment heat loads are calculated and submitted to the HVAC consultant. When locating equipment, care is taken to avoid excessive heat buildup within the equipment enclosures while still maintaining a comfortable environment for the operators.

Electrical power loads are calculated and submitted to the electrical consultant, and steps are taken to provide for sufficient power and proper phase balance.

Customer Support

The systems engineer can assist in purchasing equipment and help coordinate the move to a new or renovated facility. This can be critical if a great deal of existing equipment is being relocated. In the case of new equipment, the customer will find the systems engineer's knowledge of prices, features and delivery times to be invaluable. A good systems engineer will see to it that equipment arrives in ample time to allow for sufficient testing and installation. A good working relationship with equipment manufacturers helps guarantee their support and speedy response to the customer's needs.

The systems engineer can also provide engineering management support during planning, construction, installation and testing to help qualify and select contractors, resolve problems, explain design requirements and assure quality workmanship by contractors and technical staff.

The procedures described in this chapter outline an ideal scenario. In reality, management may often try to bypass many of the foregoing steps to save money, thinking this will eliminate unnecessary engineering costs and allow construction to start right away. Although a small company may attempt to handle the job by using in-house personal rather than outside professionals, this puts an added burden on staff who are already working full time taking care of the daily operation of the facility. With inadequate design detail and planning, which may result by using unqualified people, the job of setting technical standards and making the system work then defaults to the construction contractors, in-house technical staff or the installation contractor. This can result in costly and uncoordinated work-arounds and, of course, delays and added costs during construction, installation and testing. It makes the project less manageable and less likely to be completed successfully.

When large amounts of money and other resources are involved, management is well advised to recruit the services of qualified system engineers.

Budget Requirements Analysis

The need for a project may originate with customers, management, operations staff, technicians or engineers. In any case, some sort of logical reasoning or a specific production requirement will justify the cost. On small projects, like the addition of a single piece of equipment, it is easy to determine how much it will cost to purchase and install the equipment. On large projects, it is not always immediately apparent how much the project will cost. The project has to be analyzed by dividing it up into its constituent elements:

- Equipment
- Materials
- Resources (including money and staff needed to complete the project)

An executive summary or capital project budget request should contain a detailed breakdown of these elements to give management the information it needs to determine the return on investment and to make an informed decision on whether or not to authorize the project. A capital project budget request containing the minimum information might consist of the following items:

- Project name. (Use a name that describes the result of the project, such as "control room upgrade")
- Project number (if required). (A large organization that does many projects will use a project numbering system of some kind, or it may use a budget code assigned by the accounting department)
- Project description. (A brief description of what the project will accomplish, such as "design the technical system upgrade for the renovation of production control room 2")
- Initiation date. (The date the request will be submitted)
- Completion date. (The date the project will be completed)
- Justification. (The reason the project is needed)

- Material cost breakdown. (A list of equipment, parts and materials required for construction, fabrication and installation of the equipment)
- Total material cost
- Labor cost breakdown. (A list of personnel required to complete the project, their hourly pay rates, the number of hours they will spend on the project and the total cost for each)
- Total project cost. (The sum of material and labor costs)
- Payment schedule. (Estimation of individual amounts that will have to be paid out during the course of the project and the approximate dates each will be payable)
- Preparer's name and the date prepared
- Approval signature(s) and date(s) approved

More detailed analysis, such as return on investment, can be carried out by an engineer, but financial analysis should be left to accountants or other personnel with access to company financial data.

Feasibility Study and Technology Assessment

A feasibility study is necessary to evaluate new technology under consideration, including its ability to perform a desired function. The systems engineer may be called upon to assess the state-of-the-art in order to develop a new application. An executive summary or a more detailed report of evaluation test results may be required, in addition to a budget estimate, to help management make its decision.

Planning and Control of Scheduling and Resources

Several planning tools have been developed for planning and tracking project progress as well as scheduling and controlling resources. The most common ones are the Gantt Chart and the Critical Path Method (CPM) utilizing the Project Evaluation and Review (PERT) technique. Computerized versions of these tools have greatly enhanced management's ability to control large projects.

Project Tracking and Control

A standardized project status report form can provide consistent and complete information to the project manager regarding work completed, and money spent on resources and materials. A project status report containing the minimum information might contain the following items:

- Project number (if required)
- Date prepared
- Project name
- Project description
- Start date
- Completion date (the date this part of the project was completed)
- Total material cost
- Labor cost breakdown
- Preparer's name

Change Control

After part or all of a project design has been approved and money allocated to build it, any changes may increase or decrease the cost. Factors that affect the cost include:

- Components and materials
- Resources, such as labor and special tools or construction equipment
- Costs incurred because of manufacturing or construction delays

A *change order request* or *change order* is a method of reporting changes to management and soliciting its approval to proceed with the change. A change order includes a brief description of the change, the reason for the change, a summary of the effect it will have on costs and what effect it will have on the project schedule.

Management will exercise its authority and approve or disapprove each change based upon its understanding of the cost and benefits, and its own perceived need for modification of the original plan. Therefore, it is important that the systems engineer provide as much information and explanation as necessary to management.

A change order form containing the minimum information might include the following items:

- Project number
- Date prepared
- Project name
- Preparer's name
- Description of the change
- Reason for the change
- Equipment and materials to be added or deleted
- Material costs or savings
- Labor cost breakdown
- Labor costs or savings
- Total cost of this change (increase or decrease)
- Impact on the schedule.

Program Management

The Defense Systems Management College in Fort Belvoir, Virginia, defines systems engineering as:

Systems engineering is the management function which controls the total system development effort for the purpose of achieving an optimum balance of all system elements. It is a process which transforms an operational need into a description of system parameters and integrates those parameters to optimize the overall system effectiveness.

Systems engineering is both a technical process and a management process. Both processes must be applied throughout a program for it to be successful. The persons who plan and carry out a project constitute the project team; its makeup will vary depending on the size of the company and the complexity of the project. It is management's responsibility to provide the necessary human resources to complete the project.

Executive Management

The executive manager is the person who can authorize a project and who bears ultimate responsibility for its success. This person can allocate funds and delegate authority to others to accomplish the task. This person's job is to get things done through other people by assigning group responsibilities, coordinating activities between groups and resolving group conflicts. The executive manager establishes policy, provides broad guidelines, approves the project master plan, resolves conflicts and assures project compliance with commitments.

Executive management delegates the project management functions and assigns authority to qualified professionals, allocates a capital budget for the project, supports the project team and establishes and maintains a healthy relationship with project team members.

Management is responsible for providing clear information and goals—up front—based upon its needs and initial research. Before initiating a project, the company executive should be familiar with daily operation of the facility, analyze how the company works, how the staff do their jobs and what tools they need to accomplish the work. Some points that may need to be considered by an executive before initiating a project include:

- What is the current capital budget for equipment?
- Why does the staff currently use specific equipment?
- What function of the equipment is the weakest within the organization?
- What functions are needed but cannot be accomplished with current equipment?
- Are the staff satisfied with current hardware?
- Are there any reliability problems or functional weaknesses?
- What is the maintenance budget and is it expected to remain steady?
- How soon must the changes be implemented?
- What is expected from the project team?

Unless the manager has made a systematic effort to evaluate all the obvious points about the facility requirements, the not-so-obvious points may be overlooked. Overall requirements must be broken down into their component parts. The planning should be as basic as possible, and ideas that have too many branches should be simplified. Only after answering the appropriate questions will the executive manager be ready to bring in expert project management and engineering assistance. If the company executive does not make a concerted effort to investigate the needs and problems of a facility thoroughly before consulting experts, the expert advice will be shallow and incomplete, no matter how good the engineer.

Engineers work with the information they are given. They put together plans, recommendations, budgets, schedules, purchases, hardware and installation specifications based upon the information they receive from interviewing management and staff. If the management and staff have failed to go through the planning, reflection and refinement cycle before those interviews, the company will likely waste time and money.

PROJECT MANAGER

Project management can be applied to any undertaking that has a specific end objective. It is an outgrowth of the need to accomplish large complex projects in the shortest possible time, within the anticipated budget and with the required performance and reliability. Project management is based upon the realization that modern organizations may be so complex as to preclude effective management using traditional organizational structures and relationships.

The project manager must be a competent systems engineer, accountant and manager. As a systems engineer, project managers must understand analysis, simulation, modeling, reliability and testing techniques. The project manager must be aware of state-of-the-art technologies and their limitations. As an accountant, the project manager must be aware of the financial implications of their decisions and know how to control them. As a manager, planning and control of schedules is an important part of controlling the costs of a project and completing it on time. Also, as a manager, a project manager must possess the skills necessary to communicate clearly and convincingly with subordinates and superiors to make them aware of problems and their solutions.

The project manager has the authority to carry out a project and has been given the legitimate right to direct the efforts of the project team members. The project manager's power comes from the acceptance and respect accorded by superiors and subordinates. The project manager has the power to act and is committed to group goals.

The project manager is responsible for getting the project completed properly, on schedule and within budget, by utilizing whatever resources are necessary to accomplish the goal most efficiently. The manager provides project schedule, financial and technical requirement direction and evaluates and reports on project performance. This requires planning, organizing, staffing, directing and controlling all aspects of the project.

In this leadership role, the project manager is required to perform many tasks including:

- Assembling the project organization
- Developing the project plan
- Publishing the project plan
- Setting measurable and attainable project objectives and performance standards
- Setting attainable performance standards
- Determining the appropriate scheduling tools (PERT, CPM, and/or GANTT) for the project
- Using the scheduling tools to develop and coordinate the project plan, which includes budget, resources, and project schedule
- Developing the project schedule and project budget
- Managing the budget

- Recruiting personnel for the project
- Selecting subcontractors
- Assigning work, responsibility and authority so team members can make maximum use of their abilities
- Estimating, allocating, coordinating and controlling project resources
- Dealing with unrealistic specifications and resource needs
- Deciding on the right level of administrative and computer support
- Training project members on how to fulfill their duties and responsibilities
- Supervising project members, giving them day-to-day instructions, guidance and discipline as required to fulfill their duties and responsibilities
- Designing and implementing reporting and briefing information systems or documents that respond to project needs
- Controlling the project

Basic project management practices that can improve the chances for success include:

- Securing the necessary commitments from top management to make the project a success
- Setting up an action plan that will be easily adopted by management
- Using a work breakdown structure that is comprehensive and easy to use
- Establishing accounting practices that help, not hinder, successful project completion
- Preparing project team job descriptions properly upfront to eliminate conflict later on
- Selecting project team members appropriately the first time.

After the project is under way, the project manager should follow these steps:

- Manage the project, but make the oversight reasonable and predictable
- Get team members to accept and participate in the plans
- Motivate project team members for best performance
- Coordinate activities so they are carried out in relation to their importance with a minimum of conflict
- Monitor and minimize interdepartmental conflicts
- Get the most out of project meetings without wasting the team's productive time. Develop an agenda for each meeting and start on time. Conduct one piece of business at a time. Assign responsibilities where appropriate. Agree on follow-up and accountability dates. Indicate the next step for the group. Set the time and place for the next meeting. End on time.
- Spot problems and take corrective action before it is too late
- Discover the strengths and weaknesses in project team members and manage them to get desired results
- Help team members solve their own problems
- Exchange information with subordinates, associates, superiors and others about plans, progress and problems
- Make the best of available resources
- Measure project performance
- Determine, through formal and informal reports, the degree to which progress is being made
- Determine causes of and possible ways to act upon significant deviations from planned performance
- Take action to correct an unfavorable trend or to take advantage of an unusually favorable trend
- Look for areas where improvements can be made
- Develop more effective and economical methods of managing
- Remain flexible
- Avoid *activity traps*
- Practice effective time management

The project manager should make sure their subordinates:

- Comprehend what they are supposed to do, preferably in terms of an end product
- Have a clear understanding of what their authority is and its limits
- Understand their relationships with others
- Recognize what constitutes a job well done in terms of specific results
- Appreciate when and what they are doing exceptionally well
- Are shown concrete evidence that there are just rewards for work well done and for work exceptionally well done.
- Comprehend where and when they are falling short of expectations
- Are made aware of what can and should be done to correct unsatisfactory results
- Feel that their superior has an interest in them as individuals, believes in them and is anxious for them to succeed and progress.

By fostering good relationships with associates, the project manager will have less difficulty communicating with them. The fastest, most effective communication takes place among people with common points of view.

By watching what is going on. the competent project manager can perceive problems long before they flow through the paper system. A project manager who spends most of their time in the management office instead of roaming through the places where the work is being done is headed for disaster.

Systems Engineer

Systems engineer means different things to different people. The systems engineer is distinguished from the engineering specialist, who is concerned with only one aspect of a well defined engineering discipline. By contrast, the systems engineer must be able to adapt to the requirements of almost any type of system. The systems engineer provides a wealth of experience gained from successful approaches to technical problems and developed through hands-on exposure to a variety of situations. A professional with knowledge, experience and skills in a specialized and learned field or fields, the systems engineer is highly trained in analyzing problems and developing solutions that satisfy management objectives. They take data from the overall development process and, in return, provide data in the form of requirements and analysis results to the process.

Education in electronics theory is a prerequisite for designing systems that employ electronic components. As a graduate engineer, the systems engineer has the education required to design electronic systems correctly. Mathematics skill acquired in engineering school is one of the tools used by the systems engineer to formulate solutions to design problems and analyze test results. Knowledge of testing techniques and theory enables the specification of system components and performance and measurement of results. Drafting and writing skills are required for efficient preparation of the necessary documentation needed to communicate the design to technicians and contractors who will have to build and install the system.

A competent systems engineer has a wealth of technical information available for speeding up the design process and helping make cost effective decisions. If necessary information is not at hand, the systems engineer knows where to find it. The experienced systems engineer is familiar with proper fabrication, construction, installation and wiring techniques and can spot and correct improper work.

Training in personnel relations, a part of the engineering curriculum, helps the systems engineer communicate and negotiate professionally with subordinates and management.

Small in-house projects can be completed on an informal basis and, indeed, this is probably the normal routine when projects are simple and uncomplicated. On large projects, however, the systems engineer's involvement usually begins with preliminary planning and continues through fabrication, implementation and testing. The degree to which program objectives are achieved is an important measure of the systems engineer's contribution.

During the design process, the systems engineer:

- Concentrates on results and focuses work according to management objectives
- Receives input from management and staff
- Researches the project and develops a workable design
- Assures balanced influence of all required design specialties
- Conducts design reviews
- Performs trade-off analyses
- Assists in verifying system performance
- Resolves technical problems related to the design, interface between system components and integration of the system into any facility

Aside from designing a system, the systems engineer has to answer questions and resolve problems that may arise during hardware fabrication and installation and must also monitor the quality and workmanship of the installation. The systems engineer also has to be concerned with the testing and calibration of hardware and software upon completion.

During the production or fabrication phase, the systems engineer is concerned with:

- Verifying system capability and system performance
- Maintaining the system baseline
- Forming an analytical framework for producibility analysis

Depending on the complexity of the new installation, the systems engineer may have to provide orientation and operating instruction to the users. During the operational support phase, systems engineers:

- Receive input from users
- Evaluate proposed changes to the system
- Establish their effectiveness
- Facilitate the effective incorporation of changes, modifications and updates.

Depending on the size of the project and the management organization, the systems engineer's duties will vary. In some cases the systems engineer may have to assume the responsibilities of planning and managing smaller projects.

Other Project Team Members

Other key members of the project team where building construction may be involved include the following:

- Architect—responsible for design of the structure
- Electrical engineer—responsible for power system design if not handled by the systems engineer
- Mechanical engineer—responsible for HVAC and plumbing designs
- Structural engineer—responsible for concrete and steel structures
- Construction contractors—responsible for executing the plans developed by the architect and mechanical and structural engineers

Other outside contractors may be employed for certain specialized custom items that can not be developed or fabricated internally or by any of the other contractors.

CONCLUSION

Systems theory is the theoretical basis of systems engineering, which is an organized approach to the design of complex systems. The key components of systems theory applied in systems engineering are a holistic approach, the decomposition of problems, the exploitation of analogies and the use of models.

A formalized technical project management technique used to define systems includes three major steps:

- Defining the requirements in terms of functions to be performed as well as the measurable and testable requirements that describe how well each function must be performed

- Synthesizing a way to fulfil the requirements
- Studying the tradeoffs and selecting one solution from the alternative solutions.

In the final analysis, beyond any systematic approach to systems engineering, engineers have to engineer. Former NASA Administrator Robert A. Frosch, in a speech to a group of engineers in New York, urged a common sense approach to systems engineering:

Systems, even very large systems, are not developed by the tools of systems engineering, but only by the engineers using the tools. . . . I can best describe the spirit of what I have in mind by thinking of a music student who writes a concerto by consulting a check list of the characteristics of the concerto form, being careful to see that all of the canons of the form are observed, but having no flair for the subject, as opposed to someone who just knows roughly what a concerto is like, but has a real feeling for music. The results become obvious upon hearing them. The prescription of technique cannot be a substitute for talent and capability . . .

9.4
HUMAN EXPOSURE TO RADIO FREQUENCY FIELDS

KELLY T. WILLIAMS
NATIONAL ASSOCIATION OF BROADCASTERS, WASHINGTON, DC

Since the last edition of this handbook was published the Federal Communications Commission has made comprehensive changes to its guidelines for human exposure to radio frequency fields. These changes were adopted in the *Report and Order* in ET Docket 93-62, released August 1, 1996. Guidance on complying with these new regulations is provided by the FCC in *OET Bulletin 65, Evaluating Compliance with FCC Guidelines for Human Exposure to Radiofrequency Electromagnetic Fields*, and in *Supplement A* to this bulletin, *Additional Information for Radio and Television Broadcast Stations*.

The most significant change incorporated into the new rules is the institution of a two-tiered table of human exposure limits. The first tier applies to environments where the general population is exposed to radio frequency fields and the second tier applies to environments where only workers who are fully aware of, and able to control, their potential for exposure are exposed.

On October 15, 1997, all applications to the FCC for construction permits, license renewals and station modifications became subject to analysis under the new RF exposure standards. All facilities constructed after October 15, 1997, were required to comply with the new standards even if the construction permit authorizing their construction was granted and/or applied for before this deadline.

Existing stations that were in compliance with the old RF exposure standards on October 15, 1997, are not required to bring their facilities into compliance with the new standards until September 1, 2000, unless they file a license renewal or station modification application prior to that date. If they are not in compliance by September 1, 2000, they must file an Environmental Assessment with the FCC on that date in accordance with the requirements in Part 1, Subpart I of the FCC Rules.

Compliance with the FCC's RF exposure guidelines is the responsibility of FCC licensees. Even though tower owners are now primarily responsible for compliance with the FCC's tower painting and lighting requirements, FCC licensees remain responsible for ensuring that the emissions from their antennas do not result in excessive levels of human exposure to RF energy. If a tower owner will have maintenance workers climbing on a tower, tenant licensees must cooperate with the tower owner in controlling the workers' exposure to RF energy.

Because the FCC RF exposure guidelines are *human exposure* guidelines, they apply only to locations that are accessible to humans. If a particular antenna produces an RF field that is above the FCC limits, but it only produces this field in a location that is never occupied by humans, then the antenna does not pose an RF exposure hazard according to the FCC guidelines. Also, the FCC RF exposure guidelines are based on the average level of exposure over a fixed period of time (six minutes for the occupational/controlled exposure limits, 30 minutes for the general population/uncontrolled limits). It is therefore possible for a person to be exposed to a level of RF energy that exceeds the FCC average limit for a brief period of time, say one minute, yet not be exposed to a level of RF energy that exceeds the FCC guidelines because their average exposure over the 6- or 30-minute period falls below the FCC limit. This might be the case, for example, if a transmitter were located near a roadway and the vehicles passing through an area of excessive RF energy were only in the area for a second or two. Of course, in such a case, a person could be exposed to a level of RF energy that exceeds the FCC limit if their vehicle were to come to a stop within the area of excessive RF energy and remain there long enough for their average exposure to exceed the FCC guidelines. As illustrated in this example, it is often not possible to control exposure to the extent that averaging times can be applied, especially with regard to the general population. When it comes to general population exposure, it is usually necessary to assume continuous exposure. The exposure guidelines specified by the FCC are shown in Table 9.4-1.

According to FCC rules, if an area around an antenna produces RF fields that exceed the exposure guidelines in Table 9.4-1, the actions that must be taken by the licensee will depend on whether or not the area of high exposure will be occupied only by people who are fully aware of the potential for exposure and can exercise control over their exposure. If the area will be occupied by anyone who is not fully aware of the potential for exposure, or by anyone who cannot exercise control over their exposure, then the more restrictive general population/uncontrolled exposure limits apply.

If the area will only be occupied by workers who understand RF exposure hazards then the licensee must ensure that the appropriate steps are taken to prevent workers in the vicinity of the high exposure area from

Table 9.4-1
FCC RF Exposure Guidelines

(a) FCC RF Exposure Standard for Occupational/Controlled Exposure

Frequency Range (MHz)	Electric Field Strength (E) (V/m)	Magnetic Field Strength (H) (A/m)	Power Density (S) (mW/cm^2)	Averaging Time $\|E\|^2$, $\|H\|^2$ or S (minutes)
0.3–3.0	614	1.63	100	6
3.0–30	1842/(freq. in MHz)	4.89/(freq. in MHz)	900/(freq. in MHz)^2	6
30–300	61.4	0.163	1.0	6
300–1,500	—	—	(freq. in MHz)/300	6
1,500–100,000	—	—	5	6

Notes:

V/m = volts per meter
A/m = amperes per meter
mW/cm^2 = milliwatts per square centimeter

The occupational/controlled limits apply in situations where people are exposed to RF energy as a consequence of their employment, provided these people are fully aware of the potential for exposure and can exercise control over their exposure. These limits also apply in situations where any person is passing through the RF field and is made aware of the potential for exposure.

(b) FCC RF Exposure Standard for General Population/Uncontrolled Exposure

Frequency Range (MHz)	Electric Field Strength (E) (V/m)	Magnetic Field Strength (H) (A/m)	Power Density (S) (mW/cm^2)	Averaging Time $\|E\|^2$, $\|H\|^2$ or S (minutes)
0.3–1.34	614	1.63	100	30
1.34–30	824/(freq. in MHz)	2.19/(freq. in MHz)	180/(freq. in MHz)^2	30
30–300	27.5	0.073	0.2	30
300–1,500	—	—	(freq. in MHz)/1,500	30
1,500–100,000	—	—	1.0	30

Notes:

V/m = volts per meter
A/m = amperes per meter
mW/cm^2 = milliwatts per square centimeter

The general population/uncontrolled exposure limits apply in situations where the general public may be exposed. They also apply in situations where people are exposed as a consequence of their employment and may either not be fully aware of the potential for exposure or unable to exercise control over their exposure.

being exposed to RF levels in excess of the occupational/controlled exposure limits. Generally, this means identifying and marking the area where the levels of RF energy exceed the occupational/controlled limits, and taking the necessary steps to ensure that when workers must enter the area, they are not exposed to RF levels in excess of the occupational/controlled limits. This can be accomplished by reducing the transmitter's output power or turning the transmitter off. It can also be accomplished by limiting the amount of time that workers may spend in the hazardous area and/or requiring the exposed workers to wear RF protective clothing that provides effective RF shielding over the appropriate frequency range.

If an area around or near a tower contains RF fields that exceed the general population/uncontrolled exposure limits in Table 9.4-1, *and* the area is accessible to either a) workers who may not be fully aware of the potential for exposure or b) the general public, then measures must be taken to make the area inaccessible to these people. Generally, these measures will involve the use of fences and warning signs. Fences and/or warning signs are required, even if the area that contains the dangerous RF fields is located entirely on private property (licensees must also protect *trespassers* from exposure to dangerous RF fields).

RF HOT SPOT

An RF hot spot is a localized area where the RF field strength is substantially higher than the surrounding area. An RF hot spot is generally caused by one of three factors: 1) the intersection of multiple beams of RF energy; 2) standing waves produced by reflective surfaces, such as the ground; and 3) induced currents in conductive objects exposed to ambient RF fields. Broadcasters are responsible for reducing the radiation at RF hot spots to within the FCC RF exposure limits.

Hot spots that could expose the general public to levels of RF radiation higher than the FCC limits are usually the result of induced currents in conductive objects. Conductive objects that may cause RF hot spots include, but are not limited to, metal playground equipment, storage sheds, and heating/air conditioning ducts.

When confronted with a potential hot spot problem, a broadcaster should first determine if the level of RF exposure at the hot spot exceeds the FCC limits. It is generally advisable to hire a professional engineer to determine whether or not the suspected hot spot exceeds these limits.

If the measured exposure level *does not* exceed the FCC limits, the broadcaster is not obligated to take any corrective action. However, in the interest of good public relations, many broadcasters may want to alleviate the RF radiation problem anyway. If the measured exposure level *does* exceed the FCC limits, then the broadcaster must work with the property owner to develop a means for reducing the RF radiation. This could mean, for example, developing a grounding system for metal playground equipment, or adding nonconductive spacers to interior duct work.

Broadcasters are responsible for reducing the electromagnetic energy at RF hot spots to within the FCC limits *even if* the hot spot is the result of new building construction that was performed after the broadcaster commenced operations. In cases where the hot spot is the result of multiple RF signals from multiple broadcast (or other radio service) antennas, it is the shared responsibility of all transmitter licensees to correct the hot spot problem. However, in multiple transmitter situations, if any particular transmitter's contribution to the hot spot is less than 5% of the FCC limit, then the licensee of that transmitter is not required to participate in the correction of the hot spot problem.

Hot spots are often found in the immediate vicinity around radio towers because towers are in close proximity to the transmitting antennas. The metal tower structure is located in the strongest portion of the electromagnetic field produced by the tower's antenna(s), so the level of currents induced in the tower are generally at a maximum for the antenna(s) in question. These hot spots are of particular significance because radio towers often come in direct contact with human tissue when workers are climbing them, thus exposing the workers to the maximum level of energy that is produced by the hot spot. In these instances, broadcasters should take whatever steps are necessary to ensure worker safety.

Addressing RF hot spot problems is an important issue for broadcasters because Section 1.1307(b) of the FCC rules requires that, when filing applications for new stations, major modifications, and license renewals, broadcasters include information about the potential of their facilities to expose workers or the general public to levels of RF energy in excess of the FCC RF exposure guidelines—if such potential exists. A certification of RF exposure compliance can amount to a misrepresentation if, later in the license term, it is determined that a hot spot in the station's radiation pattern was resulting in excessive exposure to workers and/or the public, and the station was aware of this problem when it filed its application with the FCC.

FENCING AND SIGN POSTING REQUIREMENTS

The FCC requires fences around many AM towers to protect people near the towers from electrocution. Although the FCC does not specifically require fences around other towers, it does require licensees to restrict access to areas where there are excessive levels of electromagnetic energy. Constructing a fence is a very practical means of restricting access to these areas.

Certain types of AM towers—series fed, folded unipole, and insulated base—can shock or electrocute anyone who touches the tower while standing on the ground. These towers must be enclosed within a locked fence to prevent human contact. Appropriate warning signs must be posted on the outside of the fence facing all normal angles of approach. The fence must be designed to allow authorized personnel ready access to each tower base at all times for meter reading and maintenance purposes.[1]

As noted above, FM and TV towers, and AM towers that do not have series fed, folded unipole, or insulated base antennas, are not specifically required by FCC rules to be fenced. However, the FCC does require broadcast stations to indicate, on their applications, that the radio frequency radiation of the facility will not have a significant environmental impact (*i.e.*, it will not expose *anyone* to radio frequency fields that exceed the FCC RF exposure limits described in Table 9.4-1). If a station cannot make such a statement, it must submit an Environmental Assessment to the FCC, and may be required to modify its facility or risk denial of its application (whether the application is for new construction, a modification to an existing facility, a license renewal, etc).

In order for a station to be able to indicate that its application will not have a significant environmental impact, it must 1) control workers' access to areas with RF fields that exceed the occupational/controlled exposure limits described in Table 9.4-1; and 2) restrict public access to areas with RF fields that exceed the general population/uncontrolled exposure limits described in Table 9.4-1. To restrict worker access to areas that exceed the occupational/controlled exposure limits, the posting of signs is generally sufficient. To restrict general public access to areas that exceed the general population/uncontrolled exposure limits, a fence must usually be constructed around the area *and* appropriate warning signs must be posted. If the station's antenna is located in an extremely remote location not likely to be visited by the public then only warning signs are required to restrict access—though fences are still recommended.

The FCC expects licensees to restrict general public access to RF fields that exceed the general population/uncontrolled exposure limits. It includes trespassers among those whose access must be restricted, since trespassers may be inclined to climb a tower to an area close enough to an antenna where the exposure limits are exceeded, therefore, NAB generally recommends that all broadcast towers be fenced.

Height of Fence

The FCC recommends that an antenna fence be high enough to prevent people from jumping over it. It

[1] See Section 73.49 of the FCC rules.

recognizes that people who want to climb a fence will usually do so, regardless of its height, and the fencing requirement is not intended to keep these individuals out.

Distance from Tower to Fence (AM Towers)

The fence should be located far enough from the tower so that anyone standing outside of the fence will not be exposed to radio frequency fields in excess of the FCC limits for general population/uncontrolled exposure. Because the areas where exposure to RF energy in excess of the FCC limits will be in the near-field of an AM broadcast antenna, compliance with *both* the electric *and* magnetic field limits must be evaluated. (In contrast, for FM and TV broadcast facilities, compliance at the base of the tower can generally be based on measurements of *either* the electric or magnetic field because compliance with one of these in the far field of the antenna will generally mean compliance with the other.) The Environmental Protection Agency (EPA) developed a computer program that was used by the FCC to predict how far away a person must be from an AM tower to ensure compliance with the FCC's limits for electric and magnetic field human exposure. Using the EPA program, the FCC produced four tables (one each for four different tower heights) that can be used to determine the required distance between the tower and the fence.[2] The FCC tables are reproduced here as Table 9.4-2 (a)–(d). For transmitter power values and/or tower heights that are not listed in Table 9.4-2 linear interpolation may be used.

The tower heights listed in Table 9.4-2 are the electrical heights. The electrical height of most AM towers is generally a little higher than the physical height because the velocity of propagation in a metal tower is less than in the air and is a function of the tower's cross-section.

Distance from Tower to Fence (FM Towers)

The fence around an FM tower should be located far enough from the tower so that anyone standing outside the fence will not be exposed to radio frequency fields in excess of the FCC limits for general population/uncontrolled exposure. If the FM antenna is high enough off the ground, compliance with these limits will be achieved anywhere on the ground, and a fence is not necessary. Table 9.4-3 shows the minimum height of the center of radiation for various *single* FM antennas that is necessary to keep locations on the ground from exceeding the FCC general population/uncontrolled exposure limits.[3] Readers should take particular note that the ERP values in Table 9.4-3 are for *total* effective radiated power. For example, a 6 kW

Table 9.4-2

Minimum Required Distances from Various AM Towers to Their Fences.

(a) 1/10-Wave Tower

	Transmitter Power (kW)			
Frequency (kHz)	50	10	5	1
535–740	13 m	7 m	6 m	3 m
750–940	12 m	7 m	5 m	3 m

1150–1340	4 m	2 m	2 m	1 m
1350–1540	4 m	2 m	2 m	1 m
1550–1705	4 m	2 m	2 m	2 m

1 m = 3.28 feet

Class A station that is using a circularly polarized antenna with 6 kW horizontal ERP and 6 kW vertical ERP has a *total* ERP of 12 kW.

In order for a location *on the ground* to be compliant with the FCC standard, it must not exceed the FCC exposure limit anywhere from ground level up to 2 meters above ground level. This is because 2 meters is the approximate upper range of the height of a standing person. The antenna height above ground level figures in Table 9.4-3 take this 2 meter "standing person" factor into account.

If, according to Table 9.4-3, a particular FM antenna is close enough to the ground to create a *danger zone*—

(antenna heights are in meters)

Notes:

1. For each ERP/number-of-bays entry, the number on top represents a dipole antenna, which is the worst case. The number on the bottom represents a best-case, typically available modern antenna (i.e., one that has minimal radiation in the downward direction).
2. The data in this table applies to single FM antennas with supporting tower bases that are no lower than the surrounding terrain.
3. Interpolation can be used to obtain intermediate values.
4. The entries marked with an asterisk ("*") are cases where, if the antenna's center of radiation were located at the minimum safe height predicted using the FCC exposure standard, the lowest antenna element would actually be below ground level. Since this would clearly be unacceptable, these numbers have been adjusted upward to ensure that the bottom antenna element will be at least 3 meters above the ground, which is the approximate maximum height for a standing person plus one meter for safety.

where the levels of RF energy exceed the FCC limits for general population/uncontrolled exposure—the most appropriate thing to do is have a professional engineer measure the RF fields around the tower and produce a map illustrating the *danger zone*. This area must then be fenced and posted with RF radiation warning signs.

Distance from Tower to Fence (NTSC Analog TV Towers)

The fence around an NTSC television tower should be located far enough from the tower so that anyone standing outside the fence will not be exposed to radio frequency fields in excess of the FCC limits for general population/uncontrolled exposure. If the TV antenna is high enough off the ground, compliance with these limits will be achieved anywhere on the ground, and a fence is not necessary.

The FCC uses a formula developed by the EPA to predict the strength of RF fields at the base of television towers. This formula assumes that some of the transmitted energy is reflected off of the surface of the earth, thus increasing the level of RF energy at ground level over what would be expected without surface reflection. The formula is as follows:

Equation 1: Minimum Height for Single TV Antenna Compliance with FCC Exposure Limits

$$[MAH] = 2 + \sqrt{\frac{419.84F^2(0.4(VERP) + AERP)}{4\pi S}}$$

where:

MAH = minimum antenna height in meters (2 is added to ensure compliance at head level for a standing person)

F = typical relative field factor in the downward direction (*i.e.*, the amount of energy that the antenna radiates downward expressed as a fraction of the amount of radiation in its main beam. "Downward" is defined as any downward direction that is at an angle of at least 60°, and no more than 90°, with respect to the antenna's horizontal plane.

VERP = total (horizontal plus vertical) peak visual ERP in watts

AERP = total (horizontal plus vertical) aural ERP in watts

S = FCC power density limit for human exposure in $\mu W/cm^2$

Equation 1 can be used for both VHF and UHF stations. For VHF stations with *batwing* elements, the typical value for F is 0.20. The FCC general population/uncontrolled exposure limit at VHF frequencies is 200 $\mu W/cm^2$. For UHF stations, the typical value for F is 0.10, and the FCC general population/uncontrolled exposure limit is $0.67f$ $\mu W/cm^2$, where "f" is the center frequency of the UHF channel in MHz. If the manufacturer's data for a particular antenna includes a value for F, then that value should be used.

If, according to Equation 1, a particular TV antenna is close enough to the ground to create a *danger zone*—where the levels of RF energy exceed the FCC guidelines for general population/uncontrolled exposure—the most appropriate thing to do is have a professional engineer measure the RF fields around the tower and produce a map illustrating the *danger zone*. This area must then be fenced and posted with RF radiation warning signs.

Distance from Tower to Fence (ATSC Digital TV Towers)

When the FCC adopted its latest edition of *OET Bulletin 65*, it indicated that its model for predicting RF exposure hazards around television broadcast towers would have to be modified for use with digital television signals.[4] It is possible that this will occur in the future. However, in the meantime, it is appropriate to use Equation 1 for DTV towers with an appropriate relative field factor for the type of antenna being used.

WARNING SIGNS

Areas that are fenced to prevent people from being exposed to RF energy levels in excess of the FCC exposure limits must also be posted with RF hazard warning signs so that people will understand why access to the areas is restricted. The number and location of signs should be sufficient enough to be noticed from any normal angle of approach.

AM towers that are fenced to prevent shock or electrocution (series fed, folded unipole and insulated base), must have signs that warn of the high voltage danger. The number and location of signs should be sufficient enough to be noticed from any normal angle of approach.

If a series fed, folded unipole or insulated base AM antenna creates an area of excessive RF energy, signs must be posted to warn of *both* the excessive RF energy and the potential for electric shock. Broadcasters can purchase RF and high voltage warning signs from the NAB.

MEASUREMENT PROCEDURES

Whenever practical, field measurement of the RF power density levels is to be preferred over calculation, as the definitive method of determining those levels. Care must be taken, however, when taking measurements for the purposes of determining compliance with the ANSI RF exposure guidelines, in order that the examination of the site be complete. The principal concern when taking these measurements is to identify all areas requiring access restrictions, in order to protect fully the liability exposure of the FCC licensee(s) at the site. Failure to identify these areas begs the question of licensee candor in self-certification to the FCC at license renewal, as well as the issue of negligence in the event of legal action based upon "excessive" exposure to RF energy. It is important that the measurement process should be accurately described to allow for a high degree of repeatability in future measurements by others.

Physical Parameters

Power density is most commonly expressed in units of milliwatts per square centimeter (mW/cm^2). Instruments designed for electromagnetic field hazard surveys are typically calibrated in terms of either field strength, field strength squared units, or plane wave equivalent power density. As will be seen, many instruments use detectors that are actually responsive to the square of the field strength, either electric or magnetic, but provide meter readings in plane wave equivalent power density; the meter indications are obtained via an electronic manipulation equation. In other cases, instruments designed to sense the magnetic field are calibrated in terms of plane wave equivalent electric field strength.

Other parameters of importance are the frequency or frequencies of the principal source(s) and the duration of the exposure. Virtually all current standards for electromagnetic field exposures are frequency dependent; this dependence takes into account the frequency response of the human body in terms of energy extraction from the incident fields. Because the body acts much like a radio antenna absorbing energy from the field better at certain frequencies, most recommended limits for exposure levels vary in accordance with this frequency selectivity of the body, with the most stringent controls in the body resonance range and less restrictive levels at frequencies both lower and higher than this range. Therefore, when performing a survey of exposure, knowledge of the frequency of the field is necessary to relate to permitted exposure limits and the instrument being used for the measurements must be capable of accurate response at the frequency of exposure.

Electromagnetic fields have a wide range of waveforms depending on their use. For example, a pulsed radar signal typically will exhibit a very high peak to average field strength ratio due to the use of very narrow pulse widths but very high peak powers. In the case of normal AM radio broadcasting, again the average value of the field will be dependent on the programming material and adjustments to the transmitter. TV broadcasting involves the transmission of synchronization pulses which have considerably greater peak powers than the associated video programming material. The waveform of some fields may be of interest because of their rapid changes in time, which, for magnetic fields, may be important from the standpoint of induced currents in the body.

Broadband Instruments

In terms of convenience, broadband instruments are considerably more popular than narrowband instruments for evaluating exposure to electromagnetic fields. Broadband instruments, as their name implies, respond over a wide range of frequencies, possessing nearly flat responses independent of frequency within their frequency pass band. Most common broadband meters feature isotropic probes, consisting of three mutually orthogonal detecting elements connected electronically in such a manner that the output of the

[4] See FCC OET Bulletin No. 65, *Evaluating Compliance with FCC Guidelines for Human Exposure to Radiofrequency Electromagnetic Fields, Supplement A*, August 1997, p. 29.

meter becomes essentially independent of probe orientation within the field. Isotropy is typically achieved to within ±0.5 of 1 dB, but no information on the electrical phase of the fields is retained.

Probe detection elements are normally either thermocouples or diodes. Thermocouples exhibit the useful property of being average-responding detectors. When placed in a modulated field, such as a pulsed radar field, they will accurately respond to the average value of the field squared or average plane-wave equivalent power density. This same property, i.e. true root mean square (RMS) detection, of thermocouples, makes them useful in multiple frequency electromagnetic field environments since they can accurately respond to the sum of the average fields present at the probe. Diode detectors, on the other hand, tend to be peak detectors rather than average detectors unless operated within limited field strength ranges where they can exhibit so-called square law responses, i.e. they will respond correctly to the power density or square of the fields. In some instruments, special circuits are used to correct for the nonsquare law operation of diode detectors. This technique works well for single frequencies, but cannot properly correct readings when multiple signals are being measured. In summary, while diode detectors have certain disadvantages, they also have several advantages over thermocouples, including durability, ability to withstand overloads from strong fields, significantly better thermal stability, and high sensitivity.

While isotropic survey instruments have separate probe assemblies connected by cable to the meter, some survey instruments have single or multiple sensing probes mounted directly on the instrument package. Those instruments equipped with one probe element are responsive to only one field polarization component at a time. The absence of a connecting cable between the probe and the readout package, in some cases, is responsible for superior performance when used in low-frequency fields; it is common for cables to "pick up" or couple with the electric field at lower frequencies, typically below about 3 MHz, often leading to erroneous indications of field strength. Cableless instruments, or ones equipped with nonconductive, fiber optic cables, are preferred for electric field measurements at low frequencies.

Broadband instruments can exhibit flat frequency responses over large frequency ranges. For example, electric field probes can be purchased with specified passbands as wide as 200 kHz to 40 GHz. Magnetic field probes have narrower passband characteristics, such as 0.5 MHz to 300 MHz, and are not generally available for UHF measurements. Care must be used in conducting broadband magnetic field surveys in the presence of UHF broadcast stations, since the loop sensors of the instrument may exhibit high frequency resonances leading to erroneous indications of fields.

The most common broadband isotropic field strength meters, well suited to measurements taken for purposes of ANSI compliance determination, are shown in Table 9.4-4.

Table 9.4-4

Make & Model Series	Probe Freq. Range	Suitable Applications
IFI RFH	E-field: 0.01–220 MHz	AM
Holaday HI-3000	E-field: 0.5–6000 MHz	FM, VHF, UHF, some microwave
	H-field: 0.3–300 MHz	AM, FM, VHF
Narda 8700	E-field: 0.003-40 GHz	FM, VHF, UHF, microwave
	H-field: 0.3–300 MHz	AM, FM, VHF

Most consulting engineering firms own meters of this type to support their work in this field, and some of the meters are available, as well, from certain equipment leasing companies. The total accuracy of these meters is typically ±2 to 3 dB, due to variations in frequency response, isotropicity, and repeatability. Other errors can be introduced, as well, but none which would cause the meter to read low, according to the manufacturers' literature. Therefore, while the measurements are expected to be conservative, leeway should be allowed when establishing the locations of ANSI-threshold contours.

There is also a measurement probe that accounts for the frequency variation of present ANSI RFPG by weighting strength of the fields according to frequency such that it indicates in units of percentage of the exposure criterion permitted. As with any broadband type of instrument, however, it does not indicate how the resultant field magnitude is distributed across the frequency spectrum.

Narrowband Instruments

Broadband instruments, while convenient for conducting area surveys and rapidly assessing exposure levels of electromagnetic fields, do not yield information on the frequency of the fields at a measurement point. Because of the frequency dependence of most RF field protection guides, however, such information is often desired, particularly where frequencies are present for which different exposure limits apply. If total RF power density exceeds 1 $\mu W/cm^2$ in such a situation, the contribution that each field makes to the total must be determined in order to know whether the protection guide is actually being exceeded.

A tunable receiver is the most common instrument for this purpose, allowing each emission frequency to be individually tuned and measured. A spectrum analyzer, which repetitively scans between a lower and upper frequency, producing a graphical display of the measured signal strengths in that range, permits rapid assessment of the relative signal amplitudes across a wide range of frequencies. It is particularly effective when the frequency of a specific source is unknown or when the presence of the field is intermittent.

In either case, however, narrowband meters and their companion sensing antennas are not as portable as broadband meters. It can be very inconvenient or simply impractical to conduct the measurement using the large antennas typically employed with narrowband instruments. This is a serious consideration when performing field measurements under difficult circumstances, such as on tall broadcast antenna towers, and in other situations where it is impractical to carry narrowband equipment. In these cases, arrangements must be made to operate the various sources individually, so that their individual contributions can be assessed with a broadband type of instrument.

Special Adaptations or Applications of Instruments

In the last several years, data processing hardware has been introduced that can be configured with portable RF survey instruments to simplify the data collection task. These devices, which have taken the form of microprocessor based data-loggers or analog devices for simply integrating exposure over some prescribed time interval, now allow direct assessment of the time-averaged exposure to electromagnetic fields. The attractiveness of such devices is that one can use them to actively manage personnel exposures in areas where the exposure levels may reach substantial values momentarily. By constantly monitoring the time-averaged value, the exposed individual has the knowledge to remove himself from the field to keep the average level within acceptable limits.

An area of instrumentation highly developed in the ionizing world of radiation, personal dosimetry, has not been successfully developed for the general case of electromagnetic fields. This has been the case because of the difficulty in relating radio frequency field strengths determined very close to the surface of the body to equivalent, unperturbed values from which SAR may be derived. At lower frequencies, however, personal dosimeters have been developed for use in power frequency fields, i.e. 50 and 60 Hz. At these frequencies, especially for magnetic fields, body perturbation effects can be accounted for in a simpler manner than for higher radio frequencies. Some of these dosimeters contain advanced digital circuitry which allow the retention of data on exposure levels versus time of day. Hence, very complete exposure histories can be determined for subjects wearing these devices. Recently, new developments in the form of personal RF monitors useful in the microwave frequency range have been commercially announced.

Measurement Techniques

There are several different approaches to using broadband exposure meters, depending on the type and number of stations at the site of interest and the purpose of the measurements. In general, a top-down approach is recommended, ensuring that no areas of the site are neglected while also ensuring that potential problem areas are examined in sufficient depth.

The basic technique is to make a quick pass first, throughout the site, of ambient fields, to determine where to concentrate and what fields/boundaries to locate and record. It may be, for instance, that an area exists in which the ambient fields exceed the ANSI RFPG; this is the type of area that would be examined next. There, the location of the ANSI-threshold contour should be defined carefully, for fencing or marking at the time the mitigation measures are determined.

Next, the localized measurements are done, looking for the so-called "hot-spots." The FCC adopted under Docket 88-469 a relaxed distance requirement for measuring hot-spots. In the concluding paragraph (42) of the *Report and Order*, the following statement by the Commission provided somewhat conflicting directions:

"In summary, it is recommended that during routine measurements of radio frequency fields for compliance purposes, a minimum separation distance of 20 cm be maintained between a re-radiating object and the closest sensing element of a probe. However, as a precautionary measure, it is also recommended that consideration be given to the presence of intense, localized fields in the range of 10 to 20 cm from a reradiating object."

This paragraph has been interpreted by some with emphasis on the first sentence, so that measurements are generally made no closer than 20 cm from reradiating objects, but with sufficient measurements made at a distance of 10 cm to determine whether the RFPG is exceeded where "intense, localized fields" are present. Others interpret the paragraph more conservatively, reasoning that, without consistently measuring as close as 10 cm, one cannot give "consideration" to the presence of intense, localized fields in the 10 to 20 cm range. Nevertheless, this increase in measurement spacing, from 5 cm specified in the ANSI RFPG, has alleviated the worries at many sites about localized fields, which tended to occur frequently atop wire-mesh fences or at gates, locations where whole-body SARs would probably remain low but where reproducible measurements indicate fields in excess of the RFPG.

Finally, measurements are made inside the transmitter buildings at the site, looking for both ambient and localized fields and searching with particular care, since these are generally areas of prolonged exposure. Additional grounding will often remove or reduce the severity of localized fields. It is also often helpful for later reference, when determining mitigation measures, to temporarily ground possible sources of reradiation to evaluate the effectiveness of grounding in that specific case.

APPENDIX

Further Guidance for Broadcasters Regarding Radio Frequency Radiation and the Environment

(Federal Communications Commission Public Notice, January 28, 1986)

The National Environmental Policy Act of 1969 (NEPA), 42 U.S.C. Sections 4321–4361, requires all federal agencies to ensure that the environment is given appropriate consideration in agency decision-making.

In a *Report and Order* in General Docket No. 79-144, 100 FCC 2d 543 (1985), the Commission decided that human exposure to radiofrequency (RF) radiation was a proper environmental concern of this agency and specified that the guideline for determining the significance of such exposure will be the "Radio Frequency protection Guides" adopted in 1982 by the American National Standards Institute (ANSI C95.1-1982). As of January 1, 1986, all applications for new facilities, modifications to existing facilities, and renewals must contain *either* a specific indication that the RF radiation of the particular facility or operation will not have a significant environmental impact *or* an environmental assessment which will serve as the basis for further Commission action.[1] *See* Part 1, Subpart I of the Commission's rules for specific regulations regarding environmental matters.

Most broadcasting facilities produce high RF radiation levels at one or more locations near their antennas. That, in itself, does not mean that the facilities significantly affect the quality of the human environment. Each situation must be examined separately to decide whether humans are or could be exposed to high RF radiation. Paragraph 37 of the *Report and Order* points out that accessibility is a key factor in making such a determination. As a general principle, if areas of high RF radiation levels are publicly marked and if access to such areas is impeded or highly improbable (remoteness and natural barriers may be pertinent) then it may be presumed that the facilities producing the RF radiation do *not* significantly affect the quality of the human environment and do not require the filing of an environmental assessment.

Because we wish to avoid burdening applicants with unnecessary work, expenses and administrative filings, we offer the following guidance as to how we will view typical situations. The term "high RF level" means an intensity of RF radiation, whether from single or multiple sources, which exceeds the ANSI guidelines.

Situations

A. High RF levels are produced at one or more locations above ground level on an applicant's tower

If the tower is marked by appropriate warning signs, the applicant may assume that there is no significant effect on the human environment with regard to exposure of the general public.

B. High RF levels are produced at ground level in a remote area not likely to be visited by the public

If the area of concern is marked by appropriate warning signs, an applicant may assume that there is not significant effect on the human environment with regard to exposure of the general public. It is recommended that fences also be used where feasible.

C. High RF levels are produced at ground level in an area which could reasonably be expected to be used by the public (including trespassers)

If the are of concern is fenced *and* marked by appropriate warning signs, an applicant may assume that there is not significant effect on the human environment with regard to exposure of the general public.

D. High RF levels are produced at ground level in an area which is used or is likely to be used by people and to which the applicant cannot or does not restrict access

The applicant must submit an environmental assessment. This situation may require a modification of the facilities to reduce exposure or could lead to a denial of the application.

E. High RF levels are produced in occupied structures, on balconies, or on rooftops used for recreational or commercial purposes

The applicant must submit an environmental assessment. The circumstances may require a modification of the broadcasting facility to reduce exposure or could lead to a denial of the application.

F. High RF levels are produced in offices, studios, workshops, parking lots, or other areas used regularly by station employees

The applicant must submit an environmental assessment. The circumstances may require a modification of the facilities to reduce exposure or the application may be denied. This situation is essentially the same as E. We have included it to emphasize the point that station employees as well as the general public must be protected from high RF levels. Legal releases signed by employees willing to accept high exposure levels are not acceptable and may not be used in lieu of corrective measures.

G. High RF levels are produced in areas where intermittent maintenance and repair work must be performed by station employees or others

ANSI guidelines also apply to workers engaged in maintenance and repair. As long as these workers will be protected from exposure to levels exceeding ANSI guidelines, no environmental assessment is needed. Unless requested by the Commission, information about the manner in which such activities are protected need not be filed. If protection is not to be provided, the applicant must submit an environmental assessment. The circumstances may require corrective action to reduce exposure or the application may be denied. Legal releases signed by workers willing to accept high exposure levels are not acceptable and may not be used in lieu of corrective measures.

The foregoing also applies to high RF levels created in whole or in part by reradiation.

A convenient rule to apply to all situations involving RF radiation is the following:

[1] In applications for new and modified facilities, the requirement for a specific indication is satisfied by answering the question on the form regarding environmental matters. An environmental assessment is the narrative statement described in Section 1.1311 and elsewhere in the Commission's rules.

1. Do not create high RF levels where people are or could reasonably be expected to be present *and*
2. Prevent people from entering areas in which high RF levels are necessarily present.

Fencing and warning signs may be sufficient in many cases to protect the general public. Unusual circumstances, the presence of multiple sources of radiation, and operational needs will require more elaborate measures.

Intermittent reductions in power, increased antenna heights, modified antenna radiation patterns, site changes, or some combination of these may be necessary, depending on the particular situation.

For further discussion *see* Office of Science and Technology Bulletin No. 65, "Evaluating Compliance with FCC-Specified Guidelines for Human Exposure to Radiofrequency Radiation," October 1985. Copies of this bulletin may be ordered from the National Technical Information Service, (800) 336-4700, Order No. PB 86-127081.*

For further information regarding this *Notice*, applicants should contact the AM Branch, FM Branch, TV Branch, or LPTV/Translator Branch, as appropriate.

* NOTE: A limited number of copies are also available from the FCC, (202) 653-8169.

9.5
ELECTRICAL SHOCK

CLIFFORD D. FERRIS
UNIVERSITY OF WYOMING, LARAMIE, WY

INTRODUCTION

The possibility of electric shock must be taken very seriously in the operation of electrical, electronic and broadcast systems because it can produce permanent injury and death. The best approach to electric shock is prevention. Human tissues individually, and the human body as a whole, are electrical conductors. An electric shock is produced when a potential difference is applied across human tissues such that a response current results. The severity of the resulting shock is a function of skin quality, contact pressure, nature of the voltage source (ac or dc), and frequency when alternating current sources are involved.

General Definitions

Human body tissues, both solid and fluid, are classified as *electrolytes*. Thus they are electrically conductive and may be characterized at dc and low frequencies as ohmic resistances. As frequency increases, human tissues also manifest capacitive properties. This latter attribute is of considerable importance with respect to broadcast and communications equipment.

Two general categories of electric shock are recognized: *microshock* and *macroshock*. The former describes an inadvertent electric shock that occurs within the body, and associated electric current levels range from 10 μA to 100 μA. Such a shock may result from improper electrical grounding techniques associated with various surgical and diagnostic medical procedures (such as cardiac catheterization) in which electrically operated sensors are placed internally in the body.

Macroshock (electric shock) is the result of simultaneous physical contact between the external body surface and two or more electrical conductors at different potentials. Electric shock can be induced by body contact between energized conductors, such as two of the phase conductors in a three-phase system, or by contacting a hot wire and neutral or ground.

Current Levels

The electric current levels and associated physiological responses are somewhat different between ac and dc. Table 9.5-1 presents typical data for alternating current shocks at 60 Hz (50 Hz data are similar).

Generally speaking, women react to electric shock at current levels that are about two-thirds of those necessary to elicit the same response in men. For example, current level versus frequency studies published by C.F. Daziel indicate that the mean *let go threshold* at 60 Hz for women is approximately 10 mA as opposed to 16 mA for men.

Table 9.5-1
60 Hz Electric Shock Current RMS Levels and Physiological Responses

Current Level	Physiological Response
1 mA	Lower limit for sensation of shock
5 mA	Upper limit for what is normally considered a harmless shock
10–20 mA	Let go threshold: contractions of *flexor muscles* are stronger than extensions of *extensor muscles*. Victim cannot let go of conductor and begins to perspire
30–40 mA	*Tetany* with sustained contraction and cramping of muscles
50–70 mA	Intense pain with physical exhaustion, fainting, permanent nerve damage, possible respiratory arrest and asphyxiation; potential for ventricular fibrillation (heart)
100 mA	Death by cardiac arrest if the current passes through the body trunk
>100 mA	*Ventricular fibrillation;* if shock is survived: severe burns, amnesia, severe electrolysis at body contact sites
>5 A	Little chance for survival

By a strange quirk of nature, the electrical impedance of the human body is at a minimum between approximately 30 Hz and 80 Hz. This situation, along with other factors to be addressed subsequently, renders a sustained electrical shock at 60 Hz and 120 VAC rms potentially extremely lethal. The threshold levels indicated in the table increase markedly on either side of the low impedance frequency window. The average value for the let go current at dc is on the order of 75 mA. This value is greater than the corresponding ac peak-to-peak value at the 20 mA rms level. The dc threshold of sensation level is increased to 5 mA. On the high-frequency side of the window, the let go threshold increases to an average value of approximately 60 mA at 5 kHz. A momentary direct shock current path through the heart of 60 mA rms at 60 Hz can induce *ventricular fibrillation,* while 300 to 500 mA is required for dc.

Primary and Secondary Effects

There are both primary and secondary effects associated with electric shock. The primary or direct effect is the passage of an electric current through body tissues. Secondary effects include immediate physiological damage, psychological shock, physiological shock and involuntary muscle contractions. In some cases, the latter are strong enough to cause the victim to be thrown some distance from the source of the shock, which can then result in broken bones and/or death if massive objects are impacted.

Various factors control the severity of an electric shock. The intensity of the electric current that is driven through the body as a consequence of the externally applied potential difference is the cause of the reversible and irreversible effects produced by an electric shock. The electrical resistance of the body volume involved and the contact pressure and surface area at the electrical contact sites have major influence on the severity of a shock. The potential seriousness of an electric shock is influenced by the paths that the shock current takes through the body. Current paths that do not involve the body trunk or head are normally not fatal, although permanent injury may result in the form of partial or complete paralysis of a limb, neuromuscular damage, loss of limbs and scars. A severe electric shock to the head may produce loss of memory, loss of motor function (voluntary muscle motion) or death. Shock current paths that pass through the body trunk in the region of either the heart or lungs can cause death. A current path through the heart may induce cardiac arrest, while a path through the lungs can paralyze the nerves that control the breathing diaphragm. The two most dangerous current paths through the chest are from hand-to-hand and hand-to-leg or foot, especially the path from the left hand to the left leg/foot (see Figure 9.5-1).

Human response to an electric shock is both objective and subjective. The condition of the skin surface that comes into contact with the shock source and the contact pressure are major factors, since they determine the contact interface resistance. If an adult tightly grasps the probes of an ohmmeter between the thumb and forefinger of each hand, the resistance that is subsequently measured will vary widely across individuals. Individuals whose hands are calloused from physical activity may generate resistance readings on the order of 1 or 2 MΩ with dry hands, and on the order of 100 kΩ when the hands are wet. Individuals with soft and pliant skin may generate readings of 5–10 kΩ with dry hands, and as low as a few hundred ohms when the hands are wet or damp with perspiration. The resulting current changes by a factor of 1000 from a 1 MΩ contact resistance to a 10 kΩ contact resistance.

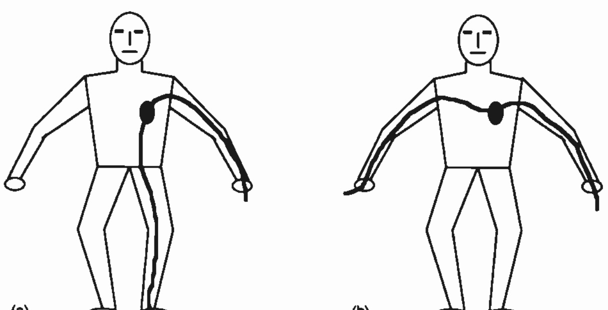

Figure 9.5-1. Most lethal electric shock paths: (a) left hand-to-left foot; (b) hand-to-hand.

Individuals who experience the same low level electric shock may experience very different sensations. Among the sensations reported are tingling (pins and needles), burning, buzzing and jolts. To a large extent, the body location of the shock and the emotional state of the individual at the time may strongly influence response. Response to an electric shock tends to be amplified in individuals who are already tense. Shocks that occur close to major nerves or nerve endings that lie close to the skin surface also tend to elicit amplified reactions. An analogous example is the reaction when one bumps an elbow and triggers the funny-bone response.

There are several secondary effects of electric shock that may produce serious injury even when the shock itself is not life threatening. Most commonly the startle reflex is triggered, which may cause the victim to flail limbs, fall down, drop objects or otherwise move in a manner that causes injury. High voltages, including those produced by capacitor discharges, can produce generalized severe muscle contractions of sufficient intensity to throw a person across a room. Because of the violence of such reactions, the victim may sustain serious bone fractures, internal injuries or even death from impact with nearby objects. The violence of the muscle contractions alone may be sufficient to fracture spinal vertebrae, produce shoulder dislocations and other injuries.

DIRECT PHYSIOLOGICAL EFFECTS

An examination of Table 9.5.1 indicates that the medical consequences of an electric shock range in severity from no effect at all, to minor burns, muscle and nerve damage, and in the extreme case, death. Factors that affect the physiological consequences of electric shock are:

- The effective electrical resistance between the shock contact points on the body
- The portion of the body traversed by the shock current path(s)
- Type of electrical source that produced the shock
- Victim's body weight.

The first two items have been addressed to some extent in the introductory section. As contact resistance at the shock points decreases, the resulting shock current increases along with the potential for severe physiological damage. Current paths through the head and the body trunk are potentially the most lethal. The electrical properties of the human body are frequency dependent such that minimum electrical impedance and consequently maximum shock currents occur in the frequency range from 30 to 80 Hz. Shock threshold parameters are lower for women than men by approximately 30%, and may result from differences in skin condition and associated electrical resistance.

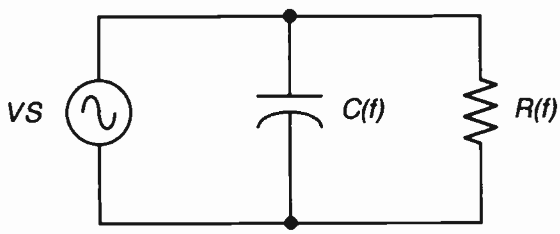

Figure 9.5-2. Elementary electrical model for tissue impedance.

Shocks that exceed the let go threshold are particularly dangerous because the victim begins to perspire. The resulting increase in perspiration moisture on the skin surface reduces contact resistance at the shock sites, thus increasing the shock current and the effects thereof.

Alternating current shocks at 50–60 Hz are potentially more serious than dc shocks because the body impedance has a minimum value. Radio frequency shocks have some additional attributes that will be discussed subsequently.

Soft Tissue and Skeletal Damage from Electric Shock

Human tissues are electrolytes and they can be grossly characterized electrically by the simplistic parallel resistance-capacitance model illustrated in Figure 9.5-2 (*VS* represents the applied electric shock voltage). Both the resistance and capacitive components of tissue are functions of frequency, which is why the model elements are shown as R(f) and C(f). Only the resistive element is significant at dc. As frequency increases into the radio frequency range, both the resistance and capacitance values decrease. The relative change in these parameters results in the minimum value of body impedance in the 30–80 Hz range. At radio frequencies, the capacitive component of the current is significant.

Electrolysis is a primary effect of the passage of an electric current through tissue. Ionic dissociation of the electrolyte (tissue) occurs with the production of heat. When current level is high, steam is generated from the tissue water component, with the consequent rupture of cell membranes and cell destruction. Sustained passage of current causes coagulation of proteins and tissue death along the current path. Medical effects include surface burns at the shock contact sites, penetrating burns along the current path (especially when radio frequency currents are involved) and the potential for permanent damage to both nerve and muscle tissues.

Traditionally, thermal burn severity has been classified as first, second or third degree, with a designation of fourth degree for certain burns resulting from electric shock. Thermal burns resulting from localized contact with a hot object differ from those produced by electric shock in that only one circumscribed portion of the body surface is affected. With electric shock, burns may occur at all contact sites. Burns may be categorized as follows:

- **First-Degree.** Superficial with local discoloration or reddening of the skin in the burn area, mild swelling and associated pain. Healing is normally rapid and without medical complications unless the victim has some underlying medical condition such as diabetes
- **Second-Degree.** Burn damage penetrates more deeply into the skin than in the first-degree case. The skin at the burn site develops a red or mottled aspect with blister formation and substantial pain. The area may swell considerably over the course of several days. The skin surface becomes wet from loss of plasma from the damaged skin layers. Medical attention should be sought to prevent secondary infection, and especially in cases of underlying medical disorders
- **Third-Degree.** Deep penetration into the skin occurs, often into the underlying tissue, with coagulation of the skin tissues, destruction of red blood cells and charring of the skin. The skin surface may initially appear white or charred, or it may resemble a second-degree burn. Full healing of the skin may occur only at the edges of the burned area, with scar tissue replacing the normal tissue in the central portion of the area injured. Risk of infection at the burn site is high and medical attention is important
- **Fourth-Degree** (electrical burns). Overlying tissues are charred such that underlying bone is exposed. This type of injury can be sustained from contact with high-voltage transmission lines or the high-power output section of a radio frequency transmitter. If the incident does not result in death, permanent physical disability can be anticipated
- **High-frequency.** Deep penetration of the tissues at the contact sites. Intense electrolysis and searing of the tissue. Fourth-degree burns may result. The shock current may pass over the skin surface (because of the capacitive component of the skin tissue) as well as through a portion of the body. Multiple damage sites may occur, especially when the current passes over the skin surface and then arcs to grounded objects in the near vicinity. Because high-frequency burns are deep with severe electrolysis, they are very slow to heal, and very painful. Immediate medical attention is important and necessary.

Burns produced by high-frequency energy have beneficial medical uses although they may have grave consequences in the work place. *Electrosurgery apparatus* (ESA), also called an *electric scalpel*, is used to provide the surgical functions of cutting, cauterizing or simultaneous cutting and cauterizing. In effect, a controlled high-frequency shock current is applied at the surgical site (shock entrance site). A large-contact-area return-path (exit) electrode is located elsewhere on the body. The current density at the return electrode is normally very low so that skin injury does not occur. ESA apparatus typically operates in the 300–400 kHz range. Appropriate modulation of the waveform produces the surgical functions required. Even when ESA is used under highly controlled conditions, extraneous burns may occur to the patient if the surface conduction component of the current finds an alternative path to ground (such as an area of the skin surface that has accidentally contacted some grounded metal object that is present in the operating room).

Electric arcs are another source of electrical burns, which may or may not be associated with electric shocks. Burns can be produced by heat and flying hot debris from electric arcs even if the victim is not in electrical contact with the associated circuit. The temperatures within an electric arc can be on the order of 5000° C and above. Fourth-degree burns may be expected if an arc occurs in conjunction with and electric shock.

Skeletal damage may be a secondary effect produced by an electric shock. High voltages, either from momentary contact with a continuous source of electrical energy or a charged capacitor, generally cause violent muscle contractions. Such muscle contractions may be of sufficient intensity to break bones, or cause joint dislocations. In some cases, the victim is propelled away for the shock source. Broken necks and other serious skeletal injuries have been reported when the victim has been thrown against some object (such as a table or workbench).

Shock Paths—Limbs and Extremities

In most cases, electric current paths restricted to the limbs and extremities (excluding the head) are not fatal, although permanent damage and/or disability may be consequences. Loss of a limb may occur, and permanent skin scars, partial or total limb paralysis, and physical impairment are not uncommon.

Shock Paths—Head

High intensity shocks to the head may cause permanent injury to the neck and spine (as a result of body spasms), loss of memory and/or motor function and permanent brain damage. Various bones in the body may be fractured as a result of severe and generalized muscle contractions. At one time electroshock therapy, in which high intensity shock currents were passed through the temples, was used medically to treat patients with certain mental disorders. There are records in the medical literature of the many side effects of such treatments.

Shock Paths—Body Trunk

When the shock current passes through the heart or lungs in the body trunk, grave consequences may occur. The human body is a complex electrical machine. Sensory information from our environment is translated into electrical pulses that are transmitted along nerve pathways to sites in the brain for central processing. Our senses of sight, smell, hearing, temperature and touch depend upon electrical pulses. Our voluntary actions associated with muscle movement and locomotion, as well as involuntary actions such as digestion, heartbeat and respiration, all depend upon electrical pulses. Muscle motion is activated when pulses are transmitted along nerves to *myoneural junctions* where they then initiate muscle extension or contraction.

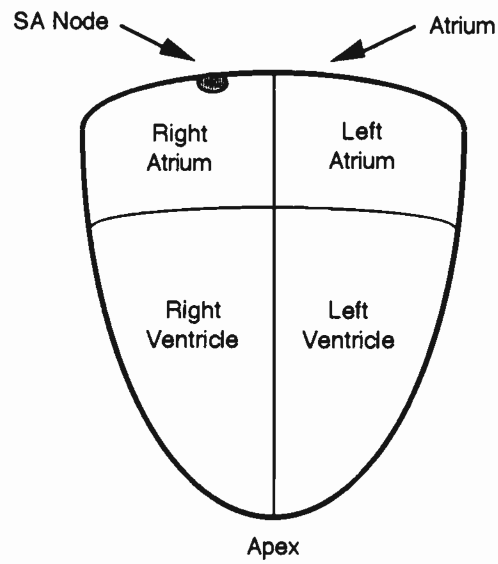

Figure 9.5-3. Stylized anatomical cross-section of the heart.

The heart mechanically is a simple four-chambered pump that is composed of muscle tissue. Its pumping action is controlled by electrical signals generated by a physiological multivibrator, called the *pacemaker* or *sinoatrial (SA) node*. The SA node is a small region of specialized tissue located at the top of the heart. A stylized diagram of the heart is presented in Figure 9.5-3.

The right and left atria that form the two upper chambers of the heart are reservoirs that store the blood that is returned to the heart from the lungs and the body organs. Through appropriate valves, these atrial chambers supply blood to the ventricles, which are the two lower and larger pump chambers. When the ventricular muscles contract to produce a heartbeat, blood from the right ventricle is pumped through the pulmonary artery to the lungs (the pulmonary circulation); blood from the left ventricle is pumped through the aorta for distribution to the body organs (the systemic circulation). Additional valves in the ventricles prevent blood backflow. The beating of the heart is controlled by the regular electrical pulses that are generated by the pacemaker, which cause the ventricles to contract in unison (one pulse per heartbeat). The repetition frequency of the pacemaker in a normal heart automatically adjusts to the body's demand for oxygen through a complex physiological feedback system.

Contraction and relaxation of the skeletal muscles also generates electrical pulses. Contraction of the heart is initiated by electrical pulses generated by the pacemaker, but at the same time, the contraction and relaxation of the heart muscle tissue produces electrical pulses. This electrical activity caused by the beating of the heart can be detected on the external body surface because the human body is an electrical volume con-

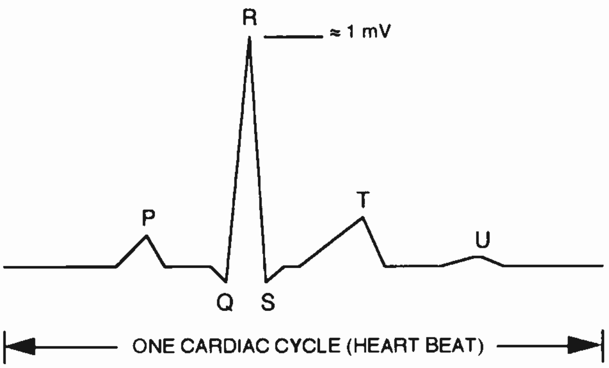

Figure 9.5-4. Stylized ECG waveform for one cardiac cycle.

ductor. The electrical impulses so produced can be detected and recorded electronically to produce an *electrocardiogram* (ECG). There are several protocols and body locations for placing electrodes on the surface of the body to record an ECG. When a reference electrode is placed on the inside of the right ankle and two recording (active) electrodes are placed respectively on the insides of the left ankle and left wrist, a signal of the form illustrated in Figure 9.5-4 can be obtained. It is a representation of the Lead II signal produced by one of the standard methods for recording the electrical activity from the heart. The presentation has been linearized and stylized for purposes of discussion. Actual ECG records are somewhat less linear and the peaks of some of the pulses are rounded. The illustration represents one cardiac cycle or heartbeat. In the Figure, the time axis has been normalized to a length of one heartbeat. The major events in the record (waves) are designated as P, Q, R, S, T, and U. The peak voltage amplitude produced by the R wave on the body surface typically ranges from approximately 1 mV to 1.5 mV. These waves or events relate to the beating of the heart as follows:

- The P wave represents the electrical activity produced when the atria contract to force blood into the ventricles
- The R component of the QRS complex represents the contraction of the ventricles and the pumping of blood out of the heart and into the aorta and pulmonary artery
- The T wave represents the electrical activity of the relaxation (called repolarization) of the ventricular muscles following their contraction
- The electrical signal produced by the relaxation (repolarization) of the two atria is masked by the high amplitude R wave
- The origin of the U wave is somewhat unclear, but is thought to be produced by the repolarization of the aorta after the blood volume produced by the left ventricle has passed through its length.

When an intense electrical shock current passes through the chest cavity, it may cause the entire heart muscle to contract and cease beating during the time duration of the current. If this shock current is of short duration, normal heart rhythm usually returns following the passage of the current and there is no irreversible cardiac tissue damage. Less intense shock current levels can momentarily disrupt the regularity of the normal heart rhythm. The heart is most sensitive to external electrical stimulation during the occurrence of the T wave. A shock current amplitude that does not ordinarily disrupt cardiac rhythm during other portions of the cardiac cycle may produce cardiac arrest if it occurs during the T wave event.

Either of two conditions is described under the designation cardiac arrest: *cardiac standstill* and *ventricular fibrillation (VFIB).* As the name implies, the heart does not beat in the condition of standstill, and the ECG is a flat line. Ventricular fibrillation describes a condition in which individual muscle groups of the ventricles contract randomly and out of unison. No blood is pumped and the blood pressure drops to zero, but a low level random ECG signal is produced, as is shown in Figure 9.5-5. To differentiate between the conditions of flat line and VFIB, an ECG recorder is required.

Involuntary contraction of the respiratory muscles is often a consequence of the passage of an electric shock current through the chest region. Since respiration ceases, the victim can die from asphyxiation if the current is not interrupted. Cessation of breathing (respiratory paralysis) can occur if the electric shock current that passes through the body trunk damages the nerve that controls the diaphragm. In such a case, the victim typically inhales deeply; the chest then expands and becomes rigid and remains so after the shock current has ceased. Initially, the heart may or may not be affected. In the latter case, the heart continues to beat, but the beats become irregular and erratic with time as the blood carbon dioxide level increases (acidosis). Acidosis produces irritability of the heart muscle tissue and makes restoration of a normal heartbeat difficult even if respiration can be restored.

Dangers of 120 VAC rms 60 Hz Electric Shocks

The electrical impedance of the human body is at a minimum value for 60 Hz. A voltage level of 120 VAC rms is generally not sufficiently high to cause muscle contractions that throw the victim away from the source of the shock current. It is also low enough that a strong startle reflex may not occur. Consequently

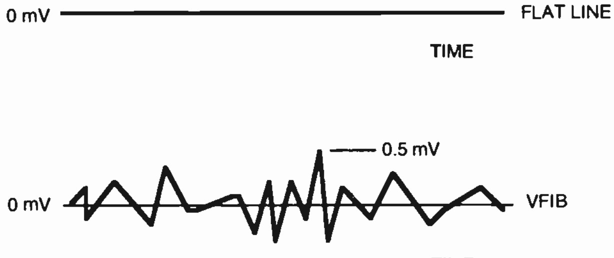

Figure 9.5-5. Cardiac arrest ECG waveforms.

the subject may not be able to let go of the source if the conductor has been firmly grasped. If the effective impedance presented by the body to the shock source is 500 Ω, then the shock current will be 240 mA rms, which is more than enough to produce ventricular fibrillation. Even if a higher impedance was presented initially, the continuation of the shock produces perspiration buildup on the skin that lowers the effective resistance. Shock charges on the order of 100 mA seconds (rms current values) are sufficient to produce VFIB. The cardiac cycle at a heart rate of 70 beats per minute is 857 ms or 0.857 seconds. At a current level of of 240 mA, the shock energy generated during one cardiac cycle is 206 mA seconds. Thus VFIB can be anticipated as one of the consequences of a sustained 120 V 60 Hz shock.

ELECTRICAL SHOCK PREVENTION

Because death or permanent disability may be a consequence, electric shock must not be taken lightly. Shock prevention is far superior to medical remediation after the fact. Some general guidelines are:

- **Workplace safety regulations.** Observe all company and local regulations regarding electric shock prevention. In many industrial sitings, the regulations promulgated by the Occupational Safety and Health Administration (OHSA) apply as well
- **Clothing and jewelry.** When working in close proximity to exposed energized electrical circuits, loose clothing and jewelry should not be worn (remove neckties, scarves, etc). Exposed skin should be minimized (do not wear shorts, sandals or open-toed shoes, etc.). It is strongly recommended that ALL jewelry (including wrist watches) be removed
- **Protective clothing.** Observe all company regulations regarding the use of safety clothing and accessories. Safety goggles, non-metal hard hats, electrically insulating safety shoes and various safety garments (electrically insulating gloves, for example) may be required. OHSA regulations generally require the use of goggles, hard hats, and safety shoes in most industrial venues
- **Equipment servicing.** Power switches should always be turned off and electrical/electronic equipment should be disconnected from the power mains before opening the equipment cabinet for servicing or calibration of internal circuits. Never rely on switches to disconnect power. Sometimes they are defective, and sometimes a switch may be miswired or mislabeled such that the normal off and on positions are reversed
- **High-voltage capacitors.** High-voltage capacitors associated with power supplies, cathode ray tubes, radio transmitters and other high voltage electronic and radio frequency equipment must be discharged prior to equipment repair or servicing. Use appropriate discharge cables designed for this application. Always discharge the external surfaces of cathode ray tubes and other devices on which high static charges can develop.
- **Live circuits.** When diagnostic tests or calibration procedures must be conducted on energized equipment, use all appropriate electrical safety procedures. A large body of modern electronic equipment utilizes switching/regulating power supplies that are potentially lethal because portions of the internal printed circuit boards are hot at the ac power line voltage. For servicing, an isolation transformer must be used between the power mains and the equipment to reduce electric shock hazard. The hazard results from a bridge rectifier that is connected directly across the ac power mains when the equipment is energized. This condition causes the circuit board ground to be at a different potential from the ac power line neutral or Earth ground. Without the use of an isolation transformer, accidental contact between Earth ground and the circuit board ground may result in a lethal electric shock. As general practice, an individual should not work alone on energized circuits. There should always be at least one noninvolved observer who can disconnect electric power and obtain help as required in the event of an accident
- **Earth ground connections.** Never disable or remove the Earth ground connections on power cords and within equipment
- **Equipment design and modification.** All appropriate codes and guidelines should be observed, such as those promulgated by: the National Electrical Code of the National Fire Protection Association; Medical Devices Safety Act of 1971, 1973, and subsequent amendments; American National Standards Institute (ANSI); Institute of Electrical and Electronics Engineers (IEEE); American Society of Mechanical Engineers (ASME); Underwriters Laboratories (UL); Canadian Safety Association (CSA); industry standards for equipment design and manufacture; other regulations and guidelines as appropriate
- **Antenna installation.** Erection of antenna towers and antenna installation requires skilled workers. Mechanical assembly should follow good engineering practices and be in compliance with all local and federal codes. Care must be taken that overhead power lines and other electrical distribution systems are not accidentally touched by personnel, equipment or structural components. Where appropriate, structures must be correctly grounded
- **Transmitters.** The high-voltage power supplies and high-voltage radio frequency tuned circuits associated with transmitters present strong potential for electric shock. Extreme care must be taken by personnel who work in close proximity to such installations. Corona discharge to electrically conducting objects (including human flesh) that come in close proximity to energized circuits is an ever present possibility. Areas of high energy concentration, such as low radius bends in conductors, connections to high-voltage capacitors and inductors, and the like, are likely sources for corona discharge. The potential danger for both electric shock and severe radio frequency burns cannot be ignored.

High-Frequency Hazards

There are other electrical hazards in addition to direct electric shock that are associated with high-frequency equipment. It has been widely assumed that the human body is transparent to electromagnetic radiation below microwave frequencies, although there has been some discussion in the media about 900 MHz cellular telephones and human exposure to low-frequency electric/magnetic fields. Since the 1950s, it has been known that high power microwave transmitters can present extreme health hazards for any personnel who place themselves in line with the transmitting horn or antenna array. Local or generalized elevation in body temperature produced by the absorbed microwave energy can damage internal organs and produce cataracts. This phenomenon, of course, is the basis for microwave ovens.

Ungrounded conducting surfaces located in high flux electromagnetic fields can develop large induced circulating currents. When high power radar and communications transmitters are positioned in close proximity, such as on some ships, an electric discharge hazard can develop. This situation is the basis for the requirement that aircraft be electrically grounded before fueling, or arming in the case of military aircraft, and that radio transmitters be turned off in the vicinity of blasting operations. These induced circulating currents may be of sufficient intensity to activate ordinance if a discharge path is generated, and to produce serious electrical shocks in personnel. Caution should be observed when working close to energized transmitting antennas, regardless of the frequency. Nearby ungrounded conductors may be at dangerous potentials.

FIRST AID

Prevention is the best first aid for electric shock. When a person has sustained or is sustaining an electric shock, several suggested guidelines for remedial action are:

- **Shock in progress.** In the situation when an individual is sustaining an electric shock and cannot let go of the electrical source, the safest action is to disconnect the circuit. This should be accomplished by tripping a circuit breaker in the power mains supply, or by pulling the power line plug that feeds the equipment involved if this can be accomplished safely. Under no condition should the rescuer touch the victim, since the rescuer's body also may then be placed in the dangerous current path. In the event that neither the circuit breaker nor the power plug can be located, then an attempt should be made to separate the victim from the electrical source by physical means using an insulating object. The implement employed should not contain metal or other electrically conducting materials. The optimum device is a *hot stick* (with the use of insulating lineman's gloves) to pull or push the victim away from the hazard. Pulling on a hot stick normally provides more motion control than pushing. Lacking a hot stick, a wooden broom handle or wooden chair/stool may be used in an attempt to free the victim. The rescuer must use extreme caution not to touch either the victim or the shock source, and thus also become a victim. Once the victim has been completely separated from the shock source (either by disconnecting the power or by physical removal), first aid measures should be initiated immediately
- **Post-shock care with conscious victim.** In situations when the victim is conscious and moving about, convince the victim to sit or lie down. Often there is a delayed action to electric shock that causes the individual to faint or collapse. Summon the appropriate in-plant paramedical personnel immediately, or call 911. If the arrival of emergency medical personnel will be delayed, check for electrical burns and any additional immediately obvious injuries. In instances of severe electric shock, there will be burns at both the current entrance and current exit sites. These burns should be covered with (preferably sterile) dry dressings. Examine the victim for possible bone fractures and dislocations if the individual sustained spasms associated with the shock, or was violently thrown from the source (whether or not there was impact with nearby objects). As required, splints should be applied if the rescuer has appropriate training and suitable materials are available. Use a coat or a blanket to cover the victim when the environmental temperature is low, or if the individual complains of feeling cold
- **Post-shock care with unconscious victim.** In the case of an unconscious victim, summon appropriate paramedical personnel immediately. In the interim, check to see if the victim has a pulse and is breathing. Normally a pulse can be felt above the thumb joint at the inside of either wrist (radial pulse), or in the neck above and to either side of the Adam's apple (carotid pulse). It is generally preferable to check the carotid pulse, which is typically stronger and generally easier to locate than the radial pulse. The thumb should not be used to feel a pulse, but rather the index and middle fingers. Many persons have a strong thumb pulse that can be mistaken for the victim's. When a pulse can be felt but the subject is not breathing, mouth-to-mouth resuscitation should be used. If no pulse if felt (and presumably the subject is not breathing), and the rescuer has been trained in cardiopulmonary resuscitation (CPR), then the individual should be moved very carefully to a firm surface and CPR initiated. When the oxygen supply to the brain is cut off, loss of memory or permanent brain damage may occur within a few minutes even when a subject is successfully resuscitated. When a victim has been resuscitated successfully and appears to be stable, follow the previously discussed first aid procedures if there will be a delay in the arrival of paramedical personnel
- **Defibrillator use.** It is ironic that the treatment for cardiac arrest (as a result of electric shock) is a massive countershock delivered from a device called

a *defibrillator*. The massive countershock causes a massive contraction of the heart, and stills the random fluttering produced by ventricular fibrillation when it exists. When conditions are ideal, a normal heartbeat starts spontaneously following the countershock. Portable defibrillator units are available for use by paramedical personnel and other trained individuals. Even when a defibrillator unit is available, it should never be used by an untrained person. If a defibrillating shock is indiscriminately applied to an unconscious person whose heart is beating, cardiac arrest can be induced, just the condition that the instrument was designed to correct.

KEY TERMS

Atrial. Pertaining to the atrium or two reservoir chambers at the top of the heart

Cardiac. Pertains to the heart

Coagulation. The formation or production of a blood clot

Defibrillator. An electronic instrument used in an attempt to shock the heart into beating normally

Electrocardiogram (ECG). A visual record of the heart's electrical activity as recorded from electrodes placed on the body surface; also abbreviated EKG

Electrolyte. A substance that is chemically decomposed by the passage of electric current through it

Extensor muscle. A muscle that extends a joint

Fibrillation. Spontaneous and random contraction of individual muscle groups

Flexor muscle. A muscle that flexes a joint

Pacemaker. A small area of specialized tissue at the top of the heart that produces the electrical pulses that initiate heartbeats

Tetany. The state of a muscle when it is in sustained contraction

Ventricular. Pertaining to the main pump chambers of the heart

9.6

TOWER SAFETY, FALL ARREST SYSTEMS, AND OSHA

LINDA D. KELLEY
CBS CORPORATION, PITTSBURGH, PA

INTRODUCTION

Each year, workplace accidents claim the lives of thousands of workers and cause serious injuries too countless others. Sadly, many of these accidents easily could be avoided. There is no question that it is in the best interest of all employers to reduce exposure to workplace hazards. Besides protecting workers, proactive safety programs save time and money—fewer people off the job as well as lower workers' compensation costs, medical expenses, temporary replacements and salary continuance costs—and they're mandated by law.

The Occupational Safety and Health Administration (OSHA) was created in 1970, as a result of the Act which bears its name. The Act resulted in the promulgation of a series of general and specific workplace standards. Many of those standards have application in the broadcasting arena whether a small radio transmitter site or a large production facility. For example, in the area of life safety, employers are required to have clearly marked and accessible emergency exits, an evacuation plan and some form of fire protection—like sprinklers or fire extinguishers. Electrical hazards, vehicle safety, tripping hazards, asbestos monitoring and maintenance are just a few other examples of safety issues facing many broadcasting locations.

Since OSHA's formation in 1970, numerous regulatory programs have been adopted that apply to worker safety and protection in the broadcast industry.

While this chapter is limited to a review of OSHA requirements related to tower safety (fall protection and lockout/tagout), readers should be aware that there are other OSHA regulations that may apply to broadcasting operations.

Information Resources

OSHA's webpage (http://www.osha.gov) contains links to a wealth of information including the full text of standards, guidelines, technical information and frequently asked questions. (See this chapter's Appendix for details on OSHA's home page.) Also included in the Appendix are the following Code of Federal Regulations (CFR) excerpts:

- 29 CFR Part 1910 Table of Contents to General Industry Standards
- 29 CFR Section 1910.147 Lockout/Tagout requirements
- 29 CFR Section 1910.147/Appendix A Sample Lockout/Tagout Program
- 29 CFR Section 1926.502 Fall Protection Standards
- 29 CFR Part 1926 Subpart M/Appendix C Non-Mandatory Guidelines for Fall Arrest Systems
- 29 CFR Part 1926 Subpart M/Appendix E Sample Fall Protection Plan

Practical Tips

Many tower owners/operators use contractors to repair, inspect or paint their towers. In cases where the owner or operator"s employees do not climb towers, it is recommended that the towers be equipped with appropriate anchorage points only, and that contractors be required to provide their own equipment (harnesses, lanyards, lines etc.).

Owners and operators should then verify that the contractor has the right equipment to use on the tower, that its employees and sub-contractors have been trained and that the contract documents set forth the responsibilities of the parties with respect to safety standards. Be aware, however, that using a contractor or its subcontractors to perform work does not insulate tower owners and operators from the application of OSHA. (See *Case Law* section of this chapter).

Before hiring any contractor, check its safety record either by direct request to the contractor for its compliance history or through OSHA's home page.

When erecting new towers, take fall protection into consideration in the overall construction plan. Include anchorage points, work platforms, guardrails etc., in the design.

Regulatory Requirements[1]

The specific standards applicable to tower safety are fall protection standards, electrical safety standards, and general industry standards. In addition, OSHA imposes an overall "general duty" on employers to provide a safe working environment.

Fall protection applies anywhere a worker is exposed to a fall from an elevation of six feet or more. (1.8 m).[2] The fall protection standards are found at 29

[1]This review covers federal regulations only. Readers are encouraged to check for specific state standards in those jurisdictions where OSHA has approved state programs.

[2]The distance is four feet under 29 CFR 1910.268(g). (See footnote 3).

CFR Section 1926.502.[3] The applicable requirements of this standard are reflected in the fall arrest system criteria, which are reprinted in the Appendix.

The "control of hazardous energy" standards, commonly known as "lockout/tagout," are found at 29 CFR Section 1910.147. These standards apply to exposure to energy sources during servicing and/or maintenance of machines and equipment. The purpose of the standards is simple: to prevent the unexpected energizing or start up of equipment, or release of stored energy, which could cause injury to employees. The full text of the standards are reproduced in the Appendix.

General industry standards—29 CFR Part 1910—cover a wide range of activities. The table of contents to these standards is reproduced in the Appendix. All of these standards, and others, are available through the OSHA website or from the U.S. Government Printing Office.

TOWER SAFETY

The two critical elements of a tower safety program are fall protection and lockout/tagout of energized sources. The law provides that workers must be protected when required to work at elevations of six feet (1.8 m) or more. If engineering-controlled fall prevention mechanisms such as guardrails are not feasible or practicable, a personal fall protection system must be used. In addition, workers must be protected against exposure to energized sources while working on or near a tower.

This section provides an overview of fall protection plans, personal protective equipment and lockout/tagout programs. Relevant case law and enforcement actions also are included.

Guidelines for Establishing a Fall Protection System

These guidelines provide suggested components and strategies for complying with fall protection and lockout/tagout requirements. It should be noted, however, that each situation must be reviewed and evaluated to ensure all potential hazards are addressed and the correct programs are in place to ensure compliance.

Hazard Analysis

Each tower location should be evaluated to determine potential exposure to falls and the type of fall arrest system/personal protective equipment that best addresses each exposure. The evaluation should include a review of all tasks and the mobility necessary to perform those tasks. The analysis should identify any obstructions in the potential fall path and should address escape and/or rescue methods.

Feasibility of Engineering Controls

As noted previously, engineering controls, like guardrails, can be used to address some fall hazards. Towers, however, traditionally require fall arrest systems and personal protective equipment because of fall hazards associated with climbing and descending. Elevated work platforms on some towers (where a worker stands to make repairs, change lights etc.) can be equipped with railings to allow additional mobility and protection while performing those tasks.

The various types of personal protective equipment are described in detail later in this chapter.

Policy and Procedure

Written fall protection/prevention procedures should be an integral part of an employer's overall safety policy. It is not enough, however, to have a written policy on a shelf in an office. Implementation, employee awareness and enforcement of the policy are critical to its success.

A procedure should be developed for each type of potential fall hazard, with details sufficient to address the identified risks. Once appropriate training has been provided and workers are familiarized with fall arrest systems and personal protective equipment, a simple checklist can be developed and reviewed each time the equipment is used.

Written procedures should be reviewed periodically to ensure they reflect changes in the work environment, "lessons learned" etc.

Employee Training

Once a hazard analysis has been performed, written procedures developed and appropriate protection identified all employees who may be exposed to fall hazards must be trained in the procedures and the proper use of equipment.

Training should be reinforced periodically, and all new employees should be trained prior to conducting any work that might expose them to identified risks.

Training Elements

Employee training should address proper methods of equipment use, including capacity limits of equipment; anchoring and tie-off techniques; equipment inspection, storage and maintenance and emergency escape and rescue procedures.

Training aids, such as videos and instructions from equipment manufacturers, can be utilized as a component of training. Some fall protection equipment manufacturers will develop customer-specific videos. In any case, training should be tailored to the various hazard exposures and equipment being used.

[3] Although a specific industry standard exists at 29 CFR 1910.268 for "Telecommunications" (which standard does include some provisions regarding fall protection), OSHA views tower erection, alteration, repair or painting as "construction", covered under 1910.502. Therefore, readers are cautioned not to rely on 1910.268 as the *only* applicable standard to broadcasting operations. (The same is true regarding lockout/tagout of energized sources). See, e.g., 29 CFR 1910.12 (definition of "construction work"); 29 CFR 1910.268 (a)(2) (application of Telecommunications Standard). See, also, OSHA Interpretation Memos and Letters available on this subject on line through the OSHA Home Page or by written request.

In addition, OSHA has published non mandatory guidelines to assist employers in developing training programs. These and other guidelines are available through the OSHA home page and the Government Printing Office. (See the Appendix and Reference for more details).

Program Audit

All employers should conduct periodic audits to ensure that all elements of the safety program are being followed and to determine whether any modifications to the program are necessary.

Lockout/Tagout

Lockout/tagout of energy sources is a critical part of any tower safety program. This includes electric current as well as radiofrequency electromagnetic fields (RFE). Energy sources must be locked out prior to repairs or other work being performed. It is not sufficient merely to shut off electrical power or reduce RFE. The source must be locked out to prevent unknowing re-energization of the source during repairs. For that reason, a locking mechanism must be used. In addition, some form of identifying information—a "tag"—should be used to notify others when, why and by whom the source has been locked out.

Standard locks and tags can be purchased for many types of equipment. In other instances, as with certain transmitters, it may be necessary to have a locking device or hasp designed—either by the manufacturer of the transmitter or an engineer familiar with the operation of the system. It is imperative that workers not be permitted to assume that everyone involved knows that repairs are taking place. Many injuries occur because incorrect assumptions are made.

Because a tower may serve more than one operating entity, it is critical that operators develop a plan to address lockout/tagout and fall protection issues. Besides obvious safety concerns, coordination among the entities is critical to prevent exposure to civil or criminal liability (see the Case Law example).

Consideration should also be given to FCC requirements adopted on August 1, 1996, with respect to occupational exposure to RF electromagnetic fields (RF safety programs, training, warning labels etc.). (See FCC Office of Engineering and Technology (OET) Bulletin 65, Edition 97-01, August 1997 and Supplement A thereto.)

As with fall protection, a hazard analysis, written procedure and training should be performed with respect to energy sources.

FALL ARREST SYSTEMS

As noted previously, a hazard analysis should be conducted at each work location to determine the types of hazards and the best means to eliminate or minimize risk to employees or other workers. This section covers the types of equipment required by OSHA regulations to address climbing and descending hazards.

Personal Fall Protection Equipment

Personal fall protection equipment consists of body support, lanyards and lifelines, restraint lines, connectors, anchorage and tie-offs. The equipment described below meets the elements of a fall arrest system as prescribed by OSHA standards.

Body Support

Body support consists of either a body harness or a body belt. A body harness is a system of straps which, when properly secured about the user, distributes fall arrest forces over at least the thighs, pelvis, waist, chest and shoulders. Body belts, which are secured only around the waist, do not provide the level of security that a body harness gives. OSHA regulations prohibit the use of body belts after January 1, 1998. Keep this in mind when updating an existing fall protection system or developing a new one.

Lanyards and Vertical Lifelines

A lanyard is a flexible line with a connector at each end to connect the body harness to a deceleration device or lifeline. Lifelines can be vertical or horizontal. A vertical lifeline is a flexible line used for connection to an anchorage at one end. Vertical lifelines should be limited to one user per line. Horizontal lifelines are connected between fixed anchor points on the same level. Horizontal lifelines are designed to minimize the potential for pendulum-like swing falls. Horizontal lifelines should be designed, installed and used under the supervision of a qualified person as part of a complete personal fall arrest system, which maintains a safety factor of at least *two.* (A "qualified person" is a professional who can identify hazardous conditions in all aspects of a fall protection program, including application and use of related equipment.)

OSHA regulations require the following with respect to the use of lanyards and lifelines:

- Each employee should have a separate vertical lifeline with a minimum breaking strength of 5,000 lbs (2,268 kg)
- Self-retracting lifelines and lanyards which automatically limit free-fall distance to two ft (.6 m) or less should be capable of sustaining a minimum static tensile load of 3,000 lbs (1,361 kg) applied to the device with the lifeline or lanyard in the fully extended position
- Lifelines and lanyards should not be constructed of natural fibers
- Lanyards should be constructed with at least 0.5 in. (1.27 cm) diameter synthetic rope with a length which limits the opportunity to fall to no more than six ft (1.8 m).

Restraint Lines

Restraint lines may extend from an anchorage or between anchorages to which an employee is secured to prevent a fall from an elevated work surface. Restraint lines should be capable of sustaining a tensile load of at least 3,000 lbs (1,361 kg).

Connectors

Connectors are the devices used to couple parts of the system together, such as "D" rings and snap hooks. A locking snap hook is a connector that requires two separate forces to release it. Locking snap hooks are used to prevent rollout or accidental disengagement.

OSHA regulations require that connectors meet the following criteria:

- Corrosion-resistant finish with smooth surfaces and edges
- Dropped forged, pressed, formed steel or equivalent construction
- Capable of sustaining a minimum tensile load of 5,000 lbs (2,268 kg)
- "D" rings and snap hooks should be tested to a minimum tensile load of 3,600 lbs (1,633 kg) without cracking, breaking or sustaining permanent deformation
- Locking snap hooks should require two separate forces to disengage.

OSHA regulations prohibit the use of non-locking snap hooks as a part of a personal fall arrest system effective January 1, 1998.

Anchorage

An anchorage is a secure point of attachment for lifelines or lanyards that is not a part of the working surface or equipment rigging points. Anchorage points are the key to designing an effective fall protection and arrest system. The strength and utility of the system is based on an anchoring system that will support each of the system's component parts. Therefore, anchorage points should meet the following criteria:

- Capable of supporting at least 5,500 lbs (2,495 kg) per employee using the system
- Designed, installed and used under the supervision of a qualified engineer as part of a complete fall protection system which maintains a safety factor of at least two.

Tie-Offs

A tie-off is the method to connect a user to an anchorage. The following should be considered when placing tie-offs:

- The attachment point to the lifeline or anchor should be located at or above the connection point of the fall arrest equipment to the body harness to ensure a free fall distance of no greater than six feet (1.8 m)
- Obstructions in the potential fall path should be considered when locating a tie-off
- Special provisions need to be made when tying off around an "H" or "I" beam, as the cutting action of the beam edges can reduce system strength by as much as 70%.

(See OSHA guidelines for more details on tie-offs, anchorage, lanyards and other system components.)

Overall System Criteria

A personal fall arrest system should meet the following criteria when stopping a fall:

- Arresting force on user should be limited to 1,800 lbs (816 kg) when used with a body harness
- System should bring user to a complete stop and limit maximum deceleration distance to 3.5 ft (1.1 m)
- System should have sufficient strength to withstand twice the potential impact energy of a user free-falling a distance of six feet (1.8 m) or the free-fall distance permitted by the system, whichever is less
- The attachment point of the body harness should be located in the center of the user's back near shoulder level or above the user's head.

Additional Criteria for Climbing Activities

In addition to the minimum criteria established here, climbing activities require the following system capabilities:

- The user should be able to ascend or descend without the need to continually hold, push or pull any part of the system
- The connection between the lifeline and the point of attachment to the body harness should not exceed nine inches (22.9 cm) in length
- The arrest system should activate within two feet (.6 m) when a fall occurs.

Mountings for rigid carriers should be attached at each end of the carrier. Cable guides used with flexible carriers should be installed no less than 25 ft (7.6 m) and no more than 40 ft (12 m) apart along the length of the carrier.

Ladder safety devices and related support systems should be capable of withstanding a test, without failure, of a 500 lb (227 kg) weight over an 18 in. (45.7 m) drop.

All other personal fall protection systems for climbing activities should be capable of withstanding a test, without failure, of a 250 lb (113 kg) weight over a four foot (1.2 m) drop.

Any fall protection system component that is subjected to impact loading should immediately be removed from service and not reused until it has been inspected and determined by qualified personnel that it is not damaged and is suitable for its intended use.

Inspection and Maintenance

To ensure protection, fall arrest systems should include routine inspection and maintenance. As with other procedures, a written checklist should be developed for use in the inspection and maintenance program. Key elements of the program include:

- System components (safety harnesses, lanyards etc.) should bear identification of the supplier and include the date of manufacture, as well as the OSHA standard to which it was constructed (29 CFR Section 1926.502(e)(5) minimum tensile load for D-rings

and snap hooks). The supplier should certify that the equipment meets the minimum requirements of the appropriate standard
- The manufacturer's instructions should be incorporated into maintenance and inspection (including cleaning) procedures
- Prior to each use, the equipment should be inspected for mildew, wear, damage or other deterioration
- Equipment should be stored in a cool, dry place, protected from UV exposure and the elements
- Equipment should be easily accessible to trained users
- Documented inspections of all protection equipment should occur every six months. (Some manufacturers provide an inspection and recertification service)
- Permanent anchorage points should be inspected periodically by a qualified engineer and immediately following an accidental fall arrest
- Testing should not be permitted when the equipment is in service.

Escape and Rescue

Having a fall protection or lockout/tagout system or procedure is not enough. The law requires employers to address the means by which an employee will be rescued once the exposure occurs. Rescue considerations are part of the OSHA standards (See, for example, 29 CFR Section 1926.502(d)(20) which requires that "the employer shall provide for prompt rescue of employees in the event of a fall or shall assure that employees are able to rescue themselves.") Whether the rescue system is provided directly by the employer, by a contractor or through a local fire department or other emergency team, a rescue plan must be in place in advance of conducting the work.

CONCLUSION

The importance of tower safety programs cannot be overstated. The bottom line is to have a safety program and to enforce it.

RECENT CASE LAW; CIVIL AND CRIMINAL ENFORCEMENT

Employers who violate OSHA standards are subject to civil and/or criminal enforcement. Following are some recent examples of enforcement actions.

Civil Enforcement

An Ohio painting company was cited in February 1997, for willful and serious violations of OSHA requirements by exposing employees to a 183 ft (55.8 m) fall hazard. The citation arose from an accident that left one of the workers paralyzed. Penalties were assessed for $178,000.

On July 2, 1997, it was reported that a Colorado steel company received citations for 61 violations with proposed penalties of $1.1 million (or just over $18,000 per citation). Eight willful citations were issued for items including fall protection and electrical components. Thirty-seven serious violations were identified relating to such things as defective ladders, tripping hazards, blocked exits, electrical components and wiring; 16 repeat violations were included for unguarded floor holes, blocked exits etc.

On August 15, 1997, federal officials levied a fine in excess of $200,000 against a wholesale distributor of doors as a result of a fatal fall suffered by one of the distributor's workers earlier in the year.

The steel erection contractor at Guam International Air Terminal was issued citations and proposed penalties of $8,260,000 for 118 alleged willful violations of fall protection requirements, after a welder fell 65 ft (19.8 m) to his death on March 28, 1995. A settlement was reached in the amount of $1.85 million.

A Texas tower services company was cited for seven serious violations and fined $29,400 for the October 12, 1996 collapse of a TV tower, which killed three men. The family of at least one of the men has sued the company for monetary damages in connection with the incident.

A construction company received six citations and was assessed penalties of $85,000 following an accident in which an employee was electrocuted. The man was killed when the raised boom on his flatbed truck came into contact with overhead power lines.

Another construction company—inspected 16 times in six years—was fined $299,000 for willful violations of fall protection and electric hazard requirements.

Among OSHA's list of the six top egregious cases for 1996 were the following: A Texas bakery was assessed $1,040,000 for willful violations of, among others, lockout-tagout standards; an Indiana steel erector was fined $396,200 after the death of a worker who fell 35 ft; a Boston construction company was assessed $770,000 after the death of one of its subcontractor's employees in a fall (the subcontractor was fined $448,000).

If you think broadcasters are immune to such civil action, think again. A Mississippi TV production manager was electrocuted while setting up a live shot outside a local city hall. He had touched the side of the station's van, unaware that its boom antenna was touching an 8,000 V electrical wire. A few months earlier another station employee was electrocuted while working on the station's tower. OSHA's findings on these incidents had not been published when this chapter was submitted.

The *Florida Times-Union* reported a worker's death on October 14, 1997, in Jacksonville. The 28-year-old man was pronounced dead at the scene where he had been painting a billboard. He apparently had been electrocuted by nearby power lines and fell to the ground.

On October 23, 1997, the *Commercial Appeal Memphis,* TN reported that three men were killed when a 2,000 ft (.6 km) TV tower in Raymond, MI twisted and toppled to the ground. The workers were adjusting the guy wires when the accident occurred. One of the men was about 1,500 ft (.5 km) up when he radioed to others on the ground that "the tower is crumbling, get out of the way," just before falling to his death. OSHA investigations into this incident were anticipated as this book went to press.

Criminal Enforcement

In addition to civil penalties, employers are subject to criminal enforcement under certain circumstances. Here are a few examples of recent criminal actions:

On June 26, 1997, the owners of a South Carolina radio transmission company were sentenced to three months in prison for committing willful violations of OSHA. The incident in question involved the death of an employee who fell 150 ft (45.7 m) from a communications tower. The employee was not properly trained and was not provided with personal protective equipment. (U.S. v. Smith, DC MFla., No. 97-71-CR-J-21A).

In October, 1997, a Wisconsin jury convicted a malting company in the death of a worker who fell 100 ft (30.5 m) from a fire escape outside a grain elevator. The U. S. magistrate who imposed the fine of $450,000 following the guilty verdict cited "decades of indifference" on the part of the employer, and further stated that he wanted to send a message to "corporate America . . . that deliberate indifference to worker safety should come at high cost." At the time of sentencing, 31 other OSHA violations were pending in civil court against the company. (*Milwaukee Journal Sentinel,* December 18, 1996).

Case Law

On April 21, 1997, the *New Jersey Law Journal* reported that a former construction worker would receive $3.6 million from a settlement of his claim against Sea Isle City. The 32-year-old worker was rendered paraplegic in a fall. The complainant in the case alleged that the accident could have been prevented if there had been barriers, harnesses and other fall protection equipment.

The *Bureau of National Affairs, Boston,* reported on April 2, 1996 that five Boston firms agreed to pay $2.7 million to the family of a worker killed in the Boston Harbor cleanup project. The worker was crushed between two concrete sections being moved into place by a crane. In addition to the civil settlement with the four sub-contractors, a workers' compensation settlement was reached with the deceased's employer, the general contractor.

An OSHA official who investigated the case called the death "totally, absolutely, completely, and easily preventable." OSHA cited the employer, who paid penalties of $195,497, as well as the company that leased the crane, which paid $38,000 in penalties.

Controlling Employer Theory

OSHA uses a *controlling employer* or *multiple employer* theory to hold owners/operators liable for OSHA violations in addition to those imposed on the worker's actual employer. A prime example of this was reported by the *Bureau of National Affairs, Washington,* on May 12, 1997. The Occupational Safety and Health Review Commission (OSHRC) held an owner responsible for violations created by its independent contractor. The owner failed to ensure that its contractor followed lockout/tagout procedures during nightly cleaning of machinery at the owner's plant. The OSHRC found that the owner had supervisory authority and control over the work site and, although it was not the employer, the fact that it owned the hazardous equipment gave it responsibility to do what was "reasonably expected" to prevent the hazardous conduct. According to the OSHRC, "hazardous conduct by another employer's employee clearly is not beyond the reasonable control of all but the actual employer." (Secretary of Labor v. IBP Inc., OSHRC, No. 93-3059, 4/18/97).

It is important to note that, in addition to the OSHRC's ruling in this case and others there also exists in common law a theory of recovery against property owners for exposure of others to hazardous conditions on the property. The OSHRC's ruling and the common law theory pose a significant threat to broadcast owners/operators since liability is not limited to workers' compensation benefits as in the traditional employer-employee relationship.

9.7
DISASTER RECOVERY FOR BROADCAST FACILITIES

RICHARD RUDMAN
RADIO STATION KFWB, LOS ANGELES, CA

INTRODUCTION

Disaster planning and recovery is at once an art, a science and a technology. Disaster planners have their own professional groups and certification standards. If the resources are available, hiring a professional is a wise course of action. No matter who develops your disaster recovery strategy, an essential part of the process will be a written plan that will be periodically tested.

PREPAREDNESS 101

The private sector can learn from government emergency professionals, who recognize that *preparedness* is only the starting point of a continuous cycle.

The second step is the actual *response* to an emergency. *Recovery* comes third after immediate safety issues and other dangers are under control. The emphasis is restoring things to what passes for normal. The last phase is *mitigation* when the lessons of the emergency are studied. These lessons are applied as the circle is completed to another round of preparedness.

What Do You Prepare For?

Disaster planners think in terms of realistic risk. Simply put, it means do not spend as much time and effort planning for floods if the primary risk is earthquakes and the facility is on high ground. Those that have lived in an area for some time, will already have a fair idea of the greatest risks. If new to a region, research is a must. Be wary of advice from those who have lived there for awhile. They may overlook something that could be a significant risk. For instance, there are no 150-year-old transmitter sites. Long-term risks like 100- or 150-year floods may not have even been considered when the site was designed.

How Do You Prepare?

Disaster planners know that there are certain elements common to many types of preparedness. Both floods and earthquakes can isolate victims from utilities, supermarkets and emergency medical assistance.

Responsibility for Preparedness

Local emergencies can easily be triggered by preventable failures in air supply systems, roof leaks or uncoordinated telephone, computer or ac wiring changes. Seemingly harmless acts, such as employees plugging electric heaters into the wrong ac outlet, have brought down entire facilities.

Broadcast engineers should have responsibility (if not direct supervision of) the environmental infrastructure of broadcast facilities. This includes studios and transmitter sites. Without this critical element that tightly couples oversight to responsibility, critical electronic systems will be at the mercy of whomever or whatever controls the environment. Without responsibility, essentials such as proper installation practices, preventive maintenance, training and testing may fall by the wayside.

STARTING YOUR PLANNING PROCESS

Disaster recovery will be an easier task if some level of preparedness is in place. The process begins with a realistic risk assessment. The list should identify hazards based on local conditions.

Include the likelihood that threats from present or former employees who may hold grudges could turn into violent actions. Listeners and viewers sometimes get mad at broadcasters. Consultation with both the programming and security departments is strongly recommended. Some things to consider might be:

- Are there any nearby manmade hazards such as airports or chemical plants?
- What about nearby buried pipelines?
- What about the construction of the facility?[1]
- What hazardous materials are stored on the premises?
- Do not forget the obvious hazards like compressed gas cylinders and fuel for the emergency generator.

Risk Assessment and Business Survival

Once the list of realistic risks has been compiled, decide what to do to protect the staff and the facility. Preparedness depends on top management commit-

[1] Information from the Northridge, CA earthquake could rewrite seismic building codes for many types of structures. The Northridge quake showed that some high-rise structures thought to be quake-safe are not. Designers should be aware that seismic building codes usually allow for safe evacuation. They do not embody design criteria to prevent major structural damage. Quake-safe is not necessarily quake-proof.

ment. Without high-level support, funding and time to do proper preparedness will be hard to come by. Write a thoroughly researched report to top management in non-technical language. Relate risks to time off the air, potential for injury or death to staff or audience and potential damage to community image. Consider what 24 or more hours off the air would do to drive time ratings.

Adding Your Skills

Part of this process will rely on your broadcast engineering trouble-shooting skills and senses. Do not overlook the obvious. Computers, transmitters and telephone equipment depend on cool air. How long can they continue to operate during a heat wave if the one central building air system fails?

Take Practical Precautions

Preparedness should be considered in the same light as an insurance policy—the greater the risk, the higher the premium. Some communications facilities in earthquake country have three diesel generators and three air handling systems. Quake-resistant buildings sometimes rest on huge rubber isolators at the base of each supporting column.[2] These isolators can protect the structure and its contents from the most violent types of lateral movement during earthquakes. Proper seismic design and preparedness may be expensive or impossible for existing facilities, but may add no more than 10% to construction costs of a new building.

The Business Resumption Plan

A formal written *business resumption plan* (BRP) is just as important as an organization's written disaster plan. Some experts argue that the written disaster plan and the BRP should be formulated, tested and updated in concert. The prime directive: When disaster strikes, the first concern of an organization must be for the safety of its employees, customers, vendors and visitors.

The BRP is activated only when the basic requirements of life safety have been fulfilled. A BRP is a template to perform damage assessments, salvage operations, emergency restoration and, if needed, relocation of critical functions.

The focus of business resumption planning is maintaining or resuming core business activities following a disaster. The major goal of any BRP is resumption of production and delivery, customer service and notification and cash flow. In broadcasting, it begins with getting back on the air under adverse conditions when a facility is impaired.

What a BRP Can Do for You

A comprehensive and well designed BRP can accelerate recovery, thereby saving time, money and jobs. A good BRP is an insurance policy, if not a major investment. The following actions are the backbone of a BRP:

- Conduct a *business impact analysis* (BIA)[3]
- Promote employee buy-in and participation
- Seek input starting at the lowest staff levels
- Build a recovery strategy
- Build a validation process and testing procedure
- Assure a continuous update of the BRP.[4]

An Ounce of Prevention

While the title of this chapter incorporates the word *recovery*, the reader will not find a specific list of things to do that will magically prevent fatalities or injuries that have already taken place, or reconnect wiring to equipment lying on the floor in pieces. If faced with rehabilitating a facility where there has been no preparedness, competent broadcast engineers will eventually get the facility back on its feet. If you are faced with such a prospect, your main resource will be your ability to reach out to suppliers and other who you will need to begin the rebuilding process. Emergencies sometimes make this more difficult since others who have planned ahead may have written agreements in place with the very assets you may need on short notice. Roads may be impassible, limiting delivery possibilities. Recovery in such cases is not impossible; it just takes a lot longer. There is a lesson here you can convey to your owner or general manager.

Workplace Safety

Employers must always ensure safety in the workplace at all times. Some states like California have passed legislation that mandates that most employers identify potential hazards and protect their workers. Natural emergencies create special hazards that can maim or kill. A strong foundation of day-to-day safety can lessen the impact of major emergencies. For instance, assuring that plate glass in doors has a safety rating could avoid an accidental workplace injury, as well as compounding injuries during a major disaster.

Our Special Hazard

Special and dangerous hazards are found in the information and communications workplace. Tall equip-

[2] These rubber shock mounts are sometimes called base isolators. They are built using laminated layers of neoprene rubber and metal. The new Los Angeles County Emergency Operations Center is designed for 14 in. of lateral movement from normal or a bit more than 28 in. of total movement in one axis. The entire structure floats on 26 of these base isolators, designed to let the earth move beneath a building during an earthquake, damping transmission of rapid and damaging acceleration.

[3] A proper Business Impact Analysis (BIA) should yield the answer to the question of what level of damage your operation can sustain and still operate. When the cost of protecting against an emergency exceeds the benefit derived from protection, the law of diminishing returns sets in. It is far beyond the scope of this chapter to go into more detail on the BIA process.

[4] Thanks to Mary Carrido, President, MLC & Associates of Irvine, CA, for core elements of business resumption. It is far beyond the scope of this chapter to go into more detail on the BIA process.

ment racks are often not secured to floors, much less secured to load-bearing walls. Preventing equipment racks from tipping over during an earthquake may avoid crippling damage to both systems and people. Bookcases and equipment storage shelves should be secured to walls. Certain objects should be tethered, rather than firmly bolted. While securing heavy objects is mostly common sense, consult experts for special cases. Do not forget seismic rated safety chains for heavy objects like TV studio lights and large speakers.

Computers and monitors are usually not secured to work surfaces. A sudden drop from workstation height would ruin the day for most computers, video monitors and their users. Special Velcro® quick-release anchors and fasteners can support the entire weight of a personal computer or printer, even if the work surface falls over.

Bolting workstations to the floor and securing heavy equipment with properly rated fasteners can address major seismic safety issues. *G* forces[5] measured in an upper story of a high-rise building during the Northridge, CA, quake were greater than 2.7 times the force of gravity. A room full of unsecured workstations could do a fair imitation of a slam dance contest, even at lower accelerations. Cables can be pulled loose, monitors can implode and delicate electronics can be smashed into scrap. Even if your region has not been affected by seismic activity, consider that some parts of the earth have been given a long overdue rating by respected seismologists.

Glass Houses

Many local building codes now call for shatterproof glass for sliding doors and windows in homes and businesses. Large plate glass windows, including those used in studios, can become killers during major emergencies. A moment magnitude 7.4 earthquake can lethally hurl dagger-line shards from untreated plate glass windows through the air.[6] Extreme wind pressures during hurricanes can have a similar effect. The solution—purchase shatterproof glass or retrofit. Several companies manufacture a special film coating that can be applied to existing non-safety plate glass. This film will hold the glass together to reduce the danger of flying fragments.

Safety Maintenance

Maintaining safety standards is difficult in any size organization. A written safety manual outlining specific practices and procedures for normal workplace hazards as well as emergency-related hazards is not only a good idea, it may lower your insurance rates. If outside workers set foot in your facility, prepare a special safety manual for contractors. Include in it installation standards, compliance with *Lock-Out/Tag-Out*[7] and emergency contact names and phone numbers. Make sure outside contractors carry proper insurance and are qualified, licensed or certified to do the work for which they have been contracted.

RESCUE PLANNING FOR DIRE EMERGENCIES

When people are trapped and professionals cannot get through, our first instinct may be to attempt a rescue. More people are injured or killed in rescue attempts during major emergencies than are actually saved. Experts in Urban Search and Rescue (USAR) not only have the know-how to perform their work safely, they also have special tools that make this work possible under impossible conditions. The *Jaws of Life*, hydraulic cutters used to free victims from wrecked automobiles, is a common USAR tool. Pneumatic jacks can lift heavy structural members in destroyed buildings to free trapped people.

As a broadcast engineer you may never be faced with a life or death decision concerning a rescue when professionals are not available. However, those in the facilities you are responsible for may be faced with tough decisions. Consider that your planning could make their jobs easier or infinitely more difficult. Also consider recommending USAR training for those responsible for on-line management and operations of the facilities as a further means to ensure readiness.

The Recovery Process

The disaster has happened. Fatalities have been identified and the injured are being given first aid. What happens next?

Facility Integrity: Roof, Walls and Floor

A qualified person must first inspect the facility to make sure that it is safe. If you have just experienced the full effects of a hurricane or significant earthquake, damage may or may not be obvious. Most construction codes provide only that a structure must be built strong enough to allow evacuation without loss of life or

[5] One *G* is equal to the force of earth's gravity. An acceleration of 2 *Gs* doubles the effective force of a person or object in motion and nullifies the effectiveness of restraints that worked fine just before the earthquake. Force = (Mass) × (Acceleration). Seismic accelerations cause objects to make sudden stops—60 to zero in one second.

[6] The Richter Scale is no longer used by serious seismic researchers. Moment magnitude calculates energy release based on the surface area of the planes of two adjacent rock structures (an earthquake fault) and the distance these structures will move in relation to one another. Friction across the surface of the fault holds the rocks until enough stress builds to release energy. Some of the released energy travels via low frequency wave motion through the rock. These low frequency waves cause the shaking and sometimes violent accelerations that occur during an earthquake. For more on modern seismic research and risk, please refer to the bibliography for this chapter.

[7] *Lock-Out/Tag-Out* is a set of standard safety policies that assure that energy is removed from equipment during installation and maintenance. It ensures that every member of a work detail is clear before power is reapplied.

serious injury. You may be faced with the ultimate irony of a building that meets all local code provisions for an earthquake but may be rendered unsafe by the actual event.

Circumstances Beyond Your Control

Serious and obvious damage may result in a revocation of your building occupancy permit. You may not even be allowed in the facility to remove broadcast equipment. Do you have a contingency plan in place for an alternate studio site? A remote truck may be your only resort. Consider installing a locked access box outside the building where you may be able to connect to your microwave or phone company provided studio transmitter link (STL).

Basic Assumptions

Assuming your facility is intact or you have a contingency plan to get a signal on the air, what other considerations come into play during recovery? Your critical considerations can range employee morale to erecting an emergency antenna or getting your computer system working again.

Outside Plant Communications Links

Your facility may be operational, but failure of a wire, microwave or fiber communications link could be devastating. All outside plant links discussed in the following section presuppose proper installation. For wire and fiber, this means adequate *service loops* (coiled slack) so quake and wind stresses will not snap taut lines. It means that the telephone company has installed terminal equipment that will not fall over in a quake or be easily flooded out. A range of backup options is available.

Outside Plant Wire

Local telephone companies still use a lot of wire. If your facility is served only by wire on telephone poles or underground in flood prone areas, you may want what the telephone industry calls *alternate routing*. Alternate routing from your location to another central office (CO) may be very costly since the next nearest CO is rarely close. Ask to see a map of the proposed alternate route. If it is alternate only to the next block or duplicates your telephone pole or underground risk, the advantage you gain will be minimal.

Essential Service Designation

Most telephone companies can designate an *essential service*—a limited block of telephone numbers at a given location for lifeline communications. Lines so designated are usually found at hospitals and public safety headquarters. Contact your local phone company representative to see if your facility can qualifies. Many broadcasters who have close ties to local government emergency management should qualify easily.

Public Pay Telephones Are Essential

Inform your news departments that pay phones in public areas are at the top of the priority list for restoration by phone companies. This is not true of private pay phones or pay phones not located in public areas.

Dial Tone Trivia

Most broadcast engineers are aware of the basics of the telephone system in use in the United States. What they may not know is that the luxury of getting dial tone the instant they pick up a telephone instrument is not the norm in many parts of the world. The lesson: If you pick up an instrument properly connected to an outside line and detect side tone, you will eventually get a dial tone.[8] Jiggling the hook switch or hanging up will delay your access to an available dial tone. Patience is not just a virtue you need to teach those having to make emergency calls; it is a necessity.

Microwave Links

Wind and seismic activity can cause microwave dishes to go out of alignment. Quake-resistant towers and mounts can help prevent alignment failure, even for wind-related problems. Redundant systems should be considered part of your solution. A duplicate microwave system might lead to a false sense of security. Consider a non-microwave backup such as fiber for a primary microwave link. Smoke, heavy rain and snowstorms can cause enough path loss to disable otherwise sound wireless systems.

When a major link failure does occur, you ideally will have recorded ahead of time azimuth and elevation readings that will enable more rapid restoration. A stock of emergency restoration hardware, including brackets, bolts and short tower sections is a wise precaution. An alternate STL path, even telephone lines, can likewise be prudent insurance.

Fiber Optics Links

If you are not a fiber customer today, you will be tomorrow. Telephone companies will soon be joined by other providers (including cable) to seek your fiber business. You may be fortunate enough to be served by separate fiber vendors with separate fiber systems and routing to enhance reliability and uptime. Special installation techniques are essential to ensure fiber links will not be damaged by earth movement, subject to vandalism or vulnerable to single-point failure.[9]

---

[8] If you blow or talk into the telephone transmitter and hear yourself in the receiver, what you hear is called side tone. Telephone systems provide a small amount of feedback so users can judge their voice levels. Side tone depends on dc voltage on the line, an almost 100% sign that the line is connected all the way back to your first phone company Central Office. Connection beyond that point will of course depend on the integrity of the rest of the public switched network (PSN).

[9] Single point failure can occur in any system. Single point failure analysis and prevention is based on simple concepts: A chain is only as strong as its weakest link, but two chains, equally strong, may have the same weak link. The lesson may be make one chain much stronger, or use three chains of material with different stress properties.

Fiber should be installed underground in a sturdy plastic sheath called an interliner.[10] This sheath offers protection from sharp rocks or other forces that might cause a nick or break in the armor of the cable or actually sever one or more of the bundled fibers. Systems that only have aerial rights-of-way on utility poles for their fiber may not prove as reliable in some areas as underground fiber. Terminal equipment for fiber should be installed in quake-secure equipment racks away from flooding hazards. Fiber electronics should have a minimum of two parallel dc power supplies that are in turn paralleled with rechargeable battery backup.

Sonet® technology is a proven approach you should look for from your fiber vendor. This solution is based on topology that looks like a circle or ring. A fiber optics cable could be cut just like a wire or cable. A ring-like network will automatically provide a path in the other direction, away from the break. However, fiber installations that run through unsealed access points such as manholes can be easy targets for terrorism or vandalism.

Satellite

Ku- or C-Band satellite is a costly but effective way to link critical communications elements. C-Band has an added advantage over Ku during heavy rain or snowstorms. Liquid or frozen water or thick smoke can disrupt Ku-Band satellite transmission. A significant liability of satellite transmission for ultra-reliable facilities is the possibility that a storm or major fire could cause a deep fade, even for C-Band links. Another liability is short but deep semi-annual periods of *sun outage* when a link is lost while the sun is focused directly into a receive dish. While these periods are predictable and last for only a minute or two, there is nothing that can prevent their effect unless you have alternate service on another satellite with a different sun outage time or a terrestrial backup.

EMERGENCY POWER

Uninterruptible power supplies (UPS) are now common in the information workplace. From small UPS that plug into wall outlets at a personal computer work station to giant units that can power an entire facility, they all have one thing in common—batteries.

UPS Systems

UPS batteries must be tested regularly. Once exceeded, a UPS battery is nothing more than an expensive door stop. Allow the UPS to go on-line to test it. Some UPS test themselves automatically. Routinely pull the UPS ac plug out of the wall for a manual test. Some UPS applications require hours of power, while some only need several minutes.

While UPS provide emergency power when the ac mains go dead, many are programmed with another electronic agenda. They protect the plugged in devices from *bad power*. Many diesel generators in emergency service are not sized for the load they have to carry nor do they have proper power factor correction. Computers and other devices with switching power supplies can distort ac power waveforms. The result: power degraded to the point that a smart UPS will not trust it. The solution may be as easy as using a less educated UPS if the equipment being protected can tolerate it.

After a UPS comes on-line, it should go back to sleep after the emergency generator picks up the load and charges its batteries. If it senses the ac equivalent of poison, it stays on or cycles on and off. Its battery eventually runs down and it crashes. The best defense is to test your entire emergency power system under full load. If a UPS cycles on and off to the point that its batteries run down, you must find the cause. Consult your UPS manufacturer, service provider or service manual to find out if your UPS can be adjusted to be more tolerant. Some UPS cycling cannot be avoided with engine-based emergency power, especially if heavy loads like air conditioner compressors switch on and off-line.

Generator Testing

Technicians sometimes believe that starting an emergency generator without equipment load is an adequate weekly test. If your generator is diesel-driven, this may lead to *wet stacking*. Wet stacking occurs when a generator is run repeatedly with no load or a light load. When the generator is asked to come on-line to power a full equipment load, deposits that build up during no-load tests prevent it from developing full power under load. Use the load the diesel has to carry during an emergency to run the test. If that is not possible, obtain a resistive load bank to simulate a full load for an hour or two of hard running several times per year.

Fuel Considerations

Fuel stored in tanks gets old. Old fuel is unreliable. Gum and varnish can form and fuel begins to break down. Certain forms of algae can grow in diesel oil. Fuel additives can extend the storage period and prevent algae growth. A good filtering system and a planned program of cycling fuel through it can extend storage life dramatically. Individual fuel chemical composition, fuel conditioners and the age and type of storage tank all affect useful fuel life.

There are companies that will analyze fuel. If necessary, they can filter out dirt, water and debris that can rob the engine of power. The cost of additives and fuel filtering is nominal compared to the cost of new fuel plus hazardous material disposal charges for old fuel. Older fuel tanks can spring leaks that either introduce water into the fuel or introduce costly hazardous materials clean-up projects. The tank will be out of service while it is being replaced.

[10] Interliners are usually colored bright orange to make them stand out in trenches, manholes and other places where careless digging and prodding could spell disaster.

Generator Maintenance

Most experts recommend a generator health check every six months. Generators with engine block heaters put special stress on fittings and hoses. Vibration can loosen bolts, crack fittings and fatigue wires and connectors. If your application is critical, a second generator may give you a greater margin of safety. Your generator maintenance technician should take fuel and crankcase oil samples for testing at a qualified laboratory. The fuel report will let you know if your storage conditions are acceptable. The crankcase oil report might find microscopic metal particles, which are an early warning of a major failure.

Mission dictates need—need dictates reliability. If the design budget permits, a second or even third emergency generator is a realistic insurance policy. When you are designing a facility you know must never fail, consider redundant UPS wired in parallel.[11] During major overhauls and generator work, make sure you have a local source for reliable portable power. High-power diesel generators in wheels are commonly used to supply field power for events from rock concerts to movie shoots. Check your local phone directory for listings under *Generators—Electric or Emergency Lighting Equipment.* If you are installing a new diesel, remember that engines over a certain size may have to be licensed by your local air quality management district. Permits must be obtained to construct and store fuel in an underground tank.

AIR HANDLING SYSTEMS

Clean, cool, dry and pollutant-free air in generous quantities is critical for modern communications facilities. If you lease space in a high-rise, you may not have your own air system. Many building systems often have no backup, are not supervised nights and weekends and may have uncertain maintenance histories.

Your best protection is to get the exact terms for air conditioning detailed in your lease. You may wish to consider adding your own backup system, a costly but essential strategy if your building air supply is unreliable or has no backup. Several rental companies specialize in emergency portable industrial-strength air conditioning. An emergency contract for heating, ventilating and air conditioning (HVAC) that can be invoked with a phone call could save you hours or even days of downtime. Consider buying a portable HVAC unit if you are protecting a critical facility. Do not forget to have several hundred feet of inexpensive flexible ducting and a lot of duct tape available in advance.

Wherever cooling air comes from, there are times when you need to make sure the system can be forced to recirculate air within the building, temporarily becoming a closed system. Smoke or toxic fumes from a fire in the neighborhood can enter an open system. Toxic air could incapacitate your staff in seconds. With some advanced warning, forcing the air system to full recirculation could avoid or forestall calamity. It could buy enough time to arrange an orderly evacuation and transition to an alternate site.

[11] Consult the vendor for details on wiring needs for multiphase parallel UPS installations.

Emergency Actions

If no recirculation function is designed into the system, be prepared to shut it down for as long as possible. This may buy time to force the outside dampers closed or allow the outside source of polluted air to dissipate.

WATER HAZARDS

Water in the wrong place at the wrong time can be part of a larger emergency or be its own emergency. A simple mistake like locating a water heater where it can flood out electrical equipment can cause short circuits when it finally wears out and begins to leak. Unsecured water heaters can tear away from gas lines, possibly causing an explosion or fire during an earthquake.

Floods

Your facility may be located near a source of water that could flood you out. Many businesses are located in flood plains that see major storms once every 100 or 150 years. If you happen to be on watch at the wrong time of the century, you may wish that you had either located elsewhere or that you had stocked a very large supply of sandbags in advance. Remember to include any wet or dry pipe fire sprinkler systems as potential water hazards.

Water and electricity create a special hazard to you and your staff. Do not trust rubber gloves, rubber rainwear or other protective great. Always play it safe and disconnect power when working around flooded areas.

ELECTROMAGNETIC PULSE PROTECTION (EMP)

The EMP phenomenon associated with nuclear explosions can disable almost any component in a communications system. EMP energy can enter any component or system coupled to a wire or metal surface directly, capacitively or inductively. Some chemical weapons can produce EMP, but on a smaller scale.[12]

FEMA and EMP

The Federal Emergency Management Agency (FEMA) has been involved in EMP protection since 1970 and is the Federal agency charged with the overall direction of the EMP program. FEMA provides de-

[12] FEMA publishes a three-volume set of documents on EMP referenced in the bibliography, they cover the theoretical basis for EMP protection, protection applications and protection installation.

tailed guidance and, in some cases, direct assistance on EMP protection to critical communications facilities in the private sector. AM, FM and TV transmitter facilities that need EMP protection should discuss EMP protection tactics with a knowledgeable consultant before installing protection devices on radio frequency (RF) circuitry. EMP devices such as gas discharge tubes can fail in the presence of high RF voltage and disable the facilities they are supposed to protect.

ALTERNATE SITES

No matter how well you plan, something still could happen that will require you to abandon your facility for some period of time. Government emergency planners usually arrange for an alternate site for their Emergency Operations Center (EOC). Communications facilities can sign mutual aid agreements. Sometimes this is the only way to access telephone lines, satellite uplink equipment, microwave or fiber on short notice. If management shows reluctance to share, respectfully ask what they would do if their own facility is rendered useless.

Security

It is a fact of modern life that disasters caused by humans must now be considered in the planning and risk assessment process. Events ranging from terrorism to poor training can cause the mightiest organization to tumble. The World Trade Center and Oklahoma City bombings are a warning to us all. Your risk assessment might even prompt you to relocate if you are too close to ground zero.

Hostile Takeovers

Federal Communications Commission (FCC) Rules still state that licensees of broadcast facilities must protect their facilities from hostile takeover. Breaches in basic security have led to serious incidents at a number of places throughout the country. It has even happened at major-market TV stations. Since it is much easier to prevent such incidents than to recover from them, here are a few suggestions:

- Approve visits from former employees through their former supervisors
- Escort non-employees in critical areas
- Secure roof hatches from the inside and have alarm contacts on the hatch
- Check for legislation that may require a written safety and security plan.[13]
- Use video security and card key systems where warranted
- Keep fences in good repair, especially at unattended sites
- Install and test alarms at unattended sites
- Limit places bombs could be planted
- Consider limiting the number of outside windows or using bullet-resistant glass
- Plan a safe way to shut the facility down in case of invasion.

[13] California Senate Bill 198 mandates that California businesses with more than 100 employees write an industrial health and safety plan for each facility addressing workplace safety, hazardous materials spills, employee training and emergency response.

WORKPLACE AND HOME: HAND-IN-HAND PREPAREDNESS

A critical facility deprived of its staff will be paralyzed just as surely as if all the equipment suddenly disappeared. Employees may experience guilt if they are at work when a regional emergency strikes and they do not know what is happening at home.

Guilt and Bad Decisions

Encourage employees to prepare their homes, families and pets for the same types of risks the workplace will face. Emergency food and water and a supply of fresh batteries in the refrigerator are a start. Battery-powered radios and flashlights should be tested regularly. If employees or their families require special foods, prescription drugs, eyewear, oxygen, over-the-counter pharmaceuticals, sun block or bug repellent, remind them to have an adequate supply on hand to tide them over for a lengthy emergency.

Workplace and Home Basics

Heavy objects, like bookcases, should be secured to walls so they will not tip over. Secure or move objects mounted on walls over beds. Make sure someone in the home knows how to shut off natural gas. An extra long hose can help with emergency fire fighting or with draining flooded areas. Suggest family *hazard hunts*. Educate employees on what you are doing to make the workplace safe. The same hazards that can hurt, maim or kill in the workplace can do the same at home.

Contact Person

An excellent preparedness measure is to identify a distant business, relative or friend who can serve as the emergency message center. Employees may be able to call Aunt Tilly from work to find out if their family is safe and sound. Disasters that impair telephone communications teach us that it is often possible to make and receive long distance calls when a call across the street will not get through. Business emergency planners should not overlook this hint. A location in another city or a key customer or supplier may make a good out-of-area emergency contact.

On the Road

Personal and company vehicles should all have emergency kits that contain basic home or business emergency supplies. Food, water, comfortable shoes and old clothes should be added. If their families are prepared at home or on the road, employees will have added peace of mind. It may sustain them until they can get home safely.

Expectations, 911 and Emergencies

Television shows depicting 911 saving lives over the telephone are truly inspirational. But during a major emergency, resources normally available to 911, including their very telephone system, may be unavailable. Emergency experts used to encourage people to be prepared to be self-sufficient at the neighborhood and business levels for 72 hours or more—some now suggest a week or longer.

Managing Fear

Normal human reactions when an emergency hits are colored by a number of factors, including fear. As the emergency unfolds, we progress from fear of the unknown to fear of the known. While preparedness, practice and experience may help keep fear in check, admitting fear and the normal human response to fear can help us keep our cool.

Some people prepare mentally by reviewing their behavior during personal, corporate or natural emergencies. They then consider how they could have been better prepared to transition from normal human reactions like shock, denial and panic to abnormal reactions like acceptance and steady performance. The latter behaviors reassure those around them and encourage an effective emergency team.

Other "Normal" Reactions

Most people experience a rapid change of focus toward their own personal well-being. "Am I ok?" is a very normal question at such times. Even the most altruistic people have moments during calamities when they regress. Even the best of us can temporarily become selfish. Once people realize they do not require immediate medical assistance, they can usually start to focus again on others and on the organization.
